trajectory representing the specific batch, which operational settings are used as input for the simulation.

Unlike the pilot-scale scenario, the $k_La$ predictions at large scale do not align well with the observed data. This mismatch indicates the limitations of the empirical $k_La$, developed at pilot scale and employed at production scale. Because of these challenges, there might be the need for either re-calibration at production scale or a theoretically grounded $k_La$ model that can scale effectively from pilot to production.

Since the hybrid models generally overpredict $k_La$, the process operates at its maximum feed ramp due to the DO-control, whereas the purely mechanistic model underpredicts $k_La$, resulting in a reduced feed rate and deviations in both reactor fill and product predictions. No biomass measurements are available due to limited availability at production scale.

Overall, the results demonstrate that capacitance measurements, enables the development of a more accurate and realistic biological model at pilot scale. In contrast, integrating online viscosity data does not lead to a noticeable improvement in prediction accuracy for this case, but it also does not negatively affect the physical $k_La$ model. Combined with the advantage that both, capacitance and online viscosity reduce the need for frequent offline sampling, these findings highlight the value utilizing online data for model development.

## Cost optimization

Cost optimization was carried out using model ii at a pilot scale, as it is known from previous work that this model provides so far, the most robust and broadly applicable predictions [17]. This is essential for such a cost optimization analysis in which a wide range of operational conditions are evaluated. The primary objective is to minimize the overall campaign cost under specific constraints as elaborated in the method section.

Due to confidentiality constraints, the results in these sections are presented in relative terms. Accordingly, the individual cost factors of a fermentation process in Table 2 are shown as percentages of the total fermentation cost. This allows identification of each factor's contribution under different electricity price scenarios. The analysis of Table 2 reveals that as electricity prices increase, the share of electricity costs rise substantially, from 12.4% for 0.8 DKK/kWh to 24.9% for 2.8 DKK/kWh, which is expected. Consequently, the relative contribution of other cost factors decreases. This trend aligns well with the general understanding of cost distribution in fermentation processes: at lower electricity prices, recovery, substrate and fixed costs dominate, whereas at higher prices, electricity contributes more than substrate alongside recovery and fixed costs.

**Table 2:** Individual fermentation cost factors at each electricity price, scaled by the corresponding total fermentation cost.

| **Electricity [DKK/kWh]** | **0.8** | **1.8** | **2.8** |
|---|---|---|---|
| **Starting costs [%]** | 2.2 | 2.2 | 2 |
| **Electricity [%]** | 12.4 | 18 | 24.9 |
| **Substrate [%]** | 17.3 | 13.9 | 12.7 |
| **Ammonia [%]** | 1.9 | 1.5 | 1.4 |
| **Recovery [%]** | 56.6 | 55 | 50.4 |
| **Fixed costs [%]** | 9.6 | 9.3 | 8.6 |

Table 3 lists the process decision variables $x$ across the three electricity price scenarios. The decision variables $x$ in Table 3 are normalized by their respective upper bound $x_i^{\max}$, providing insights into how intensively each decision variable is utilized. Interestingly, fermentation time remains nearly constant across all cases. Pressure is found at approximately 93% of its maximum value for the low electricity scenario and increases to almost 99% under higher electricity prices, which is consistent with its low-cost impact on the process. Higher headspace pressure reduces evaporation by lowering the vapor liquid driving force, thereby influencing the water balance and indirectly affecting the mass-based calculations [15].

In contrast, energy-intensive parameters such as agitation and aeration are significantly reduced. For example, aeration starts at about 100% for 0.8 DKK/kWh but drops to around 60% for 1.8 and 2.8 DKK/kWh. Agitation already starts with 60% utilization of $x_i^{\max}$ for the low energy cost scenario and drops to 50% for the higher energy costs, which also aligns with the overall expectations, as those decision variables are directly linked to higher electricity costs.

**Table 3:** Optimized decision variables $x$, scaled by their corresponding upper limit $x_i^{\max}$ .

| **Electricity [DKK/kWh]** | **0.8** | **1.8** | **2.8** |
|---|---|---|---|
| **Aeration [%]** | 100 | 61.6 | 61.4 |
| **Agitation [%]** | 60.7 | 52.8 | 51.8 |
| **Pressure [%]** | 92.7 | 95.5 | 98.8 |
| **Fermentation time [%]** | 81.8 | 81.8 | 82.1 |

Finally, the results in Table 4 and Figure 4 are scaled relative to the cost associated with a reasonable current industrial standard fermentation, defined as operating all decision variables $x$ at their respective upper limits $x_i^{\max}$, as implied in [2], [3]. Table 4 summarizes the scenario-specific total campaign costs. The results indicate that rising electricity prices amplify the cost advantage of the optimized campaign relative to a strategy in which all operational variables are maintained at their maximum setpoints. E.g. at a price of 0.8 DKK/kWh, the optimized campaign costs only 80.5% of the cost of the campaign that would result from a typical current standard strategy.

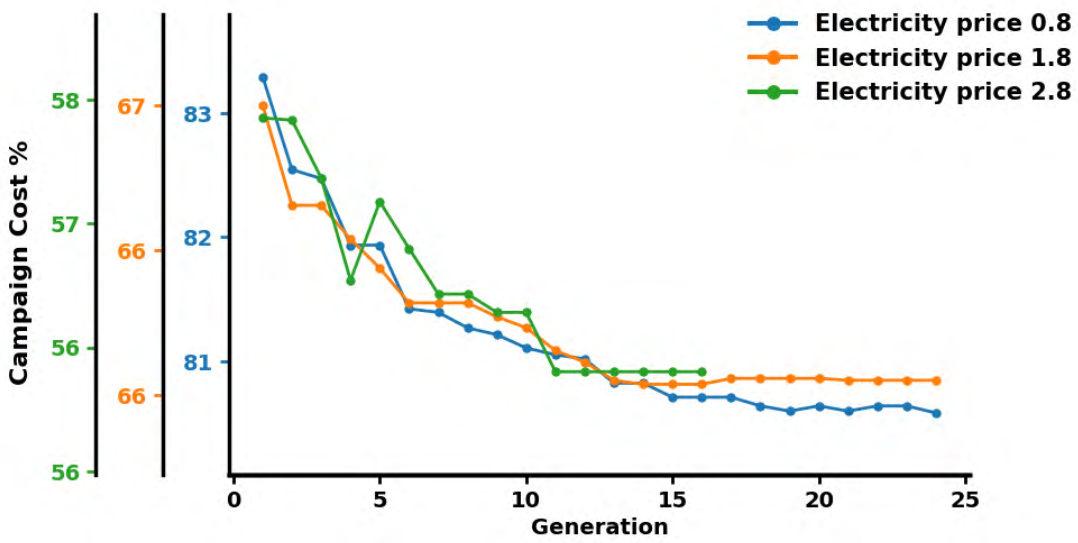

**Figure 4.** Campaign costs in percentage, scaled in the same manner as in Table 4.

**Table 4:** Total campaign costs for each electricity cost scenario, scaled by cost of a state-of-the-art operational strategy ($x_i = x_i^{max}$)

| **Electricity [DKK/kWh]** | **0.8** | **1.8** | **2.8** |
|---|---|---|---|
| **Total campaign costs [%]** | 80.5 | 65.6 | 56.3 |

Figure 4 illustrates the campaign cost progression across generations of the differential evolution algorithm, scaled in the same manner as the values in Table 4. The visualization reveals that for each electricity price scenario, the optimizer convergences and successfully identifies optimal process conditions within the given constraints. It also reveals that the optimization finds a very good first condition in the first generation of the optimization, which is likely caused by the broad initial LHS screening.

The study provides an example of how a bioprocess model can be used to evaluate the cost implications for different electricity price scenarios. The results reveal that operating all parameters at 100% ($x_i = x_i^{max}$) is not the most cost-efficient, which becomes increasingly evident as energy prices rise. Also, the results indicate that increasing energy prices primarily affect energy-intensive operations such as agitation and aeration, which should be scaled down to reduce costs, while pressure can remain near its maximum due to its negligible cost impact [16]. Interestingly, the comparison between 1.8 and 2.8 DKK/kWh shows minimal differences in the process conditions, suggesting a potential plateau in cost sensitivity beyond a certain threshold.

The optimization, performed at pilot scale, assumes constant values for agitation, aeration, and pressure throughout the fermentation process, which may not reflect the most efficient strategy in practice, but should be efficient enough for this purpose of energy cost evaluation. Furthermore, the results are considered to be highly dependent on the underlying model, scale and cost assumptions, limiting their generalizability to other processes. Future work could address time-dependent operational adjustments and include a broader range of electricity price scenarios to better capture system dynamics and identify potential tipping points for operational changes. Similar analysis at large scale might also be very interesting but first requires a similar broadly accurate process model . Finally, many more industrial relevant business cases can be approached using the same framework and subsequently customized for the specific application.

## Advanced control for the reactor end fill

Advanced control was implemented using the viable cell model (model iii), which offers the advantage of incorporating additional online measurements into the control strategy. To imitate a realistic scenario for MPC of an industrial fermentation process, the first step is to define a target reactor fill and perform an optimization to determine the required initial fill, which has been done with the same procedure as for the cost analysis. This analysis was executed using a distorted process model to create a discrepancy between the model and the process, as might occur in a real case.

The mimicked fermentation process, implemented by using the correct model and initiated with the estimated start fill, is represented by the black trajectories in

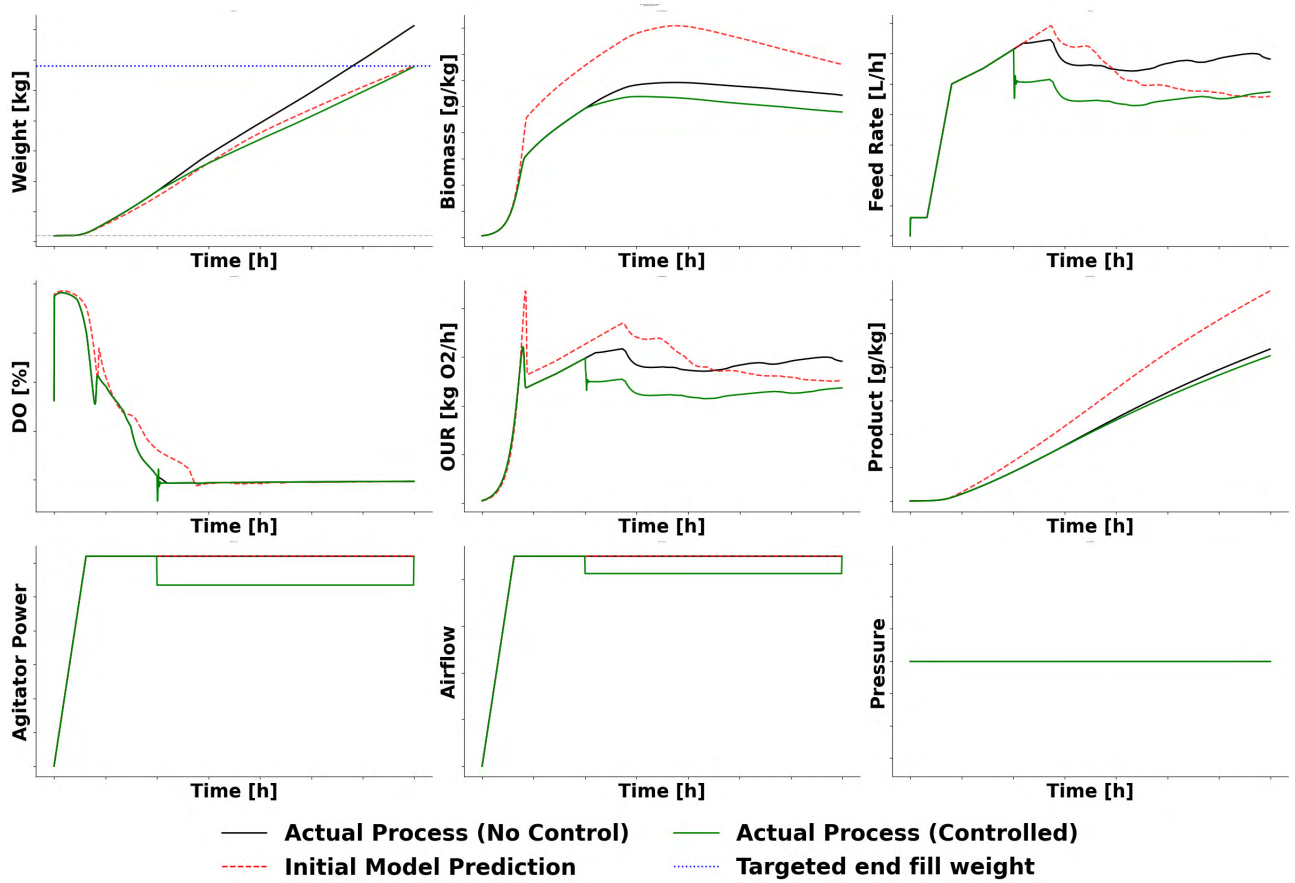

**Figure 5.** Full Fermentation process for the initial model and the synthetic process with and without advanced control.

Figure 5. As expected, without a corrective control mechanism, this leads to a reactor end fill that deviates from the defined end fill, underscoring the need for a corrective control strategy.

In contrast, the controlled fermentation process successfully reaches the target end fill. The optimizer adjusts agitation and aeration by lowering their setpoints, consequently reducing the DO-controlled feed rate and thus the final fill. The agitation is tuned a bit more than the aeration, which can be explained by the greater influence on the oxygen mass transfer. In addition, less aeration not only reduces the feed rate, but also evaporation, which lowers the total effect on the final weight.

Those results demonstrate the effectiveness of the control strategy described in the *Methods* section. Enabling sequential adjustments in which agitation and aeration are modified to achieve the desired final fill, while keeping DO close to its setpoint.

Under control, the final product concentration is slightly lower compared to the uncontrolled scenario and the initial model, reflecting the reduced feed addition and corresponding decrease in biomass concentration. Nevertheless, the reactor does not overfill, which is set as the main objective. This scenario illustrates that, even with an inaccurate initial model, the proposed framework can iteratively correct the model and control the process by fine-tuning agitation and aeration to ensure the process meets the end fill target without violating DO constraints.

Future work should focus on implementing and validating this approach in a real-world setting, which requires careful consideration. System boundary conditions, easily overlooked in simulations, could lead to operational failures if not properly addressed. These constraints must be incorporated into the simulation and thoroughly evaluated before deploying such a closed-loop model predictive control strategy in a pilot plant environment.

Additionally, attention must be given to the time intervals for evaluating control actions. These intervals should align with process dynamics and ideally exceed the time required by the computational framework to update the model, and adjust agitation, aeration and feed rate settings before the next evaluation point.

## CONCLUSION

This study first discusses the benefits of utilizing online rheology and online biomass measurements for fermentation models, emphasizing that especially the integration of capacitance data seems to improve the biological sub-model accuracy. Combined with the reduced labor associated with offline measurements, this supports the usage of online data to tackle the resource-intensive and time-consuming model development.

Secondly, the study demonstrates the applicability of bioprocess models tailored for industrial enzyme production, showing that electricity prices substantially influence the optimal operating strategy. The results clearly indicate that maximizing all decision variables, such as agitation, aeration, or fermentation time, is not cost-efficient under the given optimization problem and varying electricity prices. Finally, the in-silico MPC case illustrates that an initial model–process mismatch can be corrected in real time, enabling dynamic adjustment of agitation and aeration to ensure that the reactor achieves its target end-fill while maintaining DO control throughout the process.

## ABSTRACT

Accurate life cycle assessment (LCA) depends on robust characterization factors (CFs), which quantify impacts such as ecotoxicity through the integration of fate (FF), exposure (XF), and effect (EF) factors. While databases such as USEtox and Ecoinvent provide essential CFs, significant data gaps remain, particularly in ecotoxicity endpoints like hazardous concentration 50% ($HC_{50}$), which directly inform effect factor calculations. Existing machine learning models can predict such values, but they often lack interpretability, which limits trust and transparency in environmental modeling. To address this, a machine learning framework is applied that utilizes symbolic regression (SR) and genetic programming (GP) to predict missing $HC_{50}$ values from physicochemical descriptors. A dataset with 14 descriptors was used to train SR models capable of generating interpretable mathematical expressions that link chemical properties to $HC_{50}$ values. SR models were benchmarked against prominent black-box models such as random forest (RF) and neural network (NN) models. SR performance was consistent across multiple parameter configurations, while revealing recurring patterns in variable selection. These results demonstrate that symbolic regression can both predict ecotoxicity values with comparative accuracy and provide transparent functional relationships, thereby filling existing data gaps in characterization factors needed for a complete LCA.

**Keywords**: Life Cycle Assessment, Symbolic Regression, Machine Learning

## INTRODUCTION

Life Cycle Assessment is a cornerstone of environmental modeling, enabling quantification of the potential impacts of chemical substances across their life cycles. Among the various impact categories, ecotoxicity assessment is particularly important for evaluating risks to aquatic and terrestrial ecosystems. Ecotoxicity characterization within LCA depends on effect factors such as the *Hazardous Concentration for 50% of species* ($HC_{50}$), which represents the concentration at which half of the tested species experience a measurable toxic effect. Reliable $HC_{50}$ data for chemicals are essential for computing characterization factors used in assessment frameworks such as USEtox and TRACI [1, 2]. However, measured $HC_{50}$ values are missing for many chemicals, limiting the completeness of LCA inventories and impact models.

Machine learning (ML) models are powerful tools for estimating missing ecotoxicity values based on physicochemical properties of substances. While black-box algorithms such as random forests or neural networks provide accurate predictions, their limited interpretability can hinder informed decision-making. Symbolic regression (SR) offers a promising alternative, deriving analytical expressions that directly relate input descriptors to target variables. The use of explainable data-driven models in chemical engineering is well established, with a review of past efforts, developments, and future directions presented in [3]. Most interpretable SR methods rely on genetic programming, as discussed in [4], where it was applied to mechanism discovery. Researchers have also explored optimization-based formulations; for example, in [5], a mixed-integer nonlinear programming (MINLP) model is proposed for SR to compete with traditional, stochastic genetic programming methods. The benefit of optimization is stronger optimality guarantees, unlike

genetic algorithms, which can be computationally less expensive but may yield lower solution quality [6].

Despite growing interest in data-driven methods, few studies have applied ML models to predict chemical properties in the context of life-cycle assessment or environmental impact evaluation. One such example is [7], where the authors employed ML models to estimate environmental endpoint indicators such as human health, resource utilization, and climate change, though these efforts relied exclusively on black-box models.

The present study applies symbolic regression to predict $HC_{50}$ values using a dataset of 14 physicochemical descriptors (e.g., molecular weight, partition coefficients, solubility, and bioconcentration factor). The overall goal is to derive an interpretable model that connects the property to the descriptors. The applied SR workflow encompasses data preprocessing, model training via evolutionary optimization, and performance evaluation across multiple configurations of population size and generation count. Model interpretability is investigated through the analysis of recurrent variable patterns and expression structures.

By comparing predicted $HC_{50}$ values against baseline models also assessed in [8] for the same dataset, we evaluate whether symbolic regression can achieve comparative predictive performance while preserving explicit analytical expressions. These equations can help bridge existing data gaps in effect factor estimation, thereby improving the robustness of LCA-based ecotoxicity characterization. The remainder of this paper details the symbolic regression framework, presents the results and interpretability analysis, and examines implications for model generalization, descriptor roles, and ecotoxicity characterization.

# METHODS

## Dataset

The ecotoxicity dataset used in this study originates from [8] and contains 2, 122 chemicals with experimentally determined values for $HC_{50}$ and 14 descriptors. These descriptors include molecular weight, boiling point, and water solubility and are listed in Table 1. The descriptors were compiled into a numerical matrix and $HC_{50}$ values were log-transformed ($\log(HC_{50})$) to form the target vector.

**Table 1:** Description of molecular features

| Variable | Descriptor | Abbreviation |
|---|---|---|
| $X_0$ | Molecular Weight | MW |
| $X_1$ | Atmospheric Hydroxylation Rate | AOH |
| $X_2$ | Bioconcentration Factor | BCF |
| $X_3$ | Biodegradation half-life | BioHL |
| $X_4$ | Boiling point | BP |
| $X_5$ | Henry's law constant | HL |
| $X_6$ | Fish biotransformation half-life | KM |
| $X_7$ | Octanol/air partition coefficient | KOA |
| $X_8$ | Octanol/water partition coefficient | LogP |
| $X_9$ | Melting point | MP |
| $X_{10}$ | Soil adsorption coefficient | KOC |
| $X_{11}$ | Vapor pressure | VP |
| $X_{12}$ | Water solubility | WS |
| $X_{13}$ | Mode of action | MoA |

## Baseline Models

Two common ML models are used to benchmark the symbolic regression approach: a Random Forest (RF) regressor and a Neural Network (NN). The RF model consists of an ensemble of decision trees constructed using bootstrap samples of the training data. Each tree is built by recursively partitioning the descriptor space using impurity-minimizing splits, while random feature selection at each node promotes decorrelation between trees. Final predictions are obtained by averaging the outputs of all trees. This structure enables RF to capture nonlinear interactions between descriptors while maintaining robustness to noise and outliers [9].

The NN model is a fully connected feed-forward network trained using backpropagation. The network maps the standardized descriptor vector to the $\log(HC_{50})$ target through a sequence of nonlinear transformations defined by hidden layers and activation functions. By adjusting its weights during training, the NN model can capture complex continuous relationships. Although it requires careful regularization to avoid overfitting on medium-sized datasets [10].

## Symbolic Regression Framework

Symbolic regression was implemented using a genetic programming (GP) framework developed in [11]. SR searches for explicit analytical expressions that relate the input descriptors to the target $\log(HC_{50})$. The approach evolves populations of candidate mathematical expressions using operations such as mutation, crossover, and selection.

The GP search was configured to explore functional structures while preventing unnecessary algebraic complexity. The operator set was restricted to the four arithmetic operations {+, −, ×, ÷}. Candidate expressions were initialized as shallow trees with depths between 0 and 3, and the maximum allowable depth during evolution was

constrained to 10. Population sizes ranged from 4 to 12 individuals, and each evolutionary run proceeded for 100–2, 000 generations.

At every generation, each candidate expression was evaluated using the root-mean-square error (RMSE) between predicted and measured $\log(\mathrm{HC}_{50})$ values. To balance accuracy and interpretability, adjusted $R^2$ was incorporated into the fitness function to penalize unnecessarily complex expressions. After the evolutionary search identified a set of high-performing symbolic structures, the coefficients associated with each expression were re-optimized using a post-evolution linear regression step.

The final SR model takes the general form shown in Equation (1), where each term $f_i(X)$ represents an evolved symbolic transformation of the descriptor set $\{X_0, X_1, \ldots, X_{13}\}$, and the coefficients $\beta_i$ correspond to optimized weights.

$$\hat{y} = \sum_i^k \beta_i f_i(X) \qquad (1)$$

## Model development

All baseline models were trained using a three-way data partition consisting of training (70%), validation (10%), and testing subsets (20%). The training set was used for model fitting, the validation set for hyperparameter tuning, and the test set for final out-of-sample evaluation. The SR development strategy described in [11] is applied here to develop the SR models. The strategy involves training and validation on multiple data splits and GP parameters. To address the probabilistic nature of the algorithm, multiple runs are made for each data split and configuration. For the study, 100 expressions are generated per configuration and data split. Five data splits are evaluated for six parameter configurations varying in population size and number of generations, yielding a total of 3000 expressions.

Population size and number of generations control how thoroughly the genetic program explores the search space. Higher values for both increase the computational budget, and larger populations increase the set of candidate solutions maintained and evolved in each generation. By assessing various configurations, we can evaluate the effect of these parameters on predictive performance. This is done by performing statistical tests on the validation set to compare different data splits and model configurations. The Friedman and Wilcoxon Rank tests are employed to measure statistical significance between configurations and data splits. The Friedman test determines whether configurations differ significantly within each split. The Wilcoxon test evaluates statistical significance in performance differences between configurations. All tests are performed for a 99% confidence level.

The development of the RF and NN baselines is streamlined by the scikit-learn [12] and hyperopt [13] Python packages for model construction and hyperparameter optimization, respectively. Model accuracy was evaluated using the standard regression metrics (RMSE and $R^2$). The coefficient of determination ($R^2$) quantifies the proportion of variance in the measured $\mathrm{HC}_{50}$ values explained by the model, while the root-mean-square error (RMSE) measures the average magnitude of prediction error in the units of the log-transformed target variable. These metrics were computed for the training, validation, and test subsets to evaluate model fit and generalization behavior.

## Feature Importance and Structural Analysis

The contribution of each feature to the predicted target value for all models is evaluated using SHAP (SHapley Additive exPlanations) [14]. SHAP is an approach for explaining individual predictions of an ML model by attributing a contribution value to each input feature. It builds on Shapley values from cooperative game theory, which fairly distribute total gains or costs among collaborating players. In this context, each feature acts as a player, and SHAP fairly allocates the model's prediction difference (from a baseline) across them.

In addition to understanding how individual features contribute to model predictions, we examine the structural diversity of the expressions generated via SR. This structural analysis provides complementary insights into the models and their underlying patterns. To characterize the diversity of the discovered expressions, we perform structural pattern mining by extracting abstract syntax tree (AST)-based features for each unique mathematical expression. Each expression is parsed into its AST representation, from which quantitative features, including operation counts, tree structural properties (depth, total nodes), and variable usage patterns, are extracted. Two feature extraction modes are considered: a variable-agnostic mode that treats all variables as generic placeholders (focusing purely on the expression skeletal structure) and a variable-specific mode that encodes which molecular descriptors are used with binary indicator features. AST features are compiled into a feature matrix with rows representing unique expressions and columns representing the extracted structural characteristics. Once these feature vectors are obtained, a systematic comparison of the structural characteristics of the different expressions follows.

To quantify structural similarity between expressions, we compute pairwise Euclidean similarity matrices from the standardized feature vectors. Euclidean similarity measures the distance between feature vectors with values ranging from 0 (completely dissimilar) to 1 (identical) after taking the normalized inverse distance. By computing separate similarity metrics for both modes, we assess whether expressions share similar structural motifs and/or molecular descriptors.

To illustrate this, consider the analytical expressions

in Equation (2). In the variable-agnostic case, we evaluate the number of variables used, the types of operations, and the overall structure. The variables, $X_0$,$X_1$, and $X_2$ are treated as interchangeable placeholders, as are $X_5$,$X_7$, and $X_9$. Consequently, $f_1$and $f_2$ are structurally similar despite their different variable names, resulting in a Euclidean similarity score of 1. In contrast, in the variable-specific case we also consider exact variable usages. Since $f_1$and $f_2$ use different variables, the measured similarity score is low, with a score of 0.143.

$$\begin{aligned} f_1 &= X_0 + X_1X_2 \\ f_2 &= X_5 + X_7X_9 \end{aligned} \quad (2)$$

## RESULTS & DISCUSSION

### SR Hyperparameter Tuning

Symbolic regression experiments were performed for six configurations of generation and population size pairs; performance was measured by the RMSE values on the validation set. Figure 1 depicts the RMSE distribution for each configuration across all data splits. Model statistics averaged across the splits for the validation set are recorded in Table 2.

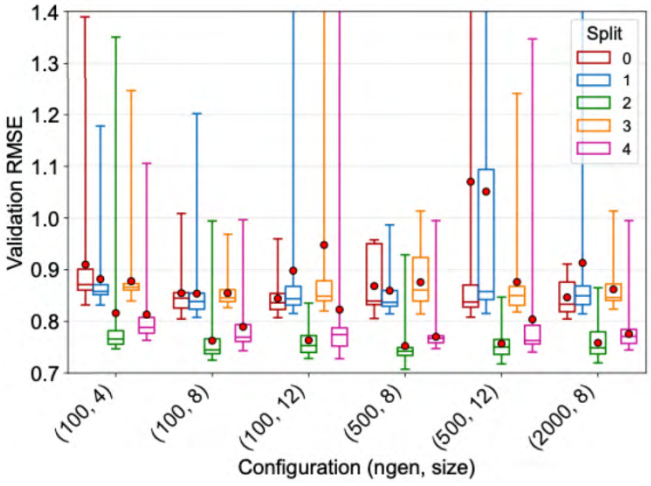

**Figure 1:** RMSE distribution across evolutionary parameter configurations and data splits. The red dot is the mean. In the box, the middle line is the median, the bottom line is the 1st quartile, and the top line is the 3rd quartile. The tails are the minimum and maximum values.

Friedman and Wilcoxon tests were conducted across data splits and configurations. In all splits, the Friedman test yielded p-values ≤ 0.01, indicating statistically significant differences among configurations. Building on these results, of the 75 Wilcoxon pairwise comparisons, 32 were significant, with the parameter set (ngen = 100, size = 8) showing statistical dominance. Notably, this configuration also exhibits a stable RMSE distribution and the lowest mean validation RMSE (see Table 2); therefore, it was selected as the optimal SR model parameter set. Consequently, all subsequent SR model results and baseline comparisons are based on this configuration, and use Split 1 to ensure consistent training, validation, and testing sets. The SR model with the lowest validation RMSE under these specifications is presented in Equation (3).

**Table 2:** RMSE validation statistics averaged across split sets.

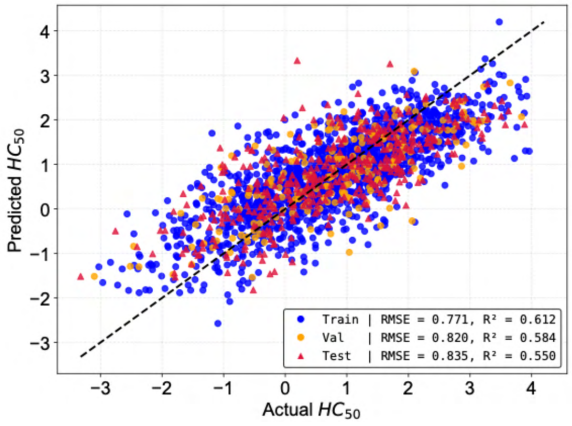
| Config. | Mean | Median | Std |
|---|---|---|---|
| (100, 4) | 0.860 | 0.856 | 0.0985 |
| (100, 8) | 0.823 | 0.826 | 0.0652 |
| (100, 12) | 0.855 | 0.831 | 0.3044 |
| (500, 8) | 0.825 | 0.829 | 0.0699 |
| (500, 12) | 0.912 | 0.828 | 0.9603 |
| (2000, 8) | 0.831 | 0.827 | 0.1161 |

$$\begin{aligned} \log(\mathrm{HC}_{50}) = \; & 0.241X_{12} + 0.279X_{13} - 0.259X_2 \\ & -0.113X_9 - 0.000413\frac{X_8^2}{X_2X_9} \\ & + 0.106\frac{X_8}{X_2X_5} + 0.145\frac{-X_1 + \frac{X_{11}}{X_4} - X_{13}}{X_0} \\ & + 27.1\frac{-X_1 + \frac{X_{11}}{X_4} - X_{13}}{X_1X_{13}(X_1 - X_7)} \end{aligned} \quad (3)$$

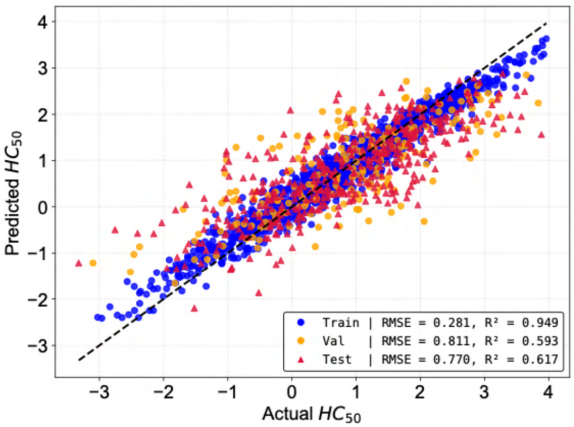
As shown, Equation (3) is a compact interpretable model with high variable diversity, using 11 out of the 14 available descriptors; several appear multiple times. The optimal weights ($\beta_i$) are the coefficients preceding each subexpression. Prominent monomials include water solubility ($X_{12}$), mode of action ($X_{13}$), bioconcentration factor ($X_2$), and melting point ($X_9$). Based on the signs of each variable, water solubility and mode of action appear to be positively correlated with $\log(\mathrm{HC}_{50})$, while bioconcentration factor and melting point are inversely correlated with $\log(\mathrm{HC}_{50})$. However, this is not the full picture, considering the presence of polynomial terms. These relationships are made explicit via feature importance analysis in the subsequent section.

### Comparative Performance of SR, RF, and NN

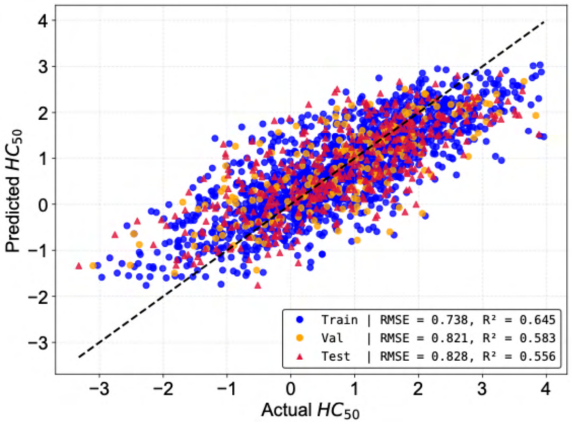
All models were evaluated using the same train/validation/test sets and assessed using the coefficient of determination ($R^2$) and the root-mean-square error (RMSE). The performance results for training and testing are summarized in Table 3. Furthermore, parity plots (Figure 2) provide a visual assessment of model generalization, comparing SR, RF, and NN models.



(a) SR model



(b) RF model



(c) NN model

**Figure 2:** Parity plots comparing predicted and actual $\log(\mathrm{HC}_{50})$ values for the SR, RF, and NN models on split set 1.

As shown in Table 3, the RF model achieves the highest performance on the training set, but its accuracy drops considerably on the test set- suggesting overfitting. This is evident from the large differences in both RMSE and $R^2$ between the training and test results. The NN model displays lower performance than the RF model in training and testing, while the SR model has the lowest training scores but performs about equally to the NN model on the test set. While RF achieves the strongest apparent fit on the training data, this advantage does not translate to unseen samples. On average, all three models perform roughly equally on the test set across all data splits.

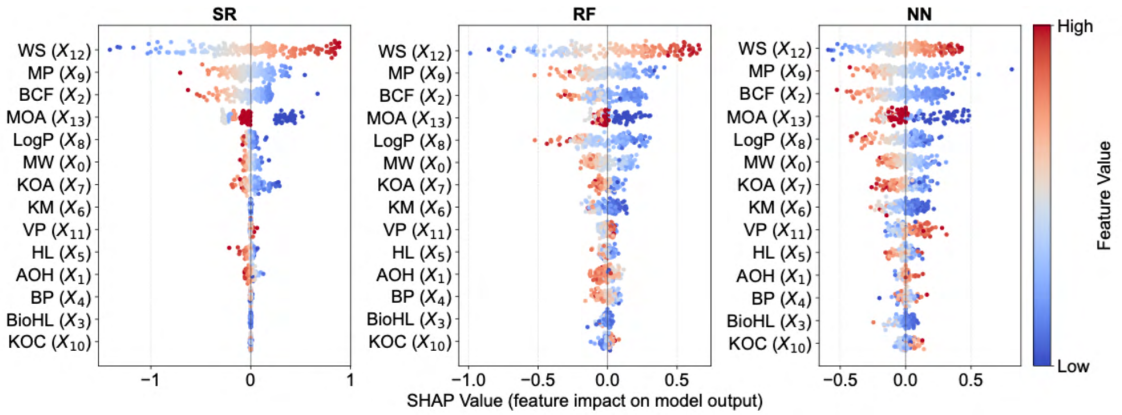


**Figure 3.** SHAP-based feature importances for SR, RF, and NN models. Particles are samples representing the impact distribution of each feature on the target output, indicating the direction that each feature value drives the predicted $\log(\mathrm{HC}_{50})$ output. High positive values are positively correlated with the target, and high negative values are negatively correlated.

**Table 3:** Average model performance metrics for RF, NN, and SR models on 5 data splits. SR corresponds to configuration (*ngen*=100, *size*=8). Standard deviations in parentheses.

| Model | $R^2$ (Train) | RMSE (Train) | $R^2$ (Test) | RMSE (Test) |
|---|---|---|---|---|
| RF | 0.930 (0.0446) | 0.322 (0.0874) | 0.609 (0.0136) | 0.766 (0.0142) |
| NN | 0.719 (0.0598) | 0.659 (0.0707) | 0.573 (0.0269) | 0.800 (0.0225) |
| SR | 0.606 (0.004) | 0.785 (0.012) | 0.573 (0.019) | 0.801 (0.030) |

## Feature Importance Across Models

The feature importances for the three models, obtained using the SHAP methodology, are shown in Figures 3 and 4. Figure 3 describes the effect of each feature on $\log(\mathrm{HC}_{50})$ prediction, while Figure 4 shows the cumulative mean absolute SHAP value for all features of the compared models. The two most important features across all models are water solubility ($X_{12}$) and melting point ($X_9$). The next prominent features include bioconcentration factor ($X_2$), mode of action ($X_{13}$), and the octanol/water partition coefficient ($X_8$).

Figure 3 reveals that for the top features, higher water solubility increases the predicted $\log(\mathrm{HC}_{50})$ value, while higher melting point reduces the predicted value. A negative correlation is also observable for bioconcentration factor, mode of action, and octanol/water partition coefficient with higher feature values reducing the predicted $\log(\mathrm{HC}_{50})$ value.

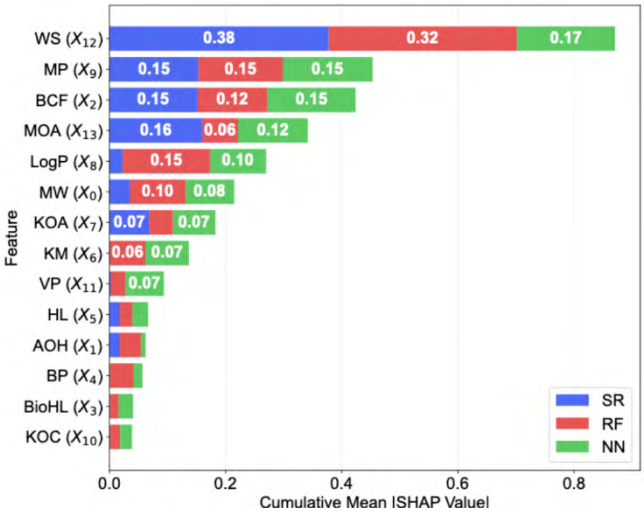

**Figure 4.** Mean absolute Shapley values for SR, RF, and NN models.

Overall, the findings of the feature importance analysis agree with the visual inspection of the expression in Equation (3). It clarifies the contributions of the octanol/water partition coefficient ($X_8$) and mode of action ($X_{13}$), which are ambiguous in Equation (3) due to their repeated occurrences. The analysis also reveals that vapor pressure ($X_{11}$) and boiling point ($X_4$) primarily act as structural constructors in Equation (2), as they do not exert a direct influence on the predicted value, as shown by Figure 4. While feature importances can be used to effectively extract variable information from black box models, an explicit expression remains desirable. It can be inspected against domain knowledge to verify if the discovered relationships are plausible and consistent with established theory or intuition. Furthermore, when an expression satisfies these criteria, it may uncover new

mechanistic insights.

## Structural Expression Analysis

Having established how the individual features in each model contribute to predicting the target, we next examine the structural characteristics of the expressions obtained by symbolic regression. The goal is to see if a common canonical form emerges among the generated expressions. From this data-driven assessment, we seek to uncover mechanistic insights and identify the elements of these expressions that drive their convergence.

Across all evolutionary configurations, 3000 symbolic expressions were generated, of which 999 are unique and used to quantify structural similarity. Figure 5 summarizes the distribution of these expressions. The most frequent expression (Equation (4)) occurs 16 times, while roughly 300 expressions appear only once, indicating that most derived expressions are recurrent.

$$\begin{aligned}\log(\mathrm{HC}_{50}) = \quad & 0.161X_1 - 0.000167X_{10} \\ & - 0.265X_{12} - 0.170X_2 \\ & - 0.00133X_8 - 0.161X_9 + \frac{0.654}{X_{13}}\end{aligned} \tag{4}$$

Comparing the expression with the most frequent appearance against Equation (3), there is a clear divergence in the structures. Equation (4) is more compact and uses fewer features than Equation (3). Except for the soil adsorption coefficient ($X_{10}$), which is accompanied with a low coefficient value, all variables present in (4) also appear in (3).

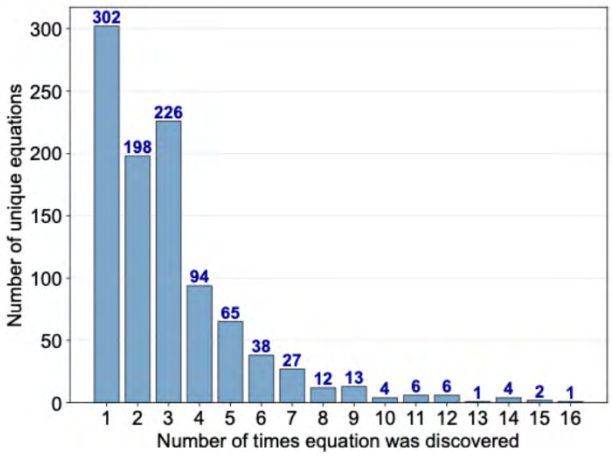

**Figure 5.** Frequency of unique expressions from all SR models. Labels above each bar represent the number of unique expressions for the corresponding appearance count on the x-axis.

After identifying the unique expressions, we

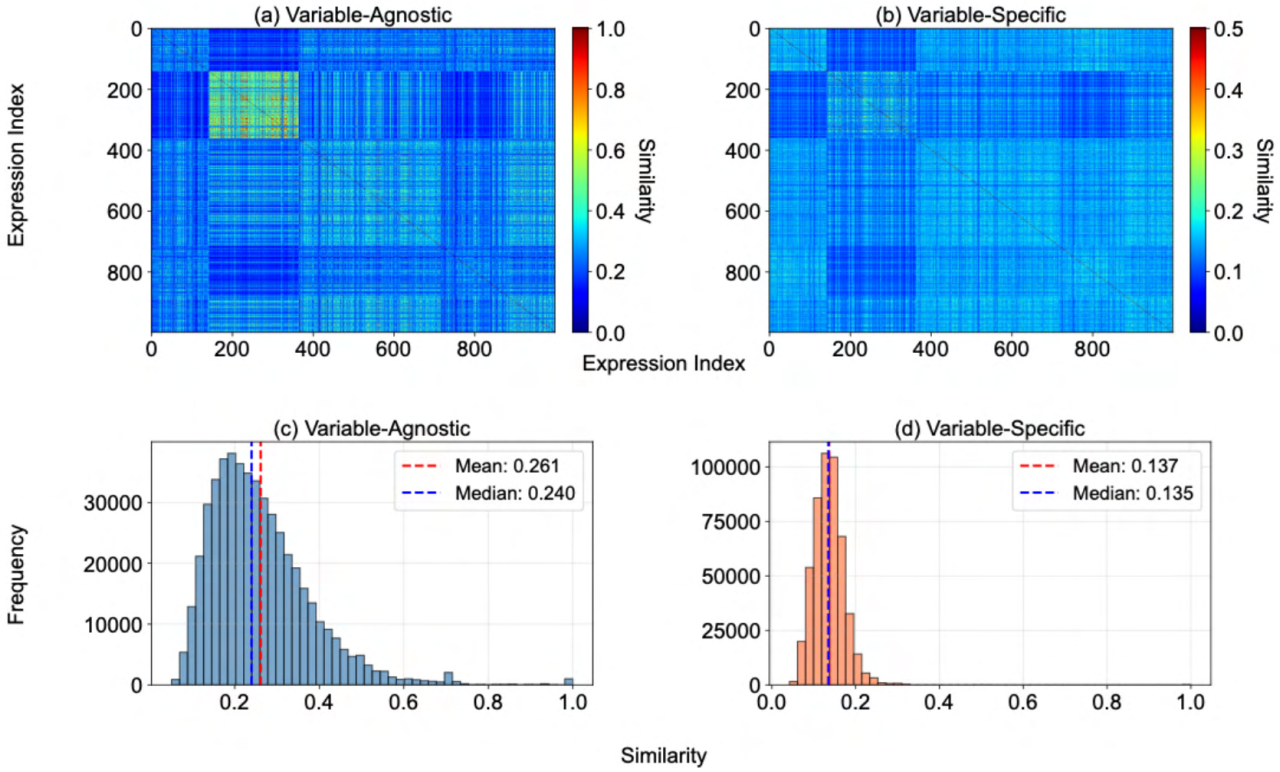

**Figure 6.** Characterization of structural diversity of SR expressions for variable-agnostic (left) and variable-specific (right) structural signatures. Frequencies in (c) and (d) are the number pairs appears with the similarity score on the x-axis.

proceed to characterize the structural diversity of the SR expressions for both variable-agnostic and variable-specific evaluations by measuring the similarity between expression pairs. The findings of this analysis are presented in Figure 6. Figure 6 (a and c) shows that for the variable-agnostic case (variables not explicitly considered), most expressions are not structurally similar, with a mean similarity score of 0.261. This means that expressions are extremely diverse in their use of number/type of operators, as well as in expression lengths. If we consider Equations (3) and (4), for example, the similarity score is 0.138, which falls below the mean.

The variable-specific case shown in Figure 6 (b and d) also indicates high feature diversity with a mean similarity score of 0.137. Again, comparing Equations (3) and (4), the similarity score in this case is 0.110. The near-zero mean and the distribution of the similarity scores shown in Figure 6 suggest that most expressions have little to no overlap in the overall structure. Yet, performance remains consistent across all models.

## CONCLUSION

This study demonstrates that symbolic regression is a strong alternative to conventional black-box models for predicting ecotoxicity effect factors used within life cycle assessment frameworks. The symbolic regression models showed stable performance across multiple evolutionary configurations. When benchmarked against random forest and neural network models, symbolic regression achieved comparable predictive accuracy while offering an explicit analytical expression. This is particularly valuable for LCA, where traceability and scientific justification of characterization factors are paramount. Furthermore, feature importances obtained with SHAP were consistent across models, reinforcing SR's ability to compete with traditional black-box methods. Lastly, the structural analysis of the derived SR expressions revealed substantial variation, indicating that caution is needed when assigning causality. At the same time, this variation can be viewed positively, as it provides multiple pathways to accurately compute a property based on the data available. In summary, our results highlight symbolic regression as a promising method for reducing data gaps in CF estimation.

## ABSTRACT

Cement is regarded as the most widely used construction material worldwide; however, its production is also recognized as a major contributor to global $CO_2$ emissions. Strict control of cement quality is therefore required to prevent excessive consumption of raw materials and energy, which would otherwise increase the process environmental footprint. Cement quality is largely governed by clinker quality, which is primarily characterized by two quality control parameters: free-lime content and alite fraction. At present, these are characterized by costly and time-consuming laboratory analyses that are not optimal for real time process control and optimization. Hence, in this work, a soft sensor for the real-time estimation of the clinker alite fraction is proposed. The developed soft sensor is designed to adapt to process drifts and operating condition changes, capture nonlinear and dynamic behavior, and retain interpretability through a Partial Least Squares (PLS) modelling framework. To this end, a novel recursively adaptive local dynamic soft-sensing strategy (ALD-PLS) is introduced and implemented within a multi-model ensemble structure referred to as Quasi-Ensemble PLS (QE-PLS). Unlike conventional ensemble approaches, where model diversity is generated through data resampling or training–testing partitioning, the proposed framework constructs multiple sub-models using combinations of model hyperparameters, evaluated on the same evolving dataset. As a result, improved predictive accuracy and robustness are achieved, while estimation uncertainty is quantified. The proposed QE-PLS soft sensor is shown to outperform, in terms of $R^2$ and $RMSE$, PLS-based and single-instance implementations ALD-PLS for a similar task. The novel methodology is validated against data collected from an industrial cement production plant.

**Keywords**: Modelling, adaptive modelling, cement industry, ensemble modelling, PLS, soft sensing

## 1. INTRODUCTION

Cement is regarded as the most widely used construction material worldwide due to its scalability, affordability, and widespread availability. Nevertheless, cement production is recognized as a major contributor to global carbon emissions, accounting for ca. 8% of total anthropogenic $CO_2$ emissions [1]. Strict quality control is therefore required, since deviations in product quality may result in unnecessary consumption of raw materials and energy, increasing the overall environmental footprint of the process and product. Cement quality is largely governed by clinker quality, which is primarily controlled by two key indices, i.e. free-lime content and alite fraction, to mention a few [2]. At present, these are determined by laboratory analyses, which are costly and time-consuming, thus not optimal for real-time process monitoring, control, and optimization.

An alternative to laboratory measurements is provided by soft sensors, through which difficult-to-measure quality variables are estimated using data-driven models built from readily available process measurements, e.g. temperatures, pressures, and material flow rates [3]. In clinker production, real-time estimation of critical quality indices by soft sensors can support advanced control strategies and improved operational efficiency. However, research on soft sensing in the cement industry has remained limited, with most existing studies

focusing on free lime and few addressing the alite fraction. Existing approaches can be grouped into three categories. First, black-box models, e.g. neural networks, have been associated with high predictive accuracy, while limited process interpretability has been provided [4]. Second, white-box Partial Least Squares (PLS)-based models have been employed to retain interpretability; however, performance has often been constrained by difficulties in capturing nonlinearity, dynamics, and process drifts typical of modern cement plants [5]. Third, mechanistic first-principles models have been characterized by both accuracy and interpretability, but high computational demand has frequently rendered their use impractical for real-time control and optimization [6].

In this work, the focus is on the real-time estimation of clinker alite fraction through an interpretable, adaptive soft-sensing strategy. In particular, PLS modelling has been adopted as the modelling strategy due to its robustness in handling collinearity and high-dimensional process data. A recursively adaptive PLS-based soft sensor has been proposed based on the established incremental PLS (I-PLS) strategy [7]. Process dynamics have been explicitly incorporated using lagged variables [8], while local modelling strategies have been employed to tailor the model to the prevailing data environment; improving predictive performance under nonlinear and non-stationary conditions. Such adjustments are needed since conventional PLS-based soft sensors do not adapt to evolving industrial conditions. In clinker production, non-stationarity, seasonal drifts, abrupt operating changes, and dynamic behavior have frequently been observed, often in association with multiple operating modes, thereby challenging static, global modelling approaches.

Note, however, that the proposed models' predictive performance was found to depend on a relatively large number of interdependent hyperparameters, including the number of latent variables and the dynamic lag structure, whose optimal values vary over time and operating conditions. Thus, the models' hyperparameters have been allowed to vary within physically and statistically meaningful bounds - instead of being fixed a priori. As a result, a new methodology based on a multi-model structure that is inspired by ensemble learning principles has been developed, resulting in an ensemble over model structures, not calibration datasets. This novel strategy is referred to as Quasi-Ensemble PLS modelling. To prove its predictive superiority the performance of QE-PLS, in terms of estimation $R^2$ and $RMSE$, is compared to that of its components, I-PLS and ALD-PLS.

## 2. MATERIALS AND METHODS

The proposed novel soft-sensing methodology was developed and validated using industrial data collected from a cement production plant. In this section, the clinker production process is briefly described, followed by an overview of the dataset and preprocessing steps, and a detailed presentation of the modelling framework adopted in this work.

### 2.1 Clinker production process

Cement is produced by grinding clinker together with supplementary cementitious materials and gypsum. Clinker itself is obtained by thermally processing a raw meal composed mainly of limestone and clay. The raw meal is preheated in a multistage cyclone tower, partially calcined in a precalciner, and subsequently fed into a rotary kiln where clinker formation occurs. The hot clinker is then rapidly cooled to preserve the formed alite phase [10]. A schematic representation of the clinker production process is shown in Figure 1.

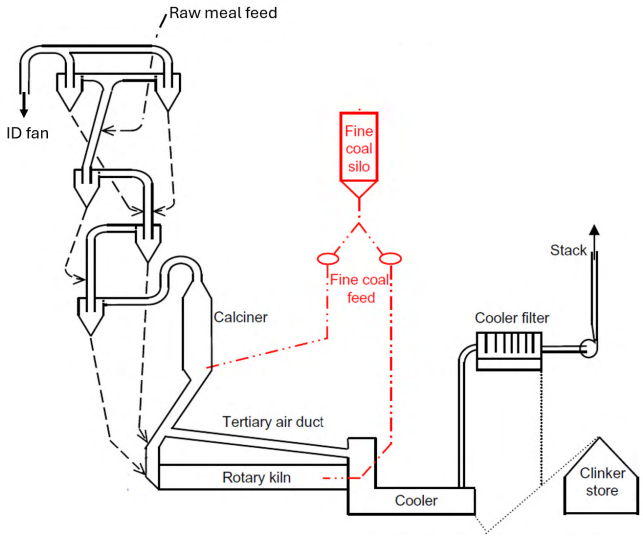

**Figure 1.** Clinker production process; adapted from [10].

### 2.2 Dataset preprocessing

The dataset used in this study comprises 74 process variables and the corresponding product quality measurements in terms of alite fraction. For confidentiality reasons, the dataset origin (cement plant) and the description of individual variables cannot be disclosed. All process variables were recorded at a nominal sampling interval of 1 min. While process variables were continuously measured, the alite fraction was obtained through laboratory analysis at a lower frequency (ca. once per hour). Hereafter, the process variables and the alite fraction are referred to as the **X**-block and the **y**-vector.

Data preprocessing steps include: (i) removal of missing values, sensor decoupling periods, and unphysical measurements; and (ii) outlier detection and removal based on Q (SPE) residuals and Hotelling's $T^2$ statistics [11], exceeding twice their respective 95% confidence limits in PLS modelling. This resulted in a final dataset spanning ca. two months of operation, where $\mathbf{X}$ has the

dimension of $[N_{observations} \times V_{variables}] = [826 \times 74]$ and **y** of $[N_{observations} \times 1] = [826 \times 1]$.

## 2.3 Partial Least Squares (PLS)

Partial Least Squares (PLS) regression was selected due to its effectiveness in handling highly correlated, high-dimensional industrial data. All PLS models were built using the NIPALS algorithm [12]. Equations 1-4 represent the model formulation and estimation formulae.

$$\mathbf{X} = \mathbf{T}\mathbf{P}^{\mathbf{T}} + \mathbf{E} \quad (1)$$

$$\mathbf{Y} = \mathbf{U}\mathbf{Q}^{\mathbf{T}} + \mathbf{F} \quad (2)$$

$$\mathbf{U} = \mathbf{T}\mathbf{B} \quad (3)$$

$$\hat{\mathbf{y}}_{\text{new}} = \mathbf{x}_{\text{new}}\mathbf{W}(\mathbf{P}^{\mathrm{T}}\mathbf{W})^{-1}\mathbf{B}\mathbf{Q}^{\mathrm{T}} \quad (4)$$

where, $\mathbf{X}, \mathbf{Y}$ refer to the predictor and response matrices, $\mathbf{T}$ and $\mathbf{U}$ the scores matrices, $\mathbf{P}$ and $\mathbf{Q}$ the loadings matrices, and $\mathbf{E}$ and $\mathbf{F}$ the residual matrices resulted from the decomposition of the predictor and response blocks. Besides, $\mathbf{W}$ represents the weights matrix, $\mathbf{B}$ the regression coefficients vector, and $\mathbf{x}_{\text{new}}$ the new observation vector while $\hat{\mathbf{y}}_{\text{new}}$ the estimation for the corresponding response.

However, an adjustment to classical PLS is needed, since it is inherently linear and static. In particular, models are calibrated once and, subsequently, applied without adaptation, rendering them incapable of accounting for the frequent process drifts and operating mode changes – typical of industrial clinker production. Hence, an adaptive modelling strategy – described as follows – is required to overcome these limitations.

## 2.4 Incremental update strategy PLS

The incremental recursive updating strategy for PLS [7] is adopted to enable model adaptation over time. Specifically, at each time instant, a PLS model is recalibrated using all available historical data, and the current process observation is projected to estimate the corresponding alite fraction. Once the true measurement becomes available, it is incorporated into the historical dataset and the procedure is repeated.

While this recursive approach allows for tracking process changes, it suffers from two drawbacks: (i) as the dataset size grows, diminishing influence on the recalibrated model is exerted by the new observations, reducing adaptivity; and (ii) increasing computational cost due to repeated recalibration on an ever-growing dataset. These limitations motivate the proposal of a local adaptive dynamic PLS framework (see Section 2.6), where a similarity-based selection of historical samples is used to maintain model relevance and estimation accuracy.

## 2.5 Lagged variables PLS

The standard PLS framework is extended by lagged-variables PLS through augmentation of the **X**-block with time-shifted versions of the process variables, enabling the model to capture process dynamics and temporal autocorrelation [8]. In classical dynamic PLS, the augmented **X**-block is formed by concatenating copies of the original variables shifted by predefined time lags.

In this work, a modified lag-construction strategy is adopted for the adaptive local dynamic PLS framework (Section 2.6). Specifically, instead of generating lagged variables from the main modelling dataset, lagged information is extracted from the higher-resolution 1-minute dataset (Section 2.2). This helps incorporate the dynamic information present at finer time scales, while the main **X**–**y** modelling dataset remains aligned with the lower sampling frequency of the alite measurements (ca. one hour).

As for lagged variables, they are constructed by selecting a lag spacing $W$, defining the time shift between consecutive lags. In the main dataset, for each sample at time $t$, process variable observations at times $t - W, t - 2W, \ldots, t - R$ are retrieved from the 1-minute dataset and horizontally concatenated to form the augmented **X**-block. Thus, the total number of lags added in the dynamic X-block reads $R/W$.

Altogether, this approach enables the incorporation of dynamic process information without increasing the temporal resolution of the primary dataset and forms the basis for the adaptive local modelling strategy described as follows.

## 2.6 Proposed methodology: adaptive local dynamic PLS (ALD-PLS)

The proposed methodology integrates I-PLS, dynamic lagged-variable methods, and local modelling into a unified adaptive local dynamic PLS (ALD-PLS) strategy. The objective is to retain the adaptability and interpretability of PLS while overcoming the limitations of static global models when applied to non-stationary, dynamic industrial processes. A schematic overview of the methodology is provided in Figure 2.

At each time $t$, the modelling procedure is carried out according to the following update paradigm:

1. **Step 1:** data from time $1$ to $t - 1$ are used to construct a global dynamic PLS model, where the **X**-block consists of the lag-augmented process variables and the **y**-vector the corresponding alite fraction measurements. The construction of the dynamic **X**-block requires the selection of a proper lag $W$ and the maximum lag range $R$ (Section 2.5). The global model is built using $A_g$ latent variables.

2. **Step 2:** the current observation of the $V = 74$ online process variables at time $t$, represented in its dynamic lagged-variable form, is projected into the global PLS

score space.

3. **Step 3:** Euclidean distances between the score vector of the current point and those of all historical samples are computed, and the $L$ closest historical points are selected. These samples are considered the most relevant local neighborhood for modelling the current process state.
4. **Step 4:** using the selected $L$ samples, a local dynamic PLS model is constructed with $A$ latent variables.
5. **Step 5:** Variable Importance in Projection (VIP) indices [13] are calculated for each predictor in the dataset. Predictors with VIP < 1 are subsequently removed [13], and the local dynamic PLS model is recalibrated using the reduced predictor set.
6. **Step 6:** the current observation at time $t$ is projected onto the score space of the refined local PLS model, and the alite fraction is estimated.

The abovementioned local modelling strategy ensures that estimations are based on the most relevant historical data while maintaining robustness against irrelevant or degenerate predictors.

## 2.7 Quasi-Ensemble PLS Modelling

The predictive performance of the proposed methodology depends on a set of critical hyperparameters (Section 2.6) summarized in Table 1. Note that the choice of hyperparameters is interdependent.

**Table 1**. Hyperparameters of the proposed ALD-PLS.

| Hyperparameter | Description |
|---|---|
| $L$ | size of similarity neighborhood |
| $A$ | number of LVs of the local PLS model |
| $A_g$ | number of LVs of the global PLS model |
| $W$ | lag frequency (time shift of the variables between two consecutive lags) |
| $R$ | maximum time shift considered |

Instead of selecting a single optimal hyperparameter configuration, a multi-model strategy inspired by ensemble learning [9] was adopted. In contrast to classical ensemble approaches, where diversity is generated through resampling or partitioning of the dataset, the proposed framework constructs diversity through different combinations of model hyperparameters evaluated on the same evolving dataset. This approach is referred to as Quasi-Ensemble PLS modelling (QE-PLS).

All possible combinations of hyperparameters values in reasonable ranges are selected to build the sub-models of the Quasi-Ensemble (QE). The selected values of the hyperparameters, selected through heuristics, are shown in Table 2. For each sub-model, the ALD-PLS is executed, yielding an independent estimation of the alite fraction at each time point.

The QE estimation is obtained by averaging the sub-model outputs, while the associated estimation uncertainty is quantified through the standard deviation in the estimation. Specifically, for the $i$-th observation, the ensemble mean and standard deviation are given by Equations (5-6):

$$\hat{y}_i = \bar{y}_i = \frac{1}{M}\sum_{j=1}^{M} \hat{y}_i^{(j)} \quad (5)$$

$$\sigma_i = \sqrt{\frac{1}{M}\sum_{j=1}^{M}\left(\hat{y}_i^{(j)} - \bar{y}_i\right)^2} \quad (6)$$

where, $\hat{y}_i^{(j)}$denotes the estimation of the $i$-th sample produced by the $j$-th sub-model, and $M$ is the total number of sub-models in the QE; $M$ =3840 in the present case.

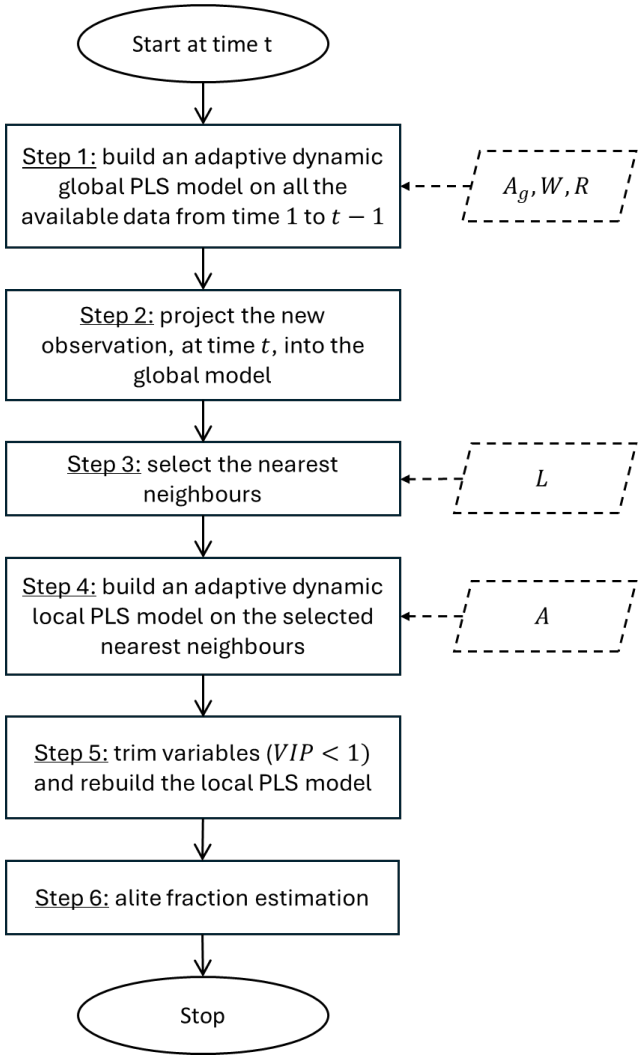

**Figure 2.** Schematic of the ALD-PLS at time t.

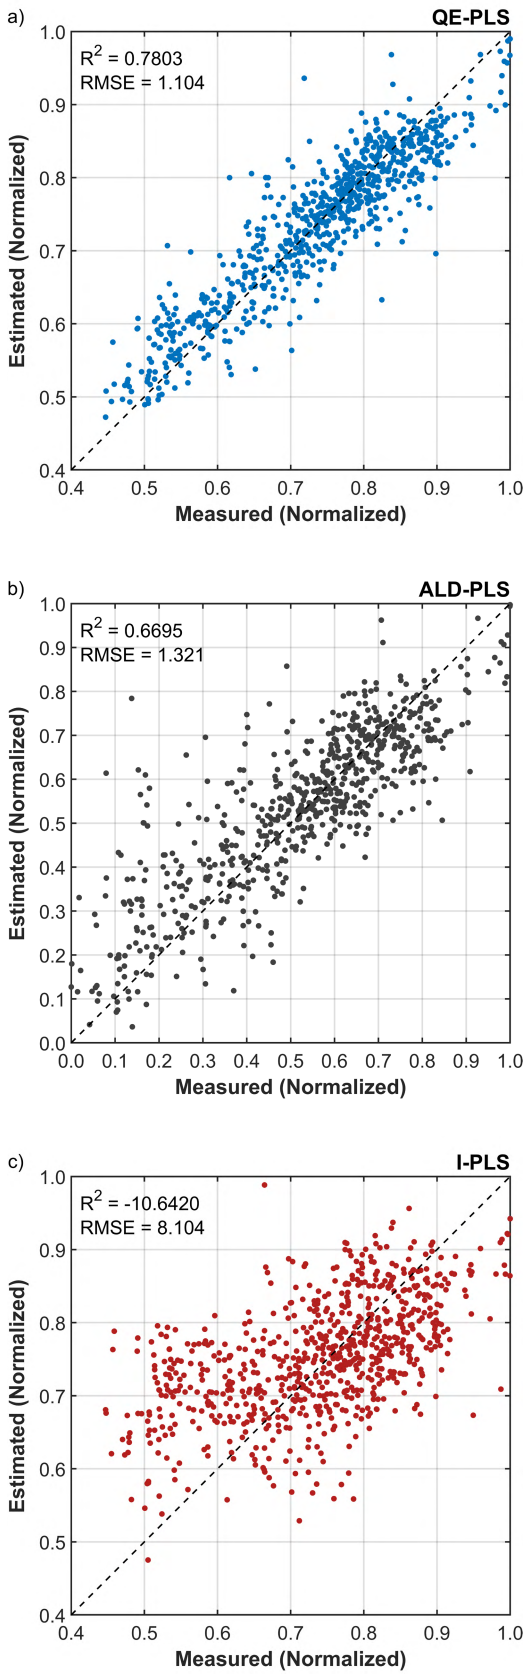

**Figure 3.** Parity plot of predicted alite fraction vs measured alite fraction: a) QE-PLS, b) ALD-PLS and c) I-PLS.

Based on $\sigma_i$, approximate 95% confidence intervals for the final estimations are computed as $\bar{y}_i \pm 2\sigma_i$. The QE-PLS allows the proposed soft sensor to remain robust to hyperparameter uncertainty and process variability, while simultaneously providing predictive uncertainty estimates without requiring explicit probabilistic modelling.

**Table 2**. Selected hyperparameters ranges.

| Hyperparameter | Range |
|---|---|
| $L$ | 30:10:60 |
| $A$ | 1:1:8 |
| $A_g$ | 1:1:10 |
| $W$ | 30 minutes |
| $R$ | 2:2:24 hours |

## 2.8 Performance Metrics

In this work the performance metrics used to assess the quality of the proposed soft sensor are the determination coefficient, $R^2$, and the root mean square error, $RMSE$; i.e.:

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2} \quad (7)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (8)$$

where, $y_i$ is the $i$-th elements of the **y** measurements, $\hat{y}_i$, the estimation for that element, $\bar{y}$ the mean alite fraction data, and $n$ the number of samples in the **y** dataset.

# 3. RESULTS

The proposed methodology was applied to the preprocessed **X** and **y** datasets (Section 2.2). The resulting alite fraction estimations are shown in the parity plot of Figure 3 a). The QE-PLS soft sensor achieved an $R^2$ of 0.7803 and a $RMSE$ of 1.1037. Considering the intrinsic variability of the alite fraction measurements, this indicates an accurate and reliable predictive performance.

To further assess the proposed approach, a comparative study was conducted against two state-of-the-art PLS-based soft-sensing strategies, i.e.: (i) a standard incremental update PLS model, i.e. I-PLS (Section 2.4), and (ii) a single instance of the adaptive local dynamic PLS model, i.e. ALD-PLS, corresponding to one submodel of the QE. The corresponding parity plots for a single instance of the ALD-PLS and the I-PLS are presented in Figure 3 b) and 3 c), respectively.

The comparative study results are listed in Table 3. They indicate that the QE-PLS model outperforms both I-PLS and ALD-PLS models on $R^2$ and $RMSE$. Besides, QE-PLS is shown to improve the performance of ALD-PLS sub-models, demonstrating the benefit of aggregating

estimations across multiple hyperparameter configurations. Such improvement highlights the ability of the QE framework to enhance robustness and adaptability when modelling the nonlinear and dynamic behavior of alite fraction data in industrial clinker production.

**Table 3**. Comparison of the estimation performance of tested models on predicting alite fraction.

| Model | $R^2$ | *RMSE* |
|---|---|---|
| QE-PLS | 0.7803 | 1.1037 |
| ALD-PLS | 0.6695 | 1.3212 |
| I-PLS | -10.6420 | 8.1038 |

The tested models were evaluated on a laptop equipped with a 13th Gen Intel Core i9-13900H processor (2.60 GHz), 32 GB RAM, and MATLAB R2024b. Under this configuration, I-PLS showed the lowest computational cost, requiring milliseconds for the estimation of one observation, compared with deciseconds for ALD-PLS and a few minutes for QE-PLS. Thus, I-PLS was much faster than ALD-PLS and QE-PLS. This trend is consistent with the increasing complexity of the models; notably, QE-PLS comprises 3840 ALD-PLS sub-models, which explains its substantially higher runtime. Although this computational burden is a limitation of the proposed soft sensor, the method remains suitable for quality control, since the current laboratory-based reference measurements are acquired only once per hour.

## 4. CONCLUSIONS & FUTURE WORK

In this work, a soft-sensing framework for the real-time estimation of clinker alite fraction was proposed. The results obtained for the industrial case study (clinker production) indicate that the proposed adaptive PLS-based soft sensor is capable of effectively capturing the nonlinear and dynamic behavior of the alite fraction under realistic operating conditions.

In addition, a novel modelling strategy, i.e. Quasi-Ensemble PLS (QE-PLS), was introduced. The proposed strategy constructs multiple sub-models using different combinations of model hyperparameters evaluated on the same evolving dataset. The QE-PLS framework was shown to outperform both classical incremental PLS (I-PLS) models and single-instance adaptive local dynamic PLS (ALD-PLS) models, demonstrating improved predictive accuracy and robustness.

Despite the achieved favorable performance, the proposed QE-PLS framework entails a relatively high computational cost due to the evaluation of several sub-models. Hence, future work shall focus on reducing computational requirements through optimization of the hyperparameter combination space, as well as through the investigation of more advanced parallelization and asynchronous execution strategies. Besides, further validation will allow for assessing the generalizability and robustness of the proposed approach. Finally, the inherent interpretability of the PLS-based framework will be exploited to support process understanding, anomaly detection, and explainability in industrial process monitoring and control applications.

## ABSTRACT

Modular plants emerged as the key solution for reducing time-to-market and increasing flexibility in the process industry by combining different modules known as Process Equipment Assemblies (PEAs). While PEA automation is standardised through the Module Type Package (MTP), comparable tools for their documentation remain absent. This work presents the Semantic PEA Datasheet (SPEAD) ontology, which represents PEA documentation as a machine-readable knowledge graph that adheres to the FAIR principles. SPEAD integrates established standards such as DEXPI and the VDI 2776 guidelines and ensures data quality through comprehensive annotations and constraint-based validation. The ontology was evaluated against twelve competency questions derived from a representative use case as well as competency questions from the literature using a continuous stirred-tank reactor PEA as well as a dosing PEA as example systems. SPEAD successfully covers operational and design parameters as well as interface definitions, and provides provenance tracking through rich metadata. Comparison with existing information models OntoCAPE and DEXPI shows that SPEAD provides enhanced provenance tracking essential for trust in engineering documentation. Future work includes enriching capability and safety descriptions and exploring integration with the Asset Administration Shell (AAS).

## INTRODUCTION

In recent years, modular process plants have emerged as a key solution to tackle the growing need for reduced time-to-market and increasing flexibility in the process industry [1]. Modular plants are built by combining several modules, known as Process Equipment Assemblies (PEAs) [2]. PEAs perform single process steps, such as dosing or heating [2]. By combining and re-combining different PEAs, the Owner/Operator (O/O) of the plant can adapt their plant to fit the requirements of the product to be produced [2]. This process is called orchestration and replaces detailed equipment engineering with module selection [2].

Guidelines for the design of modules, their automation both on PEA and plant level, and the documentation of the modules are already established. The design of a PEA depends on the vendor, the operator, and general design requirements and is thus not unified across the industry [3]. The automation of a module is performed in a standardised manner using the Module Type Package (MTP) [4]. However, no comparable standard tool for the documentation of modules exists to date. In the guideline VDI 2776-1 [2], minimum requirements for the content of the documentation are given. The guideline further recommends the provision of documentation in a modular, machine-readable format. Guideline VDI 2770 provides such a format [5], which defines the minimum requirements for the exchange of digital manufacturer documentation. Neither guideline specifies how these requirements should be fulfilled, nor how information should be represented. This may lead to inconsistent data, metadata and contradictory interpretation of data. In order for the documentation to be usable across the lifecycle of a PEA, it must contain information on all aspects of the PEA and provide clear, unambiguous definitions of critical terminology and data.

## Research Objective

To address this gap, we previously proposed the Semantic PEA Datasheet (SPEAD) [6]. SPEAD utilises semantic web technologies to represent the documentation of a PEA as a knowledge graph.

In this work, we present the SPEAD ontology, focusing primarily on the modelling of physical properties. This paper is structured as follows: First, we present current documentation standards and guidelines, semantic web technologies, and related models and standards. Next, we present our modelling methodology and the resulting ontology. Afterwards, we evaluate our model against competency questions developed during the modelling phase using a continuous stirred-tank reactor PEA and a dosing PEA as examples. Finally, the results are discussed and a conclusion is given.

## Documentation Standards and Guidelines

Guideline VDI 2776-1 recommends that the documentation of a modular plant is hierarchically structured in the same way as its modular structure [2]. Documentation for PEAs, their contained functional equipment assemblies (FEAs), and additional components should be stored in a database that enables cross-referencing between corresponding entities. Updates performed on any element are thus inherited by higher level elements.

Guideline VDI 2776-2 recommends that PEA documentation contains at least (1) an overview of implemented process functions, (2) an overview of implemented services, (3) the interface requirements both towards adjacent PEAs as well as the (non-modular) environment, and (4) a presentation of the intended area of use. The PEA documentation should reflect its life cycle [3]. Services should be described according to the MTP [4], and a P&ID should be provided in an open data format such as DEXPI. Furthermore, it is recommended that documentation be supplied as modular digital information with an open data format, and that the exchange format described in guideline VDI 2770-1 be used. In this guideline, documents are classified according to their purpose and stored alongside relevant metadata such as ID and provenance in containers [5].

Lastly, Regulation 2023/1230 of the European Parliament and of the Council (commonly “Machinery Directive”) demands certain information to be present in the technical documentation in accordance with harmonised standards or common specifications, such as design and manufacturing drawings [7]. Where these standards and specifications have not been or have only been partially applied, descriptions of the utilised standards or specifications must be provided [7].

## Semantic Web Technologies

Engineering documentation for modular plants should adhere to the FAIR principles to ensure data is Findable, Accessible, Interoperable, and Reusable throughout the plant lifecycle and across organisational boundaries. Semantic web technologies provide the standardised framework necessary to achieve these goals through structured, machine-readable knowledge representation. In the following paragraph we introduce the core W3C standards that form the technical foundation of our ontology.

The Resource Description Framework (RDF) is the core technology for the semantic web. It allows information about resources, e.g., documents, physical objects, etc., to be expressed in the form of triples [8]. Triples always have the form subject-predicate-object, where the subject and object are the resources being related, and the predicate is their relationship. A collection of these triples forms a directed labelled graph in which the subject and object are nodes and relationships are edges. RDF enables the creation of vocabularies and ontologies that provide reusable definitions of common terminology. The creation of ontologies is aided by the Web Ontology Language (OWL). OWL itself is an RDF vocabulary and supports the publication and sharing of ontologies by providing abstract constructs for the definition of classes, properties, restrictions, and logical axioms [9]. To ensure data quality and consistency, RDF graphs can be validated against a set of constraints using the Shapes Constraint Language (SHACL). Shapes are defined to specify how targeted class instances and properties can be constructed. These constraints include but are not limited to data type, cardinality, and logical constraints [10]. In this work we use the Terse RDF Triple Language (Turtle) syntax for serialising RDF data due to its human-readable format and widespread support.

## Related vendor-independent standards

Koch et al. [11] evaluated existing vendor-independent standards in information modelling for process engineering, identifying three key standards: OntoCAPE, DEXPI, and IEC 61512.

1. OntoCAPE [12] is an ontology covering the domain of computer aided process engineering. It consists of multiple modules spread across six layers, each covering different topics across the process engineering domain.
2. The DEXPI (Data Exchange in the Process Industry) specifications [13] provide two complementing data models, DEXPI Plant and DEXPI Process. DEXPI Plant is a standardised data model for P&IDs, whereas DEXPI Process is a data model for process engineering information. Both specifications aim to enable consistent data exchange in the process industry. Both were recently unified into the DEXPI 2.0 model.
3. The IEC 61512 standard [14] deals with batch control and defines three models: a process model, a physical

model, and a procedural model for linking automation, operations and procedures to the other models. It defines three types of control and distinguishes between different recipe types.

Based on their evaluation, OntoCAPE and the DEXPI specifications were identified as the most suitable information models for modular plants [11]. However, neither model should be considered as a standalone solution. Instead, Koch et al. suggest the integration and extension of these models towards an ontology for modular plants [11]. The goal of this work is to lay a foundation for such an ontology, with the focus of applying the model to the documentation of modular plants.

# METHODOLOGY

## Development Approach

The SPEAD ontology was modelled using the use case- and competency question-based method by Kendall and McGuinness [15]. Competency questions (CQ) are derived from the use case and represent requirements for the knowledge graph that must be fulfilled by it. A representative, iteratively developed use case for the SPEAD ontology is given in the following.

### Use case: Exchange of PEAs in a modular plant

> A service technician is charged with replacing the reactor PEA from an existing plant with a new one from a pool of available reactor PEAs. To do this, they require information about the operating conditions, structure, and available services of all PEAs in the pool.

The derived competency questions CQ1 – CQ8 are listed in Table 1. These CQs focus on the content of the information model. Based on the CQs, lists are created which contain the necessary terminology to answer the CQs. For example, to answer CQ1, terms such as “PEA” and “operating pressure” must be defined. Further, a representation for quantitative properties in the format name/symbol = value-unit, e.g., vessel diameter D = 300 mm, must be established. To further organise the domain knowledge, we group the information into five categories: (i) operating range, (ii) construction, (iii) interfaces, (iv) services, and (v) safety. In this work we focus on (i) and (ii) and only briefly introduce our concept for (iii), (iv), and (v).

In addition, we derived questions regarding the provenance and terminology of the model, which is shown in Table 2. The provenance-related questions enable the model to capture information that is critical for regulatory compliance, change management, and establishing accountability in collaborative engineering environments. The terminology-related questions ensure that domain concepts are consistently defined, thus enabling unambiguous communication between stakeholders and interoperability between systems. Together these CQs address the metadata layer essential for trust, traceability, and quality assurance in engineering documents.

**Table 1:** Competency questions and the expected answers regarding the content of the information model.

| CQ | Competency Question | Expected answer |
|---|---|---|
| 1 | What is the maximum operating pressure of this PEA? | The maximum operating pressure of this PEA is X bara. |
| 2 | List the boundaries of the operating temperature of this PEA. | A table with the desired boundaries. |
| 3 | Find all PEAs with a maximum operating pressure larger than 20 bar and a minimum operating temperature below 10°C. | A list of IDs of PEAs that fulfil the criteria. |
| 4 | What is the total volume of the reactor vessel of this PEA, and how much of it is heated? | The total volume and the heated volume of the reactor vessel. |
| 5 | Which FEAs and components does this PEA contain? | A list of FEAs and components of this PEA. |
| 6 | How many inlet interfaces does this PEA have that can be used for educts or flushing? | The count of inlet interfaces with the specified function. |
| 7 | What is the IP rating of this PEA? | The IP rating of this PEA. |
| 8 | Which MTP services are available at this PEA? | A list of services this PEA provides. |

**Table 2:** Competency questions and the expected answers regarding the terminology and provenance of information inside the model.

| CQ | Competency Question | Expected answer |
|---|---|---|
| 9 | Which document is the source of this value? | Reference to the source document. |
| 10 | When was this value added to the documentation of this PEA? | The date on which the value was added. |
| 11 | What is the definition of the class *spead:ProcessEquipmentAssembly*? | The definition text from the ontology. |
| 12 | List all physical properties of this PEA whose *rdfs:label* property contains the substring “flow”. | A list of physical properties with labels such as “volume flow” or “flow rate”. |

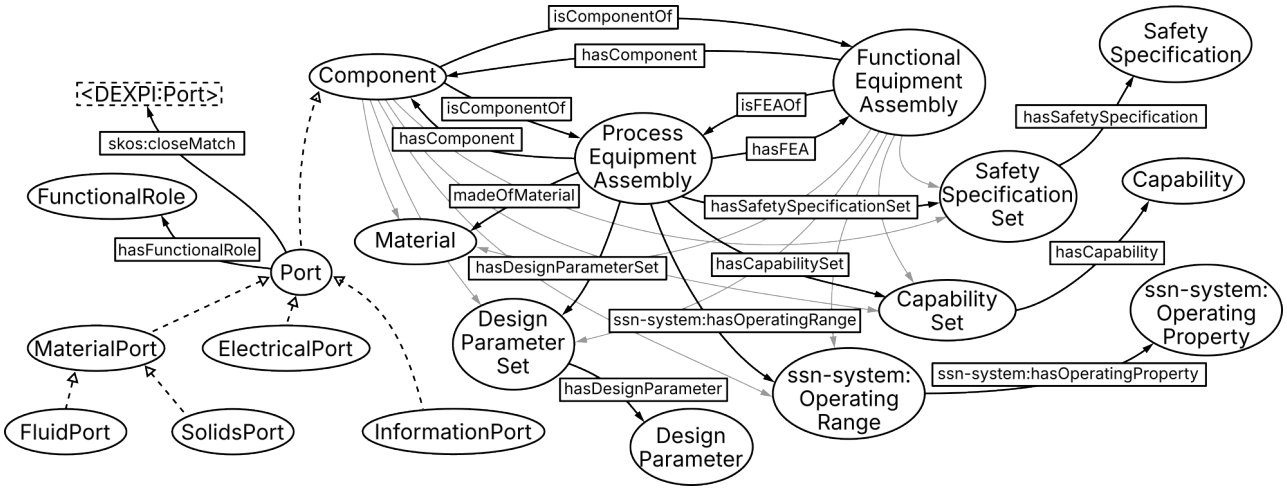

**Figure 1.** Core classes and properties from the SPEAD ontology. The thin grey lines depict relationships between the Component class and FEA class and other core classes that are only labeld between the PEA class and other core classes. Dashed lines indicate that the subject is a subclass of the object. The *spead:Port* class closely matches the definition of a port from the DEXPI 2.0 specification.

## SPEAD Ontology

The core classes and properties are shown in Figure 1. Unless otherwise stated, all definitions shown are our own, and labelled with the prefix *spead:*. Components, FEAs, and PEAs are specialisations of OntoCAPE's plant item. Their aggregation relationships are derived from the VDI 2776-1 guideline [2]. We introduce intermediate grouping classes (e.g., *spead:SafetySpecificationSet* and *spead:DesignParameterSet*) to aggregate related property specifications from four of our five categories, drawing on the system capabilities module of the Semantic Sensor Network (SSN) ontology (prefix *ssn-system:*) [16] for the operating range. While these add verbosity, the grouping allows logically related specifications to be directly referenced. Further, sets can carry their own metadata and can be shared across different PEA instances, which simplifies the instance graph when a PEA pool contains multiple copies of the same type of PEA. Components and FEAs may also carry these sets, as indicated by the thin grey lines in Figure 1.

For interfaces, we define the abstract *spead:Port* class, which is specialised further into material, electrical, and information ports. This split was derived from the DEXPI 2.0 process model [13], and is mapped to the respective classes using *skos:closeMatch* as shown in Figure 1.

We define the abstract class *spead:QuantifiableProperty* for all equipment-related properties which are typically expressed as a name, a value, and a unit. In some cases, these kinds of properties occur as single values, e.g., the volume of a tank vessel. In other cases, values are a range or set, e.g., the maximum and minimum operating pressure of a tank vessel. These properties are also categorised differently, e.g., design parameters for attributes such as tank volume or procedure parameter for properties related to an MTP service [4]. In the instance graph, these properties can also be instances of the *spead:QuantifiableProperty* class, providing them with a shared structure. We choose this approach over subclassing to allow qualitative properties (categorisations, colours, etc.) to be described using the same classes as quantitative properties.

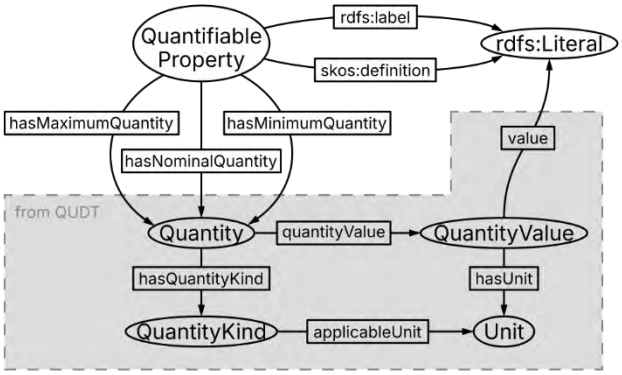

**Figure 2.** Schema for describing quantifiable properties. Classes and properties outside the gray box are own definitions, excluding SKOS and RDFS terms.

A detailed schema for the *spead:QuantifableProperty* class is shown in Figure 2. We utilise the structure of the Quantities, Units, Dimensions and Data Types Ontologies (QUDT), which provides a schema for the description of quantities (prefixed with *qudt:*) as well as vocabularies that define a large number of quantity kinds (prefix *quantitykind:*), units (*prefix unit:*), dimension vectors, and constants [17]. Using these kinds of vocabularies ensures

that every stakeholder in the PEA lifecycle has the same, unambiguous understanding of the described quantities. This is relevant in cases where vendors and operators use different internal vocabulary. For example, one party might call the rate at which a fluid flows through a dosing module “flow rate”, while the other calls it “volume flow”. In our model, both parties link to the QUDT instance of *quantitykind:VolumeFlowRate*, maintaining their internal naming schema whilst preserving the interoperability of the data. We deviate from the structure of physical quantities in OntoCAPE, since QUDT provides an actively maintained, cross-domain, standardised structure for the representation of quantities, dimensions and units. Additionally, it contains an extensive vocabulary of kinds of quantities and units. These include 2896 unit descriptions, whereas OntoCAPE’s 41 unit descriptions miss crucial units for process systems, such as those for volume flow. By leveraging QUDT, we eliminate the need of creating additional unit and quantity descriptions, thus removing a potential source of inconsistencies.

For provenance tracking, we transform the data model from the VDI 2770 guideline [5] into an RDF format. As a base we use the PROV Ontology due to its extensive vocabulary for tracking entities, their derivations, involved agents, and activities [18]. Figure 3 shows a small part of the transformed data model and how it relates to the components, FEAs, and PEAs.

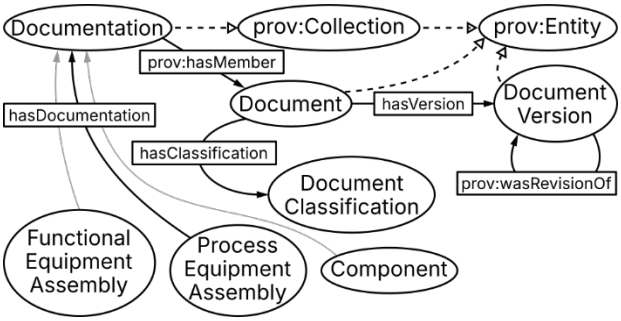

**Figure 3.** Classes and properties for tracking provenance. The thin grey lines depict the hasDocumentation relationship between FEAs and Components and their documentation.

## Data Quality Assurance

Data quality is ensured at two levels. Our OWL ontology is intentionally kept lightweight, defining only class hierarchy and property semantics and avoiding complex class restrictions. Structural validation is instead delegated to SHACL shapes. In an industrial context, the Closed World Assumption SHACL operates under is important: unlike OWL’s Open World Assumption, which treats missing information as merely unknown, SHACL treats absence as a validation error.

At the ontology level, we utilise ontologies for metadata and provenance descriptions such as Simple Knowledge Organization System (SKOS, prefix *skos:*) [19] and DCMI Metadata Terms (DC Terms, prefix *dcterms:*) [20]. All class and property definitions were annotated with labels, definitions and examples, as well as common alternative labels and sources where appropriate in both English and German. External resources (e.g., definitions from DEXPI) were related using SKOS mapping properties. Finally, we utilise the Basic Formal Ontology (BFO, prefix *bfo:*), as a foundational ontology. Foundational ontologies supply generic categorisation of the kind of things that an ontology describes, domain-independent relations, and means to represent attributes of the described things. The use of foundational ontologies provides a framework of fundamental distinctions, and facilitates the integration of different domain-specific ontologies based on the same foundational ontology. In our ontology, we use the OWL implementation of BFO, and declare our classes and properties as specialisations of the appropriate BFO terms. For example, a PEA is an object aggregate, i.e., a material object that consists of multiple parts that work together as a functional entity. We document the alignment rationale with the *skos:scopeNote* property. The serialisation of this example is as follows, where the object aggregate term is called *bfo:BFO_0000027*:

```
spead:ProcessEquipmentAssembly a owl:Class ;
  rdfs:subClassOf bfo:BFO_0000027 ;
  skos:scopeNote “Aligned to BFO 'object
aggregate’, as PEAs are aggregations of FEAs
and components that together form a
unit.”@en .
```

At the instance level, SHACL (prefix *sh:*) shapes are used to validate structural conformance. Amongst others, these include shapes that validate the aggregation of components and FEAs to PEAs, which is comprised of validating the domain and range of the properties shown in Figure 1, as well as ensuring that components and FEAs are only part of one PEA, excluding transitive relationships (e.g., a component that is part of a FEA which is part of a PEA is by the transitive characteristic of their relationships also part of that PEA). Further, we introduced shapes to ensure that all instances have an identifier, expressed as *dcterms:identifier*, and a source expressed as *dcterms:source.*

Since we retained the structure of QUDT, the SHACL shapes provided by QUDT can be reused. We expand on them, adding cardinality restrictions and further structural requirements. For example, QUDT allows for a quantity to have zero or more quantity kinds. Since the data in a documentation must be clear and leave as little room for faulty interpretation as possible, we enforce that every quantity has exactly one quantity kind, as shown in the following.

```
spead:QuantityShape a sh:NodeShape ;
```

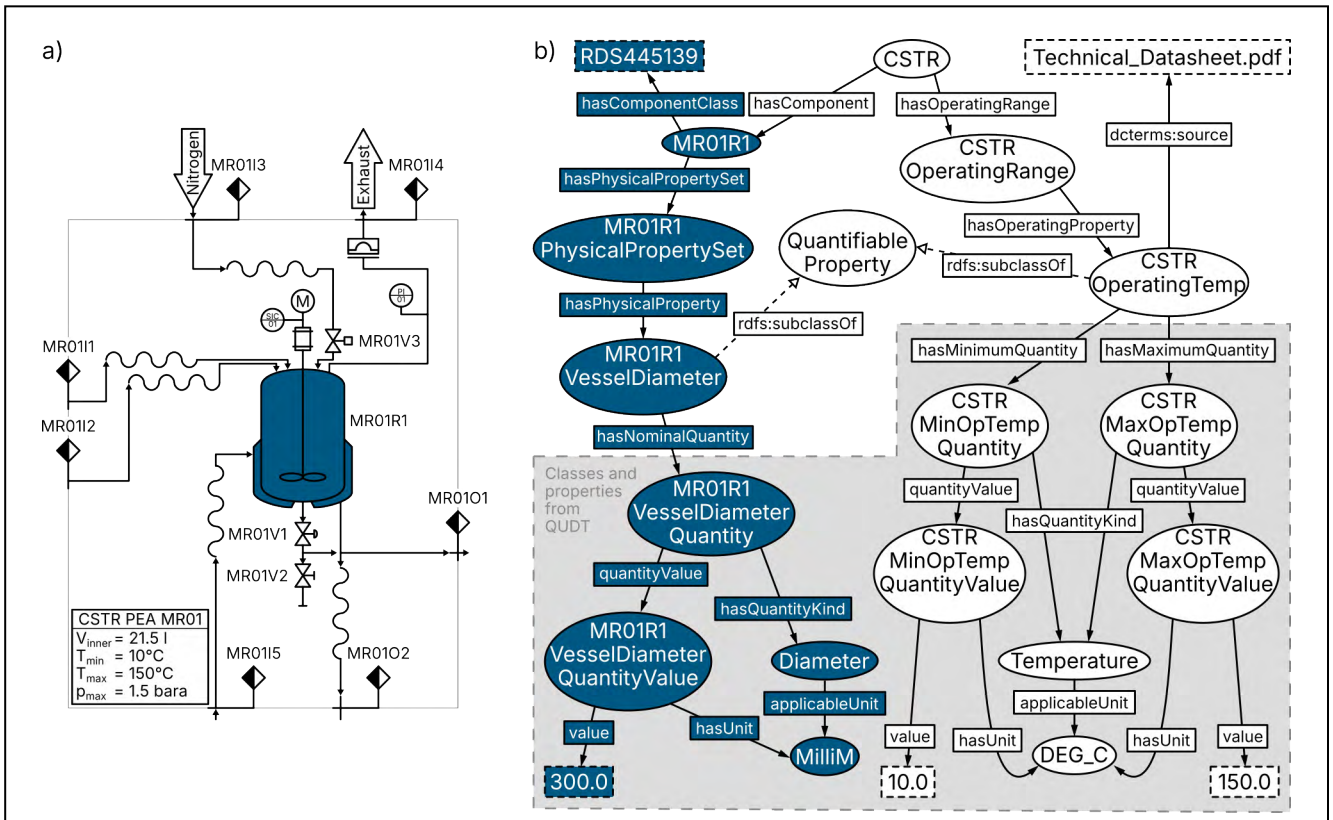

**Figure 4.** a) Simplified P&ID of a Continuous Stirred-Tank Reactor (CSTR) PEA developed within the project REUNION. The reactor component is highlighted in blue. b) Excerpt from the SPEAD representing the CSTR PEA. Highlighted in blue are nodes and properties relating to the reactor component in a). Boxes with dashed outlines indicate literal values, and the properties they are the subject of are datatype properties. Unless otherwise stated, all classes and properties are own definitions.

```
sh:targetClass qudt:Quantity ;
sh:property [
   sh:path qudt:hasQuantityKind ;
   sh:class qudt:QuantityKind ;
   sh:minCount 1 ;
   sh:maxCount 1 ;
] .
```

Further, the minimum and maximum quantity of a property must link to the same quantity kind using the *qudt:hasQuantityKind* property. The quantity values of those quantities must also be associated with at least one unit that is applicable to that specific quantity kind.

## EVALUATION

### Case study: CSTR PEA & Dosing PEA

Two PEAs are used as case studies for the evaluation of our ontology: a continuous stirred-tank reactor (CSTR) PEA as well as a dosing PEA. Figure 4a) shows a simplified P&ID of the CSTR PEA, which is developed as part of the REUNION project. The reactor component is highlighted in blue. The documentation of both PEAs was evaluated and information relevant to the competency questions was transformed into an instance graph of the SPEAD ontology, an excerpt of which is shown in Figure 4b) for the CSTR PEA. Nodes, relationships and values that directly relate to the reactor component are highlighted in blue. Figure 4b) shows how the diameter of the reactor vessel as well as the operating temperature of the CSTR PEA are modelled using our ontology. The vessel component is identified as a vessel-class component through a reference to the same Reference Data Library (RDL) used by DEXPI via the datatype property *spead:hasComponentClass*. Provenance of the operating temperature property is given with the *dcterms:source* property. In total, the SPEAD of the CSTR PEA contains 358 triples, while the SPEAD of the dosing PEA includes 214 triples, excluding any inferred triples.

We validated the ontology against the CQs shown in Table 1 and Table 2 through SPARQL queries. As an example, the following query was used to validate CQ1:

```
SELECT ?val ?unitLbl
WHERE {
   ?pea dcterms:identifier “MR01” .
   ?pea ssn-system:hasOperatingRange/
ssn-system:hasOperatingProperty ?prop .
```

```
   ?prop spead:hasMaximumQuan-
tity/qudt:hasQuantityKind quantitykind:Pres-
sure .
   ?prop spead:hasMaximumQuantity/qudt:quan-
tityValue ?valNode .
   ?valNode qudt:value ?val .
   ?valNode qudt:unit/rdfs:label ?unitLbl .
}
```

For the content-related questions, the instance graph of both PEAs successfully covers operating parameters (CQs 1-3, see also Figure 4b)), as well as design parameters and PEA structure details (CQs 4-6). Certification and service details (CQs 7 and 8) are technically answerable, though the current implementation has limited expressiveness compared to the structure of quantifiable properties, which is discussed below. Integration of metadata properties from VDI 2770 enables the instance graph to answer provenance-related questions (CQs 9 and 10). CQ11 is covered through our strict policy to include labels, alternative labels, definitions, and sources for every newly introduced class and property. By validating the instance graph with our SHACL shapes we ensured that CQ12 was also successfully met.

In addition to our own CQs, we evaluated the ontology against 8 of the 11 competency questions derived by Koch et al. based on the selection of PEAs for a neutralisation process [11]. The remaining 3 CQs cover the entire modular plant, which exceeds the scope of our ontology. SPEAD performs well in answering their questions related to asset specification. For example, the question "How many centrifugal pumps does the PEA module have?" can be answered by counting the number of component nodes directly or indirectly linked to the PEA node through the *spead:hasComponent* property which are the subject of the property *spead:hasComponentClass* with the value set to the appropriate component class from the DEXPI RDL. However, the questions regarding the functional design cannot be answered, since SPEAD does not include mathematical models for the process design. This could be addressed in the future by further integrating the relevant submodels of OntoCAPE.

## DISCUSSION

The SPEAD ontology sufficiently addresses CQs 1-6 by modelling the structure of PEAs and their quantifiable properties in a consistent, verifiable manner. However, in its current state, the implementation of the *spead:Capability* and *spead:SafetySpecification* classes limit the quality of the stored information. This stems from a deliberate design choice. In automation terms, the capabilities of a PEA are reflected through the implemented MTP services. While enriching the SPEAD ontology with service descriptions would improve human readability, the operational information already exists in the MTP files. The current implementation only adds metadata, avoiding the duplication of information.

We did not focus on the safety specifications, only implementing and validating them in a string-based format. In the future, especially in cases such as ATEX certifications or the IP rating of a PEA, small controlled vocabularies could be used to express safety related properties of a PEA instead.

Compared to OntoCAPE and DEXPI, SPEAD defines terminology definitions more precisely (*rdfs:comment* vs. *skos:definition* and *dcterms:source*), though all three models are capable of answering CQ11. However, neither OntoCAPE nor DEXPI can answer CQ9 and CQ10, which are crucial for traceability and trust, especially in documentation. These questions are addressed by SPEAD through its utilisation of PROV-O and its implementation of metadata properties from VDI 2770.

The evaluated CSTR and dosing PEAs in our study consisted of 358 and 214 triples respectively. Information was primarily drawn from P&IDs and technical data sheets, which were the only available documents due to the ongoing development of the PEAs. We expect a single SPEAD to be of the order of $10^4$ triples, and a modular plant to be of the order of $10^5$ triples.

At this scale, both reasoning and validation remain tractable. The OWL constructs used in SPEAD are intentionally conservative, avoiding complex role chains and nominals. This keeps reasoning complexity polynomial with respect to graph size, meaning that a tenfold increase in graph size does not lead to a disproportionate increase in reasoning time. SHACL validation performance is similarly predictable: most shapes are node- or property-scoped and scale linearly with the number of instances. One exception is the path-based constraint excluding transitive aggregation relationships, which could become costly for deeply nested structures. In practice, nesting depth is bounded by the four-level component-FEA-PEA-MP hierarchy defined in VDI 2776-1.

## CONCLUSION & OUTLOOK

We introduced the SPEAD ontology for the documentation of Process Equipment Assemblies that collects and categorises information on PEAs and enriches this information with documentation metadata. We evaluated the ontology against competency questions that cover both content of the information model as well as terminology and provenance-related information, which we derived from an exemplary use case. We also evaluated the ontology against competency questions from the literature. The results show that the ontology works well for the considered use case of exchanging PEAs in an existing plant. Compared to existing data models, it improves the tracking of provenance related metadata.

The next steps in the development of SPEAD include

the improvement of the description of module capabilities and safety-related properties. Further, additional use cases for SPEAD will be investigated. For example, we aim to investigate how SPEAD can be used in the matching of PEAs during the plant engineering phase. SPEAD could also be used as a source of static information for process simulation models, e.g., stirrer speed or wall thickness. Further, we aim to extend the ontology to also cover the non-modular environment. This is based on the VDI 2776-1 guideline, which states that the non-modular environment can be considered as a PEA in the context of automation [2]. We extend this assumption to the documentation. The resulting "Infrastructure SPEAD" can be used to perform matching queries with the SPEADs of a pool of PEAs to select PEAs based on their compatibility with the infrastructure.

Since the creation of instance graphs can be a time-consuming task, an automated pipeline to convert existing documentation such as technical data sheets into SPEADs should also be explored.

Lastly, due to the emergence of the Asset Administration Shell (AAS) as a key digital twin technology, integration of SPEAD either as a source for semantic identifiers or as its own submodel should also be considered.

## ABSTRACT

Hierarchical optimization problems such as (generalized) semi-infinite optimization problems and bilevel problems appear in various disciplines of process systems engineering, such as flexibility analysis or parameter estimation. Adaptive discretization-based algorithms are a family of methods to solve these problems. In these methods, the original problem is decomposed into subproblems, which are solved with a standard optimization solver and then refined iteratively. Several related algorithms have been published. Until recently, computational studies have typically been performed using publication-specific implementations and benchmark problems. We recently published a software package – libDIPS – comprising existing adaptive discretization-based algorithms and a library of test problems for comparison. Several of the algorithms implemented in libDIPS exhibit strong parallelization potential in their algorithmic steps: In the algorithms of Mitsos [Optimization 60:1291-1308 (2011)] and Mitsos and Tsoukalas [J Glob Optim 61:1-17 (2015)], the upper- and lower-bounding procedures are independent. In the algorithm of Tsoukalas and Rustem [Optim Lett 5:705-716 (2011)], several objective function values can be probed independently for feasibility. However, algorithm statements in the literature typically only consider serial execution of the algorithm steps. While parallelization of the used subsolver is already possible in libDIPS, leveraging parallelization in the algorithmic steps has not been investigated until now. In this contribution, we present an overview of libDIPS and introduce our parallelized implementations of several existing algorithms. We investigate the effect of parallelization at the algorithm-level compared to parallelization within the subsolver. Furthermore, we propose two improvements to speed up the solution process of the algorithms compared to their original publications. Results are presented for the existing library of test problems collected from literature.

**Keywords**: Optimization, Parallelization, Numerical Methods, Semi-Infinite Programming

## INTRODUCTION

Hierarchical optimization problems occur in various applications in process engineering, such as flexibility analysis [12] or thermodynamics [11]. Broadly speaking, hierarchical optimization problems include (generalized) semi-infinite optimization problems ((G)SIPs), existence-constrained semi-infinite optimization problems (ESIPs), bilevel problems and minmax problems. In hierarchical optimization problems, an upper-level problem is constrained by the solution of an embedded lower-level problem. Solving these optimization problems to global optimality is challenging especially when their lower-level problems are nonconvex, since even establishing feasibility of a point requires global optimization of the lower-level problem.

Several approaches for global optimization of hierarchical problems have been developed over the past decades, among them adaptive discretization-based methods, which decompose the original problem into several subproblems and iteratively refine them. A major advantage of adaptive discretization methods is that standard optimization solvers can be used to solve the subproblems. However, until recently, computational

studies to evaluate different methods' performance were typically done using publication-specific prototype implementations and benchmark problems, thereby limiting the possibility for fair comparisons between different methods. In previous work, we published libDIPS [7], a software of unified implementations of existing adaptive discretization-based algorithms [1-6, 8-10] and a large library of test problems collected from literature, enabling benchmarking and comparisons of the different algorithms.

In this contribution, we present several recent additions to libDIPS aimed at improving the computational performance of several solvers. We focus on solvers for SIPs and GSIPs and exploit parallelization potentials at the algorithmic level (as opposed to the subproblem level, which is already possible with appropriate subproblem solvers). Furthermore, we present two heuristics that improve some of the solvers' performance compared to their original publications.

We consider SIPs (1) and GSIPs (2):

$$\min_{\boldsymbol{x}\in X} f(\boldsymbol{x}) \tag{1a}$$
$$\text{s.t. } g(\boldsymbol{x},\boldsymbol{y}) \leq 0 \;\forall \boldsymbol{y} \in Y \tag{1b}$$

$$\min_{\boldsymbol{x}\in X} f(\boldsymbol{x}) \tag{2a}$$
$$\text{s.t. } g(\boldsymbol{x},\boldsymbol{y}) \leq 0 \;\forall \boldsymbol{y} \in Y(\boldsymbol{x}) \tag{2b}$$

We call $\boldsymbol{x}$ the upper-level variables and $\boldsymbol{y}$ the lower-level variables. We assume continuity of $f$ on $X$ and $g$ on $X \times Y$. Further, we assume that the sets $X, Y$, and $Y(\boldsymbol{x})$ are compact and defined by continuous functions. These assumptions are made by the algorithms considered in the following [8, 9, 13] and are also typically required by the subsolvers. We only consider a single semi-infinite constraint ((1b) and (2b), respectively) for ease of notation, although the algorithms and our implementations can handle multiple semi-infinite constraints.

## A SOFTWARE FRAMEWORK FOR SOLVING HIERARCHICAL OPTIMIZATION PROBLEMS

We briefly describe libDIPS from a user's perspective, specifically focusing on aspects of modeling and solving hierarchical optimization problems. For a detailed description of all features and implementation details, we refer to [7] and the libDIPS repository (see Digital Supplementary Material).

To model a problem in libDIPS, users must specify the subproblems as text files using the domain-specific language provided by libALE [18], which allows writing optimization problems in an intuitive fashion. There are two options for modeling the subproblems: users can formulate them in an opinionated way or use the provided template files to automatically derive the subproblems from the overall problem description. While the latter approach is arguably simpler to follow, the former allows users to exploit problem characteristics to potentially construct subproblem formulations tailored for the used subsolver. We illustrate this using an example workflow below.

As mentioned above, one advantage of adaptive discretization algorithms is that their subproblems can be solved by state-of-the-art MINLP optimization solvers. libDIPS provides interfaces to several commercial and open-source solvers, among them CPLEX [15], Gurobi [16], and our in-house solver MAiNGO [17]. For a continuously updated list of supported solvers, we refer to the libDIPS repository.

### Example workflow

At a high level, the workflow for solving problems with libDIPS consists of writing the subproblems into text files, parsing these and passing the parsed problem objects to one of the solvers implemented in libDIPS, which then solves the problem. Output is written to the console and subsolver logs are written to files, enabling the user to track the overall solution progress.

#### Modeling in libDIPS

Assume we want to solve the following SIP using the *B&F* algorithm [1] (to be described):

$$\min_{\boldsymbol{x}\in[-2,2]^2} x_1^2 + 2x_2^3 \tag{3a}$$
$$\text{s.t. } \min\{x_1 - y_1, x_2 - y_2\} \leq 0, \forall \boldsymbol{y} \in [-1,1]^2 \tag{3b}$$

The required input files are given in Listings 1-4. Note that we show two formulations of the lower-level problem: Listing 2 uses the provided template and Listing 3 formulates the problem in an opinionated way. Besides defining the subproblems `lbp` and `llp`, a definitions file is required to mark special symbols in the subproblems, such as those related to the discretization or algorithm-specific ones.

#### Solving problems using libDIPS

As the name suggests, libDIPS is a library of solvers, which users can utilize in their own software tools. Furthermore, we provide standalone demos for all solvers, which demonstrate how to call the solvers from a C++ workflow. The demo executables can also be used to solve any problem defined in the format specified above. The default subsolver for the subproblems is MAiNGO; users can easily change this to their preferred solver in the build configuration file.

## IMPROVING THE PERFORMANCE OF (G)SIP ALGORITHMS

The original publications of all algorithms

```
definitions:
real[2] x in [-2,2];
set{index} lbp_k_disc := {};
real[0,2] lbp_y_disc := 0;
real f(real[2] x) := x[1]^2+2*x[2]^3;
real g(real[2] x, real[2] y) := min(x[1]-y[1], x[2]-y[2]);
objective:
f(x);
constraints:
forall k in lbp_k_disc:
    g(x, lbp_y_disc[k]) <= 0;
```

**Listing 1:** The file `lbp.txt` for the example problem (3). Function symbols `f` and `g` are used to enable templated derivation of the subproblems.

---

```
definitions:
real[2] y in [-1,1];
objective:
-g(x,y);
```

**Listing 2:** The file `llp.txt` for the lower-level problem of the example problem (3), using the provided template. For this problem, this results in a nonlinear optimization problem due to the min-operator. Note that subproblems are always written as minimization problems.

---

```
definitions:
real[2] y in [-1,1];
real t in [-3,3];
objective:
-t
constraints:
x[1]-y[1] >= t;
x[2]-y[2] >= t;
```

**Listing 3:** The file `llp.txt` for the lower-level problem of the example problem (3), using an opinionated formulation. For this problem, this results in a linear optimization problem.

---

```
programdefinitions("lbp"):
set_disc(1) = lbp_k_disc;
set_disc_parameter_src(1, lbp_y_disc) = y;
```

**Listing 4:** The file def.txt for the example problem (3), defining `lbp_k_disc` as the set of discretization indices and `lbp_y_disc` as the discretized set $Y^{\mathrm{LBP}}$.

implemented in libDIPS only consider serial execution of the algorithmic steps. Multi-core architectures can still be exploited by parallelism in the subsolver called to solve the subproblems. However, several of the algorithms offer potential for parallelization on their own. Here, we consider the *RRHS* algorithm [8], the *GSIP-RRHS* algorithm [9] and the *Oracle* algorithm [13]. Furthermore, we propose changes to the algorithmic steps to improve the algorithms' performance.

## Parallel bounding in *RRHS* and *GSIP-RRHS*

*RRHS* [8] and *GSIP-RRHS* [9] combine the lower-bounding procedure from the *B&F* algorithm [1] with an upper-bounding procedure based on restricting the

right-hand-side of the semi-infinite constraint. We briefly state the main ideas of the algorithm here and refer to the original publications for full details. The two subproblems are given for an SIP in the following:

$$\min_{\boldsymbol{x}\in X} f(\boldsymbol{x}) \tag{4a}$$
$$\text{s. t. } g(\boldsymbol{x}, \boldsymbol{y}^k) \leq 0 \; \forall \boldsymbol{y}^k \in Y^{\text{LBD}} \tag{4b}$$

$$\min_{\boldsymbol{x}\in X} f(\boldsymbol{x}) \tag{5a}$$
$$\text{s. t. } g(\boldsymbol{x}, \boldsymbol{y}^k) \leq -\varepsilon \; \forall \boldsymbol{y}^k \in Y^{\text{UBD}}, \tag{5b}$$

Where $\epsilon > 0$, and $Y^{\text{UBD}}, Y^{\text{LBD}}$ constitute sets of finite cardinality, i.e., discrete subsets of the infinite set $Y$. Problem (4) is the lower-bounding problem. Problem (5) is the upper-bounding problem, which is generally neither a relaxation nor a restriction and may not yield an upper bound in every iteration. Note that the two problems use separate discretizations, $Y^{\text{LBD}}$ and $Y^{\text{UBD}}$ (a shared discretization is possible, but this leads to larger subproblems and may offset any performance gains seen by reducing the number of iterations). Thus, while the original publications alternate between solving the upper- and lower-bounding subproblems, these can be solved in parallel, as subsequent iterations are not dependent on information from the respective other procedure.

Candidate points $\bar{\boldsymbol{x}}$ computed from problems (4) and (5) are checked for feasibility by solving the lower-level problem:

$$g^* = \max_{\boldsymbol{y}\in Y} g(\bar{\boldsymbol{x}}, \boldsymbol{y}) \tag{6}$$

If $g^*$ is non-positive, the candidate point $\bar{\boldsymbol{x}}$ is SIP-feasible, otherwise, it is infeasible. In the latter case, the associated value $\boldsymbol{y}^*$ is used to refine the discretization of the corresponding upper-level problem (i.e., if $\bar{\boldsymbol{x}}$ was generated by (4), $Y^{\text{LBD}}$ would be updated to $Y^{\text{LBD}} \cup \{\boldsymbol{y}^*\}$). Note that problems (4) and (6) are the subproblems used in the *B&F* algorithm, which only computes lower bounds.

Besides the obvious benefit of potentially being able to solve more subproblems in a fixed amount of time, decoupling the upper- and lower-bounding procedures has another advantage: It enables the algorithm to progress faster when one procedure has already found a "good" bound. The sequential implementation of *RRHS* and *GSIP-RRHS* alternates between solving problems (4) and (5). If one of the procedures quickly finds a "good" bound and stops progressing, subsequent iterations of that procedure are still performed but do not contribute to convergence of the algorithm. By decoupling the two procedures, the optimality gap may be closed faster because neither procedure needs to wait for an iteration of the other to complete before continuing. We test this claim using the library of test problems in libDIPS.

## Early refining of the upper-bounding discretization in *RRHS* and *GSIP-RRHS*

For *RRHS*, we already presented a guard heuristic in [7], in which the upper-bounding procedure is skipped until the lower-bounding procedure produces $\varepsilon^a$-SIP-feasible points with $\varepsilon^a > 0$. Whenever the upper-bounding procedure is skipped, the upper-bounding discretization is populated with the discretization point obtained from the lower-bounding procedure. The aim of the guard is to quickly refine the upper-bounding discretization in early iterations, when the upper-bounding procedure is unlikely to find a feasible point. For *GSIP-RRHS*, this approach is analogously applicable. However, the guard heuristic only makes sense when the algorithms are executed in serial fashion. In the parallel implementations, such a guard cannot be directly applied, as the upper- and lower-bounding procedures are run in parallel, so skipping the upper-bounding procedure does not make sense.

In the parallel versions of *RRHS* and *GSIP-RRHS*, we propose to achieve this aim in a similar fashion. Whenever the lower-bounding procedure furnishes a new discretization point, we check if a valid upper bound has been found. If this is not the case, we add the discretization point to the upper-bounding discretization.

## Parallel objective probing in *Oracle*

The *Oracle* algorithm [13] adapts the algorithm from [1] to obtain both lower bounds and feasible points. It does so by solving the oracle problem (7) to determine whether an objective function value $f^{\text{target}}$ is attainable.

$$\min_{\boldsymbol{x}\in X} \max\{f(\boldsymbol{x}) - f^{\text{target}}, \max_{\boldsymbol{y}^k \in Y^{\text{ORA}}} g(\boldsymbol{x}, \boldsymbol{y}^k)\}, \tag{7}$$

Where $Y^{\text{ORA}}$ is a set of finite cardinality If $f^{\text{target}}$ is not attainable with a given discretization $Y^{\text{ORA}}$, it is a lower bound to the optimal objective value. On the other hand, if the target is attainable in the discretized subproblem and the lower-level problem proves the candidate point SIP-feasible, an upper bound is obtained. In the latter case, the lower-level problem may also declare the candidate point SIP-infeasible, in which case the discretization is refined, and the oracle problem is re-solved for the same target value. After successfully finding a new upper or lower bound, the target value is updated (in the original publication by bisection) and the oracle problem is solved again, starting with the discretization of the last iteration.

The *Oracle* algorithm offers great potential for parallelization similarly to runahead computing [14], where additional threads operate a few steps ahead of the main thread to speculate on the future state. In *Oracle*, this means that multiple objective value targets can be probed in parallel. For example, rather than just probing the midpoint between the current lower and upper bound, two additional threads can be used to probe the

upper and lower quarter of the interval as well, thereby effectively computing the next iteration of the algorithm in parallel. This idea can be generalized to arbitrarily many targets, assuming sufficient computing capabilities. Whenever a thread computes a new bound, any threads probing targets outside the remaining interval are aborted and assigned new valid targets.

Using multiple threads to solve multiple instances of problem (7) for different values of $f^{\text{target}}$ raises the question of how to deal with the discretization $Y^{\text{ORA}}$. On one hand, $Y^{\text{ORA}}$ should not grow unnecessarily large to avoid generating overly large subproblems. On the other hand, discretization points generated by one thread for a particular value of $f^{\text{target}}$ may also be relevant for other target values. Thus, we present three strategies for handling the discretization. First, it is possible for each thread to have its own discretization, which is never synchronized with other threads (referred to as strategy "Off" in our numerical experiments later). This results in discretizations of minimal size in the sense that every thread only includes those points in its discretization which have been proven to be necessary in at least one iteration. However, this approach may lead to multiple threads computing the same discretization points, potentially increasing the total number of subproblems solved.

Second, it is possible for the threads to share a single common discretization (strategy "All"). Whenever the solution of a lower-level problem in a thread adds a discretization point, all other threads also use that point in subsequent iterations. While this leads to the subproblems becoming tighter and potentially requiring fewer iterations, it may also yield unnecessarily fine discretizations, increasing the difficulty of solving individual subproblems.

A third option is to combine the previous two approaches. Each thread uses its own discretization, but whenever a thread produces an update to the lower or upper bound, all other discretizations are updated to include the discretization points of the successful thread (strategy "Opt"). This approach attempts to combine the best aspects of the other two approaches: sharing discretization points that have proved useful in computing tighter bounds without producing unnecessarily fine discretizations. We test all three approaches using the library of test problems in libDIPS to confirm our claims.

### A secant-based heuristic for updating the target value of *Oracle*

In the original publication of *Oracle* [13], new objective function target values are selected through bisection of the objective space. While this approach is simple to implement, it may lead to situations where a very good upper or lower bound is found quickly, but many iterations are required to prove (approximate) optimality or find a "good" feasible point.

To improve the convergence of the algorithm, we attempt to improve on the simple bisection of the objective space when selecting a new target objective value. In particular, we want to exploit iterates that lie near the boundary of the semi-infinite constraint. Once the algorithm has furnished an upper or lower bound with a sufficiently small absolute value of the semi-infinite constraint, we propose to probe the objective space in the vicinity of this bound as follows:

$$f^{\text{target}} = LBD + \frac{-g^{\text{LBD}}}{g^{\text{UBD}} - g^{\text{LBD}}}(UBD - LBD) \quad , \tag{8}$$

Where $g^{\text{LBD}} > 0$ and $g^{\text{UBD}} < 0$ are the violations of the semi-infinite constraint at the solutions generating the lower and upper bound, respectively, and $LBD$ and $UBD$ refer to the current lower and upper bounds on the objective value. The intuition behind (8) is to estimate a root of the semi-infinite constraint using the secant method, and that this approximation provides a valid proxy for the optimal objective function value, i.e., we expect the ratio $\frac{-g^{\text{UBD}}}{g^{\text{LBD}}}$ to be a good approximation of $\frac{UBD - f^*}{f^* - LBD}$, where $f^*$ denotes the optimal objective value. In a neighborhood around the optimum, this is typically a valid assumption and can lead to significant reductions in the remaining objective space compared to bisection. We only apply the heuristic once a threshold $g^{\text{t}}$ for the absolute value of the semi-infinite constraint is reached, i.e., $\min\{g^{\text{LBD}}, -g^{\text{UBD}}\} < g^{\text{t}}$, as we do not necessarily expect the linear approximation from the constraint space to the objective space to be sufficiently accurate far away from the minimum due to non-convexity. We present numerical experiments to determine this threshold below.

## NUMERICAL RESULTS

We performed numerical experiments using the library of test problems collected in the libDIPS repository, which contains 336 SIPs and 86 GSIPs. Further details on the test set can be found in [7].

All computations were performed on the RWTH High-Performance Computing cluster CLAIX-2023. All subproblems were solved with MAiNGO v0.9.1, configured to use CPLEX v22.1.2 to solve (mixed-integer) linear or quadratic optimization problems. Additionally, multistarting in MAiNGO was performed using SLSQP, implemented as part of NLopt [19]. In some of the following experiments, we configured MAiNGO to use multiple threads. In those runs, MAiNGO set the number of threads used by CPLEX correspondingly. All other settings were left unchanged compared to those used for benchmarks in [7]. As in [7], we rounded all runtimes below 1 second (s) to 1 s, as we compare the solver configurations relative to each other and cannot fairly differentiate times below 1 s. Due to the increased memory requirement of the multithreaded implementation, 18 large

SIP instances were not tractable (despite being tractable but unsolved in [7]) and are omitted in the results below. This omission increases the relative percentage of problems solved compared to [7], however, the absolute numbers of our serial implementation are consistent with the results reported there.

## Parallelization of *RRHS* and *GSIP-RRHS*

We first investigated the performance of our parallelized implementations of *RRHS* and *GSIP-RRHS* using several parameter configurations. The results in [7] already showed that the guard heuristic performs favorably for a serial implementation of the algorithm. We now compare this to our parallel implementation, both with and without the heuristic enabled. For the parallel implementation, we ran the upper- and lower-bounding procedures using a single thread each. We also re-ran the serial implementation using two threads for the subsolver to enable a fair comparison and demonstrate the difference between parallelizing the algorithmic steps and parallelizing in the subsolver.

Figure 1 shows the performance profile for all configurations of *RRHS* on the SIP problem set. The multithreaded implementation without the early refinement of the upper-bounding problem's discretization performs best, solving problems faster than the other configurations and solving a larger fraction of problems overall. Surprisingly, the early refinement does not carry its advantage from the serial case to the parallel case. We suspect that this is due to the extra discretization points not being as useful in the parallel case, as the upper-bounding problem is solved from the start. Thus, the upper-bounding problem's discretization may become unnecessarily dense in this case, leading to harder subproblems.

For unsolved instances, we define the remaining optimality gap as $\min\{UBD - LBD, \frac{UBD-LBD}{UBD}\}$. In Figure 2, we plot the percentage of unsolved problems over the remaining optimality gap for each configuration. The multithreaded implementation achieves better remaining gaps than the serial implementation, indicating that parallelizing the algorithmic steps of *RRHS* is indeed more efficient than using all available threads for the subsolver.

We show the performance profile for GSIP-*RRHS* applied to the GSIP problem set in Figure 3. Again, parallelism at the algorithmic level pays off, as the multithreaded implementations are faster and solve a slightly higher percentage of the problem set. In contrast to the SIP case, extra refinement of the upper-bounding procedure does not seem to impact the performance of the multithreaded implementation but harms the serial one.

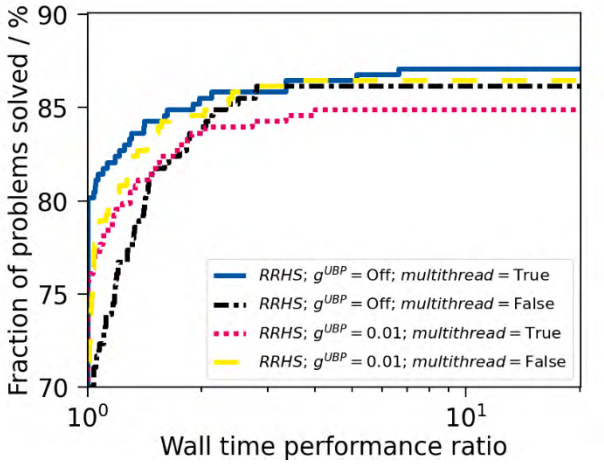

**Figure 1.** Dolan-Moré plot of wall time performance ratio for *RRHS* on the SIP problem test set.

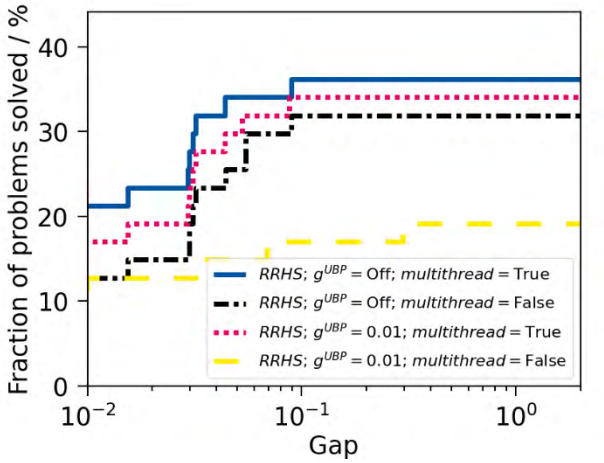

**Figure 2.** Fraction of SIP instances that are not solved by one of the *RRHS* configurations but would have been considered solved with a larger optimality tolerance.

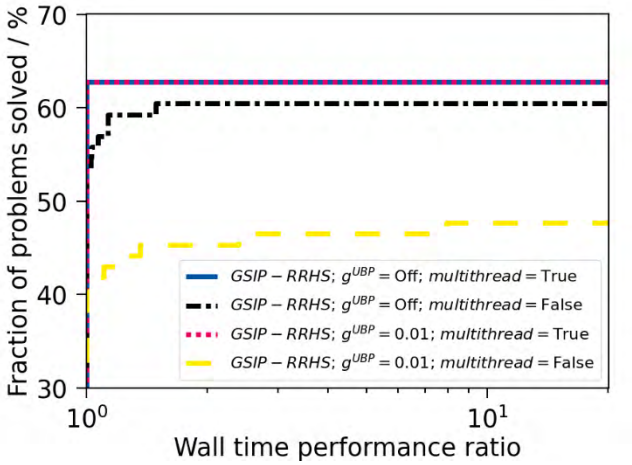

**Figure 3.** Dolan-Moré plot of wall time performance ratio for GSIP-*RRHS* on the GSIP problem test set.

## Secant-based heuristic in *Oracle*

To determine a good value for the threshold hyperparameter $g^t$, we solved the benchmark set of SIPs using the serial implementation of *Oracle* while varying $g^t \in \{0, 0.01, 0.1, 0.5, 1, 1000\}$. Note that setting $g^t = 0$ disables the heuristic and setting $g^t = 1000$ effectively enables it as soon as a feasible upper bound is found. We evaluated each setting based on (rounded) runtime (RT) and the total number of subproblems (NSP) solved. We present the results in Table 1. Note that in many cases, multiple settings yielded equal numbers of subproblems or (rounded) runtimes. The number of unique winners is lower for both metrics.

The results indicate that always using the secant heuristic for target selection is superior in terms of the number of subproblems solved in many cases, while there are some problems in the test set that benefit from setting the threshold $g^t$ to a small value or completely disabling the heuristic. In terms of runtime, all settings performed similarly due to most of the problems being solvable in under 1 s. Nevertheless, the number of unique winners exhibits qualitatively similar behavior for runtime as for the number of subproblems.

We found that enabling the heuristic resulted in up to six problems (depending on the value of $g^t$) of the test set not being solved that were solved without the heuristic. There were two reasons for this: in some cases, the heuristic was exact and proposed a target value equal to the minimum, in which case finite termination is not guaranteed [13]. In other cases, the initially computed upper bound was feasible and triggered the heuristic, but the ratio $\frac{-g^{\mathrm{UBD}}}{g^{\mathrm{LBD}}}$ was significantly smaller than $\frac{UBD - f^*}{f^* - LBD}$, leading to target updates close to the upper bound. In combination with a very large upper bound, this resulted in the algorithm failing to converge within the iteration limit. On the other hand, there were two instances that were solved with some settings of the heuristic but were unsolved without it.

**Table 1.** Statistics for the secant heuristic over the entire benchmark set. The number of unique winners is given in parentheses.

| Threshold $g^t$ | # lowest NSP | # lowest RT |
|---|---|---|
| 0 | 99 (11) | 217 (11) |
| 0.01 | 125 (15) | 228 (19) |
| 0.1 | 143 (19) | 220 (12) |
| 0.5 | 132 (0) | 215 (6) |
| 1 | 139 (3) | 224 (23) |
| 1000 | 214 (95) | 228 (28) |

## Parallelization of *Oracle*

We investigated multiple configurations of *Oracle* to determine the benefit of parallelism. Based on the results of the previous section, we always enabled the secant heuristic as it usually required fewer subproblems to be solved. As a baseline, we used the serial implementation, giving 16 threads to the subsolver. We then compared this to two levels of parallelism: probing four targets in parallel with four threads per subsolver and probing 16 targets in parallel with one thread per subsolver. For both configurations involving parallelism at the algorithmic level, we investigated all three strategies for the discretization as mentioned earlier.

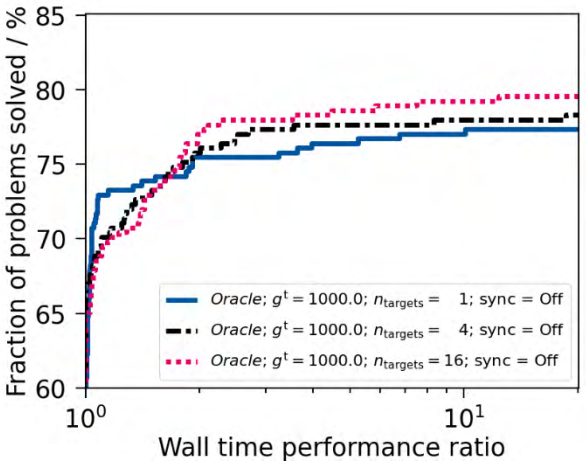

**Figure 4.** Dolan-Moré plot of wall time performance ratio for different parallelization strategies in *Oracle*.

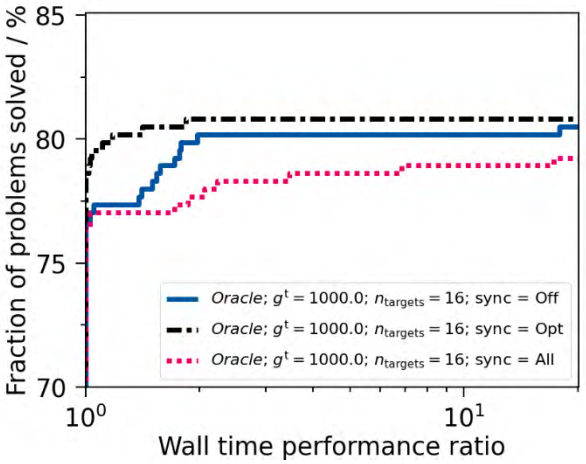

**Figure 5.** Wall time performance ratio for different discretization synchronization strategies in *Oracle*.

We plot the wall time performance ratio for all three parallelization strategies with no synchronization of discretizations in Figure 4. As for *RRHS*, parallelization at the algorithmic level leads to a larger percentage of the test set being solved. At small time ratios, the plot shows that the serial strategy outperforms the parallel strategies. We attribute this to the lack of a proper method to abort the optimization within MAiNGO. Thus, the parallel implementations may achieve optimality faster than their reported runtimes, as they must wait for all running

MAiNGO instances to complete before terminating. In some rare instances, this led to an estimated performance degradation by a factor of 10 or more. We aim to add an abort-functionality to MAiNGO in a future release and test this hypothesis.

In Figure 5, we plot the performance ratios of different discretization synchronization strategies when probing 16 targets in parallel. Strategy "Opt" performs best, resulting in faster solutions and solving the largest fraction of the problem set. Synchronizing every discretization point (strategy "All") performs worst, indicating that the extra information gained from more discretization points is not worth the extra computational effort involved with solving larger subproblems. Letting each thread use its own discretization with no synchronization (strategy "Off") performs in between the other two strategies, achieving similar performance to strategy "All" for fast problems (likely due to computing the same discretization points across multiple threads), but solving nearly the same fraction of the problem set overall as strategy "Opt" (likely due to the better performance of later subproblems with smaller discretizations).

## CONCLUSION

We presented improved implementations of some of the algorithms for hierarchical optimization problems in libDIPS. We exploited parallelism in the algorithmic steps and demonstrated that this is a more efficient use of available threads than parallelizing only at the subsolver level, enabling faster solutions and increasing the percentage of solved problems. This observation holds for all investigated algorithms. However, parallelism increases memory usage, which led to some instances becoming intractable. Additionally, we presented a promising strategy for synchronizing the discretization used in the multithreaded implementation of the *Oracle* algorithm. The open-source nature of libDIPS enables others to implement and benchmark their algorithms.

We plan to extend parallelization in libDIPS in future releases. This includes investigating parallelization in the steps of other implemented algorithms as well as improving the existing parallelization, such as also enabling the solution of multiple lower-level problems in parallel.

## ABSTRACT

This work aims at verifying the $CO_2$ absorption capture model using monoethanolamine (MEA) solvent developed by the U.S. DOE's Carbon Capture Simulation Initiative (CCSI) and performing uncertainty propagation of mass transfer, liquid hold-up and reaction kinetics properties in the complete model, which includes absorber and stripper columns. The verification of the Aspen Plus CCSI model, based on pilot plant data from the National Carbon Capture Center (NCCC) for a $CO_2$ flue gas concentration between 7 and 11% (mol) allowed uncertainty quantification (UQ) analysis for four different selected operational points using Monte Carlo Simulation (MCS), where low liquid mass transfer parameters exhibited an impact on calculation convergence. Gaussian Processes (GP) surrogate model was implemented, followed by a sensitivity analysis in order to correlate the most sensitive parameters with studied outputs.

**Keywords**: Carbon Capture, Simulation, Aspen Plus, Absorption, Surrogate Model

## INTRODUCTION

Carbon capture, utilization and storage (CCUS) is emerging as a technology to support the energy transition toward net-zero emissions by 2050, to limit the rise in global temperatures as close as possible to 1.5°C. According to the International Energy Agency (IEA) Net Zero Emission (NZE) scenario, CCUS technologies play some critical roles in the transition to net zero, especially considering the difficulty of eliminating emissions in hard-to-abate industrial sectors, aviation and maritime shipping. Since carbon capture technologies can also be applied to already existing energy assets, it has been considered as part of the energy transition strategies, with a post-combustion application of CCS technologies (targeting 95% capture) from fossil-fuel thermal power plants.

The most mature technique for $CO_2$ capture is chemical absorption with amine-based aqueous solutions as absorbents. A steady-state open-source $CO_2$ capture model with 30 wt.% aqueous monoethanolamine (MEA) as the solvent was developed and validated by the U.S. DOE's Carbon Capture Simulation Initiative (CCSI) based on a pilot plant at National Carbon Capture Center (NCCC) [3, 4]. The flowsheet (v3.2.1) of the NCCC pilot plant MEA Steady State Model developed by the U.S. DOE's CCSI and modelled in the process modelling software Aspen Plus is represented in Figure 1. The open-source code is available on the release page [5].

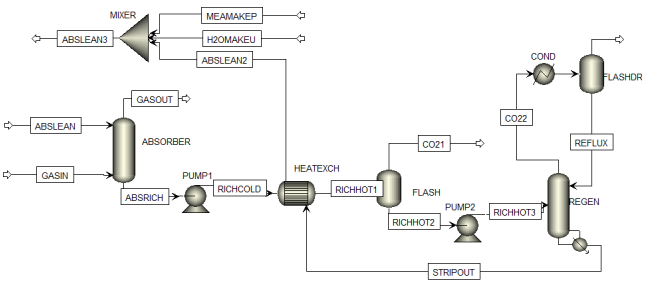

**Figure 1.** CCSI model flowsheet based on NCCC pilot plant, available in [5].

$CO_2$ is captured through the absorber column and recovered in the flash unit and stripper column. A design specification is used in Aspen Plus (rate-based columns using RateSep) to adjust the reboiler duty based on lean $CO_2$ loading setpoint. An economiser heat exchanger is

also included between the lean solvent stripper output and rich solvent absorber output for energy integration.

Uncertainty Quantification (UQ) is a method used to determine the confidence level of a numerical model, outlining the most sensitive sources (process variables or model parameters) and predict outlet variabilities, considering the uncertainty carried by those sources. UQ analysis requires having first verified the model for physical consistency. To allow the UQ analysis in the CCSI $CO_2$ capture model, a set of operational data from NCCC pilot plant from 2014 and 2017 was used for model verification. The %$CO_2$ capture, rich $CO_2$ loading, reboiler duty and rich solvent flow rate were compared to data points to attest model accuracy. Once the model is verified, uncertainty quantification implementation requires the definition of: (1) uncertain sources and their respective distributions and (2) output variables and their quantities of interest (e.g., mean, median, dispersion parameters).

The CCSI initiative developed a complete $CO_2$ absorption process model [3, 4] using UQ analysis while other recent studies such as [8] compared different UQ analysis techniques for an absorber model under one operational condition. This work complements the CCSI uncertainty propagation over larger ranges of liquid and gas flow rates to obtain %$CO_2$ capture and reboiler duty probability distributions. Mass-transfer, hold-up and reaction kinetics properties are used as uncertain sources to obtain %$CO_2$ capture and reboiler duty probability distributions. Then, sensitivity analysis is performed to correlate the most sensitive parameters with studied outputs. While the CCSI initiative obtained the input probability distributions by parameter regression, in this work they are built based on literature data.

# METHODOLOGY

## Uncertainty Quantification Techniques

In general, UQ consists of identifying uncertain parameters and propagating their uncertainty to the numerical model. Different routes exist for UQ. The most straightforward way uses a rigorous model (in the case of this work, the Aspen Plus model) to propagate uncertainties. Initially, a sample from the probability distributions of the chosen uncertain sources is generated. For this work the chosen sampling method is the Monte Carlo Simulation (MCS) where samples are randomly generated according to the defined set of sources probability distributions. Because MCS (as well as other sampling methods) requires a large number of simulations, UQ can be propagated through surrogate models, which approximate the rigorous models with lower complexity and computation cost, but do not represent chemical or physical phenomena. MCS and other computations can then be performed at a lower cost with the surrogate model instead of the rigorous model, for example to perform sensitivity analysis. In this work, Gaussian Processes (GP) surrogate model was implemented in order to obtain 1$^{st}$ and total Sobol indices.

## Uncertain properties and selected outputs distributions

Mass-transfer properties in both absorber and stripper columns (including mass-transfer coefficients and interfacial area), liquid hold-up and reaction kinetics are chosen as uncertainty sources considering previous works on UQ analysis of $CO_2$ chemical absorption process models [3, 4, 8]. The probability distributions were defined according to a literature review of the variability of selected properties or parameters.

Because experimental data are primarily based on measured properties rather than model parameters (except for the reaction rate, for which dedicated experiments were conducted to estimate the rate constant) this work focuses on propagating uncertainties associated with properties rather than parameters. However, in order to perform an uncertainty analysis under different operating conditions, parameters that are directly proportional to these properties were selected to represent the property uncertainty.

The selected uncertain sources, their relative Absolute Average Deviation (AAD), relative standard deviation ($\sigma$) or coefficient of variation (CV), the name of the parameters used to propagate property uncertainty, their mean value and standard deviation are presented in Table 1. The relative AAD is presented in Equation 1 where $N$ is the number of experimental points. The relative AAD is defined as the average of normalised absolute deviations of literature models compared with experimental values. The CV is the normalised standard deviation of the data points with respect to the mean value.

$$relative\ AAD(\%) = \frac{1}{N}\sum \frac{|y_{exp} - y_{model}|}{y_{exp}} \quad (1)$$

For the liquid and gas mass-transfer coefficients and interfacial area, the relative standard deviation is obtained from the relative AAD considering a normal distribution and the Mean-Absolute Deviation model, as discussed in [15]. For liquid hold-up, the AAD and standard deviation were directly obtained using experimental points from [10].

Regarding reaction kinetics, although the rate constants were directly measured, they differ from those implemented in the CCSI model. Usually, reaction rate equations are measured as functions of components concentrations. However, the CCSI model calculates kinetics from components activities, which changes rate constant dimensions. To maintain consistency, the coefficient of variation obtained from the literature rate constants is used to calculate the standard deviation of the CCSI model rate constants.

**Table 1:** Sources of uncertainty and probabilities for uncertainty analysis on the CCSI model

| Measured Source | Source | Relative AAD (%) | Relative $\sigma$ (%) | CV | Parameter | Mean | Standard deviation |
|---|---|---|---|---|---|---|---|
| Liquid mass-transfer coefficient ($k_L$) | [9] | 24 | 30.08 | - | $C_L$ | 0.2033 | 0.0612 |
| Gas mass-transfer coefficient($k_G$) | [9] | 21 | 26.32 | - | $C_G$ | 0.3522 | 0.0927 |
| Interfacial area ($a_e$) | [9] | 8.9 | 11.15 | - | $A_1$ | 1.4225 | 0.1586 |
| Hold-up ($h_L$) | [10] | 14.3 | 17.22 | - | $H_{L1}$ | 11.45 | 1.9725 |
| Kinetic coefficient for Reaction 1 ($k_{F1}$) | [11,12] | - | - | 0.22 | $k_{F1}$ | $2.51\ 10^9$ | $5.54\ 10^8$ |
| Kinetic coefficient for Reaction 2 ($k_{F2}$) | [13,14] | - | - | 0.17 | $k_{F2}$ | $2.29\ 10^4$ | $3.85\ 10^3$ |

Reactions 1 and 2 presented below are used in the CCSI model [3, 4]. Reaction 2 can also be written as a combination of Reactions 3 and 4. Due to a lack of experimental data for Reaction 2, Reactions 3 and 4 were used for literature review. Since Reaction 4 is considered to be at equilibrium, Reaction 3 is therefore rate-limiting. Its coefficient of variation is used to predict the standard variation of $k_{F2}$.

$$2MEA + CO_2 \leftrightarrow MEAH^+ + MEACOO^- \quad (1)$$

$$MEA + CO_2 + H_2O \leftrightarrow MEAH^+ + HCO_3^- \quad (2)$$

$$CO_2 + OH^- \leftrightarrow HCO_3^- \quad (3)$$

$$MEA + H_2O \leftrightarrow MEAH^+ + OH^- \quad (4)$$

The mean and standard deviation of obtained probability distributions are then reported in Table 1. The standard deviations are the product of the AAD or the CV (in the case of rate constants) and the parameters values from the CCSI model [4], used as the mean value. All probability distributions are considered as gaussian distributions.

## RESULTS AND DISCUSSION

### Model verification

For the purpose of uncertainty analysis, the CCSI model was verified using NCCC pilot plant data. The variation range of NCCC data is presented in Table 2. The open-source data were reported in [6, 7]. Figure 2 compares pilot plant data and CCSI model simulations for different outputs over the operational range reported in Table 2. The $\%CO_2$ capture is obtained through the gas mass balance in the absorber, which is equivalent to the $CO_2$ produced in the flash and at the top of the stripper. The data was classified by the use of intercooling at two different heights of the absorber and the number of activated absorber sections, which changes packing height in the simulation model. Out of 52 simulation runs, 44 successfully met the convergence criteria, providing a statistically significant dataset for this study.

**Table 2:** Variation range of NCCC pilot plant data

| Inlet conditions | Range |
|---|---|
| Lean solvent flow rate (kg/h) | 3016-11794 |
| Lean loading (mol $CO_2$/ mol MEA) | 0.065-0.419 |
| Flue gas flow rate (kg/hr) | 1000-2997 |
| $\%CO_2$ vol in flue Gas | 0.067-0.115 |
| Absorber active sections | 1-3 |

A good agreement between model predictions and reference data provides an indication of the quality of the overall model and, by extension, of the mass transfer model. Nevertheless, higher deviation is observed at lower $CO_2$ capture rates.

Since the lean solvent loading is an input variable and the $CO_2$ capture rate is well represented, it is expected that the rich solvent loading should also be accurately reproduced. As, in addition, solvent flow rate does not vary significantly throughout the absorber and the flash unit, the rich solvent flow rate presents a good model prediction for a wide range of flow rates.

Among the output variables, the reboiler duty is the less accurately represented. This variable is more strongly influenced by thermodynamic modelling within the stripper, where only equilibrium reactions are considered. After verifying the model with the operational conditions in Table 2, the uncertain parameters in Table 1 were propagated to obtain the $\%CO_2$ capture and reboiler duty probability distributions.

### Uncertainty Quantification analysis

For the Monte Carlo Simulation (MCS), four different sets of operating conditions, representative of conditions reported in [6, 7] and showed in Table 3, were chosen to propagate the mass-transfer, reaction kinetics and hold-up probability distributions through the simulation model.

The selected cases, K1 and K13, differ primarily from each other due to the presence of intercooling, as well as

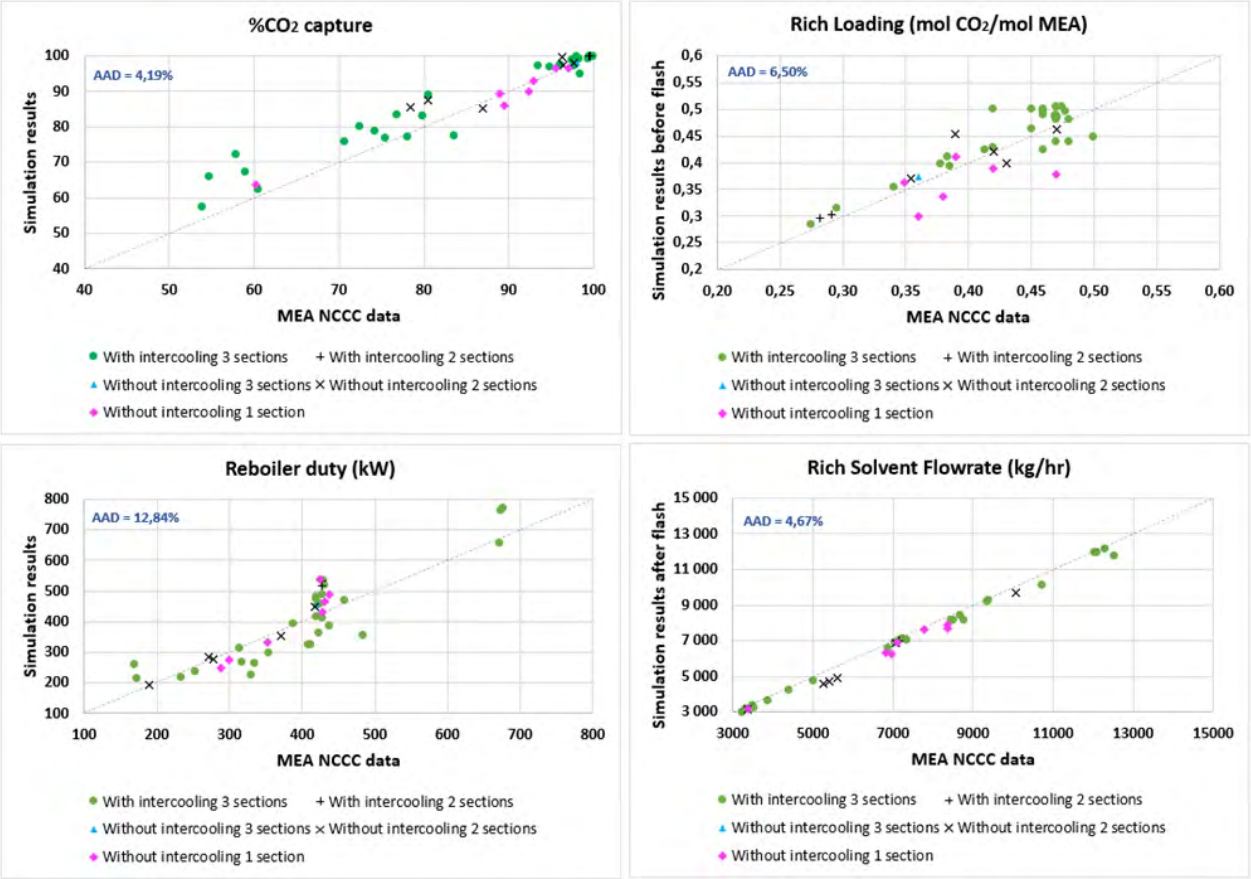

**Figure 2:** CCSI model verification using NCCC data pilot plant with respective relative AAD for the following outputs: $\%CO_2$ capture, rich loading, reboiler duty and rich solvent flowrate.

slight variations in other operational variables. In contrast, the last two cases, 12A and 2D, differ mainly from the first pair because of the lower ratio of lean solvent flow rate to flue gas flow rate. Additional distinctions include minor variations in other operational variables, the presence or absence of intercooling, and, in the case of 2D, a different number of active sections.

A sample consisting of 300 points was generated for each operational condition using Persalys, a graphic interface of OpenTURNS, an open-source software developed by EDF R&D and Phimeca Engineering to facilitate uncertainty analysis in numerical simulation. The $\%CO_2$ capture and reboiler duty probability distributions were analysed with the same sample for the four operational conditions. A Gaussian Processes (GP) metamodel was then constructed for each operational condition for Sobol indices computation.

## Monte Carlo Simulation

### Convergence domains

The simulation framework demonstrated high numerical consistency, achieving a success rate of 95.7% across 1200 runs (300 per operational point). 1148 calculations were completed successfully, while the remainder resulted in warnings (21), errors (26) or non-convergence (5).

**Table 3:** Operational conditions chosen for MCS

| **Cases** | **K1** | **K13** | **12A** | **2D** |
|---|---|---|---|---|
| Lean solvent flow rate (kg/h) | 6804 | 6804 | 4166 | 4600 |
| Lean loading (mol $CO_2$/ mol MEA) | 0.152 | 0.172 | 0.144 | 0.200 |
| Flue Gas flow rate (kg/hr) | 2248 | 2238 | 2976 | 1998 |
| $\%CO_2$ vol on flue gas | 0.115 | 0.093 | 0.097 | 0.107 |
| Absorber active sections | 3 | 3 | 3 | 2 |
| Intercooling | Yes | No | Yes | No |
| ***$\%CO_2$ capture of deterministic model*** | ***99.95*** | ***98.37*** | ***76.81*** | ***87.4*** |

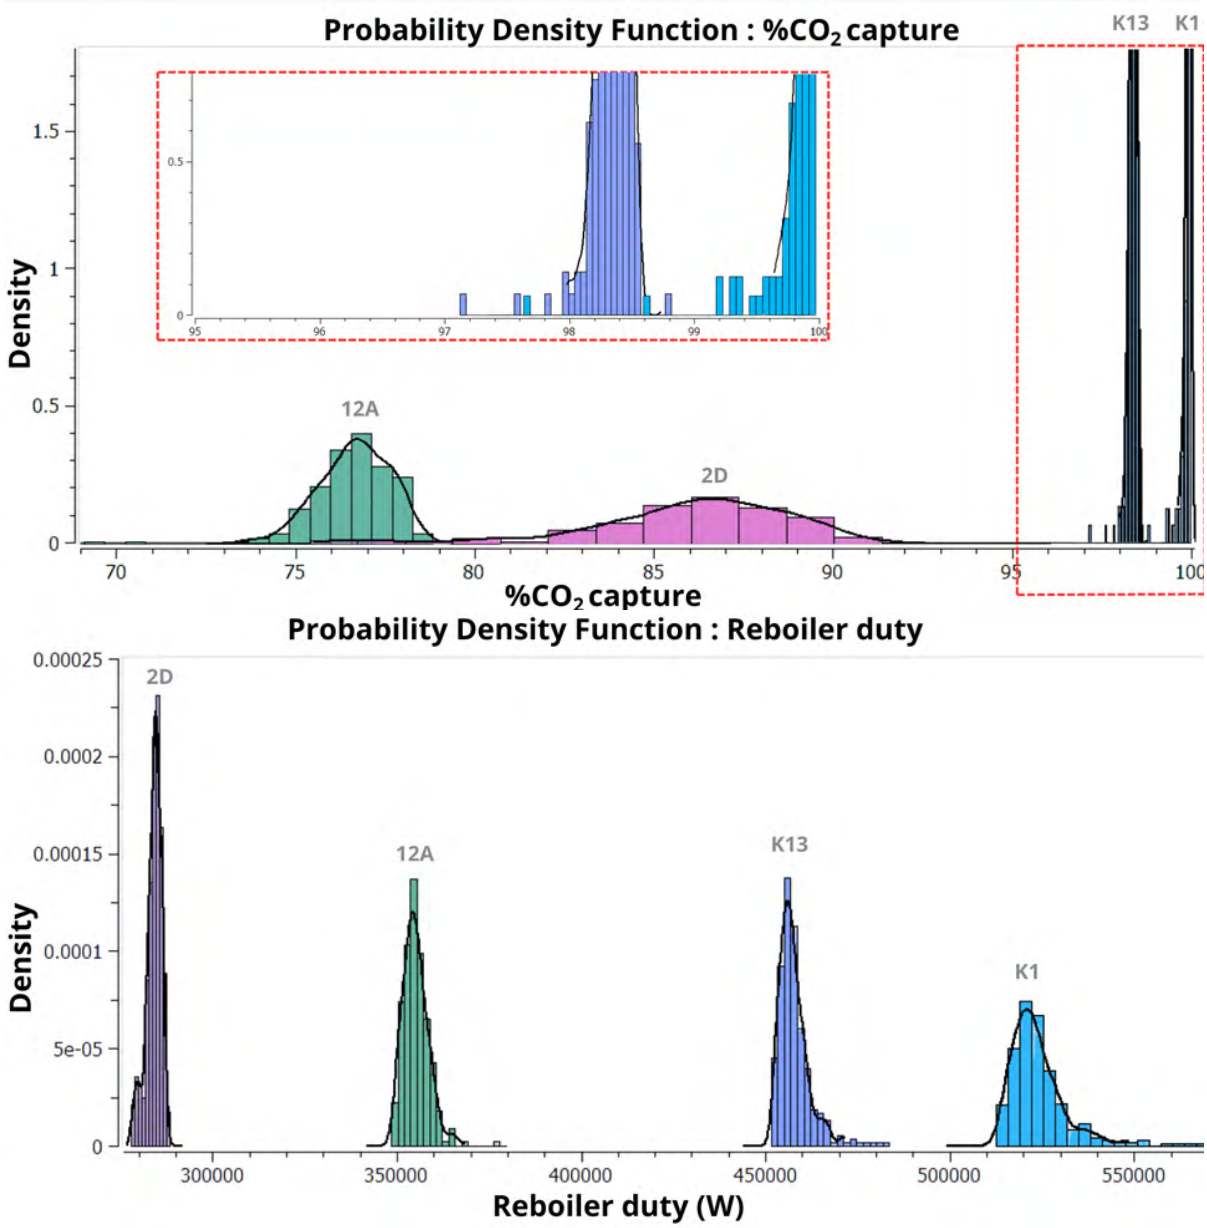

**Figure 3.** Probability distribution of $\%CO_2$ capture (%) and reboiler duty (W) using CCSI model for mass transfer and hold-up uncertain parameters listed in Table 1 and operational points listed in Table 3 : Blue (K1), purple (K13), green (12A) and pink (2D).

To maintain the independence of the results and prevent error propagation, the system was reinitialised following any failure to converge. Discrepancies were primarily confined to cases involving low liquid mass transfer $C_L$ coefficient (< 0.2) and/or lower lean flow rates.

## RESULTS

Figure 3 reports the probability distribution of $\%CO_2$ capture and reboiler duty for the conditions reported in Table 3. Table 4 reports the probabilistic moments, mean ($\mu$) and standard deviation ($\sigma$), for a wider range of outputs for the studied operational conditions.

For the cases K1 and 12A, the most divergent $\%CO_2$ capture result of 45.5% and 32.4% respectively, and reboiler duty of 652 kW and 465 kW respectively, were removed from the figure in order to better display the results (even if the simulations were completed normally; the probabilistic moments presented in Table 4 still include those outlier values). This divergence is explained by the lower $C_L$ value (0.01). The other two cases resulted

**Table 4:** Probability moments for UQ analysis of CCSI model using MCS sampling

| Cases | $\mu_{CO2\ capture}$ (%) | $\sigma_{CO2\ capture}$ (%) | $\mu_{reboiler\ duty}$ (kW) | $\sigma_{reboiler\ duty}$ (kW) | $\mu_{CO2\ loading}$ (mol $CO_2$/ mol MEA) | $\sigma_{CO2\ loading}$ (mol $CO_2$/ mol MEA) | $\mu_{rich\ solvent\ flowrate}$ (kg/h) | $\sigma_{rich\ solvent\ flowrate}$ (kg/h) |
|---|---|---|---|---|---|---|---|---|
| K1 | 99.71 | 3.15 | 524.60 | 11.28 | 0.411 | 0.0084 | 7125 | 12.88 |
| K13 | 98.34 | 0.14 | 458.10 | 4.90 | 0.374 | 0.0003 | 6905 | 4.57 |
| 12A | 76.43 | 2.79 | 355.60 | 7.73 | 0.493 | 0.0139 | 4200 | 5.33 |
| 2D | 86.26 | 3.14 | 284.16 | 2.03 | 0.461 | 0.0057 | 4585 | 0.88 |

in an error for this parameter value. The other outlier %$CO_2$ capture points on the PDF were also obtained with low $C_L$ values.

## Surrogate Models

To complete UQ analysis of CCSI model obtaining the Sobol indices, the GP surrogate model was implemented and tested using Persalys. The two mentioned outlier points in cases K1 and 12A (%$CO_2$ capture result of 45.5% and 32.4%) were removed from the database for surrogate model construction in order to improve the model accuracy. Because GP implementation for K1 was not successful using the complete sample (model not validated for the test set), two additional outlier points were removed (with %$CO_2$ capture result of 97.7% and 98.61%).

Table 5 gives the residue ($\varepsilon$) and the agreement with the test set ($Q^2$) using the leave-one-out (LOO) analytic cross-validation method for each output for the Gaussian Process (with Matern method). LOO analytic method details can be consulted in [17].

**Table 5:** Residual error and $Q^2$ LOO for Gaussian Process Metamodel

| Cases | K1 | K13 | 12A | 2D |
|---|---|---|---|---|
| $\varepsilon_{CO_2\ capture}$ (%) | 0.002 | 0.003 | 0.017 | 0.015 |
| $Q^2_{CO_2\ capture}$ | 0.87 | 0.88 | 0.94 | 0.99 |
| $\varepsilon_{reboiler\ duty}$ (kW) | 0.046 | 0.031 | 0.046 | 0.008 |
| $Q^2_{reboiler\ duty}$ | 0.99 | 0.99 | 0.96 | 0.99 |
| $\varepsilon_{CO_2\ loading}$ (mol $CO_2$/ mol MEA) | 6.4 $10^{-6}$ | 5.7 $10^{-6}$ | 7.7 $10^{-5}$ | 4.5 $10^{-5}$ |
| $Q^2_{CO_2\ loading}$ | 0.87 | 0.89 | 0.95 | 0.98 |
| $\varepsilon_{rich\ solvent\ flowrate}$ (kg/h) | 0.05 | 0.03 | 0.02 | 0.01 |
| $Q^2_{rich\ solvent\ flowrate}$ | 0.32 | 0.99 | 0.99 | 0.97 |

The surrogate model of K1 is less accurate and does not present a good agreement with the original model for rich solvent flow rate (rich $CO_2$ loading and %$CO_2$ capture are also less accurate compared with the other GP surrogate models).

Figure 4 reports the 1st and total Sobol indices obtained by the GP surrogate model presented in Table 5 for %$CO_2$ capture and reboiler duty. As a method based on variance decomposition, the 1st order Sobol index is a global measurement of the output sensitivity to each parameter input [16], while higher-order Sobol indices also show parameter interactions. The total Sobol indices represent the global contribution of the parameters to the variance of the outputs. For cases with lower solvent flow rate (12A and 2D), $C_L$ present-ed the stronger impact on the %$CO_2$ capture, followed by $A_1$. For cases with higher solvent flow rate (K1 and K13), the parameters $A_1$ and $K_{F1}$ were more influent for %$CO_2$ capture, with a contribution of $C_L$ for $K_1$ and $C_G$ for $K_{13}$. Those cases also have a bigger deviation between the 1st and total Sobol indices for $C_L$, $A_1$ and $K_{F1}$ for %$CO_2$ capture results. $C_L$ presented an impact on the reboiler duty for all operational conditions. Since the gas flow rate is in a similar range for the analysed cases, higher solvent flow rates reduce the contact time between the liquid and gas phases. With less time to reach equilibrium, the interfacial area and reaction kinetic properties become limiting factors in the $CO_2$ absorption process. However, the reboiler duty does not follow the same phenomena as $CO_2$ capture because it is connected with the stripper column thermodynamics, which is less dependent on the contact area between the liquid and gas phases and where no kinetic reactions are considered. Therefore, the most influential property for reboiler duty analysis is the liquid mass-transfer coefficient.

# CONCLUSION

The model validation was sufficiently accurate to allow the uncertainty quantification analysis for different points across operational condition ranges. For the analysed uncertain properties (mass-transfer, liquid hold-up and reaction kinetics), uncertainty propagation using

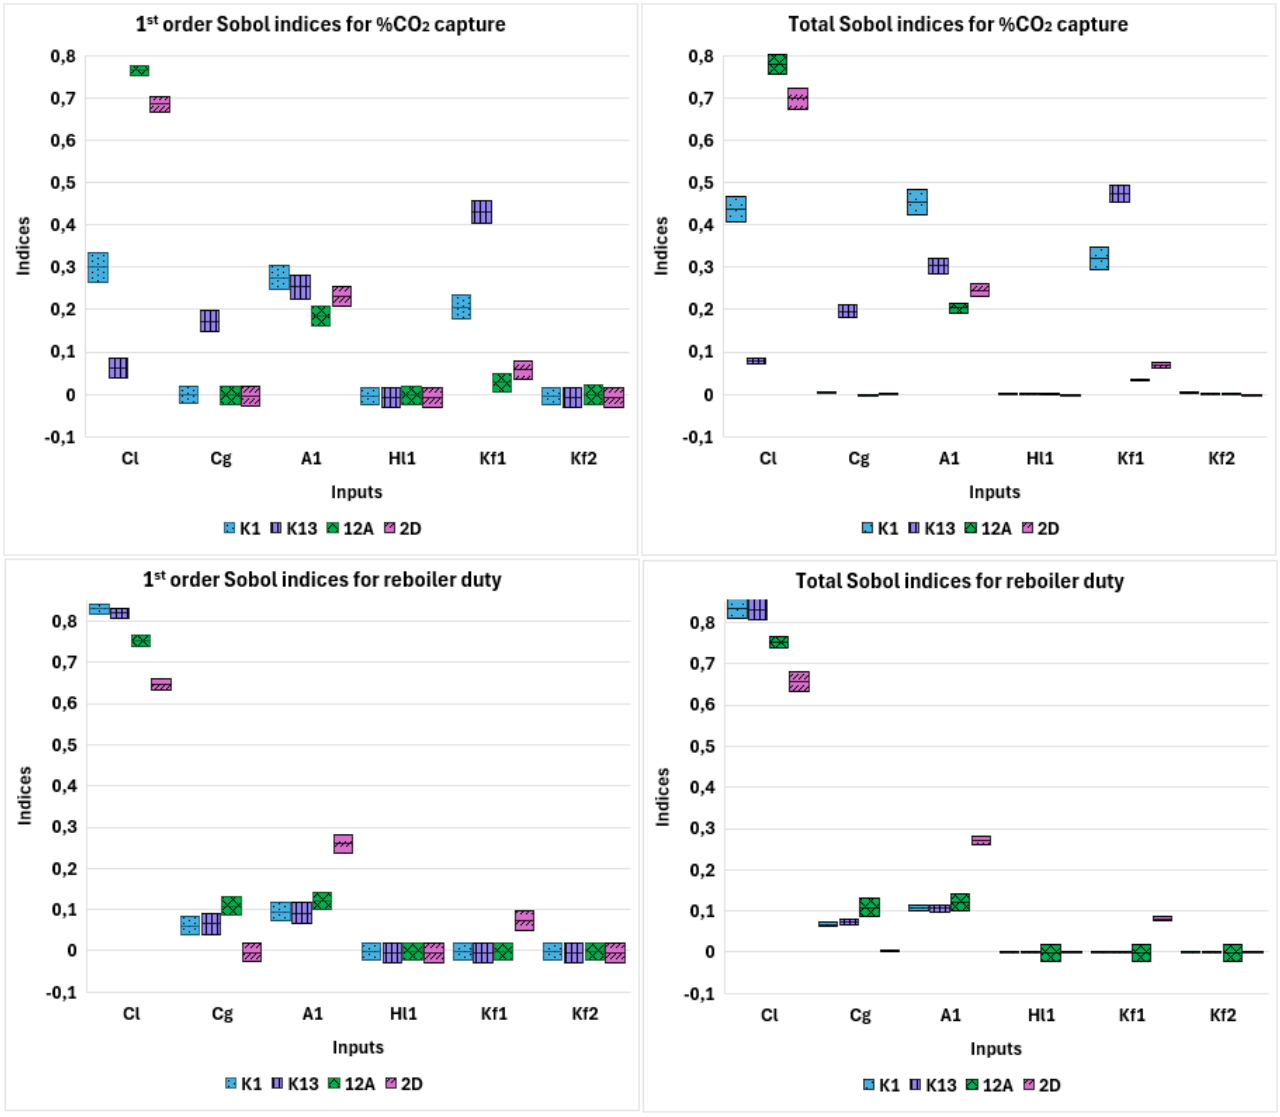

**Figure 4:** 1st and total Sobol indices with 95% confidence interval obtained by the GP surrogate model: Blue (K1), purple (K13), green (12A) and pink (2D).

MCS sampling demonstrated a reasonably low deviation from average values for the analysed outputs, especially for $\%CO_2$ capture which presented a maximum standard deviation of 3.15% for the four operational conditions investigated (considering outlier points). Therefore, the GP surrogate model presented satisfying agreement for K13, 12A and 2A cases and presented some limitations for K1 (for rich solvent flow rate property). The sensitivity analysis of the complete model shows different impacts on the output distributions according to operational conditions. Among analysed properties, liquid mass-transfer coefficient shows the highest impact on the convergence of the samples. This is consistent with sensitivity analysis that demonstrated the strong impact of the $C_L$ parameter, especially for lower solvent flow rate, indicating the liquid mass-transfer property influence. Interfacial area and reaction kinetic properties become more influent for greater liquid-gas ratio.

A more thorough analysis is expected for further works: (1) to consider other uncertain properties in the UQ analysis, and (2) other methods for sensitivity analysis. Surrogate models could also be built to replace the rigorous model, with varying operational conditions, which would require a deeper investigation on model convergence (e.g., initialisation) but allow wider UQ analysis techniques with larger samples.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge the Agence Nationale de la Recherche et de la Technologie (ANRT) for their financial support (Cifre 2024/0837).

Additionally, the authors would like to thank Bertrand looss for UQ- and Persalys-related discussions and Joshua Morgan for very open data and information-sharing on the CCSI model and NCCC experimental campaigns.

## ABSTRACT

The accurate prediction of pure component properties has consistently been a critical issue in fields such as chemical engineering, biomedicine, and environmental science. In recent years, end-to-end deep learning methods have shown significant improvement over traditional machine learning approaches. This is due to their ability to automatically learn task-relevant representations from raw molecular data. In addition to accurate property prediction, researchers have increasingly focused on how specific fragment structures influence molecular properties. However, existing fragmentation methods based on predefined rules and group libraries struggle to capture novel molecular structures, which hampers the development of new materials and drugs. To address these challenges, this work proposes a hierarchical molecular fragmentation method. This method can automatically segment molecules into multiple fragments containing key functional groups. Then a three-branch graph attention network was constructed to achieve multi-level representation. Finally, a multi-layer perceptron is employed to establish the mapping relationship between molecular features and physical property values. Twenty datasets were used for validation, which can be grouped into four categories: Thermodynamic Properties, Pharmacokinetics, Toxicological Properties, and Industrial Safety. The results show that the best performance is achieved, with the average error reduced by 6.8% compared to existing research.

## INTRODUCTION

Accurate prediction of molecular physicochemical properties relies on effective molecular representations. Traditional descriptors like MACCS keys and Extended-Connectivity Fingerprints (ECFP) have been widely used to encode structural information into vectors [1]. However, these fixed-length representations suffer from limitations such as hash collisions, information loss in many-to-one mappings, and a lack of direct chemical interpretability. In parallel, Group-Contribution (GC) methods estimate properties by summing the contributions of predefined structural groups [2]. While recent integrations with machine learning have improved their nonlinear expression ability [3]. However, GC methods inherently ignore topological connectivity. Furthermore, their reliance on fixed libraries results in high-dimensional, sparse feature vectors that can lead to model overfitting and poor generalization to molecules containing novel substructures [4].

With the rise of deep learning, Graph Neural Networks (GNNs) have achieved success by treating molecules as graphs and updating atomic representations via message passing [5], meanwhile attention mechanisms have further improved accuracy [6]. However, chemists typically reason via specific structural motifs rather than treating the molecule as an indivisible whole. Hence, researchers have employed the predefined BRICS scheme to decompose molecules into fragments, subsequently treating each fragment as a subgraph and representing it using GNNs. Similarly, predefined group libraries have been used to fragment molecules, where each group is regarded as a subgraph. These approaches have been shown to effectively improve predictive accuracy,

because molecular properties are often governed by specific functional groups; for example, nitro, amino, and quinone groups often increase molecular toxicity, whereas carboxyl groups are widely recognised as detoxifying motifs. The resulting fragments can capture common functional groups and establish mappings to target properties via attention mechanisms. However, owing to the limited coverage of predefined rules, prediction accuracy often deteriorates when extrapolating to out-of-distribution (OOD) molecules. To address the aforementioned issues, Li et al. [7] proposed SMILES Pair Encoding (SPE) method, which learns frequent SMILES substrings from a large dataset, then segments molecules into tokens based on learned SMILES substrings. Benefiting from the large scale of the dataset, the learnable chemical space is substantially expanded, thereby alleviating the out-of-distribution (OOD) issue. However, SPE completely loses topological information. The model only knows that the molecule contains these three fragments. It does not know how these fragments are connected.

To address these challenges, based on a novel hierarchical fragmentation method, a molecular property prediction framework is proposed. Then, a three-branch GNNs was developed to enable representations at both the molecular-graph level and the fragment level. Twenty datasets were used for validation, which can be grouped into four categories: Thermodynamic Properties, Pharmacokinetics, Toxicological Properties, and Industrial Safety.

# METHODOLOGY

## Hierarchical molecular fragmentation method

The quality of molecular fragments depends on whether they contain functional groups that determine molecular properties or the core scaffolds that host these functional groups. Such motifs are typically highly cohesive in topology; they exhibit dense internal bonding and are connected to the rest of the molecule via only a small number of external bonds. In this subsection, we propose a novel hierarchical molecular fragmentation method. It systematically searches for highly cohesive topological substructures within molecules and enables explicit modelling of molecular fragments.

We treat each molecule as an undirected molecular graph $G = (V, E)$, where $V$ are non-hydrogen nodes and $E$are bonds. Fragmentation is performed by a greedy-and-recursive procedure that repeatedly extracts one dominant local substructure and then applies the same procedure to the remaining subgraph.

### Step 1: State initialization and candidate generation.

We first define the core $C$ as a set of $k$ directly connected atoms in graph $G$. We set a maximum core order $k$ (in this work $k = 4$) and define $S_k(G)$ denote the collection of all such connected $k$ -atom cores $S_k(G) = \{ C \subseteq V \mid |C| = k, G[C] \text{ is connected} \}$.

For each core $C \in S_k(G)$, we define its environment as the core together with all atoms directly bonded to any atom in the core: $\Omega(C) = C \cup \{u \in V \mid \exists v \in C, (u, v) \in E\}$. Cores that yield the same environment are grouped, producing a candidate environment set $\mathcal{M}_{ca}$.

### Step 2: Weight evaluation and greedy selection.

For each candidate environment $M \in \mathcal{M}_{ca}$, we assign a weight based on how many cores map to it across orders:

$$W(M) = \sum_{k=1}^{K} |\{C \in S_k(G) \mid \Omega(C) = M\}|$$

We then select the environment $M^*$ with the largest weight as the dominant fragment, $M^* = \arg\max_{M \in \mathcal{M}_{ca}} W(M)$.

### Step 3: State update and recursive splitting.

After selecting $M^*$, we remove $M^*$ from the graph $G$ to obtain the residual subgraph. At this stage, we examine whether the residual subgraph contains more than two non-hydrogen nodes. If so, the residual subgraph is treated as an intact unit, and Steps 1–2 are repeated to further fragment the residual subgraph until the stopping criterion is satisfied.

The final fragmentation results for the molecule O=C(N)Nc1ccc(C)cc1 are shown in **Fig. 1**. As can be seen, the proposed method successfully identifies the urea moiety (–NH–C(=O)–NH2) and isolates it as an individual fragment (blue), while the remaining part corresponds to a tolyl aromatic ring (red). For this molecule, the urea group governs its polarity and hydrogen-bonding capability and is therefore one of the most critical structural units for property characterization.

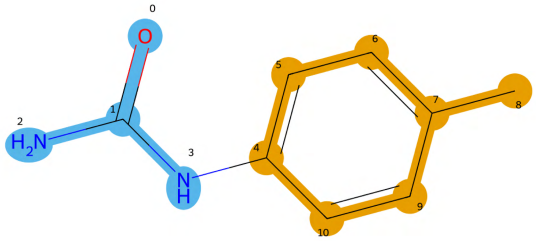

**Figure 1.** The fragmentation results of O=C(N)Nc1ccc(C)cc1 based on the proposed hierarchical molecular fragmentation method.

In addition, we fragmented the molecule using a predefined group-contribution (GC) library [8] and the BRICS rules [9], as shown in **Figs. 2–3**. Under the GC scheme, the phenyl ring is decomposed into multiple

aromatic carbon atoms, and the methyl group becomes disconnected from the ring, preventing the formation of an intact fragment. Under BRICS, the complete urea structure is not preserved; instead, it is split into a carbamoyl fragment (–NH2C(=O)–) and an –NH fragment.

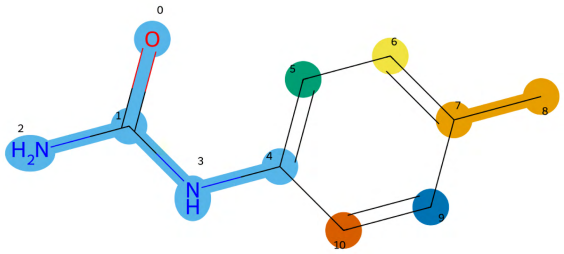

**Figure 2.** The fragmentation results of O=C(N)Nc1ccc(C)cc1 based on the group contribution method.

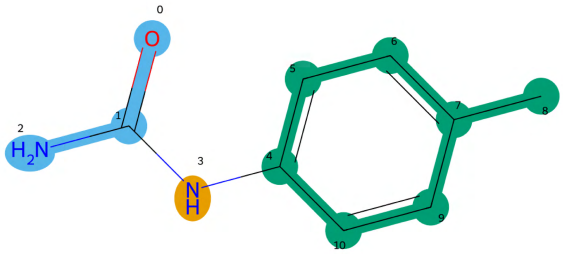

**Figure 3.** The fragmentation results of O=C(N)Nc1ccc(C)cc1 based on the BRICS method.

## HierAttnGNN

The HierAttnGNN contains three branches. The first branch learns representations at the whole molecule level. The second branch encodes molecular fragments. The third branch is a junction tree that represents the connectivity relationships between fragments, as shown in **Fig. 4.**

### Molecule level representation

This branch learns a global embedding for the complete molecular graph. Given the molecular graph defined above, let $x_v$ and $x_{e(v,u)}$ denote the node and edge features, as shown in **Table 1-2** respectively.

**Table 1** Atom information used to featurize the molecular graph

| No. | Feature Name | Description | Encoding | Dim |
|---|---|---|---|---|
| 1 | Atom Symbol | Atom type (C, N, O, S, F, P, Cl, Br, I) | One-hot | 9 |
| 2 | Atom Degree | Number of covalent bonds (0–5) | One-hot | 6 |
| 3 | Total Num Hs | Total number of hydrogen atoms (0–4) | One-hot | 5 |
| 4 | Implicit Valence | Implicit valence electrons (0–5) | One-hot | 6 |
| 5 | Hybridization | Orbital hybridization type (SP, SP2, SP3, SP3D, SP3D2) | One-hot | 5 |
| 6 | Is Aromatic | True (1) / False (0) | Boolean (Numeric) | 1 |
| 7 | Chirality Possible | Potential for chirality (RDKit property) | Boolean (Numeric) | 1 |
| 8 | Chirality Type (CIP Code) | CIP code classification (R, S) | One-hot | 2 |
| 9 | Formal Charge | Electrical charge of the atom | Direct Numeric | 1 |
| Total | | | | 36 |

**Table 2** Bond information used to featurize the molecular graph

| No. | Feature Name | Description | Encoding | Dim |
|---|---|---|---|---|
| 1 | Is Single Bond | Single, Double, Triple, or Aromatic | Boolean (0/1) | 1 |
| 2 | Is Double Bond | Conjugation status of the bond | Boolean (0/1) | 1 |
| 3 | Is Triple Bond | Checks if the bond type is Triple | Boolean (0/1) | 1 |
| 4 | Is Aromatic Bond | Checks if the bond type is Aromatic | Boolean (0/1) | 1 |
| 5 | Is Conjugated | Checks if the bond is conjugated | Boolean (0/1) | 1 |
| 6 | Is In Ring | Ring membership status | Boolean (0/1) | 1 |
| Total | | | | 6 |

We first project the atom and bond feature vectors into a shared hidden space, yielding the initial hidden states of atoms and bonds, $h_v^{(0)}$ and $h_{e(v,u)}^{(0)}$, as in Eqs. (1)–(2).

$$h_v^{(0)} = \mathrm{ReLU}(\mathbf{W}_{node} x_v + b_n) \quad (1)$$

$$h_{e(v,u)}^{(0)} = \mathbf{W}_{edge} x_{e(v,u)} + b_e \quad (2)$$

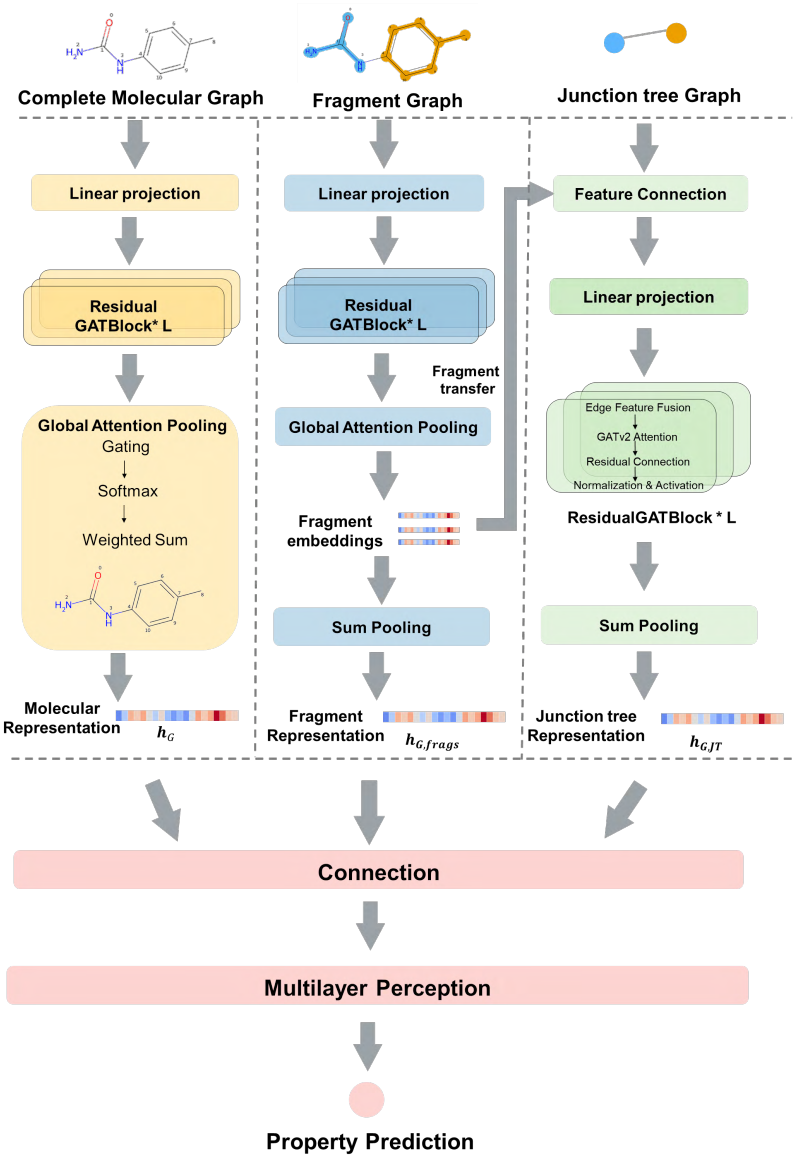

**Figure 4.** The architecture of the proposed HierAttnGNN framework, consisting of molecule-level, fragment-level, and junction-tree branches

We then stack $L$ ResidualGATBlock modules to update node representations. Each block is built on a GATv2 layer, which performs neighbourhood aggregation with learnable attention. At layer $l$, edge features incident to node $v$ are first fused into the node state, so that subsequent attention can depend on both node and bond information, as in Eq. (3).

$$h'_v = h_v^{(l)} + \sum_{u \in \mathcal{N}(v)} h_{e(v,u)}^{(l)} \tag{3}$$

Next, for each neighbour $u$ of $v$, GATv2 computes an unnormalised attention score $a_{vu}$ using a dynamic attention function (Eq. (4)), which is more expressive than the original GAT and can capture more complex structural dependencies [10]. The scores are normalised with a softmax to obtain the importance weights $\alpha_{vu}$ (Eq. (5)).

$$a_{vu} = w_{attn}^{T} \bullet \mathrm{LeakyReLU}(\mathbf{W}_L h'_v + \mathbf{W}_R h'_u) \tag{4}$$

$$\alpha_{vu} = \mathrm{softmax}_u(a_{vu}) = \frac{\exp(a_{vu})}{\sum_{k \in \mathcal{N}(v) \cup \{v\}} \exp(a_{vk})} \tag{5}$$

where, $\mathbf{W}_L$ and $\mathbf{W}_R$ are learnable weight matrices. Specifically, $W_L, W_R \in \mathbb{R}^{d_h \times d_h}$ are learnable linear transformation matrices. The vector $w_{\mathrm{attn}} \in \mathbb{R}^{d_h}$ is a learnable attention weight vector.

Using $\alpha_{vu}$, the model forms a weighted sum of neighbour features to update each node. A multi-head

mechanism is applied for stability and capacity, and the outputs of $K$ heads are concatenated, as shown in Eq. (6).

$$h_v^{(l+1)} = \|_{k=1}^{K} \sum_{u \in \mathcal{N}(v) \cup \{v\}} \alpha_{vu}^{(k)} \mathbf{W}^{(k)} h_u' \quad (6)$$

where, $\|$ denotes concatenation.

To mitigate over-smoothing and to stabilise optimisation, each block combines residual connections with batch normalisation, giving the complete update in Eq. (7).

$$h_{v,\text{out}}^{(l+1)} = \text{BatchNorm}(\text{ELU}(h_v^{(l+1)}) + h_v^{(l)}) \quad (7)$$

After $L$ GATv2 layers, we obtain the final node embeddings $\{h_v^{(L)}\}$. A Global Attention Pooling readout is then applied to produce the graph-level representation $h_G$, as in Eq. (8), where $W_{gate}$ learns the gating (importance) score of each node and $h_G$is taken as the final molecule-level representation.

$$h_{\mathcal{G}} = \sum_{v \in V} \left( \frac{\exp(\mathbf{W}_{gate} h_v^{(L)})}{\sum_{u \in V} \exp(\mathbf{W}_{gate} h_u^{(L)})} \right) h_v^{(L)} \quad (8)$$

where, $h_v^{(L)}$ is the final feature vector of node $v$after $L$ GNN layers. $\mathbf{W}_{gate}$ is a learnable linear transformation used to compute the gating or importance score of each node. The aggregated vector $h_{\mathcal{G}}$ is taken as the final representation of the molecular graph.

### Fragment level representation

The second branch encodes molecular fragments produced by the hierarchical fragmentation. Each fragment is treated as an independent subgraph and is processed using the same representation pipeline as the whole-molecule branch, i.e., feature initialization, GATv2-based message passing, and Global Attention Pooling. This yields a fragment embedding $h_{\mathcal{G}_{frag}}$ that summarizes the corresponding fragment subgraph.

To aggregate fragment-level information back to the parent molecule, we apply sum pooling over all fragment embeddings that originate from the same molecular graph $G$. The resulting vector $h_{G,frags}$ is defined as:

$$h_{\mathcal{G},frags} = \sum_{g_{frag} \in \mathcal{F}(\mathcal{G})} h_{\mathcal{G}_{frag}} \quad (9)$$

where, $F(\mathcal{G})$ denotes the set of fragments derived from the original molecular graph $\mathcal{G}$.

### Junction tree

In the third branch, we explicitly model fragment connectivity by constructing a junction tree, where each molecular fragment is treated as a super node and bonds between fragments are treated as edges. Message passing on this coarse grained graph enables the model to capture spatial and chemical interaction patterns among fragments. The initial feature vector of each junction tree node, $x_{v,jt\text{-}aug}$, is formed by concatenating two parts: (i) static fragment descriptors and (ii) a dynamic fragment embedding. In particular, the scalar $W_i$ incorporates the fragment weight, allowing the network to recognise more stable structural cores and assign them higher importance during message passing, as shown in Eq. (10).

$$x_{v,jt-aug} = [c_i;\ W_i; h_{\mathcal{G},frag}] \quad (10)$$

where, $c_i$is the number of atoms contained in fragment $i$, $W_i$ is the statistical weight of this fragment, and $h_{\mathcal{G},\text{frag}}$ is the graph level embedding of this fragment obtained from the second branch.

Next, the augmented feature vector is passed through a linear projection layer and mapped into the hidden space of this branch, yielding the initial hidden state of each junction tree node, as shown in Eq. (11).

$$h_{v,jt}^{(0)} = \mathbf{W}_{jt} x_{v,jt-aug} + b_{jt} \quad (11)$$

As in the first two branches, node features on the junction tree graph are then updated by $L$ ResidualGATBlock modules. Information is propagated between nodes along edges, and the updated hidden states $h_{v,jt}^{(L)}$ represent each fragment in the context of its fragment neighbourhood. Finally, to obtain the junction tree view representation of the whole molecule, we aggregate the final hidden states of all junction tree nodes using sum pooling, as shown in Eq. (12).

$$h_{\mathcal{G},jt} = \sum_{v \in V_{JT}(\mathcal{G})} h_{v,jt}^{(L)} \quad (12)$$

where, $V_{JT}(\mathcal{G})$ denotes the set of nodes in the junction tree corresponding to molecule $\mathcal{G}$.

## DATASETS AND MODEL TRAINING

This work uses 20 datasets released by Alshehri et al. [3, 11], covering four property categories: thermophysical, pharmacokinetic, toxicological, and industrial safety properties, summarised in **Table 3**. Thermophysical property prediction is directly relevant to process design and operation; for example, the normal boiling point $T_b$ is a basic design parameter that affects equipment selection and operating conditions, while the critical constants $(T_c, P_c)$ determine the critical point and are widely used in equations of state and phase-equilibrium calculations, including supercritical-fluid applications. Accurate prediction of safety- and environment-related properties is likewise essential for chemical safety management and environmental risk evaluation. As a representative example, auto-ignition temperature is important for fire and explosion prevention and risk assessment, and reliable prediction of solubility is critical for toxicological evaluation, drug discovery, and human-health risk assessment.

**Table 3**. Dataset categories and descriptions

| Classification | Property | Sample number | Description |
|---|---|---|---|
| Thermophysical properties | $T_b$ | 5276 | Normal boiling point (K) |
| | $T_m$ | 9248 | Normal melting point (K) |
| | $T_c$ | 776 | Critical temperature (K) |
| | $P_c$ | 774 | Critical pressure (bar) |
| | $V_c$ | 773 | Critical volume (cc/mol) |
| | $H_v$ | 425 | Enthalpy of vaporization at 298 K (kJ/mol) |
| | $H_{fus}$ | 748 | Normal enthalpy of fusion (kJ/mol) |
| | $H_f$ | 1059 | Standard enthalpy of formation (kJ/mol) |
| | $G_f$ | 756 | Gibbs energy of formation at 298 K (kJ/mol) |
| | $L_{mv}$ | 1055 | Liquid molar volume at 298 K (cc/mol) |
| | HSolP | 1368 | Hildebrandt solubility parameter at 298 K ) (MPa1/2) |
| Pharmacokinetics properties | BCF | 589 | Bioconcentration factor |
| | LogP | 12184 | Octanol–water partition coefficient |
| | $LogW_s$ | 2563 | Aqueous solubility (mol/L) |
| | PCO | 606 | Photochemical oxidation potential |
| | pKa | 1632 | Acid dissociation constant |
| Toxicological Properties | $LC50_{(FM)}$ | 705 | Fathead Minnow 96-H LC50 (mol/L) |
| | LD50 | 4780 | Toxicity (oral rat) (mol/kg) |
| Industrial Safety | OSHA-TWA | 422 | Permissible exposure limit (mol/m3) |
| | AiT | 570 | Auto ignition temperature (K) |

A six-fold cross-validation is used for dataset splitting. Specifically, 10% of the samples are first held out as an independent test set. This test set is strictly excluded from model training, hyperparameter tuning, and validation, and is used only once for the final evaluation of the selected model. The remaining 90% of the data are then randomly and evenly divided into six folds. For each run, five folds are used for training and the remaining fold is used for validation, and the procedure is repeated six times such that every fold serves as the validation set exactly once. To prevent data leakage, data standardisation is performed only after the test set has been separated.

## Training, evaluation metrics and hyperparameters

Model parameters were optimised using AdamW with decoupled weight decay, which applies weight decay independently from the gradient-based Adam update and thus provides more effective regularisation than coupling L2 penalties into the gradient. The training objective was to minimise the mean squared error (MSE). To improve training stability and avoid gradient explosion, we applied gradient clipping: after backpropagatio, the global L2 norm of all parameter gradients $\| \mathbf{g} \|_2$was computed, and when it exceeded a threshold $g_{\text{clip}}$, gradients were rescaled. Following common practice, we set $g_{\text{clip}} = 1$. To mitigate overfitting, two complementary strategies were used. First, early stopping was adopted by monitoring the validation root mean squared error (RMSE); if no improvement was observed for 25 consecutive epochs, training was terminated and the checkpoint with the lowest validation RMSE was retained. Second, a learning-rate scheduler was employed: when validation performance plateaued, the learning rate was multiplied by 0.5 until reaching a minimum of $1 \times 10^{-5}$, enabling finer optimisation in later training stages.

Generalisation performance was evaluated using

RMSE and the coefficient of determination $R^2$. Under six-fold cross-validation, model selection and reporting followed a consistent protocol: within each fold, the checkpoint achieving the lowest validation RMSE was saved as the best model for that fold. After all six folds, the six resulting models were evaluated on the independent held-out test set, and the reported test metrics were computed as the average across these six models rather than from a single run.

Because different fragmentation schemes produce fragments with substantially different sizes and topological complexity, a single fixed hyperparameter configuration can unfairly constrain some models and obscure their attainable performance. We therefore applied Bayesian hyperparameter optimisation using Optuna [12]. A unified search space was defined, and for each GNNs variant constructed under a specific fragmentation method, 50 Optuna trials were executed independently. To avoid information leakage, the dataset splits used during hyperparameter search were generated with random seeds independent of those used in final evaluation. Validation RMSE was used as the optimisation objective; the best hyperparameter set was then fixed and used for the subsequent six-fold cross-validation. The complete search space and ranges are reported in **Table 4**.

**Table 4** The detailed search space and ranges of all hyperparameters

| Hyperparameter | Search space and ranges |
|---|---|
| Learning Rate | $[1\times10^{-4}, 1\times10^{-2}]$ |
| Hidden Dimension | {128, 256, 512} |
| Attention Heads | {4, 8} |
| Layers | [2, 11] |
| Dropout | [0.0, 0.5] |
| Weight Decay | $[1\times10^{-6}, 1\times10^{-3}]$ |

## RESULTS

The final predictive results are reported in **Table 5-8**. The results of the GP-WP model were taken directly from the literature [13]. The BRICS-GNN, SPE-GNN and GC-GNN models were built under different fragmentation methods. For each dataset, molecular fragments were generated for every molecule, a three-branch architecture was constructed, and property prediction was performed. HiGNN [14] and AttentiveFP [6] model were evaluated using publicly available molecular encoding pipelines, and public implementations were used for prediction and hyperparameter optimisation. To further validate the effectiveness of incorporating fragment weight features in the junction tree branch, an ablation model, Hier-AttnGNN-Ablation, was also constructed. All results are reported as the average performance on the test set over six-fold cross validation.

**Table 5** Predictive performance of different models across Pharmacokinetics property datasets

| | BCF | LogP | $LogW_s$ | PCO | pKa |
|---|---|---|---|---|---|
| HierAttnGNN | 0.72 | 0.39 | 0.76 | 0.14 | 1.67 |

**Table 8** Predictive performance of different models across Thermophysical property datasets (Part 2)

| | $H_f$ | $H_{fus}$ | HSolP | $H_v$ | $L_{mv}$ |
|---|---|---|---|---|---|
| Hier-AttnGNN | 20.95 | 3.74 | 1.66 | 4.82 | 0.0068 |
| Hier-AttnGNN-Ablation | 24.25 | 3.88 | 1.68 | 4.95 | 0.0103 |
| GPR-WP | 37.42 | 4.099 | 2.31 | 5.72 | 0.007 |
| BRICS-GNN | 28.56 | 4.44 | 1.78 | 5.97 | 0.019 |
| SPE-GNN | 45.72 | 4.53 | 1.72 | 5.95 | 0.02 |
| GC-GNN | 24.9 | 5.3 | 1.71 | 5.01 | 0.0105 |
| HiGNN | 27.83 | 4.04 | 1.7 | 5.18 | 0.007 |
| Attention FP | 26.69 | 3.76 | 1.72 | 4.98 | 0.0074 |

HierAttnGNN achieved the best performance across all 20 prediction tasks, with an average RMSE of 12.44, representing a 6.8% reduction relative to GC-GNN at 13.36. Among the models sharing the same three-branch architecture, SPE-GNN consistently produces the highest errors, confirming that discarding topological connectivity between fragments severely impairs predictive accuracy. BRICS-GNN generally outperforms SPE-GNN but suffers notable degradation where its predefined rules fail to preserve intact functional groups, as evidenced by RMSE values of 0.96 on $LC50_{(FM)}$ and 89.97 on AiT, compared with 0.67 and 76.09 for HierAttnGNN. GC-GNN performs comparably to HierAttnGNN on classical thermophysical properties where its predefined library provides adequate coverage, yet it yields the worst RMSE of 5.3 on $H_{fus}$, illustrating how fine-grained fragmentation of out-of-library substructures leads to sparse feature vectors and poor generalisation. AttentiveFP achieves competitive results on properties governed by local atomic environments, attaining RMSE values of 3.76 on $H_{fus}$ and 0.68 on $LC50_{(FM)}$, but falls behind on tasks requiring multi-level structural reasoning, such as Hf and pKa. HiGNN ranks among the top three on many datasets but inherits the functional-group integrity limitations of BRICS, leading to higher errors on toxicological and structurally diverse thermophysical datasets.

## CONCLUSION

A hierarchical molecular fragmentation method is proposed in this work. Without relying on predefined rules or a static vocabulary, the proposed method can automatically partition a molecule into fragments that contain key functional groups. On this basis, a three-branch GNNs is constructed to learn hierarchical representations from the atom level to the fragment level and further to the junction tree level. Evaluation on 20 benchmark datasets shows that HierAttnGNN significantly outperforms existing mainstream model. The average RMSE is reduced by 6.8% relative to the second-best model.

## ABSTRACT

Global optimization of industrial-scale chemical process flowsheets remains challenging due to nonlinearity, nonconvexity, and large problem scale. While equation-oriented modeling frameworks enable high-fidelity representation of industrial processes, obtaining globally optimal solutions is often computationally intractable for off-the-shelf solvers. In this work, we present a decomposition-based global optimization strategy that solves a high-fidelity flowsheet model from the IDAES framework with the Structured Nonlinear Global Decomposition (SNoGloDe) framework. The proposed approach exploits spatial decomposability by partitioning the flowsheet into coupled subproblems linked through a small set of complicating variables and solving them within a prioritized spatial branch-and-bound framework. The methodology is demonstrated on a hydrodealkylation (HDA) process for benzene production, a nonconvex and industrially relevant case study. The flowsheet is decomposed into reactor and separation subproblems, enabling efficient computation of valid global bounds while preserving convergence guarantees. SNoGloDe successfully identifies a (verifiably) globally optimal solution. These results illustrate the potential of decomposition-based global optimization for complex process systems and highlight the advantages of integrating rigorous process modeling with flexible, customizable global optimization algorithms.

**Keywords**: Optimization, Algorithms, Parallelization, Process Operations

## INTRODUCTION

Optimizing chemical process flowsheets presents a central challenge in process systems engineering due to the inherent nonlinearity, nonconvexity, and scale of industrially relevant processes. Traditional nonlinear programming techniques for large-scale process optimization are limited to locally optimal optima. Global solutions to these flowsheets are frequently intractable for general off-the-shelf solvers. On the other hand, global solvers, such as BARON [6], have promising capabilities, but many realistic flowsheets remain computationally intractable at scale [1, 4]. We aim to develop a decomposition-based framework for tackling process flowsheet optimization problems, enabling its use within a global optimization framework.

## BACKGROUND

Global optimization of process flowsheets with high-fidelity models remains a major open challenge in process systems engineering: such problems are typically large-scale, nonconvex, and computationally intractable for general-purpose solvers. In this work, we demonstrate a framework for globally optimizing complex process flowsheets by decomposing them spatially into more manageable subproblems. We solve the decomposed problem using a prioritized spatial-branch-and-bound algorithm implemented within the Structured Nonlinear Global Decomposition (SNoGloDe) framework [5]. The Institute for the Design of Advanced Energy Systems (IDAES) provides high-fidelity equation-oriented flowsheet models [3]. Utilizing the extensive process modeling framework in IDAES, in conjunction with the solution strategies developed in SNoGloDe, demonstrates the potential to obtain globally optimal solutions to critical process systems problems that are intractable with widely available off-the-shelf solvers, such as BARON [6]

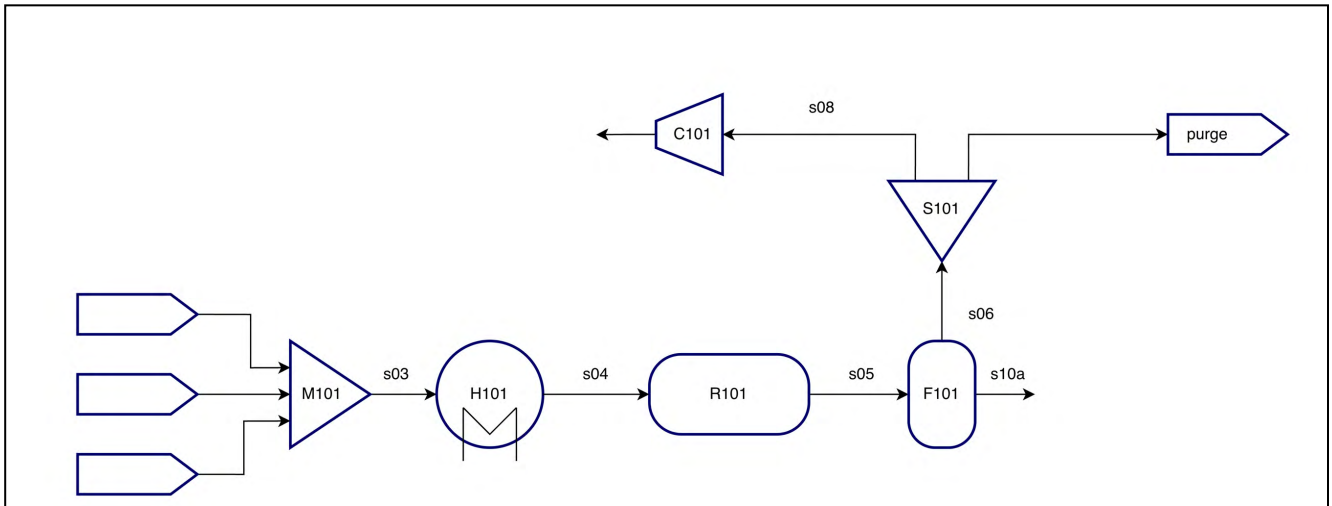

**Figure 1:** Complete flowsheet for hydrodealkylation process [3]. Three feed streams (toluene feed, hydrogen feed, and combined vapor feed) are combined in a mixer (M101), then heated in a heat exchanger (H101). Reactor (R101) is a CSTR, and its product is fed to a flash (F101). The resulting liquid stream (s10a) is the product, and the remaining vapor stream (s06) is fed to a splitter (S101) sent to purge or to a compressor (C101).

or Gurobi [2]. To evaluate this approach on an industrially relevant and economically significant problem, we select the hydrodealkylation (HDA) process for benzene production as our case study.

Benzene is a highly versatile aromatic raw material used in the production of ethylbenzene and cumene, which are feedstocks for producing styrene and phenol [7], cyclohexene [8], and chlorobenzene derivatives [9]. The major industrial sectors that use these products include the chemical, automotive, pharmaceutical, consumer products, and renewable energy sectors [10-12]. The demand for benzene and its derivatives is projected to grow rapidly between 2024 and 2030, driven by growth in the industry sectors [13]. According to the market research report, the market size was valued at 39.30 billion USD in 2023, with a compound annual growth rate of 6.5%, and is expected to reach 61.07 billion USD by 2030.

The primary process for producing benzene is hydrodealkylation, in which toluene is reacted with hydrogen to produce the simpler aromatic hydrocarbon benzene (without functional groups) and methane as a by-product [14]. Recent work by Yalçın (2025) compared HDA with catalytic reactions – hydrocracking, isomerization, dehydrocyclization, and dehydrogenation - versus the thermic reaction [15]. While catalytic reactions can produce commercially relevant benzene and its derivatives, the process's operational conditions, energy intensity, and catalyst degradation outweigh the economic viability. As a result, recent optimization advances aimed at enhancing heat and energy integration of the HDA thermic reaction have shown promising results in achieving yield, energy, and cost reductions [14-16]. A model of this process serves as the case study for our global optimization approach based on spatial decomposition.

## HDA FLOWSHEET MODEL

For our case study, we adapt a hydrodealkylation flowsheet from the Institute for Design of Advanced Energy Systems (IDEAS) example library [3] and modify its objective function to maximize revenue. This process converts toluene and hydrogen into benzene; the reaction is described in Equation 1.

$$C_6H_5CH_3 + H_2 \longrightarrow C_6H_6 + CH_4 \quad (1)$$

Figure 1 shows the complete flowsheet, where three feed streams (hydrogen feed, toluene feed, and a mixed vapor stream) are combined in a mixer (M101). The resulting stream is fed into a heater (H101) and then reacted in a continuous stirred tank reactor (CSTR) (R101). The reactor outlet is flashed in F101, yielding a liquid product stream primarily composed of benzene and a vapor stream containing the remaining hydrogen, toluene, methane, and some benzene. The vapor stream is split (S101) and either purged or sent to a compressor (C101). In future work, the compressor outlet will be recirculated to the mixer (M101); in this study, the compressor outlet is treated as an additional vapor waste stream.

The following subsections summarize the features of each unit operation.

### Mixer (M101)

Three feed streams, fresh toluene, hydrogen, and a vapor recycle stream, are fed to the mixer unit and combined into a single outlet stream. As no recycle is implemented in this case study, the composition of the vapor recycle feed stream is fixed. Mixer units have zero degrees of freedom, as all outlet conditions are fully determined by the inlet streams and balances [3].

The mixer maintains all mass and energy balances. Energy conservation is satisfied by calculating the outlet stream temperature such that enthalpy is conserved among inlet streams that may enter at different temperatures. Vapor stream enthalpies are calculated using Equation 2.

$$h_{\mathrm{Vap},i} = \Delta H_{\mathrm{vap},i} + \frac{c_{p,5,\,\mathrm{Vap},i}}{5}\left(T^5 - T_{\mathrm{ref}}^5\right) + \frac{c_{p,4,\,\mathrm{Vap},i}}{4}\left(T^4 - T_{\mathrm{ref}}^4\right) + \frac{c_{p,3,\,\mathrm{Vap},i}}{3}\left(T^3 - T_{\mathrm{ref}}^3\right) + \frac{c_{p,2,\,\mathrm{Vap},i}}{2}\left(T^2 - T_{\mathrm{ref}}^2\right) + c_{p,1,\,\mathrm{Vap},i}\left(T - T_{\mathrm{ref}}\right) \quad (2)$$

Where $h_{Vap,i}$ is the component enthalpy for species $i$, the $c_p$'s are specific heat coefficient values, $\Delta H_{\mathrm{vap},i}$ is the heat of vaporization for component $i$, $T_{\mathrm{ref}}$ is a reference temperature (298.15 K), and $T$ is the temperature of the stream. Liquid-stream enthalpies are calculated similarly but do not include the heat of vaporization term.

### Heater (H101)

The heater raises the temperature of the mixer outlet stream to the level required for the downstream reaction. The heater model in IDAES has one degree of freedom, typically specified by the outlet temperature or the heat duty [3]. All mass and energy balances are enforced, and there is no pressure drop across the heater.

### Continuous Stirred Tank Reactor (R101)

The reactor in this flowsheet is modeled as a continuous stirred-tank reactor. The unit has one degree of freedom, namely the reactor volume and conversion, which impact capital cost (see Reactor Subproblem section) [3]. The rate constant of the reaction is governed by the Arrhenius equation. The reactor enforces all mass and energy balances. Since the reaction between toluene and hydrogen is exothermic, the reactor outlet stream is at a higher temperature than its inlet.

### Flash Unit (F101)

The flash unit performs a vapor-liquid equilibrium separation of the reactor outlet stream, enabling recovery of benzene from the remaining components. In general, the flash unit has two degrees of freedom, typically either the heat duty or the pressure drop across the unit [3]. The flash is isobaric in this case study, leaving the heat duty as a degree of freedom. The phase equilibrium is determined using Antoine's equation, along with Raoult's law and the energy balance. In this model, toluene and benzene are treated as condensable species that may enter the liquid phase, while hydrogen and methane are assumed to be non-condensable and remain entirely in the vapor phase after the flash.

### Splitter (S101)

The splitter divides the vapor outlet stream of the flash unit into two streams: a purge stream and a vapor-recycle stream. The IDAES splitter model has one degree of freedom, defined by the split fraction between the outlet streams [3]. Although the outlet stream is labeled vapor recycle, it is not returned to an upstream unit in this case study. The splitter enforces overall mass balance, with each stream receiving a fixed fraction of the inlet flow. Outlet streams inherit the same temperature, pressure, and composition as the inlet stream.

### Compressor (C101)

The compressor is included in the flowsheet to account for potential pressure changes in the vapor-recycle stream. This flowsheet uses the Pressure Changer model from the IDAES library, which has one degree of freedom in this application, the outlet pressure.

## SOLUTION METHODOLOGY

SNoGloDe is a framework (built in Python relying on the algebraic modeling language Pyomo [7]) that exploits the decomposable structure of an optimization problem and integrates it into a priority spatial branch-and-bound algorithm to efficiently solve large-scale optimization problems to global optimality [5]. To use SNoGloDe, the optimization formulation must contain variables that couple otherwise separable subproblems, which are first reformulated as complicating constraints to enable decomposition. This transformation allows the overall problem to be expressed as a collection of subproblems linked through a shared set of complicating variables. The resulting structure is particularly amenable to algorithms that exploit this decomposability to solve larger problems by decomposing them into significantly smaller, more manageable subproblems. SNoGloDe exploits this structure via a prioritized branching strategy and strategically constructed lower and upper bounds.

### Algorithm

The underlying solution strategy is based on spatial branch-and-bound, a global optimization approach that explores the feasible region by recursively partitioning variable domains. Each node in the search tree corresponds to a restricted domain for the decision variables and is associated with both a lower bound, obtained from a relaxation, and an upper bound, obtained from a feasible solution. Nodes are pruned if they are infeasible or if their lower bound exceeds the best known upper bound. As the algorithm progresses, global bounds tighten, and the optimality gap decreases until a specified tolerance

is met. This process guarantees convergence to a globally optimal solution under standard assumptions [5].

To exploit the decomposable structure of the reformulated problem, a priority spatial branch-and-bound scheme is used. Rather than branching on *all* optimization variables, the search tree is restricted to the *complicating* variables only, while subproblem-specific variables are handled implicitly within each node. At a given node, the lower bound is computed by dropping the complicating constraints and solving each subproblem independently to global optimality with respect to the current bounds on the complicating variables, and then aggregating the resulting objective values. This ensures valid global lower bounds without requiring additional relaxations, although such enhancements can be incorporated if desired. Importantly, global convergence is preserved because all variables are ultimately optimized to global optimality, either through the branch-and-bound tree or within the subproblem solvers.

Upper bounds are generated by fixing a candidate assignment of the complicating variables and solving each subproblem independently to obtain a feasible solution. If all subproblems are feasible, their combined objective value provides a valid upper bound for the node. When a node cannot be pruned, branching is performed by selecting a complicating variable and splitting its domain, creating two child nodes that are added to the search queue. Throughout the algorithm, node-level computations are separable across subproblems and can therefore be parallelized. The method terminates when the optimality gap is sufficiently small or no nodes remain, at which point the best feasible solution found is returned.

**Algorithm 1**: Priority Spatial Branch-and-Bound (SNoGloDe)

***In:*** Subproblems $\{P_1, \ldots, P_k\}$, complicating variables $z \in Z^0$, tolerance $\varepsilon$

***Out:*** Globally optimal solution $z^*$, $x^*$

1. Initialize: $UB \leftarrow +\infty$, $LB \leftarrow -\infty$, queue $Q \leftarrow$ {root node}
2. **while** Q not empty and $(UB - LB) > \varepsilon$ **do**
3. Select node N from Q *[customizable: node selection]*
4. Compute lower bound by relaxing complicating constraints and solving each subproblem $P_k$ independently: $LB_n \leftarrow \sum_k \min f_k(x_k, z)$ s.t. $x_k \in X_k$, $z \in Z_n$ *[customizable: relaxation refinement]*
5. **if** $LB_n \geq UB$ **then** prune N and continue
6. Select candidate solution, fix values for complicating variables z *[customizable: incumbent generation]*
7. Compute upper bound by solving each $P_k$ with z fixed: $UB_n \leftarrow \sum_k \min f_k(x_k, \hat{z})$ s.t. $x_k \in X_k$ (if all $P_k$ feasible)
8. **if** $UB_n < UB$ **then** $UB \leftarrow UB_n$; store best solution
9. Select $z_i \in z$ to branch on and split point s *[customizable: branching variable & split point]*
10. Add child nodes $N^+$ ($z_i \leq s$) and $N^-$ ($z_i \geq s$) to Q
11. **end while**
12. **return** best feasible solution

## Algorithm Customization via SNoGloDe

The algorithmic framework SNoGloDe implements the priority spatial branch-and-bound approach described above. Within this setting, the proposed approach is intentionally designed to be highly customizable. Rather than prescribing a fixed set of heuristics, the package exposes multiple decision points throughout the branch-and-bound process at which problem-specific knowledge can be incorporated. These include strategies for node selection, refinement of lower-bound relaxations, generation of incumbent solutions, selection of branching variables, and determination of split points. Each of these choices directly influences how the search tree evolves, affecting both solution quality and computational efficiency.

The flexibility of this design is critical, as the performance of prioritized branch-and-bound methods is driven primarily by heuristics tailored to the specific problem. Intelligent node selection can dramatically reduce the size of the search tree by prioritizing regions with higher potential for bound improvement. Similarly, tighter relaxations enable earlier pruning, whereas effective incumbent generation accelerates convergence by improving global upper bounds more quickly. Branching and partitioning strategies further shape the combinatorial and numerical properties of the tree. By allowing these components to be tailored to the structure of a given application, the framework supports a wide spectrum of problem-aware strategies, transforming a generic decomposition into a tailored algorithm.

Allowing models to be expressed in Pyomo [7] ensures broad compatibility with nonlinear, mixed-integer, and nonconvex formulations and enables seamless interaction with global and local solvers. The implementation further supports parallel execution via an MPI-based workflow, enabling efficient distribution of subproblem solves and bound computations. To facilitate customization, SNoGloDe provides base classes with virtual methods that map directly to the key algorithmic decision points, making it straightforward for users to experiment

with and deploy customized heuristics.

## HDA FLOWSHEET DECOMPOSITION

To solve using SNoGloDe, the hydrodealkylation flowsheet was partitioned into two subproblems. The first subproblem included the feed streams, the mixer (M101), the heat exchanger (H101), and the reactor (R101). The second subproblem included the flash (F101), the splitter (S101), and the compressor (C101). The first subproblem was called the reactor subproblem, and the second subproblem was called the flash subproblem. The reactor outlet temperature and the component molar flow rates were treated as complicating variables, meaning that their equality was enforced when generating the upper bound and candidate solution, but relaxed when determining the lower bound for a given node. This resulted in nine complicating variables (4 components, 2 phases, and 1 temperature). This decomposition scheme was chosen to place the two most complex unit operations, R101 and F101, in separate subproblems. Each subproblem has its own objective function and can be solved to global optimality using Baron [6] or Gurobi [2].

### Reactor Subproblem

The model for the reactor subproblem included all equations and constraints that govern the unit operations and flows among the feeds, mixer, and reactor. The objective was to minimize the capital and operating costs. The costing equations were adopted from [3]. The heat exchanger outlet temperature (affecting the heat duty) and the reactor volume are both free variables. The annualized operating cost of the heat exchanger was found using Equation 3.

$$\text{Operating Cost} = (3600 \times 24 \times 365) \times \text{Heating Cost} \quad (3)$$

The heating cost for the heat exchanger was determined using Equation 4.

$$\text{Heating Cost} = 2.2 \times 10^{-7} \times Q_{\text{heater}} \quad (4)$$

Where $Q_{\text{heater}}$ is the heat duty of the H101. The capital cost for the CSTR was calculated using Equation 5.

$$\text{Capital Cost} = 1.0 \times 10^{5} \times V \quad (5)$$

Where $V$ is the reactor volume in cubic meters. The objective function for the reactor subproblem is found in Equation 6.

$$\text{min.} \quad (\text{Operating Cost} + \text{Capital Cost}) \times 10^{-6} \quad (6)$$

The objective function was scaled by $10^{-6}$.

### Flash Subproblem

The subproblem model for the flash included all equations and constraints that govern the unit operations and flows among the flash, splitter, and compressor. The objective for the flash subproblem was to maximize profit by minimizing negative profit. The costing equations were adopted from [3]. The free variable was the flash outlet temperature, which impacts the heat duty of the flash and the amount of liquid benzene generated. Annual revenue was calculated using Equation 7.

$$\text{Revenue} = F^{\text{out}}_{\text{Liq, benzene}} \times (3600 \times 24 \times 365) \times 78.11 \times 0.82 \times 10^{-3} \quad (7)$$

The annualized operating cost for the flash was found using Equation 8.

$$\text{Operating Cost} = (3600 \times 24 \times 365) \times \text{Cooling Cost} \quad (8)$$

The cooling cost for the flash was determined using Equation 9.

$$\text{Cooling Cost} = 0.25 \times 10^{-7} \times (-Q_{Flash}) \quad (9)$$

Where $Q_{\text{Flash}}$ is the heat duty of the F101. It was negated because the flash is cooled. The objective function for the reactor subproblem is reported in Equation 10.

$$\text{min} \quad -(\text{Revenue} - \text{Operating Cost}) \times 10^{-6} \quad (10)$$

Note that capital cost is not included for the flash unit since the vessel cost is assumed to be much less than the reactor cost. Similarly to the reactor subproblem, the objective was scaled by $10^{-6}$.

## RESULTS

As highlighted in the Methodology section, a significant advantage of SNoGloDe is its ability to customize multiple elements. For this problem, we developed a warm-start capability at the lower bound (first solving a reduced square problem with IPOPT to obtain strong initial values for process variables and then solving globally with Gurobi [2]). This approach improved the convergence reliability for Gurobi on this NLP. To produce upper bounds, we used the built-in option to solve the monolithic problem *locally* with IPOPT and used the solutions for the complicating variables as the candidate solution for that upper-bound iteration. For branching, we selected variables using a Pseudocost methodology (also built in) and a worst-bound node queue. The results for the flowsheet optimization are summarized in Table 1 and shown in Figure 2.

SNoGloDe reached the globally optimal objective value with a 0.6% gap. Note that the monolithic model was also solved using Baron to confirm global optimality; both approaches yielded the same solution. This approach demonstrates a method for decomposing a nonlinear, nonconvex process flowsheet.

This model and solution are available as an example problem in the SNoGloDe code base.

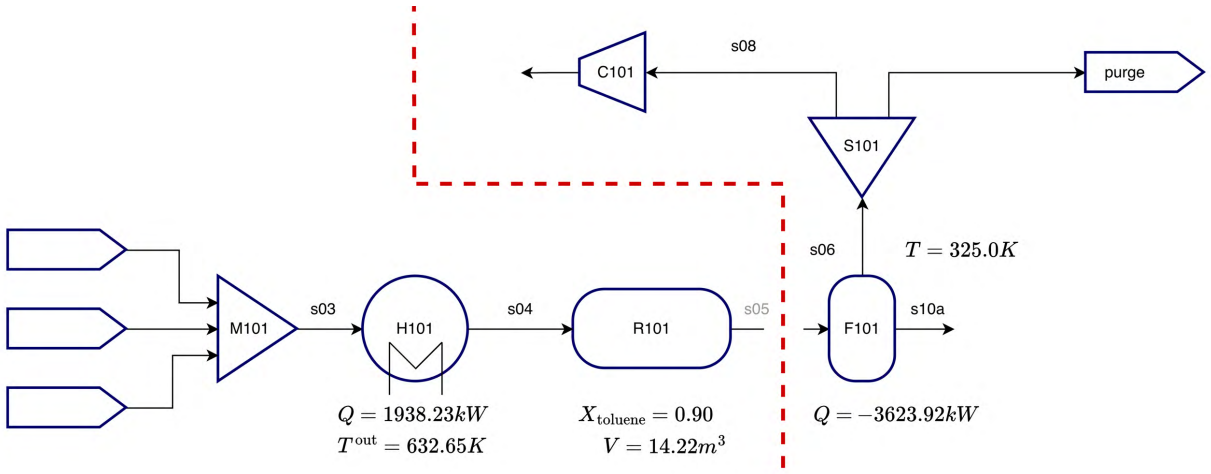

**Figure 2.** Summary of solution for the decomposed flowsheet. Values are summarized in Table 1. The first subproblem is the feed streams, mixer (M101), heat exchanger (H101), and the reactor (R101). The second subproblem is the flash (F101), splitter (S101), and compressor (C101). The molar flowrate for each component and the temperature of the reactor outlet are taken as complicating variables.

**Table 1:** SNoGloDe results for HDA flowsheet

| Variable | Value | Units |
|---|---|---|
| Profit | 9.96 | M$/year |
| H101 Outlet Temperature | 632 | K |
| H101 Heat Duty | 1, 940 | kW |
| Reactor Volume | 14.2 | $m^3$ |
| Toluene Conversion | 0.90 | |
| F101 Outlet Temperature | 298 | K |
| F101 Heat Duty | -3, 620 | kW |

The resulting costs for the flowsheet are reported in Table 2.

**Table 2:** Costing Results for HDA Process

| Item | Value | Units |
|---|---|---|
| H101 Operating Cost | 13, 447, 000 | $/yr |
| F101 Operating Cost | 2, 857, 000 | $/yr |
| R101 Capital Cost | 1, 421, 000 | $ |
| Annual Revenue | 27, 687, 000 | $/yr |
| Net Profit | 9, 961, 000 | $/yr |

## CONCLUSIONS

Our approach and case study illustrate how decomposition-based global optimization can provide results for complex, integrated flowsheet models. Beyond this example, integrating SNoGloDe with IDAES enables the extension of these methods to large-scale industrial challenges. By combining rigorous process modeling with a solution framework that yields globally optimal solutions, we present an alternative approach to solving process-system flowsheet optimization problems. Future work includes connecting the recycle between the compressor outlet and the mixer inlet.

## ABSTRACT

Modular plant design requires assessing whether independently characterized process requirements and module capabilities are compatible—a challenge that established methods address incompletely. Feasibility and flexibility analysis, as well as Quality by Design, typically assume integrated single-domain models where all variables belong to one coherent description, yet modular design involves domains that originate from different sources, evolve independently, and connect through interface variables. This work proposes Quantified Constraint Satisfaction Problems (QCSPs) as a formulation for interface-level suitability assessment: universal quantification encodes properties that must hold across their entire admissible range (e.g., physical properties, uncertain or environment-dependent characteristics requiring robustness), while existential quantification encodes variables where at least one feasible value must exist (e.g., critical process parameters, control inputs, configuration options). By operating over domain interfaces rather than requiring integrated system models, the formulation accommodates heterogeneous information sources within a common problem specification, with uncertainty handled through probabilistic intervals governed by a global confidence threshold. The framework supports both finite-domain solving on pre-evaluated datasets and numeric solving through on-demand model evaluation. A bioreactor suitability case study provides proof-of-concept, illustrating how the framework accommodates realistic problem complexity and offering initial observations on method selection trade-offs.

## INTRODUCTION

Modular plant design has emerged as a paradigm for flexible, reconfigurable production systems in process industries facing volatile markets or rapid scale-up needs [1, 2]. By composing standardized, pre-engineered equipment units rather than designing monolithic facilities [3, 4], modular approaches have the potential to reduce engineering effort and support faster time-to-market [5]. However, this introduces a fundamental challenge: assessing whether a given module is suitable for a specific process before committing to detailed engineering [6, 7].

Two established methods offer relevant foundations. Feasibility and flexibility analysis evaluates whether process designs can maintain feasible operation under uncertainty [8, 9]. A key aspect within Quality by Design is the design space: the region of input variables and process parameters within which product quality is reliably met [10–12]. Despite their complementary strengths, neither directly addresses the module selection problem: determining whether independently characterized process requirements and module capabilities are compatible. Both typically assume integrated single-domain models, yet modular design involves domains that originate from different sources.

Bridging this gap requires confronting several challenges. First, process requirements and module capabilities may be characterized using different model types, information sources, and uncertainty representations.

Second, the interface between domains involves shared variables where semantic alignment introduces uncertainty. Third, practical suitability assessment must accommodate varying levels of detail: coarse screening across large module libraries demands different methods than detailed verification of selected candidates.

This work proposes a framework that addresses these challenges by reformulating suitability assessment as a Quantified Constraint Satisfaction Problem (QCSP) operating over domain interfaces. The framework provides a unified problem description capable of integrating diverse information types, systematic handling of uncertainties through interval specifications, and scalable assessment procedures. The following sections describe the theoretical foundations, present solution procedures, and demonstrate the framework through a case study in bioprocess equipment selection.

## CONCEPTUAL FOUNDATIONS

Assessing module suitability requires clarity on what is being compared and at what level of abstraction. This section establishes the conceptual structure: domains as bodies of knowledge, their diverse characterizations, and approaches for comparison.

### Domains and Abstractions

A domain denotes a bounded, abstract description space in which variables, constraints, and relations are defined—a consistent viewpoint independent of physical realization. In module-based plant design, a separation is typically made between the (equipment-) module domain and the process domain [13, 14].

Each domain may be characterized through diverse means—mechanistic models, experimental data, datasheets, simulation results, or expert knowledge—varying in fidelity, formalism, and the phenomena they capture. Crucially, characterizations from different domains are often not directly comparable: a detailed dynamic model of a bioreactor and a Quality-by-Design design space for a cultivation process do not share a common language.

Two strategies exist for enabling evaluation across domains. The first connects domain characterizations directly—for instance, coupling dynamic process and equipment models—and derives abstractions that evaluate the joint system's suitability for a given goal. This integrated approach permits analytical depth but introduces complexity: proprietary interfaces must propagate uncertainties across subsystems, and metrics must address the combined system. The second strategy, emphasized here, derives abstractions from individual domain characterizations independently, then assesses compatibility at the interface level. From process characterizations, requirements are derived (e.g., operating ranges, quality specifications); from module characterizations, capability metrics are extracted (e.g., operational envelopes). These transformations require analytical effort but yield quantities that are comparable without coupling the underlying characterizations, sacrificing analytical depth for manageability and accepting conservatism in exchange for modularity.

In practice, process and equipment characterizations are rarely created independently: experimental data emerges from specific equipment configurations, while equipment specifications are refined based on target processes. The framework accommodates such entanglement through uncertainty specifications on interface variables, allowing imperfect separation to be represented explicitly rather than assumed away.

### Assessment Scope

Adopted from the concept of intra-modular safety in modular safety engineering [15, 16], this work introduces *intra-modular suitability*: the suitability of an individual module for a given process, assessed via boundary variables that characterize its interface with the environment. A module is considered intra-modularly suitable if its capability envelope covers the corresponding process requirements across all relevant boundary variables. If intra-modular suitability is established for all modules within a configuration, system-wide suitability can be inferred without further analysis.

## CSP FRAMEWORK FOR SUITABILITY ASSESSMENT

The preceding conceptual foundations established the domains and the scope of the suitability assessment considered in this work. This section introduces a formal framework that operationalizes these concepts using QCSPs [17–19]. The following section relates the framework to feasibility analysis and Quality by Design, presents the advantages of the CSP-based formulation, provides the formal QCSP definition with uncertainty handling, and defines satisfaction semantics.

### Relation to Feasibility Analysis and Quality by Design

The suitability assessment problem shares foundational objectives with feasibility and flexibility analysis as well as Quality by Design: ensuring constraint satisfaction under uncertainty through appropriate use of degrees of freedom. Classical feasibility and flexibility analysis evaluates whether feasible operation can be maintained for all uncertain parameters $\theta$ within a specified set $T$ through appropriate adjustment of control variables $z$ given constraints $g(d, z, x, \theta) \leq 0$ [8, 20, 21]. Quality by Design similarly distinguishes between material attributes and process parameters that define a design space

within which product quality is assured [10, 11]. Both frameworks implicitly encode a quantifier structure analogous to that of QCSPs: in flexibility analysis, uncertain parameters $\theta$ correspond to universal quantification $\forall$ (feasibility must hold across their entire range), while control variables $z$ correspond to existential quantification $\exists$ (finding any feasible adjustment suffices). In Quality by Design, Critical Material Attributes (CMAs) typically relate to universal quantification as properties that must be tolerated across their specified ranges, while Quality Target Product Profiles (QTPPs), Critical Quality Attributes (CQAs), and Critical Process Parameters (CPPs) relate to existential quantification as targets where achieving any value within acceptable bounds suffices.

However, neither method directly addresses the matching problem in module-based plant design. Both typically require an integrated model relating all variables within one coherent description. Performing a feasibility test for a given process-module combination therefore requires semantic alignment: the meaning encoded in design space characterizations must be transferred into a problem structure compatible with flexibility analysis. This translation is non-trivial and may need to be repeated for each combination, as these approaches are commonly implemented ad hoc rather than integrated into information model standards. While recently established standards such as VDI/VDE/NAMUR 2658 (Module Type Package) [22] or DEXPI [23] provide structured representations of equipment and process data, they do not prescribe a formal problem structure for suitability assessment. An interface language is therefore needed that encodes the semantics of feasibility and flexibility analysis and Quality by Design into a common problem specification.

## Advantages of CSP-Based Formulation

QCSPs address this by providing a *common interface language* for independently characterized domain constraints. Each domain translates its characterization into QCSP-compliant interval specifications; matching then operates on these specifications without requiring knowledge of underlying models.

This interface-language property derives from several characteristics of the CSP formalism. First, CSP formulations treat all variables uniformly without requiring explicit differentiation between inputs, outputs, or other dependency structures. This uniformity shifts modeling complexity into the domain descriptions themselves, decoupling problem specification from solution strategy. The framework thus accommodates heterogeneous information sources—mechanistic models, empirical correlations, experimental datasets, manufacturer specifications—without prescribing how these sources internally relate variables.

Second, while the quantifier structure underlying feasibility and flexibility analysis and Quality by Design remains implicit in their problem formulations, the QCSP formalism makes this structure explicit and systematic. Variables are declared with their quantifiers as part of the problem specification, enabling direct expression of which conditions must be tolerated versus which represent degrees of freedom. This explicitness facilitates communication across domain boundaries and supports automated reasoning about suitability.

Third, the formulation accommodates expressiveness beyond classical approaches. Quantifier semantics may depend on assessment context: a critical process parameter such as cultivation temperature is existentially quantified for single-product assessment (one feasible setpoint suffices) but universally quantified for multi-product flexibility (all temperatures in the range must be achievable). The QCSP formulation handles such context shifts through quantifier specification rather than problem reformulation. Furthermore, discrete variables representing categorical choices (equipment variants, operating modes) integrate naturally alongside continuous variables—a capability that flexibility analysis handles less directly.

Fourth, integrating uncertainty directly into constraint specifications enables cleaner problem descriptions and more generic uncertainty handling than approaches common in flexibility analysis or Quality by Design. The formulation presented below embeds probability distributions as first-class constraint elements, with a global confidence threshold governing the overall satisfaction guarantee.

The approach localizes transformation effort to domain boundaries: while defining the translation from domain-specific characterizations to QCSP specifications requires non-trivial effort, such effort is inherent whenever knowledge from different sources must be integrated. The formalization provides a uniform interface that, once established, simplifies subsequent usage across different assessment contexts. Beyond binary satisfaction, CSP-based analysis can yield information analogous to flexibility analysis, including identification of binding constraints, feasible region characterization, and flexibility quantification through systematic constraint bound variation [24].

## Quantified Constraint Satisfaction Problem Formulation

The QCSP is defined as a tuple $\langle X, D, C \rangle$ where:

- $X = \{X_1, \ldots, X_n\}$ is a set of variables
- $D = \{D_1, \ldots, D_n\}$ where each $D_i$ is the domain for variable $X_i$, which may be continuous ($D_i \subseteq \mathbb{R}$) or discrete ($D_i = \{v_1, \ldots, v_k\}$)
- $C = \{C_I, C_F, C_D, C_\alpha\}$ is a structured set of constraints

Each constraint type serves a distinct role in the problem specification: The set $C_I$ contains interval constraints that bound individual variables:

$$C_I = \{(Q_i, X_i, B_i) : i \in \mathcal{I}\} \tag{1}$$

where $Q_i \in \{\exists, \forall\}$ denotes the quantifier specifying whether satisfaction is required for *some* ($\exists$) or *all* ($\forall$) values of the variable, $X_i \in X$ is the constrained variable, and $B_i$ specifies the constraint bound. The bound $B_i$ may take the form of either a *deterministic interval* $[l_i, u_i]$ with $l_i, u_i \in \mathbb{R}$, or a *probabilistic specification* $P_i$, i.e., a probability distribution from which operational bounds are derived during solving. Deterministic intervals directly restrict a variable to a known range. Probabilistic specifications, by contrast, encode uncertain knowledge about the constraint—for example, a process viscosity requirement subject to measurement or modeling uncertainty, or an equipment limit known only within confidence bounds. The translation from a probability distribution to an effective interval depends on the global confidence threshold and the solving procedure, allowing the same problem specification to induce different operational constraints under different confidence requirements.

The set $C_D$ restricts variables to specific discrete values:

$$C_D = \{(X_k, V_k) : k \in \mathcal{K}\} \tag{2}$$

where $V_k \subset D_k$ is a finite set of allowed values for variable $X_k$. These constraints represent categorical choices such as equipment variants, operating modes, or material selections.

The set $C_F$ captures relational constraints among multiple variables:

$$C_F = \{(t_j, R_j) : j \in \mathcal{J}\} \tag{3}$$

where $t_j \subseteq X$ denotes the scope of the constraint, i.e., the subset of variables involved, and $R_j \subseteq \prod_{X_k \in t_j} D_k$ defines the relation specifying the allowed combinations of values over that scope. The relation $R_j$ may be specified explicitly (e.g., as a lookup table or pre-evaluated dataset) or implicitly (e.g., through algebraic equations, differential equations, or trained surrogate models). This flexibility accommodates the diverse information types encountered in modular plant design.

For any variable $X_i \in X$, an optional associated distribution $P_{X_i}$ may be specified, indicating that values of $X_i$ are known only probabilistically. The impact of such variable-level uncertainty on constraint satisfaction is governed by the global confidence threshold.

The constraint $C_\alpha$ specifies the required confidence level for the overall problem:

$$C_\alpha = \alpha_{\text{global}} \in [0, 1) \tag{4}$$

This threshold defines an upper bound on the probability with which a declared solution may violate one or more constraints. A high confidence requirement (e.g., $\alpha_{\text{global}} = 0.01$) demands that uncertainties be treated conservatively, yielding solutions that are highly trustworthy but potentially restrictive. Larger values of $\alpha_{\text{global}}$ permit more optimistic interpretations of uncertain constraints, expanding the solution space. The global confidence constraint affects all probabilistic elements in the problem: interval constraints specified as distributions ($B_i = P_i$) and variables with associated uncertainty ($P_{X_i}$). Deterministic constraints remain unaffected. The specific mechanism by which $\alpha_{\text{global}}$ propagates to individual uncertain elements—for instance, through Bonferroni correction (as described in the case study) or more sophisticated allocation schemes—is a solver concern rather than a problem specification concern. This separation ensures that the problem formulation remains independent of the solution method.

## Satisfaction Semantics

The QCSP is satisfied if a strategy $\sigma$ exists for existentially quantified variables such that, for any assignment to universally quantified variables, all constraints are satisfied with significance at least $\alpha_{\text{global}}$.

Formally, let $X_\forall = \{X_i : \exists (Q_i, X_i, B_i) \in C_I \text{ with } Q_i = \forall\}$ denote the universally quantified variables, and $X_\exists = X \backslash X_\forall$ the existentially quantified variables. The QCSP is satisfied if and only if:

$$\mathbb{P}\left[\exists \sigma : \prod_{X_j \in X_\exists} D_j \text{ s.t. } \forall \mathbf{x}_\forall \in \prod_{X_i \in X_\forall} \tilde{B}_i : (\mathbf{x}_\forall, \sigma(\mathbf{x}_\forall)) \vDash C\right] \geq 1 - \alpha_{\text{global}} \tag{5}$$

where $\tilde{B}_i$ denotes the effective interval for variable $X_i$ (either the deterministic interval $[l_i, u_i]$ or an interval derived from $P_i$ consistent with $\alpha_{\text{global}}$), and $\vDash C$ indicates satisfaction of all constraints in $C$. When $\alpha_{\text{global}} = 0$ and all constraints are deterministic, this reduces to classical QCSP semantics. When only existential quantifiers are present ($X_\forall = \varnothing$), the problem simplifies to a standard CSP.

# CASE STUDY

This section demonstrates the framework through a proof-of-concept assessment of bioreactor suitability for cell cultivation processes. First, the solving procedures are presented; then, these procedures are applied to four representative scenarios.

## Solving Procedures

The QCSP formulation admits various solving strategies; the methods employed here prioritize simplicity to illustrate the connection between the problem formulation and established techniques. More sophisticated solvers from flexibility analysis or constraint programming can be substituted as problem complexity

increases, while the fundamental structure of QCSP solving remains unchanged.

As noted above, constraint relations may be specified through pre-evaluated datasets (finite-domain solving via direct lookup) or model structures requiring computation (numeric solving via on-demand evaluation). This distinction is decisive: these information sources entail fundamentally different solver strategies and different potentials for characterizing domain properties.

For uncertainty handling, a spectrum of approaches exists between repeated sampling from probability distributions followed by solving CSP instances, and conservative treatment through worst-case bounds on confidence intervals. The latter approach, employed here via Bonferroni correction, offers computational efficiency at the cost of conservatism. When multiple uncertain constraints must be satisfied jointly, the union bound controls overall failure probability: if $\alpha_{\text{global}}$ is the acceptable global significance level and $N$ constraints carry uncertainty, allocating a budget $\alpha_i$ to each constraint such that $\sum_{i=1}^{N} \alpha_i = \alpha_{\text{global}}$ guarantees that the global failure probability remains below $\alpha_{\text{global}}$. The simplest allocation divides $\alpha_{\text{global}}$ uniformly; more sophisticated schemes can assign stricter thresholds to critical constraints, enabling optimized prioritization. For a constraint with probabilistic specification (e.g., Gaussian with mean $\mu_i$ and standard deviation $\sigma_i$), the effective interval becomes $[\mu_i - z_{\alpha_i/2}\sigma_i, \mu_i + z_{\alpha_i/2}\sigma_i]$, where $z_{\alpha_i/2}$ is the critical value corresponding to the allocated local significance level. This transformation converts probabilistic constraints into deterministic intervals suitable for standard constraint checking, while preserving statistical guarantees on the overall solution.

For standard CSPs (only existential quantifiers), satisfaction requires finding at least one assignment satisfying all constraints. The solving procedure applies a search strategy appropriate to the information type: for finite-domain problems, constraint propagation successively filters candidate points, or backtracking examines candidates sequentially with early termination upon finding a valid assignment; for numeric problems, sampling-based search (e.g., random or structured sampling) generates input configurations for on-demand model evaluation. In both cases, uncertain constraints are checked against intervals derived from their associated distributions using the allocated local significance thresholds.

For QCSPs containing universal quantifiers ∀, direct verification would require checking infinitely many value combinations within ∀-intervals—an intractable task. The approach adopted here decomposes universal constraints into boundary evaluations: each ∀-constraint on interval $[l_i, u_i]$ generates sub-problems at the boundary values $\{l_i, u_i\}$, yielding $2^{|X_\forall|}$ standard CSP sub-problems. Under a continuity assumption—that feasible regions form convex sets such that boundary feasibility implies interior feasibility—satisfaction of all boundary sub-problems guarantee satisfaction of the original QCSP. This assumption holds for many physical systems but may yield false positives when solution spaces exhibit discontinuities or non-convexities; such cases require explicit mode enumeration or conservative interior sampling.

Algorithm 1 is a unified solving procedure. The algorithm accepts a QCSP specification and returns a satisfaction status. The SEARCH subroutine encapsulates information-type-specific strategies: for finite-domain problems, it implements constraint propagation or backtracking over pre-evaluated datasets; for numeric problems, it implements sampling-based search with on-demand model evaluation. The DECOMPOSE subroutine generates boundary sub-problems from universal constraints.

**Algorithm 1:** QCSP Solver

**Input:** QCSP $\langle X, D, C\rangle$ with $C = \{C_I, C_F, C_D, C_\alpha\}$
**Output:** Satisfaction status
$X_\forall \quad \{X_i : (Q_i, X_i, B_i) \in C_I \wedge Q_i = \forall\}$
$\mathcal{S} \leftarrow$ Decompose$(C_I, X_\forall)$ // $2^{|X_\forall|}$ sub-problems (1 if $X_\forall = \emptyset$)
Compute $\alpha_{\text{local}}$ from $\alpha_{\text{global}}$ $|\mathcal{S}|$, and uncertain constraint count;
Derive effective intervals $\tilde{B}_i$ from probabilistic specifications using $\alpha_{\text{local}}$
**foreach** *sub-problem* $s \in \mathcal{S}$ **do**
  **if** SEARCH$(X, D, C, \tilde{B}^{(s)}) =$ *unsatisfied* **then**
    **return** unsatisfied
**return** satisfied

## Bioreactor Suitability Assessment

The suitability assessment integrates a process domain characterized by Quality-by-Design-style cultivation requirements with a module domain described by a steady-state simulation model. Four representative scenarios, selected from a broader set of 18 assessment cases, illustrate the trade-offs between finite-domain and numeric solving while validating the framework's capability to handle problems of typical complexity in this domain. The remaining cases are omitted for brevity.

The bioreactor model represents a 10–200 L stirred-tank reactor typical of pilot-scale cell culture systems. The model accepts 12 input variables spanning thermal properties, equipment parameters, operational settings, and medium physical properties. Each output incorporates Gaussian uncertainty distributions with mechanistically derived mean values and standard deviations, enabling uncertainty propagation through the assessment. Despite the 12-dimensional input space, gradient-based principal component analysis revealed an effective dimensionality of approximately 5.4 dimensions, indicating significant redundancy due to variable correlations—a

**Table 1:** QCSP formulation for Case 1: CHO high cell density cultivation (20–30 × $10^6$ cells/mL) with high tempering capability of the bioreactor.

| Variable | Unit | Interval | Quant. |
|---|---|---|---|
| *Process Requirements* | | | |
| Medium Temperature | °C | [36.5, 37.0] | ∀ |
| Medium Volume | $m^3$ | [0.15, 0.17] | ∀ |
| Dynamic Viscosity | Pa·s | [0.001, 0.008] | ∀ |
| Medium Density | $kg/m^3$ | [1010, 1040] | ∀ |
| Specific Heat Capacity | J/(kg·K) | [3800, 3900] | ∀ |
| Thermal Conductivity | W/(m·K) | [0.58, 0.62] | ∀ |
| Eff. Shear Stress | Pa | [0.0, 1.4] | ∃ |
| Mixing Time | s | [0.0, 30] | ∃ |
| Min. Spec. Heat Flow | W/kg | [−732, −2.25] | ∃ |
| *Equipment Specification* | | | |
| Min. Jacket Temp. | °C | [15, 25] | ∃ |
| Max. Jacket Temp. | °C | [50, 70] | ∃ |
| Wall Therm. Resistance | $m^2$·K/W | [0.0002, 0.0006] | ∃ |
| Jacket Heat Trans. Coeff. | W/($m^2$·K) | [400, 800] | ∃ |
| Fouling Resistance | $m^2$·K/W | [0.00015, 0.0005] | ∃ |
| Max. Spec. Heat Flow | W/kg | [−203, 557] | ∃ |
| Agitation Speed | rpm | [20, 400] | ∃ |

characteristic that influences data requirements for explicit capability characterization.

The cultivation scenarios were selected to represent diverse assessment outcomes: Case 1 with requirements well within equipment capabilities; Case 2 requiring significantly more data due to proximity to capability boundaries; Case 3 where requirements approach the equipment limits; and Case 4 representing genuine incompatibility. Table 1 shows the complete QCSP formulation for Case 1 as an exemplary problem specification, showing how cultivation requirements and equipment specifications are transformed into interval constraints with appropriate quantifiers. The six universally quantified variables—representing process conditions that must be satisfied across their entire specified range—yield $2^6 = 64$ subproblems per assessment. A global confidence threshold of $\alpha_{\text{global}} = 0.05$ governed uncertainty propagation via Bonferroni correction.

For finite-domain solving, a dataset of $5 \times 10^6$ uniformly random samples were generated across the 12-dimensional input domain. The solver employed hybrid constraint propagation and backtracking with early termination. The numeric solver implemented uniform random search with on-demand model evaluation. Both solvers were implemented in Julia and executed single-threaded on a Windows system with 64 GB RAM and Intel vPRO EVO Edition CPU.

The assessment outcomes are summarized in Table 2. Both methods correctly identified Case 1 and Case 2 as satisfiable and Case 4 as infeasible. However, for Case 3, the finite-domain approach produced a false negative: it failed to find satisfying assignments despite the numeric solver confirming that feasible operational configurations exist. This discrepancy arises because the requirements in Case 3 approach capability boundaries where the feasible region becomes too narrow for the pre-computed dataset to capture. The finite-domain method cannot detect feasible regions between sparse datapoints, regardless of total dataset size—a fundamental precision limitation when requirements lie near equipment limits.

The performance comparison for Cases 1 and 2 (see Table 3) reveals the trade-off structure between methods. Case 1, with requirements well within capabilities, achieved satisfaction with $5 \times 10^5$ datapoints in 5.2 s, while the numeric solver required only 64 model evaluations. Case 2, despite both methods succeeding, demanded $5 \times 10^6$ datapoints and 36.9 s for finite-domain solving—a tenfold increase in data requirements due to proximity to capability boundaries—whereas numeric solving required only 69 evaluations. The breakeven simulation time, at which both methods require equal computational effort, shifts from 0.081 s per evaluation (Case 1) to 0.535 s (Case 2). For models with evaluation times above these thresholds, pre-computed datasets offer superior performance for repeated assessments; below them, on-demand evaluation becomes more efficient. This breakeven analysis, combined with the precision limitations observed in Case 3, suggests a practical strategy: finite-domain methods provide efficient initial

**Table 2:** Suitability assessment results for four representative scenarios comparing finite-domain (pre-evaluated dataset) and numeric (on-demand evaluation) solving approaches. Temp. indicates the bioreactor's tempering capability configuration (high: extended jacket temperature range; low: restricted range).

| Case | Cultivation | Temp. | Numeric | Finite-D. |
|---|---|---|---|---|
| 1 | CHO high cell dens. | high | satisfied | satisfied |
| 2 | E. coli low-temp expr. | high | satisfied | satisfied |
| 3 | E. coli low-temp expr. | low | satisfied | unsatisfied |
| 4 | P. pastoris methanol | low | unsatisfied | unsatisfied |

**Table 3:** Computational performance comparison for cases where both methods found satisfaction. Datapoints: minimum dataset size required for finite-domain satisfaction; FD Time: finite-domain solving duration; Num. Evals: model evaluations required by numeric solver; Breakeven: simulation time per evaluation at which both methods require equal total computation time.

| Case | Datapoints | FD Time (s) | Num. Evals | Breakeven (s) |
|---|---|---|---|---|
| 1 | $5 \times 10^5$ | 5.20 | 64 | 0.081 |
| 2 | $5 \times 10^6$ | 36.92 | 69 | 0.535 |

screening when requirements lie safely within anticipated capabilities, while numeric methods become essential for boundary exploration. The framework's unified problem formulation enables seamless transition between these approaches as assessment demands evolve.

## CONCLUSION

This work addressed a methodological gap in modular plant design: while feasibility and flexibility analysis provide rigorous frameworks for evaluating process robustness, and Quality by Design establishes systematic design space characterization, both traditions typically assume integrated single-domain models. Modular plant design, however, requires assessing compatibility between process requirements and module capabilities that originate from different sources, evolve independently, and connect through shared interface variables.

The proposed QCSP formulation addresses this gap primarily as a *formal interface language*. Rather than requiring integrated models that connect diverse domains manually—which demands detailed knowledge of both domain-specific model structures—the QCSP provides a common specification through which independently characterized domains can express their constraints. Each domain translates its characterization into QCSP-compliant interval specifications; the matching process then operates on these specifications without requiring knowledge of underlying model structures.

The framework accommodates heterogeneous information sources—mechanistic models, empirical datasets, expert-specified bounds—through uniform variable treatment, and supports both finite-domain solving on pre-evaluated datasets and numeric solving through on-demand model evaluation. The bioreactor case study provided proof-of-concept that the formulation can represent realistic suitability problems and that established solving techniques remain applicable.

Several limitations warrant emphasis. The case study employed an unvalidated first-principles model; industrial validation remains necessary. The solving procedures presented are illustrative rather than contributory—more sophisticated solvers from flexibility analysis or constraint programming literature can and should be substituted when problem complexity demands. Furthermore, while the framework provides mechanisms for uncertainty handling, systematic study of how uncertainty specifications affect assessment outcomes in practice was out of scope.

The breakeven thresholds (0.08–0.54 s per evaluation) illustrate trade-offs critical when assessing large module libraries. Separating problem specification from solution method enables staged workflows where inexpensive screening precedes costly verification. Capability characterizations generated during assessment can be stored and reused across future queries, amortizing effort and improving assessment efficiency over time.

## OUTLOOK

The primary need is empirical validation: applying the framework to industrial module selection problems would test whether the formalization provides practical value beyond conceptual clarity. Integration with

industrial information model standards could enable automated translation from existing domain characterizations to QCSP specifications, reducing the manual effort currently required; relevant standards include the Module Type Package (VDI/VDE/NAMUR 2658) for modular automation [22], DEXPI (IEC 62424) for process equipment data [23], IEC 61512 for batch control models [25], and ICH Q8–Q12 for pharmaceutical design spaces [10]. Development of accessible tooling would facilitate transition from methodological contribution to practical engineering workflow. Finally, comparative studies against established flexibility analysis tools would help quantify whether the interface-language benefits outweigh the translation overhead in realistic engineering contexts.

## ABSTRACT

In this work, we present quantum reinforcement learning algorithms for process flowsheet synthesis. Particularly, we discuss the implementation of encoding strategies to improve the algorithmic scalability. Reinforcement learning (RL)-driven flowsheet synthesis techniques provide a promising approach for conceptual process design, in addition to traditional optimization-based methods. These RL-based strategies identify the optimal flowsheet configurations from a maximum set of available processing units, without requiring to pre-postulate an interconnected superstructure. However, the resulting combinatorial design space for RL can scale extensively with the increased number of available processing units, which can render the algorithms to be computationally intensive or even intractable. To address this challenge, our prior work has introduced a quantum-enhanced approach to RL-driven process synthesis. However, this algorithm was limited in its capacity to solve larger flowsheeting problems as a large number of qubits were needed. To reduce qubit requirements and improve scalability, this work presents two different encoding strategies to embed information into the gates of quantum circuits instead of embedding it into qubits alone. We demonstrate the efficacy of these algorithms on three different scenarios of a flowsheet synthesis problem and interpret the results obtained from the IonQ quantum computing platform.

**Keywords**: Process Synthesis, Process Design, Reinforcement Learning, Quantum Computing, Machine Learning

## 1. INTRODUCTION

There has been increasing interest in RL-driven process synthesis methods [1-3], which strive to determine the optimal design solutions while minimizing the impact of prior expert knowledge and the solution of large-scale combinatorial optimization algorithms (e.g., generalized disjunctive programming, mixed integer nonlinear programming). However, a significant challenge for these strategies is the large process design space which can be highly computationally intensive or even intractable for RL to identify the truly optimal design solution.

RL-driven process synthesis involves training an agent to build optimal flowsheet designs for a given process application. This is posed as a discrete decision-making process. The RL agent is usually represented via a neural network (NN). This parameterization allows a deep RL algorithm to adjust tunable parameters within the NN-based agent. In this way, the agent iteratively becomes better at developing process flowsheets. Several techniques have been developed by the research community in recent years [1]. These include graph-based [2] or matrix-based [3] flowsheet representations, leveraging transfer learning models instead of expensive simulators [4], and simultaneously addressing design and control decisions [5].

To potentially speed up the RL-driven process synthesis, our prior work [4] presented the use of Quantum computing to leverage the theoretical advantages and continuous improvements of quantum hardware [5-6]. However, this quantum-accelerated methodology was constrained to very small flowsheet synthesis problems due to the poor scaling relationship between the required number of qubits and the problem size (e.g., the number of unit operations considered for process design). In this work, we improve this methodology by applying new

information encoding strategies to reduce the number of qubits needed in the quantum algorithm. This allows larger process design problems to be solved.

The remaining sections are organized as follows: Section 2 provides an overview of RL-driven process synthesis and covers the fundamentals of quantum RL. Section 3 introduces the re-uploading parameterized quantum circuit (PQC) approach used in our prior work and the proposed two new encoding strategies for qubit reduction. Section 4 showcases the new algorithms performance in solving three different scenarios of a process flowsheet synthesis problem. Section 5 discusses the outlook for next-step implementation on current-scale quantum hardware. Section 6 gives the concluding remarks and directions of ongoing research.

## 2. BACKGROUND

In this section, we review the basics of: (i) the RL-driven process synthesis approach adopted in this work, and (ii) quantum machine learning (QML).

### 2.1 RL-driven Process Synthesis

In this work, we adopt the matrix-based method developed by Wang et al. [3], which was also used in our prior works [4, 7].Fig. 1 provides a conceptual overview of this approach [3]. The flowsheet is represented by a stream matrix which represents the interconnectivity between potential unit operations using binary (0-1) values. It is important to note that not all available unit operations must be used. This stream matrix representation is then used as the input to an NN-based agent. The agent serves as a Q-function approximator by assigning a Q-value to each potential action. In the context of process synthesis, the action involves adding, changing, or removing a connecting stream within a process flowsheet. By taking the action that corresponds to the highest Q-value, the agent has made the theoretically optimal decision.

In this algorithm, the agent is limited to making only one action per step (i.e., only one stream connection can be changed). The RL agent can thus determine all the mixed-integer variables through iterations with the environment, which define the flowsheet structure. Afterwards, the resulting flowsheet is simulated using the Institute for the Design of Advanced Energy Systems (IDAES) platform and the continuous process variables are optimized using nonlinear optimization solvers (e.g., IPOPT) [8-9].

This nonlinear optimization is conducted by maximizing a reward or objective function defined by the user. Examples of the reward functions include maximizing economic profits, productivity, sustainability, etc. This function is also used within the RL algorithm to update the tunable parameters of the agent. At each step of the algorithm, a gradient-based constraint-free optimization technique is used to improve the agents decision-making capability. The RL method used here is the Deep Q-Network algorithm.

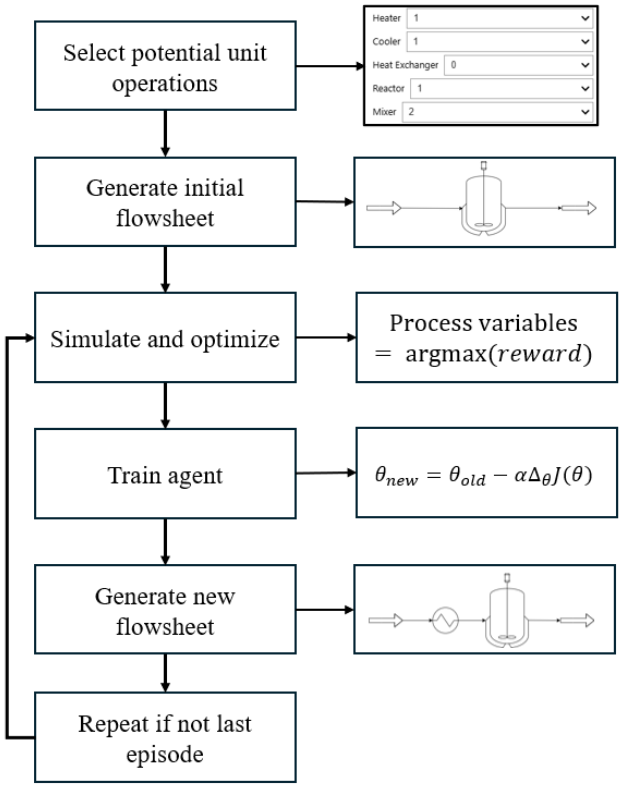

**Figure 1.** An overview of RL-driven process synthesis.

### 2.2 Quantum Reinforcement Learning

Quantum RL relies on QML which implements ML algorithms on quantum computing platforms and manipulates information encoded in qubits. The fundamental component of QML is the use of parameterized quantum circuits (PQCs), which can be described as the quantum analog of classical NNs [10].

PQCs consist of quantum circuits that take in classical or quantum data typically as quantum states and produce outputs via measurement combinations known as observables. The quantum gates have adjustable parameters that are trainable. Figure 2 illustrates an example of PQC with three qubits. Each qubit is sequentially acted upon by single-qubit rotation gates $R_X$, $R_Y$, and $R_Z$, followed by an entangling architecture composed of controlled-Z (CZ) gates. The rotation gates implement transformations about the x, y, and z axes of the Bloch sphere representation of the qubit's quantum state. The rotation angles are defined by the trainable parameters $\theta_i$. The CZ gates introduce conditional phase shifts that depend on the state of another qubit, thereby generating quantum entanglement among the qubits. In this work, we will refer to a sequence of x, y, z rotation gates followed by CZ

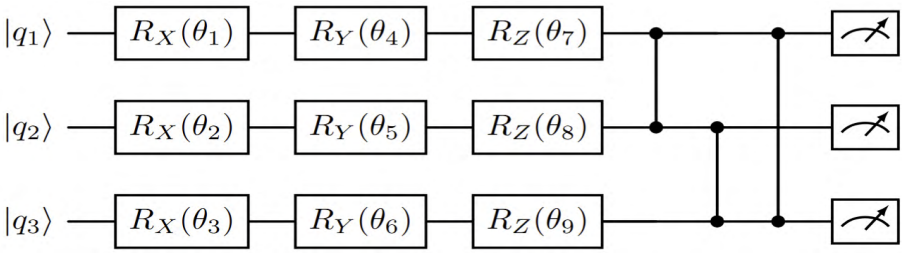

**Figure 2.** PQC with measurments: a 3-qubit example.

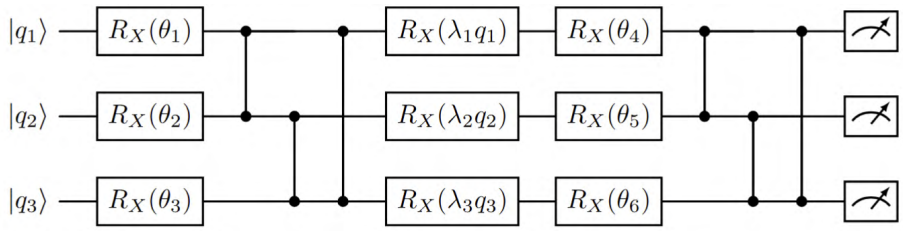

**Figure 3.** 3-qubit re-uploading PQC with measurements.

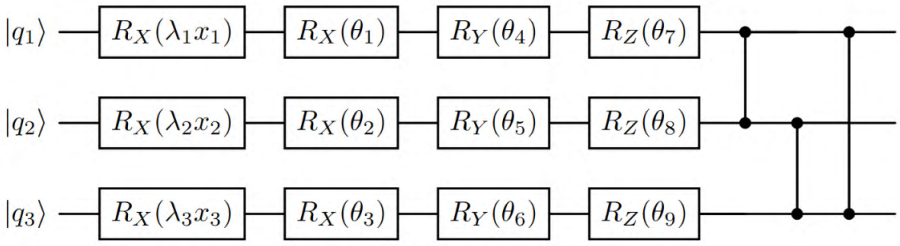

**Figure 4.** 3-qubit PQC using "X-only" encoding: an example of one PQC layer.

gate entanglement as a "layer" of a PQC.

For quantum RL, these PQCs can replace NNs in deep RL algorithms, as that developed in our prior work [4]. These would act as quantum agents to be trained. In addition, different with the data fed to NNs, the data fed to PQCs may need to be encoded as a quantum state. All other components of the classical RL algorithms may remain the same for quantum RL. Essentially any modern RL algorithm (e.g., DQN, DDPG) can be modified to use quantum agents by replacing NNs with PQCs [10].

## 3. QUANTUM RL-DRIVEN SYTHESIS

In this section, we first provide a brief review of the re-uploading PQC algorithm for the quantum RL-driven process synthesis approach presented in our prior work. We then present two new encoding approaches for qubit reduction and scalability improvement.

### 3.1 Quantum RL with Re-Uploading PQC

Our prior work utilized a special type of PQC, called a re-uploading PQC as shown in Fig. 3 [4]. This type of PQC increases expressibility by reinjecting the input data into the circuit after sets of CZ gates. This reinjection is accompanied with its own set of tunable parameters, which is represented by λ in Fig. 3. The data re-encoding step can be repeated many times, thus forming a quantum circuit with several layers. Despite the advantage, re-uploading PQC does require that the number of qubits in the circuit equals the size of the input data. The many layers of entanglement may also be expensive to compute.

For the RL-driven process synthesis algorithm, the input dimension is determined by the number of available unit operations. This is not an issue for classical RL, since NNs can handle extremely large input dimensions. However, for PQCs the circuit complexity increases vastly with more qubits. This necessitates the need for new quantum-based approaches which can reduce the number of qubits needed and therefore solve larger process synthesis problems.

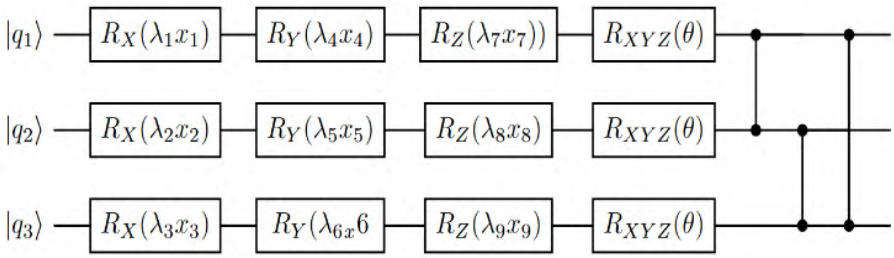

**Figure 5.** 3-qubit PQC using "XYZ" encoding: an example of one PQC layer.

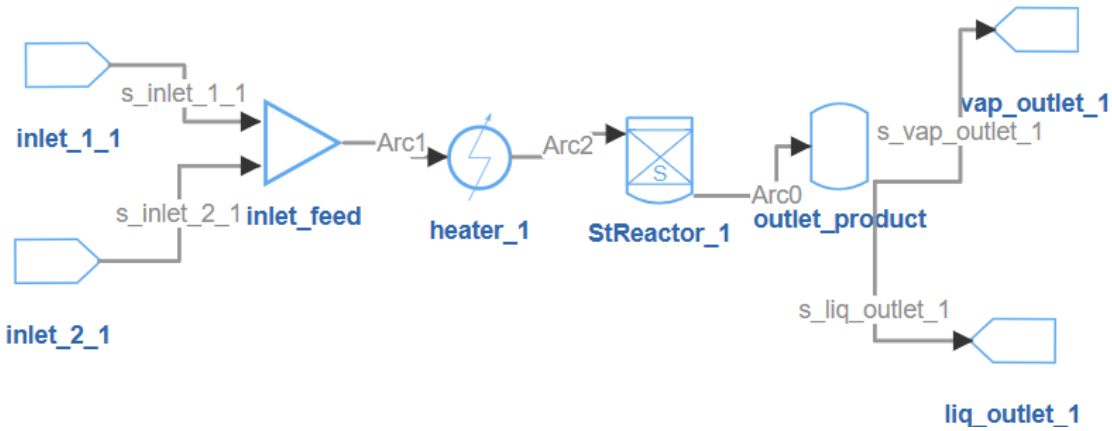

**Figure 6.** Optimal flowsheet corresponding to the maximum acheivable reward.

## 3.2 Improved Algorithm with Encoding

Motivated by the re-uploading PQC and other works in the field of QML [11-12], our proposed approaches below adopt new encoding strategies. These strategies take advantage of the fact that input data can be encoded into the angle of rotation gates. This differs with the previous algorithm which only encodes the input information to the qubits. In this way, larger problems can be solved using fewer qubits and less complex circuits.

### 3.2.1 X-only Encoding

In the "X-only" encoding strategy, the input features are injected directly into rotational gate angles with an additional trainable parameter λ used as a multiplier (Fig. 4). The input to each qubit of the circuit first enters an x rotation gate. It is then processed by a PQC layer, i.e. a sequence of x, y, z rotation gates followed by CZ gate entanglement. Since each qubit can only encode one extra input per layer, the number of qubits used in the circuit plus the number of layers needed should be equal to the size of the input. In other words, the number of qubits used or available determines how many layers should be added.

### 3.2.2 XYZ Encoding

The "XYZ" encoding strategy is similar to the "X-only" but adds additional y and z rotation gates before the qubit reaches the remaining parts of the PQC layer (Fig. 5). This allows more information to be encoded into each layer which can drastically save computational time. Again, the number of qubits used determines the number of layers needed since there is an encoding limit on each qubit per layer. This algorithm theoretically saturates the amount of information that can be embedded per layer using rotational gates, since x, y, and z are the only possible rotations.

## 4. CASE STUDIES

The section applied the improved encoding strategies on a case study, solving three process synthesis problem with increasing sizes to investigate algorithmic scalability. We also compare the performance of the quantum RL algorithm with classical RL.

## 4.1 Problem Description

Consistent with our prior works, this case study focuses on the flowsheet design of a hydrodealkylation (HDA) process which converts toluene ($C_6H_5CH_3$) into the product benzene ($C_6H_6$). This reaction is carried out in the presence of hydrogen ($H_2$) as described by Eq. 1. The reaction is solely active in the vapor phase and is

considered to occur without producing any byproducts.

$$H_2 + C_6H_5CH_3 \rightarrow H_2 + C_6H_6, \Delta H = -1.08 \times 10^5 \frac{\text{J}}{\text{mol}} \quad (1)$$

The HDA process feed conditions are summarized in Table 1 and consist of two inlet streams: (i) a liquid-phase stream with hydrogen and methane, and (ii) a vapor-phase stream composed entirely of toluene. A range of process units is available for flowsheet development, including a heater, cooler, heat exchanger, reactor, mixer, flash separation, splitter, compressor, expander, and a turbine. Each unit involves their own operational constraints, such as maintaining outlet temperatures in the range of 500-600 K. All phase separations within the process are assumed to obey ideal vapor-liquid equilibrium. The final product of the process must be a vapor-phase stream with a benzene mole fraction greater than 0.55.

In the following scenarios, the amount of available process units varies. The primary design goal is to maximize the vapor product stream flowrate and purity, forming a productivity-based reward function. The optimal flowsheet for this problem only uses a reactor and a heater with no other processing units, as shown in Fig. 6. The goal of each scenario is to build this optimal flowsheet given a set of potential process unit operations.

## 4.2 Scenario Analyses

### 4.2.1 Scenario 1

This scenario matches with the case study presented in our previous work [4], except the amount of training episodes has been extended from 1, 500 to 30, 000. The extended number of episodes is made possible by the newly proposed algorithms which only requires 4 qubits. The prior approach required 12 qubits. There are only two available unit operations: (i) reactor, and (ii) heater. This set represents the smallest possible subset of unit operations where the optimal flowsheet design can be found. The results of each algorithm for this scenario are provided in Table 2. Note that "classical" refers to the classical RL algorithm without quantum computing. "X-only" and "XYZ" refer to the quantum RL algorithms respectively with X-only encoding and XYZ encoding.

### 4.2.2 Scenario 2

In this scenario, there are three potential unit operations: (i) reactor, (ii) heat exchanger, and (iii) heater. Each algorithm is run for a total of 30, 000 episodes. In our previous algorithm with re-uploading PQC, this scenario would have required twenty qubits which is approaching the limit for simulation capability. The newly proposed encoding algorithms allow to solve this problem via quantum RL, only needing 5 qubits. The results of this scenario are highlighted in Table 3.

**Table 1:** Compositions and inlet conditions for feed streams.

| | Liquid Feed | Vapor Feed |
|---|---|---|
| Temperature (K) | 303.2 | 303.2 |
| Pressure (kPa) | 350 | 350 |
| Flowrate (mol/s) | | |
| Hydrogen | 0.30 | 0.00 |
| Toluene | 0.00 | 0.30 |
| Methane | 0.02 | 0.00 |
| Benzene | 0.00 | 0.00 |

**Table 2.** Algorithm results for Scenario 1.

| | Classical | X-only | XYZ |
|---|---|---|---|
| Max Reward Solutions | >100 | >100 | >100 |
| Unique Flowsheets | 3 | 3 | 3 |
| Feasible Designs | 1 | 1 | 1 |
| Tunable Parameters | 2, 374 | 64 | 40 |
| Qubits Required | n/a | 4 | 4 |
| Number of Layers | 2 | 3 | 1 |
| Total Time (hr) | 0.056 | 1.029 | 0.499 |

**Table 3.** Algorithm results for Scenario 2.

| | Classical | X-only | XYZ |
|---|---|---|---|
| Max Reward Solutions | 20 | 12 | 11 |
| Unique Flowsheets | 7 | 11 | 11 |
| Feasible Designs | 2 | 1 | 1 |
| Tunable Parameters | 2, 374 | 100 | 80 |
| Qubits Required | n/a | 5 | 5 |
| Number of Layers | 2 | 5 | 2 |
| Total Time | 0.0599 | 1.433 | 0.959 |

**Table 4.** Algorithm results for Scenario 3.

| | Classical | X-only | XYZ |
|---|---|---|---|
| Max Reward Solutions | 6 | 1 | 0 |
| Unique Flowsheets | 31 | 19 | 19 |
| Feasible Designs | 1 | 1 | 0 |
| Tunable Parameters | 2, 374 | 144 | 96 |
| Qubits Required | n/a | 6 | 6 |
| Number of Layers | 2 | 5 | 2 |
| Total Time | 0.086 | 3.040 | 2.315 |

### 4.2.3 Scenario 3

For this scenario, there are four potential unit operations: (i) reactor, (ii) cooler, (iii) heat exchanger, and (iv) heater. The number of episodes is extended to 60, 000, because no algorithm (including the classical RL algorithm) can find the optimal solution within 30, 000 episodes. For our previous algorithm with re-uploading PQC, this study would have required multiple simulations of a 30-qubit circuit which is not feasible. The results of this scenario are given in Table 4.

### 4.3 Results and Discussion

The ability of the quantum algorithms to use fewer parameters but achieve similar performance to classical algorithms is evident through the three scenarios. The quantum algorithms use an order of magnitude less tunable parameters. All three algorithms perform exceptionally well for Scenario 1 and find the optimal flowsheet over one-hundred times within the total training episodes (Table 1). In Scenario 2, an interesting result occurs in which the quantum algorithms propose more unique flowsheet designs than the classical algorithm, yet they find the maximum reward solution at only about half of the rate (Table 2). Additionally, the classical algorithm find two feasible designs while the quantum algorithms only find one each. For Scenario 3, the classical algorithm outperforms the quantum algorithms by discovering the optimal flowsheet six times compared to one and zero times for the quantum approaches, while also proposing significantly more unique flowsheets (Table 3).

Of the two newly proposed algorithms, the "X-only" encoding approach significantly outperforms the "XYZ" approach. This is particularly evident in Scenario 3 when the "X-only" method finds the optimal flowsheet while the "XYZ" method does not. This could be explained by the difference in trainable parameters. In these studies, the minimum number of layers are used. By design, the "X-only" encoding scheme must use more layers than "XYZ" encoding. It is possible that the superior performance is indicative on only the increased circuit complexity but not the different encoding schemes.

The classical RL algorithm appears to perform better than the quantum approaches especially when considering the computational time taken. However, there are two important aspects to consider: (i) the classical algorithm does use significantly more tunable parameters, and (ii) the computational time of the quantum algorithms are for simulated circuits run on a classical computer. Adding additional trainable parameters in the quantum circuits via increasing qubit or layer amounts may allow the quantum agents to become more expressive and therefore potentially as competitive as the classical agent. The computational time taken for the quantum approaches may be reduced when moving to quantum hardware.

## 5 CURRENT-SCALE QUANTUM HARDWARE OUTLOOK

The full end-to-end RL algorithm cannot currently run on quantum hardware due to prohibitive cost restrictions. It is technically possible, but the sampling costs of current-scale quantum circuits render this approach infeasible because of the large amount of total training episodes needed. However, it is still critical to understand whether the trained quantum agents could be realized via real-world quantum machines. To do this, we ran our trained circuits on IonQ's quantum computing simulator which mathematically represents their quantum hardware. These results are provided in Figs. 7 and 8 for the "X-only" algorithm in Scenario 1.

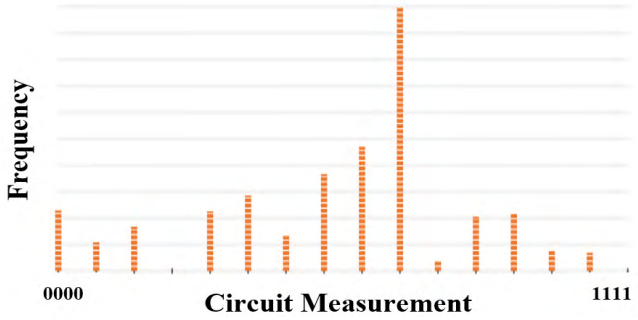

**Figure 7.** Scenario 1 X-only agent before training.

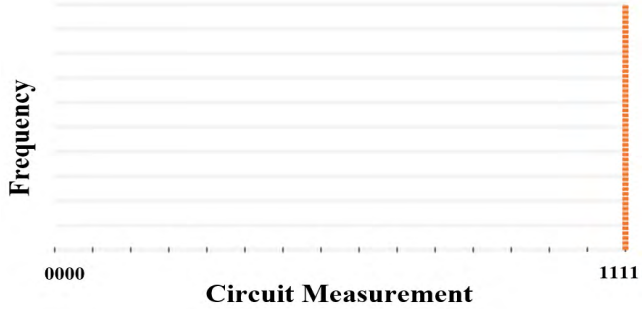

**Figure 8.** Scenario 1 X-only agent after training.

The results from the IonQ simulator give a probability distribution over the expected circuit measurement. These results are for the same random flowsheet before and after training. Before training the agent is random in its decision-making on which action to take while after training the probability distribution collapses to a single measurement. This shows that the agent's decision-making becomes deterministic in selecting the optimal action.

## 6 CONCLUDING REMARKS

In this work we presented two new quantum-accelerated RL-driven process synthesis algorithms. These algorithms were introduced to overcome a limitation of our previous approach which scaled poorly with problem size. The algorithms were demonstrated through three different scenarios of varying problem sizes. It was shown that the quantum algorithms can solve these problems while needing fewer parameters than classical RL algorithms without quantum computing. Ongoing efforts will include trying to reduce the algorithm complexity further to shorten the computational time needed on both simulated and real-world quantum hardware.

## ABSTRACT

Batch manufacturing is central to fine chemicals, pharmaceuticals, and bioprocessing. Its operation evolves across phases and recipes, which yields high-dimensional trajectories and strong batch-to-batch variability. Meanwhile, key quality-indicative variables are often measured offline and cannot be used as online model inputs. This work presents an integrated deep learning framework that unifies soft sensing and process monitoring in a single module using only process variables as inputs. A multi-scale Temporal Convolutional Network with multiple kernel sizes extracts complementary dynamic features from sliding windows. These features are concatenated and pooled into a compact representation that feeds two task branches. A variational autoencoder branch reconstructs the input window and provides fault monitoring signals via reconstruction deviation while regularizing the latent space through KL divergence. In parallel, a prediction branch estimates the quality-indicative variable directly from the pooled temporal features without using the variational latent sample. This separation preserves a stable quality mapping while retaining a probabilistic reconstruction model for monitoring. During inference, reconstruction error and prediction error are fused into a joint state score that more comprehensively reflects system state changes than either deviation alone. Diagnostic heatmaps are produced from residual maps and optional SHAP attributions to highlight contributing variables and time segments. The framework is validated on the Industrial Penicillin Simulation, an industrial-scale penicillin fermentation benchmark. Results show stable convergence of reconstruction, prediction, and KL terms, clear fault-set monitoring trajectories, and interpretable heatmaps that support actionable diagnosis.

## INTRODUCTION

Modern batch manufacturing increasingly operates in an environment that is both data-rich and information-poor. Hundreds of process variables are measured online, but the variables that truly define economic value and product quality are often unavailable in real time. Many quality-indicative variables require laboratory assays, which are expensive and delayed. Operators therefore face a practical dilemma: the plant generates high-frequency trajectories, yet the most critical quality information arrives late. In this work, we use the term **quality-indicative variable (QIV)** to denote a product-quality-related variable that is economically important but typically unavailable online and only measured through delayed laboratory assays.

This reality is particularly severe in dynamic batch systems. A batch is not a stationary time series. It is a sequence of phases with changing kinetics, changing control objectives, and changing degrees of freedom. Recipes evolve. Controllers are tuned. Disturbances occur. These factors produce distribution shifts across batches and time, which is now recognized as a central scientific and engineering challenge in process monitoring [1].

Two tasks are indispensable for safe and profitable operation. The first task is soft sensing, which aims to estimate quality-indicative variables from process measurements. Deep learning has become a major driver for soft sensors because it can model nonlinear and dynamic relationships and it can exploit large-scale historical data [2]. The second task is fault monitoring, which aims to

detect abnormal states early, before they propagate into off-spec product or unsafe operation. Variational autoencoders provide a principled approach to fault monitoring because reconstruction deviation can indicate departures from a learned normal operating manifold [4].

However, in many practical deployments, soft sensing and monitoring are still implemented as separate modules. This separation is convenient but it is scientifically limiting in evolving batch environments. It forces independent feature extraction mechanisms, reduces feature efficiency, and increases maintenance cost under shift. Life-cycle studies in industrial fermentation emphasize that drift handling and model maintenance become bottlenecks once a soft sensor is deployed [3]. At the same time, recent ESCAPE-related work on IndPenSim demonstrates that even predictive monitoring frameworks must address frequent operational shifts and high retraining demand, which motivates architectures that can reuse learned temporal representations [18].

This paper addresses a core scientific question:

**How can we build a unified architecture that learns a shared temporal representation for batch trajectories, performs online soft sensing and process monitoring simultaneously, does not require online quality variables as inputs, and yields interpretable diagnostic outputs that operators can trust?**

Bearing the core scientific question in mind, we propose this work which makes four contributions.

1. It formulates joint soft sensing and monitoring as a unified representation learning problem under the industrial constraint that QIV is not an online input stream.
2. It proposes a multi-scale multi-kernel TCN backbone that extracts complementary temporal patterns from batch windows and supports two monitoring tasks through a shared feature space.
3. It designs a dual-branch head in which a VAE branch provides probabilistic reconstruction learning with KL divergence for monitoring, while a separate prediction branch provides a stable quality mapping that does not depend on latent sampling.
4. It introduces a joint state score that fuses reconstruction deviation and prediction deviation to better capture system state changes, and it supports diagnosis with residual heatmaps and optional SHAP explanations [12].

## RELATED WORK

### Batch Process Monitoring under Non-stationary and Operational Diversity

Batch processes exhibit multi-phase dynamics and recipe dependent policies. These properties yield strong non-stationarity. They also yield batch to batch variability. In such settings, monitoring must remain reliable when the operating distribution shifts. Zhao discussed nonstationary monitoring in the era of industrial AI and summarized how distribution shift challenges classical condition monitoring assumptions [2].

Non-stationarity is amplified by practical realities. Operating strategies evolve, controllers are retuned, raw materials vary, equipment ages, and so on. These factors create gradual drift and abrupt change. Monitoring systems must therefore emphasize robustness and maintainability. A practical monitoring framework should reuse representations and reduce fragmentation. This is especially important for batch operations where each run is a finite trajectory that must be interpreted in context.

### Soft Sensing with Scarce and Delayed Quality Measurements

Soft sensing is essential when quality is hard to measure online. Deep learning soft sensors can learn nonlinear mappings from multivariate trajectories to quality outcomes. **Sun et al.** surveyed deep learning for soft sensors and emphasized feature learning for complex dynamics [1].

A persistent barrier is label scarcity. Quality labels can be sparse and delayed. In many plants, QIV is not available as an online input stream. Semi supervised learning provides one route. It allows the model to learn from abundant process trajectories while using QIV only as supervision when it exists. **Lee et al.** developed a semi supervised latent dynamic variational framework to improve quality prediction under limited quality labels [7].

Beyond temporal modeling, some works model variable relations explicitly. Graph convolutional soft sensors embed interactions among variables to improve prediction [8]. Temporal graph approaches integrate temporal dependence with structured relationships and add transparency modules for interpretability [9]. Transfer and adversarial learning have also been studied to improve generalization across grades and modes when operating conditions change [10]. These directions highlight the need for representations that remain useful across shifting batch environments.

### Fault Detection and Monitoring with Reconstruction based Generative Models

Reconstruction based monitoring is widely used in process monitoring. It learns normal behavior and detects deviation through residuals. Variational autoencoders provide a principled generative formulation. They pair a reconstruction term with KL divergence regularization of the latent distribution. Kingma and Welling introduced the core variational framework and the reparameterization method that enables stable training.

VAE based monitoring has been extended in

chemical processes. Interpretable variants embed attention to support fault identification and variable contribution analysis. **Bi et al.** proposed an orthogonal self-attentive VAE for interpretable fault detection and identification [4]. Distributed VAE monitoring has also been proposed for large scale systems and variable group structures [5].

A limitation of purely reconstructive monitoring is that reconstruction deviation does not always align with quality relevance. A deviation may be detectable in variables yet have limited effect on quality. A quality critical deviation may also be subtle in measured variables. This motivates quality related monitoring and combined monitoring statistics. **Tang et al.** proposed a nonlinear quality related method that combines variational information bottleneck ideas with VAE learning [6]. This line of work supports monitoring metrics that reflect both operating deviation and quality impact.

### Unified Learning across Soft Sensing and Monitoring

Soft sensing and monitoring are often implemented separately. Yet both tasks aim to infer a latent process state from trajectories. Separate modeling duplicates feature extraction and increases lifecycle burden. It also creates inconsistencies across modules when the operating distribution shifts.

Lifecycle and deployment studies in industrial fermentation highlight this problem. **Metcalfe et al.** discussed MLOps oriented soft sensors and showed that drift handling and maintenance can dominate the cost of deployment [3]. This motivates unified architectures that share temporal representations and reduce retraining effort.

Recent work on IndPenSim also reflects community interest in transferable monitoring. **Hung HY et al.** reported predictive monitoring enhanced by transfer learning on IndPenSim [13]. This underscores the importance of representation reuse under operational shift. A remaining gap is a unified architecture that performs both online quality estimation and monitoring while respecting the constraint of no online quality inputs.

### Explainability and Actionable Diagnosis

In industrial operation, an alarm alone is not sufficient. Operators require diagnosis that supports corrective actions. Explainability is therefore critical.

**SHapley Additive exPlanations (SHAP)** provides an additive attribution framework grounded in Shapley values from cooperative game theory. It offers a consistent approach for interpreting model outputs through feature contributions. Explainable diagnosis in chemical processes increasingly combines data driven learning with domain structure. **Wu et al.** proposed a topology aware diagnosis model that integrates process topology knowledge with self attention mechanisms [11]. Comprehensive fault detection and diagnosis studies continue to highlight interpretability as a key requirement for industrial adoption.

**Positioning of this work:** This paper proposes a unified batch monitoring module. It uses process variables only as inputs. It learns one shared temporal representation. It supports soft sensing and monitoring simultaneously. It provides interpretable diagnosis artifacts that can be used in practice.

## PRELIMINARIES

### Variable Screening with Lagged Mutual Information and Redundancy Control

Batch trajectories are often high dimensional. Many variables can be weakly related to quality. Many variables can also be redundant. Feeding all variables into a deep model can increase noise sensitivity and reduce interpretability. We therefore perform variable screening using nominal batches only.

We quantify nonlinear relevance to QIV using lagged mutual information. For each candidate variable $x_i$, we compute mutual information between $x_i(t-k)$ and $y(t)$ for lags $k = 0, \dots, K$. We take the maximum over lags as the relevance score. We also record the lag that achieves the maximum. This captures delayed effects of process variables on quality.

We control redundancy using an mRMR style greedy selection. Each candidate is penalized by its redundancy with already selected variables. Redundancy is approximated through correlation. The procedure yields a compact variable subset that preserves relevance and reduces collinearity.

Pseudocode is available in Algorithm 1.

### Temporal Convolutional Networks for Causal Multi Scale Dynamics

Batch monitoring requires models that can learn long range temporal dependence. Training must remain stable. We adopt Temporal Convolutional Networks based on causal dilated convolutions and residual blocks. Causal convolution enforces that the representation at time $t$ depends only on present and past samples within a window. Dilation expands the receptive field without recurrent computation. Residual connections stabilize optimization. We implement a multi scale TCN using parallel branches with different kernel sizes. Each branch captures temporal patterns at a different scale. Branch outputs are concatenated and pooled. This yields a compact shared temporal representation that is used by both downstream tasks.

**Inputs:** Nominal batches $D_0 = \{(X, y) \mid Fault = 0\}$, Candidate variables $X = \{x_1, \ldots, x_d\}$, QIV $y$, Maximum lag $K$, Redundancy weight $\lambda$ Number of selected variables $k$.

**Outputs:** Selected variable set $S$, Relevance scores $Rel(x_i)$ and optimal lags $k_i^*$.

**Step 1: Compute lagged MI relevance**

1. for each $x_i \in X$ do
2. for $k = 0$ to K do
3. Construct paired samples $\{(x_i(t-k), y(t))\}_t$ using nominal batches $D_0$
4. $I_{i,k} \leftarrow MI(x_i(t-k), y(t))$
5. end for
6. $Rel(x_i) \leftarrow max_{k\in[0,K]} I_{i,k}$
7. $k_i^* \leftarrow argmax_{k\in[0,K]} I_{i,k}$
8. end for

**Step 2: Greedy mRMR-style selection**

9. $S \leftarrow \emptyset$
10. while $|S| < k$ *do*
11. for each $x_i \in X \backslash S$ *do*
12. if $S = \emptyset$ *then* $R_i \leftarrow 0$
13. else
14. $R_i \leftarrow \frac{1}{|S|} \sum_{x_j \in S} |corr(x_i, x_j)|$
15. end if
16. $Score(x_i) \leftarrow Rel(x_i) - \lambda R_i$
17. end for
18. $x^* \leftarrow argmax_{x_i \in X\backslash S} Score(x_i)$
19. $S \leftarrow S \cup \{x^*\}$
20. end while
21. *return* $S, \{Rel(x_i), k_i^*\}$

**Algorithm 1:** Variable Screening with Lagged Mutual Information and mRMR-style selection

## Semi Supervised Training with Sparse Quality Labels

In realistic plants, QIV labels are sparse and delayed. QIV is not used as an online input channel. It is used only as a training label when it exists. We adopt a semi supervised training protocol.

A reconstruction objective is trained on nominal windows. It uses only process variables. This objective is always available. A prediction objective is trained only when a QIV label exists. We use a label mask $m_{b,t} \in \{0, 1\}$ so that unlabeled windows do not contribute to the prediction loss. This enables joint training on mixed labeled and unlabeled data.

# PROBLEM FORMULATION

Let $x_{b,t} \in \mathbb{R}^D$ denote process variables at time $t$ for batch $b$. We use a sliding window

$$X_{b,t} = [x_{b,t-W+1}, \ldots, x_{b,t}] \in \mathbb{R}^{W\times D}$$

Let $y_{b,t}$ denote a quality indicative variable aligned with the window end. In the target setting, $y_{b,t}$ is sparse and delayed. It is not an online input channel.

We aim to build one module that:

1 takes $X_{b,t}$ as input.
2 outputs a reconstructed window $\hat{X}_{b,t}$ for monitoring.
3 outputs a quality estimate $\hat{y}_{b,t}$ for soft sensing.
4 computes a joint state score by fusing monitoring deviation and quality deviation.
5 supports interpretable diagnosis through heatmaps and optional SHAP attributions.

# METHODOLOGY

## Architecture Overview

The framework consists of a shared temporal backbone and two task branches.

1. Shared backbone. A multi scale TCN uses multiple kernel sizes in parallel.

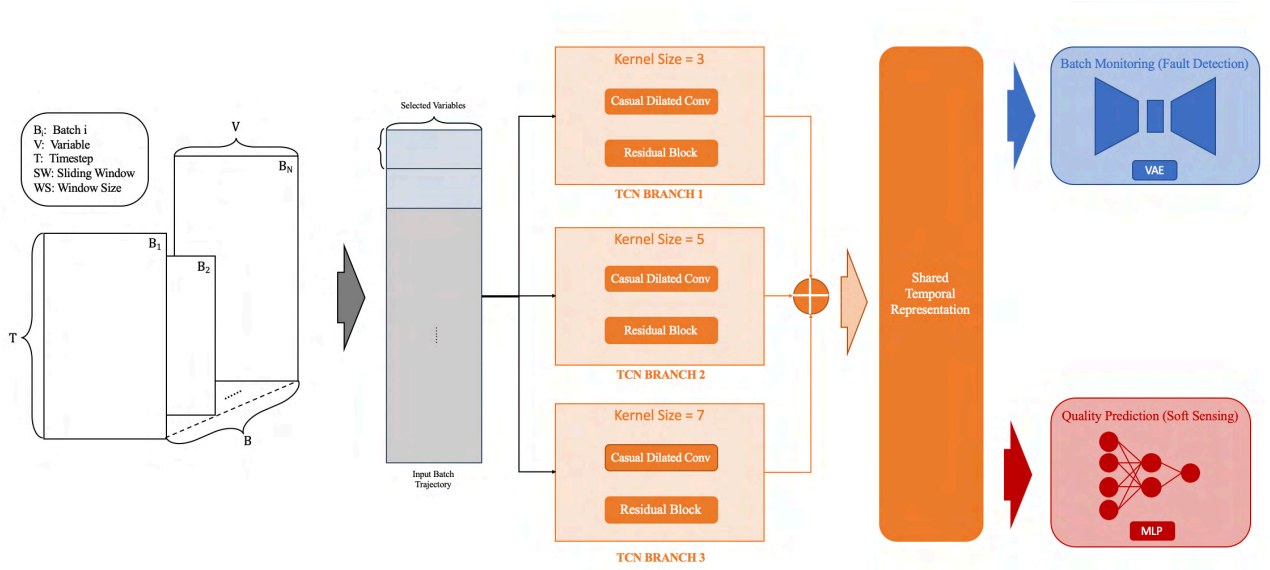

**Figure 1.** Multi scale multi kernel TCN backbone with two branches

2. Monitoring branch. A VAE reconstructs the input window. Monitoring is based on reconstruction deviation.
3. Soft sensing branch. A predictor estimates QIV from pooled temporal features. It does not use the latent sample.

This design enforces controlled sharing. Both tasks reuse temporal features. The predictor avoids stochastic sampling to preserve stable quality mapping.

## Multi Scale TCN Backbone with Multiple Kernel Sizes

Batch trajectories contain patterns at different time scales. Early phases can exhibit fast transients. Later phases can exhibit slow drifts. A single kernel size can under represent this diversity. We therefore build parallel TCN branches with kernel sizes $k_1, k_2, \ldots \ldots$.

Each branch uses causal dilated convolutions. Dilation increases receptive field efficiently. Residual connections improve stability for deep temporal stacks. Let $f_{b,t}^{(k)}$ denote features from kernel branch k. We concatenate:

$$F_{b,t} = Concat(f_{b,t}^{(k_1)}, f_{b,t}^{(k_2)}, \ldots \ldots)$$

We pool across time to obtain compact shared features:

$$g_{b,t} = Pool(F_{b,t})$$

## VAE Monitoring Branch with KL Divergence Regularization

The VAE branch maps $g_{b,t}$ into a latent distribution $q(z_{b,t} \mid g_{b,t})$ with parameters $\mu_{b,t}$ and $\sigma_{b,t}$. We sample using reparameterization:

$$z_{b,t} = \mu_{b,t} + \sigma_{b,t} \odot \epsilon, \qquad \epsilon \sim \mathcal{N}(0, I)$$

A decoder reconstructs the window and outputs $\hat{X}_{b,t}$ Reconstruction loss:

$$\mathcal{L}_{rec} = MSE(X_{b,t}, \hat{X}_{b,t})$$

KL divergence:

$$\mathcal{L}_{KL} = D_{KL}(q(z_{b,t} \mid g_{b,t}) \,||\, \mathcal{N}(0, I))$$

Monitoring deviation:

$$e_{rec} = MSE(X_{b,t}, \hat{X}_{b,t})$$

## Prediction Branch for Soft Sensing without Latent Sampling

The prediction branch estimates QIV from pooled temporal features:

$$\hat{y}_{b,t} = f_{pred}(g_{b,t})$$

The prediction branch does not take $z_{b,t}$ as input. This avoids sampling noise in the quality mapping. QIV is not an input stream. It is only used as a label when available.

We use a robust prediction loss:

$$\mathcal{L}_{pred} = m_{b,t} \bullet Huber(y_{b,t}, \hat{y}_{b,t})$$

where $m_{b,t}$ is the label mask defined in the Semi-Supervised Training section.

## Joint Multi Task Objective

The overall objective is:

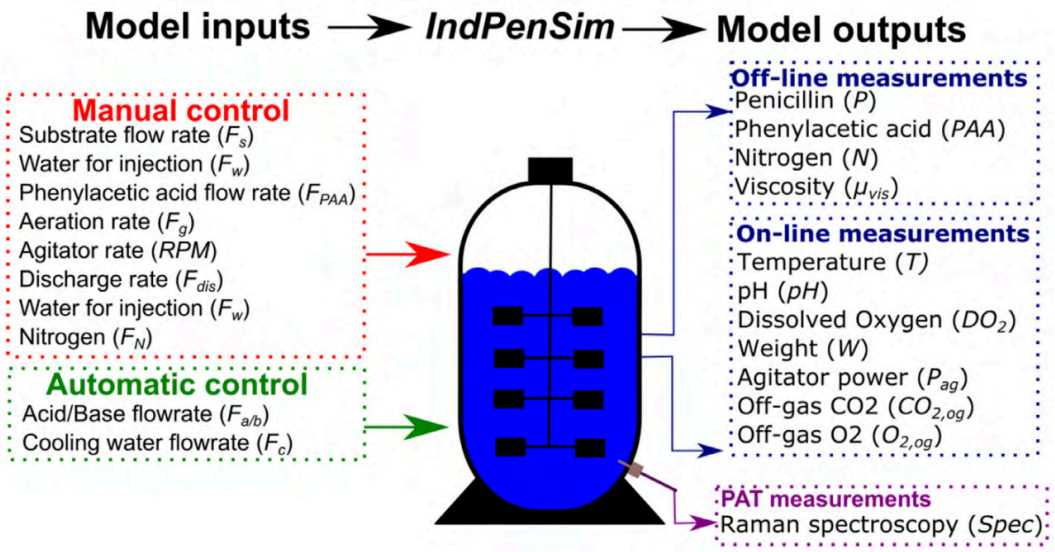

**Figure 2.** Summary of Inputs and Outputs of IndPenSim

$$\mathcal{L} = \lambda_{rec}\mathcal{L}_{rec} + \lambda_{pred}\mathcal{L}_{pred} + \beta\mathcal{L}_{KL}$$

This objective forces the backbone to learn shared temporal features. It also maintains a regularized latent space for stable reconstruction learning.

### Joint State Score by Fusing Reconstruction and Prediction Deviation

At inference, the model provides reconstruction deviation:

$$e_{rec}(t) = MSE(X_{b,t}, \hat{X}_{b,t})$$

The model also provides a quality estimate $\hat{y}_{b,t}$. When a lab assay arrives, prediction deviation can be computed:

$$e_{pred}(t) = |y_{b,t} - \hat{y}_{b,t}|$$

We define a joint state score:

$$S(t) = \alpha \bullet norm\left(e_{rec}(t)\right) + (1-\alpha) \bullet norm\left(e_{pred}(t)\right)$$

When $y_{b,t}$ is not yet available, the system runs in early warning mode with $S(t) = norm\left(e_{rec}(t)\right)$. This supports online monitoring under delayed quality measurement.

### Interpretable Inference with SHAP Heatmaps

For diagnosis, we compute the residual map:

$$R_{b,t} = (X_{b,t} - \hat{X}_{b,t})^2$$

We visualize $R_{b,t}$ as a variable time heatmap for alarm windows. This highlights which variables and which time segments contribute most to reconstruction deviation.

If attribution based interpretation is required, we apply SHAP to the prediction output or to the joint score. This yields variable contribution values that support human interpretation.

## CASE STUDY: INDPENSIM BATCH PENICILLIN FERMENTATION

We validate the framework on IndPenSim. IndPenSim simulates an industrial scale fed batch penicillin fermentation process and includes realistic variability, disturbances, and sensor noise.[16] It is widely used as a benchmark for monitoring and soft sensing studies. Unlike the traditional PenSim benchmark [15], IndPenSim models a 100, 000 L bioreactor, bringing it closer to real-world industrial conditions and validated by historical industrial data. Detailed process descriptions and operational specifics can be found at the IndPenSim website and in the original publications [14]. **Figure 2** illustrates the summary of IndPenSim.

Recent ESCAPE community work also used IndPenSim to study predictive monitoring with transfer learning under changing control strategies [13]. This supports the view that transferable temporal representations are important. Our focus differs in one key constraint. We enforce that QIV is not an online input. We unify soft sensing and monitoring within one module and fuse reconstruction and prediction deviations for system state tracking.

## RESULTS AND DISCUSSION

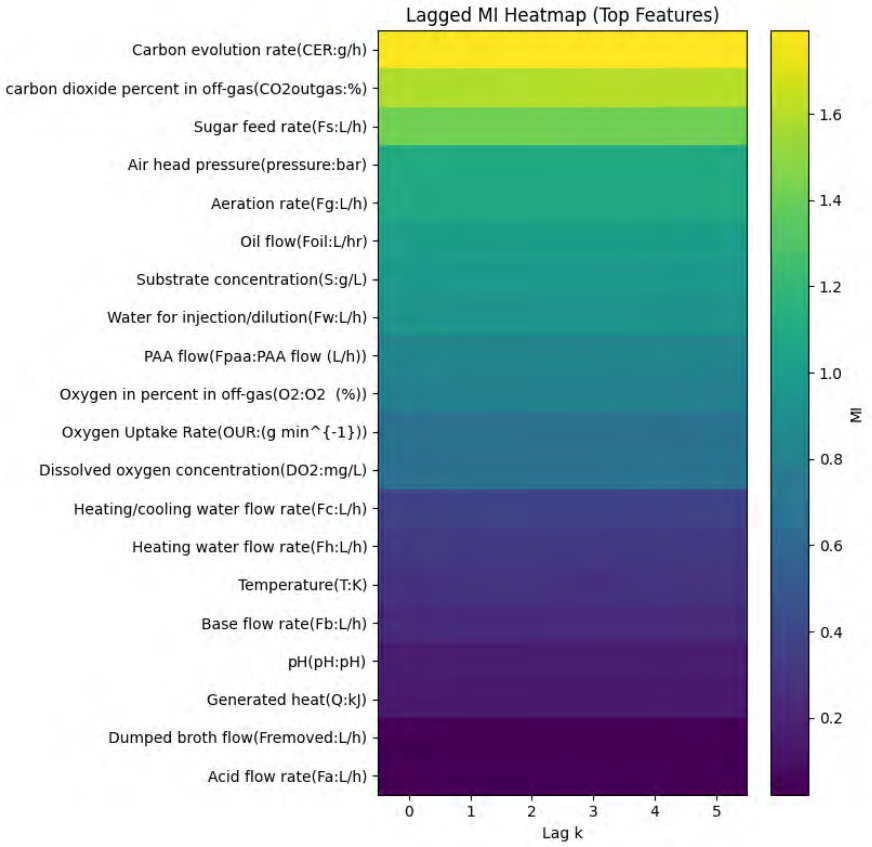

**Figure 3.** Lagged MI heatmap of top variables

## Variable Screening Results

To reduce input dimensionality while retaining quality relevance, we performed variable screening using **nominal batches only**. For each candidate variable $x_i$, we computed **lagged mutual information (MI)** between $x_i(t-k)$ and the quality-indicative variable $y(t)$ over lags $k = 0, \dots, 5$. The **maximum** MI across lags was used as the relevance score $Rel(x_i) = max_k I(x_i(t-k), y(t))$, and the corresponding **optimal lag** $k_i^*$ was recorded.

**Figure 3** above visualizes the lag-dependent MI patterns for the most informative variables. Clear delayed effects can be observed: several key variables achieve their peak relevance at $k^* = 4$~5, including **CER** ($k^* = 4$), **CO**_2 in off-gas ($k^* = 4$), **substrate concentration** ($k^* = 5$), **OUR** ($k^* = 5$), and **temperature** ($k^* = 5$). This is consistent with fed-batch fermentation where operational actions (e.g., feeding/aeration) and physiological responses propagate to quality with a time delay.

**Figure 4** summarizes the **max-MI ranking**, where variables related to **metabolic activity and gas exchange** (CER and off-gas CO_2) dominate the relevance ranking, followed by **feeding** and **aeration/pressure** variables. These variables are physically meaningful: gas-out measurements and CER reflect respiratory activity and carbon balance, which are closely tied to the process state and product formation, while feed and aeration govern substrate availability and oxygen transfer.

Because high-dimensional trajectories often contain strong collinearity, we further applied an **mRMR-style greedy selection** to control redundancy. Each candidate variable was penalized by its average absolute correlation with already selected variables, and the selection score was computed as

$$Score(x_i) = Rel(x_i) - \lambda Red(x_i)$$

This step prevents the final input set from being dominated by highly correlated variables. For example, although **CO**_2 in off-gas has the second highest max-MI, it is selected after **CER** and **sugar feed rate**, reflecting redundancy suppression against already selected strong predictors.

The final selected subset contains **18 variables**, reported in **Table 1**, which are used as the input channels for the subsequent multi-kernel TCN backbone. Overall, the screening results indicate that the quality-relevant information is concentrated in variables representing **respiration/gas exchange**, **feeding**, and **oxygen-transfer-related operations**, while low-MI variables (e.g., control

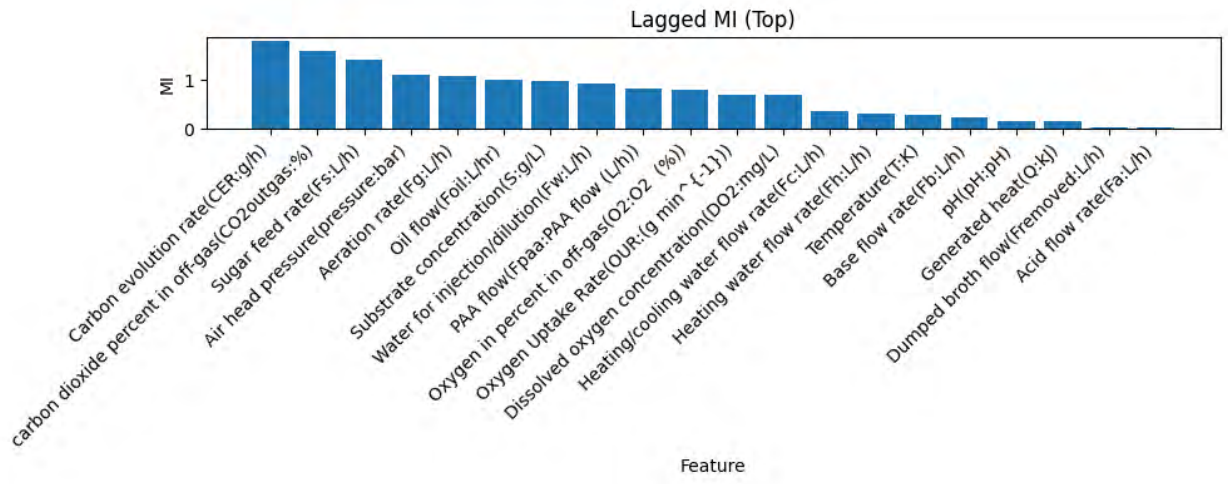

**Figure 4.** Max lagged MI ranking of candidate variables

reference flags) are naturally deprioritized.

## Baseline Comparison with the Proposed Framework

This section compares the proposed unified predictive monitoring framework with two recurrent baselines. The baselines are **Baseline-1 (LSTM)** and **Baseline-2 (GRU)**, both following the same predictive monitoring pipeline with a fixed alarm threshold. Here, **LSTM** denotes **Long Short-Term Memory**, and **GRU** denotes **Gated Recurrent Unit**. Both are recurrent neural network architectures for sequential modeling, while GRU uses a simpler gating mechanism with fewer parameters than LSTM.

The proposed method combines a shared temporal representation with a reconstruction-based monitoring

branch and a deterministic quality prediction branch, and triggers alarms using a unified monitoring score.

To ensure a fair comparison, all methods were trained and evaluated under an identical experimental specification. The dataset was split into 80%/10%/10% train/validation/test batches. All models used sliding windows of length $W = 10$ with stride 1. The same feature screening procedure was applied: lagged mutual information was computed up to max lag $K = 5$, followed by redundancy control with weight $\lambda = 0.5$, and the **top** $k = 18$ variables were retained as input channels for every model.

All networks were optimized with **Adam** using a learning rate of $1 \times 10^{-3}$ and weight decay $1 \times 10^{-4}$, with batch size 64 and up to 50 epochs. Early stopping was applied with patience = 6 on the validation set. Input variables were scaled using robust scaling (clipping at 5.0), and the target was scaled during training (scale_y = True). For the joint learning objective, we used the same loss weights across runs:$\lambda_{rec} = 1.0, \lambda_{pred} = 1.0$, and $\lambda_{pred} = 0.5$. During inference, the alarm threshold was computed consistently as the 0.99 quantile of nominal scores for all methods. We note that this choice is not claimed to be a universal or golden standard. Rather, it is a practical empirical calibration rule that uses the upper tail of the nominal score distribution to control false alarms. In this study, we selected a high nominal quantile because batch trajectories contain strong phase evolution and transient variability, and a conservative threshold helps suppress nuisance alarms during nominal operation. More importantly, using the same thresholding principle for all methods ensures a fair comparison, so that the observed differences reflect the quality of the learned monitoring statistic rather than method-specific threshold tuning.

We evaluated all methods on eight fault batches generated by simulator. For each batch, the result sheet reports the fault interval $[t_{fault_start}, t_{fault_end}]$, the first alarm time $t_{alarm,}$ (FAT, the first time index where the score exceeds the threshold), and the detection delay $\Delta t = t_{alarm,} - t_{fault_start}$. If a method never crosses the threshold during the entire batch, then $t_{alarm,}$ is undefined and the table records "-", which also makes $\Delta t$ undefined.

According to **Table 2**, across the eight fault batches, the LSTM baseline does not produce valid alarms and therefore has 0/8 detection. At the same time, it generates frequent nuisance alarms before the fault (average 19.75 pre-fault false alarms), which indicates that its monitoring statistic is strongly affected by early-batch transients or phase evolution. The GRU baseline achieves 8/8 detection, but the detection delay is highly variable, with a large worst case delay (maximum 631). In contrast, the proposed framework achieves 8/8 detection with zero pre-fault false alarms, and yields substantially smaller delays (mean 17.5, median 6.5, maximum 54). Overall, the proposed method improves both reliability (consistent detection) and timeliness (lower delay) while maintaining clean monitoring behavior.

**Table 2.** Overall comparison

| Method | Detection rate | Mean delay | Median delay | Max delay | Avg. false alarms (pre-fault) |
|---|---|---|---|---|---|
| Baseline-1 (LSTM) | 0/8 (0%) | – | – | – | 19.75 |
| Baseline-2 (GRU) | 8/8 (100%) | 99.75 | 29.0 | 631 | 0.125 |
| Proposed | 8/8 (100%) | 17.5 | 6.5 | 54 | 0.0 |

The stark difference between GRU and LSTM suggests that, under the present data scale and training budget, the simpler recurrent parameterization of GRU is easier to optimize than LSTM. GRU uses a lighter gating structure and may therefore adapt more effectively to the nonstationary batch trajectories and limited fault examples considered here. By contrast, the LSTM monitoring score appears to be more strongly affected by early-batch transients and phase evolution, which leads to poor separation between nominal and faulty score distributions. This interpretation is consistent with the high pre-fault false alarm count of LSTM (19.75 on average) and its failure to produce any valid alarm in the actual fault intervals.

**Table 3.** Batch Wise Result

| batch_id | fault_start_t | fault_end_t | LSTM FAT | LSTM delay | GRU FAT | GRU delay | Proposed FAT | Proposed delay |
|---|---|---|---|---|---|---|---|---|
| 1 | 379 | 459 | – | – | 407 | 28 | 386 | 7 |
| 2 | 349 | 449 | – | – | 417 | 68 | 403 | 54 |
| 3 | 499 | 549 | – | – | 503 | 4 | 503 | 4 |
| 4 | 379 | 459 | – | – | 409 | 30 | 387 | 8 |
| 5 | 379 | 459 | – | – | 409 | 30 | 385 | 6 |
| 6 | 499 | 549 | – | – | 503 | 4 | 504 | 5 |
| 7 | 499 | 549 | – | – | 502 | 3 | 501 | 2 |
| 8 | 349 | 449 | – | – | 980 | 631 | 403 | 54 |

The batch-wise results clarify where the baselines fail. For the LSTM baseline, the first alarm time and delay are missing ("-") because the score never exceeds the threshold; hence, detection cannot be declared. This is not a reporting issue but a direct consequence of the

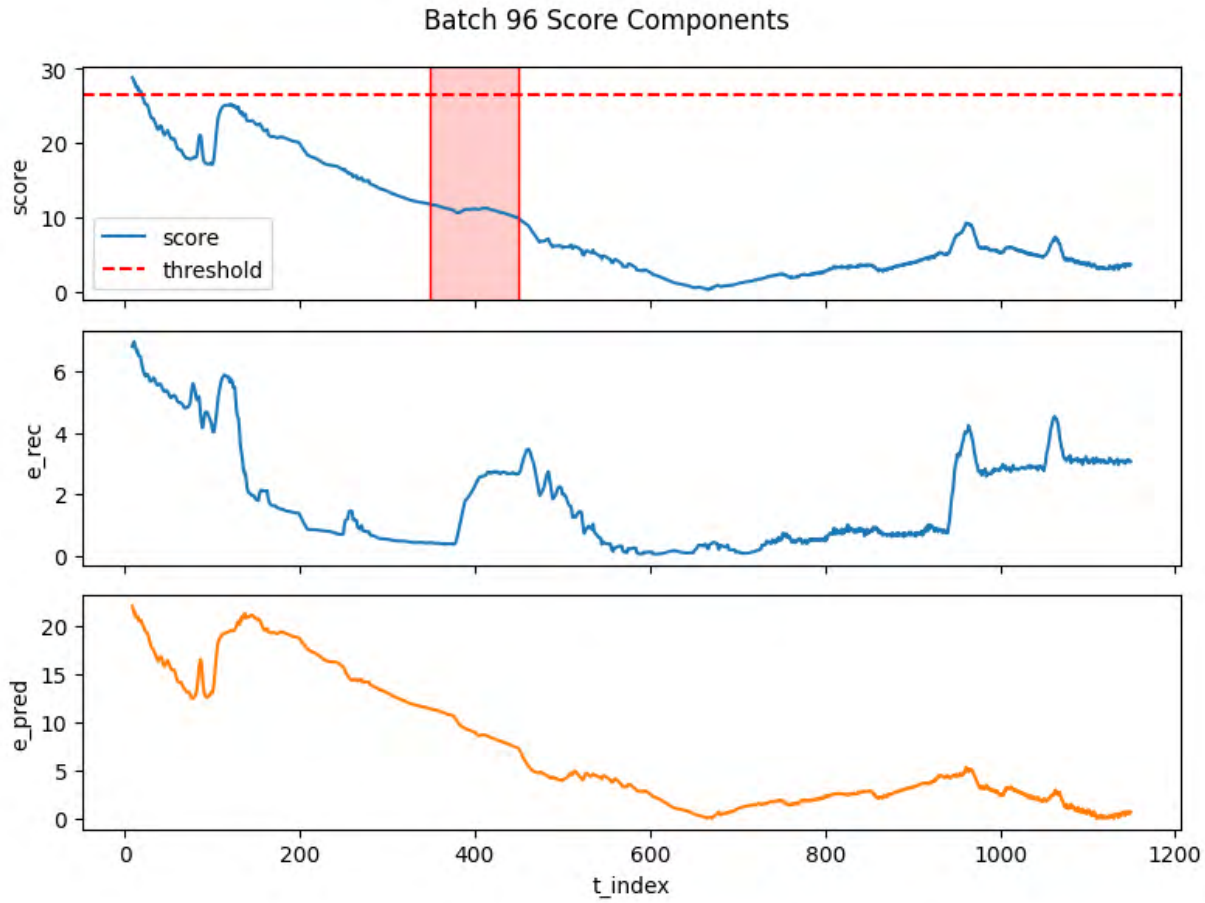

**Figure 5.** Score components for Batch 8 under the LSTM baseline. The shaded region denotes the fault interval and the dashed line denotes the fixed alarm threshold.

alarm rule. Batch 8 provides a representative example and is used to illustrate the mechanism behind these missing entries.

**Table 4.** Fault Batch 8 case study result

| Batch ID | Fault Type | FDS | FAR | EDT |
|---|---|---|---|---|
| 8 | Coolant-Flowrate Fault | 1 | 0 | 54 |

**Figure 5** shows the monitoring score and its components for Batch 8. The score (top) stays below the fixed threshold throughout the highlighted fault interval, so the LSTM baseline never triggers an alarm; therefore $t_{alarm}$ and the detection delay are recorded as "-". This indicates that the LSTM score is strongly influenced by early-stage variability and phase transitions, which raises the calibrated threshold and makes mid-batch faults difficult to detect. Therefore, the underperformance of LSTM in this study is not merely a consequence of one difficult batch, but reflects a systematic calibration issue: nominal early-phase variability inflates the threshold-relevant score distribution and reduces sensitivity to mid-batch faults.

The reduced delay of the proposed framework can be attributed to two design properties. First, the multi-scale TCN backbone extracts temporal patterns at different receptive fields, which is beneficial for batch processes where short transients and slow drifts coexist. Second, the proposed monitoring statistic fuses reconstruction deviation with prediction deviation, so the model can respond not only to trajectory abnormality but also to quality-relevant inconsistency. This dual evidence appears particularly useful in difficult cases such as Batch 8, where a single recurrent monitoring pathway may detect the fault only after a substantial lag.

Overall, under identical training and inference settings, the proposed framework delivers more actionable

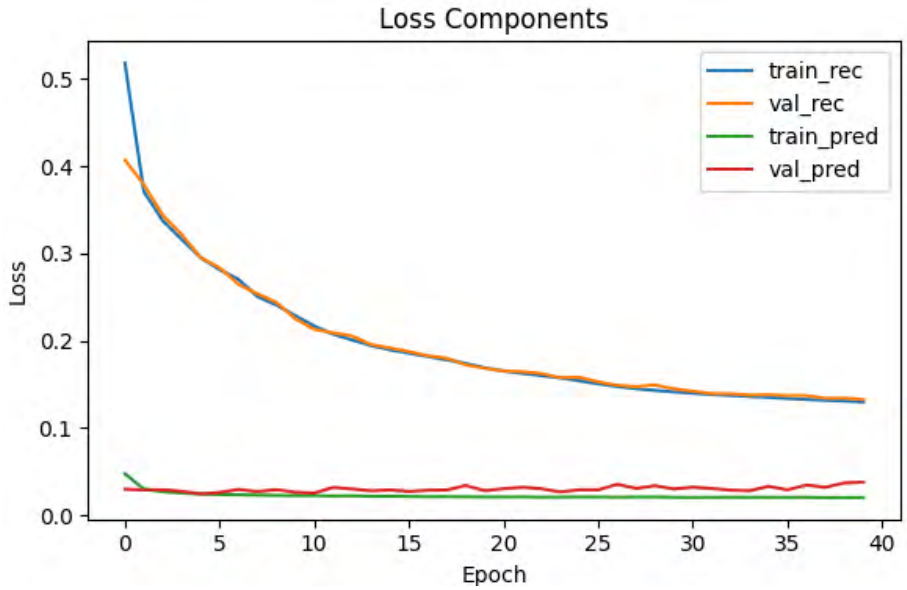

**Figure 6.** Training Loss Component

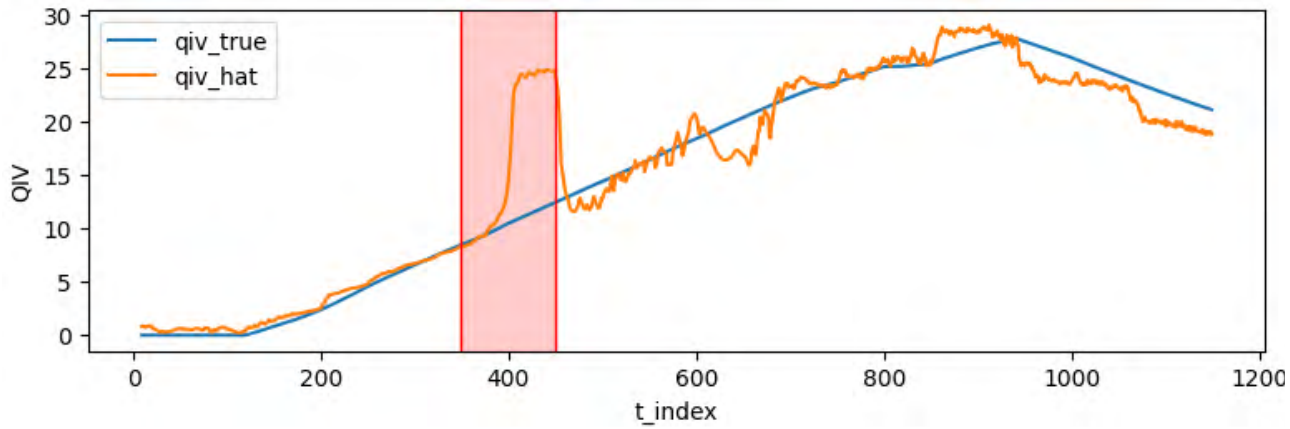

**Figure 7.** QIV prediction vs. true QIV for Batch 8

monitoring than the recurrent baselines: LSTM suffers from frequent pre-fault false alarms and missed detections, while GRU can detect faults but may alarm very late on hard cases (e.g., Batch 8). The proposed method achieves reliable detection with lower delays and cleaner alarm trajectories.

## Case Study of Batch 8: Monitoring, Soft-Sensing and SHAP Diagnosis

This subsection presents a representative fault-batch case study to illustrate how the proposed framework behaves during inference and how the diagnostic module supports interpretation. In our experimental outputs, the plots run corresponds to fault batch_id = 8 in the evaluation list. For this batch, the fault-metric summary reports Fault Detect Success (FDS) = 1, False Alarm Rate (FAR) = 0, and Event/early detection delay (EDT) = 54 time steps, indicating that the fault is detected successfully with no pre-fault alarms and a moderate detection delay.

We first verify that the joint learning objective is optimized stably. The overall loss curve (**Figure 6**) decreases smoothly for both training and validation, and the gap remains small, suggesting stable convergence without severe overfitting. The loss component plot further shows that the reconstruction term dominates the objective, while the prediction term remains comparatively small yet consistent across epochs. This behavior is expected under semi-supervised operation: reconstruction learning is always available from process trajectories, while prediction learning is constrained by sparse quality labels. Together, these curves support that the shared temporal representation can be trained reliably and that both task branches are optimized simultaneously.

We then examine the online soft-sensing behavior for this batch. **Figure 7** plots the ground-truth QIV $(y)$ and

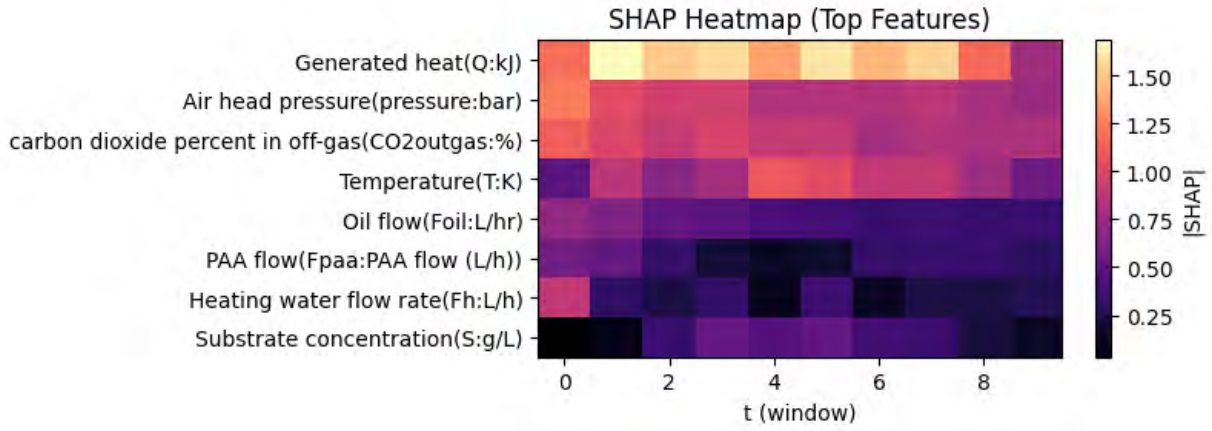

**Figure 8.** SHAP heatmap for the alarm window of Batch 8. Warmer colors indicate larger positive contributions to the score.

the model estimate ($\hat{y}$) over time, with the fault interval highlighted. Outside the fault window, $\hat{y}$ generally tracks the smooth trend of $y$, indicating that the deterministic prediction head provides a stable quality mapping from the pooled temporal features. In the highlighted fault interval, the predicted QIV shows a pronounced deviation from the true trajectory, which is consistent with the idea that faults can manifest as quality-relevant inconsistencies even when process trajectories are still within a plausible operating range. This mismatch later becomes a key contributor to the monitoring statistic through the prediction deviation component.

Finally, we demonstrate interpretability using SHAP attributions on an alarm window. **Figure 8** visualizes a SHAP heatmap for the top contributing variables within the local inference window (the horizontal axis corresponds to time positions inside the sliding window). The heatmap indicates that the score at this alarm moment is dominated by Generated heat (Q), Heating/cooling-related signals, Temperature, and closely coupled variables such as Air head pressure and CO_2 in off-gas, with additional contributions from Oil flow, PAA flow, and Heating water flow rate. Importantly, this attribution pattern is not only interpretable but also diagnostically specific: the concentration of contributions on thermal-balance and heat-removal pathways is consistent with the known fault label for Batch 8, i.e., a Coolant-Flowrate Fault. A reduction or perturbation in coolant flow directly weakens heat removal, which manifests as abnormal thermal behavior (Q and temperature), and subsequently propagates to gas-exchange and pressure dynamics through shifts in metabolic state and mass-transfer conditions. Therefore, the SHAP heatmap provides an actionable diagnosis that can localize the event to a cooling/coolant subsystem disturbance, rather than suggesting a feed-driven or aeration-driven root cause, effectively aligning the model's explanation with the ground-truth fault type (Coolant-Flowrate Fault) for Batch 8.

In summary, Batch 8 illustrates the full workflow of the proposed framework: (i) stable joint training with simultaneous reconstruction and prediction learning; (ii) online quality tracking with fault-induced prediction deviation during the fault window; and (iii) SHAP-based explanation that localizes the alarm to a small set of physically interpretable variables, supporting actionable diagnosis.

## CONCLUSIONS

This work advances batch analytics beyond isolated "soft sensor + monitor" toolchains by introducing a unified, explainable framework that learns a reusable process-state representation for nonstationary operations while respecting the industrial reality that quality measurements are delayed and unavailable online. Looking forward, this architecture provides a strong foundation for the next step in industrial AI: integrating topology or physics constraints for sharper root-cause localization, adopting uncertainty-aware and adaptive fusion to handle evolving label availability, and enabling transfer/continual learning across recipes and plants to minimize retraining. Together, these directions point toward monitoring systems that are not just accurate, but trustworthy, maintainable, and decision-shaping in order to close the loop from data to diagnosis to intervention in modern batch manufacturing.

## ABSTRACT

Accurate prediction of solubility limits of organic compounds in mixed solvents is critical for the design and optimization of chemical and pharmaceutical processes. Recent advances in machine learning have enabled fast and reliable prediction of physicochemical properties of molecules, including solubility. In this work, we present a Bayesian Optimization framework to identify optimal solvent combinations, compositions, and temperatures that maximize the solubility of active pharmaceutical ingredients. The optimization strategy leverages a multicomponent directed-edge message passing neural network trained on solvent mixtures to predict solubility in ternary systems consisting of a solute and two solvents. To enable efficient Bayesian optimization, we represented the solvents in a continuous space and compare three different strategies: integer enumeration, numerical descriptors, and deep embeddings. The proposed approach was tested on a dataset comprising 14 299 points in solvent mixtures. The results indicate that integer enumeration and embedding-based representations achieve the best performance in identifying solvent mixtures that maximize solubility for each compound at a fixed number of model evaluations. While demonstrated on ternary systems, the framework is readily extensible to mixtures with a larger number of components. With this work we aim to identify which chemical representation is most suitable for similar optimization problems, providing a solid foundation for further and broader exploration, for example in the optimization of crystallization processes.

**Keywords**: Bayesian Optimization, Deep Learning, Mixed Solvents, Solubility

## INTRODUCTION

Predicting solubility limits of organic compounds in mixed solvents is crucial in various fields, including environmental science, chemical engineering and pharmaceuticals. In the pharmaceutical industry, for instance, the synthesis of Active Pharmaceutical Ingredients (APIs) is gradually moving from traditional batch processes to processes in continuous flow, due to their enhanced safety and sustainability [1, 2]. However, one of the main hurdles of continuous flow reactors is the precipitation of solids within the reactor, leading to equipment clogging and severe safety risks. Therefore, controlling the solubility of reaction intermediate species and products is crucial for the design and optimization of such processes. Moreover, information on solubility limits is equally important in the stages following the synthesis, such as crystallization, as well as in telescoped reaction sequences.

Traditionally, solubility is calculated using thermodynamic cycles of fusion or sublimation. When considering a fusion cycle, the solubility can be calculated using the definition of ideal solubility which is expressed in terms of the fusion properties of the solute, namely the melting temperature and the enthalpy of fusion [3]. The non-ideality is accounted through activity coefficients (γ). Several approaches are available to estimate γ, including the Wilson equation of state [4] and the Non-Random Two-

Liquid (NRTL) model [5]. However, these models rely on interaction parameters that must be regressed from vapor–liquid equilibrium data, which are often unavailable for many systems of practical interest. In the absence of such parameters, group contribution methods, including UNIFAC [6] can be employed. Methods from quantum chemistry, including both implicit and explicit solvent models, can also be used to compute activity coefficients. Nevertheless, these approaches are computationally demanding, as they require extensive geometry optimization. Moreover, such methods often do not account for the presence of a solid phase, limiting their applicability for accurate solubility predictions. More recently, purely data-driven techniques, including quantitative structure-property relationship (QSPR) models [7] and machine learning (ML) [8] approaches have been promising in predicting molecular properties. In particular, ML has emerged as a valuable alternative to traditional modeling approaches in chemical engineering applications, enabling fast and accurate predictions of complex physicochemical properties.

Algorithms for solvent optimization are closely tied to the accuracy of the predictive models they rely on. Although several studies exist, most of them employ group-contribution approaches as predictive models [9]. In our recent work, we developed robust deep learning models for solubility prediction in mixtures of organic solvents [10]; thanks to these accurate and predictive models, it is now possible to develop optimization strategies to identify solvent mixtures and experimental conditions that optimize solubility. Such tools enable a more efficient exploration of solvent space, reduce the experimental costs and improve the process efficiency. The main limitation of using these ML models is the computational cost associated with their evaluation; direct evaluation of all possible solvent combinations with predictive deep learning models is often computationally prohibitive due to the combinatorial explosion of possible mixtures, especially when considering multiple solvents beyond binary systems.

Bayesian Optimization (BO) [11] is an effective approach for optimizing costly objective functions when their analytical form is unknown or difficult to evaluate, as is the case with graph neural networks. In BO, a surrogate model, often a Gaussian process (GP), is constructed to approximate the expensive objective function. This surrogate is then used to guide the selection of new evaluation points through an acquisition function, which balances exploration and exploitation. By leveraging the acquisition function, BO can efficiently identify maxima or minima with a limited number of function evaluations. A key strength of this approach is its ability to handle both continuous and discrete variables.

In this work, we present an optimization tool based on BO to identify optimal solvent combinations, compositions, and temperatures that maximizes the solubility of APIs. The method leverages a multicomponent directed-edge message passing neural network (D-MPNN) [12] to predict the solubility in ternary systems, i.e., an API dissolved in two solvents [10]. BO is employed to efficiently explore the solvent design space by constructing a GP surrogate model of the mixture D-MPNN, using a radial basis function kernel defined over continuous input variables. Since the molecular identifiers for the solvents cannot be directly incorporated into the Gaussian process kernel, three representation strategies were adopted: integer labels, molecular descriptors, and deep embeddings. This study primarily investigates the selection of chemical representations for the optimization algorithm, aiming to develop a fully automated digital framework that allows users, given a target molecule and a set of solvents, to determine the optimal conditions for pharmaceutical substance design, from chemical synthesis to purification.

## BACKGROUND

### Directed-Message Passing Neural Networks

D-MPNNs are a variant of message passing neural networks (MPNNs) [13] in which, in contrast to standard MPNNs, each bond is represented as two directed edges, allowing messages to flow explicitly from a source atom to a target atom. For each directed edge, a message is computed in a message passing function $M_t$ (eq. 1) based on the features of the source atom, neighboring atoms, and the connecting bond. These messages update the hidden states of the edges through learned transformations and non-linear activations (e.g., ReLU) (eq.2). The initial hidden state for each edge is created by concatenating the features of the source atom and the directed bond. This combined vector is transformed using a learned weight matrix and an activation function (eq.3). The final hidden state for a certain atom, $h_v$, is computed by using the final message, $m_v$, obtained by summing all the messages from the previous steps (eq.4). The final message is then used together with the initial atom features, $x_v$, to give a representation of the atom. Then all the atom hidden states are aggregated, e.g. summed, and a feature vector for the molecule is obtained (eq.5).

$$m_{vw}^{t+1} = \sum_{k \in N\{(v)\setminus w\}} M_t\,(x_v, x_k, e_{vw}) \quad (1)$$

$$h_{vw}^{t+1} = U_t(h_{vw}^{t}, m_{vw}^{t+1}) = \tau(h_{vw}^{0}, + W_m\, m_{vw}^{t+1}) \quad (2)$$

$$h_{vw}^{0} = \tau(W_i\, cat\,(x_v, e_{vw})) \quad (3)$$

$$m_v = \sum_{k \in N(v)} h_{kv}^{T} \quad (4)$$

$$h = \sum_{v \in G} h_v \quad (5)$$

Finally, the molecular vector is passed through a neural

network to predict the properties of interest.
The D-MPNN architecture is implemented in Chemprop [12], one of the most widely used software tools in chemistry.

## Bayesian Optimization

Bayesian Optimization (BO) is a probabilistic framework for the global optimization of functions $f(\mathbf{x})$ that are costly to evaluate or lack analytical expressions. The primary goal of BO is to find a value of $\mathbf{x}^*$, which is the globally optimal value of $\boldsymbol{x}$, that maximizes the objective function $f(\mathbf{x})$ over a predefined domain $\mathcal{X} \subset \mathbb{R}^d$

$$\mathbf{x}^* = \arg\max_{\mathbf{x}\in\mathcal{X}} f(\mathbf{x}) \tag{6}$$

In some cases, evaluating $f(\mathbf{x})$ requires substantial computational resources or experimental effort. Moreover, BO is particularly useful when the objective function is treated as a black box, meaning that only function evaluations are available while derivatives are either inaccessible or difficult to compute (e.g., D-MPNN models). Bayesian optimization addresses this challenge by constructing a probabilistic surrogate model that approximates the objective function, often a Gaussian Process, while quantifying uncertainty. A GP is defined by a mean function $\mu(\mathbf{x})$ and a covariance kernel $k(\mathbf{x}, \mathbf{x}')$

$$f(\mathbf{x}) \sim \mathcal{GP}(\mu(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')) \tag{7}$$

Given a set of observations $\mathcal{D}_n = \{(\mathbf{x}_i, y_i)\}_{i=1}^n$, where $y_i = f(\mathbf{x}_i) + \epsilon$ and $\epsilon \sim \mathcal{N}(0, \sigma_n^2)$ represents observational noise, the GP posterior at a new input $\mathbf{x}_*$ is Gaussian with mean and variance

$$\begin{aligned}\mu_n(\mathbf{x}_*) &= \mathbf{k}_*^\top (\mathbf{K} + \sigma_n^2\mathbf{I})^{-1}\mathbf{y}, \sigma_n^2(\mathbf{x}_*) \\ &= k(\mathbf{x}_*, \mathbf{x}_*) - \mathbf{k}_*^\top (\mathbf{K} + \sigma_n^2\mathbf{I})^{-1}\mathbf{k}_*\end{aligned} \tag{8}$$

where $\mathbf{K}$ is the covariance matrix of training points and $\mathbf{k}_*$ is the covariance vector between $\mathbf{x}_*$ and the training points. This probabilistic prediction allows BO to identify regions of high uncertainty and guide exploration efficiently. The next point to evaluate is chosen by maximizing an acquisition function $\alpha(\mathbf{x}; \mathcal{D}_n)$, which balances exploration and exploitation. Common acquisition functions include Expected Improvement (EI), Probability of Improvement (PI), and Upper Confidence Bound (UCB), each combining the GP mean and variance in different ways to guide the search. The BO procedure is iterative: the surrogate is updated with new observations, the acquisition function is optimized to propose the next evaluation point, and the objective function is sampled. Finally, this loop continues until convergence, or a maximum number of evaluations is reached. By efficiently leveraging both the predicted mean and uncertainty, Bayesian Optimization reduces the number of expensive function evaluations, making it particularly suited for applications where computational or experimental costs are significant.

# METHODOLOGY

## Solvent Feature Encoding

In this section we describe the three molecular representations employed for the BO kernel: integer enumeration, numerical descriptors and deep embeddings. For the integer enumeration, all unique solvents and solutes were assigned discrete numerical identifiers. Specifically, the solvent SMILES were extracted, mapped to integer values starting from one and stored in a dictionary, where the keys correspond to the SMILES strings and the values to the assigned integers. The second encoding method employs molecular descriptors. Numerical descriptors were computed using RDKit (version 2024.09.6). Each solvent SMILES was converted into an RDKit mol object, from which a set of physicochemical and structural descriptors was calculated. These included molecular weight, LogP, topological polar surface area, numbers of hydrogen bond donors and acceptors, number of rotatable bonds, ring count and fraction of $sp^3$-hybridized carbons. The descriptors were manually selected to capture relevant chemical properties for solubility. Finally, solvent embeddings were generated using the multicomponent directed edge graph neural network trained on single solvent systems and mixtures. To ensure consistency, embeddings were extracted using the same pre-trained model employed as the objective function in the optimization framework (see "Solubility predictor"). The latent representation of the solvents was extracted from the solvent-specific message-passing block of the D-MPNN. For dimensionality reduction and visualization, principal component analysis (PCA) from scikit learn (version 1.7.1) was applied, retaining the first 5, 10, 20, and 30 principal components for comparison. The reduced representations were subsequently used both for visualization and exported in JSON format for downstream analysis.

## Solubility Predictor

We employ a D-MPNN extended to multicomponent solvent systems implemented in Chemprop (version 2.1.2) as objective function. Molecular graphs of the solute and solvents are encoded using a shared bond-centered D-MPNN in which messages are defined on directed bonds and propagated for three message-passing steps while excluding reverse-bond information. Initial bond messages are constructed from default atom and bond features (86-dimensional) and projected into a latent space of dimension 300. Message updates are performed using learned linear transformations with ReLU activations, resulting in 300-dimensional directed bond embeddings. After 3 message passing steps, bond representations are aggregated to atom-level embeddings

and pooled using mean aggregation to obtain fixed-size 300-dimensional molecular embeddings for each component. Solvent embeddings are then combined using a mixture aggregation module that incorporates solvent mole fractions in a permutation-invariant manner, yielding a 300-dimensional mixture embedding. The solute and mixture embeddings are concatenated (602 dimensions in total, including global features) and passed to a feed-forward neural network with a single hidden layer of size 300 to predict solubility.

An ensemble of four models was trained on logarithmic solubility data (logS [mol/L]) in binary and ternary systems from the datasets BiggerSolDB [14] and MixtureSolDB [15] respectively. The combined dataset comprises 227 998 datapoints, 9 690 unique solutes, and 132 unique solvents in the range of 243.15-592.9K. Training was performed for 100 epochs with a batch size of 256 for training and 2048 for validation and testing. The mean squared error (MSE) was used as the loss function. The dataset was randomly split into training, validation, and test sets with ratios of 0.89, 0.10, and 0.01, respectively. The Chemprop default optimizer (Adam) and learning rate were used, and the predictive performance of the model was evaluated on a held-out test set. Figure 1 shows a schematic representation of the multicomponent D-MPNN architecture.

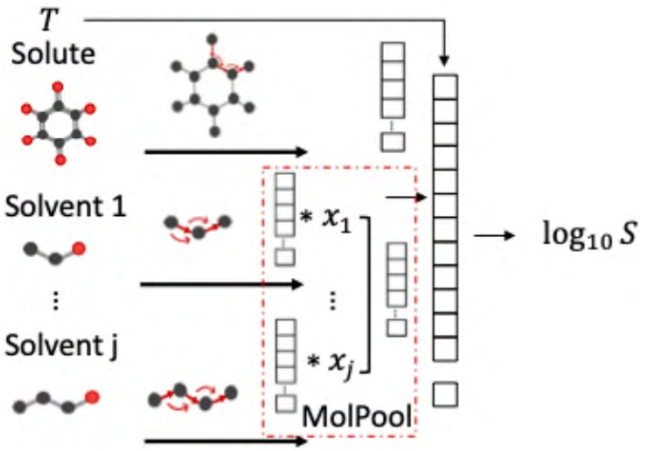

**Figure 1**. schematic representation of the D-MPNN architecture employed in this work as the objective function within the optimization framework.

## Optimization algorithm

As the optimization algorithm, gp_minimize from the scikit-optimize library (version 0.10.2) was employed. Regarding the search space, different bounds were adopted for the categorical variables depending on the solvent representation (i.e., integers, descriptors, or deep embeddings). In the case of integer enumeration, each solvent variable was represented as a discrete integer corresponding to a unique solvent in the dataset. The search space was therefore discrete, ranging from 1 to the total number of unique solvents.

For descriptors and deep embeddings, the search space was instead constructed directly in the continuous representation space of the solvents. Optimized continuous solutions in the descriptor or embedding space were subsequently mapped back to real solvents using a nearest-neighbor projection, selecting the solvent whose representation is closest in Euclidean distance to the optimized point, without modifying the kernel.

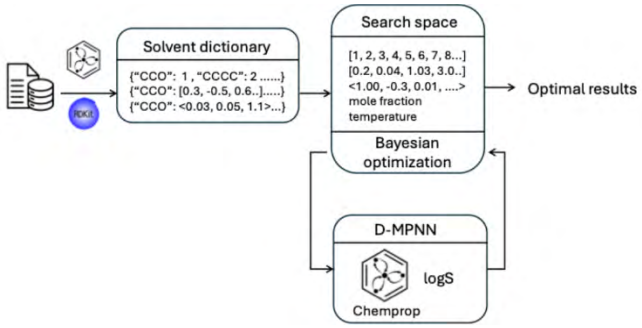

**Figure 2**. Overview of the optimization workflow: Solvents are extracted from the dataset and encoded as random integers, deep embeddings, or numerical descriptors, which are stored in dictionaries. Bayesian optimization iteratively searches for the best combinations, which are evaluated by the predictor. This loop continues until convergence or a fixed number of iterations is reached.

For all three optimization approaches, the mixture composition was encoded as a continuous variable. The temperature was also modeled as a continuous variable, defined over a real-valued domain bounded by the minimum and maximum temperatures observed in the dataset. The boiling temperature of each pure solvent was estimated using the Joback group contribution method [16]. These boiling temperatures were encoded as numerical values and used together with the solvent representations (integer encoding, molecular descriptors, or embeddings). These values were implemented as a hard-coded constraint in the optimization algorithm, ensuring that solvent mixtures were not proposed at temperatures exceeding the boiling point of the individual pure solvents. This constraint represents an approximation, as the pure component boiling point does not necessary represent the one of the mixtures. Future work could improve this aspect by incorporating predictive models for bubble and dew points. Additionally, to prevent the optimization algorithm from proposing solvent combinations that are implausible from a miscibility standpoint, a constraint based on the water–ethanol partition coefficient was introduced. Future work will focus on extending this framework by incorporating more accurate thermodynamic models for miscibility. Finally, the BO procedure was initialized with 10 random samples and employed

expected improvement as acquisition function. Figure 2 shows an overview of the optimization tool.

## RESULTS

The performance of the optimization framework was evaluated on a dataset consisting of 14 299 data points, 66 solutes and 38 solvents in the temperature range 263-367 K. Before reporting the results of the optimization algorithm, we evaluate the performance of the D-MPNN predictive model for the solubility of these solutes. The performance of the model to predict solubility in mixtures of organic solvents for a broader set of solutes and solvents was already extensively evaluated in prior work. In Figure 3, a parity plot shows the performance on the solubility of the 66 tested solutes in the experimentally reported solvents mixtures. Also, for these solutes, a good performance is achieved, indicating that the predicted solubility in new, optimized solvents can be expected to be reliable. Nevertheless, further experimental validation is needed to support these conclusions.

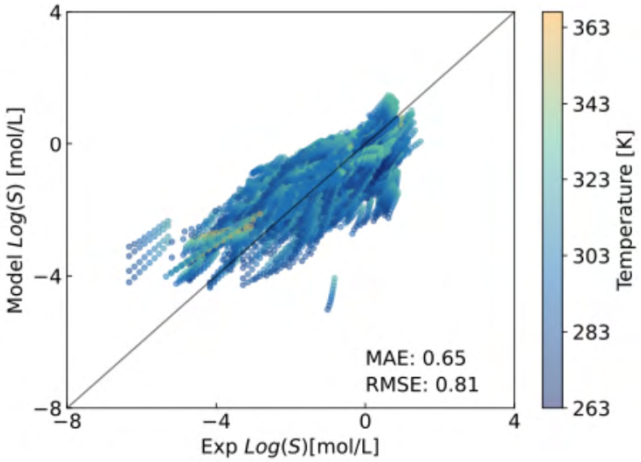

**Figure 3**. performance of the D-MPNN evaluated on the dataset used in this work, which comprises 66 solutes, 38 solvents, and a total of 14 299 datapoints.

As an example of the performance of the optimization algorithm, we report mixtures proposed by the tool for the three encoding strategies that yield high predicted solubilities. For the enumeration approach, the tool reaches a predicted solubility of 1.4950 $\log_{10}$ mol·L$^{-1}$ for the compound octadecane in a mixture of 4-methylpentan-2-one (0.1 mole fraction) and hexane (0.9) at 333.26 K. This solution is chemically feasible, as both solvents are known to be suitable for octadecane, and the temperature is below their boiling points. The dataset used in this study contains experimentally measured solubilities for only a limited number of solvent mixtures. For octadecane, available experimental data are limited to mixtures of ethanol and cyclohexane. The highest experimentally measured solubility for octadecane was obtained in a mixture of ethanol (0.4) and cyclohexane (0.6) at 297.45 K, with a value of 0.8506 $\log_{10}$ mol·L$^{-1}$. For the descriptors-based approach, we report the example of propylparaben in a mixture of ethyl acetate (0.2) and dimethylformamide (0.8) at 318.39 K, which was found to have the highest solubility among all solute–solvent combinations. This mixture is feasible because the polar solvents are compatible with the polarity of propylparaben. The optimization algorithm predicted a solubility of 0.8487 $\log_{10}$ mol·L$^{-1}$ for the compound, exceeding the highest experimentally measured solubility in the dataset (0.6249 $\log_{10}$ mol·L$^{-1}$ in pure methanol at 298 K). This demonstrates that the use of solvent mixtures can enhance solubility compared to single-solvent systems. Using the embeddings approach, the maximum predicted solubility (1.6623 $\log_{10}$ mol·L$^{-1}$) was found for octadecane in a mixture of hexane (0.25) and n-heptane (0.75) at 338.7 K, using an embedding size of 5; since this embedding size yielded the best performance, only results for this setting are reported. The temperature is below the boiling points of both solvents, making the mixture chemically appropriate for octadecane, a paraffin. These results highlight that the embeddings-based approach successfully identified the optimal solvent combination for octadecane, outperforming both other encoding schemes (the descriptor-based model reaches 0.5333 $\log_{10}$ mol·L$^{-1}$) and the experimental data.

In Figure 4, we present two examples, fumaric acid and 5-nitro-8-hydroxyquinoline, for which we compare the performance of the three representations. In the first case, the enumeration approach achieves higher predicted solubility than both the experimental value and the two encoding schemes. In contrast, for 5-nitro-8-hydroxyquinoline, the chemistry-informed representations (deep embeddings and descriptors) yield better results. For fumaric acid, the enumeration procedure predicts the highest solubility (0.8273 $\log_{10}$ mol·L$^{-1}$) in a mixture of ethyl acetate (0.1) and dimethylformamide (0.9) at 324.24 K. Descriptors suggest best solubility (-0.0355 $\log_{10}$ mol·L$^{-1}$) to be in a mixture of diethylene glycol monoethyl ether (0.6) and n-methylpyrrolidone (0.4) at 327.1 K. Finally, for the deep embeddings, the optimal mixture corresponds to diglyme (0.1) and n-methylpyrrolidone (0.9) at 336.97 K (0.0625 $\log_{10}$ mol·L$^{-1}$). The highest experimentally measured solubility for this molecule, fumaric acid, was obtained in a methanol (0.8) and water (0.2) mixture at 333 K, 0.0898 $\log_{10}$ mol·L$^{-1}$.

For the other compound, 5-nitro-8-hydroxyquinoline, the best mixture predicted by the enumeration procedure consists of acetone (0.2) and cyclohexanone (0.8) at 300.94 K, yielding −0.2633 $\log_{10}$ mol·L$^{-1}$. In contrast, the deep embeddings suggest 2-butanone (0.05) and cyclopentanone (0.95) at 324.2 K, with a predicted solubility of 0.1172 $\log_{10}$ mol·L$^{-1}$. Finally, the descriptor-based model predicts the highest solubility (−0.1440

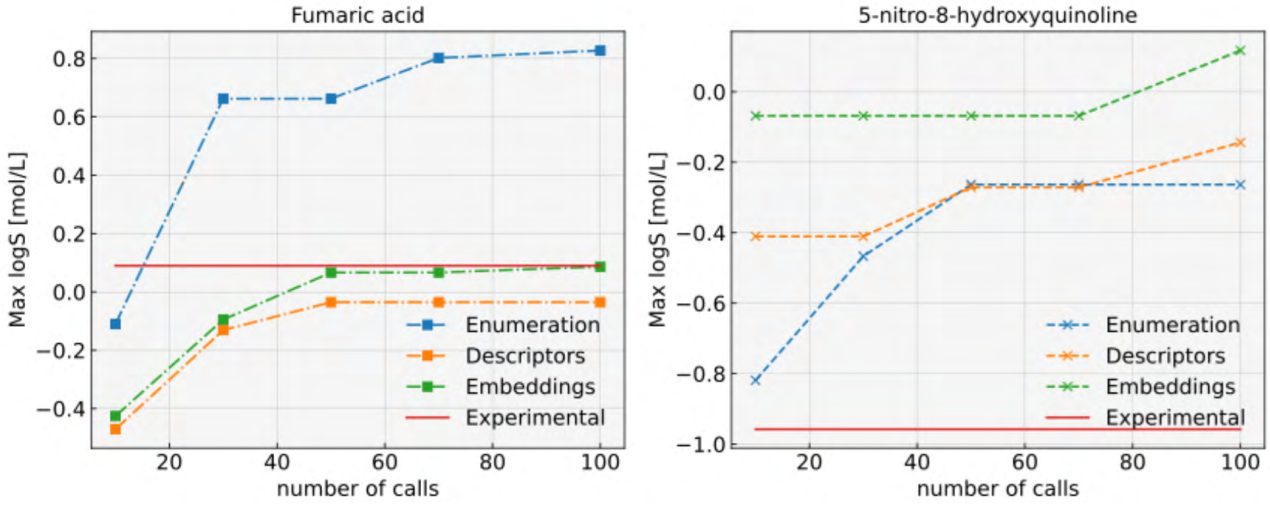

**Figure 4.** Maximum solubility as a function of the number of optimization calls for the three representations, shown for fumaric acid and 5-nitro-8-hydroxyquinoline. For fumaric acid, integer enumeration and embeddings yield the best performance, whereas for 5-nitro-8-hydroxyquinoline all three representations achieve solubility values higher than the experimental reference. The red continuous line indicates the highest experimentally measured solubility for fumaric acid and 5-nitro-8-hydroxyquinoline.

$\log_{10}$ mol·L$^{-1}$) in a mixture of pyridine (0.35) and propionic acid (0.65) at 307.5 K. The highest experimental value was -0.9578 $\log_{10}$ mol·L$^{-1}$ found for the mixture ethyl acetate (0.77) and methanol (0.33) at the temperature of 313.15K.

We further analyzed the maximum solubility achieved for each compound in the original curated experimental dataset and compared it with the maxima predicted by the optimization algorithm. Under the enumeration scheme, the algorithm proposed improved solvent mixtures for 36 out of 66 solutes, indicating that for more than half of the compounds it can suggest solvent mixtures that improve solubility as compared to the best experimental measurement. For the embeddings-based approach, 33 solutes exhibited higher predicted solubility than in the original experimental dataset, whereas for the descriptors-based approach, 21 out of 66 solutes showed improved solubility (see table 1). Table 1 summarizes the results for the three enumeration schemes in terms of improvement with respect to the experimental data, mean gain, and mean loss.

These results highlight several important points. First, the enumeration and embedding approaches are the most effective at identifying solvent mixtures that maximize solubility. Second, the proposed method is computationally efficient and improve solubility for a substantial subset of solutes, demonstrating their practical utility for experimental planning. In practice, this approach can significantly reduce the cost associated with testing large numbers of solvent mixtures experimentally. Third, all predicted solutions are chemically reasonable, as they account for solute–solvent, solvent-solvent compatibility and safe temperature ranges.

**Table 1:** Summary of the three molecular representations in terms of improvement relative to experimental data.

| Representation | Better than experiments | Worse than experiments | Mean gain | Mean loss |
|---|---|---|---|---|
| Enumeration | 36 | 30 | 0.4881 | -0.654 |
| Descriptors | 21 | 45 | 0.5628 | -0.644 |
| Embeddings | 33 | 33 | 0.5554 | -0.599 |

## CONCLUSIONS

In this work, we developed an optimization workflow based on directed message passing neural networks to identify, for each solute, the optimal combination of solvents, mole fractions, and temperatures that maximize solubility. Three different solvent representations were investigated: integer enumeration, physicochemical descriptors, and learned deep embeddings. Our results show that, for a curated dataset with a limited number of solvents and solutes, enumeration and embedding-based representations are the most effective at identifying solvent mixtures that maximize solubility. Both the enumeration strategy and the embeddings-based approach were able to propose improved solvent mixtures for 36 out of 66 solutes and 33 out of 66 solutes whereas the descriptors-based approach led to improved

solubility for a smaller subset of compounds (21 out of 66). To ensure physically meaningful predictions, solvent constraints were imposed to avoid phase separation and to restrict solutions to chemically reasonable temperature ranges. These constraints are necessary because current predictive models do not account for phase stability and lack inherent temperature constraints. However, they should be viewed as approximations that may ultimately be replaced by models that directly enforce thermodynamic constraints within the architecture. Ultimately, the proposed approach lays the groundwork for a fully automated optimization pipeline capable of identifying optimal experimental conditions for organic molecules, spanning the entire workflow from synthesis to crystallization. Future directions include modifying the kernel to directly incorporate physicochemical information, developing improved models for boiling point estimation, enabling the use of optimization algorithms that leverage the structure of the ANN model (e.g., gradient-based methods or mixed-integer linear programming), and experimental validation of the proposed improvements.

## ABSTRACT

Modular process simulators are widely used in industry due to their robust and detailed unit operation models. However, their application to gradient-based process optimization remains challenging, as these simulators are typically treated as black boxes, limiting access to internal equations and derivatives. As a result, finite difference methods are commonly employed for gradient estimation, despite their sensitivity to numerical noise and poor scalability. While previous studies have demonstrated the benefits of analytical derivatives in modular simulators, these approaches have largely relied on tangent differentiation modes. This work proposes a non-intrusive methodology that couples analytical derivatives with the adjoint mode of automatic differentiation to efficiently compute gradients for process optimization in modular simulators. The approach preserves the robustness of existing simulation tools by performing simulations normally to convergence, followed by external adjoint-based derivative evaluation using analytically available sensitivities. Theoretical advantages of adjoint differentiation are thus exploited, particularly for optimization problems where the number of decision variables exceeds the number of objective outputs. The proposed framework is evaluated through a case study based on a combined heat and power cycle, using three benchmark objective functions. Gradient computation cost, robustness, and overall optimization performance are compared against forward and centered finite difference methods. Results demonstrate that the analytical adjoint approach significantly reduces gradient computation time while maintaining high robustness, achieving up to 56% reduction in computational cost compared to finite differences. These findings highlight the potential of analytical adjoint differentiation as an efficient and reliable alternative for optimization in modular process simulators.

## INTRODUCTION

Effective decision-making to address societal challenges, such as how energy, fuels, chemicals, and other products should be produced and stored, requires advanced tools and methodologies [1]. In the context of chemical and biochemical processes, Computer-Aided Process Engineering (CAPE) is the field related to the development and application of computational models, methods, and software tools to support their design, simulation, optimization, control, and operation [2]. Most of the CAPE methodologies or tools require the calculation of numerical values for a mathematical function (e.g., process efficiency, product purity, etc), often computed by running the simulation of a process, and its derivatives as well. In particular, derivatives play a central role in product-and-process design optimization, operating parameter sensitivity analysis, or even data reconciliation.

In the case of a steady-state process design, the aforementioned simulation contains material and energy balances, along with physical and thermodynamic property estimations. The simulation is performed by process simulators, which offer a rigorous modelling environment that rely on extensive thermodynamic properties databanks and tailored flowsheeting algorithms. These simulators act as black-box tools and generally rely on sequential-modular or equation-oriented (EO) approaches [3]. The former solves one unit operation at a time,

determining output streams from input streams and equipment parameters. In contrast, the EO approach gathers all the equations of all the units included in the flowsheet resulting in a system of equations which must be solved simultaneously [3].

Concerning derivative calculation, there exist four alternatives: (1) analytical, (2) finite, (3) symbolic, and (4) automatic differentiation. Analytical differentiation consists of determining the exact derivative of a function using calculus rules and formulas. Finite differentiation corresponds to the approximation of derivatives using finite differences formulas. Symbolic differentiation computes derivatives using algebraic manipulations by computer algebra systems. Finally, automatic differentiation applies the chain rule systematically to computer programs to compute derivatives with machine precision.

In the context of process simulation, various of the differentiation techniques presented above have been employed. EO simulators compute derivatives analytically [4], which gives virtually direct access to Jacobians, gradients and sensitivities with no numerical error. On the contrary, modular ones, due to their black-box nature, use finite differentiation for derivative calculation, which may result in inaccurate derivatives due to truncation errors and an elevated computational cost.

Several studies have been focused on analytical derivative calculation in modular process simulators. Early work by Chen and Stadtherr [5] highlighted the benefits of analytical derivatives in flowsheet calculations, while Chan and Prince [6] showed improved accuracy over methods using finite differentiation. Wolbert et al. [4] demonstrated the benefits from exact derivatives for flowsheet optimization. Nevertheless, all of these methods effectively employed a tangent, AD-like differentiation mode, propagating derivatives from input variables to output variables [7]. The objective of this work is to explore the capabilities of coupling analytical derivatives with the adjoint mode of AD, since, in theory, it offers better performances for problems such as optimization, in which the number of input variables is larger than the number of output variables [8].

The paper is structured as follows: background information is provided in Section 2, the methodology is described in Section 3, the case study and benchmarks are presented in Section 4, results are discussed in Section 5, and conclusions are drawn in Section 6.

## BACKGROUND

This section provides the necessary background for introducing the proposed methodology. It first outlines the structure and numerical operation of modular process simulators, highlighting their modular organization and coupling with external tools. Next, existing strategies for derivative calculation in such simulators are discussed, with particular attention to intrusive and non-intrusive approaches. Finally, the fundamentals of automatic differentiation are introduced, focusing on the tangent and adjoint modes that underpin the derivative propagation framework used in this work.

### Structure of a modular process simulator

A module in a modular process simulator determines the output stream values of a unit ($\eta_k$), given its input stream values ($\xi_k$) and the unit parameter values ($p_k$). This is achieved by solving a set of equations representing the model of that unit, i.e., mass and energy balances, phase equilibrium [3].

In modular process simulators, once the flowsheet units are connected through material and energy balance equations, the simulator automatically establishes a calculation sequence and applies internal numerical algorithms to solve the resulting system. These simulators typically embed robust numerical methods for tasks such as root-finding, convergence of recycle loops, and local optimization of unit or flowsheet variables. However, their built-in capabilities do not preclude the use of external tools. In many advanced applications, the process simulator can be coupled with external optimization solvers, allowing users to exploit more specialized or large-scale optimization algorithms, integrate custom objective functions and constraints, or link the simulation to broader decision-making frameworks such as process design, control, or economic optimization.

### Derivative calculation with modular process simulators

Two strategies can be considered for derivative calculation with a modular process simulator. The first one consists of “opening” the simulator’s source code and implementing derivative expressions for function relationships within each unit module. Then, derivatives can be evaluated as part of the simulation process [4]. The second strategy does not modify the simulator’s source code. In contrast, the simulation is performed first, followed by a derivative calculation procedure that receives the calculated output stream values and unit parameter values.

The first strategy provides exact gradient information that can be used by both internal or external numerical methods. For instance, if a flowsheet contains a recycle stream, it is necessary to implement a root-finding algorithm that may require gradient information. Similarly, the second strategy is also able to provide exact gradient information. The difference lies in the fact that such gradients are obtained a posteriori, based on the converged simulation results, rather than being computed and propagated internally during the solution of the flowsheet equations.

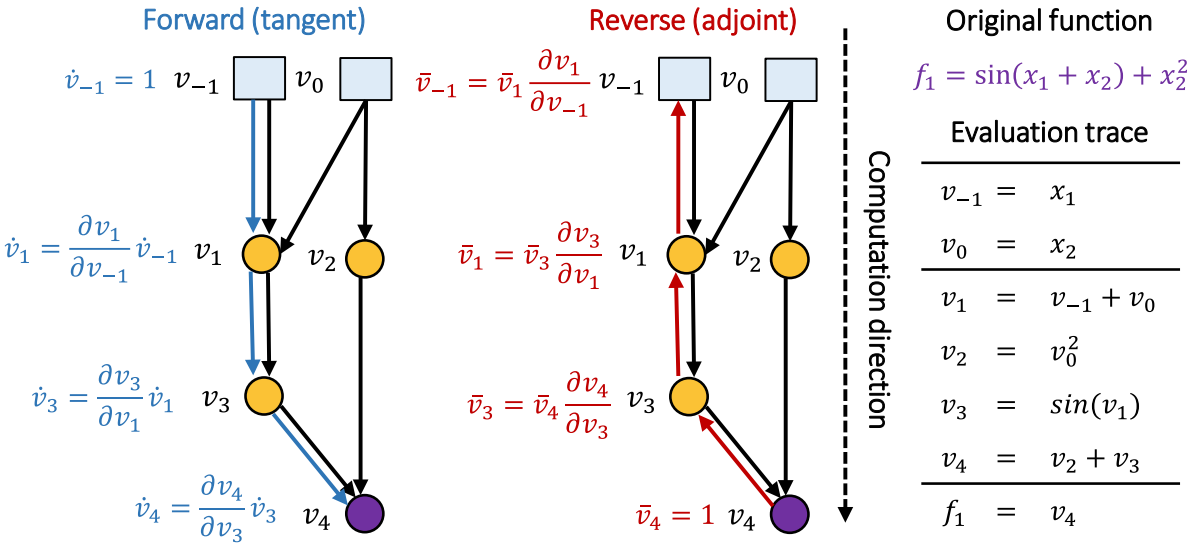

**Figure 1.** Sketch of the computational graph for the computation of $f_1$ and its derivatives.

## Automatic differentiation

Automatic Differentiation (AD) is based on the observation that a sequence of code statements can be regarded as the composition of the functions representing the computation performed by each statement. This composition is represented by a computational graph (CG). In Figure 1, vertices ($v_i$) represent each sub-function composing the original function ($f_1$), and an arc runs from $v_j$ to $v_i$ when $v_i$ depends on $v_j$ ($j \prec i$). The roots of the graph (blue) represent the independent variables ($x$), and the leaves (purple) represent the dependent ones ($f$). Then, AD works by propagating gradients in the computational graph using the chain rule. Two basic modes exist: the tangent (forward) and adjoint (reverse) mode. Forward mode propagates tangents values ($\dot{v}_i$) in the same direction as function evaluation, while reverse mode propagates adjoint values ($\bar{v}_j$) backward [8].

Automatic differentiation can be implemented through: (1) operator overloading, where standard arithmetic operations are redefined on custom data types that store both values and derivatives, enabling derivatives to be computed as the program runs. (2) Source code transformation, which analyses the original program and generates new code that simultaneously computes the function and its derivatives, often yielding highly optimized performance. (3) Tape-based execution records operations during the forward pass and replays them in reverse to efficiently propagate gradients, a technique widely used in modern deep learning frameworks [8].

For the following sections, consider a vector of input variables as $\boldsymbol{x} \in \boldsymbol{X} \subset \mathbb{R}^n$, a vector function (or vector valued) $F: \boldsymbol{X} \longmapsto \mathbb{R}^m$, which is the composition of a sequence of $l$ once continuously differentiable elemental functions $(\varphi_i)_{i=1,\ldots,l}$, representing each internal node. The Jacobian is a well-defined matrix-valued function $F': \boldsymbol{X} \longmapsto \mathbb{R}^{m \times n}$.

### Tangent mode

The first derivative vector in tangent mode depends on $x$ and a certain seed direction $\dot{x}$. The desired output is $\dot{y}$, defined as follows:

$$\dot{y} = F'(x)\dot{x} = \begin{bmatrix} \frac{\partial f_1}{\partial x_1}\dot{x}_1 + \cdots + \frac{\partial f_1}{\partial x_n}\dot{x}_n \\ \vdots \\ \frac{\partial f_m}{\partial x_1}\dot{x}_1 + \cdots + \frac{\partial f_m}{\partial x_n}\dot{x}_n \end{bmatrix} \quad (1)$$

One might be tempted to evaluate the full Jacobian $F'(x)$ and then multiplying it with the direction $\dot{x}$. In turn, the Jacobian is evaluated by tangent propagation of each element $\varphi_i$ composing the function $F$. In consequence, the first step is to define the seed direction $\dot{x}$ for which $\dot{y}$ will be calculated. Then, all the nodes $\dot{v}_i$ are calculated as follows:

$$\dot{v}_i = \sum_{j \prec i} \frac{\partial v_i}{\partial v_j}\dot{v}_j \quad (2)$$

where $j \prec i$ means that node j precedes node i. Consider the case with $\dot{x}_j = 1$ and $\dot{x}_{i \neq j} = 0$. Then, $\dot{y}$ corresponds to the j[th] column of $F'(x)$:

$$\dot{y} = \left[\frac{\partial f_1}{\partial x_j} \quad \cdots \quad \frac{\partial f_m}{\partial x_j}\right]^T \quad (3)$$

It is then possible to compute a full Jacobian matrix ($F': \boldsymbol{X} \longmapsto \mathbb{R}^{m \times n}$) in $n$ forward sweeps. In the example of Figure 1, $n = 2$ and $m = 1$. It is thus necessary to set $\dot{x} = (1, 0)$ and $\dot{x} = (0, 1)$ to obtain $\frac{\partial f_1}{\partial x_1}$ and $\frac{\partial f_1}{\partial x_2}$, respectively. Note

that if $m > 1$, the number of required forward sweeps does not increase.

### Adjoint mode

In the adjoint mode, the objective is to compute the gradient of a function defined as the weighted sum of the components ($f_k$) of a vector-valued function $F(x)$, namely,

$$s = \sum_{k=1}^{N} \bar{y}_k f_k \tag{4}$$

where $\bar{y}$ correspond to the weight vector. The desired output is $\bar{x}^T = \nabla s = \bar{y}^T \cdot F'(x)$:

$$\bar{x}^T = \left[\bar{y}_1 \frac{\partial f_1}{\partial x_1} + \cdots + \bar{y}_m \frac{\partial f_m}{\partial x_1} \quad \ldots \quad \bar{y}_1 \frac{\partial f_1}{\partial x_n} + \cdots + \bar{y}_m \frac{\partial f_m}{\partial x_n}\right] \tag{5}$$

In order to compute the gradient of $s$, the first step is to define the weight vector. Then, all the nodes $\bar{v}_j$ are calculated as follows:

$$\bar{v}_j = \sum_{i \succ j} \bar{v}_i \frac{\partial v_i}{\partial v_j} \tag{6}$$

where $i \succ j$ means that node i follows node j. Consider the case with $\bar{y}_i = 1$ and $\bar{y}_{j \neq i} = 0$. Then, $\bar{x}^T$ corresponds to the i$^{th}$ row of $F'(x)$:

$$\bar{x}^T = \left[\frac{\partial f_i}{\partial x_1} \quad \ldots \quad \frac{\partial f_i}{\partial x_n}\right] \tag{7}$$

It is then possible to compute a full Jacobian matrix ($F' : \boldsymbol{X} \longmapsto \mathbb{R}^{m \times n}$) in $m$ reverse sweeps. In the example of Figure 1, it is thus necessary to set $\bar{y} = 1$ to simultaneously obtain $\frac{\partial f_1}{\partial x_1}$ and $\frac{\partial f_1}{\partial x_2}$. Note that if $n > 2$, the number of required backward sweeps does not increase.

## METHODOLOGY

In this work, we propose a non-intrusive methodology that couples analytical derivatives with the adjoint mode of automatic differentiation to perform gradient computation in modular process simulators. The methodology proposed in this work is composed by four main steps:

1. Definition of the flowsheet, specifications, objective functions and action variables.
2. Definition of the computational graph of the process model.
3. Implementation of analytical derivatives at the unit-operation level.
4. Generation of the computation procedure for derivatives using the adjoint mode of AD.

### Implementation strategy

Once the flowsheet, specifications, objective functions and action variables are defined in the simulator. The computational graph can be automatically extracted from the simulator or manually defined by the user by following the unit operation calculation sequence. At each new equation of a given unit operation module, new nodes, if they do not exist yet, are included in the graph. In this work, the computational graph was manually defined.

At the unit-operation level, analytical derivatives involving mass and energy balances are hand-coded in a user-defined module or custom scripting environments depending on the simulator native features. If the derivative of a physical property, such as enthalpies or entropies, is required, they are obtained via simulator APIs, such as Simulis Thermodynamics, Aspen Properties, or CoolProp.

Finally, all the derivatives required for the computation of adjoints for each node of the computational graph are linked manually following Equation 6.

### Implementation example

The gradient calculation procedure is presented through an example based on the Rankine cycle described in Figure 2. Consider a function equal to the net power of the cycle: $\dot{W}_{net}$, whose calculation is described by the set of equations S1 and performed by a process simulator The variables involved in the calculation are the turbine and pump powers ($\dot{W}_T, \dot{W}_P$), their isentropic efficiencies ($\eta_T, \eta_P$), enthalpies ($h_i$) calculated at temperature and pressure conditions ($T_i, P_i$), enthalpies ($h_i^{is}$) calculated at isentropic conditions and pressure $P_i$. $\dot{m}$ represents the mass flow rate. $T_1, P_1, P_2, T_3, P_3, P_4, \eta_T, \eta_P$ and $\dot{m}$ are known.

The cycle flowsheet is created by the user, and the model will be generated and solved automatically by the process simulator. Then, the computational graph is manually generated and analytical derivatives are coded following the set of equations S1. At this point, it is necessary to define which variables from the simulation will be reused in the gradient calculation and which not. For instance, the enthalpies or entropies will be reused, while enthalpy or entropy derivatives will be calculated in the AD interface. This approach preserves the robustness of the existing simulator while leveraging adjoint efficiency.

In execution time, if $\frac{\partial \dot{W}_{net}}{\partial T_1}$ is required, the simulation will be executed first. Then, the calculated output stream values and unit parameter values that will be reused in the AD procedure are stored. This is followed by the calculation starting with $\bar{\dot{W}}_{net}$ and finishing with $\bar{T}_1$.

## CASE STUDIES AND BENCHMARK

To evaluate the proposed framework for AD adjoint mode with analytical derivatives within modular process simulators, a series of optimization tests, based on a Combined Heat and Power (CHP) cycle, were conducted. The case study considers the CHP cycle presented in Figure 3. The working fluid in a liquid state is compressed

by a pump (1-2) from a low pressure (LP) to an intermediate pressure level (IP) corresponding to $P_{LP} = P^{sat}(T_A)$ and $P_{IP} = P^{sat}(T_M)$, respectively. It is then mixed with a bleeding stream at $P_{IP}$. The resulting liquid stream is compressed by a pump (3-4) to a high-pressure level (HP) equal to $P_{HP} = P^{sat}(T_H)$. Then, the fluid is preheated, evaporated at constant pressure (4-5). At the expansion stage, part of the fluid is expanded to the IP level and cooled at constant pressure in a condenser in order to provide the required end-user heating power ($\dot{Q}_{user}$) at $T_M$. The remaining stream is condensed at constant pressure (8-1) to the initial state. The working fluid is neopentane.

**Table 1.** CHP cycle specifications.

| Variable | Value | Units |
|---|---|---|
| $T_A$ | 298 | K |
| $\dot{m}$ | 1 | kg.s$^{-1}$ |
| $\eta_T$ / $\eta_P$ | 0.75 / 0.80 | - |
| $x_{v1}$ / $x_{v7}$ | 0.0 / 0.0 | - |
| | | |

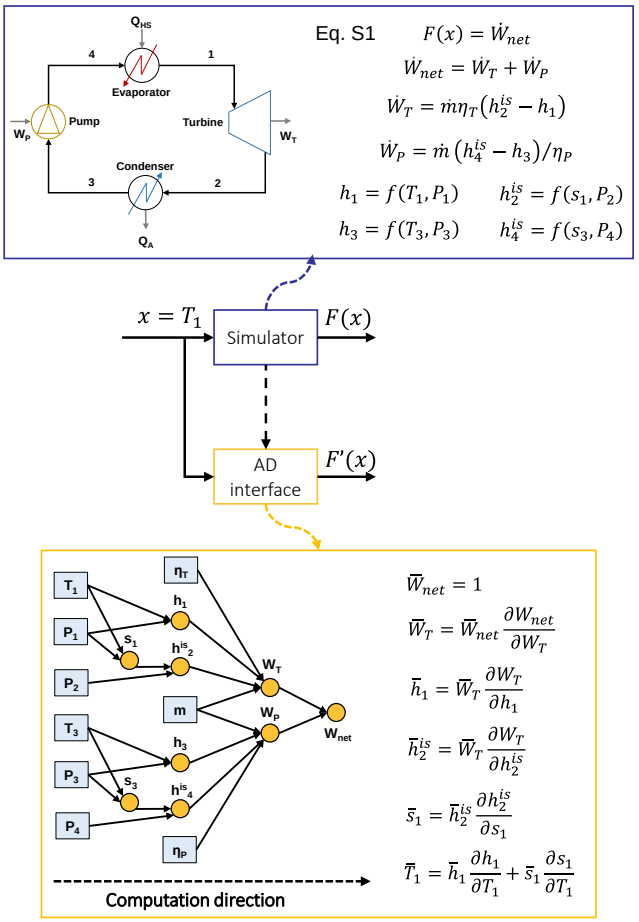

**Figure 2.** Representation of the communication between the automatic-differentiation based interface and the process simulator for gradient calculation.

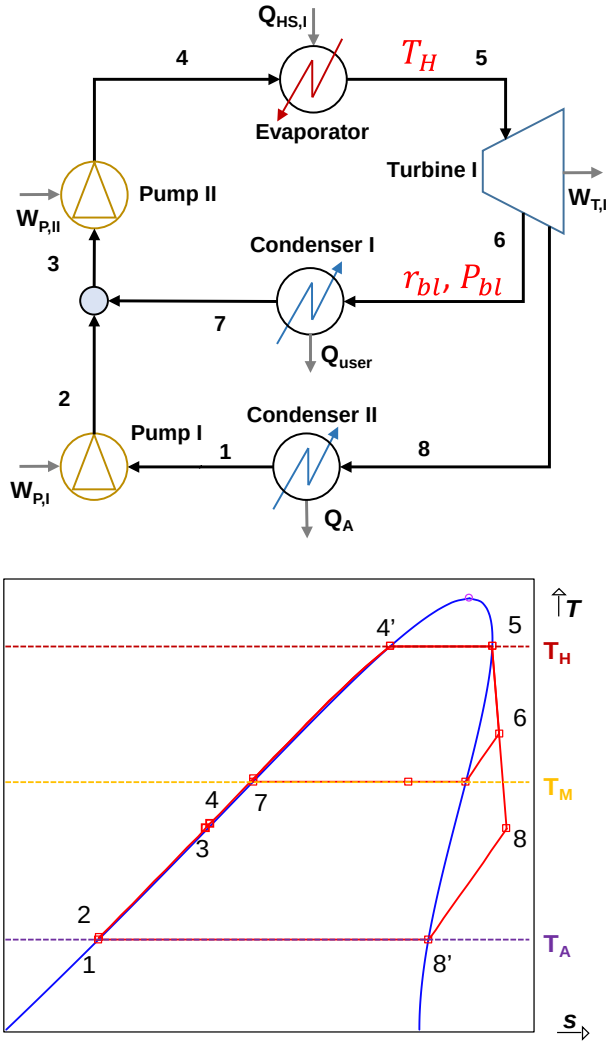

**Figure 3.** Top: process flow diagram of the studied CHP cycle. Bottom: Temperature-entropy diagram.

For this cycle, nine degrees of freedom (DoF) are initially identified: vapor fractions at states 1 and 7 ($x_{v1}, x_{v7}$), turbine and pump isentropic efficiencies ($\eta_T, \eta_P$), mass flow rate ($\dot{m}$), low-level temperature ($T_A$), bleeding ratio ($r_{bl}$), bleeding pressure ($P_{bl}$) and outlet temperature at the evaporator ($T_H$). For benchmarking, only three DoFs are accepted: $r_{bl}, P_{bl}, T_H$. The specifications of the remaining DoFs are listed in Table 1.

## Problem formulation

Given CHP cycle specifications, action variables bounds and an objective function, an optimization problem is formulated to determine optimal operating conditions that minimizes the objective function.

### Action variables

Although three DoFs and different combinations are possible, only three cases were considered. If one, two or three action variables are considered, then the

**Table 4:** Values of $a_i$, $b_i$, $c_i$ for the Rosenbrock, Spheric and Exponential functions.

| Function | Index | a | b | c |
|---|---|---|---|---|
| Rosenbrock | 0 | $\pi - 2$ | - | - |
| | 1 | 250 | 1 | -0.4556 |
| | 2 | 5 | 1 | -0.3684 |
| | 3 | - | - | -0.5360 |
| Sphere | 0 | $\pi - 2$ | - | - |
| | 1 | 100 | 1 | 0.5443 |
| | 2 | 1 | 1 | 0.6316 |
| | 3 | 1 | 1/2 | 0.4640 |
| Exponential | 1 | -100 | -20 | 0.5443 |
| | 2 | -100 | -20 | 0.6316 |
| | 3 | -100 | -20 | 0.4640 |

decision vector corresponds to $x = (r_{bl}), x = (r_{bl}, P_{bl})^T$ or $x = (r_{bl}, P_{bl}, T_H)^T$, respectively. The bounds, or specification if a given variable is not considered in the action variable vector, are listed in Table 2.

**Table 2.** Action variables defined in this study.

| Variable | Bounds (Specification) | Units |
|---|---|---|
| $r_{bl}$ | 0.05 – 0.95 (NA) | - |
| $P_{bl}$ | 3 – 9 (5.4) | bar |
| $T_H$ | 343.15 – 413.15 (390.65) | K |

## Objective functions

A common choice for the objective function is the Energy Utilization Factor (EUF): $EUF = -\frac{(\dot{W}_{net} + \dot{Q}_{user})}{\dot{Q}_{HS}}$, where $\dot{W}_{net}, \dot{Q}_{HS}$ and $\dot{Q}_{user}$ represent, respectively, the net mechanical power, the required heat-source duty, and the heating power provided to the end user. One might be tempted to adopt the EUF or other efficiency-based indicator as a benchmark objective, given its clear physical meaning and widespread use in cycle optimization. However, the resulting landscape is largely determined by the coupled physics and constraints of the cycle, which can make features such as smoothness, conditioning, and multimodality difficult to assess independently. Efficiency-based objectives may therefore reflect characteristics of the full thermodynamic formulation, potentially limiting the ability to adjust features such as curvature, scaling, or the presence of local optima.

To address this, the process model is first used to map physical decision variables to $\dot{W}_{net}, \dot{Q}_{HS}$ and $\dot{Q}_{user}$, which are then normalized and used as coordinates of a benchmark test function, creating a controlled optimization landscape over the physically admissible operating space. The benchmark functions implemented in this work are:

Rosenbrock:

$$F_{obj} = \sum_{i=1}^{N-1}\left[a_i \cdot (\phi_{i+1} - \phi_i^2)^2 + b_i \cdot (1 - \phi_i)^2\right] + a_0 \quad (9)$$

Spheric:

$$F_{obj} = \sum_{i=1}^{N}\left[a_i \cdot \left(\frac{\phi_i}{b_i}\right)^2\right] + a_0 \quad (10)$$

Exponential:

$$F_{obj} = \sum_{i=1}^{N}\left[a_i \cdot exp(b_i \cdot \phi_i^2)\right] \quad (11)$$

with $N = 3$, corresponding to the number of physical decision variables ($\dot{W}_{net}, \dot{Q}_{HS}$ and $\dot{Q}_{user}$), and $\phi_i$ defined as follows:

$$\phi_i = \frac{\alpha_i - \alpha_{i,min}}{\alpha_{i,max} - \alpha_{i,min}} - c_i \quad (12)$$

with $\alpha_1 = \dot{W}_{net}, \alpha_2 = \dot{Q}_{HS}$ and $\alpha_3 = \dot{Q}_{user}$. The values of $\alpha_{i,min}$ and $\alpha_{i,max}$ were obtained via systematic sampling of the admissible operating space for $r_{bl}, P_{bl}$ and $T_H$, and are reported in Table 3. The values of $a_i, b_i$ and $c_i$, are constant and reported in Table 4 for each benchmark function.

**Table 3.** Admissible bounds for $\dot{W}_{net}, \dot{Q}_{HS}$ and $\dot{Q}_{user}$.

| Variable | $\alpha_{min}$ | $\alpha_{max}$ | Units |
|---|---|---|---|
| $\dot{W}_{net}$ | 7197 | 63362 | W |
| $\dot{Q}_{HS}$ | 255973 | 428123 | |
| $\dot{Q}_{user}$ | 12247 | 349282 | |

## Computational graph

The computational graph linking the input variables with the objective function is represented in Figure 4. For the sake of readability, the graph is represented by three layers representing the input nodes (9) corresponding to the maximum DoFs, the internal nodes (39) and the output node (1). It is worth recalling that, at most, three of the input nodes represent action variables of the optimization problems. The resulting computational graph is not

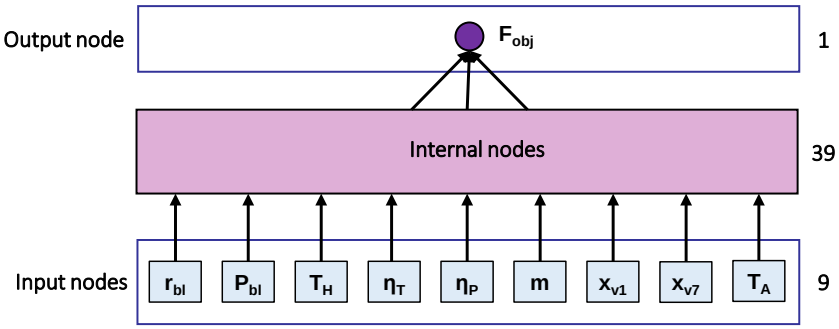

**Figure 4.** Sketch of the computational graph for the computation of $F_{obj}$ and its derivatives.

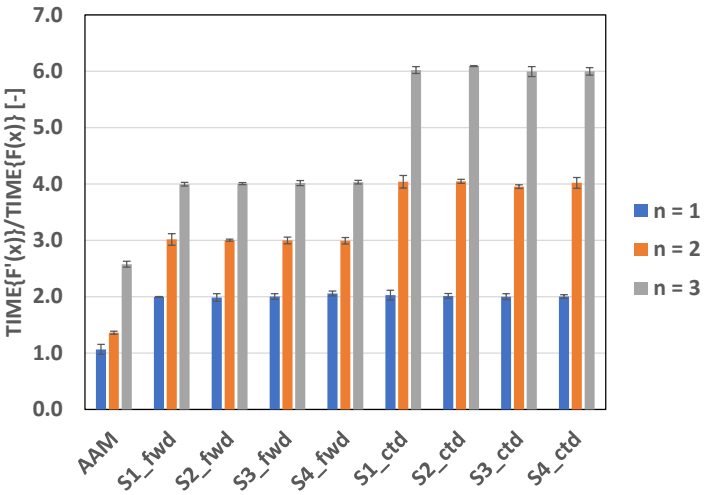

**Figure 5.** Average relative runtime of the gradient calculation compared to a single function evaluation over all the runs and objective functions. Abbreviations: AAM: analytical adjoint mode. fwd: forward finite difference. ctd: centered finite difference.

a complete graph, i.e., where every pair of distinct nodes is connected by an edge. In consequence, the number of nodes connecting two different input nodes to the output node is not necessarily the same.

## Benchmark procedure

Each benchmark test consisted of 30 independent runs, corresponding to 30 different initializations of the design variables. For each run, gradients were computed using both automatic differentiation and finite difference methods. Finite difference gradients were calculated using four perturbation step sizes, defined as: $S_1 = 10^{-2}, S_2 = 10^{-3}, S_3 = 10^{-4}, S_4 = 10^{-5}$. A solution was declared optimal if it satisfied the following $f(x^*) \leq \max(f(z^*) \cdot \epsilon, f(z^*) + \epsilon)$, where $f(x^*)$ denotes the objective function evaluated at the computed optimal solution for a given run, $f(z^*)$ corresponds to the analytically known optimal value, and $\epsilon$ represents the tolerance. It was set to $10^{-2}$ as reference [9].

## Computational details

The optimizations were performed on an Intel(R) Core(R) Ultra 7, 3.80 GHz, 32 GB RAM, Windows 11 64-bit operating system. The optimization solver is based on a Sequential Least Squares Programming (SLSQP) algorithm, implemented via pySLSQP, while all simulations were carried out using ProSimPlus 3.7.9.

# RESULTS

In this section, gradient computation cost, robustness, and overall optimization performance of the analytical adjoint mode (AAM) are compared against forward and centered finite difference methods. For clarity in the presentation of results, finite-difference gradients computed using centered difference schemes are denoted as $S_i$_ctd, while those obtained using forward difference schemes are denoted as $S_i$_fwd, with $i = 1, \ldots, 4$ indicating the corresponding perturbation sizes $S_1$-$S_4$.

## Gradient computation cost

Figure 5 illustrates the average relative runtime of the gradient calculation with respect to a single function evaluation ($TIME\{F'(x)\}/TIME\{F(x)\}$), computed over all

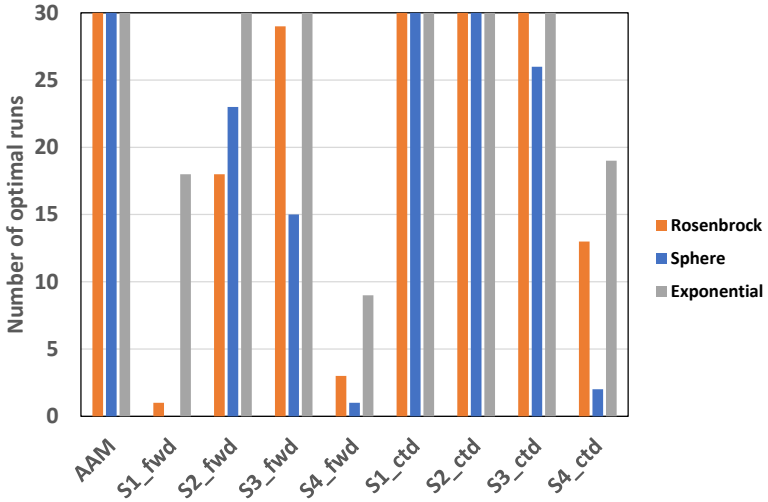

**Figure 6.** Number of optimal runs. Abbreviations: AAM: analytical adjoint mode. fwd: forward finite difference. ctd: centered finite difference.

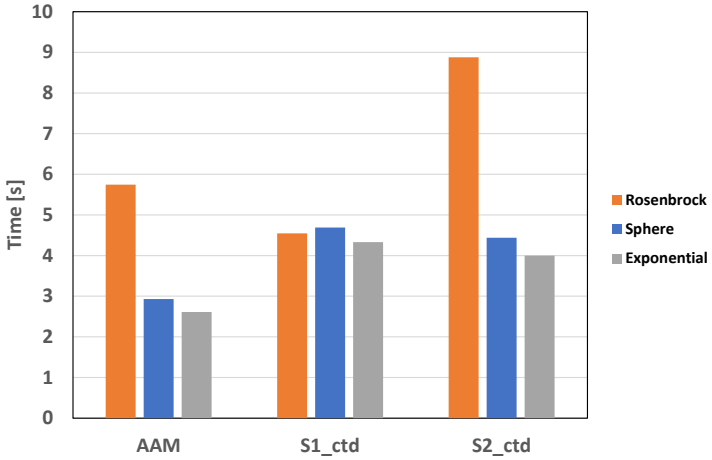

**Figure 7.** Optimization time of analytical adjoint mode (AAM), and centered differences with a perturbation step of $S_1 = 10^{-2}$ and $S_2 = 10^{-3}$.

runs and objective functions. From this figure, it is possible to verify that the computational cost of the gradient calculation ($F'(x)$) for a function $F(x)$ with $n$ inputs and $m$ outputs using finite differentiation corresponds, as expected, to $(n+1)$ and $(2n)$ function evaluations for forward and centered differences, respectively**.** Adjoint mode of AD with analytical derivatives offers better scaling, requiring, at most, $(3m)$ function evaluations [5]. For the case with $n = 3$, it is around 2.6 times the cost of a function evaluation, which results in a reduction of 35% and 56% compared to forward and centered finite differentiation, respectively.

It is possible to observe that the ratio for AAM is not the same for the three cases. This difference can be explained, in part, by the fact that the computational graph is not a complete graph. For instance, the number of internal nodes involved in the cases with $n = 1$ is 17, $n = 2$ is 26 and $n = 3$ is 37. Nevertheless, it is observed that the ratio does not increase linearly. Although the difference of internal nodes ($\Delta v_{2\to3} = 11$) between cases 2 and 3 is almost the same between cases 1 and to ($\Delta v_{1\to2} = 9$), the change in the ratio is not the same. It would have meant that each node has the same computational cost. In contrast, when $n = 3$, the outlet temperature at the evaporator ($T_H$) is an action variable and involves nodes in which derivatives of enthalpy, entropy or vapor pressure at a dew point are calculated.

It is also important to highlight that by considering $x = (r_{bl}, P_{bl}, T_H)^T$ as action variables vector among the 9 potential input nodes (Figure 4), only two internal nodes are not visited during the gradient calculation. Such nodes would be visited if $T_A$ was included as an action variable. Consequently, assuming $n = 3$ as the baseline case, adding one additional action variable ($n = 4$) or up to five additional variables ($n = 9$) should not significantly affect the computational cost of the gradient calculation.

## Robustness and runtime

In this section, it is decided to discuss the case with $n = 3$ since it included the highest number of internal nodes for gradient calculation in AAM. In terms of robustness, in Figure 6 it is observed that only three approaches were able to reach 30 optimal runs for each benchmark function: analytical adjoint mode, and centered differences with a perturbation step of $10^{-2}$ and $10^{-3}$.

Optimization times for these three approaches are presented in Figure 7. At a first glance, it is observed that for the Sphere and Exponential functions, the computation time of analytical adjoint mode is reduced by 35%. In the case of the Rosenbrock function, centered differences with a perturbation step of $10^{-2}$ outperforms by 26% analytical adjoint mode and by 49% centered differences with a perturbation step of $10^{-3}$.

It is worth noting that even when using AAM, the optimization time may not follow the trends presented in Figure 5. This is due to the fact that the SLSQP algorithm may require substantially more evaluations of the objective function than of its gradient. This disparity arises because, at each major iteration, SLSQP typically computes the gradient only once to form the quadratic programming subproblem, whereas the objective function may be evaluated multiple times during the subsequent line search and step acceptance procedures. In particular, candidate step lengths along the computed search direction are repeatedly probed to enforce sufficient decrease in a merit function that combines the objective value with constraint or bound violation measures.

## CONCLUSION

This work demonstrates the feasibility and benefits of coupling analytical derivatives with the adjoint mode of automatic differentiation in modular process simulators. The proposed non-intrusive methodology enables efficient and robust gradient computation without modifying the internal structure of existing simulation tools. Through a combined heat and power cycle case study, the analytical adjoint approach was shown to outperform finite difference methods in terms of computational efficiency and robustness, particularly for problems with multiple decision variables. While finite difference schemes can occasionally achieve competitive performance, they require careful tuning of perturbation steps, which increases overall optimization effort. In contrast, the analytical adjoint method provides consistent accuracy and favorable scaling properties without additional sensitivity analysis. These results confirm the strong potential of adjoint-based analytical differentiation as a practical solution for gradient-based optimization in industrial modular process simulation environments.

## ABSTRACT

High-throughput analysis of microfluidic droplets and bubbles is essential for chemical engineering but remains challenging due to the inherent loss of high-frequency details in standard deep learning models. This study proposes a novel Hand-crafted Feature Fusion framework that explicitly integrates physical priors, specifically Local Binary Patterns and Discrete Wavelet Transform, into a two-stage instance segmentation network. We design an adaptive attention-based fusion module embedded within both the Feature Pyramid Network and Region Proposal Network to synergize explicit texture cues with implicit semantic features. Validated on a large-scale dataset comprising over 64000 instances, our method achieves a test mAP of 0.808, significantly outperforming state-of-the-art architectures. Crucially, the framework effectively resolves the detection bottleneck for minute targets and elevates the small-object accuracy to 0.764, representing an improvement of nearly 20% over the baseline. This work demonstrates that incorporating physical priors offers a superior strategy for precise scientific image analysis compared to generic data-driven models.

## 1. INTRODUCTION

Microfluidics involves manipulating fluids at the micrometer scale (typically 10–100 μm), creating a high surface-area-to-volume ratio. This configuration enables superior mass and heat transfer and a narrow residence time distribution (RTD) [1]. Consequently, microfluidics has become a critical platform in chemical engineering, biomedicine, and materials synthesis. The properties of the dispersed phase, such as size, flow pattern, and velocity, are key determinants of mechanistic understanding and product quality in both research and industry. Therefore, high-speed cameras coupled with microscopy serve as a primary means of capturing this essential information.

This high-speed imaging inherently generates a prohibitive volume of visual data, typically yielding thousands of frames per second. Conventionally, quantitative analysis relied on manual measurement using software tools such as ImageJ. While effective for small datasets, this laborious workflow is time-consuming and prone to subjective bias, creating a significant bottleneck for high-throughput analysis. To overcome the limitations of manual measurement, the field initially adopted traditional computer vision algorithms such as Canny edge detection and Watershed segmentation. These methods rely on explicitly engineered hand-crafted features and operate by detecting low-level attributes like pixel-intensity gradients or geometric contours. Although these rule-based algorithms offer mathematical interpretability, they inherently lack the adaptability required to distinguish targets effectively within complex or noisy microfluidic backgrounds.

The subsequent emergence of deep learning precipitated a fundamental shift from manual feature engineering to automatic representation learning. Convolutional Neural Networks (CNNs), such as YOLO and Mask R-CNN, surpassed earlier methods by extracting hierarchical features directly from raw data. More recently, this evolution has extended to large-scale Transformer-based architectures, such as the Segment Anything Model (SAM), which leverage self-attention mechanisms to capture global context. However, while these data-driven approaches provide enhanced robustness and

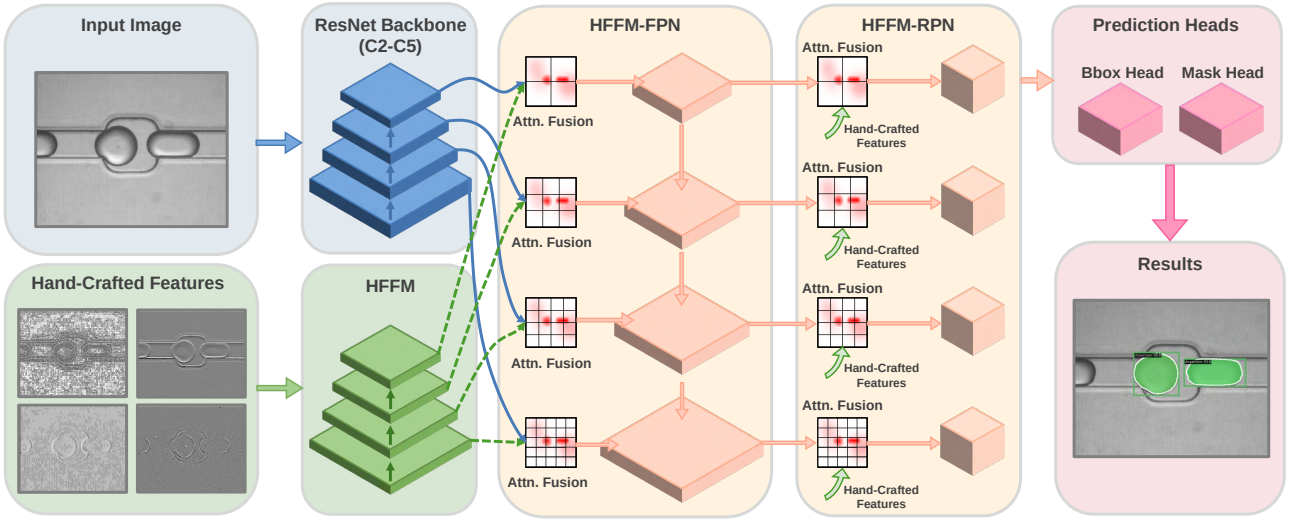

**Figure 1:** Overview of our proposed HFFM-Intergrated model.

end-to-end automation, they often obscure the precise physical priors explicitly preserved by traditional mathematical operators. This limitation suggests that relying solely on implicit deep features may be insufficient for high-precision microfluidic analysis.

To address these challenges, this study aims to explicitly integrate hand-crafted physical priors into a deep learning architecture, thereby enhancing model robustness and interpretability in complex microfluidic scenarios. The primary contributions of this work are summarized as follows:

1. HFFM-Integrated model: We propose a deep learning-based instance segmentation framework that explicitly integrates hand-crafted features. Through the proposed Hand-crafted Feature Fusion Module (HFFM), the model effectively fuses explicit physical prior knowledge with implicit deep representations. This synergy enhances robustness and interpretability in complex microfluidic scenarios without altering the core backbone of the detection architecture.

2. Attention-based embedding mechanism: We design a specialized attention-based weighting scheme to govern the feature fusion process. This mechanism allows the model to adaptively assess the relevance of hand-crafted inputs and effectively bridges the semantic gap between explicit physical descriptors and implicit deep features.

3. Generalized dual-stage integration strategy: We introduce a hierarchical fusion framework tailored for two-stage detectors. This strategy incorporates the fusion module into the Feature Pyramid Network for multi-scale feature alignment and restructures the Region Proposal Network with a guided anchoring mechanism, strictly enforcing physical constraints during proposal generation.

## 2. METHODS

The overall architecture of the proposed framework is illustrated in Figure 1. While adhering to the fundamental paradigm of two-stage instance segmentation methods, our approach distinguishes itself from conventional models that rely solely on implicit deep learning for feature extraction. To complement these deep representations, we introduce an auxiliary hand-crafted feature extraction branch explicitly designed to capture texture and edge information. To synergize these dual streams, we propose the hand-crafted feature fusion module, which performs dimensional alignment and adaptive fusion of the heterogeneous features. This mechanism is strategically integrated into the Feature Pyramid Network and the Region Proposal Network to strictly enforce physical constraints. A detailed description of these components follows.

### 2.1 Overall Architecture

Current methodologies in instance segmentation can be primarily categorized into three distinct paradigms comprising one-stage detectors, query-based transformers, and two-stage frameworks. One-stage detectors typified by SOLO and PolarMask prioritize computational efficiency by formulating detection as a dense regression problem in a single pass. However, this speed often comes at the cost of localization precision particularly for minute targets. Recently, query-based approaches such as DETR have emerged by leveraging self-attention mechanisms to capture global context. Despite their potential, these transformer-based architectures typically lack the inductive biases inherent in convolutional neural networks resulting in high data

dependency and slow convergence which constitute significant drawbacks for microfluidic applications where annotated data is often scarce. Conversely, two-stage frameworks operate on a robust coarse-to-fine philosophy where region proposals are first generated and subsequently refined.

We adopt the two-stage Mask R-CNN [2] as our baseline framework, as it offers a superior balance of stability, data efficiency, and segmentation accuracy. The workflow initiates with a convolutional backbone, such as ResNet, which extracts hierarchical features. These features are further enhanced by a Feature Pyramid Network to accommodate the multi-scale nature of microfluidic droplets and bubbles. Subsequently, the multi-scale features are then processed by the Region Proposal Network to generate a sparse set of candidate regions of interest effectively filtering out background noise. To ensure pixel-level precision, the architecture incorporates the RoIAlign layer which is a critical mechanism that eliminates the quantization errors associated with traditional pooling operations by preserving exact spatial alignment. Finally, the aligned features are fed into parallel multi-task heads to simultaneously predict class labels, regress bounding box coordinates, and generate binary segmentation masks.

## 2.2 Hand-crafted Features

Although deep learning architectures excel at extracting semantic representations, they inherently suffer from the erosion of high-frequency details due to successive down-sampling and pooling operations [3]. This information loss is particularly detrimental in microfluidics, where the precise delineation of phase boundaries and internal morphology is critical. To mitigate this limitation, we explicitly incorporate hand-crafted feature extraction to capture texture and frequency-domain attributes, serving as immutable physical priors. Specifically, we employ Local Binary Patterns (LBP) and the Discrete Wavelet Transform (DWT) as primary descriptors to complement deep features.

### 2.2.1 LBP Feature

Local Binary Patterns serve as a robust texture descriptor that characterizes the local spatial structure of the images [4]. The LBP code is derived by evaluating the local difference between the center pixel and its neighbors, formulated as:

$$LBP_{P,R} = \sum_{p=0}^{P-1} s(g_p - g_c) \cdot 2^p \quad (1)$$

Where $g_c$ denote the gray-level value of the center pixel and $g_p$ $(p = 0, \dots, P-1)$ represent the gray values of $P$ equally spaced sampling points on a circle of radius $R$. And $s(x)$ is the sign function, defined as:

$$s(x) = \begin{cases} 1, if\ x \geq 0 \\ 0, if\ x < 0 \end{cases} \quad (2)$$

In this calculation, the term $s(g_p - g_c)$ effectively captures the local gradient direction. By assigning a binomial weight $2^p$ to each position, the operator transforms the topological relationship of the neighborhood into a unique integer value.

A concrete instance of this calculation process is illustrated in Figure 2(a). For a standard $3 \times 3$ neighborhood, taking the central pixel with an intensity of 6 as the threshold, neighbors are compared against this center. Sequentially collecting these bits produces the binary pattern "11110001", which corresponds to the decimal value 241.In this study, we employ a configuration of $(P = 8, R = 1)$ to capture fine-grained details. The practical efficacy of this approach is demonstrated in Figure 2(b). While the raw microfluidic image exhibits subtle phase boundaries, the LBP-transformed image significantly enhances these high-frequency edge features while suppressing low-frequency background variations, thereby facilitating more precise segmentation.

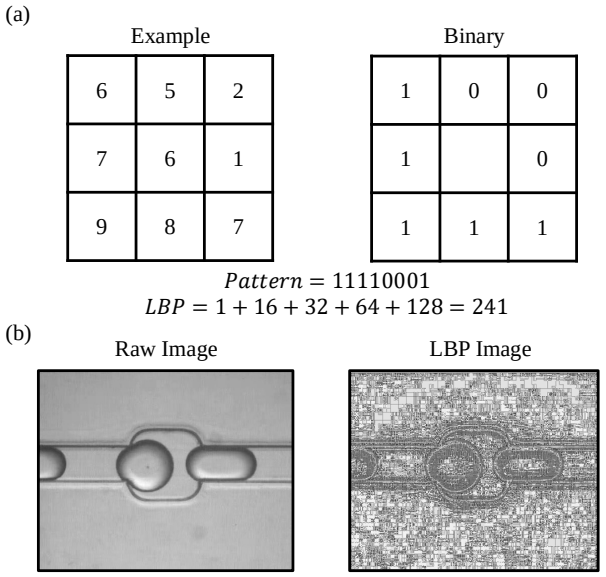

**Figure 2:** Illustration of the Local Binary Pattern operator. (a) Schematic representation of the LBP calculation process within a $3 \times 3$ neighborhood. (b) Visual comparison showing the efficacy of LBP in enhancing high-frequency edge features against the original image.

### 2.2.2 DWT Features

Discrete Wavelet Transform is utilized to decompose the input image into orthogonal frequency subbands, allowing for the separation of high-frequency edge information from low-frequency background [5]. Mathematically, the 2D-DWT operation on an input image $I$ can be succinctly expressed as:

$$\{LL, LH, HL, HH\} = \mathrm{DWT}(I) \tag{3}$$

In this decomposition, the $LL$ component retains the low-frequency global topology, while the detail components $LH, HL$, and $HH$ capture high-frequency features corresponding to horizontal, vertical, and diagonal edges respectively. Figure 3 visually underscores this distinct separation where the low-frequency component is dominated by smooth background intensity while the high-frequency sub-bands collectively isolate the sharp intensity gradients characteristic of phase boundaries. Consequently, we explicitly prioritize these high-frequency details to provide the network with a robust structural guide for precise edge delineation, effectively discarding the redundant background information present in the low-frequency approximation.

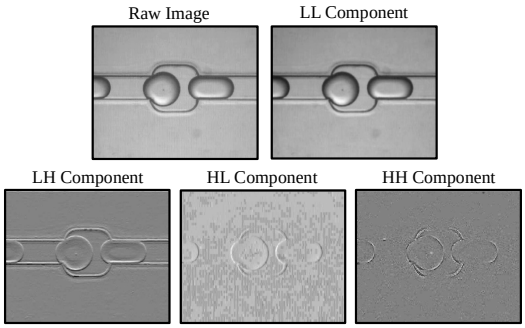

**Figure 3:** Visualization of the 2D-DWT decomposition.

## 2.3 Hand-crafted Feature Fusion Module

The core objective of the proposed Hand-crafted Feature Fusion Module is to synergistically integrate the explicit physical priors extracted by traditional operators with the implicit representations learned by the deep neural network. Within the standard convolutional backbone, the generated feature hierarchy inherently exhibits a trade-off between resolution and semantic abstraction where deeper feature maps possess reduced spatial dimensions but enriched semantic information while shallower feature maps retain high-resolution spatial details yet lack high-level contextual understanding.

To address this hierarchical discrepancy, the HFFM first implements a multi-level alignment strategy utilizing simple convolutional layers to independently project the raw hand-crafted features onto the varying spatial resolutions and channel dimensions corresponding to different stages of the feature pyramid. Following this dense alignment, we employ a specialized attention-based fusion mechanism rather than naive element-wise addition to integrate these heterogeneous features. This attention mechanism dynamically generates spatial weight maps to selectively emphasize regions rich in high-frequency textural and structural details effectively filtering out irrelevant background noise. By guiding the network to focus specifically on the informative boundary cues provided by the physical priors, this strategy ensures that the hand-crafted features are robustly incorporated into the deep representation space at every scale of the network.

## 2.4 Dual-Stage Fusion Strategy

To maximize the efficacy of the proposed physical priors, we deploy a dual-stage integration strategy that embeds the HFFM into both the feature enhancement and region proposal phases as shown in Figure 1. In the first stage, the integration is performed within the Feature Pyramid Network where the hierarchical feature maps generated by the backbone are fed into the HFFM alongside the hand-crafted priors. This early-stage fusion serves to fundamentally enrich the foundational feature representation to ensure that the multi-scale pyramidal features are imbued with explicit structural cues before reaching any downstream functional heads.

In the second stage, we restructure the Region Proposal Network to further exploit these enhanced features by replacing the standard anchor generation mechanism with the Guided Anchoring strategy [6]. This modification is essential because the conventional fixed heuristic is often ill-suited for the irregular and deformable shapes of microfluidic droplets and bubbles. Unlike rigid sliding windows, this mechanism dynamically predicts the probability of object presence and regresses the optimal anchor shapes based on the underlying image semantics. Crucially, we substitute the standard input features of the anchor generation branch with our physically-enhanced fused feature maps to leverage the sharpened edge information and texture details. This integration directs the Guided Anchoring module to generate proposals that are not only spatially adaptive but also strictly aligned with the actual physical boundaries of the dispersed phase thereby improving the quality of the initial candidate regions.

# 3. RESULTS AND DISCUSSIONS

## 3.1 Dataset Construction and Statistical Overview

To rigorously validate the efficacy of the proposed method in real-world scenarios, we curate a comprehensive dataset specifically focused on microfluidic bubbles and droplets. This dataset encompasses over 2200 high-resolution images aggregating to more than 64000 individual targets. To ensure consistent evaluation standards, all collected instances are meticulously annotated manually and unified under the single category of "dispersion". For experimental purposes, the dataset is randomly partitioned into training, validation, and testing subsets following a ratio of 60%, 20%, and 20%

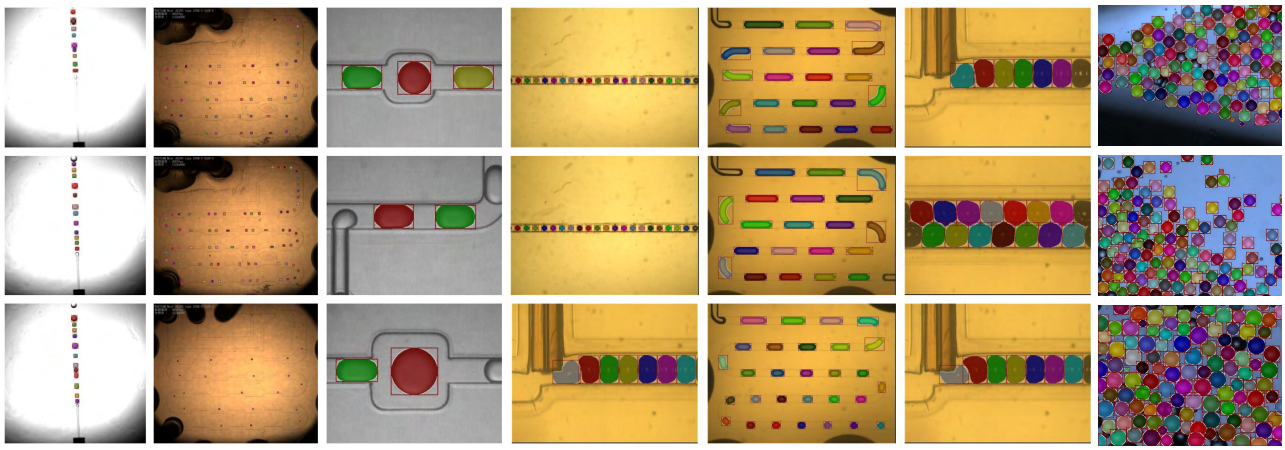

**Figure 4:** Overview of the constructed microfluidic dataset.

respectively.

As illustrated in Figure 5, we analyze the distribution of critical attributes across these subsets, including instance counts, object area ratios, and aspect ratios. The visualization confirms that there is no significant statistical divergence among the three subsets, indicating a homogeneous data distribution. This consistency ensures that the subsequent evaluation results accurately reflect the model's true generalization capability rather than artifacts of dataset bias.

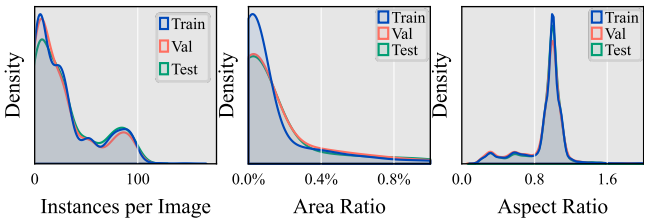

**Figure 5:** Statistical overview of the constructed microfluidic dataset.

## 3.2 Training and Evaluation Metrics

To strictly benchmark the performance of the proposed HFFM-Integrated framework, we conduct comparative experiments against a diverse suite of state-of-the-art (SOTA) instance segmentation models. To ensure a unified and fair evaluation, all architectures are implemented within the MMDetection framework and are trained under identical environmental settings. Furthermore, to accelerate model convergence and bolster generalization, the backbone networks are initialized with weights pre-trained on the COCO dataset [7].

To quantitatively assess the performance of the proposed framework, we employ the standard evaluation protocols defined by the Microsoft COCO dataset. The primary metrics utilized are Mean Average Precision (mAP) and Mean Average Recall (mAR), which serve as rigorous indicators of segmentation accuracy. mAP reflects the model's ability to correctly identify and precisely delineate target boundaries without generating false positives, while mAR indicates the model's success in capturing all existing dispersed phases within a frame.

These metrics are fundamentally derived from the Intersection-over-Union (IoU), defined as the ratio of the intersection area to the union area between the predicted mask and the ground truth:

$$IoU = \frac{\text{Area}(\text{Pred} \cap \text{GT})}{\text{Area}\ (\text{Pred} \cup \text{GT})} \tag{4}$$

Based on the IoU thresholds, the predictions can be classified into True Positives (TP), False Positives (FP), and False Negatives (FN). The Average Precision ($AP_{IoU}$) and Average Recall ($\text{AR}_{IoU}$) are subsequently calculated as:

$$AP_{IoU} = \frac{TP}{TP + FP} \tag{5}$$

$$AR_{IoU} = \frac{TP}{TP + FN} \tag{6}$$

And the mAP and mAR are calculated by averaging the AP over 10 distinct IoU thresholds ranging from 0.50 to 0.95 with a step size of 0.05:

$$mAP = \frac{1}{10}\sum_{i=0}^{9} AP_{IoU=0.50+0.05\times i} \tag{7}$$

$$mAR = \frac{1}{10}\sum_{i=0}^{9} AR_{IoU=0.50+0.05\times i} \tag{8}$$

Furthermore, given the significant scale variations inherent in microfluidic dispersed phases, we conduct a stratified analysis based on object size. We report $AP_S, AP_M$, and $AP_L$ for objects with pixel areas less than $32^2$, between $32^2$ and $96^2$, and greater than $96^2$, respectively. This granular breakdown allows for a specific assessment of the model's robustness in detecting minute

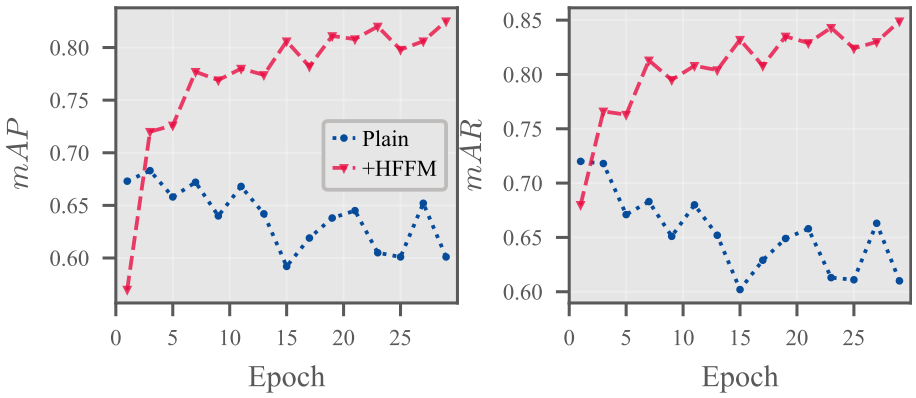

**Figure 6:** Comparative evaluation of detection accuracy.

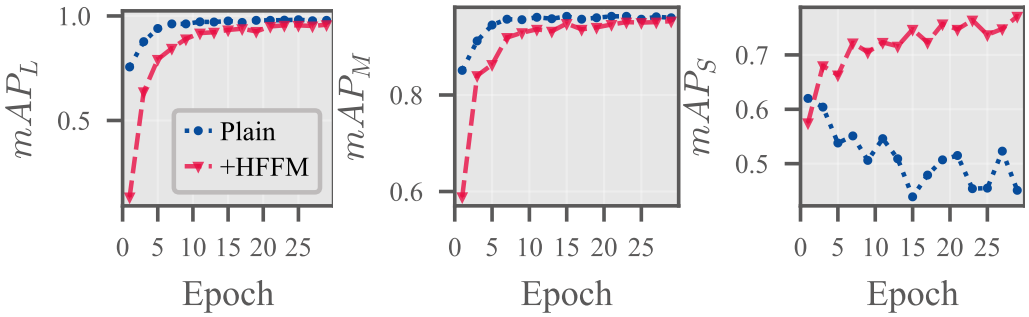

**Figure 7:** Comparative evaluation of detection accuracy stratified by object size.

targets.

## 3.3 Training Curves

The training progression of our proposed framework versus the baseline is visualized in Figure 6. As evidenced by the curves, the baseline model (denoted as 'Plain') exhibits a tendency to plateau early, consistently fluctuating within the 0.60–0.70 range for both mAP and mAR without showing further convergence. In contrast, the HFFM-Integrated model catalyzes a significant performance leap. Despite a brief initial adjustment period, the proposed model establishes a robust and monotonic upward trajectory, rapidly surpassing the baseline around the 3rd epoch and steadily converging to high-performance values exceeding 0.80. This substantial margin validates that the explicit injection of physical priors effectively prevents the network from stagnating in local optima, resulting in superior global precision and recall. To rigorously deconstruct the source of these performance gains and strictly verify whether the hand-crafted features successfully enhance the detection different scales of targets as hypothesized, it is imperative to conduct a stratified evaluation based on object size metrics.

To investigate the underlying drivers of the performance improvement, we further deconstruct the evaluation metrics based on object scale as illustrated in Figure 7. The comparative curves for large ($mAP_L$) and medium ($mAP_M$) targets reveal that both the baseline and the proposed framework achieve high saturation levels, with detection accuracy exceeding 0.95. In these categories, the baseline model already exhibits robust performance, indicating that deep semantic features are sufficiently distinct for identifying prominent dispersed phases. However, a striking disparity emerges in the small-object regime ($mAP_S$). As clearly depicted in the rightmost subplot, the baseline model struggles significantly to resolve minute targets, suffering from severe instability and failing to surpass 0.60 after the initial training phase. This degradation corroborates the limitation of standard CNN architectures, where successive downsampling erodes the spatial cues necessary for detecting small-scale features. In sharp contrast, the HFFM-Integrated model maintains a vigorous upward trajectory for $mAP_S$, steadily converging to approximately 0.78. This substantial margin, representing an improvement of nearly 20% over the baseline, provides empirical evidence that the fused hand-crafted physical priors successfully preserve high-frequency edge details. Consequently, the proposed method effectively recovers the detection capability for micro-scale targets that are otherwise lost in the deep feature hierarchy.

**Table 1:** Comparison with SOTA models and ablation study on test set.

| Methods | | Val | | | | Test | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | $mAP$ | $mAR$ | $mAP_S$ | $mAR_S$ | $mAP$ | $mAR$ | $mAP_S$ | $mAR_S$ |
| Mask R-CNN Based | Plain | 0.741 | 0.788 | 0.693 | 0.744 | 0.613 | 0.649 | 0.55 | 0.585 |
| | +HFFM FPN | 0.811 | 0.837 | 0.752 | 0.787 | 0.751 | 0.773 | 0.686 | 0.717 |
| | +HFFM RPN | 0.819 | 0.845 | 0.769 | 0.799 | 0.798 | 0.824 | 0.750 | 0.782 |
| | +HFFM (Both) | **0.825** | **0.849** | **0.771** | **0.802** | **0.808** | **0.834** | **0.764** | **0.795** |
| SOTA Models | Mask2Former | 0.574 | 0.626 | 0.451 | 0.523 | 0.458 | 0.515 | 0.329 | 0.405 |
| | CondInst | 0.617 | 0.670 | 0.510 | 0.569 | 0.390 | 0.417 | 0.244 | 0.268 |

## 3.4 Comparison with SOTA Models and Ablation Study

To validate the superiority of the proposed framework within the specific domain of microfluidics, we conduct a comparative analysis against representative state-of-the-art architectures, including the transformer-based Mask2Former and the CNN-based CondInst. As detailed in Table 1, the quantitative results reveal a substantial performance gap favoring our approach. While Mask2Former utilizes powerful self-attention mechanisms to capture global context, it achieves a test $mAP$ of only 0.458 and a remarkably low $mAP_S$ of 0.329. In the context of microfluidics where training data is relatively scarce and targets are minute, the transformer struggles to converge on precise boundaries. Similarly, CondInst yields the lowest performance with a test $mAP$ of 0.390. In contrast, our proposed method achieves a test $mAP$ of 0.808 and a test $mAP_S$ of 0.764. This significant margin demonstrates that explicitly embedding hand-crafted physical priors into a stable two-stage baseline is a far more effective strategy for scientific image analysis than merely applying complex generic deep learning models.

To rigorously decouple the individual contributions of the Hand-crafted Feature Fusion Module at different stages of the detection pipeline, we perform an ablation study as summarized in the upper section of Table 1. The baseline Mask R-CNN, denoted as Plain, establishes a starting performance of 0.613 for test mAP. The first experimental configuration introduces the HFFM solely into the Feature Pyramid Network. This integration results in a significant performance boost, raising the test mAP to 0.751. This improvement verifies that injecting texture and edge cues at the feature extraction level fundamentally enriches the representational power of the network. Subsequently, we evaluate the impact of integrating the HFFM exclusively into the Region Proposal Network to guide anchor generation. This configuration yields a test mAP of 0.798, indicating that physically-guided proposals are critical for reducing false negatives and accurately localizing small targets. Finally, the complete architecture which synergistically combines HFFM in both the FPN and RPN achieves the highest performance metrics across all categories with a test mAP of 0.808 and a test $mAP_S$ of 0.764. These results confirm that the dual-stage fusion strategy offers a complementary gain where the FPN enhances feature discriminability while the RPN ensures precise spatial localization.

## 3.5 Qualitive Analysis

To provide an intuitive understanding of how the hand-crafted features enhances the network's representational capability, we visualize the qualitative detection results and the corresponding intermediate feature maps in Figure 8. The bottom row compares the feature maps at FPN Level 0, which is the critical stage for retaining high-resolution spatial details. As observed in the bottom-right subfigure, the feature map of the plain model appears diffuse and lacks structural definition, indicating that the subtle boundaries of the targets are eroded during the feature extraction process. In sharp contrast, the HFFM-Integrated model (bottom-left) exhibits distinct, high-contrast activations that precisely delineate the serpentine channel structure and the individual droplets. This visual evidence confirms that the attention-based fusion successfully injects the hand-crafted physical priors into the deep feature hierarchy. Consequently, this enhanced feature discriminability directly translates to the superior detection performance shown in the top row. While the Plain model misses minute targets or generates ambiguous bounding boxes in low-contrast regions, the HFFM-Integrated model demonstrates robust localization capabilities, accurately capturing the targets with high fidelity.

## 3.6 Computational Efficiency

To evaluate the impact of the introduced modules on inference speed, we conduct a comprehensive benchmark comparing the baseline Mask R-CNN with our HFFM-Integrated model. For a fair comparison, all input images are resized to 512×512 pixels, and testing is performed on an NVIDIA RTX 5880 Ada GPU. The stage-wise results are summarized in Table 2.

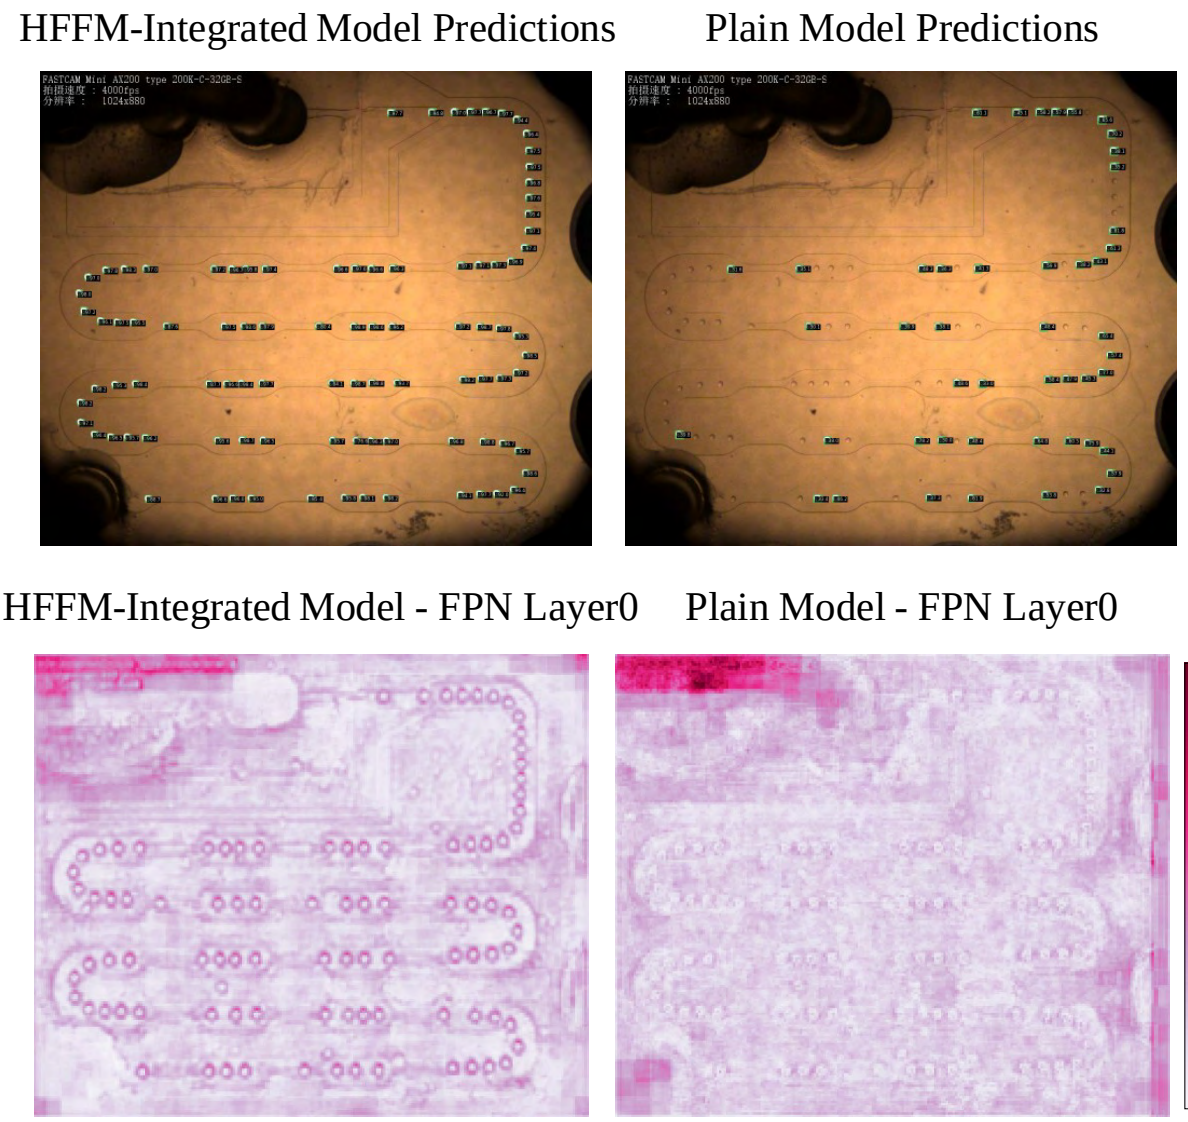

**Figure 8:** Visualization of detection results and intermediate outputs.

**Table 2:** Comparison of inference latency between models (ms).

| Stage (ms) | Plain | +HFFM |
|---|---|---|
| Image Read | 3.46 | 3.58 |
| Preprocess | 4.41 | 8.53 |
| Backbone | 4.92 | 5.09 |
| FPN | 0.73 | 2.81 |
| RPN | 0.80 | 8.46 |
| Prediction Heads | 7.00 | 9.95 |
| Total | 21.32 | 38.41 |

The results indicate that the integration of handcrafted features and the Guided Anchoring mechanism introduces a computational overhead of approximately 17 ms per image. This latency represents a strategic trade-off. While the plain model is slightly faster, our proposed framework ensures a more stable training process and significantly faster convergence.

## 4. CONCLUSIONS

In this study, we propose a novel HFFM-Integrated instance segmentation framework that synergistically integrates explicit physical priors with implicit deep representations. By embedding Local Binary Patterns and Discrete Wavelet Transform into the deep learning pipeline, our approach effectively compensates for the erosion of texture and boundary details caused by down-sampling operations. Comprehensive evaluations on our constructed dataset comprising over 64000 instances

demonstrate the framework's superiority. Our method achieves a test $mAP$ of 0.808, significantly outperforming state-of-the-art architectures like Mask2Former and CondInst. Most notably, the proposed strategy effectively resolves the detection bottleneck for small-scale targets, elevating the $mAP_S$ to 0.764. These findings confirm that injecting domain-specific physical constraints is a highly effective strategy for scientific image analysis, superior to relying solely on generic deep models. Ultimately, this study provides a robust, high-precision tool for automated microfluidic monitoring, paving the way for more accurate mechanistic studies in microreaction.

While the current performance is substantial, there is still progress needed to reach an ideal accuracy of 0.99. This gap primarily stems from the inherent complexity of the microfluidic dataset, which encompasses targets with vast disparities in size, geometric morphology, and experimental conditions. Achieving absolute saturation in precision remains a persistent challenge even in mainstream computer vision benchmarks like COCO. Consequently, future research focuses on developing even more robust, multi-scale deep learning architectures to capture these diverse dispersed phases more effectively across various flow regimes. Furthermore, although the integration of physical priors introduces a manageable computational overhead of approximately 17 ms per image, optimizing inference efficiency remains a priority for ultra-high-speed monitoring. Future efforts involve transitioning the current CPU-bound preprocessing operations, specifically the LBP and DWT transformations to high-performance GPU CUDA kernels to maximize real-time processing capability for online chemical process analysis.

## ABSTRACT

Type your abstract text here. This work presents an essential methodological framework oriented to the implementation of sustainability promotion measures in process industries. It makes use of a previously developed paradigm, designated as Water and Energy Integration Systems (WEIS), which are fundamentally conceptual systems based on the implementation of several technologies implemented with the end to minimize water use, energy use and related environmental burdens. The primarily conceptual nature of these systems is significant that these have not been significantly implemented in real-life, and that these have been essentially implemented in the virtual basis of digital twin-based computational models. This work extensively presents a methodology developed for the assessment of the integrity of WEIS models, which have been developed using the capacities of a customised computational tool designated as ThermWatt. Two previously approached case-studies have been considered to perform a proof-of-concept in respect to the applicability of the delineated methodology. The delineated methodology proved to be adequate for the whole process of the elaboration of the WEIS Engineering projects, paving way to the implementation of these in real-life in a future perspective.

**Keywords**: Water and energy integration systems, simulation, optimisation, model integrity, sustainability promotion

## INTRODUCTION

This is Header 2Water and Energy Integration Systems (WEIS) subsist in complex installations to be installed in end-use sector facilities set to perform the maximum use of the recirculation of waste heat and water streams for the purpose of causing an overall sustainability promotion. These systems use a set of technologies that may be used in the context of the exploitation of the interdependencies of energy and water resources, as encompassed by the concept of water-energy nexus [1].

The WEIS paradigm was introduced and extensively developed in previous works developed by the authors [2], along with the tool created for the purpose of modelling, the ThermWatt computational tool [3]. This tool subsists in several simulation and optimisation models created in the Modelica and Python languages, which fundamentally serve as digital twins of real-life installations.

The duality between the WEIS paradigm and the ThermWatt tool has been making possible the existence of a complex framework in which the viability associated to sustainability promotion technologies-based systems is set to be firstly assessed in a virtual basis. In this sense, it is possible to develop proposals of systems that promote overall sustainability in a site with minimized requirements of real-life testing of technologies to be implemented. Owing to the primarily conceptual nature of the WEIS paradigm, the assurance of the integrity of computational models of this type of systems is essential

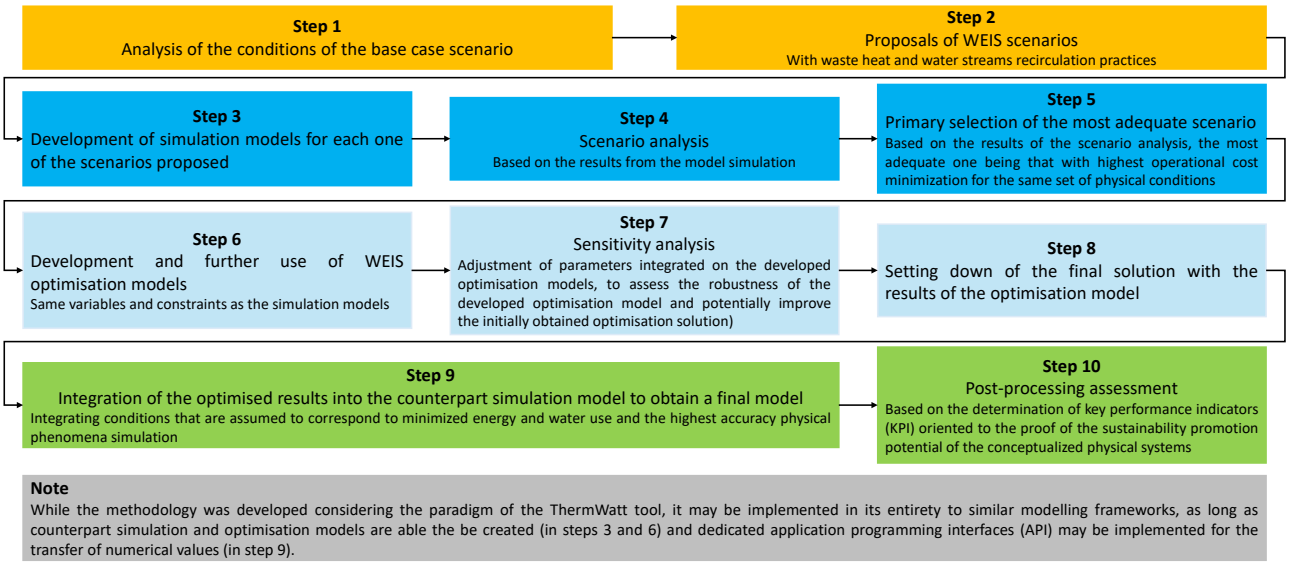

**Figure 1.** Methodology for model integrity assessment

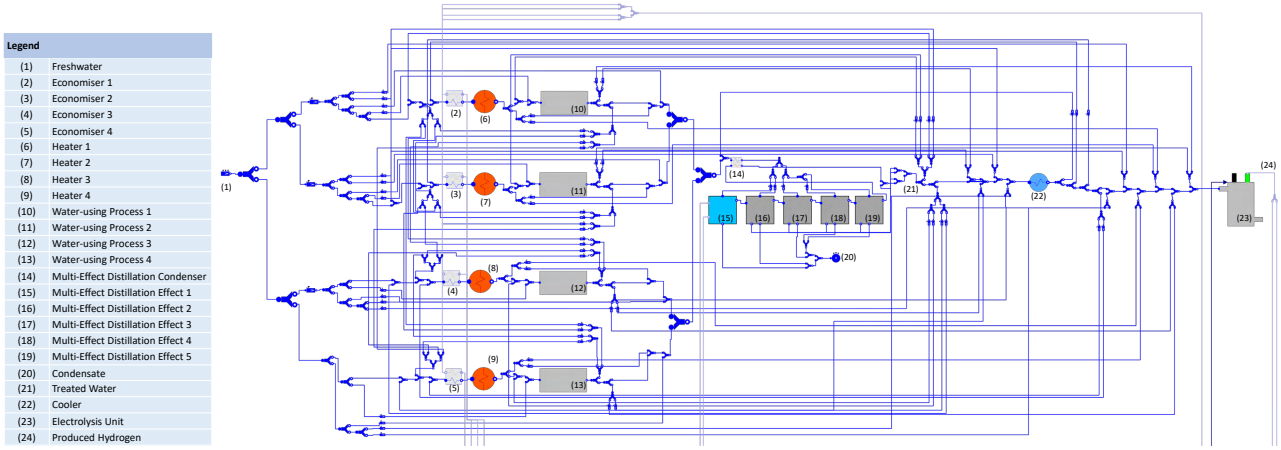

**Figure 2.** Water system side of both WEIS Scenarios 1 and 2 for Case-study 1 (flowsheet-based model created using the capabilities of the ThermWatt tool)

to proceed with the most accurate analysis of the physical phenomena inherent to these systems and the assessment of the sustainability promotion potential of these.

In this work, the methodology developed for the purpose of assessing the integrity of WEIS models is extensively presented. A set of results related to two case-studies within the Portuguese process industry (namely a ceramic plant) are presented and furtherly used to prove the applicability of the developed methodology.

## METHODOLOGY

The assessment of the potential implementation of Water and Energy Integration Systems (WEIS) must subsist on a methodology that is set to allow the whole process from the initial analysis of a case-study (which is commonly a process industry plant and its whole system comprising energy sources, energy supply, energy demand and energy-using processes) to the obtainment of indicators reflecting the sustainability promotion potential brought by the implementation of such systems. In the context of the integration of computational model (which has been the main form of study of the implementation of WEIS, owing to the mostly still conceptual nature of these systems), the implementation of such methodology requires the development of validated and useful models. As such, the delineation of such methodology requires that this is not only one oriented to the assessment of the potential implementation of WEIS Engineering projects but also to the evaluation of the integrity of computational models of these systems.

In Figure 1, the methodology inherent to the process of WEIS model integrity evaluation (and, in this prospect,

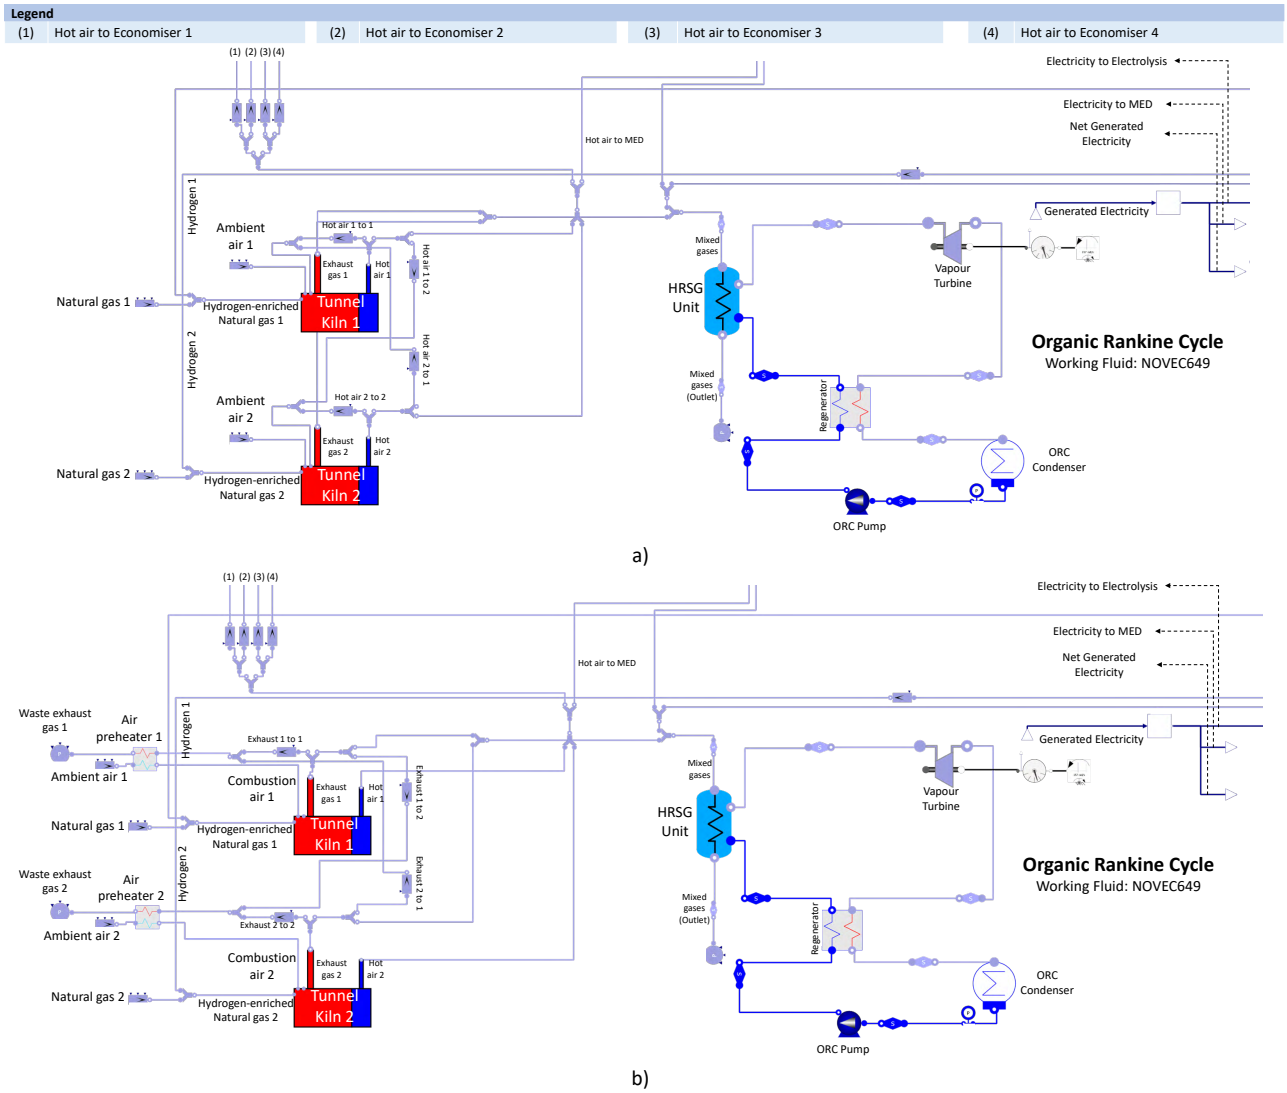

**Figure 3:** WEIS (Thermal system side) a) Scenario 1 and b) Scenario 2 for Case-study 1 (flowsheet-based model created using the capabilities of the ThermWatt tool)

the assessment of the potential implementation of WEIS within specific case-studies) is extensively detailed.

The development of all the previous works within the overall topic of Water and Energy Integration Systems [2, 3] have subsisted on the application of the afore identified methodology in a subtle manner. The delineation of this methodology which serves as the main subject of this work serves as a manner to turn accessible the implementation of the WEIS paradigm by interested parts of scientific communities, as well as interested parts from end-use sectors representatives.

In the prospect to assess model integrity, the methodology delineated in Figure 1 must be implemented in an aggregated manner, in which the application of each one of the delineated steps converges in the proof of integrity of a developed modelling framework. The quality of a model to be integrate subsists on the verification of the following aspects:

- Simulation-based scenarios must be able to generate most favourable results in comparison to the base case scenarios;
- Optimisation results must be overall more favourable in comparison to the results generated by running of the corresponding simulation models;
- Models are valid, according to the comparison between real-life and simulation data;
- The sustainability promotion capacity (economic, environmental and social pillars) associated to WEIS implementation must not be compromised by the application of the overall modelling framework.

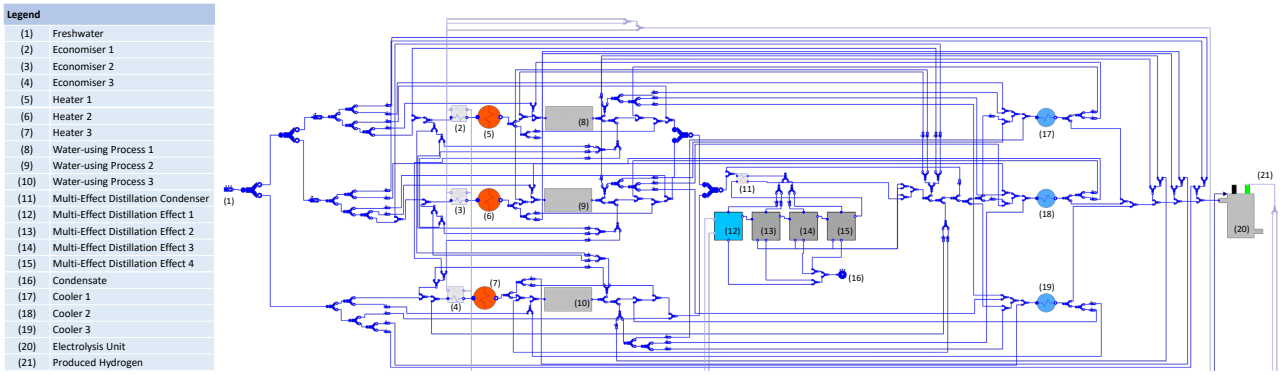

**Figure 4.** Water system side of both WEIS Scenarios 1 and 2 for Case-study 2 (flowsheet-based model created using the capabilities of the ThermWatt tool)

## BACKGROUND

In the prospect to perform a proof of concept of the WEIS paradigm, a set of two process industry-oriented case-studies have been approached. Both these case-studies are set in a Portuguese ceramic plant, has been exploited through the development and further use of simulation and optimisation models (integrated in the ThermWatt computational tool), followed by a complex post-processing assessment based on the evaluation of the viability associated to proposed WEIS.

The afore proposed methodology has been implemented for both case-studies (up until step 3). For both case-studies, the conceptualized WEIS consider the implementation of:

- An Organic Rankine cycle (ORC) to generate electricity;
- A multi-effect distillation (MED) unit for removal of contaminants (salts) from wastewater streams (and thus to produce treated water streams with negligible concentration of contaminants);
- An Electrolysis unit to produce hydrogen streams from treated water streams, which are then blend with the natural gas fuel streams at the inlet of the combustion-based processes.

For case-study 1, the conceptualized WEIS specifically considers:

- A steady-state perspective (owing to the inexistence of combustion-based processes operating in batch);
- Two tunnel kilns as combustion-based processes;
- Four water-using lines (each one encompassing a heater and a water-using process), which are mixed in single water-using line which is then cooled down in a cooler;
- The recirculation of the waste heat streams (either exhaust gas or hot air) to constitute additional energy inputs in combustion-based processes with direct mixture with inlet combustion air (Scenario 1) or by the implementation of air preheaters (Scenario 2).

- For case-study 2, the conceptualized WEIS specifically considers:
- A transient-state/ dynamic perspective (owing to the existence of batch combustion-based processes);
- Four combustion-based processes, two tunnel kilns and two intermittent kilns;
- Three water-using lines (each one encompassing a heater, and a water-using process and a cooler);
- The recirculation of the waste heat streams (either exhaust gas or hot air) to constitute additional energy inputs in combustion-based processes with direct mixture with inlet combustion air;
- The aforementioned streams are also recirculated to a phase change material (PCM)-based thermal energy storage (TES) unit, which is heated up by the passage of the exhaust gases (Scenario 1) or hot air (Scenario 2) streams (while the intermittent kilns are not operating) and from which thermal energy is discharged by the passage of an ambient air stream which is then distributed to each one of the four combustion-based processes.

Each one of the WEIS scenarios developed for case-studies 1 are pictorially presented in the sequence of Figures 2 and 3. Each one of the WEIS scenarios developed for case-studies 1 are pictorially presented in the sequence of Figures 4 and 5.

## MODEL INTEGRITY ASSESSMENT

The assessment of model integrity associated to each one of the approached case-studies may be performed by the analysis of aggregated results. In this case, the results which may be analysed in aggregated manner and thus allow the attainment of the specific objectives of the implementation of the afore presented methodology are the energy use or production associated to each one of the energy sources of interest (natural gas use in combustion-based processes, net electricity generation, freshwater consumption and hot/ cold utility consumption), as well as the total operational costs attributed to the overall inputs of energy and water. In the context of the integration of developed computational models, the following sets of results are set to be considered for analysis:

- Base cases;
- Simulation results for each WEIS scenario;
- Initial Optimisation results obtained by the running of the developed optimisation models before sensitivity analysis;
- Optimisation results obtained by the running of the

**Table 3:** Model integrity assessment for each one of the approached case-studies

| Case-study 1 | Case-study 2 |
|---|---|
| • Scenario 1 is favoured in relation to scenario 2, owing to the relatively lower operational costs;<br>• It is possible to verify that the obtained values for the hot utility consumption in heaters 1, 2 and 3 are higher in the context of the final model, being slightly higher than the null values obtained by the previous two sets of optimisation results. Such is attributed to the different temperature of the water streams at the inlet of the mentioned three heaters on the final model, which results from the mixture of several recirculated water streams within the whole water system within the overall WEIS;<br>• These temperatures values are slightly lower on the final model (developed in the Modelica language) in relation to the optimisation models (developed with the Python languages), owing to the different modelling packages used to simulate water properties in both categories of models. Such slight decrease of temperature at the inlet of the heaters are responsible for a slight requirement of hot utility supply to achieve the objective temperature values at the outlet of the heaters. | • Scenario 2 is favoured in relation to scenario 1, owing to the relatively lower operational costs (as may be verified by the operational costs associated to the thermal process systems standalone);<br>• The results associated to each one of the parcels associated to energy use (namely the natural gas consumption in each one of the four kilns) are generally lower in the respective optimisation-based scenarios in comparison to the counterpart simulation-based scenarios (which is according to the expected verifications);<br>• The respective energy use levels are relatively higher in the final model (which also causes the total operation costs to be relatively higher). Such relative increase may be attributed to the respective methods implemented for the modelling of the PCM-TES unit in the optimisation model developed for Case-study 2 and in the equipment-level model implemented within the case-study's system-level model. The latter uses a much more accurate method, based on the finite difference method (FDM) for the modelling of heat transfer phenomena;<br>• The afore delineated verification does not considerably affect overall model integrity. The disparity between the results from the counterpart optimisation and final models may be considered a negligible difference, not affecting the balance between modelling accuracy and attainment of the highest sustainability promotion level for the approached case-study. |
| **Overall** | |
| • The implementation of all scenarios for both case-studies is set to generate significant results in terms of reduced energy and water-related operational costs in relation the base case scenario;<br>• All the sets of optimised scenarios generate more favourable results in comparison the ones obtained by simulation models (proving the primary effectiveness of the developed optimisation models);<br>• The results obtained after the sensitivity analysis correspond to a point in which the thermal-to-electric efficiency considered to assess potential electricity generation on the optimisation models is reduced in order to ensure that this parameter is certainly higher in the context of the running of the final simulation model;<br>• The aforementioned verification ensures that the definitive solution is the one associated to the minimum possible level of total operational costs, while still considering the most accurate modelling of physical phenomena. In this sense, the net generated electricity (and thus operational costs savings) is relatively lower after the performance of the sensitivity analysis;<br>• The final results (optimisation results integrated in the simulation model) correspond to significant operational costs savings, evaluated using a model proved to be accurate in terms of the simulation of physical phenomena. | |

developed optimisation models after the performance of sensitivity analysis;

- Final results obtained by the aggregated model.

In Tables 1 and 2, the aggregated results for each one of the WEIS scenarios of interest are presented. In Table 3, the aspects related to the model integrity assessment process for each one of the approached case-studies are presented.

Overall, model integrity associated to the whole modelling framework developed for each one of the case-studies may be considered to have been secured, attending that:

- All sets of simulation results are considered to be more favourable in comparison to base case scenarios (significant reduction of total operational costs);
- All sets of optimisation results are considered to be more favourable in comparison to the

counterpart simulation scenarios (considerable relative reduction of total operational costs);

- Models are valid;
- The overall modelling framework allows the attainment of final WEIS configurations that have a secured sustainability promotion capacity.

In the framework of the present work, the implementation of methodology presented in Figure 1 may be considered to have been fully fulfilled by section 3 (up until step 3) and the present section 4 (up until step 9). The sustainability assessment process (corresponding to step 10) is considered to also have been completed in the scope of the overall study inherent to this work, although such process have been mostly presented and extensively exploited in the previous related works developed by the authors [4]. In this prospect, the presentation of a significantly higher detail related to this step is considered to be unnecessary in a standalone perspective of the focus of this work. An extensive model validation procedure have been also presented in previous works (the models approached in this work are considered to be a priori valid in terms of the representation of physical phenomena) [5].

An extensive delineation of the sustainability promotion capacity associated to the implementation of the conceptualized WEIS (in respect to the proof of the attainment of benefits associated to the economic, environmental and social pillars of sustainability) is presented in the digital supplementary material (with information adapted from [5]).

## CONCLUSIONS

This work extensively presents the methodology developed for the purpose of assessing the integrity of Water and Energy Integration Systems (WEIS) computational models. Although the WEIS paradigm has been introduced and extensively exploited in previous works, the delineation of the approached methodology is fundamental for the scientific communities and end-use sectors representative to replicate similar sustainability promotion results for case-studies other than the ones that have been already exploited. The existence of such a methodology is important due to the primarily conceptual nature of the WEIS paradigm. As such, the assurance of the integrity of models of this type of systems is essential to proceed with the most accurate analysis of the physical phenomena inherent to these systems and the determination of several sustainability promotion indicators (which is the foremost final objective of these of these models).

From the analysis of aggregated results obtained by the use of computational model created for two Portuguese process industry case-studies, it is possible to affirm that:

- The running of initial simulation models for several WEIS scenarios for a same case-study allow the attainment of significant savings at the level of energy use, water use and total operational costs;
- The running of counterpart optimisation models allows the attainment of significantly more favourable results in comparison to the simulation models, with such attainment process being later refined by the consideration of results obtained after the performance of sensitivity analyses to these models;
- The integrity of the final models (through the integration of optimisation results into the counterpart simulation models, considering a compromise between the accuracy of physical phenomena modelling and optimised results) is not compromised by the allocation of numerical outputs from the optimisation models as inputs on the simulation models.

The proposed methodology may be considered adequate for the whole process of the elaboration of the Engineering projects of a WEIS, from the first step of analysing base case data to the final proof of sustainability promotion. Such is supported by the successful implementation of the delineated methodology in two real-life case-studies, having been proved that the integrity of the developed overall modelling frameworks is secured for both cases.

## ABSTRACT

This work explores Generative Flow Networks (GFlowNets) as a computational approach for sustainable fragrance design, focusing on generating novel molecules that reproduce the scent profile of vanillin while reducing reliance on resource-intensive synthesis and environmentally vulnerable natural sources. An integrated pipeline couples a GFlowNet generator with a fragrance note predictor, which guides learning toward a target odor by rewarding molecules predicted to be aromatically similar to vanillin. Chemical validity and realism are enforced through chemistry filters that penalize unstable or implausible structures and through an odorless-vs-odorant classifier, so only chemically and olfactorily plausible candidates are selected. The agent is trained in a hybrid offline–online regime, implementing reinforcement-based exploration, with hyperparameters tuned via Bayesian optimization. As an independent validation layer, an olfactory receptor docking model estimates binding affinities to receptors associated with vanillin, and several generated candidates show comparable or higher predicted affinities than vanillin while retaining structural novelty. Overall, the results suggest that GFlowNets can capture multidimensional olfactory patterns and support CAPE-style exploration of vast chemical spaces under uncertainty, enabling more efficient exploration of olfactory ingredients.

**Keywords**: GFlowNet, molecular generation, odorant design, sustainability, green chemistry, CAPE, fragrance engineering, generative AI, vanillin

## INTRODUCTION

Odors play a central role in human perception, influencing emotion, memory, and cultural experience [1-3]. Odors are central to the global fragrance and flavor industry, underpinning applications ranging from perfumes and cosmetics to food flavorings and household products [4]. The market was valued at approximately 30.61 billion USD in 2023 and is projected to grow to 44.6 billion USD by 2030 [4]. Many commercially relevant odorants rely on resource-intensive laboratory experimentation or extraction from rare and environmentally vulnerable natural sources, raising concerns related to sustainability, scalability, and long-term supply security [3].

Recent advances in artificial intelligence, particularly in generative modeling, offer new opportunities for in silico molecular design [5]. By learning from existing datasets of odorants and their associated properties, generative models can propose candidate molecules with desired sensory characteristics, potentially reducing reliance on trial-and-error laboratory synthesis. From a sustainability perspective, such approaches align with green chemistry principles by enabling the design of synthetic alternatives to naturally sourced odorants, thereby reducing environmental pressure while maintaining sensory fidelity.

Among generative approaches, Generative Flow Networks (GFlowNets) [6] have emerged as a promising framework for sampling diverse candidates from complex target distributions. They provide an alternative to conventional reinforcement learning (RL) and Markov Chain Monte Carlo methods, which often struggle in drug

discovery settings to identify diverse molecules efficiently [7]. GFlowNets are trained so that the probability of sampling a terminal molecule is proportional to its assigned reward, thereby aligning generation with the desired target distribution. Training proceeds in an active learning setting similar to RL, where an agent, typically parameterized by a graph neural network, constructs molecules through sequential actions that define trajectories [6]. This formulation supports exploration of large combinatorial chemical spaces while preserving diversity among high-reward solutions, which is particularly important in molecular design where multiple distinct structures can satisfy the same functional objective.

This work investigates the use of GFlowNets for targeted odorant generation, focusing on reproducing the characteristic vanilla scent associated with vanillin. Vanilla is among the most widely preferred odor profiles across cultures [8], and the interactions between vanillin and multiple olfactory receptors have been well studied in prior work, making it a well-suited reference target for this project [9]. We present a GFlowNet pipeline that integrates learned olfactory representations, explicit chemical validity constraints, and an independent bio-informed validation step, enabling the generation of structurally novel candidates consistent with the desired sensory profile.

## BACKGROUND AND RELATED WORK

Computational approaches to odor modeling have gained increasing attention. Graph neural network-based models have demonstrated the ability to embed molecules into high-dimensional representations that capture perceptual odor similarities across multiple scent descriptors [10]. These models enable data-driven prediction of odor categories and provide a quantitative basis for guiding molecular design [3, 10].

Generative molecular design has relied on architectures such as Variational Autoencoders (VAEs), Generative Adversarial Networks (GANs), and Reinforcement Learning (RL). While effective in specific scenarios, these methods face distinct challenges in navigating discrete chemical spaces. As highlighted in comprehensive reviews, VAEs and GANs often struggle to maintain chemical validity or suffer from mode collapse, failing to capture the full diversity of the target distribution [11]. Similarly, standard optimization strategies can have difficulty balancing exploration and exploitation, frequently leading to premature convergence on narrow regions of chemical space rather than generating a diverse set of high-performing candidates [11].

GFlowNets address this challenge by learning a policy that samples entire trajectories through a construction space such that the probability of reaching a terminal state is proportional to its assigned reward [6]. This formulation enables controlled exploration of multiple high-reward regions and is particularly attractive for problems where the reward function is sparse, noisy, or expensive to evaluate. Previous work has shown that GFlowNets are well suited for molecular graph construction [12], where molecules are built sequentially through valid chemical transformations.

Despite these advantages, the application of GFlowNets to olfactory molecule generation remains relatively unexplored, particularly in settings that require explicit chemical plausibility constraints and evaluation beyond internal reward-model scores.

## METHODOLOGY

### Problem Formulation

Building on the objective of generating novel molecular structures with olfactory characteristics similar to vanillin, molecules are represented as graphs and constructed step-by-step through a sequence of chemically valid actions. The generative process is framed as a trajectory sampling problem in which each completed molecule corresponds to a terminal state and is assigned a scalar reward reflecting its suitability as a vanilla-like odorant.

Formally, a state represents the current partial molecular graph, while an action applies a valid graph modification, such as adding an atom or bond, or a terminal stop action that completes the molecule. The GFlowNet agent is parameterized by a policy that assigns probabilities to valid actions given the current state. Applying an action transforms the current state into a new partial graph. A sequence of such state transitions defines a trajectory that terminates in a complete molecule. Each terminal molecule is assigned a reward based on its predicted similarity to the vanilla odor profile, together with chemical validity and odorant feasibility constraints. Training is performed in a hybrid offline–online regime, where offline samples are drawn from a dataset of known fragrant molecules [13] and online samples are generated by the current policy. Both sets of samples are used jointly to compute the training loss and update the model parameters.

The reward function is designed to favor molecules that (i) exhibit a high predicted similarity to the vanilla odor profile, (ii) fall within the distribution of known odorants, and (iii) satisfy chemical validity and safety constraints. This multi-component formulation ensures that high-reward samples are not only perceptually relevant but also chemically plausible. Figure 1 summarizes the workflow.

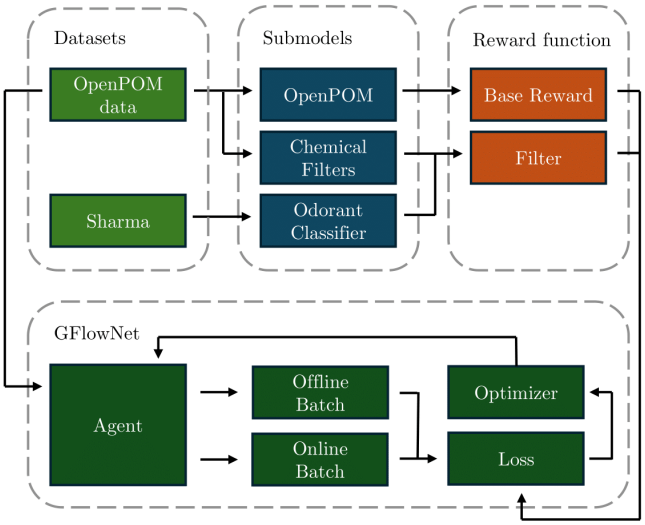

**Figure 1.** – Flowchart summarizing the methodology.

## GFlowNet Architecture

A GFlowNet agent is employed to sample molecular construction trajectories. At each step, the agent selects an action that modifies the current molecular graph, such as adding an atom or bond, subject to chemical valency rules. A special stop action terminates the trajectory and yields a complete molecule.

The agent's policy is trained to distribute probability mass across terminal molecules in proportion to their reward values. Training follows the standard GFlowNet paradigm, where batches of trajectories are sampled, rewards are computed for terminal states, and network parameters are updated to minimize the discrepancy between inflow and outflow of probability mass along each trajectory.

## Olfactory Reward Modeling

Olfactory similarity is quantified using OpenPOM [10, 13], a message-passing neural network trained to predict odor categories across a wide range of fragrance notes. For each generated molecule, OpenPOM outputs a probability vector over odor descriptors, including vanilla-related dimensions such as sweet, phenolic, smoky, spicy, floral, and vanilla.

The base reward component is computed by comparing cosine similarity between the predicted odor profile of a generated molecule to that of vanillin, encouraging alignment across multiple odor dimensions rather than a single scalar label. This multidimensional formulation allows the model to capture the complex perceptual structure of vanilla scent.

The reward formulation is intentionally defined over the full predicted odor probability vector rather than relying solely on the vanilla odor probability. This design choice addresses the inherent sparsity of vanilla-labeled molecules in the dataset and reflects the perceptual reality that vanilla scent is characterized by a combination of correlated odor dimensions rather than a single categorical label. By rewarding similarity across all odor dimensions, molecules with moderate vanilla probability but high perceptual coherence are retained, resulting in a denser and more informative reward landscape during training. This approach was found to be essential for maintaining learning signal in early and intermediate training stages.

## Chemical and Odorant Constraints

To prevent the generation of chemically implausible or unsafe molecules, several constraint mechanisms are incorporated. Rule-based chemical filters penalize structures containing reactive or undesirable functional groups, excessive ring strain, or unstable motifs. These filters are derived from properties observed in the training data and from established chemical safety considerations. The filters considered and their ranges are shown in Table 1. Here, LogP denotes the logarithm of the octanol–water partition coefficient, TPSA the topological polar surface area, and NRB the number of rotatable bonds.

**Table 1:** Chemical filters considered and their ranges

| Parameter | Min | Max |
|---|---|---|
| LogP | 0.06 | 4.91 |
| Molecular weight | 100.12 | 282.46 |
| Hydrogen bond acceptors + donors | 0 | 5 |
| TPSA | 0 | 63.32 |
| NRB | 0 | 11 |
| $NO_2$ | 0 | 0 |
| Heteroatoms | 0 | 5 |
| Aromatic rings | 0 | 1 |
| Atoms | 0 | 20 |
| Triple bonds | 0 | 0 |
| Radical electrons | 0 | 0 |
| Oxygen chain length | 0 | 1 |

In addition, a random forest classifier trained on molecular fingerprints is used to distinguish odorant molecules from non-odorants. This classifier serves as an auxiliary filter to ensure that generated candidates are likely to be perceptible at all, rather than chemically valid but odorless. The dataset used for training this model is the Sharma dataset [14].

Only molecules passing both chemical and odorant plausibility checks are assigned nonzero rewards and propagated during training, reducing noise in the learning signal and improving convergence, though they are still quantified for loss metrics.

## Training Strategy and Hyperparameter Optimization

The GFlowNet is trained in a hybrid offline–online

regime. Offline training batches are drawn from the OpenPOM dataset, providing stable supervision during early learning phases by exposing the model to chemically valid and odor-relevant molecular structures. Online batches are generated by the current policy, enabling exploration of novel molecular graphs beyond the training data and progressively refining the sampling distribution toward high-reward regions of chemical space.

Training can be formulated using the Trajectory Balance (TB) objective, which enforces consistency between the probability of sampling a complete trajectory and the reward assigned to its terminal state. In this formulation, the product of forward transition probabilities along a trajectory is matched to the terminal reward, ensuring that the probability of sampling a molecule is proportional to its reward. The TB objective provides a principled mechanism for learning a target distribution over terminal states, but it is known to be sensitive to long trajectories, since trajectory probabilities are obtained as products of many terms and can therefore become extremely small, leading to large loss values when paired with mismatched rewards.

To mitigate this issue, the Subtrajectory Balance (SubTB) objective is employed. Instead of enforcing balance only at the level of complete trajectories, SubTB decomposes each trajectory into overlapping subtrajectories and applies the balance condition to each of them. The final loss is computed as a weighted aggregation over all subtrajectories. This formulation preserves the theoretical objective of matching the target distribution while reducing the impact of extreme probability values associated with long molecular construction paths. In practice, SubTB provides improved numerical stability and smoother training dynamics, particularly in molecular generation tasks where trajectory lengths can vary substantially.

In this work, SubTB is preferred over the standard TB objective due to the presence of long and heterogeneous construction trajectories and the additional noise introduced by hybrid offline–online training. While SubTB does not fully eliminate instability, it significantly reduces loss explosions and improves convergence behavior compared to TB, making it more suitable for the present setting.

Model training follows the standard GFlowNet procedure. At each training iteration, a batch of trajectories is constructed by sampling actions from the current policy. Each trajectory starts from an initial empty molecular graph and is extended through sequential graph-modifying actions until a terminal stop action is selected, yielding a complete molecule. Rewards are computed only for terminal states and reflect olfactory similarity, chemical validity, and odorant plausibility. Model parameters are then updated by minimizing the SubTB loss computed over both offline and online trajectories.

Hyperparameters governing learning rates, batch composition, reward scaling, and gradient clipping are optimized using Bayesian optimization with Optuna [15]. The tuned parameters and the two final configurations retained for evaluation are reported explicitly in Table 2. The sampling tau controls the rate at which the sampling policy is updated toward the latest trained parameters, trading off exploration stability against responsiveness. The Z learning rate sets the step size for updating the GFlowNet normalization constant Z, which stabilizes the global flow matching between trajectory probabilities and rewards. The learning rate controls the update magnitude for the main network parameters, whereas momentum accelerates optimization by smoothing gradients across iterations. Weight decay applies $L_2$ regularization to limit parameter growth and reduce overfitting. Finally, gradient clipping caps the gradient norm to prevent occasional large updates, which is particularly important under long trajectories and noisy offline–online mixing. Based on validation performance and training stability, we retain two optimized configurations (Table 2) for the final experiments.

**Table 2:** Final hyperparameter values

| Parameter | Search space | First | Second |
|---|---|---|---|
| Sampling tau | 0.8 - 1 | 0.95864 | 0.98403 |
| Z learning rate | $10^{-8}$ - $10^{-1}$ | 9.1725 x $10^{-4}$ | 3.1573 x $10^{-5}$ |
| Gradient clipping | 0.1 – 100 | 9.9068 | 32.278 |
| Momentum | 0.5 – 0.9999 | 0.65129 | 0.65129 |
| Learning rate | $10^{-8}$ - $10^{-1}$ | 3.3456 × $10^{-4}$ | 2.5660 × $10^{-4}$ |
| Weight decay | $10^{-10}$ - $10^{-4}$ | 3.9731 × $10^{-7}$ | 3.9731 × $10^{-7}$ |

## VALIDATION AND EVALUATION STRATEGY

Model validation was conducted using multiple complementary criteria. Offline validation was performed by computing loss values on a held-out set of unseen molecules from the OpenPOM dataset, while online validation considers the molecules being generated by the GFlowNet model. However, because the OpenPOM model is used both during training and reward computation, these metrics alone are susceptible to circular validation. Olfactory receptor docking was therefore introduced as an independent, physically motivated validation layer, selected for its interpretability and relevance to

molecular-level odor perception.

A receptor docking model is constructed using AutoDock Vina [16] to simulate binding interactions between generated molecules and ten human olfactory receptors known to exhibit high affinity for vanillin. Protein structures are obtained from AlphaFold [17], and active site bounding boxes are defined manually based on literature-reported amino acid residues. Docking exhaustiveness is set to a moderate value to balance computational cost and accuracy.

Prior to evaluating generated molecules, the docking model is benchmarked by repeatedly simulating vanillin–receptor interactions. The resulting binding energy distributions exhibit low variance and reasonable agreement with literature values, indicating that the model provides a suitable independent metric for comparative evaluation. After training, generated molecules can be sampled and checked on existing databases such as PubChem [18] to check if the they are already catalogued, or novel. Figure 2 summarizes the validation strategy.

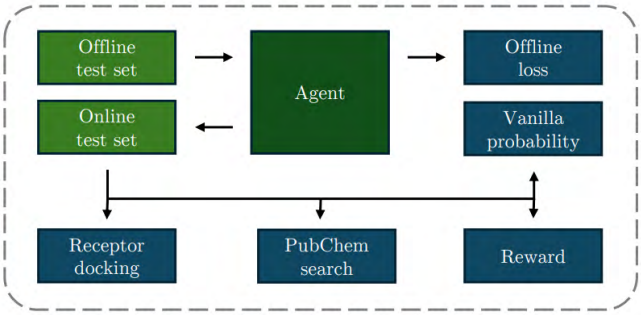

**Figure 2.** – Scheme of the validation strategy.

## RESULTS AND DISCUSSION

The model was trained with two different hyperparameter configurations. For each training regimen, 500 molecules were sampled and analyzed at two checkpoints: an intermediate stage (3000 iterations) and the end of training (6000 iterations). Across both checkpoints, the first hyperparameter configuration consistently outperformed the second.

The best-performing configuration achieved median reward values above 0.5, with improved reward concentration at the final checkpoint compared to the intermediate stage, indicating progressive refinement of the sampling distribution. Median docking energies across vanillin-sensitive receptors were comparable to those obtained for vanillin itself, with reduced variance relative to intermediate checkpoints. In contrast, the second hyperparameter configuration exhibited both lower median rewards and broader docking energy distributions, indicating less consistent receptor engagement. These results highlight the sensitivity of GFlowNet performance to hyperparameter selection and training stability.

Qualitative inspection of high-reward molecules reveals structural diversity, including candidates with and without ring systems. While certain high-reward structures exhibit features that may pose synthetic challenges, others remain relatively simple and chemically feasible. Radar plots of predicted odor profiles show that the best-performing molecules align closely with the six dominant odor dimensions associated with vanillin. This qualitative diversity is more pronounced for the first hyperparameter configuration, which consistently samples a broader range of structurally distinct candidates at comparable reward levels. Figure 3 shows four of the best molecules sampled in the first hyperparameter configuration.

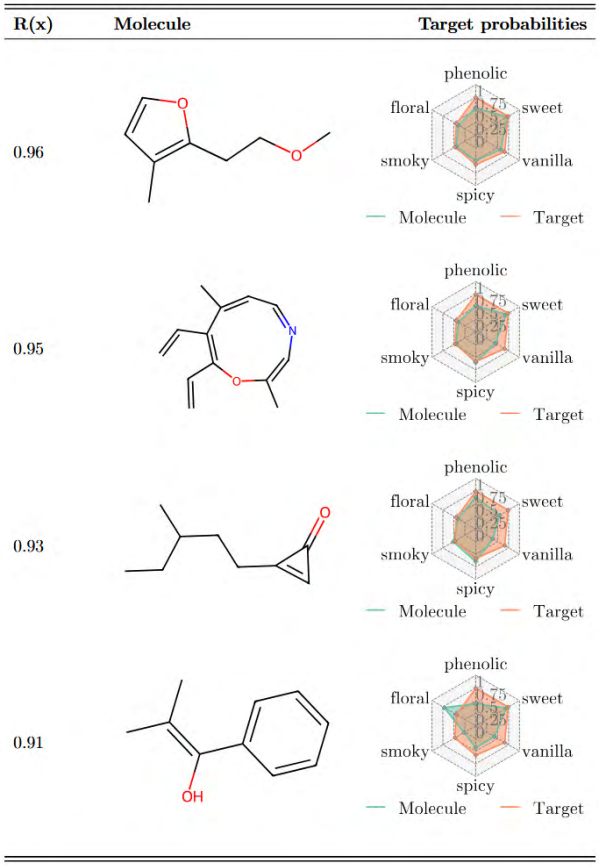

**Figure 3.** – Four best molecules sampled from the best configuration of hyperparameters.

Docking-based validation indicates that many generated molecules exhibit binding affinities to vanillin-sensitive receptors that are comparable to, and in some cases stronger than, those predicted for vanillin itself. Although median binding energies are generally slightly weaker than vanillin, the distributions suggest meaningful receptor interaction rather than random binding. Importantly, the best-performing model shows a reduction in high-energy outliers relative to intermediate

checkpoints, indicating improved consistency. Figure 4 shows the predicted binding energies for the molecules sampled using the first configuration for several receptors known to bind with vanillin. Additionally, the estimated values for vanillin using the AutoDock Vina and and the values from literature [9] are given for comparison.

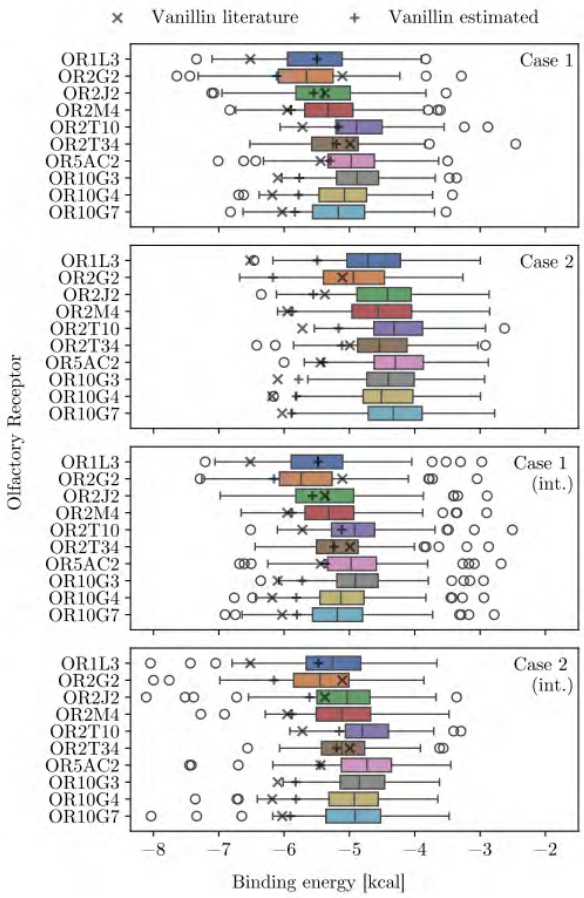

**Figure 4.** - Docking binding energies for the molecules sampled from the first hyperparameter configuration run.

The second hyperparameter configuration yields less favorable results, with lower reward values and weaker receptor binding. Training dynamics for this configuration exhibit stronger oscillations, suggesting instability and misalignment between offline and online objectives. These findings highlight the sensitivity of GFlowNet training to hyperparameter choices and reward sparsity.

Despite the overall improvement in sampled molecule quality over training, learning dynamics presented instabilities. In particular, oscillatory reward trajectories and sporadic spikes in offline loss were observed. These effects are attributed to a misalignment between offline and online training objectives, since offline molecules bypass several validity and plausibility filters that are applied during online sampling. As a result, offline trajectories can induce large loss gradients that do not reflect the effective online sampling distribution, leading to noisy parameter updates. As anticipated, the use of the Sub-Trajectory Balance (SubTB) objective reduced the severity of loss explosions associated with long trajectories, although oscillatory dynamics were still observed. Figure 5 and 6 show the loss metrics during training for both configurations. Note that reward curves shown during training include unfiltered offline and online trajectories, which is lower than the reward of chemically valid, odorant-positive molecules only, reported earlier. Figure 7 shows the percentage of molecules generated by the model that could be found in the PubChem [18] database; molecules were sampled at 3000 and 6000 iterations, as previously described. For this figure, 500 molecules were sampled without applying chemistry filters, presented under “All”; the second row shows the results considering only chemically valid molecules, and predicted to be odoriferous.

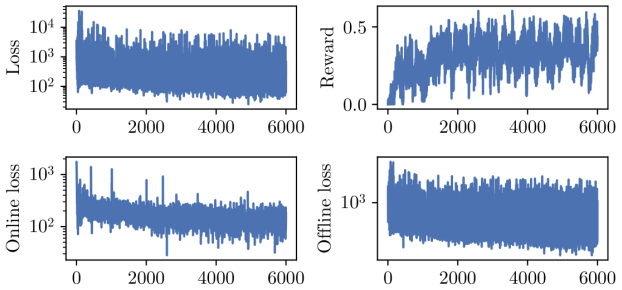

**Figure 5.** – Loss metrics for the first hyperparameter configuration.

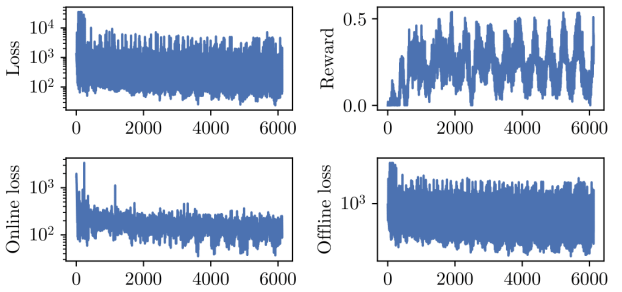

**Figure 6.** – Loss metrics for the second hyperparameter configuration.

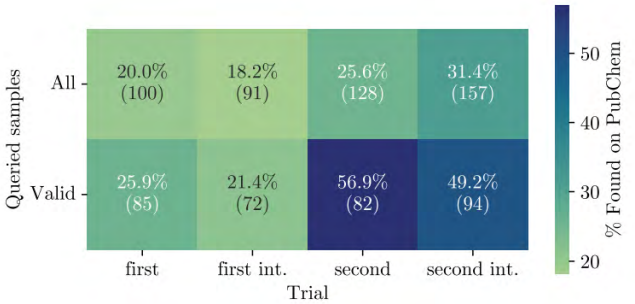

**Figure 7.** – Percentage of sampled molecules found in Pubchem.

Taken together, these results indicate that model performance is governed not only by the expressiveness of the reward function, but also by the interaction between offline supervision, online exploration, and trajectory-level credit assignment. While the Sub-Trajectory Balance objective reduces the impact of extreme loss values, instability persists when offline trajectories induce gradients that are inconsistent with the effective online sampling distribution. This misalignment manifests as oscillatory reward dynamics and sporadic spikes in offline loss, particularly in less favorable hyperparameter configurations.

From a modeling perspective, these findings suggest that training stability, rather than representational capacity, currently constitutes the primary bottleneck for applying GFlowNets to chemically constrained generative tasks. Improving the alignment between offline and online objectives, for example through staged training or uncertainty-aware weighting of offline samples, is therefore expected to yield more consistent convergence and improved sampling efficiency.

## CONCLUSION

This work demonstrates that Generative Flow Networks can be applied to targeted olfactory molecule generation, producing structurally novel candidates with predicted sensory characteristics similar to vanillin. Despite training instabilities and reward noise, the proposed framework consistently generates high-reward molecules and exhibits meaningful agreement with independent receptor-based validation metrics.

At the same time, the study highlights important limitations. Oscillatory training dynamics and misalignment between offline and online objectives affect loss stability and complicate hyperparameter optimization. In addition, high reward or strong predicted receptor affinity does not guarantee synthetic accessibility, and receptor docking remains an approximate proxy for olfactory perception. Future work should therefore focus on improving reward smoothness, incorporating synthesis-aware and uncertainty-aware objectives, and refining training strategies to better balance exploration and constraint enforcement. Experimental validation and synthesis-informed modeling represent critical next steps toward practical deployment.

From a broader CAPE perspective, the proposed approach can be interpreted as a feasible-region exploration problem in a vast molecular design space under uncertainty. By enabling the generation of synthetic alternatives to naturally sourced odorants, the methodology contributes to sustainability and supply-chain resilience while extending established CAPE concepts from process-level design to molecular-level innovation.

# A Strategy for Limiting the Effects of Nonconvexities in Mixed-Integer Nonlinear Programming Reformulation of Nonconvex Generalized Disjunctive Programs

**Miloš Bogataj[a*], Chiara Železnik[a], and Zdravko Kravanja[a]**

## ABSTRACT

Nonconvex generalized disjunctive programs (GDPs) frequently arise in chemical engineering applications and are commonly reformulated as mixed-integer nonlinear programs (MINLPs). However, nonconvexities in these reformulations often lead to numerical difficulties, sensitivity to initialization, and degraded solution quality when solved with general-purpose MINLP solvers. This work proposes a two-phase strategy to mitigate these effects by generating improved initial points through the solution of a sequence of relaxed MINLPs, which are subsequently used to initialize the original formulation. The approach is evaluated on a family of purely disjunctive benchmark problems, referred to as the Crescent problems, with sizes ranging from 60 to 1000 binary variables. Numerical experiments using the DICOPT and SBB solvers assess performance in terms of objective value distributions, the percentage of feasible initial points, and average constraint violation. The results indicate that the proposed strategy improves solution quality, increases the likelihood of feasibility, and reduces the magnitude of constraint violations across all problem sizes.

**Keywords**: nonconvex optimization, mixed-integer nonlinear programming, generalized disjunctive programming, global optimization, local optimization

## INTRODUCTION

Optimization problems in chemical engineering are predominantly nonlinear because the relationships describing reaction kinetics, thermodynamic equilibria, and transport phenomena are inherently governed by nonlinear dependencies among variables. Additionally, constraints such as energy and mass balances, as well as equipment design and sizing relationships, are often described by nonlinear – generally nonconvex – equations. In the context of optimization, this poses two problems: first, the need to provide good initial points, and second, the potential existence of multiple local optima.

In the past two decades, significant advances have been made in the field of global optimization. Numerous global optimization strategies have been reported in the literature [1-4], some designed for very specific problems and others more general. Additionally, there has been substantial improvement in the computational efficiency of commercially available deterministic general-purpose global optimization solvers (BARON, ANTIGONE, LINDO-Global). However, when nonconvex nonlinear optimization problems include discrete decisions – namely, mixed-integer nonlinear problems (MINLP)—the ability to find the global optimum arguably decreases exponentially with problem size. Therefore, research into approaches that provide good locally optimal solutions using general MINLP solvers is relevant.

## PROBLEM STATEMENT

The “Crescent” problem considered in this work is stated as a Generalized Disjunctive Program (1). It is a purely disjunctive problem consisting of a nonconvex objective function, $D$ disjunctions and $T_d$ terms per disjunction $d$.

Each term $t$ includes a Boolean variable $Y_{td}$, two nonlinear constraints (one of which is nonconvex), and a “charge” parameter $\gamma_{td}$. The logical propositions

$\Omega(Y_{td})$ ensure that only one Boolean variable in each disjunction is *True*.

$$\min Z = (x_1 - 3)^2 - (x_2 - 3)^2 + \sum_{d \in D} c_d$$

s.t.

$$\bigvee_{t \in T_d} \begin{bmatrix} Y_{td} \\ (x_1 - a_1)^2 + (x_2 - b_1)^2 - r_1^2 \le 0 \\ (x_1 - a_2)^2 + (x_2 - b_2)^2 - r_2^2 \ge 0 \\ c_d = \gamma_{td} \end{bmatrix}, \quad d \in D$$

$$\Omega(Y) = True$$

$$\boldsymbol{x}^{\mathrm{LO}} \le \boldsymbol{x} \in \mathbb{R}^2 \le \boldsymbol{x}^{\mathrm{UP}}, c_d \in \mathbb{R}^1,$$

$$Y_{td} \in \{True, False\}, t \in T_d, d \in D \qquad (1)$$

The disjunctive nonconvex feasible region of a fifteen-term disjunction is shown schematically in Figure 1.

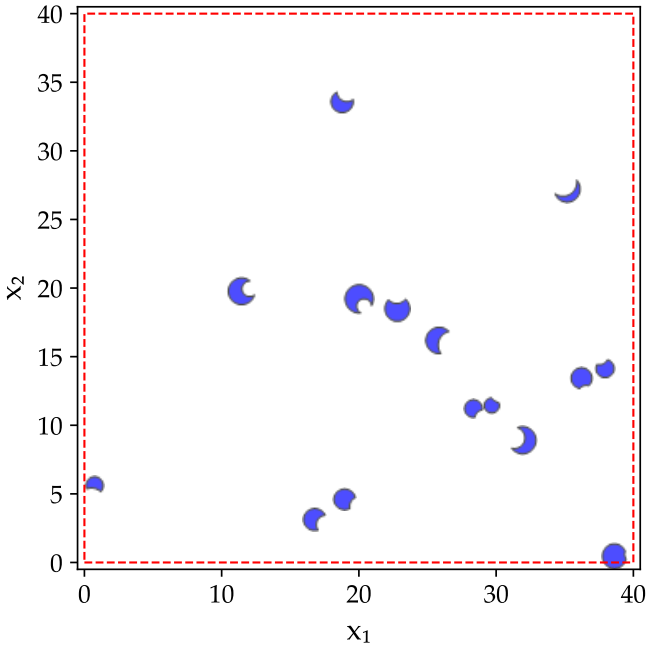

**Figure 1.** Projection of a disjunctive feasible region onto $X_1$-$X_2$ plane.

## GDP-to-MINLP reformulation

The proposed GDP-to-MINLP reformulation is a variation of the method proposed by Bogataj and Kravanja [5] and can be viewed as a hybrid between the Hull Reformulation [6-7] and the Big-M reformulation.

The nonlinear constraints in the terms of the disjunctions $g(\boldsymbol{x}) \le 0$ are formulated in terms od disaggregated variables $\boldsymbol{x}^{\mathrm{D}}$as $g(\boldsymbol{x}^{\mathrm{D}}) - (1-y)g(\boldsymbol{x}^{\mathrm{F}}) \le 0$, where $y \in \{0,1\}$, and $\boldsymbol{x}^{\mathrm{D,LO}} \le \boldsymbol{x}^{\mathrm{F}} \le \boldsymbol{x}^{\mathrm{D,UP}}$ is a fixed parameter. The disaggregated variables are bounded by $\boldsymbol{x}^{\mathrm{LO}}\boldsymbol{y} + (\boldsymbol{1}-\boldsymbol{y})\boldsymbol{x}^{\mathrm{F}} \le \boldsymbol{x}^{\mathrm{D}} \le \boldsymbol{x}^{\mathrm{UP}}\boldsymbol{y} + (\boldsymbol{1}-\boldsymbol{y})\boldsymbol{x}^{\mathrm{F}}$. The latter constraint enforces the disaggregated variable to satisfy $x^{\mathrm{LO}} \le x^{\mathrm{F}} \le x^{\mathrm{UP}}$ if $y = 1$, and $x^{\mathrm{D}} = x^{\mathrm{F}}$ if $y = 0$. Finally, the constraint $x = \sum(x^{\mathrm{D}} - (1-y)x^{\mathrm{F}})$ ensures the regularity of the relationship between the original variable $x$ and the disaggregated variables $\boldsymbol{x}^{\mathrm{D}}$. For more information on the reformulation, we refer the reader to Bogataj and Kravanja [5].

## Algorithm

The algorithm (2) consists of two phases. In the first phase, the continuous relaxation is tightened by solving a sequence of relaxed MINLPs using a local NLP solver (e.g., CONOPT). In the second phase, the MINLP formulation is solved from the initial points determined in the first phase. Regarding first-phase initialization, it should be noted that if the initial points $(\boldsymbol{x}_0, \boldsymbol{x}_0^{\mathrm{D}})$ are selected randomly, most are expected to be infeasible with respect to the constraints in the original GDP. However, it should also be emphasized that any initial point $\boldsymbol{x}_0^{\mathrm{D}}$ for which the corresponding constraints $g(\boldsymbol{x}) \le 0$ in the GDP are defined is a feasible point from the perspective of the proposed MINLP formulation.

$$\begin{aligned}
&set\ Z = -\infty \\
&set\ \boldsymbol{x}_0, \boldsymbol{x}_0^D, \boldsymbol{x}^F = \boldsymbol{x}_0^D \\
&loop\ (i = 1, \ldots, I \\
&\quad solve\ \text{R-MINLP}\quad \min(Z\ ) \\
&\quad get\ \ Z_i^*, \boldsymbol{x}_i^*, \boldsymbol{x}_i^{D*} \\
&\quad\quad \text{if } |Z - Z_i^*| \le \varepsilon\ \text{ break} \\
&\quad\quad else\ Z = Z_i^*, \boldsymbol{x}^F = \boldsymbol{x}_i^{D*}) \\
&set\ \boldsymbol{x}_0 = \boldsymbol{x}_i^*, \boldsymbol{x}_0^D = \boldsymbol{x}_i^{D*}, \boldsymbol{x}^F = \boldsymbol{x}_i^{D*} \\
&solve\ \text{MINLP}\ \min(Z)
\end{aligned} \qquad (2)$$

## NUMERICAL EXPERIMENTS

The proposed approach was evaluated on three groups of Crescent problem instances containing 60, 200, and 1000 binary variables, respectively; the full set of instances is listed in Table 1. Each instance, defined by the parameter pair (D, T), was solved $N_s = 200$ times from randomly generated initial points, with a time limit of 200 seconds per run. Two MINLP solvers were considered: the Outer Approximation/Equality Relaxation algorithm (DICOPT with CONOPT4 as NLP and CPLEX as MIP solver) and the Branch-and-Bound algorithm (SBB with CONOPT4 as NLP solver). To ensure the solvers do not terminate before the set time limit per run if the default

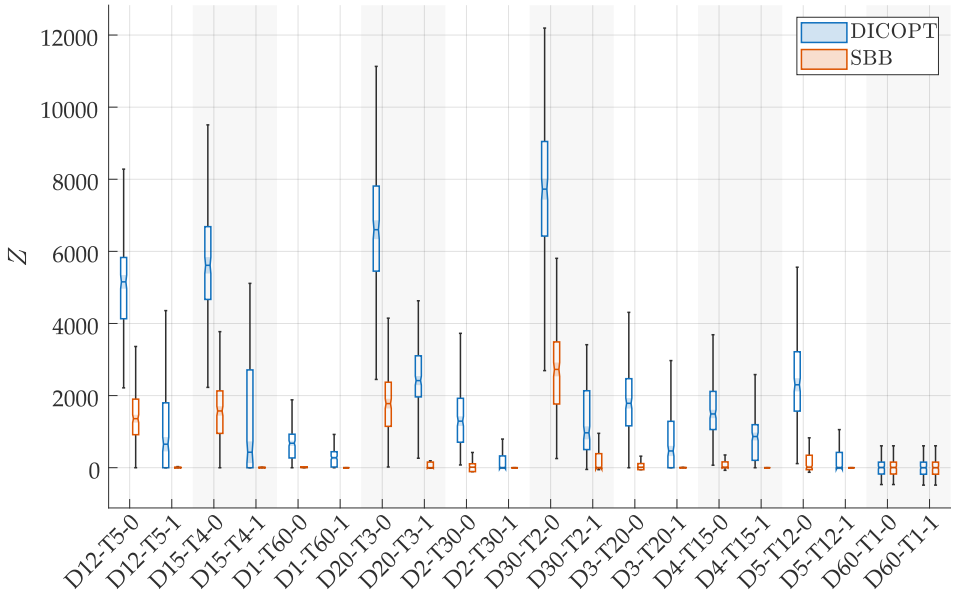

**Figure 2.** Distribution of objective function values (Crescent 60).

optimality criteria are not reached, the following changes were made to the default algorithmic options: DICOPT – convex = 0, maxcycles = 200, stop = 1; SBB – memnodes = 10000. For each solver, instances were solved both without the initial phase of algorithm (2) and using the full algorithm (2). For each instance and solver, both algorithmic variants were initialized using the same randomly generated starting points.

## RESULTS

The goal of the numerical experiments was to assess the efficiency of the proposed methodology in limiting the effects of nonconvexities. The numerical experiments were statistically analyzed. Box-plots were used to characterize the distribution of objective functions. To further assess the efficiency of the algorithm, average constraint violation and the percentage of feasible initial points were utilized. The average constraint violation per instance $\bar{v}$ was computed as $\bar{v} = \frac{1}{2K}\sum_{k=1}^{K}\sum_{j=1}^{J} v_{j,k}$, where $v_{j,k} = \max\left\{0, g_j\left(\boldsymbol{x}_{0,k}^{\mathrm{D}}\right)\right\}, K = N_{\mathrm{s}} \bullet D \bullet T$, and $J = 2$. The percentage of initial feasible points was determined by $P_{\mathrm{f}} = N_{\mathrm{f}}/K$, where $N_{\mathrm{f}}$ denotes the number of initial points $\boldsymbol{x}_{0,k}^{\mathrm{D}}$ that satisfy both constraints in disjunctive terms.

### Distributions of objective function values

Figures 2–4 summarize the distributions of the objective function values. For clarity, the box plots in each figure are best interpreted in groups of four, with each group corresponding to a single problem instance defined by the pair (D, T).

For each instance, results are shown for two solvers—DICOPT (blue) and SBB (red)—and for two algorithmic variants. In the first variant, the MINLP formulation is solved directly from randomly generated initial points, without the initial phase of the algorithm; in the second variant, the full algorithm (2), including the initial phase, is applied. In the Figures, these two variants are distinguished by the suffixes "–0" and "–1, " respectively, appended to the instance label.

To account for instance-dependent variability in objective function values, the results were normalized independently for each problem instance. For a given instance (D, T), four sets of objective values are therefore available, corresponding to the two solvers and the two algorithmic variants. The normalization constant was defined as the minimum of the four corresponding medians, and this value was subtracted from all objective function values associated with that instance. Note that although the normalization alters the absolute magnitude of the objective function values, it leaves the shape of the distributions and the relative performance of solvers within each instance unchanged.

Analysis of the box plots in Figure 2 (problem Crescent 60) clearly shows that better solutions are obtained when the full algorithm (2) is used. The solutions are improved not only in terms of objective values, but also in the reduced spread around the median. This is indicated by the shorter heights of the boxes and the shorter lengths of the whiskers. An exception to this general observation is instance (D60-T1), which is a somewhat

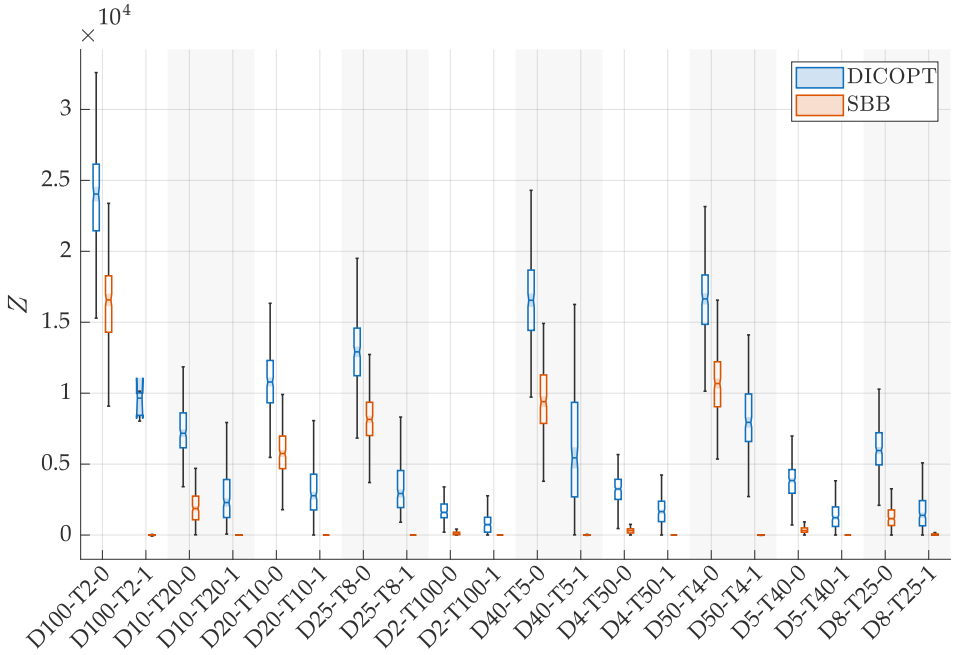

**Figure 3.** Distribution of objective function values (Crescent 200).

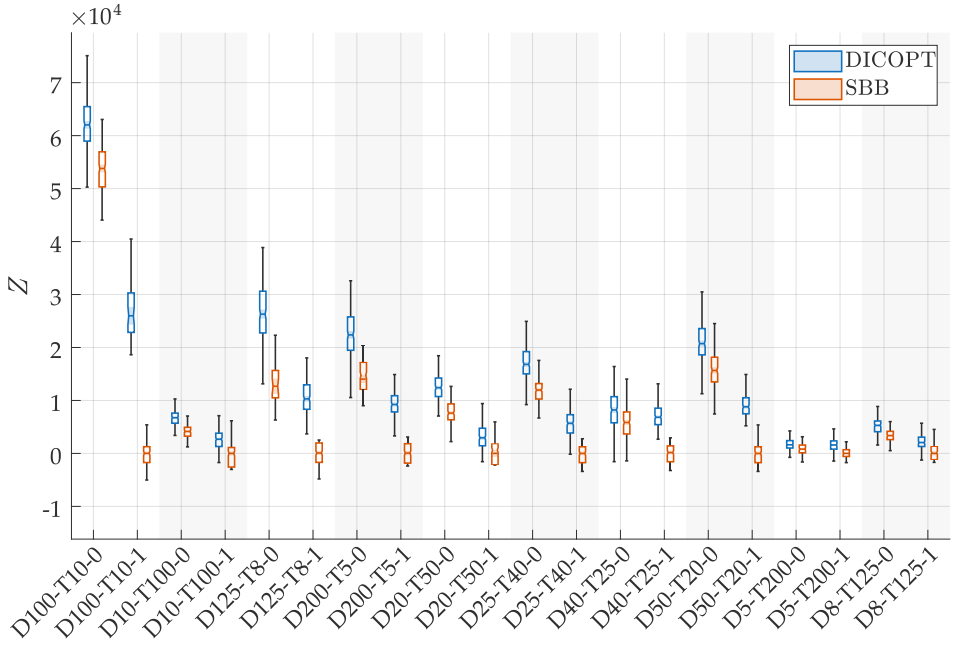

**Figure 4.** Distribution of objective function values (Crescent 1000).

trivial case because each disjunction consists of a single term. An integer solution is guaranteed in the relaxed MINLP for this instance; therefore, the impact of the first phase of the algorithm is negligible.

Similar observations can be made regarding the results shown in Figure 3 (problem Crescent 200) and Figure 4 (problem Crescent 1000). In both problems the improvement of objective function values is clearly visible when full algorithm (2) is applied. Perhaps the most noticeable among all is the considerably tightened distribution of objective function values in problem Crescent 200 obtained using SBB solver.

## Percentage of feasible initial points

When local optimization solvers are applied to nonconvex optimization problems, the choice of initial points is critical for obtaining high-quality locally optimal solutions. Poor initial points can lead the solver to inferior local optima, infeasible solutions, or premature termination. In practice, effective initialization often relies on a deeper

understanding of the optimization problem, including valid bounds on the variables and, more importantly, the geometric structure of the feasible region. However, such information is difficult to obtain, especially for high-dimensional problems, which motivates the need for systematic and robust initialization procedures.

Figures 5–7 report the percentage of feasible initial points. In total, 12, 000 initial points were generated per instance for Crescent 60, 40, 000 for Crescent 200, and 200, 000 for Crescent 1000. As expected, given the random generation of starting points, only a small fraction of the initial points was feasible with respect to both constraints in (1) for each problem instance (see Table 2).

**Table 2:** Number of feasible randomly generated points.

| **Problem** | **Crescent 60** |
|---|---|
| Instance ($N_f$) | 1-60(**0**), 2-30(**0**), 3-20(**0**), 4-15(**0**), 5-12(**0**), 60-1(**0**), 30-20(**0**), 20-3(**0**), 15-4(**0**), 12-5(**0**) |
| **Problem** | **Crescent 200** |
| Instance ($N_f$) | 2-100(**5**), 4-50(**1**), 5-40(**0**), 10-20(**0**), 25-8(**0**), 100-2(**0**), 50-4(**0**), 40-5(**0**), 20-10(**0**), 8-25(**0**) |
| **Problem** | **Crescent 1000** |
| Instance ($N_f$) | 5-200(**3**), 8-125(**1**), 10-100(**0**), 20-50(**0**), 25-40(**0**), 200-5(**0**), 125-8(**0**), 100-10(**0**), 50-20(**0**), 40-25(**0**) |

When the full algorithm (2) is applied, however, a substantial increase in the number of feasible points is observed. The highest percentage of feasible points, approaching 50 %, occurs for instance D200–T5–1 (Crescent 1000), whereas the lowest percentage, approximately 2 %, is observed for instance D2–T100–1 (Crescent 200).

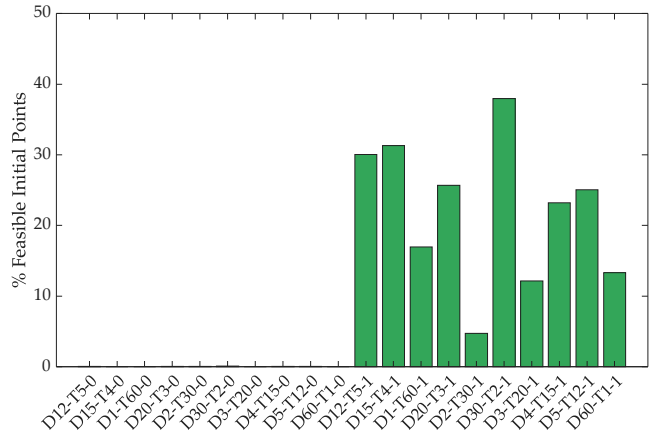

**Figure 5.** Percent of feasible initial points (Crescent 60).

## Average constraint violation

Average constraint violation complements the percentage of feasible initial points by capturing the severity of constraint violations when infeasibility occurs. Lower average violations indicate that a solver consistently produces solutions close to the feasible region, reflecting potentially greater numerical robustness.

The results for the average constraint violation show consistent trends across all three problem sizes (see Figures 8-10). The magnitudes of average constraint violations for randomly generated initial points, shown in orange, are almost uniform across the three problems. In contrast, the configurations using the full algorithm (2), shown in green, yield lower average violations, often close to zero, which indicates convergence of initial points toward disjunctive feasible regions.

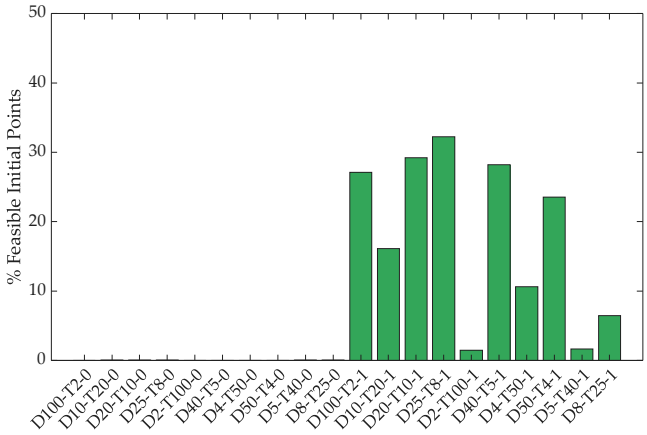

**Figure 6.** Percent of feasible initial points (Crescent 200).

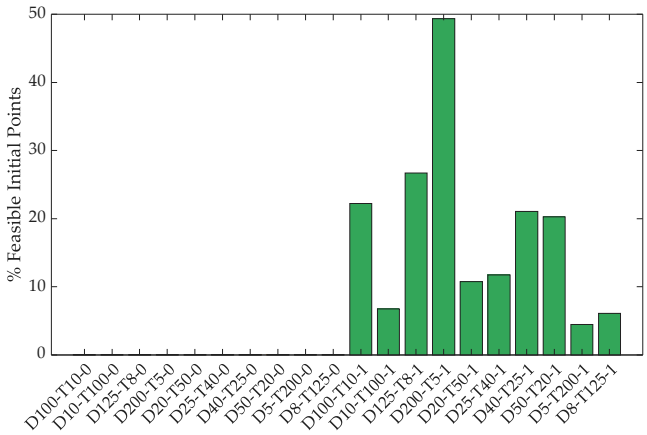

**Figure 7.** Percent of feasible initial points (Crescent 1000).

## Computational efficiency

Finally, we briefly discuss the computational efficiency of the first phase of the algorithm. Across all

instances, the first phase required on average five R-MINLP iterations, with a minimum of two and a maximum of ten. Since these iterations involve solving NLP problems, the computational effort of the first phase is relatively modest compared to solving the full MINLP. In numerical terms, the CPU time of the first phase corresponded to approximately 1–10% of the imposed computational time limit. Although the computational cost of the first phase increases with problem size, the cost of solving the full MINLP increases as well.

## CONCLUSIONS

This work investigated a two-phase strategy for limiting the effects of nonconvexities in MINLP reformulations of nonconvex generalized disjunctive programs. The approach combines a preliminary phase, in which a sequence of relaxed MINLPs is solved to improve initial points, with a subsequent solution of the original MINLP formulation. The strategy was assessed on the Crescent benchmark problems of increasing size using two general-purpose MINLP solvers, DICOPT and SBB, and evaluated through statistical measures of objective values, feasibility, and constraint violations.

The numerical results demonstrate that the proposed approach improves solver performance. Across all problem sizes, the use of the full algorithm leads to improved objective function values and reduced variability, as evidenced by tighter distributions in the box-plot analysis. In addition, the percentage of feasible initial points is consistently higher when the first phase is applied, highlighting its effectiveness in steering solutions toward disjunctive feasible regions. Complementary to this measure, the analysis of average constraint violation shows that the proposed strategy not only increases feasibility but also reduces the severity of constraint violations when infeasibility persists.

While the improvements are problem-dependent, the observed trends are consistent across solvers and problem sizes, suggesting that the proposed approach enhances numerical robustness without relying on problem-specific tuning. The results indicate that systematic initialization procedures can play a significant role in mitigating the challenges associated with nonconvex MINLP reformulations. Future work will focus on extending the approach to more general GDP structures and investigating its interaction with global optimization techniques.

# Beyond Tennessee Eastman: Benchmarking Deep Anomaly Detection on Real-World Pilot-Scale Continuous Distillation Data

**Fabian Hartung[ac†], Aparna Muraleedharan[b†], Marius Kloft[a] and Jakob Burger[b*]**

[a] RPTU Kaiserslautern, Department of Machine Learning, Kaiserslautern, Germany

## ABSTRACT

Anomaly detection is essential for ensuring the safe and efficient operation of chemical plants. Although many deep-learning-based methods have been proposed in recent years, their evaluation remains largely limited to synthetic benchmarks such as the Tennessee Eastman Process (TEP) [1]. While these simulators enable controlled and reproducible comparisons, they fail to capture the noise characteristics, operational complexity, and irregular fault dynamics of real industrial plants, leaving the practical generalizability of many methods unclear. In this work, we extend our earlier ESCAPE study [2] beyond water-based systems to industrially relevant chemical processes. We analyze multivariate time-series data from two continuously operated pilot-plant scenarios at the Technical University of Munich, namely *n*-butanol/water heteroazeotropic distillation and poly(oxymethylene) ether purification, whose datasets were recently published at NeurIPS 2025 [3]. Using the open-source TimeSeAD library [4], we benchmark 30 anomaly detection methods, including 26 deep-learning-based and 4 classical approaches, under a unified preprocessing, model-selection, and evaluation pipeline. Performance is assessed using the F1-score and the area under the precision–recall curve (AUPRC). Our results show a substantial performance drop when moving from synthetic to real process data, with average scores far below those commonly reported for TEP. No single method performs consistently best across all datasets, and the ranking depends strongly on the chosen metric and process scenario. These findings highlight the limitations of synthetic benchmarks and underscore the need for more realistic industrial datasets, process-aware methods, and evaluation practices that better reflect real operating conditions.

## 1. INTRODUCTION

Continuous distillation is the most widely used separation technique in the chemical industry, enabling steady-state operation through continuous feed input and simultaneous product withdrawal [5, 6]. Anomaly detection (AD) is therefore critical, as accidents in chemical plants—although rare—can result from leaks, fires, or explosions and may harm personnel, equipment, or the environment. Over the past two decades, numerous data-driven AD techniques have been developed, ranging from classical multivariate statistical to principal component analysis, and, more recently, unsupervised machine-learning-based approaches [7, 8].

Most existing AD methods have been developed and evaluated on simulated benchmarks such as the Tennessee Eastman Process (TEP) [1]. Despite their strong reported performance, it remains unclear to what extent models trained and validated on simulated data generalize to real industrial processes operating under

† These authors contributed equally to this work.

non-ideal and evolving conditions. Cheng et al. [7] report that only 12% of the processing methods in their analysis have been applied to real industrial data, primarily due to data confidentiality and limited public availability. This highlights a key challenge: while simulated data represent idealized scenarios with a limited set of fault cases, real industrial data are far more complex, influenced by factors such as minor operational disturbances, equipment aging, and complex chemical mixtures. Industrial process data are typically proprietary, as they contain sensitive information on instrumentation, operating conditions, process variables, and control strategies, and are therefore rarely accessible in the public domain.

To address this gap, we recently published process data from three scenarios of a continuous distillation mini-plant at the TUM Campus in Straubing [3]. This publicly available dataset [9] is used to train and evaluate AD methods. By benchmarking a broad range of anomaly detection approaches from the literature on our data, this work provides a more realistic assessment of model performance under practical industrial operating conditions.

## 2. RELATED WORK

The detection of anomalous behavior in industrial systems has a long tradition in process engineering. Early work framed fault diagnosis as a multivariate statistical process control problem, relying on dimension-reduction techniques such as PCA, PLS, or SIMCA to construct control charts that identify deviations from regular operation [10, 11]. Subsequent approaches explored probabilistic models, including Gaussian mixture models [12], and kernel-based one-class methods [13]. While these “shallow” models have proven effective at small to medium scales, their ability to capture the complex, nonlinear dynamics of chemical plants is inherently limited. As a result, recent advances in deep learning have been transferred to the process domain. Ruff et al. [14] introduced deep one-class classification, followed by numerous studies proposing autoencoder-, GAN-, and VAE-based architectures tailored to multivariate time series from simulators such as the TEP [15, 16].

Comprehensive surveys [17, 18] categorize AD techniques into probabilistic, distance-based, domain-based, reconstruction-based, forecasting-based, and classification-based approaches. Our previous work presented the first large-scale comparison of 27 deep AD algorithms on the TEP and demonstrated the strong performance of reconstruction-based models [15]. While these results are promising, it remains unclear whether models that perform well on synthetic benchmarks generalize to real industrial processes. The present paper addresses this gap by evaluating the same methodological spectrum on three newly released real plant datasets [9]. In practice, anomalies in real plants rarely manifest as abrupt, well-defined events; instead, they often evolve gradually, resemble normal process variability, or are partially masked by control actions.

A key challenge in AD benchmarking is choosing evaluation protocols that account for the temporal nature of anomalies. Point-wise metrics such as the F1-score and AUPRC are still most commonly reported, as they summarize precision–recall trade-offs in a single value [19, 20]. However, they ignore event duration and detection latency. Consequently, different metrics can yield substantially different conclusions about model performance. To mitigate this issue, the literature has proposed window-based scores (NAB, NAB-modified) [21], time-to-detect measures [22], and cost-sensitive utility functions [23]. In this work, we report both F1 and AUPRC in time-series-adapted variants.

The continued popularity of the TEP is driven by its realistic flowsheet, stochastic disturbances, and public availability. However, several limitations warrant caution: (a) faults are introduced as persistent step changes over entire test runs, amplifying anomaly signals and biasing results toward high recall; (b) only a single operating point is represented, whereas real plants undergo grade changes and load variations; (c) the simplified control structure lacks advanced layers such as MPC or APC; and (d) hyperparameter optimization on a small set of standard faults increases the risk of overfitting and score inflation. Recent studies have shown that even trivial baselines, such as an untrained LSTM autoencoder, can achieve F1-scores above 0.93 on TEP [24]. These limitations suggest that results obtained on synthetic benchmarks should be interpreted with care when assessing real-world applicability, underscoring the need for more rigorous and realistic benchmarks—an objective addressed by the datasets used in this study.

## 3. DATASETS

We use recently published steady-state multivariate time-series data [9] generated on a pilot-scale continuous distillation mini-plant with a capacity of 5 t/a located at the TUM Campus Straubing. The setup comprises two distillation columns and a decanter, instrumented with 34 sensors and actuators. Three operating scenarios of increasing industrial relevance are considered: water runs, a heteroazeotropic *n*-butanol/water system, and a reactive poly(oxymethylene) ether (OME) system. Water runs were performed on a single column, yielding approximately 520 h of steady-state operation. Experiments with the *n*-butanol/water system used two columns and a decanter, with campaigns averaging 10 h and 80 h of steady-state data. The OME system was operated in a single-column configuration (30h of data).

All process variables were recorded at a 30s sampling interval, sufficient to capture relevant steady-state

dynamics. Measurements include column and reboiler temperatures, mass flow rates, column head pressure, pump power, and differential pressure signals. A detailed description of the plant setup, process, and instrumentation diagram, sensors and actuators, control strategies, data preparation, and occurring anomalies is provided in the related work [9]. Startup and shutdown phases were removed prior to analysis, leaving only steady-state operation. During routine operation, a range of typical industrial anomalies was observed, including clogging, reboiler level instabilities, overheating, instrument malfunctions, pressure control deviations, and human operating errors. When specific anomaly types did not occur naturally, they were deliberately induced under controlled conditions to ensure a representative yet realistic range of fault behaviours, cf. [9] for details.

Anomalies were labeled following the classification commonly used in anomaly detection studies [15]. For each anomaly, metadata describing its type and cause, affected sensors, and timestamps are provided in the related work [9]. We additionally document the time of fault introduction, its first observable manifestation in the data, and the return to regular operation. Detailed dataset statistics are given in [3]; for the continuous water, butanol, and OME datasets, anomalous samples account for 20%/25%, 24%/41%, and 4%/36% of train/test time steps, respectively. Table 1 summarizes the key characteristics distinguishing our pilot-scale datasets from the TEP benchmark, namely: (1) real sensor noise levels 5–20× higher than in simulation, (2) closed-loop control that actively responds to and masks faults, and (3) gradual fault development rather than step changes.

**Table 1:** Process comparison of TEP data [1] vs data available from the pilot plant [9]

| Aspect | TEP | Butanol Data | OME Data |
|---|---|---|---|
| Fault Behavior | Step Changes | Gradual Evolution | Very Gradual |
| Control Mode | Often open-loop | Closed-loop automatic | Closed-loop automatic |
| Sensor Noise | Roughly 0.1% | 0.5-2% | 0.5-2% |
| Time Constants | Fast | Medium 10-30 min | Slow 30-60 min |

The Supporting Information compares faulty and normal runs from TEP and our plant, illustrating that anomalies in our data are more gradual and subtle. Additional examples in [9] further show that behavior appearing anomalous to a neutral observer may in fact correspond to normal and expected plant operation.

## 4. COMPUTATIONAL EXPERIMENTS

All experiments are conducted using **TimeSeAD**, our open-source benchmark library for time-series anomaly detection [4]. The evaluated methods were benchmarked using their implementations in the open-source TimeSeAD framework and trained by the authors on the considered datasets under a unified preprocessing, hyperparameter-selection, and evaluation protocol. The framework handles data ingestion, stratified splitting, normalization, hyperparameter selection, and metric aggregation, ensuring full reproducibility across datasets and methods. Training data are split into folds for model training and validation across different hyperparameter configurations. To ensure a fair comparison, the total runtime is limited to 24 hours per method. The best-performing configuration is then applied to compute anomaly scores on the test data. For each dataset, sensor channels with constant readings are removed, and the initial transient phase is discarded. The remaining channels are standardized to zero mean and unit variance within each dataset to stabilize optimization [25].

We benchmark 30 state-of-the-art anomaly detection methods, grouped into the following categories:

- **Reconstruction-based (8 methods):** Models are trained to reconstruct normal data accurately; anomalies are identified when reconstruction errors exceed a threshold.
- **Prediction-based (5 methods):** Temporal or probabilistic dynamics are learned to predict future values; large deviations between predictions and observations indicate anomalies.
- **GAN-based generative (3 methods):** A generator and discriminator are trained adversarially; anomalies are poorly reconstructed or classified as unlikely by the discriminator.
- **VAE-based generative (6 methods):** Models learn a latent probabilistic representation while optimizing reconstruction fidelity; anomalies correspond to low likelihood or high reconstruction error.
- **Hybrid (4 methods):** Multiple paradigms are combined to exploit complementary strengths, typically integrating representation learning with explicit anomaly scoring.
- **Shallow baselines (4 methods):** Classical, non-deep approaches based on statistical or simple machine-learning principles, included as interpretable and computationally efficient reference methods.

### Evaluation Metrics

Model performance is assessed using the F1-score and the area under the precision–recall curve (AUPRC), both derived from true positives (TP), false positives (FP), false negatives (FN), and true negatives (TN). Precision measures the fraction of correctly detected anomalies among all detections, while recall quantifies the fraction of actual anomalies that are successfully identified.

$$Precision = \frac{TP}{TP+FP} \quad Recall = \frac{TP}{TP+FN}$$

The F1-score is defined as the harmonic mean of precision and recall:

$$F1 = 2.\frac{Precision.Recall}{Precision + Recall}$$

In addition, we report the AUPRC, which balances precision and recall across all detection thresholds and is particularly well suited to the highly imbalanced nature of anomaly detection datasets. However, conventional point-wise definitions of these metrics are ill-suited for time-series data, where anomalies typically occur as contiguous temporal segments rather than isolated points.

To address this, we use the time-series-aware versions of F1 and AUPRC implemented in the TimeSeAD library [26]. These formulations extend the classical TP/FP/FN definitions by evaluating the temporal overlap between predicted and ground-truth anomaly intervals instead of comparing individual time points. Each predicted segment contributes to precision and recall in proportion to its overlap with one or more true anomaly segments. Partial overlaps are weighted by their intersection length and penalized when a predicted segment covers multiple true segments, or vice versa. The resulting time-series-aware precision and recall are obtained by aggregating these weighted overlaps across all predicted and true intervals, and the F1-score and AUPRC are then computed analogously to their classical definitions.

## 5. RESULTS

Detailed results for all 30 evaluated methods on the three pilot-plant datasets, including F1-score and AUPRC, are provided in the supplementary material (Tables S8–S10). Table S11 reports the mean performance across all three datasets, while Table S12 lists the corresponding results on the Tennessee Eastman Process (TEP) for comparison. To give a compact overview of score distributions, Table 2 summarizes the average, minimum, and maximum F1-scores achieved per dataset.

A clear performance gap emerges when comparing simulated TEP data with real pilot-plant data. While TEP achieves high average scores (F1 = 0.859, AUPRC = 0.906), performance on the pilot-plant datasets is substantially lower across all cases (F1 = 0.532, AUPRC = 0.361). No method exceeds an F1-score of 0.718 or an AUPRC of 0.597, indicating that none of the evaluated approaches approaches the benchmark performance observed on synthetic data.

Despite this overall performance degradation, deep-learning-based methods consistently outperform shallow baselines on the real-world datasets. Multiple deep learning approaches achieve substantially higher F1-scores than the best-performing shallow baseline across all settings, reaffirming the advantage of deep representation learning even under realistic industrial conditions (Table S11 – results for AUPRC in supporting information). Among the deep-learning-based approaches, the strongest performers vary by dataset: LSTM-2S2-P achieves the best F1-score on Butanol and Water, whereas generative VAE methods, particularly LSTM-VAE and LSTM-DVAE, perform best on OME. At the method-type level, hybrid approaches achieve the highest mean F1-score across the three pilot datasets, whereas, for deep methods, reconstruction-based methods rank first in mean AUPRC, highlighting strong dataset- and metric-dependence.

**Table 2:** Dataset-level F1-score statistics across evaluated AD methods showing average, minimal, and maximal F1-Score, and the span (AUPRC results in appendix)

| F1 | average | min | max | Δ |
|---|---|---|---|---|
| Butanol | 0.538 | 0.291 | 0.624 | 0.333 |
| OME | 0.629 | 0.215 | 0.718 | 0.503 |
| Water | 0.428 | 0.104 | 0.531 | 0.427 |
| Average | 0.532 | 0.267 | 0.590 | 0.323 |
| TEP | 0.859 | 0.497 | 0.911 | 0.414 |

**Table 3:** F1-scores of the best-performing deep-learning and shallow methods, and the mean across all three datasets

| | n-butanol | OME | water | mean |
|---|---|---|---|---|
| Best Deep | 0.624 | **0.718** | 0.531 | **0.624** |
| Best Shallow | 0.588 | 0.666 | 0.433 | 0.562 |

## 6. DISCUSSION

Our earlier benchmark study on the TEP dataset [11–15] showed that most deep anomaly-detection methods achieve near-perfect performance when anomalies appear as persistent fault states. In contrast, our evaluation

of real pilot-plant distillation data reveals a markedly different picture. When anomalies are transient, gradual, or intermittent, as is typical in industrial practice, the same methods achieve at best an F1-score of 0.718. This pronounced performance degradation highlights a key limitation of current approaches: their strong reliance on temporally persistent and clearly separable fault signatures, which are common in synthetic benchmarks but rare in real plants. Importantly, this performance gap cannot be attributed to label uncertainty. In our datasets, the onset and resolution times of anomalies are known, allowing us to rule out annotation noise as a confounding factor. Instead, the observed differences directly reflect model behavior under realistic operating conditions.

Across the three datasets and both evaluation metrics, no single method or method family consistently dominates. However, across all datasets, several deep-learning-based methods outperform all shallow baselines in terms of F1-score, and in two out of three datasets also with respect to AUPRC. While GenAD [27] and AnomalyTransfer [28] achieve comparatively low average F1-scores, they exhibit stronger AUPRC performance on selected datasets. Hybrid approaches show a slight average advantage but also pronounced dataset-specific weaknesses, underscoring the lack of robust generalization across fault types and evaluation metrics.

The root cause of this discrepancy lies in the development of industrial faults. Real process anomalies typically evolve gradually due to fouling, clogging, drift, or degradation rather than abrupt step changes. The fault scenarios in our datasets [3, 9] were explicitly designed to reflect this behavior. Gradual faults are inherently more difficult to detect: early deviations often remain within normal variability, fault signatures evolve slowly, and closed-loop control systems may partially compensate disturbances, thereby masking their effects. Controllers suppress deviations in controlled variables while redistributing the effects of anomalies into manipulated variables, such as flow rates or reboiler duties. Consequently, faults may be physically present but only indirectly observable through control actions, in stark contrast to TEP, where faults are introduced as step disturbances with clear onsets and pronounced responses.

These differences lead to a systematic performance gap, with F1-scores of approximately 0.80–0.90 on TEP compared to 0.55–0.72 on real plant data. Crucially, this gap does not primarily indicate insufficient model complexity or flawed algorithmic design. Instead, it reflects fundamental process-engineering challenges: (i) gradual fault evolution, (ii) active feedback control that masks faults in controlled variables, and (iii) sensor noise levels that are 5–20 times higher than in synthetic benchmarks.

From a deployment perspective, reduced detection performance on real industrial data should therefore be expected rather than interpreted as model failure. Anomalies often become observable first through changes in control actions rather than deviations in process outputs. Effective anomaly-detection systems must explicitly incorporate manipulated variables and control behavior and align detection window sizes with process time scales. For continuous distillation, fault dynamics on the order of 10–60 minutes imply an unavoidable trade-off between detection reliability and alarm latency.

Robust methods must therefore demonstrate stable performance across diverse datasets rather than excelling only on highly structured synthetic benchmarks. Deep-learning-based methods not only outperform shallow approaches under realistic conditions but also offer greater potential for further methodological advances, making them a promising path toward closing the current performance gap between synthetic and real-world benchmarks.

Finally, this work provides the first publicly available pilot-scale distillation benchmark featuring realistic faults, industrial noise characteristics, and closed-loop control interactions. We hope it fosters the development of process-aware anomaly-detection methods that explicitly account for plant physics and control behavior and are validated under realistic industrial conditions, rather than treating chemical plants as generic time-series systems.

## 7. LIMITATIONS AND FUTURE WORK

While this benchmark focuses on distillation-related process data, several limitations should be acknowledged. Although the datasets and benchmarks presented in this work provide a more realistic assessment of anomaly detection methods than commonly used synthetic benchmarks, they cannot exhaustively represent all anomalies encountered in industrial distillation processes. Rare or safety-critical events, such as severe equipment failures or cascading faults, are inherently difficult or unsafe to reproduce in a pilot-scale plant. Future data collection campaigns could therefore expand the diversity of fault types, include additional separation processes, and capture longer-term degradation phenomena as well as more subtle control-related anomalies. In addition to collecting further real-world data, data augmentation and generation offer substantial potential to mitigate current data limitations [58].

Second, the benchmarking framework relies on the current capabilities of the TimeSeAD library. While TimeSeAD enables reproducible preprocessing, training, and evaluation across a wide range of anomaly detection methods, it does not yet cover all approaches or evaluation protocols proposed in the literature. Future work will extend TimeSeAD with additional models, improved hyperparameter optimization strategies, and alternative evaluation metrics that more explicitly account for

temporal aspects such as detection delay and fault duration. Given the still considerable development potential of deep-learning-based methods, compared to the largely saturated performance of shallow approaches, the integration of transformer-based models, in particular the recently proposed NeuTraL AD method [56], into the library and our benchmark datasets is of high interest.

Third, while F1-score and AUPRC provide complementary perspectives on model performance, they can lead to different rankings and interpretations. To achieve a more comprehensive and task-specific evaluation, future work should investigate additional metrics tailored to anomaly detection, such as the recently proposed ALARM metric [57], which may improve comparability across datasets and operating conditions.

Finally, although the presented pilot-scale and industrial datasets capture realistic process dynamics, noise characteristics, and operational variability, they cannot be assumed to be universally representative of all large-scale industrial systems. Differences in plant design, control strategies, sensor quality, and operating regimes may substantially influence anomaly characteristics and model performance. Consequently, future studies should incorporate data from additional plants and process types to further assess the robustness and generalizability of anomaly detection methods across industrial settings.

## 8. SUMMARY OF CONTRIBUTIONS

The main contributions of this work are:

- We benchmark 30 anomaly detection methods, including deep-learning-based and classical approaches, on steady-state multivariate time-series data from pilot-scale and industrial continuous distillation processes.
- We show that methods achieving strong performance on synthetic benchmarks, such as the Tennessee Eastman Process, experience a pronounced drop in performance when evaluated on real process data.
- We demonstrate that no single method consistently performs well across datasets and operating conditions, while several deep-learning-based methods outperform shallow baselines under realistic process conditions.
- We highlight the strong dependence of benchmarking outcomes on the choice of evaluation metrics and emphasize the need for time-series–aware evaluation in industrial anomaly detection.

## ABSTRACT

Piping and instrumentation diagrams (P&IDs) encode the functional structure of process plants and are a critical yet underutilised source of engineering knowledge for digital twins and intelligent decision support. However, digitising legacy P&IDs remains challenging due to heterogeneous drawing standards and the reliance of existing methods on brittle symbol recognition and rule-based connectivity reconstruction. This work reframes P&ID digitization as the extraction of equipment tags and inference of process topology, rather than graphical reproduction. We propose a two-stage workflow based on multimodal large language models, in which visual extraction and topology reconstruction are treated as distinct reasoning stages guided by chemical engineering process knowledge. The approach is evaluated on two ANSI-standard P&ID case studies of increasing complexity. Results show that decomposing visual extraction and topology reasoning yields more accurate and structurally consistent process representations than end-to-end digitization, highlighting the potential of language-model-based, knowledge-guided workflows for scalable and semantically reliable P&ID digitization.

**Keywords**: P&ID digitisation, Multimodal large language models, Graph reconstruction

## INTRODUCTION

Piping and instrumentation diagrams (P&IDs) constitute the structural backbone of a process plant, capturing how equipment, instrumentation, and control elements are interconnected to realise the intended process operation. Beyond providing spatial or locational information, P&IDs encode the functional logic of the plant, describing how units interact, how material and signals propagate, and how control strategies are implemented. As such, they represent an authoritative source of process understanding that spans design intent, operational constraints, and safety considerations.

Despite their central role, the information embedded in P&IDs remains largely underexploited in industrial practice. In many plants, P&IDs continue to be treated primarily as static reference documents rather than as structured, machine-interpretable sources of knowledge. This limits their integration into advanced engineering workflows, where explicit representations of process topology could support automated consistency checking, decision support, and interaction with digital twins. As the process industries move toward smart factories and data-driven operation, the ability to interrogate and reason over P&IDs becomes increasingly important.

A major barrier to such “smart” use of P&IDs is the legacy nature of existing documentation. A substantial fraction of industrial P&IDs still exists as paper drawings or unstructured raster images, often produced over decades using heterogeneous drafting standards and conventions. Converting these legacy artefacts into structured, machine-readable representations remains labour-intensive and typically requires extensive manual interpretation by domain experts. This manual effort does not scale and represents a significant obstacle to unlocking the full value of P&IDs within modern digital infrastructures, including retrieval-augmented generation systems and interactive engineering tools.

From a technical standpoint, P&ID digitization is challenging due to variability in symbol rendering, annotation practices, and drawing quality across companies and engineering contractors. While human engineers resolve such variability using contextual and domain knowledge, automated systems must operate on

inconsistent and ambiguous graphical representations. Conventional digitization pipelines therefore rely on deep learning models for symbol and text recognition combined with rule-based methods to reconstruct process connectivity [1–3]. Although effective in constrained settings, these approaches exhibit limited generalisation across drawing standards [1, 5], require extensive manual engineering of reconstruction rules [4], and propagate errors from early recognition stages into the reconstructed topology. Consequently, many existing methods emphasise graphical detection while falling short of producing semantically reliable representations of process structure.

Recent advances in vision-language models (VLMs) and multimodal large language models (MLLMs) provide an opportunity to reconsider this paradigm. By jointly grounding visual and semantic information, such models can reduce dependence on specific symbol appearances and bespoke training for individual drawing standards. When combined with language-based reasoning, they further enable inference over extracted engineering artefacts in a manner that more closely resembles expert interpretation of P&IDs.

In this work, we investigate the use of multimodal language models and multi-agent workflows to transform legacy P&IDs into structured, semantically meaningful representations of process topology. By decoupling visual extraction from topology reasoning, the proposed approach aims to reduce manual digitization effort and enable P&IDs to function as active, machine-interpretable sources of process knowledge, supporting intelligent interaction and decision-making in future smart manufacturing environments.

## LITERATURE REVIEW

Existing research on P&ID digitization has primarily focused on automating the extraction of symbols, text, and connectivity from legacy diagrams using computer vision and machine learning techniques. The following review summarises the main methodological directions, highlighting their strengths and limitations with respect to robustness, scalability, and semantic correctness.

### Classical image processing and rule-based pipelines

Early approaches to P&ID digitization predominantly relied on classical image processing, optical character recognition (OCR), and engineering heuristics. These systems typically detect graphical primitives such as symbols, lines, and text using template matching and rule-based algorithms, followed by proximity-based association to identify equipment tags and infer connectivity. Kang et al. [6] demonstrated the feasibility of converting raster P&IDs into structured databases using such techniques, while maintaining compatibility with downstream engineering tools. However, these methods are highly sensitive to drawing quality, symbol variability, and vendor-specific drafting conventions, which limits their robustness when applied to heterogeneous industrial datasets [7].

### Deep learning for visual recognition

To address the limitations of purely rule-based methods, subsequent research has integrated deep learning for visual recognition tasks. Convolutional neural networks and modern text detection architectures have been applied to identify equipment symbols, instrumentation, and tag text in P&IDs [3]. Industrially oriented pipelines combine deep learning–based detection of symbols, text, and lines with heuristic association rules to reconstruct connectivity and export structured representations aligned with engineering information models [8]. While these approaches significantly improve robustness in component recognition, topology reconstruction remains challenging, as rule-based connectivity inference is sensitive to broken lines, ambiguous junctions, and overlapping annotations commonly found in real plant drawings.

### Graph-based formulations of topology reconstruction

Recognising that the primary engineering value of a P&ID lies in its process topology, several studies explicitly model digitization as a graph reconstruction problem. In this formulation, equipment and instruments form graph nodes, while piping and signal connections define edges. Mani et al. (2020) [9] combine deep learning–based detection with graph search techniques to traverse line structures and infer connectivity. Similarly, Digitize-PID introduces a structured pipeline that incorporates domain-based validation to correct implausible connections and improve graph consistency [1]. More recently, relation-based and transformer-style models have been proposed to directly infer connectivity from diagram images, framing P&ID understanding as an image-to-graph task [9]. Although these methods show improved structural reasoning, they typically require specialised training data with explicit edge annotations and may struggle to generalise across diverse drafting styles.

### Data scarcity and generalisation challenges

A practical challenge in P&ID digitization is the scarcity of annotated datasets, as industrial drawings are often proprietary. To mitigate this, recent work explores semi-supervised and weakly supervised learning strategies. Gupta et al. (2024) [11] propose a semi-supervised symbol detection approach that reduces annotation effort while improving generalisation across symbol variants. Complementary methods exploit auxiliary

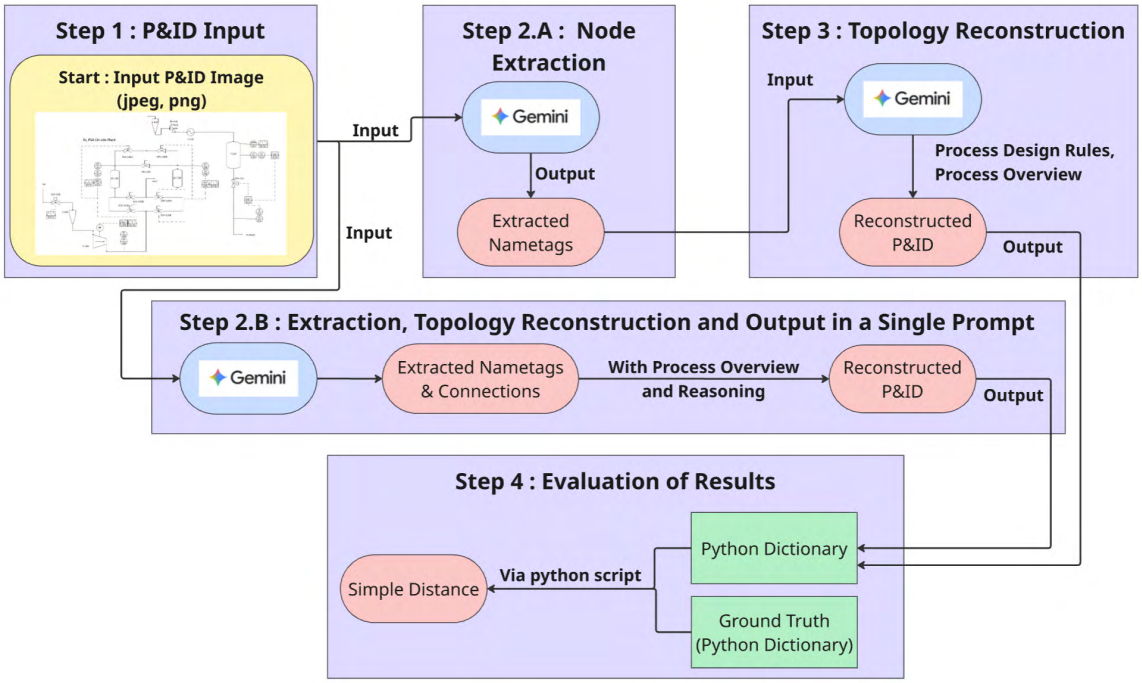

**Figure 1.** Overview of the proposed P&ID digitisation workflows

engineering artefacts such as legend sheets to infer symbol semantics with minimal manual labelling [12]. While these approaches improve robustness in symbol recognition, they do not directly address the inference of process connectivity under uncertainty.

## Engineering knowledge and validation

Across the literature, it is widely acknowledged that purely visual or data-driven methods are insufficient to guarantee engineering correctness. Equipment type, tag nomenclature, and process conventions impose strong constraints on allowable connectivity—for example, pumps require suction and discharge connections, vessels connect via nozzles, and instruments interface through signal rather than process lines. Several studies therefore incorporate post-processing validation stages based on engineering rules to filter implausible structures and enforce consistency with expected process behaviour [8, 9]. However, such rules are typically applied locally and procedurally, limiting their ability to resolve global ambiguities in complex diagrams.

## Language-based reasoning for P&ID understanding

Recent advances in large language models (LLMs) and vision-language models (VLMs) have motivated exploratory studies on their application to engineering diagrams. Initial investigations indicate that direct application of LLMs to P&ID digitization without grounding or constraint enforcement leads to inconsistent or non-physical interpretations [13]. Nevertheless, these models demonstrate strong capabilities in reasoning over structured engineering information when provided with explicit inputs and constraints, suggesting their potential role in topology inference when combined with reliable visual extraction and engineering knowledge.

# METHODOLOGY

## Problem formulation

We adopt a process-centric formulation of the P&ID digitization problem. Rather than aiming to reproduce graphical details of the diagram, the primary objective is to extract (i) identifiable process units and instrumentation, represented by their tags, and (ii) the interconnections between these units that define the process topology. Under this formulation, a digitised P&ID is represented as a graph, where nodes correspond to equipment or instrumentation tags and edges represent material, signal, or control connections between them.

Conventional digitization pipelines typically address this task through a combination of deep learning–based visual recognition and rule-based connectivity reconstruction. In contrast, we investigate whether modern multimodal large language models (MLLMs), combined with language-based reasoning, can directly infer structured process representations from P&ID images, and whether decomposing the task into extraction and reasoning stages improves robustness and accuracy.

## Overview of evaluation pathways

We assess language-model-based P&ID digitization using two complementary workflows, illustrated schematically in Figure 1. The first workflow performs extraction and topology reconstruction in a single step using an MLLM. The second workflow decomposes the task into two stages—node extraction and topology reconstruction—handled by separate language model instances, with the reconstruction stage augmented by explicit chemical engineering process knowledge. In both cases, the final output is a structured graph representation of the P&ID, which is evaluated against a manually constructed ground truth.

## Pathway I: End-to-end digitization with an MLLM

In the first workflow (Figure 1, Step 2.B), the P&ID image is divided into eight spatial slices to mitigate resolution and context-length limitations of the multimodal model. These image slices, together with a short high-level textual description of the diagram, are provided as input to an MLLM. The model is prompted to digitise the P&ID directly into a structured representation expressed as a Python dictionary, encoding process units as nodes and their interconnections as edges.

To assess the quality of the generated representation, a ground-truth graph of the same P&ID is manually constructed using the same dictionary format. The predicted and ground-truth graphs are compared using three metrics. Node identification accuracy measures the proportion of correctly identified tags, while edge recognition accuracy measures the proportion of correctly inferred connections. In addition, overall structural similarity is quantified using a simple distance metric. The simple distance is defined as the total number of node- and edge-level discrepancies between the predicted and ground-truth graphs, including missing nodes, extra nodes, missing edges, extra edges, and edge-type mismatches.

This workflow evaluates the feasibility of treating P&ID digitization as a single-step multimodal reasoning task.

## Pathway II: Decomposed extraction and topology reconstruction

The second workflow (Figure 1, Steps 2.A and 3) explicitly separates visual extraction from topology inference, reflecting the hypothesis that reasoning over process structure benefits from abstraction away from raw visual input.

## Node extraction

In the extraction stage (Figure 1, Step 2.A), an MLLM is provided only with the P&ID image slices and tasked with identifying the set of process units and instrumentation present in the diagram, essentially functioning as an advanced Optical Character Recognition (OCR) tool. The model outputs a list of equipment and instrument tags without attempting to infer connectivity, thereby isolating the visual recognition task.

## Topology reconstruction with engineering knowledge

In the reconstruction stage (Figure 1, Step 3), the output of the extraction step is passed to a second language model. This model has no access to the original P&ID images and relies exclusively on symbolic inputs. In addition to the extracted node list, the model is provided with (i) a high-level process overview and (ii) a document describing general chemical engineering process design rules. It is important to note that the inclusion of such chemical engineering context does not involve fine-tuning or training the underlying model. Instead, this study utilises an off-the-shelf MLLM (Gemini-3.0-Pro), where domain-specific knowledge is introduced entirely via prompt engineering, supplied to the language model in the form of an accompanying text document.

The process design rules are organised into three categories. The first category defines common tag nomenclature and abbreviations for equipment, valves, and instrumentation, capturing typical conventions used to encode process streams, destinations, and unit sequencing. The second category describes common physical connectivity patterns between process units, reflecting standard design and maintenance practices. The third category addresses control and instrumentation structure, guiding the model in inferring control loops and signal hierarchies, including the directionality of signals between sensors, controllers, and actuators.

Using these inputs, the reconstruction model infers the connectivity between nodes and outputs a structured graph representation in the same format as Workflow I.

## Evaluation Protocol

For both workflows, the reconstructed P&ID graph is evaluated against the same ground-truth representation using identical metrics, as shown in Figure 1 (Step 4). This enables a direct comparison between end-to-end multimodal digitization and the decomposed extraction–reasoning approach, isolating the effect of task decomposition and explicit process knowledge on topology reconstruction accuracy.

# CASE STUDY

To evaluate the proposed P&ID digitization workflows, two representative process diagrams were selected as case studies. Both P&IDs were designed in accordance with the ANSI standard and use consistent naming conventions for equipment and instrumentation

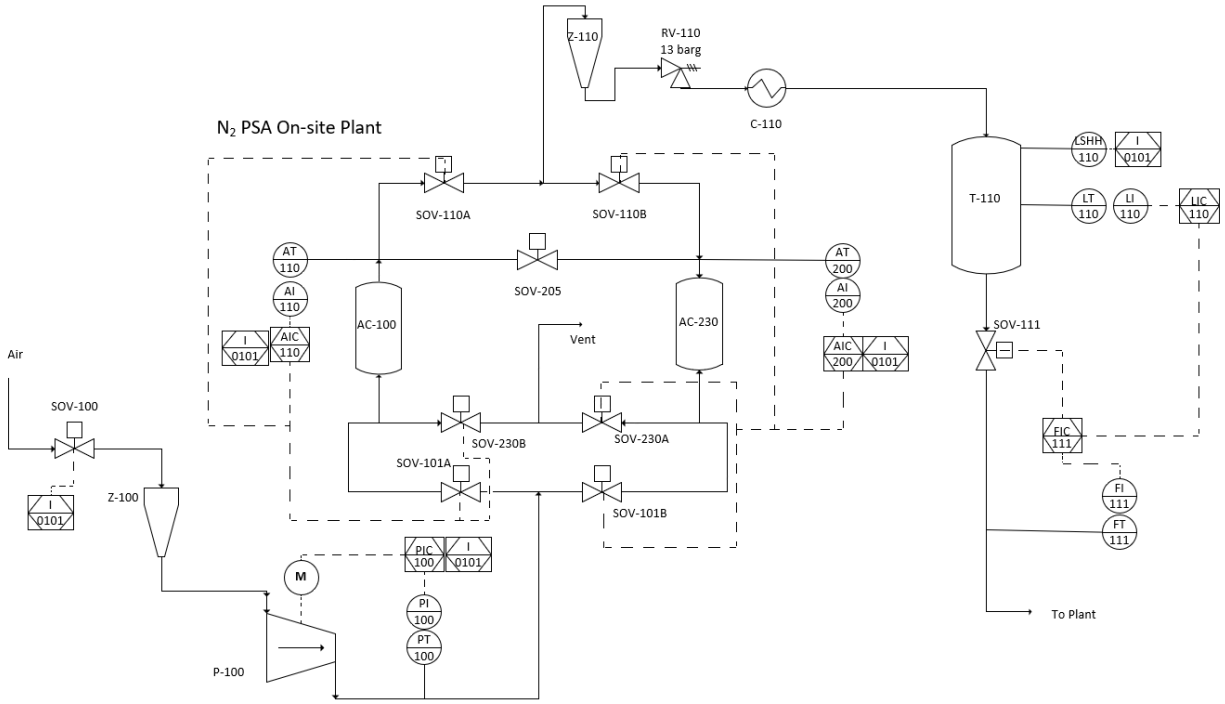

**Figure 2.** Nitrogen Pressure Swing Adsorption P&ID

to minimise variability arising from tag nomenclature rather than diagram structure.

The first case study, shown in **Figure 2**, corresponds to a nitrogen pressure-swing adsorption (PSA) process. The second case study, shown in **Figure 3**, represents a wet flue gas desulfurization (FGD) process. These two systems were chosen to reflect different levels of process and topological complexity while remaining representative of industrial process flows commonly encountered in practice.

## P&ID complexity

We quantified the complexity of each P&ID by comparing the total number of nodes and edges, where a higher number of nodes and edges represents a more complex case study, as shown in Table [1].

**Table 1.** P&ID Complexity Metrics

| P&ID | Complexity |
|---|---|
| Nitrogen Pressure Swing Adsorption | Total nodes: 38<br>Total edges: 53<br>Total combined: 91 |
| Wet Flue Gas Desulfurization | Total nodes: 73<br>Total edges: 101<br>Total combined: 174 |

## Experimental setup

At the start of each case study, the P&ID image was divided into eight equal-resolution slices to mitigate resolution and context-length limitations of the multimodal language models. In addition, a short, high-level textual description of the process was prepared for each P&ID to provide contextual information where applicable.

For the end-to-end workflow, the P&ID slices and process overview were provided to Gemini-3.0-pro in a single prompt. The model was instructed to output a Python dictionary representing the P&ID, with equipment and instrumentation tags as nodes and their interconnections as edges.

For the decomposed workflow, digitization was split into two stages using a multi-agent setup implemented in Dify, an agentic workflow framework. In the first stage, the language model was provided only with the P&ID image slices and tasked with extracting equipment and instrumentation tags without inferring connectivity. The model is prompted to solely extract equipment tags and numbering while ignoring the graphical symbols entirely. In the second stage, the extracted node list was passed to a separate instance of the language model, together with the process overview and a document describing general chemical engineering process design rules. This second instance inferred the interconnections between nodes using language-based reasoning on the linguistic meaning of the extracted tags, guided by chemical engineering domain knowledge regarding standard configurations of process design. Since no graphical symbols are used as an input to this reconstruction stage, the

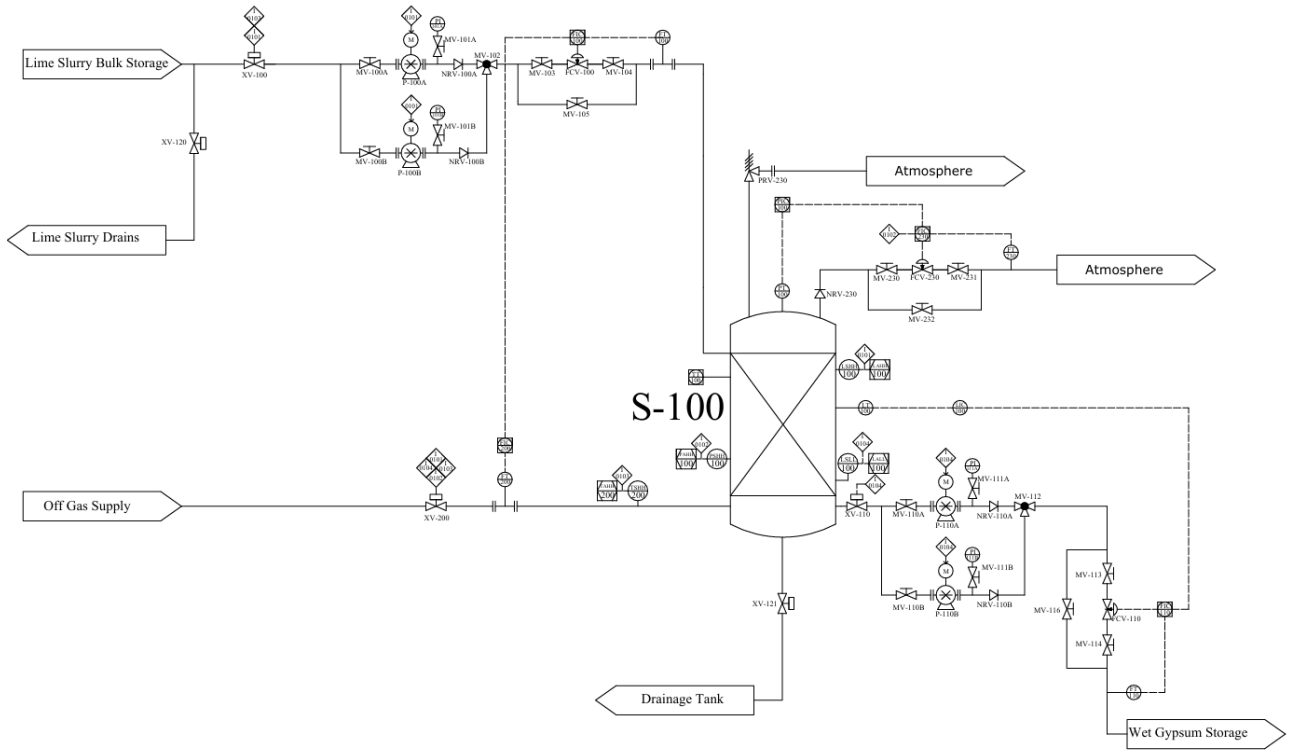

**Figure 3.** Wet Flue Gas Desulfurization P&ID

traditional challenge of spatially mapping text annotations to corresponding visual symbols is bypassed. Importantly, the reconstruction model had no access to the original P&ID images and shared no memory with the extraction model beyond the list of identified nodes.

Although Gemini-3.0-pro was used for both extraction and reconstruction in this case study, the workflows are model-agnostic. Any vision-language model can be substituted in the extraction stage, and any reasoning-capable language model can be used in the reconstruction stage.

## Evaluation procedure

For each P&ID case study, a ground-truth representation was manually constructed in the same Python dictionary format as the model outputs, with equipment and instrumentation tags represented as nodes and their interconnections represented as edges. Performance was evaluated by comparing the predicted graph against the ground truth using accuracy-based metrics and a structural discrepancy metric.

To account for stochastic variability in language model outputs, each workflow was executed ten times using identical prompts. All reported results correspond to the mean and standard deviation across these runs.

## Comparative Analysis

The experimental design enables several comparative analyses. First, the performance of end-to-end digitisation with an MLLM (E2E-MLLM) is compared against decomposed extraction and topology reconstruction (DETR) to assess the effect of task decomposition. Second, the end-to-end workflow is evaluated with and without a high-level process overview to examine the impact of contextual information. Finally, within the decomposed workflow, topology reconstruction with and without explicit chemical engineering design rules is compared to quantify the contribution of domain-specific knowledge to connectivity inference.

Together, these comparisons isolate the roles of contextual information, task decomposition, and engineering knowledge in language-model-based P&ID digitisation.

# RESULTS

The results reported in Tables 2.A and 2.B are evaluated using three accuracy-based metrics and one structural discrepancy metric. Total accuracy measures the proportion of correctly reconstructed nodes and edges relative to the ground truth, while node accuracy and edge accuracy quantify the correctness of equipment identification and connectivity inference, respectively.

In addition to these local accuracy measures, global structural similarity between the predicted and ground-truth graphs is quantified using a simple distance metric. This metric counts the total number of discrete modifications required to reconcile the predicted graph with the ground truth, including missing nodes, extra nodes, missing edges, extra edges, and edge-type mismatches. A lower simple distance therefore indicates that fewer structural changes are required for the reconstructed P&ID to match the reference topology, providing a direct and interpretable measure of topological correctness. All reported values are expressed as mean ± standard deviation over ten independent runs.

Formally, the simple distance is defined as:

$$D_s = | V_{miss} | + | V_{extra} | + | E_{miss} | + | E_{extra} | + | E_{type} | \quad (1)$$

where $V_{\text{miss}}$ and $V_{\text{extra}}$ denote missing and extra nodes, $E_{\text{miss}}$ and $E_{\text{extra}}$ denote missing and extra typed edges, and $E_{\text{type}}$captures edge-type mismatches between the predicted and ground-truth graphs.

The accuracy metrics are computed as follows:

$$\textbf{\textit{Total Accuracy}} = \frac{\sum(\textbf{\textit{Correct Nodes}} + \textbf{\textit{Correct Edges}})}{\sum(\textbf{\textit{Total Nodes}} + \textbf{\textit{Total Edges}})} \quad (2)$$

$$\textbf{\textit{Node Accuracy}} = \frac{\sum \textbf{\textit{Correct Nodes}}}{\sum \textbf{\textit{Total Nodes}}} \quad (3)$$

$$\textbf{\textit{Edge Accuracy}} = \frac{\sum \textbf{\textit{Correct Edges}}}{\sum \textbf{\textit{Total Edges}}} \quad (4)$$

## Nitrogen PSA plant

Results for the nitrogen pressure-swing adsorption (PSA) P&ID are summarised in Table 2.A. Using end-to-end digitization with a multimodal large language model (E2E-MLLM) as the baseline configuration, the model achieves a total accuracy of 68.56%, with relatively high node accuracy (86.32%) but substantially lower edge accuracy (55.58%). This disparity indicates that while equipment identification is largely successful, connectivity inference remains challenging when extraction and reasoning are performed jointly.

Augmenting the end-to-end prompt with a process overview yields a modest improvement across all metrics, increasing total accuracy to 70.67% and reducing the simple distance from 45.6 to 41.0. This suggests that high-level contextual information helps resolve some connectivity ambiguities; however, structural discrepancies remain pronounced, as reflected by the still relatively high simple distance.

A more substantial improvement is observed when switching to the decomposed extraction and topology reconstruction (DETR) workflow augmented with both a process overview and explicit process design rules. In this configuration, DETR achieves a markedly higher total accuracy of 88.78%, with node accuracy reaching 100% and edge accuracy improving to 80.58%. This improvement is accompanied by a significant reduction in simple distance to 24.0, indicating that substantially fewer node and edge modifications are required to align the reconstructed graph with the ground truth.

## Slime and Off gas Plant

Results for the slime and off-gas plant P&ID, which represents a more complex process topology, are shown in Table 2.B. In this case, the limitations of end-to-end digitisation are more pronounced. The baseline E2E-MLLM configuration achieves a total accuracy of 67.31% and exhibits a high simple distance (68.20), indicating substantial structural deviation from the reference topology.

Providing a process overview in the end-to-end workflow improves total accuracy to 71.81% and reduces the simple distance to 59.70, highlighting the increasing importance of contextual information as diagram complexity grows. Nevertheless, a significant number of structural discrepancies persist, particularly in connectivity inference.

Transitioning to the decomposed extraction and topology reconstruction (DETR) workflow further clarifies the role of domain knowledge. While decomposed extraction and reconstruction without explicit process knowledge does not consistently outperform end-to-end digitisation, the highest performance is achieved when DETR is augmented with both a process overview and chemical engineering design rules. In this configuration, the model attains a total accuracy of 85.21%, near-perfect node accuracy (99.73%), and a substantially reduced simple distance of 48.30, indicating a closer match to the ground-truth process topology.

**Table 2A.** Nitrogen PSA Plant Results

| | E2E | E2E + Knowledge | DETR | DETR + Knowledge |
|---|---|---|---|---|
| Total Acc.(%) | 68.56 ± 0.07 | 70.67 ±0.06 | 71.22 ± 0.03 | 88.78 ± 0.02 |
| Node Acc. (%) | 86.32 ± 0.07 | 87.37 ± 0.05 | 100.00± 0.00 | 100.00 ± 0.00 |
| Edge Acc. (%) | 55.58 ± 0.08 | 59.98 ± 0.09 | 50.19 ± 0.05 | 80.58 ± 0.04 |
| Simple Distance | 45.60 ± 6.52 | 41.00 ± 6.70 | 51.80 ± 3.99 | 24.00 ± 4.67 |

**Table 2B.** Slime & Offgas Plant Results

| | E2E | E2E + Knowledge | DETR | DETR + Knowledge |
|---|---|---|---|---|
| Total Acc. (%) | 67.31 ± 0.07 | 71.81 ± 0.06 | 64.74 ± 0.02 | 85.21 ± 0.03 |
| Node Acc. (%) | 78.38 ± 0.08 | 78.20 ± 0.09 | 100.00± 0.00 | 99.73 ± 0.01 |
| Edge Acc. (%) | 58.87± 0.07 | 66.63 ± 0.07 | 37.84± 0.04 | 74.12 ± 0.05 |
| Simple Distance | 68.20 ± 12.64 | 59.70± 10.90 | 116.60 ± 8.22 | 48.30 ± 10.23 |

Across both case studies, several consistent trends emerge. First, DETR augmented with process knowledge consistently outperforms end-to-end digitisation across all metrics, with the largest gains observed in edge accuracy and simple distance. Second, providing high-level process context improves performance for both workflows but does not fully resolve structural inconsistencies when extraction and reasoning are coupled. Third, incorporating explicit chemical engineering design rules during topology reconstruction yields the most structurally faithful representations, as evidenced by the lowest simple distances.

Taken together, these results show that accurate P&ID digitisation requires not only reliable visual extraction but also explicit reasoning over process structure, and that separating these concerns—when guided by domain knowledge—leads to reconstructions that are both more accurate and more closely aligned with engineering intent.

## CONCLUSION

This work investigated the use of multimodal large language models and decomposed, agent-based workflows for the semantic digitisation of piping and instrumentation diagrams. By reframing P&ID digitisation as a problem of extracting equipment tags and inferring process topology, we demonstrated that separating visual extraction from topology reconstruction leads to more accurate and structurally consistent representations than end-to-end digitisation with a single prompt. Across two industrially representative case studies, the proposed decomposed extraction and topology reconstruction workflow consistently outperformed end-to-end approaches, particularly in edge accuracy and structural consistency.

The results show that incorporating high-level process context and explicit chemical engineering design rules during topology reconstruction substantially improves performance, especially for more complex diagrams. This highlights the importance of embedding domain knowledge directly into the digitisation workflow, allowing chemical engineers to actively contribute to the definition of process rules rather than relying on extensive manual refinement of rule-based or data-driven computer vision systems. The resulting structured representations align naturally with graph-based standards such as DEXPI, supporting downstream integration with digital twins and intelligent engineering tools.

A practical limitation of the proposed approach is the use of proprietary language models, which raises confidentiality concerns when handling sensitive industrial P&IDs. However, the workflow itself is model-agnostic and can be readily adapted to open-source multimodal language models, enabling deployment in environments with strict data governance requirements. A systematic comparison between proprietary and open-source models was beyond the scope of this study and remains an important direction for future work.

Future research will focus on closing the loop between reconstruction and validation by introducing feedback mechanisms that iteratively refine the inferred topology based on consistency checks and engineering constraints. Such feedback-driven refinement has the potential to further reduce structural discrepancies and enable fully automated, trustworthy P&ID digitisation pipelines based on multimodal language models.

## ABSTRACT

Machine learning (ML) has attracted growing interest in process systems engineering for its potential in process design, synthesis, and optimization. By learning complex patterns from data, ML methods complement traditional first-principles modelling and heuristic approaches, particularly for conceptual process design and the exploration of alternatives. Although current text-based representations capture unit-level connectivity, they lack a holistic view of process intent, equipment hierarchy, and contextual information to guide learning and inference. Consequently, models trained on such linear token sequences tend to reproduce syntactic structure rather than underlying process reasoning, thus limiting interpretability and user control. In this work, we introduce a contextual framework for representing process flowsheet information in ML models that embeds process engineering logic directly into the model inputs. The approach combines a structured, text-based representation of process topology with context descriptors that define the process type and synthesis task. The task context, such as simplified block flow design, enables engineers to steer learning and generation towards intended designs. This shifts control from post-training filtering to context-driven learning, allowing models to act as flexible, engineer-guided synthesis tools rather than passive pattern generators. Transformer models were trained on 100, 000 synthetic ethylene glycol process flowsheets, with and without context features. To emulate user-guided synthesis, the models were asked to generate different design configurations involving critical equipment (reactors and distillation columns). Models trained without contextual input achieved an average success rate of 24.6% on average (59.6% in the best case), whereas context-aware models achieved 98.8% on average.

**Keywords**: Artificial Intelligence, Process Synthesis, Machine Learning, Process Design, Intelligent Systems

## INTRODUCTION

Machine learning (ML) and artificial intelligence (AI) have a long history in both computer science and chemical engineering research. Since the 1980s, early trials sought to integrate AI methods into chemical engineering toolboxes [1]. Although research activity was intermittent, progress was made in property prediction, process control, and surrogate modelling. There were some trials, even in process synthesis and design as early as expert systems [2], but the exploration was not continuous until recently. With the progress of ML research since the 2010s, a new wave of AI-assisted or ML-integrated process synthesis approaches has emerged. Recent advances in generative AI have shown promise for producing candidate flowsheets, completing partial designs, and accelerating conceptual process design studies [3–7]. Different methodologies and models have been applied, ranging from power cycles [8, 9] to chemical production processes of ethylene oxide [10], ethyl tert-butyl ether [11], dimethyl ether [12], and methyl acetate [13]. These developments raise the prospect of interactive, data-driven tools that can support engineers in exploring wide design spaces during early-stage process development.

One of the central challenges lies in how to represent process flowsheet information for ML. Depending on the chosen models and approach, text sequences [9, 14], graphs [13], or matrices [15] can be used to carry the topological information. These representations capture unit-

level connectivity and basic chemical engineering principles and may include control elements [14] or operational information [16]. Nevertheless, when training ML models, most approaches treat process flowsheets as pure autoregressive problems, learning how to predict the next token from previous information. As a result, higher-level engineering concepts, such as equipment hierarchy or relative importance, are not explicitly communicated to the model. It is expected that the model should infer such abstractions from sufficient examples.

This limitation becomes particularly apparent when generative models are used to explore alternatives or to produce a certain type of process. Without explicit information about the desired process identity or design objective, models tend to reproduce biases occurring in the training data. In the work of Nabil et al. [9], although the model can learn higher-complexity structures syntactically, these gradually disappear from the outputs due to computational limitations, finite sample sizes, and complex structures failing filters more frequently. This creates an undesired and uneven exploration-exploitation trade-off that is dominated by simpler designs [17].

Probable solutions include inference-time masking strategies to promote exploration or information-gain objectives to increase solution-space coverage. Although the latter have not yet been explored in the process synthesis literature, there are masking examples to increase model accuracy and success rates [12]. However, its primary role is to simplify decision-making and accelerate convergence rather than to increase structural diversity. Although such strategies can improve many performance metrics, they effectively force outputs toward prescribed patterns rather than enabling the model to internalize nuances or design principles.

These limitations motivate incorporating controllability into the representation itself, rather than relying on inference-time interventions. Moreover, aggressive masking intended to enforce user-specified topologies may push models outside their learned distributions, leading to degraded quality or unrealistic design actions. In contrast, human engineers naturally reason at multiple levels of abstraction and information before engaging with detailed process structures.

In this work, we argue that embedding these engineering abstractions directly into ML inputs is essential for controllable and interpretable AI-assisted process synthesis. We introduce a contextual framework that augments flowsheet representations with task descriptors specifying the number and ordering of critical units with an emphasis on unit hierarchies. This formulation enables the model to associate each training example with an explicit design intent, such as simplified block-flow design, rather than inferring such objectives implicitly from topology alone. To complement this approach, we introduce a new representation that linearizes process flowsheets by focusing on the main branch, which is constructed from major feed to major product to emphasize the primary design objective.

The proposed approach is demonstrated using the ethylene glycol process. Synthetic flowsheet examples were generated for two datasets of increased structural complexity. Transformer models trained with and without task context are compared to evaluate syntactic learning, predictive performance, and the ability to generate user-specified process identities.

## METHODS

### Task Context

The task context is not the same as the context used in NLP applications, but rather an additional feature to further describe the flowsheet topology based on the design intent. Nevertheless, they both serve the purpose of reducing the ambiguity in learning and generating token sequences. Task context is not inherently present in the process topology data. It is an engineering perspective to create an elevated level of abstraction analogous to the ideas in PSE, such as block flow diagrams (BFD) and process flowsheet diagrams (PFD). Like BFDs and PFDs, task context is aimed at pointing to the same process flowsheet information as the topology at a different level without any contradiction.

The importance hierarchy of process elements is another core idea. From the earliest examples of systematic process synthesis approaches to the contemporary research efforts in specific units, the criticality of the equipment is not related to the frequency of its presence. While the reaction and separation approaches in the process shape the process identity, the rest of the equipment is there to create a feasible foundation or enhance the process performance most of the time. However, this idea is not present when applied to process topology alone. These critical units that define the characteristics of the process can be reduced to a small group of tokens that are necessary for successful completion but not critical.

Combining these two ideas of information abstraction and importance hierarchy for conceptual process synthesis gives us a task context that relates to the number and the sequence of the critical equipment that is desired to be present in the process flowsheet. It signals the model what the process identity or design intent is when it is learning or generating the process flowsheets with desired characteristics. It does not provide any information about how the rest of the process equipment should be constructed or constrain certain outputs directly through the manipulation of probability distributions.

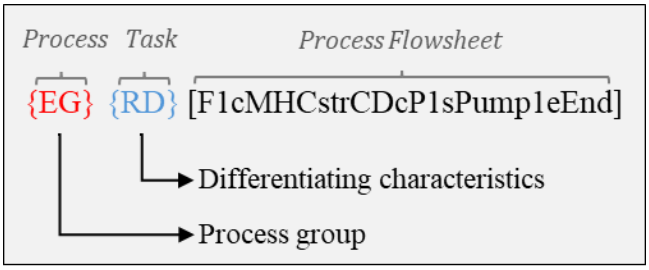

**Figure 1.** Task context and corresponding text-based flowsheet representation for an EG process. The {R, D} task context specifies the number and ordering of critical units.

A simple example is illustrated in **Figure 1** using a simple ethylene glycol production process based on ethylene oxide hydrolysis. The {R, D} task context indicates that the following process flowsheet has exactly 1 reactor equipment that precedes 1 distillation equipment in the process flow. It does not tell where exactly they are placed or any restrictions regarding the ancillary equipment.

## Text Representation

The task context approach is an independent abstraction feature that can be modified to work with any kind of process representation. However, since the approach is based on better distinction between the process topology characteristics, a new style of text-based representation was developed for process flowsheet information to aid this purpose. The representation is similar to SFILES 2.0 [14] in some parts, but it is combined with case sensitivity and numerical tokens [8, 9].

Building on this foundation, three critical aspects were further improved. Unlike the current local graph traversal approaches, this representation tries to focus on the process flowsheet holistically to create a linearized global connection. The assumption comes from the fact that most processes have raw materials that are either consumed heavily or a critical stream, which constitutes the major feed as the starting point to reach the major product as the end. The shortest path of streams and equipment between the major feed and the major product defines the main branch, which contains the most critical equipment for achieving the desired production.

Additionally, all the equipment is assumed to have a major outlet, which is signified by the subtype of representing token in the case of multiple outlets. The connections and detachments created by minor feeds and products, recycles, and other equipment outlets creates subbranches that are represented uniquely. This procedure yields a canonical textual form for each flowsheet topology, reducing alternative linearizations when the main feed and product are fixed. Such invariance is expected to improve learning efficiency for limited datasets similar to the graph representation [18].

Lastly, human readability was also prioritized. All representations are aimed at transforming the process flowsheet information into a machine-readable and easy-to-store format. Nevertheless, as the machine itself just sees them as vectors or tensors, the text side should aim for humans to bridge the gap between human and machine understanding. Units and connectivity tokens with their representations are shown in **Table 1**. Capital letters denote the start of unit tokens, lowercase characters for remaining characters or specify sub-types, and numbers indicate the subbranches with lowercase characters to signal start, connection, and end of the subbranch.

**Table 1**: Equipment and connectivity used in the proposed text-based representation.

| Equipment | Text Representation |
|---|---|
| Major Feed | F |
| Minor Feed | Fa, Fb, … |
| Major Product | P |
| Minor Product | Pa, Pb, … |
| Subbranch Starter | 1s, 2s, 3s |
| Subbranch Connector | 1c, 2c, 3c |
| Subbranch End | 1e, 2e, 3e |
| Mixer | M |
| Heater | H |
| Cooler | C |
| Pump | Pump |
| CSTR | Cstr |
| PFR | Pfr |
| Distillation C. (Top P.) | Dc |
| Distillation C. (Bottom P.) | Dcb |
| End | End |

The representation is still under active development for further grouping based on unit purpose, inclusion of more unit types, and rules for complex process topologies. Regardless, it is fully functional for the scale of this example.

## Dataset

The datasets for the tasks were composed of synthetic process examples of EG production processes via EO hydrolysis. All samples are unique and passed through the syntax filter to ensure a valid process flowsheet representation. To ensure variety and an adequate representation of process topology domain, random sampling from uniform distributions was used for the total token number, task contexts, and equipment placement.

Using bounded random generation and syntactic filtration, we obtain D1 and D2 datasets, each containing 100, 000 unique process flowsheet representations. To illustrate the procedure, more than 400, 000 examples were generated and filtered to create the D2 dataset. The datasets differ in the total number of reactors and

distillation columns per flowsheet (3 for D1 and 4 for D2) and their task representations. It results in increased topological complexity and length of representations in D2. Distribution of data with respect to the task context is reported in **Table 2**. Uniform distribution across task context classes was not enforced, as a skewed distribution is more realistic and helps the analysis of the model performance in underrepresented configurations.

**Table 2**: Distribution of task context classes in the training datasets of D1 and D2

| Task Context | D1 (%) | D2 (%) |
|---|---|---|
| RD | 22.9 | 6.4 |
| RDD | 21.5 | 7.0 |
| RDR | 39.6 | 13.8 |
| RRD | 16.1 | 4.9 |
| RDDD | - | 7.1 |
| RDDR | - | 12.7 |
| RDRD | - | 7.9 |
| RDRR | - | 18.6 |
| RRDD | - | 6.1 |
| RRDR | - | 11.8 |
| RRRD | - | 3.7 |

Although it is out of scope for this experiment, a batch of 1000 designs was simulated in Aspen Plus to see if generated data and syntax filters would lead to real process examples. All designs were successfully built, simulated, and the unit design parameters were explored. Over 50% of the designs converged to feasible operating conditions with a limited computational budget.

### Models, Training, and Inference

As the representation and the problems are formulated as symbolic sequences like NLP applications, a standard transformer architecture with ~1M parameters and 4 attention heads was used. This is a considerably smaller model compared to both applications in NLP and process synthesis [3]. The resulting token to parameter-ratio is on the lower side of the acceptable bounds for this kind of model training, but higher than contemporary works in chemical engineering applications.

All models were trained using an 80/20 train–validation split for ten epochs with an autoregressive objective, cross-entropy loss, and the Adam optimizer. Identical datasets and training protocols were used for both context-aware and no-context models; in the latter case, task tokens were removed from the inputs to replicate the standard autoregressive model behavior.

To illustrate the effectiveness of task context, all models were asked to generate 10, 000 process flowsheets for every trial at the inference stage. In the first trial, models are just generating examples without any restrictions to show their syntax learning capabilities to establish the baseline. Then, models are tasked to generate processes with a desired identity for which similar examples were already present in their respective training datasets. This trial is the main experiment that imitates the model control by an engineer. The generation requests are picked from a uniform random distribution to symbolize user input, e.g., “Provide me an EG hydrolysis process example with 1 reactor and 1 distillation column”. Lastly, a dynamic inference masking was introduced to help models generate designs with the chosen task context. The mask tries to control the model outputs by blocking the probability distribution of unwanted critical equipment until the necessary ones are picked according to the desired sequence.

## RESULTS AND DISCUSSION

Training with task context influences the evolution of the loss function, as shown in **Figure 2**. Introducing task descriptors provides an additional conditioning signal that helps the model differentiate equipment choices associated with varying process structures. Although the primary objective of task context is improved controllability during generation, it also improves predictive performance during training by better capturing variations based on task context in process topology. This trend is reflected in the final perplexity values reported in **Table 3**, where context-aware models achieve consistently lower scores across both datasets.

**Table 3**: Training and validation perplexity for transformer models trained with and without task context.

| Model | $PP_{tr}$ | $PP_{val}$ |
|---|---|---|
| No-context (D1) | 3.05 | 3.05 |
| Context (D1) | 2.77 | 2.77 |
| No-context (D2) | 3.20 | 3.21 |
| Context (D2) | 2.77 | 2.77 |

The magnitude of the improvement remains modest, indicating that the model capacity and dataset size are already sufficient for learning syntactic structure. Nevertheless, the consistent reduction across datasets suggests that task context provides a useful inductive bias in the training.

To further establish the model capabilities, the first trial is conducted without any restrictions on process identity, focusing only on syntactic production and process representation. All models are fully capable of producing text representations that pass our syntax filters with almost perfect scores. As it is shown in **Table 4**, the numerical differences are insignificant. We used nucleus sampling (p = 0.9) to generate these results; however, they did not show any noteworthy change when multinomial sampling was used as well. For the successful synthesis rate, not just validity but uniqueness was enforced, as the model that answers a single process configuration

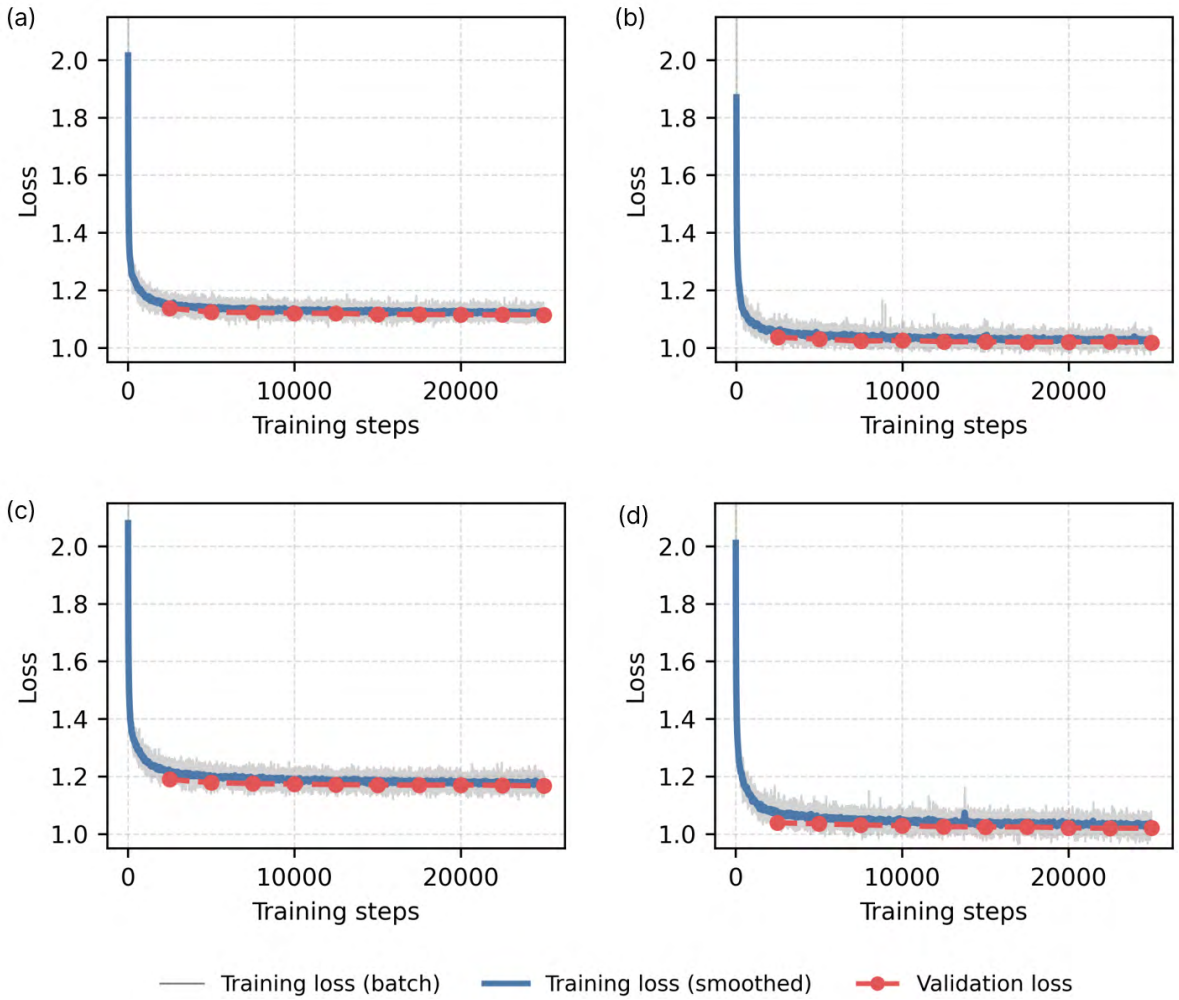

**Figure 2.** Training and validation loss for the four experimental configurations: (a) no-context training on D1, (b) context-conditioned training on D1, (c) no-context training on D2, and (d) context-conditioned training on D2. Grey lines denote batch level training loss, blue lines show the smoothed trajectory, and red dashed lines correspond to validation loss.

for 10, 000 requests would not be a desired final model.

**Table 4**: Successful synthesis rates (valid and unique) for unrestricted generation across datasets and model variants.

| Model | Successful Synthesis (%) |
|---|---|
| No-context (D1) | 98.94 |
| Context (D1) | 98.88 |
| No-context (D2) | 99.10 |
| Context (D2) | 98.65 |

These results indicate that the structure and the amount of data are appropriate for the complexity of the task. Reducing the dataset size from 100, 000 to 1, 000 leads to a substantial performance drop in both cases. Success rates dropped as low as 86.9% for D1 and 79.6% for D2, reflecting the increased complexity of designs in D2. In heavily restricted data regimes, context-conditioned models initially perform worse than their counterparts because they must learn an additional conditioning signal. Notably, this difference diminished as structural complexity increased, reducing from 7% to 0.6% between D1 and D2.

As the generative competence of models is established, the next step was to measure their performance under user-specified process synthesis based on critical equipment number and sequence. As no-context models cannot receive explicit information, they have no way of distinguishing the input and the process that is generated. The outcomes basically reflect the model bias from training data towards certain types.

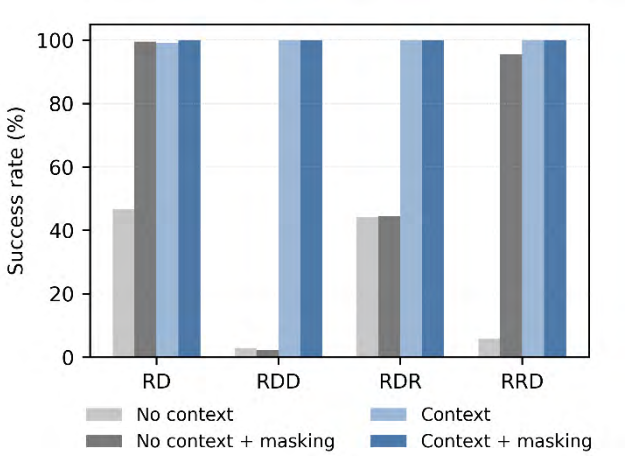

**Figure 3.** Distribution of generated process identities for no-context and context-aware models under uniform user requests, with and without inference-time masking, for dataset D1.

As shown in **Figure 3**, no-context models favor designs with a reactor and a distillation column (RD) and the addition of another reactor (RDR) as its output. These two categories account for more than 90% of the model answer. However, since the requests are sampled from a uniform distribution, the average correct answer rate drops to 24.6%. Even with the dynamic inference mask, this number only reaches 60%. The mask can be improved further by disabling end token selection until the desired sequence is produced to increase the success rate, but it risks pushing the model outside of the learned distribution. Thus, the accuracy and quality of generated designs can degrade. On the other hand, task context conditioned models perform almost perfectly with or without the mask, as their average performance never drops below 98.6% for both datasets.

The effect becomes even more pronounced in the more complex D2 dataset, where the number of possible task categories increases substantially. Here, the no-context model's average success rate drops from 24.6% to 8.72%. Category-level analysis in **Figure 4** shows that four configurations (RD, RDR, RDRR, and RRDR) account for 76% of generated designs, further highlighting strong structural bias. Masking again improves performance, but only to 40.3%, whereas task-conditioned models sustain an average success rate of 98.8%.

Overall, these results demonstrate that task context embeds high-level design intent directly into the learning

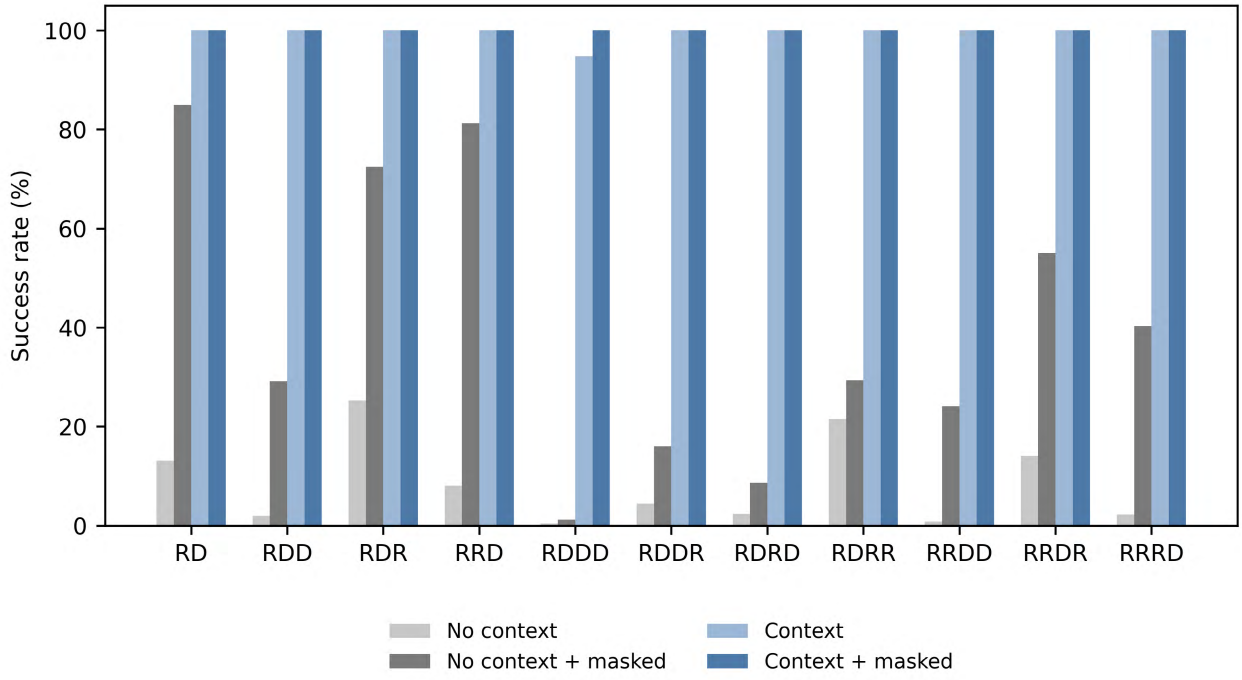

**Figure 4.** Success rates for generating valid and unique flowsheet structures under four settings for D2 dataset for user control trial. Bars compare models trained without contextual conditioning ("No context"), with masking only ("No context + masked"), with task context conditioning ("Context"), and with both conditioning and masking ("Context + masked"). Each group corresponds to a target structure class that was present in the training dataset. Contextual models achieve near-perfect compliance across all specifications, while masking alone improves but does not close the gap relative to explicit contextual conditioning.

problem, improving not only controllability during synthesis but also predictive performance during training. When deployed in AI-assisted conceptual process design, contextual conditioning provides a practical mechanism for interpreting model biases, steering generation toward desired structures, and reducing reliance on brittle post-processing rules.

## CONCLUSION

In this work, we introduced a task-context feature for AI-assisted process synthesis to increase the interpretability of model outputs and user control. By embedding a higher-level abstraction of process topology into the training data through the number and ordering of critical units, machine-learning models move beyond purely syntactic generation. These models are therefore able to capture relationships between design examples and can be guided by an engineer during both learning and generation.

A new text-based representation emphasizing a main process branch and global traversal was developed to complement this objective. Together with task descriptors, this representation provides the model with explicit structural cues while retaining flexibility in the construction of ancillary equipment and subbranches. The resulting models achieve near-perfect syntactic validity across datasets of increasing complexity, while modestly improving perplexity relative to their no-context counterparts. More importantly, the inclusion of task context enables reliable controlled synthesis. Models trained without context largely reproduce dataset and model biases and perform poorly when asked to generate specific process identities, even when supported by dynamic inference masking. Context-aware models consistently satisfy user-specified design objectives across both simple and complex datasets. These results highlight that conditioning during training is substantially more effective than post-hoc probability manipulation at inference.

Beyond quantitative performance, the proposed framework offers practical advantages for AI-assisted process design. Task context provides an interpretable interface between human engineers and generative models and supports interactive exploration of alternative process concepts. In this sense, the approach shifts generative models from passive pattern reproducers toward controllable design assistants. Although demonstrated here for ethylene glycol production, the proposed framework is process-agnostic and intended to extend to other synthesis domains.

Future work will focus on expanding the vocabulary of task context and developing extensions for additional process design objectives, such as process integration and process intensification. Within process synthesis, the framework will be extended to accommodate more complex flowsheets and cross-process training to alleviate data limitations in further applications. Integrating optimization and evaluation algorithms with this framework will further enable efficient exploration of design alternatives and identification of high-quality solutions within the feasible design space. Overall, this study demonstrates that embedding engineering intent directly into representations is a promising direction for scalable and controllable AI-assisted process synthesis.

## ABSTRACT

Porous materials such as Metal-Organic Frameworks and Covalent Organic Frameworks are emerging adsorbent materials with tunable structures and chemistry, making them useful for applications such as carbon capture, drug delivery, gas separations, and storage. This work aims to design and develop a systematic approach to build a data-driven recommendation system that leverages the historical experimental data or simulation data to assist process engineers in identifying the most suitable adsorbents from a large candidate space. In general, only some of the adsorption properties are available for porous materials owing to limited experimental data. In this scenario, this problem can be formulated as a matrix completion problem, which aims to impute the missing data by exploiting the underlying pattern in the available data. To this end, we propose a parameterization of the kernelized probabilistic matrix factorization framework, which aims to determine the nonlinear latent factors that are parameterized. The resulting bi-convex Maximum a Posteriori objective with reproducing kernel Hilbert space penalties can be solved using an alternating minimization approach. We demonstrate this approach on a publicly-available COF dataset. Of the 16 adsorption properties considered in this study, 15 of them can be predicted very accurately for a missing percentage of up to 60%. Further, the proposed approach preserves the ranking of COF candidates, which helps in accurate screening of best COFs for a given task.

**Keywords**: Matrix factorization, Alternating Minimization, Kernels, COFs

## INTRODUCTION

Porous materials, particularly Metal-Organic Frameworks (MOFs) and Covalent Organic Frameworks (COFs), have emerged as materials characterized by their exceptional tunability in structure, and chemical functionality [1]. COFs are built from elements connected through covalent bonds, yielding materials with permanent porosity, high surface areas, and controllable pore environments [2]. These attributes have positioned these porous candidates as leading for a diverse applications including carbon capture, hydrogen and methane storage, selective gas separations, and catalysis. The vastness of the COF chemical space emphasizes the need of computational screening to identify promising candidates for specific applications, yet this screening is fundamentally constrained by the availability of property data. Experimental measurement of adsorption isotherms, selectivity, and Henry coefficients is time-consuming and resource-intensive, often requiring specialized equipment and expertise. Molecular simulations, can predict these properties computationally, but remain expensive for large-scale screening across diverse conditions [3, 4]. This scenario gives rise to a matrix completion problem.

To formally define the problem, consider an incomplete matrix $\mathrm{X} \in \mathrm{R}^{\mathrm{m}\times\mathrm{p}}$ where the rows correspond to $m$ COF candidates, and the columns correspond to $p$ adsorption properties. Only a subset of entries $\Omega \subseteq \{1,\dots,\mathrm{m}\} \times \{1,\dots,\mathrm{p}\}$ is observed, and the goal of the recommendation engine is to accurately impute the missing entries to allow complete screening and ranking of COF candidates for a given task. This problem of imputing missing values in materials property matrices has been

approached by Sturluson et al. where they used linear matrix factorization with $l_2$ regularization [5]. However, the relationships among material properties are nonlinear, and thus kernel methods offer an attractive approach to incorporate the similarity between materials and properties while guaranteeing the computational tractability of the proposed model [6].

In this work, we develop a parameterization of the kernelized probabilistic matrix factorization approach for imputing missing entries to provide reliable predictions for the recommendation system. Our approach extends the Kernelized Probabilistic Matrix Factorization (KPMF) by parameterizing both row and column latent factors through kernel matrices. The resulting inference problem is formulated as Maximum a Posteriori (MAP) estimation problem with RKHS-induced penalties on the latent factors, yielding a bi-convex objective that we optimize efficiently via alternating minimization. We demonstrate the efficacy of our approach on a benchmark adsorption property dataset [3, 4].

The main contributions of this work includes: (a) a parameterization of the kernelized matrix factorization model that uses latent factors as $\mathrm{Z} = \mathrm{K_M A}$ and $W = K_P B$, enabling the incorporation of side information on both materials and properties, (b) formulate the corresponding learning problem as MAP estimation with RKHS-induced penalties, (c) demonstrate the imputation performance of the proposed approach in a publicly available COF dataset for varying missing percentages, and (d) finally, we present screening of adsorbent materials to identify the best COF candidates for targeted adsorption applications.

The remainder of this paper is organized as follows. Firstly, we present the problem statement for developing the data-driven recommendation system, which involved accurate imputation and screening of materials. Next, we propose a data imputation technique using kernelized probabilistic matrix factorization followed by a parametrization strategy. Next, an alternating minimization algorithm for solving the proposed formulation is presented. Later, the screening of adsorbent material is presented. In the subsequent section, we demonstrate the effectiveness of the proposed recommendation system in a COF dataset. Finally, conclusions are presented.

## PROBLEM STATEMENT

The objective of this work is to design and develop a systematic approach to build a data-driven recommendation system that leverages the historical experimental data or simulation data to assist process engineers in identifying the most suitable adsorbents from a large candidate space. The recommendation system should be capable of handling sparse and noisy data to capture the nonlinear relationship to accelerate screening of adsorbents and improve the decision quality. The computational screening of porous materials generates vast datasets of potential material candidates. However, the cost of molecular simulations – particularly Grand Canonical Monte Carlo (GCMC) calculations for generating the adsorption isotherms – scales up significantly, making comprehensive characterization of all candidates computationally infeasible. On the other hand, performing experiments to determine the adsorption properties of all adsorbent candidates is prohibitive due to the high cost. This naturally leads to datasets with substantial missing entries, thus solving a matrix completion problem is a crucial step in the development of a recommendation system.

In this context, given partial observations $\{\mathrm{X_{mp}}: (\mathrm{m}, \mathrm{p}) \in \Omega\}$ of a materials property matrix, our goal is to determine the missing observations $\{\mathrm{X_{mp}}: (\mathrm{m}, \mathrm{p}) \notin \Omega\}$ of the complete data matrix $\hat{\mathrm{X}}$ such that, $\hat{X}_{\mathrm{mp}} \approx \mathrm{X_{mp}}$ for all $(\mathrm{m}, \mathrm{p}) \in \Omega$ and the complete data matrix exhibits low-rank structure or lies on a low-dimensional manifold. This low-rank assumption is physically motivated, as in practice, material properties are governed by a smaller set of underlying factors that collectively determine macroscopic adsorption behavior. This latent structure enables imputation of unobserved entries by exploiting correlations among materials and properties. Consider the observation model of the form

$$X_{mp} = \sum_{l=1}^{r} f_l(m) g_l(p) + \epsilon_{mp} \quad \epsilon_{mp} \sim \mathcal{N}(0, \sigma^2) \quad (1)$$

where $\mathrm{f_l}(.)$ and $\mathrm{g_l}(.)$ denote the $l^{th}$ latent function of materials (rows) and properties (columns), respectively. $r$ denotes the latent dimensions. The measurement errors $\epsilon_{\mathrm{mp}}$ follow a univariate Gaussian distribution with mean zero and variance $\sigma^2$. Let $\mathrm{X_{mis}}$ and $\mathrm{X_{\Omega}}$ denote the missing and observed entries of a complete data matrix $X$. Then, the standard imputation problem is often cast as a maximum-a-posteriori (MAP) inference problem, and it can be stated in a probabilistic setting as follows

$$\hat{\mathrm{X}}_{miss} = \arg\max P(X_{mis} \mid X_{\Omega}) \quad (2)$$

The proposed formulation belongs to a class of probabilistic methods in a collaborative filtering framework. This approach enables one to reconstruct the full data matrix, which is useful for providing the ranking of adsorbent materials for a decision-focused objective of a recommendation system.

## PROPOSED METHODOLOGY

This section develops a parametrized kernelized probabilistic matrix factorization approach for imputing missing entries. Firstly, we present the vanilla version of a non-parameterized kernelized probabilistic matrix factorization, followed by the parameterized version for

accurate imputation of adsorption properties [6]. To this end, we formalize the problem with kernel-encoded side information, derive the MAP formulation. Next, we develop the alternating minimization technique to solve the probabilistic imputation problem. Finally, we present the screening of adsorbent materials for potential applications.

## Kernelized Probabilistic Matrix Factorization

In this section, we present the kernelized probabilistic matrix factorization approach to solve the matrix completion problem that characterizes the nonlinear latent dimensions, following the work of Zhou et al. [6]. In a standard matrix factorization problem, all materials' specific factors are considered to be independent (i.e., the isotropic Gaussian prior), regardless of any structure or similarity. However, in materials science applications, we often have side information indicating that certain materials/properties are similar---for instance, MOFs sharing amine functional groups are likely to exhibit good $CO_2$ adsorption properties [7], Here, we use kernels to encode prior knowledge about similarity among materials or properties. In this method, each latent dimension follows a Gaussian process prior. In other words, each latent dimension is assumed to be a random function drawn from a Gaussian process.

$$f_l(.) \sim \mathcal{GP}(0, k_m) \quad g_l(.) \sim \mathcal{GP}(0, k_p) \qquad l = 1, \cdots, r$$

where $k_m, k_p$ are covariance functions which signify the similarity between two COFs (rows) or two properties (columns), respectively. Denoting $z_{ml} = f_l(m)$ and $w_{pl} = g_l(p)$, the observation model can be expressed as

$$X_{mp} = \sum_{l=1}^{r} f_l(m) g_l(p) + \epsilon_{mp} \qquad (3)$$

$$X_{mp} = \sum_{l=1}^{r} z_{ml} w_{pl} + \epsilon_{mp} \qquad (4)$$

Notice that it is a product of two Gaussian processes which makes the model non-Gaussian over $X$. It is not a Gaussian process over matrix entries. Now, the MAP estimation problem is presented as follows:

$$\{f_l^*, g_l^*\} = \arg\max P(X_{mis} \mid X_\Omega) = \arg\max P(\{f_l, g_l\} \mid X_\Omega) \qquad (5)$$

We can equivalently express it as,

$$\mathcal{L}_{\text{KPMF}}(Z, W) = \sum_{(m,p)\in\Omega} \left( X_{mp} - \sum_{l=1}^{r} f_l(m) g_l(p) \right)^2 + \lambda_M \sum_{l=1}^{r} |f_l(m)|_{\mathcal{H}_m} + \lambda_P \sum_{l=1}^{r} |g_l(p)|_{\mathcal{H}_p} \qquad (6)$$

This is a variational problem in infinite-dimensional Reproducing Kernel Hilbert Spaces. This defines the matrix completion problem entirely in a function space. As this is computationally not-tractable, we consider evaluating the Gaussian process at discrete indices (say $n$) gives

$$f_l(.) = [f_{l1}(.), \cdots, f_{ln}(.)]^\top \sim \mathcal{N}\left(0, \frac{1}{\lambda_M} K_M\right) \qquad (7)$$

$$g_l(.) = [g_{l1}(.), \cdots, g_{ln}(.)]^\top \sim \mathcal{N}\left(0, \frac{1}{\lambda_P} K_P\right) \qquad (8)$$

where $K_M$ and $K_P$ are Gram matrices obtained by evaluating the Gaussian process covariance functions on the row and column index sets. Let $\mathrm{Z} = [\mathrm{f}_1(.)\ \mathrm{f}_2(.)\ \cdots \mathrm{f}_\mathrm{r}(.)] \in \mathrm{R}^{\mathrm{M}\times\mathrm{r}}$ and $\mathrm{W} = [\mathrm{g}_1(.)\ \mathrm{g}_2(.)\ \cdots \mathrm{g}_\mathrm{r}(.)] \in \mathrm{R}^{\mathrm{P}\times\mathrm{r}}$. Each column is a GP draw evaluated at all row indices, and columns are independent across latent dimensions $l$. Thus, the prior over the whole matrix $Z$ is given by

$$p(Z) = \Pi_{l=1}^{r} \mathcal{N}(f_l | 0, K_M) \propto exp\left( -\frac{1}{2} \sum_{l=1}^{r} f_l^\top K_M f_l \right) \qquad (9)$$

Similarly, the prior over the whole matrix $W$ is given by

$$p(W) = \Pi_{l=1}^{r} \mathcal{N}(g_l | 0, K_P) \propto exp\left( -\frac{1}{2} \sum_{l=1}^{r} g_l^\top K_P g_l \right) \qquad (10)$$

Now, the MAP objective with the GP prior on $Z$ and $W$ becomes [6]:

$$\mathcal{L}_{\text{KPMF}}(Z, W) = \sum_{(m,p)\in\Omega} \left( X_{mp} - z_m^\top w_p \right)^2 + \lambda_M tr\left( Z^\top K_M^{-1} Z \right) + \lambda_P tr\left( W^\top K_P^{-1} W \right) \qquad (11)$$

It can be observed that (eq 11) is a bi-convex function in $(Z, W)$, enabling the solution to the matrix completion problem using the alternating minimization technique. While KPMF can successfully incorporate side information on materials and properties, it has limitations such as the regularization term requires computation of $K_M^{-1}$, which is computationally expensive for large $M$ and can be numerically unstable for ill-conditioned kernels, and optimization over $Z$ and $W$ cannot fully exploit the kernel structure.

## Parametrization of Kernelized Probabilistic Matrix Factorization

We now present the Parameterization of Kernelized Probabilistic Matrix Factorization (P-KPMF) model, to addresses the limitations of KPMF through: (i) kernel regularization on both materials and properties, and (ii) a reparameterization that avoids explicit kernel matrix inversion. Inspired by the representer theorem from kernel methods, we parameterize the latent factors as linear combinations of kernels

$$Z = K_M A, \qquad W = K_P B \qquad (12)$$

where $\mathrm{A} \in \mathrm{R}^{\mathrm{M}\times\mathrm{r}}$ and $\mathrm{B} \in \mathrm{R}^{\mathrm{P}\times\mathrm{r}}$ are coefficient matrices to be learned and we place Gaussian priors on the columns of $A$ and $B$:

$$a_l \sim \mathcal{N}\left(0, \frac{1}{\lambda_M} K_M^{-1}\right), \quad b_l \sim \mathcal{N}\left(0, \frac{1}{\lambda_P} K_P^{-1}\right), \quad l = 1, \ldots, r \qquad (13)$$

Notice that each column of matrices $\mathrm{Z}$ and $\mathrm{W}$ are

realizations of a zero-mean Gaussian Process with covariance functions $k_m$ and $k_p$, respectively. The resulting MAP objective is:

$$\mathcal{L}_{\text{P-KPMF}}(A,B) = \sum_{(m,p)\in\Omega} \left(X_{mp} - k_m^\top A B^\top k_p\right)^2 + \lambda_M tr\left(A^\top K_M A\right) + \lambda_P tr\left(B^\top K_P B\right) \quad (14)$$

Define the residual for $j^{th}$ latent as $r_{mp}^{(j)} = X_{mp} - \sum_{l\neq j}\left(k_p^\top b_l\right)\left(k_m^\top a_l\right)$

$$\mathcal{L}_{\text{P-KPMF}}(a_j,b_j) = \sum_{(m,p)\in\Omega} \left(r_{mp}^{(j)} - \left(k_p^\top b_j\right)\left(k_m^\top a_j\right)\right)^2 + \lambda_M tr\left(A^\top K_M A\right) + \lambda_P tr\left(B^\top K_P B\right) \quad (15)$$

Similar to (eq 11), the above objective function (eq 15) is also bi-convex; however, it is expressed in terms of Gram matrices $K_M$ and $K_P$ without requiring inverse computation. Owing to the bi-convexity, we can use alternating minimization to solve for the parameterization matrices $A$ and $B$. Thus, the first derivative of the objective function with respect to $a_l$ and $b_l$ yields

$$\left[\sum_{(m,p)\in\Omega} \left(k_p^\top b_j\right)^2 k_m k_m^\top + \lambda_M K_M\right] a_j = \sum_{(m,p)\in\Omega} r_{mp}^{(j)} \left(k_p^\top b_j\right) k_m \quad (16)$$

$$\left[\sum_{(m,p)\in\Omega} \left(k_m^\top a_j\right)^2 k_p k_p^\top + \lambda_P K_P\right] b_j = \sum_{(m,p)\in\Omega} r_{mp}^{(j)} \left(k_m^\top a_j\right) k_p \quad (17)$$

Now, we present the alternating minimization-based solution methodology for imputing the missing observations using the proposed parameterized kernelized probabilistic matrix factorization. The detailed methodology is presented in Algorithm 1. This iterative approach involves two steps: in the first step, we fix $b_j$ and solve for $a_j$ using (16) and in the second step, we fix $a_j$ and solve for $b_j$ using (17). Notice that fixing one variable, result in a convex optimization problem. Thus, the alternating minimization enables one to solve the imputation problem.

**Algorithm 1**: Alternating Minimization for P-KPMF

1: Initialize $a_l, b_l, K_M, K_p$
2: Set hyperparameters $r, \lambda_M, \lambda_P$
3: Set tolerance $\epsilon$, maximum iterations $T$
4: **for** $t = 1, \ldots, T$ **do**
5: **for** $j = 1, \ldots, r$ **do**
6: **(A-step)** Fix $b_j$
7: Solve for $a_j$ using (16)
8: **(B-step)** Fix $a_j$
9: Solve for $b_j$ using (17)
10: **end for**
11: Compute $\mathcal{L}^t_{P-KPMF}$ via (15)
12: **if** $|\mathcal{L}^{t-1}_{P-KPMF} - \mathcal{L}^t_{P-KPMF}|/|\mathcal{L}^t_{P-KPMF}| < \epsilon$ **then**
13: **break**
14: **end if**
15: **end for**

## Screening of Adsorbent Candidates

The primary objective of the proposed framework in a recommendation system is to rank candidate materials. Therefore, the model performance will also be evaluated using rank-based metrics in addition to regression error measures. To this end, we use Spearman's rank correlation coefficient ($\rho_s$), which quantifies the monotonic agreement between the imputed and true material properties. The Spearman rank correlation coefficient is defined as:

$$\rho_s = 1 - \frac{6\sum_{i=1}^{n} d_i^2}{n(n^2-1)} \quad (18)$$

where $d_i$ denotes the difference between the ranks of the corresponding imputed and observed values for the $i^{th}$ COF, and $n$ denotes the total number of COFs. A higher value of Spearman correlation indicates the true ranking is preserved by the proposed imputation model, and a lower value of Spearman correlation indicates that the ordering of COFs obtained by the imputation model is significantly different from the true order of COFs. Thus, high values of Spearman correlation signify that the recommendation system can provide a reliable ranking of COFs for screening.

# RESULTS AND DISCUSSION

In this section, we demonstrate the proposed parameterization of the kernelized probabilistic matrix factorization approach to learn the nonlinear surface from the adsorption properties of COF materials when there are missing data. In this work, we use the adsorption data of 573 COF candidates taken from AiiDA platform [3] for 16 features which includes uptake values and Henry Coefficients for $CH_4$, $CO_2$, $H_2$, $H_2O$, $H_2S$, Kr, $N_2$, $O_2$, Xe gas species (same as in the work of [5]). We performed preprocessing of the data using logarithmic transformation for features that have values in the range ($10^{-5}$ to $10^{-7}$).

For fair comparison, we consider the same missing data points for performing imputation using the three models: Linear Matrix Factorization (LMF) - studied by [5], Kernelized Probabilistic Matrix Factorization (KPMF), and the proposed parameterized form of Kernelized Probabilistic Matrix Factorization (P-KPMF). To systematically evaluate different models, we consider imputation performance across a range of missingness fractions between 10% to 90%. For each missingness, we generate 20 independent Missing Completely At Random (MCAR) experiments, yielding a total of 180 experimental runs per method. These experiments enable statistical

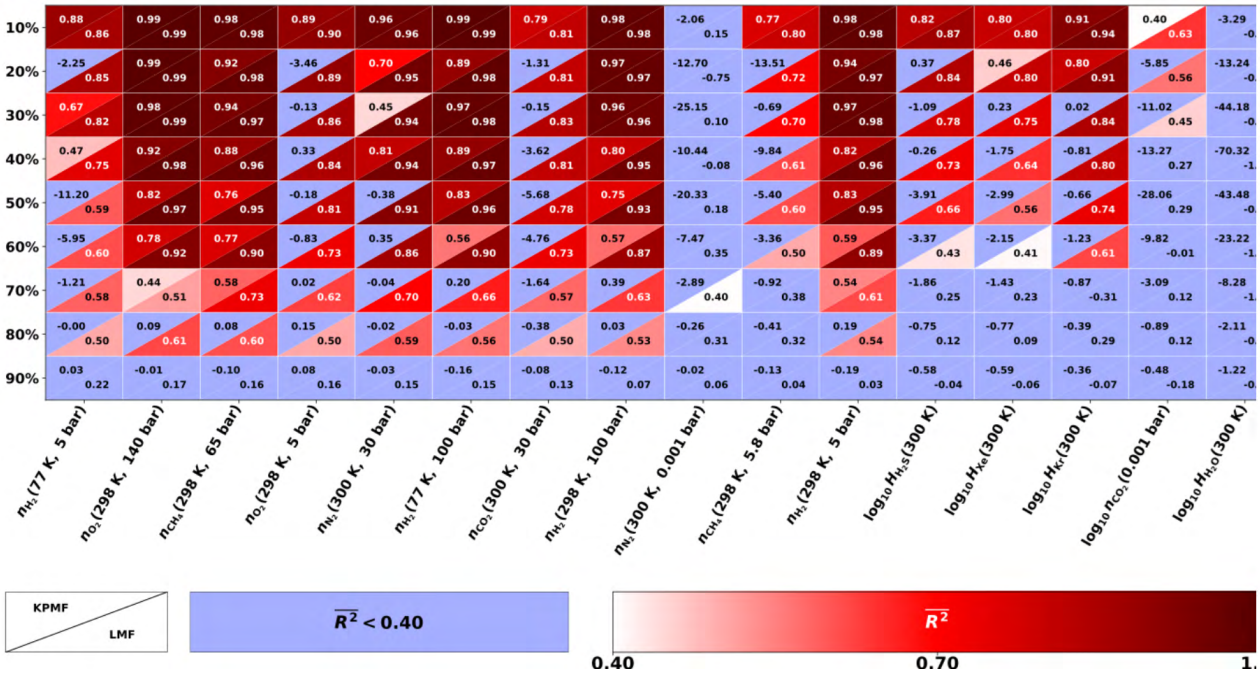

**Figure 1:** Heatmap showing the comparison of the imputation performance of all 16 adsorption properties for varying percentages of missingness using LMF (bottom triangle) and KPMF (top triangle), respectively.

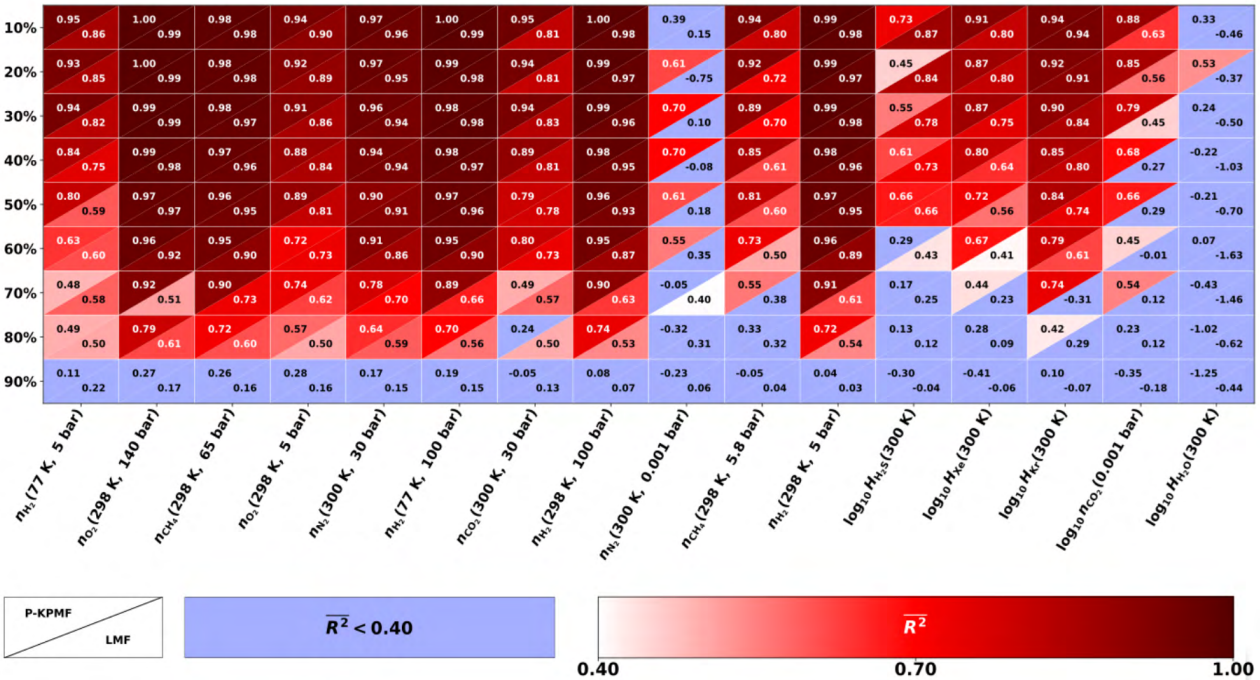

**Figure 2.** Heatmap showing the comparision of the imputation performance of all 16 adsorption properties for varying percentage of missingness using LMF (bottom traingle) and P-KPMF (upper traingle), respectively.

characterization of performance variability attributable to the increase in the percentage of missingness for various imputation models under consideration. Hyperparameters are optimized using grid search, and we use radial basis function kernels in this study.

Figure 1 presents the heatmap showing the comparison of imputation performance (that is, coefficient of determination $R^2$) of all 16 adsorption properties over 20

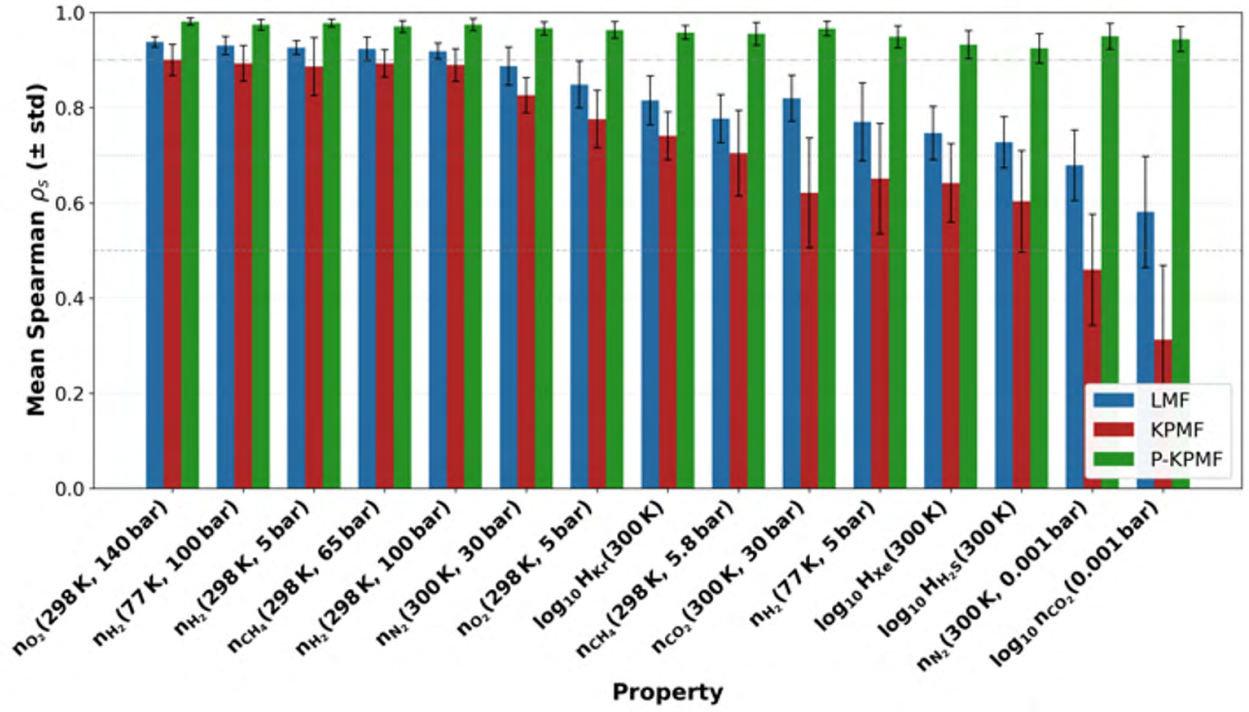

**Figure 3.** Bar plot showing the comparison of mean Spearman rank correlation obtained using LMF, KPMF, and P-KPMF models.

MCAR runs for varying percentages of missingness using LMF (bottom triangle) and KPMF (top triangle), respectively. The imputation performance of the LMF model shows good predictions in 13 of the 16 adsorption properties. The adsorption properties such as uptake values of $H_2$ and $CO_2$ (at 300 K and 0.001 bar), and Henry coefficient of $H_2O$ at 300 K cannot be predicted using both models. It can be observed that the imputation performance of the KPMF model is very poor, as can be seen from the blue colors in the top triangles. This can be attributed to the numerical instability in determining the inverse of the Gram matrices $K_P$ and $K_M$. Thus, it can be observed LMF performs better than the non-parameterized KPMF model.

Figure 2 presents the heatmap showing the comparison of imputation performance (that is, coefficient of determination $R^2$) of all 16 adsorption properties over 20 MCAR runs for varying percentages of missingness using LMF (bottom triangle) and P-KPMF (top triangle), respectively. Notice that the predictive performance of 15 out of 16 adsorption properties can be determined accurately by the proposed parameterization of the KPMF model. More specifically, the adsorption properties such as uptake values of $H_2$ and $CO_2$ (at 300 K and 0.001 bar) can be accurately predicted up to a missing percentage of 60%. Recall that these properties were poorly predicted by the LMF model. Further, it can be observed that the overall prediction accuracy of the remaining 15 properties shows improved performance using the P-KPMF model over the LMF model. However, Henry coefficient of water cannot predict accurately using both models. This improvement in performance can be attributed to the numerical stability of the proposed parameterization of PKMF, and use of kernel methods to capture the nonlinear relationship among different adsorption properties. Thus, the proposed P-KPMF model can provide accurate imputations even when there is a missing percentage of 60%.

Figure 3 presents the bar plot showing the comparison of mean Spearman rank correlation obtained for 60% missing data using LMF, KPMF, and P-KPMF models. Standard deviation values in predictions across 20 MCAR runs for the 15 properties are also shown in the bar chart. As the predictions for the Henry coefficient of $H_2O$ are poor using all methods, we have omitted it. Among all models, our proposed parametrization of kernelized probabilistic matrix factorization yields a Spearman rank correlation of 0.9, which indicates that the predicted ranks are close to the true ranks. This highlights that our proposed P-KPMF-based recommendation system will yield reliable COF candidates for a given task. To illustrate, we have considered the screening of best-performing COFs that achieves higher uptake values for $CO_2$. Table presents the COF IDs as obtained from Materials Cloud repository of the best 3 COFs selected for $CO_2$ uptake at 30 bar and 300 K using LMF, KPMF, and P-KPMF

models. True indicate the COF IDs with three highest $CO_2$ uptake values at 30 bar and 300 K reported in the Materials Cloud repository. The proposed P-KPMF-based recommendation system can identify all three best COFs showing superior performance over the LMF and KPMF models.

**Table 1:** Top 3 COF IDs for $n_{CO_2}$(300 K, 30 bar).

## CONCLUSIONS

In this work, we presented a systematic approach to develop a recommendation system that is based on the parameterization of kernelized probabilistic matrix factorization. This parameterization provided the accurate determination of the material properties by eliminating the inverse of computation of Gram matrices, which improved numerical stability. Also, the use of Gaussian process-based latent functions effectively captured the nonlinear relationship. The resulting bi-convex MAP objective with regularization on the latent function has been efficiently solved using an alternating minimization approach. We demonstrated that this proposed approach showed superior predictive performance of adsorption properties over the linear matrix factorization technique, and also preserves the ordering for the effective screening of COF candidates up to 60% missing data. This highlights the significance of the proposed P-KPMF-based recommendation system can predict the adsorption properties and screening the candidates under a data-scarce scenario. Future work will explore the multi-kernel or deep kernel learning strategies that integrate heterogeneous material descriptors, such as geometric, chemical, and topological features, within a unified latent representation.

## ABSTRACT

Large-scale mixed-integer programs (MIPs) typically cannot be solved by standard solvers with reasonable computational cost. MIP-heuristics decompose large-scale monolithic mixed-integer programs into polylithic programs such that they can be solved with reasonable computational cost at the price of loosing their optimality certificate. The decomposition is steered by hyperparameters that impact the solution quality and the computational cost diametrically. The proper selection of the hyperparameter values is a black-box optimization problem which is mostly solved by grid search or random search. In previous publications the authors proposed a novel hyperparameter optimization method based on Bayesian optimization and studied a use case from the PSE domain. Computational studies showed that the BO-based algorithm is superior for objective functions with few optimal solutions.This contribution generalizes the description of the MIP-Heuristic Optimization Problem (MIP-HOP) and the computer implementation of the solution-method. It supports the transferability of the method to other use cases. The general mathematical description of the MIP-HOP comprises eight expressions covering the monolithic and the polylithic MIP-model, the heuristic decomposition and composition operator, and the MIP-HOP. The formulation is explained and linked to the computer implementation of the solution method. The Python-code integrates state-of-the-art tools for mathematical programming (Pyomo and CPLEX) and Bayesian optimization (SMAC3) and will be published on GitHub.

## INTRODUCTION

Mixed-integer programming (MIP) is a methodology to model and solve optimization problems with mixed (integer and continuous) degrees of freedom subject to complex constraints. Exact MIP-algorithms provide proven optimal solutions or feasible solutions along with conservative optimality certificates (“optimality gaps”). However, many real-world optimization problems are NP-complete such that their computational costs scale poorly with their sizes. A common approach to deal with large-scale problem instances is to heuristically decompose a monolithic MIP-model into a polylithic MIP-model consisting of a set of partial MIP-models of smaller size. By sequentially solving the set of partial MIP-models by exact MIP-algorithms the polylithic MIP-model can be solved faster than the monolithic MIP-model at the price of losing its optimality certificate.

Schemes that decompose monolithic MIP-models into polylithic MIP-models based on problem insights are a special type of matheuristics named MIP-heuristics. They typically comprise hyperparameters that steer the decomposition and have an impact on both, the computational cost for solving the polylithic MIP-model and the objective value of its solution. MIP-heuristics as well as MINLP-heuristics are applied to a wide range of optimization problems, such as batch scheduling, maintenance planning, project scheduling, supply network planning, production routing, bin packing, locomotive assignment, healthcare planning, flowsheet optimization and lot sizing. The MIP/MINLP-heuristics comprise different decomposition approaches like temporal, area, activity, scenario and geographic decomposition. State-of-the art methods for tuning the hyperparameters of the MIP-heuristics are limited to grid search, random search and heuristic search; these methods suffer from their computational costs for large hyperparameter spaces (grid search and random search) or explore only a heuristically reduced hyperparameter space (heuristic search).

In previous publications the authors proposed a

novel hyperparameter optimization method based on Bayesian optimization (BO) and studied a use case from the PSE domain [7, 8]. The use case is a two-step moving horizon heuristic for a hoist scheduling problem comprising a construction step and an improvement step. The six hyperparameters are the window size and the step size in each step, the initial job sequence and the accepted optimality gap of the solutions of the polylithic MIP-models. The contribution at hand generalizes the description of the MIP-Heuristic Optimization Problem (MIP-HOP) and the computer implementation of the solution-method.

The remainder of the paper is structured as follows: The following section "Generic Formulation" describes and explains the MIP-HOP in detail. The section "Related Work" summarizes existing research on tuning of MIP-heuristics, hyperparameter tuning methods and the authors' own work in this field. The section "Software Architecture" describes the implementation of the BO-based approach for solving the MIP-HOP with references to the generic formulation. "Conclusions" and a link to "Digital Supplementary Material" close the paper.

## GENERIC FORMULATION

The following large scale monolithic MIP-model $M$ (describing a hoist scheduling problem for instance, see above) is given:

$$M\colon z = \min_{x \in \mathbb{R}^{n1} \times \mathbb{N}^{n2}} cx \mid Ax \leq d \tag{1}$$

In (1) $z$ denotes the scalar objective value, $x$ denotes the vector of variables, $n1$ and $n2$ denote the number of continuous and integer variables, $c$ denotes the parameter-vector of the linear objective function $cx$, and $A$ denotes the parameter-matrix and $d$ denotes the parameter-vector of the linear constraints $Ax \leq d$. A feasible or optimal solution of $M$ is denoted as $\hat{x}$.

The decomposition scheme of the monolithic MIP-model $M$ into a polylithic MIP-model $P(\lambda)$ according to a MIP-heuristic is also given and described by a decomposition operator $\mathcal{D}$:

$$P(\lambda) = \mathcal{D}(M, \lambda) \tag{2}$$

In (2) the $\lambda$ denotes the vector of hyperparameters of a MIP-heuristic. For the hoist scheduling example, the hyperparameters "window size" control the size of the partial MIP-models and the hyperparameters "step size" control the number of the partial MIP-models. It is assumed that the hyperparameters can be represented by real or integer values:

$$\lambda \in \mathbb{R}^{h1} \times \mathbb{N}^{h2} \tag{3}$$

In (3) $h1$ and $h2$ denote the number of real-valued and integer-valued hyperparameters, respectively. Their values may be subject to a vector of (non-linear) constraints:

$$g(\lambda) \leq 0 \tag{4}$$

For the hoist scheduling example, the step size must not be greater than the window size.

The polylithic MIP-model $P(\lambda)$ consist of a set of $n(\lambda)$ partial MIP-models $P_i^\lambda$:

$$P(\lambda) = \{P_1^\lambda, P_2^\lambda, \dots, P_i^\lambda, \dots, P_{n(\lambda)}^\lambda\} \tag{5}$$

Each partial MIP-model $P_i^\lambda$ is defined as shown below and typically much smaller than the large-scale monolithic MIP-model $M$:

$$P_i^\lambda\colon z_i^\lambda = \min_{x_i^\lambda \in \mathbb{R}^{n1_i^\lambda} \times \mathbb{N}^{n2_i^\lambda}} c_i^\lambda x_i^\lambda \mid A_i^\lambda x_i^\lambda \leq d_i^\lambda \tag{6}$$

In (6) $z_i^\lambda$ denotes the scalar objective value, $x_i^\lambda$ denotes the vector of variables, $n1_i^\lambda$ and $n2_i^\lambda$ denote the number of continuous and integer variables, $c_i^\lambda$ denotes the parameter-vector of the linear objective function $c_i^\lambda x_i^\lambda$, and $A_i^\lambda$ denotes the parameter-matrix and $d_i^\lambda$ notes the parameter-vector of the linear constraints $A_i^\lambda x_i^\lambda \leq d_i^\lambda$.

The composition of the partial solutions $\hat{x}_i^\lambda$ according to the given MIP-heuristic to a solution $\hat{x}^\lambda$ is described by a composition operator $\mathcal{C}$:

$$\hat{x}^\lambda = \mathcal{C}(M, \lambda, \hat{x}_1^\lambda, \hat{x}_2^\lambda, \dots) \tag{7}$$

Finally, the MIP-heuristic optimization problem (MIP-HOP) can be stated as the following multi-objective optimization problem with mixed degrees of freedom subject to three types of constraints:

$$\begin{aligned} &MIP-HOP\colon \hat{\lambda}(f_1, f_2, \dots) = \\ &\underset{\lambda}{argmin}(f_1(\lambda), f_2(\lambda), \dots) \mid g(\lambda) \leq 0, P(\lambda) = \\ &\mathcal{D}(M, \lambda), \hat{x}^\lambda = \mathcal{C}\left(M, \lambda, \hat{x}_1^\lambda, \dots, \hat{x}_{n(\lambda)}^\lambda\right) \end{aligned} \tag{8}$$

In (8) $f_1(\lambda), f_2(\lambda), \dots$ denote general scalar objective functions and $f_1, f_2, \dots$ denote the corresponding objective values.

The MIP-HOP typically exhibits the following properties:

- The exact values of the general objective functions $f_1(\lambda), f_2(\lambda), \dots$ for a certain value of $\lambda$ can only be observed a posteriori, i.e. after a $P(\lambda)$ is solved.
- Two natural objective functions $f_1^n(\lambda)$ and $f_2^n(\lambda)$ of the *MIP-HOP* are the objective function of the monolithic MIP-model $M$ and the computational cost for solving $P(\lambda)$, respectively.
- The optimal objective value of $M$ is a lower bound of the exact $f_1^n(\lambda)\ \forall\lambda$.
- Exactly solving $M$ (and possibly $P(\lambda)$ for some values of $\lambda$) is prohibited by too high

computational costs.

Exact MIP-algorithms can solve the monolithic MIP-model $M$ and the partial MIP-models $P_i^\lambda$ exactly (feasible solution with optimality gap 0), or they can approximate their solutions (feasible solutions with optimality gap >0). In this paper, a solution of a polylithic MIP-model $P(\lambda)$ is called "exact" if all partial MIP-models $P_i^\lambda$ are solved to optimality. Exact MIP-algorithms are steered by special hyperparameters (e.g. an accepted optimality gap); these special hyperparameters are included in $\lambda$.

The MIP-model $M$ and the partial MIP-models $P_i^\lambda$ are "white-box" optimization problems since the mathematical formulation is fully accessible to the solver at any time of the solution process. Due to the algorithmic nature of the MIP-heuristic, in general no such formulation exists for $\mathcal{C}$ and $\mathcal{D}$, such that the MIP-HOP belongs to the class of "black-box" optimization problems.

# RELATED WORK

## Tuning of MIP-Heuristics

A search in Google scholar for "MIP-heuristic" leads to around 700 publications from the years 1965 to 2025; some 100 of them were published since 2024. To gain a deeper insight into the state of the art of tuning of MIP-heuristics 30 publications were selected and analyzed. The publications comprise MIP-based as well as MINLP-based decomposition heuristics for a wide range of optimization problems, such as batch scheduling, maintenance planning, project scheduling, supply network planning, production routing, bin packing, locomotive assignment, healthcare planning, flowsheet optimization and lot sizing. The MIP/MINLP-based heuristics comprise different decomposition approaches like temporal, area, activity, scenario and geographic decomposition. The selected papers were published between 2002 and 2025, and include 26 journal articles, 3 conference papers, and 1 book chapter.

A majority of 25 of the 30 reviewed publications (83%) exhibits MIP/MINLP-based heuristics that include at least one hyperparameter. These hyperparameters are not in all papers explicitly mentioned in the text but were identified during the review by closely analyzing the proposed heuristics. Only 12 publications (40%) report some form of tuning: 9 use grid search while 3 rely on hyperparameter values derived from random or heuristic sampling (based on pre-studies). The remaining 13 publications with hyperparameters do not describe any tuning procedures while 2 of them devise the tuning to the user. In the remaining 5 publications no hyperparameter could be identified. A full list of the reviewed papers along with the detailed analysis will be provided in [10].

The result from this literature review shows that most MIP-heuristics exhibit tunable hyperparameters and roughly half of the authors identified the tuning of hyperparameters as an optimization problem. However, the applied tuning methods still leave space for methodological improvement: Grid search as the predominant tuning method requires the continuous hyperparameters to be discretized. It finds the global optimum in the discretized hyperparameters space, but its computational cost suffers from its sample-inefficiency in higher dimensional hyperparameter-spaces. Random and heuristic sampling typically use less samples but do not explore the hyperparameter space effectively.

## Hyperparameter Tuning Methods

The application of hyperparameter tuning and algorithm selection methods to mixed-integer programming was recently reviewed by the authors in [9]; it can be summarized as follows:

Numerous studies have demonstrated that proper hyperparameter tuning can enhance machine learning model accuracy, generalization and performance, as well as prevent overfitting (see e.g. [1-3]). Beyond traditional machine learning models, hyperparameter tuning and algorithm selection techniques have also been applied to mathematical programming (see e.g. [4-6]). However, there is no research on its use in MIP-heuristics known to the authors. A key challenge in MIP-heuristic tuning is the high computational cost associated with evaluating each hyperparameter value, as it involves solving one or more MIPs. Consequently, exhaustive methods such as grid search, random search, or even population-based approaches like evolutionary algorithms or particle swarm optimization often become impractical due to their high computational cost and low sample efficiency. To address this issue, more efficient methods such as successive halving, hyperband, and BO have been proposed. Both bandit-based methods (like successive halving and hyperband) and BO-based methods are promising approaches for the hyperparameter tuning of matheuristics.

## Own Work

The authors proposed a novel BO-based algorithm based to solve the MIP-HOP (see (1)-(8)) and studied it for a hoist scheduling problem [7-10]. The description of the MIP-heuristic and hyperparameters can be found in [9]. The architecture of the algorithmic is shown in Figure 1.

In each iteration, the BO proposes a new point in the space of hyperparameters $\lambda$ using a surrogate model for the objective functions $f_1(\lambda), f_2(\lambda), \ldots$ and an acquisition function such that the hyperparameter constraints (4) are met. The decomposition operator $\mathcal{D}$ and the composition operator $\mathcal{C}$ represent the MIP-heuristic. The decomposition operator $\mathcal{D}$ uses the $\lambda$-values and the formulation of

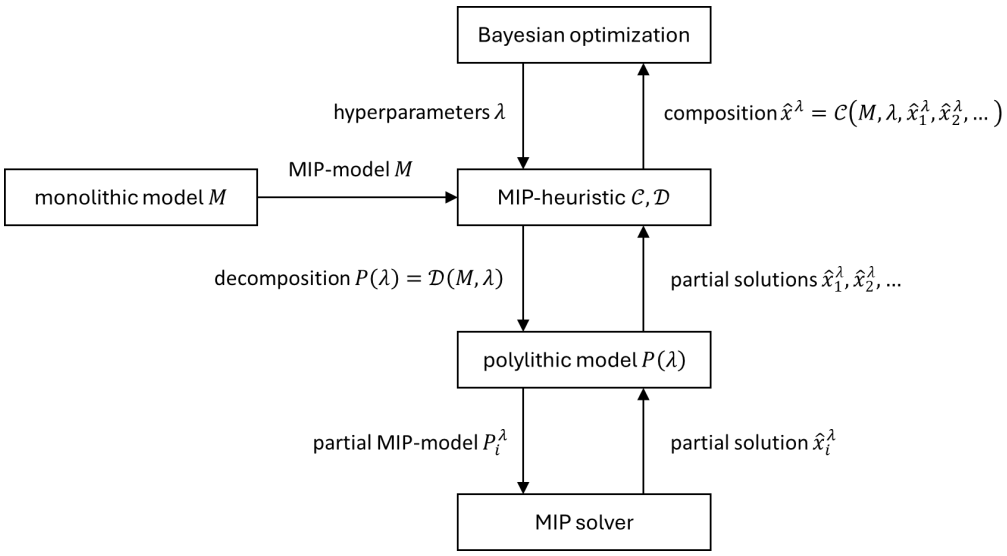

**Figure 1.** Algorithmic architecture

the monolithic MIP-model $M$ as input to generate the polylithic MIP-model $P(\lambda)$ according to (2). The polylithic MIP-model $P(\lambda)$ consists of a set of interconnected partial MIP-models $P_i^\lambda$; they are solved sequentially by a MIP standard solver. The MIP standard solver computes a solution $\hat{x}_i^\lambda$ of the partial MIP-model $P_i^\lambda$ which is used to parametrize the next partial MIP-model $P_{i+1}^\lambda$. The composition operator $\mathcal{C}$ uses the $\lambda$-values, the formulation of the monolithic MIP-model $M$ and the solutions $\hat{x}_1^\lambda, \hat{x}_2^\lambda, \dots$ as input to generate a solution $\hat{x}^\lambda$ of $M$. The objective functions $f_1(\lambda), f_2(\lambda), \dots$ are evaluated and the objective values $f_1, f_2, \dots$ are returned to the BO. The BO updates its surrogate model and calculates new promising values for the hyperparameters $\lambda$ using an acquisition function. This is done until a termination criterion for the BO, such as the number of iterations, a computational time limit or the number of retries to propose new $\lambda$-values is met.

## SOFTWARE ARCHITECTURE

The proposed approach is implemented in python within a modular software architecture that separates MIP-heuristic execution $\mathcal{D}, \mathcal{C}$, MIP-model definition $M$, and hyperparameter tuning of the MIP-heuristic (MIP-HOP). This separation enables the individual components e.g. the MIP-model to be exchanged or extended independently.

The software architecture supports multiple solving strategies for the underlying MIP-model: Monolithic solving with adapted solver parameters $\lambda$ like the target optimality gap and polylithic solving based on MIP-heuristics $\mathcal{D}, \mathcal{C}$ that decompose the monolithic model $M$ into a sequence of partial MIP-models $P_i^\lambda$ are implemented. In the polylithic case, the MIP-heuristic is parameterized by a set of hyperparameters $\lambda$ that control, among others, the number $n(\lambda)$ and size of the generated partial MIP-models and thus define the trade-off between the two natural, competing objectives of the MIP-HOP, the solution quality $f_1^n(\lambda)$ and computational cost $f_2^n(\lambda)$. The hyperparameters $\lambda$ can either be evaluated using a single fixed hyperparameter configuration or optimized automatically using hyperparameter tuning.

Several hyperparameter tuning methods are implemented, including grid search and random search as baseline methods, as well as Bayesian optimization for more efficient exploration of the non-linear hyperparameter spaces. All tuning methods interact with the MIP-heuristic through evaluations of $P(\lambda)$ and the resulting objective values $f_1(\lambda), f_2(\lambda), \dots$, and thus treat the MIP-heuristic as a black-box objective function.

The implementation integrates several external optimization tools. The MIP-model $M$ and all partial MIP-models $P_i^\lambda$ are formulated using the algebraic modeling language Pyomo, while all MIPs are solved using the commercial MIP-solver CPLEX. Bayesian optimization for solving the MIP-HOP is realized using SMAC3 [11].

Figure 2 illustrates the main components of the software architecture (`experiment setup`, `experiment controller`, `heuristic execution`, `model definition` and external optimization tools) as well as the control flow between them.

Figure 2 illustrates the main components of the software architecture (`experiment setup`, `experiment controller`, `heuristic execution`, `model definition` and `external optimization tools`) as well as the control flow between them.

The `experiment setup` specifies the hyperparameters $\lambda$ and selects the solving strategy, such as

monolithic solving or polylithic solving combined with random search. The `experiment controller` then orchestrates the execution by invoking either the monolithic solving strategy or the MIP-heuristic and, if selected, executes the hyperparameter tuning procedure to solve the MIP-HOP. The `heuristic execution` and `model definition` implement the problem-specific logic of the underlying application, such as hoist scheduling. The following subsections describe these components in detail, following the order in which they interact during an experimental run.

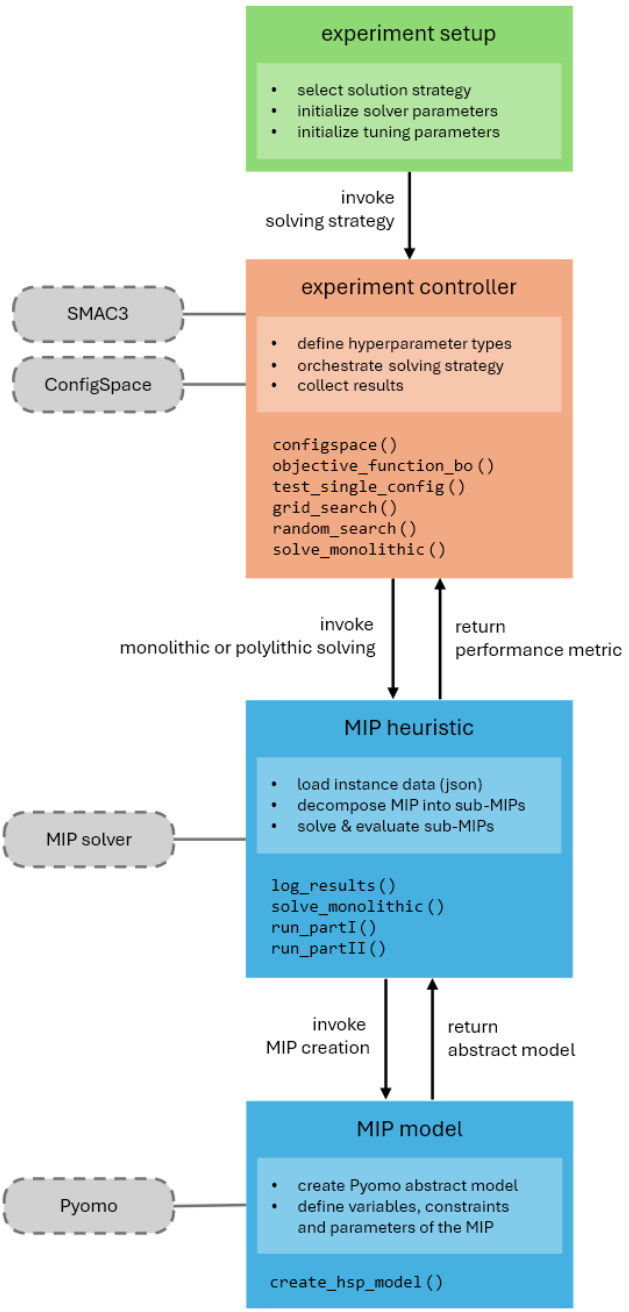

**Figure 2.** Software architecture

## Experiment setup

The `experiment setup` is implemented in `main.py` and serves as the central entry point of the software architecture. Its primary responsibility is to configure and initiate experimental runs and delegate their execution to the `experiment controller`.

At the beginning of an experimental run the `experiment setup` loads the problem instance data from a JSON file and forwards the instance-specific information to the `experiment controller`. These data remain fixed throughout an experimental run. In addition, `experiment setup` initializes output structures for storing results and metadata, supporting reproducibility and systematic comparison of experiments.

`Experiment setup` defines solver-related parameters. These include parameters such as time limits, number of threads, clock type, and target optimality gap. The parameters are passed to the `experiment controller` and subsequently applied during solution of the MIP-model.

The solving strategy selected in `experiment setup` determines whether the `experiment controller` evaluates a monolithic or polylithic MIP-model. In the monolithic case, decomposition-specific parameters are inactive, while parameters, such as the initial job sequence (see [9]), can still be provided explicitly. For polylithic solving, `experiment setup` specifies whether a single hyperparameter configuration $\lambda$ is evaluated or whether automated hyperparameter tuning is applied. In the latter case, `experiment setup` selects the tuning strategy (grid search, random search, or Bayesian optimization) and defines termination criteria such as a time budget or a maximum number of evaluations. When Bayesian optimization is selected, `experiment setup` additionally specifies hyperparameters of the Bayesian optimization, such as the choice of acquisition function and surrogate model, and delegates the execution of the MIP-heuristic hyperparameter tuning to the `experiment controller`.

## Experiment controller

The `experiment controller`, implemented in `experiment_controller.py`, is responsible for orchestrating the execution of the selected solving strategy. It acts as the central coordination component that links experiment setup, heuristic execution, model solving, and hyperparameter tuning.

For monolithic solving, the `experiment controller` delegates execution to the monolithic solving routine where the full MIP-model $M$ is instantiated and solved. The resulting solution quality $f_1^n(\lambda)$, computational cost $f_2^n(\lambda)$, and solver status are collected and passed to

the logging routines.

For heuristic-based solving, the `experiment controller` instantiates and executes the MIP-heuristic $\mathcal{D}$. Depending on the selected hyperparameter tuning method, it either evaluates a single fixed hyperparameter configuration or systematically explores multiple configurations using grid search, random search, or Bayesian optimization.

For Bayesian optimization the type of the hyperparameters to be tuned and the constraints between them are defined using `ConfigSpace`. Based on the defined configuration space the `experiment controller` employs the SMAC3 framework to iteratively select and evaluate hyperparameter configurations. Each hyperparameter configuration proposed by SMAC3 is evaluated by executing the MIP-heuristic $\mathcal{D}$, which is treated as black-box objective function returning performance metrics such as solution quality $f_1^n(\lambda)$ and computational cost $f_2^n(\lambda)$.

For heuristic execution of the hoist scheduling problem, the experiment controller manages the two-phase structure of the rolling horizon approach described in [7]-[9]. It first triggers the initial construction phase (Part I). If this phase completes successfully and the overall time limit is not exhausted, the `experiment controller` initiates the improvement phase (Part II). If a termination criterion is reached within the construction phase, a composition $\mathcal{C}$ is required to ensure a feasibility of the resulting schedule. In this case the remaining unscheduled jobs are appended by the `experiment controller`.

By design, the `experiment controller` interacts with the heuristic exclusively through its external interface and does not modify its internal logic or the structure of the MIP model. Its role is limited to configuration, orchestration, and result collection, ensuring a clean separation between control flow and algorithmic implementation.

## MIP model and heuristic execution

The mathematical model and the heuristic execution are implemented in HSP_MIP_model.py and HSP_MIP_heuristic.py, respectively.

The MIP-model is defined as a Pyomo abstract model, encapsulating decision variables, constraints, and the objective function independently of any specific data instance. A factory function returns this abstract model, which is instantiated at runtime using instance data provided via JSON files. This design allows the same model definition to be reused for monolithic solving of $M$ as well as for all heuristic subproblems $P_i^\lambda$.

The `HeuristicSolving` class provides methods for:

## Solving the full monolithic MIP-model

Executing Part I of the rolling horizon heuristic, which incrementally constructs an initial schedule by solving a sequence of partial MIP-models, and

Executing Part II of the rolling horizon heuristic, which iteratively improves the initial solution by rescheduling subsets of jobs

The `heuristic execution` receives all hyperparameters of the MIP-heuristic, solver settings, and instance references from the `experiment controller`. Based on the hyperparameters provided, it dynamically constructs the corresponding partial MIP-models $P_i^\lambda$ by fixing or relaxing subsets of decision variables while reusing the same underlying Pyomo abstract model. Solver execution, result extraction and status handling are encapsulated within the heuristic implementation.

Result logging is handled directly within the class `HeuristicSolving` and includes both human-readable text files and structured CSV output capturing solver parameters, heuristic settings, solution quality $f_1^n(\lambda)$, computational cost $f_2^n(\lambda)$, and termination status. This ensures consistent reporting across monolithic and polylithic runs.

# RESULTS AND CONCLUSIONS

In previous work, computational studies with the hoist scheduling use case were performed to compare the BO-based algorithm with random search. The MIP-HOP was solved with two different single objective functions: The makespan (objective of the large-scale MIP model $M$) with many optimal solutions (see Figure 3); and the computational cost (measured by the CPU-time) with few optimal solutions (see Figure 4).

The results showed that the BO-based algorithm is slower than the random search but finds better (or at least equally good) solutions than the random search [10].

This paper introduced a generic formulation of the MIP-heuristic optimization problem (MIP-HOP) and a corresponding modular software architecture. By abstracting from problem-specific characteristics, the formulation unifies the description of monolithic and polylithic MIP models, heuristic decomposition and composition, and hyperparameter optimization of MIP-heuristics within a single architecture. The proposed software reflects this formulation and supports reproducible experimentation by separating experiment setup, experiment control, heuristic execution, and model definition. The integration of established tools for mathematical programming and Bayesian optimization, together with the public release of the code, facilitates reuse and transfer of the approach to other application domains.

Future work will build on the presented formulation and software to conduct an extensive empirical

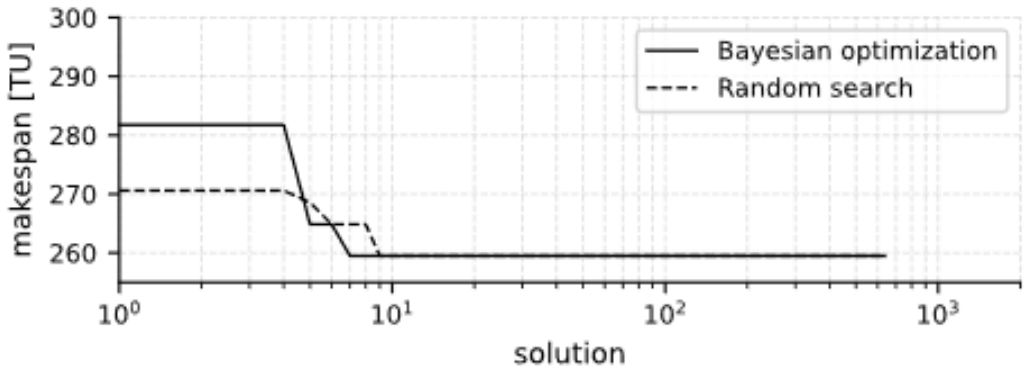

**Figure 3.** Convergence of the makespan (in time units) over the number of solutions $\lambda$ in the hyperparameter space

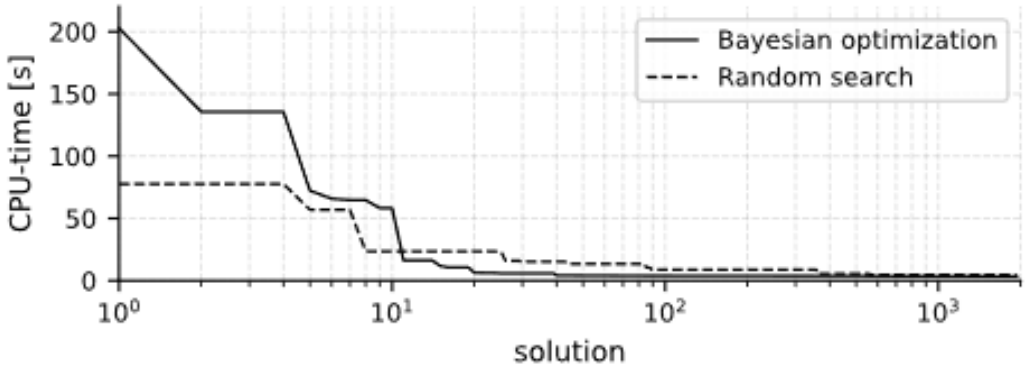

**Figure 4.** Convergence of the CPU-time (in seconds) over the number of solutions $\lambda$ in the hyperparameter space

evaluation. The behavior of the two-phase rolling horizon heuristic will be analyzed on small- and large-scale hoist scheduling instances within two- and five-dimensional hyperparameter spaces. This evaluation aims to quantify how MIP-heuristic hyperparameters affect solution quality and computational cost, depending on instance characteristics and dimensionality of the hyperparameter space. Different hyperparameter tuning strategies, including grid search, random search, and Bayesian optimization, will be compared to derive recommendations on the choice of the tuning strategy with respect to the competing objectives solution quality and computational cost.

## DIGITAL SUPPLEMENTARY MATERIAL

The digital supplementary material accompanying this paper is publicly available at:

https://github.com/SoHildebrandt/ES-CAPE36_MIP-HOP_GenericFormulationAndCode

The repository contains the complete implementation described in the Software Architecture section, including:

- the experiment setup and control logic (main.py, experiment_controller.py),
- the mixed-integer programming model of the hoist scheduling problem (`HSP_MIP_model.py`),
- the two-phase rolling horizon MIP-heuristic (HSP_MIP_heuristic.py), and
- a set of small-scale and large-scale hoist scheduling instances provided in JSON format.

The provided code realizes the modular software architecture described in this paper, including the interaction between experiment setup, experiment control, heuristic execution, and mathematical model definition. The included input instances serve as illustrative examples and enable readers to inspect, execute, and extend the implementation.

## ABSTRACT

Fault diagnosis is essential for ensuring safety and efficiency in chemical process industries. Conventional diagnostic systems often generate raw numerical outputs that require extensive human interpretation, increasing the operator's workload and slowing decision-making during abnormal events. To overcome these limitations, this work introduces a model context protocol (MCP)-integrated fault diagnosis framework, where a Large Language Model (LLM) functions as the MCP client, coordinating multiple diagnostic tools through a unified protocol. Within the proposed framework, the LLM interacts with specialized diagnostic tools, including a convolutional neural network-based fault diagnosis model and an ensemble-based variant for uncertainty-aware analysis. The LLM synthesizes the outputs of these tools and generates operator-oriented natural-language reports that summarize diagnostic results and explicitly communicate uncertainty, thereby supporting more transparent and efficient decision-making.A benchmarking study based on the Tennessee Eastman (TE) process is conducted to evaluate the framework using multiple LLMs under identical settings. The evaluation assesses diagnostic accuracy, tool adherence, and operator report quality using an LLM-as-a-judge methodology. Experimental results show that LLM performance varies significantly across models, and that reliable tool calling and uncertainty-aware reasoning are more critical than model size for effective fault diagnosis assistance.Overall, the proposed framework demonstrates strong potential for enhancing fault diagnosis workflows in chemical processes by improving usability, interpretability, and decision-making efficiency without modifying existing diagnostic algorithms.

**Keywords**: Artificial Intelligence, Fault Detection, Large Language Model

## 1. INTRODUCTION

Fault diagnosis plays an important role in chemical process industries, where undetected or misdiagnosed faults can lead to severe safety incidents, environmental damage, and significant economic losses [1]. To address these challenges, machine learning and deep learning techniques have been widely applied for fault detection and diagnosis [2], enabling earlier identification of abnormal operating conditions and improving overall process safety and reliability [3, 4]. Despite their performance, most existing fault diagnosis systems remain algorithm-centric, providing outputs in the form of numerical scores or fault probabilities [5]. Such results often lack intuitive, human-friendly explanations, increasing the cognitive workload of operators and potentially slowing down decision-making during abnormal events.

In parallel, recent advances in natural language processing have led to the rapid development of large language models (LLMs) based on transformer architectures [6]. These models demonstrate strong capabilities in reasoning, contextual understanding, and natural-language generation [7]. Beyond standalone text generation, LLMs have evolved into agentic systems, where an LLM can autonomously select and invoke external tools, interact with real-world applications, and maintain contextual memory to support more adaptive and personalized interactions [8]. In chemical engineering, LLMs have begun to emerge as promising tools for different tasks. Caccavale et al. [9] introduced ChatGMP, an LLM-based chatbot to support student learning in chemical engineering education. Liang et al. [10] leveraged LLM agent in

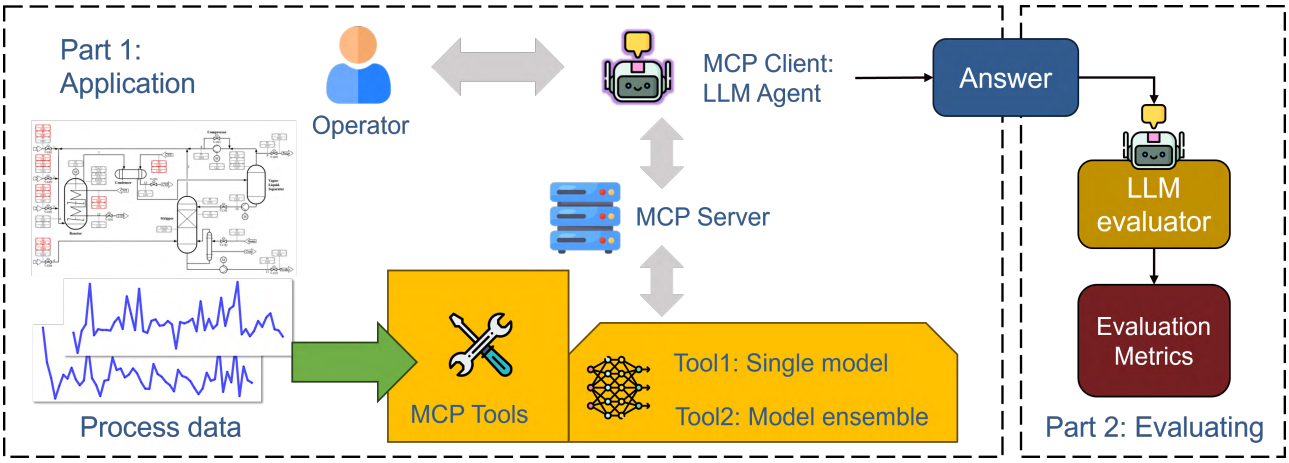

**Figure 1.** The proposed LLM-enhanced fault diagnosis framework with Model Context Protocol (MCP)

chemical simulations for simulation flowsheet analysis and synthesis. Zeng et al. [11] demonstrate an LLM-guided multi-agent optimization system that outperforms traditional methods on hydrodealkylation optimization . In fault diagnosis, FaultExplainer [12] demonstrates the potential of large language models to enhance fault diagnosis systems by generating interpretable, human-readable explanations alongside data-driven diagnostic results.

Motivated by the reasoning and tool-interaction capabilities of LLM agents, this work proposes a framework that integrates LLMs into chemical process fault diagnosis to enhance usability and decision support. Operators can query the system using natural language, while the LLM agent autonomously selects and invokes appropriate diagnostic tools using model context protocol (MCP), evaluates confidence in the results, and synthesizes the outputs into interpretable, operator-oriented explanations. By combining the reliability of established fault diagnosis algorithms with the flexibility and expressiveness of LLM agents, the proposed framework aims to reduce operator workload, improve situational awareness, and support faster and more informed decision-making during abnormal operating conditions.

In addition to proposing the framework, this work conducts a systematic benchmarking study using a dedicated evaluation dataset to compare the performance of different LLMs in terms of diagnostic accuracy, tool adherence and report quality. This study provides practical insights into LLM selection for fault diagnosis tasks that require both tool calling and operator-oriented report generation.

The main contributions of this paper are summarized as follows:

1) An MCP-based fault diagnosis framework is proposed, in which an LLM agent selects diagnostic tools based on prediction uncertainty and generate user-friendly report.

2) A structured evaluation experiment for LLM agents in fault diagnosis is carried out, enabling a comparative study of different LLMs under fair settings.

The remainder of this paper is organized as follows. Section 2 introduces the methodologies used in the proposed framework, including the CNN-based fault diagnosis algorithm, the MCP tools, and the LLM-as-a-judge evaluation strategy. Section 3 presents the experimental study of the proposed framework under different language models, using the Tennessee Eastman Process as a benchmarking dataset. Section 4 concludes the paper and outlines directions for future work.

## 2. METHODOLOGIES

### 2.1 Proposed workflow

As shown in Figure 1, the proposed framework defines an interaction between the operator, the LLM agent, the MCP server, diagnostic tools, and the chemical process. The operator interacts with the system by submitting natural-language queries to the LLM agent, which acts as an MCP client. The chemical process generates process data that are accessed by fault diagnosis algorithms exposed as MCP tools. These tools are managed by an MCP server, which provides standardized interfaces for tool discovery and invocation to the LLM. Upon receiving a query, the LLM agent interprets the user intent, selects appropriate diagnostic tool(s) via the MCP server, and invokes them using the relevant process data. The MCP tools perform fault diagnosis and return structured results to the LLM agent. The LLM agent aggregates and interprets the tool outputs and generates a user-facing fault diagnosis response for the operator.

In addition, an evaluation module is incorporated, where the generated responses are assessed using an LLM-as-a-judge [13] approach to compute multiple evaluation metrics. This evaluation provides insights into the usefulness, reliability, and decision-support quality of the LLM agent.

The following sections describe the diagnostic tools, the LLM tool-calling strategy, and the evaluation methodology, which together form the key components of this work.

## 2.2 Fault diagnosis algorithms

In this work, a multi-scale convolutional neural network (MSCNN) [14] is adopted as the core fault diagnosis algorithm due to its demonstrated effectiveness in previous fault diagnosis studies. Two variants are employed: a single MSCNN model and an ensemble-based MSCNN approach designed to provide more robust predictions.

The single MSCNN model is trained using the training dataset of the Tennessee Eastman Process. For the ensemble approach, multiple MSCNN models with identical network architectures and hyperparameters are trained independently. Model diversity is introduced through random initialization of model parameters and by training each model on different subsets of the training data. The final ensemble prediction is obtained by aggregating the outputs of all individual models, resulting in improved robustness against uncertainty in individual model predictions.

Based on prior experimental results, the ensemble-based MSCNN achieves an overall diagnostic accuracy of 73.67% in difficult faults, outperforming the single-model MSCNN, which attains an accuracy of 68.04%. These results demonstrate the advantage of the ensemble approach in providing more reliable fault diagnosis outcomes for subsequent interpretation by the LLM agent.

## 2.3 MCP tools

By using the Model Context Protocol (MCP) [15], a standardized protocol designed to expose external tools and their interfaces to large language models, the LLM is provided with structured contextual information about the available tools, including their functionality, required input parameters, and expected outputs. The tools are defined in a MCP server, the LLM agent, is a MCP client that can connect to the MCP server and get the available tools. MCP enables LLMs to interact with domain-specific software in a controlled and interpretable manner without requiring direct access to the underlying code or execution environment.

With this information, the LLM can reason about when and how to invoke a tool to solve tasks that require interaction with external software or applications. In this way, MCP serves as a standardized interface between the LLM and domain-specific tools, significantly simplifying tool invocation and integration. In this work, two diagnostic tools are exposed to the LLM through MCP, along with their corresponding descriptions:

**Predict_sample_single_model():** Predicts the fault type and associated probabilities for a given sample index using a single diagnostic model.

**Predict_sample_ensemble_with_plot():** Predicts fault types and probabilities using a model ensemble and generates a probability distribution plot across fault classes.

By invoking these tools, the LLM gains access to the fault diagnosis results produced by the underlying algorithms. The LLM then interprets, summarizes, and presents these results in a human-readable form, enabling operators to understand both the predicted fault and the associated uncertainty.

## 2.4 Agent Reasoning and Response Strategy

A rule-based tool selection logic is defined to guide the reasoning behavior of the LLM agent. Let $p_{\max}$ denote the maximum fault probability predicted by the single-model fault diagnosis algorithm. The tool selection strategy is formulated as follows:

- If $p_{\max} \geq 0.95$, the LLM agent directly uses the output of the single-model diagnosis.
- Otherwise, the LLM agent invokes the ensemble-based diagnosis tool and analyzes alternative faults, as well as plotting the result to the operator.

The rationale behind this strategy is to balance efficiency and robustness in operator-facing fault diagnosis. When the prediction confidence is high, the LLM agent is expected to provide a concise and confident report that focuses on the primary fault, thereby minimizing unnecessary computation and cognitive load. In contrast, when the prediction confidence is low, the LLM agent prioritizes robustness and transparency by incorporating ensemble results into the report. In such cases, the agent presents the most likely fault together with plausible alternative faults and their corresponding vote counts, explicitly communicating diagnostic uncertainty to the operator. This design supports efficient yet transparent decision-making in uncertain fault conditions.

## 2.5 LLM-as-a-judge

To evaluate the quality of the responses generated by the LLM agent, human feedback is generally regarded as the most reliable approach, since the goal of the system is to support human operators. However, for large-scale and repeated evaluations, relying on human assessment can be time-consuming, costly, and inconsistent. As an alternative, this work adopts an automated evaluation strategy known as LLM-as-a-judge [13], where a well-defined LLM is used to assess the outputs of another LLM.

The evaluation workflow using LLM-as-a-judge is illustrated as follows. First, a user submits a query to the LLM agent, which then performs reasoning and tool invocation to complete the fault diagnosis task and generate a final response. All intermediate information, including

the user query, tool calls, and the final answer, is logged and provided as input to the LLM evaluator. In addition, auxiliary information from the evaluation dataset—such as the true fault label and the predefined uncertainty level of the sample—is included. A system prompt is also supplied to guide the judge LLM on the evaluation criteria and scoring procedure.

Based on the provided information, the judge LLM performs its own reasoning and assigns scores according to the specified metrics. This process closely resembles human evaluation, while offering improved efficiency and consistency across repeated experiments. The specific evaluation metrics used in this study are detailed in the following section.

# 3. EXPERIMENTAL STUDIES

## 3.1 Tennessee Eastman Process Dataset

The Tennessee Eastman process is used as a case study for the proposed LLM-enhanced fault diagnosis task. It is used to simulate fault scenarios in a chemical process where an operator queries an LLM agent to analyze process data, invoke diagnostic algorithms, and generate fault diagnosis reports. The TE process is a widely used benchmark in the literature for fault detection and fault diagnosis in chemical processes. In this work, its usage is extended to evaluate how LLMs can enhance fault diagnosis workflows through tool calling and natural-language interaction.

The dataset consists of simulation running with 21 different fault types [16]. In total 52 process variables are input to the algorithm. The output of the algorithm is typically the fault number with the highest probability, which is usually regarded as the predicted fault. However, in the uncertainty aware method, we take the probability distribution of all faults, so that we can see how confident it is for the model to predict the primary fault. The training, validation and test sets are separated by the ratio of 6:2:2, and the test set will contribute to the LLM evaluation dataset in section 3.2.

## 3.2 LLM-fault diagnosis evaluation dataset

To evaluate the behavior of the LLM agent in a controlled and quantitative manner, an evaluation dataset with ground-truth labels is constructed. This dataset enables systematic assessment of the LLM's reasoning, tool usage, and response quality under different levels of diagnostic uncertainty. A total of 100 samples are selected, consisting of 50 low-uncertainty samples and 50 high-uncertainty samples. All samples are drawn from the test set of the Tennessee Eastman process dataset, ensuring that they are not seen by the diagnostic models during training.

Each data instance in the evaluation dataset is formulated as a natural-language query and is accompanied by additional labels used for evaluation. The structure of the dataset is illustrated in Table 1.

**Table 1:** Example of the LLM Evaluation Dataset

| Question | True label | Uncertainty level |
|---|---|---|
| What is the fault type of sample 761? | 13 | Low |
| ... | ... | ... |
| What is the fault type of sample 4201? | 21 | High |

It is important to emphasize that this work focuses on evaluating the role of LLMs in enhancing fault diagnosis workflows, rather than improving the predictive accuracy of the underlying diagnostic algorithms. Accordingly, this study does not aim to develop or benchmark new fault diagnosis models. Instead, the emphasis is on exploring an LLM-centered framework that improves usability, transparency, and decision support in fault diagnosis by integrating existing diagnostic models with LLM agents.

## 3.3 Evaluation Metrics

To comprehensively evaluate the performance of the proposed LLM-enhanced fault diagnosis framework, three complementary metrics are employed. These metrics assess technical correctness, rule compliance, and operator-oriented response quality.

**1) Diagnostic Accuracy**

Diagnostic accuracy is evaluated using an LLM-as-a-judge approach with a tiered scoring scheme of $\{0, 0.5, 1\}$, based on the true fault label and the response generated by the LLM agent. A score of 1 is assigned if the primary fault reported by the agent matches the true label. If the true fault is mentioned as an alternative fault, a score of 0.5 is assigned. Otherwise, a score of 0 is given. This tiered scheme accounts for uncertainty-aware responses and avoids penalizing the agent for explicitly acknowledging diagnostic ambiguity.

**2) Tool Adherence**

Tool adherence is evaluated using a rule-based evaluator that checks whether the LLM agent follows the tool selection strategy defined in Section 2.4. The evaluation is performed based on the labeled uncertainty level of each sample and the corresponding expected tool invocation. An LLM agent is considered compliant if it consistently invokes the appropriate diagnostic tool (single model or ensemble) according to the predefined uncertainty threshold.

**3) Operator Report Quality**

Operator report quality is assessed using an LLM-

as-a-judge approach, with scores ranging from 1 to 5. A system prompt is provided to guide the judge LLM in scoring the responses based on multiple criteria, including alignment with the labeled uncertainty level, clarity and directness of the explanation, effectiveness in supporting operator decision-making, and the actionability of the generated report.

To help readers better understand the LLM's reasoning in the fault diagnosis task, Table 2 presents an example output generated by *gemini-2.5-flash* for sample 4201.

**Table 2:** Answer from gemini-2.5-flash of sample 4201

| Question: What is the fault type of sample 4201? |
|---|
| Answer: For sample 4201, the primary fault type is 15. However, the confidence in this prediction is low (around 30%), indicating significant uncertainty.<br>Alternative fault types to consider are:<br>▪ **Fault type 21** (with a mean probability of 29.17%)<br>▪ **Fault type 9** (with a mean probability of 11.84%)<br>To distinguish between these, the operator should check for symptoms related to both fault type 15 and fault type 21, as they have very similar probabilities. Additionally, a review of indicators for fault type 9 would be prudent. |

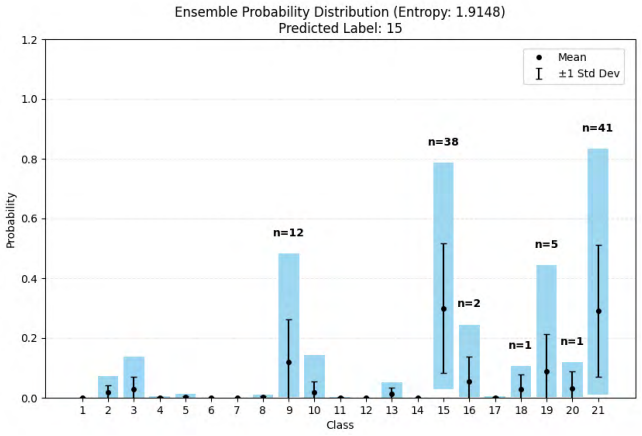

**Figure 2.** Diagnostic result visualization of sample 4201 by calling tool Predict_sample_ensemble_with_plot()

For this sample, the generated response achieves a fault accuracy score of 0.5, a report quality score of 5, and a tool adherence score of 1. These scores reflect that, although the prediction is uncertain, the LLM correctly follows the intended diagnostic strategy. Specifically, the LLM invokes the ensemble-based diagnostic tool, which produces a visualization of the fault probability distribution and exposes the uncertainty across fault classes. The LLM then incorporates this information into a structured and cautious explanation, discussing multiple plausible fault hypotheses instead of over-committing to a single class.

Overall, this example illustrates how the LLM leverages tool outputs and uncertainty information to generate an interpretable, decision support-oriented diagnosis, highlighting its potential role in enhancing fault diagnosis beyond raw classification results.

## 3.4 Results and Discussion

To evaluate the effectiveness of different LLMs within the proposed MCP-based fault diagnosis framework, experiments were conducted using multiple LLMs under identical settings. The evaluated models span multiple providers, architectures, and deployment types, including both open-source and closed-source models with varying parameter sizes. All models were evaluated under the same environment with identical prompts and tools, ensuring a fair comparison. The experimental results are summarized in Table 3.

**Table 3:** Experimental results from the LLM-enhance fault diagnosis report

| Model name | Fault Accuracy | Tool Adherence | Report Quality |
|---|---|---|---|
| openai/gpt-4o-mini | 0.83 | 1.00 | 5.00 |
| x-ai/grok-4-fast | 0.82 | 1.00 | 5.00 |
| anthropic/claude-3.5-haiku | 0.82 | 0.99 | 5.00 |
| google/gemini-2.5-flash | 0.82 | 1.00 | 4.94 |
| openai/gpt-4o | 0.82 | 1.00 | 5.00 |
| deepseek/deepseek-chat-v3.1 | 0.79 | 0.97 | 4.85 |
| meta-llama/llama-3.1-8b-instruct | 0.75 | 0.85 | 4.60 |
| google/gemini-2.5-flash-lite | 0.70 | 0.69 | 4.89 |
| qwen/qwen3-235b-a22b-2507 | 0.62 | 0.86 | 4.47 |
| meta-llama/llama-3.3-70b-instruct | 0.60 | 0.64 | 3.20 |

From these results, several conclusions can be drawn.

First, models from major commercial providers consistently demonstrate strong performance across all three metrics, with relatively small performance differences among them. This indicates that advanced LLMs are generally capable of strictly following the proposed tool selection strategy and generating high-quality, operator-oriented fault diagnosis reports. These results highlight the effectiveness of leveraging LLMs to enhance

fault diagnosis workflows in chemical processes.

Second, differences between lightweight and full-scale models are model-dependent rather than universal. For example, Gemini-2.5-Flash-Lite performs noticeably worse than Gemini-2.5-Flash, suggesting that model compression may negatively impact tool adherence and diagnostic reasoning. In contrast, gpt-4o-mini achieves performance comparable to its full-scale counterpart (gpt-4o), demonstrating that it is possible to deploy lightweight models while still achieving high diagnostic accuracy and report quality when tool-calling behavior is well aligned with the task requirements.

Third, open-source models are generally less competitive in this setting, exhibiting lower fault accuracy, weaker tool adherence, and reduced report quality. Among them, deepseek-chat-v3.1 performs the best, while llama-3.1-8b, qwen3-235b, and llama-3.3-70b show significantly poorer performance. Notably, the wide variation in parameter sizes among these models further indicates that larger model size does not necessarily lead to better performance in MCP-based fault diagnosis tasks.

Finally, it can be observed that the upper bound of fault diagnosis accuracy across all evaluated models is approximately 0.83, even when tool adherence reaches 100%. This suggests that the accuracy of the LLM agent is fundamentally constrained by the performance of the underlying diagnostic tools. This behavior is intuitive: by mitigating hallucinations through strict tool usage, the LLM's outputs are limited to the information provided by the invoked algorithms.

Overall, these results demonstrate that LLMs can effectively assist fault diagnosis in chemical processes by leveraging tool-calling capabilities and natural-language report generation. The findings further indicate that LLM performance varies across models, and that selecting models with strong tool-calling reliability and reasoning ability is more important than choosing models solely based on parameter size. Rather than establishing a permanent ranking of LLMs, these results highlight the importance of a systematic benchmarking process for evaluating LLM-based agents in fault diagnosis tasks.

## 4. CONCLUSION AND FUTURE WORK

This work proposes an LLM-enhanced fault diagnosis framework that integrates large language models with fault diagnosis algorithms through structured tool calling. By enabling the LLM to invoke diagnostic tools and generate operator-oriented reports, the proposed framework improves the usability and efficiency of fault diagnosis in chemical processes. Experimental results across multiple LLMs demonstrate that many models are capable of correctly following the proposed strategy, while the achievable diagnostic accuracy is fundamentally constrained by the performance of the underlying fault diagnosis algorithms. Advanced LLMs, however, are effective in interpreting diagnostic results and communicating them to operators in a clear and actionable manner.

Overall, the results highlight the potential of applying LLMs to enhance fault diagnosis workflows in chemical engineering, particularly by improving user experience, transparency, and decision-making efficiency rather than by replacing existing diagnostic models.

Future work will focus on extending the proposed framework toward more advanced multi-agent systems and scaling up the validation to a broader range of industrial process systems. In addition, the observed performance gap between open-source and commercial LLMs motivates further research into improved system design and agent strategies to narrow this gap. Advancing the capability of open-source LLM-based systems is particularly important for addressing data privacy and deployment constraints in industrial environments.

Specifically, many critical chemical facilities operate on strictly air-gapped control networks without internet access to mitigate cybersecurity risks and protect sensitive intellectual property. Cloud-based commercial LLMs cannot be deployed in these settings, making locally deployed open-source models a strict industrial necessity. Furthermore, because chemical process monitoring is a continuous task, relying on commercial APIs would incur significant ongoing token costs, whereas locally deployed open-source models incur zero variable query costs once established. Therefore, enhancing the performance of local, open-source LLMs remains a critical priority for practical industrial deployment.

## ABSTRACT

Dynamic simulation of distillation columns and chemical reactors remains essential for plant design, controllability analysis, and economic optimization. High-purity separations of close-boiling mixtures present significant computational challenges due to nonlinear thermodynamic behavior and stiff differential-algebraic equation (DAE) systems. This work presents a unified Python/JAX framework integrating four computational modules: (1) Peng-Robinson thermodynamics with complex-step differentiation, (2) nonlinear solvers (Newton, Broyden, Newton-Krylov) with automatic Curtis-Reid scaling, (3) DAE solver with Radau IIA collocation and intelligent auto-selection, and (4) constrained optimization using the Augmented Lagrangian Method with JAX automatic differentiation. The framework leverages JAX's just-in-time compilation (JIT), vectorization (vmap), and automatic differentiation (AD) to achieve near-compiled-language performance. Validation includes: nonlinear solver benchmarks with Newton-Krylov achieving 100% success across seven problems (n=2 to 5000), Williams-Otto reactor optimization with 0.06% deviation from published literature and 1325× real-time speedup, and a 180-stage propylene-propane splitter with 18× real-time performance under three concurrent disturbances. The framework shows that is possible to have an open-source alternative suitable for real-time optimization, operator training, and advanced process control applications.

**Keywords**: Python, JAX, Process Simulation, Nonlinear Solvers, DAE Systems, Optimization, Distillation

## 1. INTRODUCTION

Dynamic modeling of chemical processes supports applications from conceptual plant design to real-time optimization and operator training. However, several technical challenges complicate simulation of hydrocarbon separation processes. High-purity product specifications (>99%) demand rigorous thermodynamic models that accurately capture vapor-liquid equilibrium. The resulting mathematical models are differential-algebraic equations (DAE) systems in which algebraic constraints (phase equilibrium, summation) couple with differential mass balances. Large industrial distillation columns (50-200 stages) produce systems with thousands of coupled equations, necessitating efficient sparse linear algebra.

This work addresses these challenges using Python with JAX [1, 2], providing: (1) automatic differentiation for exact Jacobians and gradients, (2) just-in-time compilation via XLA [2], achieving near-C++ performance, (3) vectorization through vmap for batch processing, and (4) functional purity ensuring reliable transformations.

The framework comprises four modules: **thermodynamics** (Peng-Robinson with complex-step differentiation), **nonlinear solvers** (Newton/Broyden/Newton-Krylov with Curtis-Reid scaling), **DAE solver** (Radau IIA with auto-selection), and **optimization** (Augmented Lagrangian with JAX AD).

Sections 2–5 present methods, Section 6 validates via benchmarks and applications, and Section 7 concludes.

**Table 1:** JAX Commands Reference.

| Command | Description | Application | Example |
|---|---|---|---|
| **@jit** | **JIT compilation to machine code via XLA** | **All computational kernels** | **@jit def f(x): return x**2** |
| vmap(f, in_axes) | Vectorize function over batch dimension | Multi-stage VLE, collocation | vmap(stage_func)(stages) |
| jacfwd(f)(x) | Forward-mode AD: Jacobian via n forward passes | Newton solver, constraints (n_out ≥ n_in) | J = jax.jacfwd(F)(x) |
| grad(f)(x) | Reverse-mode AD: gradient via 1 forward + 1 backward | Scalar optimization objectives | g = jax.grad(f)(x) |
| jvp(f, (x, ), (v, )) | Jacobian-vector product J·v | Newton-Krylov matrix-free solver | _, Jv = jax.jvp(F, (x, ), (v, )) |
| jnp.* | JAX NumPy functions (GPU/TPU compatible) | All array operations | jnp.sum(x), jnp.linalg.solve(A, b) |

# 2. THERMODYNAMIC MODEL

## 2.1 Peng-Robinson Equation of State

The Peng-Robinson equation of state [3] relates pressure P, temperature T, and molar volume V. Parameters a(T) and b are computed from critical properties (Tc, Pc) and acentric factor ω [4]. For mixtures, van der Waals mixing rules employ binary interaction parameters kij fitted to experimental VLE data. Fugacity coefficients φi enable K-value calculations: $K_i = \varphi_i^L / \varphi_i^V$. Complete derivation in [3]; property calculations following [4].

## 2.2 Complex-Step Differentiation

Computing derivatives for Newton-Raphson VLE solvers requires careful consideration of JAX transformation composition. Using JAX automatic differentiation inside PREOS functions would create nested JIT/vmap contexts when called from DAE solvers, causing exponential memory growth and compilation overhead.

Complex-step differentiation [12] computes derivatives via $f'(x) = \mathrm{Im}[f(x + ih)]/h$ with $h \approx 10^{-20}$, achieving machine precision ($10^{-16}$ accuracy). This approach operates as pure arithmetic without additional JAX transformations, avoiding nested issues while maintaining exact derivatives. Care was taken to contain complex dtype within thermodynamic kernels through dtype-agnostic implementations. Complete mathematical treatment in [12].

## 2.3 JAX Implementation

All thermodynamic kernels use @jit for compilation (10–50× speedup). Vectorization via vmap enables batch VLE calculations across stages (8–15× speedup). Precision enforced at 64-bit: jax.config.update("jax_enable_x64", True).

# 3. NONLINEAR EQUATION SOLVERS

## 3.1 Problem Formulation

General nonlinear system: $F(x) = 0$ where $F: \mathbb{R}^n \to \mathbb{R}^n$. Jacobian computed via forward-mode AD: J = jax.jacfwd(F)(x) evaluates n forward passes for exact derivatives.

## 3.2 Newton Method

Newton iteration: $J(x_k)\Delta x_k = -F(x_k)$, $x_{k+1} = x_k + \alpha_k \Delta x_k$. Three variants implemented: pure (α=1), line search (backtracking Armijo condition), dogleg (trust-region [10]). Cost: $O(n^3)$ due to LU decomposition.

## 3.3 Broyden Quasi-Newton

Broyden's method [10] uses rank-1 Jacobian approximation where $s_k = x_{k+1} - x_k$, $y_k = F(x_{k+1}) - F(x_k)$. Periodic Jacobian refresh (every 10–20 iterations) improves convergence. Cost: $O(n^2)$ per iteration.

## 3.4 Newton-Krylov Method

For large sparse systems, Newton-Krylov [6] solves the Newton equation using GMRES (Generalized Minimal Residual method for linear systems [6]) without forming the explicit Jacobian. Matrix-vector products computed efficiently via JVP. For n=5000, jax.jvp evaluates J·v in O(n) time with single forward pass, versus $O(n^2)$ to form explicit Jacobian. Eisenstat-Walker forcing terms [7] adapt GMRES tolerance dynamically.

Parameter sensitivity: Requires tuning GMRES restart (10–40), linear solver tolerance (1e-4 to 1e-6), and preconditioner choice. Framework uses conservative defaults (restart=40, tolerance=1e-4, no preconditioner) ensuring reliability without manual tuning. Cost: O(n) per iteration for sparse systems.

## 3.5 Curtis-Reid Scaling

Ill-conditioned systems with variables spanning multiple orders of magnitude cause convergence failure. Curtis-Reid scaling [5] addresses this through diagonal scaling. Activated when conditioning ratio $\kappa = \max(Dx)/\min(Dx) > 1000$. Scaled system: $\tilde{F}(\tilde{x}) = F(Dx \cdot \tilde{x})/Df = 0$ is solved iteratively.

# 4. DAE SOLVER

## 4.1 DAE Formulation

We solve an index-1 DAE in residual form

$$\mathbf{F}(t,\ \mathbf{y},\ \dot{\mathbf{y}},\ \mathbf{z}) = \mathbf{0},$$

with differential states $\mathbf{y} \in \mathbb{R}^{n_y}$ and algebraic variables $\mathbf{z} \in \mathbb{R}^{n_z}$. For example, for a distillation column, $\mathbf{y}(t)$ stacks stage component holdups (and controller integrators, if any), while $\mathbf{z}(t)$ stacks stage temperatures and algebraic quantities needed to enforce VLE + summation constraints. The model is semi-rigorous: it advances component material balances dynamically and enforces phase equilibrium algebraically, without explicit tray-by-tray energy balances. Temperatures are therefore algebraic unknowns solved from equilibrium closure.

## 4.2 Radau IIA Collocation

Time integration uses a stiffly accurate Radau IIA implicit collocation method with $K = 3$ nodes

$$\tau_1 = \frac{4-\sqrt{6}}{10}, \qquad \tau_2 = \frac{4+\sqrt{6}}{10}, \qquad \tau_3 = 1,$$

chosen for L-stability (critical for stiff DAEs).

For each time step $[t_n, t_{n+1}]$ with $h = t_{n+1} - t_n$, introduce collocation unknowns

$$\mathbf{Y}_i \approx \mathbf{y}(t_n + h\tau_i), \qquad \mathbf{Z}_i \approx \mathbf{z}(t_n + h\tau_i), \qquad i = 1, \dots, K,$$

with $\mathbf{Y}_0 = \mathbf{y}(t_n)$ known.

### Differentiation matrix.

Collocation reconstructs $\dot{\mathbf{y}}_i$ from nodal values using a differentiation matrix $\mathbf{A}$:

$$\dot{\mathbf{Y}}_i \ = \ \sum_{j=0}^{K} A_{ij}\, \mathbf{Y}_j, \qquad i = 1, \dots, K.$$

In the implementation, $\mathbf{A}$ is computed once from the Lagrange basis polynomials on $\{0, \tau_1, \tau_2, \tau_3\}$, and its derivatives are obtained via JAX AD (no numerical differencing for $\mathbf{A}$).

### Collocation residuals.

At each collocation node, enforce the DAE residual:

$$\mathbf{F}\left(t_n + h\tau_i,\ \mathbf{Y}_i,\ \sum_{j=0}^{K} A_{ij}\, \mathbf{Y}_j,\ \mathbf{Z}_i\right) = \mathbf{0}, \qquad i = 1, \dots, K.$$

This produces a single nonlinear system per step with

$$K\left(n_y + n_z\right) \text{ unknowns} \quad \leftrightarrow \quad K\left(n_y + n_z\right) \text{ equations},$$

over the stacked vector

$$\mathbf{w} = \begin{pmatrix} \mathbf{Y}_1 \\ \vdots \\ \mathbf{Y}_K \\ \mathbf{Z}_1 \\ \vdots \\ \mathbf{Z}_K \end{pmatrix}.$$

So, "time integration" is dominated by repeatedly solving $\mathbf{R}(\mathbf{w}) = \mathbf{0}$ for each step.

## 4.3 Residual Structure and Vectorization

The DAE residual $\mathbf{R}(\mathbf{w})$ decomposes naturally into:

**Differential residuals:** stage component material balance mismatches, using $\dot{\mathbf{Y}}_i$ from the collocation reconstruction.

**Algebraic residuals:** VLE relations, e.g.,

$$y_j = K_j(T, P, \mathbf{x})\, x_j,$$

and summation constraints ($\sum_j x_j = 1,\ \sum_j y_j = 1$, etc.).

Residual evaluation is organized stage-wise and then vectorized across stages via a single vmap call. This avoids Python loops over trays and exposes SIMD parallelism to XLA. Practically, one batched evaluation replaces $\mathcal{O}(10^2)$ sequential stage evaluations, which is a major speed driver in stiff dynamic runs.

## 4.4 Dense Newton vs. Matrix-Free Newton–Krylov

Each step solves $\mathbf{R}(\mathbf{w}) = \mathbf{0}$. Two solvers are supported:

### Dense Newton (explicit Jacobian).

Compute the Jacobian $\mathbf{J} = \partial\mathbf{R}/\,\partial\mathbf{w}$ with JAX forward-mode AD (jacfwd) and solve the Newton system

$$\mathbf{J}\Delta\mathbf{w} = -\mathbf{R}(\mathbf{w})$$

via dense linear algebra (LU). This is robust and low-tuning, but the linear solve cost grows rapidly with $n$.

### Newton–Krylov (matrix-free).

Avoid forming $\mathbf{J}$ explicitly. Use JVP to evaluate Jacobian–vector products $\mathbf{Jv}$ inside GMRES, i.e.,

$$\mathbf{Jv} = \mathrm{jvp}(\mathbf{R},\ \mathbf{w};\ \mathbf{v}).$$

This reduces memory pressure and can be faster for large $n$, especially when the effective Jacobian is sparse/structured.

### 4.5 Auto-Selection: Size/Sparsity-Aware Method Choice

Because the "best" method depends on system size and effective sparsity, the solver estimates Jacobian density $\rho$ by sampling a small number of columns using JVP and computing

$$\rho = \frac{\text{nnz}}{n^2}.$$

A simple cost model compares:

**Dense Newton:** Jacobian build $\mathcal{O}(n^2)$ + factorization $\mathcal{O}(n^3)$

**Newton–Krylov:** residual $\mathcal{O}(n)$ + GMRES $\mathcal{O}(k \cdot n)$ per Newton step

Decision rules:

- *Very large systems:* force matrix-free (memory-bound)
- *Small systems:* prefer dense (robust, minimal tuning)
- *Intermediate:* choose lower predicted cost based on $\rho$ and $n$

When Newton–Krylov is chosen, conservative defaults (tolerances/restarts) are used to preserve convergence without case-specific parameter tuning. However, for ill-conditioned or highly nonlinear systems, some tuning may still be necessary.

## 5. CONSTRAINED OPTIMIZATION

### 5.1 Augmented Lagrangian Method

General constrained problem: minimize f(x) subject to equality constraints h(x) = 0 and inequality constraints g(x) ≤ 0. Augmented Lagrangian formulation [11] uses penalty parameter μ > 0 and Lagrange multiplier estimates λh, λg. Algorithm alternates between solving unconstrained subproblem for x and updating multipliers. Penalty parameter μ increases if constraint violations persist, gradually enforcing feasibility.

### 5.2 Gradient Computation via JAX AD

JAX automatic differentiation provides exact derivatives with minimal computational overhead. For Williams-Otto reactor (n=2 decision variables), jax.grad returns exact 2D gradient in one forward plus one backward pass. Forward-mode AD is optimal when n_outputs > n_inputs [10]. The framework includes complex-step and finite-difference options for comparison.

BFGS quasi-Newton [10] solves unconstrained subproblems using rank-2 Hessian approximation updates with line search satisfying Wolfe conditions.

## 6. RESULTS AND VALIDATION

### 6.1 Nonlinear Solver Benchmarks

Seven Moré-Garbow-Hillstrom benchmark problems [13] spanning dimensions n=2 (Rosenbrock) to n=5000 (Brusselator 2D). Convergence tolerance $10^{-6}$, maximum 100 iterations, default parameters.

**Table 2:** Success Rates on Standard Benchmarks.

| Solver | Successful | Failed | Success Rate |
|---|---|---|---|
| Newton-Pure | 6/7 | 1/7 | 85.7% |
| Newton-LineSearch | 5/7 | 2/7 | 71.4% |
| Broyden-Pure | 6/7 | 1/7 | 85.7% |
| Newton-Krylov-Pure | 7/7 | 0/7 | 100.0% |
| Newton-Krylov-LineSearch | 6/7 | 1/7 | 85.7% |

Newton-Pure and Broyden-Pure achieved 85.7% success using fixed default parameters. Newton-Krylov-Pure achieved 100% success across all seven problems, notably solving ill-conditioned Brown Almost Linear (n=100) where all other methods failed due to near-singular Jacobians. This demonstrates the fundamental advantage of iterative linear solvers for poorly conditioned systems [6].

For Brusselator 2D (n=5000): Newton-Pure 15 iterations/19.5s versus Newton-Krylov-Pure 16 iterations/18.6s, validating theoretical O(n) scaling advantage of matrix-free methods.

Parameter sensitivity analysis: Newton-Krylov required problem-specific tuning of GMRES restart (10–40), linear tolerance (1e-4 to 1e-6), and preconditioner to achieve optimal performance. Newton-Pure converged reliably with fixed defaults, representing the fundamental trade-off between asymptotic complexity and configuration effort [6, 7].

### 6.2 Williams-Otto Reactor

#### Reaction System

The Williams-Otto reactor [14] consists of three series-parallel reactions occurring in a continuous stirred-tank reactor (CSTR) with constant holdup W = 2105 kg. Six components participate: reactants A and B, intermediate C, desired products P and E, and by-product G.

#### Reaction Scheme

$$A + B \rightarrow C, r_1 = k_1 C_A C_B$$

$$B + C \rightarrow P + E, r_2 = k_2 C_B C_C$$

$$C + P \rightarrow G, r_3 = k_3 C_C C_P$$

where Ci denotes the mass fraction of component i in the reactor (dimensionless), and ri is the reaction rate ($s^{-1}$).

## Arrhenius Kinetics

The temperature-dependent rate constants follow the Arrhenius law:

$$k_i = k_i^0 \, exp\left(-\frac{E_{a,i}}{RT_R}\right), i = 1,2,3$$

where $k_i^0$ is the pre-exponential factor, $E_{a,i}$ is the activation energy, R = 8.314 J/(mol·K) is the universal gas constant, and $T_R$ is the reactor temperature (K).

**Table 3.** Arrhenius kinetic parameters for the Williams-Otto reactor [14].

| Reaction | Stoichiometry | $k_0$ ($s^{-1}$) | $Ea/R$ (K) | $Ea$ (kJ/mol) |
|---|---|---|---|---|
| 1 | A + B → C | $5.9755 \times 10^9$ | 12000 | 99.77 |
| 2 | B + C → P + E | $2.5962 \times 10^{12}$ | 15000 | 124.71 |
| 3 | C + P → G | $9.6283 \times 10^{15}$ | 20000 | 166.28 |

## Component Mass Balances

For a CSTR with constant holdup W (kg), the dynamic mass balances for the six components are:

$$\frac{dC_A}{dt} = \frac{F_A C_{A,in} - FC_A}{W} - r_1$$

$$\frac{dC_B}{dt} = \frac{F_B C_{B,in} - FC_B}{W} - r_1 - r_2$$

$$\frac{dC_C}{dt} = -\frac{FC_C}{W} + r_1 - r_2 - r_3$$

$$\frac{dC_P}{dt} = -\frac{FC_P}{W} + r_2 - r_3$$

$$\frac{dC_E}{dt} = -\frac{FC_E}{W} + r_2$$

$$\frac{dC_G}{dt} = -\frac{FC_G}{W} + r_3$$

where F = $F_A + F_B$ is the total inlet mass flow rate (kg/s), $F_A$ = 1.8275 kg/s is the fixed feed of pure A ($C_{A,in}$ = 1), and $F_B$ is the adjustable feed of pure B ($C_{B,in}$ = 1). No C, P, E, or G enter with the feed.

## Steady-State Condition

At steady state, all time derivatives vanish. The system reduces to six nonlinear algebraic equations:

$$F(C, T_R, F_B) = 0, where\ C = (C_A, C_B, C_C, C_P, C_E, C_G)$$

Given the reactor temperature TR and feed flow FB, the steady-state concentrations C are implicitly determined by solving the nonlinear system (11) via Newton's method.

## Operating Conditions and Economic Parameters

**Table 4.** Reactor operating parameters and economic data.

| Parameter | Symbol | Value | Units |
|---|---|---|---|
| Reactor holdup | W | 2105 | Kg |
| Feed flow of A (fixed) | $F_a$ | 1.8275 | kg/s |
| Feed flow of B (adjustable) | $F_E$ | 4.0–6.0 | kg/s |
| Reactor temperature range | $T_r$ | 70–100 | °C |
| **Parameter** | **Symbol** | **Value** | **Units** |
| Base case temperature | $T_r^0$ | 85.0 | °C |
| Base case feed flow B | $F_E^0$ | 4.50 | kg/s |
| Price of product P | $p_P$ | 80 | $/kg |
| Price of product E | $p_E$ | 20 | $/kg |
| Cost of reactant A | $c_A$ | 40 | $/kg |
| Cost of reactant B | $c_Æ$ | 25 | $/kg |

## Constrained Optimization Problem

The economic optimization seeks to maximize the instantaneous profit by selecting the reactor temperature and feed flow of B. The problem is formulated as a constrained Nonlinear Programming (NLP) problem, where the decision variables are $x = (T_R, F_B)^T \in \mathbb{R}^2$

## Objective Function

The profit function Π ($/h) accounts for product revenues minus raw material costs: The complete optimization problem is defined as:

$$max_{T_R, F_B}\ \Pi = (p_P X_P + p_E X_E) F - (c_A F_A + c_B F_B)$$

subject to: $F(C, T_R, F_B) = 0$

$$T_R \le T_R^{max} = 100\ °C$$

$$F_B \le F_B^{max} = 6\ kg/s$$

$$T_R^{min} \le T_R \le T_R^{max}, F_B^{min} \le F_B \le F_B^{max}$$

## Inequality constraints (operational limits):

$$g_1(x): T_R \le 100\ °C\ (thermal\ safety\ limit)$$

$$g_2(x): F_B \le 6\ kg/s\ (pump\ capacity\ limit)$$

## Equality constraints (steady-state process model):

$$h(x): F(C, T_R, F_B) = 0\ (6\ nonlinear\ algebraic\ equations$$

## Variable bounds:

$$70\ °C \le T_R \le 100\ °C, 2\ kg/s \le F_B \le 6\ kg/s$$

where $X_P$ and $X_E$ are the mass fractions of products P and E at steady state (functions of x through the implicit steady-state solution), and F = $F_A + F_B$ is the total outlet flow.

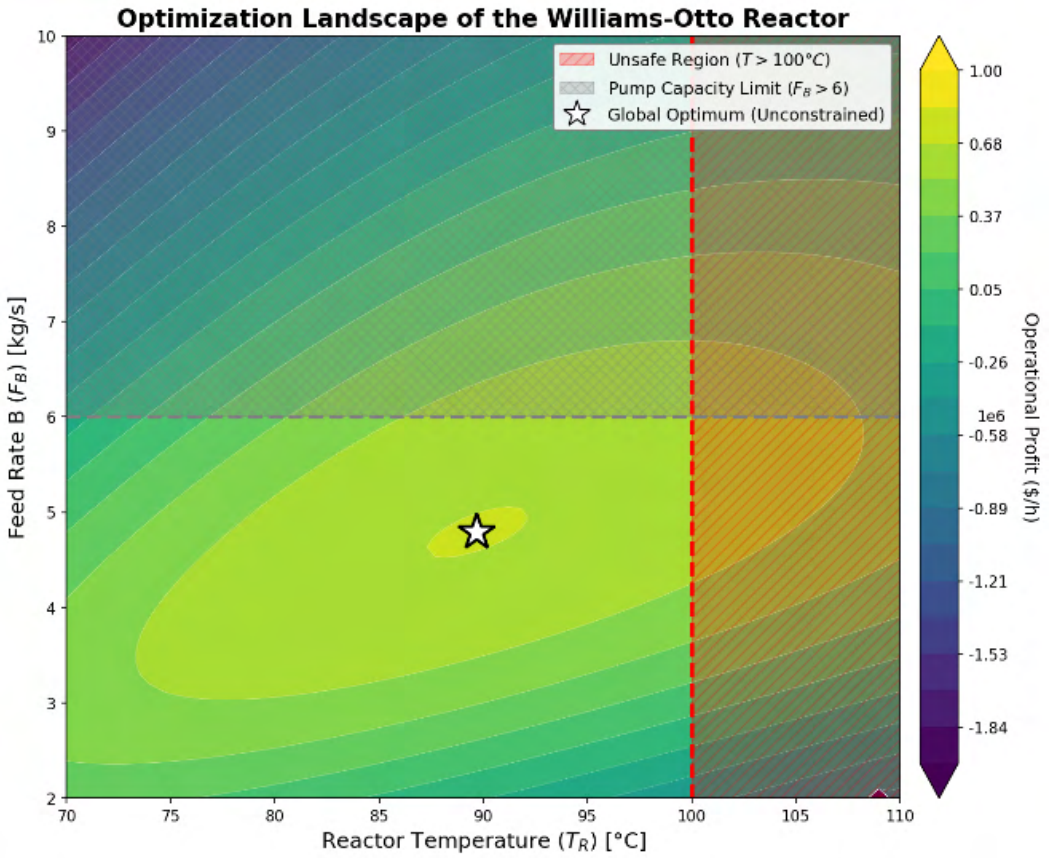

**Figure 1.** Optimization landscape over $T^R \in [70, 110]$°C and $F^B \in [2, 10]$ kg/s. Constraint regions indicated by red hatching (T>100°C) and gray hatching ($F^B$>6 kg/s). White star marks constrained global optimum.

The steady-state equations couple the decision variables to the component mass fractions, making the objective function implicitly dependent on the process model solution. The problem is solved using the Augmented Lagrangian Method with JAX automatic differentiation for exact gradient computation.

This is a two-dimensional NLP with 6 implicit equality constraints (steady-state model), 2 inequality constraints (safety and capacity), and box bounds on the decision variables. The steady-state equations couple the decision variables to the component mass fractions through the nonlinear kinetic model, making the objective function implicitly dependent on the process model solution.

The problem is solved using the Augmented Lagrangian Method with JAX automatic differentiation for exact gradient computation (see Section 5).

Steady-state calculation at base operating point converged in 5 Newton iterations to machine precision (residual $9.96 \times 10^{-16}$). Dynamic simulation over 1500s horizon using K=3 Radau IIA collocation completed in 1.132s wall-clock time, demonstrating 1325× real-time capability suitable for operator training simulators.

Constrained optimization via Augmented Lagrangian Method with JAX automatic differentiation converged in 0.894s (12 outer iterations) to global optimum: profit increased 1.9% from base case ($687, 529/h versus $674, 580/h). Both constraints remain inactive at optimum (temperature slack 10.3°C, flow slack 1.21 kg/s). Solution exhibits strong sensitivity to temperature as evidenced by tight contour spacing near optimum, justifying gradient-based optimization.

Comparison with Roberts (1979) published results [15] shows excellent agreement: temperature deviation +0.057°C (0.06%), flow deviation +0.004 kg/s (0.08%), profit deviation <0.01%. This validates all four framework modules against established literature benchmarks.

## 6.3 Propylene-Propane Splitter

High-purity separation of propylene from propane represents a major challenge in petrochemical industry due to close boiling points. At typical operating conditions (15–16 bar), these C3 hydrocarbons exhibit relative volatility α≈1.1 as computed from rigorous thermodynamics, requiring tall columns (150–200 stages) to achieve commercial purity specifications.

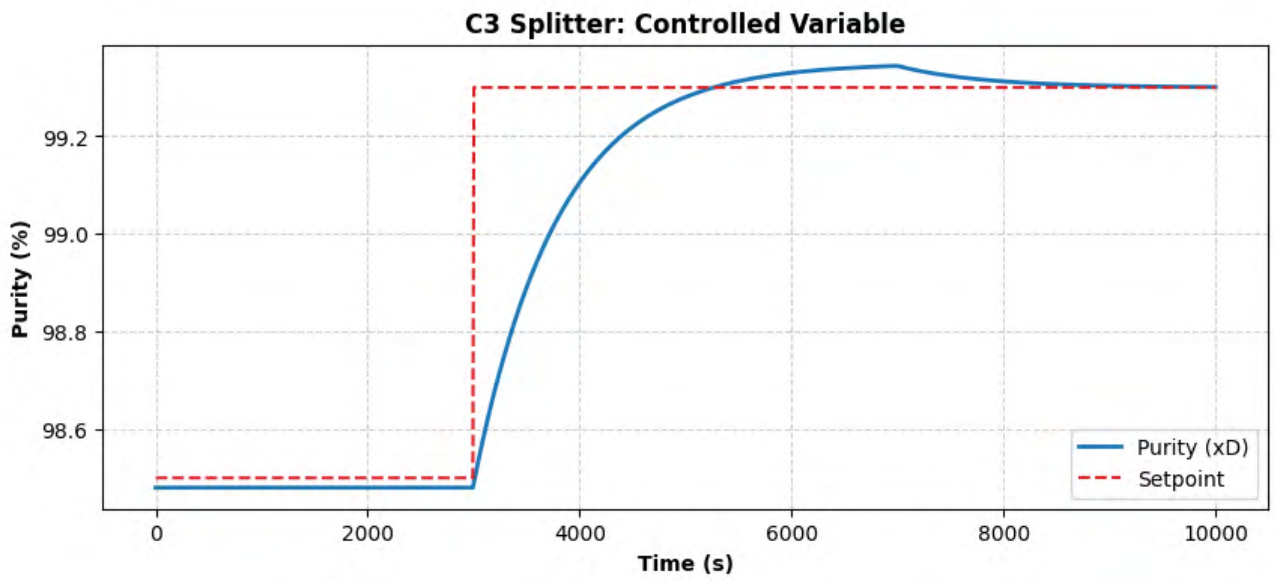

**Figure 2.** Dynamic response: propylene purity tracking

**Table 5:** Williams-Otto Comprehensive Performance.

| Parameter | Base Case | Optimum | Units |
|---|---|---|---|
| **Reactor Temperature TR** | **85.00** | **89.70** | **°C** |
| Feed Rate FB | 4.50 | 4.79 | kg/s |
| Profit Π | 674, 580 | 687, 529 | $/h |
| Profit Increase | — | +1.9 | % |
| Product P mass fraction XP | 0.1098 | 0.1095 | — |
| Product E mass fraction XE | 0.2840 | 0.2906 | — |
| Newton iterations | 5 | 8 | — |
| Residual norm | $9.96\times10^{-16}$ | $1.2\times10^{-15}$ | — |
| Optimization time | — | 0.894 | s |
| Dynamic simulation time (1500s) | 1.132 | — | s |
| Real-time speedup | 1325× | — | — |
| Temperature deviation | — | +0.057 | °C |
| Flow deviation | — | +0.004 | kg/s |
| Profit deviation | — | <0.01 | % |

**Table 6:** C3 Splitter Complete Specification and Results.

| Parameter | Value | Units |
|---|---|---|
| Number of stages | 180 | — |
| Feed stage | 90 | — |
| Top pressure (Ptop) | 15.91 | bar |
| Stage pressure drop (ΔP) | 50 | Pa |
| Feed flow rate (F) | 100 | mol/s |
| Feed temperature (Tfeed) | 315 | K |
| Propylene composition (z_C3H6) | 0.55 | mol frac |
| Binary interaction ($k_{12}$) | 0.0063 | — |
| Controller gain (Kc) | 85 | — |
| Integral time constant (τI) | 150 | s |
| t=3000s: Setpoint step | 98.5→99.3 | % |
| **Parameter** | **Value** | **Units** |
| t=3000s: Feed flow ramp | 100→120 | mol/s |
| t=6000s: Composition ramp | 0.55→0.60 | — |
| Differential states (holdups) | 360 | — |
| Algebraic states (T, compositions) | 180 | — |
| Total DAE variables | 540 | — |
| Physical time simulated | 10, 000 | s |
| Wall-clock computation time | 544.2 | s |
| Real-time speedup factor | 18.4× | — |
| Auto-selected DAE method | Dense Newton | — |

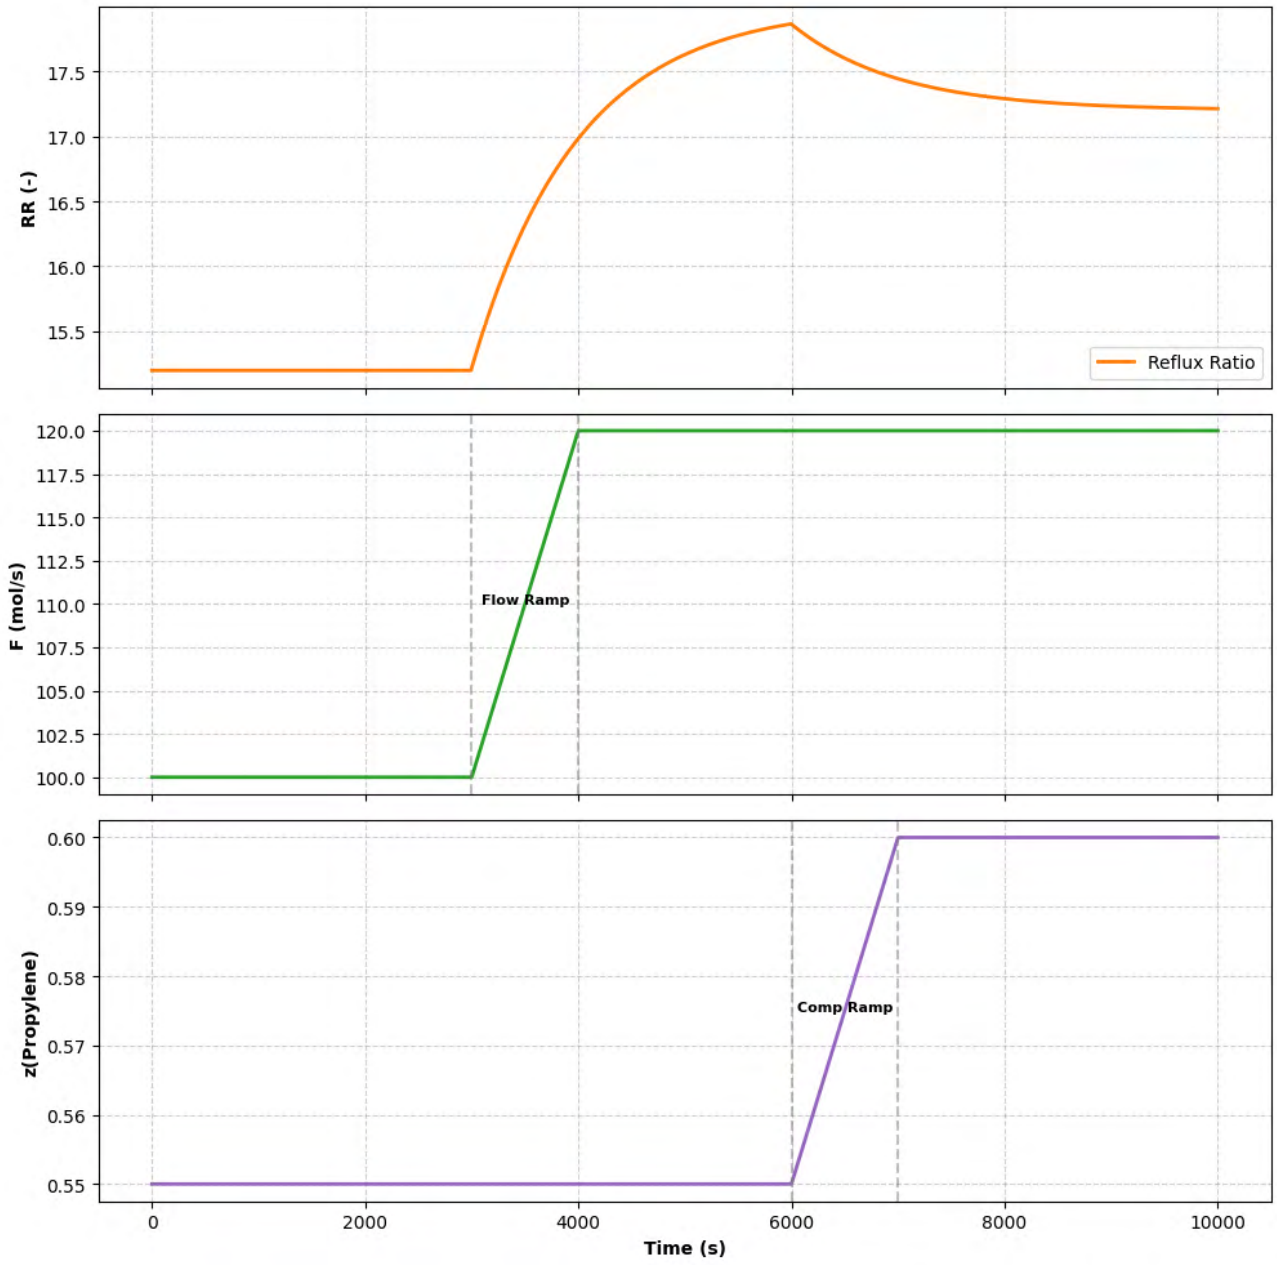

**Figure 3** Dynamic response: top plot, reflux ratio manipulation (15.3 to peak 19.2); middle plot, feed flow ramp (+20%); bottom plot, feed composition evolution. Vertical dashed lines mark disturbance events.

The framework employs stage-specific rigorous VLE calculations rather than simplified constant relative volatility correlations. Pressure profile construction: Given top pressure Ptop = 15.91 bar and stage pressure drop ΔP = 50 Pa/stage, yielding pressures from 1591 kPa (top) to 1600 kPa (bottom). Rigorous VLE via Peng-Robinson EOS at each stage with binary interaction parameter $k_{12}$=0.0063 fitted to experimental C3–C3 VLE data. This rigorous approach captures pressure-dependent thermodynamic behavior during large flow disturbances.

Three sequential disturbances stress-test the controller: (1) t=3000s: concurrent setpoint step from 98.5% to 99.3% propylene purity synchronized with severe feed flow ramp from 100 to 120 mol/s over 1000s (+20% throughput increase); (2) t=6000s: feed composition ramp from 55% to 60% propylene over 1000s (+9% relative increase).

The controller successfully tracked the 99.3% setpoint with 0.4% overshoot and ~600s rise time. During the concurrent feed flow ramp, the controller increased reflux ratio from 15.3 to 19.2 (+25%) to maintain separation, demonstrating excellent disturbance rejection with

a maximum purity deviation of only −0.1%. The delayed composition disturbance at t=6000s was smoothly compensated, with the system stabilizing by t=8000s.

The DAE solver auto-selected dense Newton method based on system size (540 collocation variables < 800 threshold), completing 10, 000s physical time in 544.2s wall-clock time (18.4× real-time capability). With 540, 000 rigorous VLE calculations using Peng-Robinson thermodynamics with complex-step differentiation, this performance demonstrates suitability for control system design, operator training simulators, and multi-scenario optimization studies.

Additional validation: A 15-stage benzene-toluene-o-xylene (BTX) ternary column was simulated to validate multi-component capabilities beyond binary mixtures. The BTX column achieved 49× real-time performance under multiple disturbances, confirming that the framework's complex-step differentiation strategy and JAX vectorization scale effectively to systems with three or more components.

## 7. CONCLUSIONS

This work presents a Python/JAX framework for hydrocarbon process simulation validated through three applications: (1) nonlinear solver benchmarks with Newton-Krylov achieving 100% success on seven standard problems (n=2 to 5000), (2) Williams-Otto reactor optimization showing 0.06% deviation from published literature with 1325× real-time dynamic simulation capability, (3) 180-stage propylene-propane splitter achieving 18× real-time performance with 540, 000 rigorous VLE calculations under three concurrent disturbances.

**Key implementations:** Peng-Robinson thermodynamics with complex-step differentiation [12], avoiding nested JAX transformation issues, Newton/Broyden/Newton-Krylov solvers with Curtis-Reid auto-scaling [5], Radau IIA DAE solver with auto-selection between dense and matrix-free methods [8, 9], Augmented Lagrangian optimization with JAX automatic differentiation [11].

**Current limitations:** Semi-rigorous distillation formulation without tray-by-tray energy equations, Peng-Robinson equation of state limited to nonpolar hydrocarbon systems, Newton-Krylov methods may require parameter tuning for optimal performance.

**Why a JAX-friendly DAE solver?** While several Python libraries exist for DAE systems (Assimulo [17], GEKKO [18], CasADi [19]), they typically lack one or more of: (1) native automatic differentiation for exact Jacobians, (2) JIT compilation for near-C++ performance, (3) vectorization primitives (vmap) for batch stage-wise calculations, or (4) transparent pure-Python implementations enabling straightforward debugging and customization.

**Future directions:** (1) Rigorous distillation models implementing MESH equations and/or the DDPA model of Matias et al (2018) [16], (2) extended thermodynamics including CPA and NRTL/UNIQUAC activity models, (3) state estimation integration (EKF, UKF, MHE) for real-time applications, (4) GPU acceleration evaluation for large-scale simulations, (5) Sparse matrix handling JAX-friendly, as an alternative for Newton-Krylov

## ABSTRACT

The use of equipment digital twins of standardized, multi-purpose units can accelerate process development and reduce experimental effort. Experimental data are essential not only for identifying critical process parameters and enabling model-based methods within a Quality by Design framework, but also for constructing and validating the simulation models that describe digital twin behavior. To achieve high-fidelity and robust predictive models, structured concepts are required to manage metadata and process-, product-, and resource-specific information exchanged between physical and digital twins. Electronic lab notebooks (ELNs), which contextualize experimental data, must therefore be structured and standardized to ensure interoperability and seamless data exchange. For integration into digital twin workflows and process transfer between equipment instances of the same category, ELNs must comply with FAIR (Findable, Accessible, Interoperable, Reusable) data principles. This work proposes a Semantic Integration Pattern for FAIR-compliant ELNs to document simulated experiments using domain-specific, vendor-independent standards such as DEXPI 2.0 and ISA 88/IEC 61512-1. DEXPI 2.0 supports standardized descriptions of equipment and process steps, while ISA 88/IEC 61512-1 structures experimental recipes. The resulting FAIR ELN Semantic Integration Pattern enables standardized data exchange between ELNs and digital twin tools. Its applicability is demonstrated through an illustrative example documenting simulated saponification experiments in gPROMS® using simple batch reactor model. The results will support subsequent real experiments conducted in a 2L stirred tank unit.

**Keywords**: digital twins, electronic lab notebooks, gProms, Simulation, Process Design

## MOTIVATION

Digital twins can be utilized to support process development, optimization, and scale-up. In modular and multi-purpose process environments, application of digital twins of the equipment enables the reuse of simulation models across different process applications and equipment instances, thereby reducing experimental effort and time-to-process. However, the predictive quality of digital twins critically depends on the availability of high-quality experimental and simulation data together with rich contextual metadata.

Electronic lab notebooks (ELNs) play a central role in capturing experimental data and associated metadata. In current practice, ELNs are often used as flexible documentation tools with limited structure, leading to heterogeneous data representations, incomplete metadata, and poor interoperability. As a result, experimental data rapidly lose their value for reuse, model validation, and transfer between projects, tools, and organizations.

To address these challenges, the FAIR data principles [1] provide a widely accepted framework for sustainable scientific data management. Applying FAIR principles to ELNs is particularly important in digital twin workflows [2], where experimental data from both the laboratory and simulation models must be exchanged between modeling tools, automation systems, and laboratory or pilot-scale equipment. This paper focuses on the documentation of experimental data from simulation models (simulated experiments), which are a key component of model-based process development and Quality by Design (QbD) methodologies.

In this paper, first the relevant background is presented and key domains specific ontology, metadata

models, and data models presents. Next, a concept for a structured Semantic Integration Pattern for FAIR-compliant ELNs for simulated experiments based on established, vendor-independent domain specific metadata guidelines are proposed. This Semantic Integration Pattern is explained for a saponification reaction in a 2L batch process using a gPROMS® Process simulation.

# METHODOLOGY

## Digital Twins in Modular Plants

Digital twins for modular plants have been discussed in terms of a single PEA [3] and for process transfer [2]. Here, the common approach is to use a Product-Process-Resource-Model to structure the digital twin [4] and leverage the knowledge distribution between the equipment vendor and the owner/operator [3] as well as for process transfer between modules [2]. A similar approach is used in the domain of discrete manufacturing with a focus on standardized description of tasks and skills of machinery, e.g. [6], [7], [8]. For modular plants, these equipment-based digital twins can be used to facilitate faster time-to-process. These equipment -based digital twins are integrated into digital twin workflows for process development which typically span multiple asset lifecycle phases, including process concept design, model development, parameter identification, optimization, and scale transfer. In modular plant concepts, digital twins are often associated with standardized equipment classes rather than single physical assets. This enables the transfer of process knowledge between different equipment instances of the same category.

Within such workflows, simulated experiments are used extensively to explore design spaces, analyze process dynamics, and support model-based design of experiments. The results of these simulations must be traceable, reproducible, and interpretable to be reused for decision-making and subsequent validation with physical experiments.

# FAIR DATA

A critical consideration for the effective utilization and reuse of experimental data is adherence to the FAIR data principles [1]. Alignment with these principles ensures that metadata is sufficiently enriched with descriptive information that captures the context in which the data were collected, including data quality, collection conditions, and other relevant characteristics. In accordance with FAIR requirements metadata must “be richly described with a plurality of accurate and relevant attributes.” Within the context of ELNs and simulated experiments, these principles imply:

- **Findable:** Experiments and datasets can be located based on product, process, resource, purpose, or author.
- **Accessible:** Data and metadata can be retrieved via well-defined access mechanisms, including access restrictions where required.
- **Interoperable:** Data and metadata use shared vocabularies, formats, and semantics to enable interpretation by humans and machines.
- **Reusable:** Data are sufficiently well-described to allow repetition of experiments and reuse in new contexts.

Applying FAIR principles requires explicit information models and controlled vocabularies rather than ad-hoc documentation.

## Electronic Lab Notebooks

The increasing shift towards digitalization in the laboratory extends beyond the use of electronic devices to encompass the networking of experimental workflows and the management of research data in accordance with the FAIR principles. Electronic laboratory notebooks (ELNs) support structured, machine- and human-readable metadata capture, enable direct integration of measurement data, and facilitate data traceability, reuse, and long-term archiving.

NFDI4Chem [9] provides guidelines for managing research data in chemistry and chemical domain specific guidelines for the following aspects: type of experiment, planning of experiments, documentation of experiments, data producing methods, data analysis, and publication.

## Simulation-Supported DoE

Model-based Design of Experiments (MBDoE) [10] integrates simulation models, typically formulated as differential–algebraic equations, with classical Design of Experiments to systematically plan informative experiments. Simulation models incorporating prior knowledge of process structure and parameter estimates are used to identify experimental variables with high sensitivity to model parameters, thereby maximizing information gain. This model-driven approach enables efficient identification of optimal process conditions while reducing experimental effort, making it particularly valuable in time- and resource-constrained process development.

## Information Models and Standards

In addition to the FAIR Data requirements [1], other ontology and data model standards exist to describe the high-level metadata.

### Dublin Core Metadata Terms

The **Dublin Core Metadata Element Set** [11] is a widely adopted standard for describing digital and physical resources to support discovery, interoperability, and long-term access. It consists of 15 core metadata

elements, such as *title, creator, subject, description, publisher,* and *date*, which are designed to be simple, generic, and domain independent. Dublin Core is formally standardized as ISO 15836. The standard supports extensibility through qualified elements and encoding schemes, allowing more precise descriptions when required by specific communities.

### ProMetaS

**ProMetaS** [12] is a comprehensive metadata schema designed to document and describe data generated in chemical process engineering and industry to support interoperability and reuse. The schema was developed within the **KEEN research project** to address the diversity and complexity of industrial and research data, improving findability and understanding. In line with FAIR principles ProMetaS builds on international metadata standards (e.g., Dublin Core) and was iteratively refined with domain experts to include only relevant metadata elements. The applicability of this schema has been demonstrated for real use cases in process data collection and management in the KEEN project.

The information model divides the data in the process industry into categories: plant info, process info, chemical, sensor, image control valve, time series, and machine learning.

### DEXPI 2.0 for Process and Equipment Descriptions

DEXPI (Data Exchange in the Process Industry) is an initiative of the process industry to create a universal data model for the information described in flow diagrams along the asset lifecycle. DEXPI Plant [13] provides a standardized, vendor-independent representation of process equipment and piping and instrumentation diagrams. DEXPI Plant can be used to describe equipment classes and topology. DEXPI Process serves to describe the block and process flow diagram type information which can be mapped to simulated data, particularly for flowsheet simulation. The DEXPI 2.0 und data model serves to provide a consistent reference between simulation models and physical assets.

### ISA-88 / IEC 61512-1 for Recipe Descriptions

In addition to the process description, it is necessary to describe the experimental procedure, or “recipe.” ISA-88 which is formally standardized in Europe with the IEC 61512 [14] specifies a hierarchical recipe model consisting of procedures, unit procedures, operations, and phases. This structure is well suited for documenting experimental workflows in both simulation and laboratory contexts. In the FAIR ELNs, ISA-88 is used to: (1) structure the experimental procedure of simulated experiments, (2) define input parameters, control actions, and execution order, and (3) support repeatability and comparison between experiments.

### PEA Harmonization for Modular Plants

Additionally, for modularization further requirements with respect to the documentation are needed. Here, it is important to be able to describe both process and equipment in a modular way. To address this challenge, the Process-to-Order Group has introduced a PEA Harmonization [17] which aligns the hierarchical modular terms from process engineering [16] and automation engineering [17] and links it to the process steps in the DEXPI Process specification [18]. This harmonization enables a direct link from the domain specific terms in modularization to domain specific process steps used in the process industry to describe process phenomena in different levels of abstraction.

## REQUIREMENTS

Based on experience from experimental and simulation studies, several challenges motivate this work. First, the same process step can be carried out in models as well as different apparatus configurations, leading to ambiguous documentation. This is an issue for both real experiments as well as simulation runs. A second issue is that equipment of the same category may exist in multiple instances with different geometries, sensors, or performance characteristics. This is important because depending on the purpose of the simulation, the same simulation models can be applied to different equipment instances, but with different parameterization. Another issue is sensors. Sensors with different accuracies and variances are often used without explicit documentation of uncertainty models, however, uncertainty models and estimates play a significant role on the predicted outcome of a simulation. Another challenge is the data itself, experimental data may originate from both online (time-series) and offline (sample-based) sources, which are rarely integrated consistently. These challenges highlight the need for structured, semantically rich ELNs.

Another issue to address is the separation of the domain specific data. Here, it is necessary to have a separation of data and metadata: Raw simulation results, derived results, and metadata must be clearly distinguished. Next, it is necessary to structure the domain specific data. As in the ProMetaS [12], it is necessary to have structured description for the different domains. For ELNs specifically, this means separate descriptions of process, product, and resources. Therefore, equipment topology, process steps, and material information must be described using standardized models.

In addition to the above listed challenges, it is further necessary to delineate between the type of simulation which is being carried out. Here, the follow categories are suggested:

- Static simulations for design space identification,

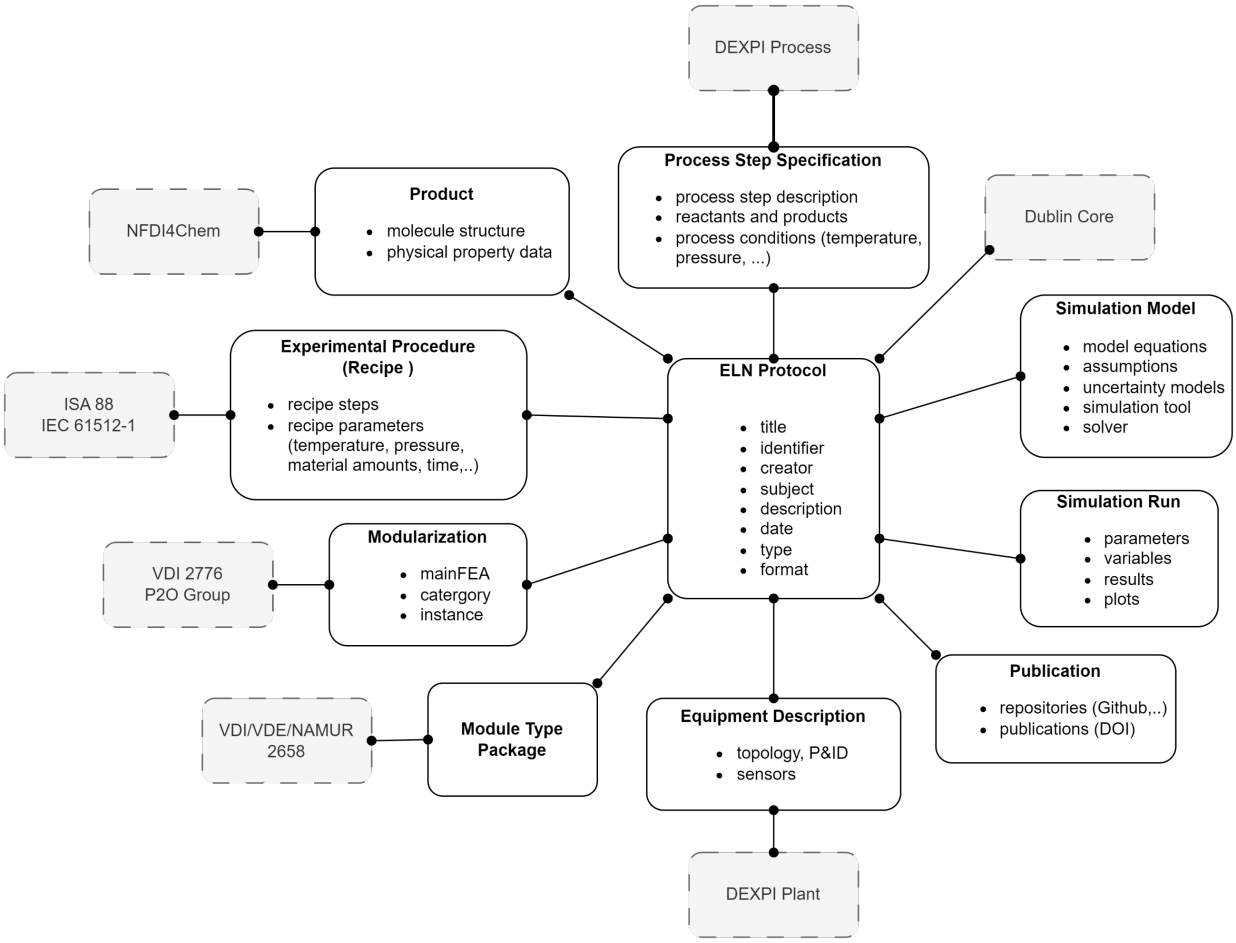

**Figure 1.** ELN Semantic Integration Pattern for documentation of simulated experiments.

parameter estimation, process design, and optimization

- Dynamic simulations for system behavior analysis, model discrimination, and control loop design
- Stochastic simulations for model-based experimental design and uncertainty analysis/reduction

## ELN SEMANTIC INTEGRATION PATTERN FOR SIMULATED EXPERIMENTS

To address the above-mentioned challenges, an ELN semantic integration pattern is proposed for documentation of simulation runs for application in digital twin workflows for modular plants. Here, the Dublin Core [11] was utilized for the ELN Protocol, ISA 88 for the experimental procedure, and ProMetas for domain specific categories. The following domains for ELNs documenting simulated experiments are identified as:

- **ELN Protocol** for the explicit identification of experiments. Each ELN entry must have a unique and persistent identifier and should include metadata according to the Dublin Core [11]. Specifically, experiment title, unique identifier, creator, subject (purpose of experiment), description, data, type of simulation, format of the simulation, and the source.
- The **Product** must include a description of the chemicals. Here, information such as molecule structure, physical property data, physical property models, etc. is included. The NFDI4Chem [9] provides domain specific guidelines depending on the chemical domain.
- The **Process Step Specification** describes the type of process step which is considered and utilized terms from the DEXPI Process specification
- The **Equipment Description** to describe the topology, P&ID and available sensors in alignment with the DEXPI Plant [13] .
- The **Experimental Procedure** must be documented

in a reproducible, machine-readable form. Definition of the experimental procedure using ISA-88/IEC 61512-1 [14] structures to include recipe steps and parameters.

- **Modularization:** Functional Equipment Assemblies (FEAs), module category, and instance as outlined in the PEA Harmonization.
- **Module Type Package:** Link to the data in the real plant along with the Human Machine Interface (HMI).
- **The Simulation Model** to document versions, solvers, and assumptions must be recorded: Documentation of assumptions, observations, and derived quantities.
- The **Simulation Runs** to document the parameters, variables, results, and plots unique to the simulation run.
- **Publication:** Storage of ELN entries in a repository enabling search, access control, and reuse.

This ELN Semantic Integration Pattern ensures that simulated experiments are documented consistently and can be FAIRly [1] integrated into digital twins for modular plants.

## ILLUSTRATIVE EXAMPLE

To demonstrate the utilization of the ELN Semantic Integration Pattern, a small illustrative example is provided. Here, a simple batch model created in gPROMS® Process was used to validate kinetics of a saponification reaction at $T = 313\,K$ according to the following equation:

$$CH_3COOC_2H_5 + NaOH \rightarrow CH_3COONa + C_2H_5OH$$

The simulation model employs three equations: Equation 1 describes the concentration profile of each reaction component $i$ over time with the assumption of constant volume $V$, Equation 2 describes the Arrhenius rate constant kinetics, and Equation 3 describes the reaction rate.

$$\frac{\mathrm{dCi}}{\mathrm{dt}} = -\mathrm{r} * \mathrm{V} \tag{1}$$

$$k = k_{i,\infty} \exp\left(\frac{-E_{A,i}}{R\,T}\right) \tag{2}$$

$$r = kC(1)C(2) \tag{3}$$

Next, for the simulation run values are assumed for the parameters of the Arrhenius rate expressions:

$$k_\infty = 3.5e^7 \frac{L}{mol\ s}$$

$$E_A = 48000\ \frac{J}{mol}$$

Additionally, it assumed that an equimolar ratio of the reactants, 1 = ethyl acetate ($CH_3COOC_2H_5$) and 2 = sodium hydroxide ($NaOH$) is present in the reactor at the start of the reaction time. The results and plots from the simulation run are stored in a gPROCESS Case File.

Figure 2 shows a delimited ELN Protocol in XML utilizing the ELN Semantic Integration Pattern. The ELN Protocol highlights the following domains from the ELN Semantic Integration Pattern from Figure 1: ELN Protocol, Modularization, Simulation Model, and Simulation Run. Here, an example of the general meta data in accordance with the Dublin Core [11] is provided in the ELN Protocol section. The **Modulization** description of M22 which is an instance of a 2L Glass Stirred Tank Unit whose main Functional Equipment Assembly is a reactor. Next, the **Simulation Model** is described according to equations (1) to (3), the modelling assumption of constant volume, along with a list of parameters and units, as well is the solver and any uncertainty assumptions. Lastly, for the **Simulation Run** domain estimates of the Arrhenius parameters is provided as well as the initial amount of moles of the reaction constitutes in the vessel at the start of the reaction. The name of the Case File where the simulation results are stored is also provided in the XML code.

## CONCLUSION AND OUTLOOK

The proposed FAIR ELN Semantic Integration Pattern addresses key challenges in documenting simulated experiments for digital twin workflows in modular plants. By combining domain-specific standards with general metadata vocabularies, both semantic richness and broad interoperability are achieved. The integration of DEXPI Plant [13], DEXPI Process [18], ISA-88/IEC 61512-1 [14], and Dublin Core [11] provides a structured, vendor-independent approach to experimental documentation which can be extended to modularization and simulation. However, it should be noted that this work focuses on the concept, thus the illustrative example in Figure 2 is underspecified. This example is not intended to be exhaustive in scope; rather, it aims to describe the ELN documentation method for a simulation run, not the subsequent utilization of the simulated results within the digital twin.

Remaining challenges comprise the effort required for initial model alignment, the establishment of controlled semantic vocabularies, and the development of integration tools. However, the long-term benefits in terms of data reuse, reproducibility, and model fidelity outweigh these initial limitations. Future work will therefore focus on the implementation of tool-supported approaches, the automation of metadata capture, and the extension of the framework to facilitate digital twin–supported information exchange based on documented simulation runs.

## ABSTRACT

Artificial neural networks (ANNs) have emerged as powerful surrogate models in process design and optimisation, capable of capturing complex nonlinear process behaviour while significantly reducing computational cost compared to detailed first-principles simulations. However, ANN prediction errors in safety-critical applications can lead to suboptimal or vulnerable designs, necessitating rigorous treatment of approximation uncertainties. While probabilistic approaches exist for surrogate-based decision making, risk-averse contexts that require formal robustness guarantees face a fundamental challenge: the nonconvex nature of ANN-embedded models hinders the employment of standard robust optimisation methods. To this end, in this work we explore the global robust optimisation of process design problems with embedded ANNs. A robust spatial branch-and-bound (RsBB) algorithm to achieve global optimality is proposed while enforcing constraint satisfaction across all uncertainty realisations. This approach integrates spatial branch-and-bound with adversarial cuts generation, concurrently searching for the global optimum while ensuring robust feasibility despite ANN prediction uncertainties. We test the proposed algorithm on the ANN-embedded optimisation of a cumene manufacturing process, across a range of conservatism levels. The algorithm computes solutions within the prescribed optimality tolerance while quantifying the robustness-performance trade-off.

## INTRODUCTION

Recent developments in Process Systems Engineering (PSE) have accelerated the use of optimisation to support decision-making in process design and operations. However, many process design problems remain computationally challenging [1]. High-fidelity, first-principles models can be expensive to evaluate and strongly nonlinear, which makes repeated model evaluations during optimisation impractical. This has motivated approaches that retain sufficient model fidelity while achieving more tractable optimisation problems [2, 3]. In this context, data-driven surrogate models, particularly machine-learning (ML) models such as artificial neural networks (ANNs), have become attractive because they can approximate complex input-output relationships learned from simulation or plant data while enabling fast, differentiable evaluations suitable for embedding in optimisation problems [4, 5].

Despite these advantages, surrogate-based optimisation introduces a critical challenge, as uncertainty is intrinsic to data-driven models. In practice, ANN surrogates carry inherent uncertainty due to prediction error, limited or biased training data and variability in training procedures and model architecture choices [2]. Consequently, designs that appear optimal under nominal surrogate predictions may perform poorly, or even violate constraints, when evaluated on the real system, especially near tight feasibility boundaries or when extrapolating beyond the training region. Robust optimisation provides a way to address this by explicitly accounting for uncertainty during optimisation, aiming to identify designs that remain feasible and perform well across a prescribed uncertainty set [6, 7]. This is particularly relevant

in process engineering settings where hard feasibility constraints must be satisfied, and probabilistic characterisation of uncertainty may not be available [6-8].

At the same time, embedding ANNs into process optimisation models can significantly increase nonlinearity and introduce nonconvexities due to the nature of their activation functions. This often yields large-scale nonconvex problems, motivating the use of global optimisation methods [1]. Spatial Branch-and-Bound (sBB) is a standard methodology for deterministic global optimisation of nonconvex problems that relies on partitioning the variable domain, solving convex relaxations to obtain lower bounds, and pruning regions that cannot contain a globally optimal solution, but its performance depends strongly on the tightness of the relaxations and variable bounds [9, 10]. For ANN-embedded formulations, relaxations based on conventional McCormick envelopes can be weak, particularly for convexo-concave activation functions such as sigmoid and hyperbolic tangent, leading to poor relaxations, excessive branching and poor algorithmic scalability [11-13]. This has motivated the development of more tight envelopes for activation functions to reduce the size of the search tree in ANN-embedded global optimisation. Recent research efforts in this direction include the software packages MeLOn[12] and the recent extensions to EAGO.jl [11].

Robust optimisation of nonconvex problems adds another layer of difficulty, since standard tractable robust reformulations rely on convexity and duality assumptions that often do not hold in surrogate-embedded optimisation formulations [6]. Cutting-set methods provide an iterative alternative by alternating between optimisation and worst-case "pessimisation" checks [14], but can become expensive when the underlying nonconvex problem is already challenging. In [15], Wolfe duality and robust chance constraints were proposed to tackle uncertainty in problems with warped Gaussian Processes. Recently, Marousi and Charitopoulos proposed a Robust spatial Branch-and-Bound (RsBB) algorithm that combines robust infeasibility checks at each node of the branch-and-bound tree with robust cuts inside the global search for solving nonconvex QCQPs [7].

Nonetheless, a key gap remains: a robust global optimisation framework for surrogate-based process design problems in which (i) an ANN surrogate is embedded within an algebraic optimisation model, (ii) uncertainty in the surrogate predictions is explicitly accounted for, and (iii) tight relaxations tailored to ANN activation functions are used to solve the resulting nonconvex problem. This work addresses that gap using a cumene process design case study [12, 13]. High-fidelity data is generated from Aspen Plus and used to train an ANN surrogate, which is then embedded in an optimisation model to couple the surrogate consistently with process constraints and decision variables. The resulting nonconvex optimisation problems are solved using an RsBB framework that incorporates tailored activation function envelopes [11] and Optimisation-Based Bound-Tightening (OBBT), and robustness is enforced under prescribed uncertainty sets on the ANN outputs. Preliminary computational results compare deterministic and robust variants and quantify the trade-off between conservativeness of the solution and objective performance.

## METHODOLOGY

### Robust spatial Branch-and-Bound Algorithm

Our approach builds on the RsBB algorithm of Marousi and Charitopoulos, which integrates a spatial branch-and-bound (sBB) global optimisation with a robust cutting-set method to enforce feasibility under uncertainty. A schematic overview of the resulting workflow is provided in Figure 1. In robust optimisation, feasibility is required for all uncertainty realisations in a prescribed set $\mathcal{U}$, resulting in a semi-infinite program of the form

$$\min_{x \in X} f(x)$$

$$\text{s.t. } g(x,u) \leq 0 \; \forall u \in \mathcal{U}$$

The aim of RsBB is to avoid spending large effort optimising solutions that later turn out to be robust-infeasible, by performing robustness checks during the tree search [5]. At each node $n$ of the tree, RsBB maintains two optimisation models defined on the node's variable bounds: (i) a nonconvex "sampled" problem that provides an upper bound and (ii) a convex relaxation that provides a lower bound used for fathoming. Robustness is enforced using a cutting-set method where, instead of requiring $g(x,u) \leq 0$ for all $u \in \mathcal{U}$ directly, the algorithm maintains a finite sampled set $\hat{\mathcal{U}} = \{u^0, \ldots, u^K\} \subseteq U$ and solves the sampled problem with constraints enforced only for $u \in \hat{\mathcal{U}}$. The robustness of any candidate solution $x^*$ is then evaluated by an infeasibility test that searches for the worst-case uncertainty realisation $u^* \in \mathcal{U}$ that maximises constraint violation, and if a violation is found, $u^*$ is appended to $\hat{\mathcal{U}}$ and the node is re-solved. This is repeated until no further violations are detected, at which point the node solution is certified robust-feasible with respect to $\mathcal{U}$ [7].

The global-search component of the algorithm follows standard sBB logic [16]. Nodes are selected using a best-first strategy based on the lower bound provided by the relaxation, prioritising the most promising subdomains in the waiting set. At a selected node, the branching variable is selected as the pre-activation variable with the largest relaxation gap score, measured as the deviation between the post-activation variable and the activation function evaluated at the relaxed pre-activation variable value. If all candidate gaps fall below a small tolerance, the algorithm reverts to branching on the variable

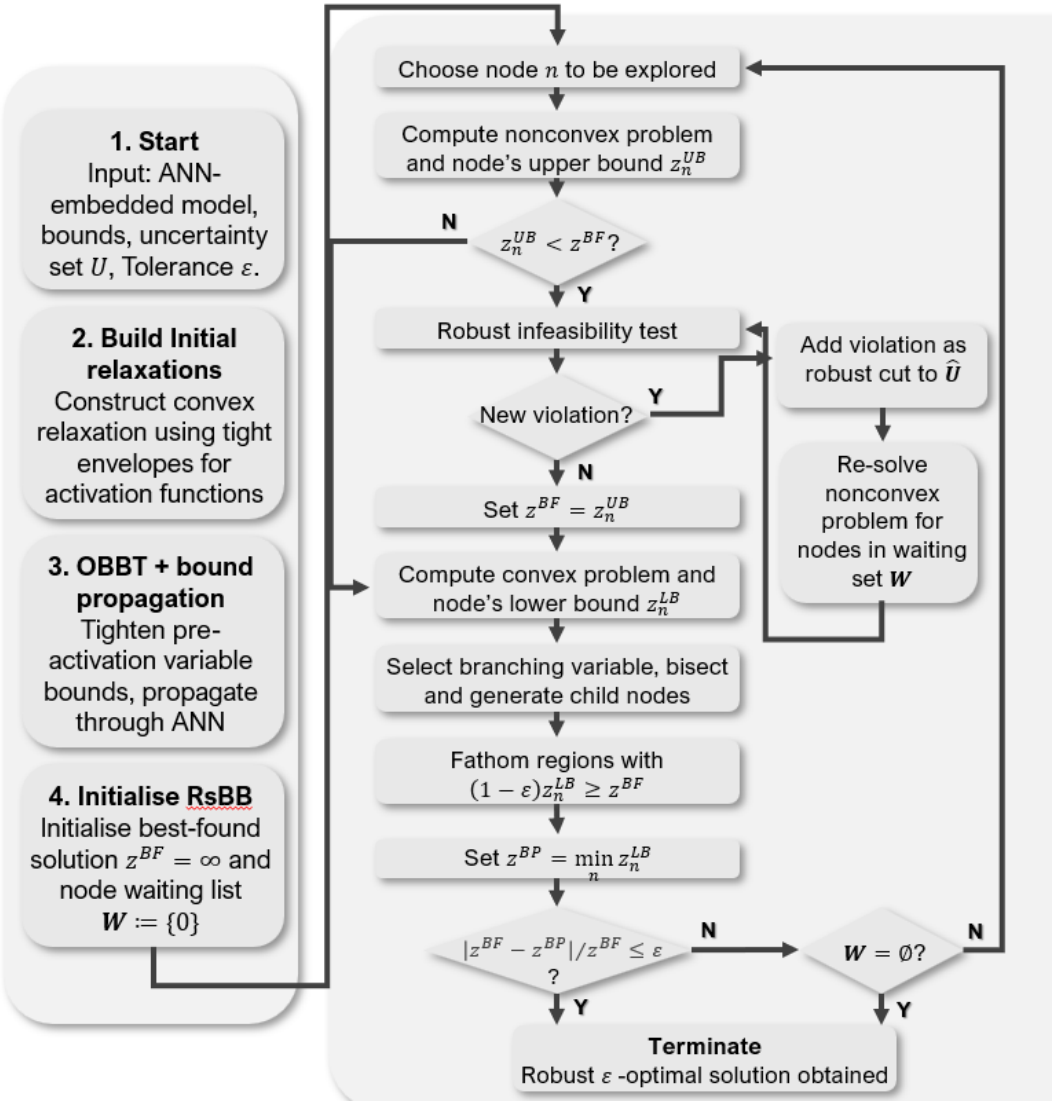

**Figure 1.** Algorithmic flowchart of RsBB with ANNs-embedded.

with the largest bound interval width. Once the branching variable is selected, bisection branching is applied. Nodes are fathomed whenever their relaxation bound cannot improve upon the incumbent objective within the predefined tolerance.

## Relaxation Envelopes

To obtain the convex relaxations required for the RsBB algorithm, the ANN activation functions $z = f(x)$ are relaxed using tight envelopes for convexo-concave activation functions such as hyperbolic tangent and sigmoid. For a pre-activation variable $x \in [x^L, x^U]$ and post-activation variable $z$, we define the secant on $[a, b]$ and the tangent at $c \in [a, b]$ as:

$$sct_{[a,b]}(x) = f(a) + \frac{f(b) - f(a)}{b - a}(x - a)$$

$$tan_c(x) = f(c) + f'(c)(x - c)$$

The activation function is then relaxed via $z \geq f^{cv}(x)$ and $z \leq f^{cc}(x)$, where $f^{cv}$ and $f^{cc}$ are the convex under-estimator and concave over-estimator, respectively, given by the following expressions [9]:

$$f^{cv}(x) = \begin{cases} f(x), x^U \leq 0 \\ sct_{[x^L, x^U]}(x), x^L \geq 0 \\ \max\{tan_{x^L}(x), tan_{\xi^L}(x), sct_{[x^{cv}, x^U]}(x)\}, x^L < 0 < x^U \end{cases}$$

$$f^{cc}(x) = \begin{cases} sct_{[x^L, x^U]}(x), x^U \leq 0 \\ f(x), x^L \geq 0 \\ \min\{tan_{x^U}(x), tan_{\xi^U}(x), sct_{[x^L, x^{cc}]}(x)\}, x^L < 0 < x^U \end{cases}$$

The tie points $x^{cv}$ and $x^{cc}$ are defined as the points where the tangent to $f(x)$ matches the secant connecting the tie point to $x^U$ and $x^L$, respectively [11]:

$$f'(x^{cv}) = \frac{f(x^U) - f(x^{cv})}{x^U - x^{cv}};\ f'(x^{cc}) = \frac{f(x^{cc}) - f(x^L)}{x^{cc} - x^L}$$

Additionally, the points $\xi^U$ and $\xi^L$ are defined as:

$$\xi^U = \frac{x^U + x^{cc}}{2};\ \ \xi^L = \frac{x^L + x^{cv}}{2}$$

Compared to McCormick relaxations, the envelopes presented here are significantly tighter for convexo-concave functions, avoiding the dependency problem whereby repeated occurrences of the same variable are relaxed independently, leading to overestimation and loose bounds [9].

### Optimisation-Based Bound Tightening

Since the tightness of the envelopes depends strongly on the bounds $[x^L, x^U]$, we apply Optimisation-Based Bound Tightening (OBBT) for domain reduction and to improve relaxations. In our implementation, OBBT is performed as a preprocessing step by solving a pair of auxiliary optimisation problems for each pre-activation and input variable: one problem minimises the variable and one maximises it, subject to all constraints of the current relaxed model. The resulting optimal values provide tighter feasible bounds, which are accepted only if they improve the current bounds and do not invert the interval.

Because this procedure is computationally expensive, we run it iteratively with a pre-specified budget and reduction improvement tolerance. After each OBBT iteration, we perform bound propagation through the ANN to improve the tightening without additional optimisation problems: bounds are propagated through affine layer relations using interval arithmetic and through the activation functions. Then, the updated bounds are passed on to the relaxation envelopes so that they are updated consistently with the new bounds.

## CASE STUDY

### Process and Decision Problem Description

We test the proposed algorithm on the optimisation of the cumene process, which synthesises cumene via Friedl-Crafts alkylation of benzene with propene over a solid catalyst [17]. The process exhibits a classic trade-off between reactor design and separation efficiency, where lower reactor temperatures improve selectivity to cumene but require a larger vessel and higher recycle rates, while higher temperatures permit smaller reactors but produce more side products. The flowsheet comprises of three main sections: preheating of fresh and recycled feeds, a cooled packed-bed reactor, and a distillation train that separates light inerts, recovers unreacted benzene for recycle and delivers the final cumene product [17, 18]. This work develops a neural network surrogate model to predict cumene product purity and flow rate, which are the two primary output variables controlling revenue, as functions of seven input variables. The input variables comprise of the propylene and benzene feed flow rates ($F_{C3}$ and $F_{BZ}$), the reactor inlet temperature ($T_R$), the reboiler duty of the two distillation columns ($Q_{C1}$ and $Q_{C2}$) along with their associated reflux ratios ($RR_{C1}$ and $RR_{C2}$) [17]. The process economics are driven by maximising profit, which is simplified as the revenue generated from cumene sales minus the cost of feeds. The surrogate ANN model enables the evaluation of alternative operating strategies to balance the competing objectives such as purity vs feed efficiency vs throughput, along with constraints imposed on the minimum product purity and flow rate. The combination of nonlinearity and multiple active constraints makes the cumene process an appropriate case study for surrogate-based optimisation.

### Optimisation Problem Formulation

We seek the design and operating decisions that maximise profit while guaranteeing feasibility for all realisations of bounded uncertainty on the ANN outputs (product purity and flow rate). The robust problem is formulated as:

$$\min_{\boldsymbol{x}\in\mathcal{X},\boldsymbol{y}\in\mathcal{Y}} -\Pi(\boldsymbol{x},\boldsymbol{y})$$

$$s.t.\ \boldsymbol{y} = f^{ANN}(\boldsymbol{x},\boldsymbol{u})$$

$$\boldsymbol{\mu}(\boldsymbol{x},\boldsymbol{y},\boldsymbol{w}) \le 0$$

$$y_P^{(u)} \ge 0.99\ \ \forall u_P \in \mathcal{U}_P = [-\Delta P, \Delta P]$$

$$y_F^{(u)} \ge 70\ \ \forall u_F \in \mathcal{U}_F = [-\Delta F, \Delta F]$$

$$\boldsymbol{x} \in \mathcal{X}, \boldsymbol{y} \in \mathcal{Y}, \boldsymbol{u} \in \mathcal{U}$$

where $\Pi(\boldsymbol{x},\boldsymbol{y})$ is the profit (thousand £/year), $\boldsymbol{y} = [y_P, y_F]$ are the ANN outputs, $\boldsymbol{x} \in \mathcal{X}$ are the process decision variables, $f^{ANN}(\cdot)$ represents the trained ANN, $\boldsymbol{\mu}(\boldsymbol{x},\boldsymbol{y},\boldsymbol{w}) \le 0$ denotes the activation function envelope constraints (with auxiliary variables $\boldsymbol{w}$), $y_P^{(u)}$ and $y_F^{(u)}$ denote the uncertain purity and flow rate outputs associated with uncertainty realisation $\boldsymbol{u} \in \mathcal{U}$, and $\mathcal{U} = \mathcal{U}_P \times \mathcal{U}_F$ is the box uncertainty on $(\Delta P, \Delta F)$.

### Data Generation and ANN Training Workflow

Data were generated using Aspen Plus V14, using the flowsheet proposed by Luyben [17] and Schultz [18]. Python 3.10.19 was then used to automate the Aspen Plus simulations by utilising Aspen's COM interface to programmatically set inputs, run simulations and extract results, which were stored in a CSV file. Within the Python code used for sampling, the Aspen Plus stream variable bounds were set along with a fixed number of input samples using Sobol sampling. A varying number of samples were used for ANN validation, ranging from 1, 000 to 10,

000 samples. The sampled data were then cleaned to ensure only physically viable results were used in the ANN training, e.g. non-convergent runs and infeasible solutions (e.g., negative flow rates, unbounded temperatures) were excluded, retaining 99.95% of generated samples.

ANN training was completed using PyTorch. After training the ANN in PyTorch, a set of weights and biases for each neuron were generated. Within PyTorch, the data were split into training and testing sets using an 80/20 training-testing split and min-max scaling was selected. The ANN architecture consisted of 7 input nodes (representing feed composition and operating parameters), five hidden layers (16→32→32→32→16 neurons) with tanh activation functions, and 2 output nodes (representing product purity and flow rate) with linear activation. This architecture was selected to balance the nonlinear complexity of the Aspen flowsheet while minimising the computational burden for the RsBB optimisation algorithm. Batch normalisation was applied after each linear layer (16, 32, 32, 32, 16 nodes) to stabilise training and accelerate convergence. Dropout with a rate of 30% was applied after the activation functions to reduce overfitting. This ordering ensures that batch normalisation statistics are not corrupted by dropout-induced sparsity

The trained ANN was then exported to ONNX for it to be in a format compatible with the Optimization and Machine Learning Toolkit (OMLT). OMLT v1.2.2 was used to embed the trained ANN into Pyomo [19]. The ANN constraints were built using FullSpaceSmoothNNFormulation for tanh activations and the final ANN block was then stored in order to be inserted into the RsBB algorithm.

### Validation and Errors

The trained ANN model was evaluated on 10, 000 process samples to predict the output product purity and flow rate. The model demonstrated strong predictive performance with an overall $R^2$ of 0.772, with an $R^2$ of 0.739 for purity and 0.804 for flow rate. Error analysis reveals that purity predictions were exceptionally consistent with a mean signed error of 0.000378 and a standard deviation ±0.0186, indicating a minimal systematic bias and tight clustering around the true values. The model exhibits a slight bias towards underestimation, as 48.31% of purity predictions fall within the -0.05 to 0 unit range, while overestimations only account for 1.29% of predictions. Only 0.31% of purity predictions are classified as outliers (>3 standard deviations) and these outliers are all negative, suggesting the model rarely produces overestimations.

Flow rate predictions demonstrate broader variability, with a mean signed error of -0.000593 and a standard deviation of ±4.575. The flow rate error distribution spans from -56.63 to +39.72, with approximately 52% of predictions concentrated within ±3 unit range. An outlier rate of 0.89% was observed and the extremes were distributed relatively symmetrically between overestimations and underestimations, indicating no directional bias.

## RESULTS

All computations were performed on a workstation with an Intel Core i9-13900K (13th Gen) CPU (24 cores, 32 logical processors, 3.00 GHz base clock) and 128 GB RAM.

### Deterministic Optimisation

The deterministic optimisation problem (i.e., without uncertainty on ANN outputs) was solved globally using the proposed RsBB framework with the tailored relaxations for activation functions and a preprocessing OBBT step. At the root node, the baseline relaxation gap was 3.47%, with a best-found objective of -16, 299.70 and a lower bound of -16, 865.76. Applying OBBT reduces the gap to 2.02% after seven OBBT iterations.

The globally optimal nominal solution returned by RsBB corresponds to a profit of 16, 299.70 thousand £/year. The optimal decision vector is: $F_{C3} = 105.00\ kmol\ h^{-1}, F_{BZ} = 95.00\ kmol\ h^{-1}, T_R = 360.00\ °C, Q_{C1} = 1.3100\ Gcal\ h^{-1}, Q_{C2} = 1.5758\ Gcal\ h^{-1}, RR_{C1} = 0.9999,$ and $RR_{C2} = 1.1998$. At this optimum, the ANN predicts a product purity of 0.9900 mol/mol and a flow rate of 86.90 kmol/h. The total solution time was 299.75 s, of which 204.66 s were spent in OBBT and 95.09 s in the RsBB tree search, exploring a total of 202 nodes.

For benchmarking, the same deterministic model was solved with BARON (v24.10.10 using GAMS 48.1.0) under a 5, 400 s time limit. BARON recovered an identical best-found solution with the same decision variables; however, terminating with a reported gap of 8.356%. A summary comparison of RsBB and BARON [20] on the deterministic problem is provided in Table 1.

### Robust Optimisation Under Box Uncertainty

Robust optimisation was performed by enforcing feasibility for all uncertainty realisations within a box uncertainty set defined on the ANN outputs: product purity uncertainty with radius $\Delta P$ (mol/mol) and product flow rate uncertainty with radius $\Delta F$ (kmol/h). Results are reported for several uncertainty levels, from the deterministic case up to $(\Delta P, \Delta F) = (0.004, 10)$. A detailed solver comparison with RsBB vs BARON for the nominal case, plus a representative robust run at $(\Delta P, \Delta F) = (0.002, 5)$, is given in Table 1, while Figure 2 summarises the profit-conservativeness trade-off across all uncertainty levels tested.

For the representative robust case $(\Delta P, \Delta F) = (0.002, 5)$, RsBB returns a globally robust solution with a profit of 15, 850 $10^3$£/year, a 2.75% reduction with respect to the deterministic case. Robust feasibility is

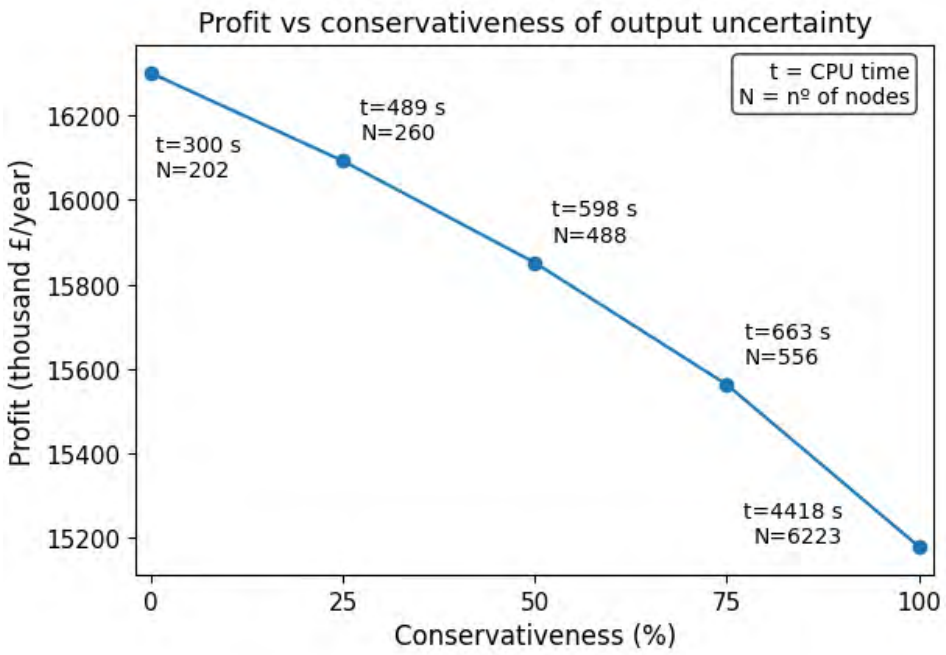

**Figure 2.** Profit-conservativeness trade-off under box uncertainty on ANN outputs. Conservativeness is scaled relative to the maximum uncertainty and annotations report CPU time and number of nodes explored.

enforced through the cutting-set mechanism embedded within the sBB search. In this representative case, a single robust cut was generated (at node 5) to enforce the purity requirement at the worst-case realisation, after which the solution was certified robust-feasible. Relative to the nominal optimum, the robust solution changes through the reflux ratio of the first column and the reboiler duty of the second column: $RR_{C1}$ decreases from 0.9999 to 0.6107 and $Q_{C2}$ decreases from 1.5758 to 1.5373, while other inputs remain unchanged. The robust optimum corresponds to ANN outputs of product purity 0.9920 mol/mol and flow rate 86.00 kmol/h, reflecting the need to maintain feasibility under the prescribed box uncertainty.

Increasing the conservativeness of the uncertainty set imposes a clear penalty in the objective value. As shown in Figure 2, profit decreases monotonically as the uncertainty scale increases from 0% (nominal) to 100% $\big((\Delta P, \Delta F) = (0.004, 10)\big)$, quantifying the robustness-performance trade-off as shown in Figure 2. These results highlight both (i) the practical cost of robustness in terms of objective value and solve time, and (ii) the ability of the proposed RsBB framework with tailored envelopes and preprocessing OBBT to provide globally optimal and robust solutions for ANN-embedded process optimisation problems.

## CONCLUSIONS

This work presented a robust global optimisation framework for ANN-embedded process optimisation under uncertainty by integrating RsBB with tight envelope relaxations for convexo-concave activation functions and a preprocessing OBBT step. Using a cumene process case study, an ANN surrogate trained on Aspen Plus simulation data was embedded into an algebraic optimisation model, and robustness was enforced via a cutting-set strategy under box uncertainty on ANN outputs (product purity and flow rate).

For the nominal (deterministic) case, RsBB obtained a globally optimal solution after exploring 202 nodes in 299.75 s total CPU time. In contrast, BARON recovered an identical best found solution but did not close the optimality gap within the 5, 400 s time limit, and therefore did not provide a global optimality certificate for this ANN-embedded problem. These results highlight the value of tailored activation function relaxations, which improve envelope tightness and allow for effective pruning in the RsBB algorithm for ANN-embedded global optimisation.

Robust optimisation introduced the expected performance-conservativeness trade-off. For the representative uncertainty level $(\Delta P, \Delta F) = (0.002, 5)$, the robust

objective worsened by 2.75% relative to the nominal optimum, reflecting the cost of enforcing feasibility across the uncertainty set. As conservativeness increased, the objective worsened monotonically, reaching a 6.87% degradation at the maximum uncertainty considered $(0.004, 10)$. This higher conservativeness also increased computational effort considerably, as stricter robust feasibility requirements and associated robust cuts increased the search required to meet the same optimality tolerance. Overall, the proposed RsBB approach provides a practical framework to obtaining certified globally optimal robust solutions for surrogate-based process optimisation under bounded uncertainty.

## ABSTRACT

Real-time monitoring of metabolite concentrations is critical for optimising bioprocess performance. While Raman spectroscopy offers a non-invasive solution, translating spectra into metabolite concentration estimates requires robust machine learning models. Foundation models such as TabPFN demonstrate exceptional predictive performance but suffer from high inference complexity when trained on large calibration datasets, hindering their use in real-time laboratory settings. This study proposes a batch Active Learning (AL) strategy to efficiently calibrate TabPFN using a minimal subset of data. We employ a weighted K-means clustering strategy that balances model uncertainty and dataset diversity to select the most informative calibration samples. We evaluated this method on a dataset of nearly 7, 000 Raman spectra covering eight substances. Our AL strategy achieved a mean $R^2$ score greater than 0.95 with approximately 1, 000 samples, significantly outperforming random sampling. Notably, the method matched the accuracy of a model trained on the full dataset using only 20% of the data. This reduction lowers computational complexity by a factor of 25, enabling millisecond-scale inference times suitable for high-throughput bioprocess monitoring.

## INTRODUCTION

In bioprocess engineering, the ability to monitor metabolite concentrations in real time during microbial or cell cultivations is critical for understanding, controlling, and optimising biotechnological processes with respect to yield and product quality. Traditionally, metabolite analysis is based on offline sampling and subsequent analytical techniques such as High-performance liquid chromatography or Gas chromatography–mass spectrometry, which are time-consuming, labour-intensive, and often unsuitable for high-throughput experimentation.

As an alternative, Raman spectroscopy has emerged as a promising Process Analytical Technology (PAT) for non-invasive monitoring of metabolite concentrations as it is fast, label-free, and capable of simultaneously quantifying multiple compounds in complex mixtures. Recent advancements enable the integration of Raman spectrometers into high-throughput systems, significantly enhancing the volume and quality of data generated during parallel cultivations [1], [2].

However, a major challenge remains the translation of raw Raman spectra into metabolite concentration estimates. This requires a machine learning model that maps Raman spectra to estimations of concentration values. Traditionally, this has been achieved using multivariate statistical methods such as Partial Least Squares (PLS) [2] or Deep Neural Networks [4].

However, training deep learning models typically requires large, diverse calibration datasets, which are costly and time-consuming to generate. A recent study

showed that a tabular foundation model TabPFN [5] delivers exceptional prediction performance when provided with a large calibration dataset [6]. This model is different from classic regression models as it uses in-context learning. When predicting concentrations for an unknown Raman spectrum, the model computes similarities between all calibration data points and the unknown spectrum using a Transformer architecture [7]. Unfortunately, the computational complexity of this step increases quadratically with the number of calibration points. This results in slow prediction speeds, particularly in laboratory contexts where modern GPUs are often unavailable. On a CPU, the average inference time per spectrum is approximately 10 seconds [6].

To address this limitation we reduce the size of the calibration dataset using Active Learning (AL) algorithms which select the most informative data points from the calibration set [8]. While many AL algorithms suggest one sample at a time this procedure is not efficient when each step requires retraining a whole neural network. A naive approach is to select the most informative data points based solely on a specific metric. However, this approach might lead to a batch of similar data points such that the model would be better off with labelling more diverse data points that yield better a generalisation error. This diversity-informativeness trade-off is addressed by methods that optimise the informativeness of the whole batch of data points [9], [10], [11].

# MATERIAL AND METHODS

## Dataset

In this study we use a dataset of nearly 7000 Raman spectra with annotations for 8 substances [6] that are relevant in high-throughput bioprocess development [12]. As the different substances have been added to the dataset over time the concentration labels of some substances are imbalanced which makes the dataset an interesting subject to study for AL.

## Model

As a model we use version 2.5 of TabPFN [5], [13], [14] which is a foundation model for tabular datasets that uses in-context learning on the whole training set when predicting new labels. This model has been used in version 2 on this dataset before and showed exceptional performance in particular for low concentrations [6].
For regression problem like ours the model discretises the concentration space and actually solves a classification problem under the hood. Therefore, it yields probabilistic predictions of the concentration labels [15] that widen the range of possible information criteria that can be used during AL.

## Setup

To select Raman spectrum–concentration pairs that most improve the predictive performance of the model we perceive the problem as pool-based active learning [8]. We join the training dataset with the validation dataset to a pool of more than 6000 spectra to choose from. We use the test dataset for evaluating the model in each step.

The reason why we can merge the training and the validation set in our evaluation setup is that we chose to not do any hyperparameter tuning. This decision is motivated by two considerations. First an foremost, TabPFN is a foundation model that uses in-context learning [14]. Therefore we did not do classic model training on the spectral datasets where we can pick hyperparameters that shape TabPFN's architecture like the encoding dimension, the number of transformer encoder layers, the dropout rate etc. Second, for the hyperparameters that we could have tuned like the number of estimators or the kernel size for the average pooling step, we use the same values as in [6].

Typically, active learning algorithms suggest labeling one sample at a time. However, that procedure is very time-consuming for a datasets size above 6000 when each suggestion requires retraining the whole model. Therefore, we choose an AL procedure that suggests batches of data points.

## Algorithm

The batch suggested by the AL algorithm should be optimised in terms of two objectives. On the one hand, we need to quantify the informativeness of unlabelled data points. On the other hand we need a mechanism that ensures diversity within the batch.

### Informativeness

As most machine learning algorithms do not deliver probabilistic predictions the classic active learning approach is to work with an ensemble of regressors and judge the informativeness of an unlabelled data point by the discrepancy of their predictions. Since we use TabPFN, we obtain a predictive distribution over discretised bins of the concentration space [13]. Consequently, we can use information criteria that are directly related to the posterior distribution$P(y|x)$and which are usually used for classification models. As the discretisation consists of 5000 bins the typical least confident approach [8] or margin sampling [16] neglect most of the distribution. Therefore, we use the entropy [17] of the predictive distribution to measure the uncertainty of the model

$$U(x_i) = \sum_{j=1}^{5000} -P(y_j|x_i) log P(y_j|x_i) \quad (1)$$

in its own prediction. We use this uncertainty as a metric for the informativeness of each spectrum.

**Algorithm 1** Batch Active Learning with Weighted K-Means

**Require:** Pool of training spectra $X_{\text{train}}$,
Test set $X_{\text{test}}$,
batch sizes $\{n_0, n_1, \ldots, n_T\}$,
number of independent runs $N = 10$,
**Ensure:** $R^2$ scores per step for Active Learning

Preprocess all spectra: average pooling + water-peak intensity filtering
**for** run $= 1$ **to** $N$ **do**
  $X_u \leftarrow X_{\text{train}}$
  $\mathcal{L} \leftarrow \text{RandomSample}(X_u, n_0)$
  **for** $t = 1$ **to** $T$ **do**
    Fit TabPFN on $\mathcal{L}$; Evaluate TabPFN on $X_{\text{test}}$
    **for** $s \in \mathcal{S}$ **do**
      Fit TabPFN on $\{(x_i, y_i^s) : x_i \in \mathcal{L},\ y_i^s \neq \text{NaN}\}$
      Compute uncertainty for all $x_i \in X_u \setminus \mathcal{L}$:

$$U^{(s)}(x_i) = \sum_{j=1}^{5000} -P(y_j^s \mid x_i) \log P(y_j^s \mid x_i)$$

    **end for**
    $U(x_i) \leftarrow \frac{1}{8} \sum_s U^{(s)}(x_i)$
    Select candidate pool: $\mathcal{C} \leftarrow \text{top}_{5n_t}(\{U(x_i)\}_{i \in X_u \setminus \mathcal{L}})$
    Solve weighted K-means on $\mathcal{C}$ with $K = n_t$ clusters:

$$\min_{\mu_k,\, z_{ik}} \sum_{x_i \in \mathcal{C}} \sum_{k=1}^{K} U(x_i)\, z_{ik}\, \|x_i - \mu_k\|$$

    $\mathcal{S} \leftarrow$ spectra in $\mathcal{C}$ closest to each cluster centre $\mu_k$
    Resolve duplicates using the highest-$U$ unselected candidate
    $\mathcal{L} \leftarrow \mathcal{L} \cup \mathcal{S}$
  **end for**
**end for**

**Algorithm 1.** Uncertainty-guided batch active learning for spectral calibration. Candidate spectra are scored by averaged predictive entropy across substances and clustered via weighted K-means to balance informativeness with diversity in each acquired batch.

Active Learning Method

## Diversity

We use a method that is suggested in [11] and incorporate minor changes that are inspired from [9]. So let $X_u$ be the set of unlabelled spectra and let $S \subseteq X_u$ be the set of $K$spectra that we want to label. This subset should be most representative of the set of unlabelled spectra which we quantify via:

$$\sum_{x \in X_u} min_{s \in S} ||x - s|| \quad (2)$$

However, this problem is known to be NP-hard which is why we solve a similar problem that is known as K-means clustering

$$\sum_{x_i \in X_u} \sum_{k=1}^{K} z_{ik} ||x - \mu_k|| \quad (3)$$

where we would like to find both the cluster centres $\mu_k$and the binary assignment$z_{ik}$for each spectrum$x_i$to the clusters$k$. Even though the two optimisation problems look very similar the crucial difference is that for K-means the cluster centres$\mu_k$do not need to be part of the set of unlabelled spectra$X_u$. So instead of the cluster centres we choose the spectra that are closest to the cluster centres of K-means. In case there is one spectrum that is closest to two or more cluster centres we pick the spectrum with the highest uncertainty that has not been picked before.

Moreover, we do not cluster the whole set of unlabelled spectra, but choose thespectra that are most informative according to their entropy. This is inspired from [9] and increases the fraction of highly uncertain spectra

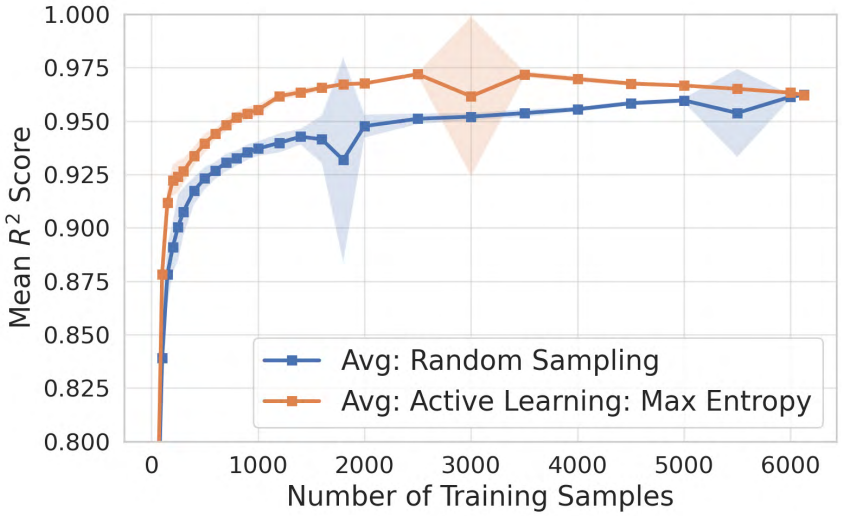

**Figure 1.** Overall model performance comparison, averaging $R^2$ scores across all eight substances. This plot summaries the aggregate performance of the active learning and random sampling strategies. The x-axis is the number of training samples, and the y-axis is the mean $R^2$ score. Lines and shaded areas represent the mean and standard deviation over 10 runs, respectively

within the batch.

### Joint Objective

To consider both aspects of informativeness and diversity we alter the K-mean clustering problem (Equation 3) by introducing the informativeness criterion as a weight for each spectrum. So we solve the weighted K-means clustering problem

$$\sum_{x_i \in X_u} \sum_{k=1}^{K} U(x_i) z_{ik} ||x - \mu_k|| \quad (4)$$

that gives more importance to unlabelled spectra based on the model's uncertainty $U(x_i)$.

To evaluate the effectiveness of that approach we compare it against Random Sampling (RS). As the first batch of data is randomly selected for both methods we conduct 10 independent experiments while we use the same first batch for both AL as well as RS. More details on the exact procedure are given in Algorithm 1.

## RESULTS

We compare the AL method described previously against RS.

### Overall Predictive Performance

The predictive performance of both methods, RS and AL, follows a characteristic learning curve, with $R^2$ scores improving rapidly before reaching a plateau. When averaged across eight substances and ten experimental runs, the AL strategy consistently outperformed RS (Figure 1). While RS shows a slight advantage on five substances in low-data scenarios, AL makes significant gains on the remaining substances (Figure 2). This results in a higher mean $R^2$ score throughout training sizes.

### Substance-Specific Sensitivity

A breakdown of performance by substance reveals that the effectiveness of AL is highly dependent on the specific substance (Figure 2) and can be grouped into three distinct categories:

**AL-Dominant Profiles (EnPump and Yeast Extract):** AL provides a substantial advantage here. For EnPump, RS fails to exceed an $R^2$ of 0.85 even with 6, 000 samples, whereas AL reaches near-perfect prediction almost immediately. This suggests these substances are defined by features sparsely distributed in the parameter space, which benefit significantly from targeted sampling.

Rapid **Convergence Profiles (Glucose, Glycerol, Acetate, Nitrate, and Total Phosphate):** Both strategies perform similarly, reaching $R^2$ values above 0.90 within the first 500 samples. The underlying relationships for these substances appear easy to capture regardless of the sampling method.

**RS-**Dominant **Profile (Total Sulfate):** RS outperforms AL until the training set reaches 3, 000 samples. The high variability in the AL results suggests that model uncertainty for Sulfate did not effectively guide the selection of data points, leading to a less balanced training set.

### Convergence and Significance

As the training set size approaches 6, 000 samples, the gap between AL and RS narrows for most substances. However, the early-stage superiority of the AL

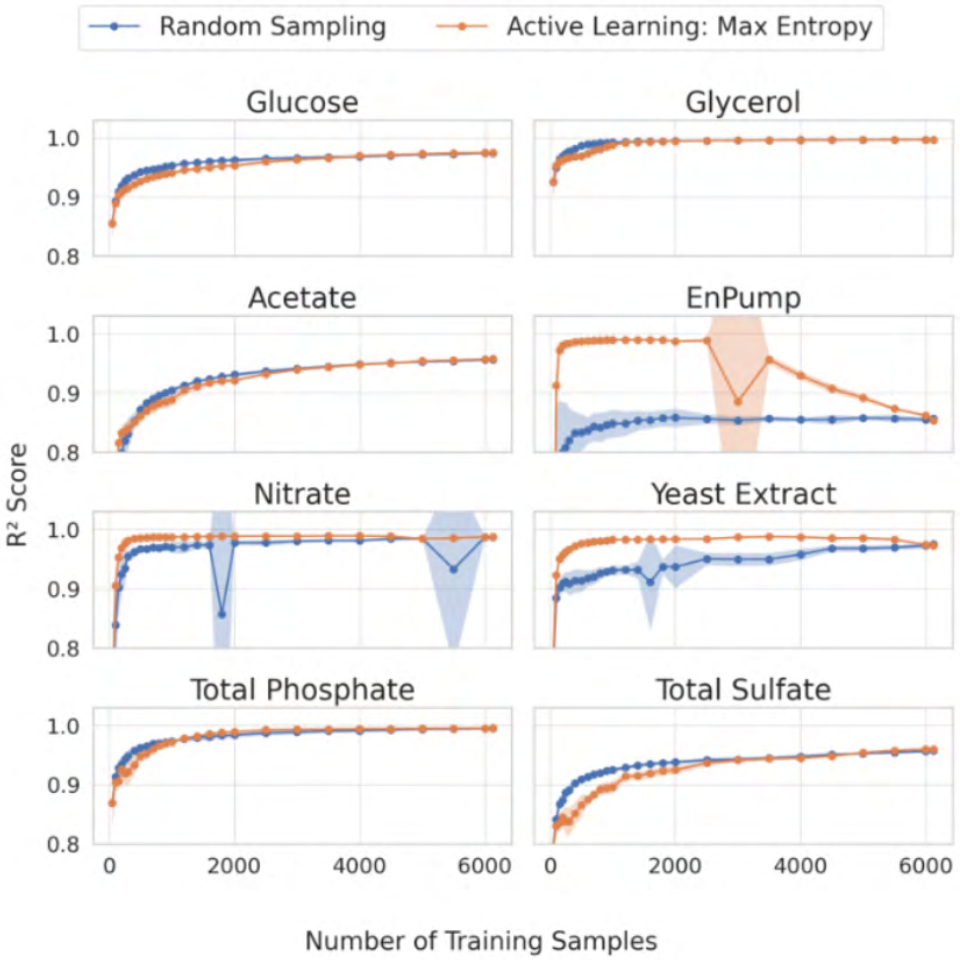

**Figure 2:** Comparison of model performance ($R^2$ score) for predicting individual substance concentrations using active learning versus random sampling. Each subplot corresponds to a specific substance. The x-axis represents the number of samples used for training the model, while the y-axis shows the resulting $R^2$ score on a held-out test set. The solid lines indicate the mean performance across 10 independent experimental runs, and the shaded areas represent the standard deviation.

Data Efficiency and Peak Performance

approach remains significant. A paired t-test to compare the two strategies via p-values (Figure 3) confirms that the advantage of AL is statistically significant across the majority of training set sizes.

The AL algorithm demonstrated superior data efficiency, reaching high accuracy levels much faster than RS. Specifically, AL achieved a mean $R^2$ score of 0.95 with approximately 1, 000 samples, whereas RS required nearly 2, 500 samples to reach the same threshold (Figure 1).

Notably, the AL model reached the same accuracy as the final model (trained on the full dataset) with only 1, 200 samples. Performance continued to climb until it peaked at 2, 500 samples, where the AL-selected subset actually achieved a higher accuracy than the model trained on the complete dataset. Paired t-tests (Figure 4) indicate that this peak performance at 2, 500 samples is statistically significant. This suggests that by the 2, 500-sample mark, the AL algorithm had successfully identified the most informative data points, and the slight improvements for some substances cannot make up for the deterioration of EnPump and Yeast Extract.

## DISCUSSION

First, the use of an AL algorithm based on entropy as a selection criterion to discriminate between different Raman spectra is quite new as using accurate probabilistic regression models on Raman spectra is a very recent phenomenon. However, TabPFN delivers very high accuracies in a probabilistic form that enables the AL algorithm to select training samples that improve model performance compared to RS.

Therefore, the results discussed here highly depend

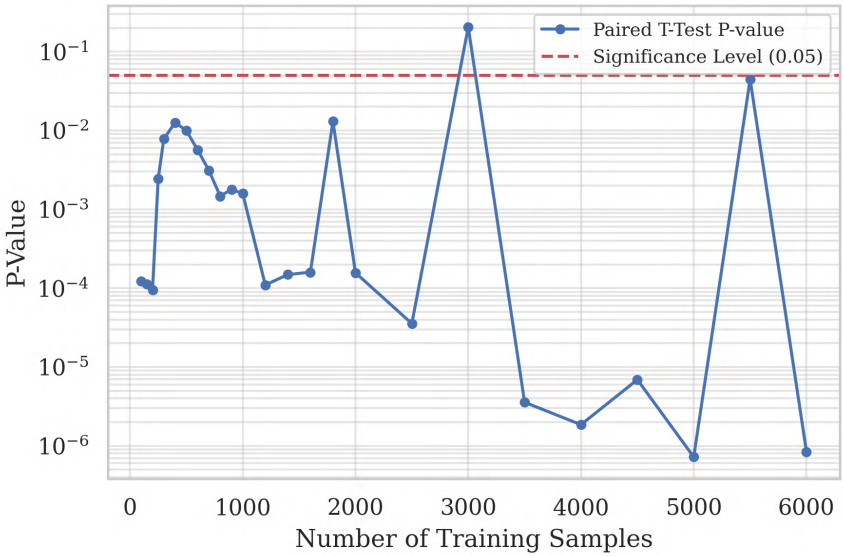

**Figure 3.** Statistical significance of the performance improvement of Active Learning over Random Sampling. The plot shows the p-value from a paired t-test performed on the $R^2$ scores across all predicted substances at different training set sizes and across 10 trials.

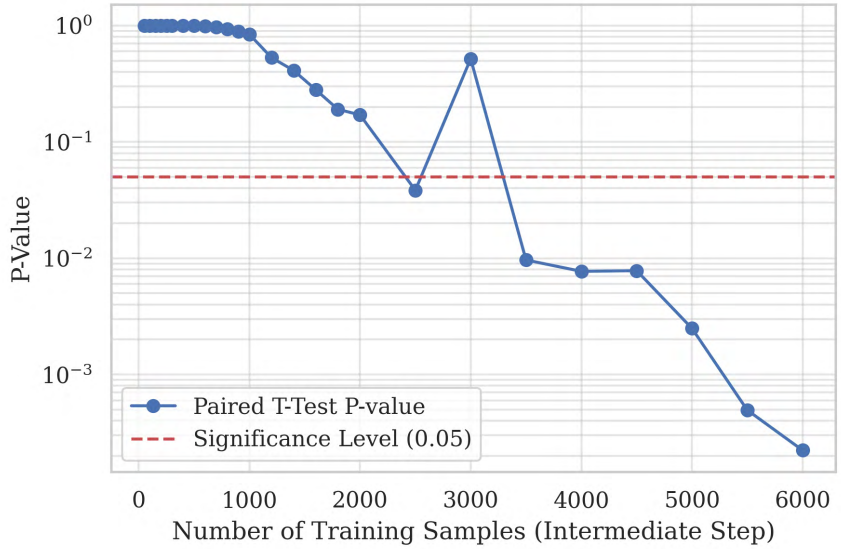

**Figure 4.** The plot displays the p-values from a one-sided t-test comparing the model's performance at intermediate training stages against its final performance. The x-axis represents the number of training samples, while the y-axis shows the corresponding p-value.

on the model type TabPFN. In particular, the structure of TabPFN with its in-context learning paradigm enables evaluations like this one, that would otherwise require a whole hyperparameter tuning run for each number of training samples.

The data selection strategy of the AL algorithm is helpful from an efficiency perspective. In particular, we can reach the level of accuracy of the model with the full dataset with already 1200 data points which is roughly 20 percent of the whole training dataset. Therefore, the computational complexity for training and inference is reduced by a factor of 25. This allows inference times in the realm of milliseconds compared to 10 seconds before. This represents an important speed improvement, particularly for high-throughput bioprocess development.

When there is a powerful GPU available that enables fast computations we can even use AL as a filter on the training dataset that picks the most informative points as long as the validation performance increases. So in this case we would use the 2500 data points for training that achieved the highest overall accuracy.

Model performance varies substantially across substances. While for most substances the accuracy increases with the number of data points, for EnPump, Nitrate and Yeast Extract the accuracy of both models decreases for dataset sizes over 2500. Looking at the data distributions in [6] we observe that these are the three most imbalanced substances in the dataset and mostly contain zero concentrations. It is likely that the AL algorithm predominantly selects zero-concentration samples, exacerbating the label imbalance that is harder to handle for the model. This also highlights the importance of carefully designing one's calibration dataset with methods like Design of Experiments.

For the future it would be interesting to compare other batch AL methods to the current approach, for instance [9], [10]. Or one could use the Core-Set approach from [18] and combine it with an informativeness criterion. Moreover, evaluating the benefit of AL approaches on other imbalanced Raman datasets in particular from fermentations might be an approach to increase the model accuracy on the small datasets present in biotechnological applications.

## ABSTRACT

The increasing demand for energy, water, and chemical products signals the need for more sustainable and efficient process design methodologies. Traditional methods for conceptual process design constrains the exploration of novel and intensified process alternatives, as they rely on prior knowledge in defining the design space. Previous studies employing bottom-up approaches, such as phenomena building blocks (PBBs), suggest that the synthesis of complex bottom-up flowsheets remains computationally challenging and is thus limited to the synthesis of individual units of operation. This work proposes a bottom-up, data-driven framework for process synthesis and intensification based on phenomena building blocks (PBBs), in which process flowsheets are constructed from their underlying physical and chemical phenomena rather than conventional units of operation. The proposed framework introduces a phenomena-based text representation and data collection module. Furthermore, a sequence training and generation module is developed, which learns patterns governing PBB interactions and placement within flowsheets. A case study on ethylene glycol production is presented, in which nine fundamental phenomena yield 49 distinct PBB tokens. Results show that the trained model successfully reproduces established flowsheet structures and generates flowsheets using novel PBB combinations, highlighting its potential to support sustainable and intensified process designs.

**Keywords**: Process Design, Process Synthesis, Process Intensification, Artificial Intelligence, Machine Learning

## INTRODUCTION

In conceptual process design, finding the optimal flowsheet for a process often involves the predefinition of units of operation and their possible configuration [1]. This paradigm limits the discovery of novel process alternatives involving unconventional units of operation and configurations, as it relies on expert knowledge to define the process's design space [2]. Rather than defining existing units of operation, phenomena-based methods offer an innovative solution to process design, as they rely on defining existing chemical components and their physicochemical interactions. This led to the introduction of phenomena building blocks (PBBs) [3], where abstract blocks are used to model chemical species and the phenomena that govern them. Then a process flowsheet may be constructed using a combination of these PBBs.

Demirel et al. [4] proposed a phenomena-based optimization framework, where superstructures of PBBs are formulated as a mixed integer non-linear programming problem (MINLP), that are solved to obtain the optimal allocation of PBBs in a 2D grid, leading to the synthesis of intensified process flowsheet. Then, Demirel et al. [5] modified the design framework by explicitly defining the grid structure, introducing an initializing strategy, and including a two-block formulation for vapor-liquid equilibria, showcasing the framework's ability in intensifying an ethylene glycol production process. Moreover, Monjur and Hasan [6] built upon this modification to develop a design framework for the intensification of natural gas to

methanol process that includes membrane reactors.

Krone et. al. [7] proposed an optimization framework employing mixed-integer non-linear programming (MINLP) to synthesize distillation columns using superstructures of VLE building blocks. To address the large design space of the problem, which often prevents MINLP solvers from converging, they introduced a structural screening procedure to eliminate infeasible process alternatives prior to optimization. On the other hand, Cortés-Peña and Zavala [8] explored the application of phenomena-based representation for the simulation of process flowsheets formulated as graphs consisting of equation and variable nodes.

Nonetheless, using mathematical programming to solve superstructures of PBBs remains challenging. One challenge is the computational complexity of handling a large combinatorial design space. Another challenge is that achieving optimal design alternatives depends heavily on the formulation and may require the inclusion of disjunctive programming, which increases the model complexity. Moreover, solving these complex models requires good initial conditions, an effective initialization strategy must be developed to complement formulation.

In data-driven approaches, a design framework often trains a machine-learning (ML) model on process data to learn structural relationships and decision-making rules directly from data rather than prescribing them using expert knowledge. Because such frameworks enable the simultaneous generation and evaluation of process alternatives, they can also navigate large design spaces to discover new alternatives [9].

Inspired by how the Simplified Molecular Input Line Entry System [10] (SMILES) can represent molecular structures using text, d'Anterroches [11] proposed the Simplified Flowsheet Input Line Entry System (SFILES). Moreover, Zhang et. al. [12] proposed a pattern recognition framework that can detect patterns for flowsheets represented using SFILES, and discovered patterns that match those described by heuristic rules in the literature. Nabil et. al. [13] employed some elements of the SFILES representation in developing vocabulary and grammar rules tailored for the synthesis of a supercritical $CO_2$ power cycle, and trained a long short-term memory (LSTM) model to predict the syntax of a text-based process flowsheet.

With recent interest in data-driven approaches, further developments on the SFILES notation have been made. SFILES 2.0 [14] expanded the notation to capture more interactions between units of operation and represent control modules within flowsheets [15]. While eSFILES [16] built on the original representation to establish hierarchical grammar trees and process ontology that can be utilized for machine learning. Li [17] demonstrated that PBBs can be employed for the synthesis of a hybrid extraction and distillation unit using phenomena-based string representation. Using a ML model on a dataset of vapor-liquid equilibrium (VLE), liquid-liquid equilibrium (LLE), and mixing building blocks. The results highlighted the framework's potential in generating novel extraction-distillation configurations with lower separation costs.

Nevertheless, recent works remain constrained to the representation of phenomena across single units of operations, as extending these approaches to entire process flowsheets will result in large and complex problems that are difficult to solve and require expert knowledge.

This work adopts a phenomena-based, data-driven approach for conceptual process design, enabling the automatic completion of process flowsheets. The proposed framework aims to represent complex process flowsheets as structured sequences of PBB tokens and train an ML model to learn relationships between PBBs and their placement within process flowsheets, providing a computationally lighter alternative for exploring large design spaces compared to superstructure-based methods. A case study for the production of ethylene glycol from ethylene oxide and water is highlighted.

## METHODOLOGY

The proposed methodology follows a two-step approach: (1) text-representation and rule-consistent data preparation; (2) LSTM model training, finetuning, and generation of string-based flowsheets.

### Data Preparation

An existing text-based representation paradigm, the SFILES 2.0 [14], is adopted for encoding process flowsheet information. In this notation, strings are read left to right, with parentheses-enclosed words representing a unit of operation token, and the tokens appearing next to one another have an implicit connection from left to right. However, we modify the notation to be based on PBBs rather than units of operation.

Each block token can represent one or more phenomena and connects to other blocks via directed, branch, and recycle/bypass streams to form the process topology. SFILES 2.0 encodes a flowsheet as a single linearization of a process graph, augmented with special symbols to mark branches. The same augmentation style is retained, but the vocabulary and grammar rules are modified to suit a phenomenon-based representation.

A concise vocabulary is defined to align with the PBBs representation; consequently, tokens fall into three classes: (a) input/output blocks, (b) phenomena tokens, and (c) topology control tokens. Input/output blocks are process-specific and rely on a prior definition of available raw materials and possible products. With input blocks being denoted as ($ik$) where i refers to an input, and $k$ refers to the chemical species. Similarly, for output blocks, ($ok$) is used to denote an outlet block, where $o$

refers to an outlet, and $k$ refers to the chemical species.

Furthermore, phenomenon tokens are derived from nine basic phenomena across three types, with each phenomenon being denoted using a unique letter, as shown in **Figure 1.a**. From these basic phenomena, 49 tokens are defined. These tokens were defined to allow one or more phenomena to exist in a block, as illustrated in **Figure 1.b**, the tokens follow simple thermodynamic rules (e.g., cooling and heating cannot occur in the same block). In a string format, input/output tokens and phenomena tokens are enclosed by parentheses to clearly distinguish them, as shown in **Figure 1.c**.

On the other hand, topology control tokens use symbols to denote a special action on the topology of the process, such as a branch entering or exiting, or a recycle or bypass stream from one block to another. **Table 1** shows the full list of the topology control tokens. Moreover, recycle/bypass streams come in pairs where each inlet must have an outlet, where '#' is an integer number that appears in both the stream's inlet and outlet. For a process with 2 input blocks and 2 output blocks, and one allowed recycle/bypass stream, this makes up a vocabulary size of 59, which consists of 49 phenomena tokens, 6 topology control tokens, and 4 input/output tokens. This vocabulary is not only expressive enough to support complex flowsheet patterns, but also to encode the grammar and thermodynamic rules that are used to generate the initial dataset.

**Table 1:** Process Topology Tokens.

| Token | Description |
|---|---|
| <& | Start of a nest for a mixing branch. |
| <&\| | End of a nest for a mixing branch. |
| [ | Start of a nest for a splitting branch. |
| ] | End of a nest for a splitting branch. |
| <# | Recycle/bypass stream inlet |
| # | Recycle/bypass stream outlet |

The initial dataset is randomly generated using a rule-guided procedure, where two sets of rules govern how a string-based dataset of process flowsheets is generated. The set of heuristic rules is shown the supplementary material. In **Table S.1**; these rules consist of grammar rules that describe how text-based representation is achieved, and thermodynamic rules that ensure that a design-informed string is generated. On the other hand, the sampling logic rules establish string targets as shown in **Table S.2**. Some of these rules follow probabilistic controls to randomly sample the next token in the string.

Also, these rules can be modified to control the complexity of the generated string-based flowsheet, such as modifying the maximum length of strings or the size of nests for branches. Although the sampling logic rules can be considered heuristic, they enforce constraints related to the string generation logic that are not grammar or thermodynamic rules.

Finally, an algorithm that combines the heuristic and sampling logic rules is used to sequentially build up strings, following a token-to-token approach. For each position in the string, a list of eligible tokens is updated, so that the algorithm picks a token that follows the rules. Moreover, for each step, the algorithm conducts checks related to which tokens have appeared in the string, their count, and whether sampling targets have been met. Nonetheless, the algorithm only requires the definition of the number of strings to be generated, and can output the full list of generated strings, including unique ones.

## Model Training and Flowsheet Generation

A machine-learning pipeline is employed to build a data-driven model capable of autocompleting string-based flowsheets and generating new valid strings. The pipeline begins by retrieving the initial dataset from the data preparation step, preprocessing it into a suitable format, training an LSTM model, and finally generating

new strings. The LSTM architecture is chosen because it can handle short and long-range interactions in sequences, which is essential in capturing various token dependencies in string-based flowsheets.

Each flowsheet string is tokenized and mapped to integer IDs in $[1, v]$, where $v$ is the vocabulary size; with ID =0 reserved for padding. The IDs are to be used by an embedding layer in the LSTM model, which maps integers to $d$-dimensional vectors, which are then fed to an LSTM cell. Label encoding is used to assign integer IDs to tokens, which can then be used as the embedding layer input. While the integers themselves carry no physical meaning, encoding strings into integers serves as a reference for the learning.

To ensure that strings have uniform sequence lengths during training, all sequences are padded to a global maximum length $L_{max}$, corresponding to the longest string in the dataset. Nonetheless, this padding token is masked when calculating the loss and accuracy values. Given a dataset of sequences as input, output token sequences are created by shifting input sequences by one position to the left and removing the first token; tokens in any given position in the shifted sequence are output tokens (ground truths) to their corresponding tokens in the original sequence.

A unidirectional LSTM is adopted with input embedding and linear projection to the vocabulary to predict the next token in a sequence. The model is trained on a synthetically generated dataset, capturing PBB strings for the production of ethylene glycol from ethylene oxide and water. The training uses class-weighted pad-masked cross-entropy, averaging the loss across all non-pad positions to handle variable-length sequences and class imbalance.

The dataset is split into 80/10/10% for training, validation, and testing respectively, with the training dataset being further divided into batches of equal lengths. The embedded token is passed to an LSTM module consisting of $l$-layers of hidden size $h$, then projected to $g$ logits per position that convert them to probabilities representing next-token placement.

The training commences with the first LSTM consuming the embedded sequence one token at a timestep, as shown in **Figure 2**, carrying hidden states forward. Initial states are set to zero per sequence. At each timestep, the LSTM's layer output is passed through a linear projection to produce logits over the vocabulary size. Softmax converts these logits to a next-token probabilities that are compared with the ground truth of the next-token to calculate the loss function. For timestep $t$, the loss function is calculated using equation (1), where $L_t$ is the class-weighted cross-entropy function, $m$ is the masking term with 0 for padding tokens and 1 for other tokens, $w_y$ is the weight of the class, and $p_y$ is the probability of picking that class as the next token.

$$\mathcal{L}_t = -m w_y \log p_y \qquad (1)$$

At the end of an epoch, the loss function across all batches is averaged to produce a class-weighted cross-entropy for that epoch, which is then used in backpropagation to update the hidden states and embedding table for the next epoch. Moreover, accuracy calculation can be performed to better understand how the predictions are. For a single timestep, the accuracy is calculated by taking the highest probability of non-pad tokens in the next-token prediction and checking whether it matches the ground truth, assigning an accuracy of 1 if it does, and 0 if it does not. This is then averaged across all batches in an epoch to get that epoch's accuracy.

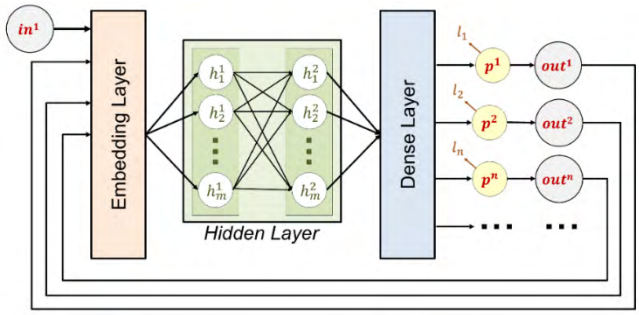

**Figure 2.** Unidirecotional LSTM module used in training.

As the aim of the training is to get a model that minimizes the cross-entropy loss function, selecting appropriate hyperparameter values is crucial for this stage. Consequently, a grid search will be used where the combination of selected hyperparameter values will be used to get their initial estimates. Furthermore, Adam [18] optimizer is to be employed to dynamically change the learning rate across batches, rather than using a global learning rate. Finally, Optuna [19] optimizer is to be used for a final round of hyperparameters finetuning.

After a trained model is obtained, it is used to generate new phenomena-based flowsheets using text-based representation. The generation procedure employs a top-$k$ probabilistic decoding strategy, where the next token in the sequence is sampled from the $k$ most likely predictions for the output token. First, a sequence is initiated by randomly sampling an input token in the first timestep. The sequence is then autocompleted until a maximum string length is reached, or the stopping criteria are met, namely, the presence of all output tokens and balanced process topology symbols. Then, each generated sequence is checked for adherence to the original heuristic rules and flagged as a valid sequence.

## RESULTS

The first step in data preparation is to establish the vocabulary set representing tokens that can appear in

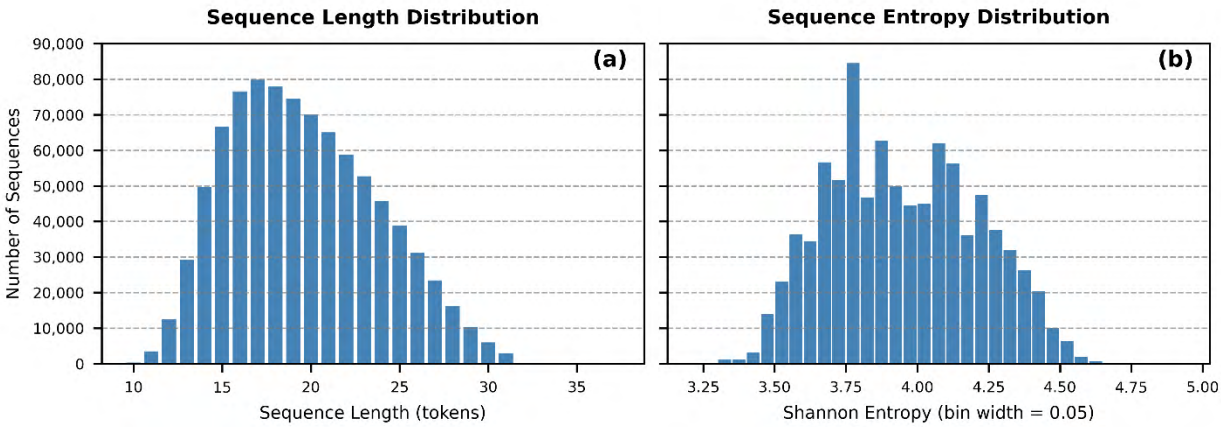

**Figure 3.** Initial dataset analysis: **(a)** sequence length distribution, and **(b)** entropy distribution.

string-based flowsheets. The proposed framework incorporates all nine basic phenomena to enable a more comprehensive flowsheet representation for a case study on ethylene glycol production from ethylene oxide and water. Consequently, many multi-phenomena tokens introduced during the token definition stage were not previously examined within the context of ethylene glycol production. Furthermore, two input tokens, ($iW$) and ($iEO$), were defined to represent the water and ethylene oxide feed streams respectively. Similarly, two output tokens. ($oW$) and ($oEG$), were defined to represent the water and ethylene glycol product streams, respectively, with ($oEG$) designated as the desired product output token.

A maximum of two recycle/bypass streams was allowed in the process. Based on these definitions, a vocabulary set containing 61 tokens was constructed, comprising 49 PBB tokens, 4 input/output tokens, and 8 process topology tokens. Consequently, a total of 2, 000, 000 strings were prepared, yielding 900, 425 valid strings that complied with the heuristic rules. Among these, 892, 768 were unique, non-repeating strings. A maximum sequence string length of 30 is used for the generation procedure; however, the observed maximum sequence length is 37. This is due to the post-processing step in the procedure, which enforces the sampling logic rules, such as balancing recycle and branching symbols, or ensuring that the desired output appears in the string.

As a result, the sequence length distribution shown in **Figure 3.a** exhibits a unimodal, centred around sequence length 17, reflecting the constrained randomness of the generated sequences. Additionally, the sequence entropy distribution presented in **Figure 3.b** highlights entropy values ranging from 3.3-4.7 bits, corresponding to 10-26 tokens respectively. This indicates that the generated sequences have sufficient randomness and token diversity to represent the design space of the process.

The LSTM model is trained through a multi-stage procedure, which starts by pretraining using an initial set of hyperparameters to obtain baseline learning curves and assess the model's ability to learn. Then, to find the minimum cross-entropy loss function, these hyperparameters were optimized using grid-search exploration, Adam optimizer, and Optuna optimizer. The final stage is to generate novel strings and validate their structure and adherence to heuristic rules. All training was done using the PyTorch library, utilizing a CUDA-compatible GPU (Nvidia 4070 Super).

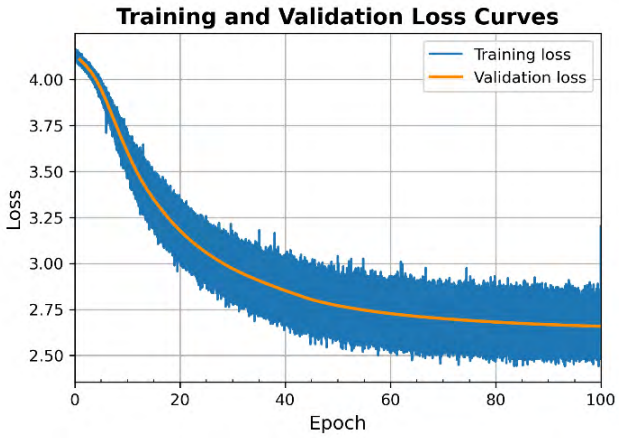

**Figure 4.** Training/validation curves in pretraining.

The pretraining stage was carried out using initial hyperparameter values similar to those used by Hirtreiter et. al. [16] in their SFILES 2.0 representation. Using a batch size of 32, hidden size and embedding dimension of 64, 1 LSTM layer, and a learning rate of 3e-4. Stochastic Gradient Descent (SGD) is initially used to calculate the gradient in backpropagation. **Figure 4** shows the evolution of training and validation loss over 100 epochs, where the training curve is composed of per-batch loss evaluations to demonstrate how the model is changing the LSTM states for each batch, while the validation curve is evaluated at the end of each epoch. The curve

shows a gradual decrease in the cross-entropy loss function, converging to a loss of 2.63.

Although these results confirm that a baseline model is capable of learning sequential ordering of how tokens appear in the strings, the slow convergence indicates the chosen hyperparameters are not optimal. And any reruns using the same -or different- datasets will be computationally expensive. Moreover, early stopping is to be implemented in the subsequent stages, where training terminates when the validation losses across the last 5 epochs are within 0.001. The grid search provided coarse insight into the suitability of certain hyperparameter ranges, as shown in **Figure S.1** and **Figure S.2** in the supplementary material, highlighting how the training loss responds to variations in batch size, learning rate, hidden dimensions, and embedding dimensions over the first ten epochs.

Consequently, an Optuna study consisting of 50 trials was performed using continuous sampling of the learning rate and discrete sampling for all other hyperparameters. An additional training run using a batch size of 512 and the optimized hyperparameters produced the loss curve shown in **Figure 5**. Compared with the pretraining results, the optimized model exhibits faster convergence, with the training loss stabilizing within the first epoch and converging to a loss of around 2.58.

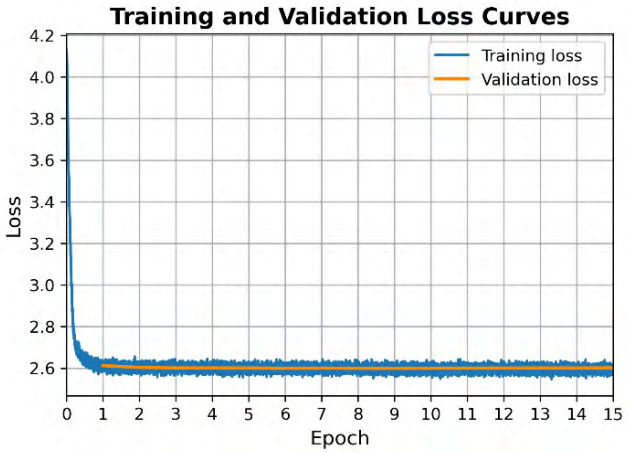

**Figure 5.** Training/validation curves after finetuning.

The rapid convergence of the optimized model indicates that the selected hyperparameters not only offer a slight improvement in accuracy but also enhance the efficiency and smoothness of the training process. To evaluate the generative capabilities of the trained LSTM model, a generation module was constructed. It starts by retrieving the best LSTM model after the last training cycle and implements basic decoding rules. These rules include balancing or process topology tokens, the presence of raw materials and desired products, and termination conditions. Using top-$k$ sampling (with $k$=20), the module is tasked with generating a batch of 10, 000 flowsheet strings without any explicit rules or structural guidance.

Across the full batch, the module outputs 9, 760 valid sequences, with valid sequences defined as those that do not violate the heuristic rules used in generating the initial dataset, demonstrating that the learned sequence distribution is highly consistent with the rules embedded in the training data. This high validity is notable given that the generator applies no grammar rules, thermodynamic rules, or sampling logic rules. Furthermore, only 170 valid sequences (about 1.7% of the generated dataset) appeared in the initial dataset, indicating that the model is not simply memorizing the training dataset. This means that the trained model can synthesize novel, previously unseen string-based flowsheet configuration that do not violate any of the heuristic rules.

The model was also tested for the autocompletion of strings, where the first couple of tokens are provided and the model predicts a valid continuation of the string. The module first checks whether the given initial sequence of tokens is probable under the model, with structurally inconsistent combinations being labelled as an invalid input sequence. When a probable input sequence is provided, the model extends it into a full flowsheet string. Examples of generated and autocompleted strings are presented in **Table 2**. The examples demonstrate the model's ability to generate alternatives that include no recycle streams, one or multiple recycle streams, alternatives with or without side products, and complex reaction-separation sequences.

**Table 2:** Examples of Input strings and their corresponding autocompleted strings.

| Input String | Autocompleted String |
|---|---|
| (iW) | (iW)(m)<&\|(iEO)(h)(d)&\|(dr)(rt)[(d)(oEG)](h)(d)(oW) |
| (iEO) | (iEO)(hm)<1(dmr)<&\|(iW)(d)&\|(pt)[(h)(d)(oEG)](df)1 |
| (iW)(p)(m) | (iW)(p)(m)<&\|(iEO)(d)&\|(dr)(fr)[(d)(h)(oEG)](oW) |
| (iW)(cr) | invalid input |

A parsing module is also developed to translate each string into a graph representation that can be easily interpreted. An example of this is provided in **Figure 6**, showing a string being parsed into a graph-representation, with input PBB blocks highlighted in light red, output PBB block in light green, red arrows for directed edges on the main branch, grey arrows for directed edges on side branches, and green arrow for the recycle stream.

## CONCLUSIONS

The reliance on predefined units of operation in traditional process design constrains the exploration of

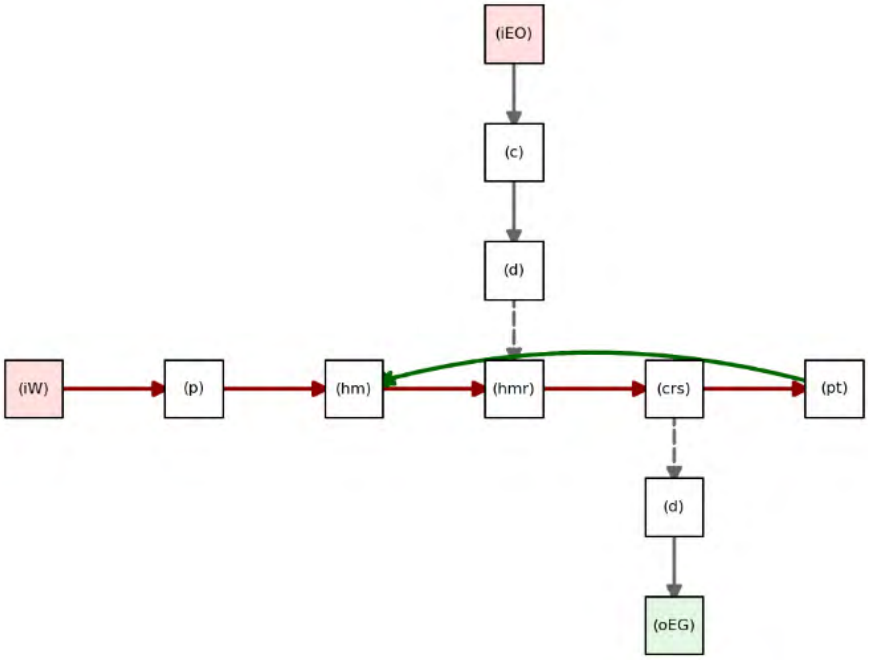

**Figure 6.** Process Graph of the Generated String '(iW)(p)(hm)<1(hmr)<&|(iEO)(c)(d)&|(crs)[(d)(oEG)](pt)1'.

novel and intensified process alternatives. Recent phenomena-based studies have highlighted the advantages of representing processes through fundamental physicochemical interactions, although their extension to complex, complete flowsheet synthesis remains challenging.

The proposed framework demonstrates the potential of a text-based data-driven approach for conceptual process design, and its ability in generating novel and large design spaces for chemical processes. Using an initial dataset of about 900, 000 alternatives, the model underwent multiple training stages, including pretraining with initial hyperparameters, followed by finetuning. The optimized model was used to generate 10, 000 alternatives, of which 97.6% implicitly follow the heuristic rules. Furthermore, among the generated alternatives, 98.3% were novel and had not appeared in the initial dataset, indicating that the model successfully learned phenomena building block relationships using the modified SFILES 2.0 representation.

Nonetheless, several limitations arise when implementing text-based representation for PBB flowsheets. The current vocabulary and grammar rules do not provide a true phenomenon representation for separation. This is due to the inherent restriction associated with the adopted SFILES 2.0 representation, which does not allow mixing and splitting to occur simultaneously in the same token. Similarly, mixing and splitting tokens are restricted to a single branch each, further limiting the representation of separation phenomena.

Although the trained model generated novel strings, their thermodynamic feasibility is to be investigated. The heuristic and sampling logic rules ensure structural consistency and basic PBB logic. However, process conditions need to be incorporated, and the process alternatives should be evaluated, simulated, and optimized. As process conditions were not considered in the current framework, certain thermodynamic interactions may be infeasible during evaluation, such as using a simple distillation for azeotropic mixtures. Another limitation is that the LSTM model was trained only on synthetically generated data, without incorporating real process data or simulation results. Future work should address these limitations to achieve a more robust phenomena-based design methodology.

## ABSTRACT

Pharmaceutical and fine chemical industries face strong pressure to shorten time-to-market while maintaining compliance with complex regulatory frameworks. These conflicting demands require rapid process design, validation, and scale-up. Modular production plants standardized in VDI 2776 and VDI/VDE/NAMUR 2658 have emerged as a promising strategy to shorten engineering and validation efforts. The Product–Process–Resource (PPR) philosophy represents a key approach to efficient data management in modular plant engineering. It enables the separation of different flexibility dimensions into distinct, relevant aspects that can ideally be exchanged or modified independently. To realize this principle in practical applications, formalized information models and ontologies serve as a key enabler for structuring and managing semantic data. This work investigates several information models and ontologies for the process engineering domain regarding their suitability to support separation according to the dimensions defined by the PPR approach. As a metric for separability, coupling measures from Design Mapping Matrix (DMM) research are applied. This work provides the foundation for improving computer-aided engineering tools to efficiently handle modular processes while considering the reshaped information distribution.

**Keywords**: Process Design, Industry 4.0, AAS, DEXPI, Modular Plants

## INTRODUCTION

The chemical and fine chemical industry has an increased need for shorter times to market [1]. One approach to address this challenge is the utilization of modular plants [2]. In this context, the chemical process is divided into sub-functions, each provided by a Process Equipment Assembly (PEA). PEAs may be engineered prior to or in parallel with process development. As detailed PEA engineering is performed independently by the manufacturer, process-specific requirements are reduced to selecting an appropriate PEA topology.

This approach results in a significant knowledge shift compared to traditional monolithic plants. In monolithic plants, most of the knowledge about the chemical process, its operating conditions, recipes, operation, and detailed plant engineering is centralized within a single organization, often supported by service providers [3]. In modular plants, this knowledge is distributed among different parties, each specialized in a specific domain. [4] introduced a philosophy that represents this changed knowledge distribution and its functional implications as a key approach for efficient data management in modular plants. This philosophy is known as the Product-Process-Resource (PPR) model. Building on this concept, the model has since then been extended with additional requirements[5][4], [5], [6], [7].

Because the different domains represented in the PPR model must interact and exchange information, efficient and standardized information exchange is a key factor in realizing the advantages promised by the modular plant approach [8], [9]. For instance, VDI/VDE/NAMUR 2658 [10] introduced the Module Type Package (MTP) as a standardized, machine-readable exchange format that enables rapid integration of PEAs into the Process Orchestration Layer (POL) of a modular plant. The MTP was specifically designed to address a particular information exchange requirement.

In addition, further standards exist that were not specifically developed for modular plants but can

nevertheless contribute to the need for standardized, machine-readable information exchange. [11] demonstrated the application of the Data Exchange in the Process Industry (DEXPI Plant & Process) standard [12] in the context of modular plants. Furthermore, it showed that a piping and instrumentation diagram (P&ID) modeled using DEXPI Plant can be successfully transferred to an MTP representation [11]. Furthermore, [9] demonstrated that interlinked information between DEXPI Plant and OntoCAPE [13] can support modular plant design within the context of the PPR model.

This work aims to provide a structured overview of how existing information models contribute to defined requirements derived from the PPR model. The overview supports the future development of machine-readable information exchange throughout the engineering and operation of modular plants. To enable systematic mapping, only information models that provide a sufficiently high level of abstraction to allow allocation within the PPR model are considered. At the same time, the evaluated information models are required to offer a technical specification that is detailed enough to enable matching at the class level.

## PRODUCT PROCESS RESOURCE MODEL

In [4] the authors describe the structure of a digital twin for the process industry from a user-oriented perspective. They identify several data models that play an important role throughout the lifecycle of a chemical process plant. The authors argue that a plant-independent description level is a prerequisite for the effective use of digital twins and for the efficient and effective design of new production methods and processes [4]. To address this, the digital twin is structured into partial models that can be created and maintained by different disciplines, departments, and organizations. Overall, the digital twin is subdivided into six models:

- **Product model:** Contains information about the intended product.
- **Process model**: Contains information about thermodynamic, chemical, physical, and control-engineering relationships.
- **Resource model:** Contains information about the mechanical functionality and operational attributes of the plant and equipment structure.
- **Transformation model:** Contains product-related information about requirements for process control as well as individual transformation and separation steps. It is derived by combining the product and process models.
- **Capabilities model:** Contains plant-related information about the capability of equipment to perform specific process-engineering operations, including static and dynamic parameters. It is derived by combining the process and the resource models.
- **Operation model**: Contains information about optimized operating parameters and recipes to enable optimized production scenarios. It is derived by combining the transformation and capabilities models.

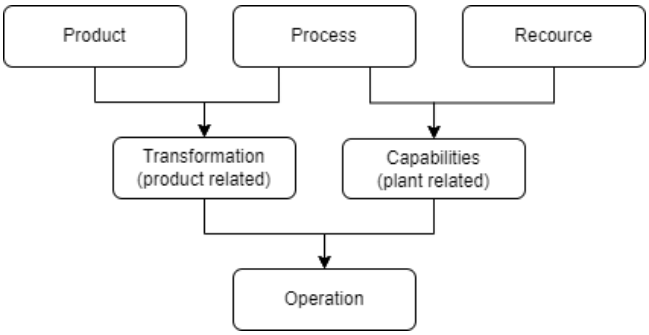

**Figure 1.** Visualization of the proposed Digital Twin structure according to the PPR-Model by [4].

In [5] several general challenges arising from this structure are highlighted, including:

- quality assurance and specification of simulation models,
- open and standardized interfaces,
- simulation and optimization algorithms that consider intellectual property (IP) issues, and
- model structuring and semantic description as key research and development challenges.

In the following section, requirements resulting from the different disciplines utilizing the model are summarized.

### Product Model

The product model encompasses information related to the properties and specifications of chemical components and products. It contains component- and substance-specific properties, including physical properties of component mixtures and detailed product specifications [4] [5]. In addition, the product model incorporates specifications and data sheets [14] and provides information on product and component storability, safety- and transport-related requirements, as well as application and sales aspects [4].

### Process Model

The process model contains information on thermodynamic, chemical, and physical engineering relationships, such as material transport coefficients and

reaction kinetics [4]. It further provides the information required for use in process simulation environments and includes the equations employed for process modeling and analysis [4], [5].

### Resources Model

The resource model represents equipment-related information of the production system. It models attributes and characteristics of equipment, including properties specific to mobile equipment, and provides a structured description of equipment-related characteristics relevant for plant operation and engineering [4], [5]. In addition, the resource model includes a comprehensive list of equipment elements forming the plant structure [8].

### Transformation Model

The transformation model contains equipment-independent information describing the production process. This includes laboratory measurement data, equipment-independent simulation models, and conceptual design knowledge related to the process [5], [8]. Furthermore, the transformation model captures key process characteristics such as residence times, throughputs, and risk potentials [4]. It also defines the capability requirements that must be fulfilled by the corresponding capabilities model [9].

### Capabilities Model

The capabilities model describes plant-related information characterizing the ability of equipment to perform specific process-engineering operations. It includes stationary and dynamic parameters of a largely product-independent process plant, as well as capabilities resulting from the boundary conditions of the employed equipment [4]. In addition, the model captures material property parameters of the equipment and provides operational and behavioral information, including aspects of automation [5] [14]. Technical operating limits, such as maximum and minimum values for temperature, pressure, and viscosity, are also represented within the capabilities model [14].

## Operation Model

The operation model addresses the execution and optimization of plant operation. It includes the modeling of recipes, as well as the monitoring and execution of operational procedures [15]. Furthermore, the model supports plant and PEA configuration and captures optimized process parameters to enable efficient and stable operation of the production system [4], [15].

# SELECTED INFORMATION MODELS

The evaluated information models are selected based on the stated criteria. Specifically, the selected models:

- provide a detailed and formally defined specification,
- exhibit a level of abstraction that allows concrete allocation to aspects of the PPR model,
- support technical implementation through machine-readable or formally specified structures, and
- classes are excluded that serve only internal or structural purposes of the model (e.g., datatype definitions), as these do not contribute directly to fulfilling PPR submodel requirements.

For example, the Asset Administration Shell (AAS) submodel *Handover Documentation* is capable of describing common document types and can therefore be applied across multiple PPR submodels. In contrast, the AAS submodel *Carbon Footprint* models calculation methods in a descriptive form (e.g., as strings) and can thus be concretely allocated to a specific PPR submodel, such as the *Product* submodel.

## DEXPI Plant & DEXPI Process

DEXPI aims to provide a general method for data exchange, interoperability, and data integration covering all lifecycle phases of (petro-)chemical plants, from functional specification to operation. It seeks to avoid format conversions and data loss across CAE system boundaries, enable efficient project handover, reduce barriers between different CAE systems, support long-term storage in CAE-independent formats, and facilitate the coexistence of multiple engineering systems within an organization.[16]

The DEXPI Specification includes the DEXPI Plant and the DEXPI Process Model. DEXPI Plant represents plant engineering information and associated graphical representations e.g. Piping and Instrumentation Diagrams (P&ID). DEXPI Process represents chemical processes and associated graphical representations e.g. Block Flow Diagrams (BFD).

## AAS Submodels

The Carbon Footprint submodel template supports the exchange of an asset's carbon footprint along the value chain to improve interoperability between stakeholders involved in documenting, evaluating, or optimizing environmental impacts. While it may contribute to initiatives such as the Digital Product Passport or Product Environmental Footprint. [17]

The Digital Nameplate submodel template provides interoperable asset nameplate information for Asset Administration Shells by defining standardized properties, ideally aligned with dictionaries such as ECLASS and the IEC Common Data Dictionary. It establishes a

standardized digital nameplate structure for process industry and factory automation equipment, while allowing application-specific extensions through supplementary submodel templates. [18]

The Functional Safety submodel defines a structured engineering data model for safety-relevant devices to support functional safety and reliability assessments in the design of safety control systems and related applications. Its intended benefits include reducing data-mapping effort, optimizing information exchange with engineering tools, supporting safety-oriented product selection, and enabling globally accessible, consistent product data independent of country, language, or culture. [19]

### Module Type Package

The Module Type Package (MTP) provides a vendor-independent description interface for the automation interface of a Process Equipment Assembly (PEA). It includes descriptions of the human–machine interface (HMI), available services, procedures, and configuration parameters, as well as IP addresses and OPC UA nodes and their relations to data objects defined in VDI/VDE/NAMUR 2658 [10].

### OntoCape

OntoCAPE is a large-scale ontology for the domain of Computer-Aided Process Engineering (CAPE), represented in a formal, machine-interpretable ontology language. It captures consensual process-engineering knowledge in a generic and reusable form, enabling knowledge sharing across software systems and supporting advanced engineering applications such as simulation model management, design data integration, electronic procurement, and mathematical modeling. [20]

### Metadata4Ing Ontology

One of the main goals of the Metadata4Ing ontology is to enable documentation of data and material provenance in research processes. It is based on a generalized process model centered on the *processing step* class, in which data and material objects are represented as outputs, while methods, tools, and other contextual information are linked via dedicated classes, allowing complex research processes to be described through compositions of processing steps. [21]

## METHODOLOGY

To achieve a transparent evaluation of various technically implemented standards with respect to an abstract philosophy representing general knowledge distribution, a multi-step methodology is applied. First, a literature review is conducted to identify suitable information models. This review focuses on standards that (i) provide a formal technical specification, (ii) exhibit an active community or documented update history, and (iii) are sufficiently mature to support practical application.

To operationalize the PPR model, a second literature review is performed to identify requirements specific to the individual PPR submodels. Based on these requirements, a mapping matrix is constructed that relates each identified PPR submodel requirement to every specified class within the selected information models. This fine-grained level of detail enables a direct connection between the technical implementation of an information model and the abstract structure of the PPR model.

The generation and evaluation of the mapping matrices are performed automatically. The assessment of whether a given class contributes to a specific requirement is carried out manually using a binary (true/false) decision. To simplify the evaluation process, the assumption is made that if a superclass within an information model satisfies a requirement, all its' subordinate classes do so as well. The resulting matrices are then evaluated automatically. To account for differing numbers of classes across PPR submodels, the results are normalized accordingly. This normalization enables a comparative allocation of each standard to the respective PPR submodels.

The Python scripts used for generating and evaluating the matrices, as well as the completed matrices themselves, are provided in the accompanying GitHub repository https://github.com/p2o-lab/-ESCAPE-36-Domain-Mapping-Matrices-supplementary-information. Finally, the results are analyzed and discussed in detail.

## DMM INTRODUCTION

To evaluate technically implemented classes against PPR submodel requirements, the Design Matrix Methodology (DMM) is adapted [22] [23]. To provide a structured overview of the suitability of the investigated information models for fulfilling PPR submodel requirements, a matrix-based evaluation is conducted for each combination of PPR submodel and information model.

In each matrix, the PPR submodel requirements are represented by the rows, while the classes of the respective information model form the columns. Each requirement–class combination is assigned a value of 0 if the class description does not contribute to fulfilling the requirement, or a value of 1 if it does. If no meaningful assignment is possible, the corresponding cell is left empty and excluded from the evaluation. This reflects the assumption that the implementation of a requirement does not necessitate the use of all available classes within an information model.

For each requirement, the assigned values are aggregated and normalized by the number of evaluated entries. This results in a representation in which, for each PPR submodel, a table is obtained where the rows

correspond to the requirements and the columns represent the normalized degree to which each information model satisfies the respective requirement. In the subsequent step, the mean value across all requirements of a PPR submodel is calculated. This yields a single value between 0 and 1 that describes the overall suitability of an information model to fulfill the requirements of that PPR submodel. A visualization is provided in Figure 2.

## RESULTS

**Figure 3** presents the outcome of the cross-dimensional coverage analysis as an overall heatmap. A higher value represents a better matching between the specification and the PPR-Submodel requirements. The rows correspond to the considered PPR-related concepts (Product, Process, Resource, Transformation, Capability, Operation), while the columns represent the analyzed standards and information models (OntoCAPE, AAS Carbon Footprint, DEXPI Process, MTP, DEXPI Plant, AAS Digital Nameplate, AAS Functional Safety, metadata ing classes). All values are normalized to the interval [0, 1] and express the relative degree to which a given model explicitly addresses a specific concept.

OntoCAPE achieves the highest overall coverage across all evaluated dimensions. In particular, strong scores are observed for Capability (1.000), as well as consistently high values for Product, Resource, and Operation (each 0.750) and Transformation (0.714). This indicates a broad and balanced semantic scope with respect to the PPR model.

The AAS Carbon Footprint submodel shows a pronounced focus on the Process dimension (1.000), with moderate coverage of Product and Transformation (0.500 each). All remaining dimensions exhibit negligible or zero coverage.

DEXPI Process demonstrates high alignment with Process (0.800) and Transformation (0.667). Product and Resource are only partially covered, while Capability and Operation are not explicitly represented.

The Module Type Package (MTP) model exhibits strong coverage for Capability (0.818) and Operation (0.750). Other PPR dimensions, including Product, Process, and Resource, are largely not addressed.

DEXPI Plant shows its highest relevance for Transformation (0.667) and Capability (0.600), with lower coverage for Operation (0.250). Product- and process-oriented aspects are only marginally represented.

The AAS Digital Nameplate submodel is strongly associated with Resource (1.000) and shows moderate relevance for Capability (0.400). All other dimensions show no explicit coverage.

The AAS Functional Safety submodel exhibits selective coverage, mainly for Capability (0.600) and Operation (0.250), while other PPR dimensions remain unaddressed.

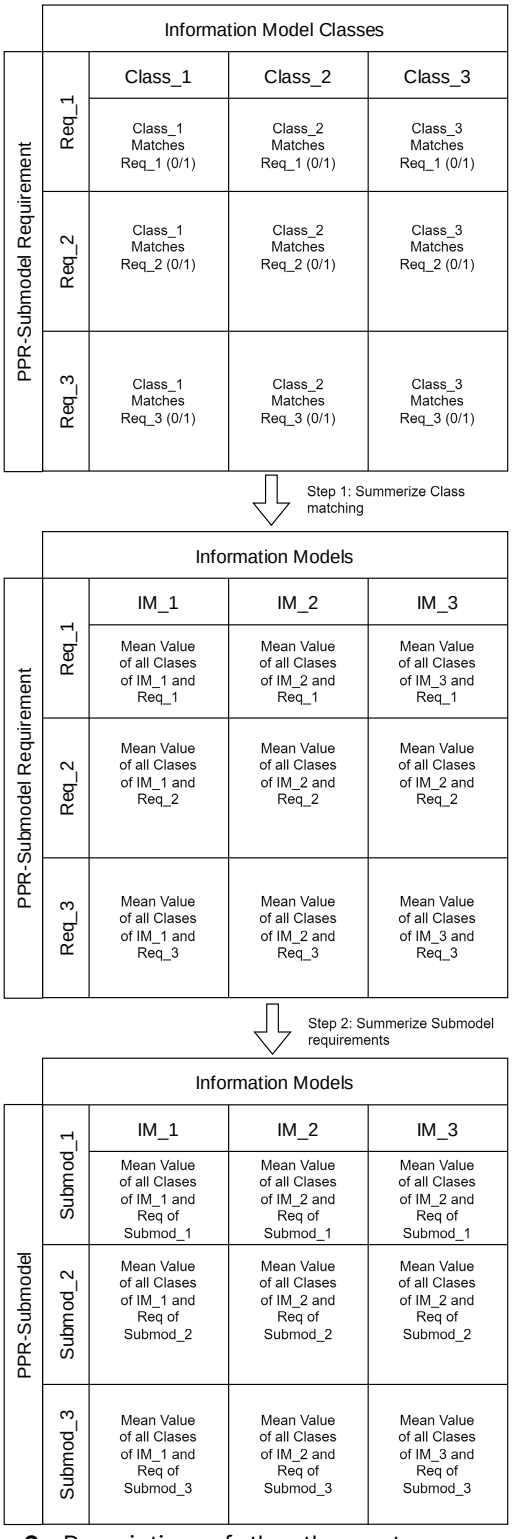

**Figure 2.** Description of the three step process to evaluate the information matching results. The corresponding data and code is available under https://github.com/p2o-lab/-ESCAPE-36-Domain-Mapping-Matrices-supplementary-information

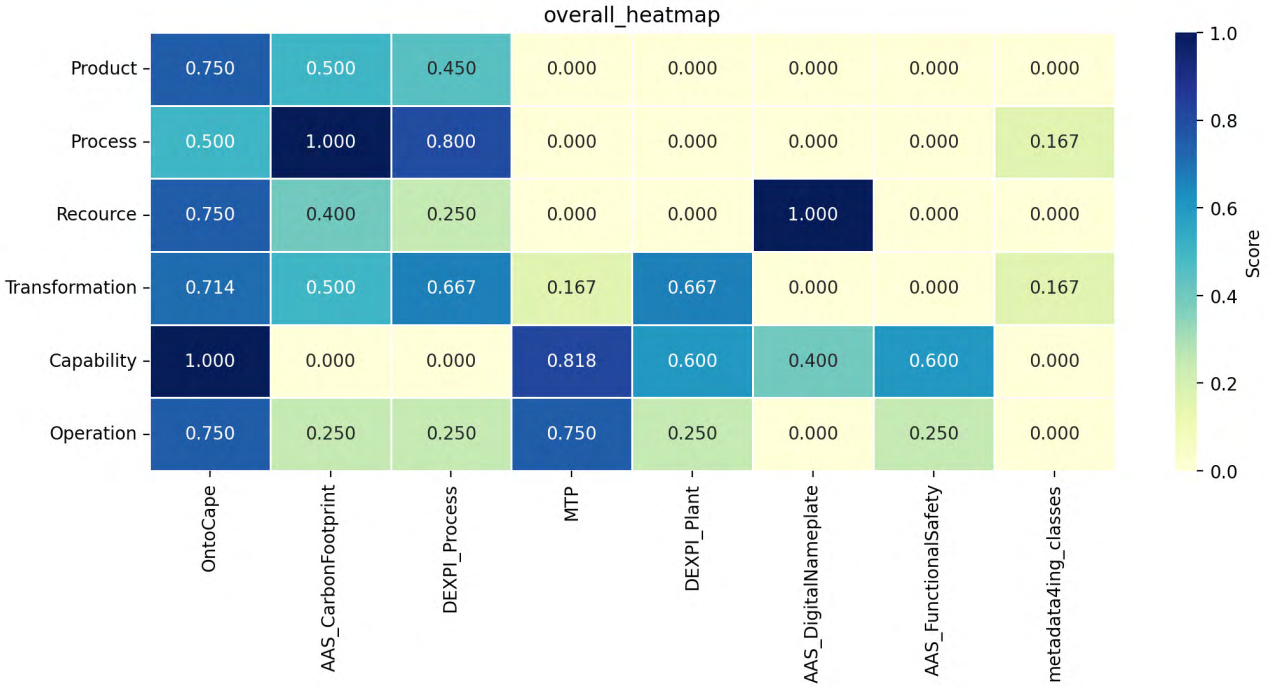

**Figure 3.** Heatmap of the cross dimensional analysis of the specified standards to the PPR-Model. A higher value represents a better matching between the specification and the PPR-Submodel requirements

Finally, the Metadata4Ing classes show only minimal coverage, primarily for Process and Transformation (0.167 each), indicating a limited contribution to explicit PPR modeling.

## DISCUSSION & OUTLOOK

The results highlight a clear differentiation between conceptually comprehensive ontologies and practically oriented engineering standards. OntoCAPE stands out with the most complete and balanced coverage across all PPR dimensions, underscoring its strength as a reference ontology from a semantic modeling perspective. However, this result must be interpreted with caution: OntoCAPE has not undergone a major specification update since 2009 and, to date, lacks documented large-scale industrial or production-level deployments. Its high scores therefore reflect conceptual expressiveness rather than validated applicability in current modular plant engineering practices.

In contrast, standards such as DEXPI, MTP, and the various AAS submodels exhibit narrower but more focused coverage profiles. DEXPI Process and DEXPI Plant emphasize process execution and plant structure, respectively, while MTP concentrates on capabilities and operations required for modular automation and orchestration. The AAS submodels further describe asset-centric, safety-related, or sustainability-related concerns. Although none of these standards individually achieve comprehensive PPR coverage, they are actively maintained and have demonstrable relevance in industrial contexts.

The limited coverage of the Metadata4ing classes reinforce their role as generic framework and metadata structure rather than as domain-specific engineering model. They are well suited to complement other standards by providing traceability and documentation capabilities, but they cannot substitute detailed PPR semantics.

Overall, the analysis reveals a trade-off between semantic completeness and practical adoption. While OntoCAPE provides a rich conceptual foundation, its limited real-world uptake constrains its immediate applicability. Conversely, industrial standards offer pragmatic, implementation-ready solutions at the cost of reduced semantic breadth. These findings support the need for a combined modeling approach in modular plant engineering, in which actively used standards are combined for expressiveness, maintainability, and industrial relevance.

In the next steps, interfaces between the individual models can be evaluated according to their allocation within the PPR model, and the foundation for computer-aided tools suitable for the modular plant approach can be further substantiated.

## ABSTRACT

A flexible start-stop operating policy that involves full shut-down and start-up may be beneficial for electrified plants under certain grid conditions, such as dispatchable demand response. This paper introduces a multi-period Hamilton-Jacobi reachability framework to explore the space of state trajectories for plant shut-down and start-up. Shut-down is defined in terms of operations leading to a stand-by state with no material flows or energy inputs, and variables within safety constraints. Candidate stand-by states are identified by constructing backwards reachability tubes from the desired steady-state operating point. The candidate shut-down/stand-by state is partitioned in fast and slow regions. Admissible control input trajectories are determined for the fast region, from which the minimum time trajectory is selected as optimal for fast start-up. A proof-of-concept simulation using a reaction/separation/recycle plant is presented.

**Keywords**: Plant Start-up, Process Electrification, Hamilton-Jacobi Reachability, Optimal Control

## INTRODUCTION

Electrified processing and, in particular, electrified process heating offer new opportunities for the precise delivery of process energy, enabling faster, smaller, safer, and more efficient processes [1]. Operational flexibility is critically important for electrified processes. With a growing share of electricity generation from renewable sources, characterized by inherent temporal variability, and rapidly increasing demand from large electricity users such as data centers, plants with large electricity loads should have the capability to modulate power consumption in response to grid conditions and (ideally) benefit economically from doing so [1-2]. Modulation typically consists of temporary decreases or increases in production rates when electricity prices are high or low, respectively, as in price-driven demand response; flexible start-stop operation extends this idea, potentially allowing plants to take further advantage of incentive-driven demand side management such as interruptible power [3].

The start-stop operation of a chemical plant is a transient mode of operation that uses start-up and shut-down procedures to temporarily interrupt and (eventually) restart continuous production [3, 4, 5, 6]. Shut-down involves transitioning the plant from the nominal operating state to a passive stand-by state without process (material and energy) flows (and likely without control input). Start-up consists of transitions from the stand-by state back to the nominal state under safety and operability constraints by restarting process flow and control [5, 6]. For continuous processes, such events are typically rare and restricted to maintenance or emergency situations. The loss of production over the start-stop period, high energy requirements to restart process units (e.g., staged units such as distillation columns) and long start-up durations are costly. Nevertheless, fast start-stop operations (where the cycle occurs over a time interval that is relevant to daily fluctuations in electricity prices) could have substantial benefits [1, 2].

Motivated by the above, the contribution of this work is to develop an analysis framework for start-stop operations based on Hamilton-Jacobi reachability. We are specifically interested in describing the “stopped/stand-by” state that meets the above conditions and results in the fastest startup and restoration of the nominal operating state. A case study on the start-up of a simple reactor/separation/recycle process illustrates

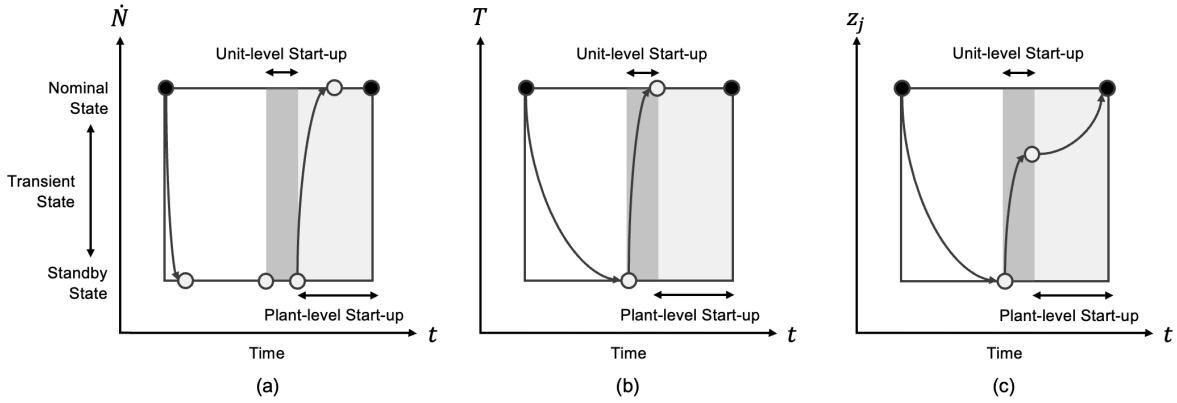

**Figure 1.** Schematic of the state trajectories for the (a) flow rate, (b) temperature, (c) composition for component *j* over a full shut-down and start-up cycle. The white region signifies the shut-down and stand-by period, the dark gray region the feed ramp-up start-up period, and the light gray region the composition control start-up period. The temperature is restored to its nominal operating state quickly followed by the flow rate, while the composition is the slowest.

the framework.

## PLANT START-STOP OPERATIONS

Plant *start-stop* operations define a full shut-down to start-up cycle where the plant temporarily stops material and energy flow. To guide the discussion, the state trajectories of the flow, temperature, and composition variables are shown in Figure 1 for the full cycle. We define the following cycle periods:

*Shut-down:* starting from nominal steady-state operating conditions, the plant stops production by closing feed and product streams. The closed plant gradually shuts interconnections between individual units (or subsystems).

*Stand-by:* individual units operate as autonomous closed systems without control action. The state derivatives are near zero and the holdup is at a near constant value. Control inputs are disabled and units are not interconnected. Material holdup is redistributed due to pressure and/or temperature gradients, resulting in changes in internal flow traffic such as draining in staged systems, pressure losses, or backmixing due to condensation. Energy is lost in the form of passive cooling from heat dissipation. The longer the standby period, the farther each sub-system drifts from the nominal steady-state operating point.

*Unit-level Start-up:* each unit starts up individually, similar to a batch operation, as their control inputs are reactivated. Their state progresses towards an intermediary (local) operating point that precedes plant-wide interconnection. This period ends when the slowest unit reaches its local operating point.

*Plant-level Start-up:* interconnections are re-established between local sub-systems to form the global system. Feed and product streams are re-introduced as well as feedback interconnections, such as recycle loops. The plant returns to the nominal steady-state driven by the manipulated variables, as dictated by a control system and/or operator inputs. The full shut-down-startup cycle is complete once the system returns to its nominal steady-state. It is assumed that the steps taken in the start-up and shut-down procedures are known (i.e., we are not attempting to devise new procedures).

## CONCEPT: REACHABILITY FRAMEWORK

Efficient and timely start-stop operations depend on finding a (set of) plant state(s) that meet the description of the stand-by state, and for which feasible trajectories exist to and from the nominal operating state.

Hamilton-Jacobi (HJ) reachability analysis [8, 9, 10] is a powerful global method to explore all possible paths between two operating points, that satisfy system constraints. It comprises of formulating a forward or backward problem that derives feasible state trajectories over a finite time horizon, subject to an admissible control input trajectory. The forward problem maps all reachable final states from an initial state. The backward problem starts from the target set and maps the set of all initial states that reach the target, which is termed as the attraction basin. For start-stop operations, we formulate the backward reachability problem as the target operating state (i.e., the nominal state), which is known *a priori*.

On a related note, HJ backward reachability is closely related to minimum-time optimal control. There may exist an initial state and some admissible control

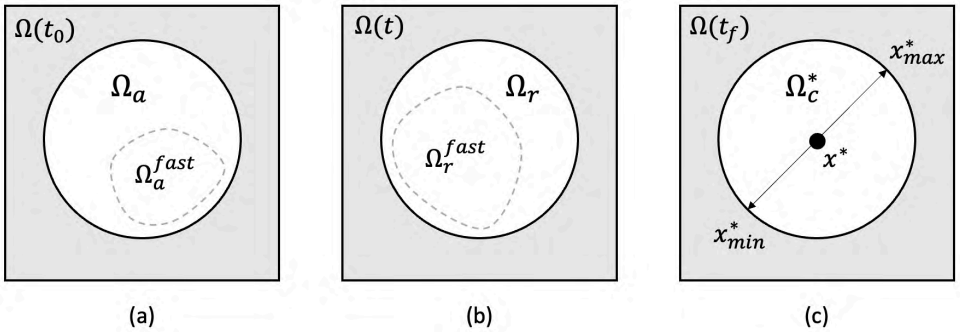

**Figure 2.** Plant abstract operating space $\Omega$ cross-sections for (a) the attraction basin $\Omega_a$ with fast region $\Omega_a^{fast}$ at initial time $t_0$, (b) the reachable set $\Omega_r$ with fast region $\Omega_r^{fast}$ at some intermediate time $t$ , and (c) the capture basin $\Omega_c^*$ at terminal time $t_f$ containing the target set $x^*$.

trajectory that reaches the target set the fastest. For plant-wide start-up, we aim to identify this path.

## MATHEMATICAL FORMULATION

### Plant Network Dynamics

Consider a plant with $i = 1, \dots, N_{units}$ process units, where each unit has state variables $x \in \mathbb{R}^m$ in the vector $\mathbf{x}$ and control inputs $u \in \mathbb{R}^p$ in the vector $\mathbf{u}$ given by:

$$\dot{\mathbf{x}}(t) = f(\mathbf{x}, \mathbf{u}, t) \tag{1}$$

over the finite time horizon $t: [t_0, t_f]$, where $t_0$ and $t_f$ represent the initial and final times, respectively. $x$ and $u$ have operability constraints $x_{min} \le x \le x_{max}$ and $u_{min} \le u(t) \le u_{max}$, which are valid for all time [11, 12]. The maximum allowable time horizon $\tau$ satisfies $\tau \ge t_f - t_0$. The state trajectory $\phi$ is defined as:

$$x(t) = \phi(t, t_0, x_0; u(t)) \tag{2}$$

while $u$ has an admissible control trajectory $\phi^{\mathrm{u}}$:

$$u(t) = \phi^u(t, t_0, u_0; x(t)) \tag{3}$$

The plant network is a collection of process units with a set of state variables $\Omega = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_{N_{units}}]^T \in \mathbb{R}^{N_{units} \times m}$ and set of control inputs $\Omega^{\mathrm{u}} = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_{N_{units}}]^T \in \mathbb{R}^{N_{units} \times p}$:

$$\dot{\Omega}(t) = (I \bigotimes A + \gamma(t) \bigotimes \zeta(t))\Omega(t) + (I \bigotimes B)\Omega^{\mathrm{u}}(t) \tag{4}$$

where $A \in \mathbb{R}^{m \times m}$ is a state matrix, $\gamma(t) \in \mathbb{R}^{N_{units} \times N_{units}}$ is a graph Laplacian matrix defining the connectivity of the network topology, $\zeta(t) \in \mathbb{R}^{m \times m}$ is a coupling matrix between the state variables of connected process units, $B$ is a control input matrix, and $I$ is the identity matrix, all of appropriate dimensions.

Equivalently, the plant state trajectory $\Phi \in \mathbb{R}^{N_{units} \times m}$ is defined as:

$$\Omega(t) = \Phi(t, t_0, \Omega(t_0); \Omega^{\mathrm{u}}) \tag{5}$$

where $\Omega(t_0)$ is the set of initial states for all state variables. $\Omega^{\mathrm{u}}$ has an admissible plant control trajectory $\Phi^{\mathrm{u}}$:

$$\Omega^u(t) = \Phi^u(t, t_0, \Omega^u(t_0); \Omega(t)) \tag{6}$$

### Backward Reachability

$\Omega^*$ is a target steady-state operating region that consists of a subset of target state variables $x^*$ subject to production and quality constraints $x^*_{min} \le x^* \le x^*_{max} \in \mathbb{R}^m$ (Figure 2c). The capture basin $\Omega_c^*$ is the region of state space enclosing $x^*$ such that $x^* \in \Omega_c^*$. It is implied that $\Omega_c^*$ is a terminal condition that is reached at $t = t_f$ such that $\Omega_c^* \subset \Omega(t_f)$. It is also assumed that $x^*$ exists on a stable equilibrium manifold.

A state $\Omega(t_0)$ is backward reachable from $\Omega_c^*$ if there exists an admissible control trajectory $\Phi^{\mathrm{u}}$ such that the state trajectory $\Phi$ reaches $\Omega_c^*$ within the finite time horizon satisfying $\tau \ge t_f - t_0$. The attraction basin $\Omega_a(t_0, \Omega(t_0))$ (Figure 2a) consists of the set of initial states that are backward reachable.

$\Omega_a$ can be extended to become a backward reachability tube $\mathcal{B}$ (Figure 3), which is defined as the collection of $\Omega_a$ for some intermediate time on the interval $[t_0, t_f]$ that reaches $x^*$:

$$\mathcal{B} = \bigcup_{t \in [t_0, t_f]} \Omega_a(t, \Omega^*) \times \{t\} \tag{7}$$

For each $\Omega_a \in \mathcal{B}$, the mapping from $\Omega_a$ to $\Omega_c^*$ contains a set of admissible state and control trajectories that span a range of reachable states $\Omega_r(t, t_0, \mathcal{B})$ (Figure 2b) within the operable state space. The reachable space $\Omega_r$ over $\tau$ is therefore:

$$\Omega_r(\Omega(t_0)) = \bigcup_{t \in [t_0, t_f]} \mathcal{B}(t, t_0) \tag{8}$$

which implies $\Omega_r \subseteq \Omega$.

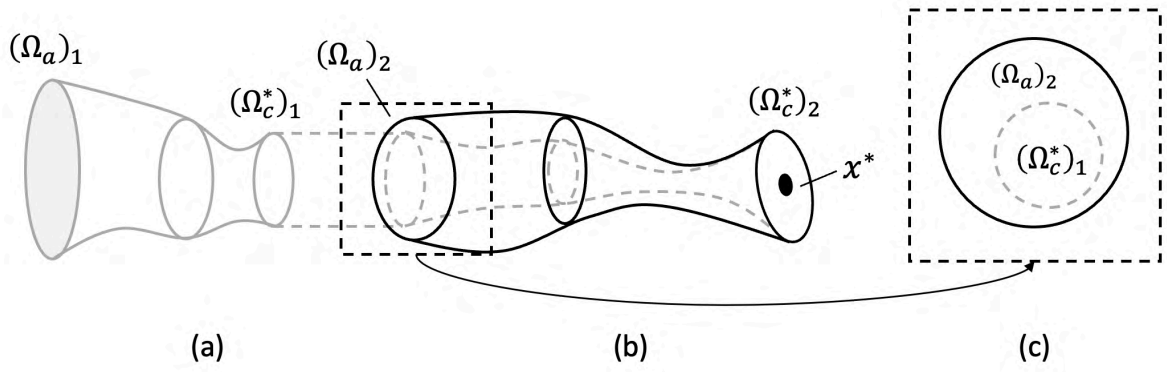

**Figure 3.** The backward reachability tube $\mathcal{B}$ for (a) $\mathcal{B}_1$ feed ramp-up start-up period (indexed by 1 and colored in gray solid lines) and (b) $\mathcal{B}_2$ composition control start-up period (indexed by 2 and black solid lines). The attraction and capture basins for each period are visible at an intermediary operating point, where the intersection between $(\Omega_a)_2$ and $(\Omega_c^*)_1$ (Equation 12), as shown in (c), forms a reachable multi-period tube (traced by the gray tube in solid lines for $\mathcal{B}_1$ and dashed lines for $\mathcal{B}_2$).

## Minimum Time Optimal Control

The backward reachability tube (BRT) is computed using Hamilton-Jacobi reachability theory. The first step is to define an implicit level set function $\Psi$ to define the proximity of the current state $x(t)$ from $x^*$ for all $x^* \in \Omega^*$:

$$\Psi = \left| x - \frac{x^*_{min}+x^*_{max}}{2} \right| - \frac{x^*_{min}-x^*_{max}}{2} \tag{9}$$

Equation 9 suggests that if $\Psi \leq 0$, then $x$ is within $\Omega_c^*$. This implies that $\Psi$ encodes $\mathcal{B}$; it is also equivalent to the value function $V$ in the constrained Hamilton-Jacobi-Bellman partial differential equation (HJB-PDE, Equation 10a) with terminal condition (Equation 10b), which computes the manipulated input trajectory that reaches the target set the fastest:

$$\frac{\partial V}{\partial t}(t,x) + \min_u \left( \nabla V(x(t),t) \cdot f(x,u,t) \right) = -1 \tag{10a}$$

$$V(x(t_f),t_f) = \Psi(t_f) \tag{10b}$$

The optimal admissible control trajectory for each possible initial state $x(t_0)$ can be derived from Equation 10 for minimum time:

$$u^*(t,x) = \underset{u}{\operatorname{argmin}} \left( \nabla V(x(t),t) \cdot f(x,u,t) \right) \tag{11}$$

which is measured by the reachability time $\tau^*$ for each initial state given $u^*$, where $\tau^* \leq \tau$ and is defined as the time interval for a trajectory to reach $\Omega_c^*$ from some initial state. The $u^*$ for each process unit constitutes the set $\Omega^u$.

After $V$ is computed, the BRT may be partitioned between fast and slow regions based on the reachability time $\tau^*$. The smallest $\tau^*$ corresponds to the fastest start-up time. As such, the initial state $\Omega(t_0)$ lying within the fast region of $\Omega_a$, denoted by $\Omega_a^{fast}$, and its corresponding minimum-time control trajectory $\Omega^u$ with the fastest state trajectory $\Omega$ is equivalent to the minimum-time optimal control solution.

## Multi-Period Reachability

The above approach for one time period can be extended to multiple time periods. Discrete behavior for start-stop operations, such as alterations to the process topology (e.g. turning on specific units or enabling/disabling streams), can be split into $k = 1, \ldots, N_{period}$ periods. The connection between periods are intermediary operating points that intersect the attraction basin of the $k^{\text{th}}$ period $(\Omega_a^*)_k$ and capture basin of the $k$-1 period $(\Omega_c^*)_{k-1}$, as visualized in Figure 3c.

**Remark:** the operating spaces in Figure 2 show one step in the backward reachability for each time period $\tau_k$, as reflected in Figure 3.

$$(\Omega_c^*)_{k-1} \cap (\Omega_a^*)_k \tag{12}$$

Thus, a reachable multi-period tube assumes that the intersection in Equation 12 is non-empty, otherwise the multi-period tube does not exist.

## Start-up Reachability

Plant start-up reachability is represented by the possible backward paths from the nominal state to the stand-by state. The following framework is proposed to map reachable and optimal trajectories:

(1) Identify the region of possible stand-by states.

(2) From the nominal steady state, identify each step in the operating sequence and their intermediary operating points based on where discrete behavior arises (Figure 3b). Examples are feed ramp-up or turning on control valves.

(3) Validate the connectivity between time periods based on Equation 12 (Figure 3c) to fully trace the $\mathcal{B}$ from the desired/target state. Work backwards until reaching the initial start-up state, which corresponds to the final stand-by state. The state derivatives are near zero and the holdup is at a constant value. Control inputs are disabled and units are not interconnected.

(4) Determine where the region of possible stand-by states in Step (1) intersect with $(\Omega_a)_1$, as depicted in in Figure 3a. This is the region in the state space that is the most favorable stand-by region for fast start/stop operation where there exists fast and slow regions.

(5) Identify the fast and slow regions based on the total time to reach steady-state from the grid of all feasible initial conditions (Figure 2a) for each time period. The full start-up time is given by the sum of $\tau_k$ for each period.

## CASE STUDY

Consider a prototype reactor-recycle-separation system with purge (shown in Figure 4), similar to systems found in [13, 14]. Assume the following: the holdup is constant for all units (and, therefore, the collective plant holdup), the temperature is constant, and the energy balance is neglected. The authors recognize that this may not be fully representative of electrified processes, where it is likely that the largest use of electricity will be in the form of process heat. Nevertheless, the features highlighted here are broadly applicable.

The process has two components: A and B, where B is the desired product. The composition variables are subject to constitutive relations:

$$1 = x_{A1} + x_{B1} \tag{13}$$

$$1 = x_{A2} + x_{B2} \tag{14}$$

$x_{A1}$ and $x_{A2}$ are differential variables of component balances:

$$\frac{d}{dt}\begin{bmatrix} x_{A1} \\ x_{A2} \end{bmatrix} = \begin{bmatrix} -\frac{F_1}{N_1} - k_1 & \frac{\alpha_A R}{\beta N_1} \\ \frac{F_1}{N_2} & -\frac{F_2}{N_2} - \frac{\alpha_A F_3}{\beta N_2} \end{bmatrix} \begin{bmatrix} x_{A1} \\ x_{A2} \end{bmatrix} + \begin{bmatrix} \frac{F_0 x_{A0}}{N_1} \\ 0 \end{bmatrix} \tag{15}$$

The overall plant material balance is between the feed $F_0$, product $F_2$, and purge $P$ streams

$$F_0 = F_2 + P \tag{16}$$

$$P = \lambda F_3 \tag{17}$$

where $P$ is determined by the split ratio $\lambda$ between the vapor stream $F_3$ and the recycle stream $R$

$$R = (1 - \lambda)F_3 \tag{18}$$

$F_0$ is pure A ($x_{A0} = 1$) and mixes with $R$ (whose composition is $x_{A3}$ and $x_{B3}$). The combined stream $F_0 + R$ enters a liquid phase reactor (indexed as Unit 1) where A converts to B in an irreversible forward reaction $A \rightarrow B$.

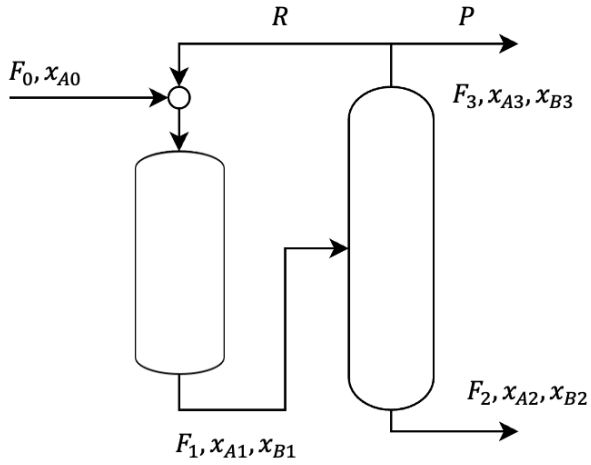

**Figure 4.** Chemical plant with a reactor, a flash drum, a recycle stream, and a purge stream.

$$\frac{d}{dt}(N_1) = 0 = F_0 + R - F_1 \tag{19}$$

The reactor outlet stream $F_1$ has composition $x_{A1}$ and $x_{B1}$, and feeds into a single stage separator (indexed as Unit 2) that splits $F_1$ into a liquid product stream $F_2$, which concentrates the desired product B, and a vapor stream $F_3$ that concentrates the unreacted A.

$$\frac{d}{dt}(N_2) = 0 = F_1 - F_2 - F_3 \tag{20}$$

The flash calculation in the separator is computed using a linearized Rachford-Rice equation, where $\alpha_A$ and $\alpha_B$ represent the relative volatility of components A and B while $\beta$ represents a phase transfer coefficient.

$$0 = \frac{x_{A2}}{(1-\alpha_A\beta^{-1})^{-1} - F_3 F_1^{-1}} + \frac{x_{B2}}{(1-\alpha_B\beta^{-1})^{-1} - F_3 F_1^{-1}} \tag{21}$$

$$\beta = \alpha_A x_{A2} + \alpha_B x_{B2} \tag{22a}$$

$$x_{A3} = \frac{\alpha_A}{\beta} \tag{22b}$$

$$x_{B3} = \frac{\alpha_B}{\beta} \tag{22c}$$

The plant start-up comprises of manipulating the split ratio $\lambda$ to control the purity of the separator product stream during the feed ramp-up and composition control periods. The goal is to identify the stand-by region that allows startup, as well as the subregion for the fastest startup. The model parameters are available in Table 1.

### Numerical Implementation

A dynamic programming approach is adopted to efficiently solve the finite horizon HJB equation. The state and time variables of Equation 10 are discretized where $x_{A1}$ in $m = 0, \ldots, N_{x_{A1}}$ grid points and $x_{A2}$ in $n = 0, \ldots, N_{x_{A2}}$ grid points. The new discrete variables are $x_{A1}^m$ and $x_{A2}^n$. The control variable $\lambda$ is discretized in $l = 0, \ldots, N_\lambda$ grid points, to form the discrete control set $\lambda^l$. Piecewise-constant controls are used, updated on an interval of $\Delta t_c$.

**Table 1:** Model parameters.

| Symbol | Parameter | Value |
|---|---|---|
| $\alpha_A$ | Relative volatility of A | 10.5 |
| $\alpha_B$ | Relative volatility of B | 3 |
| $F_0^{nom}$ | Nominal feed flow rate | 25 kmol/hr |
| $N_1$ | Reactor holdup | 50 kmol |
| $N_2$ | Drum holdup | 45 kmol |
| $k_1$ | First-order rate constant | 10 $s^{-1}$ |
| $x_{A1}$ | A mole fraction (reactor) | 0.5 |
| $x_{A2}$ | B mole fraction (drum) | 0.8 |
| $t_f$ | Time horizon | 6 hr |

## Numerical Implementation

A dynamic programming approach is adopted to efficiently solve the finite horizon HJB equation. The state and time variables of Equation 10 are discretized where $x_{A1}$ in $m = 0, \ldots, N_{x_{A1}}$ grid points and $x_{A2}$ in $n = 0, \ldots, N_{x_{A2}}$ grid points. The new discrete variables are $x_{A1}^m$ and $x_{A2}^n$. The control variable $\lambda$ is discretized in $l = 0, \ldots, N_\lambda$ grid points, to form the discrete control set $\lambda^l$. Piecewise-constant controls are used, updated on an interval of $\Delta t_c$.

The value function is defined as follows:

$$V_{nm}(t_f) = \begin{cases} 0, x \in \Omega_c^* \\ \infty, x \notin \Omega_c^* \end{cases} \quad (23)$$

There are two distinct time discretization schemes. An explicit backward Euler integration scheme for $\Delta t$ steps is applied to discretize the process dynamics:

$$\frac{dx_{A1}}{dt} = \frac{x_{A1}^{t+1} - x_{A1}^t}{\Delta t} \quad (24)$$

$$\frac{dx_{A2}}{dt} = \frac{x_{A2}^{t+1} - x_{A2}^t}{\Delta t} \quad (25)$$

and a semi-Lagrangian backward propagation scheme of the HJB equation for $\Delta t_c$ steps over the control trajectory [15].

$$V_{nm}^{t_c+1} = \min_{\lambda^l} \left[ \Delta t_c + V_{nm}^{t_c} \right] \quad (26)$$

The full $\lambda^l$ space is recursively searched for a time-optimal control $\lambda_{nm}^{l*}$:

$$\lambda_{nm}^{l*} = \operatorname{argmin}_{\lambda^l} \left[ \Delta t_c + V_{nm}^{t_c} \right] \quad (27)$$

The numerical settings are specified in Table 2. All computations were performed using Python 3.13.5 and NumPy 2.1.3. The runtime was 6 minutes.

**Table 2:** Numerical settings.

| Symbol | Parameter | Value |
|---|---|---|
| $N_{x_{A1}}$ | $x_{A1}$ grid resolution | 120 |
| $N_{x_{A2}}$ | $x_{A2}$ grid resolution | 120 |
| $\Delta t$ | Euler time step size | 0.05 |
| $\Delta t_c$ | Control time step size | 0.2 |

## Results

The purity set-point is 0.95 mol% for $x_{B2}$. Figure 5 shows the shape of the BRT (as anticipated in Figure 3a and 3b) and the intersection of the tubes for each period, tracing a full feasible BRT for start-up. Figure 6 compresses the BRT onto a 2D grid for each period.

In Figures 6a-i and 6a-ii, the attraction basin expands as the time horizon increases, implying that more initial states are reachable for longer times. Considering that the holdup is constant, the feedback from the recycle stream shows how the initial holdup composition in the reactor and separator affects the start-up length. The boundary of the attraction basin expands to more initial $x_{A2}$ states at higher initial $x_{A1}$ for a given time. While this is intuitive, we find the converse perspective more useful: the state space region that allows for fast start-up becomes narrower as the desired start-up time gets shorter.

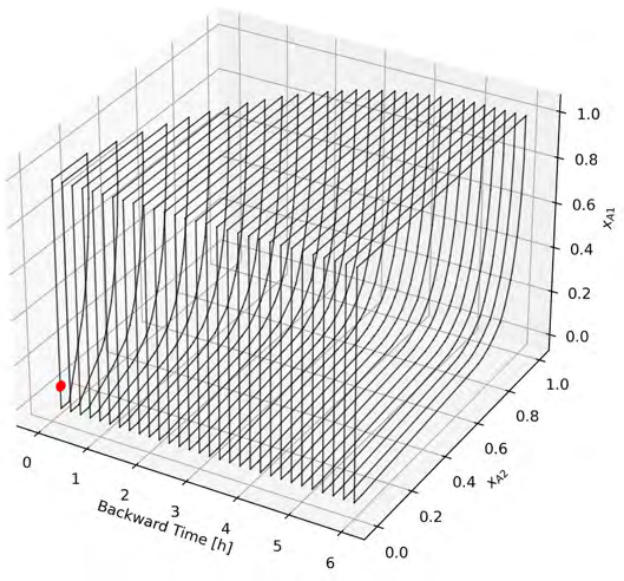

**Figure 5.** Backwards reachability tube for the start-up of the reactor-recycle-separation system. The red dot denotes the target set $x^*$.

Figures 6b-i and 6b-ii illustrate the optimal time-averaged split ratio for each initial state. Higher $x_A$ initial reactor concentrations, which are far from the nominal

state, taper towards $\lambda = 0$ and favor recycle-only operation. Purge-only operation $\lambda = 1$ is favored when $x_{A1}$ is near the target operating state. Alternative split ratios are favored over the interval $x_{A1} = [0.2, 0.5]$.

**Remark**: In Figures 5 and 6, the discretization scheme is a coarse-grained approximation of the attraction basin and set of recycle ratios, which is why the profiles have streaks along the basin boundary. A finer approximation with more grid points would generate a smoother profile but would require longer computational time.

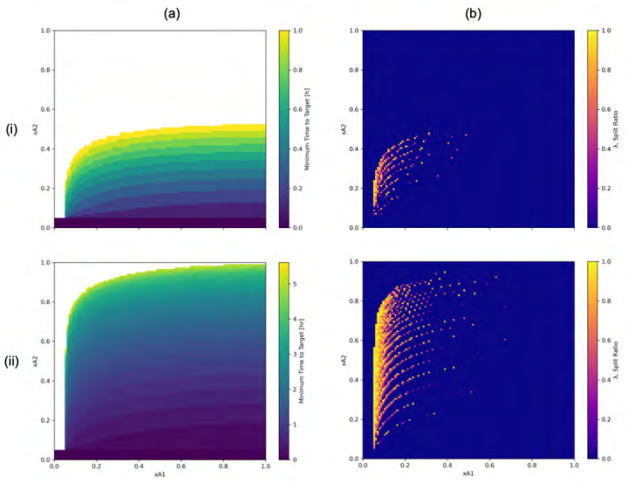

**Figure 6.** Set of (a) attraction basins and (b) optimal split ratios for (i) feed ramp-up period and (ii) composition control period.

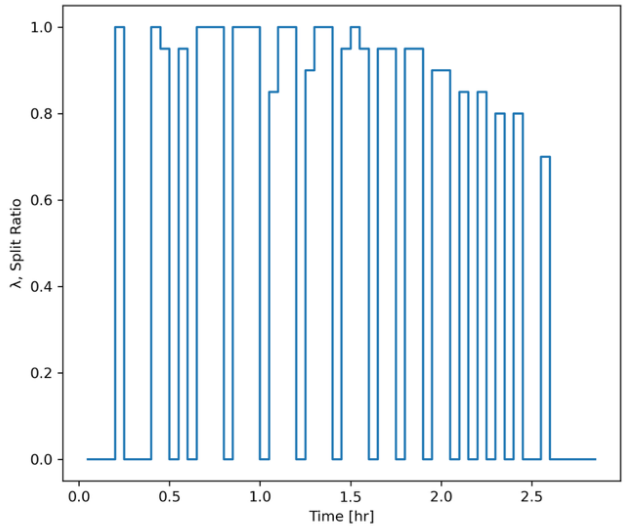

**Figure 7.** Optimal control trajectory of the split ratio during the composition control period.

From the results in Figures 5 and 6, let us consider an initial state of $[x_{A1,0} = 0.9, x_{A2,0} = 0.9]$ whose total start-up time is 2.6 hr. An optimal control trajectory for the split ratio is presented in Figure 7, where there is initially large variation until the system reaches the nominal steady state. The optimal trajectory is reflected in the black-colored trajectory on the phase portrait shown in Figure 8. Notably, state trajectories from all initial conditions converge to the same path to the capture basin. The proposed framework provides a full view of the feasible operating space under operability and finite time constraints. It is shown how the feasible state and control trajectories are systematically determined by a global exploration of the control space. Provided the shape of the BRT and its associated attraction basins, the initial state (which is, in fact, the stand-by state of the plant) has a substantial impact on the start-up speed. The ability to confine the process unit state to the fast region of an attraction basin during shut-down and stand-by has a great effect on start-up, suggesting that an interruptible operation is governed as much by its available control inputs as the ability to maintain the system state near the target conditions.

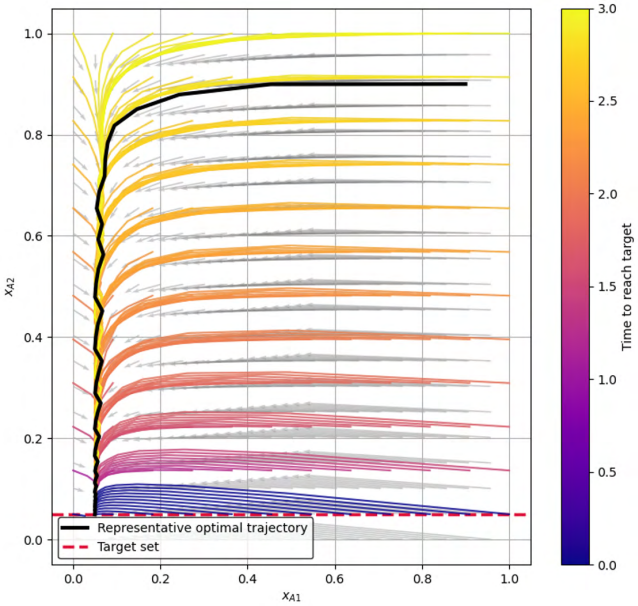

**Figure 8.** Phase portrait of control trajectories during composition control period. The black trajectory is an optimal path given the initial state ($x_{A1}$ = 0.9, $x_{A2}$ = 0.9) from stand-by.

## CONCLUSIONS AND FUTURE WORK

In this paper, a conceptual framework for analyzing start-stop operations was developed based on Hamilton-Jacobi reachability. Attraction basins were found by deriving backward reachability tubes from a target set, from which the fast region of the attraction basin was identified. Within this region, the optimal admissible control trajectory corresponding to the fastest state evolution is found. A plant start-up case study for

reactor/separation/recycle focusing solely on composition dynamics was demonstrated as a proof-of-concept. The next step is to validate the proposed framework on an industrial system with higher dimensionality.

## ABSTRACT

In this paper, PhoSim V.0, a physics-based digital twin core of a wet-process phosphoric acid (WPPA) digestion reactor, is presented as an initial step toward a high-fidelity virtual representation of industrial WPPA plants. The simulator integrates dissolution, reaction, and crystallization phenomena under strongly non-ideal electrolyte conditions. The reactor is modeled as a batch reactor, where the dissolution of tricalcium phosphate is described using a shrinking-core approach, while gypsum precipitation is represented by a one-dimensional population balance equation capturing particle size distribution evolution. Supersaturation ratios governing nucleation and crystal growth are computed from non-ideal activities using a Pitzer-based thermodynamic model, ensuring consistent coupling between dissolution, reaction stoichiometry, and crystallization kinetics. The resulting stiff system of equations is solved to predict key process indicators such as speciation, supersaturation ratio, and characteristic crystal size. Implemented within a user-friendly simulation environment, PhoSim V.0 provides a modular and extensible foundation that will be progressively refined to mimic industrial WPPA digestion units and supports future monitoring, optimization, and control-oriented applications.

**Keywords**: Digital twin, Wet-process phosphoric acid, Shrinking-core model for dissolution, Population balance modeling, Gypsum crystallization, Non-ideal thermodynamics

## INTRODUCTION

Wet-process phosphoric acid (WPPA) production is a cornerstone of the phosphate and fertilizer industries, yet it remains a highly complex process involving the strong coupling between phosphate-rock dissolution, reactions kinetics, gypsum crystallization, and thermodynamics of highly non-ideal electrolytes. The digestion reactor, typically operated as a continuous stirred-tank reactor (CSTR) at the unit scale, plays a decisive role in determining phosphoric acid yield, gypsum crystal properties, fouling behavior, and downstream filtration performance.

Reliable modeling of this unit therefore represents a critical prerequisite for process analysis, optimization, and future digitalization efforts.

Over the past years, the authors of this paper have developed an integrated modeling framework addressing the main physico-chemical phenomena governing industrial WPPA digestion.

This body of work includes first-principles process modeling and multi-criteria optimization of industrial digestion tanks [1–6], rigorous thermodynamic modeling of sulfuric–phosphoric acid systems with impurities using Pitzer-type model [7], and thermodynamic-based analysis of fouling and crystallization phenomena in WPPA [8]. In parallel, detailed gypsum crystallization models based on population balance equations have been developed and applied to industrial digestion conditions [9-11], providing quantitative information on the evolution of particle size distribution (PSD) and its operational implications.

In addition to crystallization, phosphate rock dissolution has been investigated through shrinking-core approaches, with particular emphasis on the influence of particle size distribution and dissolution mechanisms under industrial conditions [9-12]. These dissolution models have been further complemented by surrogate and

reduced-order representations to support sensitivity analysis, parameter estimability, and model-based experimental design [13-15]. Together, these contributions form a unified and internally consistent modeling foundation for WPPA digestion, with consistent thermodynamic closure and kinetically grounded sub-models.

The present work builds exclusively upon these established developments and consolidates them into PhoSim V.0, a first-generation digital twin core of the WPPA digestion reactor. Rather than introducing new sub-models, this contribution focuses on their integration within a single simulation environment, enabling time-resolved prediction of speciation, supersaturation, nucleation and growth rates, and gypsum PSD indicators. This version intentionally targets the core digestion phenomena and serves as a foundational step toward a high-fidelity digital twin capable of mimicking industrial WPPA plants.

Future developments will extend this framework toward plant-scale integration, data-driven calibration, and control-oriented applications.

## Process Description & Digital Twin Scope

### Wet-Process Phosphoric Acid Digestion

Wet-process phosphoric acid production is based on the acidulation of phosphate rock by sulfuric acid in an agitated reactor, producing phosphoric acid and calcium sulfate dihydrate (gypsum) as the principal solid by-product. The digestion step is typically operated as a continuous stirred-tank reactor (CSTR) to ensure adequate mixing between the solid phosphate particles and the acidic liquid phase. For modeling purposes, the wet-process route is represented by a two-step reaction scheme. In the first step, tricalcium phosphate (TCP) is attacked by phosphoric acid to form soluble monocalcium phosphate (MCP). In the second step, the formed MCP reacts with sulfuric acid to regenerate phosphoric acid and precipitate gypsum (Figure 1).During digestion, several strongly coupled phenomena take place simultaneously: dissolution of phosphate rock, homogeneous and heterogeneous chemical reactions in the liquid phase, and nucleation and growth of gypsum crystals. The dissolution of TCP is often governed by diffusion and reaction resistances within the solid particle, which can be described using a shrinking-core model. As dissolution progresses, calcium and phosphate species are released into the liquid phase, modifying solution speciation and supersaturation conditions, which in turn control gypsum crystallization kinetics. The resulting gypsum particle size distribution (PSD) has a direct impact on downstream filtration performance and acid losses.

The digestion environment is characterized by high ionic strength and strongly non-ideal electrolyte behavior, making activity-based thermodynamic descriptions necessary for reliable prediction of solution equilibria and supersaturation. These characteristics motivate the use of rigorous thermodynamic and process models when representing the digestion reactor.

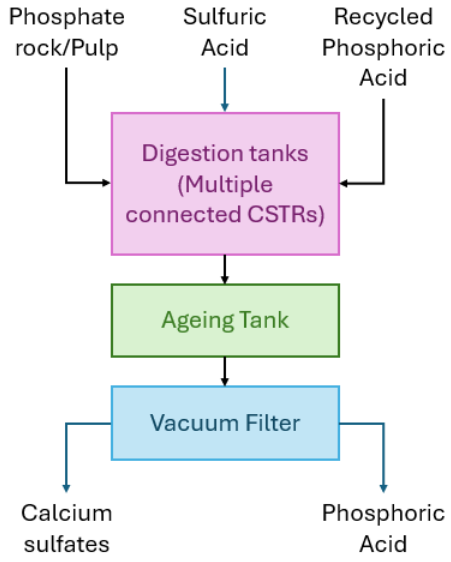

**Figure 1.** Simplified representation of the wet-process phosphoric process.

## Digital Twin Architecture

The digital twin developed in this work targets the dynamic behavior of a single Wet Phosphoric Acid (WPPA) digestion reactor operated in batch mode. The scope is deliberately restricted to the core unit operation to establish a robust, transparent, and extensible modeling framework before addressing plant-wide integration or advanced control layers. The reactor is assumed to be perfectly mixed; such that spatial gradients are neglected, while temporal variations in composition, supersaturation, and crystal population are resolved.

Figure 2 presents a high-level and simplified architecture of the digital twin, intended to illustrate the conceptual structure and data flow of the simulation code rather than its numerical or software-level implementation. At this level, the model integrates three coupled components: a shrinking-core dissolution model, a thermodynamic calculation module, and a population balance equation (PBE) for gypsum crystallization.

The simulation starts with an Inputs and Initialization block that specifies operating conditions and initial states, including the initial amounts of TCP, sulfuric acid, phosphoric acid, water, gypsum seed crystals, and temperature. These inputs define the solution composition, the initial gypsum particle size distribution (PSD), and the thermodynamic database required for activity-based calculations.

The dissolution model is based on a shrinking-core formulation and describes the progressive dissolution of

solid TCP into soluble calcium and phosphate species. At each time step, the module updates the dissolved fraction of TCP, thereby governing the availability of Monocalcium phosphate (MCP) for subsequent gypsum crystallization. The dissolution rate is influenced by the solution state, whereas feedback from crystallization on dissolution is neglected.

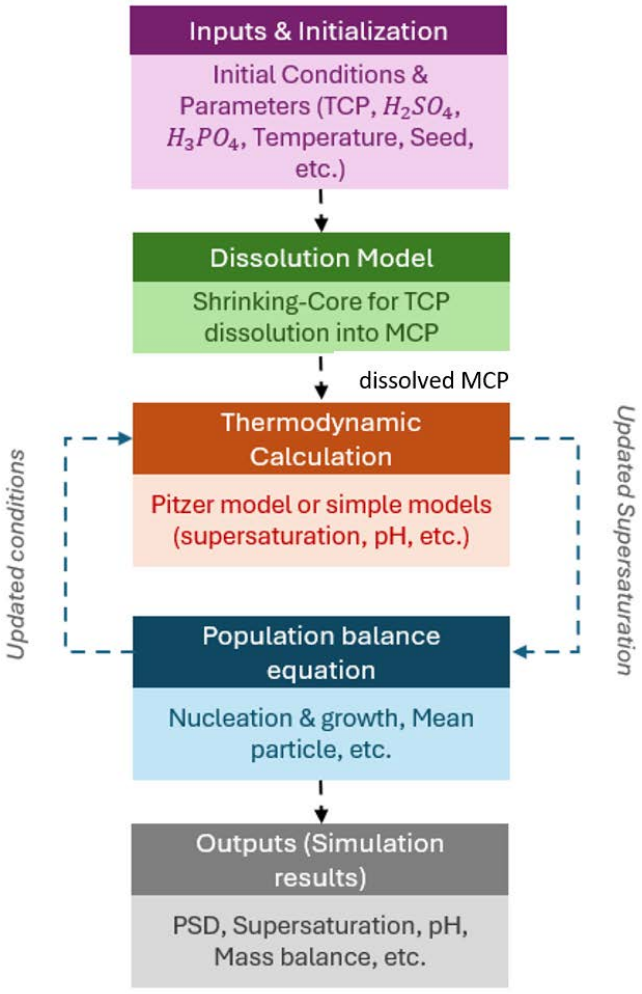

**Figure 2.** Schematic representation of the digital twin core architecture, showing the coupling between TCP dissolution, thermodynamic calculations, and gypsum crystallization via a population balance model.

The thermodynamic calculation module receives the updated solution composition and computes non-ideal solution properties, including ionic speciation, pH, and gypsum supersaturation ratio. Depending on the simulation settings, this module may rely on a rigorous Pitzer-based model or on simplified thermodynamic models. The resulting supersaturation ratio constitutes the key driving force for crystallization kinetics and is communicated to the PBE module.

The PBE describes gypsum nucleation and growth as a function of supersaturation. Solving the PBE yields the temporal evolution of the crystal size distribution (CSD), its moments (e.g. mean particle size), and the cumulative mass of precipitated gypsum. The crystallization of gypsum consumes calcium and sulfate from the liquid solution; this consumption is fed back to the thermodynamic modules to update the operating conditions.

Finally, the output block gathers both directly observable quantities and internal process states. Typical outputs include PSD metrics, supersaturation, nucleation and growth rates, speciation, and cumulative gypsum production. The digital twin core is implemented in a user-friendly simulation environment, allowing systematic variation of operating conditions, initial states, and kinetic parameters, which makes it well suited for scenario analysis, sensitivity studies, and future extensions toward optimization and control.

## MODEL FORMULATION

### Dissolution Reaction

The dissolution of TCP constitutes the first and governing step of the wet-process phosphoric acid route, as it directly determines the amount of calcium released into the liquid phase and thus available for subsequent gypsum precipitation and phosphoric acid formation. The digestion reaction considered is the acid attack of TCP by phosphoric acid, leading to the formation of MCP according to the following reaction:

$$\mathrm{Ca_3(PO_4)_2 + 4H_3PO_4 \rightarrow 3Ca(H_2PO_4)_2} \quad (1)$$

The dissolution kinetics of TCP is described using a shrinking core model, in which the solid particle progressively shrinks while maintaining a spherical shape. The model resolves mass transfer and reaction across three regions: the solid core, the surrounding liquid film, and the well-mixed liquid bulk [10-14]. The dissolution rate is expressed in terms of the temporal decrease in particle radius (or equivalently particle mass), written as:

$$\frac{dX}{dt} = \frac{3M_{\mathrm{TCP}}D_M}{x_{\mathrm{TCP}}R_0\delta\rho_s}(1-X)^{2/3}\left(C_M|_{r=R} - C'_M\right) \quad (2)$$

with $X(0) = 0, R_0$ the initial particle radius, $X$ the TCP conversion, $D_M$ the diffusion coefficient, $\delta$ the liquid film thickness, $C_M$ and $C'_M$ the concentration of MCP at the particle surface and in the bulk, respectively. For a spherical shrinking particle, the conversion $X$is related to the instantaneous particle radius $R$ through the shrinking-core relation:

$$R = R_0(1-X)^{\frac{1}{3}} \quad (3)$$

Diffusion of species $i$ (phosphoric acid or MCP) through the liquid film is described by the 2nd Fick's law in spherical coordinates:

$$\frac{\partial C_i}{\partial t} = \frac{1}{r^2}\frac{\partial}{\partial r}\left(D_i r^2 \frac{\partial C_i}{\partial r}\right) \quad (4)$$

with $C_i(0) = C_i^0$ and boundary conditions at the solid surface ($r = R$):

$$-D_i \frac{\partial C_i}{\partial r}\Big|_{r=R} = \nu_i k_r C_{H_3PO_4}|_{r=R} \quad (5)$$

and at the film–bulk interface ($r = R + \delta$):

$$C_i|_{r=R+\delta} = C_i' \quad (6)$$

The liquid-film thickness is linked to hydrodynamic conditions through a mass-transfer correlation. In our previous papers, the film thickness was derived from the Sherwood correlation, and then combined with film theory to express the evolution of $\delta$ as follows [10-12]:

$$\delta = R\left[(1+\alpha)\left(\frac{R}{R_0}\right)^{8/9} D_M^{-1/3} - 1\right] \quad (7)$$

Finally, liquid bulk concentrations evolve according to overall mass balances, which couple TCP dissolution to calcium availability in solution. The solution of this system provides the time-dependent TCP conversion and, equivalently, the amount of calcium released into the liquid phase. This calcium dissolution constitutes the direct input for gypsum precipitation and phosphoric acid formation in the subsequent modeling stages.

## Population Balance Model for Gypsum Crystallization

For a population of crystals undergoing temporal evolution, the population balance framework describes the number density function $n$ as a function of time $t$ and a characteristic crystal size $x$. In addition to the dissolving phosphate particles, a second solid phase is considered and corresponds to precipitated gypsum, formed through the following reaction between aqueous calcium and sulfate species to produce calcium sulfate dihydrate.

$$\mathrm{Ca(H_2PO_4)_2 + H_2SO_4 + 2H_2O \rightarrow CaSO_4.2H_2O + 2H_3PO_4} \quad (8)$$

Assuming an isothermal, perfectly mixed batch reactor with a constant volume, and size-independent crystal growth, the population balance equation (PBE) used within the digital twin core is written as:

$$\frac{\partial n(t,x)}{\partial t} = -G(t)\frac{\partial n(t,x)}{\partial x} + R_N(t)\delta(x - x_0) \quad (9)$$

where $R_N$ denotes the total nucleation rate, accounting for both primary and secondary nucleation mechanisms, $G$ represents the crystal growth rate, and $\delta$ is the Dirac delta function used to introduce nuclei at a critical size. The expressions for the nucleation and crystal growth rates are given by the following relations:

$$R_N(t) = A.\exp\left(\frac{-B}{\ln\ S(t)^2}\right) + k_s.[\ln S(t)]^s.\mu_3(t) \quad (10)$$

$$G(t) = k_g[\ln\ S(t)]^g \quad (11)$$

where $A, B, k_s, s, k_g$, and $g$ are unknown kinetic parameters to be identified from experimental data, $S$ denotes the supersaturation ratio, primarily governed by the speciation of the reacting medium, and $\mu_3$ is the third-order moment of the crystal number density function $n$. To solve the population balance equation efficiently, the method of moments is employed as a model reduction technique. This approach converts the original partial differential equation into a system of ordinary differential equations (ODEs) whose state variables are independent of the size coordinate $x$. The method relies on the definition and computation of the $k^{\text{th}}$-order moment $\mu_k$, which is expressed as follows:

$$\mu_k(t) = \int_0^\infty x^k n(t,x)dx \quad (12)$$

By multiplying Eq. (9) by $x^k$and integrating over the entire size domain, from zero to infinity, a closed system of ordinary differential equations governing the temporal evolution of the moments is obtained:

$$\frac{d\mu_0(t)}{dt} = R_N(t) \quad (13)$$

$$\frac{d\mu_k(t)}{dt} = kG(t)\mu_{k-1}(t), k \geq 1 \quad (14)$$

$$\mu_k(0) = \int_0^\infty x^k n_0(x)dx \quad (15)$$

where $n_0$ denotes the CSD at $t = 0$. The third moment of the crystal size distribution can be used to quantify the amount of gypsum formed during the process. Specifically, the cumulative gypsum production is expressed as:

$$C_{\Delta\mathrm{gyp}}(t) = \frac{k_v \rho_s}{M_c}(\mu_3(t) - \mu_3(0)) \quad (16)$$

where $k_v$is the volume shape factor, $\rho_s$is the crystal density, and $M_c$ is the molecular weight of the precipitated solid. Based on this definition, the overall material balance for the batch reactor can be written as follows:

$$C_i(t) = C_{i,0} + \nu_i C_{\Delta\mathrm{gyp}}(t) \quad (17)$$

where $C_{i,0}$ denotes the initial concentration of component $i$, and $\nu_i$is its stoichiometric coefficient in the reactions from Eq. (1) and Eq. (7).

## Thermodynamic Framework and Supersaturation Calculation

Solving the material balance subsequently enables the calculation of the supersaturation ratio, which is expressed as follows:

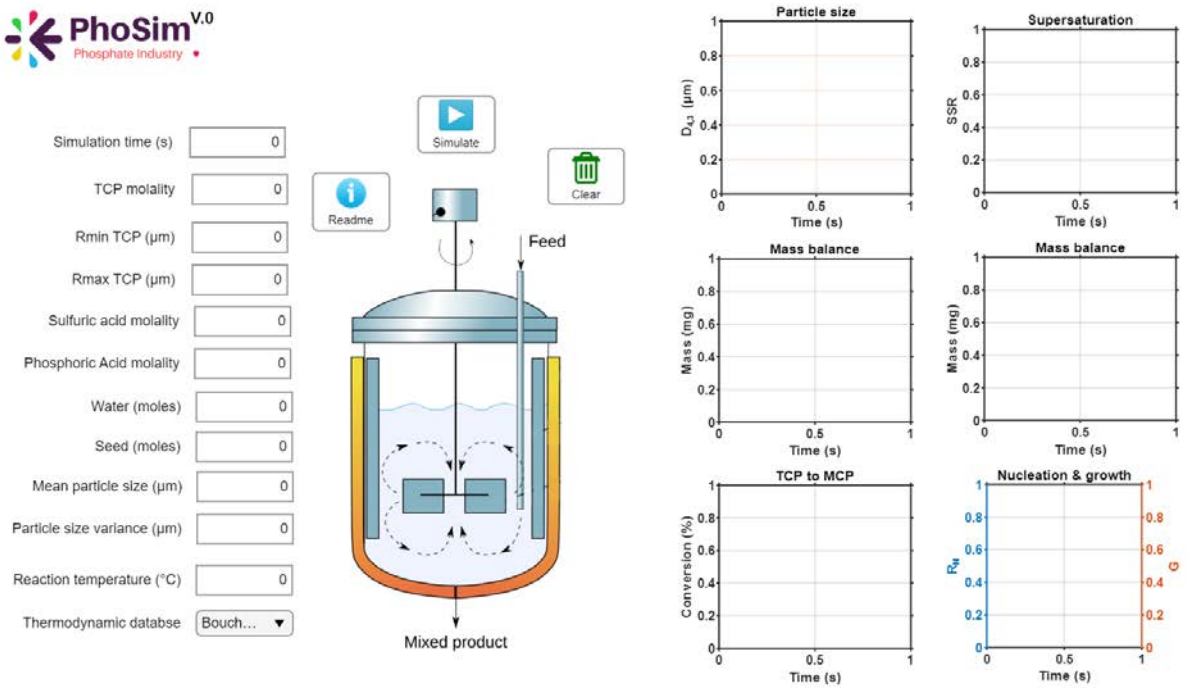

**Figure 3.** Graphical user interface of the PhoSim V.0 digital twin for batch wet-process phosphoric acid digestion and gypsum crystallization, showing input parameters, reactor schematic, and real-time simulation outputs.

$$S = \left(\frac{a_{Ca^{2+}}\, a_{SO_4^{2-}} a_w^2}{K_{sp}}\right); a_i = m_i \cdot \gamma_i \tag{18}$$

where $a_i, \gamma_i$, and $m_i$ denote the activity, activity coefficient, and molality of species $i$, respectively, and $K_{sp}$is the solubility product of gypsum. The activity coefficients are evaluated using the Pitzer model, as described below [7]:

$$\ln(\gamma_i) = \frac{z_i^2}{2} f + 2\sum\nolimits_j m_j \lambda_{i,j}(I) + z_i^2 \sum\nolimits_j m_j m_k \lambda'_{j,k}(I) + \cdots \tag{19}$$

where $z_i$ denotes the electrical charge of species $i, f$ is the Debye–Hückel term, and $I$ is the ionic strength of the solution. The parameters $\lambda_{i,j}$ and $\psi_{i,j,k}$ correspond to short-range binary and ternary interaction coefficients, respectively, whose values are identified from experimental equilibrium measurements.

## DIGITAL TWIN CORE

Figure 3 illustrates the graphical user interface (GUI) of PhoSim V.0, the digital twin core developed in this work for the simulation of the wet-process phosphoric acid (WPPA) digestion and gypsum crystallization in a batch mode. The interface is designed to ensure transparency between user-defined operating conditions, underlying physicochemical models, and the resulting simulation outputs.

The GUI is organized in three main functional areas: input and configuration, process visualization, and output monitoring.

### Input and configuration panel

The left-hand panel gathers all parameters required to initialize and configure a simulation run.

Simulation time defines the total integration horizon of the dynamic model and sets the temporal window over which all state variables are computed and displayed. TCP specifies the initial TCP amount introduced in the reactor. This parameter directly governs calcium availability for phosphoric acid production and gypsum precipitation. Minimum TCP radius (Rmin TCP) and maximum TCP radius (Rmax TCP) define the size bounds associated with the initial TCP particle population, which condition the dissolution kinetics through the shrinking-core representation. Sulfuric acid sets the initial sulfuric acid charge, controlling the extent and rate of TCP digestion and strongly influencing solution supersaturation with respect to calcium sulfate. Phosphoric acid represents the initial phosphoric acid concentration in the liquid phase and affects solution composition and thermodynamic speciation. Water defines the dilution level of the reacting medium and impacts concentrations, activities, and supersaturation behavior. calcium sulfate dihydrate (gypsum) corresponds to an initial gypsum mass, representing either pre-existing solids or deliberate seeding, which

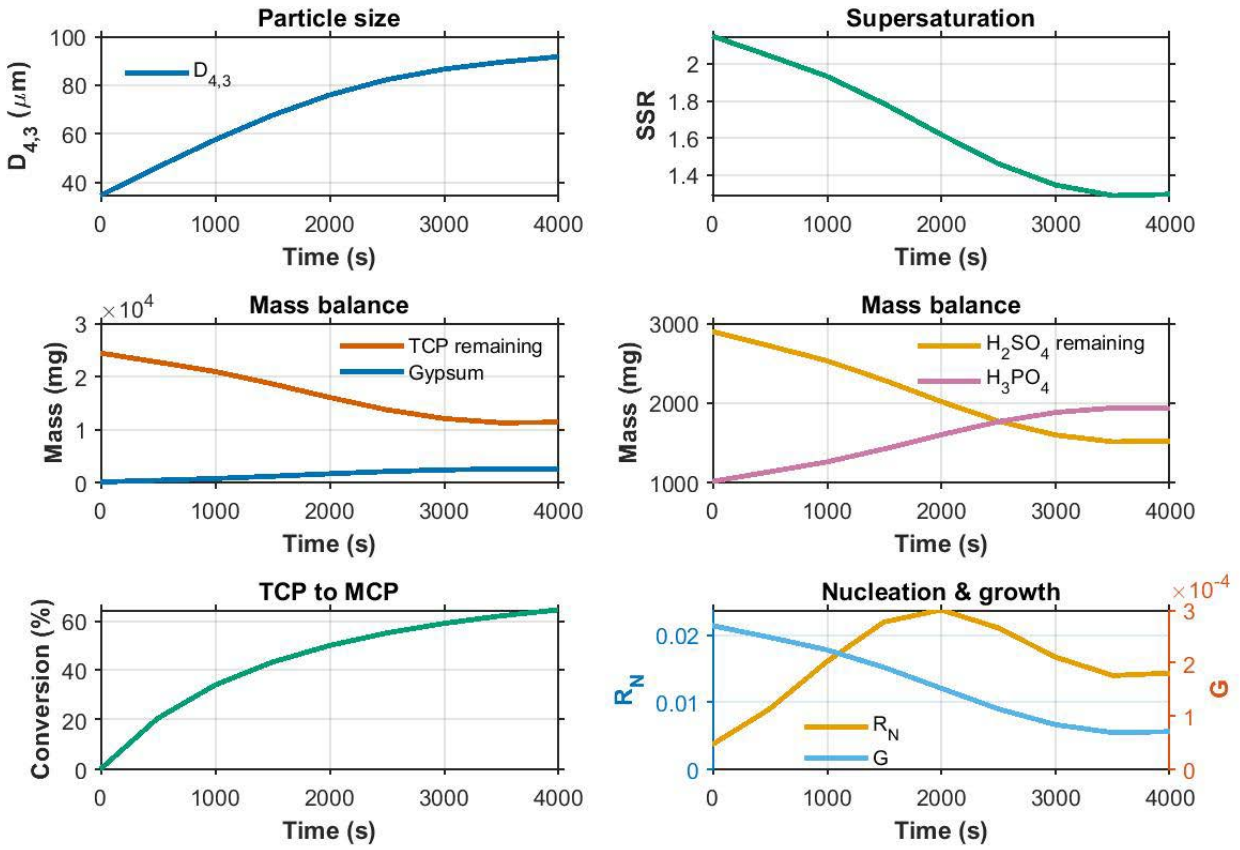

**Figure 4**. Dynamic simulation results for the case study: evolution of gypsum mean particle size $D_{43}$, supersaturation ratio (SSR), TCP and gypsum mass balances, sulfuric and phosphoric acid mass balances, TCP conversion, and nucleation and growth rates over the 4000 s batch operation.

can significantly influence nucleation dynamics and crystal size evolution. The mean particle size and gypsum particle size variance are used to define the initial gypsum particle size distribution (PSD), providing control over the initial crystal surface area available for growth. Reaction temperature sets the operating temperature used consistently across kinetic, dissolution, and thermodynamic sub models. Thermodynamic database selector allows the user to choose the electrolyte property database used for activity coefficients, speciation, and saturation index calculations, ensuring flexibility and extensibility of the digital twin.

## Simulation control and information access

Run (Simulate) button launches the simulation by initializing the digital twin, solving the coupled mass balance, dissolution, and population balance equations, and updating all output plots. Readme / information button opens a compact pop-up window providing a concise description of the model scope, key assumptions, bibliographic references, and author contact information, supporting traceability and reproducibility. Clear button removes all previously plotted curves while preserving axis limits, labels, and formatting, enabling direct visual comparison between successive simulation scenarios.

## Digital twin core graphical interface

The right-hand side of the interface contains six synchronized plots that display key model outputs in real time. Particle size evolution shows the time evolution of a representative volume-based mean particle size (e.g., $D_{43}$), summarizing gypsum crystal growth dynamics. The supersaturation (SSR) panel displays the supersaturation ratio as a function of time, representing the thermodynamic driving force for nucleation and crystal growth. Additional plots report mass balances for TCP and gypsum, sulfuric- and phosphoric-acid consumption and production, TCP conversion, and the nucleation and growth rates using a dual-axis representation. Together, these dashboards provide a comprehensive and physically interpretable overview of reaction progress, crystallization mechanisms, and particle population dynamics. The GUI enables rapid scenario testing while maintaining a clear correspondence between user inputs, model structure, and process-relevant outputs, which is a key requirement for digital twins intended for analysis, optimization, and

future control-oriented applications.

## CASE TEST DEMONSTRATION

To illustrate the capabilities of the proposed digital twin core, a representative case study is conducted using a batch digestion–crystallization scenario typical of the WPPA route. The simulation conditions are summarized below and correspond to a demonstrative, non-optimized operating point.

The batch reactor is initialized with 0.08 mol/kgw of TCP, 0.03 mol/kgw of sulfuric acid, 0.01 mol/kgw of phosphoric acid, and 40 mol of water, together with an initial gypsum amount of $5\times10^{-4}$ mol/kgw, representing either residual solids or deliberate seeding. The reactor temperature is fixed at 80 °C, and thermodynamic properties (speciation, activity coefficients, and saturation indices) are evaluated using the Bouchkira_et_al_Database.dat electrolyte database. The simulation time horizon is set to 4000 s.

The solid phase is described using a population balance framework. TCP particle sizes are bounded between R_min = $5\times10^{-4}$ m and R_max = $1\times10^{-3}$ m, while the initial gypsum particle size distribution is characterized by a mean size parameter $\bar{x}$ = 30 $\mu m$ and a variance σ = 70 $\mu m$.

Figure 4 presents the main dynamic outputs of the digital twin core. The evolution of the volume-based mean particle size $D_{43}$ shows a continuous increase throughout the batch, indicating growth-dominated gypsum crystallization. This behavior is consistent with the progressive decrease in supersaturation ratio (SSR), which initially exceeds unity and gradually relaxes as calcium sulfate precipitates and the system approaches equilibrium.

Mass balance results confirm the internal consistency of the model. TCP mass decreases monotonically due to acid digestion, while gypsum mass increases as a result of calcium sulfate precipitation. In parallel, sulfuric acid is consumed and phosphoric acid is produced, in agreement with the stoichiometry of the digestion reaction. The TCP conversion increases steadily and reaches approximately 65% at the end of the simulation, highlighting the combined effect of reaction kinetics and evolving thermodynamic driving forces.

The nucleation and growth kinetics further clarify the crystallization mechanism. The nucleation rate exhibits an initial rise associated with high supersaturation, followed by a decline as supersaturation decreases. Conversely, the growth rate remains significant over the entire batch, confirming that crystal growth dominates over nucleation kinetics.

This case test demonstrates the ability of the proposed digital twin core to coherently capture the coupled dynamics of reaction, thermodynamics, and particle population evolution, while providing physically interpretable outputs suitable for process analysis, sensitivity studies, and future optimization or control applications.

## CONCLUSIONS AND PERSPECTIVES

A physics-based digital twin core (PhoSim V.0) for WPPA digestion and gypsum crystallization has been developed and demonstrated. The framework consistently couples reaction kinetics, thermodynamic equilibrium, and population balance modeling within a dynamic simulation environment supported by a dedicated graphical interface.

The case study confirms that the model captures the main process trends in a physically coherent manner, including TCP digestion, acid consumption and production, supersaturation relaxation, gypsum precipitation, and crystal size growth. The simulated transition from nucleation-dominated to growth-dominated crystallization regimes and the associated mass balance closure illustrate the internal consistency and interpretability of the approach.

The proposed digital twin core provides a flexible tool for process analysis and scenario testing, enabling systematic investigation of the impact of operating conditions and particle properties on both macroscopic performance indicators and crystallization mechanisms.

Future work will focus on experimental validation, extension to continuous reactor configurations, integration of inline measurements, and coupling with optimization and model-based control strategies, with the objective of supporting advanced monitoring and decision-making in industrial phosphoric acid production.

## ABSTRACT

Microstructure segmentation is essential for quantitative materials analysis; however, supervised deep learning demands substantial annotation, whereas general-purpose foundation models such as the Segment Anything Model (SAM) offer limited domain-specific semantic control. This paper presents MatStudio, a human-in-the-loop framework for microstructure segmentation that is proposed and implemented end to end in this work. MatStudio couples an interactive workflow for batchwise micrograph annotation and model adaptation with a dual-head convolutional architecture and SAM-guided boundary refinement. The loop combines sparse supervision with SAM-assisted labeling, task-specific training, and iterative batch-level correction, typically converging within two to three cycles.. The network comprises a shared encoder initialized from a pretrained backbone and two decoders: a UNet-style segmentation head that jointly predicts class labels and pixelwise uncertainty, and a prototype branch that measures texture similarity against a memory bank of learnable prototypes. An uncertainty-aware training objective couples label estimation with confidence; uncertainty weighting emphasizes prototype learning in ambiguous regions, and purity filtering restricts prototype updates to phase-interior features to mitigate boundary contamination. At inference, decoder outputs are fused in a spatially adaptive manner according to local confidence. We further introduce SAMFusion, which treats SAM as a morphology-aware proposal source and accepts proposals that are consistent with the fused prediction under a hierarchical small-to-large activation criterion, yielding improved boundary fidelity without case-specific tuning of SAM prompts. Experimental evaluation on Ni-alloy micrographs and public benchmarks shows consistent gains relative to interactive scribble-based segmentation and SAM-centric reference methods.

## INTRODUCTION

Microstructure governs the mechanical, thermal, and chemical properties of engineering materials, making quantitative microstructural characterization essential for process optimization and structure-property relationship discovery [1, 2]. The spatial distribution of phases, precipitates, grain boundaries, and defects directly influences macroscopic performance metrics such as strength, ductility, and corrosion resistance. As materials informatics advances toward high-throughput analysis and autonomous experimentation, accurate and efficient microstructure segmentation has become a critical bottleneck.

Traditional image analysis approaches relied on threshold-based methods, morphological operations,

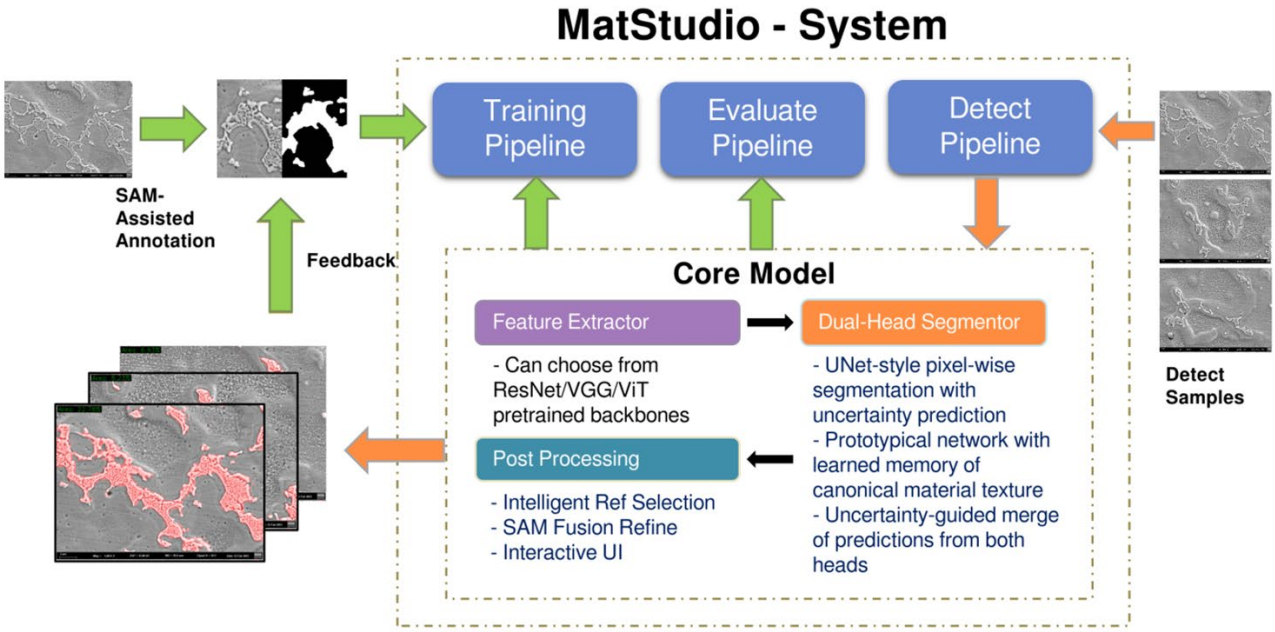

**Figure 1.** System-level overview of MatStudio. Training, evaluation, and detect interface with a shared core model (backbone, dual-head segmentor, and post-processing); feedback closes the loop between predictions and SAM-assisted annotation.

and hand-crafted features, which require extensive manual parameter tuning and exhibit poor generalization across imaging conditions. The advent of deep learning has substantially advanced automation: U-Net [3] and fully convolutional architectures demonstrated remarkable performance on biomedical and materials images, with subsequent work applying these methods to steel microstructures [4] and precipitate quantification. Pretrained encoders on large microscopy datasets have further improved generalization [5]. However, standard encoder-decoder architectures optimize for pixel-wise classification and may struggle to maintain consistent predictions across texturally homogeneous regions, particularly when training data is limited [6]. This limitation motivates complementary approaches based on metric learning.

Siamese networks [7] address few-shot recognition by learning embeddings where similar samples cluster together, enabling classification via distance comparison to reference examples. Prototypical networks [8] extend this paradigm by representing each class as a single prototype vector—the mean embedding of support examples—and classifying queries based on proximity to these prototypes. For semantic segmentation, PANet [9] demonstrated that prototype alignment enables effective few-shot segmentation by matching query features to class-specific prototypes derived from support masks. These metric-learning approaches excel at capturing texture consistency: once a canonical texture representation is established, regions sharing that texture can be reliably identified regardless of their spatial distribution. However, prototype-based methods typically operate at reduced resolution and may produce coarse boundaries, while their performance depends heavily on the quality and purity of the reference examples used to construct prototypes.

More recently, foundation models trained on massive datasets have demonstrated remarkable zero-shot generalization capabilities. The Segment Anything Model (SAM) [10], trained on over one billion masks, has attracted particular attention for materials microscopy. MatSAM [11] employs automated prompt generation to leverage SAM's zero-shot segmentation for microstructure extraction, SAM-I-Am [12] uses geometric and textural features for semantic boosting in electron microscopy, and SAMRefiner [13] adapts SAM for universal mask refinement. In parallel, Human-in-the-Loop (HITL) frameworks such as scribble-based segmentation [14] have effectively mitigated data scarcity through iterative expert feedback.

Despite these advances, each paradigm exhibits inherent trade-offs. Standard segmentation networks excel at boundary delineation but may produce inconsistent predictions in material interiors where local context alone is insufficient. Prototype-based methods enforce texture consistency but sacrifice spatial precision and require

careful reference selection to avoid prototype pollution from boundary features. SAM-based zero-shot approaches achieve impressive results without training, but directly applying SAM to material microscopy poses challenges due to the dense and dispersed nature of microstructural features; moreover, these methods create dependency on prompt quality where suboptimal prompts directly degrade results. This analysis suggests an opportunity: rather than relying on any single approach, robust microstructure segmentation may be achieved by combining texture-consistent prototype matching with pixel-precise segmentation, while leveraging SAM's morphological sensitivity for boundary refinement.

Building on this insight, we present MatStudio, a unified framework that integrates an uncertainty-guided dual-head architecture with SAMFusion—a novel proposal-guided refinement strategy. The primary segmentation head produces pixel-wise predictions along with learned uncertainty estimates [15], which guide both training and inference of an auxiliary prototype memory bank. During training, high-uncertainty regions receive amplified supervision for the prototype branch, forcing it to specialize on cases where the segmentation head struggles; at inference, predictions are dynamically fused based on local confidence. SAMFusion further refines boundaries by treating SAM purely as a morphology-aware proposal generator, activating proposals only when corroborated by the fused prediction. This design inherits the boundary precision of segmentation networks, the texture consistency of prototype matching, and SAM's morphological sensitivity—while avoiding the failure modes of each approach used in isolation.

The remainder of this article is organized as follows. Section 2 presents the MatStudio methodology. Figure 1 gives a system-level overview; the text then details the interactive workflow, the dual-head architecture with prototype-based texture modeling, uncertainty-guided training and memory updates, spatially adaptive fusion at inference, and SAMFusion for proposal-gated boundary refinement. Section 3 reports comparative experiments on Ni-alloy micrographs and public benchmarks against ScribbleSeg and MatSAM, including the qualitative assessment in Figure 2. Section 4 summarizes the principal findings and discusses implications for interactive microstructure segmentation.

## METHODOLOGY

Figure 1 sketches MatStudio at architecture level: training, evaluation, and detect pipelines connect to a shared core model, with outputs feeding back to annotation. The operational workflow follows a human-in-the-loop paradigm for narrow batches of micrographs under consistent imaging conditions. Users begin by loading a batch into an interactive annotation interface and providing sparse labels—point clicks or bounding boxes—for the target microstructural features. These annotations, optionally accelerated by SAM-assisted region proposals, bootstrap a task-specific segmentation model. After an initial training pass, the model generates predictions across the batch; the user then reviews these outputs and provides corrective feedback on under-segmented or mis-segmented regions, which refines the supervision signal for the next iteration. This iterative refinement cycle continues until the segmentation quality converges, typically within two to three rounds.

### Dual-Head Architecture with Prototype Memory

The core segmentation model employs a dual-head architecture where a primary segmentation decoder is complemented by an auxiliary prototype-based similarity head. A shared convolutional encoder, initialized from a pretrained backbone, extracts hierarchical feature representations that feed two parallel branches: (1) a UNet-style segmentation head producing dense pixel-wise predictions along with a learned uncertainty signal, and (2) a prototype head that computes texture similarity against a dynamically maintained memory bank of canonical material textures.

The segmentation head is designed to output not only class predictions but also a per-pixel confidence estimate, inspired by heteroscedastic uncertainty modeling in Bayesian deep learning [15]. This enables the network to explicitly signal regions where it lacks confidence—typically phase boundaries, texturally ambiguous zones, and imaging artifacts. The auxiliary prototype head maintains a compact set of learnable prototype vectors representing characteristic material textures. For each spatial location, the head performs texture similarity matching against all prototypes and outputs a dense similarity map that captures texture consistency across the image.

### 2.2 Uncertainty-Guided Learning

The key insight of our training strategy is that the segmentation head's uncertainty provides a natural supervisory signal for the auxiliary branch. The segmentation head is trained with an uncertainty-aware loss formulation that jointly learns predictions and confidence: when prediction error is high, the network learns to increase its uncertainty estimate, effectively admitting difficult regions. At equilibrium, the uncertainty map captures precisely those regions where the segmentation head consistently struggles.

This learned uncertainty is then used to modulate supervision for the prototype head. Regions with high uncertainty receive amplified training signal, directing the prototype branch to specialize on cases the segmentation head cannot handle reliably. This uncertainty-

weighted training ensures complementary specialization: the segmentation head handles straightforward regions while the prototype head focuses its learning capacity on challenging textures and ambiguous boundaries. The total training objective combines both components with appropriate weighting.

To maintain prototype quality, we employ a conservative update strategy with strict purity filtering. Before updating prototypes, we identify regions that are unambiguously inside material phases—far from boundaries—and use only these "pure" features to update the memory bank. This prevents prototype pollution from boundary features, which would otherwise cause boundary blurring and increased false positives.

### Inference and SAMFusion Refinement

At inference time, the learned uncertainty directly governs how predictions from both heads are combined. In confident regions, the segmentation head dominates; in uncertain regions, the prototype-based similarity takes over. This dynamic, spatially-adaptive fusion requires no additional hyperparameters and automatically adapts to local image content.

To further enhance boundary quality, we introduce SAMFusion, a proposal-guided refinement strategy that leverages SAM's exceptional morphological sensitivity without inheriting its failure modes. Unlike approaches that treat SAM outputs as authoritative segmentations—and consequently suffer when SAM misinterprets complex microstructures—SAMFusion treats SAM purely as a morphology-aware proposal generator. We invoke SAM to obtain an exhaustive set of candidate regions, then selectively activate proposals through an agreement-gated mechanism: proposals are accepted only when they exhibit sufficient overlap with the network's fused prediction. This hierarchical activation process, which evaluates proposals from small to large, ensures that SAM's boundary precision refines the segmentation without introducing spurious detections in texturally ambiguous regions. Crucially, this design eliminates the need for case-by-case hyperparameter tuning of SAM's prompt strategy.

## RESULTS

We benchmarked MatStudio against ScribbleSeg [14] and MatSAM [11] on four segmentation tasks spanning self-collected Ni-alloy micrographs (cases a–b) and public datasets—UHCS spheroidite [16] and NBS-2 eutectic carbides [14]—as shown in Figure 2.

Cases (a) and (b) expose complementary failure modes of the baselines. In (a), dendritic arms spanning the full field-of-view defeat MatSAM's edge-based prompting, which cannot reliably distinguish foreground from background when boundaries lack clear termination; ScribbleSeg under-segments due to textural ambiguity between dendrites and intermediate grey substructures in the matrix. In (b), off-axis detector gradients and secondary-electron edge halos generate spurious boundaries that MatSAM interprets as phase interfaces, producing extensive false positives; the same gradient also causes ScribbleSeg to fail.

Case (c) presents well-defined spheroidite particles that all methods largely detect; however, surface cracks partition the matrix into coarse enclosed domains that, despite containing no target particles, exhibit closed-contour morphology indistinguishable from valid regions under edge-based prompting, causing MatSAM to register these large spurious areas as false positives. Case (d) constitutes the most demanding scenario: eutectic carbides with amorphous, interconnected morphologies cause catastrophic failure in MatSAM regardless of hyperparameter tuning, while ScribbleSeg partially succeeds but cannot resolve regions where carbide and matrix textures overlap. We note that published metrics for ScribbleSeg and MatSAM on these benchmarks could not be reproduced under our experimental protocol; moreover, manual inspection revealed annotation inconsistencies in the ground-truth masks—several target particles remain unlabeled while certain background regions are erroneously marked—rendering absolute metric comparisons unreliable. Despite these caveats, IoU and Dice reported as overlay annotations on each prediction panel in Figure 2 still permit relative comparison among methods on the same exemplars and under our evaluation settings.

The IoU and Dice coefficients printed on those panels summarize performance on the displayed crops. MatStudio attains the highest IoU and Dice in every row: in (a), 0.92 and 0.96 versus 0.44 / 0.62 (ScribbleSeg) and 0.41 / 0.58 (MatSAM); in (b), 0.74 / 0.85 versus 0.15 / 0.26 and 0.56 / 0.72; in (c), 0.66 / 0.80 versus 0.48 / 0.65 and 0.57 / 0.72; in (d), 0.95 / 0.97 versus 0.64 / 0.78 and 0.05 / 0.10. These rankings are consistent with the qualitative failure modes discussed above and should be read together with the protocol and labeling limitations noted earlier.

Across all four cases, and in agreement with both the visual evidence and the panel-reported scores in Figure 2, MatStudio maintains robust performance by exploiting the complementarity between learned texture representations and SAM's morphological sensitivity. The agreement-gated activation mechanism filters out proposals that, while geometrically plausible, lack corroboration from the semantic predictor—effectively suppressing edge artifacts and spurious enclosed regions. Crucially, by treating SAM outputs as candidate refinements rather than authoritative segmentations, the framework inherits SAM's boundary-delineation strengths without suffering its failure modes when edge-

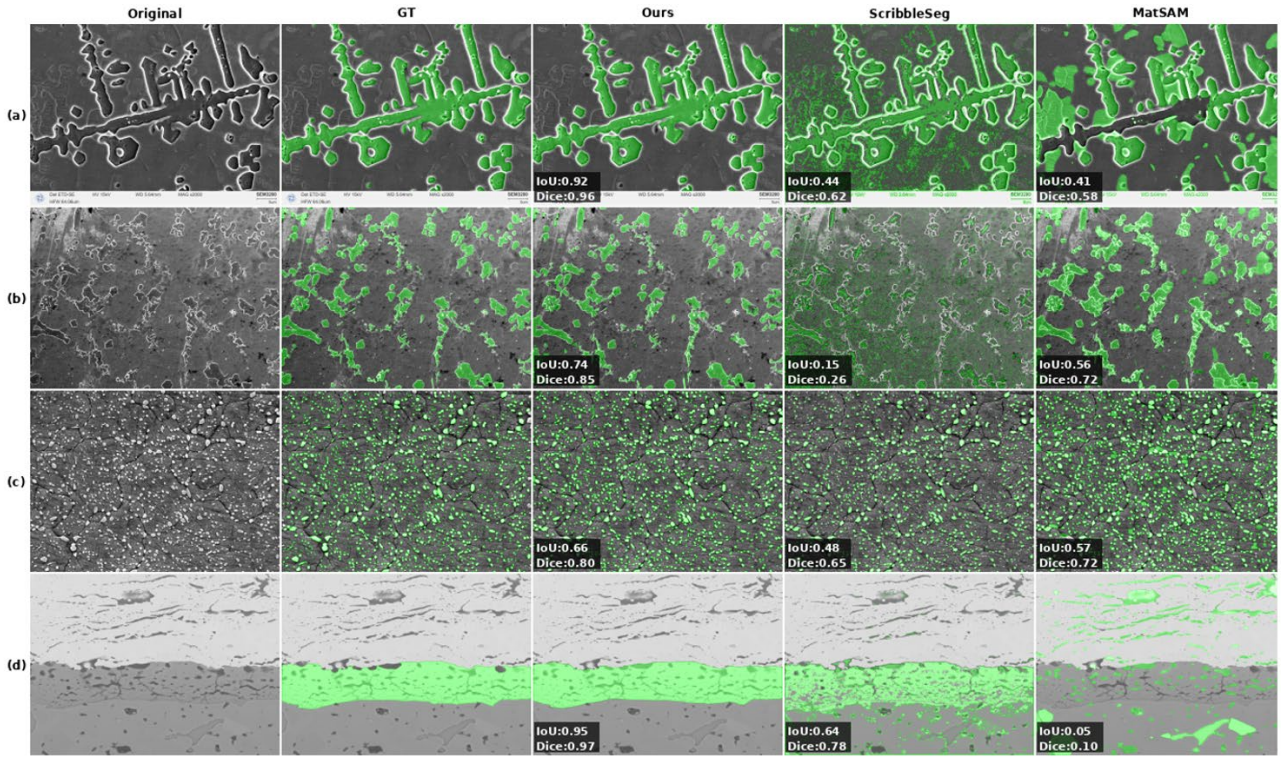

**Figure 2.** Qualitative comparison across four material systems. Columns show original image, ground truth, and predictions from MatStudio (ours), ScribbleSeg, and MatSAM. IoU and Dice scores are presented in overlay annotations. We observe that scribble-seg fails when there is no clear textural difference between the target and background. Similarly, MatSAM fails when boundary of the target area is complex or arbitrary. Our MatStudio is capable of delivering consistent and robust performance across difference scenarios and outperforms its counterparts in most cases.

based prompting encounters ambiguous or artifact-laden microstructures.

## CONCLUSION

We presented MatStudio, a human-in-the-loop framework for microstructure segmentation that combines an uncertainty-guided dual-head model with SAM-Fusion for proposal-gated boundary refinement. Across the heterogeneous microscopy settings considered in this work, the comparison in results section illustrates a recurring pattern: methods that rely predominantly on edge- or prompt-driven segmentation exhibit substantial fragility when microstructural morphology, contrast, or imaging artifacts violate the assumptions those pipelines implicitly encode, whereas MatStudio remains comparatively stable by coupling texture-aware predictions with conservative use of SAM as a geometric proposal source. The dual-head design uses estimated uncertainty to allocate responsibility between dense segmentation and prototype-driven texture reasoning at inference, and SAMFusion retains SAM refinements only when they agree with the fused model, reducing spurious activations that arise when proposals are treated as definitive masks. We report exemplar-level overlays under our training and evaluation protocol together with the limitations discussed in the Results section; accordingly, we frame the findings as consistent relative evidence for the proposed integration rather than as universal rankings or as claims of proportional improvement over prior published numbers.

## ABSTRACT

Environmental sustainability is increasingly recognized as a critical consideration in pharmaceutical development, yet it is rarely incorporated at the scale of molecular-level design. This study introduces a strategy to predict cradle-to-gate indicators that can be flexibly incorporated into multiple early-stage molecular prioritization scenarios. A dataset of 150 pharmaceutical-relevant molecules was compiled, with each molecule described by structural descriptors, thermophysical properties, and ReCiPe endpoint indicators representing human health, ecosystem quality, and resource scarcity. A dual-branch multi-task model combining graph-based and descriptor-based representations was trained to predict these three endpoint indicators. Model performance was evaluated through validation metrics, local sensitivity analysis, and SHAP-based interpretability. A case study with solubility-based feasibility constraints was then used to illustrate how different sustainability weighting schemes affect molecular ranking and to demonstrate the potential for incorporating sustainability assessment into early-stage molecular prioritization. The results indicate that sustainability preferences can lead to distinct prioritization patterns, while some candidates remain comparatively favourable across scenarios.

**Keywords**: Machine Learning, Modelling and Simulations, SimaPro, Life Cycle Analysis, Surrogate Model

## 1. INTRODUCTION

Drug molecular design constitutes a critical interface between microscopic chemical structure and macroscopic product performance [1-3]. Small-molecule therapeutics continue to dominate the pharmaceutical industry due to their well-established development pipelines, scalable manufacturing routes, and broad therapeutic applicability [4, 5]. In parallel, rapid advances in computational chemistry, machine learning (ML), and optimization algorithms have positioned computer-aided molecular design as a powerful tool for navigating the vast chemical space and enabling rational, data-driven discovery beyond traditional trial-and-error approaches [6, 7].

Environmental sustainability is increasingly being incorporated into chemical research and development, not merely to satisfy policy and regulatory requirements, but also as an important consideration in the design and manufacture of chemical products across their life cycles [8, 9]. In current pharmaceutical development practice, however, sustainability considerations are typically introduced only after target molecules have been selected. At this stage, environmental impacts are primarily addressed through downstream, process-level interventions, such as route optimization, solvent substitution, or constraint-based decision-making [10-12]. Within this established paradigm, sustainability is primarily optimized with respect to process choices, whereas molecular structure itself is rarely examined as an explicit dimension for shaping cradle-to-gate sustainability outcomes. In the drug discovery workflow, although extensive combinatorial chemistry and structure-based design efforts are routinely conducted and a range of toxicity- and safety-related indicators may be evaluated, sustainability information remains fragmented, indirect, and rarely integrated into molecular-level candidate assessment [13, 14]. As a result, cradle-to-gate sustainability risks may be implicitly embedded in early design choices and only become apparent during scale-up and manufacturing stages, where opportunities for more fundamental improvement are already limited.

Recognizing this gap, primary approaches to linking chemicals with sustainability-related attributes have primarily relied on empirical heuristics and rule-based methods. In these methods, QSPR models are often employed as surrogate mappings from molecular structure to sustainability-relevant endpoints [15]. A typical workflow involves decomposing chemical structures into molecular descriptors, functional-group counts, and/or thermophysical properties, which are then combined with life-cycle impact indicators obtained from simulation tools or experimental databases. These relationships are commonly formalized using regression-based or other empirical modeling approaches to link readily computed chemical attributes with sustainability metrics[16, 17]. Such QSPR-enabled predictive LCA strategies are particularly attractive for early-stage decision-making, as they provide fast, structure-informed estimates enriched with basic physicochemical information. However, these classical empirical approaches typically rely on extensive, system-specific datasets for calibration and tend to exhibit limited extrapolation capability when applied to novel or sparsely explored chemical spaces. ML methods have rapidly emerged as an alternative paradigm to address these challenges. By learning complex structure-property relationships, ML models can achieve improved predictive performance across diverse molecular structures [18, 19]. For example, Song et al. [20] developed descriptor-based models to predict six life-cycle impact categories of chemicals, while Karka et al. [21] proposed a standardized ML workflow to digitize sustainable process development and enable a transition from ex post to ex ante life-cycle assessment. Despite these advances, the role of sustainability in early-stage molecular-level decision-making remains insufficiently explored. In pharmaceutical settings, the predictive models used to support such decisions are expected not only to provide reasonable accuracy, but also to be accompanied by interpretability analyses that promote trust, transparency, and informed decision-making [22, 23].

Therefore, this work presents a strategy for predicting cradle-to-gate sustainability indicators and examining their use in early-stage molecular prioritization. The proposed approach integrates structural descriptors, thermophysical properties, and graph-based molecular information within a hybrid representation, and employs a multi-task learning strategy to jointly predict multiple sustainability endpoints from a curated pharmaceutical-relevant dataset. A case study with solubility-based feasibility constraints is further used to illustrate how predicted sustainability indicators can affect molecular ranking under different weighting schemes.

# 2. METHOD

## 2.1 Database

A unified molecular database was constructed to support early-stage sustainability screening in pharmaceutical applications. A focused set of 150 candidate molecules relevant to pharmaceutical manufacturing were selected. For each molecule *i*, a vector of *M* sustainability-related outputs was defined, where M corresponds to multiple environmental impact indicators. In this study, three ReCiPe-based endpoint categories aligned with the areas of protection were considered: human health, ecosystem, and resources. Environmental impacts were quantitatively evaluated using SimaPro (v9.5) with the ReCiPe 2016 v1.1 method, based on the Ecoinvent 3 database and conducted in accordance with ISO 14040–14043 standards. Endpoint indicators were adopted to provide a comprehensive assessment of environmental performance, capturing aggregated long-term consequences across the three protection areas. Human health impacts were quantified using disability-adjusted life years, representing years of life lost or lived with disability. Ecosystem quality was measured as time-integrated local species loss (species·year), while resource scarcity was expressed in monetary terms (USD), reflecting the additional future costs associated with mineral and fossil resource extraction.

## 2.2 Functional Group Representation and Thermophysical Properties

### 2.2.1 Functional-group-based representation

Molecular structures were decomposed into a predefined dictionary of structural motifs using SMARTS-based substructure matching implemented in RDKit. The dictionary comprised several categories, including acid derivatives, carbonyl motifs, O-containing motifs, N-containing motifs, S/P-containing motifs, halogen motifs, heteroaromatic motifs, and auxiliary descriptors. Representative examples are summarized in **Table 1**. A hierarchical and non-overlapping matching rule set was applied, in which more specific motifs were matched before more general ones. For atom-consuming rules, matched atoms were assigned exclusively and excluded from subsequent atom-consuming matches. Non-consuming auxiliary descriptors were evaluated separately and retained in the final representation.

For a molecule *i*, the resulting representation was expressed as a vector of motif occurrence counts, where each element denotes the number of occurrences of motif *k* in molecule *i*. Binary presence indicators were generated for the same motif set. Additional discrete descriptors were included to encode stereochemical and topological information, including the number of chiral centers, double-bond configurations, and scaffold-level discriminators reflecting pharmaceutically relevant isomeric patterns.

Prior to feature extraction, all molecules were standardized using a uniform preprocessing pipeline

**Table 1:** Main categories of the predefined structural motif dictionary and representative examples.

| Motif category | Representative examples |
|---|---|
| Acid derivatives | lactone_5, lactam_6, ester, carbamate |
| Carbonyl motifs | benzaldehyde, enone, dialkyl_ketone, carboxylate |
| O-containing motifs | phenol, alcohol, aryl_ether, epoxide |
| N-containing motifs | aniline, amine_primary, imine, amidine, guanidine |
| S/P-containing motifs | sulfone, sulfonamide, phosphate_triester, boronic_acid |
| Halogen motifs | aryl_halide, alkyl_halide, benzylic_halide |
| Heteroaromatic motifs | pyridine, oxazole, thiazole, quinoline |
| Auxiliary descriptors | aromatic_N, aromatic_O, sp2_C, sp3_C |

comprising fragment removal, charge neutralization, stereochemical assignment, and tautomer canonicalization under controlled iteration limits. In total, the structure-based representation comprised 422 discrete variables, including 211 integer-valued motif counts and 211 corresponding binary indicators.

### 2.2.2 Thermophysical property descriptors

In addition to structure-based features, 38 continuous thermophysical descriptors were included in the molecular representation. These descriptors included molecular weight, critical properties, heat capacity, vapor pressure, viscosity, surface tension, enthalpy of vaporization, and related thermodynamic variables. Thermophysical data were compiled from open-source chemical information resources and property libraries, including PubChem and the *thermo* package, using SMILES, compound names, CAS numbers, and CIDs as identifiers. Missing entries were supplemented using estimation routines implemented in *thermo* and chemicals. Property values were collected or calculated at 101325 Pa and at 298.15, 323.15, and 373.15 K.

All continuous descriptors were standardized using z-score scaling. Categorical and binary variables were retained in their original form. Descriptors with zero or near-zero variance were removed prior to model training.

### 2.2.3 Graph-level attributes and reversibility

In parallel with the tabular descriptor representation, each molecule was encoded as a graph using atom-level and bond-level structural matrices. Graph data were stored in JSON-formatted atom and bond matrices and converted into fixed-size graph tensors prior to model training.

The atom matrix was parsed into a node-feature array, and the bond matrix was parsed into a symmetric weighted adjacency matrix. Bond entries retained bond-order information, including fractional values for aromatic bonds. Self-loops were added to valid nodes. Graph tensors were generated with a maximum size of 64 nodes, consisting of node features, adjacency matrix, and node mask. Molecules with fewer than 64 atoms were zero-padded. For disconnected graphs, the largest connected component was retained. These tensors were used as inputs to the graph branch of the model.

## 2.3 Multi-Task Model Training

A dual-branch multi-task neural network was constructed to jointly predict three sustainability endpoints. The model combined a tabular branch operating on descriptor-based inputs and a graph branch operating on molecular graph tensors. Three predictions were generated during training: a fused output, a graph-branch output, and a tabular-branch output.

The tabular input was formed by combining discrete structural descriptors with continuous thermophysical descriptors when available. Continuous descriptors were imputed using training-set means, standardized, and then filtered by variance thresholding and pairwise correlation analysis. The dataset was divided into training, validation, and test subsets with a ratio of 0.7/0.2/0.1. The three target variables were processed independently using column-specific screening rules. For each endpoint, a binary mask was generated to indicate retained samples, and retained values were scaled to the interval [1, 2] using training-set minimum and maximum values. The training target for each sample therefore consisted of the scaled response vector together with the corresponding output mask. The graph branch was implemented using a two-layer graph neural network operating on node features, weighted adjacency matrices, and node masks. The graph encoder included linear node projection, adjacency normalization, graph aggregation, layer normalization, PairNorm, dropout, gated residual connection, and combined mean-pooling and attention-pooling readout. The tabular branch consisted of residual fully connected layers with layer normalization and dropout. The fused prediction was defined as the sum of the graph-branch and tabular-branch predictions. Model training used masked mean squared error with endpoint-specific weights, and masked mean absolute error was used as an additional evaluation metric. Hyperparameters were optimized using Bayesian optimization. The tabular branch and graph branch were pretrained separately, followed by joint training of the full model. Adam optimization, gradient clipping, early stopping,

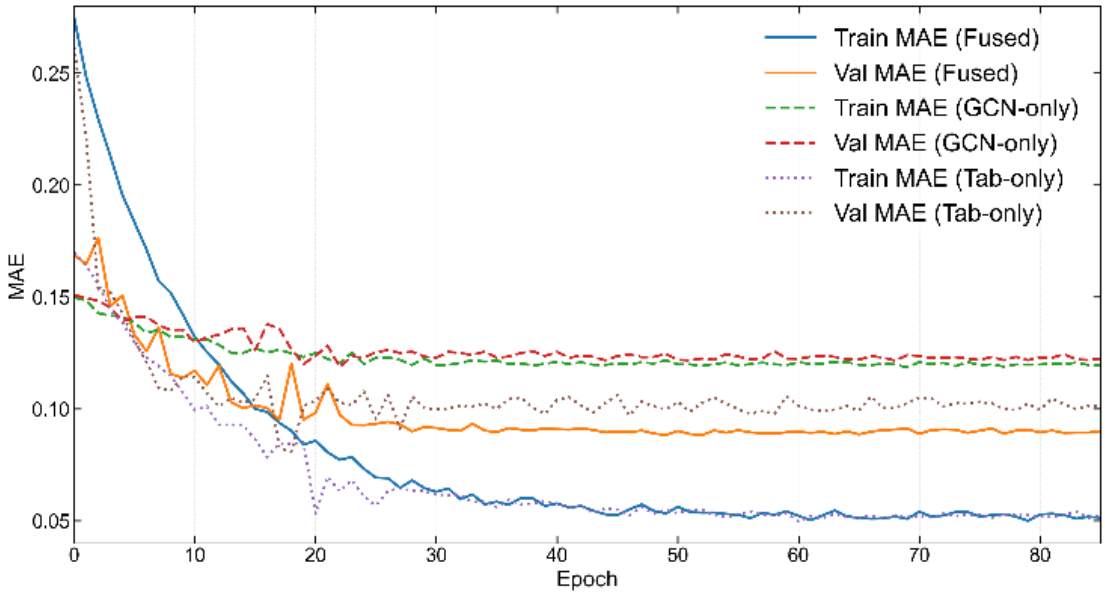

**Figure 1.** Training and Validation of MAE Across Model Heads

checkpointing, and learning-rate scheduling were applied during training. Model performance was evaluated on the held-out test set using MSE and MAE.

Model interpretability was assessed using SHAP-based feature attribution applied to the tabular descriptor branch. This analysis quantified the contributions of individual structural and thermophysical features to each sustainability endpoint, enabling chemically meaningful interpretation of learned structure–sustainability relationships and supporting transparent decision-making in early-stage molecular screening.

## 2.4 Probabilistic Molecular Design

The trained predictive model served as a surrogate evaluator within a genetic-algorithm-based search procedure. Candidate molecules were encoded using the same descriptor set as in model training and were iteratively evaluated by the surrogate to obtain performance scores. A distribution-based solubility feasibility criterion was applied, in which the feasibility of each candidate was assessed probabilistically to reflect model and property uncertainty. The detailed formulation of the optimization problem and the associated design rationale are presented in the application section.

# 3. RESULTS AND DISCUSSION

## 3.1 Dataset Description

### 3.1.1 Dataset Construction

The 150 molecular entries span a broad and representative range of chemical space relevant to pharmaceutical manufacturing. From a molecular weight perspective, the dataset covers compounds ranging from small, commonly encountered synthesis intermediates such as hydroxylamine (molecular weight 33 g·mol$^{-1}$, crystalline at ambient conditions) to formally regulated pharmaceutical chemicals and ligands such as diethylenetriaminepentaacetic acid (DTPA, molecular weight 393 g·mol$^{-1}$, crystalline at ambient conditions).

In addition to solid-state pharmaceutical compounds and intermediates, the dataset also includes a subset of widely used organic solvents, such as alcohols and esters, which are routinely involved in pharmaceutical synthesis and downstream processing. The inclusion of these solvent-type molecules further extends the chemical diversity of the dataset and ensures coverage of molecular classes for which extensive physicochemical and sustainability-related data are available.

### 3.1.2 Statistical Characteristics of Molecular Descriptors

The statistical characteristics of the descriptors were examined to assess diversity, redundancy, and representational conditioning. The pairwise binary Jaccard similarities of the discrete molecular fingerprints showed substantial heterogeneity across the 150 molecules, suggesting that the fingerprint representation preserved structural diversity and did not collapse into a highly redundant encoding.

For the continuous thermophysical property descriptors, principal component analysis indicated that variance was distributed across multiple principal components, with the first five components explaining approximately 80% of the total variance. Moreover, the property loadings were unevenly distributed across

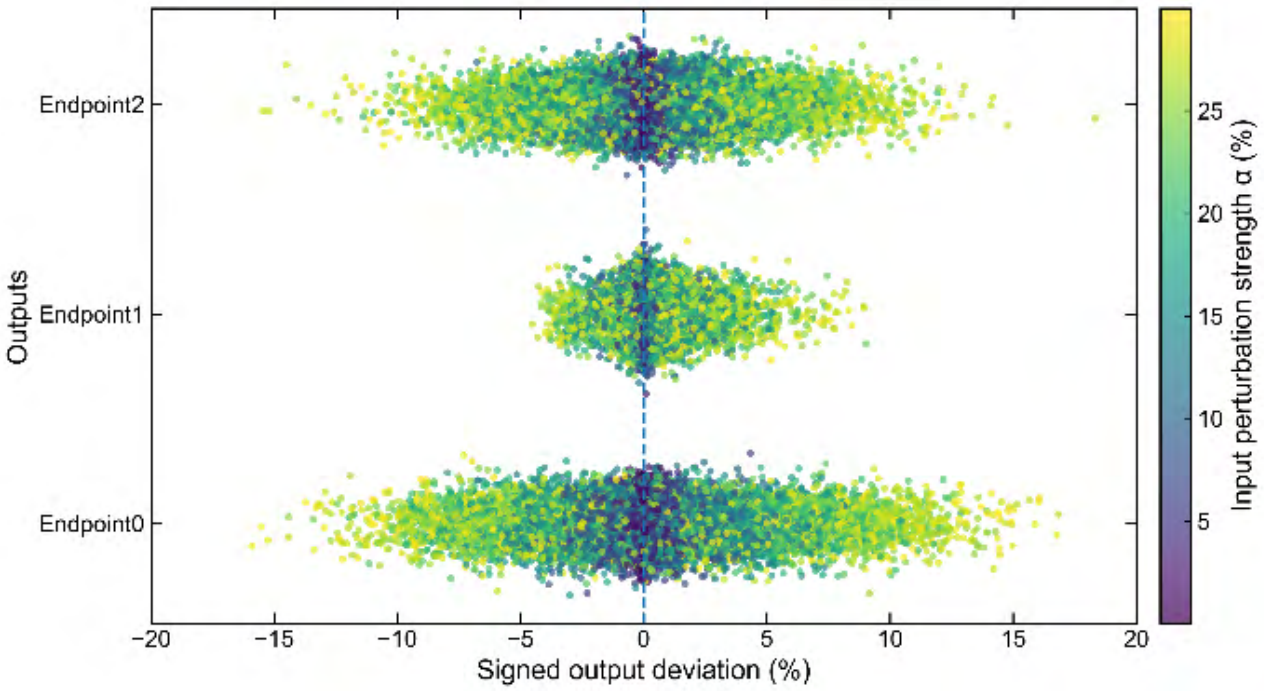

**Figure 2.** Monte Carlo Beeswarm of Output Deviations under Input Perturbations**.** For each Monte Carlo trial, a validation sample was randomly selected and its tabular input features were perturbed by a random multiplicative factor within ±α (α ∈ [0, 30%]), while the molecular graph inputs were kept unchanged. The horizontal axis shows the signed relative deviation of the predicted output from its unperturbed baseline, $(\hat{y}' - \hat{y})/(|\hat{y}| + \epsilon) \times 100\%$, centred at 0 (blue dashed line). Each point corresponds to one perturbed evaluation, and the colour encodes the input perturbation strength α (%). Narrower, more concentrated clouds around zero indicate higher robustness of the endpoint prediction; wider spreads and heavy tails indicate stronger sensitivity.

these leading components, implying that different subsets of descriptors contributed to different latent directions. Together, these observations suggest that the continuous descriptor set contained both shared and complementary information rather than complete redundancy. Furthermore, all 150 molecules were successfully reconstructed under the same fingerprint definitions, corresponding to a reconstruction success rate of 100%.

## 3.2 Model Training and Validation

This section evaluates the model's training behaviour and reliability from three perspectives: (i) the functional roles of the prediction heads and whether they operate as intended, (ii) potential overfitting under small-sample, mixed-variable conditions, and (iii) generalization performance on the validation set. Training dynamics are shown in **Figure 1** and **Table 1**. All heads show steadily decreasing training MAE with stable convergence, and the fused output exhibits consistently lower validation error than either individual branch, confirming the complementary roles of graph and descriptor representations.

Given the dataset size of 150 samples and the high-dimensional, mixed discrete–continuous feature space, overfitting risk was examined carefully. Most input variables are discrete counts without learned embeddings, and only a limited set of continuous descriptors contributes to interpolation. As shown in the training–validation curves, no divergence indicative of uncontrolled overfitting is observed.

To further assess model robustness, a local sensitivity analysis was performed by applying random multiplicative perturbations of up to ±30% to the continuous input descriptors, while keeping discrete features and molecular graph representations fixed. Across Monte Carlo perturbations, the resulting predictions remained centred around their unperturbed baselines and exhibited smoothly varying, bounded deviations (**Figure 2**). Importantly, the overall response patterns were preserved across all output endpoints, with no evidence of abrupt jumps or erratic behaviour. These observations indicate that the learned input–output mapping is locally smooth and internally consistent, supporting stable generalization rather than sensitivity to small, high-frequency input fluctuations.

Finally, the generalization performance of the proposed fused multi-task model was evaluated on the

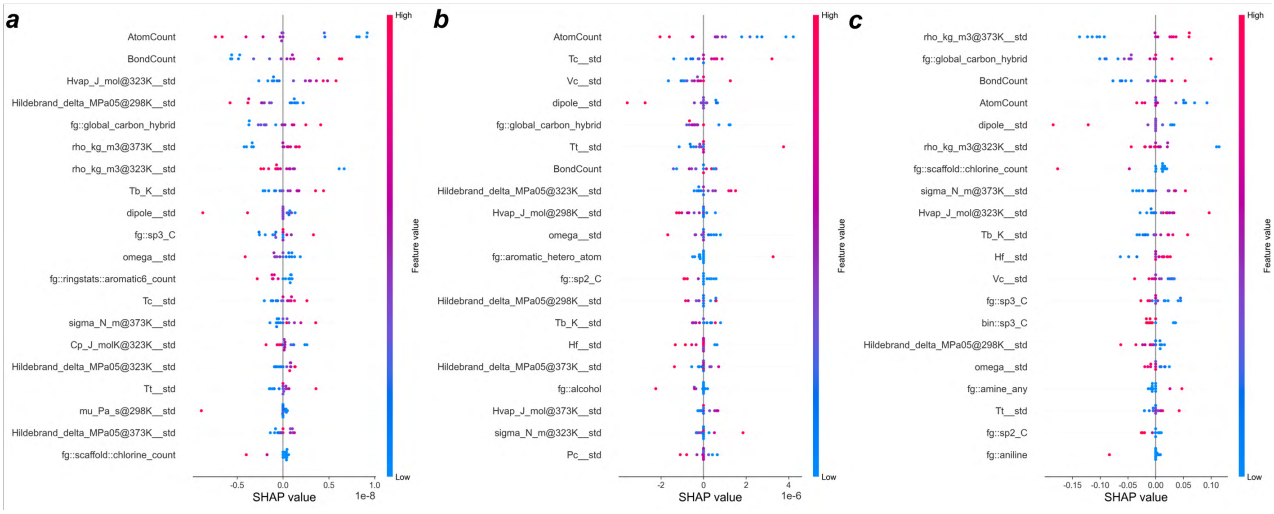

**Figure 3.** SHAP-based feature attribution on test set for three endpoints. SHAP beeswarm plots are shown for each endpoint, with features ordered by their mean absolute contribution. The x-axis denotes SHAP values reflecting the impact on model predictions, while the colour gradient (blue to red) indicates low to high feature values across the dataset.

validation set (**Table 2**). To provide a scale-aware assessment of predictive accuracy across outputs with different magnitudes, the symmetric mean absolute percentage error (sMAPE) was employed. The resulting sMAPE value of 23.82% indicates that, on average, prediction deviations remain bounded within a practically acceptable range under relative scaling. When considered together with the bounded absolute error metrics, this result suggests stable generalization behaviour on unseen data, rather than sensitivity to specific training instances.

**Table 2:** Prediction performance on the validation set.

| **Model** | RMSE | MAE | MSE | sMAPE* |
|---|---|---|---|---|
| Fused-Multi-Task Model | 0.271 | 0.190 | 0.0736 | 23.82 |

*sMAPE: Symmetric Mean Absolute Percentage Error (%)

## 3.3 SHAP

**Figure 3** presents SHAP Beeswarm plots for the three predictive endpoints on test set. For endpoint human health (a), global molecular size descriptors and thermophysical properties, such as atom and bond counts, vaporization enthalpy, and Hildebrand solubility parameters, dominate the model contributions. Endpoint ecosystem quality (b) is primarily governed by standardised thermodynamic and state variables (e.g., critical temperature and volume), indicating a stronger reliance on continuous physicochemical attributes. In contrast, endpoint resource scarcity (c) shows increased sensitivity to structural and functional-group descriptors, suggesting that local chemical features play a more prominent role in shaping the model response.

The observed SHAP attribution patterns provide additional validation of the adopted hybrid descriptor strategy. Discrete structural features and continuous thermophysical properties are both actively utilised by the model, with their relative contributions varying coherently across endpoints. Such structured and endpoint-dependent feature usage suggests that the descriptor selection captures relevant chemical and physical information, rather than relying on arbitrary or redundant inputs.

## 3.4 Application

### 3.4.1 Problem Setting

The proposed molecular design strategy can be coupled with appropriate engineering and chemical constraints across multiple unit operations in pharmaceutical manufacturing, including synthesis, separation, crystallization, and downstream filtration–washing–drying steps. As a representative application, this study focuses on crystallization. When water is regarded as the most desirable and environmentally preferred crystallization solvent, the design task reduces to identifying the “cradle-to-gate greenest” molecular candidates whose crystallization yield is thermodynamically favored. Assuming that yield is governed solely by solubility thermodynamics and that solubility follows the General Solubility Equation (GSE), the problem becomes one of selecting the optimal molecule under a solubility-driven feasibility framework. The optimization problem is expressed as:

$$\min_{x \in \mathcal{X}} F(x) = \lambda_{\text{sol}}(1 - P_{\text{sol}}(x)) + \lambda_{\text{soft}}\,\Phi(x) \qquad (1)$$

$$s.t. \quad x \text{ canonical SMILES}, \text{Elements}(x) \subseteq \{C, H, N, O, S, F\},$$

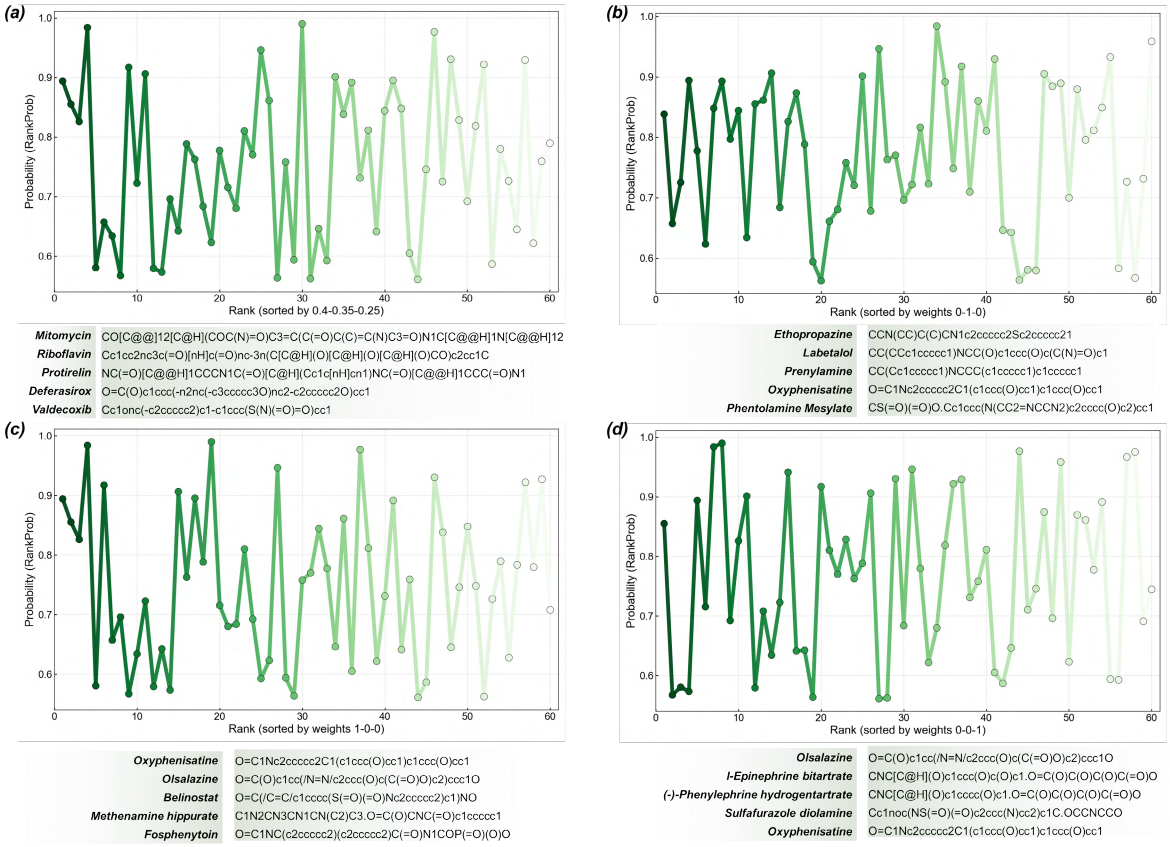

**Figure 4:** Candidates ranking profiles under four normalized endpoint weighting schemes: (a) 0.4–0.35–0.25, (b) 0–1–0, (c) 1–0–0, (d) 0–0–1, corresponding to emphasis on human health, ecosystem quality, and resource depletion, respectively.

$$\text{Atoms}(x) \le 80,\ 300 \le MW(x) \le 400,\ \text{Charge}(x) = 0$$

$$P_{\text{sol}}(x) = \Pr(\log S(x) \ge \log S_{\min} = 10^{-2}),$$

$$\text{Log}\, S(x) = a + b\,(T_m(x) - 25) + c\,\log P(x) + \epsilon,$$

$$a \sim N(0.5, 0.1^2), b \sim N(-0.01, 0.002^2),$$

$$c \sim N(-1.0, 0.10^2), \epsilon \sim N(0, 0.30^2),$$

$$\hat{\mathbf{y}}(x) = \mathcal{M}_{\text{Fused(ML), 3-out}}(x) = \big(\hat{y}_1(x), \hat{y}_2(x), \hat{y}_3(x)\big),$$

$$0 < \hat{y}_k(x) < z, k = 1, 2, 3.$$

Within this formulation, molecular design is cast as an optimization problem in which each candidate SMILES must satisfy structural and com-positional feasibility constraints. The fitness function consists of a solubility-feasibility term and a soft structural penalty, where feasibility is defined as the probability that the predicted solubility exceeds a minimum threshold. This probability is obtained through Monte-Carlo evaluation of an uncertainty-aware GSE model, where a melting-point surrogate and calculated lipophilicity serve as inputs and the regression coefficients and residual variability are represented as random variables to capture intrinsic model uncertainty and propagated input noise. Three indicators predicted by the multi-task fused ML model prediction results simultaneously from molecular structure, where lower values correspond to greener and more sustainable process outcomes. Different weight combinations were applied to flexibly adjust the relative emphasis on sustainability objectives.

### 3.4.2 Solubility-Constrained Molecular Optimization

To benchmark the design outcomes against real pharmaceutical space, the generated candidates were compared with Phase IV approved drug substances curated from ChEMBL. These approved APIs were screened under the same structural and solubility constraints, and their sustainability profiles under different weighting schemes are summarized in **Figure 4**.

Under the human health dominated configuration (1 0 0), the top ranked molecules exhibit a consistent set of structural features, including moderate polarity, low halogen content, and stable aromatic or semi rigid scaffolds. When ecosystem quality receives full weight (0 1 0), the ranking shifts toward molecules with fewer persistent functional motifs, reduced halogenation, and thermophysical attributes that correspond to faster

environmental degradation. In contrast, the resource scarcity dominated configuration (0 0 1) systematically promotes structurally simpler molecules that contain fewer heteroatoms and less complex functional groups, reflecting the cost-based nature of the resource metric.

Across the different weighting schemes, a subset of molecules consistently appears in the top ranked region. These repeatedly selected structures share general characteristics such as medium polarity, low halogenation, and the absence of resource intensive functional groups. Their recurrent presence indicates that certain structural motifs provide balanced sustainability performance across human health, ecosystem, and resource endpoints. This suggests the existence of a structural region that jointly satisfies the requirements of the three metrics.

Finally, it is important to clarify that the ranking behavior in **Figure 4** is determined entirely by ReCiPe endpoint indicators. The GSE based solubility probability serves a separate purpose within the optimization framework. It acts solely as a feasibility constraint, where a higher probability reflects a greater likelihood of meeting crystallization requirements rather than an improvement in sustainability performance.

## 4. CONCULSION

This work presents an approach for integrating environmental sustainability considerations into early-stage molecular design of pharmaceuticals. By combining structural descriptors, thermophysical attributes, and graph-level information through a hybrid representation, a multi-task model was developed to predict three ReCiPe endpoint indicators. The model exhibits stable training behaviour, controlled sensitivity to input perturbations, and interpretable feature usage, supporting its suitability for downstream design tasks.

Incorporation of the predictive model into a solubility-constrained optimization framework enables the evaluation of structurally feasible molecular candidates under uncertainty. Comparative analysis with Phase IV approved drug substances illustrates how endpoint-specific weighting schemes influence molecular prioritization. The human-health metric favours moderately polar, low-halogen rigid scaffolds; the ecosystem metric favours molecules with fewer persistent structural motifs; and the resource metric favours structurally simpler and heteroatom-sparse designs. Several molecules repeatedly appear in top-ranked regions across different weighting configurations, suggesting the presence of a structural domain that offers balanced performance across all three sustainability endpoints.

Overall, the strategy provides a systematic route for incorporating sustainability metrics at the molecular-design stage, supporting well-informed decision-making prior to downstream process development.

## ABSTRACT

Reliable multimodal monitoring in crystallization processes remains challenging due to heterogeneous PAT signal quality, sensor drift, asynchronous sampling and nonstationary noise. This work presents a machine-learning-assisted fusion framework that integrates multimodal PAT alignment, estimation and physics-guided regularisation to generate coherent concentration and particle-size trajectories. A mechanistically informed simulation platform is developed to produce synthetic Raman, FTIR, FBRM and image-based crystal size data with realistically simulated drift, heteroscedastic noise, dropouts and distortion patterns. Sensor reliability is inferred through a Random Forest model trained on variance-normalised discrepancies and quality metrics, which allows the dynamic adjustment of channel contributions. Across modalities, the Random Forest achieves MAE values of 0.03-0.20 for probability-type indicators and shows stable explanatory power for variance-inflation factors on particle-size channels ($R^2$ = 0.81-0.93). Two representative PAT scenarios illustrate the performance of the proposed framework under different cross-sensor discrepancy structures, demonstrating improved robustness, reduced local variance and enhanced physical coherence compared with individual signals. Overall, the results highlight the potential of multimodal information fusion as a foundation for trustworthy online monitoring and modelling in crystallization.

**Keywords**: Machine Learning, Process Monitoring, Modelling and Simulations, Surrogate Model

## 1. INTRODUCTION

With the rapid progression of continuous manufacturing, digital twins and process intensification, achieving reliable online observability has become central to ensuring product quality and supporting high-fidelity process modeling [1-4]. This need is particularly acute in crystallization-centered systems, where the time dependent evolution of solute concentration and crystal size governs supersaturation control, population-balance dynamics and critical quality attributes [5, 6]. Accurate and high-resolution online measurements that capture the underlying physicochemical evolution are therefore essential for model development, and model-based optimization [7, 8].

Industrial crystallization is typically monitored using process analytical technology (PAT) tools such as Raman and FTIR spectroscopy for concentration estimation, and FBRM or in situ imaging for particle size characterization [9-11]. Although these sensors provide complementary information, their performance in practice is affected by temperature- and solids-dependent spectral drift [12, 13], the structural mismatch between chord length and true particle sizes [14, 15], and imaging artefacts such as defocus or occlusion [16]. Additional challenges arise from asynchronous sampling between fast and slow PAT instruments, which leads to temporal misalignment and apparent discontinuities [17]. While various single sensor enhancement strategies have been proposed, inconsistencies between PAT channels remain common when individual sensors experience degradation or temporary downtime, complicating unified trajectory reconstruction for kinetic modeling, PBM simulation and soft sensing [18, 19].

To obtain more robust estimates of concentration and particle size in particulate processes, researchers have explored signal level fusion strategies, including basic weighting schemes such as inverse-variance

weighting [14, 20], rule-based gating heuristics [21, 22], and classical filtering or smoothing [23, 24] to combine information from heterogeneous PAT channels. While these approaches improve interpretability under relatively stable conditions, their performance remains largely confined to laboratory settings, with limited consideration of realistic industrial signal situations. In response, researchers have increasingly moved towards model level fusion frameworks that explicitly encode multi-sensor data structures, mechanistic constraints, and probabilistic noise models [25, 26]. These approaches treat heterogeneous PAT channels as jointly informative measurements embedded within unified state-space or hybrid mechanistic–statistical formulations. For example, nonlinear state estimators such as EKF, UKF and moving-horizon observers have been applied to reconstruct solute concentration and crystal size distributions from multiple process measurements in seeded and industrial crystallization systems [27, 28]. In parallel, multi-PAT sensor arrays that combine spectroscopic and particle focused modalities have demonstrated the value of structurally modelling cross channel complementarity for polymorphism and particle size monitoring [29]. Nonetheless, these methods are often built upon assumptions of stable noise characteristics and consistently reliable sensor availability, whereas industrial crystallization environments exhibit dynamic hydrodynamics, varying solids loading and fluctuating PAT signal quality. Achieving robustness, physical consistency and interpretability simultaneously therefore remains a critical open challenge.

To address these challenges, a system level framework is developed that integrates multimodal PAT data simulation, dynamic sensor weight learning, and robust fusion. First, a multi-sensor data generation platform is established. This platform emulates industrial PAT behaviours with drift, offset, heteroscedastic noise, local dropouts and asynchronous sampling, aiming to generate complex and highly perturbed signals that capture the multi-factor variability observed under realistic industrial operating conditions. Next, an ML-based adaptive weighting mechanism is introduced to adjust sensor credibility in real time according to signal quality. Finally, robust statistical methods combined with temporal and physicochemical constraints ensure that the fused concentration and particle size trajectories remain smooth, consistent and physically coherent even under challenging noise conditions.

# 2. METHODOLOGY

## 2.1 PAT Data Structure and Feature Construction

The analysis considers four PAT channels: Raman and FTIR for concentration, and image-based sensors (IMA, e.g., PVM) and FBRM-proxy channels for particle size. Temperature is taken as the reference timeline, and all PAT streams are merged using an as-of alignment within a fixed tolerance so that each time point contains a consistent set of observations and associated time-step information. The aligned dataset is defined in **Eq. (1)**.

$$\mathcal{D}(t) = \{C_{\mathrm{Raman}}(t),\ C_{\mathrm{FTIR}}(t),\ L_{\mathrm{PVM}}(t),\ L_{\mathrm{FBRM}}(t),\ T(t)\} \quad (1)$$

Concentration-related feature vectors $X_{conc}(t)$ are formed from the instantaneous Raman and FTIR values, first-order temporal differences computed over a 7-point window, local variance estimates, normalised inter-channel discrepancies, and the time step statistics inherited from the alignment procedure. Spectral quality metadata including correlation coefficients and wavelength-shift indicators are included as direct numerical features when present in the raw PAT output.

Particle size feature vectors $X_{size}(t)$ comprise the instantaneous size estimates obtained from IMA, the calibrated FBRM-proxy signals, as well as derived descriptors including local temporal gradients, rolling-window variability, and the normalised discrepancy between the image-based and FBRM-proxy channels. To represent channel specific noise behaviour, image-quality indicators and count variance metrics associated with the construction of the FBRM-proxy are also incorporated.

For general applications, the underlying dataset must provide synchronised multi-sensor time series with explicit timestamps, channel resolved variance estimates, and relevant quality metadata. In the present study, all PAT datasets used for model development and evaluation are synthetically generated cases designed to strictly conform to this structural specification.

## 2.2 Pseudo-Label Construction and Model Training

For each case, Raman–FTIR and IMA–FBRM pairs are aligned on the common time axis. At each time index t, the two sensor readings $y_1(t)$ and $y_2(t)$, together with their nominal standard deviations $s_1(t)$ and $s_2(t)$, are combined to obtain a robust reference value. The reference is defined as the minimiser in **Eq. (2).**

$$x(t) = \arg\min_{x} \left[\rho\left(\frac{x - y_1(t)}{s_1(t)}\right) + \rho\left(\frac{x - y_2(t)}{s_2(t)}\right)\right] \quad (2)$$

where $\rho(\cdot)$ is the Huber loss. When only one measurement is available, the reference is taken directly from that channel. Residuals $r_i(t)$ are computed, and the normalised deviation is calculated in **Eq. (3)**, which is used to characterise the discrepancy between each sensor reading and the reference, relative to its nominal noise level. Based on this deviation, a variance inflation factor (VIF) (**Eq. (4)**) is assigned to each sensor and subsequently clipped within a fixed interval to suppress unrealistically large inflation values.

$$z_i(t) = \frac{|\, r_i(t)\,|}{s_i(t)} \tag{3}$$

$$\alpha_i(t) = \frac{r_i(t)^2}{s_i(t)^2} \tag{4}$$

A probability type failure indicator is constructed by combining $z_i(t)$ with channel specific quality metrics, including spectral correlation and peak-shift descriptors for Raman/FTIR, and image correlation and count-variance descriptors for IMA/FBRM. The final probability is obtained in **Eq. (5)**.

$$p_{\mathrm{bad},i}(t) = \sigma(z_i(t) + \gamma\, q_i(t)) \tag{5}$$

where $q_i(t)$ is the aggregated quality score and $\gamma$ is a constant scale factor.

The input feature matrices are those constructed in Section 2.1. Two independent multi-output Random Forest regressors are trained for concentration and size separately. Each model outputs a four-dimensional vector ($p_{bad,\,i}(t)$, $\alpha_i(t)$). The regressors consist of 500 trees, use bootstrap sampling, employ mean-squared error as the splitting criterion, and restrict leaf size to a minimum of three samples to stabilise the estimates. Maximum tree depth is not constrained, allowing the ensemble to approximate nonlinear patterns. Feature subsets at each split are selected using sqrt-d sampling, where dis the number of feature dimensions.

The full dataset is randomly divided into an 80/20 train–test split with a fixed random seed to ensure reproducibility. Each Random Forest model is trained on the training portion and evaluated on the test portion using mean absolute error, root-mean-square deviation, coefficient of determination, and signed bias. After prediction, outputs corresponding to probability-type indicators are clipped to [0, 1], and VIFs are clipped to the prescribed interval. These trained regressors serve as the reliability estimators for the sensor weighting scheme used in the fusion procedure of Section 2.3.

## 2.3 Sensor Fusion with Constraints and Regularisation

The trained models provide estimates of the probability of sensor failure and the corresponding VIF. These outputs jointly modulate the effective contribution of each channel. A channel is considered unreliable when $p_{bad,\,i}(t)$ exceeds a high-risk threshold, in which case it is temporarily removed from fusion; when only one channel remains valid, the fused estimate simply follows that channel. For all remaining channels, the effective measurement uncertainty is computed in **Eq. (6)**. The precision score can be defined in **Eq. (7)**.

$$\tilde{v}_i(t) = \alpha_i(t)\, v_i(t) \tag{6}$$

$$\mathrm{prec}_i(t) = \frac{(1 - p_{\mathrm{bad},i}(t))^{\gamma}}{\tilde{v}_i(t)} \tag{7}$$

where γ controls the sharpness of the penalty applied to unreliable sensors. The contribution weights are then obtained by normalisation (Eq. (8)), after which they are smoothed in time to prevent abrupt switching caused by local noise or transient prediction variability. The fused estimate and its propagated variance follow the standard precision weighted averaging rules (**Eqs. (9-10)**).

$$w_i(t) = \frac{\mathrm{prec}_i(t)}{\sum_j \mathrm{prec}_j(t)} \tag{8}$$

$$y_{\mathrm{fused}}(t) = \sum_i w_i(t)\, y_i(t) \tag{9}$$

$$v_{\mathrm{fused}}(t) = \sum_i w_i^2(t)\, v_i(t) \tag{10}$$

Short gaps caused by sensor dropouts are filled by linear interpolation with aggressive variance inflation, ensuring that reconstructed segments carry low confidence and are naturally down weighted in later steps. To maintain consistency with crystallisation physics, the fused trajectories are further regularised by two physical constraints. The first ensures that the fused concentration remains consistent with the solubility relation at the corresponding temperature. The second enforces growth-dominated behaviour, where particle number is approximately conserved and the evolution of the characteristic size follows the prescribed baseline kinetics.

# 3. RESULTS AND DISCUSSION

## 3.1 Model Performance

The behaviour of each output in **Table 1** is consistent with the way pseudo-labels are generated in the training pipeline. In the code, both $p_{\mathrm{bad},i}(t)$ and $\alpha_i(t)$ are computed from residuals relative to a robust fused reference obtained via Huber IRLS. Channels whose simulated noise structure is tightly controlled (FBRM counts and IMA imaging) produce pseudo-labels with low intrinsic variability, resulting in smoother targets and correspondingly higher $R^2$ values for both $p_{\mathrm{bad}}$ and $\alpha$. In contrast, the Raman and FTIR channels incorporate larger fluctuations in their synthetic noise terms, including peak-shift, correlation degradation and variable spectral perturbations. These lead to a wider spread in the pseudo-labels and therefore lower $R^2$ for the corresponding regression tasks.

For the probability type indicators $p_{\mathrm{bad},i}$, the mapping is dominated by monotonic functions of the normalised deviation $z_i(t)$ and channel specific quality metrics. These relationships are relatively smooth and piecewise monotonic, which aligns well with the structure of the RF

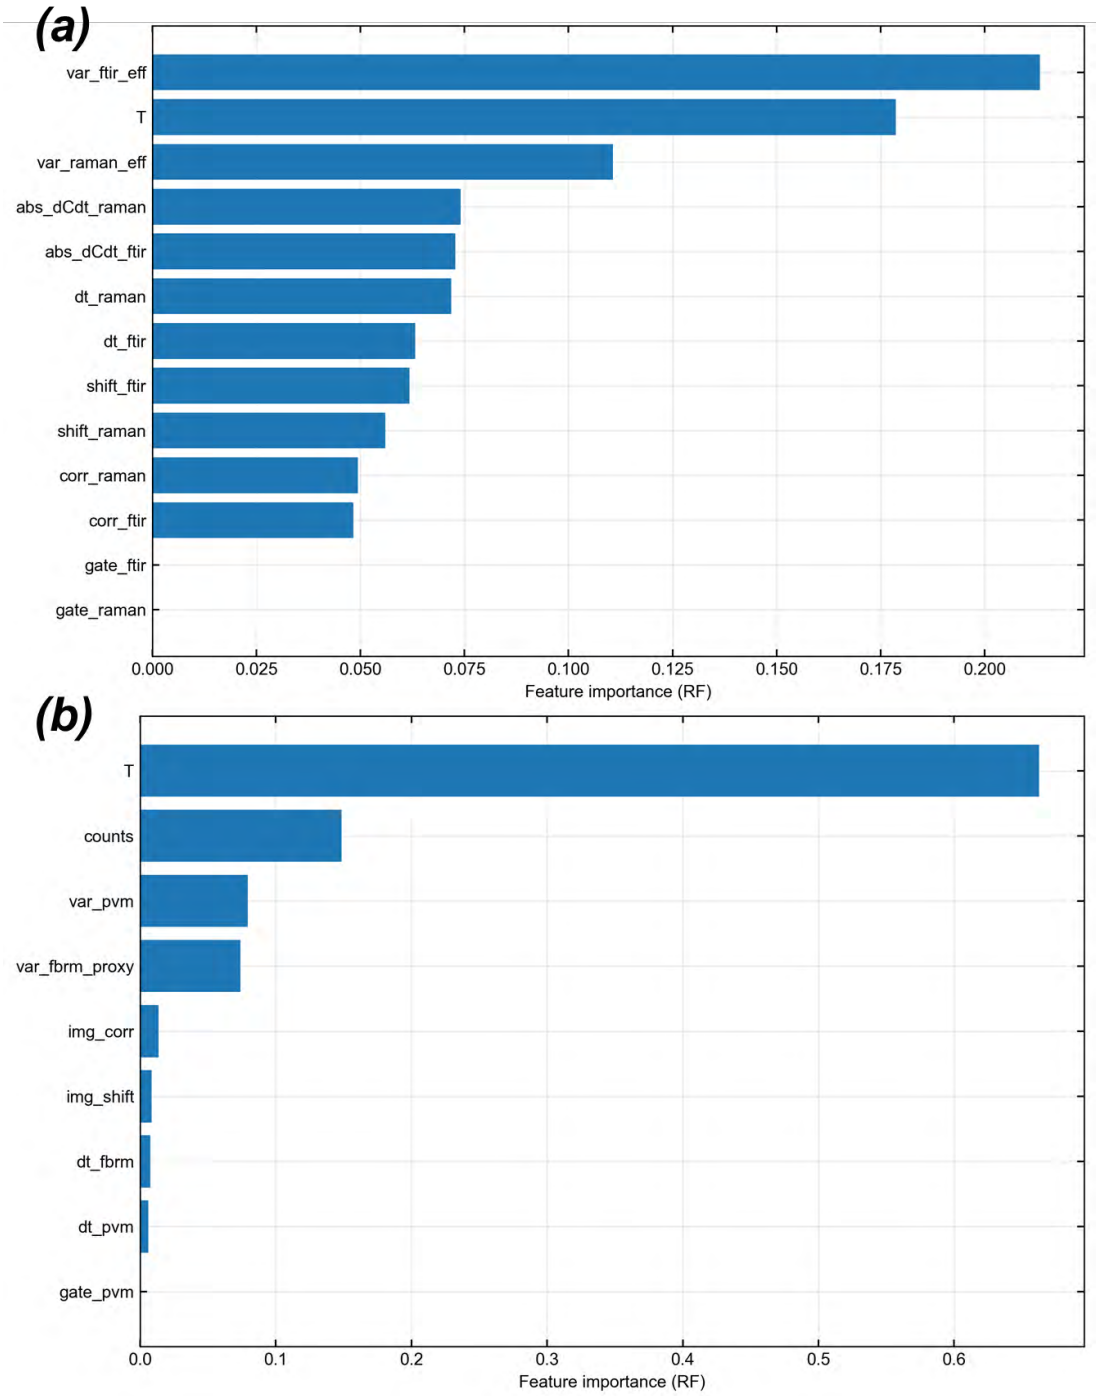

**Figure 1.** Feature importance of the RF models for (a) concentration and (b) particle size signals.

model. Consequently, all PAT channels yield low prediction errors and stable $R^2$, including the Raman and FTIR channels.

The VIFs $\alpha_i$depend quadratically on residuals, and therefore amplify local variability more strongly. In the synthetic dataset, the Raman and FTIR channels possess higher perturbation amplitude and more irregular local fluctuations. This produces labels with higher dispersion and less predictable fine-scale structure, reducing the achievable $R^2$even when MAE and bias remain small. The lower $R^2$for $\alpha_{\mathrm{Raman}}$and $\alpha_{\mathrm{FTIR}}$therefore reflects the variability present in the labels rather than a systematic model deficiency, and does not affect the downstream fusion

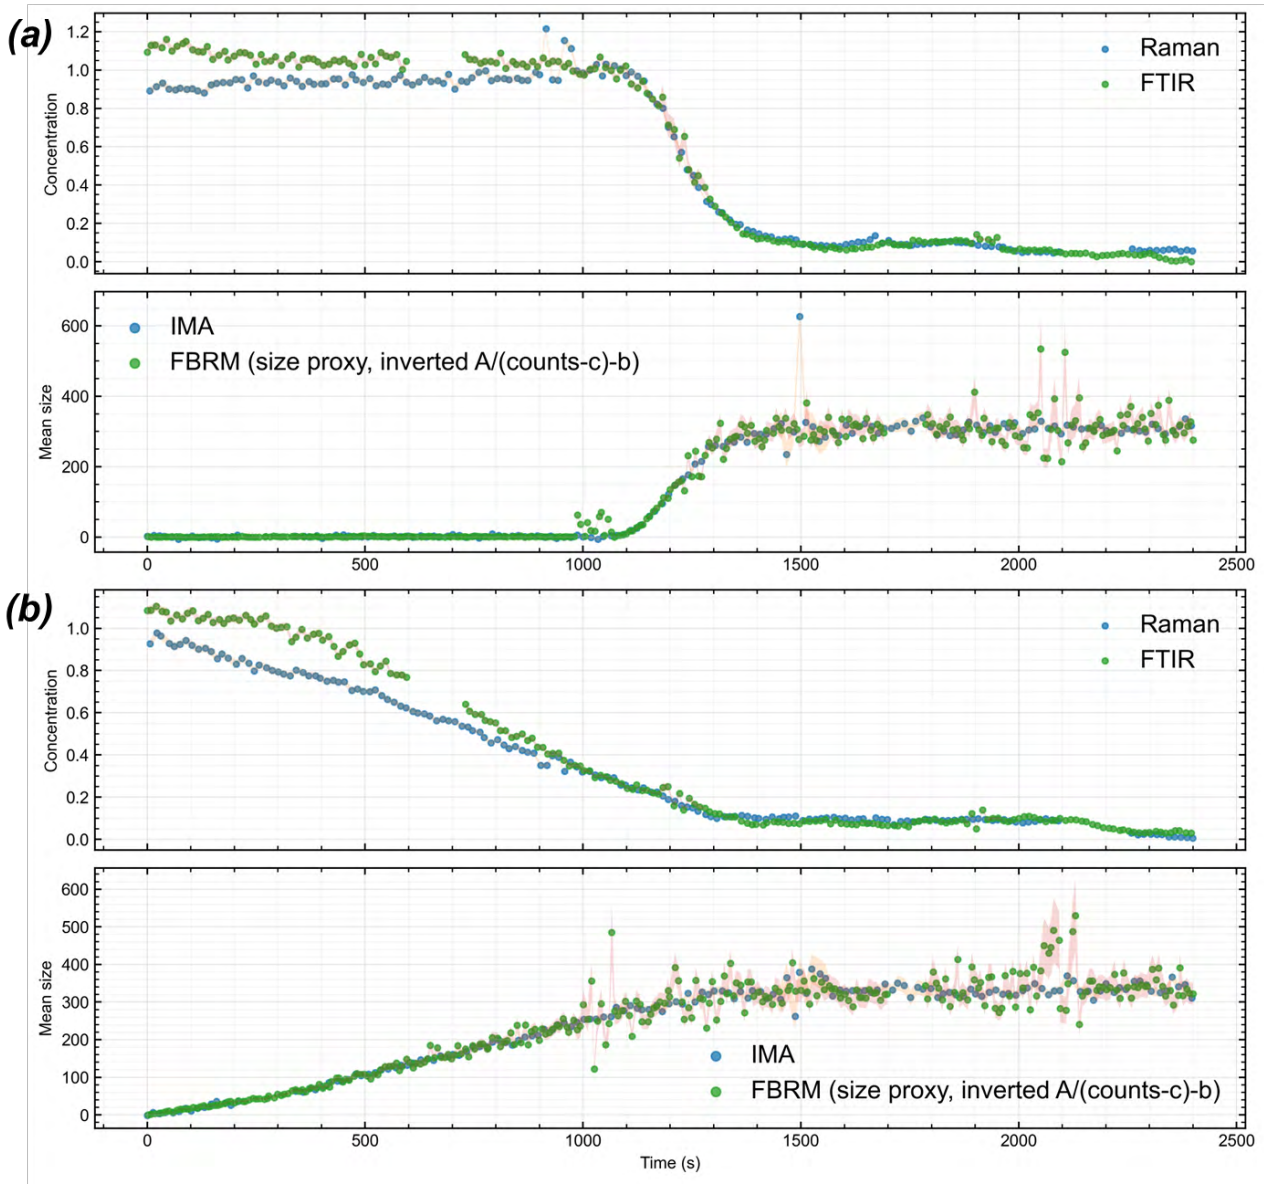

**Figure 2.** Synthetic scenarios used to evaluate fusion robustness cases (a) and (b).

stage where post clamped values are used only to modulate channel wise uncertainties.

Overall, the contrasting performance across channels directly follows from the pseudo label construction mechanism in the simulation code. The lower $R^2$for the Raman/FTIR $\alpha$outputs is expected under the imposed noise model and does not compromise the reliability estimates used in the subsequent fusion step.

The feature importance results reflect how the random forest allocates predictive weight across the input descriptors within the training dataset (**Figure 1**). For the concentration RF model, the highest ranked features are the effective variance terms (var_ftir_eff and var_raman_eff), followed by temperature and a set of short-term derivative descriptors (|dC/dt|, **Figure 1(a)**). These descriptors dominate the model's internal decision rules because they exhibit the strongest association with the pseudo-labelled reliability targets generated during training. Additional spectral structure descriptors, including peak-shift and correlation metrics, also receive non-negligible importance, consistent with their role in characterising signal perturbations within the dataset.

For the size RF model, temperature again appears with the highest importance values (**Figure 1(b)**). Other influential descriptors include the chord-count signal, variance terms derived from both IMA and FBRM-proxy channels, and image correlation and image shift measures. These variables receive higher weights

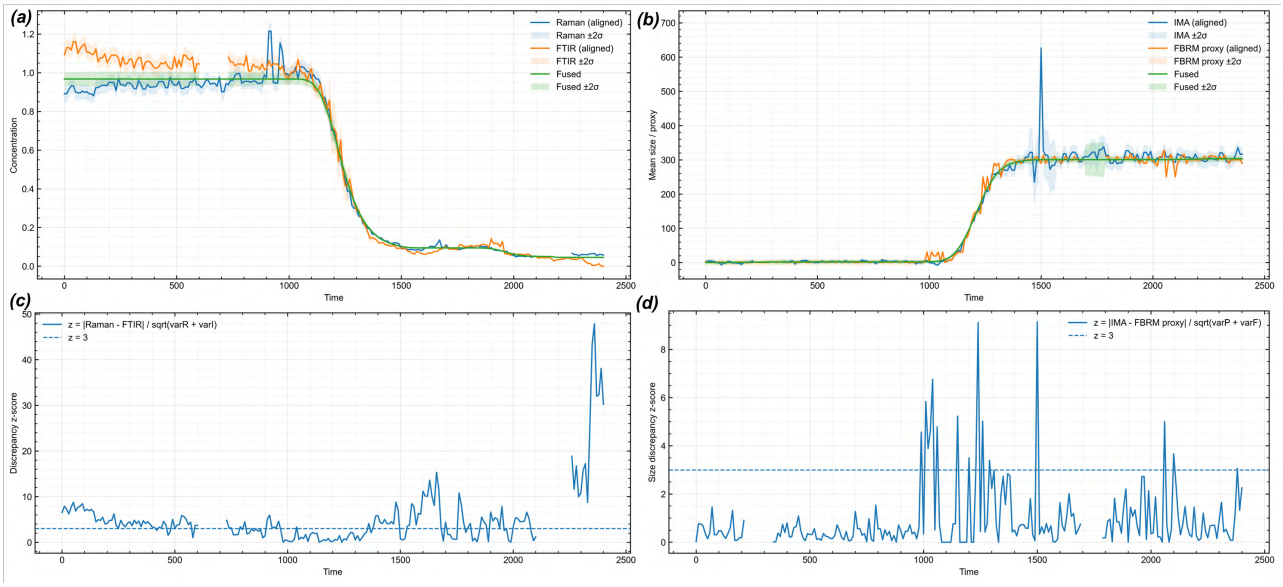

**Figure 3.** Multimodal PAT fusion results for Case 1. (**a**) aligned Raman and FTIR concentration measurements with fused estimates and uncertainty bands, (**b**) aligned IMA and FBRM-proxy mean size trajectories with fused estimates and uncertainty bands, and (**c–d**) discrepancy z-scores quantifying cross-sensor consistency over time.

because they co-vary with the reliability pseudo-labels across the synthetic cases used for training. Time-alignment and gating flags also contribute, although with lower importance relative to variance- and correlation-based descriptors.

Overall, the models emphasise descriptors that vary most consistently with the reliability pseudo-labels in the generated dataset, particularly those reflecting signal variance, short-term fluctuations, and structural perturbations in the PAT measurements. These importance patterns should be interpreted strictly as reflections of the models' internal learning behaviour under the specific data-generation and pseudo-labelling scheme adopted here, and do not imply generalisable diagnostic value beyond this study's design.

**Table 1:** Prediction performance of the multi-output Random Forest model for each PAT channel.

| Output | MAE | RMSE | $R^2$ | Bias |
|---|---|---|---|---|
| $P_{bad\ IMA}$ | 0.0605 | 0.1081 | 0.7220 | -0.0041 |
| $\alpha_{IMA}$ | 0.7789 | 2.0620 | 0.8118 | -0.0865 |
| $P_{bad\ FBRM}$ | 0.0312 | 0.0586 | 0.9001 | -0.0016 |
| $\alpha_{FBRM}$ | 0.2796 | 1.1892 | 0.9317 | 0.0017 |
| $P_{bad\ Raman}$ | 0.1596 | 0.2115 | 0.5093 | -0.0035 |
| $\alpha_{Raman}$ | 3.8445 | 5.6881 | 0.4896 | -0.1377 |
| $P_{bad\ FTIR}$ | 0.2047 | 0.2558 | 0.4654 | 0.0011 |
| $\alpha_{FTIR}$ | 6.1362 | 7.5885 | 0.4111 | -0.0160 |

## 3.2 Case Studies

In this section two representative multimodal PAT cases are examined to illustrate the primary challenges in crystallization monitoring (**Figure 2**). Case a exhibits relatively stable concentration measurements but highly dynamic particle size evolution with an initial induction period, a rapid growth phase and sensor degradation episodes including imaging defocus, chord-length distortion and temporary dropouts. Case b features stronger baseline drift and temperature-dependent bias in the concentration channels, while the size measurements display continuous growth with local anomalies and inversion-related inconsistencies.

The fusion results for case 1 are available in **Figures 3 (a-d)**. The concentration trajectories in **Figure 3 (a)** show that Raman and FTIR follow the same overall evolution, although they display a noticeable baseline offset in the early stage. When the system enters the dominant crystallization transition between approximately 1100 and 1400 seconds, the two sensors respond coherently and the fused trajectory captures a physically smooth decline while presenting a narrower uncertainty envelope than either individual channel. This behaviour indicates effective fusion: the model is able to combine the complementary information from both sensors, reduce high-frequency noise and suppress misalignment-related variability. In the final segment of the experiment, roughly after 2200 seconds, the two concentration channels diverge substantially. The discrepancy z-score in **Figure 3 (c)** rises to values far beyond the expected statistical range, signalling that the disagreement between sensors is too large to be explained by their combined variance. This pattern is characteristic of sensor drift, intermittent artefacts or reliability degradation. The fused estimate remains stable during these periods and avoids

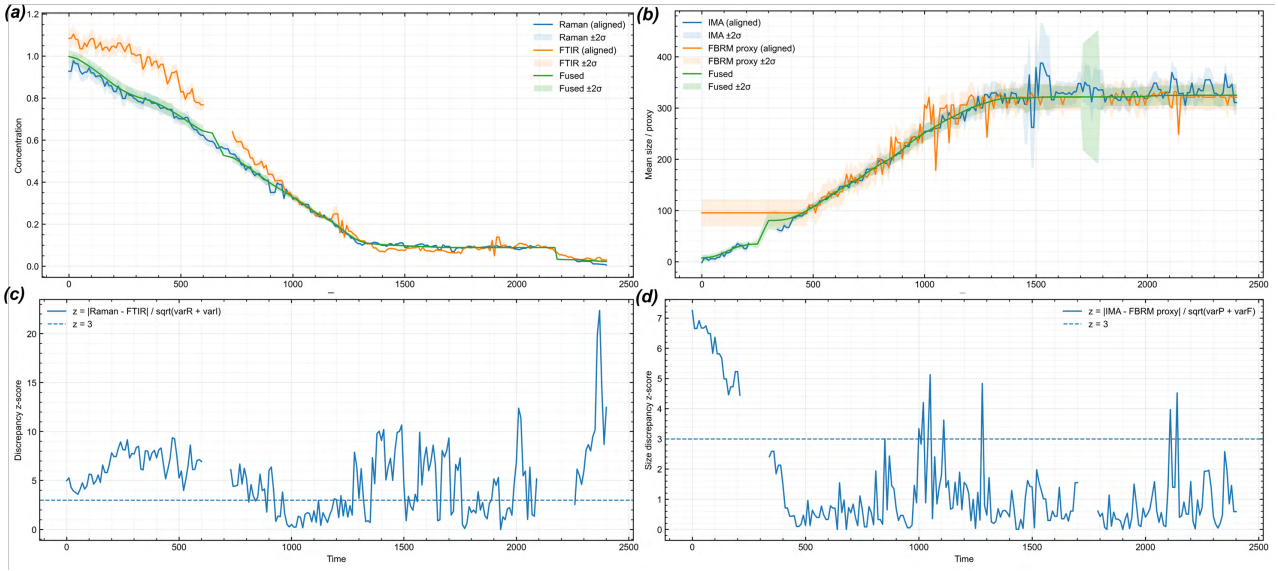

**Figure 4.** Multimodal PAT fusion results for Case 2. (**a**) aligned Raman and FTIR concentration measurements with fused estimates and uncertainty bands, (**b**) aligned IMA and FBRM-proxy mean size trajectories with fused estimates and uncertainty bands, and (**c–d**) discrepancy z-scores quantifying cross-sensor consistency over time.

propagating spurious fluctuations.

A similar behaviour is observed for the size signals in **Figure 3 (b)**. IMA and the FBRM-derived proxy exhibit consistent growth dynamics during the nucleation and growth regime and converge to a comparable plateau. IMA shows isolated spikes, most prominently near 1500 seconds. The fused estimate does not follow these irregular excursions and instead yields a smooth, monotonic trajectory that aligns with the expected crystallization trend. The discrepancy z-scores in **Figure 3 (d)** are small during the steady and slowly evolving periods, and markedly larger during transitional and disturbed regions. This indicates that the sensors agree well under stable conditions and that disagreements emerge mainly during rapid changes or localised noise events. Overall, the fused concentration and size trajectories are smoother, more physically interpretable and more robust to sensor artefacts than any individual signal.

In Case 2, the concentration signals display a stronger systematic discrepancy than in Case 1, with FTIR exhibiting an elevated baseline and larger drift throughout the early and mid stages (**Figures 4 (a-d)**). Despite the offset, both sensors follow similar downward kinetics, allowing the fused concentration to track the global trend while moderating channel specific bias and reducing local variance. The discrepancy z-scores remain consistently above the statistical threshold, indicating that the two sensors disagree more persistently than in Case 1 and signalling limited redundancy within the concentration pair.

For the particle size, IMA and the FBRM proxy show broadly similar growth behaviour during the early stage but diverge substantially after the main transition. IMA provides smoother and more continuous growth, while the FBRM proxy introduces abrupt fluctuations and intermittent artefacts, resulting in elevated size discrepancy z-scores across a wider time window. The fused size estimate mitigates these inconsistencies by suppressing FBRM-induced spikes and maintaining a physically coherent trajectory. Compared with Case 1, this case demonstrates higher cross-sensor disagreement and places greater emphasis on the fusion mechanism's ability to reject outliers and stabilise the evolution of both concentration and size.

## 3.3 Limitations and Future Perspectives

Although the present framework demonstrates robustness across heterogeneous PAT signals, several limitations remain. The analysis relies on synthetic scenarios and may not fully capture the complexity of real sensor behaviour, particularly long-term drift, chemometric model degradation, and process-dependent nonlinearities that can reshape the noise structure. In addition, the current fusion mechanism operates primarily at the signal level and does not explicitly integrate mechanistic constraints or population-balance consistency, which limits its ability to enforce global physical plausibility under severe sensor failure.

Future developments could incorporate hybrid physical statistical priors, adaptive drift modelling, and online reliability learning from historical process batches. Extending the framework to multivariate spectral domains, image-based morphological descriptors, and higher-frequency transient events would further enhance

its applicability to industrial crystallization.

## 4. CONCLUSIONS

This study developed a machine learning-assisted fusion framework for achieving reliable and physically coherent multimodal PAT monitoring in crystallization processes. By combining mechanistically informed data simulation, variance normalised discrepancy analysis and Random Forest-based reliability estimation, the method dynamically adjusts sensor contributions and mitigates the impact of drift, noise bursts, dropouts and cross-sensor inconsistencies. The physics-guided regularisation step further constrains the fused concentration and particle size trajectories to follow thermodynamic relations and growth-dominated crystallization behaviour.

Across two representative multimodal PAT scenarios, the framework consistently produced smoother, more interpretable and more robust trajectories than any individual sensor channel. In cases with mild disagreement, fusion effectively reduced noise and improved local consistency, whereas in scenarios with strong baseline drift or conflicting size measurements, the reliability model successfully down-weighted degraded sensors and preserved coherent kinetic trends. These results demonstrate that reliability-aware fusion can substantially enhance the integrity of multimodal crystallization monitoring under realistic industrial signal challenges.

## ABSTRACT

We investigate ultrasound-assisted transesterification for biodiesel production. We use inline Raman spectroscopy to quantify its impact on reaction kinetics, catalyst reduction, and temperature sensitivity. We perform a systematic experimental study at different temperatures (50, 55, and 60 °C), different catalyst loadings, with and without ultrasound. The results show that ultrasound significantly accelerates early reaction kinetics at all temperatures, with the strongest effect observed at 55 °C, where both Fatty Acid Methyl Ester (FAME) formation rate and final conversion increase by up to 7 wt%. Under reduced catalyst conditions, ultrasound restores high conversion levels, leading to up to 20 wt% higher final FAME compared to operation without ultrasound and achieving performances comparable to, or exceeding, those obtained with (normal) catalyst without ultrasound. This is mainly because ultrasound primarily enhances mass transfer and phase contact, thereby reducing the system's sensitivity to catalyst loading. These findings demonstrate that ultrasound enables catalyst reduction while maintaining high biodiesel yields, enabling more sustainable and intensified transesterification processes.

**Keywords**: Biodiesel production, transesterification, ultrasound-assisted process intensification, catalyst optimization, Raman spectroscopy, process monitoring, clean energy systems

## INTRODUCTION

Biodiesel is typically produced via the transesterification of triglycerides with short-chain alcohols. It offers advantages such as biodegradability, lower particulate emissions, and compatibility with existing diesel engines [1–3]. Despite its industrial maturity, conventional biodiesel production still faces several challenges, including high catalyst consumption, sensitivity to operating conditions, and mass-transfer limitations arising from the immiscibility between oil and alcohol phases [2, 3]. These limitations directly affect reaction kinetics, energy efficiency, and downstream purification costs, motivating the development of intensified and more sustainable processing routes.

Among the various process-intensification strategies proposed for biodiesel synthesis, ultrasound-assisted transesterification has attracted increasing attention over the past two decades [4, 5]. The application of ultrasound generates acoustic cavitation, leading to localized high temperatures and pressures, micro-jets, and intense micro-mixing at phase interfaces [4–6]. These phenomena enhance interfacial area and mass transfer between reactants, thereby accelerating reaction rates and potentially reducing the dependence on high catalyst loadings or elevated temperatures. Several studies have reported shorter reaction times and improved biodiesel yields when ultrasound is applied, particularly under kinetically or mass-transfer-limited conditions [7–8]. Nevertheless, most existing works focus on final conversion values or batch end-point analyses, providing limited insight into reaction evolution and the temperature-dependent role of ultrasound. Systematic studies quantifying the effect of ultrasound on biodiesel synthesis under different catalyst loadings remain limited.

Moreover, the potential of ultrasound to compensate for reduced catalyst loading, which is critical for improving the sustainability and economics of biodiesel production, has not been comprehensively quantified

under dynamic, inline-monitored conditions. Catalyst reduction is highly desirable, as it directly lowers raw material costs, reduces soap formation, and simplifies downstream separation. Yet, reducing catalyst loading often leads to slower kinetics and incomplete conversion, especially at lower temperatures or in the absence of efficient mixing. Understanding whether ultrasound can mitigate these drawbacks across different temperature regimes is therefore of both scientific and industrial relevance.

Raman spectroscopy has proven particularly suitable for quantifying process conditions due to its non-invasive nature, chemical specificity, and ability to operate under harsh reaction conditions. We demonstrated recently that inline Raman spectroscopy measurements can be employed successfully to monitor triglyceride consumption, fatty acid methyl ester (FAME) formation, and glycerol production during transesterification, offering unprecedented access to reaction kinetics and transient process behavior [9]. However, the combined use of ultrasound-assisted transesterification and inline Raman spectroscopy remains scarcely explored, and systematic studies coupling these two approaches are still lacking.

In this context, the objective of this work is to provide a systematic and quantitative analysis of ultrasound-assisted transesterification using inline Raman spectroscopy. To study the individual and combined effects of different parameters, we employ an experimental design combining three temperatures (50, 55, and 60 °C), two catalyst loadings (normal stoichiometry and 30% reduced), and the presence or absence of ultrasound. By continuously monitoring the evolution of key species using Raman spectroscopy, we aim to (i) study the temperature-dependent impact of ultrasound on reaction kinetics, (ii) assess the ability of ultrasound to compensate for reduced catalyst loading, and (iii) identify operating regimes where ultrasound-based process intensification delivers the greatest benefit. The insights gained contribute to the development of more energy-efficient, catalyst-lean, and digitally monitored biodiesel production processes.

# MATERIALS AND METHODS

## Materials

Refined vegetable oil is used as the triglyceride feedstock for all experiments. served as the alcohol reactant, while sodium methylate, a homogeneous alkaline catalyst, is employed to promote the transesterification reaction. Two catalyst loadings were investigated: a reference “normal” catalyst amount representative of conventional operating conditions, and a reduced catalyst loading corresponding to a 30% decrease relative to the reference case. This reduction level is selected to remain within an industrially relevant range while still inducing measurable kinetic limitations in the absence of process intensification.

All experiments were carried out using a fixed methanol-to-oil molar ratio, chosen sufficiently high to avoid equilibrium limitations and ensure comparability between runs. The reaction temperature is varied between 50 and and 60 °C (lower and higher temperatures were intentionally avoided to reach enough yield and minimize methanol evaporation).

## Experimental Setup

For the semi-batch transesterification of vegetable oil into biodiesel, we use the experimental setup illustrated in Fig. 1. The core of the system is a continuously stirred lab-scale reactor (1) with a nominal working volume of 500 mL. The reactor is jacketed and connected to a thermostatically controlled heat circulator (2) (Julabo GmbH, Germany), allowing precise regulation of the reaction temperature. The temperature inside the reactor is continuously monitored using an immersed PT100 temperature sensor (3).

The feedstock solutions, refined vegetable oil and a pre-mixed methanol/sodium methylate catalyst solution, are stored in separate supply tanks (6 and 7). Each stream is delivered to the reactor via independent high-precision metering pumps (4 and 5) (Knauer GmbH, Germany), enabling accurate control of the injection strategy and the methanol-to-oil molar ratio during semi-batch operation. The reaction mixture is agitated using an overhead mechanical stirrer (8) (Heidolph GmbH, Germany) to ensure effective macroscopic mixing and homogeneous temperature and composition throughout the liquid phase.

Ultrasound irradiation is provided by an external ultrasonic device (11) mechanically coupled to the reactor vessel. The system operates at a fixed low ultrasonic frequency characteristic of cavitation-dominated regimes and is activated continuously during ultrasound-assisted experiments. For reference experiments, the ultrasound unit is completely switched off, while mechanical stirring is maintained in all cases to provide a consistent baseline mixing condition and enable direct comparison between mechanically stirred and ultrasound-enhanced systems.
Real-time process monitoring is achieved using an inline Raman spectroscopy system consisting of a Raman spectrometer (12) (tec5 AG, Germany) equipped with a 785 nm laser source and an immersion Raman probe (9). The probe is mounted directly through the reactor headplate, allowing continuous, non-invasive measurement of the reacting mixture without the need for sampling or offline analysis. The probe position is selected to avoid direct exposure to intense cavitation zones or interfaces while ensuring representative sampling of the liquid phase.

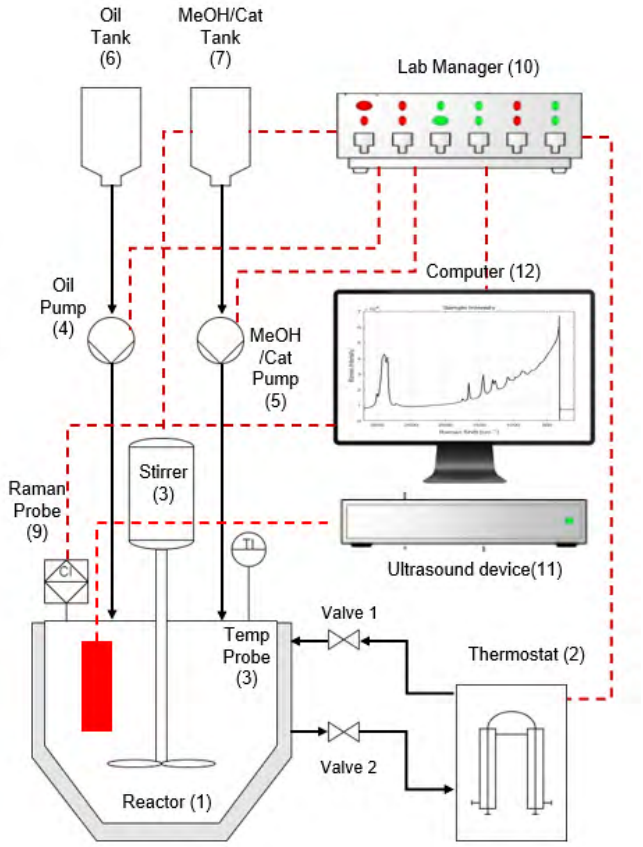

**Figure 1:** Schematic of the experimental setup showing the semi-batch reactor, mechanical stirring, ultrasound transducer, temperature control, and inline Raman.

All system components, including pumps, temperature control, and Raman data acquisition, are supervised by a custom LabManager control platform (10). This software coordinates sensor data acquisition, actuator control, and real-time visualization, ensuring reproducible operating conditions and synchronized process monitoring throughout each experiment.

## Design of Experiments

We adopt an experimental design to investigate systematically the effects of ultrasound, catalyst loading, and temperature on transesterification performance. Three temperatures (50, 55, and 60 °C), two catalyst loadings (normal and 30% reduced), and two operating modes (with and without ultrasound) were combined, resulting in a comprehensive set of operating conditions (Table 1). For clarity, the experiments are categorized into four main cases:

(A) Ultrasound applied with normal catalyst loading.

(B) Ultrasound applied with reduced catalyst loading.

(C) No ultrasound with normal catalyst loading.

(D) No ultrasound with reduced catalyst loading.

This classification enables interesting pairwise comparisons, such as: (i) the effect of ultrasound at constant catalyst loading, (ii) the effect of catalyst reduction under ultrasound, (iii) the role of catalyst loading without ultrasound, and (iv) the ability of ultrasound to compensate for reduced catalyst loading.

**Table 1:** Summary of experimental conditions with temperature, catalyst loading, ultrasound condition, and case designation (A–D)

| Case | T (°C) | Catalyst Loading | Ultrasound |
|---|---|---|---|
| A | 50, 55, 60 | Normal | Yes |
| B | 50, 55, 60 | Reduced (−30%) | Yes |
| C | 50, 55, 60 | Normal | No |
| D | 50, 55, 60 | Reduced (−30%) | No |

## Raman Spectroscopy and Data Processing

Raman spectra were collected continuously throughout each experiment with a constant acquisition time, providing high temporal resolution of the transesterification process. Characteristic Raman bands associated with triglycerides, fatty acid methyl esters (FAME), methanol, and glycerol were used to quantify the evolution of key species during the reaction, following established methodologies explained in our previous work [9]. In summary, a multivariate calibration model, developed and validated using reference samples covering the expected composition range, is employed to convert Raman spectra into quantitative concentration profiles. This approach enabled direct tracking of triglyceride consumption and biodiesel (FAME) formation without the need for offline sampling.

The resulting time-resolved composition profiles were used to analyze reaction kinetics, compare conversion rates across operating conditions, and evaluate final biodiesel yields. All Raman-based measurements are synchronized with temperature and ultrasound operation logs to ensure consistent interpretation of dynamic effects.

## Data Analysis and Performance Metrics

Reaction performance is evaluated using both kinetic and conversion-based indicators. The rate of FAME formation and triglyceride consumption during the initial reaction period is used as a measure of kinetic enhancement, while final FAME yield and residual oil content were used to assess overall conversion efficiency.

Comparisons between experimental cases were performed at identical temperatures to isolate the influence of ultrasound and catalyst loading. Attention is

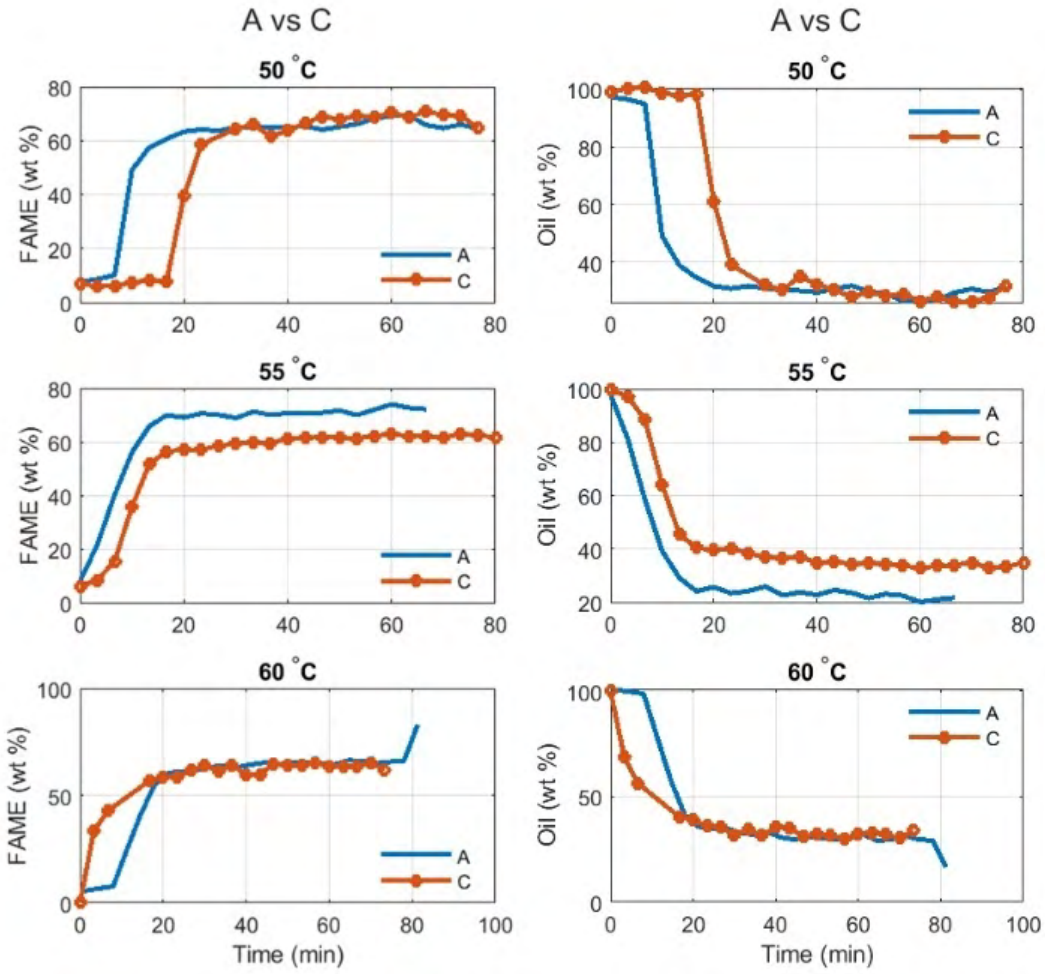

**Figure 2**. Effect of ultrasound at reduced catalyst

given to identifying temperature regimes where ultrasound-induced process intensification is most pronounced and to assessing whether ultrasound could compensate for the loss of catalytic activity under reduced catalyst conditions.

## RESULTS AND DISCUSSION

### Effect of Ultrasound at Normal Catalyst Loading

The effect of ultrasound at normal catalyst loading is assessed by comparing experiments performed with and without ultrasound at identical temperatures (Cases A and C), based on FAME formation and oil consumption (Figure 2). At 60 °C, ultrasound accelerates the initial reaction rate, but final FAME yields and residual oil contents remain similar, indicating that thermal activation already dominates the kinetics. At 55 °C, ultrasound has a pronounced and sustained effect, significantly enhancing both the rate and extent of FAME formation by overcoming mass-transfer limitations. At 50 °C, ultrasound mainly improves the early reaction stage, with faster initial FAME formation and oil consumption, while final conversions are comparable.

### Effect of Ultrasound at Reduced Catalyst Loading

The influence of ultrasound under reduced catalyst loading is evaluated by comparing experiments performed with and without ultrasound at identical temperatures (Cases B and D), using FAME formation and oil consumption as performance indicators (Figure 3). At 60 °C, ultrasound leads to a substantial improvement in reaction performance, with much faster FAME formation, higher final yields, and more oil conversion, effectively compensating for the reduced catalytic activity observed without ultrasound. At 55 °C, ultrasound continues to enhance kinetics and conversion, although the performance gap is slightly smaller than at 60 °C. At 50 °C, the effect of ultrasound is particularly pronounced: while the non-ultrasound case remains strongly kinetically limited,

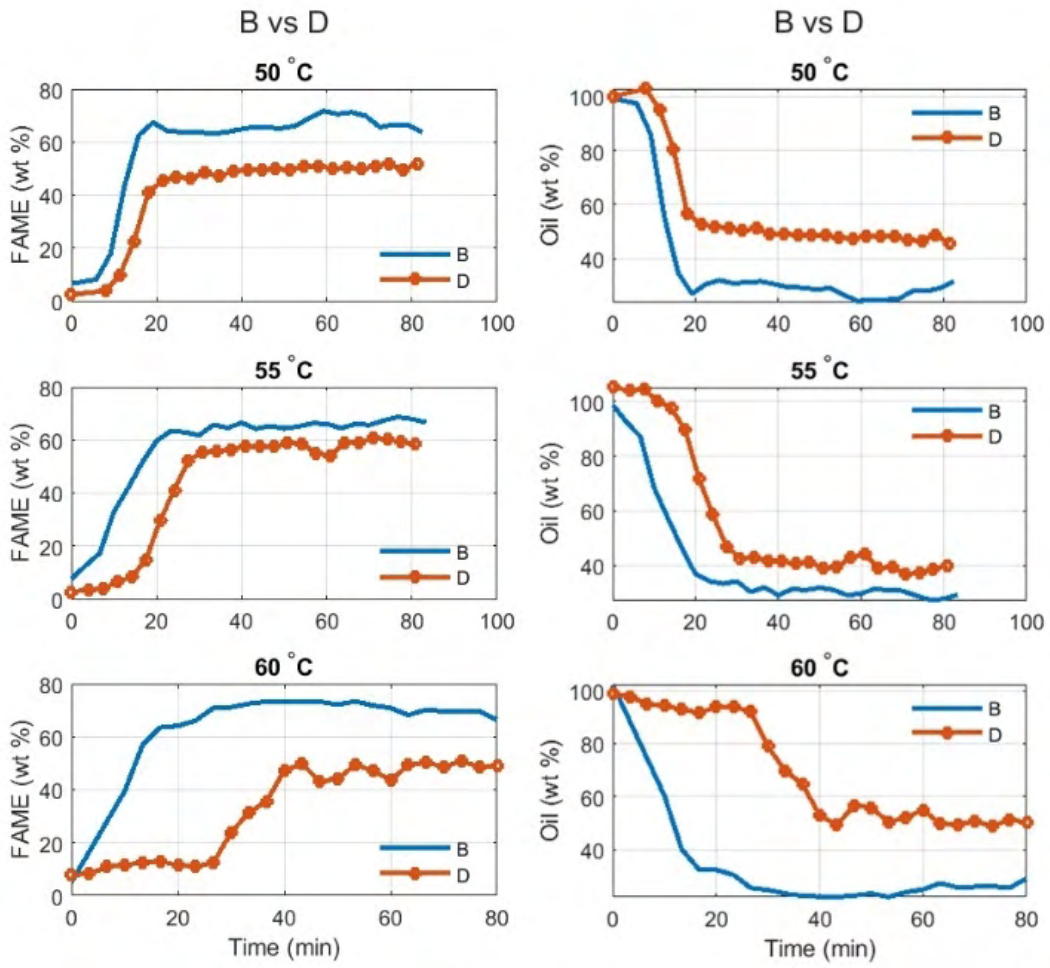

**Figure 3**. Effect of ultrasound at reduced catalyst

ultrasound-assisted operation achieves rapid oil consumption and high final FAME yields.

## Effect of Catalyst Amount under Ultrasound

The effect of catalyst loading under ultrasound-assisted conditions is assessed by comparing experiments performed with normal and reduced catalyst amounts while ultrasound is applied (Cases A and B), based on FAME formation and oil consumption (Figure 4). At 60 °C, normal catalyst loading results in slightly faster kinetics and deeper oil conversion, although the performance gap is much smaller than in the absence of ultrasound, indicating reduced sensitivity to catalyst concentration. At 55 °C, the influence of catalyst loading becomes moderate, with both cases converging toward similar final FAME yields and residual oil contents. At 50 °C, catalyst reduction has almost no effect, as FAME formation and oil consumption profiles are nearly identical. The results show thus, that under ultrasound-assisted operation, catalyst loading mainly affects reaction rate rather than final conversion, particularly at intermediate and low temperatures.

## Effect of Catalyst Amount without Ultrasound

The influence of catalyst loading in the absence of ultrasound is evaluated by comparing experiments performed with normal and reduced catalyst amounts under identical thermal and mixing conditions (Cases C and D), using FAME formation and oil consumption as indicators (Figure 5). At 60 °C, normal catalyst loading results in markedly faster kinetics, deeper oil conversion, and higher final FAME yields, whereas reduced catalyst loading leads to slow reaction rates and incomplete conversion. At 55 °C, the effect of catalyst loading remains evident, although the performance gap between the two cases is slightly reduced. At 50 °C, catalyst reduction has a particularly severe impact, with strongly kinetically limited behavior and poor oil consumption compared to the normal catalyst case.

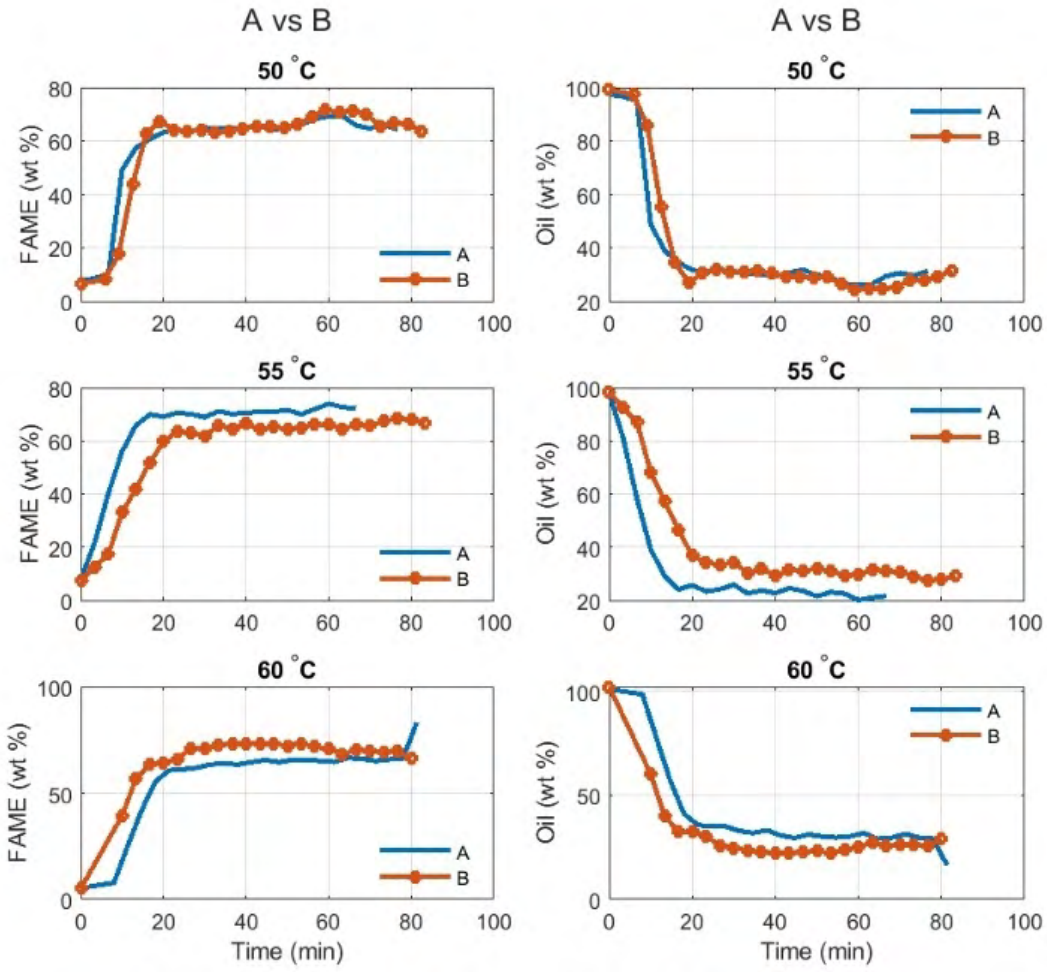

**Figure 4**. Effect of catalyst amount under Ultrasound

## Can Ultrasound Compensate for Reduced Catalyst Loading?

The ability of ultrasound to compensate for reduced catalyst loading is assessed by comparing experiments conducted with reduced catalyst under ultrasound to those performed with normal catalyst without ultrasound (Cases B and C), based on FAME formation and oil consumption (Figure 6). At 60 °C, both cases reach very similar final FAME yields and residual oil contents, while the ultrasound-assisted reduced-catalyst case exhibits faster initial kinetics, indicating effective compensation of lower catalytic activity. At 55 °C, the compensation effect is even more pronounced, as the reduced-catalyst case with ultrasound slightly outperforms the normal-catalyst case without ultrasound in terms of final FAME yield and oil conversion. At 50 °C, both scenarios converge toward similar final conversion levels, although ultrasound consistently accelerates early-stage FAME formation and oil consumption.

## Best and Worst Operating Scenarios

The combined influence of ultrasound and catalyst loading is evaluated by comparing the best operating condition—normal catalyst loading with ultrasound (Case A)—to the worst condition—reduced catalyst loading without ultrasound (Case D), based on FAME formation and oil consumption (Figure 7). At 60 °C, the performance gap is substantial: the best-case scenario shows much faster FAME formation and deeper oil conversion, while the worst-case scenario remains strongly kinetically limited and reaches significantly lower final conversion. At 55 °C, this disparity remains pronounced, with higher FAME yields and lower residual oil content under ultrasound and normal catalyst loading. At 50 °C, the contrast becomes even more striking, as reduced catalyst without ultrasound leads to severe kinetic limitations, whereas ultrasound-assisted operation with normal catalyst maintains high conversion efficiency.

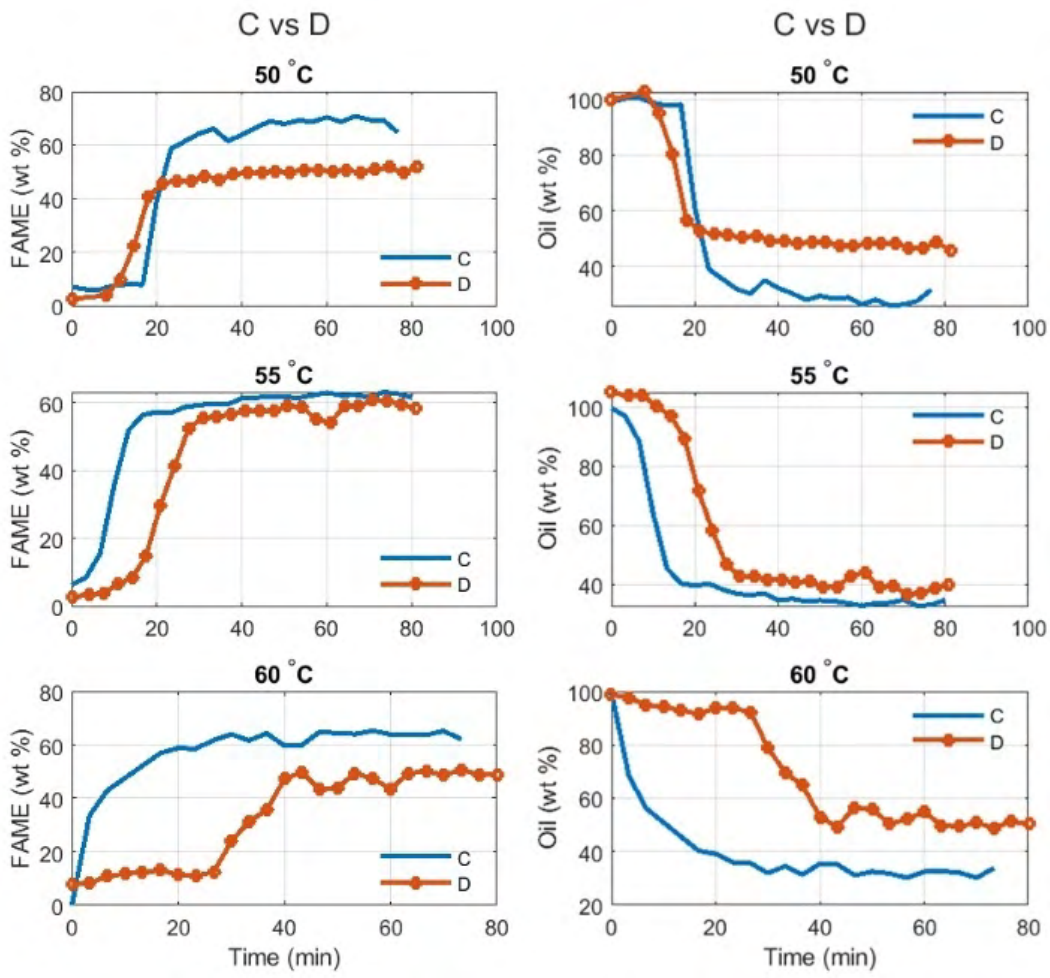

**Figure 5:** Eeffect of catalyst amount without ultrasound

## CONCLUSIONS AND PERSPECTIVES

This work provides a systematic analysis of ultrasound-assisted transesterification for biodiesel production using inline Raman spectroscopy to monitor the dynamic evolution of FAME formation and triglyceride consumption under different temperatures and catalyst loadings. The results demonstrate that ultrasound acts as an effective process-intensification strategy, accelerating reaction kinetics and significantly reducing the sensitivity of the process to catalyst loading. At normal catalyst conditions, ultrasound primarily enhances the early stages of the reaction, with the strongest and most sustained impact observed at intermediate temperature (55 °C). At higher temperature (60 °C), the additional benefit of ultrasound becomes more limited due to dominant thermal activation, while at lower temperature (50 °C) ultrasound mainly reduces the time required to reach comparable final conversion levels.

Under reduced catalyst loading, ultrasound plays a particularly important role. Without ultrasound, catalyst reduction leads to strong kinetic limitations and incomplete oil conversion across all temperatures. In contrast, ultrasound-assisted operation consistently restores high conversion levels, achieving faster oil consumption and higher FAME formation. In several cases, reduced catalyst combined with ultrasound achieves performances comparable to, or even exceeding, those obtained with normal catalyst loading without ultrasound. These findings confirm that ultrasound can effectively compensate for catalyst reduction while maintaining high biodiesel production efficiency.

From a Process Systems Engineering perspective, the combination of ultrasound intensification and inline Raman monitoring provides a valuable framework for data-rich process understanding and model development. The time-resolved composition data generated in this work constitute an important basis for developing phenomenological kinetic models capable of explicitly

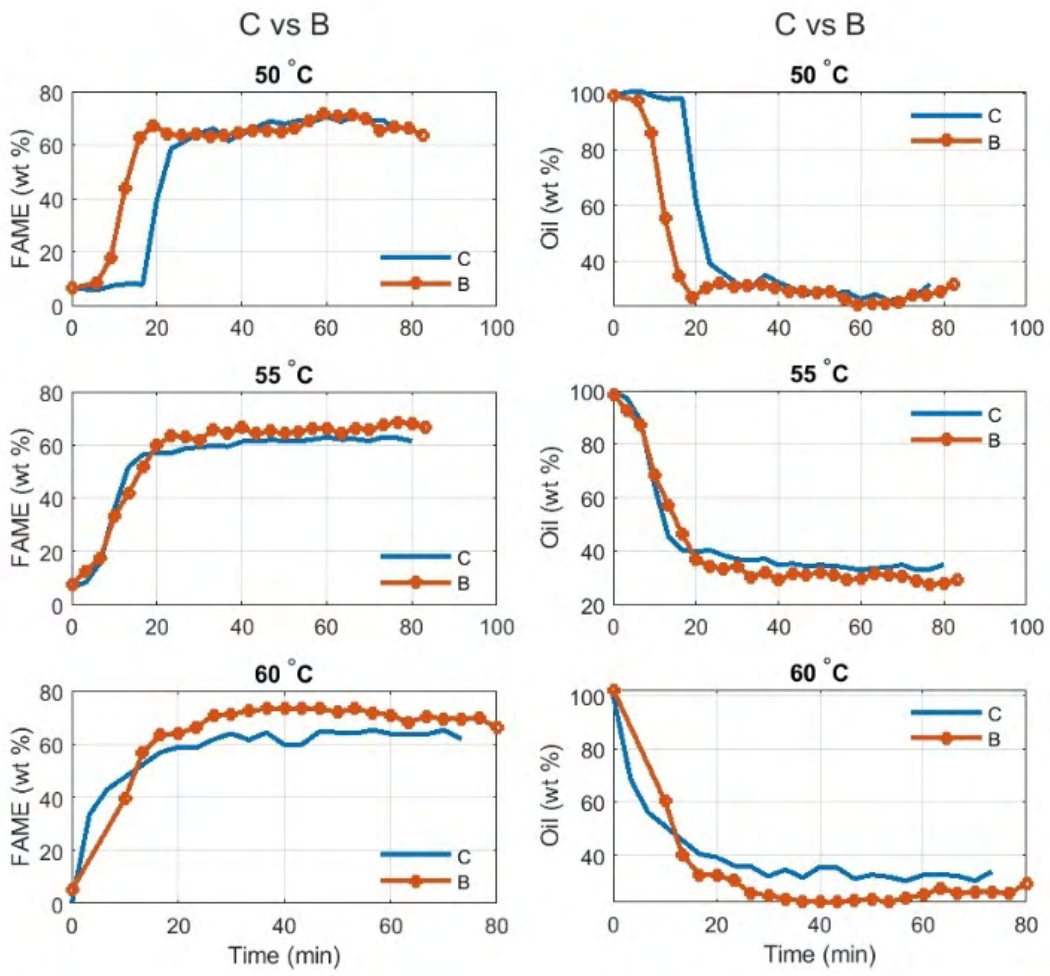

**Figure 6.** Can ultrasound compensate reduced catalyst?

capturing the influence of ultrasound-induced mass-transfer enhancement on transesterification dynamics. Such models can then be integrated into process simulation and optimization frameworks to identify optimal operating conditions balancing catalyst usage, temperature, and energy consumption.

Moreover, the use of inline Raman spectroscopy enables continuous measurement of key species, which opens the possibility of implementing advanced monitoring and model-based control strategies. Integrating ultrasound-assisted transesterification within digitalized process architectures, including soft sensors, real-time optimization, or digital twins, could further enhance process efficiency and robustness.

Future work will therefore focus on extending the current experimental insights toward first-principles modeling, model-based optimization, and control of ultrasound-intensified biodiesel reactors, as well as evaluating the scalability and energy efficiency of ultrasound-assisted systems under continuous industrial operation. These developments would contribute to the design of intensified, catalyst-lean, and digitally enabled biodiesel production processes.

## ACKNOWLEDGEMENTS

We thank Martin Kleber and Wolfgang Hoffmann (Cargill GmbH, Frankfurt) for the fruitful technical discussions on the operating scenarios and for providing the chemicals used in the experimental campaigns. We also thank the financial support of the Kopernikus project SynErgie by the Federal Ministry of Research, Technology and Space (BMFTR) and the project supervision by the project management organization Projektträger Jülich (PtJ).

## ABSTRACT

Predicting solvent effects on reaction activation barriers is central to understanding chemical reactivity and reaction kinetics, and guiding solvent selection. The solvent-induced change in activation free energy ($\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$) provides a quantitative descriptor of this effect, but remains costly to evaluate across vast reaction-solvent spaces, using quantum mechanical methods. Recent data-driven models have enabled prediction of solvent effects. However, most typically rely on two-dimensional representation of reactions and do not explicitly encode sufficient reaction context, such as transition-state information, or three-dimensional structural changes along the reaction, resulting in limited generalizability and predictive accuracy. In this study, systematic evaluation is presented of modelling strategies for predicting $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$, with a focus on the role of reaction-state representation, input-geometry fidelity, and input modality. Using a large reaction-solvent dataset, models based on two-dimensional condensed reaction graphs are compared with models incorporating three-dimensional geometries of reactants, transition states, and products. The sensitivity of geometry-based models to structural accuracy is assessed by replacing quantum-chemically optimized transition states with structures predicted by a generative model. In addition, a dual-modality architecture combining two-dimensional graph-based and three-dimensional geometry-based representations is examined. The results show that explicit inclusion of both reactant and transition-state geometries leads to improved prediction accuracy relative to representations based on reaction endpoints or transition states alone. However, model performance depends strongly on the fidelity of the input geometries, with substantial degradation observed when low-quality structures are used. The dual-modality approach partially mitigates this sensitivity by adaptively reweighting two-dimensional and three-dimensional information, leading to performance recovery under low-fidelity conditions.

## 1. INTRODUCTION

Solvents play a central role in chemical reactions because preferential stabilization of transition state (TS) relative to the reactant (R) can shift reaction energy barriers and alter reaction rate and selectivity. This solvent effect can be quantified by the solvation contribution to the activation free energy, defined as $\Delta\Delta G^{\ddagger}_{\mathrm{solv}} = \Delta G^{\mathrm{TS}}_{\mathrm{solv}} - \Delta G^{\mathrm{R}}_{\mathrm{solv}}$. The solvation free energy of reaction, $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ can serves as a key performance descriptor, making it possible to compare solvent effects across reaction-solvent combinations and therefore useful for solvent selection. Traditionally, $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ has been calculated via quantum mechanics/molecular mechanics (QM/MM) simulations or implicit solvation models, including such as the Solvation Model based on Density (SMD) and the COnductor-like Screening Model for Real Solvent (COSMO-RS). While these methods can provide reliable estimates, their high computational cost often limits scalability to a large and diverse reaction-solvent space [1]. In particular,

locating and optimising TS structures represents a major bottleneck, making systematic evaluation across many reactions and solvents impractical [2, 3].

In recent years, data-driven approaches have emerged as efficient alternatives by enabling rapid estimation of solvent effects at substantially reduced computational cost. Early work in this area has largely focused on predicting solvation energy of individual molecules [4-6] and extension to reaction kinetics have been more limited. Existing approaches for modelling solvent effect on activation energies broadly fall into two classes. The first class consider a single fixed reaction, treating solvent as the sole variable [7, 8]. While this yields meaningful results within specific reaction classes, it faces a fundamental limitation in generalizability across diverse reaction-solvent combinations. The second class aims to model general reaction-solvent combinations by using both reaction and solvent as inputs, and hence covering a broader chemical space [9, 10].

Recent progress in the latter direction has been driven by the effectiveness of two-dimensional (2D) reaction representations for modelling reaction properties, such as activation energies and reaction yields [10-12]. These representations include condensed reaction graph (CGR) [13], which is obtained by superposing 2D molecular graphs of R and product (P), and reaction fingerprint, which is generated by open-source software RDKit [14, 15] or deep learning models [16, 17]. Such representations have been used as input and achieved high predictive accuracy by effectively encoding structural changes resulting from reactions. This early success presents a promising modelling strategy of solvent effect on activation energy by combining 2D reaction representations with molecular representations of solvent. For example, Chung and Green [9] developed a data-driven model that can predict solvent-induced changes in activation energy utilizing CGR and 2D molecular graph of solvent. By integrating reaction and solvent embeddings independently encoded by directed message passing neural network (D-MPNN) encoders, the model achieved state-of-the-art performance in both $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ calculated by COSMO-RS and experimental relative rate constant ($k_{\mathrm{rel}}$) prediction. However, these representations primarily capture topological differences between R and P and do not explicitly encode information along the reaction coordinate or structural features of the TS. Moreover, 2D representations cannot uniquely determine three-dimensional (3D) properties, such as charge redistribution and spatial arrangement of functional groups, which are known to influence solvation and activation energetics. As a result, current models may struggle to generalize across reaction types and capture key physical factors governing solvent effects on reaction barriers. While employing TS geometries as input can provide richer information of reaction context, this has been considered impractical due to the difficulties in computation, as we described. To address this limitation, generative models that predict TS geometries have recently been actively proposed as a practical alternative [18-21]. These models generate TS geometries from relatively accessible inputs, e.g. CGR and geometries of R and P, at a fraction of the computational cost of QM methods. However, to the best of our knowledge, the effectiveness of explicit incorporation of the low-cost generated TS geometries for modelling solvent effect on activation energy has yet to be explored.

In this study, we develop systematic modelling strategies for $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ prediction that explicitly address these limitations. Rather than proposing a new architecture, we analyse how predictive performance depends on three controlled aspects of model input design: (i) the reaction-state(s) used to represent the reaction (R, TS, and/or P), (ii) the fidelity of the associated 3D geometries, and (iii) the representation modality, including 2D graph-based, 3D geometry-based, and combined dual-modality inputs. Using a large reaction-solvent dataset derived from COSMO-RS calculations, we compare $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$prediction performance on unseen reactions of a conventional 2D model using CGR with models that explicitly incorporate geometries of various input configurations for reactants, transition states, and products. By replacing quantum-chemically optimised structures with geometries locally optimised by force field or predicted from a generative model, the sensitivity of the model to geometry quality is assessed. Dual-modality approaches combining 2D graph-based and 3D geometry-based representations are implemented to further explore the robustness of the models depending on fidelity of input geometry.

## 2 METHOD

### 2.1 Molecular and reaction representation

To investigate how input design influences model performance, we varied three factors systematically: (i) the state(s) of the reaction path encoded as input (R, TS, and/or P), (ii) the fidelity of the associated 3D geometries, and (iii) the modality of the representation i.e., whether the model used 2D graph-based inputs, 3D geometry-based inputs, or both.

For 2D representations, reactions were encoded as CGR [13], which represent the transformation between reactants and products within a single graph. CGRs were generated from atom-mapped SMILES using Chemprop [22]. Solvents were represented as standard 2D molecular graphs. Initial atom and bond features for both CGRs and solvent graphs were constructed using standard RDKit descriptors, including atomic number, bond order, formal charge, and aromaticity.

To incorporate explicit structural information along the reaction coordinate, 3D molecular geometries were

used to construct reaction representations based on different states of the reaction path. Three reaction-path configurations were considered (Figure 1**a**): (1) an R-P representation, which encodes the reaction using the 3D geometries of reactants (R) and products (P); (2) a TS-only representation, which encodes the reaction using only the 3D geometry of the transition state (TS); and (3) R-TS representation, which encodes the reaction using the 3D geometries of both reactants (R) and transition states (TS). These configurations enable a controlled comparison of how explicit inclusion of TS information and reaction-path context affects model behaviour.

Input geometries for 3D-based representations were further grouped by fidelity to evaluate sensitivity to structural accuracy. *High-fidelity* geometries used R, P, and TS structures optimised in the gas phase at the $\omega$B97X-D3/def2-TZVP level of theory from the Grambow dataset [23]. *Moderate-fidelity* geometries used R and P structures from the Grambow dataset, while TS geometries were predicted using React-OT from the corresponding high-fidelity R and P structures. *Low-fidelity* geometries used R and P structures generated using OpenBabel [24] and locally optimised with the generalized Amber force field (GAFF), and TS geometries predicted by React-OT from these lower-cost R and P structures. Note that React-OT is a flow-matching-based generative model that predicts TS structures from interpolated R and P geometries [19] and was selected due to its deterministic predictions and computational efficiency. For solvents, 3D structures generated using the OpenBabel force field were used consistently across all fidelitiles.

## 2.2 Dataset for model training and evaluation

We used the $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ dataset proposed by Chung and Green [9]. In that work, COSMO-RS calculations were performed using optimised gas-phase geometries of R and TS from the Grambow dataset, spanning 500, 000 reaction-solvent combinations with 13, 227 unique reactions and 295 solvents. The dataset both contains neutral closed-shell and free radical reactions, restricted to systems composed of H, C, O, and N with at most seven heavy atoms (11, 876 closed-shell; 1, 351 radical). To evaluate generalization to unseen reactions, 5% of the reaction were randomly selected and reserved as a test set. The remaining data were randomly split into a 90% training set and a 10% validation set.

## 2.3 Model architecture

Based on the molecular and reaction representations defined, three model architectures, namely, a 2D graph-based baseline model, a 3D geometry-based equivariant model, and a dual-modality model combining both representations. All architectures were adopted from existing frameworks and adapted to ensure a consistent comparison across input configurations.

**2D-graph-based baseline model**: As a baseline, we adopted a directed message passing neural network (D-MPNN) architecture [25] previously used for reaction-solvent modelling. This model independently encodes for the reaction and solvent by passing the 2D CGR and 2D solvent graph through separate D-MPNNs. A four-layer D-MPNN was used for the CGR to capture changes in atom and bond features associated with reaction, while a two-layer D-MPNN was used for the solvent graph owing to its comparatively simple structure. The resulting reaction and solvent embeddings were concatenated and passed to a feed-forward predictor consisting of six fully connected layers to generate the final prediction.

**Geometry-based equivariant model**: We adopted TorchMD-Net [26] as an SE(3)-equivariant encoder. TorchMD-Net takes atomic numbers and Cartesian coordinates as inputs and constructs representations using attention mechanisms based on interatomic distance and relative position vectors, without relying on explicit bond connectivity. An eight-layer equivariant encoder was applied to all molecular species. The representations obtained from the encoder for R, TS, and P were concatenated and passed through two fully connected layers to form reaction-level embedding. This embedding was then concatenated with the solvent representation and passed through the same six-layer feed-forward predictor used in the baseline model.

**Duality-modality model**: To evaluate whether combining 2D and 3D representations improves robustness [27, 28], we implemented a dual-modality architecture that integrates the D-MPNN-based 2D encoders and the TorchMD-Net-based SE(3)-equivariant 3D encoder. In this setting, representations obtained independently from the 2D and 3D streams were combined using a late-fusion strategy. Learnable scalar weights were applied to each modality stream, allowing the model to adjust their relative contributions during training. Specifically, two scalar parameters, i.e., $\mathrm{w}_{\mathrm{2D}}$ and $\mathrm{w}_{\mathrm{3D}}$, initialized to zero, were used. These weights are passed through a softmax function to normalise them and multiplied by the embeddings from each modality stream to obtain a fused representation. The fused representation was then passed to the same feed-forward predictor used in the single-modality models (Figure 4**a**).

All models were trained for 80 epochs using a batch size of 30. Optimisation was performed with the Adam optimiser and Noam learning-rate scheduler, with an initial learning rate of $1.8\times 10^{4}$. Mean squared error (MSE) was used as the loss function. Model implementation was performed in PyTorch 2.4.0, and training was conducted using PyTorch Lightning 1.8.6.

# 3. RESULTS

## 3.1 Effect of including TS geometries

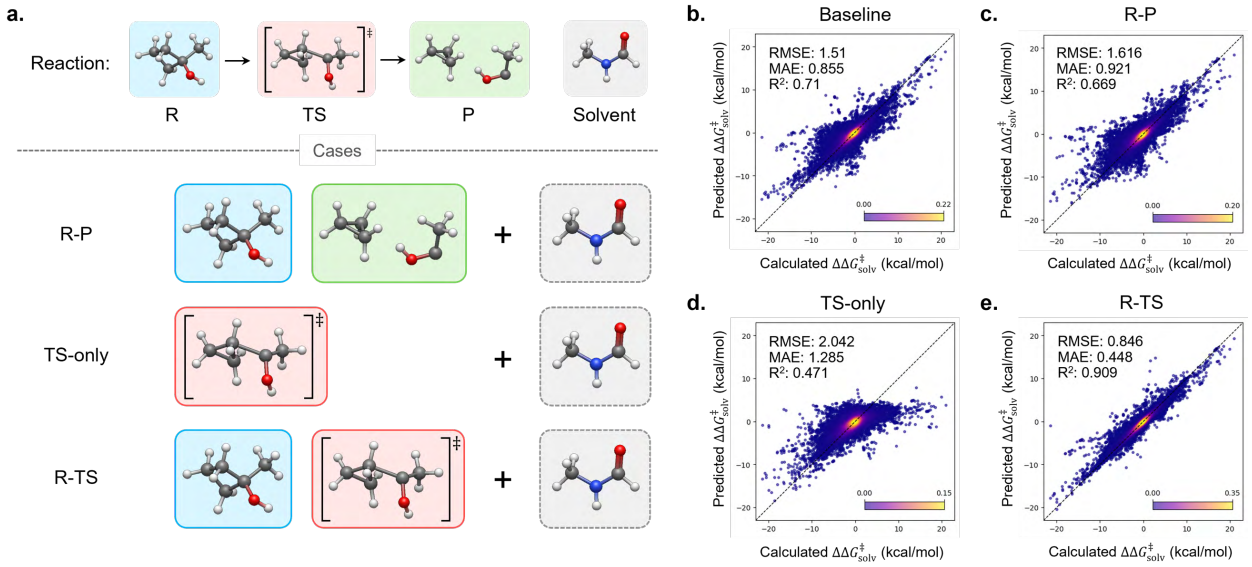

**Figure 1.** Overview of input configurations and prediction performance for different representations. (a) Schematic of the three 3D input configurations considered in this study: R-P, which uses the geometries of R and P; TS-only, which uses only the TS geometry; and R–TS, which uses the geometries of both R and TS. In all cases, the solvent is represented separately and combined with the reaction representation. (b-e) Parity plots comparing predicted and calculated $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ values for (b) the 2D graph-based baseline model, (c) the R-P model, (d) the TS-only model, and (e) the R–TS model. Root mean square error (RMSE), mean absolute error (MAE), and coefficient of determination ($R^2$) are reported for each model.

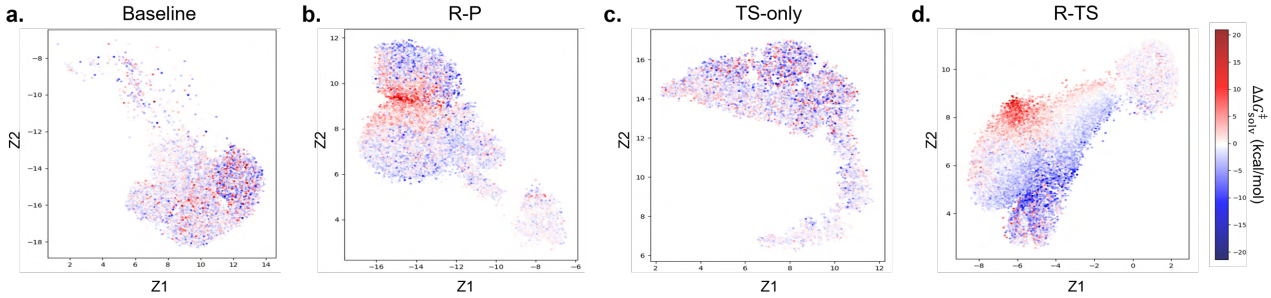

**Figure 2.** UMAP visualisations of the learned reaction-solvent representations for different input configurations. Latent embeddings are shown for (a) the 2D graph-based baseline model and the 3D models using (b) R-P, (c) TS-only, and (d) R-TS. Points are coloured by the corresponding $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ values.

To evaluate the effect of including TS geometries on $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ prediction, we compared the model performance using three distinct combinations of R, TS, and P geometries defined in Section 2.1—R-P, TS-only, and R-TS, with the 2D-based baseline model. The input configurations are summarised in Figure 1**a**, and all models in this comparison used high-fidelity geometries from the Grambow dataset.

Notably, the model using 3D geometries of R and P (R-P) exhibited lower prediction accuracy than the 2D-based baseline (Figure 1**b, c**). This result indicates that providing endpoint geometries alone does not improve prediction of solvent-induced activation free energy shifts. Although 3D molecular structures contain detailed geometric information, the absence of explicit TS information limits their relevance for describing kinetically meaningful structural changes. As a result, replacing 2D CGR inputs with 3D R–P geometries increase input complexities without improving representation of features directly associated with the target quantity.

The model using only TS geometry (TS-only) showed significantly lower prediction performance compared to the baseline, even though TS is a critical determinant of reaction kinetics (Figure 1**d**). This result likely stems from the fact that understanding reaction process requires not only TS geometry but also R structure as a reference state of change. The omission of the information of the reference state has led to overfitting, confirming that TS structure alone is insufficient to capture the relative structural evolution that is necessary to

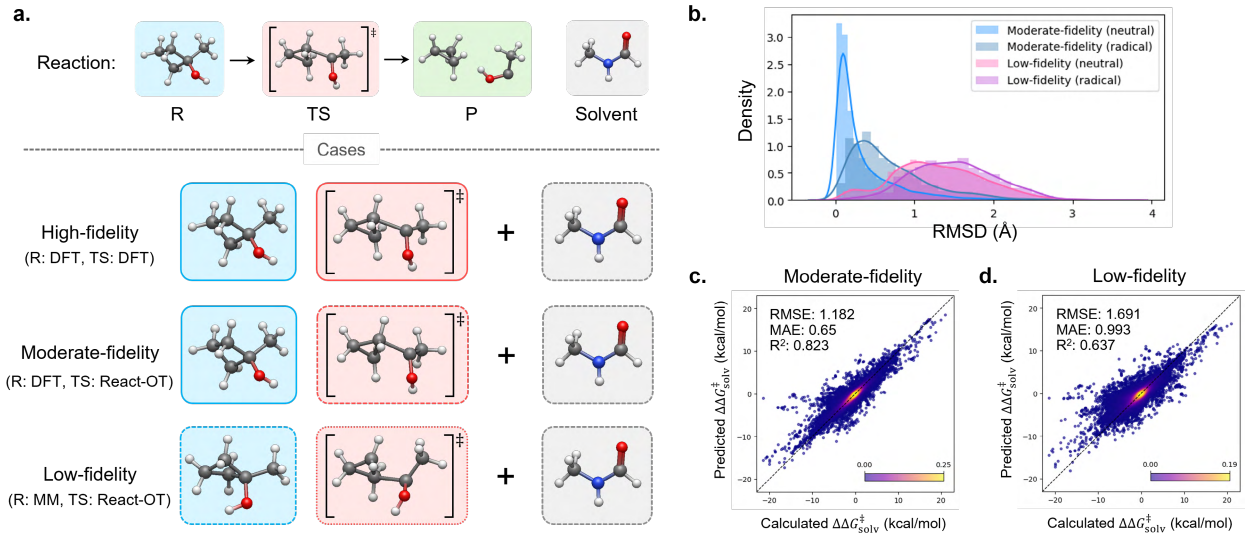

**Figure 3.** Effect of input structure fidelity on TS geometry accuracy and prediction performance. (a) Schematic illustration of the three input-geometry fidelity levels considered for the R–TS configuration. (b) Distributions of TS root-mean-square deviations (RMSDs) relative to the DFT reference structures for moderate- and low-fidelity cases, shown separately for neutral and radical reactions. (c,d) Parity plots comparing predicted and calculated

define a reaction path.

In contrast, incorporating both R and TS 3D geometries (R-TS) achieved the highest prediction accuracy (Figure 1**e**). This indicates that the model implicitly captured path dependent features, such as geometric distortion and charge redistribution, from the structural data of R and TS. Thus, explicitly incorporating R and TS 3D structures enables the model to encode structural differences between R and TS, which are directly relevant to solvent-induced changes.

To further examine how different input configurations influence the learned representation, the final reaction-solvent embeddings were visualised using Uniform Manifold Approximation and Projection (UMAP) [29]. For the baseline model and the TS-only model, the latent representations were broadly scattered and showed no clear patterns with respect to the target values (Figure2**a, c**). The R-P model showed a locally clustered region for reaction-solvent combinations with high $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$, but remained disordered for moderate to small values (Figure 2**b**), consistent with its larger prediction errors observed in this region. In contrast, the latent space learned by the R-TS model exhibited the clearest global ordering with respect to $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$, characterised by a continuous gradient across the embedding (Figure 2**d**). This suggest that the combined use of R and TS geometries yields representations more strongly associated with solvent-induced activation free energy shifts.

## 3.2 Effect of input structure fidelity

In previous section, we showed that incorporating both R and TS geometries improves prediction performance when high-fidelity structures are available. To assess the robustness of this approach under more practical conditions, we next evaluated how prediction performance depends on the fidelity of the input geometries, using the three structure-fidelity levels defined in Section 2.1.

As summarised in Figure 3**a**, model performance was compared across high-, moderate-, and low-fidelity input geometries. In the high-fidelity case, both R and TS geometries were taken from DFT-optimised structures in the Grambow dataset. In the moderate- and low-fidelity cases, TS geometries were generated using React-OT from progressively lower-fidelity R and P structures, as described in Section 2.1. Consistent with this construction, the TS RMSD relative to the DFT reference structures was smaller in the moderate-fidelity case and substantially larger in the low-fidelity case (Figure 3**b**). The broader RMSD distributions observed for radical reactions further indicate increased difficulty in accurately predicting TS geometries for open-shell systems.

Prediction accuracy decreased systematically as input structure fidelity was reduced (Figure 3**c, d**). In the low-fidelity case, the model performed worse than the 2D-based baseline, indicating that TS geometries generated from inaccurate R and P structures do not provide reliable information for learning solvent-induced changes in the activation free energy. In contrast, the moderate-fidelity case maintained superior performance relative to the baseline, demonstrating that predicted TS geometries can still be informative when the underlying R and P structures preserve essential geometric features.

Overall, these results show that models explicitly

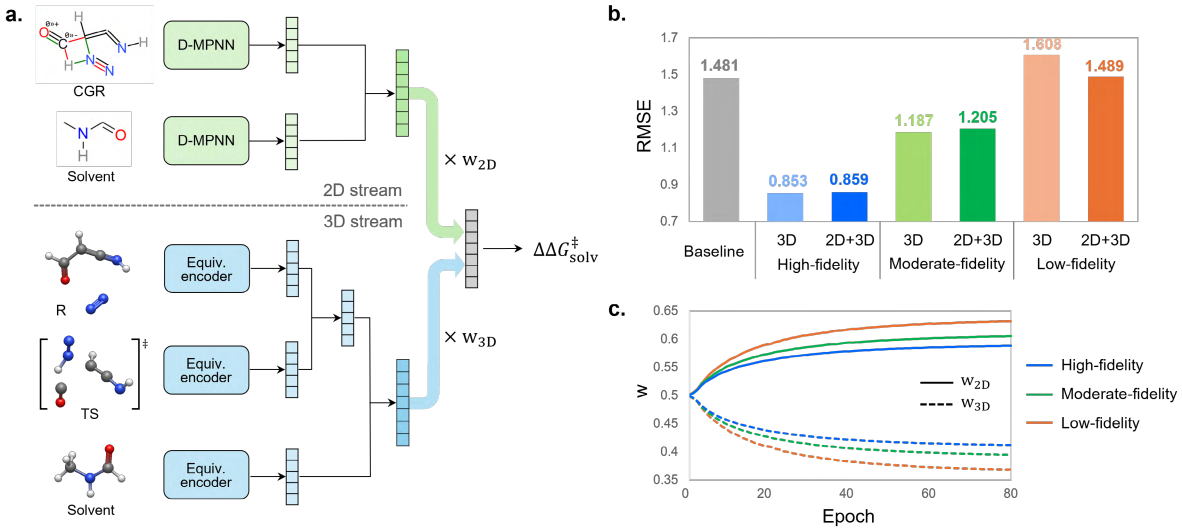

**Figure 4.** Dual-modality model architecture and performance across input-geometry fidelity levels. (a) Schematic illustration of the dual-modality architecture integrating 2D graph-based representations and 3D geometry-based representations. (b) Prediction performance, measured by RMSE, for the 2D-based baseline model, the 3D-only model, and the dual-modality (2D + 3D) model across high-, moderate-, and low-fidelity input geometries. (c) Evolution of the learned modality weights for the 2D and 3D streams during training for each fidelity level.

incorporating R and TS geometries are sensitive to the fidelity of the input structures. Nevertheless, the performance observed in the moderate-fidelity case indicates that practical modelling strategies based on low-cost TS generation are feasible, provided that the predicted structures retain key geometric characteristics of the activated complex.

## 3.3 Effect of input modality

Because prediction performance of 3D-based models depends strongly on input-geometry fidelity, we next evaluated whether combining 2D and 3D representations can improve robustness to reduced structural accuracy. Specifically, we examined a dual-modality approach that integrates 2D graph-based representations with 3D geometry-based representations, as defined in Section 2.3.

The dual-modality model integrates 2D graph-based and 3D geometry-based representations using the late-fusion architecture described in Section 2.3 (Figure 4**a**). Model performance was evaluated for high-, moderate-, and low-fidelity input geometries and compared against the corresponding 3D-only and 2D-based baseline models.

For the high- and moderate-fidelity cases, the dual modality model showed only marginal difference relative to the 3D-only model as can be seen in Figure 4**b**. This suggests that when reliable 3D structures are available, the 3D representation alone captures sufficient information for $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$, limiting the additional contribution of 2D graph-based inputs. In contrast, in the low-fidelity case, the dual modality model recovered prediction performance to a level comparable to the 2D-based baseline and outperformed the 3D-based model (Figure 4**b**). Analysis of the learned modality weights (w) provides further insight into this behaviour (Figure 4**c**). In the low-fidelity case, the weight assigned to the 2D modality increased progressively during training while the 3D weight decreased, indicating a shift toward graph-based representations as the reliability of 3D geometries decreased. Conversely, in the high-fidelity case, the modality weights stabilised early and the gap between $w_{2D}$ and $w_{3D}$ remained smallest, indicating a more balanced contribution of the two modalities.

Overall, these results indicate that dual-modality models can improve robustness to reduced input-geometry fidelity by adaptively reweighting information from different representations. The observation that performance in the low-fidelity case does not exceed that of the 2D-based baseline highlights a limitation of the current late-fusion strategy, suggesting that more effective integration schemes may be required to achieve synergistic gains from combined 2D and 3D inputs.

# 4. CONCLUSIONS

We presented systematic modelling strategies for solvent-induced change in reaction activation energy, specifically for $\Delta\Delta G^{\ddagger}_{\mathrm{solv}}$ prediction. Comprehensive analysis of prediction based on thee controlled aspects of model input design was performed: (i) the reaction-state(s) used to represent the reaction, (ii) the fidelity of the associated input geometries, and (iii) the

representation modality of 2D, 3D, and combined. The significant improvement in predictive accuracy was observed through explicit incorporation of the geometries of both R and TS. Furthermore, the visualised latent space learned by the R-TS model exhibited the clearest trend with respect to $\Delta\Delta G^{\ddagger}_{\text{solv}}$. This proves that the structural differences encoded from the R and TS geometries yield representations strongly relevant to solvent effect on activation free energy. The performance of the 3D geometry-based model was strongly influenced by input geometry fidelity. When low-fidelity geometries were used, the model showed degraded performance compared to the 2D graph-based baseline model. However, the performance under the moderate-fidelity case maintained superior performance relative to the baseline. This indicates the feasibility of the practical modelling strategies based on predicted TS geometries and concurrently highlights the importance of preserving key geometric characteristics of the activated complex. Finally, we implemented a dual modality approach that integrates 2D graph-based and 3D geometry-based representations to investigate the robustness of the model to reduced fidelity of input geometries. Under the low-fidelity cases, the model exhibited a notable recovery of prediction performance to a level comparable to the 2D-based baseline and outperformed the 3D-based model. Further analysis provided valuable insight that the improved robustness resulted from the adaptive reweighting of the information from different modalities based on their reliability. Nevertheless, the current simple late-fusion strategy failed to facilitate synergistic interaction between modalities, limiting the performance in the low-fidelity case to a similar level to the 2D-based baseline. This highlights that future works should focus on developing multi-modal frameworks that enable complementary integration of information using sophisticated techniques, such as contrastive learning and cross-attention mechanisms. We believe that such advancement can provide a practical strategy of modelling solvent-induced changes in reaction barriers by harnessing the benefits of 3D geometries while enhancing the robustness from noise-resistant inputs.

## ABSTRACT

Nonlinear model predictive control (NMPC) can substantially improve performance and constraint handling for (bio)chemical processes, but its adoption is still limited by the effort required to build maintainable first-principles models and to implement efficient dynamic optimization-based controllers. This paper presents GlycoPy, an open-source, equation-oriented and object-oriented Python framework that supports hierarchical model construction and integrated workflows for simulation, parameter estimation, dynamic optimization, and NMPC. The case study of the monoclonal antibody glycosylation process based on a multiscale model demonstrates the capability of GlycoPy.

**Keywords**: Nonlinear Model Predictive Control, Dynamic Modelling, Optimization, Simulation, Multiscale Modelling, software

## 1. INTRODUCTION

Equation-oriented (EO) environments are well suited to modeling and optimization of (bio)chemical processes: they let researchers develop new models without implementing solvers, and they provide highly accurate derivatives through automatic differentiation [1]. Yet, given the complexity of real-world systems, existing EO software often struggles to balance user-friendliness, developer productivity, flexibility, and extensibility [2]. Commercial EO tools (e.g., gPROMS [3]) provide rich modeling capabilities but are not designed for tight integration with advanced nonlinear model predictive control (NMPC) workflows or for rapid prototyping of bespoke algorithms. Open-source packages such as GEKKO [4], do-mpc [5] and SolACE [6] offer convenient optimization and NMPC, yet lack native support for hierarchical model composition, which is important for multiscale and multi-unit systems. Pyomo supports hierarchical modeling and many advanced process systems engineering (PSE) tasks [7]. However, it is difficult for its users to develop and integrate novel simulation algorithms, which are often essential for optimization workflows driven by computationally expensive simulations.

We therefore introduce GlycoPy, an equation-oriented Python framework built on CasADi to address these gaps. CasADi provides the symbolic infrastructure for efficient numerical optimal control, although it is not itself a domain-specific language for large process models and control [8]. GlycoPy emphasizes (1) object-oriented, hierarchical modeling to ease development and improve user-friendliness and maintainability; (2) advanced PSE functionalities, including parameter estimation, dynamic optimization, and NMPC with and without parameter adaptation; (3) control-vector parameterization (CVP) approach for dynamic optimization, which is typically more robust for large and strongly nonlinear model-constrained problems; and (4) direct access to CasADi symbolic variables and equations, enabling rapid prototyping of customized algorithms. GlycoPy is released as open source.

In the remainder of this paper, we first present the software and then validate its NMPC capability by controlling monoclonal antibody (mAb) glycosylation using a multiscale model.

## 2. SOFTWARE DESCRIPTION

GlycoPy is built on CasADi together with NumPy/Pandas/SciPy/Matplotlib. CasADi provides symbolic variables and equations and enables efficient differential algebraic equation (DAE) and ordinary differential equation (ODE) simulations and automatic differentiation, which are essential for large-scale dynamic optimization. Compared to native CasADi, GlycoPy provides a structured framework that streamlines model development and algorithm implementation. The following sections provide more details on how GlycoPy is used for modeling, simulation, parameter estimation, dynamic optimization, and NMPC.

### 2.1 Nonlinear modeling

In GlycoPy, a model is defined by implementing the `build()` method of the Model class using two basic objects: Variable and Equation. GlycoPy supports three variable types: differential states $x$, algebraic variables $z$, and parameters $p$ (time-invariant or time-varying but fixed during integration). Variables are created via add_var, which returns a GlycoPy symbol (a CasADi symbol or a dictionary of CasADi symbols). Users then write equations directly using standard CasADi-style operators and register them with `add_eq` as either ODE (`ode`) or algebraic (`alg`) equations.

To illustrate, we consider a small nonlinear DAE benchmark adapted from Andersson et al. (2019).

$$\begin{cases} \frac{dx_1(t)}{dt} = z(t)\,x_1(t) - x_2(t) + u(t) \\ \frac{dx_2(t)}{dt} = x_1(t) \\ \frac{d\mathrm{obj}}{dt} = x_1(t)^2 + x_2(t)^2 + u^2 \\ z(t) = p - x_2(t)^2 \end{cases} \quad t \in [0, T] \tag{1}$$

$$x_1(0) = 0, x_2(0) = 1, \mathrm{obj}(0) = 0, p = 1, \tag{2}$$

where $x \in \mathbb{R}^2$ denotes the differential variables, $z \in \mathbb{R}$ is the algebraic variable, and $\mathrm{obj} \in \mathbb{R}$ is the accumulated term to be used as the objective function in optimization. $u \in \mathbb{R}$ is the control action, and $T = 10$ is the considered time horizon. The GlycoPy implementation for the problem is shown below.

```
# Define model
Class SimpleDAE(Model):
 def build(self):
  xg = self.add_var('x', 'xg', m=2, val=[0.,
1.])
  obj = self.add_var('x', 'obj', val=0.)
  zg = self.add_var('z', 'zg')
  pg = self.add_var('p', 'pg', val=1.0)
  ug = self.add_var('u', 'ug', val=0.)
  self.add_eq('ode', 'xg', [zg * xg[0] -
xg[1] + ug, xg[0]])
  self.add_eq('ode', 'obj', xg[0]**2 +
xg[1]**2 + ug**2)
  self.add_eq('alg', 'zg', zg - (1 -
xg[1]**2) * pg)
```

Because each GlycoPy model is a Python class, users can naturally apply object-oriented design (inheritance and composition) and construct hierarchical models by assembling submodels. This modular structure improves development, testing, and maintenance for large chemical/bioprocess systems.

### 2.2 Simulation

For practical process models, time-varying inputs/parameters (e.g., piecewise-constant feed profiles) make a native CasADi workflow using built-in integrator cumbersome, especially when some input profiles are fixed while others are to be optimized. GlycoPy addresses this with the `SimulationDyn` class. With that, the code for the simulation of above DAE example is:

```
# Define simulator
initializer = Initializer('init', model)
integrator = Integrator('integrator',
'idas', dae_prob, initializer=initializer)
sim = SimulationDyn(model, integrator,
p_var=[('simple_dae.pg', 0), ])
p_var = np.random.randn(n_points-1, 1)
# Simulate
sim.simulation_with_events_numeri-
cal(t_event=time_points, p_var=p_var)
```

For numerical simulation, users specify which parameters are time-varying and provide their values at event times. The method `simulation_with_events_numerical(t_event, p_var)` runs the simulation and stores all results back into the model for convenient plotting and post-processing.

For sensitivity analysis and optimization, numerical trajectories are insufficient because automatic differentiation and symbolic Jacobians require symbolic results. Therefore, GlycoPy also provides `simulation_with_events`, which accepts symbolic input profiles and stores the resulting trajectories as CasADi expressions. Users can then directly build CasADi functions and compute Jacobians (or other derivatives) using standard CasADi operations. To further simplify robust derivative computation, GlycoPy includes `DerivativeEvaluatorSimple`, which wraps sensitivity evaluation with explicit method selection (`forward` or `adjoint`) and a safeguard: if sensitivity equations fail (a common issue for stiff, large-scale DAEs during optimization), it automatically falls back to finite differences. This design improves usability and stability for optimization workflows. The code for derivative computation is:

```
# Define derivative evaluator
evaluator = DerivativeEvaluatorSimple(y,
        p_var_sym,
  gradient_method=GradientMethod.forward)
# Evaluator derivatives
y_val = evaluator.val_fun_py(p_var)
jac_val = evaluator.jac_fun_py(p_var)
```

Finally, symbolic simulation enables developing differentiable simulation algorithms that are difficult to implement in many equation-oriented tools, such as the quasi-steady-state algorithm as will be shown later on in the case study section.

## 2.3 Dynamic optimization

A standard dynamic optimization problem (optimal control problem, OCP) shown below minimizes an integral (stage cost) plus a terminal cost subject to DAE dynamics, initial/terminal conditions, and bounds on states and inputs: differential states $x(t)$, algebraic states $z(t)$, control inputs $u(t)$, and parameters $p$.

$$\min_{x(\cdot),z(\cdot),u(\cdot)} \int_0^T L(x(t),z(t),u(t),p)dt + E(x(T),z(T),p)$$

$$\text{s.t.} \quad \left.\begin{aligned} \dot{x}(t) &= \text{ode}(x(t),z(t),u(t),p), \\ 0 &= \text{alg}(x(t),z(t),u(t),p), \\ u(t) &\in \mathcal{U}, x(t) \in \mathcal{X}, z(t) \in \mathcal{Z}, \end{aligned}\right\}, t \in [0,T]$$

$$x(0) \in \mathcal{X}_0, x(T) \in \mathcal{X}_T, z(0) \in \mathcal{Z}_0, z(T) \in \mathcal{Z}_T$$

Here, $\mathcal{U}, \mathcal{X}, \mathcal{Z}$ are given sets that the corresponding variables belong to. To solve the OCP problem numerically, the continuous-time problem is transcribed into a finite-dimensional nonlinear programming (NLP) problem:

$$\min_w f(w)$$

$$\text{s.t. } g_{lb} \le g(w) \le g_{ub},$$

$$w_{lb} \le w \le w_{ub},$$

where $w$ collects decision variables (e.g., discretized controls and possibly some initial states), and $g(w)$ includes the discretized dynamics and path/terminal constraints.

To solve the OCP problem numerically, the continuous-time problem is transcribed into a finite-dimensional NLP. GlycoPy currently uses the CVP method because of its robust convergence for highly nonlinear dynamics-constrained problems. CVP-based optimization repeatedly performs DAE simulations and (for derivative-based solvers) sensitivity/derivative evaluations across iterations.

Building on GlycoPy's differentiable simulation framework, the `MPCTool` class automates the transcription from the DAE-based optimal control problem to the NLP form. Users specify: the control grid (time points), the time-varying variables to be optimized (e.g., inputs), the objective (stage/terminal terms), and constraints (e.g., path bounds on states). `MPCTool.setup()` then generates all NLP ingredients $(w, f, g)$ and their bounds, which are passed to the `Optimization` module through a CasADi-like interface. For usability, `MPCTool` also provides a snapshot/rewind mechanism to store and restore the full model states before optimization. After solving, GlycoPy returns decision variables and key trajectories (controls and states) in convenient DataFrame structures for plotting and further analysis.

## 2.4 Parameter estimation

Parameter estimation (PE) identifies model parameters (and optionally uncertain initial conditions) by matching model predictions to measured data. For a DAE model, PE can be written as an optimization problem over

$$p = \begin{bmatrix} p_M \\ x(0) \end{bmatrix},$$

subject to the DAE dynamics and measurement equations. After transcription, PE becomes an NLP with decision variables $p$.

GlycoPy provides a modular PE workflow as shown in Fig. 1.

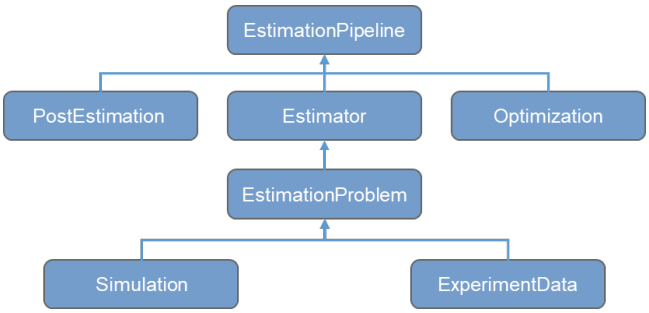

**Figure 1.** The structure of the parameter estiamtion module in GlycoPy.

The interface class `EstimationPipeline` defines and solves estimation tasks. Experimental data are stored in `ExperimentData`, including time-invariant operating parameters, time-varying operating profiles, measurements $y$, and their standard deviations $\sigma_y$. Multiple experiments are supported by creating multiple `ExperimentData` objects. For each experiment, GlycoPy runs a symbolic simulation to generate predicted responses $\hat{y}$, which enables efficient derivative-based optimization. An `EstimationProblem` object constructs residuals $r = y - \hat{y}$, stores measurement covariance $\Sigma_y$, parameter initialization and bounds $(p_0, p_{lb}, p_{ub})$, optional constraints, and priors $(\hat{p}, \Sigma_{\hat{p}})$ (when Bayesian estimation is used). An `Estimator` then builds the objective function according to the selected criterion:

$$\text{OLS: } \frac{1}{2} r^T r, \tag{3}$$

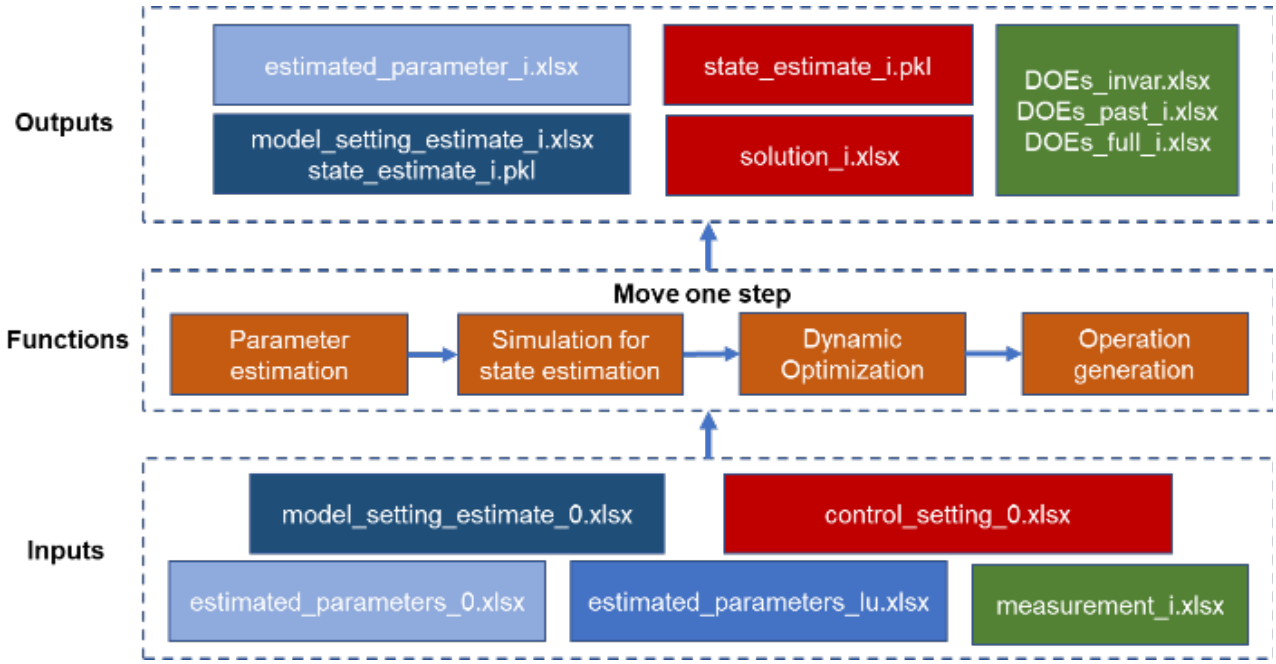

**Figure 2.** ANMPC implementation in GlycoPy.

$$\text{ML: } \frac{1}{2} r^{\top} \Sigma_y^{-1} r, \tag{4}$$

$$\text{MAP: } \frac{1}{2} r^{\top} \Sigma_y^{-1} r + \frac{1}{2} (p - \hat{p})^{\top} \Sigma_{\hat{p}}^{-1} (p - \hat{p}), \tag{5}$$

where OLS, ML and MAP stand for original least squares, maximum likelihood, and maximum a posteriori, respectively.

The resulting NLP is solved using GlycoPy's optimization interface. For post-analysis, `PostEstimation` computes the Fisher information matrix, parameter covariance, and confidence intervals using the output sensitivity $X = \partial \hat{y} / \partial p$.

For practical usability, GlycoPy supports: (i) estimating initial states together with parameters, (ii) optional log-parameter transforms to improve conditioning when parameters span orders of magnitude, (iii) diagnostic mode to debug simulations/experiments, and (iv) Excel-based inputs for experimental operating conditions, measurement data, initial guesses, bounds, and priors.

## 2.5 NMPC

The simulation, parameter estimation, and dynamic optimization modules in GlycoPy can be combined to implement state NMPC and adaptive NMPC (ANMPC) for fed-batch processes. In each control interval $k$, ANMPC follows a standard loop in a shrinking horizon: (i) when new measurements are available, update the parameter estimate $\hat{p}(k)$ using all collected data; (ii) simulate the model to obtain the current state estimate $\hat{x}(k)$; (iii) solve an optimal control problem over the remaining horizon $[t_k, T]$ using $\hat{p}(k)$ and $\hat{x}(k)$; and (iv) apply the first control move and sample again. The algorithm terminates at the end of the batch.

A practical challenge in applying NMPC for large-scale processes is debugging and diagnosis: users often need to stop, inspect intermediate results (states, parameters, predictions, control actions), and restart from any interval without rerunning the full batch. To support this workflow, GlycoPy adopts the implementation structure in Fig. 2, which separates the NMPC loop into reproducible blocks, **inputs**, **functions**, and **outputs**.

In the **inputs** block, all settings and data can be provided via spreadsheets, including model/initial-condition settings, control scheduling (manipulated variables and time grids), parameter priors (values, covariance, confidence intervals), parameter bounds, and measurement files with noise levels.

In the **functions** block, users implement four core steps based on existing pipelines in the previous section: parameter estimation, simulation for state estimation, dynamic optimization, and operation generation. Here, the operation generation function generates files recording not only the optimized future control actions but also the actual past actions. Here, recording the actual past actions is important because low-level actuators may deviate from ideal setpoints; these recorded actions are then reused for subsequent estimation and prediction.

In the **outputs** block, at each interval, the framework stores updated parameter estimates and covariance, updated model settings (including refreshed initial states),

optimized decision variables (past and full horizon), and a solution file containing predicted trajectories and applied controls.

State NMPC uses the same structure but does not update parameters; it relies on simulations with fixed parameters combined with available measurements for state updates.

## 3. CASE STUDY

We demonstrate GlycoPy on NMPC of the mAb N-glycosylation process using the multiscale glycosylation process model, which has been studied in [9]. The model provides the mapping from extracellular conditions and operating actions to intracellular Golgi processing and the resulting extracellular glycoform distribution, which can be illustrated by Fig. 3.

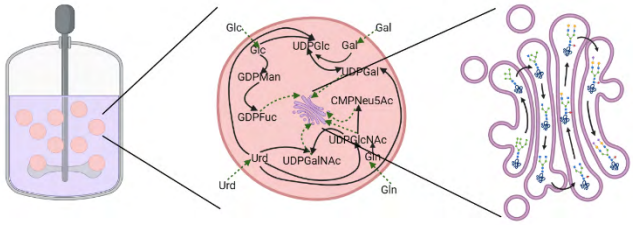

**Figure 3.** Multiscale mAb glycosylation process. The submodels, from left to right, are: the cell culture and metabolism model, the NSD synthesis model, and the Golgi glycosylation model. Reprinted from (Ma et al., 2025b) with permission.

The multiscale model consists of three interconnected layers [10]. At the bioreactor level, a cell culture submodel describes viable cell growth, extracellular metabolite dynamics, specific productivity, and secreted monoclonal antibody concentrations. These extracellular conditions are then passed to an intracellular nucleotide sugar donor synthesis submodel, which maps culture-level metabolite information to intracellular donor pools through a mechanistic representation of the relevant biosynthetic pathways and kinetics. Finally, a Golgi-level glycosylation submodel uses these donor species to predict the distribution of antibody glycoforms emerging from the secretory pathway by combining enzyme-mediated reaction networks with glycoprotein transport dynamics.

In the multiscale model, the Golgi subsystem is particularly complex, involving a large reaction network and spatially distributed dynamics. Implementing the full system as a single monolithic model would be difficult to maintain and reuse. Instead, GlycoPy enables a structured decomposition as shown in Fig. 4, where the overall model is built from the three main submodels, and the Golgi module is further organized into reusable components: transport proteins, enzyme, reaction, and network blocks. This hierarchy supports scalable simulation, estimation, optimization, and control for realistic biomanufacturing applications.

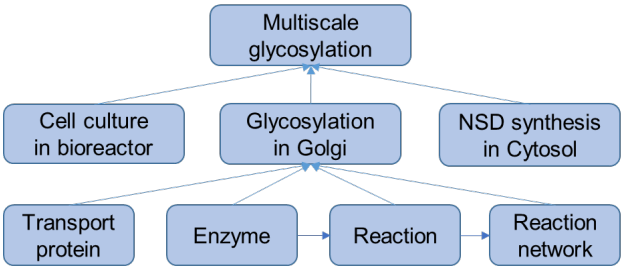

**Figure 4.** Implementation of the multiscale glycosylation model in GlycoPy.

The multiscale model takes the form of a large-scale partial differential–algebraic equation (PDAE) system, comprising 30 ordinary differential equations, 34 partial differential equations, and many strongly nonlinear algebraic relationships. The simulation using the finite difference method will be too slow to be used for NMPC. The symbolic simulation in GlycoPy enables the implementation of the quasi-steady-state (QSS) simulation algorithm and ensures differentiable simulations, which will be difficult in other modeling and control platforms. The steps of the QSS algorithm are as follows [11]: (i) the cell culture and NSD submodels with slow dynamics are simulated at selected time points and generate state variables $\mathrm{env}$ to be used for the following Golgi model simulation; (ii) the Golgi submodel is solved at steady state at each time point (parallelizable) with $\mathrm{env}$ as inputs, and generates intracellular glycosylation profiles $Y_{\mathrm{glycan}}^{\mathrm{intra}}$ ; (iii) the resulting $Y_{\mathrm{glycan}}^{\mathrm{intra}}$ are treated as time-varying parameters for the cell culture submodel to generate the extracellular glycosylation profiles $Y_{\mathrm{glycan}}^{\mathrm{extra}}$. This algorithm is packaged in `SimulationQSS` (derived from `Simulation`) and can return numerical or symbolic results depending on input types. Reported speedups exceed 300 folds for the multiscale glycosylation case. Because the QSS simulation is used, the total computation time for a single ANMPC step, including parameter estimation, state estimation, and dynamic optimization, remains below 2 h [9].

In the control problem, we maximize the galactosylation index (GI) at harvest time ($T = 288$ h),

$$\mathrm{GI}(T) = [\mathrm{FA2G1}](T) + 2\,[\mathrm{FA2G2}](T), \tag{6}$$

where $[\mathrm{FA2G1}]$ and $[\mathrm{FA2G2}]$ are the extracelluar concentrations of the corresponding glycoforms at harvest. The NMPC problem includes operational feasibility constraints on the bioreactor and product quality: (i) cell viability must remain above 60%; (ii) the media in the bioreactor volume must stay between 0.75 L and 2.25 L ; and (iii) the fraction of Man5-attached mAb is constrained by an upper bound 5% to avoid unacceptable high-mannose

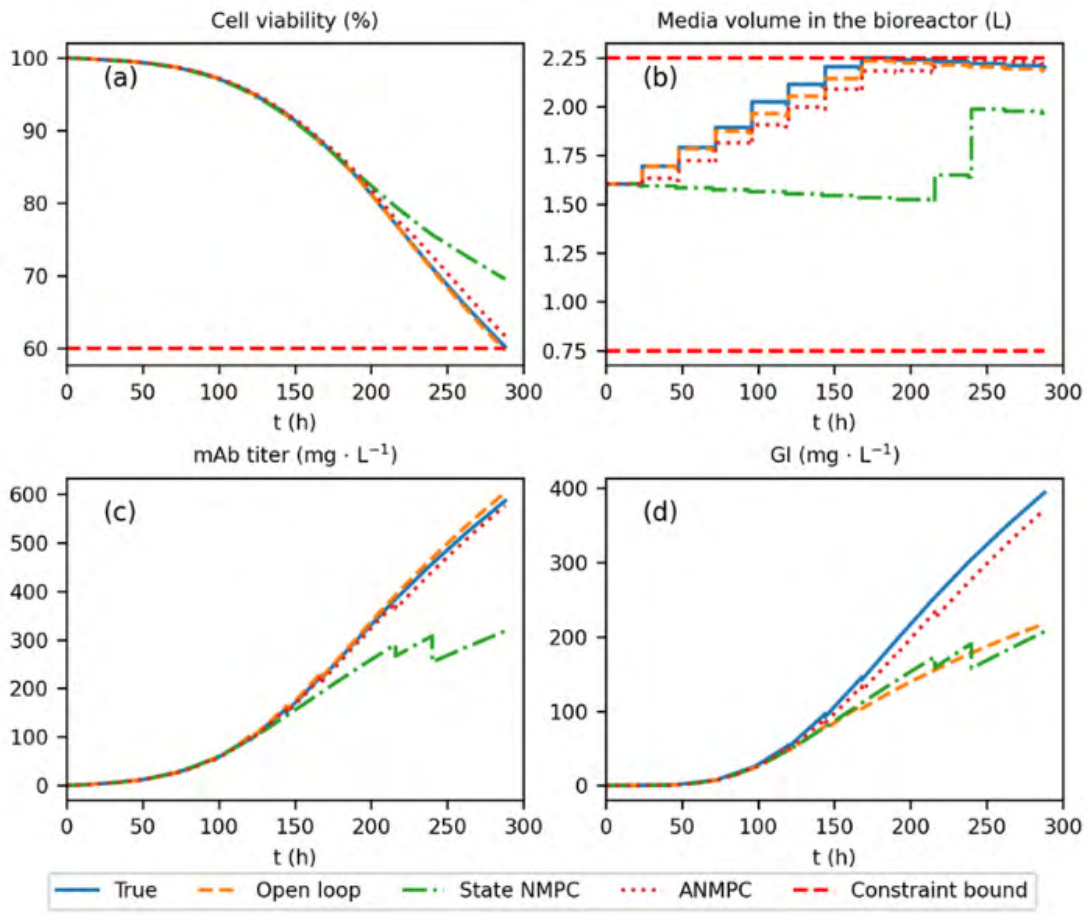

**Figure 5.** State variable trajectories under ground-truth optimization results and different control strategies.

content, where Man5 refers to High-mannose glycan containing five mannose residues. The controller adjusts two feeds commonly used in practice for the control purpose: a media supplement and a galactose (Gal) supplement. These inputs influence cell growth/metabolism and NSD availability, thereby shaping Golgi reaction fluxes and final glycoform composition.

The optimization and NMPC frameworks in the last section are used for the case study. We compare three control strategies: open-loop optimization, state NMPC, and ANMPC. Because of the use of the efficient quasi-steady-state simulation. The results are shown in Fig. 5.

All three strategies produce feasible trajectories satisfying the viability, volume, and Man5 constraints. However, ANMPC achieves a substantially higher terminal GI, which approximately doubles the GI achieved by open-loop optimization and state NMPC, and approaches the performance of ground-truth optimization. This highlights that, for glycosylation process control, closed-loop optimal control and adaptation can deliver large gains in product quality while maintaining process feasibility.

## 4. CONCLUSION

To promote the practical deployment of NMPC in real-world (bio)chemical processes, this work introduces GlycoPy, an equation-oriented (EO), object-oriented Python framework for modeling, optimization, and optimal control. GlycoPy allows users to focus on writing equations while providing hierarchical modeling capabilities that simplify the development, use, and maintenance of large-scale and multiscale process models. GlycoPy retains CasADi's powerful symbolic framework, enabling the use of symbolic simulation to develop efficient and differentiable simulation algorithms. The framework also includes parameter estimation and dynamic optimization modules, which form core building blocks for NMPC implementations. In addition, GlycoPy can export key intermediate results (e.g., parameter estimates and state trajectories), supporting transparent interpretation and efficient diagnosis of NMPC runs. Finally, a multiscale mAb glycosylation case study illustrates the effectiveness of the proposed framework.

## DIGITAL SUPPLEMENTARY MATERIAL

GlycoPy is available at https://github.com/eaglema/glycopy, and the libraries for the glycosylation process modeling, optimization and control based on GlycoPy is available at https://github.com/eaglema/glycosylation.

# Automated workflow for the configuration of modular plants and HAZOP analysis by utilizing DEXPI P&ID

**Mathias Schmitz[a*], Janis Weber[a], and Norbert Kockmann[a]**

[a] TU Dortmund University, Department of Biochemical and Chemical Engineering, Dortmund, North Rhine-Westphalia, Germany

## ABSTRACT

The increasing adoption of modular plant concepts in process engineering requires new strategies for design and safety evaluation. Conventional hazard analysis methods, such as HAZOP are time-consuming and must be repeated whenever a configuration changes, which contradicts the flexibility that modularization aims to achieve. This work combines concepts from the modular HAZOP method and the preHAZOP method to enable an automated, early-stage safety assessment for modular plants based on P&IDs. A workflow is developed that generates a combined P&ID for a modular plant from individual module (PEA) P&IDs provided in DEXPI format and performs an adapted preHAZOP analysis on the resulting plant representation.A key motivation is that P&IDs are always created during plant or module design and already contain relevant piping information, which can be reused for automated module interconnection and plausibility checks. In the proposed workflow, standardized interfaces enable automatic connection generation and validation. The safety assessment is performed by rule-based deviation propagation on a DEXPI-based P&ID graph and can operate with, without, or alongside process data. The workflow outputs structured scenario tables and selected design consistency checks and is implemented as a Streamlit web application, validated on a modular example system.

**Keywords**: Modular plants, HAZOP, DEXPI, P&ID, Safety analysis

## INTRODUCTION

Globalized markets and increasingly dynamic product demands require the process industry to react faster and design plants more flexibly. Modular plants address this need by enabling reuse of standardized units and faster (re-)configuration of production systems [1]. However, the benefits of modularization are constrained by the effort required for safety studies and approvals. Conventional HAZOP is systematic but resource-intensive; repeating a full HAZOP after each configuration change undermines modularity's speed advantage. This work therefore targets an automated workflow that supports early safety assessments and helps accelerate approval processes for modular plants.

In industrial practice, each module plant or plant section is documented in a P&ID diagram during its design phase. The P&ID is a core component in the design phase during detail engineering. Manufacturers commonly annotate piping with information such as identifiers and nominal diameters, and sometimes even material information [2, 3]. In the workflow of this contribution, such data are explicitly attached to module interfaces and exported with the P&ID, enabling automatic connection generation and interface checks when assembling modules into a plant.

To achieve the goals, this contribution combines two ideas: a modular safety approach (splitting safety knowledge into reusable module/equipment-related parts) and automated, data-driven scenario detection from machine-readable P&IDs (preHAZOP). A software tool is developed that merges multiple P&IDs of modules into one plant-level DEXPI P&ID and then runs an adapted preHAZOP analysis on the combined P&ID of the modular plant.

## BACKGROUND

### Modular plants

Modular plants decompose a process into process

equipment assemblies (PEAs), each delivering a defined process function and equipped with own automation. This automation is done by the Module Type Package (MTP) which is comparable to a driver of peripheral devices for a computer. It encapsulates the automation interface of a PEA and supports orchestration by the Process Orchestration Layer (POL). MTP ensures the manufacturer independent compatibility between each PEA as well as to the POL. Each PEA is able to execute certain services to perform dedicated unit operations. Rearrangement of the PEAs allows to perform different processes without building a completely new plant for one new product.

While the modular concept and MTP are defined by the VDI/VDE/NAMUR 2658 [4] and 2776 [5] guidelines and different vendors are offering POLs or support to create MTP-files, there is no example of a safety assessment for the approval of a modular plant.

## DEXPI P&ID

P&IDs are central documents throughout planning, construction, operation, and modification of process plants. They represent equipment, piping, valves, and instrumentation and control functions in a standardized way (e.g., via ISO/IEC-related standards), allowing consistent communication across disciplines. DEXPI e.V. is an initiative comprising various representatives from industry and academia who are working on common data exchange formats. The first implementations were carried out with the DEXPI Process Specification [6] and the DEXPI P&ID Specification [7]. In October 2025 were the DEXPI 2.0 Specification released which combines the Process Specification and P&ID Specification [8]. DEXPI is a standardized exchange format for P&IDs grounded in ISO 15926 concepts, typically realized as an XML-based schema that represents plant topology and attributes in a machine-readable form. While the DEXPI P&ID Specification relied on a Proteus-XML schema, DEXPI 2.0 uses a common XML format. The DEXPI format aligns with different international standards such as ISO 15926 [9]. The P&ID files in this work were created by using the software PlantEngineer from X-Visual Technologies GmbH.

## Modular HAZOP

A HAZOP (Hazard and Operability) analysis identifies hazards and operability problems by systematically generating deviations from design intent using guidewords and parameters, then analyzing causes and consequences in an interdisciplinary team. The considered process is divided into functional units and their intended operation is described as a target function. While effective, the method is labor-intensive. Modular HAZOP extends HAZOP thinking to modular plants by structuring safety knowledge into module-oriented pieces and defining interfaces so results can be recombined for different plant configurations. For a modular plant the PEAs can be chosen as the functional units.

The ISSA (International Social Security Association) suggests seven guidewords in combination with parameters to form a deviation [10]. These guidewords are: no, more, less, as well as, partially, inversion, differently than. Three of them are considered in this work which are ‚no', ‚more' and ‚less'. The considered parameters in this work are temperature, flow and pressure. The combination of the other guidewords with the parameters is in certain cases not reasonable or brings up an open interpretation of the deviation case and should be discussed by a HAZOP team.

Klose [11] suggested in his doctoral thesis an approach to execute a HAZOP analysis for modular plants. He considered equipment-specific safety (mHAZOP) and process safety (pHAZOP) separately in the first place. This is because each PEA is built in a more generalized way and not tailored with a certain process in mind. The operator of the modular plant knows about the planned processes and can execute the p-HAZOP. Afterwards the m- and p-HAZOP are combined to check if the selected configuration of the PEAs is suitable for the process. Klose defined a PEA as a so-called HAZOP-ode which features one or more HAZOP-Interfaces to connect to other HAZOP-Nodes (PEAs) or the plants infrastructure. The different cases of deviations are applied to the HAZOP-Nodes. The HAZOP-Interfaces are relevant to transfer deviations from one HAZOP-Node to another one. [11-13]

## preHAZOP

preHAZOP is a tool approach developed by Oeing et al. [14] that reads a DEXPI-P&ID and simulation results to build a graph model of the plant, enrich it with equipment, streams, and safeguards, and then detect typical HAZOP scenarios based on a machine-readable scenario database.

DEXPI P&IDs provide structured information about plant topology, equipment and connections. This topology is transformed into a directed graph (stored in GraphML) that becomes the basis for algorithmic searches of hazardous constellations. In addition, operating conditions are incorporated by mapping data from a process simulation onto the same graph.

Based on this combined model, preHAZOP detects potential scenarios using a scenario database that formalizes common HAZOP elements (guideword, parameter, cause and consequence) together with machine-checkable requirements expressed as graph patterns and attribute constraints. The tool is able to recognize functional and instrumentation-related structures by classifying valves and pipes, identifying measurement locations and control loops, and detecting the presence and assignment of protective devices such as relief

paths, while also accounting for disabling configurations like isolating valves. The output is a structured list of scenario instances linked to specific equipment or sections of the plant, complemented by fields that indicate where automated assessment is insufficient and manual verification is needed (e.g., confirming design limits).

This contribution adopts the graph-centric idea but adapts the method to better fit modular plants, extend scenario generation, and support use cases without simulation data. The general workflow of the preHAZOP is presented in Fig. 1, where the added and adopted steps are outlined in blue.

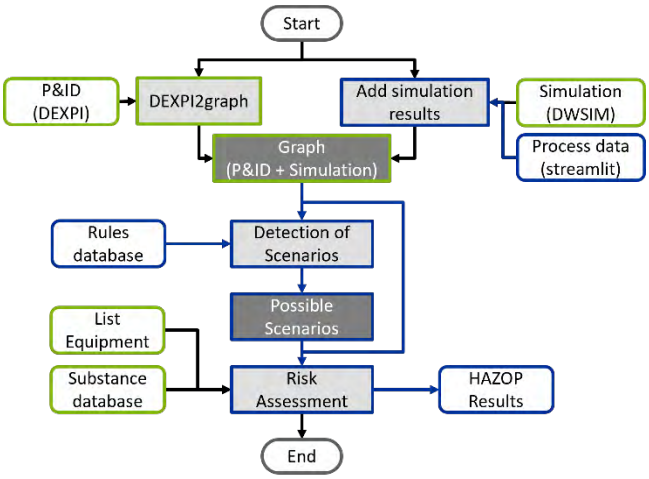

**Figure 1.** Suggested preHAZOP workflow. Blue marked steps are added or adapted from the original workflow.

# METHODOLOGY

## Laboratory set-up

The suggested workflow uses a modular reactor setup from the laboratory as an example for the P&ID flowsheets. The laboratory setup consists of four PEAs, which are shown in Fig. 2. These comprise a reactor PEA, two identical dosing units and a temperature PEA. The dosing units feed the two reactants via the temperature PEA into the reactor, where the reaction takes place before the product is discharged into another tank. The temperature PEA provides the required flow temperature for the reactants and also enables the temperature of the reactor to be controlled.

The Reactor-PEA is a continuous stirred tank reactor (CSTR) consisting of a vessel with a heating jacket, a stirrer with motor, three sensors to measure the level, the temperature and the conductivity of the substance filled in. The reactor has two inlets to feed educts inside of it and one outlet for the product with a controllable solenoid valve as well as an in- and outlet at the heating jacket.

The Dosing-PEA consists of a pump, a mass flowmeter and a storage tank. The Temperature-PEA is realized by a thermostat and is depicted here as a combination of a pump and a heater.

## P&ID merge

In the workflow of Oeing [14] it was not necessary to consider multiple P&IDs. Since each PEA provides an own P&ID it is necessary to combine them to form the P&ID of the complete modular plant. To provide a user-friendly tool, the here presented workflow can executed by using a Streamlit application. Calling the python-file opens up a new tab in the user default browser, running the HMI. In the first step, the user is able to upload a DEXPI P&ID file or can select from already uploaded files.

For P&IDs of PEAs, correct and consistent interface definition is crucial. The PEA interfaces are defined as in- or outlets and are preceded by flanges. The flange objects store interface-related engineering constraints such as nominal diameter, design pressure, and temperature range.

Interface IDs follow a structured naming convention and are stored in attributes depending on whether an interface is an inlet, outlet, or bidirectional port. This convention allows the merging tool to automatically identify connection candidates, directions, and required adjustments.

Information about the PEA interfaces is extracted and listed to select how the different PEAs are connected with each other. When combining multiple DEXPI files, ID collisions must be avoided. The tool therefore prefixes each element ID with a PEA-specific shorthand and updates all references consistently across equipment, piping networks, and instrumentation functions. Simultaneously, it extracts geometric information (coordinates and extents) for PEA layout computation and stores interface coordinate data for later routing of inter-module connections. The individual P&IDs of the PEAs from the laboratory setup are shown in Fig. 2 as well as the combination of them to the complete modular setup.

To create a readable combined P&ID, PEAs must be arranged without overlaps and ideally with short connection lines. By using constraint programming in form of the CP-SAT-solver from the OR-Tools library and modeling each PEA as rectangle on the drawing sheet, enables to enforce certain rules. The first rule is that PEAs does not overlap and must keep a minimum distance. Secondly PEAs must remain within the sheet boundary and avoid the title block area. Lastly, an objective function minimizes the sum of Manhattan distances between connected interface points, discouraging small misalignments that would create unnecessary bends. This transforms a reasonable positioning into a reproducible optimization problem. The solver output is translated into shifts applied to all elements of each PEA P&ID so that the PEA internal structure remains intact while the plant-level arrangement changes. Fig. 3 shows the steps of the

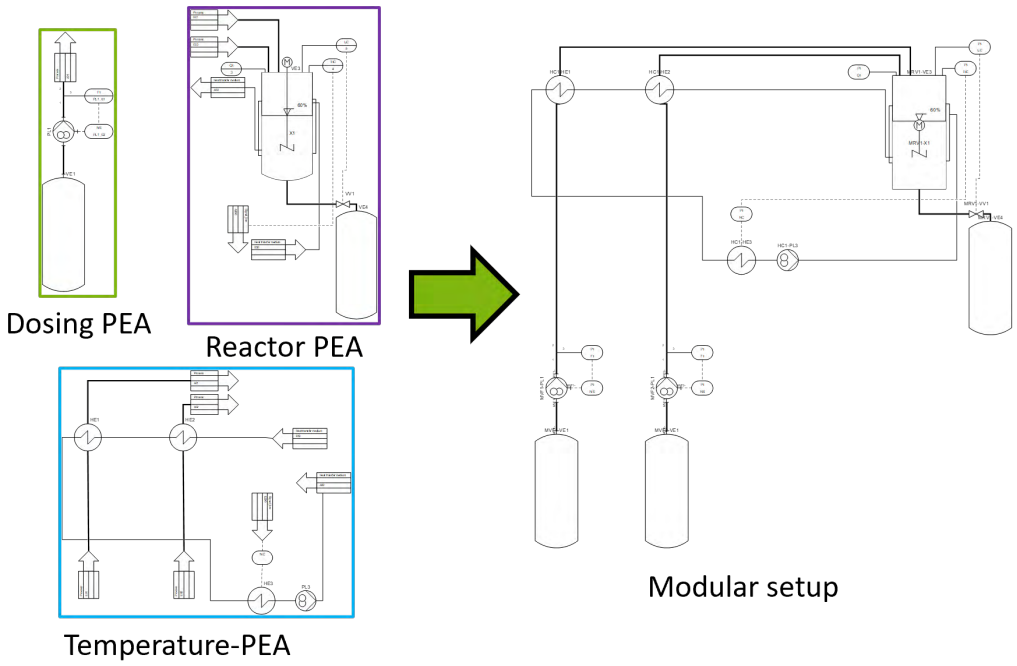

**Figure 2.** P&IDs of individual PEAs and combination to complete P&ID of the modular setup.

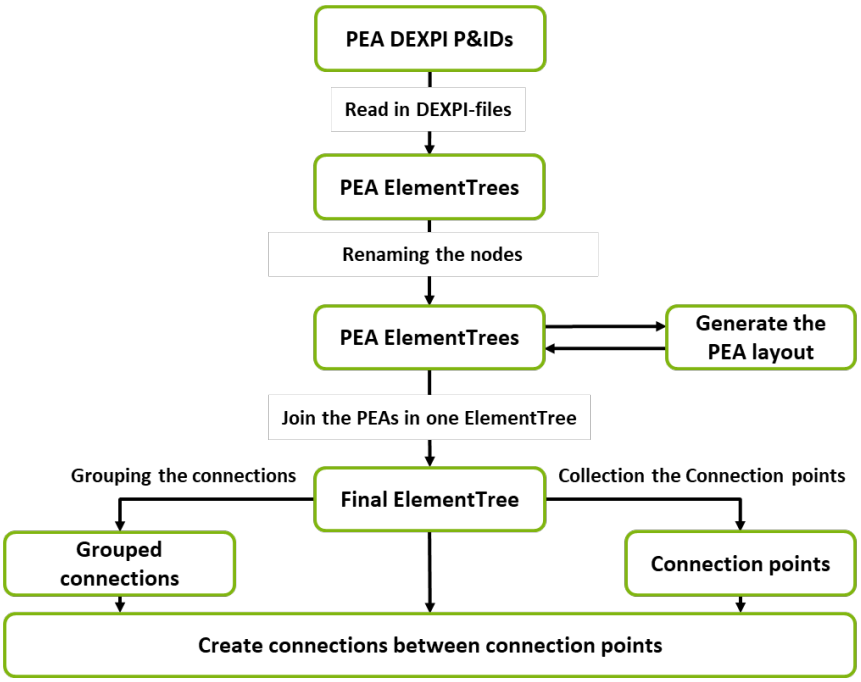

**Figure 3.** Procedure of reading out multiple PEA P&IDs and creating connections between their interfaces to create a combined P&ID.

programmed workflow to connect multiple P&IDs at their distinct interfaces.

After placement, the tool creates inter-module piping segments between flange coordinates. This is done by collecting all interfaces and grouping them accordingly to their function as inlet or outlet. Before the connections are created, they are grouped together. Connections with identical start and end points are combined. This can result in a 1:1 connection between two points (single start to single end) as well as 1:n or n:1 links (multiple starts or ends). For the later one T-pieces are inserted and positioned between PEAs to avoid placing

junctions inside PEA drawings. Additionally, a direction alignment is performed since individual interfaces can be defined as bidirectional. In Fig. 4 the procedure to create connections and inserting T-pieces if necessary is shown.

Before creating a connection, the tool compares flange attributes and records inconsistencies—for example mismatches in nominal diameter or minimum and maximum design pressure and temperature. This provides immediate feedback on interface compatibility and supports safer PEA coupling decisions early in engineering.

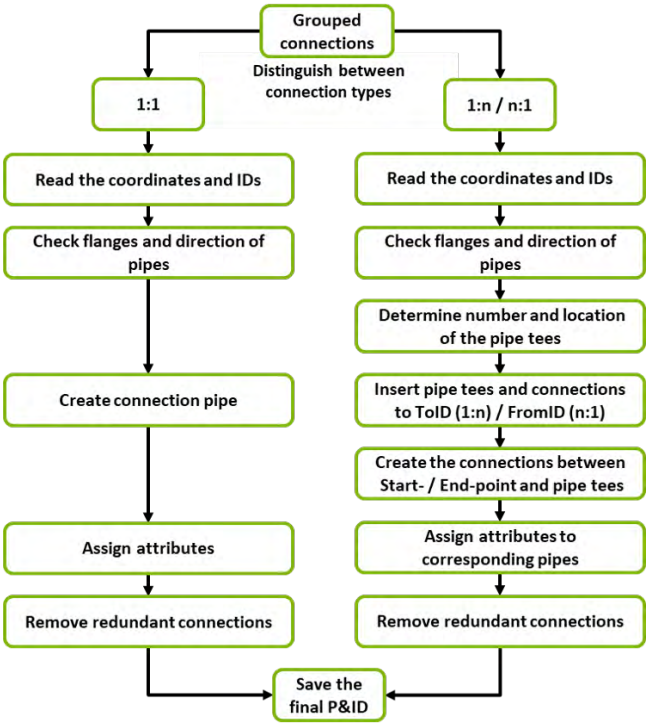

**Figure 4.** Procedure to check if its necessary to insert T-pieces between PEAs and how to connect them.

## Adapted preHAZOP for modular plants

The original preHAZOP concept depends strongly on simulation data and a scenario database. For modular plants, simulation data may not exist when assessing a single PEA, or the final plant process may not yet be fixed. This work therefore adapts the preHAZOP so that scenario recognition remains possible without a simulation, while still benefiting from simulation or manually entered process data if available.

Instead of a purely pattern-based scenario search in a spreadsheet, this workflow implements a rule database organized by individual equipment classes in separated YAML-files. Within this rule base, different rule types are distinguished: rules that define local deviations as events originating at specific equipment, including frequency estimations and associated safeguards; rules that map these deviations to local consequences such as damage or leakage based on guideword–parameter combinations; rules that specify how deviations propagate forward or backward through the system depending on the type of piping; and rules that describe how equipment responds to deviations arriving from upstream or downstream, optionally depending on specifications such as the presence of a heating jacket, inertization, an agitator, or a control loop. This organization enables richer and more explicit logic than a flat table and aligns well with modular HAZOP thinking, because deviations can be generated locally within a PEA and then combined across PEA boundaries through propagation via the defined interfaces.

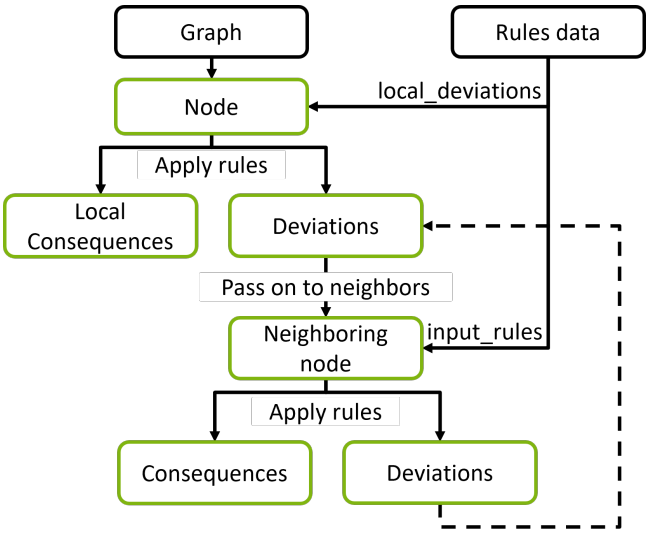

**Figure 5.** Workflow of applying the safety rules on the extracted graph.

The detection procedure follows two consecutive steps. First, the algorithm generates initial deviations at each node of the extracted graph based on the local deviation rules and records the corresponding local consequences immediately as scenario candidates. Second, these deviations are propagated through the graph using a queue-based mechanism. Whenever a deviation reaches another node, the engine checks the applicable input rules for that equipment, records any resulting consequences, and continues propagation if the defined propagation rules permit it. To keep the output manageable and to prevent an uncontrolled growth of near-identical scenarios, repeated events are filtered, for example when similar causes originate from the same equipment class at a node, and the propagation depth can be restricted, with a default limit of up to six nodes. The resulting scenarios are then stored in a structured, Excel-like table format consistent with modular HAZOP documentation, including deviation, cause, consequences with severity and frequency considerations, and safeguards that are either already present or recommended. Fig. 5

illustrates at which points the rules are applied in the procedure and how deviations are propagated to its neighbor nodes.

To support different stages of engineering maturity, the tool can handle process data in several ways. If simulation results are available, they can be imported in the same manner as in the original preHAZOP workflow. If no simulation file exists and operating conditions are determined manually, users can enter minimum and maximum operating pressure and temperature as well as relevant media, either as global default values or as equipment-specific overrides. If no process data are available at all, the scenario detection still runs, although parameter-based checks and media–material evaluation may be more limited. In addition to producing scenario lists, the adapted workflow performs two engineering checks that add practical value. Operating pressures and temperatures, whether derived from simulation or manual input, are compared against the design limits stored in the P&ID, so that exceedances and critical mismatches between neighboring equipment design limits can be documented as potential weak points during upset conditions. Furthermore, a media–material compatibility check is carried out using a dedicated database that flags problematic combinations with an A–D rating and can identify mechanisms such as catalytic decomposition, for example the incompatibility risk of hydrogen peroxide in contact with stainless steel. Any problematic combinations identified in this way are exported to support targeted follow-up in the subsequent engineering review.

## Web Application Implementation

To make the workflow usable for engineers, the toolchain is implemented as a Streamlit web app with two separate tabs. In the first tab the user uploads PEA P&IDs, selects the PEAs, defines their interface connections via dropdowns populated from detected ports, specify attributes for connecting pipes, and export the configuration for reuse. The merged DEXPI P&ID and an interface mismatch report are returned.

In the second tab, the user runs the preHAZOP with the previously generated P&ID or is able to upload an older P&ID. Process data can be optionally entered either manually or in form of a simulation file. After running the analysis, the results can be downloaded as a table.

## Validation

The workflow involving the simulation was tested by using a DWSIM simulation representing the lab set-up with a saponification reaction. In this reaction sodium hydroxide reacts with ethyl acetate to form sodium acetate and ethanol.

As a case for manual data input the oxidation of sodium thiosulfate with hydrogen peroxide is considered which serves as an example for a highly exothermic reaction [15, 16]. For 1 M sodium thiosulfate and 2.2 M hydrogen peroxide at 40 °C results in a temperature increase of 70 °C to 110 °C inside of the reactor. As a result, the HAZOP table shows that the process temperature exceeds the maximum operating temperature of the reactor. Additionally, the media and material compatibility check gives a message that hydrogen peroxide should not get contact with stainless steel.

The merging tool successfully combined multiple PEAs into a single P&ID without overlap and with short connection paths. The adapted preHAZOP detected meaningful scenarios both on the individual PEA level and on the combined plant level; when simulation data were available, the design-vs-operation checks identified a simulated design pressure exceedance (not necessarily representing the real lab setup, but validating the check mechanism). Media–material checks did not reveal issues for the lab media and materials considered.

The workflow demonstrates manual derivation and entry of operating parameters, including estimating the maximum adiabatic temperature rise for a strongly exothermic reaction. The merging workflow handled a larger number of PEAs, bidirectional interfaces, and multi-branch connections, including correct direction adjustments and T-piece insertion.

The adapted preHAZOP produced both intra-module and inter-module scenarios. Importantly, the additional checks detected a design-vs-operation temperature violation for a downstream pump (operating temperature exceeding the pump's max design temperature) and flagged a problematic media–material combination involving hydrogen peroxide and stainless steel (rated poor due to catalytic decomposition). These findings illustrate how the tool can surface concrete engineering issues early, even without detailed dynamic simulation.

# SUMMARY AND CONCLUSION

This contribution builds up an the preHAZOP tool developed by Oeing et al. and adapts it for modular plants by incorporating modular safety concepts of Klose. The preHAZOP workflow is complemented with the option to combine multiple P&IDs into a complete P&ID of a plant and gives the opportunity to enter process parameters manually instead of relying on simulation files. It demonstrates that DEXPI P&IDs can serve as a practical, machine-readable backbone for two high-impact automation steps in modular plant engineering. Firstly, showing early safety assessment via graph-based, rule-driven scenario generation. Secondly, it provides a tool for rapid planning of different kinds of possible plant configurations by merging PEA P&IDs.

One of the main focuses in this work lies on the interfaces of the PEAs to connect the P&IDs with each other as well as compatibility checks between the PEAs.

Standardized connection points combined with manufacturer-provided piping attributes allow plausibility checks that are directly relevant for modular approval discussions (compatibility of design limits, nominal diameter, etc.). This helps in early phases of setting up a new plant configuration, to check if PEAs are allowed to be combined.

At the same time, limitations remain typical of knowledge-based safety automation: scenario quality depends on the completeness and correctness of rule databases, equipment classification, and available process data. The work therefore positions the tool as an accelerator for early-stage studies and as structured input for expert HAZOP teams—not as a full replacement for interdisciplinary review.

Several extensions for the preHAZOP can be proposed to improve the workflow further. The layout can be optimized by reducing line crossings, improving T-piece placement strategies and removing the current drawing-size limitation. Additionally, the rule database should be expanded to more equipment classes, guidewords, and better equipment sub-classification (e.g., distinguishing heaters vs. coolers). The media–material database could be enriched with concentration and temperature dependence. Towards an improved compatibility check, an implementation of ex-zone detection or check whether certain components are explosion-proof or not would be helpful.

Beneficial for the further automation of this workflow is the implementation of a connection to a chemical database to fetch safety relevant information of the used substances. Borgelt et al. has shown the implementation of such databases like the ChEBI, KEGG and PubChem [17].

Because DEXPI was updated during this work, the workflow should be adapted to the newer schema and—critically—support "clean" DEXPI files where properties are mapped into standard DEXPI attributes rather than vendor-specific attribute sets. This would improve interoperability with other authoring tools and strengthen the value of standardized P&ID data for safety automation.

A practical next step for usability is to leverage the HMI information contained in MTP files as a "preview" during plant configuration. Since PEAs in modular automation are already packaged with MTP-based interfaces, an automatically generated (or extracted) HMI view could guide users to select the correct connection points between PEAs more intuitively—reducing errors in manual interface selection and aligning the P&ID-based configuration step with the operational perspective of the PEA automation.

This work presents a coherent, implementable approach for accelerating modular plant safety assessments by reusing data already present in P&IDs. By merging PEA P&IDs (DEXPI) into a P&ID of a complete modular plant and applying an adapted, rule-based preHAZOP on a graph representation, the workflow enables systematic detection of deviation–cause–consequence chains across PEA boundaries and adds practical checks for design vs. operating limits and media–material compatibility. Implemented as a Streamlit web app and validated on modular examples, the workflow demonstrates how standardized engineering data can support faster, more reproducible early-stage safety assessments—an important step toward accelerating the approval of modular plants.

## DIGITAL SUPPLEMENTARY MATERIAL

A collection of the created and used files can be found here: https://repository.nfdi4cat.org/dataset.xhtml?persistentId=hdl:21.11165/4cat/86xp-e338 This includes: Python-files, YAML-files with rules, Excel-files containing results of the HAZOP analysis and DWSIM simulation file.

## ABSTRACT

Dimethyl ether (DME) is a promising clean fuel and chemical intermediate, yet its synthesis from synthesis gas remains highly sensitive to both catalyst formulation and operating conditions. In this work, a data-driven framework is developed that combines machine learning surrogate modeling with multi-objective optimization to support systematic decision-making in DME synthesis. The novelty lies in the systematic comparison of different optimization approaches applied to an identical machine learning surrogate model for DME synthesis, thereby highlighting their respective strengths and limitations as decision-support tools under limited-data conditions. A dataset compiled from published literature includes catalyst composition, preparation methods, physicochemical descriptors, and operating conditions, with CO conversion and DME selectivity as performance indicators. After data preprocessing, feature analysis using correlation analysis and principal component analysis (PCA) is applied to explore dominant trends and interactions. Several supervised machine learning models are trained and benchmarked, and the best-performing model is selected as a surrogate for optimization. Two complementary multi-objective optimization strategies are then applied to the same surrogate model: a fuzzy-enhanced NSGA-II algorithm and a constrained multi-objective Bayesian optimization approach. Gradient boosting is found to provide the most reliable predictive performance among the tested models. Both optimization strategies identify similar catalyst formulations as optimal, while differences emerge in the recommended operating conditions. The comparative analysis highlights how different optimization paradigms influence compromise solutions when balancing CO conversion and DME selectivity.

## INTRODUCTION

The transition toward sustainable and flexible fuel production pathways has intensified interest in synthesis gas ($CO/H_2$) conversion processes [1]. Among the available options, dimethyl ether (DME) has attracted considerable attention due to its high cetane number, clean combustion behaviour, and compatibility with existing fuel infrastructure. DME can be produced either via a two-step route involving methanol synthesis followed by dehydration or through a direct, one-step process using bifunctional catalysts. Despite extensive experimental efforts, achieving high CO conversion and DME selectivity simultaneously remains challenging because of the strong coupling between catalyst preparation method, and operating conditions [2, 3].

From a process engineering perspective, DME synthesis constitutes a high-dimensional and strongly nonlinear optimization problem. Reaction temperature, pressure, feed composition, space velocity, and catalyst characteristics interact in complex ways that are difficult to capture using mechanistic models, particularly when kinetic data are scarce or inconsistent across studies. As a result, experimental trial-and-error approaches remain common, but are time-consuming and resource-intensive.

Machine learning (ML) techniques provide an alternative route by enabling the construction of surrogate

models that directly learn input-output relationships from experimental data [4]. When applied to catalytic systems, ML models can capture nonlinear trends and interactions that are not easily accessible through simplified kinetic expressions [5, 6].

Multi-objective optimization methods are particularly relevant for processes such as DME synthesis, where improvement in CO conversion may come at the expense of DME selectivity and vice versa. Evolutionary algorithms such as NSGA-II are widely used to generate Pareto fronts representing trade-offs between competing objectives [7], while fuzzy decision-making methods enable the selection of a single compromise solution from these fronts. However, these approaches typically treat surrogate model predictions as deterministic and do not explicitly account for uncertainty [8]. Bayesian optimization [9] offers a complementary paradigm by combining probabilistic surrogate models with acquisition functions that guide the search toward promising regions of the design space while quantifying uncertainty [10, 11]. Although Bayesian optimization has been applied successfully in catalyst and reaction optimization, its performance relative to evolutionary multi-objective methods in the context of DME synthesis has not been systematically assessed.

Motivated by this gap, the present work compares two surrogate-based multi-objective optimization strategies: a fuzzy-enhanced NSGA-II algorithm and a constrained multi-objective Bayesian optimization approach, applied to the same machine learning model trained on literature data for DME synthesis. By focusing on methodological comparison rather than introducing new experimental results, this study aims to clarify how different optimization frameworks influence the identification of optimal solution and compromise operating conditions under limited data scenarios.

# METHODOLOGY

## Data Collection and Preprocessing

The dataset used in this study is compiled from published experimental literature on DME synthesis from synthesis gas (CO and $H_2$ mixture). It includes operating conditions and catalyst descriptors commonly reported across studies, such as reaction temperature, pressure, $H_2$/CO feed ratio, space velocity, catalyst composition, and preparation-related parameters. CO conversion and DME selectivity are selected as the output variables, as they directly reflect process performance and selectivity toward the desired product.

Prior to model development, the dataset is screened for outliers to reduce the influence of inconsistent or erroneous entries. Categorical variables describing catalyst type and preparation method are encoded numerically. Prior to analysis, all variables are normalized using min-max scaling, which linearly transforms each feature to the range [0, 1] based on its minimum and maximum values. This step mitigates scale differences and prevents features with larger magnitudes from dominating the analysis. Missing values are imputed using automated imputation procedures in JMP. Model training and validation are performed using k-fold cross-validation to ensure robust performance assessment given the limited dataset size.

To explore relationships between descriptors and performance indicators, Spearman correlation analysis is applied to identify monotonic trends. In parallel, principal component analysis (PCA) is used to examine the structure of the dataset and to assess how catalyst-related and operating condition-related variables contribute to overall variance.

## Machine Learning Surrogate Model

Several supervised ML algorithms, such as XGBoost, Gradient Boosting, CatBoost, Random Forest, and Support Vector Regression (SVR), are trained to predict CO conversion and DME selectivity from the input variables. Model performance is evaluated using standard regression metrics, including the coefficient of determination ($R^2$) and the root mean square error (RMSE). The model demonstrating the best balance between predictive accuracy and generalization capability is selected as the surrogate model for subsequent optimization.

## Fuzzy-Enhanced NSGA-II Multi-Objective Optimization

Multi-objective optimization is formulated with the goal of simultaneously maximizing CO conversion and DME selectivity. The NSGA-II evolutionary algorithm [12] is employed to generate a set of non-dominated solutions representing trade-offs between these objectives. Since NSGA-II is inherently a minimization algorithm, the negative values of the predicted objectives are minimized. This algorithm is implemented using the Pymoo library in Python [13].

To select a single compromise solution from the Pareto front, a fuzzy logic-based decision-making approach is applied [14]. This method integrates relative preferences between objectives into a unified metric, enabling the identification of a solution that best balances CO conversion and DME selectivity. The fuzzy-optimal solution is subsequently compared with experimentally reported data by identifying the closest real datapoint in terms of Euclidean distance in feature space.

## Multi-Objective Bayesian Optimization

A constrained multi-objective Bayesian optimization strategy based on the ParEGO framework [15, 16] is also applied. In this approach, the two objectives are combined into a scalarized objective function using predefined weights, and a Gaussian process model is trained to approximate this scalarized response. An Expected

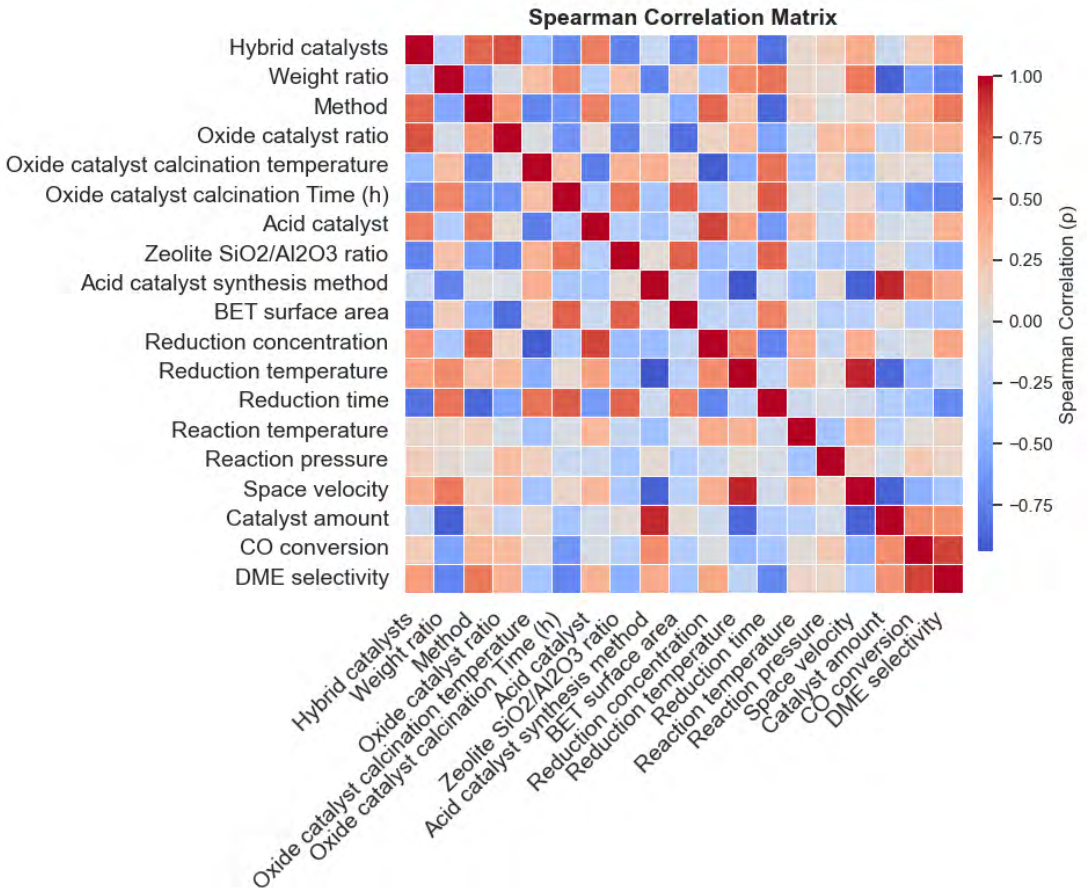

**Figure 1.** Spearman Correlation Analysis.

improvement acquisition function guides the selection of new candidate points while respecting process constraints [11, 17]. After completion of the optimization loop, the best compromise solution is identified based on the scalarized objective values. Presenting the optimized descriptors in their original physical units enables direct comparison with both experimental data and the fuzzy-enhanced NSGA-II results.

# RESULTS

## Data Preparation and Feature Analysis

The final dataset consists of 52 datapoints with 17 input features describing catalyst formulation, preparation, and operating conditions. Initial preprocessing ensures consistency across studies and prepares the data for ML analysis. After preprocessing, the data span CO conversions between 30 and 55%, and DME selectivity in the range of roughly 45-75%, reflecting the diversity of catalytic systems reported in the literature.

Spearman correlation analysis (Figure 1) provides an initial, quantitative indication of descriptor relevance. Catalyst-related, particularly synthesis method and zeolite $SiO_2/Al_2O_3$ ratio, show stronger monotonic correlations with DME selectivity, whereas operating variables such as space velocity exhibit higher correlation with CO conversion. However, several expected effects, such as the influence of temperature and pressure, are not fully captured, highlighting the importance of nonlinear modelling approaches.

PCA reveals further clarifies the structure of the dataset. As shown in Figure 2(a), the first four principal components account for approximately 90% of the total variance. The loading plot in Figure 2(b) indicates that the first two principal components are dominated by catalyst formulation and preparation descriptors, while PC3 and PC4 are more strongly associated with operating conditions such as reaction temperature, pressure, and space velocity. This separation quantitatively supports the need for modelling approaches capable of handling interactions between catalyst-related and operational variables.

## Surrogate Model Performance

Table 1 summarizes the predictive performance of the evaluated ML models. The reduction in $R^2$ and increase in RMSE from training to validation are attributed

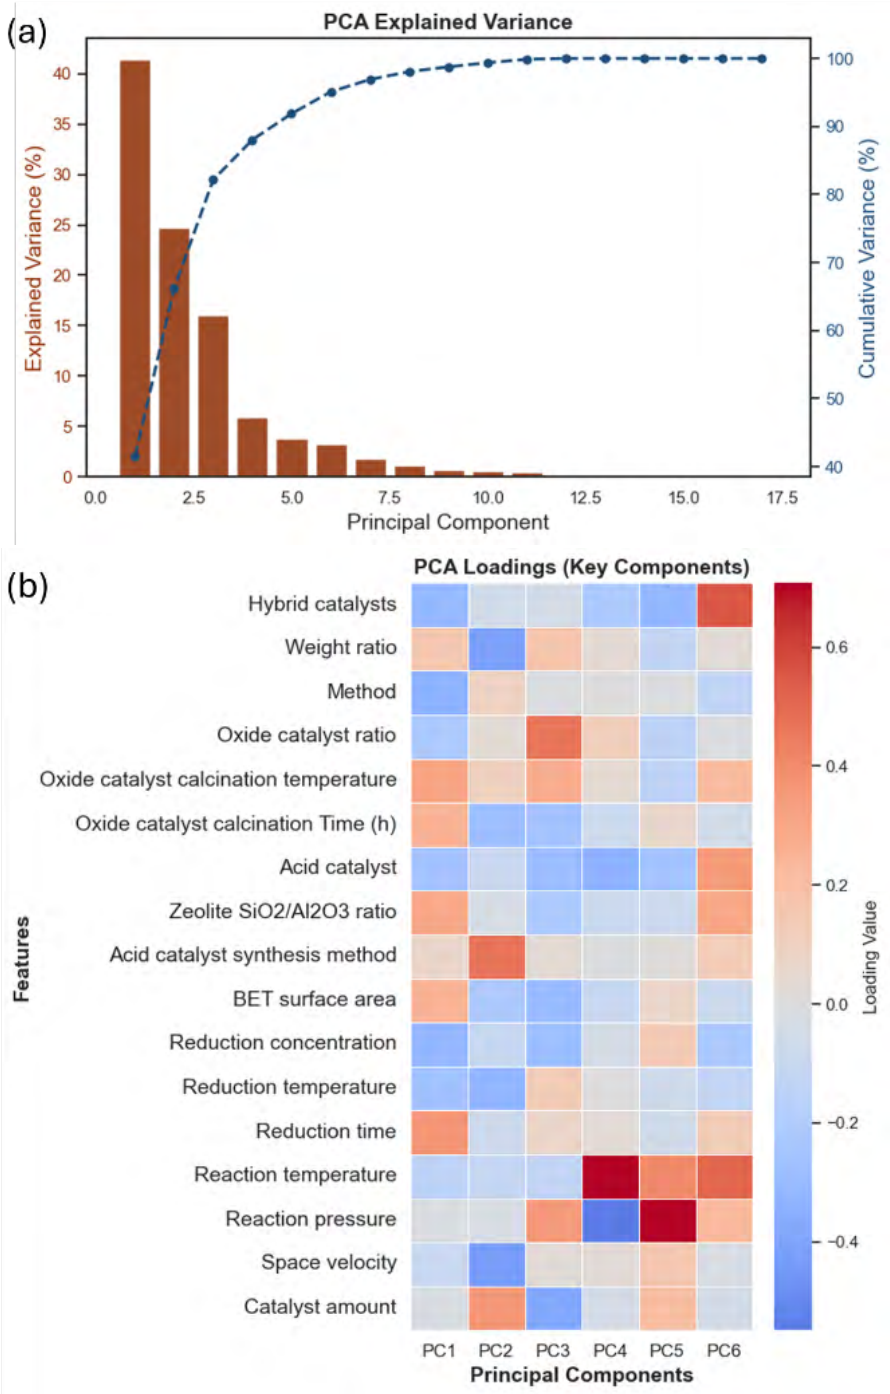

**Figure 2.** (a) Cumulative explained variance by PCA component, (b) PCA component loading.

to the generalization gap, indicating that models fit the training data more closely than unseen data, with some degree of overfitting. This effect can be reduced through improved hyperparameter tuning, regularization, and increasing dataset size.

While XGBoost and Gradient Boosting achieve similarly high training accuracy ($R^2$ of 0.99 for both CO conversion and DME selectivity), differences become apparent during validation. Gradient Boosting achieves $R^2$ of 0.83 for CO conversion and 0.89 for DME selectivity, with RMSE values of 0.01038 and 0.01258, respectively. In comparison, XGBoost shows lower generalization performance, particularly for CO conversion (validation $R^2$=0.74).

| | DME Selectivity | 0.98 | 0.00138 |
| Random Forest | CO Conversion | 0.96 | 0.00236 |
| | DME Selectivity | 0.85 | 0.01000 |
| SVR | CO Conversion | 0.83 | 0.01000 |
| | DME Selectivity | 0.91 | 0.01071 |
| **Validation** | | | |
| **Method** | **Parameter** | **$R^2$** | **RMSE** |
| XGBoost | CO Conversion | 0.74 | 0.01668 |
| | DME Selectivity | 0.82 | 0.01400 |
| Gradient Boosting | CO Conversion | 0.83 | 0.01038 |
| | DME Selectivity | 0.89 | 0.01258 |
| CatBoost | CO Conversion | 0.78 | 0.01332 |
| | DME Selectivity | 0.83 | 0.11604 |
| Random Forest | CO Conversion | 0.75 | 0.01547 |
| | DME Selectivity | 0.87 | 0.01360 |
| SVR | CO Conversion | 0.66 | 0.02115 |
| | DME Selectivity | 0.74 | 0.02619 |

These results indicate that Gradient Boosting provides the best balance between accuracy and generalization for the available dataset. Consequently, it is selected as the surrogate model for subsequent multi-objective optimization. The performance gap between training and validation metrics also reflects the limited size and heterogeneity of the literature-derived dataset, reinforcing importance of cautious interpretation of surrogate predictions.

## Fuzzy-Enhanced NSGA-II Optimization Results

Using the Gradient Boosting surrogate, the fuzzy-enhanced NSGA-II algorithm generates a Pareto front representing the trade-offs between CO conversion and DME selectivity. The fuzzy decision-making step identifies a single compromise solution, which is highlighted in Figure 3 alongside the experimentally reported datapoints. The selected fuzzy-optimal solutions correspond to a CZ/HZSM-5 catalyst prepared via a core-shell method, operated at a reaction temperature of approximately 261°C and a pressure of 37 bar. The surrogate predicts a CO conversion of about 53% and a DME selectivity close to 70%. As shown in Table 2, the closest experimental datapoint exhibits very similar performance values (CO conversion close to 51% and DME selectivity of approximately 70%), lending credibility to the optimized solution.

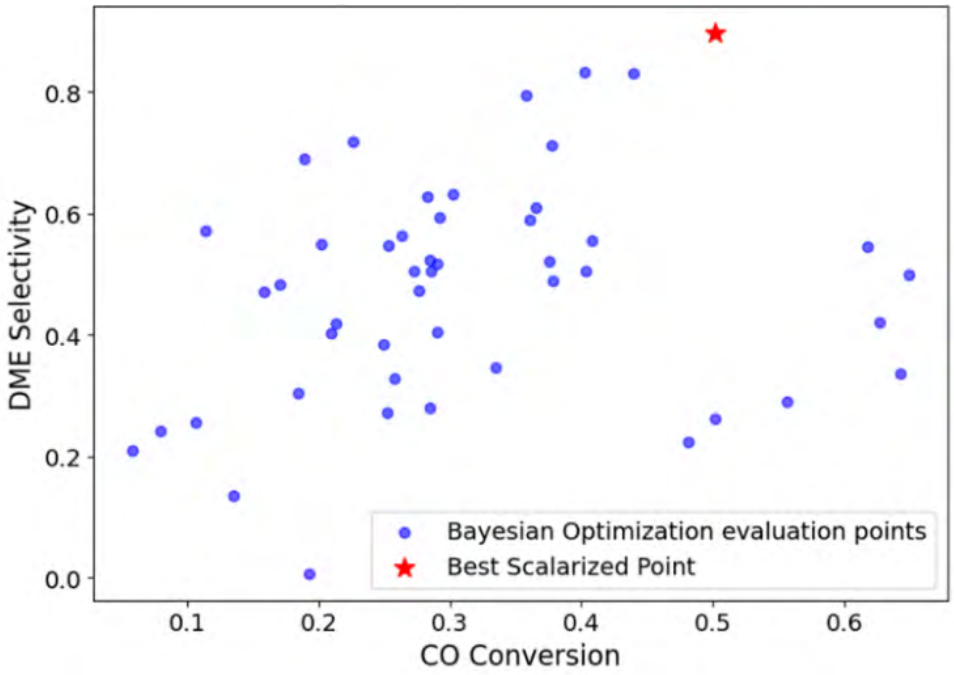

**Figure 4.** Constrained multi-objective Bayesian optimization.

**Table 2:** Feature comparison of the best solution and closest real data point.

| Feature | Best Fuzzy | Closest real point |
|---|---|---|
| Hybrid catalysts | CZ/HZSM-5 | |
| synthesis method | Core-shell | |
| Oxide catalyst ratio | 69:31:0 | |
| Oxide catalyst calcination temperature (°C) | 350.8 | 354.9 |
| Oxide catalyst calcination Time (h) | 4.0 | 67.7 |
| Zeolite SiO2/Al2O3ratio | 22.0 | |
| surface area(m2/g) | 60.4 | 67.0 |
| Reduction gas concentration (H2 %) | 90.0 | 100 |
| Reduction temperature (°C) | 270 | 270 |
| Reduction time (h) | 1.7 | 1.0 |
| Reaction temperature (°C) | 261 | 260 |
| Reaction pressure (bar) | 37 | 40 |
| Space velocity (h-1) | 14181 | 6000 |
| Catalyst amount (g) | 0.7 | 0.5 |
| CO conversion (%) | 53 | 51 |
| DME selectivity (%) | 70 | 70 |

A detailed comparison in Table 2 shows that catalyst formulation and preparation parameters are closely aligned between the fuzzy-optimal solution and the closest real datapoint. In contrast, differences are more pronounced in operating conditions, particularly space velocity and reaction pressure. These deviations suggest that the optimization framework primarily exploits operational flexibility to improve performance while remaining consistent with experimentally validated catalyst formulations.

## Bayesian Optimization Results

The constrained multi-objective Bayesian optimization results are illustrated in Figure 4, where each evaluated point represents a surrogate-predicted combination of CO conversion and DME selectivity. The best scalarized solution, indicated by the red star, reflects the optimal compromise according to the equal-weighted objective function.

As summarized in Table 3, Bayesian optimization also identifies CZ/HZSM-5 catalyst prepared by a core-shell method as optimal, confirming consistency with the evolutionary optimization results. However, the recommended operating conditions differ, with a lower reaction temperature (240°C) and a higher space velocity. The predicted performance at this point is close to 47% CO conversion and 65% DME selectivity, which is lower than the fuzzy-enhanced NSGA-II solution. The difference can be attributed to the scalarization and uncertainty-aware nature of Bayesian optimization, which tends to favour conservative solutions when model uncertainty is present. While this approach efficiently explores the design space, it may sacrifice peak performance in favour of robustness.

**Table 3:** Feature comparison of the best solution from multi-objective Bayesian optimization.

| Feature | Best Bayesian optimized point |
|---|---|
| Hybrid catalysts | CZ/HZSM-5 |
| synthesis method | Core-shell |
| Oxide catalyst ratio | 69:31:0 |
| Oxide catalyst calcination temperature (°C) | 360.00 |
| Oxide catalyst calcination Time (h) | 4.0 |
| Zeolite SiO2/Al2O3ratio | 27.0 |
| surface area(m2/g) | 151 |
| Reduction gas concentration (H2 %) | 24 |
| Reduction temperature (°C) | 261 |
| Reduction time (h) | 2.71 |
| Reaction temperature (°C) | 240 |
| Reaction pressure (bar) | 38 |
| Space velocity (h-1) | 11100 |
| Catalyst amount (g) | 0.9 |
| CO conversion (%) | 46.6 |
| DME selectivity (%) | 64.5 |

## Comparative Assessment

A direct comparison of results in Tables 2 and 3 show that both optimization strategies converge toward similar catalyst formulations, indicating that catalyst-related decisions are robust across optimization paradigms. In contrast, operating conditions vary more significantly between methods, leading to differences of up to 6-7 percentage points in predicted CO conversion and approximately 5-6 percentages points in DME selectivity.

This quantitative comparison highlights the central contribution of the present study: different surrogate-based multi-objective optimization strategies, when applied to the same dataset and predictive model, can lead to distinct yet plausible optimal operating conditions. Such differences are particularly relevant for decision-making under limited data availability, where the choice of optimization framework directly influences recommended process conditions.

# CONCLUSION

This study presents a surrogate-based multi-objective optimization framework for DME synthesis from syngas that integrates ML with two distinct optimization strategies. Gradient Boosting is identified as a reliable surrogate model capable of capturing nonlinear relationships within a limited experimental dataset. Both fuzzy-enhanced NSGA-II and multi-objective Bayesian optimization successfully identify feasible and competitive operating conditions. While the two approaches agree closely on catalyst formulations, they differ in their recommended operating conditions and predicted performance levels. These differences highlight the importance of selecting an optimization strategy that aligns with the desired balance between exploration, exploitation, and decision-making under uncertainty. These results demonstrate that comparative analysis of optimization paradigms applied to the same surrogate model and dataset provides valuable insight into the robustness and limitations of data-driven decision-support tools for complex catalytic processes such as DME synthesis. Future studies will include targeted experimental validation of the optimized conditions identified by both optimization strategies, with particular emphasis on assessing robustness under realistic process variability. Extending the framework to include additional objectives, such as catalyst stability, by-product formation, or energy efficiency, would enable a more comprehensive assessment of industrial relevance.

## ABSTRACT

Distributed deployment of process systems can benefit from modularity and shared components across multiple variants, reducing both manufacturing costs and engineering effort. Process family design formalizes this idea by simultaneously optimizing a family of process variants while determining a shared platform of common components. This results in a large-scale mixed-integer nonlinear program (MINLP) that couples nonlinear process models with discrete platform-allocation decisions. In this work, we solve the process family design MINLP using a progressive hedging (PH)-based decomposition strategy that exploits its block-angular structure. To improve convergence for this nonconvex problem, we introduce dynamic gradient-based penalty updates, a decoupled primal-dual strategy via separate PH runs, and parallel optimization-based bounds tightening of first-stage variables. Computational results on a water desalination case study demonstrate that the proposed approach improves solution quality and reduces computational time compared to baseline PH, while achieving a lower total cost of the process family than the previous discretization-based MILP formulation [1]. These results highlight the effectiveness of tailored decomposition strategies for large-scale process family design problems.

**Keywords**: Process Family Design, Mixed Integer Nonlinear Programming, Progressive Hedging

## INTRODUCTION

Increasing demand for energy and escalating resource depletion is going to require rapid and large-scale deployment of emerging process technologies. Existing process design methodologies are largely driven by economies of scale, with each process installation optimized independently to minimize capital and operating costs. While this paradigm is well suited for larger capacity single-site deployment, it becomes less effective for distributed deployment applications, where manufacturing standardization can play a significant role in reducing overall cost and engineering effort. In such contexts, modular design strategies that exploit standardization offer a promising alternative.

Process Family Design [1] has recently been proposed as a systematic optimization-based framework to support such modular design strategies while maintaining flexibility. Rather than optimizing a single instance of a process system, we optimize a family of process variants of a process system while promoting the use of shared components drawn from a common platform. A key feature of the optimization formulation is that the platform itself, i.e. the selection and sizing of shared components, is co-optimized with the individual process variants. This coupling enables trade-offs between individual process variant performance and the overall platform commonality to be explicitly captured within the optimization problem.

The resulting optimization problem is inherently a challenging large-scale mixed-integer nonlinear program (MINLP). Continuous nonlinear constraints arise from the process system model, e.g. process physics and cost correlations, while discrete decisions govern the platform assignment across the family of variants. The complexity arises not only from the nonlinearities within the individual variants but also from the coupling constraints that enforce platform commonality across the family. As the number of variants and potential platform components increases, the platform size grows rapidly, often rendering monolithic global optimization approaches intractable.

In prior work, Stinchfield et al [1] addressed the computational challenge of solving the complex MINLP by discretizing the design space of common modules on the platform. By pre-computing the feasibility of candidate designs and converting the problem into a mixed-integer linear program (MILP), the global optimum of the discretized space could be found efficiently. However, the discretization approach presents several limitations. First, it requires expensive pre-computation to evaluate the Cartesian product of all candidate platform designs across all variants, i.e. simulate each combinatoric instance of discretized candidate designs for each common module on the platform across each variant of the family. Second, the solution quality is limited by the resolution of the discretization of the design space; improving accuracy requires a finer grid, which reintroduces combinatorial explosion.

More recently, a decomposition strategy has been applied to the discretization-based process family design formulation. Stinchfield et al [2] leverage the block-angular structure arising from shared platform variables to decompose the MILP formulation and improve computational tractability. While this approach demonstrates the value of decomposition for large process family design problems, it remains dependent on discretization and the associated pre-computation. In this work, we address these limitations by formulating and solving the process family design problem directly as an MINLP. Building on prior decomposition ideas, we propose a decomposition strategy based on Progressive Hedging (PH) [3], a method used for stochastic programming but well-suited here due to the block-angular structure of the formulation. In contrast to applying PH to the discretization-based MILP, we apply PH directly to the original MINLP by relaxing the complicating platform consensus constraints and penalizing deviations. This enables full decomposition of the family of process variants into smaller subproblems that can be solved independently.

While PH is heuristic when applied to nonconvex problems [3], we demonstrate that a tailored algorithmic setup significantly improves convergence and solution quality. Specifically, we implement a dynamic penalty parameter $\rho$ update scheme that utilizes gradient information at each iteration to drive the variants towards a consensus platform design. This framework is implemented using the open-source package *mpi-sppy* [4], enabling parallel solution of the subproblems. We validate this approach on a desalination process family, comparing the computational performance and solution optimality against both off-the-shelf solvers and the previous MILP discretization method.

## BACKGROUND

Various product family design approaches have been extensively investigated across a wide range of industrial applications [4, 5]. In general, optimization approaches for nonlinear product family design have been focused on stochastic methods, e.g. genetic algorithms [7]. Although effective for yielding solutions to challenging problems in practice, there are no guarantees on the quality of solutions obtained.

Relatively few works have utilized mathematical programming techniques to the product family design problem. Khajavirad and Michalek [8] proposed an MINLP-based optimization approach for solving the nonlinear product family design problem, however they considered a fixed platform design. We are not aware of any contribution that directly addresses the MINLP formulation for simultaneous platform and family design.

To address the scalability limits of the process family design MINLP formulation, decomposition methods are required. The process family design problem exhibits a *block-angular* structure analogous to two-stage stochastic programming, where the variant-specific variables are independent ("second-stage"), and the platform-specific variables are coupled ("first-stage") and must be identical across the family ("non-anticipativity").

Progressive hedging (PH) [3] is a horizontal decomposition algorithm that is well-suited for this structure. By relaxing the coupling constraints and penalizing deviations from the group average, PH decomposes the problem into independent subproblems that can be solved in parallel. For a two-stage optimization, the PH algorithm can be stated as described in Algorithm 1.

**Algorithm 1**: Progressive hedging for two-stage stochastic programming

1 **Initialization**: Let $\nu \leftarrow 0$ and $w^{\nu} \leftarrow 0, \forall s \in \mathrm{S}$. Compute for each $s \in \mathrm{S}$

$$x^{(\nu+1)}(s) \in \operatorname{argmin}_x f_1(x) + f_2(y; \vec{x}(s))$$

where, $f_1(x)$ is the first-stage cost and $f_2(y; \vec{x}(s))$ is the second stage cost.

2 **Iteration Update**: $\nu \leftarrow \nu + 1$

3 **Aggregation**: $\bar{x}^{(\nu)} \leftarrow {\sum_{s\in S} \pi_s x^{(\nu)}(s)}/{\sum_{s\in S} \pi_s}$

4 **Price Update**: Compute for each $s \in \mathrm{S}$

$$w^{(\nu)}(s) \leftarrow w^{(\nu-1)} + \rho[x^{\nu}(s) - \bar{x}^{(\nu)}]$$

5 **Decomposition**: Compute for each $s \in \mathrm{S}$

$$x^{(\nu+1)}(s) \in \operatorname{argmin}_x f_1(x) + f_2\big(y; \vec{x}(s)\big) + w^{(\upsilon)}(s)^{\mathrm{T}} x + \frac{\rho}{2}\left\|x - \bar{x}^{(\nu)}\right\|^2$$

6 **Termination**: If a criterion is met, Stop. Otherwise go to step 2.

The PH algorithm is initialized by independently

solving all the subproblems. Each iteration of the algorithm begins with an aggregation step, in which the probability-based weighted primal mean $\bar{x}^{(\nu)}$ is computed, which provides an estimate of the optimal decision vector that satisfies the non-anticipativity constraints. The associated dual variables $w^{(\nu)}(s)$ act as Lagrange multipliers and are updated using the primal mean $\bar{x}^{(\nu)}$, the current values of the non-anticipative variables $x^{\nu}(s)$, and quadratic penalty parameter $\rho$. The algorithm subsequently decomposes by subproblem: each subproblem is resolved with its objective function augmented by the updated dual terms and a quadratic penalty term. Termination of the PH algorithm may be based on internal PH criteria, such as relative optimality gap or a specified tolerance on violations of non-anticipativity constraints.

However, while PH is guaranteed to converge for convex problems, it acts as a heuristic for non-convex MINLPs [3]. The efficiency of the PH algorithm convergence is strongly impacted by the choice of the penalty parameter $\rho$ [9]. In particular, the value of the penalty parameter $\rho$ influences both the primal decision variables and the updates of dual weights [10]. In the update of dual price $w^{(\nu)}(s)$ (Step 4), the step size based on deviation from the mean is scaled by $\rho$. As a result, $\rho$ directly controls the rate at which dual variables progress. In the following decomposition step, for each $s \in \mathrm{S}$, the algorithm minimizes an augmented objective, where the two terms of the augmented part ($w^{(\upsilon)}(s)^{\mathrm{T}}x + \frac{\rho}{2}\left\|x - \bar{x}^{(\nu)}\right\|^2$) exert competing influences during optimization: the dual term ($w^{(\upsilon)}(s)^{\mathrm{T}}x$) drives decision variables towards values favored by dual multipliers, and the quadratic term ($\frac{\rho}{2}\left\|x - \bar{x}^{(\nu)}\right\|^2$) promotes proximity to the mean decision vector. Consequently, varying the penalty parameter $\rho$ alters the trajectory of the primal variables and overall convergence of the algorithm. Larger values of $\rho$ amplify the contribution of the quadratic penalty, leading to aggressive updates to primal convergence, whereas smaller values of $\rho$ yield a smoother and gradual evolution of dual variables, which may be preferable in contexts such as lower bound computation.

Setting a standard static penalty parameter across first-stage variables often leads to slow convergence or cycling in non-convex applications. Watson and Woodruff [9] proposed a variable-specific heuristic for calculation of the penalty parameters for each variable based on their unit-cost, i.e. coefficient in the objective term. They further noted that per-iteration $\rho$ values may be more appropriate for some problems. Building on this work, Naepels and Woodruff [10] combined the heuristic with a gradient-based approach to calculate $\rho$ values and introduced a method to iteratively compute variable-dependent $\rho$ values based on a first-order condition, allowing updates as the algorithm proceeds.

In this work, we build upon these penalty parameter $\rho$ selection strategies within the PH framework. While prior approaches compute gradients only at the initial iteration under the assumption that the relevant objective terms are linear, and assume the availability of a feasible solution, either from an incumbent or starting point that must be specified by the user a priori in existing *mpi-sppy* implementations, we instead address nonlinear objectives by computing gradients at every iteration using the current primal iterates and then switching to incumbents as they are found. Moreover, motivated by challenges posed by the nonlinear nonconvex nature of the process family design MINLP, we extend these ideas by developing decoupled primal-dual penalty parameter $\rho$ strategies that address the interactions between primal and dual convergence, leading to improved overall PH convergence.

## PROBLEM SETUP

We consider the process family design problem as formalized by [1]. In this section, we explain how the process family design problem can be formulated as a nonlinear generalized disjunctive program (GDP) and subsequently transformed into a mixed integer nonlinear program (MINLP).

### Problem Description

The goal of process family design is to simultaneously design a large number of variants of a given process system that can be deployed across a wide range of installations. For example, deploying a carbon capture system at multiple industrial sites with varying flue gas sources. While the general flowsheet configuration of the carbon capture process system will remain the same at each site, the design requirements for each site (e.g. capture rate, flue gas concentration) can be different. Thus, every variant $v \in V$ will be designed to meet specific requirements; parameterized in $\boldsymbol{r}_v$.

A process system is defined by all the *unit module types* necessary to build an instance of the process; defined by $m \in M$. The unit module types could include absorber, heat exchanger, regenerator, etc. Each variant $v \in V$ requires exactly one of each unit module type $m \in M$. The *unit module type design* for each unit module type $m$ and each variant is defined by variable vector $\boldsymbol{d}_{v,m}$.

To exploit opportunities for shared components (and engineering design effort) we consider a platform of common unit modules that can be shared across the family of process variants. The unit module types $M$ are separated into *commonly design unit modules* (set $C$ included on the platform) and *uniquely designed unit modules* (set $U$), where sets $C$ and $U$ are disjoint ($C \cap U = \emptyset$) and their union gives the set $M$ ($C \cup U = M$). The common designs making up the platform $\mathcal{P}$ are indexed by label

$l \in L_c$ to capture different candidate designs for each common module type $c \in C$. The design specifications for these common unit modules on the platform are captured by $\hat{\boldsymbol{d}}_{c,l}$. All unique unit module types $u \in U$ are designed variant specific.

### Problem Formulation

The process system design of every single variant $v \in V$ with different set of design requirements $\boldsymbol{r}_v$ is governed by a set of nonlinear (in most applications) equations that describe the cost, physics, and performance of the process system. Our objective is to minimize the overall annualized cost of the process family while simultaneously determining (a) a platform with optimal designs of common unit module types for variants to choose from, (b) the distribution of these common unit module designs among the family of process variants, and (c) the variant-specific design variables for modules not in the platform and the optimal operating conditions for each of the variants.

Thus, the process family design problem can be formulated as a nonlinear generalized disjunctive program (GDP) that can be transformed into a mixed integer nonlinear program (MINLP):

$$\min_{p,i,y,d,\hat{d},o} \sum_{v \in V} w_v p_v \tag{1}$$

$$\text{s.t.} \quad p_v = f_v^p(\boldsymbol{r}_v, \boldsymbol{d}_v, \boldsymbol{o}_v) \;\; \forall\, v \in V \tag{2}$$

$$\boldsymbol{i}_v = f_v^i(\boldsymbol{r}_v, \boldsymbol{d}_v, \boldsymbol{o}_v) \;\; \forall\, v \in V \tag{3}$$

$$0 = h_v(\boldsymbol{r}_v, \boldsymbol{d}_v, \boldsymbol{o}_v) \;\; \forall\, v \in V \tag{4}$$

$$\bigvee_{l \in L_c} \begin{bmatrix} Y_{v,c,l} \\ \boldsymbol{d}_{v,c} = \hat{\boldsymbol{d}}_{c,l} \end{bmatrix} \;\; \forall\, v \in V, c \in C \tag{5}$$

$$\hat{\boldsymbol{d}}_{c,l-1} \le \hat{\boldsymbol{d}}_{c,l} \quad \forall\, c \in C, l \in L_c \backslash \{1\} \tag{6}$$

$$\boldsymbol{d}_v^L \le \boldsymbol{d}_v \le \boldsymbol{d}_v^U \quad \forall\, v \in V \tag{7}$$

$$\hat{\boldsymbol{d}}_{c,l}^L \le \hat{\boldsymbol{d}}_{c,l} \le \hat{\boldsymbol{d}}_{c,l}^U \quad \forall\, c \in C, l \in L_c \tag{8}$$

$$\boldsymbol{o}_v^L \le \boldsymbol{o}_v \le \boldsymbol{o}_v^U \quad \forall\, v \in V \tag{9}$$

$$\boldsymbol{i}_v^L \le \boldsymbol{i}_v \le \boldsymbol{i}_v^U \quad \forall\, v \in V \tag{10}$$

$$Y_{v,c,l} \in \{True, False\} \;\; \forall\, v \in V, c \in C, l \in L_c \tag{11}$$

The objective in (1) minimizes the weighted annualized cost aggregated over all variants $v \in V$. Constraints (2-4) embed, for each variant, the process model equations, including the cost ($p_v$), performance indicators ($\boldsymbol{i}_v$), and process system equations as functions of the design requirements $\boldsymbol{r}_v$, design variables $\boldsymbol{d}_v$ and operating variables $\boldsymbol{o}_v$. The formulation introduces commonality across variants through explicit logical constraints governing the selection of shared unit module designs. Constraint (5) employs disjunctions and associated Boolean variables $Y_{v,c,l}$ to assign common unit modules to variants by enforcing equality among the relevant design variables. Constraint (6) enforces a size-based ordering of the platform-level module designs as a symmetry-breaking constraint. Constraints (7 - 10) set bounds on the design variables $\boldsymbol{d}_v$, common designs $\hat{\boldsymbol{d}}_{c,l}$, operating variables $\boldsymbol{o}_v$., and performance indicators $\boldsymbol{i}_v$. Constraint (11) specifies the binary nature of the assignment variables.

## PROGRESSIVE HEDGING SETUP

### Problem Decomposition

Decomposition algorithms involve splitting a large problem into smaller problems and solving them iteratively until a convergence criteria is met. Stochastic programs inherently possess a block-angular structure that allows for the decomposition of a problem into smaller sub-problems. In this structure, first-stage variables link the subproblems through non-anticipativity constraints, while second-stage variables are specific to each subproblem.

Our problem can be represented with a similar block-angular structure, as shown in Figure 1. We decompose our problem into subproblems, each representing a smaller process family design problem, with the constraint that all subproblems share the same platform design. Therefore, our first-stage variables are continuous common unit module design variables in the platform ($\hat{\boldsymbol{d}}_{c,l}$) and the second-stage variables are all the local variables associated with each process family design subproblem ($p_v, \mathbf{i}_v, \mathbf{r}_v, \mathbf{d}_{v,m}, \mathbf{o}_v, \mathrm{Y}_{v,c,l}$).

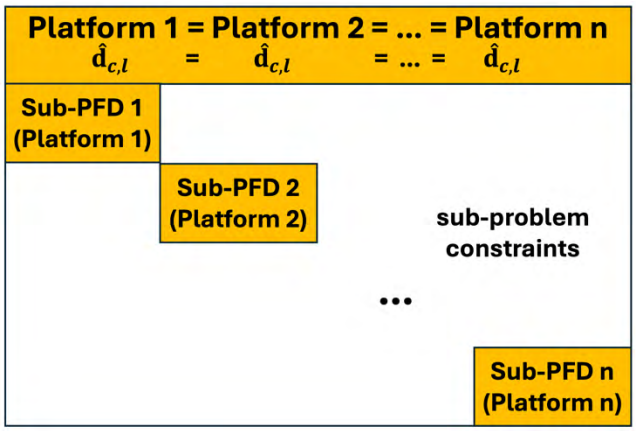

**Figure 1.** Block-angular structure of the process family design problem

### Dynamic Gradient-based $\rho$ Updates

The convergence of PH for non-convex MINLPs is highly sensitive to the penalty parameter $\rho$. A static global $\rho$ is often insufficient: values that are too small result in slower convergence and failure to enforce consensus, while values that are too large cause the algorithm to cycle or lock into suboptimal local minima. To address this, we implement a dynamic, variable-specific update

method based on the first-order optimality conditions, as proposed by Naepels and Woodruff [10]:

$$\rho^{\nu}(s) = {[c_D - w^{(\nu)}(s)]}/{[x^{(\nu)}(s) - \bar{x}^{(\nu)}]} \quad (12)$$

with $c_D = -\nabla f(\hat{x})$

However, the effectiveness of this update rule depends critically on the availability of accurate gradient information. Naepels and Woodruff [10] compute gradients only at the first iteration under the assumption of a linear objective, and thus the gradients remain constant throughout the PH iterations. In contrast, the process family design MINLP involves nonlinear terms in the objective, for which gradient information varies with iterations. Consequently, restricting gradient evaluation to the initial iteration can lead to inaccurate updates and degraded convergence behaviour. To address this limitation, we compute gradients dynamically at every PH iteration using the current primal iterates. Specifically, the gradient term $c_D$ in (12) is evaluated as $c_D = -\nabla f(x^{(\nu)})$, until a feasible incumbent solution becomes available. Once an incumbent is found, gradient evaluations are switched to the incumbent solution to stabilize updates and reduce oscillations in later iterations. This dynamic gradient evaluation enables penalty parameter $\rho$ to adapt to local curvature in the nonlinear objective, improving convergence and robustness of PH for non-convex MINLPs.

While dynamic gradient-based updates provide a well-motivated mechanism for adapting the penalty parameter $\rho$, it also introduces increased sensitivity to primal convergence. In practice, the non-anticipative variables $x^{\nu}(s)$ may rapidly approach their consensus values during early PH iterations, after which convergence slows. In such cases, the difference $|x^{\nu}(s) - \bar{x}^{(\nu)}|$ becomes very small, causing the update in (12) to produce disproportionately large values of $\rho$. Overly large values of $\rho$ are ineffective and can stall convergence in both primal and dual variables. To prevent this behaviour, Naepels and Woodruff [10] also provide explicit criteria to determine when $\rho$ should be updated based on measures of primal and dual convergence.

## Decoupled Primal-Dual Strategy

The dynamic gradient-based updates described above yields subproblem-dependent penalty parameters $\rho^{\nu}(s)$, which must be aggregated into a single subproblem-independent value to apply progressive hedging. Consequently, a rule is needed to reconcile the subproblem-specific values of $\rho^{\nu}(s)$ computed from (12).

Naepels and Woodruff [10] examine several aggregation strategies for subproblem-dependent penalty parameters, including minimum, average, and maximum values across subproblems. Consistent with preceding discussion, different aggregation rules place different emphasis on enforcing primal consensus versus stabilizing dual updates. Building on this observation, we adopt a decoupled primal-dual strategy by solving two progressive hedging procedures with distinct aggregation rules for the penalty parameter $\rho^{\nu}(s)$.

In the first PH procedure, the aggregation of the subproblem-dependent penalty parameters is chosen to promote primal consensus. Specifically, an average aggregation rule is applied,

$$\rho^{\nu}_{primal} = {\sum_{s\in S} \rho^{\nu}(s)}/{|S|} \quad (13)$$

which smooths subproblem-to-subproblem variability while maintaining sufficient penalty magnitude to enforce agreement among the nonanticipative variables. This configuration prioritizes convergence of primal decision variables.

In the second PH procedure, the aggregation rule is selected to favor stable dual behaviour. In this case the penalty parameter is defined using the minimum positive values across subproblems,

$$\rho^{\nu}_{dual} = \min\{\rho^{\nu}(s): \rho^{\nu}(s) > 0, s \in S\} \quad (14)$$

This choice limits the magnitude of the multiplier updates and mitigates oscillations in the dual variables, particularly in later iterations when subproblem solutions are near consensus.

The two PH procedures are executed independently, each using a single, subproblem-independent penalty parameter per iteration, as required by the progressive hedging framework. Together, these complementary strategies provide a practical mechanism for improving convergence behaviour in the presence of nonconvexities and discrete decisions. Although this approach does not alter the fundamental structure of the PH algorithm, it allows different aggregation strategies to be exploited. In the results presented later, this decoupled strategy is shown to improve convergence relative to a single PH configuration.

## Optimization-Based Bounds Tightening for First-Stage Variables

Bounds tightening is a critical refinement technique to strengthen relaxations and improve convergence used for solution of MINLPs [11]. Among the available approaches, optimization-based bounds tightening (OBBT) is particularly effective, albeit computationally expensive. In this work, we exploit the two-stage structure of the problem and the sensitivity of progressive hedging convergence to the bounds of the first-stage (nonanticipative) variables by applying OBBT exclusively to these variables as a pre-solve routine.

The OBBT procedure is applied to the first-stage variables independently for each subproblem. For a given first-stage variable, the lower and upper bounds are tightened by solving the auxiliary optimization problems

that minimize and maximize the variable subject to the subproblem constraints. These bound-tightening problems are solved in parallel across all subproblems, exploiting the same decomposition structure as the PH framework.

Following the solution of the OBBT subproblems, the resulting bounds are aggregated by selecting the tightest valid bounds across the subproblems. Specifically, for each first-stage variable, the updated lower bound is taken as the maximum of the subproblem-specific lower bounds, and the updated upper bound is taken as the minimum of the subproblem-specific upper bounds. This aggregation ensures that the tightened bounds remain feasible for all subproblems while reducing the feasible region of the shared variables.

The bound-tightening process is applied iteratively. After each round of OBBT, the aggregated bounds are updated, and the procedure is repeated until successive bound improvements fall below a specified tolerance. Once the updates become insignificant, the tightened bounds are fixed and used to start the PH algorithm.

By performing OBBT in parallel and restricting it to the first-stage variables, the additional computational overhead remains minimal, while accelerating convergence of PH.

## CASE STUDY

We now discuss the water desalination case study and the specific process family design problem we used to demonstrate our optimization approach. The water desalination process system model was developed under the PARETO framework [12].

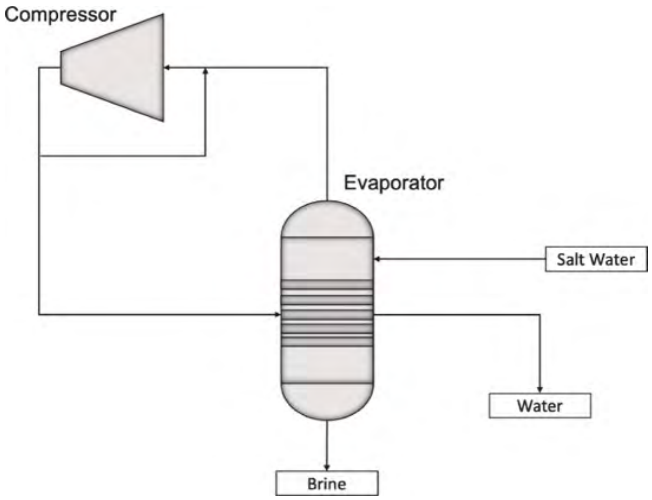

**Figure 2.** Water Desalination System

Around 60 million barrels of produced water per day is expected from oil and gas fracking across the United States by 2030, which will require treatment of produced water (i.e. desalination) at scale [12]. The salinity and flowrate of the produced water have high variability across wells in different geographical regions. One potential desalination technology is to first evaporate, and then mechanically recompress the vapor [13]. In our case study, we consider a desalination system with a single-effect evaporator and a single-stage adiabatic compressor as shown in Figure 2.

Building on the case study from previous work [1], we consider the process family design problem that accommodates a range of varying produced water feed conditions across the Midland, Texas area. Therefore, the set of process variants $v \in V$ is defined by different combinations of feed flowrates and feed salt concentrations. In this case study, we consider desired specifications of feed salt concentration between 20g/kg and 150g/kg and feed flowrate between 0.1 kg/s and 1 kg/s. Overall, a set of 76 process variants is considered for this process family design problem.

The compressor and the evaporator are the common unit module types to be designed in the platform, i.e. M = C = [compressor, evaporator], with design variables of compressor design flow (between 0.05 kg/s and 1 kg/s) and evaporator area (between 20 $m^2$ and 400 $m^2$).

## RESULTS & DISCUSSIONS

This section presents the results of the case study introduced in the preceding section by employing the decomposition approach and the algorithmic methodology described in the Progressive Hedging Setup section. The key findings derived from these results are subsequently discussed.

The process family was designed using the optimization formulation described in (1-11). The full process family design problem of 76 variants was decomposed into 19 smaller process family subproblems with 4 variants each. We consider a platform specification that allows 3 designs, i.e. $|L_c|$ = 3, for both the compressor and evaporator. The variants were ordered by size ($\boldsymbol{r}_v$) and bundled into subproblems.

Figure 3 describes which combinations of compressor and evaporator designs offered in the platform $\mathcal{P}$ are assigned to each variant $v \in V$. The x-axis corresponds to the feed flow rate that describes a particular variant $v$; the y-axis corresponds to the concentration of salt in the feed at variant $v$.

All the computational studies were performed on the TRACE HPC cluster at Carnegie Mellon University using a single node. The node has two 64-core AMD EPYC 7713 processors (2 GHz) and 2 TB RAM. To ensure consistency in our results, we limit Gurobi© to a maximum of 8 threads.

Table 1 compares the performance of three solution strategies for the water desalination case study: (1) progressive hedging with $\hat{x}$-based gradient penalty update

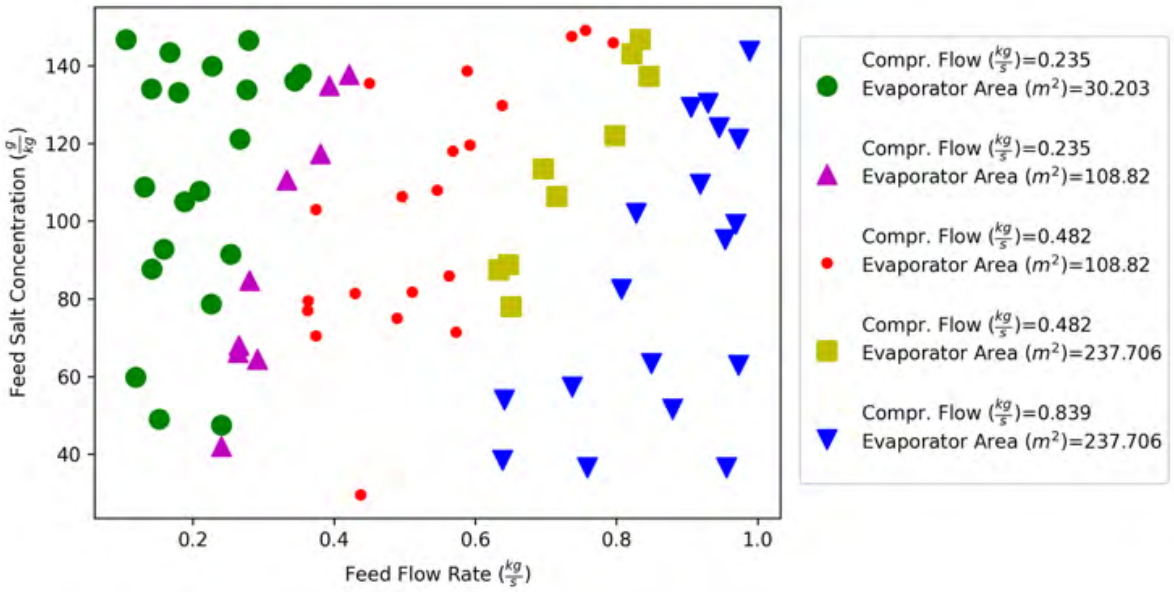

**Figure 3.** Water Desalination Process Family

following Naepels and Woodruff [10], (2) the proposed progressive hedging approach with dynamic $x^{(\nu)}$-based gradient penalty updates, optimization-based bounds tightening, and a decoupled primal-dual strategy, and (3) a direct MINLP solution using Gurobi© 13. For the progressive hedging-based approaches, the algorithm was run for 50 PH iterations.

**Table 1:** Comparison of different solution strategies on the water desalination case study.

| Solution Strategy | Incumbent Objective ($M) | Dual Bound ($M) | Solution Time (secs) |
|---|---|---|---|
| PH (Grad $\rho, \hat{x}$-based) [10] | 10, 131.93 8850.26 | 6754.36 7117.96 | 5372 4435 |
| PH (Grad $\rho$, OBBT, decoupled $x^{(\nu)}$-based) [This work] | | | |
| Gurobi© 13 MINLP | 9062.82 | 7744.95 | 7200 |

The baseline PH approach yields the highest incumbent objective value and the weakest dual bound, reflecting the limitations of $\hat{x}$-based gradient penalty updates in nonconvex settings. In contrast, the proposed PH configuration achieves a substantially lower incumbent objective value with reduced solution time, while also producing a stronger dual bound. The improvement in the dual bound is consistent with the intended effect of the decoupled primal-dual strategy, which stabilizes dual multiplier updates while maintaining effective progress in the primal iterates.

The direct MINLP approach using Gurobi© 13 produces a competitive incumbent solution with the imposed 7200 s time limit. However, the proposed PH method attains a better incumbent solution in a shorter computation time. The dual bound reported by Gurobi© 13 is included for context. Overall, the results indicate that the proposed PH-based approach provides an effective balance between primal solution quality, dual bound strength, and computational effort for large-scale process family design problems.

## CONCLUSION

This paper investigated the direct solution of process family design problems formulated as large-scale mixed-integer nonlinear programs using a progressive-hedging-based decomposition strategy. To improve the practical performance of progressive hedging for nonconvex MINLPs, dynamic gradient-based $\rho$ updates, a decoupled primal-dual strategy implemented through separate PH configurations, and optimization-based bounds tightening for first-stage variables were introduced. Computational results on a water desalination case study demonstrate that the proposed approach achieves improved primal solution quality, stronger dual bounds, and reduced computational time relative to a baseline progressive hedging implementation, while

achieving an approximately 2.5% reduction in total cost of process family compared to the discretized MILP formulation of Stinchfield et al [1].These results highlight the effectiveness of tailored decomposition strategies for large-scale structured nonconvex MINLPs that are challenging for off-the-shelf solvers. Future work will explore hybrid decomposition strategies that incorporate branching in the space of first-stage variables.

## ABSTRACT,

Machine learning (ML) reduces reliance on computationally expensive first-principles simulation while capturing complex nonlinear behaviors. However, poor extrapolation, overfitting, limited interpretability, and lack of strict consistency with governing laws limit the use of ML models in process applications. Current methods for learning optimization policies also struggle with constraint satisfaction and optimality guarantees. Approaches such as physics-informed neural networks (PINNs) incorporate constraints "softly" and do not ensure strict constraint enforcement—an issue that can be particularly detrimental in safety-critical applications, where even minor violations may lead to unsafe or infeasible decisions. To resolve these issues, we develop an ML framework with a differential projection layer that allows computationally efficient process modeling, parameter estimation, and nonlinear optimization with feasibility and optimality guarantees. The framework is general in a sense that, depending on the loss function and the projection layer, it provides different functionalities. For instance, an ANN followed by a distance minimization-based projection leads to a hybrid mechanistic/data-driven process simulator, KKT-HardNet, that ensures inference with strict satisfaction of linear/nonlinear equality/inequality constraints. An ANN with a gradient-based loss function and a Taylor approximation-based pointwise projection leads to DAE-HardNet, which solves and/or estimates parameters of ODE/PDE-based governing equations. Lastly, an ANN with a distance-minimization based projection followed by objective-based loss function leads to KKT-OptNet, which learns to solve nonlinear optimization problems for different parameter instances. We illustrate the use of these tools for the modeling, optimization, and parameter estimation of complex processes systems.

**Keywords**: AI/ML, Process Modeling, Process Optimization

## INTRODUCTION

Artificial intelligence and machine learning (AI/ML) have achieved remarkable success over the past decade, driven by advances in deep learning, large-scale optimization, and data-rich model training. Modern AI/ML systems now surpass human-level performance in perception, language understanding, and pattern recognition, and are increasingly deployed as computational engines for decision-making in scientific, societal, and technological settings. However, contemporary ML models are mostly designed as flexible function approximators, $y = f_\theta(x)$, without mechanisms to "strictly" enforce governing physical laws, conservation principles, or domain constraints. Physics-informed ML [1-2] incorporates these physical priors indirectly—through penalties and soft regularization—which often fail to guarantee feasibility, robustness, or resilience under distribution shift. As a result, even small violations can undermine reliability or lead to catastrophic failures in high-stakes applications such as autonomous nuclear reactors, chemical plants, molecular discovery, and next-generation autonomous cyber-physical infrastructures. These emerging domains require frameworks that are not only fast, but also provide guarantees of feasibility and optimality. Despite significant advances, a foundational gap remains between the dominant paradigm of unconstrained statistical learning and the realities of high-stakes, safety-critical, and resilience-demanding environments.

This disconnect presents a major barrier to the future of trustworthy and resilient computation. A central challenge in scientific machine learning (SciML) is to develop predictive models that are also scientifically reliable, interpretable, and physically valid under known domain knowledge. These requirements can be formalized through constraint sets $S =): h(x,y) = a, g(x,y) \leq b, x \in \Re^n, y \in \Re^m\}$, where $g(\bullet)$ represents inequality constraints, $h(\bullet)$ encodes equality constraints, and *a* and *b* encode multiparametric changing environments. A particular frontier of SciML, where feasibility and rigorous guarantees are essential, is learning to optimize—developing methods that enable the rapid, repeated solution of constrained, multiparametric nonlinear programs (mpNLP) arising in real-time decision environments. They appear in many applications in process systems engineering (PSE) including model predictive control, power grid operations, process safety surveillance, fault detection, and online energy management, all of which demand solutions under stringent constraints. In this work, we address the following questions:

- How can constraints—linear and nonlinear, differential and algebraic—be hard embedded into ANN architectures? What theoretical guarantees are possible for feasibility-aware generalization?
- How can we learn to optimize nonlinear problems with both feasibility and optimality guarantees?
- How can we design integrated learning and optimization frameworks in which constraints, feasibility, and optimality are strictly embedded rather than secondary penalties?

Addressing these requires new foundations that unify learning and optimization theory with algorithm design for the next-generation of trustworthy, reliable AI/ML applications in PSE, which is the core motivation of this work. The core of this is to establish constraint-embedded ML as a foundational paradigm for trustworthy scientific AI, in which feasibility, physical structure, and mathematical optimality are treated as first-class computational principles rather than soft regularization objectives. Enabling constrained learning that infers directly within the boundaries of admissible and physically meaningful solutions would enable "inverse modeling" through nonlinear parameter estimation and provide a compelling alternative to expensive first-principles by supporting amortized optimization, in which solution structure is learned across problem instances, enabling near-instantaneous inference.

## ML-AUGMENTED GENERAL FRAMEWORK FOR PROCESS MODELING, SIMULATION AND OPTIMIZATION

Our proposed constraint-embedded ML framework (see **Figure 1**) involves augmenting a standard neural network with a projection layer acting as a corrector. Given an input vector $x$, the network first computes an unconstrained output vector $\hat{y} = NN(\Theta, x)$, which may not satisfy the physical constraints. The projection layer then adjusts this output to produce a corrected prediction $\tilde{y}$ that lies exactly on the constraint manifold. Here, $\hat{y}$ denotes the unconstrained network prediction and the projection operator maps it onto the feasible set defined by the equality and inequality constraints, thereby ensuring feasibility by construction while enabling downstream guarantees on optimality. Unconstrained outputs are calculated using a standard neural net, while the constrained outputs correspond to the Karush–Kuhn–Tucker (KKT) conditions of a distance minimization problem. The projection layer enforces raw neural network output to lie on the constraint manifold.

Depending on the choice of the loss function and the choice of the projection layer, the framework shown in **Figure 1** reduces to perform different specific tasks related to process modeling, simulation, optimization and parameter estimation. This is summarized in **Table 1**, and discussed below in details.

## HYBRID MODELING

The framework presented in Figure 1 reduces to a foundational projection-based neural architecture that embeds and enforces hard nonlinear equality and inequality constraints within artifical neural networks (ANNs), ensuring predictions satisfy feasibility by construction. This establishes scalable algorithms for rigorous constraint satisfaction in hybrid data-driven/mechanistic process models for fast simulation purposes. In modeling for process simulation, the relationship between input variables $x$ and output variables $y$ is governed by mass and energy conservation laws, inter-variable dependencies, and physical limitations on the operation. These can often be expressed as linear/nonlinear equality or inequality constraints. Consider a dataset $\{(x_i, \bar{y}_i)\}_{i=1}^N$ representing the input–output behavior of a process system. The objective is to train a neural network that approximates the underlying functional mapping between the inputs $x$ and the outputs $y$. We consider that the mass and energy conservation equations and thermodynamic and kinetic models are also available in the form of algebraic constraints that relate the inputs $x$ and the outputs $y$. Formally, the goal is to learn $y = NN(\Theta, x)$ such that the predicted output $y$ always belongs to the feasible set *S*, i.e., $y \in S$, where *S* is defined as $S = \{y | h(x,y) = 0, g(x,y) \leq 0\}$. Specifically, $h(x,y) = 0$ represents a set of algebraic equality constraints, and $g(x,y) \leq 0$ represents another

**Table 1.** Setup for different tasks performed by the general framework presented in Figure 1.

| NN Loss function | Projection Layer | Specific Tool | Functionality |
|---|---|---|---|
| $\frac{1}{2N}\|\tilde{\boldsymbol{y}}_i - \bar{\boldsymbol{y}}_i\|^2$ | "Strictly" enforces nonlinear algebraic equality and inequality constraints: | **KKT-HardNet** | Hard-constrained ML, Hybrid Data-driven/Mechanistic Process Modeling, Process Simulation |
| $\frac{1}{2N}\|\tilde{\boldsymbol{y}}_i - \bar{\boldsymbol{y}}_i\|^2 + \frac{\omega}{M}\|\tilde{\boldsymbol{d}} - AD(\boldsymbol{\partial})\|^2$ | "Strictly" enforces pointwise gradient-based constraint satisfaction: | **DAE-HardNet** | Discovery of Governing Equation, Inverse Modeling, Parameter Estimation |
| min $f(\boldsymbol{x})$, or min $L(x)$, or min KKT residuals | Ensures constraint satisfaction through enforcing KKT system of the distance minimization | **KKT-OptNet** | Process Optimization, Nonlinear Multi-parametric Optimization |

set of algebraic inequality constraints. The functions $h$ and $g$ encode domain-specific knowledge, and may be nonlinear in both $x$ and $y$. Here, the tunable parameters (weights and biases) of an ANN are defined as $\Theta$.

The strict enforcement of constraints is achieved by solving a square system of nonlinear equations derived from the KKT conditions associated with the following constrained minimization problem (Eq. 1):

$$\begin{aligned} \tilde{y}^* = \arg\min_{y} \ & \tfrac{1}{2}\|y-\hat{y}\|^2 \\ \text{s.t. } & h_k(x,y) = 0, \quad \forall k \in \mathcal{N}_E, \\ & g_k(x,y) \le 0, \quad \forall k \in \mathcal{N}_I. \end{aligned} \tag{1}$$

This searches for a *minimum distance* solution from $\hat{y}$ that lies on the feasible region defined by the equality and inequality constraints (as illustrated in **Figure 1**).

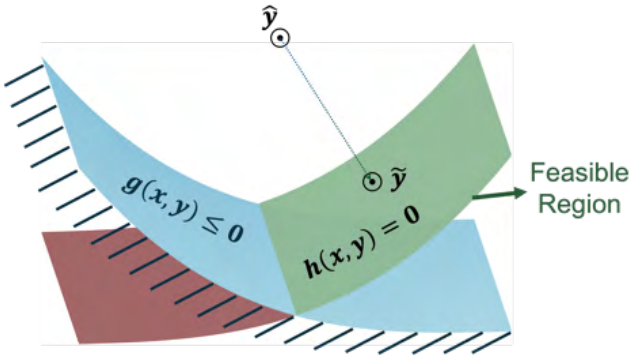

**Figure 1.** Projection of ANN output on the constraints manifold.

The optimal solution $\tilde{y}^*$ corresponds to a minimum distance projection of $\hat{y}$ onto the feasible region. We consider solving the system of nonlinear equations derived from the KKT conditions of (1) that yield a feasible projection $\tilde{y}$. For the special case of convexity, the KKT system is both necessary and sufficient to obtain the minimum distance solution $\tilde{y}^*$. This feasible projection can be directly embedded in the forward pass of a neural network architecture through a Newton-type iterative scheme, ensuring that only physically consistent predictions are used for loss computation and backpropagation. As a result, the loss function for the ANN is $\frac{1}{2N}\|\tilde{\boldsymbol{y}}_i - \bar{\boldsymbol{y}}_i\|^2$, in contrast to the conventional loss of $\frac{1}{2N}\|\hat{y}_i - \bar{\boldsymbol{y}}_i\|^2$. The overall implementation is refered to as KKT-HardNet [3].

The use of the projected outputs $\tilde{y}$ alters the learning directions during training, which is informed by the feasible manifold. This ultimately guides the model toward parameters that fit the data while respecting the known constraints. This approach is similar to that of Chen et el. [4] applied to linear equalities. However, we extend it to accommodate both nonlinear equality and inequality constraints. KKT-Hardnet is architecture-agnostic and can be integrated with any neural network backbone, including convolutional neural networks (CNNs) or recurrent neural networks (RNNs).

## Illustrative Example of Hybrid Modeling using KKT-HardNet:

We consider the example of an extractive distillation column [3]. The goal is to learn the input to output mapping while strictly satisfying the equations described by the system of nonlinear equation given in Eq (2).

$$
\begin{cases}
x_1 + x_2 - (y_1 + y_2) = 0, \\
x_1 a_0 - (y_1 y_3 + y_2 y_6) = 0, \\
x_1 a_1 - (y_1 y_4 + y_2 y_7) = 0, \\
y_3 + y_4 + y_5 - 1 = 0, \\
y_6 + y_7 + y_8 - 1 = 0, \\
x_3 y_1 - y_9 = 0.
\end{cases} \tag{2}
$$

Along with the input vector $x$, we consider two fixed value $a_0$ and $a_1$ that represents the feed composition to the column. For the forward modelling example we consider $a_0 = 0.6976$ and $a_1 = 0.3024$ while simulating the system.

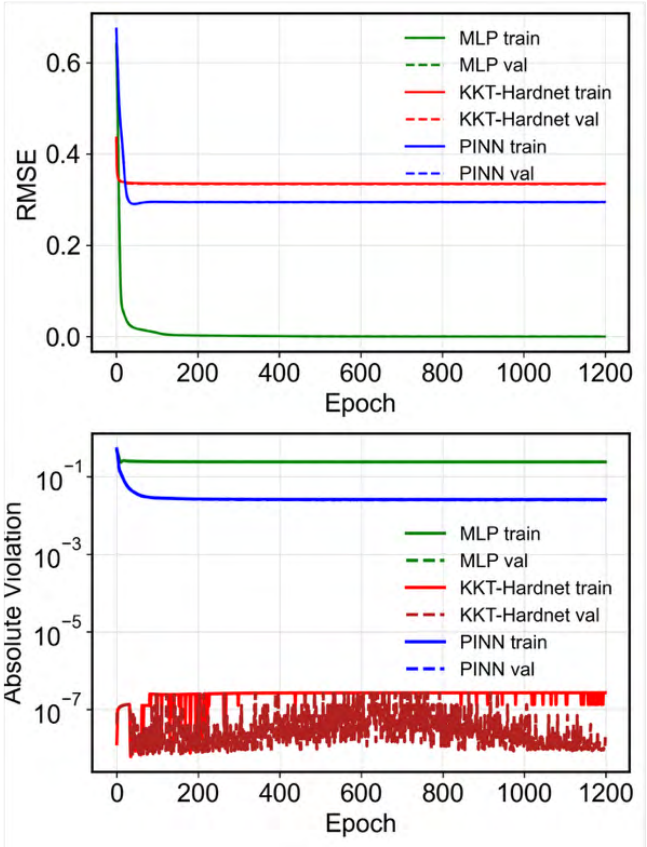

**Figure 2.** Learning curve for extractive distillation column. Top: mse loss between data and prediction, Bottom: absolute violation of the constraints, bottom: parameter evaluations during the training.

We compare the performance of KKT-HardNet with MLP and PINN, using identical backbone configuration and optimization settings (learning rate $10^{-4}$, 1200 epochs, Adam optimizer). PINN model considers the constraint violation as physics loss while training the system with a regularization fator $\lambda$ (10.0). Figure 2 shows the learning curves of three models. We observe no violation above $10^{-6}$ for KKT-HardNet iinferring that during training and validation the model outputs satisfies the physical constraints imposed on the model. The small oscillations below $10^{-6}$ arise because, in some forward passes, the Gauss–Newton iteration terminates with the residual norm dropping well below the stopping criterion of $10^{-6}$. In those cases, the final residual may lie anywhere between the tolerance ($10^{-6}$) and the numerical precision limit. Thus, the fluctuations reflect solver termination under finite precision.

## LEARNING PROCESS OPTIMIZATION

The framwork shown in Figure 1 reduces to an ML-based solver for multi-parametric constrained nonlinear programs with fast inference, stability and rigorous convergence with both feasibility and optimality guarantees. In this case, we consider convex multiparametric nonllinear programs (mpNLPs) of the form: $\min f(x)$ s.t. $x \in \mathcal{C}$ where $\mathcal{C} = \{x \mid h(x) = a, g(x) \leq b, x \in \mathbb{R}^n\}$. We are interested in convex mpNLP, when $f: \mathbb{R}^n \to \mathbb{R}$ is convex $C^2$ and continuously differentiable, $g: \mathbb{R}^n \to \mathbb{R}^p$ is convex $C^1$, and $h: \mathbb{R}^n \to \mathbb{R}^q$ is affine. Convexity ensures the optimal solution during the projection from the first order neccesary conditions only.

Similar to previous, the framework consists of a neural network backbone with a projection to the feasible space trained on a new loss function. The loss function we used is the actual objective function of the optimization problem. However, the model can be trained on different loss functions such as the lagrangian or the KKT residuals. Unlike KKT-HardNet, learning optimization problem is trained in an unsupervised framework.

### Illustrative Example of Nonlinear Optimization using KKT-OptNet:

For illustrative purpose, we take the classic transportation problem with parametric uncertainty. The problem is defined as follows:

$$
\begin{aligned}
\min_{y} \quad & \frac{1}{2} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix}^T \begin{bmatrix} 306 & 0 & 0 & 0 \\ 0 & 324 & 0 & 0 \\ 0 & 0 & 324 & 0 \\ 0 & 0 & 0 & 252 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} + \begin{bmatrix} 25 \\ 25 \\ 25 \\ 25 \end{bmatrix}^T \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} \\
\text{s.t.} \quad & \begin{bmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ -1 & 0 & -1 & 0 \\ 0 & -1 & 0 & -1 \\ -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} \leq \begin{bmatrix} 350 \\ 600 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ -1 & 0 \\ 0 & -1 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}.
\end{aligned} \tag{3}
$$

Here, we train the model for uncertainty bounds $0 \leq x_1, x_2 \leq 200$. For modeling efficiency we have normalized the optimization variables and the problem constraints. Additionally we solve the QP problem for 1000 parameter combinations sampled form the parameter bounds to

general optimal variable set data to validate our results.

**Figure 3.** shows the KKT-OptNet model performance for minimizing the objective loss function as neural network loss function parameterized by the weights and biases. Top figure shows that the model finds the optimal objective loss function with very few iterations of training. Additionally the bottom plot shows the optimality gap between the optimal solution obtained from the solver. We observe mean optimality gap of $0.0051\%$ which shows that through neural network training the model is learning a optimal mapping from the parameter space to the variable space close to the optimal solution.

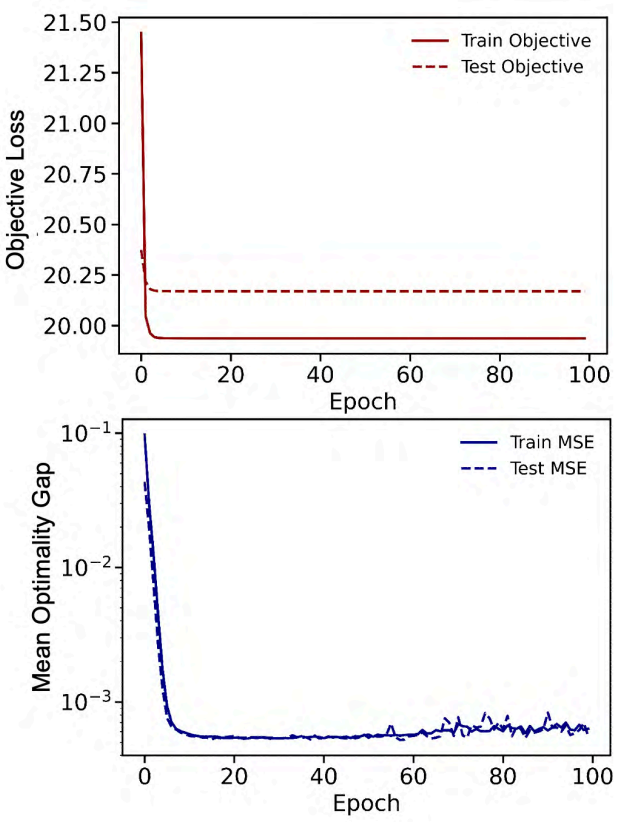

**Figure 3.** Learning curve for optimization learning of transportation optimization problem. Top: Objective Loss propagation through epochs during neural network training, Bottom: Mean optimality gap between predicted variables and solution obtained from solvers during training.

## PARAMETER ESTIMATION

The projection based constraint satisfaction method can also be used as a tool for parameter estimation for nonlinear system. While we have discussed the scope of surrogate modeling with constraint satisfaction and learning optimization problems, some constraints might have some fixed value parameters which are unknown. Traditional parameter estimation technique involves solving a rigorous optimization problem by minimizing the prediction error. However, KKT-HardNet or DAE-HardNet is capable of doing the same with minimal changes. The unknown parameters can be introduced in the framework as learning parameters of the neural network. These parameters are optimized as the training progresses. Along with model fitting, the desired parameters are obtained that satisfied the constraints.

Parameter estimation can be challenging for system of differential equations. We illustrate how a Taylor approximation based pointwise projection can be implied to model dynamic systems and estimate unknown parameters through DAE-HardNet [6].

### Illustrative Example of Parameter Estimation:

We consider a discrete-time linear time-invariant system defined by the state equation: $x_{\{k+1\}} = A_d x_k + B_d u_k$, where $x_k \in R^2$ is the state vector and $u_k \in \mathbb{R}$ is the control input.

The system matrices are parameterized as $A_d = [[1\ 1], [0\ a_1]]$ and $B_d = [0, a_0]^T$. The parameter $a_1$ represents the persistence or decay factor of the second state, governing how strongly $x_{k,2}$ propagates forward in time. The parameter $a_0$ represents the input gain and determines how strongly the control input influences the second state. Thus, $a_1$ controls intrinsic system dynamics while $a_0$ controls actuator effectiveness. For this case study we have simulated the data considering $a_0 = -1$ and $a_1 = -1$.

Given a prediction horizon N, the finite-horizon MPC problem is formulated as: minimize over $\{x_k, u_k\}$ the sum from $k = 0$ to $N-1$ of $(x_k^T Q\, x_k + u_k^T R\, u_k)$, subject to $x_{\{k+1\}} = A_d x_k + B_d u_k$, with state constraints $-\bar{x} \le x_k \le \bar{x}$ and input constraints $-\bar{u} \le u_k \le \bar{u}$.

Stacking all predicted states and inputs into a decision vector $y = [x_1, \dots, x_N, u_0, \dots, u_{\{N-1\}}]^T$, the MPC problem can be written in quadratic program form as: minimize $\left(\frac{1}{2}\right) y^T Q y + c^T y$ subject to $Ay = b + Bx_0$ and $Cy \le d$. The matrix $A$ encodes stacked system dynamics, $B$ propagates the initial condition, $C$ represents box constraints, $d$ defines bounds, and $Q$ and $c$ arise from quadratic stage costs.

In the inverse parameter estimation setting, the physical parameters $\theta = (a_0, a_1)$ are treated as unknown. Given observed trajectories $\{x_k^{data}, u_k^{data}\}$, we estimate parameters by minimizing the discrepancy between predicted and observed optimal trajectories: $\min_{a_0,a_1} \Sigma_i \left\| y\left(x_0^{(i)}; a_o, a_1\right) - y_{(i)}^{data} \right\|^2$, where $y^*(\cdot)$ denotes the solution of the MPC quadratic program.

The parameters influence feasibility through the dynamics constraints, the optimal trajectory shape, the control effort, and state propagation. Gradients $\partial y^*/\partial a_0$ and $\partial y^*/\partial a_1$ can be computed by embedding the QP

solver as a differentiable layer, enabling gradient-based learning. Figure 4 shows the parameter evaluations during the training. Table 2 includes the training results.

**Table 2.** Validation performance on the parameter estimation problem.

| | PINN | KKT-HN | KKT-HN + PINN |
|---|---|---|---|
| MSE | $1.49 \times 10^{-1}$ | $8.92 \times 10^{-6}$ | $2.43 \times 10^{-5}$ |
| Equality violation | $4.7 \times 10^{-3}$ | $3.1 \times 10^{-3}$ | $3.76 \times 10^{-5}$ |
| Inequality violation | $1.3 \times 10^{-3}$ | $1.5 \times 10^{-4}$ | $1.8 \times 10^{-6}$ |

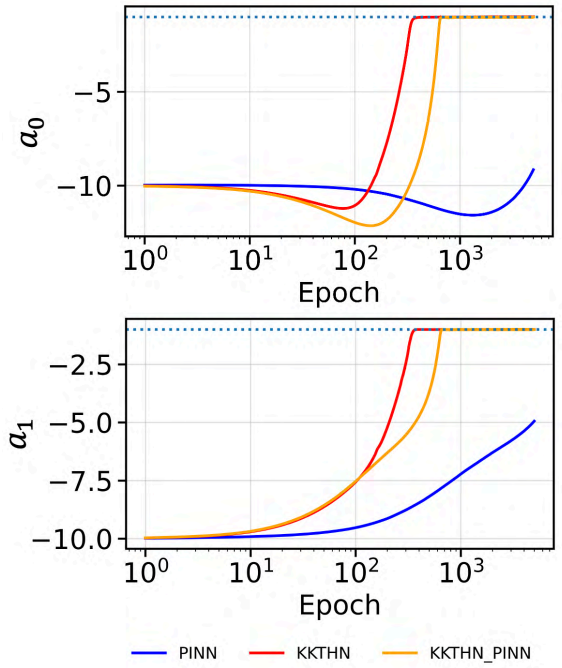

**Figure 4.** Learning curve for extractive distillation column. Top: mse loss between data and prediction, Bottom: absolute violation of the constraints, bottom: parameter evaluations during the training.

Figure 4 shows the parameter values through the training epochs for PINN, KKT-HardNet and KKT-HardNet augmented with PINN soft loss. We train all three models for 5000 epochs with standard hyperparameter settings. From the figure we observe that PINN even with 5000 epochs of training does not converge to the original value of the parameters. Both KKT-HardNet and KKT-HardNet augmented with soft loss converges to the original parameter values after training of only 500 epochs. Additionally Table 2 shows the loss values and constraint violation of all three models. PINN even though it achieves a constraint violation on the similar order as KKT-HardNet, the regression performance of PINN is five orders of magnitude higher than KKT-HardNet. Additionally, KKT-HardNet augmented with PINN loss shows more robust modeling performance with lower constraint violation compared to KKT-HardNet for this case study. Note that we have initialized the parameter values from $-10$. We observe that the KKT-HardNet converges to the actual parameter values for wide range of negative value.

## CONCLUSIONS

We have presented a projection-based neural network architechture which guarantees strict feasibility of nonlinear equality and inequality constraints. The projection is based on the first order optimality conditions of a distance minimization problem. The differentiable projection layer is iteratively solved through Gauss-Newton method. This projection layer works as a corrector for the unconstrained prediction and keeps the prediction in the feasible domain. The framework can be used as a tool for robust surrogate modeling, parameter estimation and process optimization. The projection layer can act in different forms, for example, a taylor series approximation can be implemented to satisfy dynamic systems. This allows us to estimate parameters on the dynamic domain also. We provide several illustrative examples to show the applicability of our framework in chemical processes and optimization. Additionaly we observe that combining soft PINN loss with the projection layer helps achieving lower constraint violation and higher prediction performance. Moreover, it helps estimating unknown parameters. A future direction for extending this framework is to improve the computational complexity of the model with minimal iterative scheme.

## ABSTRACT

In this work, the synthesis, design and optimization of a quaternary double dividing wall distillation column (QDDWC) is presented. The effect of the feed composition over the performance of this intensified configuration is studied. The synthesis and design of the QDDWC takes place using as basis a conventional direct sequence for the separation of a n-butane/n-pentane/n-hexane/n-heptane mixture. The column is tested for three molar feed compositions: 40/10/10/40, 25/25/25/25, and 10/40/40/10. The configurations are optimized through a multiobjective genetic algorithm to simultaneously minimize the total heat duty and the number of stages. According to the results, the proposed structure allows savings in heat duty up to 59% but requiring up to 28% more stages than the conventional sequences.

**Keywords**: dividing wall columns, quaternary mixture, metaheuristic optimization

## INTRODUCTION

Worldwide, over 90% of fluid mixtures in industrial processes are separated into different fractions or into pure components through distillation. This operation takes advantage of the differences on boiling points among the components of a given mixture using heat as separating agent. In industrial practice, this unit operation commonly takes place in distillation columns, which are devices with internals as trays or packing, whose task is to promote the contact among the phases to allow the mass and heat transfer. External heating is provided through a reboiler. Unfortunately, distillation has low thermodynamic efficiency, due to the input of high-quality energy in the reboiler which is later removed at low temperature in the condenser [1]. This implies high energy requirements, utilities costs and environmental impact.

To overcome the drawbacks of distillation in terms of its energy requirements, diverse alternatives have been developed. Among these alternatives, the thermally coupled configurations, the internally heat-integrated systems, and the cyclic distillation can be mentioned. One of the most well-known intensified distillation schemes, that has been implemented in industrial practice, is the dividing wall column (DWC). For ternary mixtures, the use of DWCs may lead to energy savings up to 40% in comparison to conventional distillation sequences [2]. In the case of quaternary mixtures, the potential in energy savings and controllability of dividing-wall distillation systems has been reported [3, 4]. In a recent study, a double dividing wall configuration has been proposed, exhibiting energy savings around 14% in comparison with a conventional direct sequence [5]. However, such study analyses the performance of the system only for a single feed composition. Indeed, it is well known that the potential for reducing energy requirements of such intensified schemes depends on the feed composition. Thus, it is mandatory to evaluate the performance of the proposed configuration for a variety of feed compositions, which is the objective of the present research.

## CASE STUDY

The purification of a mixture composed by n-butane (A), n-pentane (B), n-hexane (C) and n-heptane (D) is studied in this work. A recovery of 99% is defined as target for all the components, for all the studied configurations. The separation of the mixture will take place in a conventional direct sequence (CDS) and a double-dividing wall configuration (QDDWC). A feed flowrate of 100 kmol/h is assumed, entering the distillation schemes as saturated liquid. Three feed compositions are analyzed: 40/10/10/40, 25/25/25/25, and 10/40/40/10. The first one represents a case where the middle components have a high presence in the mixture, the second case is an equimolar mixture; finally, the third case implies that the middle components have the highest contribution to the total composition.

## METHODOLOGY

The synthesis of the QDDWC takes as basis a conventional direct sequence (CDS), as shown in Figure 1. The CDS has three columns, where A and B are obtained as distillate in the first and second column, respectively, while the third column produced pure C and D. Each column is divided in sections, as presented in Figure 1.a, where sections I, III and V correspond to the rectifying zone of each column, while sections II, IV and VI represent the stripping zones. By rearrangement of the sections, the intensified configuration shown in Figure 1.b is obtained, where a single reboiler is required [6].

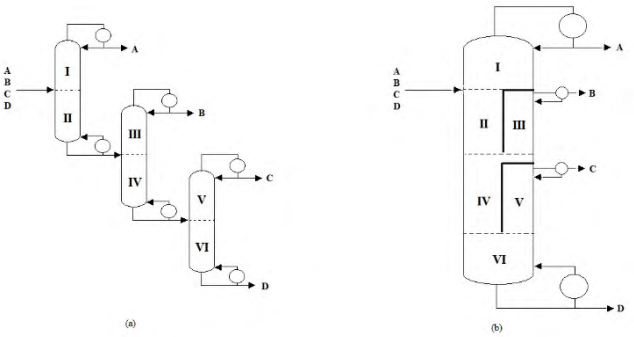

**Figure 1:** Stage rearrangement for the synthesis of the intensified distillation system (a) conventional direct sequence, (b) quaternary double dividing wall column

Conventional and intensified configurations are both simulated in the commercial process simulator Aspen Plus. To represent the phase equilibrium, the Chao-Seader model is employed, since it is recommended for hydrocarbon systems [7]. To simulate the CDS, the operating pressure is first estimated through bubble point calculations, assuming that the temperature on each condenser is approximately 49 °C; this ensure that cooling water can be used as utility on that equipment. Once the pressure has been determined, the number of stages and the feed stage are estimated through the Fenske-Winn-Underwood approach given by the DSTWU module, assuming that R = 1.33$R_{min}$ and aiming to obtain recoveries of 99% for each component. A pressure drop of 0.689 bar is assumed for all the conventional columns. All these calculations are performed for each of the studied feed compositions. Once the preliminary configuration of each column is obtained, the conventional sequences are rigorously simulated through the RadFrac module, which solves the MESH equations to obtain detailed information about the profiles on each column. The purities for each product are estimated from the mass balances, using the desired recovery. These purities are fixed by using design specifications, employing the reflux ratio as manipulated variable for the products obtained as distillate, and the reboiler duty for those products obtained as residues.

Once the design for the conventional sequences has been obtained, the structure of the intensified columns is generated by rearranging the sections of the CDSs. Since there is not a module to represent dividing wall systems in the simulator, the equivalent structure shown in Figure 2 is used. The split fraction for both splitters is adjusted until convergence is obtained, and the purities of the components are fixed by using design specifications.

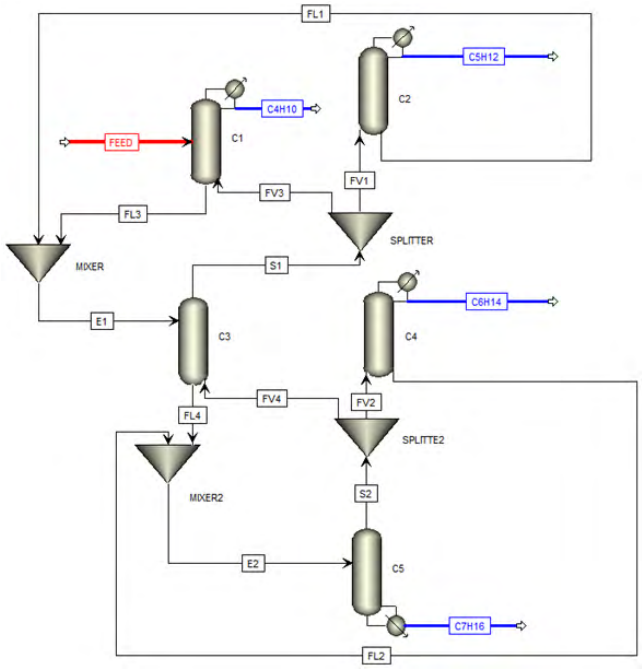

**Figure 2.** Representation of the QDDWC equivalence in the simulation environment.

Using the preliminary designs previously described as initial guesses, the optimization of the intensified schemes is performed through the NSGA-II metaheuristic. First, a dataset of decision-variable values (manipulated variables) is generated in a main MATLAB routine, using NSGA-II. Subsequently, these decision-variable

vectors are transferred to a MATLAB subroutine, which serves as a link between the software and where the data are received and forwarded to Aspen Plus. For each individual, Aspen Plus solves the rigorous mass and energy balances. When convergence is not achieved, a penalty value is assigned to the corresponding solution; otherwise, the simulation results are returned to the MATLAB subroutine interface. At this stage, process constraints are evaluated, and the objective-function values are computed and sent back to the MATLAB main routine. Once the objective functions are received, the genetic algorithm proceeds to the next generation. After completing the prescribed number of iterations, the Pareto front is obtained and plotted.

Figure 3 presents the implemented optimization workflow, including the information exchange between the decision variables and the corresponding response variables.

The NSGA-II parameters are set as follows: number of generations = 50, population size = 300, crossover fraction = 0.8, elite count = 15, and mutation rate = 0.01.

The optimization model simultaneously minimizes (i) the total number of stages in the column (Eq. 1) and (ii) the reboiler duty (Eq. 2). Process feasibility is ensured by imposing recovery constraints of nearly 99% for each component (Eqs. 3 and 4). As expressed in Eq. 1, the total number of stages is defined as a function of the stage allocation in Columns 1, 3, and 5 of the intensified configuration. Furthermore, Eq. 2 indicates that the reboiler duty is influenced by the total stage number, distillate flowrates, boil-up ratio, internal molar flowrates, and feed stage locations.

Minimize:

$$OF_1: TS = S_{C1} + S_{C3} + S_{C5} \tag{1}$$

$$OF_2: Q = f(D_{C1}, D_{C2}, D_{C4}, B_{C5}, FV_1, FV_2, S_{C1}, S_{C3}, S_{C5}, FS) \tag{2}$$

*s.t.*

$$0.988 \leq R_i \leq 0.9903 \tag{3}$$

$$R_i = \frac{\dot{n}_{i(o)}}{\dot{n}_{i(f)}} \tag{4}$$

Here, $OF_1$ = objective function 1, $OF_2$ = objective function 2, TS = total number of stages in the dividing wall column, $SC_1$= stages on column 1, $SC_3$= stages on column 3, $SC_5$= stages on column 5, Q = reboiler duty, $DC_1$= distillate rate in column 1, $DC_2$= distillate rate in column 2, $DC_4$= distillate rate in column 4, $B_{C5}$= boil-up ratio in column 5, $FV_1$= vapor molar flow from column 3 to column 2, $FV_2$= vapor molar flow from column 5 to column 4, FS= feed stage, R= molar recovery, $\dot{n}$= molar flow. Subscripts: i= molecular specie (butane, pentane, hexane, heptane), (o)= output stream for specie i, and (f)= feed stream for specie i.

Once the optimal points for each concentration level are selected, comparisons are carried out among the optimized solutions, against their corresponding base-case designs (i.e., the same configurations prior to the optimization algorithm), and with the conventional separation schemes.

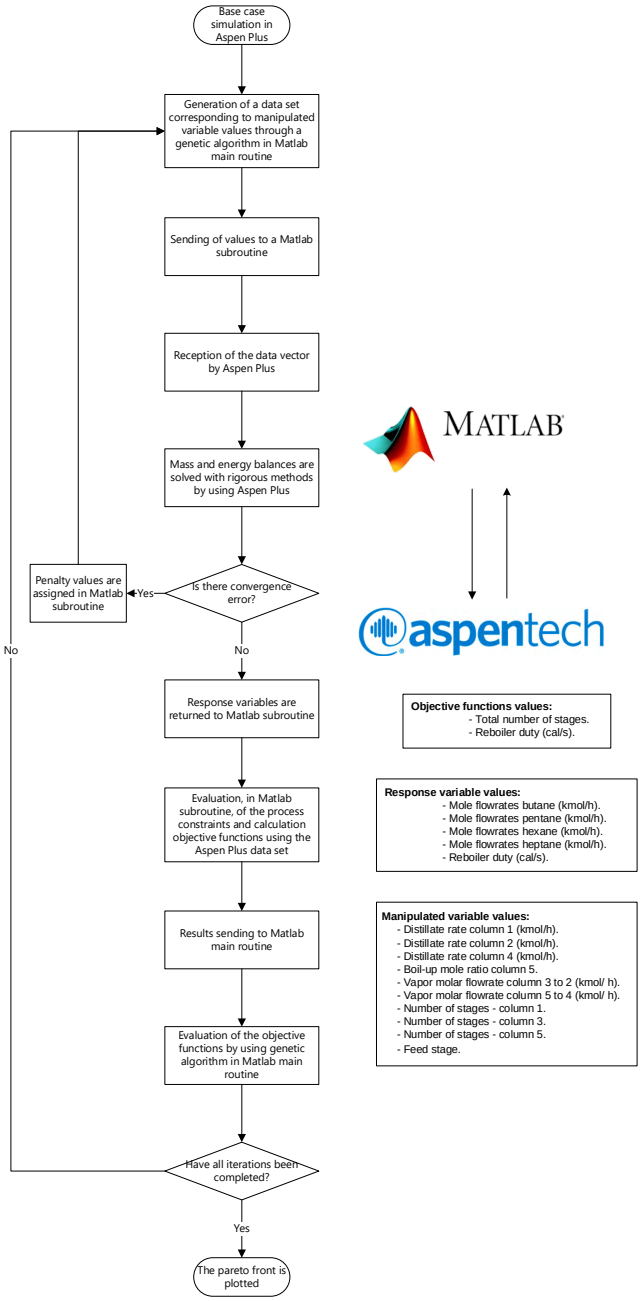

**Figure 3:** Optimization algorithm

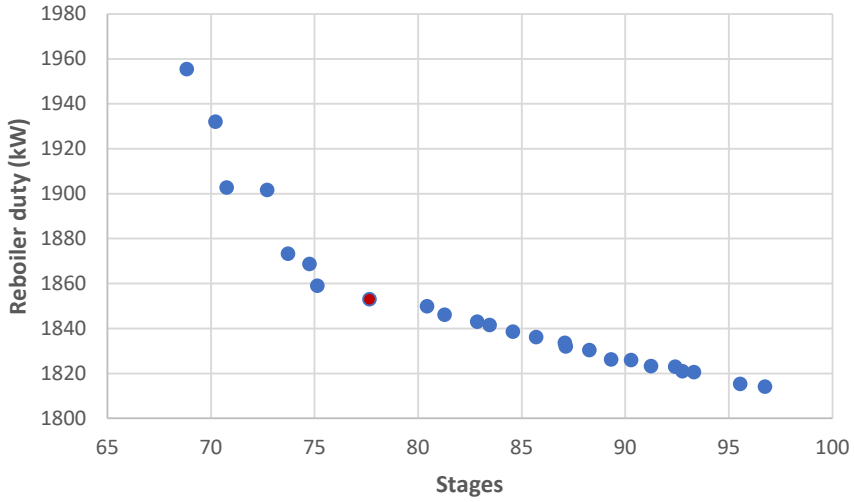

**Figure 4:** Pareto front of the intensified scheme for the 40/10/10/40 composition.

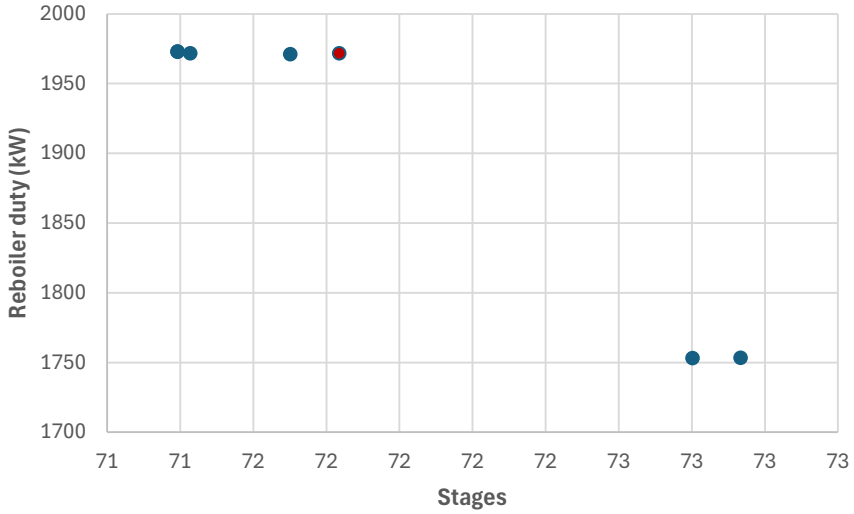

**Figure 5:** Pareto front of the intensified scheme for the 25/25/25/25 composition.

## RESULTS

Figures 4 to 6 show Pareto fronts for each case under analysis. The red point in each graph is considered the solution with the best compromise.

Table 1 reports the values of the manipulated variables for the QDDWC base-case designs, where DDW40, DDW25, and DDW10 correspond to feed compositions of 40/10/10/40, 25/25/25/25, and 10/40/40/10, respectively. Similarly, Table 2 presents the corresponding values for the optimized designs. In this case, DDW40-o, DDW25-o, and DDW10-o refer to the optimized configurations associated with feed compositions of 40/10/10/40, 25/25/25/25, and 10/40/40/10, respectively.

Table 3 reports the response-variable values for each intensified and conventional scheme at each concentration levels. The conventional ones are CDS40, CDS25, and CDS10 for 40/10/10/40, 25/25/25/25, and 10/40/40/10 concentration, respectively.

When comparing the DDWC base-case designs with the optimized schemes, a noticeable reduction in both reboiler duty and total number of stages is observed. For instance, for the 40/10/10/40 composition, the optimized configuration achieves a 5.05% reduction in reboiler duty and a 30.03% decrease in the number of stages. Similarly, for the 10/40/40/10 case, reductions of 7.72% and 31.43% are obtained in reboiler duty and total stages, respectively. In contrast, the 25/25/25/25 composition exhibits only a 2.86% decrease in reboiler duty, while a slight increase of 2.62% in the total number of stages is

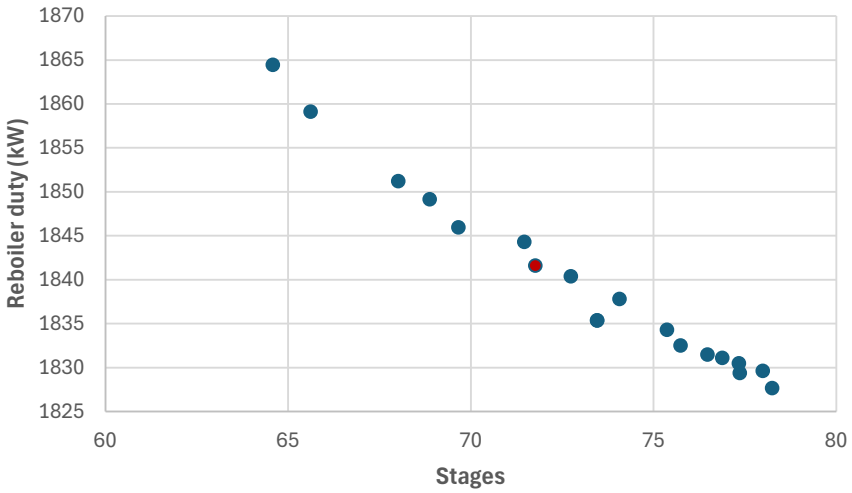

**Figure 6:** Pareto front of the intensified scheme for the 10/40/40/10 composition.

observed. This increase is mainly attributed to the shape of the Pareto set rather than to a failure of the optimization algorithm.

The comparison between the conventional distillation sequence (CDS) and the optimal intensified schemes (DDW-o) reveals a clear trade-off: a significant reduction in reboiler duty is achieved at the expense of an increase in the total number of stages. In terms of reboiler duty, the DDW-o configurations for 40/10/10/40, 25/25/25/25, and 10/40/40/10 exhibit reductions of 58.27%, 35.81%, and 59.69%, respectively, relative to the CDS. Conversely, stage requirements are increased by 27.32%, 28.28%, and 20.00% for the same compositions, respectively.

The energy savings observed in intensified schemes compared to conventional sequences can be explained by the inherent structure of each separation strategy. In the CDS, the separation is carried out in three columns: butane is recovered as the distillate of the first column, pentane as the distillate of the second column, and hexane as the distillate of the third column, while heptane is withdrawn from the bottom of the third column. Therefore, intermediate mixtures (e.g., pentane, hexane, and heptane) leaving the bottom of the first column are withdrawn at elevated temperatures (typically above 115 °C). When entering the second column, these streams are fed and cooled at significantly lower temperatures (approximately 70–80 °C). A similar situation occurs between the second and third columns: the bottom stream from the second column exits again at temperatures above 120 °C and is subsequently cooled to around 90 °C when introduced into the final column. In the third column, the heptane-rich bottom stream may reach temperatures up to 150 °C. Therefore, the conventional sequence is characterized by repetitive heating and cooling steps across columns, which results in avoidable energy losses.

In contrast, intensified configurations achieve the separation within a single integrated unit, which enables internal heat integration and significantly reduces the need for successive cooling and reheating of intermediate streams. This structural advantage explains the superior thermal performance of intensified schemes relative to the conventional sequence.

The increase in the total number of stages observed in the intensified schemes compared to the CDS can be mainly explained by differences in relative volatility (Figs. 5(a) to 5(f)). These results indicate that the hexane–heptane separation becomes more challenging in the intensified configurations than in the conventional sequence. In general, as relative volatility approaches unity, the separation difficulty increases substantially because the volatility difference between the light and heavy key components becomes less pronounced, thereby requiring a higher number of equilibrium stages to achieve the specified recoveries.

Figure 7 illustrates the effect of feed-composition changes on the performance of the evaluated sequences. Both plots exhibit a parabolic trend and show an inverse behavior with respect to each other. For instance, in the intensified schemes, DDW25 presents the highest reboiler duty, whereas in the conventional sequences the corresponding CDS25 case exhibits the lowest energy requirement. Conversely, DDW10 shows the lowest reboiler duty among intensified configurations, while CDS10 displays the highest energy consumption within the conventional set.

To interpret these trends, the relative-volatility profiles shown in Figs. 5(a)–5(f) and Figs. 8–10, where the heat capacity of each mixture are shown, must be considered.

The heat capacity profiles of the butane/pentane/hexane/heptane mixtures (Figs. 8–10) show a clear compositional dependence. In particular, the mixture heat capacity increases as the fractions of pentane and hexane rise, whereas it decreases when butane and heptane become less dominant.

The behavior of the heat capacity profiles is directly associated with the phase transition of the mixture from liquid to vapor. This relationship can be demonstrated by comparing Figures 8 and 11, where Figure 11 presents the molar vapor fraction. It is important to note that these figures correspond to the 40/10/10/40 composition. The temperatures at which the liquid phase begins to evaporate coincide with the temperatures at which the heat capacity starts to increase. Although only one molar vapor fraction profile is shown, the same behavior is observed for all the different compositions analyzed in this study.

From a thermodynamic standpoint, this trend is consstent with the fact that the heat capacity of hydrocarbon mixtures is strongly influenced by the contribution of each component to the overall sensible enthalpy. Pentane and hexane, which constitute the intermediate fractions, typically exhibit higher molar heat capacities than butane due to their larger molecular size. Therefore, enriching the mixture in pentane and hexane results in a higher mixture heat capacity, meaning that more thermal energy must be supplied to increase the system temperature by 1 °C.

Additionally, the observed behavior may reflect non-ideal mixture contributions to heat capacity, which arise from compositional changes in intermolecular interactions within the multicomponent hydrocarbon system. As a result, variations in pentane and hexane content can lead to measurable changes in the mixture heat-capacity response.

Among the intensified schemes, DDW10 exhibits the lowest energy requirements, mainly due to the internal vapor-flow conditions (boil-up) established inside the column. The vapor rate is generated in the reboiler and is

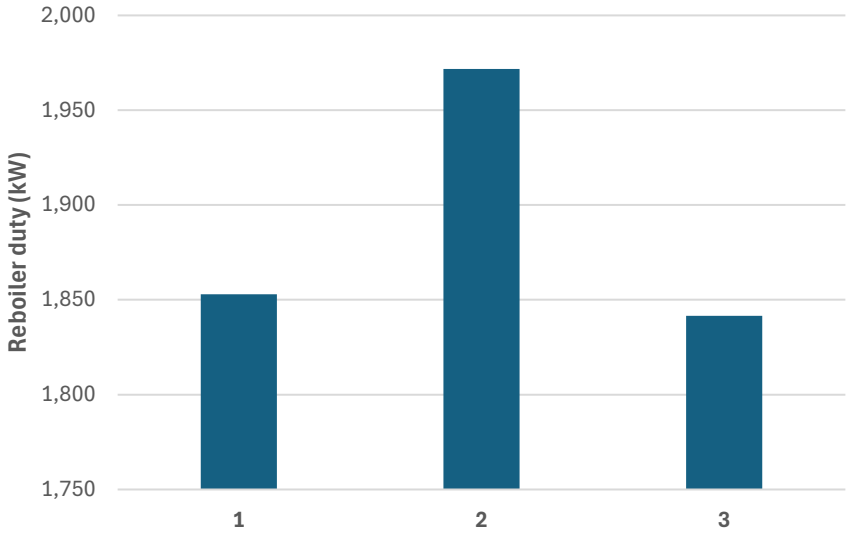

**Figure 7 (a)** Reboiler duty on intensified schemes. 1) DDW40, 2) DDW25, 3)DDW10.

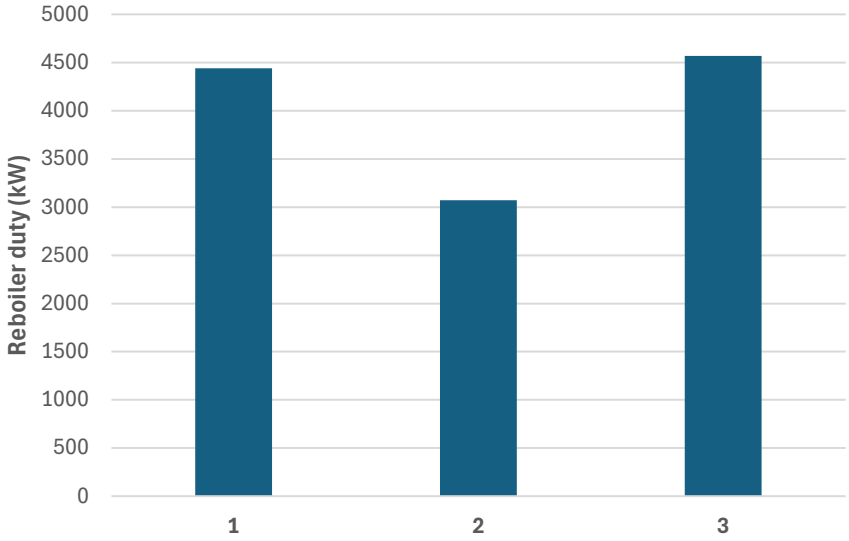

**Figure 7 (b):** Reboiler duty on conventional schemes. 1) CDS40, 2) CDS25, 3) CDS10.

predominantly composed of heptane. Although the heptane fraction in the vapor stream is lower in DDW10 than in DDW25 and DDW40, the generated vapor flow still provides sufficient thermal driving force to vaporize the required amount of hexane; thereby, maintaining the target vapor traffic throughout the DDW10 configuration. As a result, the overall reboiler duty is lower than that observed for DDW25 and DDW40.

In contrast, DDW40 demands higher energy than DDW10 because the hexane content in the system is lower. Consequently, a larger fraction of the boil-up must be carried by heptane to sustain the vapor flow within the column. From a thermodynamic perspective, maintaining heptane in the vapor phase is more energy-intensive than vaporizing hexane, since heptane is less volatile (higher normal boiling point), and typically requires a higher enthalpy input per unit of generated vapor. Therefore, schemes relying more heavily on heptane as the main vapor carrier led to higher reboiler duties.

In addition, the fact that DDW25 exhibits a higher energy requirement than DDW10 and DDW40 (Fig. 6) can be rationalized by analyzing the relative volatility behavior (Figs. 5(a), 5(c), and 5(e)). Although the heat-capacity trends suggest the following order: 10/40/40/10 > 25/25/25/25 > 40/10/10/40, the separation difficulty in these systems is more strongly governed by phase-equilibrium limitations than by sensible-heat effects. In particular, the relative-volatility profiles indicate a more unfavorable separation for the hexane-related split in the

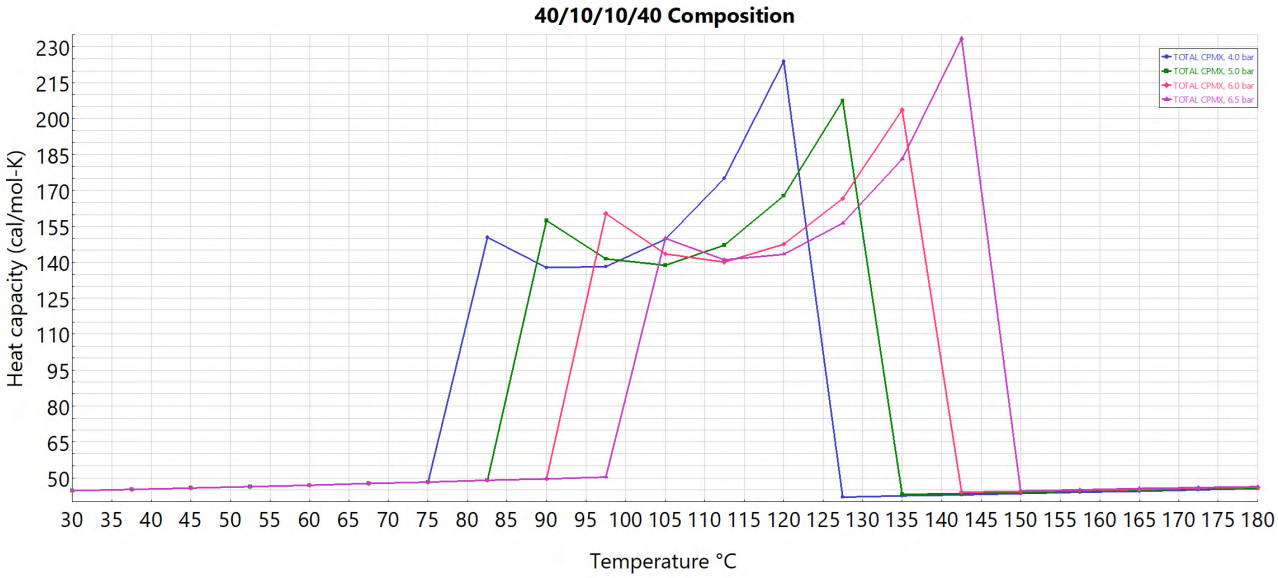

**Figure 8:** Heat capacity of the 40/10/10/40 mixture over the pressure range of 4–6.5 bar.

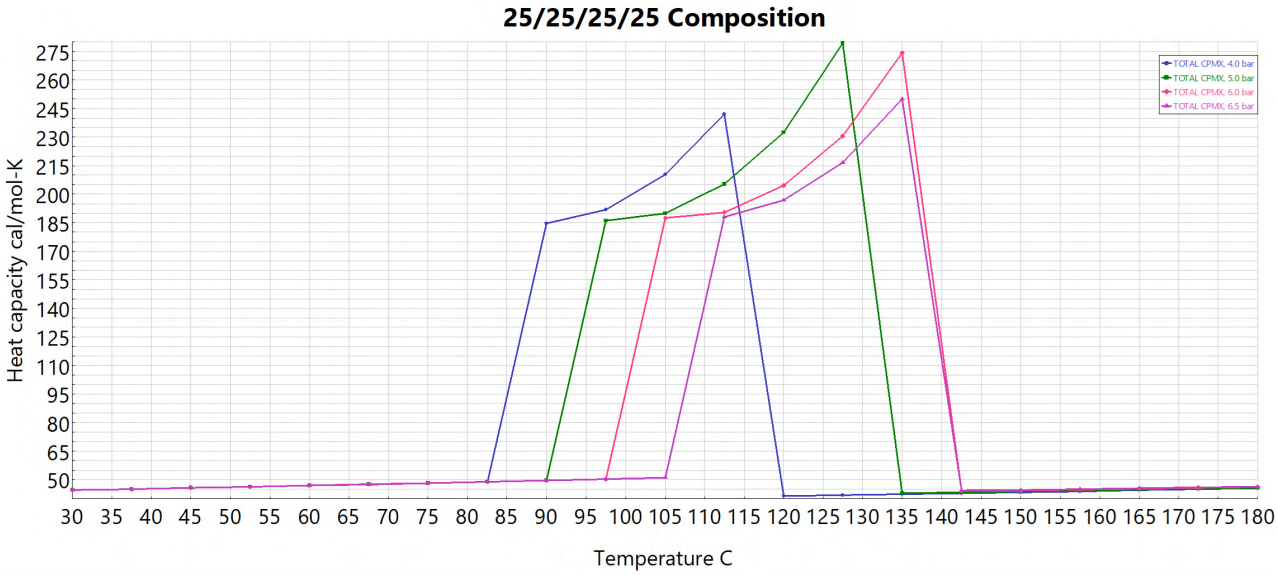

**Figure 9:** Heat capacity of the 25/25/25/25 mixture over the pressure range of 4–6.5 bar.

equimolar case (25/25/25/25), which increases the required vapor traffic and, consequently, the reboiler duty.

Therefore, the relative-volatility behavior supports the energy-demand trend observed in Fig. 6, namely: DDW25 > DDW40 > DDW10. This effect may be attributed to mixture non-ideality and composition-dependent intermolecular interactions, which are maximized when all hydrocarbons are present in comparable proportions; thereby, reducing the effective volatility differences between key components.

Finally, CDS10 exhibits the highest energy consumption among the conventional schemes, followed by CDS40 and CDS25. Similar to the intensified configurations, this trend is mainly governed by the relative-volatility behavior (Figs. 5(b), 5(d), and 5(f)), which determines the separation difficulty and the amount of vapor traffic required to achieve the specified recoveries. This behavior may also reflect composition-dependent intermolecular interactions that affect phase equilibrium and, consequently, the effective relative volatility between key components.

Since the conventional sequence performs the separation across different equipment units, sensible-heat effects become more relevant. In particular, for CDS10, the heptane-rich stream is cooled and reheated as it

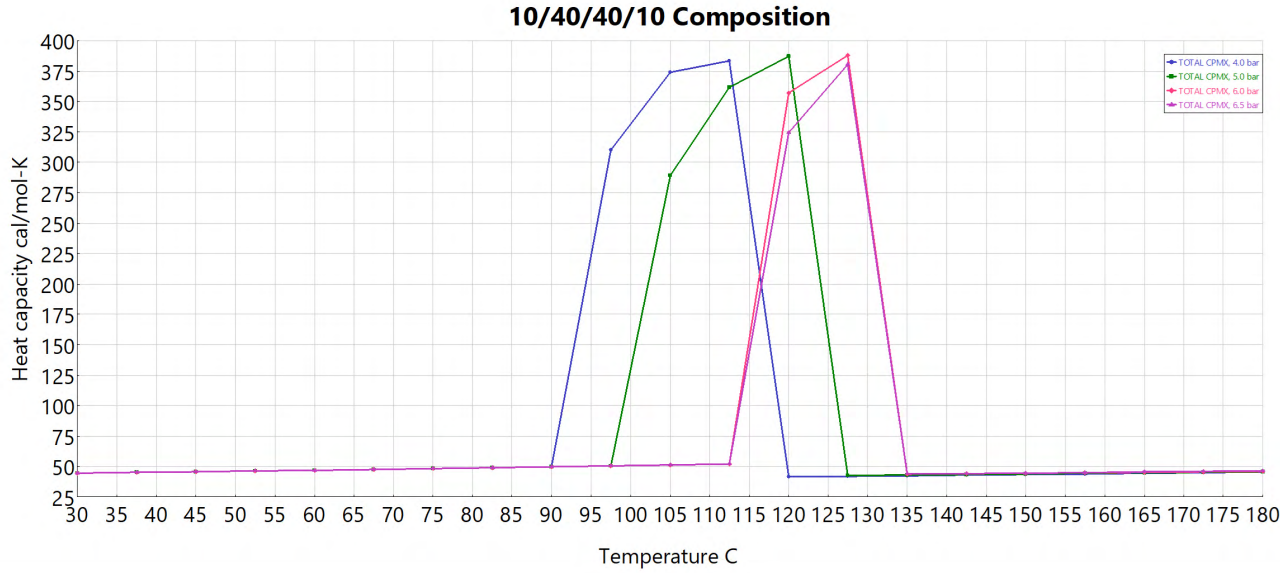

**Figure 10:** Heat capacity of the 10/40/40/10 mixture over the pressure range of 4–6.5 bar.

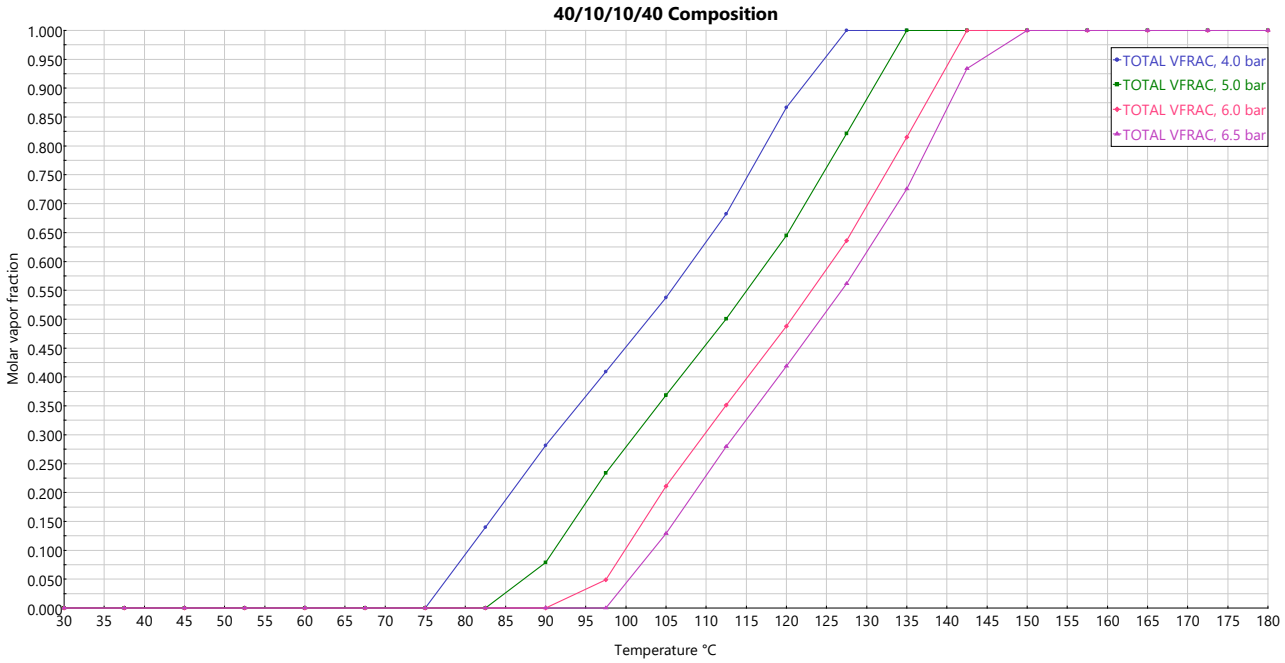

**Figure 11:** Molar vapor fraction of the 40/10/10/40 mixure over the pressure range of 4–6.5 bar.

passes through Columns 1 and 2 before entering Column 3, introducing additional utility consumption. Furthermore, because heptane is present in a lower proportion in CDS10 than in CDS40, a higher reboiler duty is required in the final column to supply sufficient boil-up, vaporize hexane, and maintain the internal vapor flow. These combined effects lead to a higher overall energy demand.

In contrast, CDS25 presents the lowest energy requirement among the conventional schemes. This result can be explained by the structure of the three-column sequence and the more balanced distribution of component loads, which reduces the severity of the limiting separation. Additionally, separating the mixture across different columns progressively changes the local composition, which tends to mitigate non-ideal mixture effects compared with intensified schemes where all hydrocarbons coexist within the same equipment.

## CONCLUSIONS

In conclusion, the intensified schemes significantly

reduce the energy requirements required to separate the butane/pentane/hexane/heptane system. In addition, feed composition plays a critical role in the performance of both intensified and conventional configurations, strongly influencing separation difficulty and utility consumption. Therefore, a broader assessment considering additional feed compositions is recommended to provide a more comprehensive understanding of the behavior and robustness of the evaluated schemes.

Although intensified configurations tend to require a higher total number of stages, they offer an important structural advantage by reducing the number of separation units, particularly the number of columns and reboilers, compared to conventional distillation sequences. This feature highlights the potential of intensified schemes as energy-efficient alternatives for multicomponent hydrocarbon separation.

## ABSTRACT

Efficient deployment of carbon capture, utilisation, and storage (CCUS) within industrial clusters requires coordinated $CO_2$ allocation under economic, technical, and environmental constraints, particularly when $CO_2$ availability is limited. This paper presents a centralised optimisation framework for allocating captured $CO_2$ from nine industrial sources to six utilisation and storage sinks within an industrial park in Qatar. A multi-objective mixed-integer linear programming (MILP) model is developed to minimise total system cost while accounting for capture, purification, transport, and utilisation processes, and enforcing an environmental feasibility constraint to ensure net $CO_2$ reduction. The model is evaluated under four scenarios: a baseline case with sufficient $CO_2$ to satisfy all sink demands, and three scarcity scenarios in which 15%, 25%, and 35% of total source emissions are available. Results show that under scarcity, allocations prioritise large EOR sinks supplied by high-volume, low-purity sources, while utilisation pathways are progressively reintroduced as availability increases. The findings highlight the critical influence of $CO_2$ purity, sink requirements, and supply constraints on allocation outcomes and underscore the importance of centralised planning for robust CCUS deployment.

**Keywords**: CCUS, $CO_2$ allocation, Life-cycle emissions, Optimisation, $CO_2$ purity

## INTRODUCTION

Carbon capture, utilisation, and storage (CCUS) has been widely recognised as a critical decarbonisation pathway for energy-intensive industrial systems, particularly in sectors where direct electrification and fuel switching remain technically or economically constrained. Previous system-level assessments emphasised that the effectiveness of CCUS deployment depended not only on capture technologies, but also on the coordinated planning of $CO_2$ transport, allocation, and end-use across interconnected industrial networks. In this context, Leonzio et al. (2022) highlighted the importance of integrated supply-chain optimisation for achieving cost-effective emissions reduction, showing that sub-optimal source-sink matching and transport design could significantly undermine the economic viability of CCUS systems.

Several studies extended CCUS optimisation frameworks to explicitly include utilisation pathways alongside storage. Zhang et al. (2024) and Iskandar & Kurihara (2025) developed co-optimisation models capturing trade-offs between $CO_2$ utilisation, storage, and transport modalities, while Susantoro et al. (2023) focused on CCUS-EOR configurations aimed at meeting net-zero or near-zero emissions targets. These studies demonstrated the potential economic benefits of integrating utilisation sinks within CCUS networks, but typically evaluated system performance under assumed availability conditions and aggregate emissions targets. Zhang et al. (2017) investigated the design of integrated CCS infrastructure under carbon trading schemes and highlighted the importance of spatial proximity and network configuration in determining optimal capture and transport strategies.

Recent literature placed increasing emphasis on the technical characteristics of $CO_2$ streams and their implications for system performance. (Alnouri & Al-Mohannadi, 2023) examined the influence of treatment design parameters on carbon integration and showed that purification requirements significantly affect capture efficiency and downstream feasibility. (Sawaly et al., 2026)

quantified the role of $CO_2$ purity and treatment costs in shaping optimal allocation within energy and petroleum systems, while (Kumcu et al., 2026) further highlighted that capture and purification processes often represent dominant cost components in CCUS supply chains.

Optimisation-based modelling approaches have been extensively applied to CCUS system design. Mixed-integer linear programming (MILP) formulations have been used to minimise total system cost while determining optimal capture, transport, and storage configurations at regional and national scales. Caselli et al. (2022) formulated MILP frameworks to support strategic CCUS infrastructure planning, while Wu et al. (2023) extended optimisation approaches to address transport and storage coordination under capacity constraints. More recent contributions incorporated broader system interactions, including energy-industry coupling and emissions reduction targets, to assess the role of CCUS within low-carbon transition pathways (Al-Mohannadi & Al-Mohannadi, 2023; Sawaly et al., 2024)

Despite these advances, several gaps remained in literature. First, most optimisation studies implicitly assumed that sufficient captured $CO_2$ was available to satisfy utilisation and storage demand, providing limited insight into allocation behaviour under supply-constrained conditions. Second, life-cycle $CO_2$ emissions were commonly assessed ex post, rather than enforced directly within optimisation frameworks through environmental feasibility constraints. Third, the combined influence of source $CO_2$ purity, sink-specific requirements, and sink-level emissions on allocation prioritisation was rarely examined in an integrated manner, particularly within industrial clusters where multiple utilisation and storage pathways compete for limited $CO_2$ supply.

This paper addressed these gaps by developing a centralised optimisation framework for $CO_2$ allocation within an industrial park in Qatar. The proposed model integrated detailed capture and purification cost functions, explicit life-cycle emissions accounting, and an environmental feasibility constraint to ensure net $CO_2$ reduction. The framework was evaluated under a baseline scenario with unconstrained $CO_2$ availability and under multiple scarcity scenarios to analyse how allocation patterns, demand satisfaction, and emissions performance evolved as $CO_2$ availability decreased. In doing so, the study provided new insights into cost-emissions trade-offs and allocation dynamics relevant to the planning and deployment of resilient, environmentally robust CCUS systems in industrial clusters.

## 2. MODELS AND OPTIMISATION

A multi-objective optimisation framework based on mixed-integer linear programming (MILP) is developed to model $CO_2$ allocation within an industrial park in Qatar. The framework optimises the allocation of captured $CO_2$ from multiple industrial sources to a set of utilisation and storage sinks while balancing economic and environmental objectives. The system consists of nine industrial $CO_2$ sources and six application sinks. The optimisation determines source-sink selection and associated annual $CO_2$ flowrates, where binary decision variables represent source-sink assignments and continuous variables describe $CO_2$ flows. Each sink is supplied by a single source, while each source may supply multiple sinks subject to its $CO_2$ availability. Economic performance is evaluated through minimisation of total system cost, and environmental performance is incorporated through explicit accounting of life-cycle $CO_2$ emissions and the enforcement of an environmental feasibility constraint ensuring net $CO_2$ reduction.

To examine system behaviour under different operating conditions, the model is solved under four distinct scenarios. The first scenario represents a baseline case in which sufficient captured $CO_2$ is available to fully satisfy the demand of all utilisation and storage sinks. The remaining three scenarios consider constrained $CO_2$ availability, where only 15%, 25%, and 35% of total source emissions are available for allocation. These scenarios enable assessment of trade-offs between cost minimisation, $CO_2$ utilisation levels, and emissions performance under increasingly stringent system conditions.

### 2.1 Available Data and Assumptions

cCapture and purification costs are calculated for each candidate source-sink match using the cost function developed in Sawaly et al. (2026). The model uses source-specific $CO_2$ availability and $CO_2$ purity, together with sink-specific $CO_2$ demand and minimum purity requirements. The $CO_2$ emissions available at each source, together with their corresponding $CO_2$ purity, and the $CO_2$ demand and purity requirements at each sink are summarised in Table 1. The spatial distribution of all sources and sinks within the industrial park is presented in Figure 1.

**Table 1.** Technical and economic characteristics of $CO_2$ sinks.

| **Sinks** | **$CO_2$ demand ($tCO_2$/year)** | **Purity required (%)** |
|---|---|---|
| QAFAC H2 | $3.86 \times 10^6$ | 78% |
| QAFAC NG | $3.90 \times 10^5$ | 80% |
| Pearl GTL | $1.28 \times 10^6$ | 47% |
| Oryx GTL | $1.28 \times 10^6$ | 38% |

| QP REFINERY | 1.20 x $10^6$ | 11% |

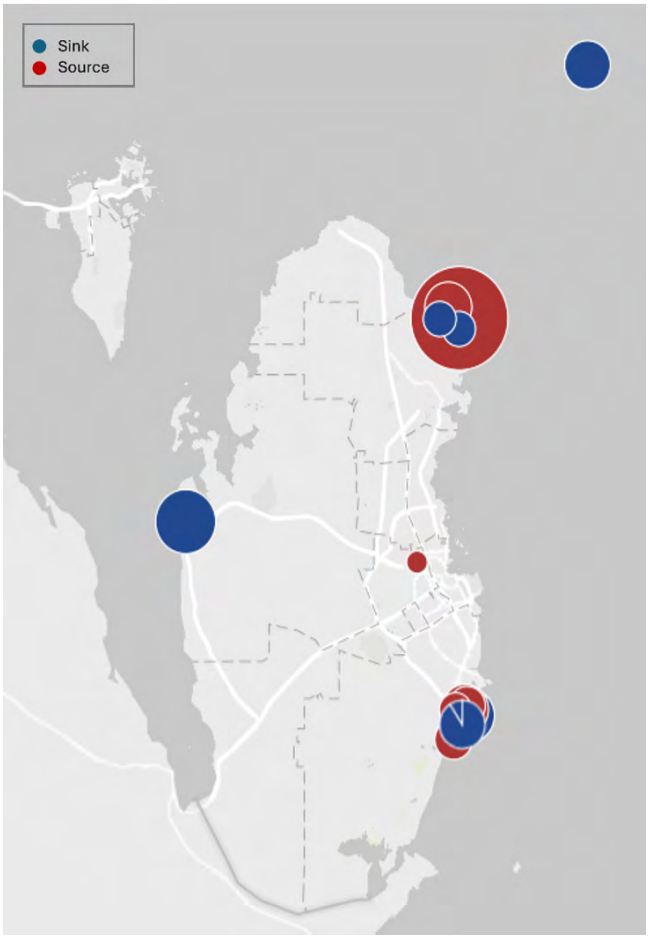

**Figure 1.** Spatial Distribution of $CO_2$ Sources and Sinks with Emissions and Demand.

The assumptions made in the model are as follows:

- $CO_2$ is transported via pipeline between sources and sinks.
- All source-sink connections are assumed technically feasible due to the availability of capture and purification technologies; feasibility is reflected through cost and emissions penalties rather than excluding pairs a priori.
- Differences in $CO_2$ purity are captured through source-sink-specific capture/purification cost and capture/purification emission factors, and through purity-adjusted transportation impacts.
- $CO_2$ is assumed to be transferred free of charge (no $CO_2$ commodity price); only operating costs are considered.
- Capital expenditures and financing effects are excluded; the optimisation accounts for annual operating costs only.
- Life-cycle $CO_2$ emissions include capture and purification, transport, and sink utilisation/storage emissions, consistent with the model's emissions accounting.

## 2.3 Model Formulation

The model includes the following decision variables:

$q_{ij}$: Mass flowrate of $CO_2$ transported from source $i$ to sink $j$ ($tCO_2$/year).

$y_{ij}$: Binary variable indicating whether sink $j$ is supplied by source $i$.

To represent $CO_2$ scarcity, a non-negative slack variable $u_j$ is introduced to capture unmet $CO_2$ demand at sink $j$.

### Objective function

The optimisation minimises the total annual operating cost of the $CO_2$ allocation network:

$$\min Z^{\text{cost}} = \sum_{i \in S} \sum_{j \in J} [C_{ij}^{\text{cap}} + C_{ij}^{\text{tr}}] q_{ij} + \lambda \sum_{j} u_j \qquad (1)$$

where $C_{ij}^{\text{cap}}$ and $C_{ij}^{\text{tr}}$ denote capture-purification and transportation costs, respectively, and $\lambda$ is a penalty parameter associated with unmet $CO_2$ demand.

The optimisation is subject to the following constraints:

(i) Source capacity constraint, limiting total $CO_2$ supplied by each source to its annual availability:

$$\sum_{j \in J} q_{ij} \leq E_i \; \forall i \in S \qquad (2)$$

where $E_i$ is the annual $CO_2$ availability of source $i$.

(ii) Sink demand constraints, ensuring that $CO_2$ demand is satisfied or, in scarcity scenarios, captured as unmet demand:

$$\sum_{i \in S} q_{ij} + u_j = D_j \; \forall j \in J \qquad (3)$$

This constraint enforces full satisfaction of each sink's $CO_2$ demand $D_j$. It ensures that every sink receives exactly the amount of $CO_2$ required for its operation, preventing both under-supply and over-supply.

(iii) Single-source supply constraints, restricting each sink to be supplied by at most one source:

$$\sum_{i \in S} y_{ij} \leq 1 \; \forall j \in J \tag{4}$$

(iv) Flow-selection linking constraints, enforcing consistency between binary source-sink selection and continuous $CO_2$ flows:

$$q_{ij} \leq D_j \, y_{ij} \; \forall i \in S, \forall j \in J \tag{5}$$

(v) Capture and purification emissions, calculating emissions associated with $CO_2$ capture and purification:

$$Z^{\text{cap, emis}} = \sum_{i \in S} \sum_{j \in J} ER_{ij}^{\text{cap}} \, q_{ij} \tag{6}$$

where $ER_{ij}^{\text{cap}}$ denote the capture and purification emission rate.

(vi) Transportation emissions, accounting for pipeline transport of $CO_2$:

$$Z^{\text{tr, emis}} = \sum_{i \in S} \sum_{j \in J} EF^{\text{tr}} \, d_{ij} \, \frac{1}{x_i} \, q_{ij} \tag{7}$$

where $EF^{\text{tr}} = 1.986 \times 10^{-6} \, \text{tCO}_2 / (\text{tCO}_2/\text{km})$, $x_i$ is the $CO_2$ mass fraction (purity) of source $i$, and $d_{ij}$ is the distance between each source-sink linkage.

(vii) Sink utilisation or storage emissions, capturing process-specific emissions at the sinks:

$$Z^{\text{sink, emis}} = \sum_{i \in S} \sum_{j \in J} ER_{j}^{\text{sink}} \, q_{ij} \tag{8}$$

where $ER_{ij}^{\text{sink}}$ represents emissions generated during $CO_2$ utilisation or residual emissions during storage.

(viii) Total system emissions, aggregating all life-cycle emission components:

$$Z^{\text{emis}} = \sum_{i \in S} \sum_{j \in J} \left[ ER_{ij}^{\text{cap}} + EF^{\text{tr}} \, d_{ij} \, \frac{1}{x_i} + ER_{j}^{\text{sink}} \right] q_{ij} \tag{9}$$

(ix) Environmental feasibility constraint (ε-constraint), ensuring net $CO_2$ reduction:

$$Z^{\text{emis}} \leq \sum_{i \in S} \sum_{j \in J} q_{ij} \tag{10}$$

This ε-constraint ensures that the total life-cycle emissions generated by the CCUS system do not exceed the amount of $CO_2$ captured and diverted from atmospheric release. It guarantees that all feasible solutions deliver a net reduction in $CO_2$ emissions relative to the baseline system without CCUS.

(x) Variable domain constraints, enforcing physical feasibility:

$$q_{ij} \geq 0 \; \forall i \in S, \forall j \in J \tag{11}$$

$$u_j \geq 0 \; \forall j \in J \tag{12}$$

$$y_{ij} \in \{0, 1\} \; \forall i \in S, \forall j \in J \tag{13}$$

These constraints ensure physical feasibility of the solution. $CO_2$ flows cannot be negative, and the binary variable enforces discrete selection of source-sink relationships.

## RESULTS AND DISCUSSION

The optimisation results reveal that, across all scenarios, system-level performance is governed by the interaction between $CO_2$ availability, sink demand, and technical compatibility between sources and sinks. Figure 2 presents an aggregate comparison of total $CO_2$ demand, supplied $CO_2$, unmet demand, and overall demand satisfaction for the baseline and scarcity scenarios, highlighting the progressive decline in system-wide demand fulfilment as $CO_2$ availability becomes constrained. To understand the allocation mechanisms underlying these aggregate outcomes, Figure 3 illustrates the optimal source-sink $CO_2$ allocation pathways for the baseline and each scarcity scenario, showing how flow magnitudes and supplier-consumer relationships evolve under constrained availability.

In the baseline case, high-volume but low-purity sources such as QatarEnergy LNG (≈17% $CO_2$) are systematically allocated to EOR sinks, where purity requirements are less stringent and large flowrates dominate system performance. This explains why Dukhan Field and Alshaheen Field EOR jointly receive more than 14 $MtCO_2$ $yr^{-1}$, despite their relatively long transport distances. In contrast, chemical and GTL sinks, which impose higher purity constraints and incur higher penalties for purification, are preferentially supplied by QAFCO (≈52% $CO_2$) and Qatar Steel (≈25% $CO_2$), even when their emission capacities are smaller. This reflects the model's internal trade-off: allocating higher-purity streams reduces both purification costs and capture-related emissions, improving overall cost-emissions efficiency for utilisation pathways. As a result, sink satisfaction in the baseline scenario is not uniform but structured around technical compatibility rather than proximity alone.

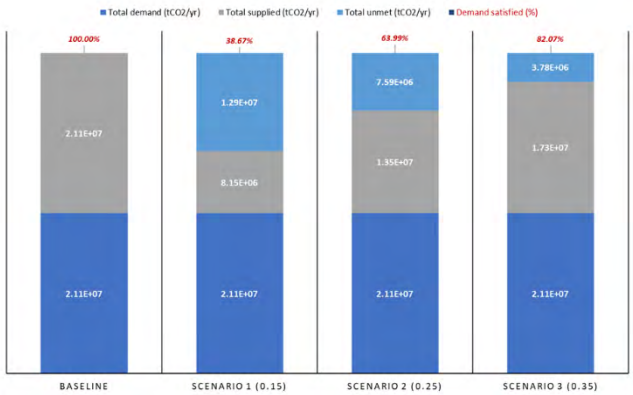

**Figure 2:** Scenario-Based Comparison of $CO_2$ Supply and Demand Satisfaction

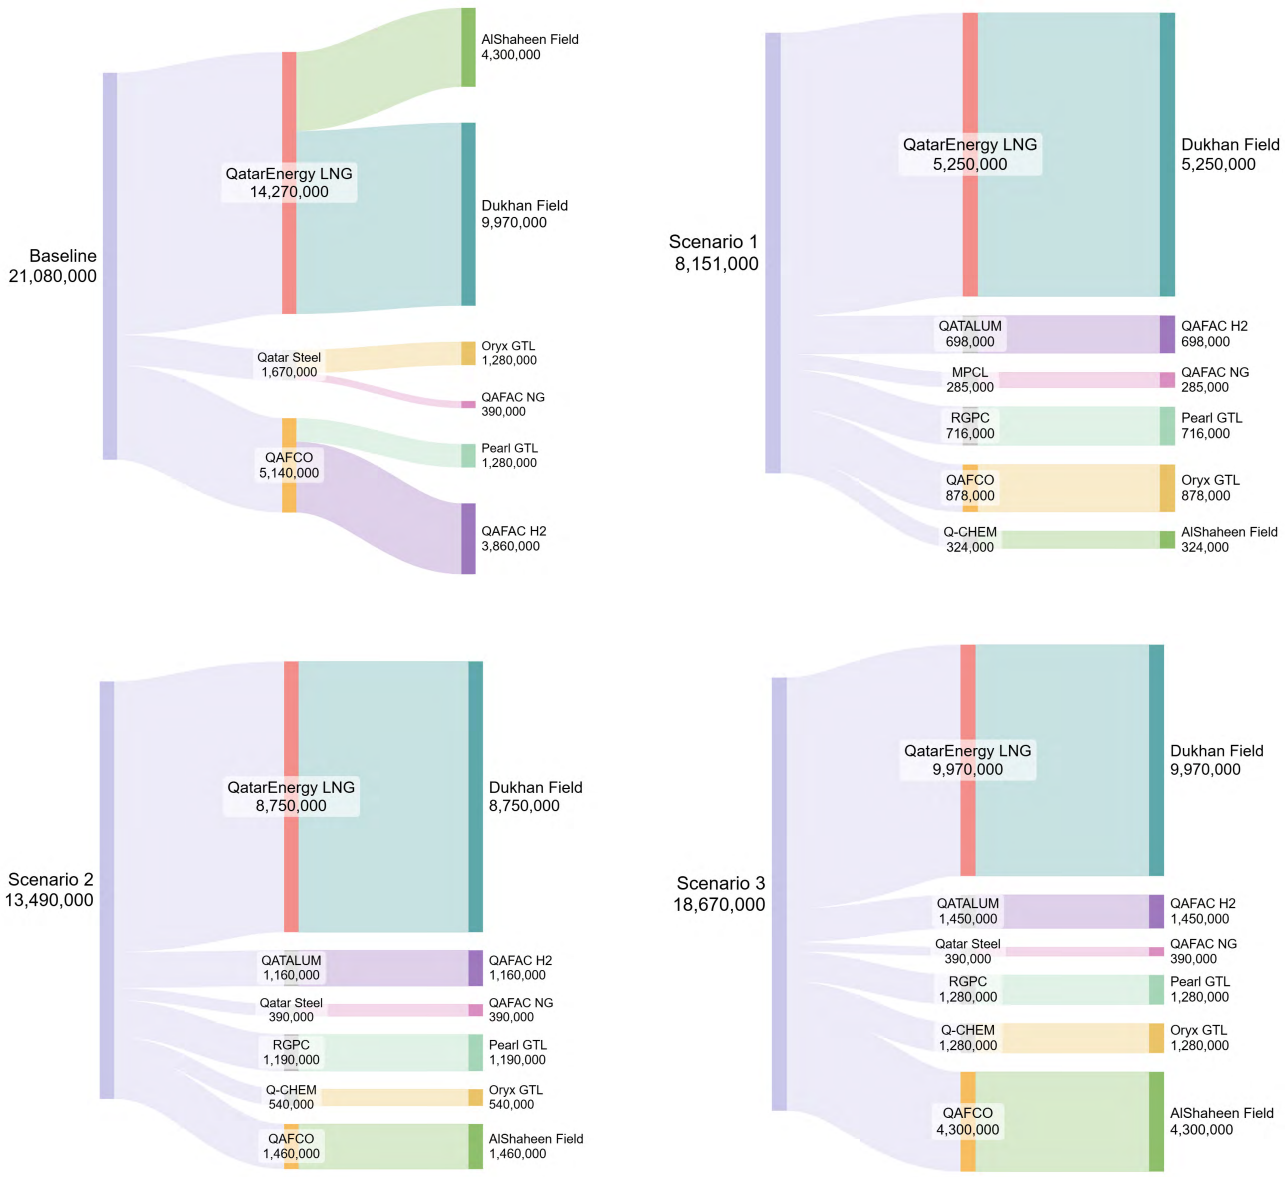

**Figure 3:** Source-Sink $CO_2$ allocation across Baseline and Scarcity Scenarios in $tCO_2$/year.

Under $CO_2$ scarcity, this compatibility-driven logic becomes more pronounced. When availability is limited to 15%, the optimisation increasingly favours sinks with lower marginal emissions per tonne utilised and greater tolerance to purity variability, particularly EOR operations. Chemical sinks such as QAFAC $H_2$, despite their strategic importance, are deprioritised because allocating scarce, high-purity $CO_2$ to these sinks displaces larger volumes that could otherwise satisfy EOR demand at lower system cost and emissions intensity. As availability increases to 25% and 35%, the reintroduction of chemical and GTL sinks reflects the point at which the marginal benefit of serving additional utilisation pathways outweighs the combined penalties of purification, transport, and sink-level emissions. Notably, sources with moderate purity and favourable locations, such as QAFCO, QATALUM, and RGPC, emerge as critical "bridging" suppliers in these scenarios, supporting diversification without sharply increasing system emissions. This behaviour highlights a key structural insight: $CO_2$ purity acts as an implicit scarcity multiplier, shaping allocation decisions even more strongly than absolute emission capacity. This progression, observed in Figure 3, explains the non-linear improvement in demand satisfaction reported in Figure 2. Consequently, the results demonstrate that CCUS system performance is governed not only by how much

$CO_2$ is available, but by how well source characteristics align with sink-specific technical and environmental constraints.

## CONCLUSION

This study develops a centralised optimisation framework to examine $CO_2$ allocation within an industrial cluster under varying availability conditions, explicitly integrating economic costs, technical compatibility, and life-cycle emissions. By formulating the problem as a multi-objective mixed-integer linear program, the framework captures the trade-offs between cost minimisation, utilisation coverage, and environmental feasibility that arise when multiple sources and sinks compete for limited $CO_2$ supply. The results demonstrate that allocation outcomes are governed not only by emission volumes, but by the alignment of source $CO_2$ purity, sink requirements, transport distances, and sink-specific emissions profiles.

Scenario analysis reveals that $CO_2$ scarcity fundamentally reshapes allocation behaviour, with large EOR sinks consistently prioritised under constrained supply, while chemical and GTL utilisation pathways become viable only as availability increases. Importantly, the findings show that modest increases in captured $CO_2$ can yield disproportionate improvements in demand satisfaction and system balance without compromising net emissions performance. These insights highlight the limitations of assuming unconstrained $CO_2$ supply in CCUS planning and underscore the value of centralised allocation mechanisms, such as $CO_2$ hubs or banks, for managing competition among sinks.

The proposed framework provides a flexible basis for supporting CCUS infrastructure planning under uncertainty and can be extended to incorporate dynamic policy instruments, investment decisions, or decentralised market behaviour. As such, it offers a practical tool for designing resilient, cost-effective, and environmentally robust CCUS systems in industrial clusters.

## ABSTRACT

Simulated Moving Bed (SMB) chromatography is widely used for a variety of separations, yet, when applicable, these systems are typically operated using offline optimization strategies. Over time, process degradation and unforeseen disturbances may cause SMB units to deviate from the calculated optimal conditions, reducing overall performance. Real-Time Optimization (RTO) offers a promising solution by continuously monitoring and adjusting operating conditions to maintain optimal performance, despite such perturbations. However, experimental implementation of RTO in industrial SMB processes is costly and requires significant interdisciplinary coordination.To address this challenge, a virtual framework is proposed for the preliminary development of a model-based RTO system. The methodology employs a virtual plant–model pair, in which a representative plant model generates *in silico* experimental data, while a structurally distinct predictive model reproduces these results. Structural mismatch was intentionally introduced to mimic real-world differences between a plant and its mathematical model, and measurement noise was added to enhance realism. Within this methodology, the *in silico* experiments were successfully generated and the parameters of the predictive model were then estimated using a Particle Swarm Optimization algorithm that sought to minimize the residuals between the *in silico* experimental data and the predictive model outputs. The parameters were successfully estimated, allowing the predictive model to closely reproduce the behavior of a structurally distinct plant model without introducing additional complications, which is expected to be analogous to a real-scenario RTO system. Hence, this work establishes a critical step towards the foundation of a virtual RTO framework.

## INTRODUCTION

Enantiomers have a critical role within the pharmaceutical industry, with current estimates indicating that more than half of all marketed drugs are administered as single enantiomer formulations [1]. It is also important to note that the use of racemic mixtures has been repeatedly associated with adverse, often severe, physiological effects [2]. Consequently, the isolation and production of enantiomerically pure compounds have become essential to ensure both the safety and therapeutic efficacy of chiral pharmaceuticals. Among the strategies available to obtain pure enantiomers, the separation of racemic mixtures has emerged as a practical and extensively investigated approach [3]. Of the various techniques employed for this purpose, chromatographic methods, in particular Simulated Moving Bed (SMB) chromatography, are of significant interest in this study due to their operational flexibility and cost-effectiveness.

### Simulated Moving Bed

SMB chromatography relies on the interaction between two continuous countercurrent phases: a

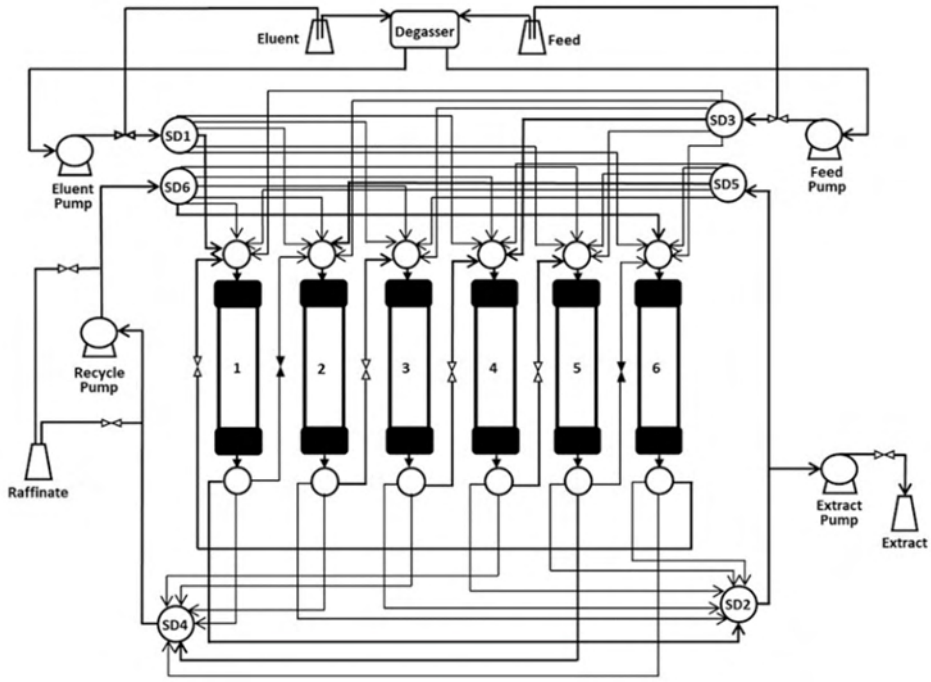

**Figure 1.** Diagram of the FlexSMB-LSRE®. Adapted from [4]

stationary solid phase, packed within a series of chromatographic columns and a mobile phase, typically a liquid or gas. Figure 1 displays the SMB unit studied in this work, the FlexSMB-LSRE® [4]. The interaction between phases enables the separation of adsorbates within the mobile phase. This separation is governed by the distinct affinities of individual components for the solid phase, which dictates their respective retention times. Therefore, in a binary system, preferential adsorption of one component onto the stationary phase subsequently increases its retention time, leading to the formation of three characteristic regions: two zones enriched in the individual components and an intermediate zone in which both species coexist, typically corresponding to the location of feed introduction. The extract stream, enriched in the more retained component, is withdrawn from one region, while the raffinate stream, containing the less retained component, is collected from the other. An eluent is introduced via a second inlet stream to sustain continuous separation [5, 6].

As can be seen in Figure 1, in an SMB unit, multiple fixed bed columns are connected in series and operated to emulate countercurrent contact between the solid and fluid phases. Although the solid phase remains physically stationary within the fixed beds, its motion is simulated by periodically shifting the positions of the inlet and outlet streams in the direction of the fluid flow at a fixed interval known as the switching time. This cyclic redistribution of streams creates an effective countercurrent movement of the solid relative to the mobile phase, enabling continuous separation [7, 8].

In SMB systems, the primary objectives are typically to maximize productivity and/or minimize eluent consumption while satisfying purity and/or recovery constraints. Consequently, optimization plays a vital role in enhancing process performance [9, 10]. However, conventional optimization approaches are typically conducted in an offline setting, which limits their ability to accommodate unanticipated disturbances, plant-model mismatch, or progressive system degradation. As a result, SMB units may operate under suboptimal conditions for prolonged periods, leading to reduced efficiency.

## Real-Time Optimization

Real-Time Optimization (RTO) systems have emerged over the past few decades as a promising approach for mitigating process disturbances and enhancing operational efficiency by combining mathematical models with real-time process measurements [11]. As such, when integrated into a separation equipment, RTO frameworks may offer means to maintain near-optimal operating conditions under changing process environments. Despite this potential, their practical implementation remains challenging. These systems require representative process models for better performance, which can be particularly difficult to obtain due to the nonlinear behavior and complexity of the underlying dynamics, and a reliable model-updating mechanism capable of

predicting and updating process parameters to compensate plant-model mismatch. Additionally, for cyclic processes such as an SMB, RTO strategies often rely on the system reaching a cyclic steady state, further complicating and limiting the applicability of these methods [12, 13]. Overall, an RTO system consists of a group of optimization techniques designed to continuously evaluate and adjust process operating conditions, consequently enabling the autonomous implementation of business-oriented decisions aimed at enhancing process efficiency and performance, while simultaneously ensuring compliance with process and operational restrictions [14, 15]. Within the plant hierarchy, RTO operates as an intermediate layer between the business planning, scheduling, and management systems, and the lower-level process control systems. As such, RTO considers the information gathered and decisions made by the company managers, such as planning, scheduling, transportation, and stock availability of the raw materials, to assess opportunities for operational improvement in real time. The resulting optimal setpoints are then communicated to the control layer, where they are implemented within the process [16]. To address the challenges associated with RTO deployment, mentioned before, various RTO strategies have been proposed and developed over time. Depending on the specific characteristics of the problem, these approaches are typically classified into three main categories: Model-Parameter Adaptation, Modifier Adaptation, and Direct Input Adaptation [12].

This work aims to build a virtual foundation to tackle these challenges by developing a virtual model pair, with different mathematical models, to mimic a real model-based RTO framework where plant-model mismatch and structural differences are present. This virtual pair, comprised of a simpler predictive model and a more complex representative plant model as a stand-in for the SMB unit, will enable the study of these limitations and how they can affect the operation of a real-scenario RTO system implemented into an SMB. This case study was specifically designed for the optimal separation of a racemic mixture of ketoprofen enantiomers, using SMB chromatography. To help build the structure of the model pair, particularly for the predictive model, a Particle Swarm Optimization (PSO) technique was also employed.

### Particle Swarm Optimization

The Particle Swarm Optimization (PSO) algorithm, introduced by Kennedy and Eberhart in 1995, was originally developed for the optimization of continuous nonlinear functions. Drawing inspiration from swarm intelligence, evolutionary computation, and genetic algorithms, PSO produces a population of candidate solutions, usually referred to as particles, that explore the search space by iteratively updating their positions based on both individual experiences and the collective knowledge of the swarm [17]. Since its inception, numerous modifications and enhancements have been proposed to improve the convergence speed, solution quality, and robustness of the original PSO algorithm. Despite the variety of PSO variants, all algorithms share a common underlying procedure. Initially, particles are distributed throughout the design space, either randomly or pseudo-randomly, to enable a controlled and comprehensive exploration of the problem's topology. Particle movement is governed by velocity vectors, which are updated based on each particle's own best-known position and the best-known position of the whole swarm. As particles traverse the search space and discover improved solutions, these newly identified best positions influence subsequent updates, dynamically guiding the swarm's exploration. Through this iterative process, the swarm progressively converges toward promising regions of the search space, facilitating the identification of near-optimal solutions for the optimization problem at hand [18].

By employing this methodology in the present study, the predictive model of the virtual pair is able to more accurately replicate the behavior of the representative plant model. This improvement is achieved by using Particle Swarm Optimization (PSO) to systematically minimize the residuals between the model's predicted outputs and the observed data, resulting in a closer and more reliable match between the two.

To summarize, the novelty of this work lies in the creation of this virtual plant–model pair, which provides a controlled environment to systematically study and understand the effects of plant-model discrepancies, providing a stepping stone toward robust RTO design. Obtaining favorable results within this study provides valuable insight into the possibility of employing similar mathematical models, with plant-model mismatch relative to the plant, for an analogous real-scenario RTO.

## METHODOLOGY

Firstly, the mathematical model for an SMB unit must be built. This was accomplished by adapting an existing, experimentally validated gPROMS model into a MATLAB framework. Although straightforward, the implementation required the use of different approaches, due to fundamental differences between the gPROMS and MATLAB programming environments, each of which offers distinct advantages and limitations. Upon completing the MATLAB implementation, the model was further validated against two literature-reported case studies to ensure robust and reliable performance [19, 20].

As a subsequent step, the original MATLAB model was transformed into a virtual model pair, consisting of a simplified predictive model and a more detailed representative model that serves as a stand-in for the plant in

a typical RTO scenario, as mentioned before. While both models share a similar structural foundation, having been derived from the same original MATLAB model, structural differences were purposely inserted to reflect the discrepancies commonly observed between model and plant in practical RTO implementations.

## Simulated Moving Bed Models

Both models are dictated by a set of simplifying assumptions. In this section, the differences between the developed mathematical models will be displayed. For the fixed bed columns within the SMB unit, the system was considered isothermal, with a constant mobile phase velocity, typical for diluted mixtures, and no interactions between solutes. The gel particles were considered spherical and uniform, and the fluid phase was modeled as exhibiting plug flow with axial dispersion. With these assumptions, the mass balance for the fluid phase is as follows:

For the predictive model:

$$\frac{\partial C_i}{\partial t} = D_{ax}\frac{\partial^2 C_i}{\partial z^2} - u_i\frac{\partial C_i}{\partial z} - \frac{(1-\varepsilon_b)}{\varepsilon_b}\frac{\partial \bar{q}_i}{\partial t} \quad (1)$$

where the parameter $D_{ax}$ refers to the axial dispersion coefficient, $u_i$ is the interstitial fluid velocity, $\varepsilon_b$ is the fixed bed porosity, $C_i$ is the concentration of component $i$ in the fluid phase and $\bar{q}_i$ is the average adsorbed concentration of enantiomer $i$. For the representative model, the mass balance for the fluid phase is instead:

$$\frac{\partial C_i}{\partial t} = D_{ax}\frac{\partial^2 C_i}{\partial z^2} - u_i\frac{\partial C_i}{\partial z} - \frac{(1-\varepsilon_b)}{\varepsilon_b}\frac{3}{R_p}k_L(C_i - \overline{C_{p,i}}) \quad (2)$$

where $R_p$ is the radius of the adsorbent particle, $\overline{C_{p,i}}$ is the average concentration of component $i$ in the particle pores, and $k_L$ is a lumped parameter, defined by:

$$\frac{1}{k_L} = \frac{1}{k_F} + \frac{1}{R_p\,\varepsilon_p\,k_p} \quad (3)$$

in which $k_F$ is the mass transfer coefficient in the film, while $k_p$ is the mass transfer coefficient in the pores and $\varepsilon_p$ is the particle porosity.

For the mass balance in the particles, slight differences also appear within the models. In the predictive model, this mass balance is described by the linear driving force (LDF) equation:

$$\frac{\partial \bar{q}_i}{\partial t} = k_{LDF,i}(q_i^* - \bar{q}_i) \quad (4)$$

in which $q_i^*$ is the adsorbed concentration in equilibrium with the fluid phase concentration of component $i$, while $k_{LDF,i}$ is the mass transfer coefficient. In the representative model, a more complex mass balance that utilizes the aforementioned lumped parameter $k_L$ is used:

$$\varepsilon_p\frac{\partial \overline{C_{p,i}}}{\partial t} + (1-\varepsilon_p)\frac{\partial \bar{q}}{\partial t} = \frac{3}{Rp}k_L(C_i - \overline{C_{p,i}}) \quad (5)$$

Lastly, the equilibrium relation between the liquid and solid phases can be represented by any chosen isotherm equation.

$$q_i = f(C_i) \quad (6)$$

Or, for the representative model:

$$\bar{q}_i = f(\overline{C_{p,i}}) \quad (7)$$

Five different equations were considered and developed to be implemented into the SMB mathematical models. These were Linear, Langmuir, Bi-Langmuir, Langmuir + Linear and Bi-Langmuir + Linear. To account for material transport between columns and across inlet/outlet ports, where no separation occurs, transfer lines were introduced into the SMB model, in which plug-flow behavior is assumed. Therefore, this approach also physically accounts for the system's dead volumes.

The model equations were solved using MATLAB® intrinsic functions, including *ode45f* and *pdepe,* with specific adaptations performed as needed. A spatial discretization of 40 intervals was employed for the adsorption columns, while 10 intervals were used to discretize the dead volumes elements. Temporal discretization was performed using 100 time intervals.

## Virtual Plant-Model Structure – Representative Model

To generate the *in silico* experiments, the representative model is utilized. In this particular study, the Linear + Langmuir isotherm was chosen. The model is executed from a primary MATLAB script that defines the operating conditions for each experiment using a Latin Hypercube Sampling (LHS) strategy, ensuring a space-filling exploration of the selected input domain. In this study, the desirable operating variables to be sampled include the feed flowrate, $Q_F$, the eluent flowrate, $Q_D$, the extract flowrate, $Q_X$, the raffinate flowrate, $Q_R$, the recycling flowrate, $Q_{IV}$, and the switching time, $t_s$. However, correct operation of the SMB unit requires that several restrictions on the operating conditions have to be strictly satisfied. The first among these is the global mass balance, as described in Equation (20). Compliance with this constraint is essential for physically meaningful operation. Therefore, only three operating conditions should be sampled, while the remaining one is computed implicitly to satisfy the overall mass balance. Additionally, for a successful SMB operation, the flowrate hierarchy shown in the following inequality must be satisfied:

$$Q_D > Q_X > Q_R > Q_F \quad (8)$$

Finally, physical constraints must also be considered. In particular, the pumps used in the FlexSMB-LSRE® system have a maximum capacity of 50 cm³/min [4], so, none of the inlet flow rates should exceed this limit. In practice, additional margin is typically maintained for safety, and prior studies and experiments indicate that the operating flow rates remain well below this maximum. Therefore, the following upper bounds were imposed:

$$Q_{F,max} = Q_{D,max} = Q_{IV,max} = 20\ cm^3 min^{-1} \quad (9)$$

Imposing these constraints requires additional modifications to the sampled operating conditions set. Although LHS is not inherently designed to generate feasible values for dependent variables under strict inequality and mass-balance restrictions, it still offers important advantages as a sampling strategy, and its limitations can be mitigated. In particular, a rejection-based brute-force method can be introduced into the LHS procedure, such that candidate operating conditions are accepted only if all constraints are satisfied, otherwise, they are discarded and resampled. However, because the probability of pseudo-randomly generated samples meeting all constraints may be low, this approach can lead to excessive and unnecessary computational effort. For this reason, the sampling procedure was modified to increase the probability of generating feasible operating conditions as much as possible.

To improve efficiency and ensure compliance with the constraints, the desired operating conditions were generated using a sequential approach rather than directly from LHS. First, the lowest flowrate, the feed flowrate, $Q_F$, was sampled, as well as two increments. The sum of $Q_F$ with the first increment $I_1$ would dictate the extract flowrate, $Q_X$, while the sum of this flowrate with the second increment $I_2$ would yield the eluent flowrate $Q_D$. The raffinate flowrate would be obtained through the global mass balance compliance. Both the flow rates and the increments were constrained by the maximum flow rate imposed by (28). In addition, a new restriction was introduced, the sum of the flowrate and the increments could not exceed the maximum allowed flowrate. This procedure ensures that all operating constraints are satisfied. The recycling flowrate and the switching time operating conditions were sampled directly through LHS. Therefore:

$$\theta_{OC,LHS} = [Q_F, I_1, I_2, Q_{IV}, t_s] \quad (10)$$

with all the remaining operating conditions being generated afterwards.

Under these constraints and boundaries, preliminary tests reveal that the LHS technique has an approximate probability of 17% of providing adequate operating conditions that ensure a correct SMB operation. Given the high efficiency of LHS in producing samples, this brute-force approach does not pose a significant computational burden within the overall methodology, and this likelihood value was deemed satisfactory.

Once the operating conditions were defined, these were employed in the representative mathematical model to generate *in silico* experiments. From these simulations, the history of the concentrations in the extract and raffinate streams were recorded and archived for subsequent use by the predictive model. To better mimic realistic plant operation and sensor limitations, measurement noise was introduced into the simulated outputs. Finally, the operating conditions and relevant metadata for each experiment were stored to facilitate the operation of the virtual model pair.

## Virtual Plant-Model Structure – Predictive model

The predictive model, which has the goal of replicating the representative model behavior, is embedded within a PSO framework. The PSO algorithm minimizes the residuals between the outputs of the predictive model and the data generated by the representative model, by modifying the parameter values present in the predictive mathematical model. This is achieved by developing an appropriate objective function and then employing an adequate number of PSO particles and iterations. Each particle represents a complete set of *in silico* experiments, including their associated metadata, with the objective of identifying a set of parameter values that accurately predicts all of the representative model's outputs. The chosen parameters to be included in the estimated set, considering the option of using a Linear + Langmuir isotherm, are:

$$\theta_p = [k_{LDF,i}, D_{ax,c}, K_i, Q, b_i] \quad (11)$$

with $i$ denoting the species, hence, $i = A, B$ in a binary mixture, and $c$ pertaining to the column number, so, $c = 1, 2, \ldots, 6$. This means the PSO technique will estimate 13 parameters.

To create a sufficiently autonomous environment, it is necessary to implement fail-safes to address the possibility of simulation error or other computational issues. Given the structural differences between the virtual and representative models, the same operating conditions can produce different results, making two limitations particularly critical: the possibility of non-convergence, and excessively long computation times due to convergence. To address the first obstacle, the solution was to introduce a variable within the mathematical model that indicates convergence status. If the variable changes to a

state of non-convergence, a predefined objective function value is assigned, and the simulation is terminated prematurely. For the second challenge, a parallel timer was implemented using MATLAB's Parallel Computing Toolbox, allowing the simulation to be interrupted once a predefined maximum runtime is reached. If the simulation still does not finish after this time limit, the same predefined objective function value is assigned, ensuring robust and fully automated operation.

When simulations are successful, the objective function values are obtained by using a modified Mean Square Error (MSE) function:

$$J(\theta_p) = \sum_{j}^{N_{exp}} MSE_j \tag{12}$$

$$MSE = \frac{1}{N}\sum_{t}^{N}(y_{predictive,t} - y_{representative,t})^2 \tag{13}$$

in which $j$ is the experiment number from a maximum of $N_{exp}$ experiments and $N$ is the amount of time instances where the residuals were determined. With this process, it may be possible to demonstrate that structural differences between the predictive and representative models, analogous to those encountered in RTO systems with a real unit and its mathematical model, do not prevent the successful operation of the framework.

## RESULTS

First, *in silico* experiments were generated through the methodology described in the last section. The simulations were executed on a computer equipped with 32 GB of RAM and an Intel® Core™ i9-9900K CPU @ 3.60 GHz with eight processing cores. By taking advantage of MATLAB's Parallel Computing Toolbox, which allows one simulation to be executed per CPU core, eight experiments were generated in parallel, one per available core.

The operating conditions sampled by LHS for each experiment are presented in the Supplementary Material. The data yielded by the *in silico* experiments were properly archived and manipulated for an appropriate use by the virtual model and PSO framework. The total computational time required to generate all the *in silico* experiments was 190 seconds. Notably, since parallel computing was used, some experiments took more computational effort than others.

Before executing the PSO algorithm, a benchmark value was obtained as a means to measure the evolution of the objective function. As this separation process pertains to the separation of a racemic mixture of ketoprofen, parameters from literature were used to generate this benchmark value [20]. These parameters were introduced in the virtual model, and the alignment of the data was evaluated for each experiment, yielding a value of 0.3041 for the objective function value. It is important to note that these values were obtained comparing output average cyclic concentrations.

The PSO was then executed with 10 particles throughout 25 iterations. The set of parameters that best adjusted against the eight *in silico* experiments' datapoints are presented in Table 1.

**Table 1:** Set of parameter values generated by the PSO for the predictive model that best describe the plant model behavior.

| Parameters | Value |
|---|---|
| $\boldsymbol{k_{LDF,A}}$ / $min^{-1}$ | 0.690 |
| $\boldsymbol{k_{LDF,B}}$ / $min^{-1}$ | 0.303 |
| $\boldsymbol{D_{ax,1}}$ / $cm^2min^{-1}$ | 0.032 |
| $\boldsymbol{D_{ax,2}}$ / $cm^2min^{-1}$ | 0.069 |
| $\boldsymbol{D_{ax,3}}$ / $cm^2min^{-1}$ | 0.100 |
| $\boldsymbol{D_{ax,4}}$ / $cm^2min^{-1}$ | 0.021 |
| $\boldsymbol{D_{ax,5}}$ / $cm^2min^{-1}$ | 0.073 |
| $\boldsymbol{D_{ax,6}}$ / $cm^2min^{-1}$ | 0.050 |
| $\boldsymbol{K_A}$ / $-$ | 0.885 |
| $\boldsymbol{K_B}$ / $-$ | 0.916 |
| $\boldsymbol{Q}$ / $mg\ cm^{-3}$ | 8.037 |
| $\boldsymbol{b_A}$ / $cm^3mg^{-1}$ | 0.021 |
| $\boldsymbol{b_B}$ / $cm^3mg^{-1}$ | 0.042 |

By employing these parameters in the virtual model, the alignment between the virtual model pair yielded a value of 0.0336, lower than the benchmark set, showcasing improvement originated by the developed methodology. Another aspect that reveals extreme importance within this work is computational time, since an RTO framework needs to operate quickly to accompany the unit's changes in behavior in real time. To operate this PSO algorithm, as described before, all 250 simulations took approximately 37000 seconds, which is equivalent to 10.5 hours. Although this value is not appropriate for an in-line optimization framework, it is expected that during the operation of the RTO, less simulations will be employed, reducing the computational effort needed and, consequently, the operation time.

A revised simulation study comprising 16 distinct experiments, 2 per CPU core, was conducted using a PSO algorithm configured with 15 particles and 25

iterations, with the aim of evaluating the reproducibility and robustness of the proposed methodology. Additionally, the feasibility of reducing the number of discretization intervals as a strategy to decrease computational time without compromising result accuracy was investigated. To this end, the adsorption columns were discretized into 20 spatial intervals, while the dead volume elements were represented using 5 intervals. The corresponding operating conditions are provided in the Supporting Information. The estimated parameters obtained from this analysis are presented in Table 2.

**Table 2:** Set of parameter values generated by the PSO for the predictive model that best describe the plant model behavior, for 16 in silico experiments.

| Parameters | Value |
|---|---|
| $k_{LDF,A}$ / $min^{-1}$ | 0.300 |
| $k_{LDF,B}$ / $min^{-1}$ | 0.300 |
| $D_{ax,1}$ / $cm^2 min^{-1}$ | 0.096 |
| $D_{ax,2}$ / $cm^2 min^{-1}$ | 0.100 |
| $D_{ax,3}$ / $cm^2 min^{-1}$ | 0.017 |
| $D_{ax,4}$ / $cm^2 min^{-1}$ | 0.080 |
| $D_{ax,5}$ / $cm^2 min^{-1}$ | 0.089 |
| $D_{ax,6}$ / $cm^2 min^{-1}$ | 0.021 |
| $K_A$ / $-$ | 1.000 |
| $K_B$ / $-$ | 1.328 |
| $Q$ / $mg\ cm^{-3}$ | 9.632 |
| $b_A$ / $cm^3 mg^{-1}$ | 0.060 |
| $b_B$ / $cm^3 mg^{-1}$ | 0.040 |

In this case, the objective function values were computed using all available output stream data points, instead of only calculating residuals with average cyclic compositions, enabling a direct comparison between methodologies during the development of the virtual RTO framework. The best objective function value obtained using the PSO algorithm was 11.84, representing a significant improvement over the reference value of 24.27 calculated for the reference parameters. The total computational time required for this estimation was 15870 seconds, equivalent to 4.4 hours. These results indicate that the proposed methodology is readily reproducible and capable of delivering satisfactory optimization performance, even when reduced spatial discretization intervals are employed. This conclusion, together with the previously stated assumption regarding the reduced scale of the PSO inserted into the virtual RTO, is another guarantee that computational effort and operation time will not present a detrimental issue in later studies.

With these results, it is possible to observe that the virtual model pair test provides favorable information regarding the structure distinctions between the plant and the mathematical model. Since in this case study these differences were not detrimental, the same can still be expected from an analogous real-scenario RTO + SMB system.

## CONCLUSIONS

This work presented a virtual-model pair that virtually represents the intricacies of the predictive elements of a real RTO framework. The goal of this work pertained to explore the possibility of a virtual predictive model predicting the behavior of representative model simulations, denoted as *in silico* experiments, much like what happens in the predictive structure of a common RTO system. With the proposed methodology, eight different *in silico* experiments were correctly executed, each one with its own operating conditions. Under a PSO algorithm, parameters were generated that enable the virtual model to accurately predict the behavior of the representative model, even though structural differences were present between mathematical models. Similar conclusions were drawn from the study involving 16 experiments, with the additional finding that reducing spatial discretization intervals significantly decreases computational effort without compromising optimization performance.

For future work, an uncertainty evaluation is deemed necessary as the first next step. Moreover, the creation of a more robust estimation methodology is proposed, with more diverse operating conditions and with the ability of exploring other adsorption isotherm structures, while maintaining the fast simulation times, essential for an adequate operation of an RTO framework.

## ABSTRACT

Cryogenic air separation units (ASUs) are the primary industrial technology for producing high purity oxygen, nitrogen, and argon gases at commercial scale. Cryogenic ASUs are large consumers of electricity, making them ideal candidates for market-driven operation research in today's volatile and uncertain manufacturing environments. To maximize profitability, ASU operation must dynamically adapt to changing market conditions as they evolve. This work explores the implementation of a rolling-horizon scheduling (RHS) strategy for the real-time market-driven operation of a high-dimensional ASU model with inventory, responding to uncertainty in future plant demand and electricity price forecasts by periodically rescheduling in response to updated market information. A dynamic latent variable-based surrogate model (LV-SM) is used within the scheduling framework as a computationally efficient substitute for an existing first-principles-based ASU model. Results show that RHS and plant inventory are effective strategies for handling uncertainties in the future market forecasts, while the LV-SM shows computational performance suitable for real-time implementation. With this scheduling framework in place, extensions involving expanded case studies and uncertainty-aware optimization are planned for future work.

**Keywords**: Dynamic Optimization, Surrogate Modeling, Air Separation, Rolling-horizon, Scheduling, Principal Component Analysis, Neural Network

## INTRODUCTION

Energy-intensive cryogenic air separation units (ASUs) are ideal candidates for real-time market-driven scheduling and optimization studies in today's uncertain and volatile manufacturing environments. To maximize profitability, ASU operation must dynamically adapt to changing market conditions as they evolve. Rolling-horizon scheduling (RHS) strategies provide a promising scheduling approach for ASU systems when responding to uncertainty in market or plant parameters. In these approaches, an initial plant schedule may be iteratively refined according to new market data or plant conditions. For instance, work by Pattison et al. [1] and Kelley et al. [2] studied the closed-loop RHS of an ASU using reduced-order scale bridging models, where rescheduling was performed in response to forecast updates or disturbances in parameters such as electricity prices, ambient temperature, and plant demand. Economic model predictive control (eMPC) schemes are also implemented in a rolling-horizon fashion and have been applied to ASU systems in work such as Schäfer et al. [3] and Caspari et al. [4]. Alternative scheduling approaches which explicitly model parameter uncertainty have also been explored, including robust optimization [5], chance-constrained programming [6], and stochastic programming techniques [7].

This work explores a rolling-horizon scheduling (RHS) strategy for the market-driven operation of a high-dimensional ASU model. To achieve computation times suitable for real-time implementation, the full-order model (FOM) originally developed by Cao et al. [8] is substituted by a dynamic surrogate model. This work implements a latent variable-based surrogate model (LV-SM), previously developed and applied in McKenzie et al. [9]. The LV-SM is trained from FOM simulation data and uses a ReLU-activated neural network to perform dynamic step-ahead predictions within a latent-variable subspace derived from principal component analysis (PCA). This modeling technique enables substantial computation time reduction, trust region enforcement to promote scheduling solution validity, and the ability to

approximate all original states of the FOM. The viability of RHS approaches using the LV-SM for real-time market-driven ASU operation under specific market conditions is assessed in this work. With the rolling-horizon framework in place, future work may consider expanded case studies which identify areas where explicit consideration of uncertainty in the problem formulation using a rolling-horizon stochastic scheduling strategy yields improved economic performance and operational robustness over deterministic alternatives.

## PROCESS MODEL DESCRIPTION

A process flow diagram of the ASU model used as a basis for this study is provided in **Figure 1**.

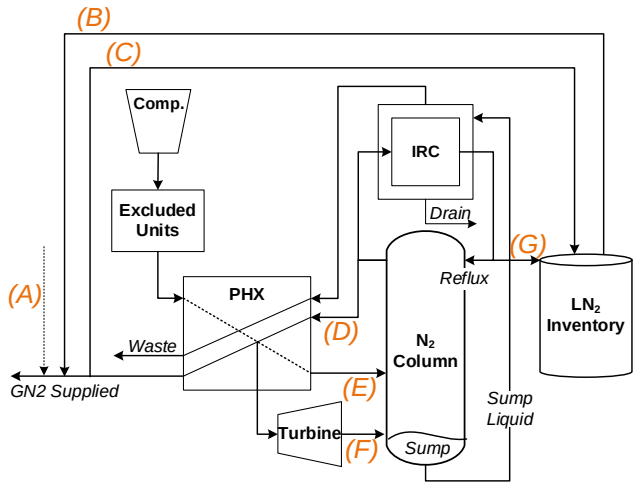

**Figure 1.** Cryogenic ASU diagram. Optimization-relevant variables are labelled in orange text as follows: (A) purchased $GN_2$, (B) vaporized $LN_2$, (C) condensed $LN_2$, (D) $GN_2$ produced, (E) liquid air feed, (F) vapor air feed, (G) $LN_2$ produced. Abbreviations: integrated reboiler-condenser (IRC), primary heat exchanger (PHX), compressor (Comp), gaseous nitrogen ($GN_2$), liquid nitrogen ($LN_2$).

The process begins with the compression and purification of ambient air which is cooled against cryogenic product and waste streams from the column in a multi-stream primary heat exchanger (PHX). A fraction of the air feed is drawn partway through the PHX and is expanded via a turbine prior to entering the column as vapor air. The remaining air enters the column as liquid air after passing entirely through the PHX. The column operates at cryogenic conditions and is configured to separate air into high-purity gaseous nitrogen ($GN_2$) and an oxygen-rich sump liquid. The $GN_2$ either exits the system as product via the PHX or continues to the integrated reboiler-condenser (IRC) where heat exchange occurs with the sump liquid. The resulting liquid nitrogen ($LN_2$) may return to the column as reflux or be stored as inventory. During market-driven operation, inventory may be vaporized or condensed as needed. The ASU was developed using the gPROMS software as a first-principles model containing 3819 state variables, adapted from Cao et al. [8]. For further modeling details, the reader is referred to Cao et al. [8].

## SURROGATE MODEL DESCRIPTION

This work implements a latent variable-based surrogate model (LV-SM), previously developed and applied by McKenzie et al. [9]. To address the high dimensionality of the FOM, the LV-SM performs dynamic step-ahead predictions within a latent variable subspace derived from principal component analysis (PCA). PCA can be used to transform a high-dimensional matrix $X \in \mathbb{R}^{n \times j}$ into a low dimensional latent variable subspace $T \in \mathbb{R}^{n \times a}$ by:

$$T = XP \tag{1}$$

where $P \in \mathbb{R}^{j \times a}$ represents the PCA model loadings with columns representing principal components. The optimal low-rank approximation of the original matrix, $\hat{X}$, is calculated as:

$$\hat{X} = TP^T \tag{2}$$

In the LV-SM, a 10-component PCA model transforms a vector of initial FOM states at steady-state operation $\boldsymbol{x}_0^{SS} \in \mathbb{R}^{3819}$ into a vector of initial latent states $\boldsymbol{\tau}_0 \in \mathbb{R}^{10}$, drastically reducing the problem dimension. Dynamic step-ahead predictions of latent states, in addition to an estimation of the squared prediction error (SPE) statistic derived from the PCA model, are predicted as a function of latent states and surrogate model inputs at discrete time steps using a ReLU-activated multilayer perceptron (MLP) neural network:

$$\left[\mathrm{SPE}_{k+1}, \boldsymbol{\tau}_{k+1}^T\right]^T = \boldsymbol{f}_{\mathrm{N}}(\boldsymbol{\tau}_k, \boldsymbol{u}_k) \; \forall k \in K^- \tag{3}$$

where $\boldsymbol{\tau}_k$ and $\boldsymbol{u}_k$ represent the vector of latent states and surrogate model inputs at a given time step $k$ and $\boldsymbol{f}_{\mathrm{N}}$ represents the neural network. In this work, the set $K = \{0, \dots, N_{\mathrm{K}}\}$ denotes all discrete time points, $K^- = \{0, \dots, N_{\mathrm{K}} - 1\} \subset K$ denotes the subset of discrete time points excluding the last, and $K^+ = \{1, \dots, N_{\mathrm{K}}\} \subset K$ denotes the subset of discrete time points excluding the initial point. Constrained FOM states are calculated using the PCA reverse-transform while all other FOM states are excluded from the optimization model for efficiency. The SPE metric is constrained within confidence limits during optimization to enforce a trust-region. Since the SPE metric describes the prediction error of a particular observation, an SPE value exceeding confidence limits suggests poor PCA model representation. Confidence limits were computed based on the SPE distribution of the surrogate

model's training data using critical values from a chi-squared distribution [10]. The 95% and 99% SPE confidence limits are commonly used thresholds. The 99% confidence limit is used here and was shown in previous work to promote surrogate model prediction accuracy while being less restrictive than lower limits [9].

The LV-SM was trained from FOM simulation data collected using a bounded random walk sampling method. A step input from the range $[-h_i, +h_i]$, where $h_i$ is the allowable step size per input variable $u_i$, was applied to each input at an interval of $\Delta t = 0.25$h to match the control intervals used in the optimization formulation. Criteria were enforced during data collection to ensure that data remained physically realizable and within an operation region relevant to the optimization problem. The storage vessel was excluded from the FOM during data collection due to its simplicity and was modeled after LV-SM development without reduction. **Figure 2** shows the process flow diagram after substitution of the LV-SM.

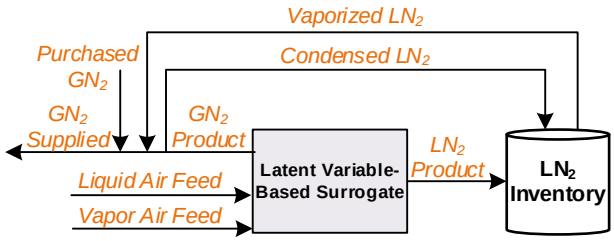

**Figure 2.** Substitution of the FOM by the LV-SM. Optimization-relevant variables are shown in orange text.

By operating within a reduced dimensional space, the LV-SM showed nearly a 1000-fold reduction in optimization computation time in previous work [9], while retaining high accuracy compared to the FOM in multistep-ahead simulation and dynamic optimization. The reader is referred to McKenzie et al. [9] for more detailed information on data collection, training, and validation of the LV-SM. Note that McKenzie et al. [9] embedded neural network equations in the optimization formulation using complementarity conditions. Direct inclusion of complementarity constraints often causes numerical difficulties due to unsatisfied nonlinear programming constraint qualifications [11]. Complementarity constraint reformulation using the exact penalty reformulation presented in Ralph and Wright [12] is used in this work and showed improved solver performance. This technique introduces a complementarity constraint violation term to the objective function with a tunable penalty parameter used to enforce constraint satisfaction.

## MARKET-DRIVEN OPTIMIZATION UNDER UNCERTAINTY

A rolling-horizon scheduling (RHS) strategy is proposed to respond to market uncertainty by dynamically adjusting plant operation and inventory use according to evolving market forecasts. A schematic of the framework is shown in **Figure 3**.

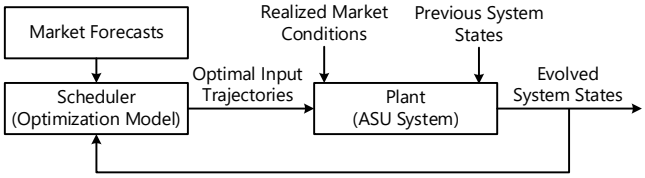

**Figure 3.** RHS strategy framework.

Upon each execution of the framework, an optimization model determines an optimal schedule over a specified horizon in anticipation of forecasted market conditions. An initial portion of the schedule, referred to as the rescheduling interval, is applied to the ASU plant. As time progresses forward in a rolling-horizon fashion, the remaining schedule is periodically refined upon in response to updated market forecasts and evolved system states. The LV-SM serves as the ASU model in the framework to enable real-time implementation while capturing the ASU's dynamic behavior at fine time scales. Future work may consider extension of the framework to explicitly model forecast uncertainty using stochastic optimization, such as done in Mathur et al. [13] for a hydropower system. Details of the optimization model, market forecasts, and plant model are provided in the following sections.

### Optimization Model Formulation

An optimal schedule consists of economically optimal operational decisions over the scheduling horizon, determined in response to market forecasts while satisfying operational and process model constraints. This is accomplished through the minimization of an economic objective function. Additional terms accounting for input move suppression and complementarity constraint satisfaction are also minimized. The deterministic objective function $z$ is defined as:

$$\min_{u_{i,k}} z = \Delta t \sum_{k\in K^-} \psi_k^{\text{Econ}} + m \sum_{i\in I} \sum_{k\in K} \eta_{i,k} + \frac{1}{\mu} \sum_{k\in K} \sum_{n_{\text{HL}}\in L} \zeta_{k,n_{\text{HL}}} \quad (4)$$

where $\psi_k^{\text{Econ}}$ represents the economic objective function (negative of profit), $\eta_{i,k}$ is an input move suppression term, $\zeta_{k,n_{\text{HL}}}$ is the complementarity constraint penalty term, the parameters $m$ and $\mu$ represent relative weights of the move suppression and complementarity constraint satisfaction terms, respectively, where $m > 0$ and $0 < \mu \leq 1$. Tuning was performed to select penalty weights $m = 0.1$ and $\mu = 0.01$. A value of $m = 0.1$ was observed to reduce nonprofitable fluctuations in the decision variables (as was observed in McKenzie et al. [9]) without

economic trade-off, while a value of $\mu = 0.01$ was observed to ensure complementarity constraint satisfaction. Further reductions in $\mu$ place higher weight on complementarity constraint satisfaction, however, were noted to increase computation time without providing additional benefit. The set $L = \{1, \dots, N_{HL}\}$ is the set of all hidden-layer nodes in the MLP network and $I = \{1, \dots, 7\}$ denotes the set of decision variables. The decision variables are defined as follows for all $k \in K^-$:

- $u_{1,k}$: Liquid air feed flowrate to the column, $F_k^{\mathrm{LF}}$
- $u_{2,k}$: Vapor air feed flowrate to the column, $F_k^{\mathrm{VF}}$
- $u_{3,k}$: $LN_2$ production from IRC to inventory, $F_k^{\mathrm{prod,\,LN_2}}$
- $u_{4,k}$: $GN_2$ flowrate from column to product stream via the PHX, $F_k^{\mathrm{GN_2}}$
- $u_{5,k}$: Vaporized $LN_2$ flowrate, $F_k^{\mathrm{vap,\,LN_2}}$
- $u_{6,k}$: $GN_2$ liquefaction flowrate, $F_k^{\mathrm{cond,\,GN_2}}$
- $u_{7,k}$: Amount of $GN_2$ purchased externally, $F_k^{\mathrm{OS}}$

These variables are applied to the plant in a piecewise-constant manner in regularly spaced control intervals of $\Delta t = 0.25$h, which match the prediction interval of the LV-SM. The economic objective function $\psi_k^{\mathrm{Econ}}$ represents the negative of the hourly operating profit and is calculated as:

$$\psi_k^{\mathrm{Econ}} = C_k^{\mathrm{elec}} W_k^{\mathrm{comp}} + C_k^{\mathrm{cond}} F_k^{\mathrm{cond,\,GN_2}} + C_k^{\mathrm{vap}} F_k^{\mathrm{vap,\,LN_2}} + C_k^{\mathrm{OS}} F_k^{\mathrm{OS}} - C_k^{\mathrm{GN_2}} F_k^{\mathrm{sale}} \forall\, k \in K^- \quad (5)$$

where $C_k^{\mathrm{elec}}, C_k^{\mathrm{cond}}, C_k^{\mathrm{vap}}, C_k^{\mathrm{OS}}$, and $C_k^{\mathrm{GN_2}}$ represent prices of electricity, $GN_2$ liquefaction, $LN_2$ vaporization, $GN_2$ purchased from outside sources, and sold $GN_2$ product, respectively. Compressor shaft work is represented by $W_k^{\mathrm{comp}}$; $F_k^{\mathrm{cond,\,GN_2}}$ and $F_k^{\mathrm{vap,\,LN_2}}$ represent the condensation rate and vaporization rate of $GN_2$; $F_k^{\mathrm{OS}}$ represents the amount of purchased $GN_2$; and $F_k^{\mathrm{sale}}$ represents the rate of $GN_2$ product sold. Note that the summation in the objective function excludes the final discrete point since the quantity $\Delta t \psi_{N_K-1}^{\mathrm{Econ}}$ accounts for costs accumulated over the final control interval. Sold $GN_2$ is calculated as:

$$F_k^{\mathrm{sale}} = F_k^{\mathrm{GN_2}} - F_k^{\mathrm{GN_2,\,cond}} + F_k^{\mathrm{LN_2,\,vap}} + F_k^{\mathrm{OS}} \;\forall\; k \in K^- \quad (6)$$

The move suppression term $\eta_{i,k}$ is calculated as the absolute difference between successive inputs:

$$\eta_{i,0} = |u_{i,0} - u_i^{\mathrm{prev}}| \quad \forall\; i \in I \quad (7)$$

$$\eta_{i,k} = |u_{i,k} - u_{i,k-1}| \quad \forall i \in I,\, k \in \{1, 2, \dots, N_K - 1\} \quad (8)$$

At the initial time point of each rolling-horizon execution, $\eta_{i,0}$ is calculated relative to input values $u_i^{\mathrm{prev}}$ which occur immediately prior to the beginning of the scheduling horizon. The values of $u_i^{\mathrm{prev}}$ are defined based on values from the previous rolling-horizon execution, except for the first execution of the algorithm where they are initialized using the plant's steady-state operating conditions. Since the derivatives of the absolute value function are discontinuous, these equations were reformulated using the following linear constraints:

$$\eta_{i,k} \geq 0 \quad \forall\, i \in I,\, k \in K^- \quad (9)$$

$$-\eta_{i,0} \leq u_{i,0} - u_i^{\mathrm{prev}} \leq \eta_{i,0} \quad \forall i \in I \quad (10)$$

$$-\eta_{i,k} \leq u_{i,k} - u_{i,k-1} \leq \eta_{i,k} \forall\, i \in I,\, k \in \{1, \dots, N_K - 1\} \quad (11)$$

Solutions of the optimization problem must satisfy the embedded LV-SM model (**Equation 3**). SPE trust region constraints constrain the predicted SPE statistic within its 99% confidence limit. Finally, several operational constraints summarized in **Table 1** are considered.

**Table 1:** Formulation of operational constraints.

| Description | Formulation | |
|---|---|---|
| Purity | $\mathrm{PPMO}_k \leq \mathrm{PPMO}^{UB}$ | $\forall k \in K^+$ |
| Sump level | $l^{LB,\,\mathrm{sump}} \leq l_k^{\mathrm{sump}} \leq l^{UB,\,\mathrm{sump}}$ | $\forall k \in K^+$ |
| Reboiler level | $l^{LB,\,\mathrm{reb}} \leq l_k^{\mathrm{reb}} \leq l^{UB,\,\mathrm{reb}}$ | $\forall k \in K^+$ |
| Dew point at turbine outlet | $T_k^{\mathrm{dew,\,TBout}} \leq T_k^{\mathrm{TBout}}$ | $\forall k \in K^+$ |
| Storage level | $0 \leq V_k^{\mathrm{storage}} \leq V^{UB,\,\mathrm{storage}}$ | $\forall k \in K^+$ |
| Final storage capacity | $V_{N_k}^{\mathrm{storage}} \geq V^{\mathrm{final,\,storage}}$ | $\forall k \in K^+$ |
| Compressor surge | $P_k^{\mathrm{surge}} \leq 100\%$ | $\forall k \in K^+$ |
| Column flood | $P_k^{\mathrm{flood}} \leq 100\%$ | $\forall k \in K^+$ |
| Bubble point at liq. air feed | $P_k^{\mathrm{BP}} \leq 100\%$ | $\forall k \in K^+$ |
| Dew point at turbine inlet | $P_k^{\mathrm{DP}} \leq 100\%$ | $\forall k \in K^+$ |
| Demand met | $F_k^{\mathrm{sale}} = F_k^{\mathrm{GN_2,\,demand}}$ | $\forall k \in K^-$ |
| Input bounds | $u_i^{LB} \leq u_{i,k} \leq u_i^{UB}$ | $\forall i \in I,$ $k \in K^-$ |
| Max step size in inputs | $\eta_{i,k} \leq h_i$ | $\forall i \in I_{SM},$ $k \in K^-$ |

In **Table 1**, PPMO represents parts per million oxygen in the $GN_2$ product; $l^{\mathrm{sump}}$ and $l^{\mathrm{reb}}$ are sump and reboiler liquid levels; $T^{\mathrm{dew,\,TBout}}$ and $T^{\mathrm{TBout}}$ are dew point and discharge temperatures at the turbine outlet; $V^{\mathrm{storage}}$ represents storage vessel liquid volume; $P^{\mathrm{surge}}, P^{\mathrm{flood}}, P^{\mathrm{BP}}$, and $P^{\mathrm{DP}}$ represent values relative to constraint limits; $F^{\mathrm{GN_2,\,Demand}}$ and $F^{\mathrm{sale}}$ represent $GN_2$ demand and amount sold; and $h_i$ are step sizes used for input variable move restriction which match those used during data collection. Lastly, $I_{\mathrm{SM}} = \{1, \dots, 4\} \subset I$ is the subset of input variables corresponding to the surrogate model inputs. The operational constraints of **Table 1** ensure that product is supplied at acceptable purity, equipment and safety

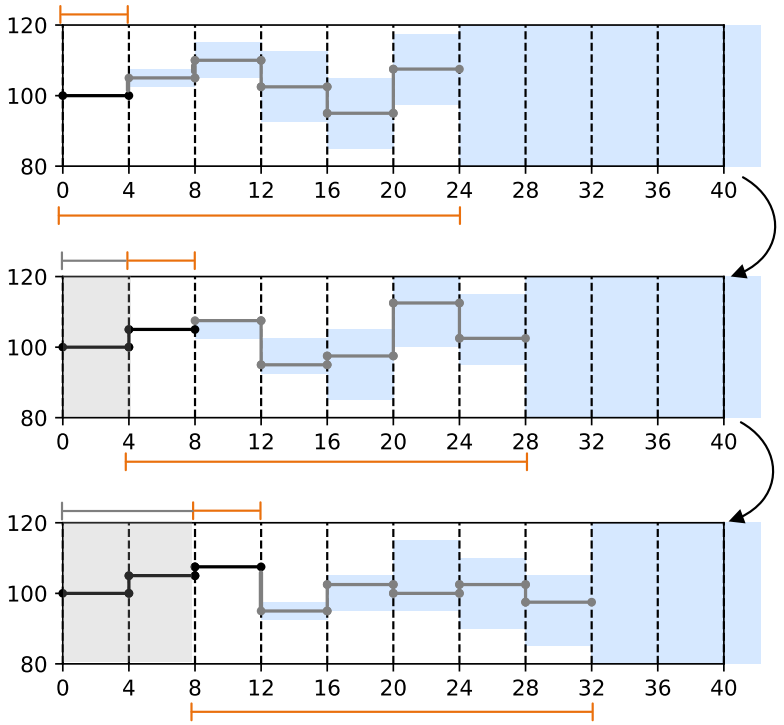

**Figure 4.** Example of three consecutive demand forecasts with simulated market updates. Realized demand levels are shown using black solid lines, forecasted demand levels using gray solid lines, and estimated demand regions using blue shading.

specifications are met, and modeling assumptions are upheld. Note that the storage vessel volume percentage at the end of the scheduling horizon is maintained above a threshold, $V^{\text{final, storage}}$, which is specified at 25%. An additional constraint enforces equality between the amount of product sold and the product demand. By **Equation 6**, any oversupplied product will be condensed to storage while any unmet demand will be supplied either from inventory or by purchase from outside sources. Move restrictions are enforced on surrogate model input variables to ensure agreement with the step sizes used in the surrogate model's training process.

Finally, the optimization problem is subject to the following set of initial conditions:

$$\boldsymbol{\tau_0} = \boldsymbol{\tau}_{\text{init}} \tag{12}$$

$$V_0^{\text{storage}} = V_{\text{init}}^{\text{storage}} \tag{13}$$

where $\boldsymbol{\tau}_{\text{init}}$ and $V_{\text{init}}^{\text{storage}}$ are the initial conditions for the PCA model scores and storage vessel volume percentage. For the first execution of the rolling-horizon algorithm, the initial scores are calculated as the product of a vector of FOM states at a known steady-state operation and the PCA model loadings, $\boldsymbol{x}_0^{\text{SS}}P$, whereas the initial storage vessel volume percentage is specified to be 25%. For all rolling-horizon executions after the first, these initial conditions are updated based on evolved system states from the plant.

## Plant Model Description

Scheduling decisions corresponding to the rescheduling interval are applied to the ASU plant upon each execution of the rolling-horizon strategy, as shown in **Figure 3**. Within the simulation model:

- Market parameters are at their realized conditions.
- Control trajectories for decision variables $F^{LF}, F^{\text{VF}}, F^{\text{LN}_2}$, and $F^{\text{GN}_2}$ are fixed at their values determined by the scheduler.
- Decision variables, $F^{\text{LN}_2,\text{ vap}}, F^{\text{LN}_2,\text{ cond}}$, and $F^{\text{OS}}$, can be recalculated in response to realized demand. Unmet demand is filled using inventory, if possible, or by purchasing from an external source at a high cost. Alternatively, oversupplied product is condensed to inventory to avoid wasted product.

The final item from the list above enables the plant to respond to market events that were not forecasted. As in the optimization model, the LV-SM model is used as a substitute for the FOM during simulation based on the

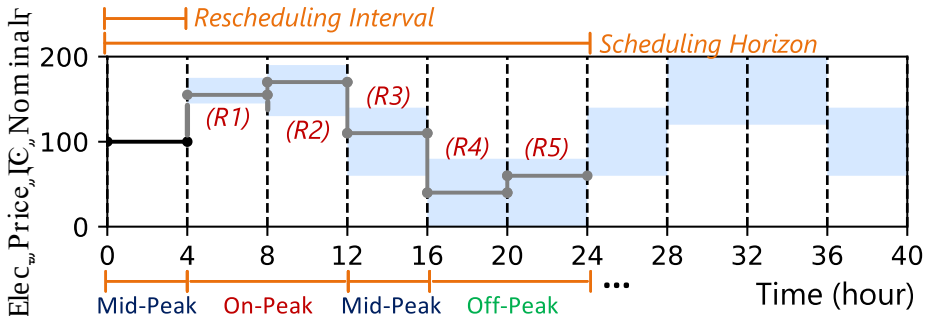

**Figure 5:** Example electricity price forecast. Realized prices are shown using black solid lines, forecasted prices levels using gray solid lines, and estimated price regions using blue shading.

assumption that discrepancies between simulations of the FOM and the LV-SM are sufficiently small. This assumption is supported by the high approximation accuracy of the LV-SM [9].

## Market Parameter Forecasts

In the absence of historical operating data, forecast models are assumed for the product demand and electricity price. These models generate forecasts by sampling a forecast scenario from within estimated regions where market parameter values are expected to fall. As time progresses, these estimated regions are updated in response to simulated evolution in market conditions with each successive rolling-horizon execution. Lastly, forecasted values near the beginning of each execution's scheduling horizon are assumed more accurate than latter values to reflect increased market uncertainty with time. An example of three consecutive demand forecasts is shown in **Figure 4**.

The product demand is allowed to vary every four hours and is bounded within ±20% of the initial demand value. At each execution, demand is assumed known only over the rescheduling interval. Estimated demand regions are labelled R1-R5, where the size of each region reflects the amount of forecast uncertainty present and relates to how far into the future that region is. Market updates are simulated with each new execution — demand within the rescheduling interval is realized by drawing uniformly from the previous forecast's R1 region, and new R1-R5 regions are vertically centered at randomly sampled levels within ranges corresponding to the previous execution. A demand forecast is generated by drawing uniformly from the discrete set of possible realized demand levels D = {80%, 82.5%, ..., 120%} which intersect with the estimated demand regions. Two demand forecast models with differing levels of forecast uncertainty are considered. The first demand forecast model (DF1) assumes that regions R1, R2, and R3-R5 have uncertainty band widths of 5, 10, and 20 units, respectively. The second demand forecast model (DF2) assumes that regions R1, R2, and R3-R5 have widths of 20, 30, and 40 units, respectively.

Two electricity price forecast models are assumed in a similar manner; however, the electricity price is assumed to follow a structured and repeating daily cycle to reflect the seasonality present in some real-world electricity prices. Each 24-hour period is divided into four repeating segments — mid-peak (four hours), on-peak (eight hours), mid-peak (four hours), and off-peak (eight hours). An example forecast is shown in **Figure 5**.

Two electricity price forecast models with differing levels of forecast uncertainty are considered. The first model (EF1) assumes that regions R1, R2, and R3-R5 have uncertainty band widths of 30, 60, and 80 units, respectively. The second model (EF2) assumes that regions R1-R2 and R3-R5 have widths of 80 and 160 units, respectively. Uncertainty regions for off-peak, mid-peak, and on-peak prices are clipped if they exceed specified ranges to ensure that seasonality in the price profiles is maintained. Electricity prices are represented as percentages relative to an assumed nominal price. Scaled off-peak prices are assumed to always fall within the range of [0%, 80%], mid-peak prices always within the range of [80%, 120%], and on-peak prices always within the range of [120%, 200%]. Electricity price forecasts are generated by drawing uniformly from the discrete set of possible scaled price levels P = {0%, 5%, ..., 200%} which intersect with the clipped price regions. The demand and electricity price forecast models are used in the case studies of the following section.

## Market-Driven Scheduling Case Studies

The RHS strategy is evaluated in terms of its economic performance and computation time requirements using several market-driven scheduling case studies. Economically optimal plant schedules are calculated over a cumulative 72-hour duration, where each rolling-horizon execution considers a 24-hour scheduling horizon, a 4-hour periodic rescheduling interval, and control interval spacing of $\Delta t = 0.25$h. The economic performance of the

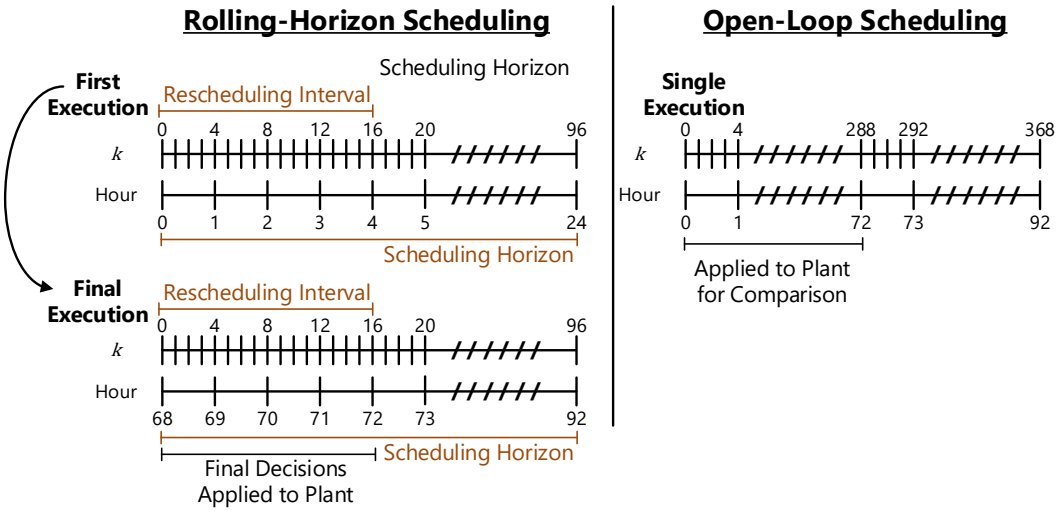

**Figure 6.** Discretization of RHS and OLS strategies

RHS strategy is compared to two open-loop scheduling (OLS) solutions for benchmarking. The first benchmark solution assumes perfect forecasts (PF) of market conditions across the 72-hour scheduling duration to provide an idealized upper bound on economic performance. The second OLS benchmark assumes limited knowledge of only the 24-hour initial forecast (IF), where mid-range values of demand and electricity prices are assumed for the remainder of the scheduling duration. To ensure consistency between the RHS and OLS solutions, the OLS solutions extend past the three-day scheduling window by the same duration as the final rolling-horizon execution; however, only the schedule from the first 72 hours is implemented to the plant for comparison. **Figure 6** provides a visual summary of the timing and discretization of the problem. The individual impacts of uncertainty in product demand and electricity price are evaluated using the four case studies outlined in **Table 2**. Due to the sampling method used when simulating market evolution and selecting forecasts, several unique subcases can be generated from the same initial forecast conditions (i.e. initial realized demand value, initial realized electricity price value, and initial R1-R5 region placement) for each of the DF1, DF2, EF1, and EF2 models. Therefore, each case study is repeated five times and average profits corresponding to the scheduling strategies, represented as percentages relative to profits obtained under the PF scenario, as well as the computation time required for RHS are reported in **Table 3**. Cases were executed on a Windows 10 Pro system (Intel Core i7-9700 CPU, 8 cores, 512GB SSD) using GAMSPy (v1.5.1) and the CONOPT (v4.36) solver within Python (v3.11.3).

**Table 2:** Summary of case studies investigated.

| Case | Demand | Electricity Price |
|---|---|---|
| C1 | Forecast (DF1) | Known |
| C2 | Forecast (DF2) | Known |
| C3 | Known | Forecast (EF1) |
| C4 | Known | Forecast (EF2) |

**Table 3:** Case results for average profit and solution time.

| Case | Strategy | Avg Profit (% of PF Profits) | Avg Execution Time(s) |
|---|---|---|---|
| C1 | IF | 89.88 | — |
| | RHS | 99.75 | 35.86 |
| | PF | 100.00 | — |
| C2 | IF | 87.37 | — |
| | RHS | 99.74 | 35.97 |
| | PF | 100.00 | — |
| C3 | IF | 99.91 | — |
| | RHS | 99.94 | 37.63 |
| | PF | 100.00 | — |
| C4 | IF | 99.91 | — |
| | RHS | 99.99 | 41.25 |
| | PF | 100.00 | — |

All scheduling strategies followed a store-then-utilize policy in their solutions, where storage was accumulated during times of low electricity prices and used during times of high electricity prices. The RHS strategy consistently demonstrated average economic performance on par with the PF solution. For example, the storage volume profile from the third realized profile in C2 is shown in **Figure 7**, showing storage usage trends which closely

align with the PF with minor discrepancies associated with overestimated or underestimated demands.

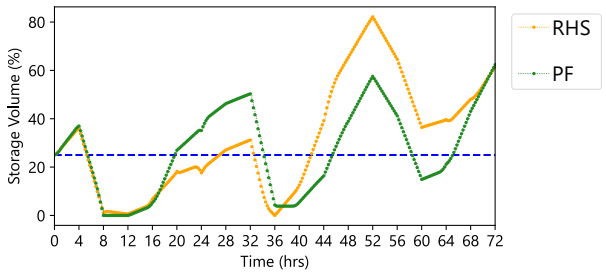

**Figure 7.** Storage volume profiles for the third realized profile in C2. Initial storage volume is indicated with a horizontal dashed blue line.

Interestingly, the average economic performance of the RHS strategy relative to the PF solution did not change significantly when forecast models with a greater degree of uncertainty were considered. This suggests that adequate response to changing future conditions could be achieved prior to suffering economic consequences. Furthermore, the RHS strategy significantly outperforms the IF solution in cases where demand forecast uncertainty is considered. Under demand uncertainty, the IF solution anticipated mid-range demands after the initial 24-hour forecast which resulted in periods of overestimation, underestimation, and suboptimal inventory usage, requiring the costly purchase of external $GN_2$ to fulfill demand on some occasions. By contrast, the RHS strategy offers only marginal improvements when electricity prices are uncertain and demand is known a priori. In these cases, no large profit losses related to unmet demand were observed and while the initial electricity price forecast was imperfect, it still followed the same periodic mid-peak, on-peak, and off-peak transitions as the realized electricity prices. This finding suggests that when plant demand and price seasonality are consistent and predictable, good scheduling decisions can be made even when specific price values are imperfectly forecasted.

Commonly activated constraints across the RHS solutions included:

- The $GN_2$ product purity constraint and reboiler low-level constraints, activated by increased $LN_2$ production and reduced column reflux rates.
- Maximum liquid feed rate and minimum vapor feed rate, activated to raise liquid content in the column for maintaining product purity.
- The compressor surge constraint, activated in response to reduced compressor air feed during periods of underproduction.
- Move restriction constraints placed on surrogate model inputs.
- Product demand satisfaction constraints.

Overall, results show that RHS combined with plant inventory are effective strategies for handling uncertainties in market forecasts under the case studies considered in this work. Notably, use of the LV-SM (implemented using a 15-minute prediction interval) offers solution times between 35-45 seconds per RHS execution, demonstrating high computational performance well within a timeframe suitable for real-time implementation considering the four-hour rescheduling interval used.

## CONCLUSIONS

This work implemented a rolling-horizon scheduling strategy for the real-time market-driven operation of an ASU. Several case studies involving assumed forecast models of plant demand and electricity prices compared the economic performance of the RHS strategy to two benchmark solutions — one based on a perfect forecast of future market conditions, and one based only on information available at the time of the initial forecast. On average, the RHS strategy demonstrated economic performance on par with the perfect forecast solution and showed significant advantages over the initial forecast solution in cases considering demand uncertainty. When electricity price seasonality and plant demand were consistent and predictable over the scheduling window, RHS offered no significant advantages. Overall, these findings suggest that periodic rescheduling combined with plant inventory provides an effective means of responding to the assumed market fluctuations considered in this work. Lastly, use of the LV-SM (implemented using a 15-minute prediction interval) within the RHS strategy offered solution times between 35-45 seconds per RHS execution, demonstrating high computational performance suitable for real-time implementation.

With the rolling-horizon framework in place, future work may consider expanded case studies which identify areas where explicit consideration of uncertainty in the problem formulation (e.g., using a stochastic rolling-horizon scheduling strategy) provides improved economic performance and operational robustness over deterministic solutions. These case studies may also include forecast models based in historical data with additional sources of uncertainty, particularly those that may lead to infeasible operation if not accounted for. To mitigate the additional computational complexity introduced by this extension, techniques such as decomposition, scenario reduction, and parallelization can be explored.

## ABSTRACT

Deep Kernel Learning (DKL) has emerged as a powerful framework for Bayesian Optimization (BO), via combining expressive representation learning models with typical Gaussian Processes (GPs) surrogate models. However, conventional DKL typically relies on weight-based feature extractors (e.g., multilayer perceptrons (MLPs)), which often lack interpretability and may suffer from overfitting under data scarcity or training instability, potentially leading to a degraded uncertainty quantification in GP models. Grounded in the Kolmogorov-Arnold representation theorem, this paper proposes a novel DKL-KAN framework that employs Kolmogorov-Arnold Networks (KANs) as adaptive feature extractors, formulating a DKL-KAN surrogate model. Unlike MLPs, the KANs learn data-driven univariate functions, yielding more sample-efficient and stable representations for regression under limited data regimes. Followed by the GP, the DKL-KAN facilitates end-to-end learning of expressive latent representations while maintaining robust uncertainty quantification. The proposed DKL-KAN framework is further validated with the Williams-Otto (W-O) process benchmarks. Compared to classical GPs and DKL-MLPs, the DKL-KANs consistently exhibit superior predictive accuracy and uncertainty calibration even under high-dimensional and scarce dataset. The results show that the KANs generate more structured and informative latent embeddings, thus enhancing the ability to capture complex physical nonlinearities in sparsely sampled edge regions of the design space where traditional models often falter. Moreover, the DKL-KAN is embedded into the BO and yields the efficient optimization performance on the W–O process benchmark, achieving faster early-stage improvement and converging to higher objective values. These results demonstrate the potential of DKL-KAN surrogates for accelerating BO in chemical engineering processes.

## 1. INTRODUCTION

Black-box optimization (BBO) has been a fundamental problem in many scientific and industrial applications, including process optimization[1], experimental design[2], drug discovery[3] and model hyperparameter tuning[4], where the objective function is expensive to evaluate and lacks accessible analytical expressions or gradient information. In the past decades, Bayesian Optimization (BO) has emerged as a premier framework in BBO, renowned for its ability to search global optima by balancing exploration and exploitation[5].

In BO, the crucial step is to develop a surrogate model to offer not only the mean predictions but also the uncertainty quantification for evaluating the acquisition function. Therefore, the Gaussian Process (GP) has been widely used in BO owing to its principled probabilistic formulation and kernel-based covariance structure. However, when applied to high-dimensional datasets, the GPs often suffer from significant computational costs for constructing the kernel matrix and kernel degeneracy, which may degrade the model performance. To resolve these limitations, Deep Kernel Learning (DKL) has been proposed to automatically learn the low-dimensional

latent embeddings and then feeding them to the GP models[6–8]. In practice, the MLPs are commonly used in most existing DKL approaches for their ability to learn flexible nonlinear feature representations from high-dimensional inputs. Singh et al.[9] proposed MLP-based DKL surrogate to convert multiple molecular representations to the latent space embedding and achieve accurate reaction yield predictions. Andrea et al.[10] developed a closed-loop DKL-based BO framework for porous lithium-ion cathode microstructure design, where a Generative Adversarial Network(GAN) generator is used to define the latent design space. Nevertheless, the limited interpretability, susceptibility to overfitting under scarce data, and poor training stability of MLPs often restrict their applicability in complex process optimization problems. Furthermore, according to prior studies, an inappropriate and over-parameterized feature extractor in DKL can lead to unreliable uncertainty estimation in BO[7].

Inspired by the Kolmogorov–Arnold representation theorem, Kolmogorov–Arnold Networks (KANs)[11], have recently emerged as a promising alternative approach to traditional MLPs. Unlike MLPs that rely on predefined activation functions to capture the nonlinearity, KANs employ learnable univariate functions as adaptive activations, enabling them to capture complex nonlinear relationships with enhanced interpretability and data efficiency. Numerous studies have demonstrated the great potential of KANs in modeling fluid dynamics, as well as in executing time-series classification and differential equation solvers[12, 13]. By providing more interpretable functional representations, KANs have shown more attraction for scientific discovery and mechanism-oriented analysis compared to MLPs[14].

Motivated by these observations, this work proposes a DKL-KAN model, in which a KAN serves as the feature extractor and is followed by a GP model within the DKL framework. The DKL-KAN model simultaneously learns the expressive latent representations and quantify the uncertainty, revealing good capture of data distribution and accurate predictions. The proposed DKL-KAN model is further integrated into the BO framework and applied to the benchmark Williams–Otto (W-O) process optimization problem. Compared to standard GPs (std-GPs) and DKL-MLP, the DKL-KAN model demonstrates a competitive performance, maintaining superior predictive accuracy, uncertainty calibration, and optimization efficiency even under high-dimensional and data-scarce regimes. Moreover, the DKL-KAN framework highlights improved interpretability and structural insight into the underlying process. The proposed DKL-KAN model offers new insights for addressing complex chemical process optimization problems.

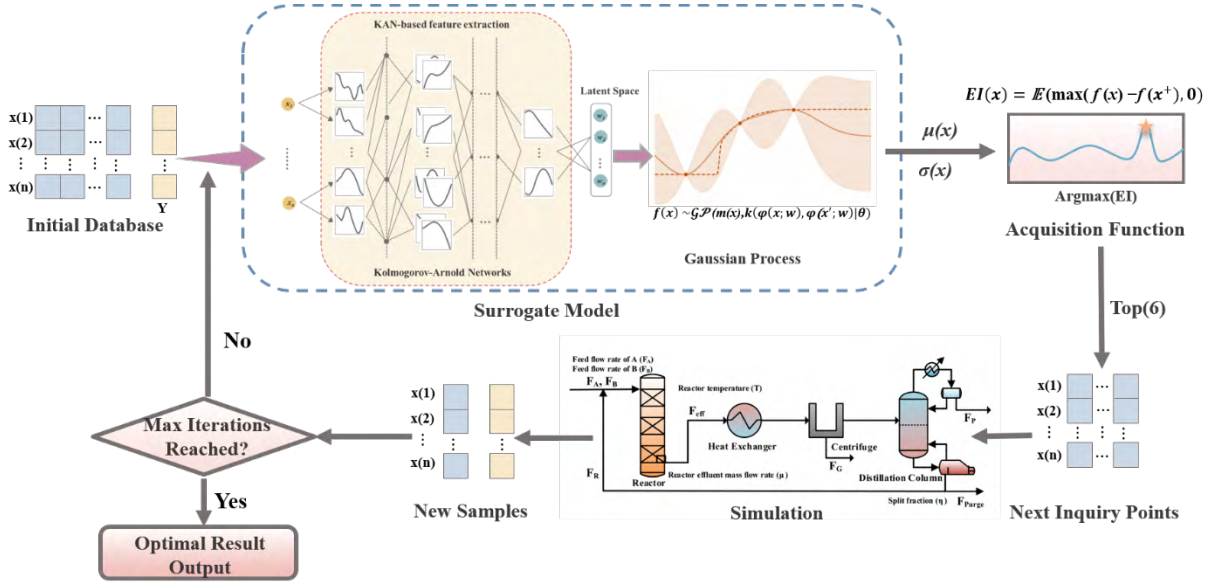

**Figure 1.** Schematic illustration of DKL-KAN framework for BO.

## 2. METHODLOGY

### 2.1 Optimization framework

In this work, a complex process optimization problem is considered to obtain the optimal operations under limited evaluation budget, which can be formulated as follows:

$$\max\ y = f(x) \tag{1}$$

$$s.t.\, x^{lb} \le x \le x^{ub}$$

$$x \subseteq R^n$$

Where $y$ denotes a scalar metric to be optimized, such as

annual profit or process yields. $x$ represents continuous decision variables, such as temperature, flow rate, and pressure. To solve the problems, the overall optimization framework which combines DKL-KAN and BO can be illustrated in Figure 1. The framework is structured as follows:

1. A small-batch dataset is generated with Sobol' sequence[15] from the design space and evaluated to get the scaler metric via process simulations.

2.With the existing dataset, the DKL-KAN surrogate model is developed by combining a KAN model as a feature extractor and a GP model which maps the normalized latent embeddings to predictive means and covariances in an end-to-end training manner.

3.Using the DKL–KAN surrogate, the expected improvement (EI) values, also known as the acquisition function, are evaluated over the candidate set. A next batch of sampling points are determined by maximizing the EI.

4.The suggested candidates from EI are subsequently evaluated in the simulation environment or retrieved from the dataset to obtain new observations, which are appended to the training set for updating the surrogate model in the next iteration.

5.The procedure terminates when the maximum number of validation iterations is reached, and the optimal solution identified so far is reported; otherwise, the workflow returns to Step 2 to update the surrogate model and continues iteratively.

## 2.2 Kolmogorov-Arnold Networks

KANs are theoretically grounded in the Kolmogorov-Arnold representation theorem[11] which asserts that any multivariate continuous function $f: [0,1]^n \to \mathbb{R}$ can be decomposed as a combination of univariate functions:

$$f(\mathbf{x}) = f(x_1, \ldots, x_n) = \sum_{q=1}^{2n+1} \phi_q \left( \sum_{p=1}^{n} \varphi_{q,p}(x_p) \right) \tag{2}$$

where $\varphi_{q,p}$ and $\phi_q$ denote univariate continuous functions. While the classical theorem restricts the architecture to a fixed depth, modern KANs generalize this into a deep stacked structure. For a network with $|L|$ layers, the forward pass is represented as a composition of functional layers:

$$\mathrm{KAN}(\mathbf{x}) = \left(\phi_{|L|-1} \circ \phi_{|L|-2} \circ \ldots \circ \phi_1\right)\mathbf{x} \tag{3}$$

where $L$ refers the set of layers and each layer $\phi_l$ consists of a set of trainable 1-D activation functions $\{\varphi_{l,j}\}$. In practice, each univariate activation $\varphi_{l,j}(x)$ is parameterized as a combination of basis function $b_{l,j}(x)$ and a B-spline function:

$$\varphi_{l,j}(x) = \omega_{l,j} \left[ b_{l,j}(x) + \sum_{m} c_{l,j,m} B_{l,j,m}(x) \right] \quad \forall l \in L, j \in J^i \tag{4}$$

Where $m = 1, \ldots, M$ indexs B-spline basis functions, and $B_{l,j,m}(x)$ denotes the $m^{th}$ B-spline basis defined on the corresponding grid. The spline coefficients $c_{l,j,m}$ and grid configurations in KANs are fully learnable, allowing the network to adaptively refine its function approximation capabilities.

## 2.3 DKL-KAN Surrogate Model

The DKL-KAN surrogate model for BO is formulated with KAN and GP where the GP converts the latent embeddings to predictive means and uncertainty quantification. Generally, the GP regression is defined as follows to obtain the black-box function $f(\mathbf{x})$[16]:

$$f(\mathbf{x}) \sim \mathcal{GP}\left(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')\right) \tag{5}$$

where $m(\mathbf{x})$ and $k(\mathbf{x}, \mathbf{x}')$ denote the mean function and kernel function. Given observations $\mathcal{D} = \{(\mathbf{x}_i, y_i)\}_{i=1}^{n}$, GP posterior yields a predictive distribution at any candidate $\mathbf{x}_i$, whose posterior mean $\eta(\mathbf{x}|\mathcal{D})$ serves as the prediction and posterior variance $\sigma^2(\mathbf{x}|\mathcal{D})$ quantifies epistemic uncertainty. This probabilistic output is directly leveraged by acquisition functions to guide sampling in BO.

Besides, conventional GP surrogates can be limited in practical applications. Exact GP inference scales cubically with the number of evaluations due to kernel matrix computation. Moreover, the representational capacity of GP is strongly determined by the choice of kernel, standard stationary kernels may struggle to capture complex nonstationarity, sharp local variations, or high-dimensional structure without substantial kernel engineering. DKL mitigates these drawbacks by learning a task-adaptive representation prior to GP modeling. Given a KAN feature map $g(\mathbf{x}|\beta)$arameterized by β, and $k(\mathbf{x}, \mathbf{x}'|\alpha)$ representing the standard kernel parameterized by α, the kernel function can be formulated as follows[17]:

$$k_{DKL-KAN}(\mathbf{x}, \mathbf{x}') = k_{base}(g(\mathbf{x}_i; \beta), g(\mathbf{x}_i', \beta)|\alpha, \beta) \tag{6}$$

This construction preserves GP-style uncertainty quantification while improving expressiveness through data-driven feature learning, enhancing the model capacity for real world applications.

Following the DKL-KAN formulation introduced above, the surrogate is trained by jointly learning $\beta$ and $\alpha$ via maximizing the log marginal likelihood $\mathcal{L}$ [18]. Let $\mathbf{y} \in \mathbb{R}^n$ denote the observations at inputs $\mathbf{X} = \{\mathbf{x}_i\}_{i=1}^{n}$, and let $\mathbf{K} \in \mathbb{R}^{n \times n}$ be the covariance matrix with entries $[\mathbf{K}]_{ij} = k_{\mathrm{DKL-KAN}}(\mathbf{x}_i, \mathbf{x}_j)$. Assuming Gaussian noise with variance $\sigma_n^2$, the $\mathcal{L}$ is given by:

$$\mathcal{L}(\alpha, \beta) = -\frac{1}{2}\mathbf{y}^{\top}(\mathbf{K} + \sigma_n^2\mathbf{I})^{-1}\mathbf{y} - \frac{1}{2}\log|\mathbf{K} + \sigma_n^2\mathbf{I}| - \frac{n}{2}\log(2\pi) \tag{7}$$

Then the surrogate model is obtained via minimizing the negative log marginal likelihood (NLL):

$$\alpha^{\star}, \beta^{\star} = \arg\min_{\alpha,\beta} -\mathcal{L} \tag{8}$$

Compared to the commonly used DKL-MLP surrogate which is usually an opaque, black-box feature extractor, the proposed DKL-KAN provides a more structured and inspectable embedding with improved data efficiency and uncertainty calibration, particularly for high-dimensional, data-scarce chemical process optimization.

## 2.4 Acquisition Function

A variety of acquisition functions have been proposed for BO, including probability of improvement (PI), EI, and upper confidence bound (UCB), which differ in how to trade off exploration and exploitation[19]. Among them, EI is particularly attractive because it directly quantifies the expected gain over the current best observation[20]. Given the surrogate predictive distribution $y \sim \mathcal{N}(\mu(\mathbf{x}), \sigma^2(\mathbf{x}))$, EI at a new point $\mathbf{x}$ can be written in closed-form as:

$$\mathrm{EI}(\mathbf{x}) = \big(\mu(\mathbf{x}) - f(\mathbf{x}^*)\big)\Phi(Z) + \sigma(\mathbf{x})\phi(Z) \tag{9}$$

where $f(\mathbf{x}^*)$ denotes the best objective value observed so far, $\Phi$ and $\phi$ denote the cumulative distribution function (CDF) and the probability density function (PDF) of the standard normal distribution, respectively. $Z$ is a random variable defined as:

$$Z(\mathbf{x}) = \frac{\mu(\mathbf{x}) - f(\mathbf{x}^*)}{\sigma(\mathbf{x})} \tag{10}$$

In the proposed framework, $\mu(\mathbf{x})$ and $\sigma(\mathbf{x})$ are provided from the DKL-KAN. At each iteration, EI is evaluated over the possible candidate set and a batch of the six points with the largest EI values is selected for querying. The resulting objective evaluations are then added to the training set to update the surrogate, and the procedure is repeated until the maximum iterations is reached.

# 3.CASE STUDY

## 3.1 Problem description

The proposed method is then applied to the W-O process optimization problem as case study. For a brief introduction, the W-O process is consist of a continuously stirred tank reactor (CSTR), a decanter, a distillation column (separator) and a splitter[21], as shown in Figure 2. The decision variables and respective bounds for W-O process can be defined in Table 1. $F_{\mathrm{A}}$ and $F_{\mathrm{B}}$ denote the feed flow rates of reactants A and B, $T$ is the operating temperature of reactor, $\mu$ represents the total mass flow rate of the reactor effluent, and $\eta$ specifies the split fraction.

Under a series of reactions, the objective for W-O process is to maximize the Return On Investment (ROI) as follows:

$$ROI = \frac{Annual\ Net\ Profit}{Total\ Capital\ Investment} \tag{11}$$

For the details of W-O process, including reaction system, mass balance constraints and reaction kinetic equations, the readers are referred to the relevant literature[21].

All computations are conducted on a workstation equipped with an Intel(R) Core(TM) i9-14900KF CPU (3.20 GHz) and 64 GB RAM. The W-O is simulated via *Python* and the KAN is constructed using the *pykan*, while GP is constructed with *GPyTorch*.

**Table 1.** Decision variable bounds of the optimization process.

| Variables | Unit | Bounds |
|---|---|---|
| $F_A$ | klb/h | [2.0, 40] |
| $F_B$ | klb/h | [2.0, 40] |
| $T$ | K | [520, 700] |
| $\mu$ | klb/h | [10, 200] |
| $\eta$ | - | [0, 0.9] |

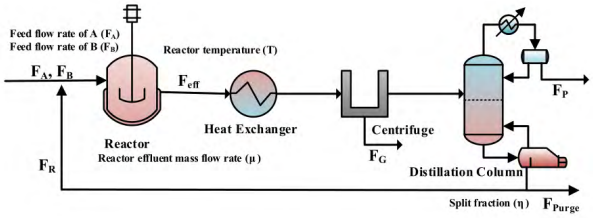

**Figure 2.** Schematic illustration of W-O process.

## 3.2 Performance of DKL-KAN

To assess the predictive capability of the proposed DKL–KAN surrogate, multiple datasets with different sample sizes are generated. For each dataset, samples were randomly split into training and test sets with an 8:2 ratio. Five models are developed for comparison, namely, std-GP, DKL–MLP, DKL–KAN, std-MLP, and std-KAN, where *std* denotes the standard model. Hyperparameter tuning is conducted by Optuna[22] to ensure a fair comparison under consistent hyperparameter optimization. The network architectures are eventually fixed as KAN: [5×4×2] and MLP: [5×64×32×2].

The R-squared ($R^2$) values with the dataset of 500 points are summarized in Figure 3 (a). Obviously, DKL-based surrogates improve generalization over std-GP, and DKL–KAN delivers superior performance. Worse still, std-GP is highly kernel-sensitive with $R^2$ ranging from 0.609±0.083(linear) to 0.794±0.068 (Radial Basis Function, RBF), indicating that the kernels cannot adequately capture the complex underlying feature structure. DKL–KAN maintains high $R^2$ across different kernels and data sizes, showing consistent performance from 0.919± 0.045, 0.935±0.036 and 0.916±0.056 for linear, RBF and

Matérn-2.5 kernels, respectively. This indicates that introducing KAN for DKL can significantly improve the model capacity regardless the kernels. In contrast, the baselines (std-GP, std-MLP and std-KAN) exhibit larger performance gaps and variability, whereas std-KAN attains relatively high $R^2$ with 0.926±0.105, but lacks the predictive uncertainty required. This superiority is further reflected in the root mean squared error (RMSE) metrics trends across dataset sizes (Figure 3 (b)), DKL–KAN yields the lowest test RMSE, with its advantage being most evident in the low-data regime and persisting as the training set grows. This enhanced performance is attributed to the integration of the KANs within the deep kernel architecture, which enables more expressive nonlinear feature mapping and superior uncertainty quantification compared to fixed-basis surrogates.

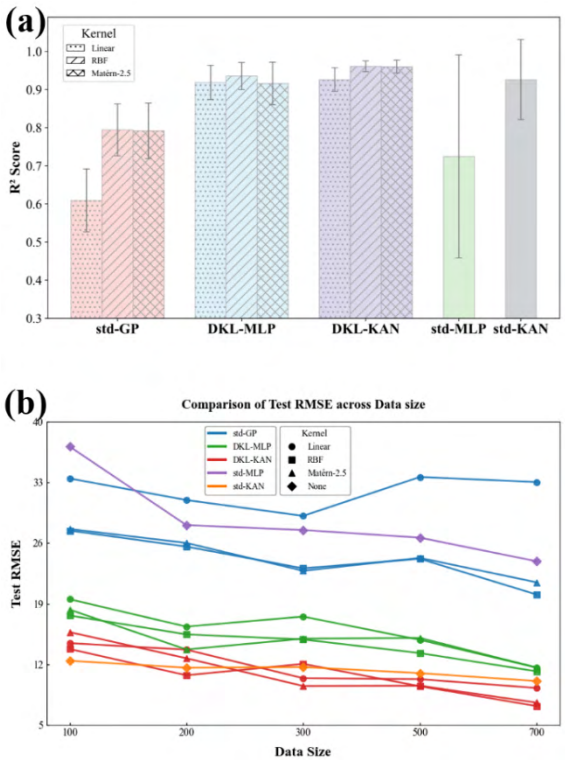

**Figure 3.** (a) $R^2$values at dataset of 500 points. (b) Test set RMSEs on different sample sizes.

## 3.3 Latent space embedding analysis

To gain deeper insights into the behavior of the models, the latent space embeddings of DKL–KAN model is analyzed and compared with the DKL–MLP and std-GP models. For the DKL-driven models, the two-dimensional embeddings from the final feature mapping layer are directly extracted, while for the std-GP, UMAP dimensionality reduction is applied[23]. Subsequently, k-means clustering[24] is performed to obtain four distinct clusters. As shown in Figure 4, the introduction of DKL significantly enhances the distribution of the latent space compared to the std-GP baseline, with clusters becoming more compact and well-separated[9]. The ROI color map reveals a clearer spatial distribution, indicating improvement by introducing DKL-driven surrogates. A closer examination of the cluster characteristics, the highest-ROI cluster is associated with higher reactor temperatures, larger outlet flow rates, and smaller split fractions, while lower-ROI clusters correspond to different combinations of these decision variables.

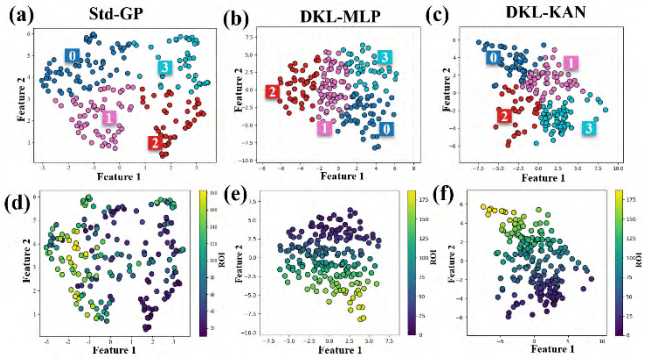

**Figure 4.** Analysis of the latent space of the (a) std-GP, (b) DKL-MLP and (c) DKL-KAN. The colors represent different clusters identified using k-means clustering. The distribution of ROI in each cluster formed from the (d) std-GP, (e) DKL-MLP and (f) DKL-KAN.

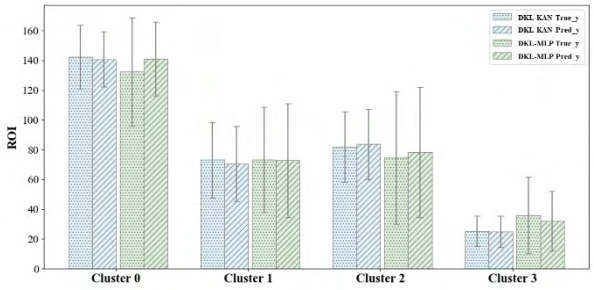

**Figure 5.** Comparison of ROI Prediction Consistency Across Clusters for DKL–MLP, DKL–KAN.

Figure 5 further illustrates the model predictions within each cluster. DKL–KAN demonstrates consistent ROI predictions across all clusters, performing well even in both high- and low-ROI regions, thus highlighting its ability to handle complex nonlinearities effectively. In contrast, DKL-MLP shows more significant fluctuations in ROI predictions across clusters, alternating between overestimations and underestimations, especially in the data-sparse, high-nonlinearity extreme regions, reflecting a fundamental limitation. While the integration of GP priors offers uncertainty quantification, the MLP feature extractor struggles to capture the highly nonlinear, multimodal nature of complex objective functions. The inherent smoothness of the MLP architecture, combined with its inability to adapt to sharp variations or multiple peaks,

leads to suboptimal performance, especially in data-scarce regions with high-dimensional nonlinearity. These results underscore the ability of DKL–KAN to effectively capture the underlying structure of the W–O process, enhancing both the separability of the learned feature embeddings and the accuracy of the predictions.

### 3.4 Optimisation performance

The DKL-KAN is further integrated with BO as the surrogate model for W-O process to validate the optimization efficiency[25]. The total optimization iteration is set to 20, with performance reported as the mean and standard deviation across five independent trials with randomized initializations, illustrated in Figure 6. Computational results from std-GP and DKL-MLP are also provided for comparison. Both DKL-MLP and DKL-KAN surrogates outperform the std-GP in terms of optimization efficiency, consistent with prior work showing that deep kernel learning can improve surrogate accuracy and thus accelerate BO convergence by capturing informative feature representations than shallow kernels alone. Notably, the proposed DKL–KAN model exhibits the most efficient performance, achieving faster improvement in the early iterations and converging to higher objective values. This superior performance is primarily attributable to the DKL–KAN surrogate, whose KAN feature extractor learns more structrued latent embeddings than MLPs and thus the GP kernel can better distinguish the datapoints and captures the highly nonlinearity. Overall, these results demonstrate that the proposed DKL–KAN model provides both excellent predictive accuracy and reliable uncertainty quantification, making it a promising alternative method for process optimization tasks where high-dimensional, nonlinear relationships are prevalent.

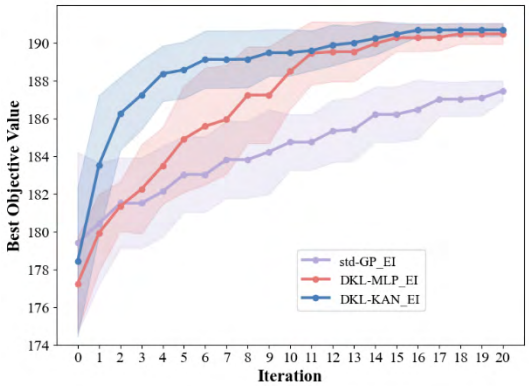

**Figure 6.** Comparison of optimization performance under EI acquisition function with std-GP, DKL-MLP and DKL-KAN surrogate models.

## 4. CONCLUSIONS AND FUTURE WORK

This work develops a novel DKL surrogate model leveraging the KAN as an adaptive feature extractor. Systematically validated on the W–O process benchmark, the proposed DKL-KAN model demonstrates superior predictive performance and more reliable uncertainty quantification compared to standard GPs and conventional DKL-MLP. Latent space analysis further elucidates that the KAN facilitates a more structured embedding distribution, maintaining high generalization and accurate uncertainty characterization even in sparse boundary regions of the sample space. When integrated with BO, the approach identifies superior optimum with significantly accelerated convergence in early iterations. This can be attributed to the more informative embeddings from KAN which better represent the highly nonlinear and strongly coupled W–O response surface. These findings underscore the significant potential of DKL-KAN surrogates as a promising method for complex chemical engineering process optimization. Future work can be done to incorporate advanced algorithms within the latent space to enhance the robustness and efficiency for global optimization exploration.

## ABSTRACT

Black-box optimization (BBO) deals with problems involving functions that are either unknown, imprecise, or costly to evaluate. Current BBO methods encounter multiple challenges, such as high computational demands from excessive function evaluations, difficulties in handling complex constraints, lack of theoretical convergence guarantees, and unstable performance due to significant variations in solution quality. This work presents a machine learning-powered feasible path (MLFP) framework for general BBO problems involving complex constraints. An adaptive sampling strategy is first proposed to explore optimal regions and pre-filter potentially infeasible points, thereby reducing the number of evaluations. Machine learning algorithms are utilized to build surrogates for black-box functions. The feasible path algorithm is integrated to accelerate theoretical convergence by updating only independent variables instead of all variables. Computational experiments demonstrate that MLFP can rapidly and robustly converge near the KKT point, even when training surrogates with small datasets. Compared to state-of-the-art BBO algorithms, MLFP stably delivers equivalent or superior solutions with fewer evaluations across benchmark examples.

**Keywords**: Optimization, Machine Learning, Black-box, Adaptive Sampling, Feasible Path Algorithm, Surrogate Model

## INTRODUCTION

Black-box optimization (BBO) refers to a class of optimization problems where the algebraic forms of the objective function and/or constraints are unknown, imprecise, or prohibitively expensive to compute. This characteristic is ubiquitous in engineering and scientific fields, particularly in chemical engineering, where many complex systems cannot be fully captured by mechanistic models. For instance, multi-step catalytic reaction networks, molecular structure–activity relationships (SARs) linking polymer architecture to material performance, and high-fidelity simulations (e.g., density functional theory calculations, computational fluid dynamics for reactor design, and rigorous distillation modeling) all exhibit black-box properties [1-5]. These systems are foundational to chemical design and manufacturing, from catalyst development and material synthesis to plant-wide operation tuning, and optimizing them relies heavily on specialized BBO approaches. Advancing BBO methods is therefore critical to reducing development cycles, cutting costs, and unlocking innovative engineering solutions.

Despite its importance, BBO faces inherent challenges rooted in the absence of gradient information for black-box functions, which prevents the use of classical gradient-based optimization. Existing methods can be broadly categorized into three classes, each with distinct limitations. Stochastic or heuristic algorithms (e.g., PSO, GA, SA) offer global search capabilities but lack theoretical convergence guarantees and require extensive function evaluations, making them impractical for expensive

systems. Deterministic partition methods (e.g., DIRECT, pattern search) avoid randomness but suffer from the curse of dimensionality and high computational costs. For example, a modified DIRECT algorithm for LNG process optimization required 20, 000 evaluations [6]. Surrogate model-based methods, the most widely adopted class, reduce black-box calls by using cheap approximations (e.g., neural networks, Gaussian processes) but introduce new issues: implicit filtering is limited to bound-constrained problems, ReLU NN-based frameworks become computationally intractable for complex architectures [7], ALAMO performs poorly for high-dimensional inputs [8], trust-region filter (TRF) methods suffer from initial value sensitivity [9], and Bayesian optimization (BO) struggles with complex equality constraints and exhibits significant result stochasticity (variations up to 300% across runs) [10]. Additionally, many surrogate-based methods overlook the computational burden of sampling and training.

To address these limitations, this study proposes a novel machine learning-powered feasible path (MLFP) framework for general BBO problems involving complex equality and inequality constraints. The framework integrates three core components to balance sample efficiency, approximation accuracy, and convergence speed. First, an adaptive sampling strategy uses support vector machines (SVM) to filter infeasible points and focus on potential optimal regions, ensuring informative samples even with limited data. Second, machine learning models (e.g., multi-layer perceptrons with Swish activation) are employed as surrogates, leveraging their strong nonlinear approximation capabilities and twice-differentiable properties to enable gradient-based optimization. Third, the feasible path algorithm is integrated to update only independent variables instead of the entire variable set, avoiding complex nonlinear terms from full-space formulations and accelerating convergence by retaining computation graphs for efficient derivative calculation.

This work validates MLFP on 2 industrial processes (Williams-Otto process and extractive distillation process). The results demonstrate that MLFP outperforms state-of-the-art algorithms by stably achieving equivalent or better solutions with fewer evaluations.

## PROBLEM STATEMENT

The general form of a BBO problem to be solved in this work is presented below, which is a nonlinear programming (NLP) problem.

$$\begin{aligned} \min_{\mathbf{x}\in\mathbb{R}^n} \quad & f(\mathbf{x}) \\ \text{s.t.} \quad & \mathbf{h}(\mathbf{x}) = 0 \\ & \mathbf{g}(\mathbf{x}) \le 0 \\ & \mathbf{x}^{\boldsymbol{lb}} \le \mathbf{x} \le \mathbf{x}^{\boldsymbol{ub}} \end{aligned} \tag{1}$$

where the function $f: \mathbb{R}^n \to \mathbb{R}$ is the objective function, $\mathbf{h}: \mathbb{R}^n \to \mathbb{R}^{p_E}$ is the equality constraints and $\mathbf{g}: \mathbb{R}^n \to \mathbb{R}^{p_I}$ is the inequality constraints excluding the bounding constraints. $p_E$ , and $p_I$ represent the dimensions of equations and inequalities respectively; $\mathbf{x}$ represent a vector of variables; the superscript $ub$ represents the upper bound, and $lb$ represents the lower bound. In this setting, the black-box function may pertain to the objective function $f$ as well as to the constraint functions $\mathbf{h}$ (equalities) and $\mathbf{g}$ (inequalities), depending on the problem structure.

Without loss of generality, we divide the equality constraints $\mathbf{h}(\mathbf{x}) = 0$ into $\mathbf{h_1}(\mathbf{x}) = 0$ and $\mathbf{h_2}(\mathbf{x}) = 0$ where $\mathbf{h_1}(\mathbf{x}) = 0$ containing all black-box constraints and $\mathbf{h_2}(\mathbf{x}) = 0$ without containing any black-box functions. If any inequality constraints $\mathbf{g_j}(\mathbf{x}) \le 0$ containing black-box functions, we can introduce auxiliary variables $\mathbf{v}$ and let $\mathbf{v} = \mathbf{g_j}(\mathbf{x})$. We then add $\mathbf{v} = \mathbf{g_j}(\mathbf{x})$ into $\mathbf{h_1}(\mathbf{x}) = 0$ and remove $\mathbf{g_j}(\mathbf{x}) \le 0$ from the inequality constraint sets $\mathbf{g}(\mathbf{x}) \le 0$. The auxiliary variable $\mathbf{v}$ is then added into variables $\mathbf{x}$. The original BBO problem (1) can be reformatted into problem (2) below,

$$\begin{aligned} \min_{\mathbf{x}\in\mathbb{R}^n} \quad & f(\mathbf{x}) \\ \text{s.t.} \quad & \mathbf{h_1}(\mathbf{x}) = 0 \\ & \mathbf{h_2}(\mathbf{x}) = 0 \\ & \mathbf{g}(\mathbf{x}) \le 0 \\ & \mathbf{x}^{\boldsymbol{lb}} \le \mathbf{x} \le \mathbf{x}^{\boldsymbol{ub}} \end{aligned} \tag{2}$$

where $\mathbf{h_1}: \mathbb{R}^n \to \mathbb{R}^{p_{E1}}$ and $\mathbf{h_2}: \mathbb{R}^n \to \mathbb{R}^{p_{E2}}$ are the equality constraints and $\mathbf{g}: \mathbb{R}^n \to \mathbb{R}^{p_I}$ is the inequality constraints excluding the bounding constraints. $p_{E1}, p_{E2}$and $p_I$ represent the dimensions of equations and inequalities respectively. In this setting, the black-box function may pertain to the objective function $f$ as well as to the constraint functions $\mathbf{h_1}$ (equalities). We assume that all functions (e.g., $f, \mathbf{h_2}$ and $\mathbf{g}$) that are not the black-box functions, are twice continuously differentiable. The black-box functions $\mathbf{h_1}$ or $f$ are unknown and their derivatives are not available; however, we assume that they can be evaluated at a given point and approximated by a twice continuously differentiable function.

## METHOD

As $f(\mathbf{x})$ and/or $\mathbf{h_1}(\mathbf{x}) = 0$ in problem (2) contain black-box functions that are unknown or expensive for evaluation, we need to develop surrogate models for these black-box functions. To do this, we can divide all variables in (2) into independent variables (denoted as $\mathbf{x}_I$) and dependent variables (denoted as $\mathbf{x}_D$) where $\mathbf{x}_D$ has the same dimension as $\mathbf{h_1}$. Then, problem (2) can be transformed into problem (3).

$$\begin{aligned} \min_{\boldsymbol{x} \in \mathbb{R}^n} \quad & f(\boldsymbol{x}_I, \boldsymbol{x}_D) \\ \text{s.t.} \quad & \boldsymbol{h_1}(\boldsymbol{x}_I, \boldsymbol{x}_D) = 0 \\ & \boldsymbol{h_2}(\boldsymbol{x}_I, \boldsymbol{x}_D) = 0 \\ & \boldsymbol{g}(\boldsymbol{x}_I, \boldsymbol{x}_D) \leq 0 \\ & \boldsymbol{x}_I^{\boldsymbol{lb}} \leq \boldsymbol{x}_I \leq \boldsymbol{x}_I^{\boldsymbol{ub}} \\ & \boldsymbol{x}_D^{\boldsymbol{lb}} \leq \boldsymbol{x}_D \leq \boldsymbol{x}_D^{\boldsymbol{ub}} \end{aligned} \tag{3}$$

## Adaptive sampling strategy

Adaptive sampling is pivotal for surrogate-assisted BBO, as it generates high-quality data, builds accurate models, and reduces function evaluations. Most existing strategies are iteratively integrated with optimization, selecting the next sampling point based on current results, which is effective for coupled sampling-optimization algorithms but unsuitable for ones that construct offline surrogate before optimization. To address this, we propose a new adaptive sampling strategy to build a global dataset for pre-optimization surrogate training, focusing on capturing details near optimal regions and variable bounds.

In this work we proposed a adaptive sampling strategy that focus on potential optimal regions and onstraint

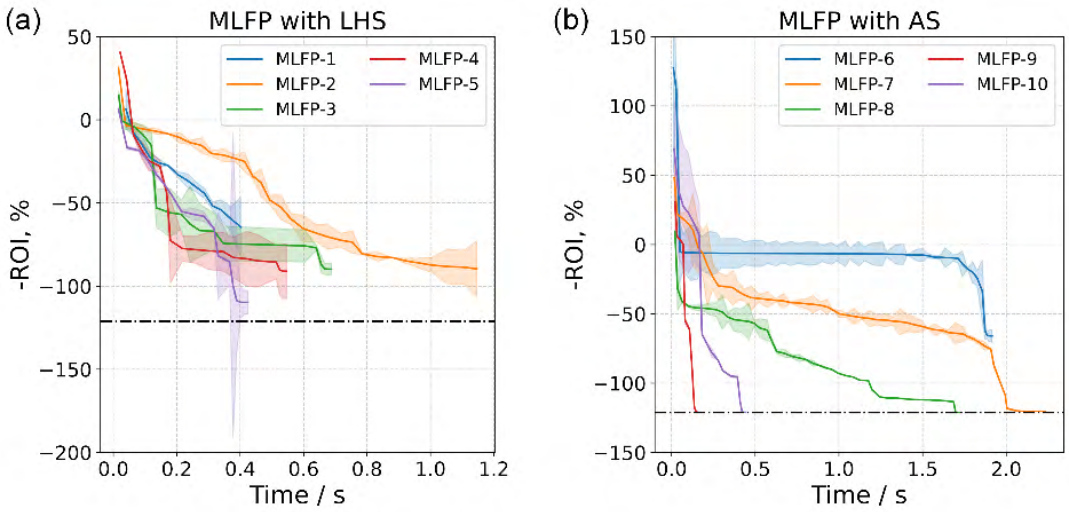

**Figure 2.** Convergence curves for WO process with error band of MLFP 1-10.

boundaries. The strategy proceeds in three steps:

1. Slightly expand the bounds of each independent variable (e.g., ±5% of original) and perform initial Latin hypercube sampling (LHS) to collect a small sample set (e.g., 10% of total required). Evaluate black-box functions at these samples to obtain dependent variable values, understand function behaviors, and identify promising regions.

2. Label samples as feasible (satisfying constraints like $g(x_I, x_D), h_2(x_I, x_D)$ and bound constraints for variables) or infeasible (1 or 0), then train a support vector machine (SVM) classifier. To mitigate inaccuracy from limited initial samples, extract support vectors from the trained SVM and retrain the classifier by treating all support vectors as feasible, which includes near-boundary infeasible points to ensure precise boundary characterization.

3. Establish a sub-region around the best feasible point, conduct LHS within this area (e.g., 10% of total samples per iteration), and use the trained SVM to filter out infeasible points (avoiding wasted black-box evaluations). Update the best feasible point and repeat until the required sample size is reached.

## Feasible path optimization algorithm

After the surrogate models for $\mathbf{h}_1(\mathbf{x}) = 0$ and/or the objective function are developed, then $\mathbf{h}_1(\mathbf{x}) = 0$ and/or the objective function in problem (3) are replaced by the surrogates denoted as $\boldsymbol{x}_D = \mathbf{s}(\mathbf{x}_I)$ and/or $fs(\mathbf{x}_I)$ and problem (4) below is obtained. We also assume that $\mathbf{s}(\mathbf{x}_I)$ and/or $fs(\mathbf{x}_I), \mathbf{h}_2$ and $\mathbf{g}$ are all twice continuously differentiable. The remaining constraints $\mathbf{h}_2$ and $\mathbf{g}$, and the objective function $f$ can be calculated without calling the black-box.

$$\begin{aligned} \underset{\mathbf{x}\in\mathbb{R}^n}{min} \quad & f(\mathbf{x}_I, \mathbf{x}_D) \text{ or } fs(\mathbf{x}_I) \\ \text{s.t.} \quad & \mathbf{x}_D = \mathbf{s}(\mathbf{x}_I) \\ & \mathbf{h}_2(\mathbf{x}_I, \mathbf{x}_D) = 0 \\ & \mathbf{g}(\mathbf{x}_I, \mathbf{x}_D) \le 0 \\ & \mathbf{x}_I^{lb} \le \mathbf{x}_I \le \mathbf{x}_I^{ub} \\ & \mathbf{x}_D^{lb} \le \mathbf{x}_D \le \mathbf{x}_D^{ub} \end{aligned} \tag{4}$$

To solve problem (4) effectively, we employ the feasible path optimization algorithms developed by Ma et al. [11]. Different from full-space formulation, which directly employs NLP algorithms to solve problem (4), feasible path optimization algorithms divide the entire problem (4) to two subproblems including a small optimization problem in the outer level and a process simulation problem in the inner level. While the small optimization problem in the outer level can be solved using the existing gradient-based optimization algorithms such as improved SQP, the process simulation problem in the inner level could be solved using solution algorithms for nonlinear equations such as a Newton-based algorithm or PTC approach [11]. In this work, the inner level only requires the use of a surrogate model to predict $\mathbf{x}_D$, which is considerably faster than rigorous simulation or black-box evaluation. Moreover, when predicting $\mathbf{x}_D$, the computation graph will be retained to compute the derivative of $\mathbf{x}_D$ with respect to $\mathbf{x}_I$, instead of calculating a large Jacobi matrix.

Detailed algorithm parameters and pseudocode are presented in the **Algorithm 1**.

In this work, the $\ell_1$ merit function, defined as Eq.(5), is used to evaluate convergence criteria.

$$\phi_1(\mathbf{x}_I^k; \boldsymbol{\lambda}_{qp}^k, \boldsymbol{\mu}_{qp}^k) = f(\mathbf{x}^k) + (\boldsymbol{\rho}^k)^{\mathrm{T}} |\mathbf{h}(\mathbf{x}_I^k)| + (\boldsymbol{\nu}^k)^{\mathrm{T}} \mathbf{g}(\mathbf{x}_I^k)^- \tag{5}$$

where, $\mathbf{g}(\mathbf{x}^k)^- := \max(0, -\mathbf{g}(\mathbf{x}^k))$, and the penalty

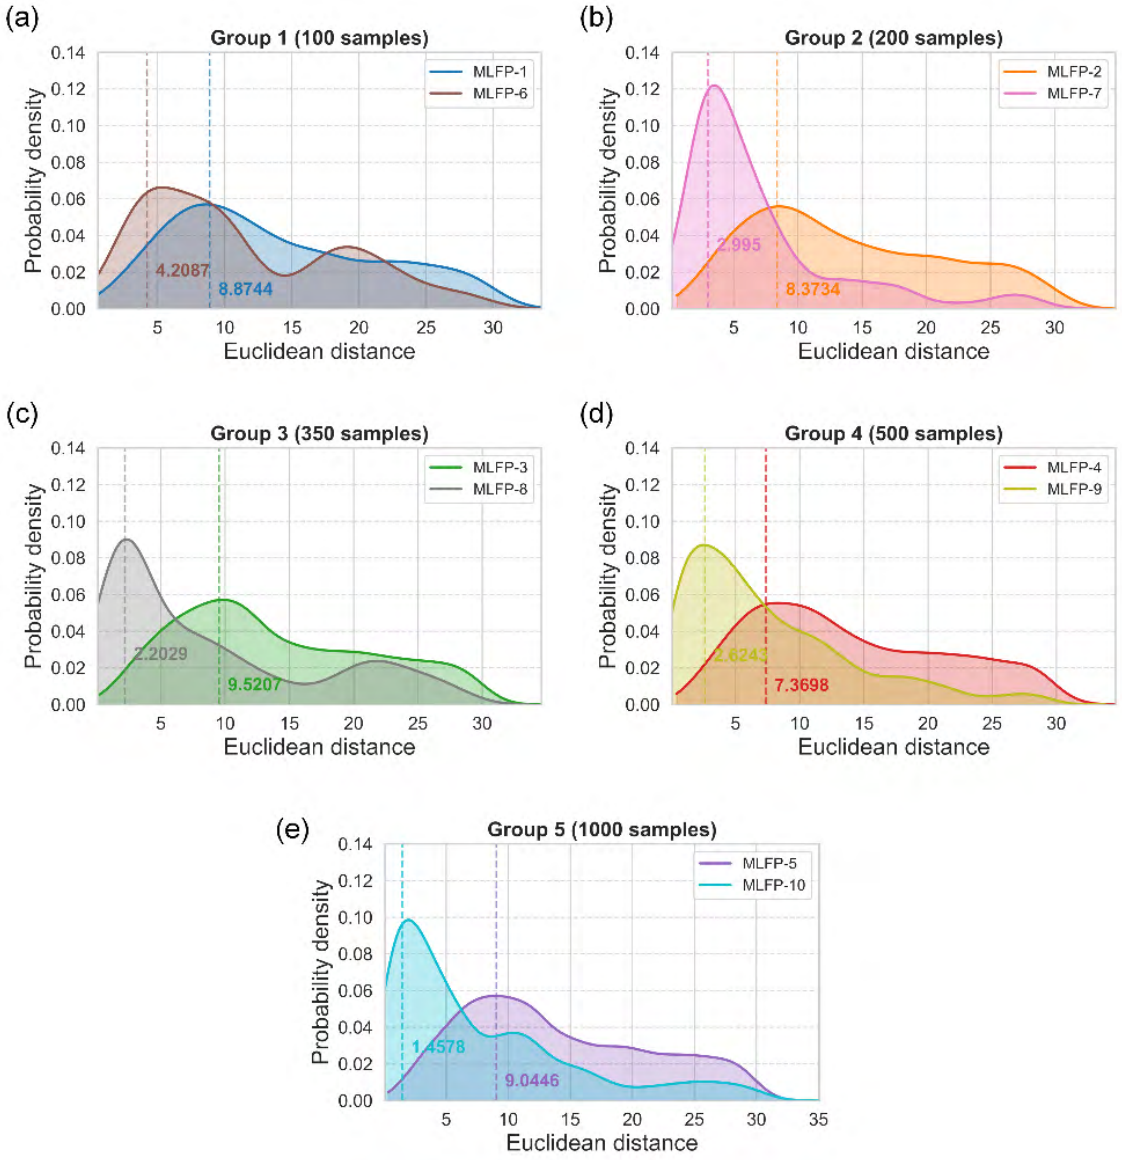

**Figure 3.** Probability density function of Euclidean distance from sampling points to rigorous model-based solution of WO process.

parameters are defined as follows [12]:

$$\boldsymbol{\rho}^k = max\left(|\boldsymbol{\lambda}_{qp}^k|, \frac{\boldsymbol{\rho}^{k-1}+|\boldsymbol{\lambda}_{qp}^k|}{2}\right) \tag{6}$$

$$\boldsymbol{\nu}^k = max\left(|\boldsymbol{\mu}_{qp}^k|, \frac{\boldsymbol{\nu}^{k-1}+|\boldsymbol{\mu}_{qp}^k|}{2}\right) \tag{7}$$

Given the $\ell_1$ merit function being not differentiable everywhere, the Eq.(8) describes the directional derivative of $\phi_1(\mathbf{x}^k;\boldsymbol{\lambda}_{qp}^k,\boldsymbol{\mu}_{qp}^k)$ along the direction $\mathbf{d}^k$ generated by the SQP subproblem.

$$D\left(\phi_1(\mathbf{x}_I^k;\boldsymbol{\lambda}_{qp}^k,\boldsymbol{\mu}_{qp}^k);\mathbf{d}^k\right) = \nabla f(\mathbf{x}_I^k)^{\mathrm{T}}\mathbf{d}^k - (\boldsymbol{\rho}^k)^{\mathrm{T}}|\mathbf{h}(\mathbf{x}_I^k)| - (\boldsymbol{\nu}^k)^{\mathrm{T}}\mathbf{g}(\mathbf{x}_I^k)^{-} \tag{8}$$

The Armijo condition guarantees a sufficient decrease of the merit function:

$$\phi_1(\mathbf{x}_I^k + \alpha\mathbf{d}^k;\boldsymbol{\lambda}_{qp}^k,\boldsymbol{\mu}_{qp}^k) - \phi_1(\mathbf{x}_I^k;\boldsymbol{\lambda}_{qp}^k,\boldsymbol{\mu}_{qp}^k) < \alpha\eta D\left(\phi_1(\mathbf{x}_I^k;\boldsymbol{\lambda}_{qp}^k,\boldsymbol{\mu}_{qp}^k);\mathbf{d}^k\right) \tag{9}$$

Where $\eta \in (0, 0.5)$ is a hyper-parameter. In this work, we choose $\eta = 0.1$ according to Ma et al. [12] and set line search multiple $\beta = 0.618$, maximum number of line search iterations $n_{max} = 10$. However, it is possible that no step length $\alpha$ can satisfy the Armijo condition, regardless of how small it is. Under such circumstances, we accept the last $\alpha$ when the maximum number of line searches has been reached. According to the backtracking method,

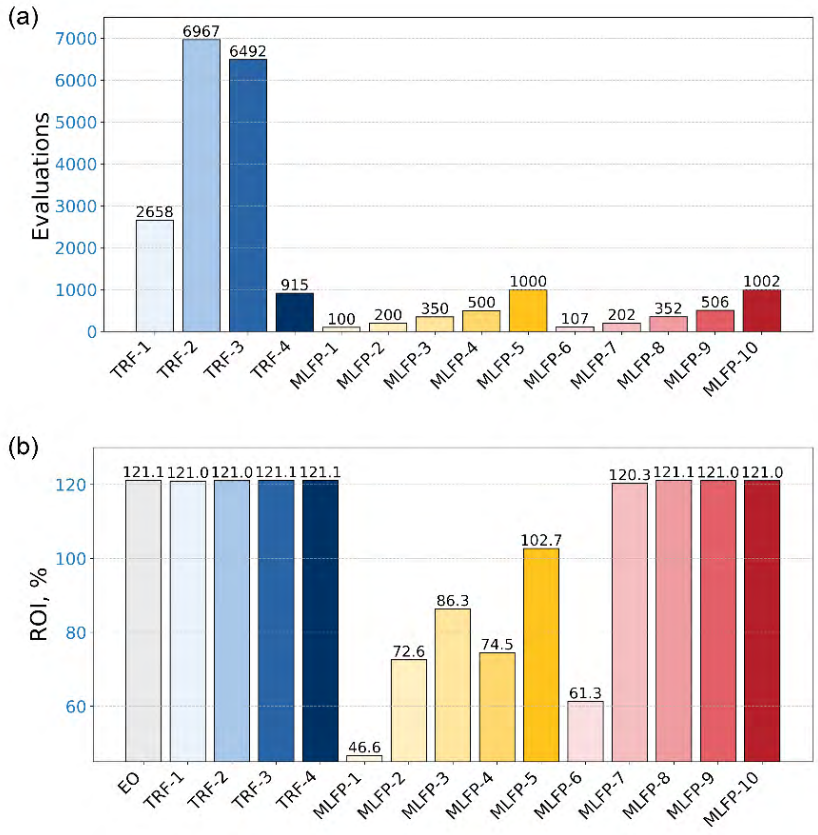

**Figure 4.** Comparasion for WO process from MLFPs and TRF1-4 on (a) the number of function evaluations of the black-box function and (b) objective function value.

after 10 reduction steps in the line search, the step size becomes approximately $8 \times 10^{-3}$. At this point, the step size is sufficiently small compared to the initial step size, yet it exerts little impact on convergence. Meanwhile, it remains larger than the tolerance, which ensures the iteration does not terminate prematurely before approaching the optimal value.

For practical engineering problems, due to numerical stability and other factors, the KKT conditions as criteria may be too strict, making the algorithm difficult to achieve convergence. Therefore, based on previous research, we check whether the following criteria are met after every line search:

$$acc_{inf} = \left\|\mathbf{h}\left(\mathbf{x}_I^k + \alpha \mathbf{d}^k\right)\right\|_1 + \left\|\mathbf{g}\left(\mathbf{x}_I^k + \alpha \mathbf{d}^k\right)^-\right\|_1 < tol \quad (10)$$

$$acc_{step} = \left|f\left(\mathbf{x}_I^k + \alpha \mathbf{d}^k\right) - f\left(\mathbf{x}_I^k\right)\right| < tol \quad (11)$$

$$acc_{opt} = \left\|\mathbf{d}^k\right\|_2 < tol \quad (12)$$

where, $tol$ represents the convergence tolerance. The solution is considered optimal if Eqs.(10), (11) or Eqs.(10), (12)are satisfied. The satisfaction of Eq.(10) indicates that the optimal solution is feasible. The satisfaction of either Eq.(11) or Eq.(12) suggests that there is little potential for further decrease in the objective function.

## CASE STUDY

In This work, MLPs are used to construct surrogate models with the Swish activation function. All examples are solved on a desktop with Intel(R) Core(TM) i9-14900K (3.20 GHz) processor and 128 GB of RAM running Windows 11 64-bit operating system.

### Williams-Otto process

The Williams Otto (WO) process is a classic benchmark that has been widely used to evaluate optimization algorithms. The schematic diagram of the WO process is shown in **Figure 1**. The goal is to maximize the return on investment (ROI) by adjusting the reactor volume $V$, reaction temperature $T$, as well as the feed flow rates ($\mathrm{F_A}$and $F_B$) and material flow cycle ratio $\eta$ of components $A$ and $B$. The inputs of the surrogate model are $V, T$, as well as $F_A, F_B$ and $\eta$, which are also independent variables in the optimization problem. The output includes the objective function value (ROI) and the product material flow rate $F_P$, which are dependent variables subject to boundary constraints. In this optimization problem, there are 27

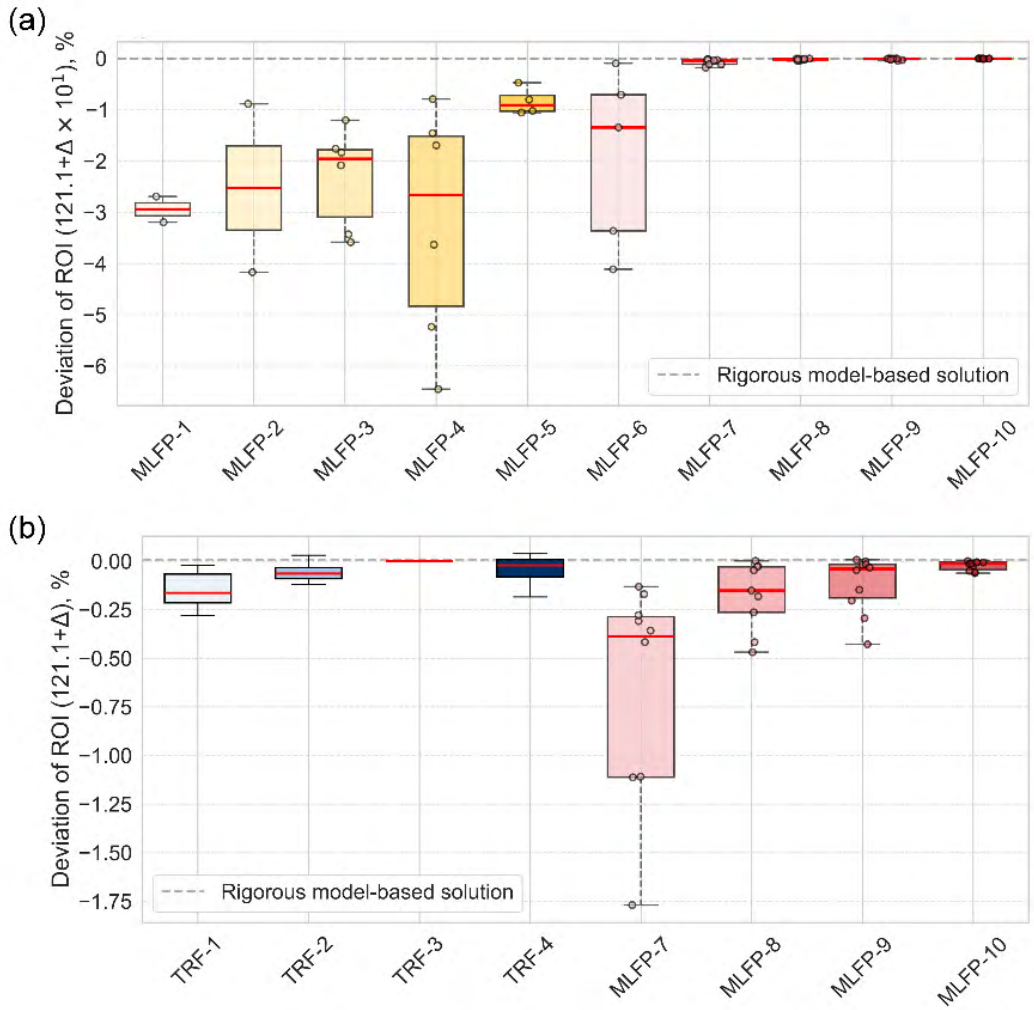

**Figure 5.** Boxplot of best ROI for WO process obtained from (a) MLFP1-10, and (b) TRF 1-4 and MLFP 7-10 with 10 runs.

variables and 54 constraints.

In this example, we compared the performance of TRF 1-4 and MLFP frameworks under different sampling sizes, and also compared the performance of the AS strategy and LHS strategy proposed in the MLFP framework. In the MLFP framework using the LHS strategy, we generate 100, 200, 350, 500, and 1000 valid sampling points respectively (simulation convergence successful), corresponding to MLFP 1-5; In the MLFP framework using the AS strategy, we also generate 100, 200, 350, 500, and 1000 valid sampling points, respectively, labeled as MLFP 6-10. The benchmark experimental results of the TRF method were taken from the study of Liang et al. [9]. It should be noted that the initial points used by Liang et al. [9] may differ from those of the MLFP framework.

The convergence curve of the MLFP series methods is shown in **Figure 2**. According to **Figure 2** (b), it can be seen that MLFP-7 to MLFP-10 can converge to the vicinity of the KKT point (as indicated by the black dashed line in the figure), while the results in **Figure 2** (a) show that MLFP-1 to MLFP-5 did not converge to the vicinity of the KKT point. The shaded area next to the convergence curve in **Figure 2** represents the difference between the predicted and actual values of the model. It can be seen that as the number of effective sampling points increases, the shaded area gradually narrows, indicating that the difference between the predicted and actual values continues to decrease. In other words, increasing the number of effective sampling points helps improve the prediction accuracy of the model. It can also be observed that as the iteration point approaches the true optimal value, the shaded area gradually shrinks, indicating that the samples generated by the adaptive sampling strategy are mainly concentrated near the optimal solution based on the strict model. To verify this hypothesis, this article combines samples obtained from 30 running experiments, divides the sampling results of the MLFP method into 5 groups, and assigns the same number of sampling points

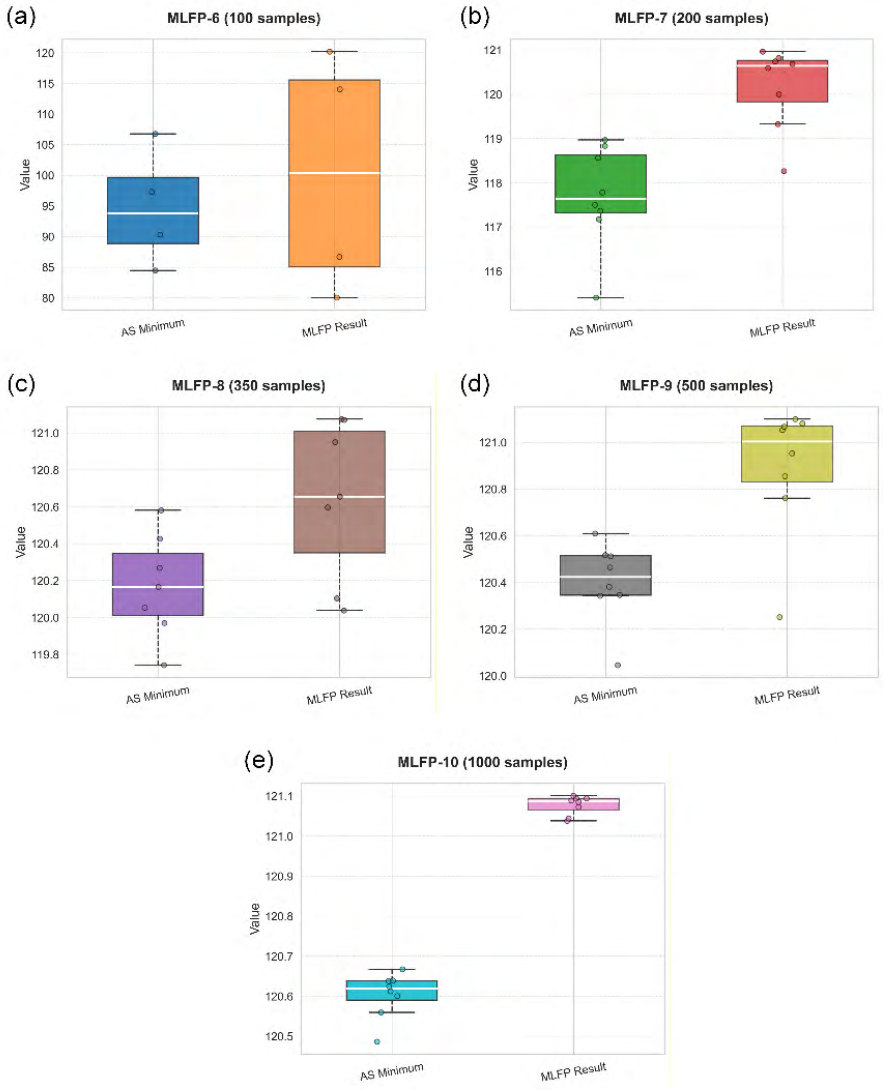

**Figure 6.** Comparison of the minimum objective value obtained with adaptive sampling and MLFP optimization results in WO process.

to each group. Then, LHS and AS strategies are used to conduct sampling experiments on each group, and the probability density function of the obtained samples is shown in **Figure 3**. **Figure 3** shows that under the same sampling size, the peak value of AS strategy sampling results is closer to 0 compared to LHS, indicating that its sample distribution is closer to the optimal solution based on the strict model; And as the number of sampling points increases, the peak of AS strategy sampling results will further approach 0.

The performance comparison results between TRF 1-4 and MLFP 1-10 are shown in **Figure 4**, where the dashed line represents the optimal solution obtained by using IPOPT solver to solve the strict model. Compared with TRF 1-4, MLFP 7-8 can achieve an optimal return on investment (ROI) of 121.1 and require significantly fewer function evaluations. **Figure 5** shows the optimization results of TRF 1-4 and MLFP 1-10 in 10 independent running experiments. As shown in **Figure 5** (a), under the same number of function evaluations, the stability of MLFP 6-10 is significantly better than that of MLFP 1-5, indicating that the MLFP method using the proposed adaptive sampling strategy performs better than the MLFP method using the LHS strategy; And as the number of sampling points increases, the stability of MLFP 6-10 further improves, as evidenced by the decrease in variance of the optimized ROI obtained from multiple experiments. Combining **Figure 4** (a) and **Figure 5**, it can be observed that TRF-4 and MLFP-10 require similar number of function evaluations (915 and 1002, respectively), and both can converge to the optimal solution based on the strict model; But the stability of MLFP-10 is better because its box line height, i.e. interquartile range (IQR) and whisker plot range, are much narrower than TRF-4.

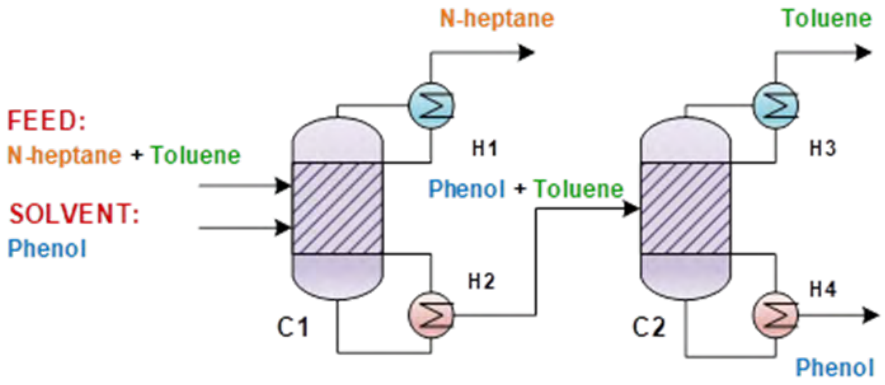

**Figure 7.** Process flow diagram for separation of toluene form n-heptane using solvent phenol in Ma et al.'s work [13].

In addition, we also compared the minimum target values obtained by AS and MLFP 6-10, as shown in **Figure 6**. In 10 runs, compared with the minimum value obtained by adaptive sampling, the median optimization results of MLFP 6-10 increased by 6.87%, 1.97%, 0.50%, 0.48%, and 0.39%, respectively.

## Extractive distillation (ED) for toluene and n-heptane separation

Process simulation-based optimization is a typical BBO problem involving expensive function evaluations or unknown functions. In this subsection, we test an example of extractive distillation to separate toluene form n-heptane using solvent phenol provided by Ma et al. [13]. The process flowsheet is provided in **Figure 7**. The process mainly consists of two columns. The first column (C1) is used to separate n-heptane, and the second column (C2) is used for separation of toluene form solvent phenol. The purity requirement for both products is not less than 0.98. All specific constraints and utility prices are referenced from Fan et al. [10]. The optimization problem using the surrogate models mainly achieves the minimum operating cost by adjusting the amount of extractant, reflux ratio, and distillate flow rate, as shown in Eq.(13).

$$\begin{aligned} \min_{F,r_1,D_1,r_2,D_2\in\mathbb{R}} \quad & c_{hu}(Q_2+Q_4)-c_{cu}(Q_1+Q_3) \\ s.t. \quad & (x_n,x_t,Q_1,Q_2,Q_3,Q_4)=s(F,r_1,D_1,r_2,D_2) \\ & 0.98\le x_n\le 1 \\ & 0.98\le x_t\le 1 \end{aligned} \tag{13}$$

where, $c_{hu}$ and $c_{cu}$ is the cost coefficients for cold and hot utilities; $Q_1$ and $Q_3$ are duties of condensers C1 and C2, $Q_2$ and $Q_4$ are duties of reboilers C1 and C2, kW; $F$ is the mass flow of solvent phenol, kg·hr$^{-1}$; $r_1$ and $r_2$ are the reflux ratio of C1 and C2; $D_1$ and $D_2$ are the distillate flow of C1 and C2; $x_n$ and $x_t$ are the mole fraction of n-heptane in C1 distillate and toluene in C2 distillate; $s(\cdot)$ is the surrogate model for extractive distillation process. The variable range and parameter values are obtained from Fan et al. [10]. In this optimization problem, there are 1, 290 variables and 1289 constraints.

According to Ma et al. [13], the surrogate models constructed using either ReLU neural networks or ALAMO exhibit great relative errors ranging from 0.2% to 25%. Despite employing complex basis functions, these models still fail to fully capture behaviors of the process system due to inherent limitations in their nonlinear representation capabilities. We use the proposed MLFP framework to generate a surrogate model for the entire process where 1014 valid sampling points are generated.

We then use MLFP to solve the problem (13). The convergence curves of the objective value, and n-heptane and toluene molar fractions are depicted in **Figure 8**. As illustrated in **Figure 8**, the predicted objective value, and n-heptane and tolumen molar fractions from the surrogated models are in good agreement with those validated from Aspen rigorous simulation, indidating the high model prediction accuracy. The best energy cost is 134.60 \$ hr$^{-1}$. The achieved purities of n-heptane and toluene products are 0.98 and 0.98 respectively, which satisfy the purity requirements.

To further illustrate the capability of the proposed MLFP framework, we also use genetic algorithm (GA), particle swarm optimization (PSO) to solve problem (13) where the surrogate model is obtained from the proposed MLFP framework. The reported network structure with the highest accuracy in Ma et al. [13] is also used to develop ReLU NN by using the sampling points generated from LHS, which is then reformulated into an MILP problem and optimized by Gurobi. All optimization results using the surrogate models are validated in Aspen Plus. The

**Table 1:** Validated optimization results for ED process from different optimization strategies.

| Algorithms | Objective ($·hr−1) | Purity | | No. of samples/Initial points | Optimization time (sec) | Total time (min) |
|---|---|---|---|---|---|---|
| | | $x_n$ | $x_t$ | | | |
| Surrogate-GA | 154.77 | 0.99 | 0.98 | 2400 | 3.59 | 62.14 |
| Rigorous-GA | 177.07 | 0.98 | 1.00 | - | 2898.55 | 48.31 |
| Surrogate-PSO | 134.73 | 0.98 | 0.98 | 2400 | 3.94 | 62.15 |
| Rigorous-PSO | 151.60 | 0.98 | 0.98 | - | 2919.47 | 48.66 |
| SQP (Aspen) | 231.18 | 0.99 | 0.99 | 1 | Failed | - |
| ASBO-I (best) | 248.60 | valid | valid | 160 | - | - |
| ReLU NN | 154.13 | 0.96 | 0.96 | 2400 | 2.57 | 79.11 |
| MLFP | 134.60 | 0.98 | 0.98 | 2400 | 0.99 | 62.08 |

validated results are provided in **Table 1**. The best results from the adaptive sampling Bayesian optimization (ASBO-I) reported by Fan et al. [10] also provided in **Table 1** for comparison.

From Table 1, it is shown that SQP (Aspen) fails to converge and halts at the initial point provided. ASBO-I requires the fewest samples, but its best objective is 248.60 $\$\cdot hr^{-1}$, which is 84.7% higher than that of 134.60 $\$\cdot hr^{-1}$ obtained from MLFP. Although the reformulated ReLU NN using the network structure reported in Ma et al. [13] obtains the best objective of 154.13 $\$\cdot hr^{-1}$, which is lower than ASBO-I, but still higher than that of 134.60 $\$\cdot hr^{-1}$ from MLFP. Moreover, the purity of n-heptane and toluene is 0.96, which does not meet the purity requirements. In contrast, MLFP exhibits the best performance, generating the lowest objective value of 134.60 $\$\cdot hr^{-1}$ and all purity constraints are met. It should be noted that the total computational time for MLFP reported in **Table 1** includes the optimization time, the effort for evaluating the black-box function and the time for training and pre-training the SVM.

## CONCLUSION

In this work, we proposed a novel machine learning powered feasible path optimization (MLFP) framework for solving general BBO problems where complex equality and inequality constraints are involved. The framework includes three main porcedures. First, an efficient adaptive sampling strategy is proposed, which filters out potentially infeasible samples with SVM and focuses on regions likely to contain optimal solutions. Second, machine learning models are leveraged to develop surrogates of black-boxes. Third, the feasible path algorithm is employed, which divides the entire optimization problem into two subproblems including a small optimization problem in the outer level and a simulation problem in the inner level (refering to the use of surrogate models for prediction in this work). Therefore, there are only independent variables that need to be updated rather than all, thus accelerating the theoretical convergence.

Computational studies show that the proposed adaptive sampling approach needs far fewer samples than the commonly used LHS strategy. The feasible path method greatly boosts computational speed, finishing optimization in just a few seconds. For benchmark problems with known global optima, the MLFP converges to solutions around the KKT point. For Williams-Otto optimization problem, MLFP shows similar performance to TRFs, but requires fewer evaluations. For an extractive distillation case, the optimal objective value obtained with MLFP is 84.7% lower than the best result of ASBO-I from its 10 runs.

## ABSTRACT

The integrated recovery of heat and mechanical work has gained increasing importance in process integration due to the strong thermodynamic coupling between temperature and pressure changes in many industrial systems. This work presents a rigorous framework for the simultaneous synthesis of Work and Heat Exchanger Networks (WHEN), in which heating, cooling, compression, expansion, throttling, and pumping are optimized in a coordinated manner. The problem is formulated using Generalized Disjunctive Programming (GDP), allowing the explicit representation of alternative thermodynamic paths, phase-dependent behavior, and logical equipment choices. Process streams are defined by supply and target states, while only bounds are imposed on intermediate pressures, temperatures, and flow rates. Streams may change classification between hot and cold multiple times and may undergo several phase transitions.Rigorous thermodynamic correlations obtained from Aspen HYSYS are embedded in the optimization model, enabling a physically consistent treatment of condensation, vaporization, and isenthalpic valve expansion without restrictive assumptions. The heat exchanger network is represented implicitly through the Pinch Location Method, avoiding the combinatorial complexity of explicit exchanger matching while accommodating multiple utilities and unclassified streams.The approach is demonstrated through a self-refrigerated alkylation process case study. The optimal solution reveals a non-intuitive thermodynamic path involving alternating vapor and liquid compression stages and multiple phase changes, which enhances internal heat recovery. Compared to a conventional design strategy, the proposed framework reduces total annual energy integration costs by 12.5%. The resulting nonconvex MINLP is solved to global optimality within seconds, demonstrating both robustness and computational tractability.

**Keywords**: Work exchanger networks, Heat exchanger networks, WHEN, Energy efficiency, Process Integration

## INTRODUCTION

In recent years, the integrated treatment of heat and work recovery has emerged as a key topic in process integration, motivated by the need to further reduce energy consumption and carbon emissions beyond what can be achieved through conventional heat integration alone. While classical Heat Exchanger Network (HEN) synthesis focuses on the recovery of thermal energy and Work Exchange Network (WEN) synthesis addresses the reuse of mechanical energy, many industrial processes exhibit strong thermodynamic coupling between heat and work. This coupling has led to the development of Work and Heat Exchanger Networks (WHEN), in which heat and shaft work are considered in a coordinated and sequential manner rather than as independent subsystems [1].

The relevance of WHEN becomes particularly evident in processes involving significant pressure changes, such as gas processing, refrigeration and liquefaction systems, air separation units, and high-pressure chemical reactors. In these systems, compression and expansion steps not only consume or produce mechanical work but also generate substantial temperature changes. As a

result, decisions related to pressure manipulation directly affect the thermal structure of the process and, consequently, the opportunities for heat recovery.

According to Haoshui et al. [1] The systematic integration of power and heat has evolved significantly over several decades, moving from basic component design to complex network synthesis. In 1983, the principles of Pinch Analysis were expanded through the "appropriate placement" concept, allowing for the strategic integration of heat engines and heat pumps [2]. This conceptual framework was further formalized in 1987 through the development of a superstructure-based optimization model for the integration of these thermal machines [3].

The specific concept of Work Exchanger Networks (WENs) was formally proposed in 1996 [4], marking a shift toward treating work as a primary utility. In 2007, the ExPAnD procedure advanced the field by combining heuristics, pinch, and exergy analyses for subambient design [5]. By 2014, the field matured into the simultaneous design of Work and Heat Exchanger Networks (WHENs) through superstructure-based MINLP optimization [6].

Recent advancements have focused on refining these synthesis methods to handle increasing complexity. In 2015, new insights regarding the appropriate placement of compressors and expanders led to the development of manual design procedures [7–10]. This was followed by the introduction of an extensive superstructure for WHENs. Perhaps the most comprehensive superstructure is attributed to Nair et al. [11]. In their model, streams are not pre-classified as hot or cold, or as high-pressure or low-pressure. Instead, the model determines their behavior, which may even change across the various stages a stream can undergo between its supply and target conditions. Furthermore, unlike previous models, it accounts for liquid-vapor phase changes. However, it only considers the use of turbines, compressors, and valves, omitting pumps to increase liquid pressure (for instance, in systems that favor condensation prior to pressure elevation to avoid the use of costly compressors).

## WHEN FRAMEWORK

The WHEN problem we are dealing with can be stated as follows:

Given a set of process streams with specified supply and target states (pressure, temperature, and phase), the objective is to determine the optimal thermodynamic path for each stream—incorporating heating, cooling, compression, and expansion stages—to synthesize a network of pressure-change equipment, heat transfer units, mixers, and splitters. This configuration is optimized based on a relevant performance metric, such as minimum energy cost, minimum total annualized cost, or minimum total exergy consumption.

Several relevant features address and overcome common limitations in existing models:

- Variable Bounds: The values for state variables (P, T) or flow rates do not need to be fixed beforehand; only the lower and upper bounds for these parameters are required.
- Stream Classification: Whenever possible, streams are pre-classified as hot (requiring cooling) or cold (requiring heating) to improve the numerical performance of the model. If the behavior is unknown a priori, streams can be defined as "unclassified, " allowing the optimization to determine their role.
- Variable Thermodynamic Paths: Streams undergoing both temperature and pressure changes may follow complex routes involving compressions, expansions, heating, or cooling. Consequently, their behavior may switch between "hot" and "cold" multiple times along the path. Therefore, these streams are generally treated as "unclassified."
- Phase-Independent Pressure Changes: Pressure changes are not restricted to gaseous streams (a common simplification in many models); the model includes also liquid compression and expansion through valves, which may result in liquid-vapor mixtures.
- Rigorous Thermodynamic Correlations: The thermodynamic behavior of each stream between its supply and target states is rigorously correlated using Aspen HYSYS. Integrating these correlations into the optimization model provides a realistic, physically consistent description of process behavior, which is particularly important for streams undergoing condensation, vaporization, or significant density variations.
- Isenthalpic Valve Expansion: Expansion through valves is assumed to be isenthalpic. By utilizing rigorous correlations, it is unnecessary to assume constant Joule-Thomson coefficients or to restrict valve expansion to temperatures below the inversion point. Besides, expansions that end in a multiple phase state can be also incorporated (i.e. typical in refrigeration cycles)
- Multiple Utilities: The model allows for the simultaneous use of multiple hot and cold utilities.
- Multistage Compression: If multistage compression is required, it emerges naturally as a

result of the optimization process.

## Superstructure and model formulation

The overall WHEN model is formulated using Generalized Disjunctive Programming (GDP), which provides a rigorous mathematical structure to represent logical conditions, operational modes, and phase-dependent behavior.

Process streams are allowed to undergo compression, expansion, throttling, or pumping across multiple pressure-change stages, potentially accompanied by condensation and/or evaporation. Indeed, a single stream may experience several phase changes as it evolves from its initial to final conditions. This behavior is represented through a stage wise model of pressure-change units, schematically shown in Figure 1. Each stage may include compressors, turbines, pumps, and valves. Compressors and turbines operate with vapor-phase streams, while pumps are restricted to liquid-phase segments. Valves may handle vapor or liquid feeds; in the latter case, partial or total condensation may occur due to isenthalpic expansion. A bypass option represents cases in which a stage does not require pressure modification. The outlet of each pressure-change stage is subsequently sent to the Heat Exchanger Network for potential heat recovery or rejection, as indicated in Figure 1

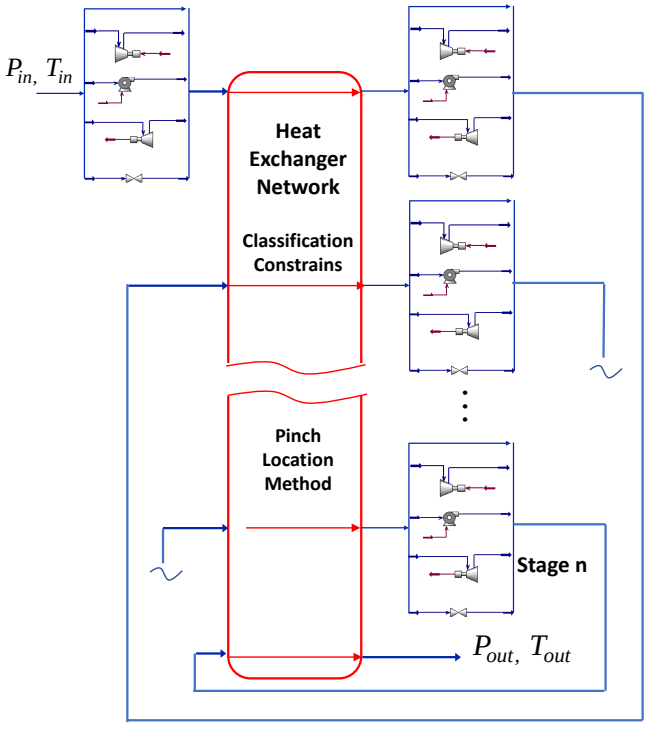

**Figure 1.** WHEN Superstructure involving streams with change in temperature and presure.

Each stage of a process stream is described as a five-term disjunction, in which each term includes a rigorous model for each one of the possible equipment involved: compression, assumed isentropic with fixed efficiency; expansion in a turbine, also isentropic with fixed efficiency; throttling through a valve assumed isenthalpic; liquid pumping assuming constant liquid density calculated at the inlet conditions; or bypass that simple equals inlet to outlet state variables.

The heat exchanger network itself is not modeled explicitly as a set of predefined exchanger matches, as this would lead to an intractable number of discrete combinations, especially when stream classification and phase behavior are uncertain. Instead, the network is represented implicitly through the Pinch Location [12, 13] Method, which efficiently handles variable heat loads, flexible temperatures, unclassified streams, and multiple hot and cold utilities without enumerating individual exchangers.

## Case Study

To illustrate the model, a case study was conducted using data extracted from the process flowsheet presented by Luyben [14] for the self-refrigerated alkylation of C4 olefins with isobutane to produce high-octane C8 components.

In this process, the alkylation reactions occur in a series of stages, which are typically simulated using boiling continuous stirred-tank reactors (CSTRs) such that the reaction product is in the vapor phase. The pressure of this stream must be increased, in this case from approximately 300 kPa to 1480 kPa, for introduction into the separation system. Given that the energy required to compress vapor is significantly higher than that required for liquid compression, and that compressors are among the most expensive equipment in the chemical industry, standard practice involves either condensing the vapor and pumping the resulting liquid or—if the condensation temperature is too low—utilizing a compressor until the condensation temperature is high enough to allow for condensation and subsequent liquid pumping. The original flowsheet uses this second approach.

While this strategy is conceptually sound, it does not account for the potential benefits of integration with the remainder of the process.

Table 1 presents the data for process streams with temperature changes only. Table 2 shows the available utilities while Table 3 details the streams involving simultaneous pressure and temperature changes.

Costs for compressors, turbines, pumps, and other equipment in the optimization model are correlated using the procedure by Turton et al. [15]. Efficiencies for compressors, turbines, and pumps are set at 75%, consistent

with the Aspen.Hysys default values.

The optimal solution includes the selection of hot and cold utilities, energy costs (thermal and electrical), and the annualized costs of pressure-change equipment (pumps, turbines, compressors, and drivers); however, it excludes the heat exchanger network (HEN) investment. Once all stream temperatures and flows are determined, designing a HEN that meets all requirements is relatively straightforward.

A simplified flowsheet identifying the process streams involved in the heat and work exchange network is shown in Figure 2.

The optimal solution includes the selection of hot and cold utilities, energy costs (thermal and electrical), and the annualized costs of pressure-change equipment (pumps, turbines, compressors, and drivers); however, it excludes the heat exchanger network (HEN) investment. Once all stream temperatures and flows are determined, designing a HEN that meets all requirements is relatively straightforward. Figure 3 presents the optimal configuration, including the pressure-change equipment for the relevant streams.

The optimal solution shows counterintuitive behavior. Initially, the vapor stream is compressed to the minimum pressure required for condensation with available cold utilities (~309 kPa at approximately 15 °C). Compression then continues using a liquid-phase pump. However, instead of reaching the final target pressure, the stream is only pumped to ~937 kPa, where it is evaporated and superheated by process streams. A second compressor then raises the pressure to the final specification. This final compression also increases the temperature to approximately 15 °C above the target temperature.

The second condensation together with the final superheating are used by the system to increase the degree of heat integration, reducing both hot and cold utilities.

The total energy integration cost using the strategy described above is 4, 395 k$/y. In contrast, following the strategy presented by Luyben [15] results in a cost of 4, 945 k$/y, which is 12.5% higher. Furthermore, decoupling the final heat exchanger network design from the energy and major equipment cost targets (such as compressors and turbines) ensures model reliability and robustness. This case study is formulated as a non-convex Mixed-Integer Non-Linear Programming (MINLP) problem, consisting of 2, 752 equations, 2, 065 variables, and 45 binary variables. It was solved to global optimality using the GUROBI solver [16] in 6.5 seconds using a personal computer (Intel(R) Core(TM) i7-10700 2.90GHz with 32 GB RAM)

## ABSTRACT

Decarbonizing ammonia by replacing grey with green hydrogen directly affects the operation of the Haber-Bosch (HB) process. When directly coupled to green hydrogen production from renewable energy, the HB process should be able operate flexibly to match variable hydrogen supply. This study presents a structured approach for designing a load-flexible HB plant, supported by a rigorous process model. First, we screen 2, 000 designs at high (100%) and low (10%) hydrogen loads to assess operability. Only 1, 100 designs are feasible for both loads, underscoring the need to account for multivariable interactions during design. Next, we assess the economic feasibility of a base design, comparing HB operation under constant and flexible loads. Flexible operation reduces the levelized cost of ammonia (LCOA) by about 5.8%, primarily by lowering green hydrogen production costs. This cost reduction results from downregulating hydrogen production during periods of high electricity prices. By contrast, HB design improvements yield only small LCOA reductions (about 0.4%), though lower reactor pressure and a larger reactor volume remain the best HB design options to further reduce renewable ammonia costs.

## INTRODUCTION

Ammonia is one of the most-produced chemicals worldwide. It is primarily used as a fertilizer, but could also serve as an energy carrier or fuel in the future [1, 2]. Most ammonia is produced from hydrogen via steam methane reforming, also called grey hydrogen. Since grey hydrogen is produced from natural gas, ammonia production inherently accounts for approximately 2% of global greenhouse gas emissions [2]. To reduce the environmental impact of ammonia production, studies suggest replacing grey hydrogen with green hydrogen as the primary feedstock [1, 2]. Pure grey and green hydrogen are chemically identical; however, their production behavior can significantly affect ammonia plant operations. Today's commercial ammonia plants all rely on the Haber-Bosch (HB) process, in which hydrogen and nitrogen are converted to ammonia over a metal catalyst at high pressure and temperature. The HB process is expected to remain the preferred option, at least in the mid-term, even when coupled to a green hydrogen supply.

The main difference between producing ammonia from green or grey hydrogen lies in the availability and flexibility of hydrogen supply. Typically, ammonia production is coupled directly with a hydrogen production process to minimize the cost of hydrogen storage and transport [3, 4]. Grey hydrogen, produced continuously from methane, enables the HB process to operate continuously at a constant hydrogen load. In contrast, green hydrogen production via electrolysis powered by renewable energy can exhibit significant load variations, mainly due to the intermittent nature of renewable electricity supply. Although modern electrolyzers can rapidly adapt to changing conditions [5], incorporating this flexibility into load-flexible HB plant design and operation remains an open challenge, increasing the design complexity.

Many previous studies have focused on the core of the HB process, the reactor system [6]. The reactor system usually consists of a combination of adiabatic beds and cooling systems to drive the strongly exothermic reaction $3\,H_2 + N_2 \rightarrow 2\,NH_3$. Most conventional HB plants today still rely on the reactor system, which couples multiple adiabatic reactor beds with quench cooling (AQCR). However, Morud and Skogestad first noted that this

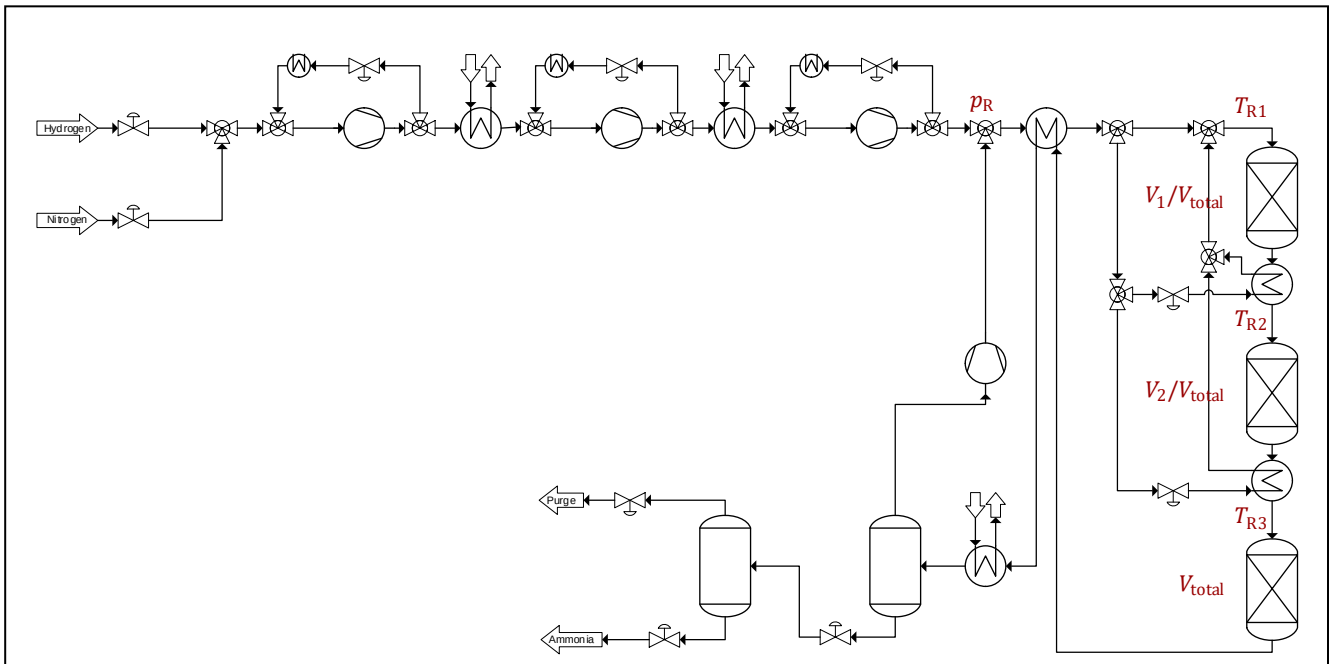

**Figure 1:** Haber-Bosch process flowsheet with indication of the seven key design variables.

AQCR system could experience stability issues during load changes [7]. In contrast, Rosbo *et al.* found that adiabatic indirect-cooled reactor (AICR) systems can handle load changes well and achieve higher conversion rates than AQCR systems [6]. Since then, several studies have focused on operating HB plants for green ammonia production using AICR systems, assuming variable hydrogen supply rates ranging from 100% to 10% of the nominal capacity [4, 8]. Furthermore, given the described advantages, ammonia plant licensors are increasingly focusing on AICR systems rather than AQCR systems, particularly for green hydrogen applications [8, 9]. Recently, the world's first large-scale demonstration plant for dynamic ammonia production opened in Denmark, operating solely on renewable energy and using an AICR system [9]. AICR systems use three reactor beds with interbed cooling in series. The coolers are usually heat-integrated, resulting in a complex HB design. Key design choices include compressor dimensions, reactor bed volumes, and heat exchanger sizes. However, dimensions are rarely publicly available.

Given the degrees of freedom, traditional process design focuses on a single steady-state operating point. In the HB process, this point corresponds to a nominal hydrogen supply rate. But, coupling the HB process to a green hydrogen source often results in a variable feed supply, making single-point designs potentially infeasible or uneconomical. Studies show that certain HB process designs can operate at reduced hydrogen feed rates through various low-load operating procedures [4, 10]. Opinions diverge on whether the reactor pressure should be reduced from the nominal setpoint during low-load operation [4] or remain constant [10]. While some studies showed better performance under varying pressure [4], we believe that, given concerns about mechanical stress from frequent pressure changes, operating at constant reactor conditions is preferable.

In this study, we provide guidance for designing a flexible HB plant to produce green ammonia using green hydrogen. We explore the range of feasible AICR system designs using a detailed, rigorous simulation model and demonstrate the potential economic advantages of flexible operation. We also examine how HB process design can be adapted and improved to further reduce costs when coupled to a green hydrogen supply.

## METHODOLOGY

In this chapter, we first detail the HB process model and its key design variables, including reactor pressure, bed inlet temperatures, and reactor bed volumes. We then introduce a sampling algorithm to efficiently explore the feasible design space defined by these variables. Further, we present how to calculate and quantify the costs of green ammonia production. Finally, we explain how dynamic electricity prices can serve as decision variables for operating the green hydrogen production and HB plant at variable loads.

### Green Ammonia Process Design

The green ammonia process design follows the same basic flowsheet as the well-known HB process, developed by Fritz Haber and Carl Bosch in the early 20$^{th}$ century, and largely unchanged since then. Our model, shown in Figure 1, comprises three main parts: (i) the feed compression of reactants (hydrogen and nitrogen), (ii)

the reactor system for converting the reactants to ammonia, and (iii) the separation system for recovering unreacted gases and product purification. The plant is designed to produce 500, 000 tonnes of ammonia per year using the commercial AVEVA Process Simulation (APS) software. For modelling details, we refer to our previous work [11], as the process design here investigated follows a very similar setup with similar assumptions.

In the process, three compressors with intermediate cooling in series compress the reactant gas from 10 bar to the specified reactor pressure. Each compressor is equipped with an anti-surge recycle that opens at feed flow rates below 60% of the nominal load to prevent surging. The reactor system is based on an AICR design with three adiabatic fixed beds and interbed cooling. Due to the exothermic reaction, the effluent from each reactor bed is hot and therefore cooled by the cold reactor feed stream. The remaining heat from the last bed is integrated to heat the reactor feed stream via the feed-effluent heat exchanger. Since single-pass conversion in the AICR system is limited by chemical equilibrium to about 30% (depending on operating conditions) [6], the reactor effluent still contains high concentrations of nitrogen and hydrogen. These gases must be recovered and recycled for efficient operation. To maximize recovery, the reactor effluent stream is further cooled and separated into two phases in a flash drum. The reactant gases in the distillate stream are recompressed to reactor pressure and recycled, while the ammonia-rich bottom stream is further purified. A second flash at lower pressure vaporizes the remaining impurities from the product, achieving 99.8 mol-% ammonia purity.

The most impactful and complex design decisions concern the selection of the AICR system's size and operating conditions. Key variables include reactor pressure, individual reactor beds' inlet temperatures, and the individual volumes of the three reactor beds. These key variables not only affect reactor conversion but also influence equipment specifications, such as compressor dimensions, reactor bed volumes, heat exchanger sizes, and, consequently, equipment costs and the required amount of utilities.

## Sampling of Design Alternatives

The values of the seven previously defined key design variables must be carefully selected by the responsible design engineer, as not all possible combinations of design variable values yield feasible design solutions; certain regions of the design space may be inherently infeasible due to process constraints. This problem becomes even more complex if the design must be operable over a broad range, rather than at a single operating point, as required for green ammonia production.

To efficiently explore the design space, we define broad bounds for all key design variables (see Table 1). We assume uniform distributions within these bounds and use Latin Hypercube Sampling (LHS), a quasi-random, space-filling technique, to generate numerous design alternatives. Each alternative is a unique combination of the key design variables and is evaluated using the rigorous process model in APS. We classify the results as feasible or infeasible based on process system constraints. To account for different operating loads, we test the feasibility at both the high hydrogen load (same as nominal) and the low hydrogen load (10% of nominal).

**Table 1:** Base design and bounds for the HB process key design variables.

| Design Variable | Base | Bounds |
|---|---|---|
| Reactor Pressure ($p_{\mathrm{R}}$) in bar | 218 | [200, 250] |
| Total Reactor Vol. ($V_{\mathrm{total}}$) in m$^3$ | 65 | [50, 80] |
| Ratio Volume Bed 1 ($V_{\mathrm{R1}}/V_{\mathrm{total}}$) | 0.3 | [0.1, 0.4] |
| Ratio Volume Bed 2 ($V_{\mathrm{R2}}/V_{\mathrm{total}}$) | 0.3 | [0.2, 0.4] |
| Inlet Temp. Bed 1 ($T_{\mathrm{R1}}$) in K | 670 | [620, 700] |
| Inlet Temp. Bed 2 ($T_{\mathrm{R2}}$) in K | 620 | [620, 700] |
| Inlet Temp. Bed 3 ($T_{\mathrm{R2}}$) in K | 620 | [620, 700] |

## Economic Evaluation

Several economic metrics can evaluate green ammonia production, such as net present value (NPV), payback time (PBT), minimum selling price (MSP), and levelized cost of ammonia (LCOA). NPV and PBT depend on financing, discount rate, and market prices, making them suitable for evaluating individual investments. In contrast, MSP and LCOA measure economic performance per unit, allowing comparison across projects. We use LCOA as our primary metric because it provides the average cost of ammonia production over the plant's lifetime, independent of market prices. Table 2 summarizes all prices and economic parameters used.

The LCOA is calculated using Equation 1: The annualized total capital investment (TCI) is split over the plant's lifetime using the capital recovery factor (CRF) (see Equation 2), then operational expenditures (OPEX) are added, and the result is divided by the annual ammonia production size.

$$LCOA = \frac{TCI * CRF + OPEX}{M_{\mathrm{NH_3,annual}}} \tag{1}$$

$$CRF = \frac{\mathrm{r}(1+\mathrm{r})^{\mathrm{n}}}{(1+\mathrm{r})^{\mathrm{n}}-1} \tag{2}$$

The TCI is calculated by summing the fixed capital investment (FCI) and additional working capital (WC) costs (see Equation 3). For the FCI calculation, the costs for all process equipments are summed up and scaled by the respective 2024 Chemical Engineering Plant Cost Index (CEPCI) [12]. In the final step, we multiply this sum by the Lang factor for fluid-processing plants (see Table 2) to estimate total installation costs [13].

$$TCI = \sum(C_{\text{equip}} * \frac{\text{CEPCI}_{2024}}{567}) * \text{f}_\text{l} * (1 + \text{f}_\text{WC}) \quad (3)$$

We calculate the cost for each piece of equipment using the equations and assumptions implemented in APS. Due to the harsh conditions (high pressure and temperature) in the HB plant, we assume stainless steel as the construction material for all equipment. The compressors are modeled as centrifugal units driven by an electric motor, with an overall compression efficiency of 95%. For the heat exchangers, we assume a counter-current design and, if necessary, cooling with cooling water. To calculate the heat exchanger area, we use an overall heat transfer coefficient (value depends on the fluids, see Table 2), along with the logarithmic mean temperature difference between the tube and shell sides, and assume a minimum temperature difference of 10 K. The flash units are assumed to be vertical drums with hemispherical heads, each with a residence time of 50 min and a length-to-diameter ratio of three. The AICR system is assumed to be placed in a vertical shell with inner and outer bed diameters of 2 and 3.5 m, and a total length determined by the selected reactor bed volumes. The required thicknesses of the hemispherical heads of the AICR and flash vessels are determined in accordance with the ASME Boiler and Pressure Vessel Code, Section VIII, Division 1, UG-32(f) [14].

**Table 2:** Parameters for the techno-economic assessment.

| Parameter | Value |
|---|---|
| CEPCI 2024 ($\text{CEPCI}_{2024}$) | 800 [12] |
| Lang factor ($\text{f}_\text{l}$) | 5.93 [13] |
| Working capital factor ($\text{f}_\text{WC}$) | 15% [15] |
| Plant lifetime (n) | 25 yr |
| Discount rate (r) | 6% |
| Overall heat transfer coefficient pressured gas – pressured gas | 0.5 kW/m²/K |
| Overall heat transfer coefficient pressured gas – liquid | 0.4 kW/m²/K |
| Price cooling water | 0.35 €/GJ [15] |
| Price catalyst | 15.36 €/kg [16] |
| Energy demand nitrogen | 0.37 kWh/kg [17] |
| Catalyst lifetime | 5 yr |
| Electricity fees and taxes | 26.26 €/MWh [18] |

We calculate OPEX (Equation 4) from reactants costs (hydrogen and nitrogen) and utilities (compression energy, cooling water, and catalyst replacement as a continuous cost). We use fixed prices for cooling water and catalyst per unit, and variable electricity prices to calculate hydrogen, nitrogen, and compression costs. The levelized cost of operation of hydrogen (LCOH) are calculated using the European Hydrogen Observatory calculator with default values for a PEM electrolyzer [19], splitting the cost into CAPEX, electricity, and OPEX (see Equation 5). We source electricity prices from Danish databases [20] and adjust operating times to match the plant operation as described in the next subsection.

$$OPEX = \left(C_{\text{H}_2} + C_{\text{N}_2}\right) + \left(C_{\text{comp}} + C_{\text{cw}} + C_{\text{cat}}\right) \quad (4)$$

$$C_{\text{H}_2} = \dot{m}_{\text{H}_2} * \left(c_{\text{H}_2,\text{CAPEX}} + c_{\text{H}_2,\text{Elec}} + c_{\text{H}_2,\text{OtherOPEX}}\right) \quad (5)$$

For load-flexible operation, we average OPEX across the two main operating points (high and low load), assuming instantaneous changes between. In reality, the HB plant, compared to the PEM system, is the limiting factor for transition time between operating points, and transitions are not rapid [4–6]. However, recent studies show that fast transitions of 3% load change per minute are possible [4, 8]. Further, we use representative electricity prices at the two operating loads to account for realistic costs when using load-flexible operation.

## Load-Flexible Operation

Green hydrogen and ammonia production depend heavily on renewable energy supply. In practice, a green ammonia plant would most likely be built alongside electrolyzer units close to renewable electricity sources, such as solar or wind farms. However, modeling renewable electricity generation is heavily dependent on location and technology and is beyond the scope of this study. To still account for variability in renewable electricity generation, we consider dynamic electricity prices driven by regional demand and supply. In particular, we use historic hourly distributed prices from the day-ahead market in West Denmark from 2024 [20]. Figure 2 displays the mean price and the histogram of all prices, which range from slightly negative to above 800 €/MWh. With these prices we calculate LCOH and LCOA to approximate the dynamic price effect on renewable production plants.

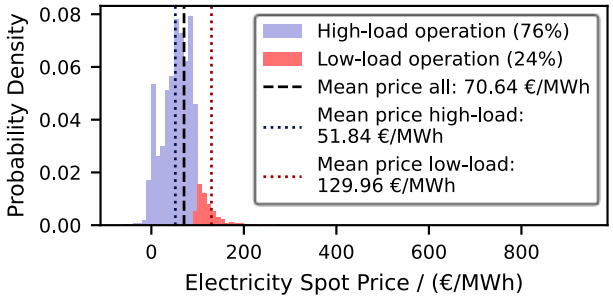

**Figure 2.** Electricity spot price probability distribution from hourly day-ahead market data from West Denmark in 2024 [20], including the indication of mean price and representative prices for load-flexible operation.

For constant operation, each electricity price would have the same impact on average production costs. However, with a load-flexible system, production at high prices can be reduced to a low-load operating point,

while at low prices, the production can be shifted back to the high operating point. In this study, we compare a constant operation at high load with the annual average electricity price to a load-flexible approach using two representative prices. The lower of these prices represents the lower 76% of the historic prices, while the high price represents the upper 24%.

## RESULTS AND DISCUSSION

In this section, we systematically explore the design space of the HB plant to identify feasible process designs that account for different loads. Then, we evaluate the economics of constant ammonia production relative to load-flexible operation and, lastly, show how an improved HB process design can influence the total LCOA.

### Finding a Feasible Process Design

The most important task when designing a load-flexible process is to identify a design that is operable over the full operating range, rather than at a single operating point. Thus, different designs must be evaluated under different loads. Since we assume that the HB process is primarily operated at two extreme load levels (high and low), we evaluate the designs at these two operating points. In total, we sample 2000 different designs and thus perform 4000 evaluations with our rigorous process model. Of the sampled designs, 1103 yield feasible solutions for both loads. Figure 3 visualizes the feasible design space by projecting it onto planes of two variables at a time and differentiating between all sampled (grey) and feasible designs (blue).

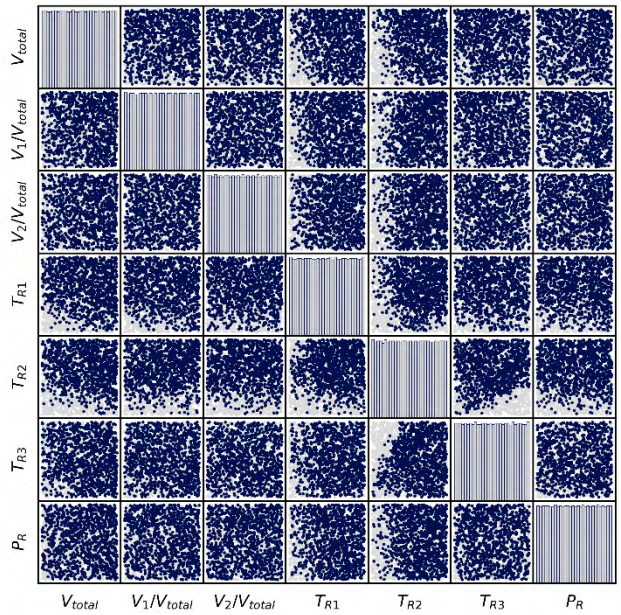

**Figure 3.** Input (grey) and feasible (blue) design-space projections in two-dimensional space.

The success of 55% of all sampled designs implies that a feasible design solution satisfying all process constraints at both loads is indeed possible, but not straightforward. Feasible design solutions exist for most combinations of one or two fixed design variables since only some regions of the two-dimensional projections of the full design space appear completely or largely infeasible, like very low $T_{R2}$ values or combinations of low $V_{total}$ and low $T_{R1}$. However, the contrast between the largely feasible region in plane projections and the large number of infeasible designs indicates that interactions among multiple variables are significant for feasibility. These multivariable interactions should be considered during the process design procedure. We also note that nearly all infeasibilities arise from high-load simulations, suggesting that the design at this operating point should be assessed first.

Based on the insights from the design space evaluation, we select a feasible base design near the center of the total design space for the following assessments. The values of the design variables for the base design are listed in Table 1.

### Comparison of Operational Approaches

Moving forward, when designing a load-flexible plant, the most important objective is that flexible operation reduces costs relative to constant operation at high load. In the following, we compare two operational approaches for integrating green hydrogen and the HB plant based on the LCOA, using the feasible base design identified earlier. Before, in the next subsection, we replace the base design with an improved alternative.

As explained earlier, for flexible operation, the plant operates at high load (76% of the time) with lower electricity prices and at low load (24% of the time) with higher prices. Electricity prices affect green hydrogen costs and other OPEX, such as nitrogen and compression costs. The total equipment costs do not scale with the load since the nominal plant size remains unchanged, but operating costs vary. However, compressor power does not scale proportionally with the load because, for low loads, anti-surge recycling is required. Table 3 highlights key differences between the operation of the base design at high and low loads.

With above assumptions for the two operational modes, the first two bars in Figure 4 directly compare the LCOA for constant versus load-flexible HB process operation using the base design. The figure details the separate contributions of HB TCI and all OPEX components. Overall, the load-flexible approach yields an LCOA about 5.8% lower than constant operation. Comparing this LCOA to literature is challenging because key parameters, such as electrolyzer technology and electricity price, vary widely. For example, our LCOA matches the values reported by Sánchez and Martín [21] (1.35 €/kg),

which are well above current grey ammonia prices. In contrast, Hartvigsen *et al.* [22] report an LCOA of 792 €/kg for green ammonia in Denmark, using alkaline electrolyzers with far lower electricity prices for 2030.

**Table 3:** Comparison between high and low load operation of HB process.

| | High | Low |
|---|---|---|
| Faction of time in operation | 76% | 24% |
| Hydrogen feed rate in t/d | 250 | 25 |
| Ammonia production rate in t/d | 1368.6 | 136.81 |
| Average electricity price + fees and taxes in €/MWh | 78.10 | 156.22 |
| Compression Demand in MW | 26.18 | 15.51 |
| Cost for Compression in €/h | 2045 | 2423 |
| TCI in M€ | 285.85 | 285.85 |

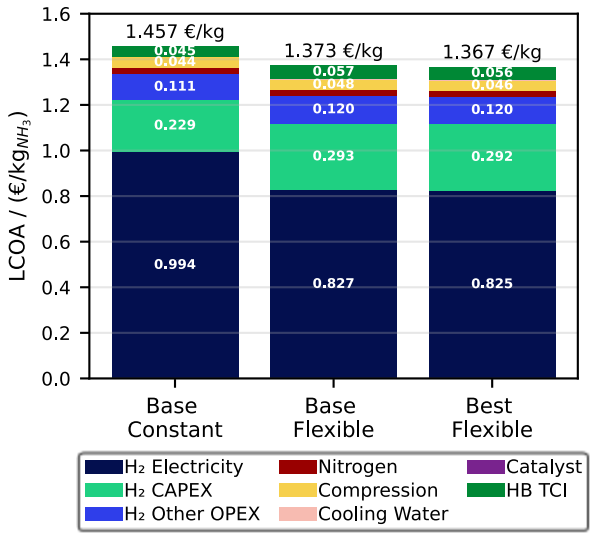

**Figure 4.** LCOA and its components for the three different case studies: Constant operated base design, load-flexible operated base design, and load-flexible operated best (LCOA) design.

As shown by the individual contributions, the green hydrogen price accounts for more than 91.5% of the total LCOA in the constant and 90.3% in the load-flexible case. The LCOH itself depends heavily on the price of green electricity; thus, using load-flexible operation for green hydrogen production reduces the share of electricity costs in the LCOH from 74.5% to 66.7%. This reduction is then inherently responsible for the lower LCOA when the HB process also operates flexibly. In the future, adding hydrogen storage between the PEM system and the HB process could be a case worth comparing. Introducing a buffer offers the advantage that PEM and HB process operations can be flexibilized separately, which could yield further LCOA reductions, despite high investment in the hydrogen storage system [5].

Another result highlighted by Figure 4 is that under flexible operation, the shares of CAPEX for the hydrogen generation process and the HB process increase. The higher share of equipment costs stems from the lower total output from the same plant during periods of low load. Thus, in particular, lower electrolyzer costs could significantly affect the LCOH and LCOA, especially when operated flexibly. In contrast, the effect of reducing the TCI or utility costs of the HB process itself on the LCOA is limited, accounting for only about 10% of the total LCOA. However, the ratio of hydrogen consumed to ammonia produced in the HB process could have a significant impact, and the HB design should be closely assessed in this regard.

## Benefit of HB Process Design Enhancements

Having examined differences in LCOA between constant and load-flexible operation, we investigate how improvements of the HB process design could further reduce the green ammonia costs. In particular, we focus on the three most influential factors related to the HB process identified in the analysis of the LCOA components: the ratio of hydrogen feed to ammonia produced (at high load), the TCI of the HB plant, and the cost for electric compression (at both loads). Figure 5 shows the LCOA for each of the three influencing factors across all feasible designs, identified during the LHS-based design evaluation. The scatter plots show that all three factors indeed influence the total LCOA, and that, starting from the base design, minimizing each factor individually also reduces the LCOA.

The LCOA of the selected base design equals the average LCOA of all feasible designs and the standard deviation of LCOA across designs is very low (0.003 €/kg), supporting the claim that the HB process design has little influence on the total LCOA. Selecting the design with the lowest LCOA yields a 0.4% reduction compared to the base design (see Figure 4, second and third bar).

The best design alternative with the lowest LCOA (Best LCOA) also yields the lowest TCI, indicating that a focus on reducing equipment costs can have a positive overall effect. However, the design with the lowest hydrogen-to-ammonia ratio (Best HtA) and the lowest compression power has only a negligibly higher LCOA. Table 4 compares the two best designs and shows similarities in the values of the key design variables.

Both designs operate almost at the lower bound of the pressure range to minimize compression and compressor costs. This suggests that, in the future, even lower pressures could be assessed if compatible with the chosen catalyst. Recently, research has focused on so-called low-pressure HB processes using special catalysts that enable pressures below 150 bar, potentially reducing overall compression costs [2]. Further, our selected two best design candidates also almost maximize the total

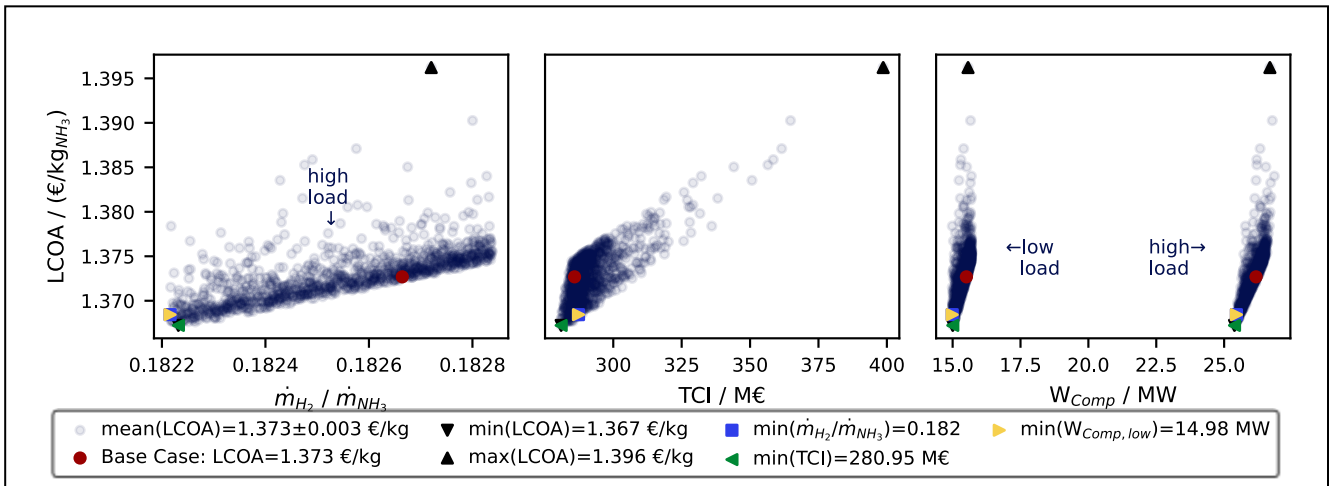

**Figure 5:** LCOA related to three HB process metrics: hydrogen-to-ammonia ratio, TCI, and compression demand.

reactor volume to its upper limit. As seen in Figure 4, catalyst costs affect the LCOA only minimally; thus, a higher reactor volume that improves single-pass conversion and reduces the demand for recycle stream compression could potentially lead to a reduction of the total LCOA. Lastly, comparing the volume shares among the three reactor beds and the reactor bed inlet temperatures for both design candidates does not reveal close similarities. However, the choice of reactor bed volume together with the reactor bed inlet temperature is essential for the feasibility of the design, as discussed earlier.

**Table 4:** Best feasible HB process designs related to the lowest LCOA and the lowest hydrogen-to-ammonia (HtA) ratio.

| Design Variable | Best LCOA | Best HtA |
|---|---|---|
| Reactor Pressure ($p_{\mathrm{R}}$) in bar | 200.7 | 200.0 |
| Total Reactor Vol. ($V_{\mathrm{total}}$) in m$^3$ | 80.0 | 79.4 |
| Ratio Volume Bed 1 ($V_{\mathrm{R1}}/V_{\mathrm{total}}$) | 0.263 | 0.333 |
| Ratio Volume Bed 2 ($V_{\mathrm{R2}}/V_{\mathrm{total}}$) | 0.373 | 0.388 |
| Inlet Temp. Bed 1 ($T_{\mathrm{R1}}$) in K | 654.0 | 638.9 |
| Inlet Temp. Bed 2 ($T_{\mathrm{R2}}$) in K | 675.2 | 679.3 |
| Inlet Temp. Bed 3 ($T_{\mathrm{R2}}$) in K | 667.3 | 628.5 |
| **LCOA** | **1.367** | **1.368** |

In summary, while the total impact of all key design variables on the LCOA could be evaluated more quantitatively by calculating sensitivity indices, the overall impact of the HB process design on the total LCOA remains small relative to the cost of green hydrogen. Thus, we find this effort is not worthwhile. The same applies to the use of optimization techniques to minimize the LCOA, treating the key design variables as decision variables.

## CONCLUSION

This work addresses the central challenge of coupling ammonia synthesis to variable green hydrogen: high fluctuations in renewable electricity and, hence, stochastic hydrogen availability and price. We proposed a structured design-space exploration to identify Haber–Bosch (HB) designs that remain operable at extreme load variations. Further, we compared constant production with load-flexible operation based on the levelized cost of ammonia (LCOA). The key finding is that load-flexible operation can lower the LCOA relative to constant operation because electricity-driven hydrogen costs dominate overall economics, and shifting production toward periods with low electricity prices reduces the average green hydrogen price. By contrast, HB process design variations have only a secondary influence on the total LCOA. We indicate that a lower reactor pressure (within catalyst constraints) and a larger total reactor volume can reduce the overall LCOA by lowering compression duty and compressor sizes, yet the aggregate cost benefits of improved HB designs remain modest relative to the price of green hydrogen.

These conclusions should be interpreted in light of the scope and modeling choices. The analysis compared two steady-state load points and did not include dynamic transients. Control constraints were enforced implicitly by feasibility, not by explicit plant-wide control design. Moreover, exogenous electricity prices and renewable availability were also not modeled at hourly resolution. To address these limitations, future work should focus on rigorous modeling of renewable generation, electrolyzer dynamics, and plant controls, while accounting for time-series market and weather data. Stochastic, multi-objective assessments (cost, emissions, reliability) can then quantify when added design complexity is justified. Overall, the dominant levers for renewable ammonia lie upstream, in electricity price trajectories, electrolyzer cost, and integration strategies, while HB design refinements provide only incremental gains.

## ABSTRACT

Manufacturing disruptions can be a major driving factor in the wastage of resources and delays which result in spiralling costs and cancelled orders. Operational decision making should therefore consider the potential for disruptions from as many sources as possible, encouraging improvements to operational resilience and agility. Our work presents a scheduling and rescheduling framework formulated as a rolling horizon problem for the emulation of real time decision making within a dynamically changing scenario. The framework is applied to a complex multistage problem with parallel lines susceptible to disruptions as a result of process or equipment failures, or ineffective inventory management that results in material shortages. The framework is demonstrated for a simple example case which highlights the impact of disruptions on the time taken to complete orders and the associated costs. It is observed that the inclusion of disruptions can alter equipment congestion, shifting focus for future process improvements. A scenario with intermittent raw material availability is explored, with greater mean and range for a large number of simulations performed, compared to the case with constant availability. A compounding effect is observed, whereby disruptions lead to a greater likelihood of further disruptions as machine runtimes increase and tasks are repeated. The presented framework presents a strong basis from which future works could be performed in a range of scenarios and with different operating policies.

**Keywords**: Scheduling, Modelling, Rolling Horizon Optimization, Supply chain, Pyomo

## INTRODUCTION

Process scheduling is a key component of the field of operations management, influencing decisions surrounding the timing of tasks in order to meet objectives using finite resources. Significant research efforts have been made globally in all almost all chemical and industrial engineering sectors to achieve improvements in order to minimise costs and increase efficiency. However, the practical reality of manufacturing often differs to the ideal case, and the ability to understand, anticipate, and respond to disruptions can prove to be influential in the ability to meet objectives. In this work, we investigate the role of disruptions in the scheduling of process tasks.

One popular approach for solving larger mixed integer scheduling problems is the fix-and-relax metaheuristic, which involves the fixing of variables from previous iterations and relaxing those for future periods [1]. This allows for the partitioning of large problems while keeping the current window optimisable. Prior works utilising this approach include Brahimi [2] who use the approach to handle a large problem with optional order acceptance and flexible due dates and Bouzid et al. [3] who use it to assess order acceptance under time-of-use costs and carbon taxation.

Works investigating disruptions or changing scheduling scenarios include that of Moghaddam and Saitou [4] who utilised a dynamic pegging approach to handle the predictive and reactive rescheduling of jobs upon changes to order arrivals, due dates, cancellations, and equipment failure. Hidri and Tlija [5] investigated the role of lag times (delays between tasks on a given piece of equipment) in determining the overall makespan (time taken to complete a set list of orders) of a facility. Zhao [6] investigated the handling of material in a multistage facility with uncertain job additions. The use of material handling equipment was dynamically rescheduled in response to orders, with the aim of minimising makespan.

Zheng et al. [7] investigated a dynamic problem with processing delays and demand changes. A Bayesian Network was used to understand the probability distributions for disturbances, informing ongoing decision making.

Our work presents a novel rolling horizon scheduling framework for complex multistage processes with parallel lines. The framework incorporates uncertain disruptions to process outcomes and equipment downtime, with alternative rescheduling responses based on the type of task impacted (setup, main process, or cleaning). Resource constraints and an inventory management system (with associated reorder policy) are incorporated to assess their potential for causing disruptions. An approach inspired by the fix-and-relax metaheuristic is incorporated to minimise computational requirements whilst maintaining dynamic responses that emulate real time decision making. The outcomes of the problems considered are quantified in terms of key metrics including makespan and cost.

# METHODOLOGY

## Problem statement

The showcased framework is targeted at the scheduling and rescheduling of a dynamically changing process. Unanticipated orders are received at set times, with disruptions in the form of process and equipment failures. Resource constraints are also considered, with an inventory management system and operating policy. The following assumptions and assertions are made to define the problem being considered.

**Scheduling**

- Processes are organised into stages which can perform tasks on dedicated equipment. Tasks are performed following defined recipes to complete batches
- The overall framework is split into defined time increments for the performance of additional jobs (batch addition, disruption testing, material ordering) but tasks are scheduled continuously
- Setup tasks immediately precede main process tasks which are followed by cleaning tasks
- In the presence of storage capabilities, tasks on a given stage have a defined minimum duration. Otherwise, fixed durations are defined
- Variables for tasks completed or undergoing completion are fixed in the absence of disruptions
- Potential infeasibility following disruptions is handled through the systematic unfixing of batches until feasibility is regained

**Disruptions**

- Disruptions occur in the form of process failures (where quality or yield deviations occur) and equipment failures (which require maintenance to be performed)
- A defined time (relative to the task start point) during material holding in storage is used to perform testing for process failures
- Failure likelihoods are known and defined as fixed probabilities
- Known distributions are used to determine the duration of equipment downtime following failure
- A defined likelihood of recovery is used to determine if repeatable tasks (e.g. purification tasks) are repeated following process failure
- Non-recovery results in material discarding and the entire batch being rescheduled. The same procedure is used should equipment failure occur during a main processing task
- Equipment failures result in equipment being blocked until maintenance is completed
- Setup, main process, and cleaning tasks are rescheduled in the event of equipment failure during a setup task
- The main process tasks are unimpacted in the event of equipment failure during a cleaning task

**Costing**

- The disposal of rejected material has no associated cost
- Labour costs are incurred upon the start of a main process task
- Payments for raw materials are made at the time of reorder
- Equipment repairs have no associated costs

**Orders**

- Orders are received at defined points and contain the order quantity, the order due date, and the desired product
- Deliveries are always completed to their fullest possible extent (based on available inventory) at the due date. Shortfalls are marked for completion at a defined later time

**Inventory management**

- Sufficient unallocated material must be present in order to schedule a batch

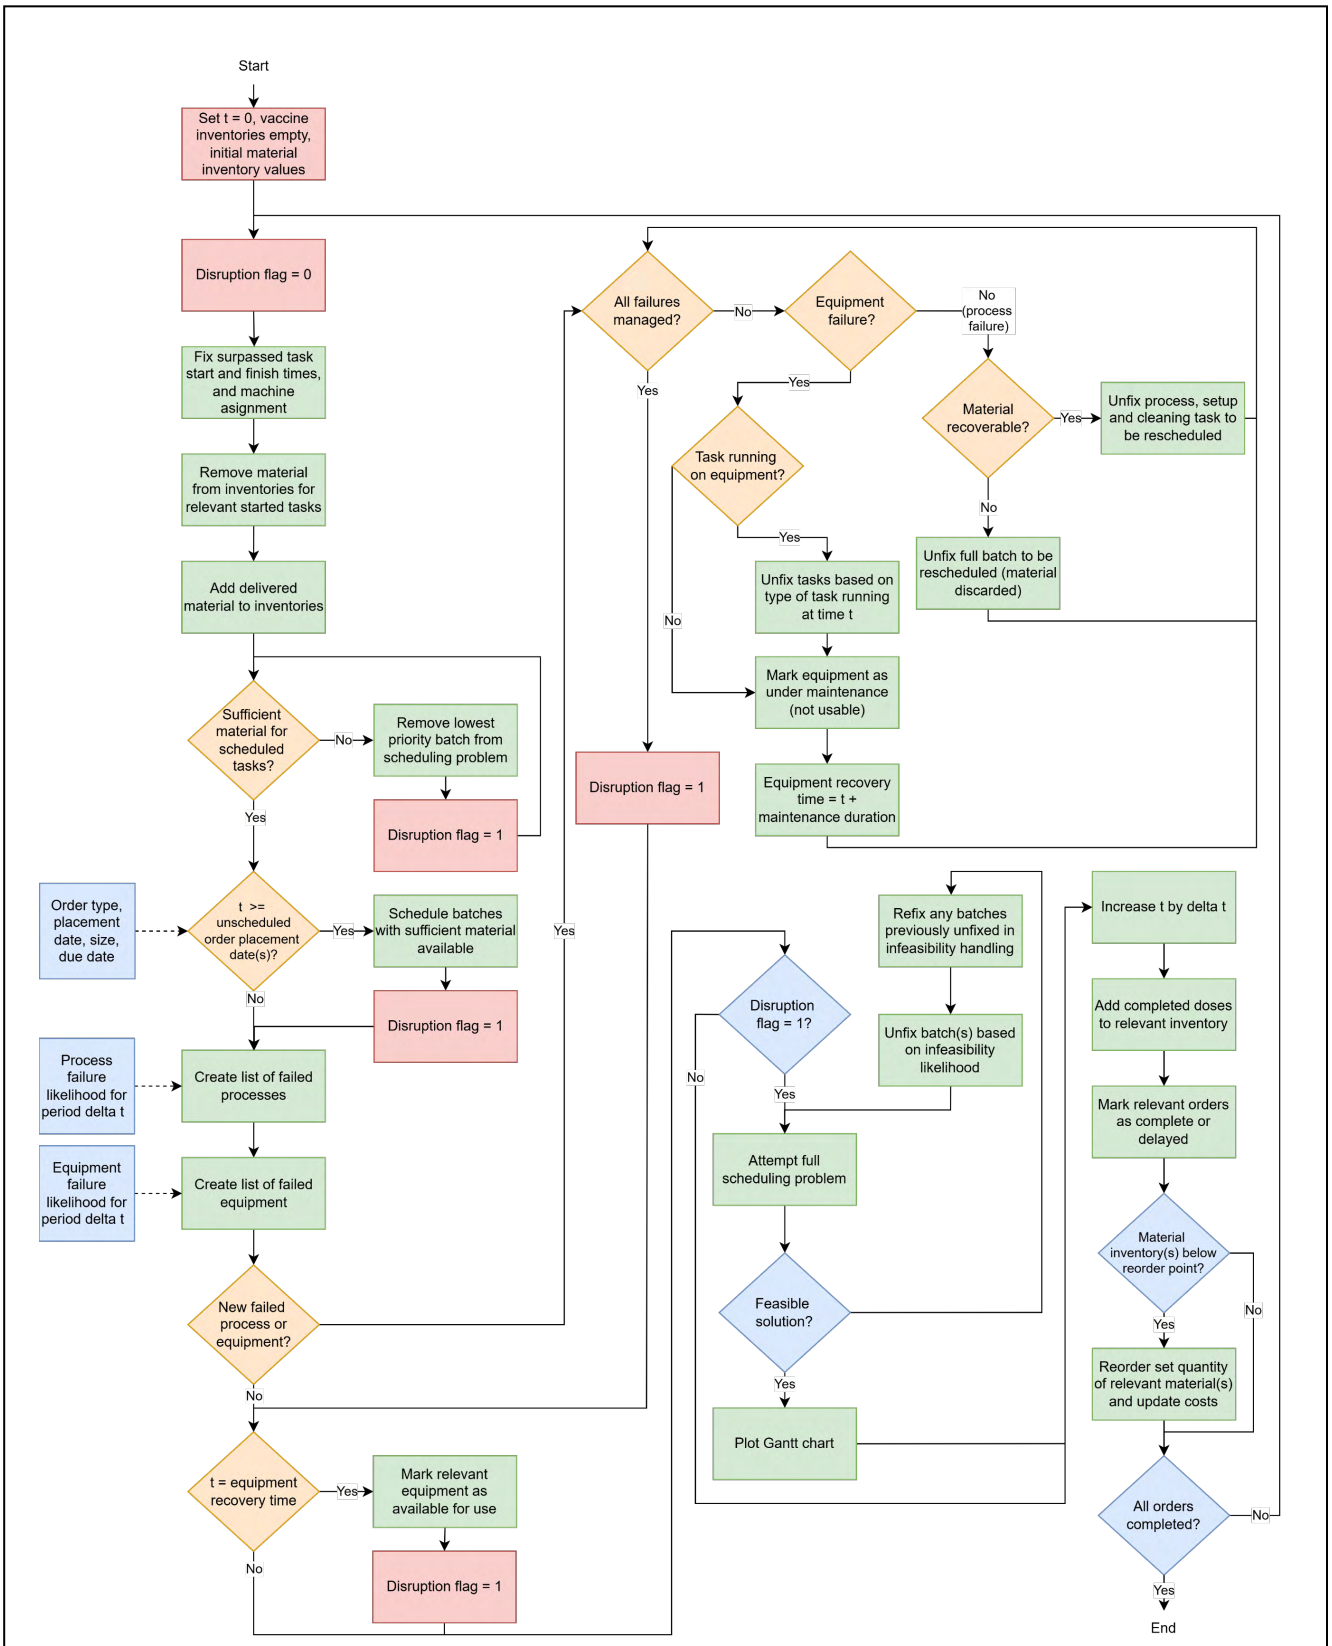

**Figure 1.** An overview of the presented scheduling framework used in this study

- In the case of disruption resulting in insufficient material for currently scheduled batches, the batch with the furthest due date is temporarily unscheduled

- A reorder policy is implemented based on a reorder point. Should the stored quantity of a given material reach this point, a defined quantity is reordered
- Intermittent supply refers to a case where a material is only available to reorder at defined times, unknown to the scheduler

## Scheduling formulation

For brevity, the full formulation for the core scheduling problem will not be presented. A summarised version will be showcased. The key novelty of the formulation is its capacity to facilitate inputs (such as the status of a disruption) from the larger framework into the scheduling problem and allow for effective variable fixing. The objective function is the minimisation of overall makespan as shown in Equations 1. Equation 2 shows the constraint used to enforce the definition of makespan.

$$min(Makespan) \tag{1}$$

$$Makespan \geq Task\ finish\ time\ \forall\ Task\ finish\ times \tag{2}$$

The remaining constraints for the model are used to achieve the following outcomes:

1. Ensure each task is only scheduled upon a single piece of equipment
2. Ensure that the finish time of a task is equal to (for fixed duration tasks) or greater than (for variable duration tasks) the start time plus the minimum duration
3. Ensure that the start time of a successive task in a recipe for a batch is equal to the finish time of the prior task minus the duration of overlap between tasks
4. In the case of a process recovery, the prior constraint is overruled to be greater than or equal to the stated condition
5. Two tasks cannot be performed on the same piece of equipment at the same time
6. The finish times of setup tasks are equal to the start time of the associated main processing tasks, and the start time of cleaning tasks is equal to the process task finish time
7. Cleaning and setup tasks are performed on the same equipment as the main process task

## Dynamic framework

An overview of the framework used to handle inventory management, order addition and completion, equipment and process disruptions, costing, and the rolling horizon model structure can be seen in Figure 1.

The framework begins with a definition of initial inventory levels followed by the main loop. The main loop first handles the fixing of variables associated with tasks completed or under completion, before managing the addition and removal of material from their associated inventories. Next, a check is performed to ensure sufficient allocated material for the currently scheduled batches, with the furthest due batch removed should current inventories be insufficient. Following this, batches from received orders that are yet to be scheduled are added to the scheduling problem, should sufficient unallocated material be available.

Process and equipment failures are determined based on their defined probabilities, creating lists of failed tasks and equipment. Should either of these occur during the current time increment, the failure handling procedure is initiated. In the event of equipment failure, currently running tasks are handled following the rules defined in the problem statement, and in all instances the equipment is marked as not usable until a later time. Should a process failure have occurred, a secondary probability is used to determine if recovery is possible, with task or full batch rescheduling as a result. Any recovered equipment is then marked as available for scheduling.

Should batch addition or removal, a process or equipment failure, or equipment recovery have occurred within the current time increment, the scheduling problem is run. Should an infeasibility occur, batches are temporarily unfixed starting with those that have been disrupted and moving onto those that are running. One batch at a time is initially unfixed, increasing once all combinations have been investigated. The first feasible solution is taken forward.

Finally, the time increment is increased, doses added to inventories, and orders completed or delayed. If inventories fall below their reorder points, those materials are reordered. This loop is repeated until all orders have been completed.

# RESULTS

## Demonstration of disruption impacts

In order to demonstrate the role of disruptions within the framework, a small example problem is showcased featuring the same case with and without disruptions. The example case is an eight stage process, with two pieces of parallel equipment assigned to each stage. The equipment is assigned in order, with stage 1 containing the equipment $k_1$ and $k_2$ and stage 2 containing $k_3$ and $k_4$ and so on. The stages contain a mixture of task types, with stages 1 and 1 being fixed in length, and all others containing storage and so are variable in length (above the minimum duration). Stages 3, 4, 5, and 8 represent

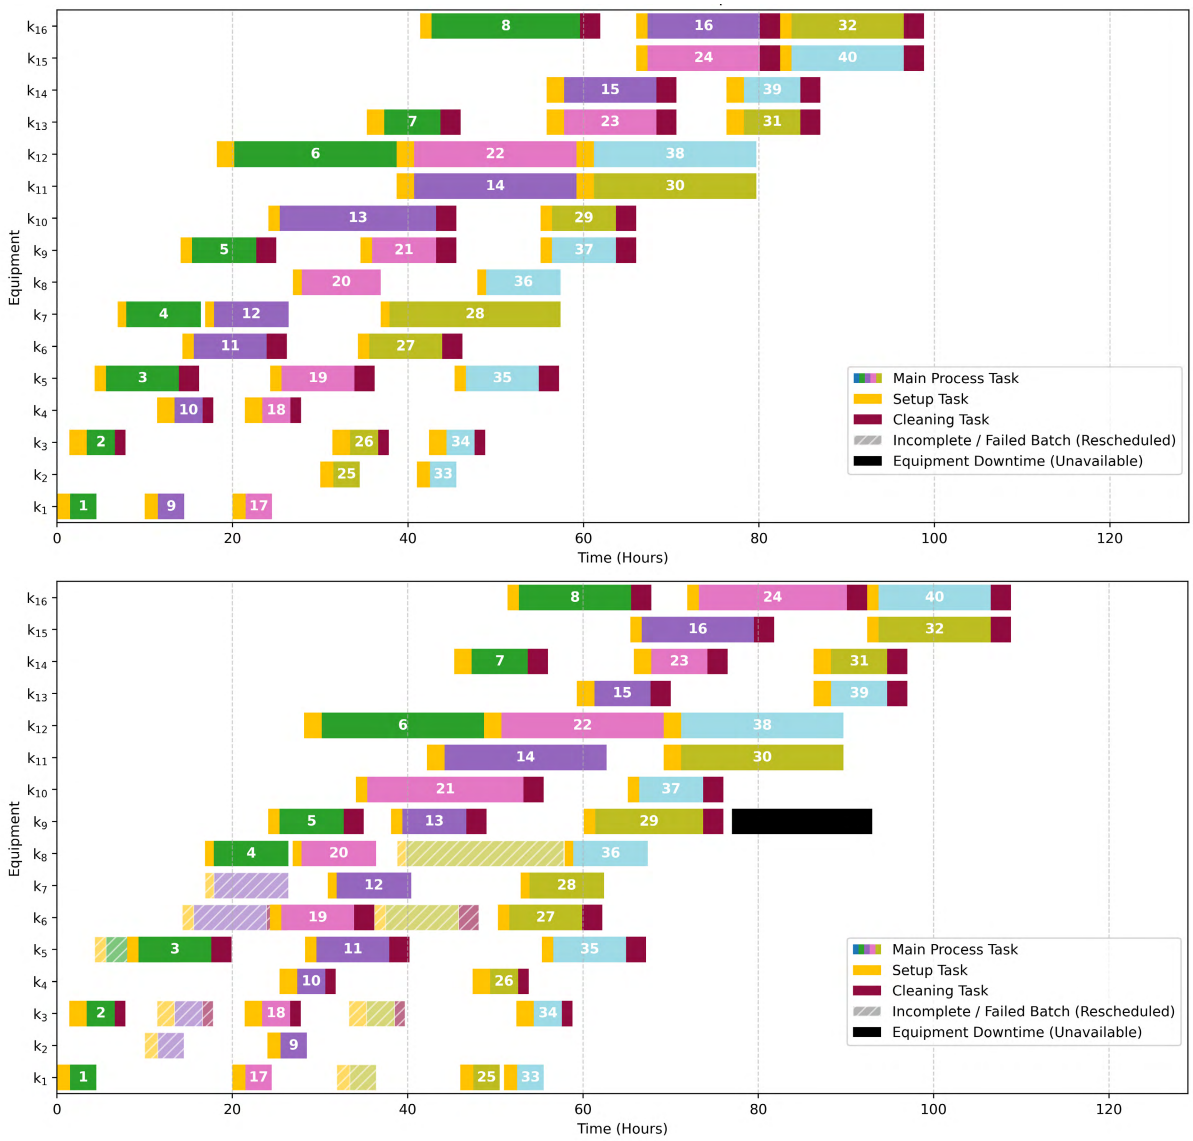

**Figure 2.** Gantt charts showing the scheduling of tasks for the example scenario without (above) and with (below) disruptions

purification tasks, and so have a probability of recovery following process failure. Stages 1, 4, and 6 represent processing using disposable equipment and so no dedicated cleaning is performed. The scenario shown is for the scheduling of 5 identical batches, the orders for which are received at 10 hour increments. A reorder point and reorder size of 3 batches worth of each material is used for the inventory management policy. A lead time of 10 hrs is used for the reordering of material.

Figure 2 shows the impact of disruptions on the scheduling of tasks in a singular instance of the problem. It can be seen that in the case without disruptions, the primary bottleneck is at stage 6 (equipment $k_{11}$ and $k_{12}$) which sees tasks performed back-to-back. This is to be expected given that these tasks have the longest minimum duration of those within the problem. For stages 1 and 2, the use of parallel equipment is not necessary as all tasks could be performed one a singular piece of equipment without any other task being impacted. The case with disruptions demonstrates several instances of process and equipment failure. The first failure is that of task 3 at the time t=7 hrs. This task is recovered, with the remainder of the batch delayed as a result. At t=24 hrs, task 12 on equipment $k_7$ fails and is not recovered. This results in a full rescheduling of the batch, including the repeat of tasks 9-11. This task repetition results in a delay in the scheduling of the batch starting with task 33 at the time t=40 hrs as there is insufficient unallocated material available. At the time t=46 hrs, task 28 on equipment $k_8$ fails and is not recovered, resulting in a full batch re-schedule in which some of the same tasks are repeated on different equipment. Upon the delivery of further

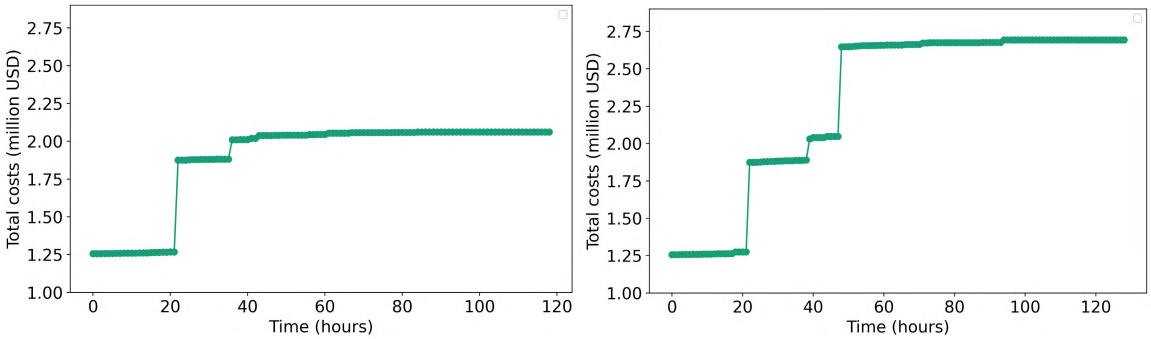

**Figure 3.** Cost increases over time for the example scenario without (left) and with (right) disruptions

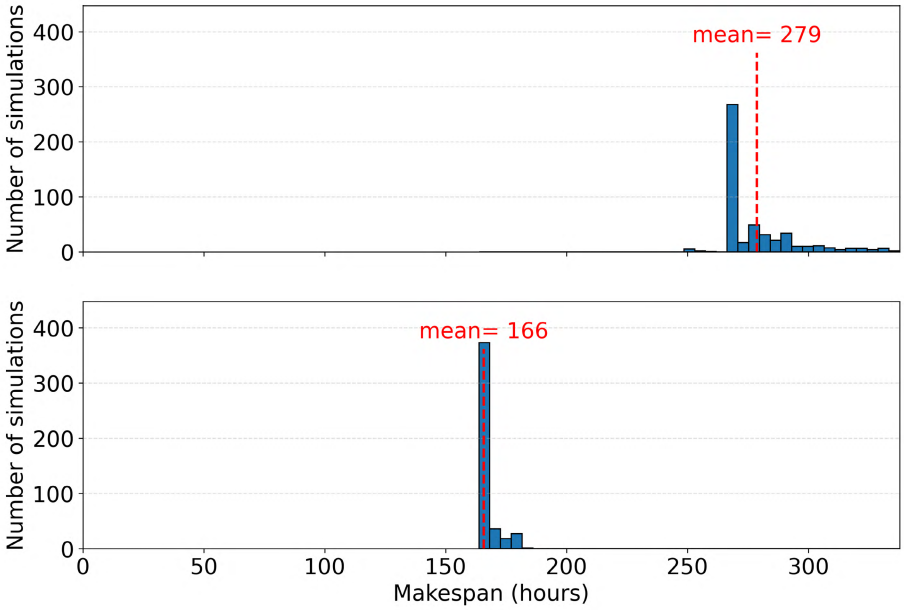

**Figure 4.** Makespan distributions for the case with (above) and without (below) intermittent material supply. 500 simulations were used in each case.

materials, the batch beginning with task 33 is able to be scheduled. At the time t=77 hrs, equipment $k_9$ fails. There is no process running and no further tasks were to be scheduled on that equipment, meaning it has no impact on overall makespan. This would not be the case in all instances of the problem.

The most noticeable impact of the incorporated disruptions is the increase in overall makespan from 98.8 hrs to 108.8 hrs. It can also be seen that the grouping of tasks changes, shifting the limiting factor from purely equipment congestion on a single stage to resource availability, changing equipment congestion, and delays themselves.

Figure 3 shows the cost in each of the same scenarios, incorporating the cost of initial raw material purchase at t=0 hrs. The case without disruptions shows that the a large increase occurs shortly after t=20 hrs. This corresponds to the purchase of materials for stage 1, which are overwhelming the highest single cost in this scenario. It can be seen that with disruptions, this reorder is repeated at t=48 hrs. This is a result of tasks being repeated, with this impact driving an overall cost increase of 30.7% as a result of disruptions.

## The impact of operational policy on makespan distributions

Figure 4 shows the same case as presented previously (with disruptions) but incorporates an intermittent supply of one of the materials used in stage 6. The material is periodically available and unavailable in 8 hour increments (starting as available). To maximise the visible impact, a reorder point and quantity of 1 batches worth of material is used in both instances.

The most readily available observation is that intermittent material supply severely increases the mean makespan, representing a 68% increase in this case.

It can be seen that in both cases the distribution is right-skewed. This is partially a result of Poisson distributions used to determine equipment downtimes, but also demonstrates the compounding effect of disruptions

and breaks in production due to material unavailability. The higher frequency with which these events occur, the longer the makespan and the greater the total number of tasks completed (due to repetition following rescheduling), which creates further instances for these disruptions to occur. This is also reflected in the spread of the distributions shown, with the case with intermittent supply showing a much larger range of makespans as disruptions interact with material unavailability, causing significant delays in some simulations.

## CONCLUSIONS

A dynamic framework was showcased for multi-product scheduling across parallel lines with a rolling horizon approach. The scenarios explored using the framework feature several continuously changing aspects including order receival and completion, uncertain disruptions in the form of process and equipment failures, and variations in raw material availability.

The framework was applied to a small example scenario, demonstrating its capability to emulate real time decision making in response to these aspects. The inclusion of disruptions was shown to increase the makespan in the instance shown, but also results in cost increases. Equipment congestion also changed, indicating that the disruptions may alter which parts of the process would be most desirable to receive further investment or improvement. Intermittent supply of materials was found to increase both the mean and range of makespans when applied to a large number of simulations, also demonstrating a compounding impact as a result of disruptions causing further disruptions.

Further work utilising the framework could investigate different operational policies and problem structures and case studies.

## ABSTRACT

For process simulation, Python and Aspen Plus can be combined to leverage the advantages of both. This work utilizes the integration of Python and Aspen Plus for the design and optimization of a lycopene production process from tomato waste. Three production pathways are studied: acetone and hexane as solvents, enzymes with ethyl acetate, and supercritical $CO_2$ with ethanol. This allows for the scaling of laboratory-scale studies into industrial-scale analyses. Genetic algorithms are used for optimization, enabling the determination of the optimal process design, costs, and operating conditions, while minimizing the total annual cost. The process with acetone and hexane yields a final production of 0.21 kg/h, the process with enzymes and ethyl acetate, 5.13 kg/h, and the process with supercritical $CO_2$ and ethanol, 0.13 kg/h. It is shown that the process with ethyl acetate has a higher production and the process with supercritical $CO_2$ and ethanol results in lower production and higher costs.

**Keywords**: Tomato waste, lycopene, solvent extraction, unconventional solvents

## INTRODUCTION

Aspen Plus is a powerful tool that helps to design processing units or even complete chemical processes [1, 2, 3]. It enables rigorous designs, especially in separation systems where thermodynamics plays a key role. However, the simulator has difficulties when handling solids that are not included in its database and when there is no rigorous information about the studied compounds. Python is, on the other hand, a language with a wide variety of characteristics that made it a useful tool for solving and analyzing mathematical models of chemical processes. It allows greater freedom in coding processes for unknown compounds, but one of its drawbacks is that to have a high level of rigor in its thermodynamics and separation systems it would involve coding huge amounts of databases and some of them are not freely accessible, leading to a less rigorous modelling. There are studies that combine the use of Aspen Plus and Python for process design and optimization, but the design is typically done entirely in Aspen Plus and the optimization in Python, so they do not use a combination of both tools for design [4, 5].

This work proposes a combination of Aspen Plus and Python, seeking to leverage the advantages offered by each tool to design and optimize various lycopene production processes from tomato waste. The decision to work with tomato waste was made due to the high production in Mexico and Spain, with reports indicating that around 30% of crops end up as waste [6]. Tomatoes have a high content of lycopene, a biopigment used primarily in the food, pharmaceutical, and cosmetics industries [7]. Additionally, an increase in demand for naturally sourced lycopene has been reported, with the food and beverage sector expected to account for 45.6% of the total by 2023 [8]. Some works that have addressed the extraction of lycopene from tomato have used various techniques from traditional solvents to techniques with unconventional

solvents [9, 10, 11]. This article compares three lycopene extraction processes based on experimental studies from literature. These processes are scaled to an industrial level to determine the economic viability of these processes.

## METHODOLOGY

### Case studies

The first lycopene extraction process uses a mixture of acetone and hexane as solvents. This case is based on the work of Poojary et al. [11], which presents a laboratory-scale study on which the industrial-scale process design is based. This process consists of passing the tomato waste through a dryer, in which the moisture is reduced to 90%, then it passes to a mill in which a particle size of 78 mm is reached, which allows the biomass to meet with its most exposed surfaces. The process then moves to the extraction stage, where a liquid-solid extraction takes place between the biomass and an acetone-hexane mixture. The solvents extract the lycopene, separating it from the solid biomass. Following this stage, there is one outlet containing the remaining solid residue and another outlet containing a solvent mixture with the lycopene. This liquid mixture is then transferred to a flash tank, which allows for the simple separation of most of the solvents. Subsequently, the mixture is transferred to a distillation column where a lycopene purity of 95% is achieved.

The second extraction process uses enzymes and ethyl acetate and is considered a more environmentally friendly extraction method for end consumers. This process was based on experimental work by Catalkaya et al. [9], and with the help of this work, the process could be defined on an industrial scale. This process involves first passing the waste through a dryer and then through a mill with the same characteristics as the previous process. Subsequently, the waste is transferred to an enzymatic reactor, where it is mixed with a solution of water and a mixture of enzymes, specifically Celluclast (cellulolytic enzyme) and Pectinex (pectinolytic enzyme). This allows an enzymatic reaction to take place, breaking down the fibers of the biomass present and thus better preparing the raw material for extraction. The mixture then passes through a filtration centrifuge, from which the liquid fraction, including water and enzymes, is removed. The solid residue goes to the extraction stage, where it is mixed with ethyl acetate as a solvent, allowing the lycopene to be extracted. The extraction process has two outlets: the first carries the solid residue, and the second carries the lycopene-ethyl acetate mixture. Subsequently, the liquid mixture is transferred to two flash evaporation tanks. The first tank removes most of the solvent, while the second achieves a lycopene purity of 95%.

The third extraction process opts for a novel alternative that includes the use of supercritical $CO_2$ with ethanol. This process is based on the experimental work of Huang et al. [10]. They did help us an industrial-scale process that could be defined. In this process, tomato waste undergoes a pretreatment of drying and grinding, followed by a saponification reactor where it is mixed with 0.5 M NaOH. Subsequently, the solution passes to a second reactor where it is mixed with a 1.0 M $H_2SO_4$ solution, resulting in a neutralization reaction. These two reaction stages allow the biomass to break down its lignocellulosic structure in a manner like that used with enzymes in the previous section. Once neutralization is achieved, the liquid phase is removed using a filtration centrifuge, and the solid phase is transferred to the extraction stage. In this stage, a mixture of supercritical $CO_2$ at 25 °C and 65 bar with 16% ethanol, initially at 1 bar and 25 °C, is added. These two solvents are preconditioned using a pressure and temperature system before being mixed with the biomass, ensuring they enter the extractor under the specified conditions. The extraction stage has two outlets: one for the solids and the other for the mixture of supercritical $CO_2$, ethanol, and lycopene. A complete system is used to separate the three components and purify the lycopene to 95%. This system requires four main expansion tanks with intermediate turbines to perform pressure changes. The domes of the expansion tanks allow for the recovery of supercritical $CO_2$ and ethanol in another complete separation system.

### Mathematical modeling

In all three cases, a combination of Python and Aspen Plus was used. Figures 1, 2, and 3 show the process diagrams for each case described, as well as the identification of the parts developed in Python and Aspen Plus.

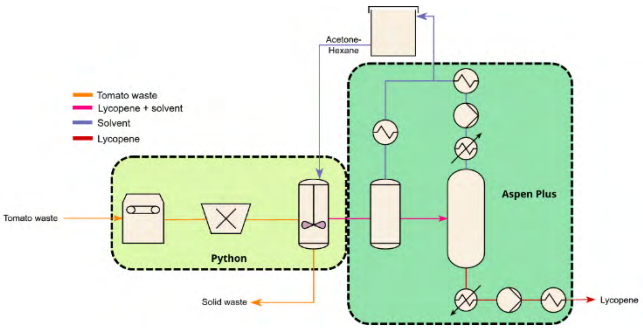

**Figure 1.** Distribution of process modeling with acetone-hexane in Python and Aspen Plus.

The parts developed in Python (light green) were chosen due to the possibility of mathematically modeling the equipment, mass and energy balances using design equations, due to the presence of solids in the process, and the greater flexibility offered by working with mathematical equations. The parts developed in Aspen Plus (darker green) correspond to separation and purification

processes due to their rigor in this type of equipment and ease of working with liquid mixtures.

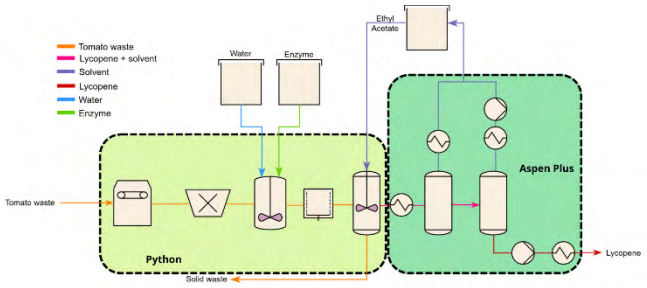

**Figure 2.** Distribution of process modeling with enzymes and ethyl acetate in Python and Aspen Plus.

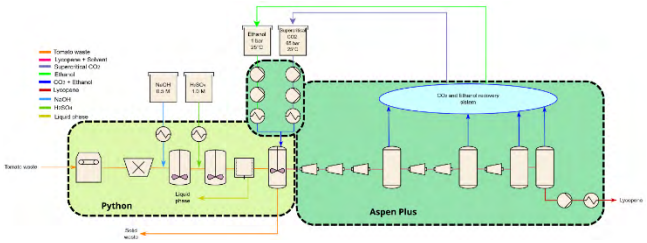

**Figure 3.** Distribution of process modeling with supercritical $CO_2$ and ethanol in Python and Aspen Plus.

## Operating conditions

To define the operating and production conditions of lycopene, it was necessary to use an equation that describes the extraction stage according to its experimental functioning; equations 1, 2 and 3 represent these behaviors for the three processes mentioned [11, 9, 10].

$$Y = 0.009621 - 0.0028125A + 0.0010875B - 0.0014875C + 0.00525D + 0.00045AB + 0.00265AC - 0.0022875AD - 0.000775BC + 0.0000375BD - 0.0009625CD \quad (1)$$

$$Y = 3.115 - 0.275X_1 + 0.125X_2 - 0.645X_3 - 0.918X_4 - 0.364X_5 - 0.112X_6 + 0.004{X_1}^2 + 0.667{X_2}^2 - 0.107{X_3}^2 + 0.279{X_4}^2 + 0.234{X_5}^2 + 0.889{X_6}^2 - 0.237X_1X_2 + 0.220X_1X_3 + 0.337X_1X_4 - 0.637X_1X_5 + 0.087X_1X_6 + 0.121X_2X_3 + 0.038X_2X_4 - 0.531X_2X_5 - 0.065X_2X_6 - 0.109X_3X_4 + 0.368X_3X_5 - 0.045X_3X_6 + 0.896X_4X_5 + 0.230X_4X_6 + 0.020X_5X_6 \quad (2)$$

$$Y = 24.05 - 1.50P - 1.33P^2 - 2.64T^2 + 2.67t - 2.46PT + 1.62Tt \quad (3)$$

These equations depend on different variables that affect the amount of lycopene extracted, so they are selected as optimization variables along with other variables depending on the process. Tables 1, 2, and 3 show the optimization variables for each case study.

Table 1 includes variables for the extraction stage, the distillation column, and the dryer. Table 2 includes variables in the enzyme reactor, extractor, and dryer. Finally, Table 3 includes optimization variables only in the extraction stage and in the dryer.

**Table 1:** Optimization variables for the lycopene production process with acetone and hexane.

| Variable | Symbol | | Units | Limits |
|---|---|---|---|---|
| Extraction temperature | A | $T_{ext}$ | °C | [30, 50] |
| Residence time | B | t | min | [1, 60] |
| Acetone-hexane ratio | C | A:H | % | [25, 75] |
| Volume of solvent mixture | D | $V_{solv}$ | L | [10, 30] |
| Number of stages | - | $N_t$ | - | [5, 20] |
| Feeding stage | - | $N_F$ | - | [1, $N_t$] |
| Reflux ratio | - | RR | - | [0.1, 2] |
| Dryer temperature | - | $T_{dry}$ | °C | [30, 50] |

**Table 2:** Optimization variables for the lycopene production process with enzymes and ethyl acetate.

| Variable | Symbol | | Units | Limits |
|---|---|---|---|---|
| Enzymatic reaction temperature | $X_1$ | $T_{react}$ | °C | [40, 60] |
| Enzymatic reaction time | $X_2$ | tR | h | [1, 5] |
| Enzymes/substrate ratio | $X_3$ | E:S | v/w | [0.2, 2] |
| Solvent/substrate ratio | $X_4$ | S:S | v/w | [5, 30] |
| Extraction time | $X_5$ | t:E | h | [1, 4] |
| Enzyme/enzyme ratio | $X_6$ | E:E | v/v | [1, 3] |
| Dryer temperature | $T_{dry}$ | TS | °C | [30, 50] |

**Table 3:** Optimization variables for the lycopene production process with supercritical $CO_2$ and ethanol.

| Variable | Symbol | | Units | Limits |
|---|---|---|---|---|
| Pressure | P | $P_{extr}$ | MPa | [40, 60] |
| Temperature | T | $T_{extr}$ | °C | [1, 5] |
| Extraction time | t | $t_{extr}$ | h | [0.2, 2] |
| Dryer temperature | - | $T_{dry}$ | °C | [5, 30] |

## Optimization procedure

The optimization for the three processes is executed from Python, always considering the link with Aspen Plus for the calculation of the separation section in each case. The objective function for this case is the Total Annual Cost (TAC) (Equation 4), which involves equipment costs (Equation 5) and operating costs depending on the process: Equation 6 for acetone-hexane, equation 7 for enzymes and ethyl acetate, and equation 8 for supercritical $CO_2$ and ethanol. such as refrigeration, heating, solvents, among others, in addition to the payback

period, which in this case was defined as 5 years.

$$TAC = CT_{oper} + \left(\frac{CT_{equip}\left(\frac{CEPCI\ 2023}{CEPCI\ 2001}\right)}{payback\ time}\right) \quad (4)$$

Where:

$$CT_{equip} = \sum_{i=1}^{7} C_{i,equip} \quad (5)$$

$$CT_{oper} = \sum_{i=1}^{n} C_{i,cooling} + \sum_{i=1}^{n} C_{i,steam} + \sum_{i=1}^{n} C_{i,elect} + \sum_{i=1}^{n} C_{i,solvent} \quad (6)$$

$$CT_{oper} = \sum_{i=1}^{n} C_{i,cooling} + \sum_{i=1}^{n} C_{i,steam} + \sum_{i=1}^{n} C_{i,elect} + \sum_{i=1}^{n} C_{i,solvent} + \sum_{i=1}^{n} C_{i,water} + \sum_{i=1}^{n} C_{i,enzym} \quad (7)$$

$$CT_{oper} = \sum_{i=1}^{n} C_{i,cooling} + \sum_{i=1}^{n} C_{i,steam} + \sum_{i=1}^{n} C_{i,elect} + \sum_{i=1}^{n} C_{i,solvent} + \sum_{i=1}^{n} C_{i,react} \quad (8)$$

The optimization was performed in Python using the PYMOO library, which works well for both single-objective, as performed in this study, and multi-objective optimizations. Genetic algorithms (GA) were employed to find the solution with the minimum total annual cost (TAC). GA was chosen for their ease of use in Python programs that link to Aspen Plus, since the equations in Aspen Plus are not explicitly defined. Figure 4 shows a flowchart that represents the general operation of the process optimization process.

## RESULTS

For the first process using acetone and hexane, the genetic algorithm was employed with a population of 100 and 21 generations, resulting in a total of 2100 evaluations. This optimization required a computation time of 117.64 minutes. Figure 5 shows a comparison between the iterations and the TAC, illustrating how the optimization process seeks the minimum TAC, marked with the red line. This yielded a TAC of 305, 425.5 USD/year and a lycopene production of 0.21 kg/h.

The second process, using enzymes and ethyl acetate, required 4, 000 evaluations. This optimization required a computation time of 125.09 minutes, yielding a TAC of 6, 038, 983.34 USD/year and a lycopene production of 5.13 kg/h. Figure 7 shows the cost distribution for each piece of equipment involved in this process, allowing us to identify the stages that contribute most to the TAC. The extraction stage accounts for the largest percentage, at 51% of the TAC, followed by the enzyme reactor at 26.1%, the first flash tank at 6.6%, and the filtration centrifuge at 6.3%.

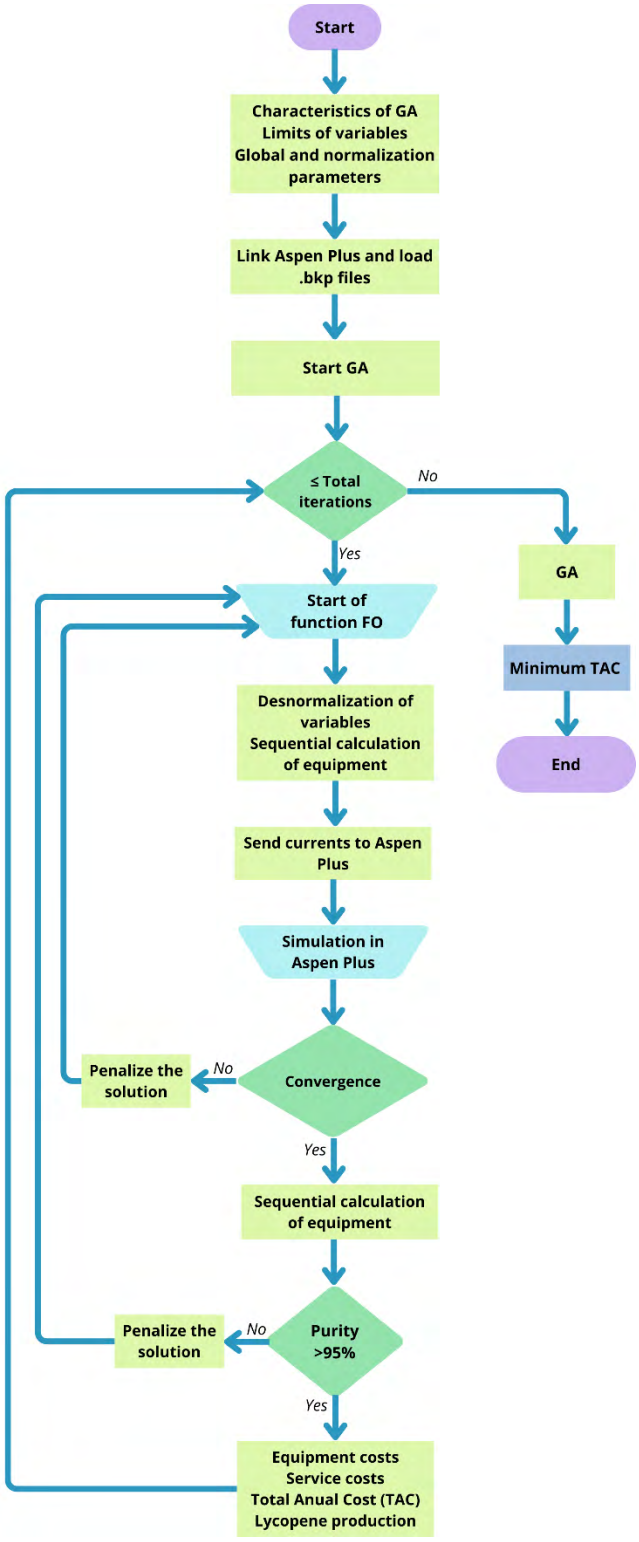

**Figure 4.** Optimization process flowchart.

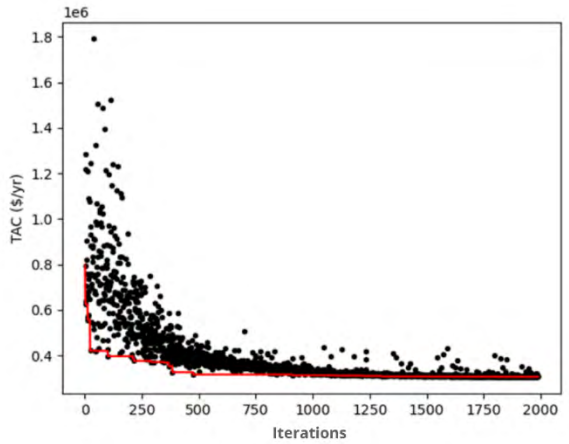

**Figure 5.** Comparison of iterations vs TAC for process with acetone-hexane.

**Figure 6.** shows a breakdown of the costs for each piece of equipment involved in this process, allowing us to identify the stages that contribute most to the total annual costs. As can be seen, the extraction stage accounts for the largest percentage at 20% of the TAC, followed by the mill and the flash tank at 19.4% and 18.1%, respectively. Additionally, heat exchangers 1 and 2 contribute approximately 10.8% of the TAC.

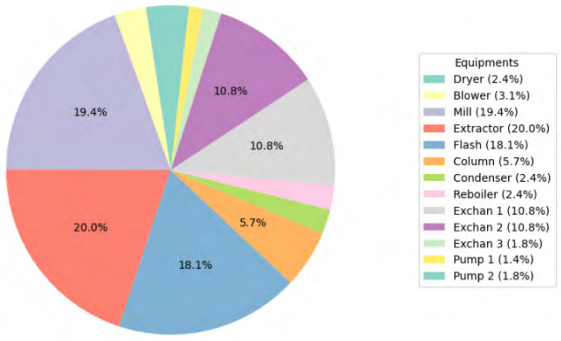

**Figure 6.** Percentage distribution of what each equipment contributes to the TAC.

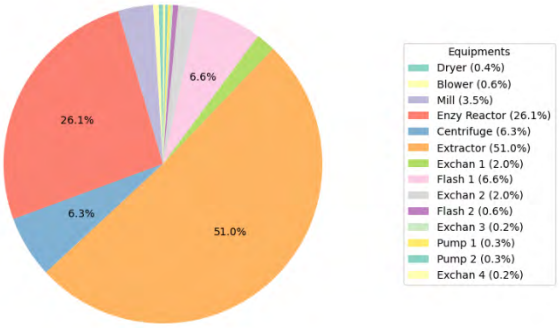

**Figure 7.** Percentage distribution of what each equipment contributes to the TAC.

For the third process with supercritical $CO_2$ and ethanol the genetic algorithm was used with a total of 2100 evaluations. This optimization required a computation time of 369.85 minutes. The TAC was 70.30 MUSD/year and a production of 0.13 kg/h of lycopene.

Figure 8 shows the cost distribution for each piece of equipment involved in this process up to the extraction stage, which corresponds to the first part of the process. This includes the cost of the entire $CO_2$ and ethanol separation system, allowing us to identify the stages that contribute most to the total annual costs. It can be observed that the extraction stage represents the largest percentage, with 81% of the TAC, followed by the neutralization reactor at 5.5% and the saponification reactor at 4.3%. This demonstrates the clear predominance of the extraction stage in this first part of the process due to the necessary operating conditions. Figure 9 now shows a comparison of the costs of this first stage of the process with the costs of the set of flash units, heat exchangers, pumps, and compressors that make up the ethanol and $CO_2$ separation and recovery section, as well as the lycopene purification. The first stage of the process accounts for most operating costs, at 62.6%, while the remainder corresponds to the second stage of the separation process, where the expansion tank section represents the largest share of these costs, at 30.8%. These graphs suggest the possibility of implementing improvements in both the extraction stage and the expansion tank separation stage.

Tables 4, 5 and 6 show the results obtained for each of the optimization variables and the objective function for the three processes studied.

Of the three processes presented, it can be observed that the one that allows the highest yield of lycopene is the process with enzymes and ethyl acetate, noting that the least viable solution is to work with supercritical $CO_2$ and ethanol due to the high operating costs of the system and the low production of lycopene.

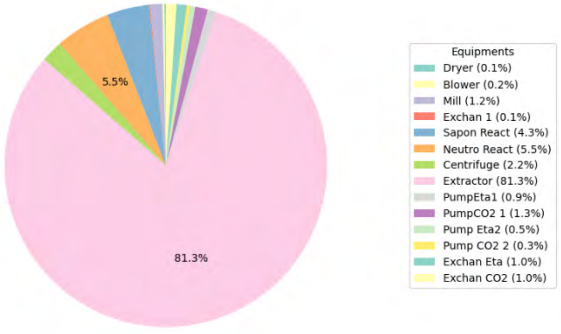

**Figure 8.** Percentage distribution of what each equipment contributes to the TAC, from the first part of the process.

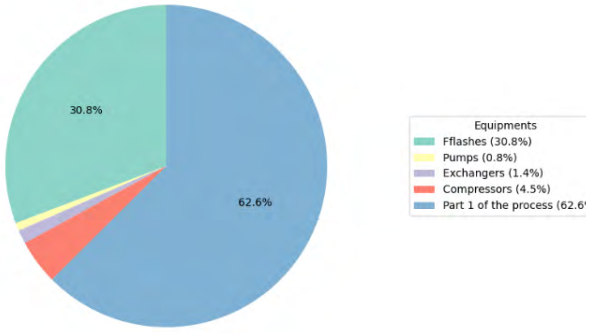

**Figure 9.** Percentage distribution of what each equipment contributes to the TAC, from the second part of the process.

**Table 4:** Results of the process optimization with acetone and hexane.

| Variable | Units | Values |
|---|---|---|
| Operating costs | USD/yr | 40, 366.58 |
| Equipment costs | USD/yr | 265, 058.86 |
| TAC | USD/yr | 305, 425.45 |
| Lycopene production | Kg/h | 0.21 |

**Table 5:** Results of the process optimization with enzymes and ethyl acetate.

| Variable | Units | Values |
|---|---|---|
| Operating costs | USD/yr | 4, 582, 107.58 |
| Equipment costs | USD/yr | 1, 456, 875.75 |
| TAC | USD/yr | 6, 038, 983.34 |
| Lycopene production | kg/h | 5.13 |

**Table 6:** Results of the process optimization with supercritical $CO_2$ and ethanol.

| Variable | Units | Values |
|---|---|---|
| Operating costs | USD/yr | 61, 032, 519.41 |
| Equipment costs | USD/yr | 9, 275, 715.16 |
| TAC | USD/yr | 70, 308, 234.57 |
| Lycopene production | kg/h | 0.13 |

## CONCLUSIONS

A mathematical algorithm combining Python and Aspen Plus was developed for the design and optimization of lycopene production from tomato waste using three different extraction solvents. The process design was obtained, including the optimal operating conditions to minimize the total annual cost of the processes, allowing for the evaluation of the amount of lycopene obtainable under these conditions. The lycopene production process using enzymes and ethyl acetate yielded the best results in terms of lycopene production, at 5.13 kg/h, for a total annual cost of 6, 04 MUSD/yr. On the other hand, the least recommended process is the one that requires supercritical $CO_2$ and ethanol due to the high operating costs and the minimal amount of lycopene produced with 0.13 kg/h.

## ABSTRACT

In the pursuit of decarbonisation, process industries are turning to electrification as a solution to avoid fossil fuels for heating and processing raw material. Transitioning to renewable electricity couples the processes to varying electricity availability and requires more consideration for production timing and scheduling to support grid stability and avoid high electricity prices. However, practical challenges limit the capability for unforeseen rescheduling for large processes. This paper explores the idea of auxiliary flexibility in an electrified steel production process, where only the auxiliary systems can react to changing conditions. We model an H2-DRI-EAF inspired process with controllable Air-Separation unit, water electrolysis, pressurized hydrogen storage, gas liquefaction units, and a battery energy storage system to react to a production related demand delay. First, we compare hourly and 15-minute DA pricing and observe that without fast flexibility the cost difference is marginal, while fast-reacting flexibility (electrolyser ramping and batteries) enables a small additional benefit from 15-minute pricing, around 0.3% on average and up to 1% at maximum. Second, without a demand delay, allowing DA+ID decisions provides significant additional cost reduction via intraday arbitrage, yielding up to about 3% lower total costs compared to DA-only operation under perfect price knowledge. Third, when introducing 15–45-minute demand delays close to delivery, the model shows little to no cost increase on average compared to no delay. This highlights that price-taker models yield optimistic results in small markets, where open positions over 100 MW would realistically influence the market price significantly.

**Keywords**: Process Operations, Energy Management, Optimization, Scheduling

## INTRODUCTION

The global transition from fossil fuels places process industries under pressure to decarbonize their operations. Electrification presents an key pathway for decarbonization for many processes but the increasing share of supply side volatility complicates operations [1]. At the same time, electrification intensifies the coupling between processes and grid conditions. This growing interdependence makes large industrial loads candidates for contributing to grid stability through demand-side management (DSM).

As of September 2025, the European day-ahead energy markets moved to a 15-minute market time unit (MTU), from a one-hour MTU, to improve supply-demand balance [2]. The shorter MTU requires more accurate control over consumption timing and -volume. Research on industrial DSM has focused on established power-intensive processes, such as air-separation units (ASU) [3], steel industries [4], and chlor-alkali electrolysis [5], using hourly electricity pricing. The 15-minute markets present potential for increased value of short-duration storage for electricity, raw materials, intermediate and final products and operational flexibility, compared to hourly markets.

Green steel represents one of the harder challenges for industrial decarbonization, as currently steel production accounts for around 7% of global emissions. Alternate production routes to replace the blast furnace and basic oxygen furnace (BF-BOF) process have been

presented, with different configurations of a hydrogen-based shaft furnace and electric-arc furnace (H2-DRI-EAF) are recognized as most promising future pathways [6]. However, reacting to 15-minute price change frequency is likely unrealistic for such large plants with quality-sensitive products.

Both iron- and steel-making processes consume large amounts of gases and are typically equipped with ASUs to meet this demand. Scheduling ASUs for providing DSM has been studied from multiple angles [7]. Similarly, hydrogen production via water electrolysis has received significant attention as a source of power system flexibility [8], where certain types of electrolysers can change load levels without excessive wear. For green steel production both hydrogen and ASUs present continuous processes that can dynamically adjust their load without disrupting the steel plant operations itself.

A practical challenge in electricity market participation is that day-ahead bids are submitted before the market clearing price is known, while scheduling decisions can be adjusted once prices are revealed. Simultaneous optimization of market bidding and process schedules has therefore been proposed [9], [10] to minimize imbalances and electricity costs. In 15-minute markets this becomes increasingly challenging, as predicting consumption and prices with higher accuracy is more difficult. Additionally, the ability of large processes to react to price changes is also likely limited. This means that changes in production schedules that occur after the day-ahead market position is locked in make auxiliary load adjustments potentially a practical tool for managing market position imbalances.

In this paper, we evaluate the demand-side flexibility of a green steel inspired process through its auxiliary units in 15-minute electricity markets. We model controllable electrolysers, an ASU, gas liquefaction units, and a battery energy storage system (BESS) within an integrated process. We take the electricity, hydrogen, argon, and oxygen consumption of the steel production process as exogenous demands and examine the flexibility generated by optimizing the auxiliary units under 15-minute day-ahead (DA) and intraday (ID) electricity markets. Specifically, we address three questions: (1) How does the transition from hourly to 15-minute DA pricing affect operational costs and the value of flexibility? (2) What is the potential cost reduction from participating in the ID market with a fixed day-ahead position? (3) Can auxiliary flexibility mitigate the settlement imbalance cost caused by short-term production delays? We use a deterministic scheduling approach based on the state-task-network (STN) framework, with a two-stage decision process where the first stage performs day-ahead scheduling and the second stage determines the intraday recourse to minimize the total electricity costs.

## THE GREEN STEEL PROCESS

We model the gas and electricity demands based on an integrated H2-DRI-EAF process configuration, which is regarded as one of the viable routes for green steel production. In the process, raw iron ore is reduced in a shaft furnace with hydrogen forming direct-reduced iron (DRI). The DRI is then fed to a steel production process with electric arc furnaces (EAF), argon-oxygen decarburization (AOD) unit and continuous casting (CC). We consider the integrated steel production to work as an uncontrollable electricity and gas demand for controllable air separation units providing the process with nitrogen, argon and oxygen. Similarly, the water electrolysis unit that provides hydrogen for the DRI process is accounted as a controllable unit. Figure 1 shows the basic process configuration.

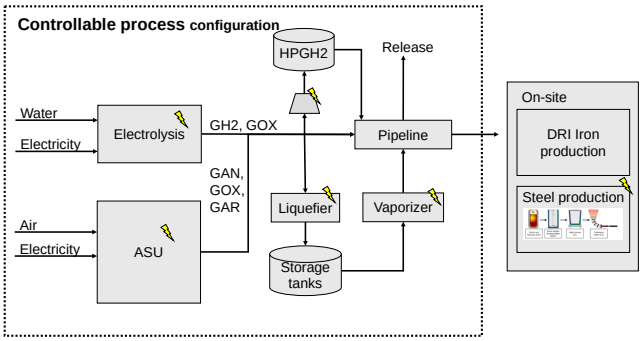

**Figure 1.** The modelled process configuration.

The process model is based on the STN framework presented in [11]. Each state represents a material in some specific state, and they can be converted to other states through tasks. The processes (tasks) are modeled with convex region surrogate models, allowing us to capture a wide range of process operating points and subsequent consumption of materials and electricity, while retaining convexity.

To account for short-term operational flexibility, we assume that gaseous product pipelines provide storage capacity (line-packing), corresponding to 15-minutes of average consumption [12]. Additionally, gaseous products can be converted to liquid products with a liquefaction step to be stored and again later vaporized for consumption. The gaseous hydrogen from electrolysis can be stored in a high-pressure storage unit, which requires compression. Gaseous products can be vented out of the system at any time.

For the iron and steel production processes, we consider a medium-sized integrated plant with an annual production rate of 1 Mton of steel, and base the demands for oxygen, and hydrogen from [6] and the argon and nitrogen consumption as described in [13]. We utilize the 24-heat steel plant schedule from [14], determining the demands for electricity, argon, oxygen, and nitrogen. We

assume EAF consumption is raised to full power in two steps: first at 70%, second at 90%.

The flexible ASU, liquefiers and vaporizers are parametrized based on [12] and extended such that gaseous nitrogen to oxygen ratio is 1.5:1 and argon about 5% of oxygen production. The electrolyser is modeled based on the model presented by [15], and hydrogen compression energy consumption calculated assuming adiabatic compression. We assume that of all hydrogen demand, we can produce 10% with variable load electrolysers giving us a controllable electrolyser capacity of 48.7 MW. We assume the remaining hydrogen demand is met through steady-state external supply or inflexible baseload production, isolating the impact of flexible capacity on the local energy system. The BESS is modeled separately on top of the STN model. We use a simplified model with a constant charge and discharge efficiency of 95%. For simplicity, no degradation effects are considered.

We model the BESS according to equations (1-4).

$$SOC_t = SOC_{t=1} + SOC_{t-1} + \eta^{BESS} \bullet p_t^{CH} - \frac{p_t^{DC}}{\eta^{BESS}} \quad (1)$$

$$0 \le SOC_t \le SOC^{max} \quad (2)$$

$$p_t^{CH} \le P^{max}\alpha_t \quad (3)$$

$$p_t^{DC} \le P^{max}(1-\alpha_t) \quad (4)$$

Here $SOC_t$ depicts the state of charge, $p_t^{CH}$ and $p_t^{DC}$ the charge and discharge energies, respectively, for each timestep $t$, and $\eta^{BESS}$ the charge and discharge efficiency. To limit the rate of discharge from the battery, $P^{max}$ is used to set the maximum energy draw per time-step and $\alpha_t$ as an on/off binary variable to limit simultaneous charging and discharging.

## MARKET PARTICIPATION MODEL

We consider two market participations for electricity procurement from the day-ahead (DA) and continuous intra-day (ID) markets. First, we procure the required energy from DA market based on demand forecast for the next day, without considering possible ID prices. This fixes a physical position that is carried over to the next stage where a possible demand forecast error is balanced by further procurement from the ID market, and where the final operational decisions are made. We utilize the real DA and ID power prices from Finland in October 2025 from Entso-e [16] and Nord-Pool continuous intra-day market [17], assuming a perfect knowledge of both prices in advance. For the hourly prices we take the average of each 15-minute price within an hour, forming a static price for each hour. It is assumed that the process can act as a price taker. We acknowledge that this assumption is a very generous one, considering the large demand of a steel plant in Finland, especially in the continuous ID market, where the average 15-minute transaction volume is in the range 150 MW for the studied period.

We use this approach to compare the effects of the transition from hourly to quarter-hourly (15-minute) DA markets to assess ability of a large process to react to faster changing prices. Additionally, we analyze the balancing capability of a plant in the case of demand forecast error. It is assumed that the steel plant acts as a balance responsible party towards the grid operator, therefore it must ensure an energy balance at each 15-minute time step, reflecting the practice in Finland. A balance responsible is expected to make power procurement from the energy markets or other contracts such that the consumed or produced energy matches the market position for each balance period. However, energy procured from DA market based on forecasts can differ drastically in the balance settlement, if there are significant errors in the consumption or production forecast if no action is taken. An imbalance in the balance settlement is penalized by fees from the TSO. We model the forecast error as a shop floor delay of 15, 30 and 45 minutes by delaying demand accordingly and forcing a power balance in the ID stage. The demand delay is shown in Figure 2.

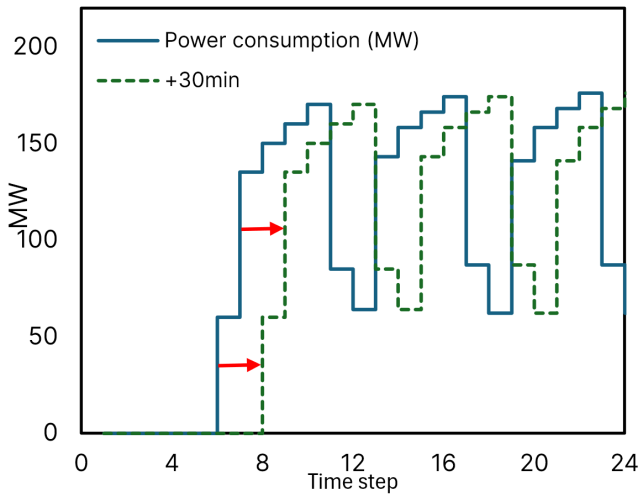

**Figure 2**. Demand delay for 30 minutes

$$\min \sum_{t \in T} C_t^{DA}\left(e_t^{buy} - e_t^{sell}\right) \quad (5)$$

$$s.t. e_t^{buy} - e_t^{sell} = E_t + p_t^{CH} - p_t^{DC} \quad (6)$$

The DA stage is governed with equations (5-6). Where $C_t^{DA}$ is the DA electricity cost for each time step, $e_t^{buy}, e_t^{sell}$ are the electricity purchase and selling variables respectively. $E_t$ is the sum of energy consumption over all units. After solving the DA stage, we have a net electricity position, which we pass over to a second optimization stage where ID operation is solved, reacting to a possible demand delay. The ID stage is represented by equations (7-8).

$$\min \sum_{t \in T} C_t^{ID}\left(e_t^{buy} - e_t^{sell}\right) \quad (7)$$

$$s.t. e_t^{buy} - e_t^{sell} + \Phi^{DA} = E_t + p_t^{CH} - p_t^{DC} \quad (8)$$

Here ID prices are represented by $C_t^{ID}$, and the DA position $\Phi^{DA}$ in equation 8. Additionally, simultaneous buying and selling is limited by a binary variable, similar to eq. 3 in both stages. The intraday stage yields a net adjustment (positive or negative) to the day-ahead outcome, which is summed to form the total electricity cost over the horizon.

## STUDIED CASES

We start by forming a base scenario where we set storage capacities to 0 and allow only steady state operation for the electrolyser and ASU. Similarly, we limit liquefaction and BESS capacity to 0. This gives us a baseline cost comparison between the quarterly and hourly DA prices and provides a sense of the costs a production delay might cause.

For further case studies we introduce flexibility into our system; for case 1 we allow flexible ASU operation. The control of an ASU is an intricate process, and changes in production setpoints are slow, so the introduction of ASU flexibility provides multi hour electricity consumption flexibility. The ASU is over-dimensioned by 10%, compared to the maximum oxygen demand of 20 000 $Nm^3/h$.

In Case 2, we introduce liquefaction and vaporization units, which allow for liquefying oxygen and nitrogen for storage and later use through vaporization.

For Case 3, we allow electrolysis units to operate flexibly with storage by giving them the ability to reduce their production rate by 100% an hour, meaning a reduction of power consumption of 2.5 MW per time-step.

Finally for Case 4, we consider BESS sizing of 5, 10, 25 and 50 MWh, with a fixed charge/discharge rate of 5 MW for 5- and 10-MWh units and 10 MW for 25- and 50-MWh units. This configuration deliberately decouples the power and energy capacities (C-rates), allowing us to analyze different storage durations and how power and energy limit capacities limit the operation.

It is important to note that this study only focuses on the operational electricity cost savings enabled by these auxiliary units. The capital investment, maintenance, and other costs associated are considered out of the scope of this work.

All cases are run for 14 separate days, with identical demands and with four demand delays of 15, 30, and 45 minutes. The cases are listed in Table 1.

**Table 1:** Studied cases. SS: steady state, F: flexible

| Case | ASU | Liquefaction | H2 storage | Electrolyser | BESS (MWh/MW) |
|---|---|---|---|---|---|
| Base | SS | no | no | SS | no |
| 1 | F | no | no | SS | no |
| 2 | F | yes | no | SS | no |
| 3 | F | yes | yes | F | no |
| 4.1 | F | yes | yes | F | 5 /5 |
| 4.2 | F | yes | yes | F | 10 /5 |
| 4.3 | F | yes | yes | F | 25 /10 |
| 4.4 | F | yes | yes | F | 50 /10 |

## RESULTS

### 15-minute pricing

We first analyze the DA costs to assess how the more frequent pricing affects our results and whether our modeled system can benefit from it. Figure 3 shows the cost distribution across the days studied in the base, steady state system and shows a very large variability between days when consumption pattern is in fact equal each day. The cost variation is caused by the variation in DA prices. Though this kind of price risk is in reality reduced by utilizing longer term contracts to control price risk, here it illustrates well how drastically electricity prices can change day-to-day costs. Since the cost variance is high, it makes sense to compare relative cost reduction. Figure 4 illustrates the relative cost difference between the mean pricings for each case and day with error bars showing the deviation between days.

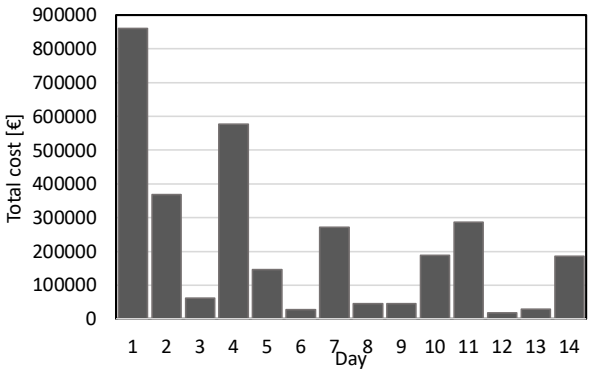

**Figure 3.** Absolute total cost for studied days in baseline case for 15-min pricing

We use DA to refer to only DA cost, q and h to refer to DA pricing granularity quarterly (15-min) and hourly respectively, and ID refers to DA+ID cost with a specified DA granularity and delay in minutes.

A comparison of the differences of the hourly and 15-minutes pricing scenarios for DA stage is shown in

Table 2. The cases are compared to base case, so we observe additional cost differences with the added components. With steady state operation, 15-minute pricing causes 0.09% more costs on average. This is likely caused by the chance of how pricing peaks hit consumption peaks with minimum and maximum values showing differences between extreme days. This can be viewed as an insignificant error associated with the method generating the hourly dataset. As price peaks and valleys in 15-minute data are averaged into hourly data, it is by chance how they line up with the consumption peaks, since with a continuous consumption average total cost would be equal.

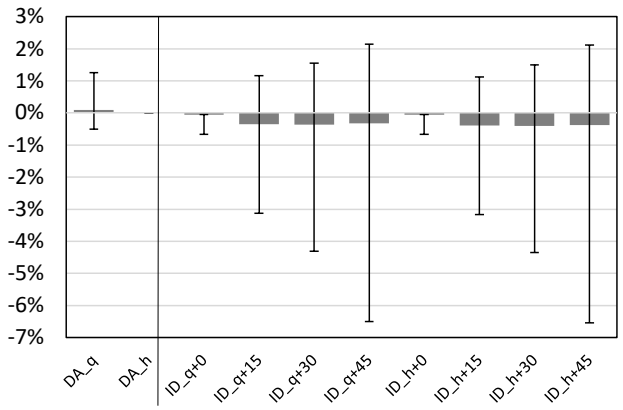

**Figure 4.** Relative cost difference in the baseline case. DA_q is relative to DA_h.

**Table 2:** Mean, minimum, and maximum cost difference of 15-min DA pricing to hourly pricing

| Case | mean diff | min diff | max diff |
|---|---|---|---|
| Base | 0.09% | -0.59% | 1.17% |
| 1 | 0.00% | 0.00% | 0.00% |
| 2 | 0.00% | 0.00% | 0.00% |
| 3 | -0.20% | -0.72% | -0.02% |
| 4.1 | -0.30% | -1.00% | -0.04% |
| 4.2 | -0.29% | -0.99% | -0.04% |
| 4.3 | -0.38% | -1.28% | -0.05% |
| 4.4 | -0.37% | -1.23% | -0.06% |

In Case 3, which has the capability to ramp the electrolysers, the shorter pricing interval allows a 0.20% cost reduction on average. Adding a BESS increases the gap from Case 3 but doesn't grow with added capacity until Case 4.3. Case 4.4 benefits less from the shorter pricing interval, compared to Case 4.3, which is explained by the increased ability of the case with hourly pricing to utilize the BESS capacity. We can also note that slow reacting flexibility by the ASU and liquid storage don't allow the utilization of the shorter pricing interval. This suggests that with increasing fast reacting flexibility a cost decrease can be achieved with the shorter pricing time interval. However, this cost decrease is likely insignificant in many industrial applications but might increase the viability for very fast reacting components such as BESS units.

**Table 3:** DA costs per studied case with difference to baseline and subsequent ID cost reduction.

| Case | DA_q | ID_q+0 | ID_h+0 | Diff to base |
|---|---|---|---|---|
| **Base** | 222397 | -0.05% | -0.05% | 0.00% |
| **1** | 221977 | -0.19% | -0.19% | -0.19% |
| **2** | 221977 | -0.49% | -0.49% | -0.19% |
| **3** | 219923 | -1.66% | -1.68% | -1.11% |
| **4.1** | 219179 | -2.08% | -2.20% | -1.45% |
| **4.2** | 218770 | -2.17% | -2.30% | -1.63% |
| **4.3** | 217282 | -2.75% | -2.90% | -2.30% |
| **4.4** | 216589 | -3.00% | -3.13% | -2.61% |

## Auxiliary Flexibility - Intraday Market participation

Next, we assess the capability of auxiliary systems to perform DSM activities to reduce electricity costs. First, without consideration of the demand delay. Table 3 shows that on average added flexibility can reduce costs by up to 2.61%. Furthermore, adding the ID stage where changing prices can be exploited against the DA position further reduces costs, up to about 3% of the DA cost.

We demonstrate this in figure 5 that shows how the electricity consumption and subsequent DA and ID prices affect the operating decisions of the production units for day 4 in Case 4.1. Here, DA operation reduces costs by 1.2%, compared to the baseline and then a further 1.49% with the ID operation. During the first price peak of the DA stage, the electrolyser reduces production significantly but is considerably limited due to insufficient time to fill the hydrogen storage. The ID prices on this day did not follow the trend of the DA prices and allowed continuous hydrogen production to deviate from the DA schedule and later utilize stored hydrogen to sell the position during the peak of the ID price on that day. The figure also visualizes the question of auxiliary flexibility for such a production process. It shows how massive the electricity consumption of the electric arc furnaces is compared to the ASU consumption, of about 10%, and other units even smaller. The majority of the shiftable demand is provided by the electrolyser units, which also shows the enormous electricity consumption of hydrogen production through electrolysis, as this only represents 10% of total hydrogen production required for DRI.

### Managing Settlement Imbalances

Figure 6 illustrates the relative cost difference between the ID costs with no demand delay and with 15-, 30-, and 45-minute demand delay. The cases 1-4 are shown as additional difference compared to the baseline difference. Against expectation, the delay causes in

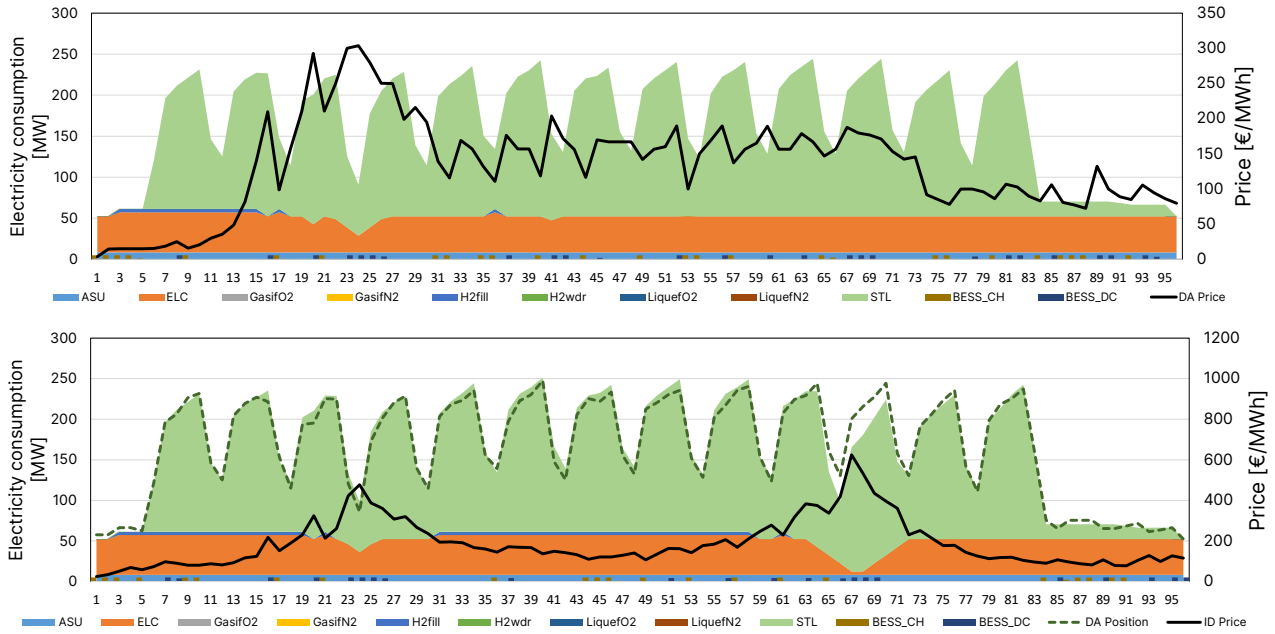

**Figure 5.** Day 4 Case 4.1 electricity consumption per unit. DA = upper, ID = lower.

these cases reduced costs on average, compared to the base case. On individual days, Figure 4 shows large variance with growing delay, as in some cases we see up to a 2% cost increase, for some a 7% cost decrease in the baseline case. In the baseline scenario this is caused just by how the shifted consumption peaks happen to hit the ID price each day as the shift causes a symmetric open position. For cases with flexibility, we see even more variation between days caused by the frequent negative prices in the ID market allowing the system to ramp consumption on those time points, even with no practical use. For the studied time-period, this creates on average a positive impact on the total costs. With a constant price, the additional cost caused by such a delay would amount to zero.

This behavior is unrealistic and highlights the limitation that comes with the price-taker assumption. The shifted demand frequently causes over 100 MW buy or sell bids in the ID market, which is close to the average 15-minute trading volume. This means that such a transaction volume would likely affect the price significantly against our favor causing large costs from a demand shift, incentivizing the auxiliary flexibility even more. We also assume that the imbalance position is corrected exclusively from the continuous market, whereas there are other ID markets available to handle such cascading delays.

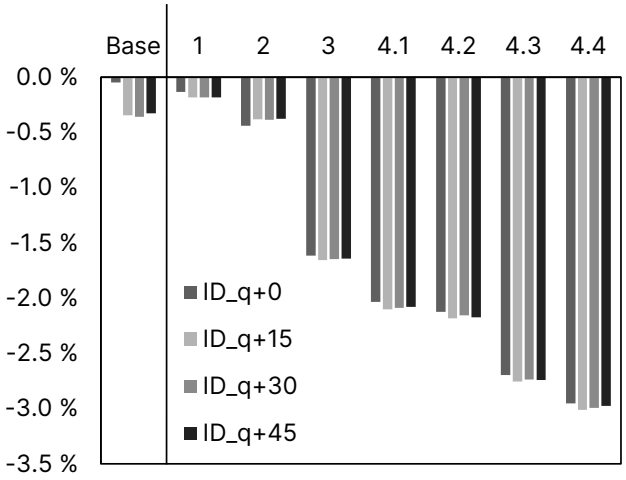

**Figure 6.** Average relative cost difference to DA_q costs. Cases 1-4 are additive to Base.

Looking at individual days, we observe that the ASU and the liquefiers are not utilized to fill the shifted position and are only turned on to increase the consumption during negative prices, which are frequent in the continuous ID market, or down during price peaks. We see in Cases 1 and 2 only little additional cost decrease compared to the base case. Similarly, while Cases 3-4 can further lower total costs, they seem to react to changes in prices rather than to the shifted demand, indicating that such a demand shift doesn't impose additional costs

that incentivize the system to correct the imbalance. This is illustrated in Figure 7, showing the ID operation of day 14 in Case 3, where the system only avoids the price spikes. Figure 7 also illustrates how a small demand delay introduces large open positions for almost 200 MW in the beginning and ends of the steel process operation period, which could occur similarly even if we perform optimal scheduling for the process for the DA markets.

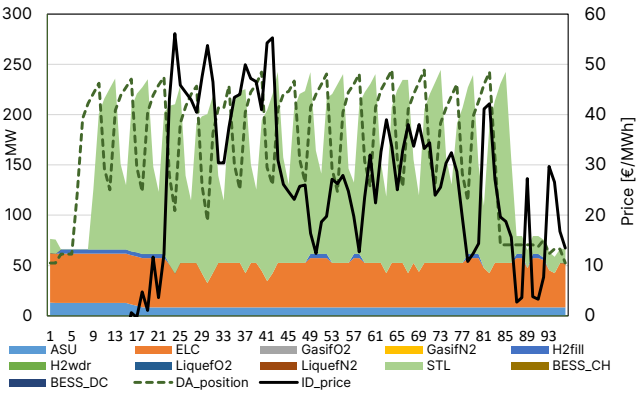

**Figure 7.** Day 14 Case 3 production profile

Our approach is very optimistic in the sense that we only consider the price-taker role in both markets. We also have perfect, risk-free, knowledge of upcoming prices. While the model shows a 3% saving (approx. 10 k€ on average cost), this benefit is dwarfed by the market risks illustrated in Figure 3. With a price volatility reaching 500%, optimizing an average day yields negligible benefits if the system remains exposed to daily costs of up to 800 k€. Therefore, future development should consider focusing on finding multi-day flexibility, as the ability to avoid consumption on high-priced days is likely more valuable than improving efficiency during them.

## CONCLUSIONS

In this work, a green steel inspired process configuration was analyzed in the view of auxiliary flexibility for demand-side management. We considered a system with controllable electricity consumption for an ASU, nitrogen and oxygen liquefiers, electrolyser and gaseous hydrogen storage, and various BESS sizes, which we studied under different combinations.

We first quantified the relative differences that hourly and 15-minute DA pricing cause on the system total cost, and whether the more frequent pricing interval could be exploited by a flexible system to reduce operational costs. It is noted that slowly reacting flexibility cannot utilize the more frequent pricing. For components that are able to react to changing prices, we see only a small decrease in total costs (around 0.3% on average and 1% at maximum). This suggests that the 15-minute pricing might increase the viability of BESS units, with more arbitrage opportunities.

Second, we looked at how arbitrage in the ID markets can be used to decrease costs with a naive DA+ID market strategy and showed that the additional arbitrage opportunity is able to provide us with up to 3% of additional cost decrease on average.

Finally, we analyzed how a delay in the steel process between the acquired DA position and delivery can be mitigated with flexibility provided by the auxiliary units. We see that with the current setup; the demand delay causes neither additional costs nor profits on average compared with a case with no delay. This exposes the limitation in assuming a price-taker scenario as we see no cost increase on average with the delay even though it creates frequent open positions in the range of 100 MW on a market that likely has limited liquidity.

## ABSTRACT

Today, beverage production plants are planned and designed from the material-handling context as a packaged-goods production facility, not as a process plant. Therefore, a lot of potential for optimization exists. This paper presents a new approach to the design of beverage production plants according to the design of process plants. A component library for the simple creation of beverage production plant process models is developed. All steps in the plant design process can be accelerated and automated to be used for the high number of existing and new installations around the world. As first use case an energy optimization upgrade for existing Carbonated-Soft-Drink production lines is described to save cooling and heating energy in warm climates.

**Keywords**: Modelling and Simulations, Dynamic Modelling, Energy Efficiency, Matlab, Process Design, Simulation, Technoeconomic Analysis

## INTRODUCTION

In the past, the focus for optimizing beverage production plants was on costs, production output and availability, while flexibility, energy and media consumption played a lower role. The entire basic design process was centered on material-flow considerations. A production plant is built as a combination of connected machines, but the connections and dependencies were only considered in a very simple way. Different modelling approaches are available for the process part of beverage preparation before filling and for the material-flow part of the packaged-goods streams after filling.

With the increasing sustainability focus of plant operators and other stakeholders, the pressure to optimize all aspects during the life cycle of a plant is growing. The main driver of course is still the Total Cost of Ownership (TCO) for the produced goods, but the optimization focus shifts from site to site depending on local material, energy and labor costs (**Figure 1**).

KRONES AG sells hundreds of beverage production lines worldwide each year. The number of quotations runs into thousands. The workflow for creating these quotations is very fragmented today, with multiple people involved and a multitude of separate, mostly Excel-based design tools. As a result, only very few iterations for optimization purposes can be carried out.

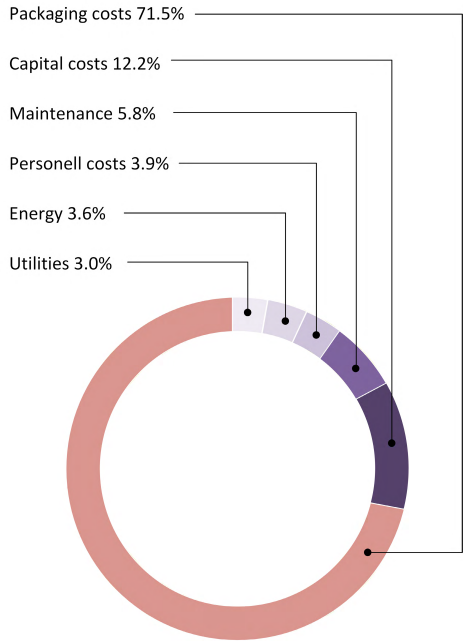

**Figure 1**. Typical Total-Cost-of-Ownership (TCO) distribution for a PET CSD or water line.

The reason for the splintered approach is the background of the main industry players in the manufacturing industry and the selling of single production machines. The design of lines and plants is often done by independent, specialized engineers. The result is that the know-how for the design of the machines and machine overarching dependencies is distributed between different areas of responsibility. KRONES AG itself emerged as an integrated enterprise with separate business units organized around the machine types in beverage production lines (blow moulder, filler, labeler, packing machines, washing machines, pasteurization machines and process equipment). This leads to today's situation, that design and simulation models are distributed over different organisations and exist in different levels of validity.

One promising option to address these challenges is the use of plant wide modeling and simulation [1]. At the same time, the current state of research shows few approaches for analyzing and simulating the energy and media consumption in the beverage industry, but these typically focus only on individual machines, specific subprocesses, or selected types of energy [2-6].

As the aim of KRONES AG is to sell turnkey plants and lines, an important value proposition is the possibility of deep line optimizations due to the available machine and process knowledge.

To this end, the authors started to develop a central cross-sectoral modelling library for basic design purposes of machines, lines, and plants. The library should enable the building of holistic design and optimization models for many use cases in the lifecycle of a plant by a straightforward drag-and-drop functionality.

# METHODOLOGY

## Definition of basic plant design process

The main design parameters for a new beverage plant are the beverage type, the nominal container volumes and the annual production schedule. The container material is known due to the existing or planned logistics, selling and recycling infrastructure. For aluminum cans and glass bottles, the containers are produced by specialized suppliers, and therefore the brand owner mostly chooses from their standard designs. In the case of PET bottles, the exact design of the containers is more flexible, as the final bottle is produced directly before filling in the production line.

The first step in the plant design process (**Figure 2**) is to design the beverage container according to the requirements during its life cycle:

1. recognition value by the final customer,
2. conservation of beverage properties (carbon dioxide concentration, no oxygen uptake to avoid oxidation reactions),
3. container stability against internal pressure and top load during storage and transport and
4. microbiologic stability

This first design step is done by the supplier of the container production machines together with the plant operator or brand owner.

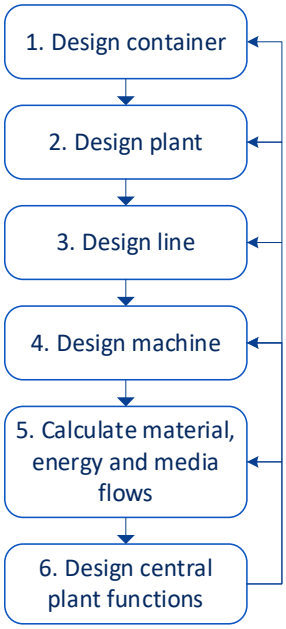

**Figure 2.** Basic design workflow for beverage production plants

The second step is to design the plant, i.e. what kind and number of production lines are required, what line production speeds are necessary, the sizing of the storage facilities for the produced beverages, and the logistics of the material supply and final product distribution.

In the third design step, the line is defined, i.e. type and nominal production speed of the used machines, together with the necessary buffer capacities.

The second and third design steps are done by plant design engineers and end with the specification documents for the machines and equipment.

In the fourth step, the machines and equipment itself are designed and sized. This step needs the most knowledge and can therefore best be carried out by the manufacturer.

When all equipment is known, the overall material, energy and media flows of the plant can be calculated in the fifth step again by the plant design engineers. Optimizations according to the customers wishes towards costs, energy and media consumption, flexibility or availability are possible by iteration of the preceding design workflow steps.

After the input and output flows are optimized, the central plant functions (water, energy, compressed air and other material supply, central cleaning and disposal

facilities) are designed in the next step again by the plant design engineers.

The optimization possibilities in the design process are greatly increased if the design steps and data interfaces are automatized as much as possible. The knowledge and methods of the different involved parties must be incorporated. Then a high number of iterations is possible to find the best configuration. With the help of AI-methods, the resulting data masses can be handled.

## Selection of design software

The authors did a market search over the available process simulation software for building the modeling library. The software should be able to incorporate new components on a well readable engineering-equations basis without requiring deep programming knowledge. It should construct large equation systems of networks to be solved, created by drag-and-drop of components from a library. The models should be nestable in different hierarchical levels to master complexity while avoiding redundancy. New stream types with variable material properties should be definable. And it should be possible to simulate stationary as well as dynamic scenarios. The most important requirement was the possibility to create a simple and well-maintainable code base, preferably manageable by a distributed version-control system such as git or subversion.

The existence of predefined components would be beneficial but not required, as none of the software tools found were used for the intended purpose in the beverage industry. The resulting models should be able to be incorporated into PLM and other software landscapes and easy to be deployed within the company.

Open-source tools were not considered due to support and service over lifetime concerns.

In the end, MATLAB/Simscape® was selected due to cost reasons, its good availability within the company, and the fact that most engineers encounter MATLAB® during their education. The drawback of fewer predefined components and material properties was put up with. One of the useful extensions was the MATLAB App Designer combined with MATLAB® Web app server, which allows fast creation of graphical user interfaces (GUIs) and easy deployment throughout the company without requiring software licences for the end user. The result was an agile and fast development, validation and testing process for the resulting engineering design tools.

## Library structure

The library consisted of physical models for simulation of physical processes such as heat transfer, gas solubility, gas permeation, mass transfer and many others. The models were implemented as custom components in the Simscape® language. Using the physical models, equipment models were created as composite components for the machines and process equipment in the beverage plant. Both physical and equipment models were centrally stored and managed in the new library (**Figure 3**).

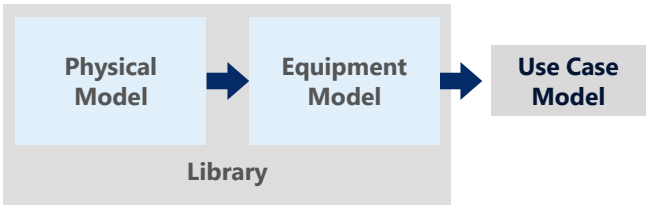

**Figure 3.** Modeling workflow and library structure

For each use case, a new Simulink/Simscape® model was created. The easy combination of the new components with all possibilities provided by Simulink/Simscape® toolboxes allowed the creation of digital twins for the design process in different levels of fidelity from basic design models to detailed Hardware-In-the-Loop (HIL) models. With the App Designer and standard MATLAB® coding the design workflows, the management of the design parameters and the new models were incorporated into use-case-specific GUIs.

# USE CASE

The first commercial use case for the new modeling library was an energy-savings upgrade for Carbonated-Soft-Drink production lines in tropical climates [77].

## Motivation

The main issue while filling carbonated beverages is foaming. The beverages are oversaturated with carbon dioxide at atmospheric pressure to achieve the fizzle mouth feeling while drinking.

The solution of the carbon dioxide into the beverage is performed at elevated pressures well above the total gas saturation pressure. The beverage containers are filled as well at pressures above the total gas saturation pressure to dissolve formed gas bubbles during the filling process and keep gas losses low. The beverage temperature is the parameter with the strongest effect on the saturation pressure, i.e. cold temperatures (5-16°C) lead to low process pressures. The container is pressurized before the filling process in the filler and vented afterwards. The foaming issues occur directly after the venting step. Small bubbles grow due to the pressure release. The bubbles grow further due to the oversaturated state of the gases in the liquid, if they are above a critical diameter [8]. Due to buoyancy effect the grown bubbles rise, and if they reach the liquid surface, they form foam. Colder filling temperatures lead to less pressure release and therefore less bubbles are above the critical diameter for further growth and foam formation.

Cold filling of carbonated beverages is state-of-the-art in the industry to handle foaming problems. The beverage is cooled down after mixing and before carbonation and filling. If the production line is in a hot and humid climate with a dewpoint above the filling temperature, the filled and capped containers are heated up again in a tunnel heater to avoid hygienic problems due to condensation (**Figure 4**).

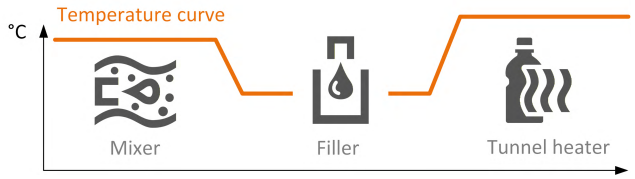

**Figure 4.** State-of-the-art temperature profile for Carbonated-Soft-Drink (CSD) filling in tropical climates

Historically, the filling temperature was a parameter that the plant operator required at a level based on experience, or that the filler supplier set as high as possible, also based on experience. However, there was no logical deduction for determining the best possible value.

In recent years, plant operators started to focus on energy efficiency, especially at sites with high energy prices, even if the energy costs are a small part of the TCO (**Figure 1**). The cooling and heating energy for CSD filling has come into focus, and ways to reduce it have been explored.

## Process model

The simplest solution to save cooling and heating energy was to raise the filling temperature as much as possible. To avoid excessive gas losses, the filling pressure had to be raised as well and led to the limiting parameter: the maximum pressure the container can withstand. There is a design pressure for cans (6.2 bar) and glass containers (10 bar) for carbonated beverages, but not for PET containers.

PET containers are widely customized, and the design pressure is not a common parameter used during the design process. Instead, each customer has its own specifications regarding maximum fill-level drop during storage or other criteria. The so-called “thermo test” is also popular, i.e. the container is stored for 24 hours at an elevated temperature of 38°C and then inspected. If the PET container is deformed beyond the given specifications, the container must be redesigned.

The reason for the “thermo test” is that a filled and capped carbonized beverage container will reach its highest internal pressure during uncooled storage in the distribution chain from the production plant to the end customer (**Figure 5**). The gases in the liquid and the gaseous head space reach equilibrium, and the pressure in the container rises according to the dissolved gas content in the beverage (carbon dioxide, oxygen and nitrogen).

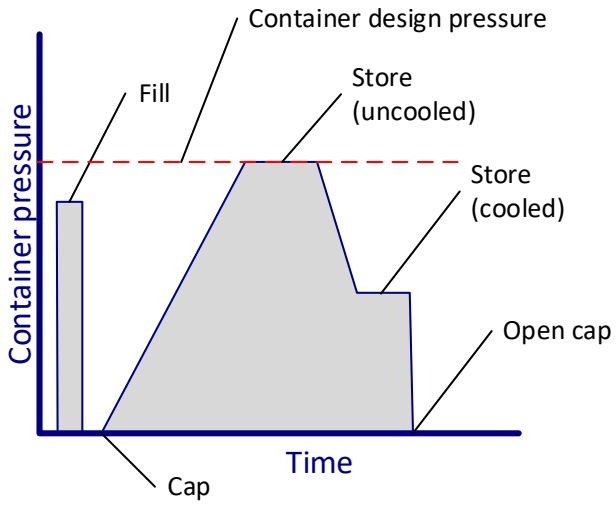

**Figure 5.** Schematic inner pressure vs. time diagram of a carbonized beverage container. The inner pressure in the container is increased before filling and decreased to atomospheric pressure after filling. The inner pressure raises slowly after capping due to reaching gas equilibration between head space and liquid up to saturation pressure at storage temperature.

The basis for the developed process model is the calculation of the highest pressure in the container during its lifetime. If the container cannot withstand this pressure, it will fail its main purpose. The calculated storage pressure provides the upper limit of the filling pressure, which allows the calculation of a conservative maximum filling temperature.

The process model accounts for the factors with most influence on the maximum filling pressure (**Figure 6**).

### Site specific:

- Dew point for calculation of the heating energy
- Altitude for correction of the internal pressure at uncooled storage
- Maximum temperature during uncooled storage
- Product water temperature as a limit of the filing temperature
- Heating costs
- Electricity costs

### Customer specific:

- $CO_2$ measurement method. While independent bottlers use standard devices and correlations [99], some larger companies have their own methods and correlations.

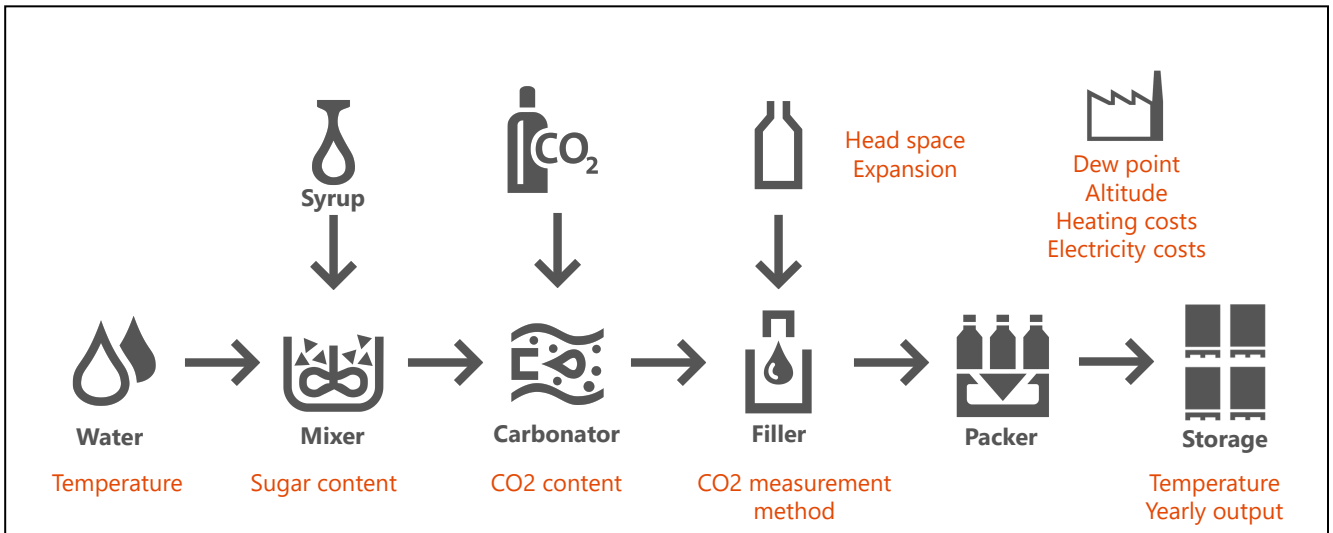

**Figure 6.** Process model for warm fill upgrades. Red are the site, customer and Stock-Keeping-Unit (SKU) specific model parameters.

### Stock-Keeping-Unit (SKU) specific:

- Sugar content
- CO2 content
- Headspace expansion due to PET elasticity
- Yearly output

## Results

With the process model the maximum feasible filing pressures could be found for each SKU at a specific production site with the limit of the calculated inner container pressure in uncooled storage and compared to the current process value ( **Figure 7**).

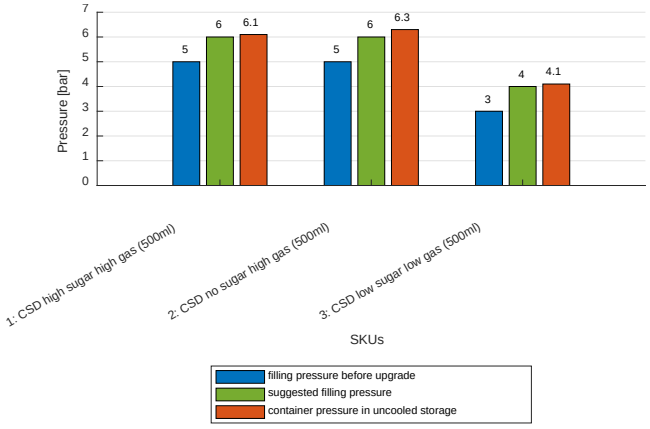

**Figure 7.** Pressures in PET container for different CSD beverages

The maximum filling pressure lead then to the calculation of the maximum filling temperature range depending on the unknown foaming potential of the beverage and compared again to the current process value ( **Figure 8**).

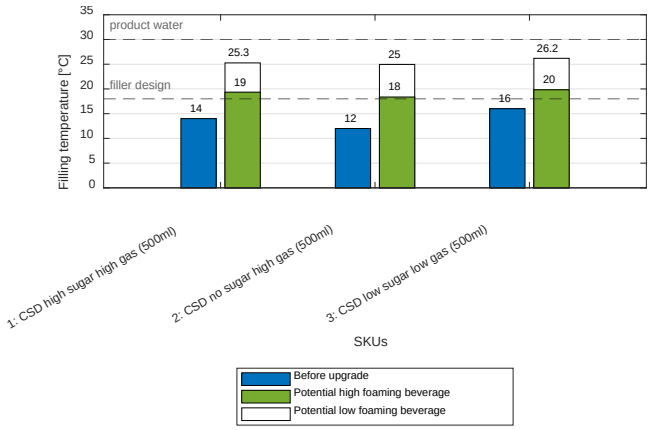

**Figure 8.** Filling temperature analysis for different CSD beverages.

Through the necessary cooling and heating energy, their associated costs and the yearly production out could then the annual energy costs for each SKU calculated (**Figure 9**) and the final Return-on-Invest (ROI) with the upgrade costs for each analysed production line.

The upgrade has been available for PET filling lines since the end of 2025. The first on-site implementations showed even higher possible filling temperatures and lower ROI numbers as calculated due to the fact, that especially small PET containers have higher stability against internal pressure than required, and the filling pressure could therefore be increased further than predicted by the process model. There will be a future update for the process model to incorporate the real container pressure limit based on simplified expansion.

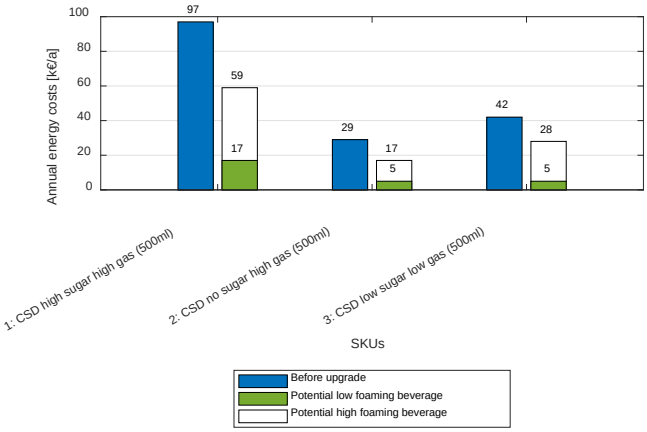

**Figure 9.** Annual energy costs for different CSD beverages.

## CONCLUSIONS

The authors started to build up a process modelling library for the beverage industry to speed up the design process and unlock new line- and plant-wide optimization possibilities. The software MATLAB/Simscape® was selected as the tool, and the machines and equipment implemented in a structured order. The first realized use case was the creation of a process model and a tool for calculating the ROI of an energy-saving upgrade for CSD filling lines in warm climates.

## ABSTRACT

To effectively distribute power to a system of multiple electrolyzer stack units, control strategies have been developed that now need to be applied to heterogeneous electrolysis systems. These are the 'segment principle', the 'slow start principle' and the 'start-stop principle'. As there are many possible combinations to the system composition of a modular heterogeneous electrolysis system together with the most suitable control strategy, a discrete multi-criteria optimisation problem can be formulated. To solve this discrete multi-criteria optimisation problem, two discrete decision variables are introduced. One is the electrolysis system composition, represented by the power ratio/configuration (C). A total of 17 different configurations were used for this, consisting of different proportions of alkaline electrolysis (AEL) and proton exchange membrane electrolysis (PEMEL). The other one are the control strategies (R). For the control strategies, the conventional strategies, mentioned above, have been adjusted to deal with the heterogeneity of the electrolysis system. Variations are made in the priorization of certain technologies for power distribution and the availability of a base load operation. The objective function was designed to be the weighted sum of the three highest ranked decision criteria in the categories 'flexibility', 'cost', and 'process engineering' from an empirical expert survey, which led to the respective decision criteria LGC, LCOH and the reciprocal of $\eta_{sys}$. The weights were derived from the ranking, a global grid search identified the combination of (R) and (C) which will be discussed in the paper together with a detailed analysis of the optimization problem.

## INTRODUCTION

The use of renewable energy leads to a volatile power supply and fluctuating energy prices, which affect energy-intensive industries (e.g., steel production). Large-scale electrolysis systems can contribute to energy flexibility by consuming electricity when demand and prices are low. Today, industrial concepts typically focus on a single electrolysis technology per electrolysis system. Alkaline electrolysis (AEL) is generally regarded as cost-effective and well-suited for base-load operation, whereas proton exchange membrane electrolysis (PEMEL) is regarded as more suitable for flexible operation. A heterogeneous plant layout could therefore combine AEL for base load and PEMEL for peak load, exploiting the strengths of each technology [1]. However, this design space, together with operational control choices, naturally results in a multi-criteria optimisation problem.

This paper aims to close a methodological gap in the design of modular heterogeneous electrolysis systems by formulating the selection of technology shares and operating concepts as a discrete multi-criteria optimization problem. While heterogeneous layouts have been discussed in prior work, the choice of technology fractions is often predefined heuristically (e.g., "reasonable" splits) or implicitly constrained by the authors' available system sizes, rather than being derived from a transparent, reproducible optimization procedure [2–4]. In contrast, we define the electrolysis configuration and the control strategy as discrete decision variables and identify trade-offs between key engineering objectives such as operational flexibility (LGC), hydrogen production cost (LCOH), and system efficiency, aggregated through expert-informed weighting and evaluated across the full

combinatorial design space.

## METHOD OF DISCRETE MULTI-CRITERIA OPTIMIZATION

### Definition of a use case

The application should meet several requirements. First, it should be equipped with a fluctuating power input, as continuously operated electrolysis systems have been state of the art for many years [5]. Furthermore, more than one electrolysis stack unit is required for the application in order to scale an electrolysis system consisting of several electrolysis stack units in a modular, heterogeneous way.

One application that meets the above requirements is a green steel model presented in [3]. As a boundary condition, the electrolysis system must be capable of supplying hydrogen to produce approximately 125, 000 t/h of hot briquetted iron. This corresponds to a total electrolysis capacity of approx. 400 MW. Since the largest electrolysis stack unit available on the market has a size of 5 MW, 80 such electrolysis stack units are required for a steel mill [6]. Since the LGC depends by definition on the incoming input profile, a synthetic power input profile was developed to ensure comparable power consumption and to separate the LGC from the scenario. In this way, the LGC can be applied to all electrolysis systems of different power ratings. [7].

### Definition of the optimization Problem

The approach follows a decision-analytical structure: definition of (i) discrete decision variables (or criteria), (ii) objectives an the objective function that aggregates objectives into a single scalar score for ranking the proposed solutions, (iii) constraints, and (iv) the complete mathematical formulation of the optimization problem [8]. First, the design and operation of a modular heterogeneous electrolysis system are defined as discrete decision variables as follows:

- Configuration (C): The system composition, expressed by the power ratio of AEL to PEMEL. Seventeen configurations (Conf. 0–16) cover edge cases from fully PEMEL to fully AEL and include variants with finer granularity. The power ratio is introduced here to enable a comparison between systems of different sizes, for example between the large-scale electrolysis system shown here and a small laboratory system. Another application for this would be the comparability of configurations with the same system power but with individual electrolysis stack units of different sizes.
- Control strategy (R): Control strategies adapted from modular electrolysis operation, including 'start-stop', 'slow-start' and 'segment' strategies, each refined by variants to prioritise base load and switching between AEL and PEMEL [9].

The decision variables are regarded as time-invariant. The configuration (C) is not changed during operation, no electrolysis systems are connected or disconnected. The control strategy (R) is not changed during operation, as changing the control strategy requires a different system layout (in terms of sensors, actuators, etc.) [10].

Secondly, objectives are defined by which the modular heterogeneous electrolysis system is to be optimized. Multiple objectives are selected and weighted base on an empirical expert survey [11]. In this paper, these shall be the following:

- process engineering: performance, represented by the reciprocal of system efficiency ($1/\eta_{sys}$).
- Flexibility: Flexibility for dynamic operation: represented by the Lange-Große coefficient (LGC) [2, 12]
- Costs: Product costs, represented by the Levelized Cost of Hydrogen (LCOH)

Based on these objectives the objective function can be formulated as in formular (1), where (a, b, c) are weighting factors derived from the survey. In the analysed case, a = 0.50, b = 0.34 and c = 0.16.

$$Z = a^* \frac{1}{\eta_{sys}} + b^* LGC + c^* LCOH \quad (1)$$

Thirdly, the constraints are defined. These are to be defined for the LCOH for green hydrogen at 7.7€/$kg_{H2}$, as this corresponds to the average value of currently estimated costs by project developers in the field of green hydrogen [13, 14]. The LCG is limited to a maximum of 2%, as already described in the literature. System efficiency is not to be further restricted [15].

In the fourth step, the optimization problem M, which is represented in formula (2), is defined. The proposed solutions are evaluated using a weighted, normalized sum with ideal point normalization.

$$M = \begin{cases} \min\limits_{C\&R} \left(a * \frac{1}{\eta_{sys}} + b * LGC + c * LCOH\right) \\ s.t.\ LGC \leq 2\% \\ s.t.\ LCOH \leq 7.7€/kg_{H_2} \end{cases} \quad (2)$$

This optimisation problem M is solved by a comprehensive grid search across the discrete space, combining all configurations C with all control strategies R. After applying the constraints, the remaining solutions are evaluated using the objective function and visualised as a heat map to determine the weighted score for each (C, R) pair.

The illustration Figure 1 shows the basic structure of the optimisation framework. This shows the two discrete decision variables (C) and (R) (different shapes), which in

this case consist of only two different discrete points (white and black). Each discrete point of a decision variable is then combined with all other decision variables, resulting in four different discrete points in this case. Z can now be calculated for each combination of the discrete decision variables. The values $\eta_{sys}$, LGC, and LOHC can then be entered in a three-dimensional diagram. The two constraints can now be entered on the axes for LGC and LOHC (blue lines). The green point at the origin of the coordinates represents the ideal point if all objectives were perfectly reached at the same time.

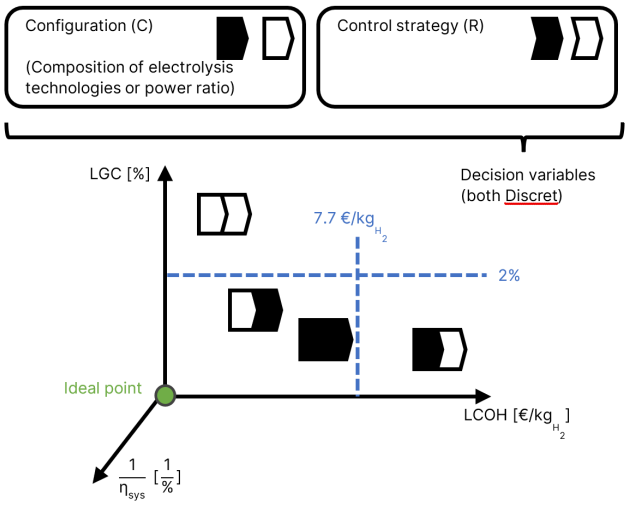

**Figure 1.** Schematic representation of the optimisation framework

## Description of the simulation models

The behavioural models used were developed to determine the operability of connected heterogeneous electrolysis systems [12, 16]. They simulate the lumped, dynamic behaviour of a connected electrolysis system, including stack-units, electrolyte circulation, gas separations and water supply. Internal control strategies enable the evaluation of cold start-up, warm start-up, stationary operation, load changes and shut-down to accurately predict the dynamic behaviour and power consumption of the systems. Operational setpoints in the models, such as temperature, flowrate and pressure were held constant across all simulation runs. The models were validated using literature data from [17].

Table 1 provides an overview of the stack unit parameters used, including their source in the literature. All of these parameters are necessary included in behavioural models, that form the basis for calculating the selected objective of system efficiency, system flexibility and the levelized cost of hydrogen for each combination of (C) and (R).

**Table 1:** List of stack unit parameters used for the simulation runs

| | | | AEL | PEMEL | Source |

| | EL-Power | [MW] | 5 | 0.7 | [6] |

## Definition of the configurations and the control strategies

Once the use case, optimization problem, and models have been defined, the decision evaluation points of the defined decision variables will be specified. Table 2 provides an overview of the composition of the individual configurations (C). The number of electrolysis system blocks and their block output are specified. The last column provides an overview of the power ratio between the electrolysis technologies AEL and PEMEL.

The basic control strategies from [9] are used as the control strategy (R). These are further refined by

additions. A base load share has been defined, as the minimum operational load of one electrolysis system, for each strategy in order to always generate a minimum amount of hydrogen. The opposite of this is a strategy without base load (woBL), where the entire electrolysis system does not produce any hydrogen as soon as the power input falls below the minimum operational load. In the segment principle, a further subdivision was made based on the control strategy. AEL1 stands for AEL having priority. First, all AEL blocks are started up to 80%, then to 100%. This is followed by the PEMEL blocks, which are started up to 80% and then to 100%. N stands for a slightly different variant of this. Here, all AEL blocks are first started up to 80%, then all PEMEL blocks to 80%. Then the AEL blocks are first run at 100%, followed by the PEMEL blocks at 100%. These strategies serve to make the partial load efficiencies of the stack units usable for longer [22].

**Table 2:** Comparison of the different configurations. No. AEL/No. PEMEL represents the number of system blocks, the specified power refers to the system power of the individual block, and the power ratio indicates the ratio of AEL:PEMEL.

| Configuration (C) | No. AEL | AEL [MW] | No. PEMEL | PEMEL [MW] | Power ratio |
|---|---|---|---|---|---|
| Con. 0 | 0 | 40 | 109 | 4 | 0.000 |
| Con. 1 | 1 | 40 | 98 | 4 | 0.102 |
| Con. 2 | 2 | 40 | 87 | 4 | 0.230 |
| Con. 3 | 3 | 40 | 76 | 4 | 0.395 |
| Con. 4 | 4 | 40 | 66 | 4 | 0.606 |
| Con. 5 | 5 | 40 | 55 | 4 | 0.909 |
| Con. 6 | 6 | 40 | 44 | 4 | 1.364 |
| Con. 7 | 7 | 40 | 33 | 4 | 2.121 |
| Con. 8 | 8 | 40 | 22 | 4 | 3.636 |
| Con. 9 | 9 | 40 | 11 | 4 | 8.182 |
| Con. 10 | 10 | 40 | 0 | 4 | ∞ |
| Con. 11 | 34 | 10 | 47 | 1.4 | 5.167 |
| Con. 12 | 35 | 10 | 40 | 1.4 | 6.250 |
| Con. 13 | 36 | 10 | 32 | 1.4 | 8.036 |
| Con. 14 | 37 | 10 | 24 | 1.4 | 11.012 |
| Con. 15 | 38 | 10 | 16 | 1.4 | 16.964 |
| Con. 16 | 39 | 10 | 9 | 1.4 | 30.952 |

The NewS strategy was introduced specifically for the start-stop strategy. This aims to distribute the load by switching from PEMEL blocks to AEL blocks when all PEMEL blocks are at 100% capacity and AEL blocks are not yet fully utilized. This strategy is intended to help make better use of the more efficient AEL blocks.

### Evaluation of simulation results

First, the objectives of operational efficiency (including increased efficiency during partial load operation and energy loss, due to minimum load constraints), LGC (taking into account the energy loss due to the control strategy and the minimum load constraints) and LCOH are calculated for each configuration (C) in each control strategy (R), using the simulation setup, described in [12], and the standardized input profile, described in [7]. The objective values are normalized using their global maxima across the control strategy (R) and configuration (C) area, to determine a weighted score comparable across all configurations (C) and control strategies (R).

## RESULTS

This section summarises the investigated configuration space and the resulting weighted optima across all combinations of configuration C and control strategy R. Across all feasible configuration strategy pairs considered in the grid search, the global minimum of the weighted score is achieved by Con. 16, which operates under the segment strategy and achieves a weighted score of 0.801. In general, the optimal combinations of (C) and (R) are located in the right area of the heat map, which means a ratio of AEL to PEMEL of 11.012-30.952. This shows that a minimally added amount of PEMEL technology in a large-scale AEL system offers advantages over a pure AEL system, as the configurations become worse with increasing AEL share. Furthermore, the results show that exploiting the partial load efficiencies of the individual stack units, such as in the ‘segment’ or ‘slow-start’ strategy, offers an advantage over pure ‘start-stop’ operation.

Finally, finer configurations across all evaluated (C) and (R) have a more consistent weighted score, suggesting that the sensitivity of system performance to the operating concept decreases with increasing modular resolution. This still needs to be confirmed in further research.

## DISCUSSION

The optimisation results highlight the central coupling between design (configuration/technology mix) and operation (control strategy) in modular electrolysis systems. Even within a relatively small discrete design space—defined here by 17 configurations and 10 control strategies—the ranking of configurations is not invariant to the chosen operating concept. This observation is consistent with process-systems intuition: control strategies influence transient loading, start–stop events, and part-load operation, which in turn affect flexibility metrics, efficiency, and ultimately the levelized hydrogen cost.

A key outcome is that PEMEL-only concepts do not emerge as optimal under the selected objective and constraints. This indicates that, for the examined use case and weighting, economic and efficiency advantages associated with AEL can dominate the aggregated

**Figure 2.** Heat Map: The color spectrum reflects the distribution from the global minimum (dark green) through a mid-range (yellow) to the global maximum (dark red). The empty cells represent all combinations of (C) and (R) that failed to meet a constraint (LGC or LCOH) and are therefore not displayed, even if the weighted score would be lower.

objective. Importantly, this is not a universal statement about technology superiority; rather, it reflects the normalization, the constraint set (especially the LCOH).

The reported benefit of finer granularity—more uniform weighted score across strategies—has a clear engineering interpretation. Smaller module sizes increase combinatorial resolution in the feasible operating region, enabling closer matching of the demand profile while respecting gradient constraints. This can reduce the penalty associated with a suboptimal control choice. However, finer granularity may increase balance-of-plant complexity, footprint, and maintenance burden. Therefore, granularity should be assessed jointly with efficiency, flexibility and LCOH considerations.

Several limitations should be considered when interpreting the results. First, the analysis excludes energy storage and focuses on direct load-following. Storage can decouple electrolysis operation from renewable variability and may change the trade-off between flexibility and cost. Second, cost and efficiency parameters are taken from literature and technology assessments; uncertainty ranges and learning-curve effects are not propagated through the optimisation. Third, the electrolysis models used were validated using literature data rather than actual operating data. Since the model from [17] was validated using real operating data, the significance of the model used is considered to be high. Despite these caveats, the discrete grid-search framework is valuable for decision making because it is transparent, reproducible, and directly compatible with modular design spaces. It also provides a consistent basis for comparing large-scale and laboratory-scale electrolysis systems, provided that decision criteria and constraints are defined in a scale-aware manner.

## CONCLUSION

A discrete multi-criteria optimisation framework was applied to identify favourable combinations of technology composition (AEL/PEMEL ratio) and control strategy for a modular heterogeneous electrolysis system in a green-steel use case. Using survey-derived weights and constraints on flexibility (LGC) and hydrogen cost (LCOH), the results show that (i) the optimal configuration depends on the operating strategy, (ii) PEMEL-only systems are not optimal under the applied objective, (iii) homogeneous AEL systems can be more optimal than homogeneous PEMEL systems when used in conjunction with suitable control concepts., and (iv) finer-granularity configurations tend to reduce sensitivity to the chosen control strategy.

## OUTLOOK

Future work should extend the configuration space to include additional technologies (e.g., high-temperature electrolysis) and heterogeneous layouts with three or more technology types. Integrating hydrogen and electrical storage, as well as grid services, would enable assessing system flexibility under broader operational paradigms beyond direct load-following. Finally, experimental validation on small-scale heterogeneous systems can support model calibration and help translate the optimisation framework to practical control implementation in modular electrolysis plants.

## ACKNOWLEDGEMENTS

We would like to thank the German Federal Ministry of Research, Technology and Space and the project management organization Jülich for their financial support within the framework of the eModule research project (FKZ 03HY116A) of the H2Giga lead platform. Furthermore, the P2O-Lab Learning Factory of the TUD Dresden University of Technology is thanked for its support.

## ABSTRACT

Grid-connected electrolyzers with intermediate hydrogen storage offer significant potential for reducing electricity costs through flexible operation under dynamic pricing. A threshold-based scheduling optimization approach is developed that derives interpretable on/off production rules from electricity price signals. The method identifies local price thresholds separating high-price from low-price periods, yielding binary production schedules. Adaptive horizon partitioning—subdividing the scheduling horizon when constant thresholds become infeasible—is combined with a receding horizon strategy that implements only a portion of each optimized schedule before re-optimization. This procedure enables systematic investigation of how characteristics of Integrated Electrolyzer–Storage Systems (IESS) influence cost reduction potential while maintaining computational tractability for both offline analysis and online implementation. A case study applying the approach to historical German electricity prices across 2, 688 scenarios reveals that storage capacity is the primary determinant of cost-saving potential, while start-up and shut-down times within the tested range (up to 120 minutes) show negligible impact. Systems with storage capacities allowing for hydrogen production stops of up to 1.4 days achieved electricity cost reductions of up to 80% compared to steady-state production. Production cycles in optimal schedules predominantly follow 24-hour rhythms, with approximately 30 cycles per month observed for high-performing configurations. These findings indicate that conventional flexibility metrics—focused on ramp rates and start-up times—are inadequate for assessing the cost-saving potential of flexibly operated, grid-connected electrolyzers under dynamic pricing. Instead, equipment wear from the frequent production cycling required by optimal schedules emerges as a key consideration for economic operation.

## BACKGROUND

The large-scale deployment of green hydrogen requires flexible electrolysis systems that can adapt to fluctuating renewable energy supply and dynamic electricity markets. Germany targets an electrolyzer capacity of 10 GW by 2030 for applications in green steel production and the chemical industry [1], yet specific flexibility requirements remain insufficiently understood despite extensive technical characterizations [2-4]. Current research explores control strategies for adaptive hydrogen production [4, 5] but rarely quantifies how start-up and shut-down dynamics impact techno-economic performance across different operational contexts [6]. This knowledge gap hinders optimal system design—especially for grid-connected electrolyzers with intermediate hydrogen storage, limiting the assessment of cost reduction potentials for electricity markets [7].

Existing scheduling approaches predominantly focus on behind-the-meter configurations, where electrolyzers adjust consumption based on local renewable availability rather than market signals [8]. Recent work demonstrates cost reductions through adaptive scheduling under dynamic prices [9–11], but these approaches

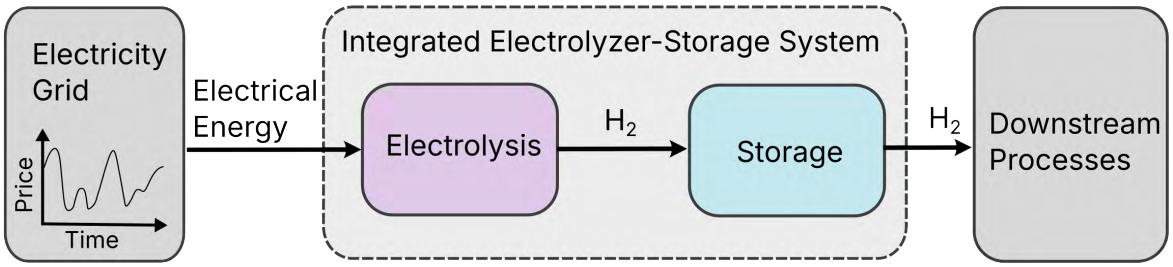

**Figure 1.** Integrated Electrolyzer–Storage System (IESS) and periphery

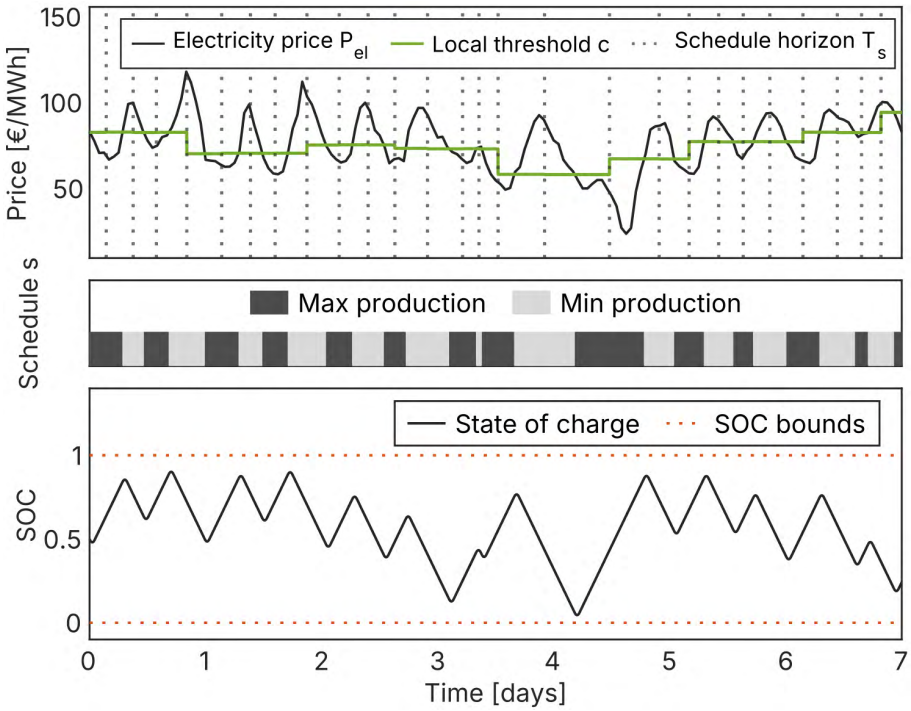

**Figure 2.** Production schedule generated by the optimization procedure. Top: electricity price $P_{\mathrm{el}}$ with local threshold $c$ and schedule horizon boundaries. Middle: resulting binary production schedule with maximum and minimum production phases. Bottom: hydrogen storage state of charge (SOC) evolution within operational bounds.

yield schedules without revealing underlying decision logic—limiting online applicability. Methods for electrolyzer-storage sizing have been proposed [12], yet critical gaps remain: existing approaches lack systematic feasibility analysis, neglect electrolyzer dynamics, and operate over fixed horizons without mechanisms to prevent dead-end states. Consequently, the relationship between system characteristics and achievable cost savings remains poorly understood.

## SCHEDULING OPTIMIZATION

Fluctuating electricity prices create a complex decision space balancing immediate costs against storage constraints and continuous downstream demand. The interdependence between production capacity, storage size, and price characteristics creates a nonlinear optimization landscape.

This work investigates optimal scheduling of grid-connected Integrated Electrolyzer–Storage Systems (IESS) under dynamic electricity prices (Figure 1). The system comprises a grid-connected electrolyzer, intermediate hydrogen storage, and downstream processes with constant demand. Variable hydrogen demand is excluded to isolate the scheduling problem.

Two main questions are addressed: (1) how to optimally schedule hydrogen production for a given IESS configuration, (2) which IESS characteristics influence the potential to minimize electricity costs.

The focus is exclusively on electricity procurement costs from the grid; capital expenditure, operational expenditure, and wear from load cycling are not considered in the optimization criterion. Additionally, behind-the-meter consumption of renewable energy sources is

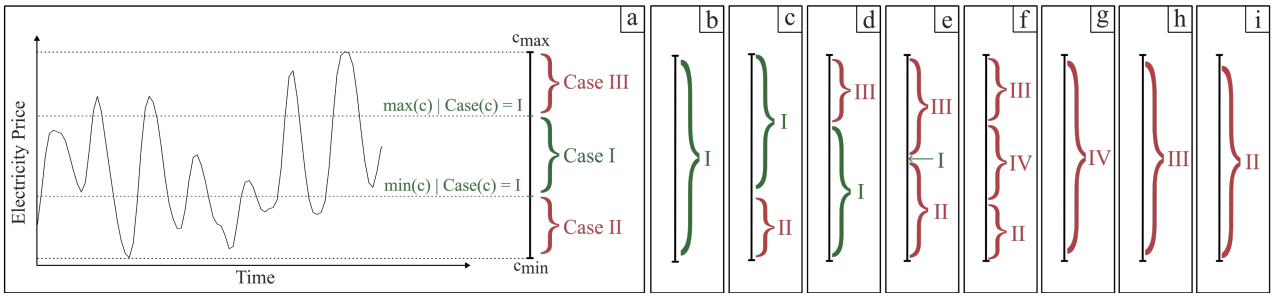

**Figure 3.** Visuallisation of all circumstances relevant for Algorithm 1 early termination and reasoning for error preventing strategies.

neglected in this work. Such consumption does not eliminate the scheduling problem but rather modifies the price input: grid prices act as a competing alternative for local generation, creating a mixed effective electricity price with analogous dynamic patterns. Since only the price input changes—not the problem structure—the proposed method remains directly applicable.

## The Optimal Production Schedule

The optimal production schedule minimizes electricity costs while maintaining continuous hydrogen supply for downstream processes. For cost functions based solely on electricity prices—deliberately excluding degradation, start-up costs, and cycling penalties to isolate dynamic pricing effects—clear patterns emerge. Cost is assumed linear with consumption; demand-dependent grid fees introduce nonlinearities but are negligible when consumption concentrates in low-price periods of generation excess, where flexible loads stabilize the grid. Intermediate load levels offer no advantage: any partial load hour could be improved by shifting to a cheaper hour at full load, leading to an on/off control concept. However, identifying the threshold separating low from high prices is non-trivial: storage capacity limits shutdown duration, production capacity determines deficit recovery speed, and start-up dynamics affect schedule precision. Thresholds must be chosen locally based on IESS state, forecast prices, and demand—creating a multi-level optimization problem. Scenarios where on/off schedules cannot achieve optimality are discussed in the Fatal Error Analysis.

## Scheduling Optimization Concept

Figure 2 illustrates a production schedule generated by the proposed optimization procedure. The interdependencies between electricity price fluctuations, production schedule, and system state are central to the approach. The ***production schedule*** defines periods of maximum and minimum production. The ***production rate set point*** translates this schedule into control commands, accounting for electrolysis system inertia to align power consumption with intended production periods. The ***hydrogen production rate*** follows the load evolution but deviates due to efficiency dependencies and transient offsets. The ***State of Charge*** (SOC) of hydrogen storage evolves according to the balance between production and downstream demand, closing the optimization loop.

Iterative refinement of the production schedule requires simulation of the IESS to evaluate SOC trajectories for candidate schedules. SOC limits impose hard boundaries on feasible schedules, while electricity price evolution defines the cost landscape. Storage size bounds the horizon over which local decisions influence future optimality, motivating two application goals: extensive offline investigation of IESS configuration impacts, and online applicability with comparable schedule quality.

The optimization procedure follows a receding horizon framework conceptually related to Model Predictive Control [13], but operates at scheduling timescales (hours to days) rather than control timescales (seconds to minutes). An outer iteration scheme adaptively determines prediction horizon lengths based on feasibility conditions rather than using fixed horizons. Three challenges must be addressed: (1) identifying local electricity price thresholds defining high and low price periods, (2) selecting appropriate prediction horizons for which constant thresholds yield feasible schedules, and (3) preventing dead-end states arising from system inertia.

## Estimation of Local Electricity Price Threshold

For a given time period, the electricity price threshold $c$ that defines high and low price periods is bounded by the electricity price $P_{\mathrm{el}}$ extrema, i.e., $c \in [c_{\min}, c_{\max}]$ where $c_{\min} = \min(P_{\mathrm{el}})$ and $c_{\max} = \max(P_{\mathrm{el}})$. The production schedule $s(t)$ is then derived from the threshold according to:

$$s(t) = \begin{cases} 1 & \text{if } P_{\mathrm{el}}(t) \leq c \\ 0 & \text{if } P_{\mathrm{el}}(t) > c \end{cases} \tag{1}$$

where $s = 1$ corresponds to maximum production and $s = 0$ to minimum production.

Within the range of $[c_{\min}, c_{\max}]$, four cases are distinguished based on the resulting SOC trajectory (see Table

1): Case I corresponds to fully feasible operation within storage limits; Case II occurs when storage runs empty at least once but never exceeds capacity; Case III occurs when storage exceeds capacity but never runs empty; and Case IV represents infeasible operation where storage both runs empty and overflows. Multiple circumstances determine which cases can occur simultaneously for a given IESS configuration. These depend on its state, price trajectory and $H_2$ demand; the relevant circumstances are shown in Figure 3. Circumstances a–e admit feasible solutions where at least one $c$ yields Case I; circumstances f–i admit no feasible threshold. Based on this classification, the search algorithm identifies the feasible interval $[c^I_{\min}, c^I_{\max}]$.

**Table 1:** Classification of Storage Operation Cases Based on State of Charge (SOC).

| Case | Description |
|---|---|
| I | If $\forall t \in [t_{start}, t_{end}]$ it holds that $0 < \mathrm{SOC}(t) < 1$, the $H_2$ storage operates entirely within its admissible limits and neither runs empty nor exceeds its capacity. Consequently, $c$ is considered sufficient. |
| II | If $\exists t \in [t_{start}, t_{end}]$ such that $\mathrm{SOC}(t) < 0$, while $\mathrm{SOC}(t) \leq 1$ for all $t \in [t_{start}, t_{end}]$, the $H_2$ storage runs empty at least once but never exceeds its capacity. |
| III | If $\mathrm{SOC}(t) \geq 0$ for all $t \in [t_{start}, t_{end}]$ and $\exists t \in [t_{start}, t_{end}]$ such that $\mathrm{SOC}(t) > 1$, the $H_2$ storage capacity is exceeded at least once, while the storage never runs empty. |
| IV | If $\exists t_1, t_2 \in [t_{start}, t_{end}]$ such that $\mathrm{SOC}(t_1) < 0$ and $\mathrm{SOC}(t_2) > 1$, the $H_2$ storage both runs empty and exceeds its capacity during the considered interval. In this case, no value of $c$ can satisfy the $H_2$ demand constraint while remaining within the storage relaxation limits. |

The minimum feasible threshold $c^I_{\min}$ is identified via interval bisection (Algorithm 1). Each candidate is evaluated by simulating the IESS: Case I indicates feasibility, Case II indicates threshold too low, Case III too high, and Case IV infeasibility. The interval narrows until convergence $|c_n - c_{n-1}| < \delta$; $c^I_{\max}$ is obtained analogously. For nonlinear IESS models, non-monotonic relationships may cause bisection failure, requiring algorithm extension.

Identification of the feasible threshold interval $[c^I_{\min}, c^I_{\max}]$ enables generation of multiple valid production schedules with different SOC characteristics. A threshold near $c^I_{\min}$ produces schedules that minimize hydrogen storage utilization, while $c^I_{\max}$ yields schedules that tend to fill the storage. To allow control over SOC behavior within the feasible range, a scheduling goal parameter $g \in [0, 1]$ is introduced:

$$c_{set} = c^I_{\min} + \left(c^I_{\max} - c^I_{\min}\right) \bullet g \tag{2}$$

where $c_{\mathrm{set}}$ is the threshold used to generate the production schedule according to Equation 1. Setting $g = 0$ selects $c^I_{\min}$, minimizing mean SOC; setting $g = 1$ selects $c^I_{\max}$, maximizing mean SOC.

The influence of $g$ depends strongly on initial conditions and the width of the feasible interval. For circumstance e (Figure 3), where the feasible interval is narrow, the scheduling goal has limited effect on SOC trajectory. This basic threshold estimation performs well when electricity prices follow uniform oscillations with period lengths compatible with storage capacity. More complex scenarios result in fatal errors discussed in the following.

## Fatal Error Analysis

Electricity price evolutions exhibit global trends, local trends, and randomness, inherently limiting periods for which a feasible constant threshold exists. A fatal error occurs when storage underflows ($\mathrm{SOC} < 0$) or overflows ($\mathrm{SOC} > 1$). Five failure modes are identified:

- **Long Periods:** When shutdown phases exceed storage hold-up duration, underflow becomes inevitable regardless of threshold selection—the system must produce during high-price periods, rendering binary switching unsuitable. Consequently, long-term price variation exploitation to reduce electricity costs is limited.
- **Short Periods:** Threshold-based scheduling triggers switching at every price-threshold crossing. When resulting cycles occur at timescales below start-up and shut-down times, the system cannot follow the schedule and these price variations cannot be exploited.
- **Changing Characteristics:** Periods with uniform price fluctuations admit relatively constant thresholds; when global or local trends shift, previously valid thresholds become infeasible.
- **Unfavorable Phase:** Initial SOC misaligned with price phase can cause SOC oscillations violating capacity limits despite otherwise suitable price characteristics.
- **Dead-Ends:** These correspond to circumstances f–i (Figure 3), where SOC approaches limits while production state is too inert to prevent violations. Dead-ends are critical when feasible schedules yield end states near circumstance e, where subsequent operation potentially fails. These failure modes motivate the error preventing strategies presented in the following section.

**Algorithm 1:** Minimum electricity price threshold for demand-feasible scheduling

**Input** : $P_{\mathrm{el}}(t)$: electricity price function, $\delta$: convergence tolerance
**Output**: $c^I_{\min}$: optimal minimal threshold, or $\emptyset$ if no solution exists

  **else if** *Case($c_n$) = II* **then**
    $c^+ \leftarrow \min\{c_i : \mathrm{Case}(c_i) \in \{\mathrm{I}, \mathrm{III}\},\ i \le n\}$
    $c_{n+1} \leftarrow (c^+ + c_n)/2$
  **else if** *Case($c_n$) = III* **then**
    $c^+ \leftarrow \max\{c_i : \mathrm{Case}(c_i) = \mathrm{II},\ i \le n\}$
    $c_{n+1} \leftarrow (c^+ + c_n)/2$
  **else**
    **return** $\emptyset$
  $n \leftarrow n + 1$

## Error Preventing Strategies

Adaptive horizon partitioning and receding horizon strategies ensure robustness of the global optimization procedure (Algorithm 2). By adaptive partitioning, the scheduling horizon is subdivided into segments, each admitting a feasible constant threshold $c^I$. Starting from initial segment length $T_0$ the algorithm iteratively reduces segment size by factor $\alpha \in (0, 1)$ until a feasible threshold exists:

$$T_{k+1} = \alpha \bullet T_k \tag{3}$$

This continues until the segment admits Case I or minimum segment length is reached. For non-dead-end circumstances (a–e in Figure 3), this guarantees a feasible schedule. Segment boundaries may be suboptimally placed, but near-optimal results in the case study indicate limited room for improvement.

Adaptive partitioning alone cannot prevent dead-end states at segment boundaries nor account for future price evolution. A locally optimized schedule may drive SOC toward extreme values, leaving insufficient flexibility for subsequent segments (e in Figure 3). To introduce predictiveness, a receding horizon framework distinguishes the *prediction horizon* $T_p$ from the *schedule horizon* $T_s$ [13]. At each iteration, the algorithm optimizes over $T_p$, applies only $T_s$, then shifts forward and re-optimizes—preventing myopic decisions that lead to dead-ends.

**Algorithm 2:** Optimized production schedule generation with adaptive horizon partitioning and receding horizon

**Input** : $P_{\mathrm{el}}(t)$: electricity price trajectory, $T_0$: initial segment length, $\alpha$: decreasing factor, $o_f$: overlap factor, $g$: scheduling goal, $T_{\min}$: minimum segment length, $\mathbf{x}_0$: initial IESS state
**Output**: $s(t)$: production schedule over scheduling horizon

$t_{\mathrm{current}} \leftarrow 0$
$\mathbf{x} \leftarrow \mathbf{x}_0$
$s(t) \leftarrow \emptyset$
**while** $t_{current} < t_{end}$ **do**
  $T_p \leftarrow T_0$
  $c^I_{\min} \leftarrow \emptyset$
  **while** $c^I_{\min} = \emptyset$ and $T_p \ge T_{\min}$ **do**
    $c^I_{\min} \leftarrow \mathrm{EstimateCmin}(P_{\mathrm{el}}, [t_{\mathrm{current}}, t_{\mathrm{current}} + T_p], \mathbf{x})$
    **if** $c^I_{\min} = \emptyset$ **then**
      $T_p \leftarrow \alpha \cdot T_p$
  **if** $c^I_{\min} = \emptyset$ **then**
    **return** infeasible
  $c^I_{\max} \leftarrow \mathrm{EstimateCmax}(P_{\mathrm{el}}, [t_{\mathrm{current}}, t_{\mathrm{current}} + T_p], \mathbf{x})$
  $c_{\mathrm{set}} \leftarrow c^I_{\min} + (c^I_{\max} - c^I_{\min}) \cdot g$
  $s_p(t) \leftarrow s(t; c_{\mathrm{set}})$ for $t \in [t_{\mathrm{current}}, t_{\mathrm{current}} + T_p]$
  $T_s \leftarrow T_p \left(1 - \frac{o_f}{1+o_f}\right)$
  Append $s_p(t)$ for $t \in [t_{\mathrm{current}}, t_{\mathrm{current}} + T_s]$ to $s(t)$
  $\mathbf{x} \leftarrow \mathrm{SimulateIESS}(\mathbf{x}, s_p, [t_{\mathrm{current}}, t_{\mathrm{current}} + T_s])$
  $t_{\mathrm{current}} \leftarrow t_{\mathrm{current}} + T_s$
**return** $s(t)$

The ratio between prediction and schedule horizons is defined through an overlap factor $o_f$, which specifies the fractional overlap between consecutive prediction horizons of equal size:

$$T_s = T_p \left(1 - \frac{o_f}{1+o_f}\right) \tag{4}$$

For $o_f = 0.5$, half of consecutive prediction horizons overlap. This parameterization provides intuitive tuning: higher overlap increases predictiveness at the cost of computational effort.

The combination of adaptive horizon partitioning and receding horizon implementation robustly generates feasible production schedules. These schedules are, due to their heuristic nature, often but not necessarily close to global optimality. Therefore, schedule quality must be assessed independently, as addressed in the following section.

## OPTIMALITY SCORE

To evaluate how effectively a schedule exploits price variability, an optimality score $\phi \in [0,1]$ is introduced comparing achieved performance to best-case (optimal) and worst-case (pessimal) consumption allocations, given identical total energy demand, temporal consumption structure, and system limitations. The score is independent of absolute price levels, instead quantifying how well local fluctuations are utilized through the dispersion of the consumption-weighted price distribution relative to global mean price $\bar{P}$.

Let $\tilde{P}_{\mathrm{el}}(t)$ denote the electricity price signal after removing non-exploitable long-term trends imposed by storage limitations, while preserving the global mean $\bar{P}$. For a given production schedule with consumption rate $\dot{E}(t)$ and total energy consumption

$$E_{\mathrm{total}} = \int \dot{E}(t)\,\mathrm{d}t, \tag{5}$$

the induced consumption-weighted price distribution is defined through the measure

$$\mathrm{d}E = \dot{E}(t)\,\mathrm{d}t \quad \text{at price} \quad \tilde{P}_{\mathrm{el}}(t) \quad . \tag{6}$$

For the same total energy consumption and the same temporal consumption profile $\dot{E}(t)$, two limiting reference distributions are defined:

- The *optimal distribution* $\mathcal{T}_{\mathrm{opt}}$, obtained by reassigning the largest consumption magnitudes to the lowest available values of $\tilde{P}_{\mathrm{el}}(t)$, with consumption magnitudes decreasing monotonically as prices approach $\bar{P}$.
- The *pessimal distribution* $\mathcal{T}_{\mathrm{pes}}$, obtained analogously by reassigning the largest consumption magnitudes to the highest available values of $\tilde{P}_{\mathrm{el}}(t)$.

In both cases, the distribution of consumption magnitudes over time is preserved; only its association with electricity prices is reordered. As a result, ramping behavior due to start-up and shut-down dynamics is inherently respected, while unnecessary production cycling does not artificially inflate the achievable optimality. The quality of each distribution is quantified using its central moment relative to the global mean price:

$$\mu_{\mathrm{opt}} = \frac{1}{E_{\mathrm{total}}} \int_{\mathcal{T}_{\mathrm{opt}}} \left(\tilde{P}_{\mathrm{el}} - \bar{P}\right)^2 \mathrm{d}E, \tag{7}$$

$$\mu_{\mathrm{pes}} = \frac{1}{E_{\mathrm{total}}} \int_{\mathcal{T}_{\mathrm{pes}}} \left(\tilde{P}_{\mathrm{el}} - \bar{P}\right)^2 \mathrm{d}E, \tag{8}$$

$$\mu_{\mathrm{schedule}} = \frac{1}{E_{\mathrm{total}}} \int \left(\tilde{P}_{\mathrm{el}}(t) - \bar{P}\right)^2 \dot{E}(t)\,\mathrm{d}t. \tag{9}$$

The optimality score is defined by normalizing the achieved second moment between the pessimal and optimal bounds:

$$\phi = \frac{|\mu_{\mathrm{schedule}} - \mu_{\mathrm{pes}}|}{|\mu_{\mathrm{opt}} - \mu_{\mathrm{pes}}|}. \tag{10}$$

By construction, $\phi = 1$ corresponds to optimal reassignment of consumption to low-price periods, $\phi = 0$ to pessimal reassignment, and $\phi \approx 0.5$ to steady-state production. The score captures theoretical scheduling effectiveness while accounting for storage capacity and production inertia limitations, deliberately excluding start-up costs, efficiency variations, cycling degradation, and capital expenditure.

## CASE STUDY

The proposed scheduling optimization was applied to a range of IESS configurations under historical electricity price data to evaluate performance across diverse scenarios. The study investigates three aspects: (1) performance of the scheduling optimization procedure, (2) IESS characteristics influencing electricity cost-saving potentials, and (3) operational strain indicated by production cycling. The section first describes the simulation model and experimental setup, then presents metrics for evaluation.

### IESS Model

For computational tractability, a simplified dynamic IESS model was employed. The production schedule is directly translated to production rate setpoints, resulting in anticipated phase lag between scheduled and actual production. Electricity consumption and hydrogen production are coupled through a linear relationship. Start-up and shut-down dynamics are represented by linear ramps following the production rate setpoint.

**Table 2:** IESS configuration parameters. Relative production and storage capacities are normalized to downstream hydrogen demand.

| Parameter | Tested Values |
|---|---|
| Relative production capacity [–] | 1.1, 1.5, 2.0, 2.6, 3.4, 4.4, 5.5, 6.0 |
| Start-up/shut-down time [min] | 0, 40, 80, 120 |
| Relative storage capacity [days] | 0.05, 0.25, 0.5, 0.7, 1.4, 2.8, 4.9 |

### Experimental Setup

IESS configurations were varied in a full factorial design according to Table 2. The ***relative production capacity*** is defined as the ratio of maximum hydrogen production rate to the constant hydrogen demand of downstream processes; a value of 2.0 indicates the electrolyzer can produce twice the demanded flow rate. The ***relative storage capacity*** is defined as the ratio of storage volume to one day of downstream hydrogen demand; a value of 1.0 indicates storage sufficient to supply downstream processes for 24 hours without production. Each

configuration was tested using historical electricity price data for each month of 2024, sourced from the German Federal Network Agency [14], yielding 2, 688 optimization runs. Parameters of the scheduling optimization were set to an overlap factor of $o_f$ = 1, scheduling goal $g$ = 0.5, and segment size reduction factor $\alpha$ = 0.7.

## Metrics

Three metrics quantify scheduling performance and electricity cost-saving potential of IESS configurations. The previously defined ***optimality score*** $\phi$ measures schedule quality relative to theoretical bounds. The ***relative electricity cost*** $C_{\mathrm{rel}}$ captures the ratio of electricity costs under the optimized schedule to costs under steady-state production:

$$C_{\mathrm{rel}} = \frac{\sum_t P_{\mathrm{el}}(t) \cdot \dot{E}(t)}{\bar{P}_{\mathrm{el}} \cdot E_{\mathrm{total}}} \tag{11}$$

where $\dot{E}(t)$ is the instantaneous electricity consumption rate. This metric should be interpreted as an indicator of cost-saving potential rather than a prediction of actual savings, as realized electricity costs are subject to considerable uncertainty including capacity charges, grid fees for flexible loads, and evolving market dynamics. The ***number of production cycles*** counts complete start-up/shut-down sequences per month, indicating operational strain relevant to equipment wear.

## Results and Discussion

The optimality score $\phi$ exhibits strong dependence on relative storage capacity (Figure 4). Configurations with relative storage capacities below 0.5 days consistently yielded $\phi < 0.8$, while capacities exceeding 1.4 days achieved $\phi > 0.9$ across most scenarios. Low storage capacity leads to the long periods problem. This indicates general unsuitability of low-storage configurations for exploiting electricity market price fluctuations, independent of the scheduling method employed.

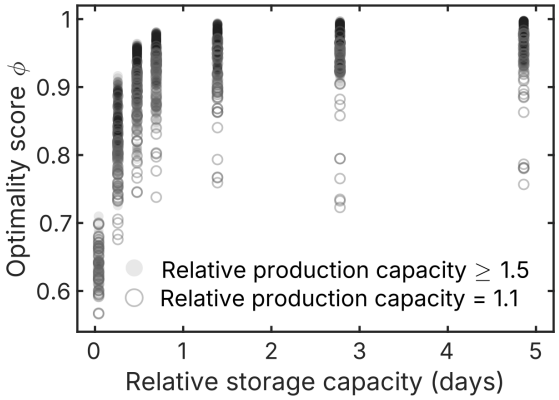

**Figure 4.** Optimality score $\phi$ as a function of relative storage capacity. The dependency to relative production capacity indicated by filled and unfilled markers.

Electricity cost-saving potential mirrors optimality score behavior (see Figure 5). Systems with storage capacities below 0.5 days achieved only marginal cost reductions, while capacities above 1.4 days overcame the storage bottleneck. Production capacities near unity (1.1) severely constrain flexibility due to insufficient surplus for shutdown periods. Cost-saving potential increases asymptotically with production capacity: values of 2.0 resulted in 70% relative electricity costs compared to steady-state production, while 4.0 achieved up to 20% relative costs in favorable months.

Start-up and shut-down times up to 120 minutes showed negligible impact on cost savings. Whether marginal observed dependencies result from the phase mismatch inherent in the simplified IESS control or reflect genuine limitations of process inertia on cost-saving potential cannot be conclusively determined from the present study.

For configurations with storage capacities above 1.4 days, a mean of 35 production cycles per month was observed (Figure 6), suggesting price fluctuations relevant

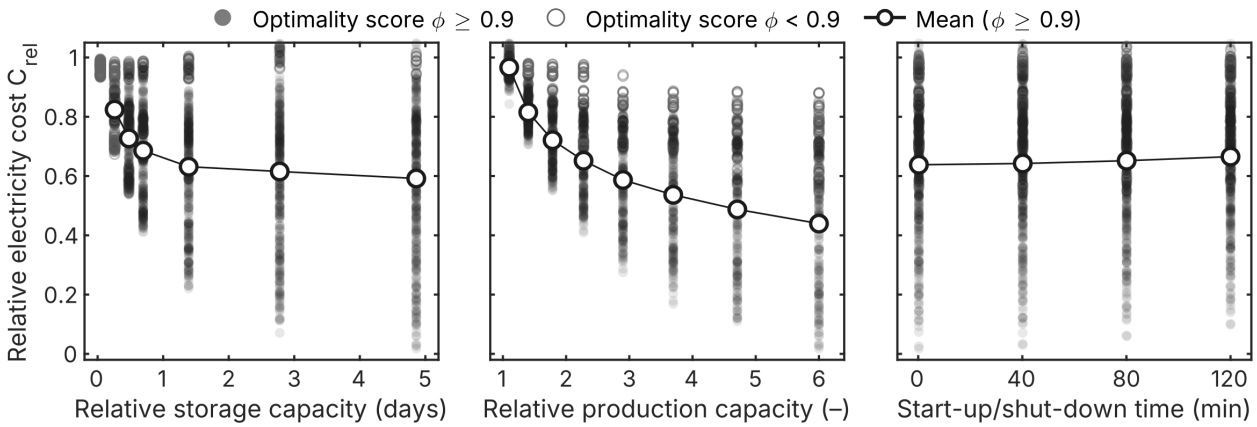

**Figure 5.** Relative electricity cost $C_{\mathrm{rel}}$ as a function of relative storage capacity, relative production capacity, and start-up/shut-down time.

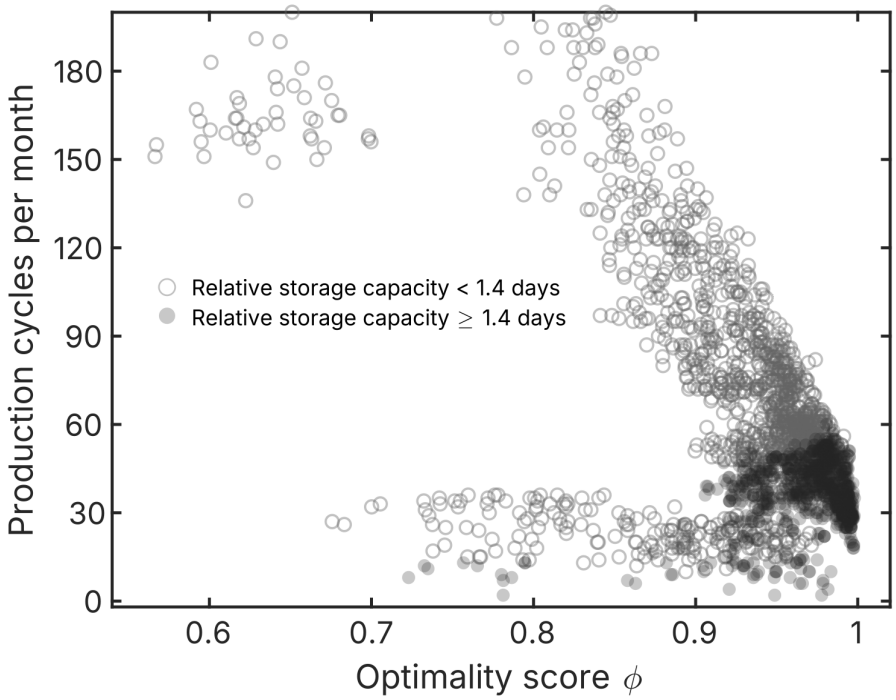

**Figure 6.** Production cycles per month as a function of optimality score $\phi$.

for cost optimization occur predominantly at daily timescales—consistent with diurnal patterns in markets with significant renewable penetration. Production cycle count remained largely independent of start-up and shut-down times.

The scheduling optimization procedure demonstrated robust performance across the parameter space. Except for configurations combining small storage capacities ($< 0.25$ days) with high production capacities ($> 4.0$), where scheduled cycle durations approached or fell below start-up and shut-down times, the algorithm reliably generated feasible production schedules. For all other configurations, the adaptive horizon partitioning and receding horizon strategies successfully prevented dead-end states and maintained SOC within admissible bounds. Computational cost was dominated by IESS simulation, with cumulative simulated time consistently between 100 and 160 times the generated schedule length for well-performing configurations ($\phi > 0.9$). While sequential dependencies between receding horizon iterations limit full parallelization, independent IESS simulations within each iteration are parallelizable, offering speedup potential by orders of magnitude.

## CONCLUSION

This work presents a threshold-based scheduling optimization approach for grid-connected electrolyzer-storage systems that derives interpretable production rules from electricity price characteristics, enabling both offline analysis and online application. The theoretical framework establishes necessary conditions for feasible schedule existence, and the optimality score $\phi$ provides a system-independent quality metric for integration into higher-level optimization.

Results challenge conventional flexibility metrics for electrolysis systems: start-up and shut-down times up to 120 minutes showed negligible impact on cost-saving potentials, while storage capacity emerged as the primary determinant. For grid-connected electrolyzers, the number of production cycles—rather than process dynamics—emerges as the critical constraint requiring assessment for economic operation.

## OUTLOOK

Future work should quantify how cycling frequency limits affect cost-saving potential by imposing minimum on-period durations to constrain cycle counts, enabling economic assessments. Extending the optimization criterion to include capital expenditure and cycling-induced degradation would support comprehensive techno-economic evaluation. Application to nonlinear IESS models, variable demand, and diverse market conditions with increasing price volatility [15] would broaden applicability.

## ABSTRACT

Industrial ammonia synthesis remains a high-impact decarbonization target due to the combined effect of large production volumes and reliance on $CO_2$-intensive fossil-based hydrogen. Replacing it partially with renewable-based (green) electrolytic hydrogen can minimize direct emissions; however, the intermittency of solar and wind complicates retrofit strategies for existing continuous plants. This paper addresses a techno-economic study centered on a retrofit-oriented hybrid concept: a conventional natural-gas ammonia plant is operated within a pre-defined "hybridization envelope", where part of the process hydrogen is supplied by a renewable Power-to-Hydrogen subsystem. A steady-state process model (gray/blue baselines) is coupled with an hourly energy dispatch and a sizing optimization of solar/wind park, electrolyzer, battery, and hydrogen storage. A case study based on 2024 California data for renewables and carbon pricing illustrates how hybridization can reduce carbon intensity while ensuring all process constraints are met, and how the optimal renewable mix trades off between overbuild and storage. Results highlight the role of solar-wind complementarity in lowering the levelized cost of hydrogen and, consequently, the levelized cost of ammonia, while leaving a clear pathway for combining hybrid-green operation with carbon capture (hybrid-blue-green) as a transitional strategy.

**Keywords**: Green ammonia, Electrolysis, Hydrogen storage, Energy storage, Retrofit, Power-to-Hydrogen

## INTRODUCTION

Ammonia is central to the global fertilizer value chain and is increasingly considered as an energy carrier for hard-to-abate sectors. However, the scientific community consistently identifies ammonia synthesis as a priority petrochemical process for decarbonization, alongside steam cracking and methanol [1, 2]. Conventional ("gray") ammonia production relies on natural gas reforming to supply hydrogen and on high-pressure synthesis loops that operate most efficiently in continuous mode. As a result, deep decarbonization of existing ammonia plants faces a dual challenge: (i) abating $CO_2$ emissions from hydrogen production and process energy, and (ii) integrating low- or zero-carbon energy vectors without destabilizing plant operation.

Green ammonia pathways typically assume renewable power fully supplies hydrogen via water electrolysis. While conceptually straightforward, the intermittency of solar and wind imposes operational and economic penalties unless extensive flexibility (grid exchange, mass and energy storage, electricity curtailment) is provided [3, 4]. Conversely, blue ammonia combines natural-gas-based hydrogen with carbon capture and storage (CCS). Blue routes can achieve meaningful emission cuts but remain vulnerable to concerns about upstream methane leakage and the associated costs of capture/transport/storage [5, 6]. Hybrid-green pathways, where a fraction of the process hydrogen is supplied by renewable electricity and the rest of the plant remains fossil-fed, can provide a pragmatic bridge, especially for retrofits [7, 8]. The hybrid approach aims to decouple "how much" renewable energy is used from "how the synthesis loop operates", by enforcing an operating envelope compatible with safe and efficient plant behavior.

Therefore, this work details the hybrid-green retrofit

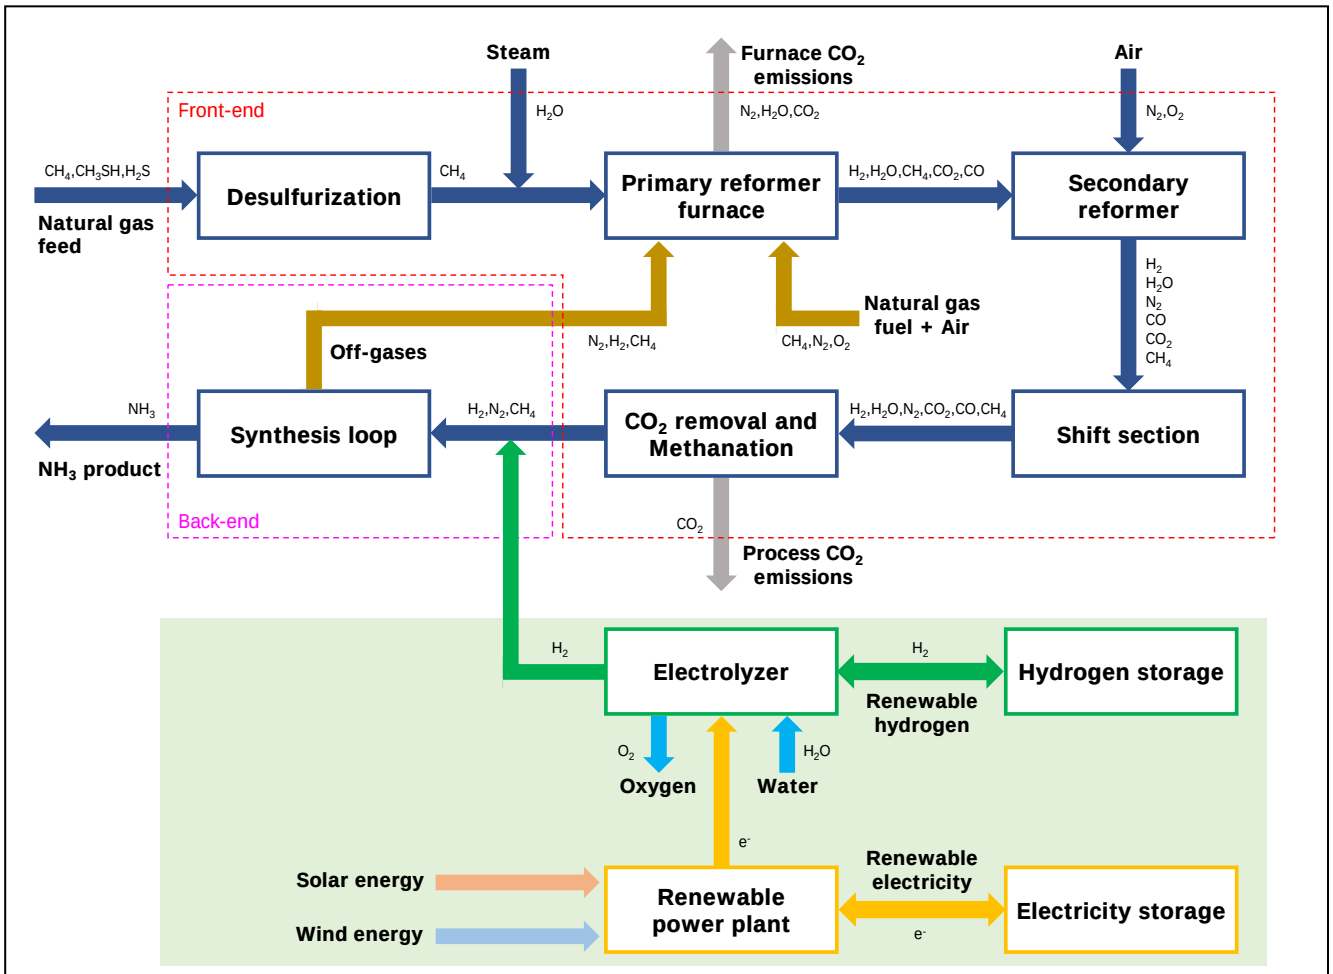

**Figure 1.** Block flow diagram of the hybrid-green retrofit for an ammonia plant. The green rectangle encloses the additional units introduced by the hybrid concept.

concept for existing ammonia plants and also provides a quantitative assessment of its techno-economic and environmental performance in the 2024 California context. Specifically, the analysis refers to published best-available-technology baselines for ammonia synthesis and recent cost data for renewables, electrolysis, and mass/energy storage. Furthermore, it expands an optimization-based sizing methodology for Power-to-Hydrogen (PtH) assets previously developed by the Authors [8].

## HYBRID-GREEN RETROFIT CONCEPT AND OPERATING ENVELOPE

The hybrid concept retrofits a conventional ammonia plant by adding a PtH subsystem (renewable electricity, electrolyzer, battery, $H_2$ storage) that can displace a fraction of the fossil-based hydrogen produced by the reformer (see **Figure 1**). To keep downstream units and the synthesis loop close to design conditions, we investigate the hybridization factor as the fraction of the plant's hydrogen demand supplied by the PtH system on average.

Rather than allowing arbitrary turndown, the retrofit is constrained to an "operating envelope" expressed by (i) minimum acceptable "throughput" (*i.e.*, the mass flow passing through the primary reformer), and (ii) maximum acceptable changes of key state variables (*i.e.*, the operating temperature in the secondary reformer and the fuel gas mass flow to the primary reformer furnace). This envelope is designed to mimic the practical constraints that arise from catalyst stability, heat-integration requirements, and process units' operating ranges [8].

More specifically, we have the following KPIs:

A. The throughput must always be above 80% of the primary reformer's nominal capacity.
B. The operating temperature in the secondary reformer must not exceed design values by more than 100°C.
C. The fuel gas mass flow to the primary reformer furnace must never drop to zero.

Accordingly, a 0–20% range of allowable hybridization factors was identified (as shown in **Table 1**).

**Table 1:** Evolution of the 3 KPIs (see the previous list) with increasing hybridization factor [8]. Values highlighted in red exceed operational constraints.

| Case | Hybrid. factor | KPI A | KPI B | KPI C |
|---|---|---|---|---|
| Gray (baseline) | 0% | 100% | ±0°C | 100% |
| Hybrid-green (mild) | 10% | 89.3% | +47°C | 92.3% |
| Hybrid-green (heavy) | 20% | 78.8% | +109°C | 82.8% |

## MODELING AND OPTIMIZATION FRAMEWORK

Our assessment links a steady-state process model of the ammonia plant with an hourly electricity-to-hydrogen dispatch model and a capacity-sizing optimization. The goal is to quantify the cost and emissions impact of hybridization at the plant level, while explicitly representing the variability of renewable generation and market electricity prices.

### Baseline process models (gray and blue)

A conventional natural-gas ammonia plant is simulated in UniSim® Design R500, following a typical flowsheet: desulfurization, primary and secondary reforming, shift conversion, $CO_2$ removal, methanation, compression, and ammonia synthesis with recycle and purge (*i.e.*, the Haber-Bosch process). Property methods rely on the Soave-Redlich-Kwong equation of state, consistent with high-pressure systems. Baseline performance and operating ranges are cross-checked against industrial manuals and engineering references.

For the blue baseline, building on the gray ammonia model, $CO_2$ capture is implemented on both the high-purity process stream (*i.e.*, the emissions from $CO_2$ removal) and flue gas streams (*i.e.*, the emissions generated by the combustion of fuel gas in the primary reformer furnace), using cost and performance assumptions aligned with public techno-economic studies for industrial capture [9, 10] (see **Table 2**). As our assessment is restricted to the production site battery limits following a gate-to-gate approach, the present analysis excludes both $CO_2$ transportation and storage.

### Power-to-Hydrogen subsystem

The PtH subsystem includes: (i) a renewable generation (solar and/or wind) power plant, (ii) an alkaline electrolyzer, (iii) a lithium-ion battery for short-term smoothing, and (iv) a pressurized hydrogen storage system for multi-hour to multi-day balancing. Component costs follow recent public reports and vendor data for low-temperature electrolysis as well as electricity and hydrogen storage technologies (see **Table 2**). Moreover, the design and flexible operating schedule of batteries and hydrogen tanks are supported by frameworks developed by the Authors for Power-to-X applications [11, 12].

**Table 2:** The complete set of input values and cost assumptions for the present techno-economic assessment.

### Electricity market and policy context

Hourly renewable profiles for 2024 are sourced from the California Independent System Operator (CAISO),

representing a high-renewables grid with pronounced diurnal and seasonal patterns [13]. Policy signals are modeled through a carbon price consistent with California's cap-and-trade mechanism [14]. Natural gas prices are based on industrial price indicators referring to industrial delivery rates for large-scale chemical facilities in California [15]. These cost assumptions are detailed in **Table 2**.

## Optimization problem

Decision variables are the installed capacities of the solar and wind farm, and the objective is to minimize the levelized cost of hydrogen (LCOH) produced by the PtH plant while meeting the hybridization target and respecting the retrofit envelope constraints.

The LCOH is computed by **Eq. (1)** from annualized CAPEX and OPEX contributions of the PtH subsystem (*i.e.*, solar plant, wind plant, electrolyzer, battery, and hydrogen storage; hereafter denoted by S, W, E, B, and H).

$$LCOH = \frac{\sum_{j=S,W,E,B,H}\left(\frac{CAPEX_j}{\sum_{y=1}^{NY_j}(1+ir)^{-y}}+OPEX_j\right)}{8760\ [\mathrm{h/y}] \bullet \dot{m}_{H_2}^{target}} \quad (1)$$

Optimization proceeds through a systematic evaluation of 1681 solar-wind installed capacity combinations (0–400 MW range, at 10 MW resolution) using MATLAB R2024a, followed by an estimation of the required electricity and hydrogen storage capacities according to the frameworks established by Isella and Manca [11, 12].

# RESULTS AND DISCUSSION

## Optimal renewable and PtH sizing

The sizing optimization reveals a clear benefit of combining solar and wind. Solar-only systems require larger batteries and hydrogen storage to bridge diurnal variability, while wind-only systems reduce storage needs but still show considerable electrolysis capacities and power generation costs. Lastly, the mixed solar-and-wind case leverages complementarity, reducing both overbuild and storage requirements, which translates into a lower LCOH (see **Table 3**).

**Table 3:** Optimal installed capacities and resulting LCOH for solar, wind, and solar-wind PtH configurations.

| | Solar | Wind | Solar-Wind |
|---|---|---|---|
| Solar [MW] | 330 | 0 | 110 |
| Wind [MW] | 0 | 310 | 210 |
| Electrolyzer [MW] | 243.20 | 147.55 | 129.88 |
| Battery [MW] | 216.45 | 16.82 | 8.47 |
| $H_2$ storage [$t_{H_2}$] | 19.52 | 2.16 | 2.95 |
| LCOH [USD/$kg_{H_2}$] | 3.75 | 3.25 | 2.94 |

## Ammonia production costs

**Figure 2** shows the ensuing levelized cost of ammonia (LCOA) for gray, blue, and hybrid pathways, including hybrid-green and "hybrid-blue-green" (*i.e.*, hybrid-green plus carbon capture). The gray baseline reflects fuel and feedstock costs plus the carbon price burden. The blue pathway benefits from captured process $CO_2$ but includes carbon capture costs. Hybrid-green pathways show higher LCOA in this scenario, primarily because renewable hydrogen remains costlier than reforming-based hydrogen under 2024 assumptions, despite rapidly declining renewable generation costs.

Numerically, the LCOA values (in USD/$t_{NH_3}$) resulting from this case study are: gray 373.44, blue 364.51, hybrid-green (solar-only) 415.04, hybrid-green (wind-only) 404.50, hybrid-green (solar-wind) 398.03, and hybrid-blue-green (solar-wind) 395.27. Such results emphasize that, in a high-gas-price moderate-carbon-price context, blue ammonia can be competitive with gray while still reducing direct emissions. On the other hand, hybrid-green becomes more competitive as renewable electricity and electrolysis costs fall further or carbon prices rise.

The cost breakdown provided helps interpret which components dominate the incremental cost of hybridization. In the hybrid-green cases, noteworthy contributors are renewable CAPEX and electrolyzer CAPEX, followed by storage (electricity and hydrogen) to buffer variability. In the hybrid-blue-green case, the addition of CCS introduces capture costs but reduces carbon liabilities and can improve competitiveness depending on policy and $CO_2$ storage or utilization availability.

## Emissions performance and CCS leverage

The operating envelope enables decarbonization progress without forcing deep turndown of the synthesis loop. In the study, increasing the hybridization factor from 0 to 10% and 20% reduces the plant-level $CO_2$ intensity from 1.64 to 1.48 and 1.31 $t_{CO_2}/t_{NH_3}$, respectively. The reduction is driven by the partial displacement of reformer-derived hydrogen by renewable electricity-derived hydrogen.

A key insight is that hybridization and CCS are not mutually exclusive. Hybrid-blue-green combines renewable hydrogen displacement with $CO_2$ capture on remaining fossil-derived streams. This stacking can reduce residual emissions beyond what either measure achieves alone while maintaining high utilization of existing assets. Such combinations align with CCS roadmaps for industrial decarbonization, where early deployment targets high-concentration $CO_2$ sources and leverages existing infrastructure.

At the same time, the environmental narrative of blue pathways depends on upstream methane emissions and on the overall capture rate achieved at the plant level. Recent debate emphasizes that "how green" blue

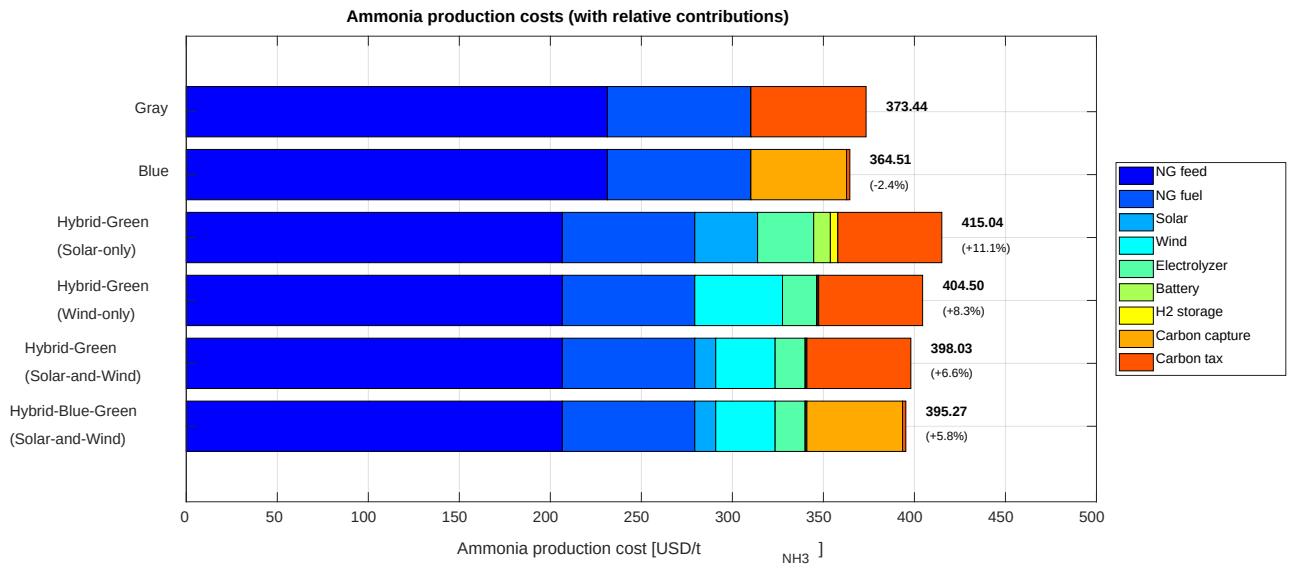

**Figure 2.** Ammonia production costs and relative contributions for the six assessed configurations. Percentages in parentheses next to the bars indicate the relative difference from the gray ammonia baseline. (NG=Natural Gas)

hydrogen and blue ammonia are depends critically on leakage rates and on capture scope [5]. For this reason, hybridization can be viewed as a hedge: increasing renewable substitution reduces exposure to upstream gas supply emissions even if CCS deployment faces constraints.

### Operational insights for retrofit deployment

From an operational perspective, the hybrid retrofit can be implemented with minimal disruption if the PtH subsystem is treated as an auxiliary unit that delivers hydrogen at a suitable mass flow. The process integration challenge is to ensure that hydrogen displacement does not violate reformer heat-balance constraints or alter the synthesis loop's inert levels and purge management. Both scientific literature and industrial practice suggest that maintaining stable inlet compositions and temperature profiles is crucial to reliable operation.

Storage plays a key role: it buffers variability so that the plant receives a smoother electricity and hydrogen supply that is also compliant with the operating requirements of the electrolyzer and the Haber-Bosch process. Battery storage is most valuable for short-term smoothing, whereas hydrogen storage provides longer balancing. In this respect, recent design criteria for flexible electricity and hydrogen storage in PtX systems were applied to select storage capacity without overinvesting in rarely used inventory [11, 12].

The optimal sizing results show that solar-only operation requires significantly larger battery and hydrogen storage capacities than wind-only or mixed operation. This indicates that, for retrofit cases with limited space or where minimizing additional equipment is essential, the availability of a diversified renewable portfolio (either on-site or via PPAs) can be as important as absolute generation cost.

## CONCLUSIONS

A hybrid-green retrofit concept can meaningfully reduce ammonia plant $CO_2$ intensity (about 20% decrease) while preserving continuous operation through an explicit operating envelope. When PtH assets are optimally sized, solar-wind complementarity cuts storage capacities and delivers the lowest LCOH among the tested cases. In the California 2024 scenario, hybrid-green remains more expensive than blue ammonia; however, the gap narrows with lower electrolyzer costs and higher carbon prices. Hybrid-blue-green offers an attractive transitional option by stacking renewable displacement and CCS.

From a deployment viewpoint, our framework supports retrofit screening by quantifying (i) the additional equipment required for a given hybridization target, (ii) the cost drivers that dominate incremental LCOA, and (iii) the emission reductions achievable without major process redesign. The same methodology can be extended to other regions by updating market prices, carbon policies, and technology costs.

## ABSTRACT

Industrial decarbonization is crucial to reducing global emissions. Efficient processes lower energy use and reduce the environmental impacts, such as material use and waste, decreasing the overall industrial footprint. In this context, the present study explores the impact of reducing steam consumption (thermal energy) during the ammonia regeneration process in the production of sodium carbonate. A key feature of the Solvay process is ammonia recycling, which significantly reduces raw material consumption and ensures both economic and environmental sustainability. However, this stage is highly energy-intensive. To enhance energy efficiency in soda ash production, a study was conducted to analyze variation in temperature, pressure, and steam flow introduced into the ammonia regeneration system. The objective is to understand its impact on both ammonia recovery and the process's energy consumption. Variations in steam pressure do not impact on energy consumption of the process. By reducing the temperature and steam flow introduced into the system, in order to reduce the energy consumption, it was found that there is no decrease in ammonia recovery. The reduction in both the total injected steam flow and operating temperature led to lower heat exchange requirements and a decreased the cooling energy demand, highlighting the potential for optimizing steam flow as an effective strategy to improve process efficiency. Instead, it underscores a potential for energy optimization, promoting a more sustainable and cost-effective operation.

## INTRODUCTION

Sodium carbonate is a key industrial chemical with widespread applications across several sectors, including glass manufacturing, paper production, detergents, and the chemical industry. Its strategic importance is reflected in the steady growth of the global sodium carbonate market, primarily driven by the expansion of the glass and detergent industries [1]). This trend is further reinforced by increasing urbanization and industrialization, particularly in emerging economies. According to market projections, the global sodium carbonate market is expected to reach USD 14.42 billion in 2025 and expand to approximately USD 25.74 billion by 2035 [1].

The Ammonia Process or Solvay Process, a widely used and efficient method to produce sodium carbonate also known as soda ash. The production of sodium carbonate through the Solvay process is divided into four stages. The first stage is limestone calcination, in which calcium carbonate ($CaCO_3$) is thermally decomposed to produce carbon dioxide ($CO_2$) and calcium oxide (CaO). The carbon dioxide generated in this step is subsequently utilized in the following stage. In the second stage, carbonation, the carbon dioxide is bubbled through a brine solution containing sodium chloride (NaCl), ammonia ($NH_3$), and water. Within this medium, carbon dioxide reacts with ammonia and sodium ions, leading to the formation of sodium bicarbonate ($NaHCO_3$), which precipitates due to its low solubility. Sodium bicarbonate constitutes the desired intermediate product, whereas ammonium chloride ($NH_4Cl$) is simultaneously formed as a by-product. The third stage involves the thermal decomposition of sodium bicarbonate. The solid obtained from carbonation is separated by filtration and subsequently subjected to calcination. Upon heating, sodium bicarbonate decomposes into sodium carbonate

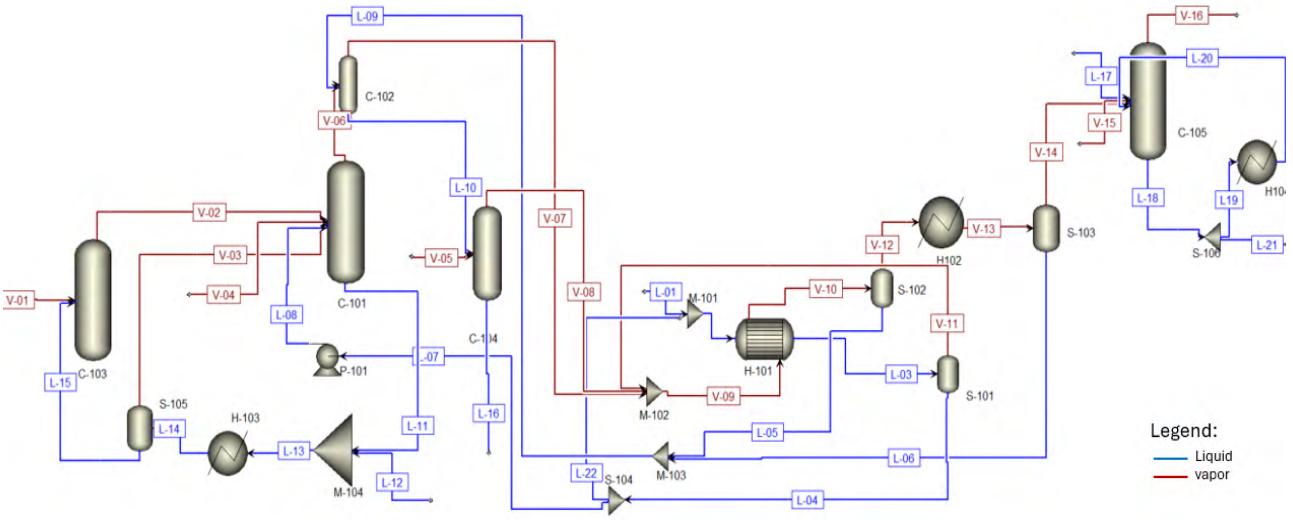

**Figure 1:** Ammonia regeneration process flow diagram in sodium carbonate production.

($Na_2CO_3$), water, and carbon dioxide. The regenerated carbon dioxide is recycled within the process, contributing to its overall sustainability. Finally, the fourth stage is ammonia regeneration. In this step, ammonium chloride reacts with hydrated calcium oxide ($Ca(OH)_2$), yielding free ammonia and calcium chloride ($CaCl_2$). The recovered ammonia is recycled into the process through absorption in brine, thus closing the operational cycle and ensuring the economic and environmental viability of the Solvay process [2].

The production of sodium carbonate is both energy-intensive and CO2-intensive [3], in part because the ammonia recovery step requires a substantial amount of steam. Despite this significant energy requirement, ammonia recovery is the operation that ensures the economic viability of the Solvay process when compared with alternative sodium carbonate production routes (Book: Manufacture of Soda). Nevertheless, even though it plays an important role in process efficiency and overall performance, the ammonia recovery step remains insufficiently addressed in the scientific literature. Most existing studies focus on eliminating the ammonia recovery stage [4, 5], replacing ammonia as the process intermediate [6, 7] or integrating carbon capture strategies into the Solvay process [8]. However, although such strategies can reduce environmental impacts, they require major modifications to existing industrial plants, which in turn demand substantial capital investment. For this reason, these modified methods have generally not been favored by manufacturers due to economic considerations[9].

The ammonia regeneration process investigated in this study presents significant advantages with respect to process efficiency, operational costs, and environmental performance. The effective recovery of ammonia and carbon dioxide reduces waste streams and decreases the requirement for fresh ammonia make-up, thereby lowering operating expenses. To further improve the energy performance of soda ash production, this study focuses on assessing the impact of steam flow rate variations in the ammonia regeneration stage. The analysis evaluates the relationship between steam input, ammonia recovery efficiency, and overall energy consumption, providing a technical basis for the optimization of industrial-scale sodium carbonate production systems.

# METHODOLOGY

## Thermodynamic model

In this study, process modeling is performed in Aspen Plus® V14.0. The Electrolyte Wizard is used to identify possible reactions, components, and intermediates, and to calculate equilibrium constants and properties. For systems with inorganic electrolytes, such as sodium bicarbonate, ionic species and reactions are also considered. The thermodynamic model ELECNRTL-RK is applied, combining the NRTL electrolyte model for the aqueous phase with the Redlich-Kwong equation of state for the vapor phase. This thermodynamic model has been validated in previous studies, such as the methodology used by Yoshi et al. (2022) [10], specifically in the simulation of the Solvay process.

## Process simulation

The simulated system (Figure 1) is based on ammonia regeneration, focusing on the processing of cold

mother liquor (L-01), which is predominantly composed of water and ammonium chloride ($NH_4Cl$), also known as fixed ammonia, as well as dissolved carbon dioxide ($CO_2$) and free ammonia ($NH_3$). Initially, L-01 is directed to the heat exchanger (H-101), where it absorbs heat for preheating, causing part of the dissolved gasses to gas phase. After this stage, the heated fluid proceeds to a gas separator (S-101), where the liquid and vapor phases are separated. The liquid phase is then sent to the column C-101.

Column C-101, designed as a stripping unit, functions to remove carbon dioxide ($CO_2$) and free ammonia present in the mother liquor. The liquid effluent from this stage is sent to the mixer (M-104), where calcium hydroxide ($Ca(OH)_2$) is added. The chemical reaction occurring here can be detailed as follows: $Ca(OH)_2 + 2NH_4Cl \rightarrow 2NH_3 + CaCl_2 + 2H_2O$. The chemical reaction between calcium hydroxide and ammonium chloride results in the formation of free ammonia and calcium chloride ($CaCl_2$). Subsequently, the mixture is transferred to a foam separator, whose primary function is to remove the gases formed, mainly composed of ammonia. The vapor extracted in this separator is redirected to column C-101, while the liquid phase proceeds to column C-103.

Column C-103, also configured as a stripping unit, is responsible for removing the free ammonia generated in the previous stage (M-104). The liquid effluent from this column is now characterized as de-ammoniated mother liquor. The vapors generated in C-103 are sent back to column C-101, along with the vapor from the foam separator and an additional flow of steam introduced into the system.

The vapor from the top of column C-101 is directed to column C-102, another stripping unit. C-102 receives condensed water from the heat exchangers in the ammonia regeneration system (H-101 and H-102). At this stage, ammonia and carbon dioxide present in the condensates are recovered and reincorporated into the vapor flow. The liquid collected at the bottom of C-102 is sent to a second stripping column (C-104), where residual $NH_3$ and $CO_2$ in the condensate are transferred to the vapor phase.

The ammonia recovered in systems C-102, C-104, and S-101 is routed to the heat exchangers (H-101 and H-102) for cooling before being introduced into the absorber. In this equipment, the gas is absorbed by the NaCl brine, allowing its reintegration into the sodium carbonate production process.

The formation of ammonia brine is accompanied by the release of a significant amount of heat, characterizing it as an exothermic process. To control the temperature and optimize $NH_3$ absorption, a pre-cooled ammonia brine (H-104) is recycled in the system, ensuring ideal conditions for the continuity of the process.

## Test optimization

The process has three steam inputs: the V-01 stream, which is added to the stripping column C-103 and represents the main steam flow of the system, with a flow rate of 38, 700 kg/h; the V-04 stream, a supplemental steam flow with a flow rate of 3, 000 kg/h, directed to column C-101; and the V-05 stream, with a flow rate of 5, 573 kg/h, introduced into column C-104.This study analyzed the variation in temperature, pressure, and mass flow rate of steam introduced into the fixed ammonia regeneration process, with the aim of understanding the impact of these variables on ammonia recovery efficiency. The temperature, pressure, and mass flow conditions of these three steam streams were modified as presented in Table 1, one variable at a time. The proposed variations are based on values practiced by the soda ash production industry.

**Table 1:** Variation in the temperature, pressure, and mass flow rate of the process's steam inputs.

| Stream | Temperature | Pressure | Mass Flow |
|---|---|---|---|
| V-01 | 116-145 °C | 1.68-1.80 bar | 10% reduction |
| V-04 | 116-145 °C | 1.30-1.50 bar | 10% reduction |
| V-05 | 116-145 °C | 1.30-1.50 bar | 10% reduction |

# RESULTS AND DISCUSSION

The effects of temperature, pressure, and mass flow rate variations on the vapor flow rate the main equipment of the ammonia regeneration process are analyzed, and the effect of mass flow variation is presented in Figure 2. The mass flow rate results of the system's vapor streams were normalized with respect to the mass flow rate obtained when the analyzed variable was at its maximum value. In addition, the results highlight the effect of reducing the analyzed variable on system behavior; therefore, in Figures 2, the *x*-axis is presented from the highest to the lowest value of the variable.

The variation in temperature and pressure has a minimum impact on ammonia recovery Similarly to the influence on the process steam flow, some variations are so small that they can be attributed to changes caused by model convergence. The most significant change observed was a 2% reduction in the steam flow exiting the C-105 column, which does not impact ammonia recovery or the stream entering the absorption column.

The low influence of temperature and pressure variations on ammonia recovery and steam mass flow rate in the system indicates that, despite the reduction in thermal energy transported by the steam stream fed into the system columns, the energy supplied is sufficient to achieve ammonia recovery. Under these conditions, the steam acts predominantly as an entraining agent, and

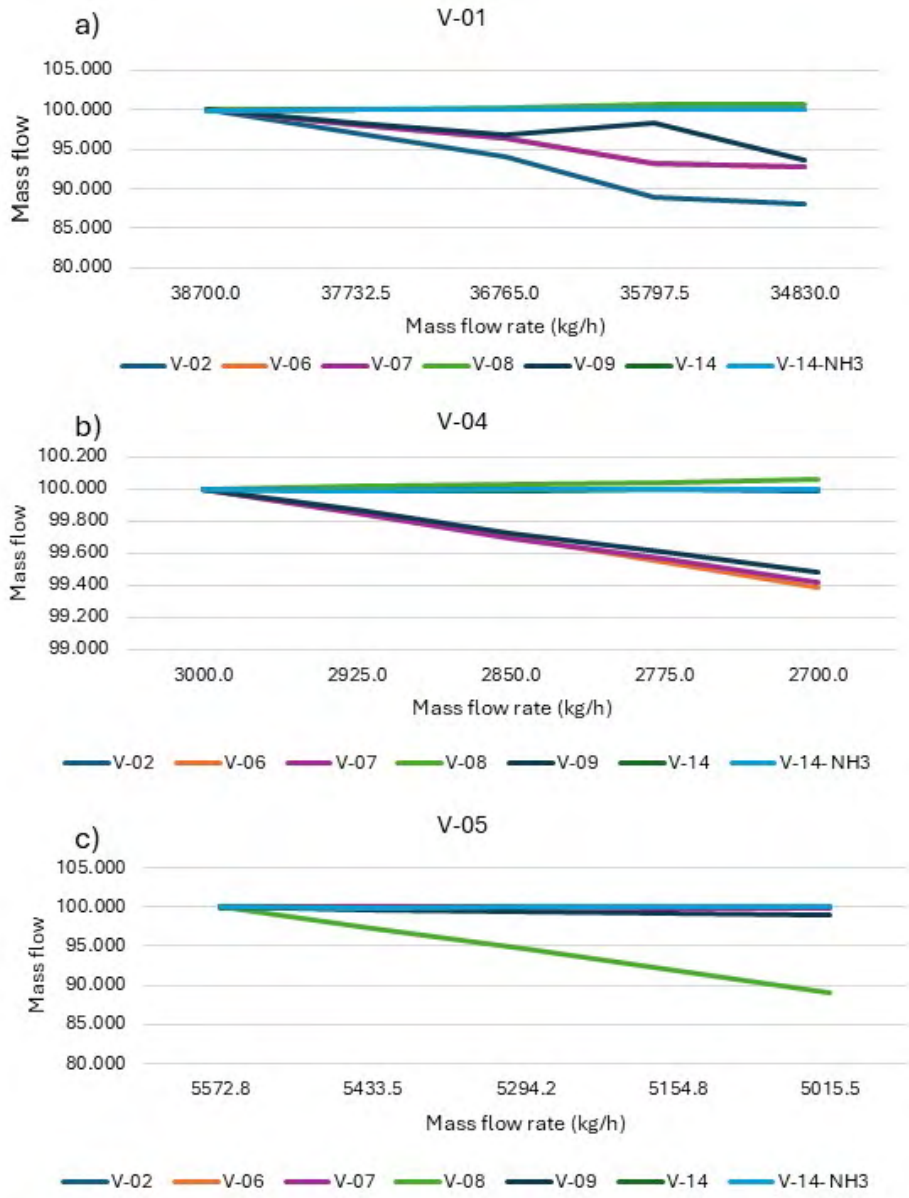

**Figure 2.** Influence of vapor mass flow rate input on the vapor mass flow rate for different vapor outputs of equipment: a) vapor input V-01, b) vapor input V-04, and c) vapor input V-05.

small variations in its temperature or pressure do not result in significant changes in the thermodynamic gradient required for ammonia vaporization. Despite the reduction in thermal energy introduced into the system, it continues to operate without major alterations. More details about the influence of temperature and pressure variations on ammonia recovery and steam mass flow rate in the system in the supplementary material.

The reduction in steam flow introduced into the system (Figure 2) implies changes in the dynamics of the vapor streams, although with variable impacts depending on the stream analyzed. In the case of stream V-04, the reduction in steam flow is minimal, less than 1% in streams V-06, V-07, and V-09, demonstrating little sensitivity to this change. On the other hand, stream V-05 shows a significant reduction of approximately 11% in the V-08 flow, which originates from column C-104, a column where the V-05 vapor stream is added, directly impacting the amount of vapor exiting this column. For the other system streams, including the absorption column's inlet stream, no significant impact is observed, with the $NH_3$ percentage remaining constant. The low influence of the reduction in the flow of V-04 and V-05 is due to the small change in the total energy supplied to the system. The

flow of V-04 represents only 6% of the steam introduced into the system, and a 10% reduction in this value results in a decrease of less than 1% in the total heat supplied to the system.

In the case of stream V-01, which is the main source of steam for the system, its reduction has a considerable impact on several vapor streams. This occurs because the steam introduced into column C-103 flows through multiple units within the system and accounts for approximately 82% of the total steam supplied to the process. This reduction, however, does not compromise ammonia recovery, which remains constant, as does the performance of the vapor stream feeding the absorption column (line v-14 and V-14NH3, which corresponds to the mass flow rate of ammonia entering the absorption column).

The observed behavior can be attributed to the thermodynamic properties of the involved compounds. Due to the high volatility of ammonia, even with the reduction in steam flow in the stripping columns, ammonia continues to efficiently migrate to the vapor phase. On the other hand, a larger amount of water remains in the liquid phase, as water requires more energy to transition to the vapor phase.

**Table 2:** Energy balance exchanged by the equipment streams in different equipment for various pressure of steam stream introduced into the system.

| Pressure | V-01 | C101 | C102 | C103 | C104 | H101 | H102 |
|---|---|---|---|---|---|---|---|
| | bar | Gcal/h | Gcal/h | Gcal/h | Gcal/h | Gcal/h | Gcal/h |
| V-01 | 1.80 | 38.86 | 12.44 | 23.33 | 3.73 | -11.27 | -8.77 |
| | 1.68 | 38.86 | 12.45 | 23.33 | 3.73 | -11.27 | -8.77 |
| V-04 | 1.50 | 38.86 | 12.45 | 23.33 | 3.73 | -11.28 | -8.78 |
| | 1.30 | 38.85 | 12.45 | 23.33 | 3.73 | -11.28 | -8.77 |
| V-05 | 1.50 | 38.85 | 12.46 | 23.33 | 3.74 | -11.28 | -8.78 |
| | 1.30 | 38.85 | 12.45 | 23.33 | 3.73 | -11.28 | -8.78 |

In the system's heat exchangers, the reduction in steam mass flow rate impacts the performance of heat transfer. In heat exchanger H-101, it is observed that the effluent steam exhibits a lower temperature compared to the scenario where the system operates with a higher steam flow rate, and a smaller amount of steam is condensed during the heat exchange process. More details regarding the temperature variation in the steam streams are available in the supplementary material. In the subsequent heat exchanger, H-102, designed to ensure that the steam reaches a temperature of 64 °C, required for entry into the absorption column, the reduction in steam mass flow rate does not alter the final steam flow rate coming from the ammonia regeneration system or the ammonia concentration present. The only modification occurs in the fraction of steam that is condensed at this stage of the process.

To better understand the heat exchange occurring within the process equipment, Tables 2, 3, and 4 present the energy transfer in the liquid phase between process streams at the maximum and minimum values of the following variables: pressure, temperature, and mass flow rate, respectively. The analysis of energy variation in a stripping column is highly complex, since the enthalpy of the liquid stream is a function of temperature, pressure, and chemical composition. The latter changes along the column as a result of mass transfer phenomena between the liquid and vapor phases. Consequently, an increase in the energy associated with the outlet stream may be attributed, among other factors, to the transfer of vapor to the liquid phase, which supplies latent heat to the system. In order to simplify the overall energy analysis, the parameter adopted to quantify the reduction of the system's thermal energy is the heat duty removed in the heat exchangers responsible for vapor cooling. These units are located at the end of the process and are designed to remove heat from the vapor stream, thus constituting the primary mechanism for energy removal from the system.

**Table 3:** Energy balance exchanged by the equipment streams in different equipment for various temperature of steam stream introduced into the system.

| Temperature | V-01 | C101 | C102 | C103 | C104 | H101 | H102 |
|---|---|---|---|---|---|---|---|
| | °C | Gcal/h | Gcal/h | Gcal/h | Gcal/h | Gcal/h | Gcal/h |
| V-01 | 145 | 38.94 | 13.31 | 19.75 | 3.75 | -11.27 | -9.25 |
| | 116 | 38.86 | 12.43 | 23.33 | 3.73 | -11.27 | -8.77 |
| V-04 | 145 | 38.86 | 12.43 | 23.33 | 3.73 | -11.27 | -8.77 |
| | 116 | 39.13 | 12.42 | 23.34 | 3.73 | -11.27 | -8.74 |
| V-05 | 145 | 38.85 | 12.46 | 23.33 | 3.73 | -11.28 | -8.78 |
| | 116 | 38.86 | 12.40 | 23.33 | 4.16 | -11.27 | -8.72 |

In the heat exchangers, the thermal behavior shows specific variations. Heat exchanger H-101 maintains its thermal exchange capacity almost unchanged in the three tables, as the equipment operates within its design range, allowing energy exchange between the hot and cold fluid streams to occur small variations. On the other hand, in heat exchanger H-102, designed to cool the vapor before its entry into the absorption column, the reduction in mass flow rate and vapor temperature results in a lower amount of heat exchanged. This reduction represents the most significant thermal alteration observed in the system, indicating a direct adaptation to the decrease in vapor flow introduced.

In Table 2, it is observed that the heat exchanged in the H-102 exchanger does not present significant variation, except for a reduction of 0.01 Gcal/h in stream V-04, indicating that pressure changes do not result in relevant

alterations in the system's thermal exchange. Changes in the temperature and mass flow rate of the vapor stream show, as presented in Tables 3 and 4, a reduction in energy consumption in the H-102 exchanger, with the most significant impact observed when modifying stream V-01, as it is the most important vapor stream in the process. Although both strategies promote a reduction in energy consumption, the reduction in vapor flow led to more pronounced decreases compared to temperature variation, considering the range of variation proposed in this study.

**Table 4:** Energy balance exchanged by the equipment streams in Different Equipment for Various Mass Flow Rates of V-01 Introduced into the System.

| Mass flow | V-01 | C101 | C102 | C103 | C104 | H101 | H102 |
|---|---|---|---|---|---|---|---|
| | Kg/h | Gcal/h | Gcal/h | Gcal/h | Gcal/h | Gcal/h | Gcal/h |
| V-01 | 38700 | 38.86 | 12.43 | 23.33 | 3.73 | -11.27 | -8.77 |
| | 34830 | 38.48 | 10.40 | 23.39 | 3.66 | -11.27 | -6.88 |
| V-04 | 3000 | 38.85 | 12.90 | 23.33 | 3.73 | -11.28 | -8.79 |
| | 2700 | 38.88 | 12.67 | 23.33 | 3.73 | -11.28 | -8.66 |
| V-05 | 5573 | 38.86 | 12.48 | 23.33 | 3.73 | -11.27 | -8.78 |
| | 5015 | 38.86 | 12.06 | 23.33 | 3.73 | -11.27 | -8.54 |

Additionally, the decrease in energy required to cool the vapor in the absorption column reflects the impact of the reduced amount of vapor generated in the system. This change not only reduces the overall energy consumption of the process but also improves the thermal efficiency of the system by operating with lower energy demands without compromising operational stability.

This scenario reinforces the robustness of the system in response to adjustments in vapor flow, demonstrating that the reduction in the mass flow rate of vapor V-01 does not compromise critical operations, such as ammonia removal or the efficiency of the heat exchangers. On the contrary, it highlights an opportunity for energy optimization, enabling sustainable and economically advantageous operation.

However, it is important to emphasize that the present work is strictly theoretical in nature and is therefore subject to the inherent limitations of mathematical models and the simplifying assumptions adopted. While the findings indicate potential operational benefits, the analyzed system exhibits high complexity, as it involves an electrolytic system where the formation of solid species (salts) may occur depending on the operational conditions of composition, temperature, and pressure. The precipitation of these species can lead to the formation of deposits on the system's surfaces, resulting in a loss of operational efficiency, changes in mass and energy transfer coefficients, as well as potential hydrodynamic impacts. Although the model calculates the formation of solids, such phenomena were not incorporated into the model used, which may limit the applicability of the results to real systems.

## CONCLUSION

Process optimization plays a fundamental role in industrial decarbonization, establishing itself as a viable strategy for reducing energy consumption and inputs in industrial processes. The results of this study demonstrate that variations in temperature and pressure do not significantly impact the system's operational performance (flow rate, temperature, composition), allowing adjustments in these variables without compromising overall operation. However, only the reduction in temperature resulted in a 5% decrease in energy consumption. Among the evaluated strategies, reducing the flow of steam injected into the process proved to be the most effective, promoting considerable reductions in steam flows, temperatures, and heat exchange, without compromising the efficiency of ammonia recovery, a crucial factor for process sustainability. These results suggest that there is significant potential for operational adjustments in the steam used in the system, even within the limits already practiced in the industry. However, to achieve even more significant advances in the process's energy efficiency, more detailed investigations involving other operational parameters are necessary. Future studies may focus on the interaction between different process variables, the impact of extreme conditions, and the application of emerging technologies, aiming to identify additional opportunities for optimization and emission reduction, thereby strengthening the commitment to industrial sustainability.

## DIGITAL SUPPLEMENTARY MATERIAL

Further details on the effects of variations in steam pressure and temperature on the system temperature and mass flow rate are provided in the digital supplementary material (LAPS.2026.0023)

## ABSTRACT

An optimized flowsheet can be generated by numerous approaches. Process optimization via superstructure is one of the methods used to provide solutions that consider the interactions between different decision layers. A process simulator-based optimization is considered in this work, as it offers a reliable and rigorous modeling environment. It is then coupled with a P-graph-based framework to reduce the tedious mathematical writing of the logical constraints to guarantee the structural coherence of a sequence of unit operations.The developed framework consists of three algorithms. The first algorithm transforms the superstructure flowsheet into a P-graph. The second algorithm gets process sub-structures from the superstructure by searching for active units corresponding to a set of decisions made, for example, by an optimizer. The third one checks structural feasibility by verifying that the resulting structure satisfies the five axioms of the original P-graph framework and two additional connectivity tests proposed in this work.The proposed methodology is then applied to an ammonia synthesis process. The results obtained in this work enable a reduction in structural logical constraints while achieving outcomes equivalent to those of a previous study, proving the methodology's efficacy.

**Keywords**: Process simulator-based optimization, superstructure, P-graph framework, process synthesis, MINLP problem

## INTRODUCTION

Climate ambition announced at COP28 requires drastic actions to be taken, such as tripling global renewable energy capacity and doubling the global average annual rate of energy efficiency improvements [1]. One solution to achieve the ambition is the use of modular and flexible plants [2]. Robust processes capable of handling variable inputs, flexible capacity, product variations and decentralized plants are highly valuable to the modern industry. However, modular processes require robust design methods and different optimization strategies as they must adapt to variable inputs or process parameters while maintaining increasing process efficiency. It is therefore essential to employ process design techniques, specifically process synthesis, to design modular processes.

Process synthesis is the selection and interconnection of units involving physical and chemical phenomena to obtain products from raw materials to satisfy economic, environmental and/or social objectives [3]. Main approaches include hierarchical decomposition, mathematical programming and even hybrid approaches combining both heuristics and mathematical programming. Mathematical programming-based strategies rigorously search through a proposed design space for the optimal configuration, unlike hierarchical decomposition. Depending on the definition of the search space, mathematical approaches can be categorized as superstructure-based or superstructure-free optimization [4, 5]. The superstructure-based approach consists of (a) postulating a set of process alternatives in superstructure form, (b) formulating it as a mathematical programming model, and (c) determining the optimal configuration with an optimization algorithm. Conversely, superstructure-free approaches create new flowsheets either from existing ones or from scratch.

In superstructure-based process synthesis, the superstructure can be modeled with different levels of detail. Models can be characterized into three main categories: high-level aggregate, shortcut, and detailed rigorous models. When detailed modelling is required, process

simulators offer a reliable and rigorous modeling environment [6]. In this context, superstructure optimization may be performed in two ways: in an external optimization environment or as a flowsheet in the process simulator itself.

This work focuses on the latter. To avoid extensive mathematical formulations for ensuring structural coherence, a P-graph-based framework is proposed [7]. The process superstructure is implemented in a simulator with the defined optimization problem (objective function, variables, and constraints). As shown in **Figure 1**, a P-graph-based feasibility block interacts with the simulator and an external optimizer to obtain the optimal solution. This feasibility block can be further decomposed into three algorithms.

The paper is structured as follows. First, the methodology is presented, including definitions and algorithm descriptions. Next, its application to an ammonia synthesis process is outlined. Finally, the approach is evaluated against a non–P-graph method, and the optimization results are discussed.

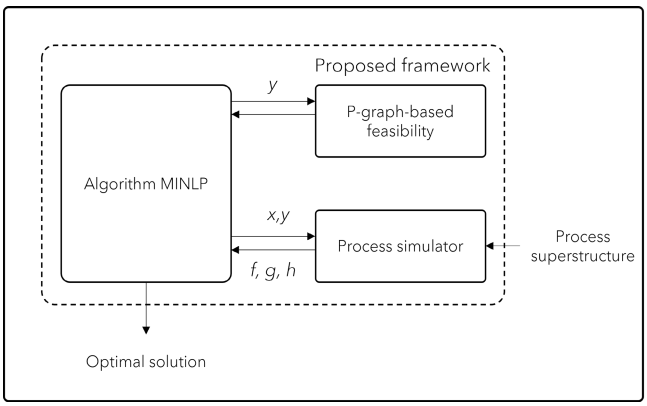

**Figure 1.** P-graph integrated into a process simulator-based optimization approach. Figure taken from Hillaby et al. [8].

## METHODOLOGY

The P-graph-based framework proposed intends to improve the generic optimization procedure by: (1) implicitly postulating the structural constraints through the superstructure topology, (2) incorporating three procedures or algorithms, to evaluate the structural feasibility of a given process throughout the optimization. The improved methodology enables general users to leverage P-graph without requiring a direct knowledge of it. There are different technical terms that are defined in this work: permanent and conditional units; opening and closing switches; conditional stream; bypass units; structural feasibility.

### Permanent and conditional units

Permanent units are defined as essential components of the structure, meaning they are necessary for the operation of the process and cannot be removed without compromising its functionality. Conditional units, on the other hand, are units that can be added or modified to optimize the structure. These units are introduced to explore different configurations or improvements in the process. If conditional units are removed, the result is the simplest or base case of the process.

### Conditional, opening switch, and closing switch

The only intricacy that exists between a typical process simulator flowsheet and a P-graph process representation is the addition of a fictive operating unit or a bypass unit, herein labeled UF. Since a P-graph is a bipartite graph, a material cannot be connected to a material, hence for a structural switch that has a bypass (i.e., the material input and the material output are equal), a bypass unit has to be defined. Technically, no material transformation is done, it is only to respect the P-graph bipartite representation and its eventual algorithm that will be used. When an opening switch is identified, the directly connected streams are treated as candidate or conditional streams. This implies that, among the alternative pathways, only one stream can be activated at a time. An opening switch is a fictive unit that indicates that a decision has to be made among two candidate pathways. A close switch is also a fictive unit that requires a decision to be made from two candidate streams, coming from the same or different opening switches.

### Bypass units

Bypass units are fictive units used to represent material flows that bypass any transformation processes. In other words, these units are used to model situations where a material goes directly from one point to another without undergoing any changes. However, as explained before, in a P-graph representation, the connection of one material node to another is not possible. Therefore, a bypass unit is introduced to facilitate this representation.

### Structural feasibility

A feasible structure indicates that the process network adheres to the principles and logic of process synthesis, meaning that the arrangement of process units and material flows forms a valid and functional sequence. In the context of P-graph framework, a feasible structure implies that the five axioms are satisfied. For example, materials must flow into operating units, and these units must either produce outputs that feed into other units or generate final products. The maximal structure generated by the Maximal Structure Generation (MSG) method ensures that the search space is defined, from which the

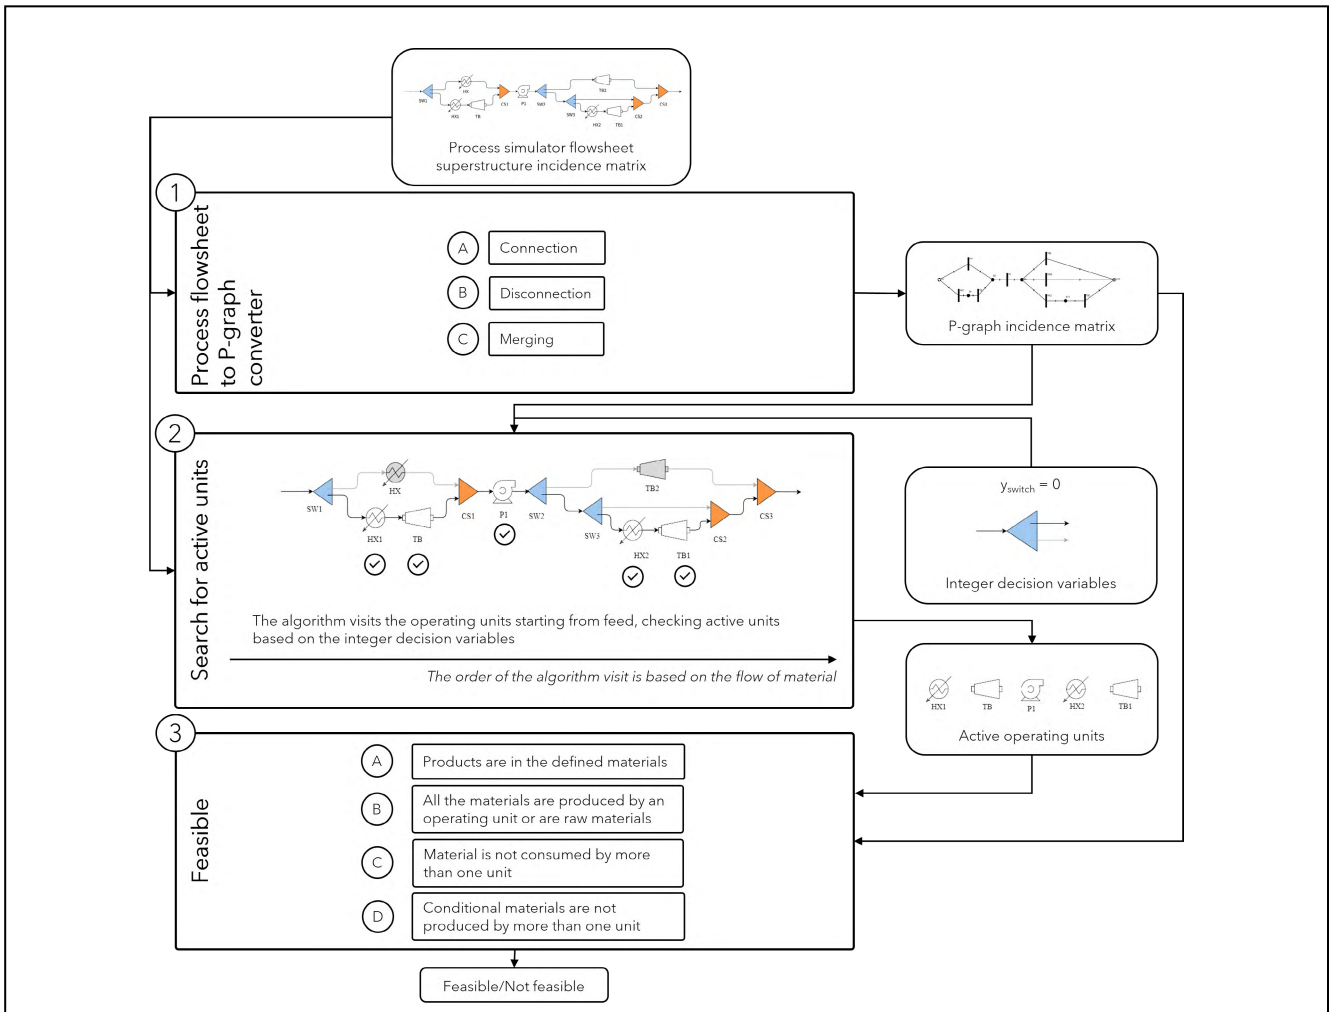

**Figure 2**. P-graph-based framework proposed, with three algorithms in three different blocks, labeled 1, 2, and 3. Figure adapted from Hillaby et al. [8].

optimal solutions can be identified.

MSG consists of two phases: the reduction phase and the composition phase. The algorithm used in the reduction phase is central to the methodology, with additional modifications to enhance compatibility with structural switches (i.e., opening and closing switches). The algorithm begins by extracting the information of the raw materials, products, and the superstructure (the potential arrangement of material flows and operating units). The algorithm initiates by performing the first feasibility test: verifying whether the defined products exist within the superstructure. The second test ensures that there are no intermediate products that are neither produced by any operating unit nor specified as raw materials, thus preventing the creation of unaccounted-for materials. These two tests enforce the five axioms of the P-graph framework. The third and fourth tests are added modifications, which ensure that when an opening structural switch is encountered, a decision must be made to select only one process path. Similarly, when a closing structural switch is encountered, a choice is required, meaning only one path can be accepted to continue the process sequence.

## Algorithms

In general, a process optimization via superstructure starts with the user generating the superstructure itself. The problem is then defined in the simulator's optimizer interface, i.e., objective functions, constraints, and action variables. Depending on the commercial simulator used, an external optimizer could be coupled with it because the optimization tools provided by default may not be as effective or as flexible as necessary. The action variables are then assigned by the optimizer, presenting a new configuration of the flowsheet. This new structure then gets checked for feasibility. If the structure is infeasible, a penalty is applied. On the other hand, if it is feasible, the objective function is evaluated. The algorithm reassigns new action variables or exits the loop, depending on the stopping criteria such as the maximum number of evaluations, optimization time limit, or tolerance on the objective function. As the loop exits, the optimal values

are assigned and the final optimization report is obtained.

Block 1 corresponds to the Process Flowsheet to P-graph algorithm. This procedure converts a process adjacency matrix into an incidence P-graph matrix. There are three main operations that are executed: (1) connection between two units, i.e., disconnection between a unit and an open switch or a close switch (3) merging close switches' inputs.

Once the P-graph superstructure is obtained, it is possible to determine the process structure defined by the binary variables assigned by the optimizer (block 2). This is achieved by employing a graph traversal algorithm such as Depth-First Search (DFS) algorithm. The active operating units are determined and sent to the final algorithm.

Finally, the current process structure is then checked for structural feasibility (block 3). Four tests are done to ensure the structure the new process structure is feasible:

1. The products of the new structure are found in the initial defined materials.
2. All the streams are produced by an operating unit or they are defined as raw materials.
3. A stream is not consumed by more than one unit.
4. Conditional streams are not produced by more than one unit.

If the four conditions are respected, the process structure is considered structurally feasible.

By integrating the framework, i.e., the three main blocks shown in **Figure 2**, into the complete process optimization via superstructure procedure, the need to manually define structural constraints is reduced, decreasing human intervention at the start of the process simulator-based optimization. This procedure is iterative and continues until the optimization criteria are met.

A list of feasible sub-structures can be made by implementing the 2nd and 3rd algorithm blocks prior to the optimization. This precomputation reduces redundancy during the optimization stage, as repeatedly proposed structures need not be revalidated. For example, if a known feasible sub-structure is suggested multiple times by the optimizer, feasibility can be confirmed by referring to the precomputed list, instead of running the full evaluation.

## AMMONIA SYNTHESIS SUPERSTRUCTURE

A case study based on Quintero-Masselski's work [9] on optimizing the Haber-Bosch (HB) process through reactors configurations is conducted to apply the developed methodology. The original ammonia process superstructure is restructured and the MINLP formulation is modified to adapt to the methodology developed. The adapted structure is shown in **Figure 3**.

Hydrogen and nitrogen from renewable sources are used to produce ammonia, which is then separated and stored. The feeds enter at 10 bar and 293.15 K and are compressed to match reaction conditions, with pressures ranging from 50 to 200 bar.

The reaction stage has different structural alternatives of adiabatic reactors, including Adiabatic Indirect Cooling Reactor (AICR) and Adiabatic Quench Cooling Reactor (AQCR). In the AICR configuration, a heat exchanger is used between the reactors to cool down the outlet stream of each reactor to the desired temperature of the following unit. This is achieved by using an external utility. In the AQCR configuration, the heat exchange is carried out by mixing the outlet stream of each reactor with a fraction of fresh process stream that is not used for reaction and bypassed from the previous reactors. There are five configurations that are implemented in the current work: (1) 1 reactor without cooling, (2) 2 adiabatic reactors in AICR configuration, (3) 3 reactors in AICR configuration, (4) 2 reactors in AQCR configuration, and (5) 3 reactors in AQCR configuration.

Iron-based (Fe) and ruthenium-based (Ru) catalysts are considered due to their industrial relevance and extensive literature availability. Process configurations (binary switches) and catalyst selection (integer variable) are modeled as discrete decision variables, as summarized in **Table 1**.

Separation by condensation is achieved by adjusting the reactor outlet mixture to its dew-point temperature, thereby separating a liquid phase composed of 99.95 % vol. ammonia with trace amounts of hydrogen and nitrogen.

These configurations are evaluated using two key performance indicators: Global Levelized Cost of Ammonia production (LCOA) and energetic efficiency. Two optimizations were performed: without the P-graph and with the P-graph methodology. The LCOA is the price of ammonia production considering every cost involved in the process, i.e., the sum of investment and operational expenditures of raw materials, electricity, and equipment.

$$\eta_E = \frac{(\dot{m}_{NH_3} LHV_{NH_3}) + \Delta\dot{W}^- + \Delta\dot{Q}^-}{(\dot{m}_{H_2} LHV_{H_2}) + \Delta\dot{W}^+ + \Delta\dot{Q}^+} \quad (1)$$

The Pré-Estime method is used to calculate the equipment cost [10]. The process energy efficiency indicator, Eq. (1), is the ratio between the useful produced energy and the supplied energy to the process: where $\eta_E$ is the overall energy efficiency, $\dot{m}$ is the mass flowrate in kg/s, $LHV$ is the Low Heating Value in kJ/kg, $\Delta\dot{W}$ is the overall balance of mechanical power in kW, and $\Delta\dot{Q}$ is the balance of thermal energy in kW. The energy terms use superscripts to indicate production (+) and consumption (-) [11].

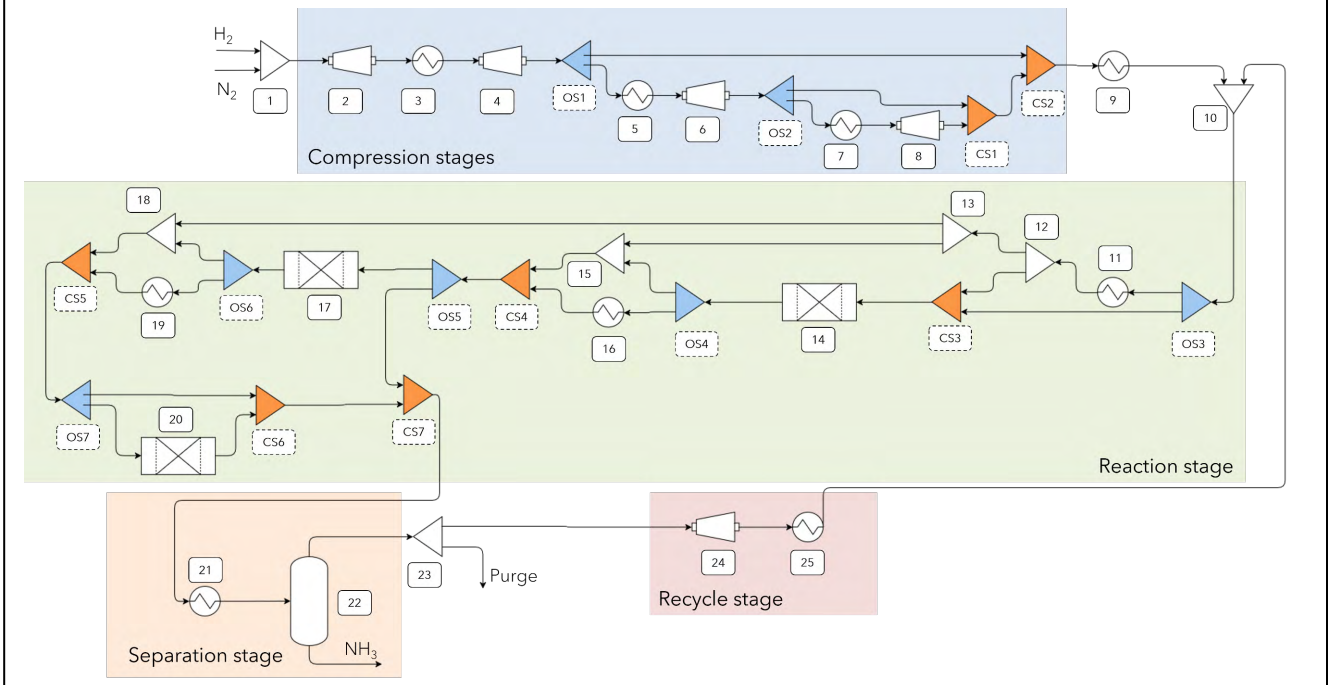

**Figure 3.** Superstructure representation for the evaluation of the adiabatic reactor configuration. The compression stage includes the selection of the number of compressors. The reaction stage has five structural variables to determine the number of reactors and the type of colling. Module nomenclature corresponds to: Mixers (1, 10, 15, 18), Splitters (12, 13, 23), Compressors (2, 4, 6, 8, 24), Heat exchangers (3, 5, 7, 9, 11, 16, 19, 21, 25), Adiabatic reactors (14, 17, 20), Separation drum (22), Opening switches (OS1, OS2, OS3, OS4, OS5, OS6, OS7), and Closing switches (CS1, CS2, CS3, CS4, CS5, CS6, CS7).

There are seven inequality process constraints that are defined in this problem, see **Table 2**. The maximum LCOA is fixed to discard solutions with high costs of production whereas the minimum H2 conversion is defined to avoid low H1 conversions per pass and important hydrogen losses on the purge stream. A maximal reactor temperature is defined to increase the catalyst lifetime.

**Table 1.** Discrete action variables defined in this study.

| Variable | Details |
|---|---|
| SW1 | Enables the 3rd compressor |
| SW2 | Enables the 4th compressor |
| SW3 | Enables the quench setting |
| SW4 | Enables either the 1st quench or the 1st external cooling heat exchanger |
| SW5 | Enables the 2nd reactor |
| SW6 | Enables the 2nd quench or the 2nd external cooling heat exchanger |
| SW7 | Enables the 3rd reactor |
| Catalyst | 0: Fe-based; 1: Ru-based |

**Table 2**. Process constraints and their values, with the catalysts' corresponding pressure intervals being the disjunctive constraints.

| Constraint | Value | Units |
|---|---|---|
| Maximum LCOA | 850 | €/t |
| Minimum $H_2$ global conversion | 90 | % |
| Maximal temperature in 1st reactor | 800 | K |
| Maximal temperature in 2nd reactor | 800 | K |
| Maximal temperature in 3rd reactor | 800 | K |
| Fe catalyst pressure range | 150 – 250 | bar |
| Ru catalyst pressure range | 50-100 | bar |

The optimizer handles the constraint violations in two layers: internally and externally. The first layer is an external layer, in which the structural feasibility is assessed. If the structure is not feasible, i.e., the P-graph axioms are violated, a death penalty (objective functions, $f(x) = 10^{300}$; constraints, $g(x) = 0$) is applied.

The second layer is the internal layer, in which the Oracle Penalty Method [12] is applied. If the candidate solutions are structurally feasible, the method ranks the solutions using both objective value and constraint residual.

**Table 3.** Continuous action variables defined in the optimization, together with the stage at which they are defined, the associated process units, and their bounds.

| Variable | Stage | Process unit | Bounds | Units |
|---|---|---|---|---|
| Pressure | Compression | 2, 3, 6, 8 | 50 – 200 | bar |
| Inlet temperature at 1st reactor | Reaction | 9, 25 | 636 – 736 | K |
| Inlet temperature at 2nd reactor | Reaction | 16 | 636 – 736 | K |
| Inlet temperature at 3rd reactor | Reaction | 19 | 636 – 736 | K |
| Length of 1st reactor | Reaction | 14 | 0.5 – 7.0 | m |
| Length of 1st reactor | Reaction | 17 | 0.5 – 7.0 | m |
| Length of 1st reactor | Reaction | 20 | 0.5 – 7.0 | m |
| Separation temperature | Separation | 21 | 253 – 275 | K |
| Split ratio at first quench splitter | Reaction | 12 | 0.4 – 0.8 | - |
| Split ratio at second quench splitter | Reaction | 13 | 0.4 – 0.8 | - |

## Implementation

The optimizations were performed on ProSimPlus 3.7.9 coupled with an external optimizer (MIDACO [13]) on an Intel(R) Xeon(R) w5-3433, 1.99 GHz, 256 GB RAM, Windows 10 64-bit operating system. The optimizations stopped when 15000 consecutive evaluations no longer improved the current solution. The optimization is done with two seeds, improving the exploration of the search space and reduce sensitivity to stochastic convergence.

# RESULTS

## Methodology comparison

**Table 4.** A comparison of the optimal point intervals between Quintero-Masselski's study [9] and this work.

| Catalyst | Objective functions | Quintero-Masselski | This work |
|---|---|---|---|
| Fe | LCOA (€/t) | 752 – 816 | 751 – 753 |
| | Efficiency (%) | 54.4 – 56.4 | 53.9 – 54.8 |
| Ru | LCOA (€/t) | 754 – 804 | 752 – 804 |
| | Efficiency (%) | 55.3 – 58.1 | 54.8 – 58.2 |

Based on the results of the optimizations performed, as shown in **Table 4**, it can be said that the modified superstructure is equivalent to the one used in Quintero-Masselski's work [9]. Hence, only the comparison between optimizations done with and without the modified P-graph methodology is done hereinafter.

The runs without the P-graph procedures and with the proposed methodology (P-graph based) took 47.7 and 36.6 hours respectively, resulting in a 22 % reduction of optimization time. The results are further detailed in **Table 5**.

90 % of the solutions proposed by the optimizer with the P-graph-based methodology implemented are feasible structurally, representing most of the evaluations performed. This is because a death penalty is applied when the solution proposed is deemed infeasible, steering the optimizer toward a feasible region. The percentage of simulator-feasible solutions among the structurally feasible points, represented by $\frac{n_{simF}}{n_{structF}}$, is similar for both cases. This suggests that the structural feasibility had more impact on the simulator convergence than the combination of continuous action variables for a given candidate design. Finally, the methodology shows a clear advantage when comparing the fraction of design-feasible over simulator-feasible solutions, at 0.94 over 0.68.

Furthermore, based on **Figure 4**, there are 45 global Pareto points, of which 35 are with P-graph and 10 are without P-graph. This shows that more non-dominated Pareto points are attained with the modified methodology.

**Table 5.** Comparison of the methodology with different fractions to analyze the efficacy of the methodology, including structural-feasible over total data points (3rd column), simulation-feasible over structural-feasible (4th column), and design-feasible over simulation-feasible (5th column).

| Case | $n_D$ | $\frac{n_{structF}}{n_D}$ | $\frac{n_{simF}}{n_{structF}}$ | $\frac{n_{designF}}{n_{simF}}$ |
|---|---|---|---|---|
| Without P-graph | 27397 | 0.27 | 0.96 | 0.68 |
| With P-graph | 18053 | 0.90 | 0.94 | 0.94 |

## Process optimization discussions

There are several interpretations that can be considered as an extended version to that of Quintero-Masselski and colleagues' work. Only the results from the P-graph methodology are studied in this section.

**Figure 5** shows that the two-compressor configuration dominates the lower efficiency and lower LCOA zone

whereas the three-compressor and a four-compressor configurations zone are mostly overlapped. This indicated that the main performance gain in energy efficiency comes from increasing the compressor number to at least three stages, while a fourth stage provides limited improvement. But increasing the number of compressors will increase the LCOA.

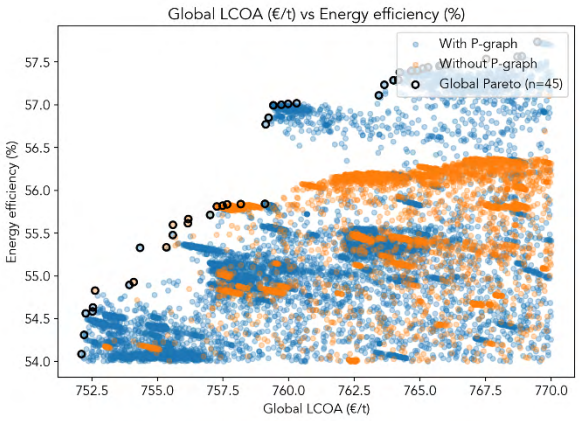

**Figure 4.** Energy efficiency vs. process LCOA. Blue points correspond to solutions obtained with the P-graph methodology, orange points to solutions obtained without it. Pareto-optimal points are shown as hollow black markers.

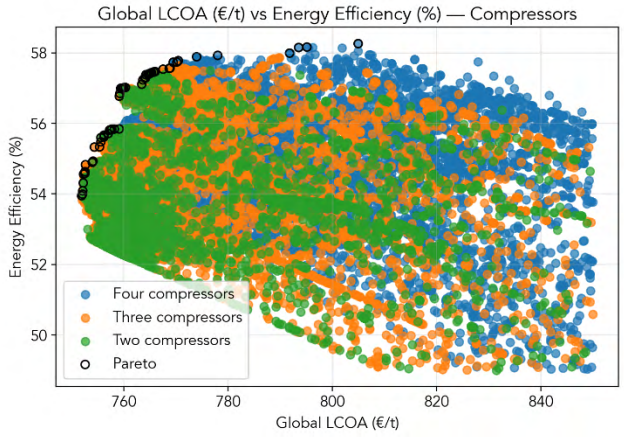

**Figure 5**. LCOA versus process energy efficiency, colored by the number of compressors (2, 3, or 4). Global Pareto-optimal solutions are indicated by hollow black markers.

**Figure 6** exhibits that the configurations with 1, 2 or 3 AICR dominates the solution space as 2 and 3 AQCR are not as visible in the figure. When comparing the AICR configurations, the systems with 1 reactor have clearly the lower efficiency and the lower LCOA values. When there is only one stage of reaction, this means lower conversion per pass, requiring massive recycle load and increasing recycle compressor duty.

**Figure 7** compares the solutions based on the type of catalyst used. There are 36643 and 44363 solution points for the Fe-based and the Ru-based catalysts respectively. There are 8 solutions on the Pareto front with Fe-catalyst ranging from 752 to 753 €/t in LCOA and from 53 % to 55 % in energy efficiency while 47 Ru-based solutions on the Pareto front ranging from 752 to 805 €/t in LCOA and from 55 % to 58 %. The increased value of energy efficiency using Ru can be explained by a lower pressure range which lead to a decrease in the compression power.

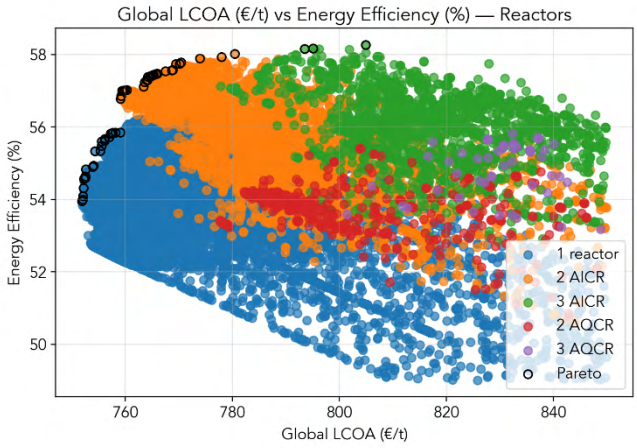

**Figure 6.** LCOA versus process energy efficiency, colored by the number (1, 2, or 3) and configuration (with or without cold shot) of reactors. Global Pareto-optimal solutions are indicated by hollow black markers.

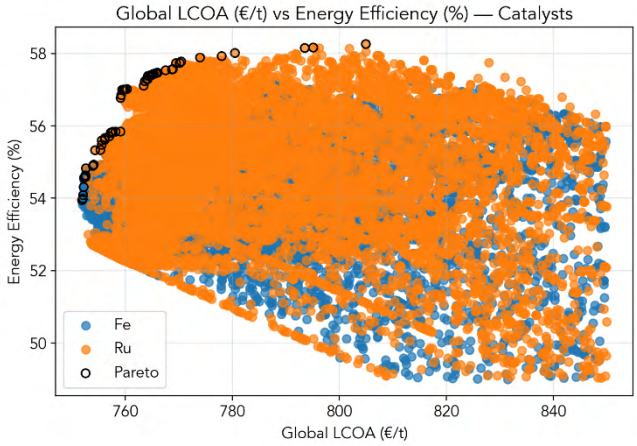

**Figure 7.** LCOA versus process energy efficiency, colored by the type of catalysts (Fe-based or Ru-based). Global Pareto-optimal solutions are indicated by hollow black markers.

## CONCLUSION

This work demonstrates a novel methodology of process simulator-based optimization via superstructure with an application for ammonia synthesis through the Haber Bosch process.

Binary opening and closing switches as well as three algorithms are introduced in this study. The binary switches are used to propose different structural alternatives in a process while the three algorithms are used to determine the feasibility of sub-structures in a superstructure.

The approach proposed not only reduced the time required to optimize a process superstructure, especially when comparing the total evaluated solutions that are design-wise feasible but also reduced the need for users to define the structural constraints.

Future work is going to be more focused on benchmarking additional case studies using the proposed methodology, as well as conducting a more holistic optimization in which a Key Performance Indicator (KPI) of the Life Cycle Assessment (LCA) is included in the objective functions.

## ABSTRACT

Heat Pumps (HPs) can play a vital role in the decarbonization of heating in industry. The performance of a HP strongly depends on the refrigerant, the working fluid within the HP. In order to maximize HP performance, systematic selection of the refrigerant is key. Refrigerant choice affects the very feasibility of employing a HP to deliver heating to a process. A flexible and robust method is required to select refrigerants that are the best fit for a given heating application. A computer-aided molecular & process design (CAMPD) method is developed to design the optimal refrigerant that is tailored to process needs. The method is applied to three case studies across which the HP performance objectives and constraints, and heat source and heat sink temperatures are varied. In addition, the design of refrigerants with low (<150) global warming potentials and zero ozone depletion potentials is investigated. For all applications across all case studies, the CAMPD approach successfully identifies high-performance refrigerants including those that are known refrigerants, other known fluids and novel molecules.

**Keywords**: optimization, molecular design, decarbonization, process design

## INTRODUCTION

Heat consumption in industries worldwide is around 110 EJ per year [1]. Over 90% of this heat is generated by the combustion of fossil fuels, resulting in 21% of global carbon dioxide emissions [2]. Heat pumps (HPs) that are powered by electrical energy and offer high energy efficiencies are a promising alternative heating solution. HPs harness heat from a low-temperature heat source and upgrade it to an increased, useful temperature by utilizing (electro-)mechanical work. HPs are able to utilize and both ambient heat or waste heat due to which the work input into the HP is only a fraction of the heat they supply. HPs can be driven by low-emissions electricity, yielding low-carbon heating.

The working fluid within the HP is known as the refrigerant. HPs based on the subcritical vapour compression cycle are the focus of this work. In the evaporator of the HP, the low-pressure refrigerant takes up thermal energy from a (low temperature) heat source, at temperature $T_{source}$, and vaporizes. The gaseous refrigerant is compressed to a higher pressure and temperature in the compressor. In the condenser, the high-temperature refrigerant releases thermal energy to the heat sink, which is at temperature $T_{sink}$, and condenses. To complete the cycle, the refrigerant passes through the expansion valve (sometimes called a throttling valve) that causes a drop in pressure and temperature. This process is illustrated in figure 1.

The application of HPs in the process industries necessitates innovation in the design of HPs. HPs may be used to deliver heating to a variety of unit operations such as distillation columns, dryers and reactors whose temperatures are below 200 °C [3]. At the same time, several (waste) heat sources whose temperature vary between 30 °C and 200 °C are available in the process industries [3]. Given the large number of heat sources and sinks and the diversity of their temperatures and heat duties, HPs and their refrigerants need to be tailored to each application to maximize performance. The refrigerant in the HP must satisfy manifold requirements: (i) the refrigerant must be able to undergo phase transitions in both the evaporator and condenser; ii) the boiling point of the refrigerant in the evaporator must be below $T_{source}$ at pressures above 1 atm (to prevent vacuum operations); iii) the critical temperature of the

refrigerant must be higher than $T_{sink}$ to allow the refrigerant to deliver heat by condensation; and iv) the refrigerant must be compatible with compressor seals and lubricant.

Apart from the performance of the refrigerant in the HP, there are several environmental and safety-related implications to the choice of the refrigerant. Refrigerants containing chlorine can have high ozone depletion potentials (ODPs) and have been phased out by the Montreal protocol [4]. They have been replaced by fluorinated refrigerants, many but not all of which have very high global warming potentials (GWPs), exceeding the regulatory limit of 150 [5]. Several fluorinated molecules are either expected to be phased out or are already banned due to their high GWPs, toxic degradation products, and pervasiveness in the environment [5]. Natural refrigerants, which include molecules such as alkanes, alkenes, and ammonia, are a promising alternative class of refrigerants. However, several of these are highly flammable, restricting their use across settings. Water and carbon dioxide are non-flammable natural refrigerants that offer high safety and good performance for a limited range of temperatures.

Given the shortcomings of known refrigerants, the discovery of new refrigerants is essential. Further, it is crucial to systematically select the best-fit refrigerant considering both process-specific needs (heat duties, temperatures) as well as the availability of waste heat streams (heat capacities and temperatures). In addition, the refrigerant must comply with environmental and safety-related regulations, e.g., the GWP of the refrigerant must be lower than the legal limit.

Most previous computational techniques for refrigerant selection use a screening process, where all molecules within a chemical database are examined to find those with desirable properties or performance. Examples of such studies include [6], [7], [8].

Computer-aided molecular & process design (CAMPD) is an alternative that can be used to identify best-fit refrigerants. In this framework, an optimization problem is formulated to find the optimal refrigerant and process conditions of the HP. [9] applied CAMPD to find refrigerant candidates for a domestic HP using detailed process models including a sophisticated compressor model.

In this work we simultaneously find the refrigerant and the process variables that satisfy performance constraints and maximize the thermodynamic performance of a subcritical vapour compression industrial HP, using a CAMPD approach. The best possible pure-component refrigerant, be it a known refrigerant, other known fluid, or a novel molecule, is identified from within a large molecular design space. To the best of our knowledge, this is the first CAMPD study on the basis of rigorous thermodynamic models that is applied to high-temperature industrial HPs and that also considers the environmental properties of the refrigerant. In this work, we systematically investigate the use of CAMPD to design HPs by i) varying heat source and heat sink temperatures; ii) varying HP performance objectives; and iii) restricting refrigerants to be low-GWP and zero-ODP. We also benchmark the performance of designed refrigerants against known refrigerants to study the effectiveness of this CAMPD approach.

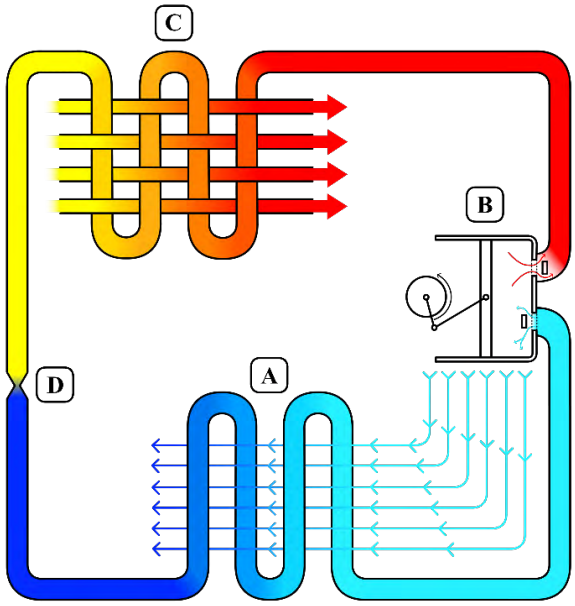

**Figure 1.** A diagram of a vapour compression HP cycle. A: Evaporator; B: Compressor; C: Condenser; D: Expansion valve

## CAMPD OF HP

The HP cycle is modelled in gPROMS Process 2024.1.0 using MESH (Mass, Equilibrium, Summation, and Enthalpy) models. These models do not consider sizing or costing of HP equipment. Several assumptions are made in modelling the HP. The heat source and heat sink are isothermal reservoirs at temperatures $T_{source}$ and $T_{sink}$, respectively. The evaporator and condenser are isobaric at pressures $P_{evap}$ and $P_{cond}$, respectively. The compressor has an izentropic efficiency of 70%, and the motor and drivetrain have a combined efficiency of 95%. The expansion valve is izenthalpic. There are no pressure drops or heat losses in the connections between unit operations.

The performance of the HP cycle is quantified using two metrics: coefficient of performance (COP) and volumetric heating capacity (VHC). The COP, a measure of energy efficiency, is the ratio of heat delivered to the heat sink ($Q_{out}$) to compressor power consumption ($W_{in}$). The VHC is the energy delivered to the heat sink per unit volume of refrigerant at the compressor inlet ($V_{comp.inlet}$),

i.e., $VHC = \frac{Q_{out}}{V_{comp.inlet}}$. VHC is indicative of the sizing of the HP. The temperature lift $\Delta T_{lift}$ of the HP is given by $\Delta T_{lift} = T_{sink} - T_{source}$.

## Process-level Degrees of freedom.

In the optimization of this HP model, the following process-level degrees of freedom are considered as continuous decision variables:

The condenser pressure $P_{cond}$

The condenser subcool $\Delta T_{sub}$

The evaporator pressure $P_{evap}$

The evaporator superheat $\Delta T_{super}$

In addition, the chemical composition of the refrigerant is a decision variable. The refrigerant is represented using a vector of integers $\boldsymbol{n}$, where each element of the vector $n_i$ represents the number of occurrences of functional/atomic group $i$ in the refrigerant. For example, to represent butanol, the vector elements corresponding to -OH, -$CH_2$-, and -$CH_3$ would be set to 1, 3, and 1, respectively, and all other elements of $\boldsymbol{n}$ would be set to 0. 20 chemical groups are allowed in the refrigerant, as outlined in Table 1. Up to 10 occurrences of each group are allowed in the molecule, other than >N- which can take a maximum value of 1 to avoid complex branching structures. The group -cO- refers to an oxygen atom that is attached to two -$CH_2$- groups, and the -eO- group is an (end) ether group in which the oxygen atom is connected to a -$CH_3$ group.

**Table 1:** The groups considered in the CAMPD problem.

| Chemical family | Groups |
|---|---|
| Hydrocarbons | -$CH_2$-, -$CH_3$, |
| Olefins | =$CH_2$, =CH- |
| Alcohols, carboxylic acids | -OH, -eO-, |
| ethers, esters, and ketones | -cO-, >C=O, -COO, -COOH |
| Chlorocarbons | -$CHCl_2$, -$CH_2Cl$ |
| Fluorocarbons | -$CF_3$ -$CHF_2$, -$CH_2F$, -$CF_2$-, -CHF- |
| Amines | -$NH_2$, -NH-, >N- |

## Group contribution methods (GCMs)

Group contribution methods (GCMs) are used to estimate physicochemical properties of the refrigerant, which is described by its chemical composition vector $\boldsymbol{n}$. The group contribution equation of state (EoS) SAFT-γ Mie [10] is used to predict the thermodynamic properties of the refrigerant molecule both as a function of $\boldsymbol{n}$ and its state (temperature, pressure) in the process. SAFT-γ Mie was chosen for its accuracy in predicting both calorific properties and vapour-liquid equilibria, its ability to describe a wide range of refrigerants and fluids, and its proven use in similar CAMPD problems [11]. The SAFT-γ Mie EoS is included in the inbuilt gProperties tool in gPROMS Process, which is used to compute thermodynamic properties. The parameters for the fluorinated groups are taken from Martínez [12] and all others are taken from the gProperties databank.

While the SAFT-γ Mie EoS can predict all thermodynamic properties of fluids, the accuracy of critical point predictions is typically low. Thus, a first-order semi-empirical group contribution model was chosen to model the critical point. [13] was chosen for its higher accuracy in comparison to two other methods [14], [15] for a small test of molecules.

The work of [16] is used for GWP prediction. Again, only first-order group contributions are considered. For groups with no computed GWP contribution, such as -$CH_2$-, the contribution is assumed to be negligible and is set to 0. However, this approach did not account for the significantly reduced GWP of molecules with double bonds - the atmospheric lifespan of these molecules is greatly reduced which causes them to have a lower GWP. Therefore, we parameterized first-order contributions for =CH- and =$CH_2$ groups by regressing to GWP data from [17]. The contribution calculated for =CH- is -1.618305, and for =$CH_2$ is -0.502935.

## Objectives & Constraints

The CAMPD problem is formulated to maximize one of two objective functions: COP, and VHC. The design problem is subject to process-related constraints to ensure feasible operation of the subcritical HP cycle. Molecular feasibility constraints are added to ensure that the octet rule is satisfied for all atoms in the molecule. Several new molecular feasibility constraints are introduced to prevent molecules that are known to be unstable stable such as geminal diols, geminal amines, α-haloalcohols, peroxides and peracids. Further, for molecules that exhibit keto-enol and amine-imine tautomerism, the enol and amine forms that are typically unstable in aliphatic molecules are excluded. The process constraints and molecular feasibility constraints are listed in the supplementary information (SI).

## Experiments

The full MINLP is implemented in gPROMS Process 2024.1.0 using gProperties v2.8 and solved using the MINLPOA solver which is based on the outer approximation algorithm [25] with equality relaxation and augmented penalty. This algorithm works by sequentially solving a primal continuous nonlinear program (NLP) and a master mixed-integer linear program (MILP). The NLP is solved using the NLPSQP algorithm.

Only local optima of this non-convex problem are obtained by solving the MINLP. To obtain high-quality

solutions, integer cuts are used to re-solve each design problem while excluding previous solutions. The integer cut is as is shown in Equation 1 ([18], [19]), where $\boldsymbol{p}$ is a vector of the first 20 prime numbers, $M$ is a sufficiently large number, 10, 000 for this problem, $\boldsymbol{n}^{cut}$ is the solution to be excluded, $y$ is a binary decision variable, and $\epsilon$ is a tolerance, which is set to 2 in this case.

$$My + \epsilon < \boldsymbol{p}^T\boldsymbol{n}^{cut} - \boldsymbol{p}^T\boldsymbol{n} < M(1-y) - \epsilon \quad (1)$$

Computational experiments are performed to observe how the solution changes across different source-sink temperatures, design objectives, and constraints. The experiments are run from source temperatures of 340 K to 420 K and sink temperatures of 360 K to 440 K at temperature intervals of 20 K. For each source-sink temperature pair, the MINLP optimization is solved 4 times using 3 successive integer cuts to generate 4 different candidate solutions. The best-found solution found over the 4 runs is then reported for each temperature pair. The initial guess for all MINLP solves is fixed and given in the SI. In order to facilitate these experiments a computer program was developed in C++ to call gPROMS optimizations through the gO:RUN feature at the specified source-sink temperatures and to automatically apply the integer cuts.

**Table 2:** Summary of experiments

| Case | Objective | Additional Restrictions |
|---|---|---|
| 1 | $VHC$ | None |
| 2 | $COP$ | None |
| 3 | $COP$ | Constraint on GWP (<150 as per EU F-gas regulations), zero ODP enforced by removal of chlorine containing groups. Restricted design space through removal of nitrogenated and fluorinated groups. |

The results are benchmarked against four existing refrigerants that are already being used in high temperature HPs [20]. The benchmark refrigerants are ammonia (R-717), pentane (R-601), 1, 1, 1, 3, 3-pentafluoropropane (R-245fa), and water (R-718). These were chosen as benchmarks in this study because they collectively cover a wide range of feasible operating temperatures and chemical families. For each source-sink temperature pair, the refrigerant was fixed to each benchmark fluid and the COP and the VHC were maximized.

# RESULTS AND DISCUSSION

## Benchmarks

In Table 3, the best of the four benchmark fluids with the highest value of COP is shown for each source-sink temperature pair. Similarly, the best benchmark fluid with VHC as the design objective has also been identified (results shown in SI). The name of the highest-COP benchmark for each source-sink pair is given. Below the name is the optimized value of the objective. In Table 3, pentane dominates at lower source temperatures, being the top benchmark for 9 out of 15 source-sink temperature pairs. Pentane is the only molecule feasible at all source-sink temperature pairs. At higher temperatures, water emerges as the best benchmark fluid.

**Table 3:** Best of four benchmark refrigerants for COP at varying source and sink temperatures.

| COP | | $T_{source}$ (K) | | | | |
|---|---|---|---|---|---|---|
| | | 340 | 360 | 380 | 400 | 420 |
| $T_{sink}$ (K) | 360 | Pentane **7.17** | - | - | - | - |
| | 380 | Pentane **4.09** | Pentane **7.31** | - | - | - |
| | 400 | Pentane **2.67** | Pentane **4.05** | Water **8.58** | - | - |
| | 420 | Pentane **1.78** | Pentane **2.52** | Water **5.28** | Water **9.03** | - |
| | 440 | Pentane **1.07** | Pentane **1.43** | Water **3.87** | Water **5.55** | Water **9.47** |

## Case 1: Maximization of VHC

In Table 4, for each source-sink temperature pair, the best-found refrigerant molecule for maximizing the VHC, after applying 3 integer cuts, is shown. The ASHRAE code is given in brackets whenever the designed molecule is a known refrigerant. The value of the VHC is given in bold in MJ $m^{-3}$. In brackets next to this, is the percentage change in VHC compared to the benchmark fluid that achieves the highest VHC for a given source-sink temperature.

For any fixed source temperature, the VHC reduces as the $\Delta T_{lift}$ increases. The maximum VHC observed was 15.14 at $T_{source} = 420$ K, $T_{sink} = 440$ K and the smallest $\Delta T_{lift}$ value of 20 K. The minimum was 1.74 at $T_{source} = 340$ K, $T_{sink} = 440$ K which is at the largest $\Delta T_{lift}$ value of 100 K.

The results indicate the refrigerant that maximizes the VHC varies with source-sink temperatures. 6 distinct optimal refrigerants were identified. In 3 out of the 15 tested instances, the VHC values obtained by CAMPD were up to 73.1% lower than that of ammonia, the best benchmark fluid for those instances. It is worth noting that ammonia was not included in the design space of the CAMPD problem and, thus, could not have been found as a solution. For 12 out of 15 instances, the use of CAMPD

**Table 4:** Maximization of VHC for case 1 at varying source and sink temperatures.

| VHC (MJ m$^{-3}$) | | $T_{source}$ (K) | | | | |
|---|---|---|---|---|---|---|
| | | 340 | 360 | 380 | 400 | 420 |
| $T_{sink}$ (K) | 360 | 1,1,2-Trifluoroethane (R-143) **6.42** (-73.1%) | – | – | – | – |
| | 380 | 1,1,2-Trifluoroethane (R-143) **5.57** (-73.0%) | 1,2-Butadiene **8.03** (-73.1%) | – | – | – |
| | 400 | 3,3-Difluoropropene **3.98** (+53.1%) | 3,3-Difluoropropene **6.26** (+42.3%) | 3,3-Difluoropropene **9.59** (+31.4%) | – | – |
| | 420 | Methyl Chloromethyl Ether **2.02** (+68.3%) | 1-Chloro-2,2-Difluoroethane **3.72** (+77.1%) | Methanol **6.39** (+77.5%) | Methanol **10.55** (+106.8%) | – |
| | 440 | Methyl Chloromethyl Ether **1.74** (N/A) | Methanol **3.39** (+182.5%) | Methanol **5.89** (+145.4%) | Methanol **9.66** (+124.7%) | Methanol **15.14** (+116.3%) |

resulted in large improvements of VHC over the best of the benchmark fluids. Methyl chloromethyl ether yielded a 194.9% increase in VHC when compared with pentane (R-601), the best benchmark fluid at $T_{source} = 340$ K and $\Delta T_{lift} = 80$ K.

The known common refrigerant R-143 was found to be optimal in 2 out of 15 instances. Several novel refrigerants were identified. Two olefins – 1, 2-butadiene and 3, 3-difluoropropene- were found in this case study. 3, 3-difluoropropene belongs to the hydrofluoroolefin family of refrigerants, several of which have been examined in HPs, due to their high COPs, low GWPs and low flammability. Two novel oxygenated refrigerants, methyl chloromethyl ether and methanol, were identified; methanol is found to be an excellent candidate in other case studies as well. The novel hydrochlorofluorocarbon (HCFC) 1-chloro-2, 2-difluoroethane was also identified; HCFCs have been widely used as refrigerants.

The average pressure ratio across all 15 instances was 8.8 with a maximum pressure ratio of 20.25. Most compressor types are able to achieve pressure ratios up to 10, and screw compressors can achieve pressure ratios up to 20 [20]. $\Delta T_{super}$ was negligible for all instances; however, $\Delta T_{sub}$ was consistently high, often reaching the upper bound of 100 K. These results are all expected because condenser pressures are increased in order to maximize the energy that is delivered by unit volume of refrigerant. In case 1, the average solve time was 129.4 seconds, with a maximum of 693.7 and minimum of 7.3.

## Case 2: Maximization of COP

In Table 5, the refrigerant that maximizes the COP for each source-sink temperature pair is shown. This refrigerant corresponds to the best-found solution after 3 integer cuts. If the designed molecule is a known refrigerant, the ASHRAE code is given. The value of the COP achieved by the refrigerant is shown in bold. In brackets, the percentage change of this COP value with respect to the COP of the best benchmark fluid for that source-sink temperature pair is shown.

The COP values in Table 5 illustrate the dependence of the performance of the HP on source-sink temperatures and temperature lifts. For each $T_{source}$, the COP decreases as $T_{sink}$ increases, i.e. as $\Delta T_{lift}$ increases. For any fixed value of $\Delta T_{lift}$, higher COPs are obtained when $T_{sink}$ is higher. The maximum obtained COP is 9.47 by the refrigerant 2-fluoroethanol at $T_{sink} = 440\,K$. Fluorinated alcohols are not common refrigerants.

The results demonstrate that the choice of objective function strongly impacts designs, including the choice of optimal refrigerant. For all of the 15 source-sink pairs that are tested, the refrigerant that maximizes the COP (Table 5) is distinct from the refrigerant that maximizes the VHC (Table 4).

The results indicate the refrigerant that maximizes the COP varies with source-sink temperatures. For the 15 total source-sink pairs that are tested, 7 distinct optimal refrigerants were identified. 3-Fluoropropene (also known as allyl fluoride) was the most common solution in case 2, appearing as the best-found solution for 7 out of 15 temperature pairs. This is a known compound but has no documented use as a HP refrigerant. A novel fluorinated amine molecule, fluoromethylamine, was

**Table 5:** Maximization of COP for case 2 at varying source and sink temperatures.

| COP | | $T_{source}$ (K) | | | | |
|---|---|---|---|---|---|---|
| | | 340 | 360 | 380 | 400 | 420 |
| $T_{sink}$ (K) | 360 | Acetone **7.80** (+8.8%) | – | – | – | – |
| | 380 | 3-Fluoropropene **4.81** (+17.6%) | 3-Fluoropropene **8.16** (+11.6%) | – | – | – |
| | 400 | 3-Fluoropropene **3.49** (+30.7%) | 3-Fluoropropene **4.98** (+22.0%) | 1,2-Difluoroethane (R-152) **8.7** (+1.4%) | – | – |
| | 420 | 3-Fluoropropene **2.71** (+52.2%) | 3-Fluoropropene **3.57** (+41.7%) | 1,2-Difluoroethane (R-152) **5.35** (+1.33%) | Methyl Vinyl Ketone **8.98** (-0.5%) | – |
| | 440 | Methanol **2.31** (+115.9%) | 3-Fluoropropene **2.76** (+93.0%) | Fluoromethylamine **3.94** (+1.8%) | 1,2-Difluoroethane (R-152) **5.53** (-0.4%) | 2-Fluoroethanol **9.47** (+0.00%) |

identified in this case study. Methyl vinyl ketone, despite being a stable compound, is known to be toxic and reactive which decrease its suitability as a refrigerant.

In case 2, improvements to the COP have been observed for 12 out of 15 source-sink pairs when compared with the best benchmark, illustrating the benefits of selecting a refrigerant tailored to the application. A COP improvement of 115.9% was obtained by choosing methanol as the refrigerant. Screening studies [6] and [8] which examined a small set of molecules have also found methanol to be a promising refrigerant.

Similarly, acetone which is the best-fit refrigerant at 360 K has been found to be a high-performance refrigerant in a screening study [8] that examined 147 molecules. It is highly promising that the CAMPD framework which is using optimization to implicitly search through a large design space with $2 * 11^{19}$ possible combinations of groups has also been able to identify these high-performance fluids.

In case 2, the pressure ratio increased as $\Delta T_{lift}$ increased. The maximum pressure ratio observed was 25.0 at the maximum $\Delta T_{lift}$ of 100 K, for methanol. The minimum pressure ratio was 1.94 observed at $\Delta T_{lift} = 20$ K and $T_{source} = 420$ K. Other than the highlighted case for methanol, all other pressure ratios were below 20 and were indeed below 10 for 9 out of the 15 source-sink pairs. Pressure ratios above ten were only observed at high values of $\Delta T_{lift}$ of 80 K and 100 K. This highlights that the design of high temperature lift HP cycles is indeed more challenging than cycles with low $\Delta T_{lift}$ and necessitates the addition of equipment-related constraints. $\Delta T_{super}$ and $\Delta T_{sub}$ remained negligible for all results in case 2. Case 2 had an average total solve time of 29.9 seconds across all MINLP solves, with a maximum solve time of 193.5 seconds and a minimum of 5.5 seconds.

## Case 3: Maximizing COP with GWP, ODP, & Design Space Constraints

In Table 6, the best low-GWP and zero-ODP refrigerant that is found for each source-sink temperature pair is shown. GWP values are constrained to be below 150 in accordance with environmental regulations [5]. If the refrigerant at the best solution is known, the ASHRAE code is given in brackets. The COP value is shown in bold. The refrigerant design space is much more restricted in case 3. Chlorinated molecules are removed from the search space to obtain zero ODP refrigerants; fluorinated molecules are disallowed as these may be phased out; and we also exclude nitrogenated molecules.

For case 3 all of the obtained solutions are oxygenated molecules, as shown in Table 6. Methanol was found to be the best-fit low-GWP refrigerant in 13 out of 15 instances. It is not currently used in vapour-compression HPs but several computational studies ([6], [8]) have indicated methanol to be a high-performance refrigerant for HPs. [6] found methanol to be a high performing refrigerant for high temperature HPs, for COP at condensing temperatures of around 200 °C . [8] found methanol to be a top performing subcritical HP refrigerant alongside acetone and ethanol. While

methanol is not yet used in industrial vapour-compression HPs, it is likely to be widely used given its superior heat transfer properties and low viscosity. It is used in adsorption HPs, and organic Rankine cycles.

For the highest source temperature pair of $T_{source} = 420$ K, $T_{sink} = 440$ K, acetic acid was found to be the best refrigerant. [21] theorize that formic acid, a molecule that is highly similar to acetic acid, is a promising refrigerant for high-temperature HPs. Formic acid is a small molecule that is not included in the molecular design space of this work: SAFT-γ Mie parameters that describe the entire molecule as a single group are available. By fixing the refrigerant to formic acid, the optimal COP at $T_{source} = 420$ K and $T_{sink} = 440$ K was found to be 9.46 which is 4.9% higher than that of acetic acid.

**Table 6:** Maximization of COP for case 3 at varying source and sink temperatures.

| COP | | $T_{source}$ (K) | | | | |
|---|---|---|---|---|---|---|
| | | 340 | 360 | 380 | 400 | 420 |
| $T_{sink}$ (K) | 360 | Acetone **7.79** (+8.6%) | – | – | – | – |
| | 380 | Methanol **4.81** (+17.6%) | Methanol **8.16** (+11.6%) | – | – | – |
| | 400 | Methanol **3.52** (+31.8%) | Methanol **5.00** (+23.5%) | Methanol **8.49** (-1.0%) | – | – |
| | 420 | Methanol **2.79** (+56.7%) | Methanol **3.63** (+44.0%) | Methanol **5.15** (-2.5%) | Methanol **8.75** (-3.1%) | – |
| | 440 | Methanol **2.31** (+115.9%) | Methanol **2.84** (+98.6%) | Methanol **3.60** (-7.0%) | Methanol **5.23** (-5.8%) | Acetic Acid **9.01** (-4.9%) |

While acetone, acetic acid, and methanol are all stable compounds with several industrial uses, their chief drawback is their flammability. These flammable refrigerants may be used in industry and even homes with appropriate controls and safety features.

Interestingly, imposing constraints on GWP, ODP and restricting the molecular design space led to only modest reductions in COP, on average solutions were 1.7% worse, ranging from +3.0% to -8.6% in comparison with case study 2 (Table 5). The optimization took an average time of 11.8 seconds, notably shorter than case 2, which is to be expected with a smaller design space. The average solve time was 11.8 seconds, with a maximum of 37.9 seconds and a minimum of 3.4 seconds. For 8/60 optimizations in this case study alone, the optimization solver failed to converge to a solution. All of these failures occurred after the addition of the third integer cut which may be due to the presence of additional constraints in this case study.

## CONCLUSIONS

This paper takes a multi-scale process systems engineering approach to the design of industrial HPs leveraging process modelling, equations of state and optimization. Industrial HPs with high COPs and high VHCs were designed in this work for a range of source-sink temperature pairs, demonstrating their potential to decarbonise heat in the chemical industry. In addition, low-GWP and zero-ODP refrigerants that maximize the COP were designed. The results of case studies 1 and 2 illustrate that there is no single universal optimal refrigerant for all use cases: the optimal refrigerant and process conditions vary with source and sink temperatures, objectives, and design constraints. The results highlight the intrinsic link between refrigerant and heat-pump performance. COP was maximized in cases 2 and 3 in an average of 20.9 seconds. The optimization implicitly searched through a vast molecular design space with combinations of groups to identify high-performing refrigerants for each source-sink pair. Refrigerants identified in this work include known refrigerants, known fluids that other authors have found to be promising and a few novel molecules. First-order GCMs were used to predict physical properties in this work, which may lead to lower-accuracy solutions. Validation steps that consider structural information of the molecule are necessary. For case study 3, we used literature data where available to certify that the identified known molecules indeed had low GWP and zero-ODP. Compressor ratios and discharge temperatures were not limited in this study, and this will be the subject of future work.

## DIGITAL SUPPLEMENTARY MATERIAL

## ABSTRACT

In recent years, research for systematic process design approaches has gained traction, especially with the rise in popularity of generative machine learning models and reinforcement learning. However, works from the literature will often focus on proof-of-concept studies, limited to a specific process synthesis problem. Despite showing promising results, it is not clear how easily these methodologies could be transposed to new applications, and whether they would be successful. In this context, this work evaluates the possibility of using a Natural Language Processing model, which has already proven itself for thermodynamic cycle generation, for another different case: seawater desalination. The processes generated by this model will initially be those using reverse osmosis processes aimed at desalinating a seawater solution containing 25000 ppm of NaCl. Results show that the model has been successful in designing structural reverse osmosis desalination processes without defining assembly rules or a superstructure. Given the large number of these generated processes, a clustering method based on their similarity has been developed. This made it possible to identify different known heuristics (like multi-stage) in process engineering. This adaptation was made possible by modifying aspects external to the original model: a dedicated vocabulary, design rules and objective function.

**Keywords**: Process synthesis, Seawater desalination, Artificial Intelligence, SFILES, Space visualization

## 1. INTRODUCTION

In the work by Nabil et al. [1] and Rocha Azevedo et al. [2], a Generative Artificial Intelligence (AI) model for process synthesis was successfully applied to the synthesis of supercritical $CO_2$ power cycles. It works by treating the process synthesis problem as a Natural Language Processing one: flowsheets are represented by sequences ("sentences") of tokens ("words"). Then, data augmentation and fine-tuning methods are used to achieve targeted generation – generation of relevant flowsheets for a given objective function (defined by the user for each case study). The model identified known design heuristics despite having no prior domain knowledge of the application, while also discovering a novel, counter-intuitive heuristic not previously reported in the literature. This capability proves how useful these methods may be for innovative applications.

This work proposes to extend the method used in [1] and [2] for the application of water desalination. Indeed, water resources have been under increasing stress leading to their depletion. The scarcity of this resource is due to the combined effects of global warming and overexploitation in irrigation, industrial and urban sectors. Faced with this challenge, it is becoming necessary to adopt more sustainable water resource management strategies. The recovery of industrial effluents therefore appears to be an interesting solution.

However, its deployment is often hindered by the high energy and equipment costs associated with conventional water treatment processes. The specific case of sodium chloride / water solution treatment for drinking water production, generally named desalination with seawater, is one of the most investigated problems. Designing optimal process architectures that balance energy, environmental, and economic criteria becomes a major

challenge considering the emerging water management difficulties. Furthermore, the development of new technologies for water treatment, such as membrane distillation, requires further studies to determine their relevance. The use of tools for autonomously evaluating process alternatives could be useful for quickly identifying new and useful solutions.

The primary objective is to assess how this method behaves to this new case study, with a focus on a single-technology seawater desalination system using Reverse Osmosis (RO). The second objective will focus on the generation of the results and how can they be visualized and interpreted. This well-known case study will allow for a critical analysis of its results and comparison with traditional industrial practices. Then, a section will be dedicated to future perspectives.

This generative synthesis approach is expected to explore a wide design space without prior assumptions, potentially identifying novel and highly performant process configurations. This design space will vary depending on the objective function and the constraints defined by each scenario.

## 2. METHODS

### 2.1. Data representation

The work by Rocha Azevedo et al. [2] is based on the use of a symbolic language dedicated to the representation of processes: SFILES 2.0. This language converts a process graph, comprising unit operations and their connections, into a sequence of tokens ("words") representing equipment, branches, recycles and tags in the process [3]. It only allows the process flowsheet to be represented without internal parameters.

This notation had previously been modified to facilitate the model's learning process for cyclic processes. The main difference between this version and the original is that a unit operation hierarchy is defined for the SFILES generation (canonical order), improving the consistency of the representation and the model's performance [4]. This version was retained, defining the seawater solution inlet as the starting point and prioritizing the equipment defined for transcribing the process into a sequence of tokens.

In the case of this study, the processes generated will include a raw seawater entry and two global exits represented by the permeate (solution with the lowest salt concentration after treatment) and retentate (solution with the highest salt concentration after treatment). The units available for the synthesis of these processes are: mixer, splitter, pump and reverse osmosis.

### 2.2. Dataset generation

Currently, there is no large-scale SFILES dataset dedicated to desalination processes. Developing this database is a crucial task. It must contain unique, random (no bias in token assembly) and valid sequences.

The algorithm proposed by Nabil et al. [1] for the generation of supercritical $CO_2$ cycles is adapted to the case of seawater desalination. The objective is to generate directed graphs (representing the processes), where the nodes correspond to unit operations and the edges to connection flows. The algorithm begins by creating the most basic desalination process: a raw seawater solution, a reverse osmosis or a membrane distillation (equal occurrence) and two exits.

An edge is then randomly selected before applying a mutation. Each mutation is characterized by the random insertion of one of the units available between two nodes linked by an edge. This step is repeated according to a random number between 4 and 20. When the maximum number of mutations is reached, the additional exits added during the mutation step are connected with mixers to ensure that there are only two exits named Retentate and Permeate (randomly). Finally, for each separation operation, the exit edges are randomly labelled "{P}" and "{R}" to distinguish the permeate and retentate flows. This directed graph is then converted into a SFILES sequence and a pre-established set of rules (see Supplementary Material) is used to certify the validity of the processes. 300 000 unique, random and valid sequences were thus generated for both cases.

The definition of the base dataset used to train the model is of utmost importance, as it strongly conditions the research space on which the model will operate. For this reason, it is desired that the dataset is as varied as possible. While in this work we try to achieve this by using purely random mutations (avoiding bias in this step), there isn't a clear metric for studying the variety of such a dataset. As the number of available and total units increases, this task becomes all the more complicated, but the use of exploration methods (such as thermal sampling, which will be mentioned in the next section) can also help the model explore the research space and even go beyond its original scopes.

### 2.3. Model architecture and implementation detail

In order to explore a large design space, the original article is based on the sequential model including a long short-term memory (LSTM) proposed by Nabil et al. [1]. The model is trained iteratively to produce valid SFILES sequences. There are two distinct phases in this model.

The first phase consists in training the model on the syntactic rules (what makes a SFILES string represent a valid process). In it, the model is trained with random but valid SFILES, stemming from the dataset described on section 2.2, plus other valid sequences generated by the model itself, in a data augmentation loop.

The second phase will finetune the model to focus

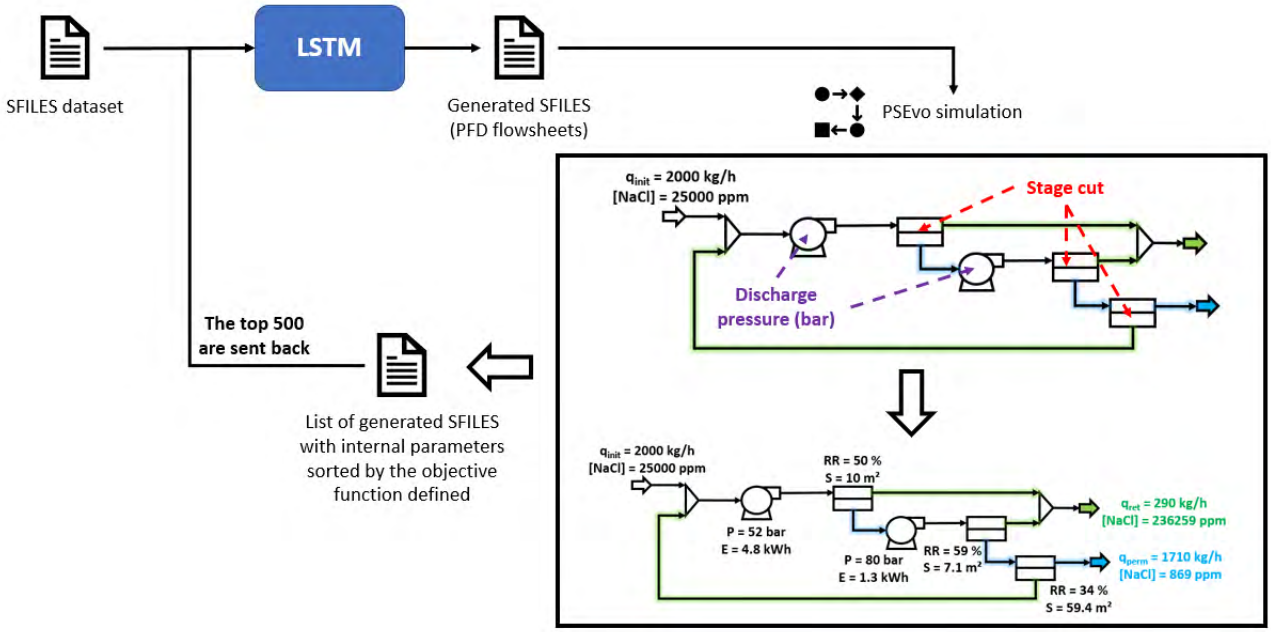

**Figure 1.** Relationship between the generative AI model and process optimization/evaluation

on the generation on relevant solutions according to a given objective function (which will be discussed in the next section). In this phase, the model is used for generating flowsheets in the form of SFILES. These SFILES processes are sent to the internal EDF simulator (PSEvo) where a simulation is launched. The aim is to maximize the objective function that has been defined by interacting with the design data (such as discharge pressure for the pumps or recovery rate for the reserve osmosis). After the optimization is complete, the process indicators (such as membrane surface, permeate NaCl concentration, permeate flow, ...) and value of the objective function will be extracted in order to evaluate the process efficiency. This internal simulator was crafted for efficiency and distributed calculations, which allowed the method to optimize over 20 000 processes in around 8 000 CPU hours (just a few real-time days thanks to the parallel computations performed by 10 Intel Xeon Platinum 8260 processors). The details of how this software works have been detailed in the article of Rocha Azevedo et al. [2].

Then, following the strategy proposed in [2], the best 500 flowsheets generated so far are used to fine-tune the model (see Figure 1). This process is repeated 10 times, iteratively refining the model and improving the quality of the flowsheets it generates. To improve the flowsheet exploration, a strategy of thermal sampling has been developed. This method allows the distribution of the tokens probability predictions to be influenced. A high temperature flattens the probability distribution, allowing more randomness and novelty in the generated SFILES sequences, but can also lead to more mistakes. Preliminary tests have shown that a temperature of 1.5 generates new design areas (see Supplementary Material), for that reason, it is used throughout the results presented in this work.

## 2.4. Objectives functions and weights

In the case of seawater desalination by reverse osmosis, we used various criteria to assess the suitability of the generated processes. These criteria are:

- The recovery rate of pure water produced (noted RR)
- The total membrane surface area used by the desalination units (noted S)
- The electrical power consumption required to generate a pressure greater than the necessary osmotic pressure (noted E)
- The NaCl concentration of the treated solution (noted x). This solution must be less than 1000 ppm (noted $c_0$) total dissolved salts for the process to be considered interesting.

Mathematically, all of these criteria were represented using the following formula:

$$f_{obj} = k_{Tr} \cdot RR - \left( \frac{1}{q_{perm}} \cdot (k_w \cdot E + k_S \cdot S) \right) - \begin{cases} \frac{k_c \cdot e^{m \cdot x}}{m \cdot e^{m \cdot c_0}} & \text{if } x < 1000 \\ k_c \cdot (x - c_0) + \frac{k_c}{m} & \text{if } x \geq 1000 \end{cases} \quad (1)$$

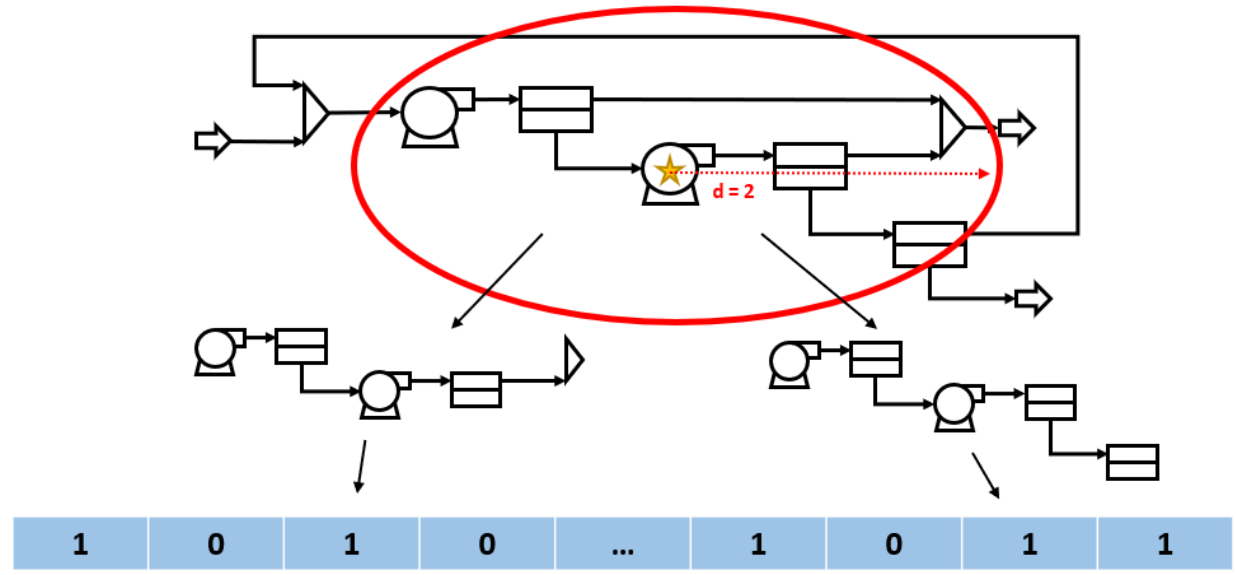

**Figure 2.** Example of fragmentation for a node in the graph (symbolized by a star) and its vector representation.

Here, weights (k) have been assigned to each of these parameters, in order to standardize their physical magnitude and/or prioritize certain parameters over others (see Supplementary Material). The NaCl concentration penalty will be strong if the permeate concentration is greater than 1000 ppm, and quickly (exponentially) otherwise. The term "m" is another weight that influences the slope of the exponential decrease.

## 2.5. Visualization of the generated design space

The AI method presented generates a large number of processes, making it impossible to analyze each process individually. It is therefore necessary to develop a global analysis strategy to extract a set of relevant information. The essential information is the common substructures of the processes and the search space explored.

Many articles in computational chemistry using AI models transform molecules into binary vectors (vectors whose elements are 0 or 1 called fingerprints) of fixed dimension. This representation is particularly suitable for visualization or similarity analysis. There are various vectorization processes (the most well known being Extended Connectivity Fingerprints [5]) based on rules specific to chemistry. The aim is not to replicate these algorithms but to redefine a digital representation strategy adapted to the processes field.

To do this, the SFILES sequences generated by the model are transformed into a directed graph. For each node in the graph, a subgraph containing all nodes at a distance less than or equal to d from the first node is isolated. This fragmentation is applied to all the processes to be studied. When all the unique subgraphs have been extracted, they are associated with a component of a vector, the dimension of which is fixed by the number of unique subgraphs. For each process, this vector is initialized with zeros. If the process includes a particular subgraph, its component takes the value 1, otherwise it remains at 0. This mechanism allows the sequences generated by the model to be represented as a binary vector indicating the presence of the local patterns that constitute it. It is important to note that the distance d is a parameter set by the operator (see Figure 2). However, it should be not too low (low discriminating patterns) or too high (many long and unique patters creating sparse vectors with little information). The value set in this work is 2.

To visualize the search space, the UMAP dimensionality reduction method is applied. UMAP (Uniform Manifold Approximation and Projection) allows complex nonlinear data to be projected into a two-dimensional space while preserving the local and global topologies of the processes (suitable for revealing significant clustering patterns) [6]. The more structurally similar two processes are, the most similar the points representing them in the reduce space will be. Once the projection had been made on all the processes, a density-based clustering technique (HDBSCAN [7]) was applied to group similar processes together. Thanks to the binary vectors, we can quickly identify the most common or dominant substructures in these process families.

# 3. RESULTS AND DISCUSSION

This section focuses on the reverse osmosis desalination processes generated. The first subsection will

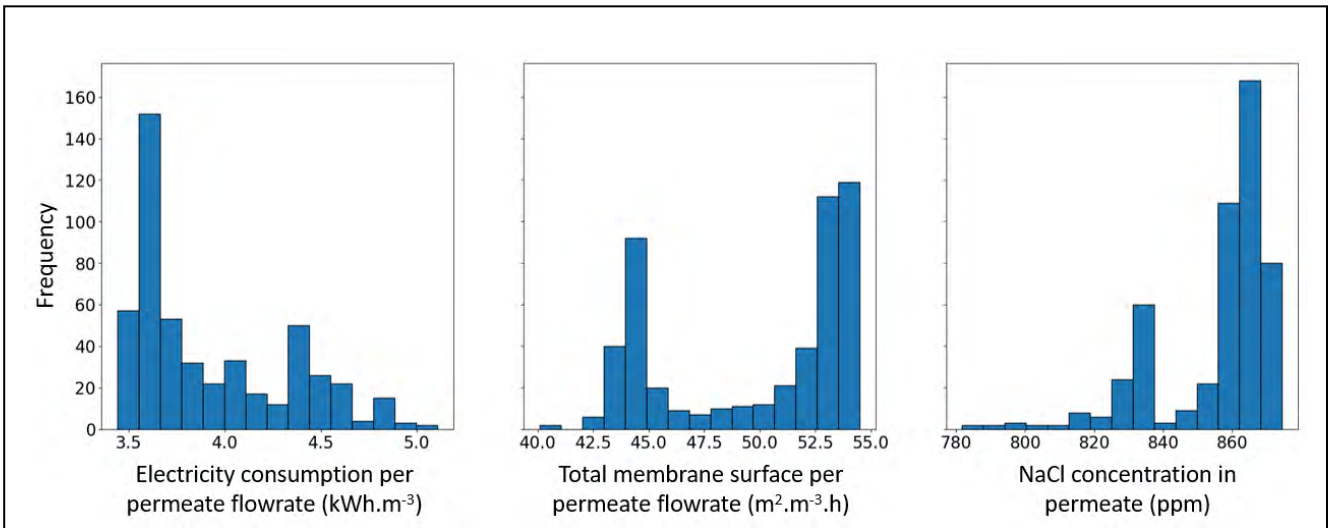

**Figure 3.** Histogram of internal parameter for the 500 best processes studied in section 3.2

investigate the steps necessary to adapt the initial model. Then, the next subsection focuses on the model exploration to determine if it converges towards a single zone (meaning that a single global architecture is found) or if several zones are explored. The 500 best solutions proposed by the model will be then investigated. Because this case study is well documented, it will be the basis for evaluating the model, as we can compare the flowsheets the model generates to known relevant processes. Finally, the perspectives of this work will be presented.

## 3.1. Model adaptation

This section lists the steps required to modify the Rocha Azevedo et al. model [2] in order to apply it to our case study.

The first step was to create the tokens used in the application. Each token has its own name, as well as an inlet number, an outlet number and a tag name for these currents (see Supplementary Material). A set of rules was created to verify the physical validity of the generated processes (see Supplementary Material). Otherwise, non-physical processes could have been simulated. When the valid token sequence needs to be optimized and then evaluated, it must be transformed into an incidence matrix where each column corresponds to a specific equipment. The algorithm used to do this had therefore to be adapted to assign the correct token to the correct simulator equipment. The same applies to the permeate/retentates flowrates. Another aspect that been modified is the post processing of the processes. Equipment that is not used for the process or unused flows has already been removed, but this post processing has been extended. The objective function has been also modified.

The LSTM model has not been modified except for the integration of thermal sampling strategy.

## 3.2. Evaluation of model exploration

In order to visualize how the model explores the research space, the search space has been modeled (see section 2.5) for the original random dataset (iteration “0”) plus the flowsheets generated by the method at each fine-tuning iteration (iterations 1 – 10). Only the flowsheets with a feasible value of objective function (equation 1) are considered. The objective is to highlight the structural evolution of the processes and the detection of areas that improve the objective function.

The results (see Figure 4) show that the generated processes differ significantly from those sent to the model in terms of structure and efficiency. Analysis of the objective function of the processes has highlighted regions that are not particularly relevant to the application. Future processes generated will tend to move away from these regions in order to exploit new designs in known regions or explore other regions.

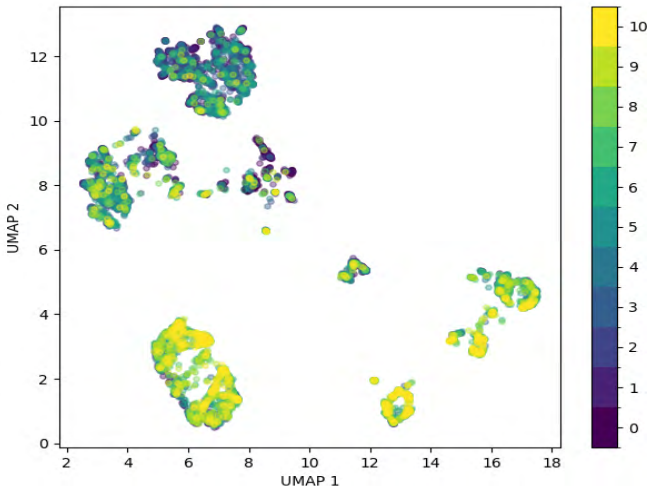

**Figure 4. :** Visualization of the processes generated by the model based on iteration (colorbar).

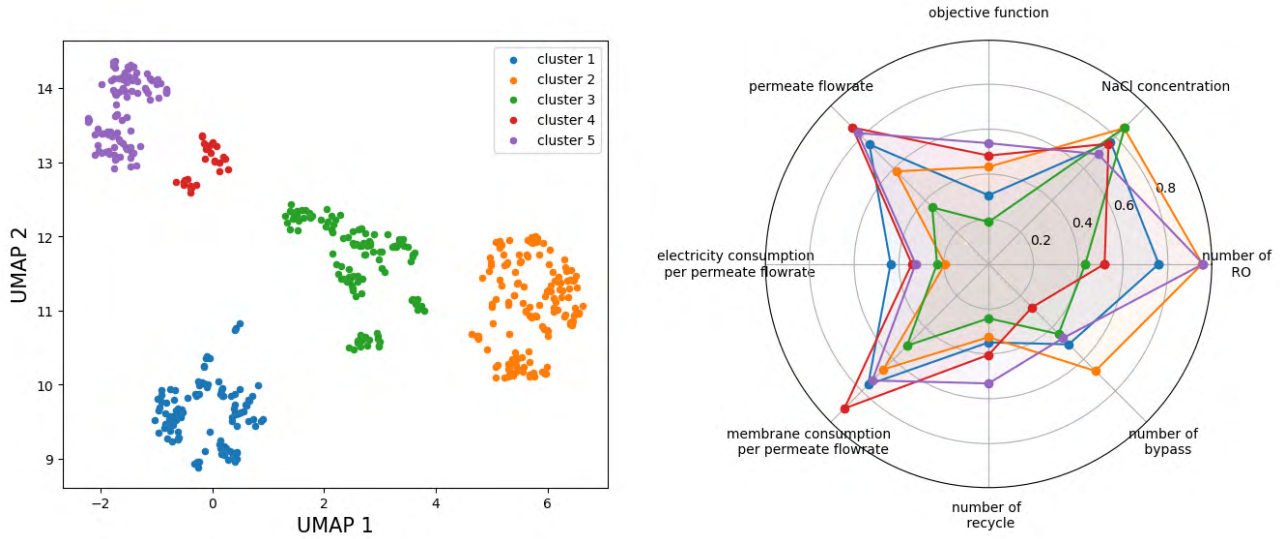

**Figure 5.** Process clustering (left) and Kiviat diagram of normalized data for each cluster (right) for the most relevant processes.

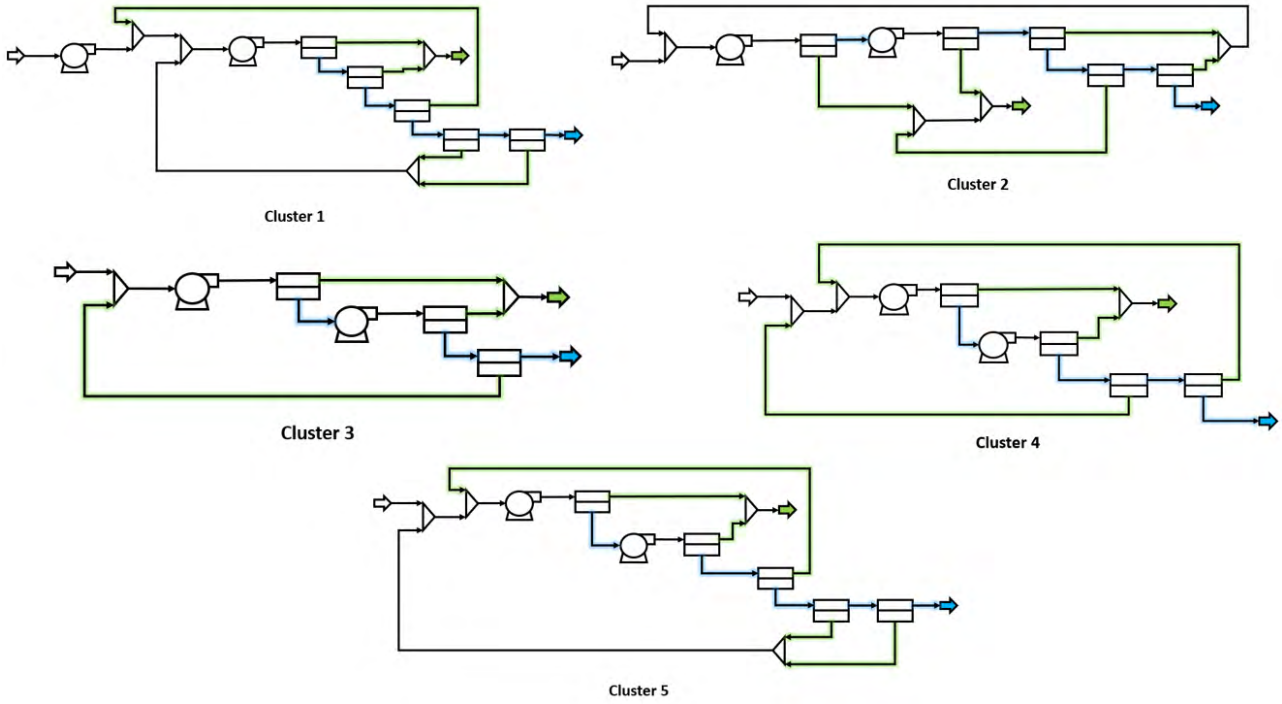

**Figure 6.** Randomly selected process of the each cluster. The green element correspond to retentate flows and the blue element correspond to permeate flows.

## 3.3. Exploitation of the most relevant processes

The 500 best processes have been selected for this study. Analysis of the results show that electricity consumption ranges from 3 and 5 kWh/m$^3$ and total membrane surface used is between 40 and 55 m$^2$/m$^3$. All these processes produce water with less than 1000 ppm in salt (see Figure 3).

Using the method described in section 2.5, five clusters were detected, each with different design architectures. According to Kiviat diagram (see Figure 6), the elements of cluster 5 have the highest objective function. A random process was therefore selected for each cluster in order to analyze its architecture in detail (overview of these processes are given in Supplementary Material).

As illustrated in the Figure 6, a number of well-

known and widely documented heuristics were found in these processes, such as:

- Use of multi-stage reverse osmosis (between 3 and 5 stages) allowing separation requirements to be distributed across several levels.
- Excessively concentrated rejects are not reprocessed to avoid the use of very high hydraulic pressure or excessive membrane use by sending them directly to the retentate.
- Low concentration effluents are reprocessed to maximize water recovery.
- Use of partial recirculation

The processes of clusters 2, 3, 4 and 5 present a heuristic that those in cluster 1 do not share: a second pressurization stage after the first reverse osmosis unit. This allows us to reduce the level of electricity needed to obtain the same permeate flowrate (see Supplementary Material). The cluster 1 processes start directly at the highest possible pressure, which requires much more electricity to operate.

Unlike the other processes, those generated in cluster 3 have less reserve osmosis. Looking at the appearance of the processes, they are generated at the beginning (iteration 1) and then their number are falling in favor of processes incorporating more complex designs (see Figure 7). This proves that the model tends to move away from simple solutions to explore possibilities for designs that are more relevant to a process engineering expert.

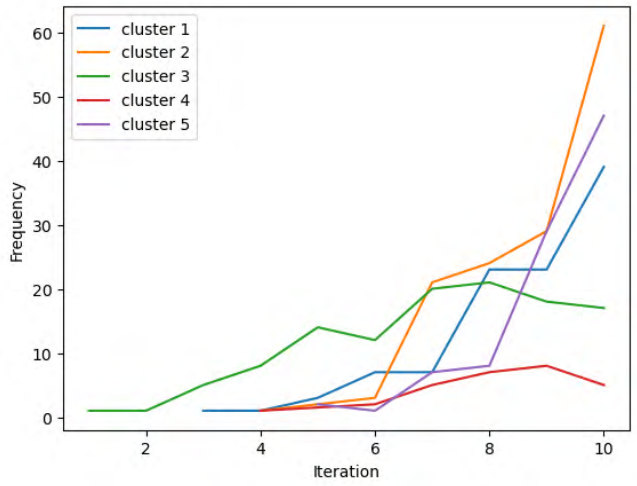

**Figure 7.** Appearance of processes in each cluster based on iterations.

## 3.4. Future perspectives

This work has demonstrated the ability of AI to generate processes incorporating reverse osmosis and certain known heuristics with strong potential for industrial application. However, several perspectives can be implemented in order to refine the results. First, the objective function can be redefined to include more elements related to CAPEX or OPEX. This economic dimension could potentially lead to identifying simpler processes (with less separation stages) for achieving the same performance indicators. The penalty for NaCl concentration in the permeate could also be increased to obtain a weaker NaCl solutions in the permeate for the most interesting processes. It would also be interesting to have a multi-objective function and study the Pareto fronts of the generated solutions.

Nevertheless, scientific literature mentions numerous studies based exclusively on this separation technology. The integration of multi-technology processes appears to be a more relevant study with the use of membrane distillation. This type of hybrid process is generating interest despite of a lack of knowledge. A working perspective of readjusting the model and then retraining it to design this type of hybrid process (reverse osmosis and membrane distillation) should also be explored.

Finally, one could imagine coupling this synthesis approach with others methods. This could either be done: upstream, mixing known heuristics to the dataset during training, for nudging the method in the right direction; or downstream, automatically extracting useful patterns from the data generated for the development of superstructures which can better refine the research space.

## 4. CONCLUSION

The objective of this work was to evaluate the integration of AI to propose relevant processes for water recovery. Although the original model was proposed for thermodynamic cycle design, processes using reverse osmosis for seawater desalination were developed. These processes offer satisfactory energy and material efficiency and incorporate design architectures commonly used in industry (multi-stage reserve osmosis, ...). Generative AI has therefore made it possible to find known heuristics without prior knowledge. These heuristics were easily highlighted thanks to the development of a visualization method using UMAP and then clustering.

## 5. NOMENCLATURE

- RR: Recovery Rate
- S: membrane surface used
- E: electricity power consumption
- $q_{perm}$: permeate flowrate
- [NaCl]: NaCl concentration
- P: Pressure discharge
- $q_{ret}$: retentate flowrate

- $q_{init}$: initial flowrate

## ABSTRACT

Although solvent-based crystallization is widely adopted for separation and purification of crystalline pharmaceutical products, solvent choice and utilisation critically influence product quality, manufacturing cost, and the environmental performance of the pharmaceutical process. Escalating demands to reduce process mass intensity (PMI), together with increasing vulnerabilities in the supply chains, necessitate the development of more efficient and resilient process designs, incorporating solvent and active pharmaceutical ingredient (API) recycling. The conceptual design of crystallization processes offers a viable route to identify flowsheets with substantially reduced solvent consumption. In this paper we present a computer-aided molecular and process design (CAMPD) formulation to explore the benefits of solvent/API recycle for two processes/APIs: (i) a continuous cooling crystallization process for mefenamic acid (MA) employing a binary solvent mixture and (ii) a batch cooling crystallization for paracetamol using a single solvent. At the conceptual design stage, the process is assumed to operate at thermodynamic equilibrium and the SAFT-γ Mie group contribution approach is used as a rigorous thermodynamic model. The optimal design for each process is determined based on the trade-off between two key performance indicators (KPIs), crystallization yield and solvent consumption. The resulting bi-objective optimization (BOO) problem is implemented in gPROMS. In addition to the solvent identities the proposed methodology also enables the simultaneous optimization of process temperatures, and the feed composition. The results demonstrate that solvents and API recycling can deliver significant benefits, leading to reduced process mass intensity (PMI) while maximizing the crystallization yield.

## INTRODUCTION

Over 80% of small-molecule pharmaceuticals are delivered in crystalline form, including tablets and capsules [1]. Consequently, crystallization and purification are crucial components in pharmaceutical manufacturing. The design of isolation and purification steps impacts the physical properties of active pharmaceutical ingredients (APIs), which influence the therapeutic performance of the drug through its efficacy, absorption, and bioavailability. Additionally, crystalline form properties affect the performance of downstream operations such as filtration, drying, milling, and tableting [2].

Most industrial crystallization processes are solvent based, primarily due to the operational simplicity of such systems [3]. However, the choice of solvent(s) has a profound impact on the overall efficiency and sustainability of the crystallization process. From a thermodynamic perspective, solvent selection influences the solubility of the API, thereby affecting both the attainable crystal yield and the solvent volume required for crystallization. Moreover, solvent usage accounts for over 70% of the total energy demand and nearly 50% of the greenhouse gas emissions associated with API production [4].

Consequently, systematic approaches to solvent choice are fundamental to developing crystallization processes that are both efficient and environmentally sustainable.

Considering these challenges, increasing attention has been directed towards integration of solvent and API recycling strategies within crystallization processes [5-7]. Among these, Wong et al. [5] and Ferguson et al. [6], have carried out experimental studies on single stage, mixed-suspension, mixed-product removal (MSMPR) crystallizers with recycle and have shown that recycling mother liquor back to the crystallizer and manipulating the recycle ratio can boost the crystallization yield.

From a computer-aided design perspective, several systematic methods for integrated solvent (or solvent mixture) and process design have been reported for standalone crystallization [2, 8-11]. Various strategies have been adopted to solve such computer-aided molecular and process design (CAMPD) problems. These include generate-and-test, in which property prediction methods or databases are used to generate a list of candidate solvents to be evaluated [11], decomposition-based approach [8, 10], where optimization subproblems are used to identify molecules for which the process is further optimized; and simultaneous optimization of solvent/solvent blend and process [2, 9], where a mixed-integer nonlinear program (MINLP) is solved with respect to the process variables and the molecular structure. As expected, optimal binary solvent mixtures often results in greater solubility than pure solvents [12].

Comparatively limited attention has been given to the design of crystallization processes with solvent and API recycling. Wang and Lakerveld [7] have recently presented a continuous molecular targeting (CoMT-CAMPD) approach for solvent selection in a continuous antisolvent crystallization process. Their process configuration integrated a crystallizer with a flash drum to recycle and reuse the antisolvent. Their approach was based on the perturbed-chain statistical associating fluid theory (PC-SAFT) equation of state [13] as the underlying thermodynamic model. The resulting MINLP problem was relaxed into a sequence of nonlinear programming (NLP) problems via continuous mapping of solvent parameters.

Building on these advances, the aim of this work is to employ a simultaneous CAMPD formulation to investigate the potential benefits of solvent/API recycling for two process configurations/APIs. The first process configuration considered, Case 1, is adapted from the continuous cooling crystallization design proposed by Wang and Lakerveld [7] using a binary solvent mixture. Two solvent and API recycling strategies are examined: direct recycling of the mother liquor and recovery via a flash separation step. The performance of these recycling strategies is compared with that of standalone crystallization, with solvent identity and process operating conditions optimised in each case. The second process configuration examined, Case 2, is adapted from a laboratory-scale batch cooling crystallization setup for paracetamol using a single solvent [19]. Here pure solvent recovery is achieved via a rotary evaporator, after which the recovered solvent is reused for washing the filtered crystal cake and subsequently recycled to the crystallizer together with the fresh feed. For both case studies, the thermodynamic properties of the pure solvent and the mixtures are evaluated using SAFT-$\gamma$ Mie [14].

The design approach, including the process models and design constraints for both configurations, is discussed in the next section. The results of BOO are presented in subsequently the Case studies section and the final conclusions are drawn in the last section.

## DESIGN APPROACH

### Problem definition

The CAMPD problem addressed in this work can be stated as: Given a crystallization process flowsheet for a pharmaceutical compound, a specified product purity, and a list of potential solvents, determine the optimal combination of solvent/solvent mixture, mixture composition and process conditions. At this stage of conceptual design, the process model is formulated based solely on thermodynamic equilibrium considerations and material balance equations.

To facilitate the formulation of the process models, a number of sets are defined as follows.

- $Q$ denotes the set of solvents used in the process. In this work, case studies with one or two solvents are used so that $Q = \{s1, s2\}$ or $Q = \{s1\}$.
- $I$ denotes the set of impurities present in the feed stream.
- $C$ denotes the set of all components that may appear in any liquid stream within the process, i.e., $C = Q \cup I \cup \{API\}$, where API represents the desired product.
- $C^k \subseteq C$ represents the set of components that may appear in the solid phase.
- $S$ represents the set of candidate solvents from which the solvents used in the process ($Q$) are selected.
- $\mathcal{T} = \{1, 2, \dots, N\}$ is the set of process streams, where $N = 10$ for Case 1 and $N = 22$ for Case 2.
- $G$ is the set of functional groups used to represent the solvents in set $S$.

### Model formulation

#### Continuous Cooling Crystallization – Case 1

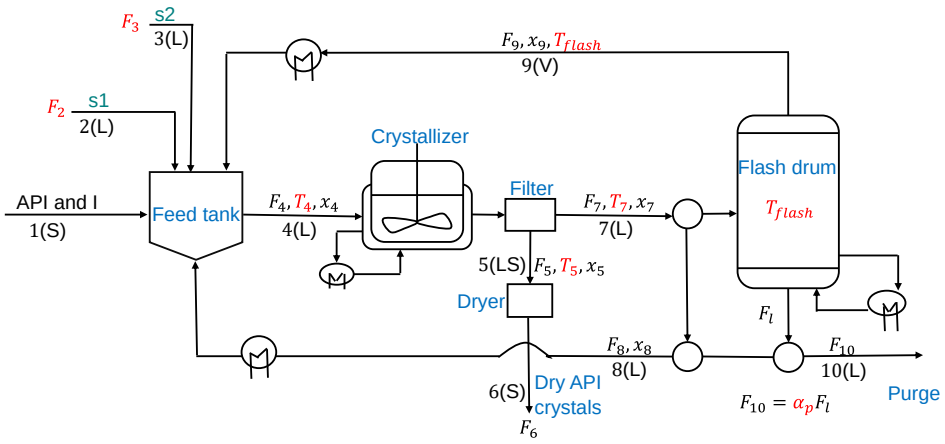

**Figure 1**: Flowsheet for continuous cooling crystallization of mefenamic acid. The letters L-liquid, S-solid, LS-liquid and solid, and V-vapour shown in parentheses after each stream number indicate the phases present in the corresponding process streams.

The continuous cooling crystallization flowsheet for a binary solvent mixture with solvent and API recycle via a flash drum is shown in Figure 1. The mass of component $i \in C$ in stream $t \in \mathcal{T}, M_{t,i}$, is given by

$$M_{t,i} = F_t x_{t,i} MW_i, i \in C; t \in T \tag{1}$$

where $F_t$ is the molar flow rate of stream $t$, and $x_{t,i}$ represents the mole fraction of the $i^{th}$ component in stream $t$, such that $\sum_{i \in C} x_{t,i} = 1, \forall t \in \mathcal{T}$.

Stream 1 is the feed entering following upstream synthesis and contains only API and impurities; hence, $x_{1,i} = 0, i \in C \backslash \{API\} \cup I$. Streams 2 and 3 correspond to pure solvent $s1$ and $s2$, respectively, $x_{2,i} = 0, i \in C \backslash \{s1\}$ and $x_{3,i} = 0, i \in C \backslash \{s2\}$. The material balance around the feed tank is given as:

$$F_1 x_{1,i} + F_2 x_{2,i} + F_3 x_{3,i} + F_8 x_{8,i} + F_9 x_{9,i} = F_4 x_{4,i}, i \in C \tag{2}$$

while that around the crystallizer and filter is given as:

$$F_4 x_{4,i} = F_5 x_{5,i} + F_7 x_{7,i}, i \in C \tag{3}$$

Stream 5 consists of the wet API cake and is modelled as a two-phase mixture of solid and liquid phases:

$$F_5 x_{5,i} = F_5^{ml} x_{5,i}^{ml} + F_5^{s} x_{5,i}^{s}, i \in C \tag{4}$$

where superscripts $ml$ and $s$ denote the mother liquor and solid phases, respectively. The solvent holdup in the wet cake is characterized by a mass fraction $\alpha_h$:

$$\Sigma_{i \in C} M_{5,i}^{ml} = \alpha_h \left[ \Sigma_{i \in C} M_{5,i}^{ml} + \Sigma_{i \in C} M_{5,i}^{s} \right] \tag{5}$$

It is further assumed that no compositional change occurs in the liquid phase during filtering; therefore, the mole fraction of mother liquor retained within the wet API cake is equal to that of the liquid stream exiting the crystallizer, stream 7, i.e., $x_{5,i}^{ml} = x_{7,i}$. Additionally, 100% impurity rejection is assumed in the crystallizer, such that only the API reaches solid–liquid equilibrium (SLE), while all impurities remain undersaturated in the mother liquor (stream 7), i.e., $x_{i,5}^{s} = 0, i \in C \backslash \{API\}$. Liquid stream 7 is at solid liquid equilibrium (SLE) with the solid APIs in stream 5, and the API solubility is calculated as:

$$\ln x_{7,API} \gamma_{7,API} = \frac{\Delta H_{API}^{m}}{R} \left( \frac{1}{T_{API}^{m}} - \frac{1}{T_7} \right) \tag{6}$$

where $\gamma_{7,API}$ denotes the activity coefficient of the API at equilibrium obtained using SAFT-$\gamma$ Mie, $\Delta H_{API}^{m}$ is the molar heat of melting of the API, $T_{API}^{m}$ is the melting temperature of the API, $R$ is the ideal gas constant, and $T_7$ is the crystallizer operating temperature.

Stream 5 is sent to a dryer to produce dry API crystals (stream 6), with residual solute impurities originating from the solvent holdup within the wet cake.

Material balance around the flash drum is given as:

$$F_5 x_{5,i} = F_9 x_{9,i} + F_{10} x_{10,i} + F_8 x_{8,i}, \forall i \in C \tag{7}$$

where $F_9$ is vapour outlet flow rate from the flash drum. The liquid stream leaving the flash drum is split into a recycle stream ($F_8$) and a purge stream ($F_{10}$), with purge fraction defined as $\alpha_p$, such that $\alpha_p = (1 - \alpha_p) F_{10} / F_8$. Phase equilibrium at the flash temperature, $T_{flash}$ and atmospheric pressure is determined via a temperature-pressure flash (TP-flash). Furthermore, API and the impurities are assumed to be non-volatile and therefore, $x_{9,i} = 0, i \in C \backslash \{s1, s2\}$.

In some streams, at least one component in $C^k$ should remain in the liquid phase. For a stream $t$, the set $\hat{C}_t^k \subseteq C^k$ of such component is defined and the solubility limit of a component $i \in \hat{C}_t^k$ is computed by assuming that only pure crystals can form (no co-crystals) [15] and by defining a hypothetical mixture with mole fraction vector $\hat{\boldsymbol{x}}_t^{(i)}$ in which the relative proportions of all components are identical to those in stream $t$:

$$\hat{x}_{t,i'}^{(i)}/\hat{x}_{t,s1}^{(i)} = x_{t,i'}/x_{t,s1}, i' \in C\backslash\{s1,i\};\ i \in \hat{C}_t^k;\ t \in \{4,7,8\} \quad (8)$$

with the normalization condition $\Sigma_{i' \in C} \hat{x}_{t,i'}^{(i)} = 1, i \in \hat{C}_t^k$ and component $i$ is assumed to be at SLE:

$$\ln \hat{x}_{t,i}^{(i)} \hat{\gamma}_{t,i}^{(i)} = \frac{\Delta H_i^m}{R}\left(\frac{1}{T_i^m} - \frac{1}{T_7}\right), i \in \hat{C}_t^k; t \in \{4,7,8\} \quad (9)$$

where $\hat{\gamma}_{t,i}^{(i)}$ is the activity coefficient of component $i$ in the hypothetical stream. The undersaturation is then imposed as:

$$x_{t,i} \leq \hat{x}_{t,i}^{(i)} - \epsilon_c, i \in \hat{C}_t^k \quad (10)$$

where $\epsilon_c$ is a small positive tolerance. These equations are applied to stream 7, where only the API crystallizes, ($\hat{C}_7^k = C^k\backslash\{API\}$), and streams 4 and 8, where no component crystallizes ($\hat{C}_4^k = \hat{C}_8^k = C^k$).

**Process design constraints:** Liquid range constraints are enforced so that the solvent mixture is in the liquid state in specific units:

$$T_t \leq T_{mix,t}^{bub} - T_0, \forall t \in \mathcal{T}^L \quad (11)$$

Here, $T_t$ and $T_{mix,t}^{bub}$ are the operating temperature and the bubble-point temperature of stream $t$, respectively, and $\mathcal{T}^L$ is a relevant subset of $\mathcal{T}$. For continuous crystallization $\mathcal{T}^L = \{4,7\}$. Bubble-point temperatures are calculated using SAFT-$\gamma$ Mie. Constraints on the melting points of the solvent(s) are not considered as the solvents have been chosen to have melting points well below the minimum process temperature. Additionally, the quaternary mixture (s1, s2, API, and l) is required to form a homogeneous liquid phase in streams $t \in \{4,7,8\}$. This is ensured by constraining a logical stability function $\phi(T_t, P_t, \boldsymbol{x}_t)$ to unity. $\phi = 1$ denotes that a TP-flash calculation at the specified conditions identifies neither a second liquid phase nor a vapour phase, while $\phi = 0$ indicates the presence of an additional fluid phase.

**Switching configurations:** In the equations presented so far, it is assumed that recycling using flash drum takes place. To model the direct-recycle configuration, the following constraints are introduced:

$$T_{flash} \leq Mz + T_7 + \epsilon_z \quad (12)$$

$$T_{flash} \geq T_7 + \epsilon_z(1-z) \quad (13)$$

$$T_{flash} \geq zT_{mix,7}^{bub} + \epsilon_z \quad (14)$$

$\epsilon_z$ is a small positive constant, $M$ is a large positive constant, $z$ parameter indicating the status of the flash drum: (active for $z = 1$, in-active for $z = 0$). denotes a binary parameter indicating the operating status of the flash drum.

## Batch Cooling Crystallization – Case 2

Figure 2 depicts the batch cooling crystallization process. The crystallization is performed in a pure solvent and is followed by filtration, washing and drying. Due its batch nature, the process requires a few iterations to reach a steady state. While this is considered via a batch index $b$ and a total number of batches $N_b$, the detailed dynamics of the process units are neglected at the conceptual design stage. Each unit is modelled by considering the initial time (inlet) and final time (outlet). As a result, the mass balances and phase-equilibrium formulations for the crystallizer, filter, and dryer are analogous to those described previously (with the addition of the batch index $b$) and are not repeated here.

As in the continuous crystallization model, 100% impurity rejection is assumed during batch crystallization. Specifically, only the API is allowed to reach SLE, while impurities are constrained to remain undersaturated in the relevant mother liquor streams (Streams 1, 2, 5, 17, 18, and 22). Furthermore, temperature constraints are also imposed for streams $t \in \mathcal{T}^L = \{1,2\}$ (cf. Eq. (11)). After filter 1, the cake is washed using a fraction of pure solvent from the solvent recovery tank. The mass of wash solvent in batch $b, M_{14}^b$ is modelled using wash mass fraction, $\alpha_w$:

$$M_{14}^b = \alpha_w M_{3,API}^{s,b} \quad (15)$$

where $M_{3,API}^{s,b}$ denotes the mass of solid API in stream 3.

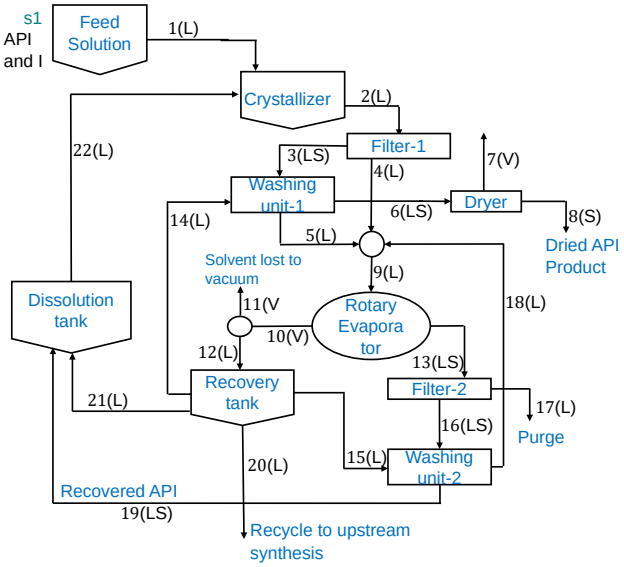

**Figure 2:** Flowsheet for Batch cooling crystallization

The washing operation is assumed to occur at room temperature (i.e., $T_5^b = T_5 = 293$ K) with the resulting mother liquor is at solid-liquid equilibrium (SLE) with respect to the API. Accordingly, API solubility in stream 5 is given by:

$$\ln x_{5,API}^b \gamma_{5,API}^b = \frac{\Delta H_{API}^m}{R}\left(\frac{1}{T_{API}^m} - \frac{1}{T_5}\right) \quad (16)$$

The resulting liquid streams from filter 1 (stream 4) and washing units 1 and 2 are combined and fed to a

rotary evaporator, where a mass fraction, $\alpha_{evap}$, of the total solvent amount in the combined stream (stream 9) is evaporated and collected in the solvent recovery tank. The corresponding mass balances are given by

$$M^b_{9,i} = M^b_{5,i} + M^b_{4,i} + M^b_{18,i}, i \in C \quad (17)$$

$$M^b_{10} = \alpha_{evap} M^b_{9,s1} = M^b_{11} + M^b_{12} \quad (18)$$

$$M^b_{11} = \alpha_c M^b_{10} \quad (19)$$

where $\alpha_c$ represents the fraction of evaporated solvent lost in the vacuum system. For clarity, the component index $i$ is omitted for the streams containing pure solvent. The concentrated mother liquor leaving the rotary evaporator is cooled to room temperature ($T^b_{13} = T_{13} = 293$ K) and sent to filter unit 2 to recover additional API. The filter cake is washed using solvent from the solvent recovery tank at room temperature. Next, the washed cake is redissolved and recycled to the crystallizer. The filtrate is discarded (stream 17) whereas the wash liquor (stream 18) is recycled back to the evaporator.

The composition of the recycle stream (stream 22) is constrained such that the mass ratio of API to the solvent is identical to that of the fresh feed stream. i.e.,

$$M^b_{API,22}/M^b_{s1,22} = M^b_{API,1}/M^b_{s1,1} \quad (20)$$

This ensures consistent feed composition upon recycle.

## Design Constraints and MINLP formulation

Additional constraints and model equations are required to describe the selection of a solvent from the set of candidates $S$ and to quantify process performance.

**Solvent assignment constraints:** Logical constraints are imposed on the binary variables representing the choice of solvent. Exactly one solvent from set candidate $S$ is assigned to the solvent component(s).

$$\Sigma_{s \in S} y_{q,s} = 1, \forall q \in Q \quad (21)$$

For continuous cooling crystallization configuration, $Q = \{s1, s2\}$, whereas for batch cooling crystallization, $Q = \{s1\}$. To prevent the same candidate solvent from being assigned to both solvent components in a binary solvent mixture, the following constraint is imposed:

$$\Sigma_{q \in Q} y_{q,s} \leq 1, \forall s \in S \quad (22)$$

Since thermodynamic properties are computed using a group contribution approach, each solvent candidate $s$ is represented by a set of functional groups $n_{s,k}$, where $k$ is a functional group in set $G$. The solvents $q \in Q$ are then defined as:

$$\tilde{n}_{q,k} = \Sigma_{s \in S} y_{q,s} n_{s,k}, \forall q \in Q, \forall k \in G \quad (23)$$

where $\tilde{n}_{q,k}$ denotes the number of functional group of type $k$ present in solvent $q$.

**KPIs:** The KPIs considered in this work are process mass intensity (PMI), product purity, and crystal yield.

- PMI is sustainability metric that quantifies material efficiency. For continuous crystallization process, it is calculated as:

$$PMI = \Sigma_{t \in \{1,2,3\}} \Sigma_{i \in C} M_{i,t} / M_{API,6}\,, \quad (24)$$

For batch crystallization, the overall PMI is evaluated over $N_b$ batches by accounting explicitly for the solvent recovered and recycled to upstream synthesis:

$$PMI = \left(\Sigma^{N_b}_{b=1}\left(\Sigma_{i \in C} M^b_{i,1} - M^b_{s1,20}\right)\right) / \Sigma^{N_b}_{b=1} M^b_{API,8} \quad (25)$$

- Product purity ($PP$) is defined as the fraction of desired product in the dry API stream. For continuous crystallization process this is defined as

$$PP = M_{API,6} / (M_{API,6} + M_{I,6}) \times 100 \quad (26)$$

An analogous expression is used for batch crystallization process. In this work, product purity is imposed as a constraint, with minimum target value set to 99.5%.

- Crystal yield ($Y_c, \%$) is the mass fraction of API recovered in the product stream relative to that in the feed. For the continuous crystallization process, the yield:

$$Y_c = (M_{API,6} / M_{API,1}) \times 100 \quad (27)$$

For batch crystallization, the yield is defined over $N_b$ batches and calculated as:

$$Y_c = \Sigma^{N_b}_{b=1} M^b_{API,8} / (N_b M^b_{API,1}) \quad (28)$$

Crystal yield is also constrained, with a minimum value of 90% imposed for both the systems.

# CASE STUDIES

To understand the trade-offs between crystal yield and material consumption, a BOO-CAMPD formulation is constructed to simultaneously minimize the PMI and maximize the yield. It is solved using the $\epsilon$-constraint method [16], reformulating a series of single level optimization problems, each maximizing crystal yield subject to a specified upper bound ($\epsilon_{PMI}$) on PMI. The formulation is implemented in gPROMS Process, version 2023.1.0.

The optimization problem is solved using OAREAP, the implementation of the outer approximation algorithm [17] in gPROMS. To increase the likelihood of finding the global solution, the NLP primal subproblems are solved using a multi-start strategy, with 16 initial guesses, and the NLPMSO local solver.

## Continuous Cooling Crystallization – Case 1

The continuous cooling crystallization of mefenamic acid (MA), with toluic acid (TA) as an impurity is

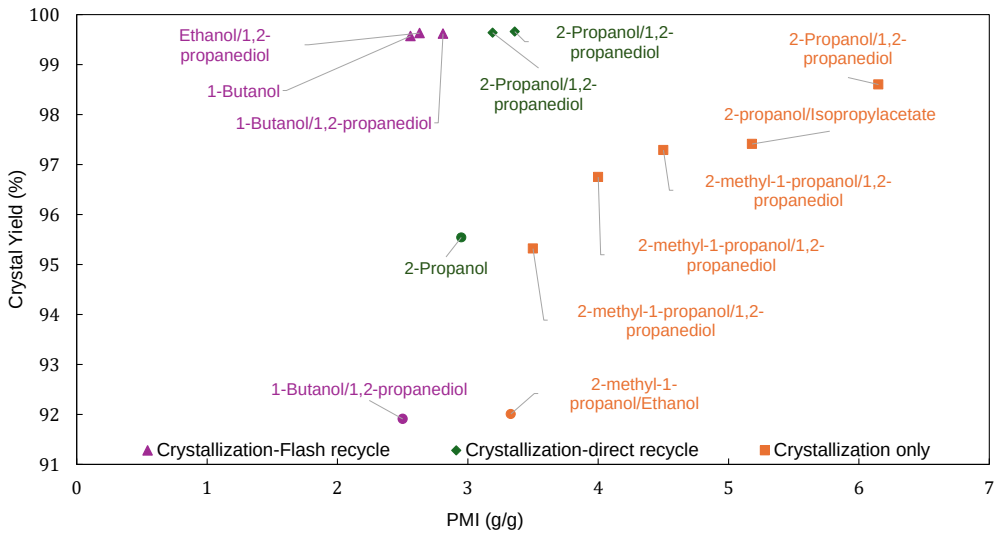

**Figure 3:** Pareto-optimal solutions for continuous crystallization of mefenamic acid, showing the optimal solvent/solvent pairs obtained for different cases.

investigated. Since all analyses are performed on relative basis, stream 1 is assigned a total molar flow of 1 mol/s, with an impurity to API weight ratio of $1:30$. The identity and composition of the binary solvent mixture, and the process operating conditions, are optimized in an integrated manner. The decision variables, their bounds, and the set of $15$ candidate solvents are shown in Table 1. The candidates are selected based on the availability of the required SAFT-$\gamma$ Mie interaction parameters [18]. The optimization problem is solved for three configurations: crystallization with direct recycle, crystallization with flash recycle, and stand-alone crystallization. For all cases, the minimum allowable PMI is fixed at $2.5$ g/g, to avoid the formation of highly viscous slurries. Upper bound on PMI is varied to generate multiple instances of the $\epsilon$-constraint formulation for maximizing crystal yield.

**Table 1**: Case 1: decision variables and bounds

| Variables | Range |
|---|---|
| $y_{q,s}$ | {0, 1} |
| $F_2, F_3$(moles/s) | [0, 1000] |
| $T_4, T_7$(K) | [290, 360] |
| $T_{flash}$ | [290, 420] |
| $\alpha_p$ | [0.2, 0.9] |
| $S$ | {water, acetic acid, cyclohexanone, acetone, ethanol, methanol, butanol, pentanol, 2-propanol, 1, 2-propanediol, 2-methyl-1-propanol, ethyl acetate, butyl acetate, isobutyl acetate, isopropyl acetate} |

The $\epsilon_{PMI}$ values are varied between the PMI at the solution of the minimization of PMI solution and the PMI at maximum yield. For stand-alone crystallization (crystallization only in Figure 3) case, $\epsilon_{PMI}$ values are set at intervals of $0.5$ between these bounds. For both recycling cases, $\epsilon_{PMI}$ values are set with an increment of $0.2$. The Pareto-optimal solutions for the three configurations are compared in Figure 3, where the optimal solvent(s) corresponding to each solution are also reported along with the associated PMI and yield values. For certain solutions, only one solvent is reported as the optimal flow rate of the second solvent is zero, implying that a pure-solvent is optimal at those conditions. The circled points denote the solutions corresponding to the minimum PMI.

For most solutions, the temperature range attains its maximum value ($T_4 = 360$ K, $T_7 = 290$ K), reflecting the increased solubility range needed to enhance API recovery. Further, the purge ratio ($\alpha_p$) is driven to lower bound of $0.2$ corresponding to the maximum allowable recycle to the crystallizer.

As expected, increasing the PMI results in higher solvent usage and process yield. Incorporating a recycle stream retains API within the process and reduces the fresh solvent demand, thereby enhancing crystal yield without proportionately increasing PMI. This is seen as a narrower range of PMI values on the Pareto front and a decrease in the number of Pareto-optimal solutions. The range of PMI values is narrowest with the use of flash drum as this reduces the fresh solvent requirement.

## Batch Cooling Crystallization – Case 2

Batch cooling crystallization of paracetamol with metacetamol and acetanilide as impurities is studied. The feed contains $16.5$ g of paracetamol, corresponding to the laboratory scale to which this process is based, with an impurity to API weight ratio of $1:30$ for both impurities. The design objective is to determine the optimal solvent,

solvent mass, and process conditions that maximize the crystal yield while minimizing PMI. The decision variables and the variable bounds are detailed in Table 2. The details of the SAFT-$\gamma$ Mie model used for paracetamol is given in the supplementary material.

The crystallization process is examined over $N_b = 20$ batches, with overall PMI constrained to a lower bound of 2.2 g/g. Multiple $\epsilon$-constraint optimization instances are generated by varying the upper bound on PMI to maximize crystal yield. The resulting BOO-CAMPD optimal solutions are presented in Figure 4. Three Pareto-optimal solutions are shown as points with $b = 1, \ldots, 20$. Ethanol yields the minimum overall PMI, while isopropyl acetate yields the maximum crystal yield. The range of operating temperatures is maximized in all cases ($T_1 = 343$ K, $T_2 = 263$ K). Similar to the continuous crystallization case, a narrow Pareto front is observed for the batch crystallization process.

**Table 2**: Case 2: decision variables and bounds

| Variables | Range |
|---|---|
| $y_{q,s}$ | {0, 1} |
| $M_{s1,1}$ (g) | [0, 1000] |
| $T_1, T_2$(K) | [263, 343] |
| $\alpha_{evap}$ | [0, 0.8] |
| $\alpha_h, \alpha_w, \alpha_c$ | 0.25, 0.5, 0.1 |
| $S$ | {water, acetic acid, acetone, ethanol, methanol, butanol, pentanol, 2-propanol, 1, 2-propanediol, 2-methyl-1-propanol, ethyl acetate, butyl acetate, isobutyl acetate, isopropyl acetate} |

The variation of PMI and crystal yield with the number of batches is also examined in Figure 4. As the Pareto-optimal solutions transition from minimum PMI (ethanol) to maximum yield (isopropyl acetate), the number of batches required to reach steady state decreases. In the case of isopropyl acetate, the changes in both PMI and yield with batch number are negligible. This behaviour arises because a large amount of solvent is used in the first batch, leading to maximum product recovery during crystallization. Consequently, very little material is available for recycle, thereby leading to minimal variation across batches. In other cases, the introduction of recycling leads to simultaneous improvement in crystal yield and PMI. Overall, the Pareto front moves closer to the utopia point as $b$ increases.

## CONCLUSIONS

We have presented a systematic methodology for the identification of optimal solvent/solvent mixtures, and process conditions for integrated crystallization and solvent/API recovery processes. A general CAMPD framework was formulated to design the crystallization processes and was applied to a continuous crystallization process for mefenamic acid and a batch crystallization process for paracetamol. Both processes incorporate solvent and API recovery and recycle. The process models were based on rigorous thermodynamics and the imposition of a number of thermodynamic constraints. The results have demonstrated the potential benefits of solvent recycling. This is reflected by a narrowing of the Pareto front upon the introduction of a recycle stream in the continuous case, indicating that improvements in crystal yield can be achieved with only marginal increases in PMI. In the batch case, this is seen as the Pareto front moves closer to the utopia after a small number of batches.

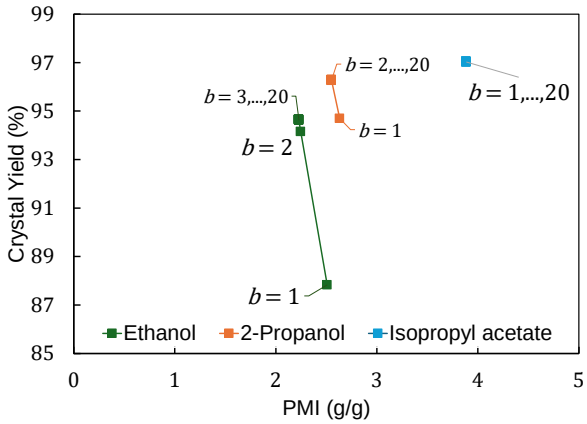

**Figure 4:** Pareto-optimal solutions obtained for paracetamol batch crystallization, showing the variation in PMI and crystal yield as a function of batch cycle $b$.

These results confirm that low-PMI operation can be realized while maintaining high levels of product recovery. Despite the sustainability advantages of recycling, the case studies also indicate that solvent selection plays a critical role and recycle may offer limited benefits for certain solvents. Integrating energy consumption into the multi-objective optimization framework will enable a more comprehensive sustainability assessment and facilitate the identification of solvent–process combinations that balance material efficiency with energy efficiency.

## ABSTRACT

This work aims to systematically generate intensified process designs by integrating reinforcement learning (RL)-driven process synthesis and phenomena-based modeling via Generalized Modular Framework (GMF). Rather than considering flowsheet synthesis with conventional unit-operations, GMF utilizes fundamental building blocks, also known as mass and heat exchange modules, to describe the physiochemical phenomena and to enhance novel process discovery. At its core are driving forces which characterize the mass transfer feasibility based on the total change in Gibbs free energy of the system. RL is integrated with this phenomena-based modeling strategy to drive flowsheet generation by exploring much of the total action space and minimizing pre-postulation of stream connections. All possible inlets, outlets, and interconnections between modules are contained in a stream matrix. Deep Q-Network is used as the RL agent, which contains a multi-layer convolution neural network followed by a multi-layer feedforward neural network. This network computes q values for each possible stream connection contained in the stream matrix and determines an optimal action from the maximum q-value (e.g., varying the stream interconnections). New designs can thus be generated and iteratively improved. This approach is demonstrated using two case studies: (1) binary separation of benzene and toluene, and (2) membrane-assisted reaction for methanol production.

**Keywords**: Process Intensification, Machine Learning, Optimization, Process Synthesis, Process Design

## 1. INTRODUCTION

With the demand for sustainable chemical production rising, novel processes are more pertinent now than ever before. These technologies should simultaneously improve cost efficiency, energy consumption, and environmental outlook. An emerging process design technique known as process intensification is a promising innovation in the chemical sector [1-2]. It is capable of significant improvements versus conventional designs by intensifying physiochemical fundamentals to overcome equilibrium limitations, often leading to equipment featuring multifunctional tasks. Representative process intensification examples are reactive distillation, membrane reactors, dividing wall columns, etc. Despite these advantages, there are limited examples of intensified systems deployed in industry. This is due to the high complexity for the conceptual process design of these units and their integration with existing processes/plants [3].

Recent research has been investigating reinforcement learning (RL) as a tool to drive process synthesis to address computational complexity associated with traditional approaches using mixed-integer nonlinear programming (MINLP) [4-7]. The RL-based methods typically start with a pool of unit operations in which connections between each can be defined using an inlet-outlet stream matrix, graphical representation, etc. without explicit postulation of a superstructure. The RL agent will

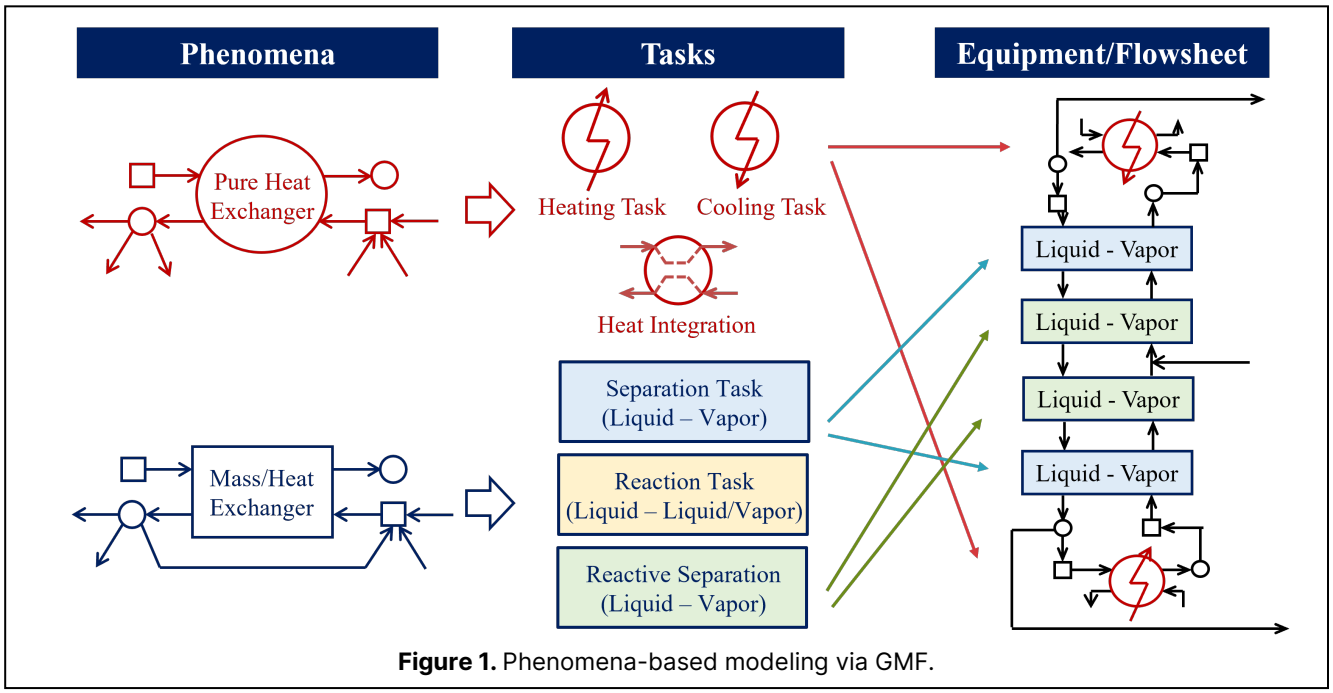

**Figure 1.** Phenomena-based modeling via GMF.

explore the design space and make decisions on e.g., changing unit operation selections or stream connections, thus generating new process designs.

This work aims to extend RL-driven process synthesis towards systematic process intensification. An integrated framework is presented which augments phenomena-based process modelling though the Generalized Modular Framework (GMF) and automated flowsheet generation through RL's exploration capabilities. The remainder of this paper is organized as follows: Section 2 introduces the RL-GMF methodology for process intensification synthesis. Section 3 showcases the proposed approach on two representative case studies including benzene/toluene binary separation and $CO_2$ to methanol production via membrane-assisted reaction. Section 4 concludes this paper with key findings and ongoing work.

## 2. RL-DRIVEN PROCESS INTENSIFICATION SYNTHESIS

### 2.1. Overview of Generalized Modular Framework

The Generalized Modular Framework is a phenomena-based modeling strategy which, rather than considering conventional chemical processing equipment, considers two fundamental building blocks describing general physiochemical phenomena [8]. As shown in Fig. 1, these phenomena building blocks include: (1) a pure heat exchange module (HE) and (2) a mass/heat exchange module (MH). The pure heat exchange module acts as a heat exchanger where the process stream can be heated, cooled, or utilized in heat integration. The mass/heat exchange module can represent any of the following tasks: separation, reaction, or reactive separation. These tasks can then be synergistically combined to model conventional/intensified units or flowsheets.

The core of GMF is its Gibbs-based driving forces which enforce the total Gibbs free energy of the system to always be decreasing or at zero for feasible mass/heat transfer to occur. While equilibrium is considered, it is not strictly enforced. Eqs. 1-3 present the driving force constraints for reaction/separation systems driven by vapor-liquid equilibrium (VLE), such as distillation-based systems [9]. For these systems, $G1$ defines the net mass transfer direction and $G2$ defines the mass transfer feasibility which is the distance from physical and chemical equilibrium. The product of $G1$ and $G2$ approximates the total change in Gibbs free energy of the system.

$$d(nG)^{tot}_{T,P} \approx G1_i \times G2_i \leq 0 \tag{1}$$

$$G1_i = dn^L_{ei} \approx f^{LO}_e x^{LO}_{ei} - f^{LI}_e x^{LI}_{ei} \tag{2}$$

$$G2_i = \left[\frac{\partial (nG)^{tot}}{d(n^L_{ei})}\right]_{T,P} \approx \ln\left[\frac{\gamma^L_{ei} x^L_{ei} P^{sat,L}_{ei}}{\phi^V_{ei} x^V_{ei} P_{tot}}\right] + \sum_i \sum_k \left[\frac{v_{ik} \Delta G^f_i}{RT^L_e} + v_{ik} \ln\left(\phi^V_{ei} x^V_{ei} P_e\right)\right] \frac{\partial \epsilon_k}{\partial n^L_{ei}} \tag{3}$$

Eqs. 4-5 give the driving force constraints for membrane-assisted reaction/separation systems [10]. $\mu^V_i$ in Eq. 4 is the chemical potential in the reaction zone and is determined from the mass transfer across the membrane calculated by Eq. 5. The product of the chemical potential and the change in material approximates the total change in Gibbs free energy for the reaction zone.

$$d(nG)^{tot}_{T,P} = \sum_i \mu^V_i dn^V_i \leq 0 \tag{4}$$

$$J_i = \lambda_i A(\mu_i^M - \mu_i^V) \quad (5)$$

The GMF process synthesis model is built with a physical model, structural model, and objective function. The physical model specifies a set of physical and/or chemical constraints of the system. These are broken down into: (1) mass balances, (2) energy balances, (3) thermodynamic properties, (4) phase defining, (5) driving forces, etc. Thermodynamic properties can be defined through any given thermodynamic model and phase defining to ensure that liquid and vapor streams are accurately represented. The structural model represents the existence (or not) of modules and streams along with the interconnectivity of the system, defined through binary variables. Mixers are placed before the module inlet stream, and splitters are placed after the module outlet stream. These allow for interconnecting streams between modules. The objective function can be defined to maximize or minimize any desired performance metric.

## 2.2. RL-GMF Methodology

The RL-driven process synthesis algorithm applied in this work is built on that developed by Wang et al. [5] for unit operation-based process design. Tian et al. [11] presented a follow-up work to accelerate the RL design search. This work introduces the RL-GMF process intensification synthesis strategy, as shown stepwise in Fig. 2.

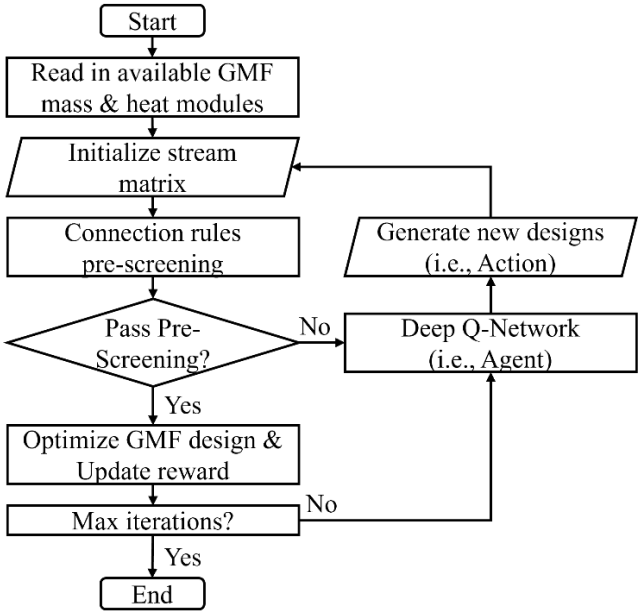

**Figure 2.** RL-GMF algorithm for process intensification synthesis.

### 2.2.1 Stream Matrix Initialization

The methodology starts off by reading in the available GMF MH and HE modules where the maximum number of available modules are user defined. Compared to our prior work for GMF process intensification synthesis using mixed-integer nonlinear optimization (MINLP) [8-9], the binary variables are redefined as parameters in RL and used to construct an inlet-outlet stream matrix. For example, the matrix for a two MH module system is shown below in Table 1. The rows correlate to inlets and the columns correlate to outlets. 18 binary parameters are present, generating a 6×3 matrix.

**Table 1.** Stream matrix representation: An example of 2 MH modules.

| | **Liquid Outlets** | | |
|---|---|---|---|
| **Liquid Inlets** | $y^{IP,L}$ | $y_1^{LP}$ | $y_2^{LP}$ |
| | $y_1^{IL}$ | $y_{1,1}^{LL}$ | $y_{2,1}^{LL}$ |
| | $y_2^{IL}$ | $y_{1,2}^{LL}$ | $y_{2,2}^{LL}$ |
| | **Vapor Outlets** | | |
| **Vapor Inlets** | $y^{IP,V}$ | $y_1^{VP}$ | $y_2^{VP}$ |
| | $y_1^{IV}$ | $y_{1,1}^{VV}$ | $y_{2,1}^{VV}$ |
| | $y_2^{IV}$ | $y_{1,2}^{VV}$ | $y_{2,2}^{VV}$ |

### 2.2.2 Connection Rules Pre-Screening

As per Fig. 2, after the stream matrix gets initialized, it is sent to a series of pre-screening checks to ensure that the constructed flowsheet satisfies the most basic requirements on connectivity. This helps to reduce computational time by completely skipping the GMF modelling of any nonsensical solution generated by RL. Examples of these checks include:

- There exists at least one feed stream connection to the system.
- There exists at least one product stream connection from the system.
- There is at least one liquid inlet and one vapor outlet for heater modules to exist.
- There is at least one vapor inlet and one liquid outlet for cooler modules to exist.
- Inlet and outlet streams from both sides of each module must exist to enforce module existence.

The last connection rule requires that there should be vapor and liquid inlets/outlets or permeate and retentate inlets/outlets on both sides for VLE-driven systems or membrane assisted reaction-driven systems respectively. Failure of any of these checks will assign either the minimum pre-score or incur a penalty to the pre-score, resulting in a failed pre-screening and negative reward.

### 2.2.3. GMF Optimization & Reward Update

Upon successfully passing pre-screening, the associated stream matrix will be translated to a GMF phenomena-based flowsheet for optimization. If there is no inlet or no outlet streams to/from a module, the module is treated as non-existing. A reward is generated based on the status of the optimizer and the value of the objective function. If the optimizer fails to converge (e.g., infeasible

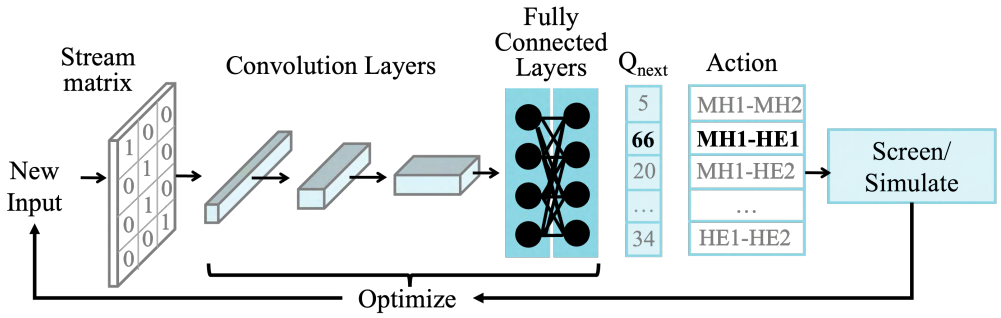

**Figure 3.** RL agent with Deep Q-Network.

solution), the minimum reward is assigned. If it successfully converges to a solution, a reward value is calculated based on e.g. objective value and process variables.

#### 2.2.4. Deep Q-Network and Generation of New Design

Upon failing pre-screening or passing through GMF optimization, the current state and reward is sent to the DQN [5]. This step uses the agent in RL to learn from given conditions and intelligently make changes to the stream matrix to drive the algorithm towards improved designs. As illustrated in Fig. 3, the DQN is comprised of a three-layer one-dimensional convolution neural (CNN) network followed by a two-layer feed forward neural network (FNN). The state is a two-dimensional matrix of the batch number and flattened stream matrix (e.g., Table 1). This is used as the input to the CNN where key features are extracted, reshaped, and subsequently processed through the fully connected layers which determine the q-values for each row. An optimal decision is made where the index of the maximum q-value in each row takes a value of one. To open the possibility for every index in a single row to take a value of zero, an additional column is generated in this step to act as a placeholder for the optimal choice. These decisions translate to the switching of module inter-connections, elimination of modules, and adjustment of inlet/product streams. In this way, a new design can be generated with a unique inlet-outlet stream matrix and is then sent back to the workflow as shown in Fig. 2.

This integration of RL and GMF allows for automated flowsheet synthesis, scanning much of the total action space. Through the reduction of flowsheet pre-postulation, enhanced discovery of innovative process designs and non-intuitive flowsheets can be observed. Additionally, GMF is inherently a MINLP problem where solution convergence is time consuming and may be infeasible without good initial guesses. In this proposed approach, RL takes care of parameterizing the GMF binary variables, and the problem can then be solved as a nonlinear problem (NLP) with enhanced solution convergence. This framework is built in Python version 3.8.20 using TensorFlow for RL development, IPOPT as the NLP solver for Case Study 1 (VLE-driven GMF), and BARON as the NLP solver for Case Study 2 (membrane reaction-driven GMF).

## 3. CASE STUDIES

This section discusses two case studies performed to test the RL-GMF framework. These are representative of the two modelling trajectories of GMF with VLE-driven systems tested through the binary separation of benzene and toluene and membrane assisted reaction-driven systems tested with modular methanol production.

### 3.1. Binary Separation of Benzene/Toluene

#### 3.1.1. Problem Statement

As a first motivating example, this case study describes a conventional separation scheme where a high purity product is to be obtained for at least 99% benzene from a liquid benzene/toluene mixture feed. Ideal vapor-liquid equilibrium conditions are used in the phenomena-based modelling with purely separation considered, neglecting the need for a reactive term in the driving force (Eq. 3). Table 2 shows the feed conditions of this scheme adopted from Proios and Pistikopoulos [12]. The GMF objective function is formulated to maximize the mole fraction of benzene from the column distillate (Eq. 6). The reward for RL is defined as the difference between the distillate rate and scaled reflux ratio (Eq. 7), which was the objective function used in [12].

$$\max \left(x_2^{VO,benzene}\right) \tag{6}$$

$$\text{reward} = f_{2,p_{liq}}^{CP} - 50\frac{f_{2,2}^{CL}}{f_{2,p_{liq}}^{CP}} \tag{7}$$

**Table 2.** Feed Stream Conditions for VLE-driven System

| Liquid Feed | |
|---|---|
| Flowrate (kmol/hr) | 360.00 |
| Temperature (K) | 359.89 |
| Pressure (bar) | 1.01 |
| Benzene | 0.70 |
| Toluene | 0.30 |

Proios and Pistikopoulos [12] solved this GMF process synthesis problem via MINLP. The resulting optimal design used two MH modules and two HE modules shown in Fig. 4. It featured a compact representation of a trayed distillation column. In what follows, we number the MH modules in ascending order. Namely, the MH module at the bottom is numbered as MH 1, the existence or not defined by binary parameter $y_1$. The MH module at the top is numbered as MH 2, the existence or not defined by binary parameter $y_2$. Each MH module has two associated HE modules. For the optimal MINLP solution shown in Fig. 4, the HE module for MH 1 acts as the reboiler. The HE module for MH 2 acts as the condenser. MH 1 defines the stripping section capturing separation below the feed stage. MH 2 defines the rectifying section capturing separation above the feed stage.

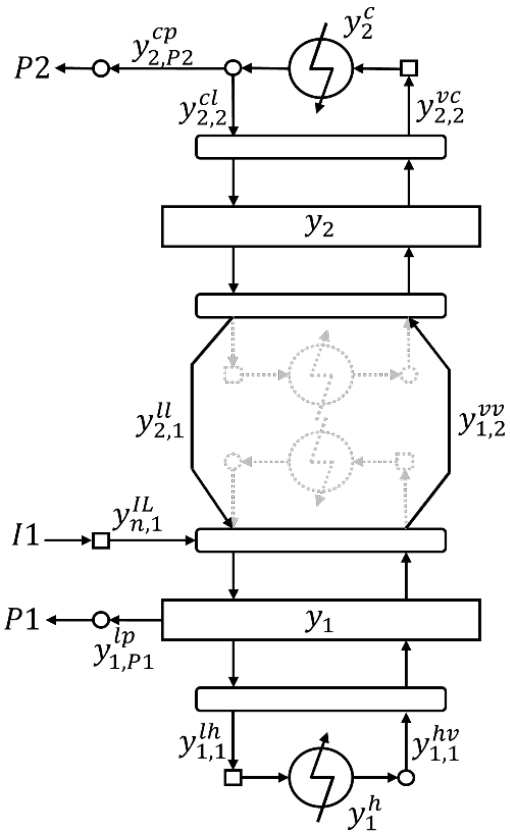

**Figure 4.** GMF representation of trayed distillation column (reproduced from [12]).

### 3.1.2. RL-GMF Implementation

The goal of this case study is to test if the RL-GMF methodology can successfully generate good design configuration(s) for this binary separation problem. A maximum of two mass heat exchange modules and four pure heat exchange modules are provided to the RL-GMF process synthesis. There are forty-two total binary variables associated with the design. All inlets, outlets, and interconnections are available for RL to explore resulting in a stream matrix of size 16×3. Note that for the stream matrix shown in Table 1, the current RL algorithm only allows one index in each row of the stream matrix to take a value of one. If it is possible that multiple indices in a single row would take the value of one, the stream matrix can be restructured.

Over 100, 000 episodes, eight unique feasible solutions were found as shown in Fig. 5. The total run time for 100, 000 episodes is 146 minutes. Out of this total run time, 139 minutes are spent on GMF optimization to evaluate the more than 2, 700 configurations which have passed the pre-screening step.

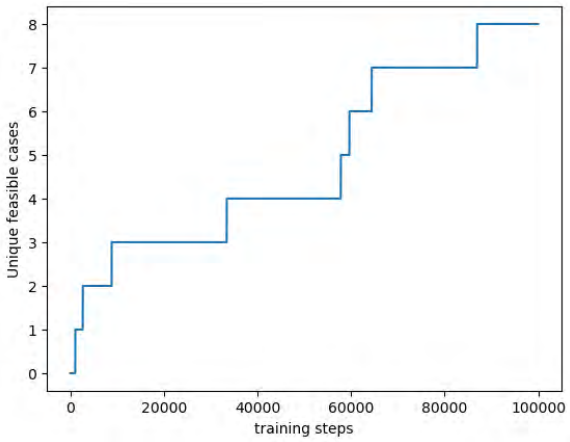

**Figure 5.** Benzene/toluene binary separation: Unique feasible solutions during RL-GMF training.

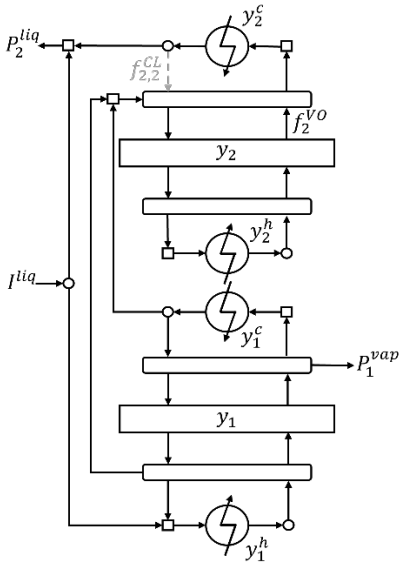

**Figure 6.** Benzene/toluene binary separation: RL-GMF design with the highest reward value.

The highest reward value achieved is 3120, the design of which is shown in Fig. 6. Using the trayed distillation column structure as base case (Fig. 4), its reward value corresponds to 2094. From optimization point of view, the RL algorithm successfully identifies a better

solution with non-intuitive design structure. However, from physical point of view, we notice that part of the initial feed stream ($I^{liq}$) is directly mixed with the product stream ($P_2^{liq}$). This happens as the problem statement only poses constraint for the purity of benzene vapor outlet from module 2 ($f_2^{VO}$). Additionally, the choice of the reward function (Eq. 3) strives to maximize the flowrate of the distillate product ($P_2^{liq}$) and minimize that of the reflux ($f_{2,2}^{CL}$), enforcing nonexistence of the reflux stream. This altogether drives the RL algorithm to identify Fig. 6 as the best solution.

The 2, 700 GMF configurations generated by RL do not include the base case configuration presented in Fig. 4. We hypothesize that this may be due to the large combinatorial design space with the forty-two total binary variables. To test this, a simplified case study is run with the HE module connections predefined and the MH connections open for RL to explore. This leads to a total of eighteen binary parameters. This simplified scenario is able to identify twelve unique feasible design structures over only 10, 000 episodes, and the base case configuration is generated on the 2, 308$^{th}$ episode. The increase from eighteen to forty-two parameters significantly adds to the design space (especially the infeasible design space), requiring longer run times to identify good design solutions.

## 3.2. Membrane-Assisted Methanol Production

### 3.2.1. Problem Statement

This case study investigates the design of a water selective membrane-assisted reaction scheme to produce methanol from $CO_2$ direct hydrogenation [13]. Kinetic models are adopted from Van den Bussche and Froment [14] using commercial catalyst $Cu/ZnO/Al_2O_3$. This kinetic model considers stoichiometric methanol production (Eq. 8) with reverse water gas shift (rWGS) as a side reaction (Eq. 9). The reactions take place in gas phase. An adiabatic reactor is considered with pressure drop negligible per the low flowrate. Feed conditions are listed in Table 3 at pilot scale. A total of ten membrane tubes are used with water permeance as $10^{-4}$ mol/s/m$^2$/Pa. Note that this permeance value is adopted higher than the reported values to more clearly showcase the impact of the membrane. A parametric study has been performed to quantify the impact of water permeance from $10^{-6}$ – $10^{-4}$ mol/s/m2/Pa but is not included here due to the page limit. The objective function for GMF optimization is to maximize $CO_2$ conversion. The reward function for RL is adopted as $10^4$ times of the $CO_2$ conversion, to drive the design toward higher conversion.

$$CO_2 + 3H_2 \rightleftharpoons CH_3OH + H_2O \quad (8)$$

$$CO_2 + H_2 \rightleftharpoons CO + H_2O \quad (9)$$

**Table 3.** Feed conditions for methanol production.

| | Feed | Sweep Gas |
|---|---|---|
| Flowrate (kmol/hr) | 44.5 | 2.5 |
| Temperature (K) | 483.15 | 483.15 |
| Pressure (bar) | 77.9 | 1.00 |
| $CO_2$ | 0.1850 | 0 |
| $H_2$ | 0.7561 | 0 |
| $CH_3OH$ | 0.0017 | 0 |
| CO | 0.0567 | 0 |
| $H_2O$ | 0.0004 | 0 |
| $N_2$ | 0 | 1 |

### 3.2.2. RL-GMF Implementation

A maximum of three MH modules are allowed for this study, which generates a stream matrix with thirty-two parameters of shape 8×4. The length of each MH module is set to 0.5 m. This model is run through the RL algorithm over 30, 000 episodes finding three unique feasible designs as shown in Fig. 7. The total computational time is 20 minutes.

Fig. 8(1-3) depict RL-GMF design solutions. Fig. 8(1) features the use of a single MH module with a $CO_2$ conversion of 9.55%. Fig. 8(2-3) use all three MH modules with $CO_2$ conversions as 26.51% and 26.34% respectively. The sweep gas recycle streams formed in Fig. 8(3) are not physically correct, but often created by the RL algorithm to obtain higher rewards numerically. This is consistent with the observation in our prior work for RL-driven unit operation-based process synthesis [11]. As such, Fig. 8(2) presents the best design solution identified by RL-GMF.

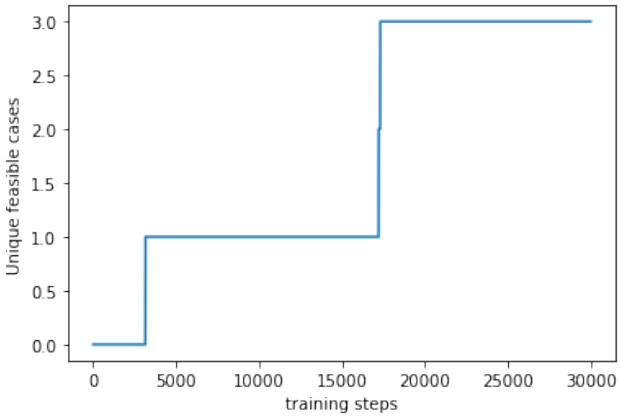

**Figure 7.** Unique feasible solutions during RL-GMF training – membrane assisted reaction-driven model.

The base case design is adopted as a counter-current membrane reactor as that shown in Fig. 8(4). The corresponding $CO_2$ conversion is 17.39%, which is lower than the 26.51% conversion provided by the design in Fig. 8(2). Table 4 compares the reaction rates and membrane permeance flux for the two designs. In the counter-flow

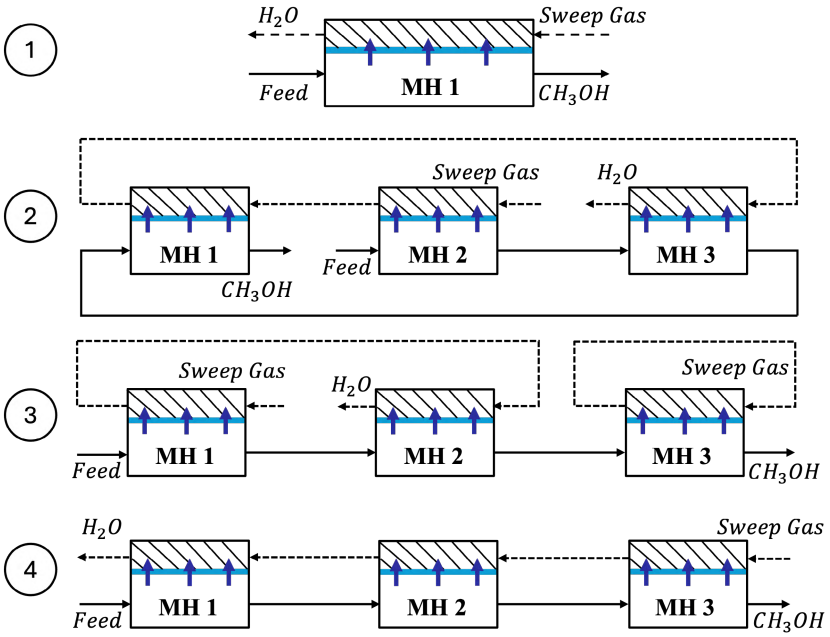

**Figure 8.** Membrane-assisted methanol production: (1-3) Feasible designs from RL-GMF, (4) base case design.

**Table 4.** Comparison of reaction rates and membrane permeance flux.

| | **Reaction Rate (Eq. 8)** Unit: kmol/h/kg catalyst | | **Membrane Permeance Flux (Water)** Unit: kmol/h/m$^2$ | |
|---|---|---|---|---|
| | RL-GMF best design (Fig. 8(2)) | Base case counter-current (Fig. 8(4)) | RL-GMF best design (Fig. 8(2)) | Base case counter-current (Fig. 8(4)) |
| MH 1 | 0.80 | 1.89 | 0.55 | 0.84 |
| MH 2 | 1.89 | 0.52 | 1.00 | 0.35 |
| MH 3 | 2.43 | 0.94 | 1.09 | 0.63 |

structure in Fig. 8(4), MH 2 presents a bottleneck with small driving forces for both reaction and membrane separation. However, the more non-intuitive design structure in Fig. 8(2) successfully debottlenecks this by altering the sequences of feed and sweep gas flowing through the three MH modules.

## 4. CONCLUDING REMARKS

This paper introduced the use of reinforcement learning and phenomena-based modeling to enhance the discovery of novel process designs. Problem complexity was reduced from MINLP to NLP with the parameterization of GMF binary variables through the RL stream matrices. Two case studies were presented to demonstrate the RL-GMF algorithm, including benzene/toluene binary separation and membrane-assisted methanol production. For both case studies, the RL-GMF algorithm was able to identify non-intuitive process design solutions which provided higher rewards than the base case designs. The large infeasible design space still presented challenges for large-scale process synthesis. Future work should address this to reduce the run time and drive more efficient solution generation. Ongoing efforts are incorporating masking methods to RL and investigating classification neural networks to rule out the infeasible designs.

## ABSTRACT

Batch production scheduling of resources to meet fluctuating product demand is a critical topic in the process industry. Existing optimisation approaches, based on heuristic and exact methods, trade off solution optimality and scalability to large problems. In this work, we investigate deep reinforcement learning as a powerful alternative in order to *learn* heuristics for batch scheduling. We formulate the batch scheduling problem as a Markov decision process operating on a state-task network representation encoded using graph neural networks, capturing relevant structural inductive biases. We propose a centralised training with decentralised execution architecture, in which agents placed on machines individually choose which tasks to complete using a global view of the network, cooperating towards task schedules that optimise the final production quantity. Preliminary results demonstrate that the proposed end-to-end framework learns to construct task schedules comparable to the optimal solution on small instances unseen during training, exhibiting strong potential for extension to more general graph structures and better scalability.

**Keywords**: Batch Process Scheduling, Reinforcement Learning, Markov Decision Process, Deep-Q Networks, Graph Neural Networks

## INTRODUCTION

Batch scheduling is a critical functionality in the supply chain of process industries that deals with the allocation of limited resources over time in order to meet market demand for products that follow a batch recipe (Harjunkoski et al., 2010). As demand for diverse products continues to rise in the chemical industries, developing adaptive batch process operations constitutes a fundamental problem in these sectors (Yoo et al., 2021). Particularly, the scheduling of batch processes is a critical factor in process operations and plays a vital role in optimising production system performance (Wu and Maravelias, 2021).

While batch scheduling problems can be effectively tackled by existing exact and heuristic methods, learning-based AI methods, and in particular Reinforcement Learning (RL), provide a powerful alternative. RL is capable of solving complex, large-scale problems in dynamic environments and discovering complex scheduling policies beyond human intuition (Dogru et al., 2024; Johnn and Charitopoulos, 2025). RL algorithms such as Deep Q-Networks (DQN) and Proximal Policy Optimization (PPO) can be used to train an agent to learn the optimal decision-making policy through trial-and-error interactions with an environment that provides feedback. Given that a natural framing of batch scheduling is through State-Task Networks (STNs), neural architectures explicitly designed to operate on graphs are highly suitable. The combination of Graph Neural Network (GNN) architectures and RL algorithms can yield a powerful approach capable of solving complex graph optimisation problems that lack satisfactory traditional algorithms (Darvariu et al., 2024).

RL has demonstrated strong adaptability and substantial potential for improving industrial-level applications (del Real Torres et al., 2022). The integration of RL into process scheduling has recently garnered emerging attention in the literature. Hameed et al. (2023) developed a PPO framework with a GNN-based scheduler for production planning problems to minimise the production makespan. Zhang et al. (2023) introduced a DQN framework with multi-agent graphs for a job-shop scheduling

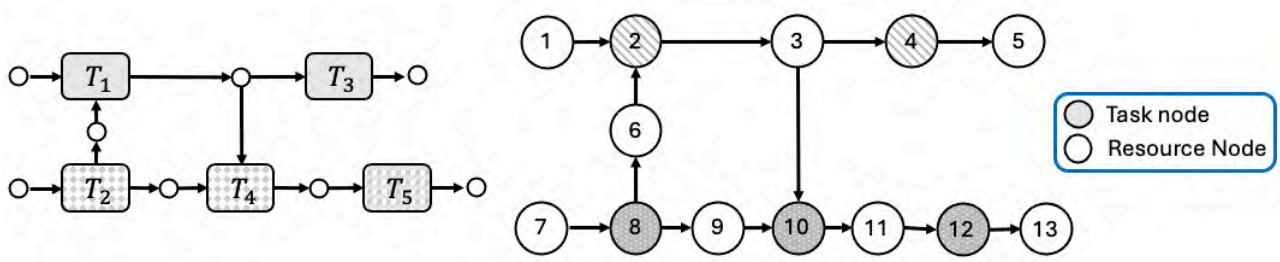

**Figure 1.** The classic STN model (left) can be converted into the directed graph structure (right) with nodes characterised by different features. Tasks TA1 and TA3, converted into nodes 2 and 4, are assigned to machine 1. Tasks TA2, TA4, TA5, converted to nodes 8, 10, 12 are controlled by machine 2. During the scheduling proces, the initial resources stored at node 1 and 7 are converted into intermediate nodes (3, 6, 9, 11) via different production processes, and eventually converted into final products as nodes 5 and 13.

process, where the job and machine-associated agents collaboratively work on job allocation, sequencing and routing. More recently, Rangel-Martinez and Ricardez-Sandoval (2025) proposed a PPO framework for multi-product batch scheduling processes, in which a hybrid agent handles multiple discrete and continuous decisions to build online schedules for STNs under uncertainty.

In this work, we propose an end-to-end DQN framework with a GNN encoder to address the batch process scheduling problem. We adopt the STN formalism by representing each production task as a node and each material flow as a link. The key differentiating characteristic of our work is the use of a multi-agent decomposition to manage the extensive decision space that arises when the problem is considered from a global perspective, enhancing scalability and computational tractability. Our approach obtains solutions close to optimality on problem instances unseen during training, significantly outperforms a single-agent baseline using joint actions, and offers strong potential for scalability and generalisability.

## PROBLEM FORMULATION

### Batch Process Scheduling Problem

STN graphs are a common way to visualise and model the batch scheduling problem (Méndez et al, . 2006). In this work, we reformulate classic STNs as directed graph structures, as shown in Figure 1. We preserve the graph topology and transform all task and resource components into indexed nodes distinguished by their node features (categories).

In this problem setting, we are given a set of machines that collaboratively schedule tasks to produce final products within a fixed time horizon. Each machine can be assigned more than one task over the time horizon. However, machines can process at most one task at any given time, which transforms the input resource(s) into output resource(s). When a task node is activated at a specific non-final time step, we assume it consumes exactly one unit of material from each precedent resource node at the start of this step, and produces exactly one unit of intermediate (or final) resource to each sequential resource node at the end of step. We assume only one type of material is stored at each resource node, and only one type of action is performed at a task node. A task node is available to process when all required input resource nodes have sufficient inventory levels and the time horizon has not yet been reached. Each task takes exactly one fixed time step to finish. Multiple machines collaboratively schedule task execution, with each machine processing at most one task at any given time to achieve maximum final production output.

### Mixed-Integer Linear Programming Model

We adapt the STN formulation introduced by Kondili et al. (1993) and present a mixed-integer linear programming (MILP) model for the basic batch scheduling problem compatible with the directed graph representation given in Figure 1.

Let $T$ denote the discrete set of time steps $\{0, 1, 2, \dots, T_{max}\}$. $K$ is the set of tasks and $L$ is the set of resource nodes, which can be partitioned into initial ($L_{init}$), intermediate ($L_{inter}$), and final product nodes ($L_{final}$). The set of machines is denoted $M$, where each machine $m \in M$ has a predefined set of tasks $K_m \subseteq K$ to execute. The binary variable $x_{k,t}$ takes the value 1 if task $k$ is being executed at the start of time step $t$. The continuous variable $J_{l,t} \geq 0$ represents the inventory level of resource $l \in L$ at the start of time $t$. The objective is to maximise the total production of final products at the end of the time horizon. The MILP formulation is presented below:

$$\max \sum_{l \in L_{final}} J_{l,T_{max}} \quad (1)$$

$$\sum_{k \in K_m} x_{k,t} \leq 1, \forall m \in M, \forall t \in T \quad (2)$$

$$V_{l,t+1} = V_{l,t} + \sum_{k \in K_{BN}} P_{k,l} x_{k,t} - \sum_{k \in K_{FN}} C_{k,l} x_{k,t}, \forall l \in L \quad (3)$$

$$V_{l,0} = I_{l,0}, \forall k \in L_{init} \quad (4)$$

$$V_{l,t} \geq \sum_{k \in K_{FN}} C_{k,l} x_{k,t}, \forall l \in L \backslash L_{final} \quad (5)$$

$$V_{min} \leq V_{l,t} \leq V_{max}, \forall l \in L, \forall t \in T \quad (6)$$

Constraint (2) restricts each machine to choose no more than one task per step. Constraint (3) ensures flow conservation between task and resource nodes, enforcing and updating the inventory balance. Each resource node $l$ is updated based on its precedent input task nodes producing resources and the subsequent output task nodes that consume it. Constraint (4) specifies the case in which all initial resource nodes start with fixed inventory levels prior to any task execution. Constraints (5) and (6) ensure that any task can only be selected if the required input resources are available and that storage limits are respected.

# RL METHODOLOGY

## Multi-agent Markov Decision Process

RL is a methodology in which an agent iteratively improves a decision-making policy through trial-and-error interactions with a dynamic environment (Sutton and Barto, 2018). The agent's objective is to map states to actions such as to maximise expected long-term rewards. Markov Decision Processes (MDP) provide the underlying model of the sequential decision-making task and can be solved using a variety of RL techniques.

An MDP is defined as a tuple $(S, A, P, R)$, where a state $s_t \in S$ represents a complete environment snapshot at a specific time step. At each non-terminal state $s_t$, the agent chooses an action $a_t \in A$ from the set of available actions $A(s_t)$ and receives an immediate reward $r_t$ specified by a reward function $R(s_t, a_t)$ for the selected state-action pair at step $t$. The subsequent state $s_{t+1}$ is governed by a transition function $P$ that captures movement from one state to another given an action.

An agent interacts with the environment through episodes, each of which represents a sequential chain of states, actions, and rewards over time. Reward feedback from the environment is incorporated iteratively to refine strategic decisions and train the agent to learn an optimal policy $\pi(a_t|s_t)$ that maximises cumulative future rewards. The state-action value function $Q(s_t, a_t)$ captures the expected reward associated with a given state-action pair under the optimal policy $\pi$. This quantity is also referred to as Q-value.

Multi-agent RL (MARL) extends classic RL by modelling how multiple agents interact within a shared environment and learn strategies to maximise their expected returns. In this setting, each agent's selected actions and the associated expected rewards can be influenced by the actions of all agents. The dynamic of the shared global state evolves by the joint actions of all agents following a Markovian transition function. Through this process, agents are trained to optimise individual or collective rewards, depending on the decision-making context being competitive, collaborative, or hybrid. Concretely, we consider a fully collaborative framing of batch scheduling, which is appropriate as all machines are under the control of a single organisation.

## Deep Q-Learning and Graph Neural Networks

Q-learning is a class of RL algorithms that estimate the state-action value function (Q) using samples of agent experience. Estimates are iteratively refined using the update rule below, where the discount factor $\gamma$ mediates the trade-off between immediate and future rewards:

$$Q^{new}(s,a) \leftarrow Q(s,a) + \alpha(r + \gamma \bullet \max_{a' \in A(s')} Q(s',a') - Q(s,a)) \quad (7)$$

Upon convergence, a greedy policy with respect to the learned Q-function is optimal.

Deep Q-learning (DQN) is a model-free RL approach that uses deep neural networks for scaling to large state and action spaces (Mnih et al. 2015). It incorporates a replay buffer and periodically updated target network. The state-action Q-value $Q(s,a)$ is estimated by the main network, while the maximum Q-value $Q(s',a')$ at the subsequent step is estimated by the target network. The target network parameters are periodically copied from the main network.

Graph Neural Networks (GNNs) are a learning representation designed to operate on graph-structured data (Velickovic, et al 2017). A GNN computes an embedding that captures node and edge features as well as underlying structural regularities. It aggregates information from neighbouring nodes through multiple message-passing layers to derive a higher-dimensional representation for the graph that exhibits desirable properties such as permutation invariance. GNNs can learn representations that achieve strong extrapolation capabilities to feature values and topologies unseen in the training set.

## End-to-end DQN Framework

Our formulation of the batch scheduling problem operates on a directed graph $G = (V, E)$ with $N_n$ nodes and $N_e$ edges, where $V = K \cup L$. In each state, every machine $m \in M$ is responsible for a disjoint subset of task nodes $K_m$. The edges $E$ connect resource nodes to task nodes, representing direct resource supply and production relationships.

We propose a multi-agent MDP framework as an alternative to using a single agent to control all machine nodes simultaneously in order to reduce the dimensionality of the problem. Instead, agents are placed at each machine and asked to individually act in a loop. The full

production schedule is established by the agents taking turns to select tasks given those chosen by the previous agents in the loop. This inner loop is executed once per time step $t$ until the final time step $T_{max}$ is reached.

We obtain a fully observable, finite-horizon, turn-based Markov game (Littman, 1994) with shared rewards. Therefore, we formulate the problem as the tuple $(S, A^{(i)}, P, R)$ containing an *agent-indexed* set of valid actions. The components are defined as follows:

- States: each state at time step $t$ of an MDP episode is denoted $s_t^{(i)} = (G, X_t^{node}, X_t^{edge}, X_t^{global}, J_t, \tau_t)$, with $i$ corresponding to index of the agent whose turn it is to act. $X_t^{node}, X_t^{edge}, X_t^{global}$ are node, edge, and global graph features respectively. Some features are updated as the episode progresses while others remain constant (see Table 2 for details). $J_t$ denotes the set of inventory levels for each resource node at step $t$, and $\tau_t$ denotes whether an agent is the final decision-maker in the agent loop (i.e., if $i = |M|$).
- Actions: at time step $t$, agent $i$ selects a task $a_t^{(i)}$ from the action space $A^{(i)}(s_t^{(i)})$ containing all production tasks available to it, along with an additional no-op action that allows the corresponding machine to stay idle for this step. Action masks are applied that prevent an agent from selecting tasks outside its allocated set $K_m$, and to dynamically filter out infeasible actions due to insufficient input resources.
- Transitions: once an agent has chosen an action $a_t^{(i)}$ that is not no-op, the selected task node is activated. The resource inputs from preceding resource nodes are converted into output resources stored at the sequential resource nodes, yielding $J_{t+1}$. The node, edge, and global features are also updated accordingly. If no-op is chosen, the machine status is set to "idle" for step $t$. Two types of transitions occur depending on the value of $\tau_t$. If $\tau_t = 0$, meaning that this is not the last agent to act at global time step $t$, the turn passes to the next agent. If $\tau_t = 1$, the global time step advances to $t + 1$, and the turn transfers to the first agent. The terminal state $s_{T_{max}}$ is reached and the episode completes when either all time steps are exhausted or the remaining time is insufficient for the minimum batch to process. The terminal state captures the complete production schedule.
- Rewards: at the terminal state, the environment generates a reward based on the production schedule $R(s_t, a_t) = F(s_{T_{max}})$. As specified in (1), this corresponds to the total number of final products at the final time step. All intermediate rewards are 0.

Figure 1 provides a visualisation of a sample process schedule involving 2 machine agents, 5 task nodes, and 7 resource nodes. We treat each machine as an individual agent that controls the execution of task $k$ at each time step $t$, representing the same decision as the binary variables $x_{k,t}$ in the MILP formulation.

A visualisation of the end-to-end framework is presented in Figure 2. To begin with, the state is represented as a graph and encoded by the GNN. The resulting feature vectors are passed to multilayer perceptrons (MLPs) representing the agents' Q-networks. These networks are iteratively updated based on the observed rewards to maximise the total amount of final products produced at the end of the time horizon.

For this work, we apply a centralised training, decentralised execution (CTDE) architecture (Amato, 2024). As mentioned, this is appropriate because all machine agents collaborate on the same graph topology to determine the schedule for a single problem instance. Given each agent will correspond to a different node representation based on the assigned task nodes and global state, parameterising each agent's policy separately is unnecessary. Instead of training $N$ MLPs based on the same graph to yield $N$ different agent policies $\pi_{i \in N}$, we therefore only train one global MLP that estimates the Q-values for the allowed actions. This is achieved by a mask layer after the MLP that is applied such that Q-values are only generated for the allocated task nodes, whereas the infeasible actions are filtered out by the mask. The CTDE framework is advantageous as only a single deep neural network is trained, yielding good computational efficiency and training stability, while still allowing for placing the neural network on every machine in an operational deployment setting.

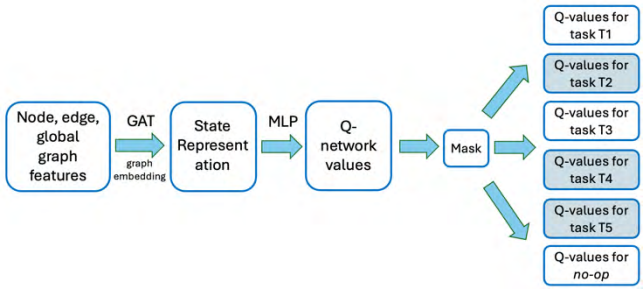

**Figure 2.** Visualisation of our end-to-end training framework with the CTDE architecture. All agents use the same global information and share the GNN encoder and MLP layers. A mask layer filters out disallowed tasks that are not allocated to this agent. In this example, corresponding to Figure 1, agent 1 is acting and therefore tasks T2, T4, and T5 are masked out.

**Table 2:** Node, edge and global features used as input for the graph representation of our end-to-end framework.

| Name | Type | Re-scaled | Static over training | Feature description |
|---|---|---|---|---|
| agent_pinpoint | node | F | F | Indicator of the active agent at this node. Uses one-hot encoding: type 1 - agent is currently acting; type 2 - not acting; type 3 - resource node. |
| decision_status | node | F | F | Indicates the decision status of the agent associated with this node. Uses one-hot encoding: type 1 - currently deciding; type 2 - task nodes already decided; type 3 - task nodes not yet decided; type 4 - resource nodes. |
| node_type | node | F | T | Node category. Uses one-hot encoding: type 1 - task node, type 2 - resource node. |
| agent_allocation | node | T | T | Index of the machine agent ID assigned to a task node (1, 2, ...); 0 for resource nodes. |
| task_node_status | node | F | F | Task occupancy status. Uses one-hot encoding: type 1 - task occupied, type 2 - task idle, type 3 - resource nodes. |
| product_rate | node | F | T | Production rate associated with the node. |
| consume_rate | node | F | T | Consumption rate associated with the node. |
| inventory_level | node | T | F | Normalised inventory level for resource nodes; −1 for task nodes. |
| final_sales_price | node | T | T | Unit profit for each final resource node, 0 otherwise. |
| job_start_time | node | T | F | Job starting time for task node at this step; -1 for resource nodes. |
| job_end_time | node | T | F | Job completion time for task node at step; -1 for resource nodes. |
| current_time | global | T | F | Tracks the current state's time step for an episode. |
| remaining_time | global | T | F | Tracks the remaining time in this episode: $(T_{max} - T_{current}) / T_{max}$. |
| current_agent_id | global | T | F | Tracks the current agent id in one-hot encoding within the agent loop. |
| remaining_agent | global | T | F | Tracks the agent decision status sequence to count how many more agents should act within the agent loop. |
| task_size | global | T | T | Tracks the number of task nodes for this instance. |
| resource_size | global | T | T | Tracks the number of resource nodes for this instance. |
| physical_edges | edge | F | T | Stores node linkage showing consumption (resource to task) or production (task to resource). |

To highlight the benefits of the proposed multi-agent decomposition, a single-agent baseline is also considered in which a DQN agent handles the scheduling of all production tasks. Instead of applying the proposed decomposition, the baseline uses a centralised architecture with a single agent selecting from a combinatorial joint action space as opposed to iterating $M$ times over individual agents. Consequently, the replay buffer records the global state $s_t$ only, together with the joint action tuple $\left(a_t^{(1)}, a_t^{(2)}, \ldots, a_t^{(m)}\right)$ generated by the single DQN agent. For the MLP output layer, rather than assign outputs to individual tasks (layer size $|K|+1$), the baseline model uses an output layer over every task combination of size $\prod_{i \in M}\left(|A^{(i)}|+1\right)$. In the illustrative example in Figure 1, this corresponds to an MLP output dimension of 6 for the multi-agent decomposition framework, and $3 \times 4 = 12$ for the single-agent baseline. A comparative performance analysis is presented in the next section.

## CASE STUDY

### Experiment Setting

We evaluate the proposed end-to-end framework on a range of process scheduling problems modelled as STN graphs, thereby demonstrating its effectiveness across varying problem parameters.

We adapt the batch scheduling problem instance given in Figure 1, with a fixed time horizon consisting of

10 steps for each episode. The graph topology remains fixed while the initial inventory level at each intermediate resource node is uniformly randomly generated from the interval $[0, 5]$. The initial resource nodes are unlimited and the final product quantities are set to zero.

Three distinct sets of training, validation and evaluation instances are generated. The training set is used to update the policy parameters during learning. The validation set is periodically used to quantify the performance of the policy specified by the learned parameters at a particular learning step. Finally, the evaluation set is used for reporting the quality of the best-performing learned model. The training, validation, and evaluation sets contain distinct problem instances.

As a GNN, we opt for the graph attention network (GAT) architecture (Velickovic et al., 2017). Parameters are updated by stochastic gradient descent using the Q-learning loss and the Adam optimiser. Hyperparameter values obtained as a result of hyperparameter tuning and other settings are specified in Table 1 below. The detailed list of GNN input features is given in Table 2.

We train our end-to-end DQN framework using an epsilon-greedy policy to ensure both exploration and exploitation. At evaluation time, a greedy policy is adopted, which always selects the action with the highest estimated Q-value.

We consider the following baselines. To derive an upper bound on performance, we use the MILP formulation in $(1)$-$(6)$ to find the optimal solution for each problem configuration. The MILP model is implemented in Pyomo and solved with the Gurobi optimizer. As a lower bound, we use a uniform random policy that allows a machine to select any task with equal chance. This uses the same time horizon and also benefits from the action masking to filter out disallowed tasks. Lastly, we compare against the centralised single-agent method described in the previous section. This agent uses identical hyperparameters to the proposed method.

**Table 1:** end-to-end framework hyperparameter values.

| Hyperparameter | Value |
|---|---|
| Learning rate | 0.0005 |
| Discount factor $\gamma$ | 1.0 |
| Initial exploration epsilon | 1.0 |
| Final exploration epsilon | 0.1 |
| GAT attention heads | 4 |
| GAT number of layers | 5 |
| GAT hidden dimension | 64 |
| MLP 1$^{st}$ hidden layer dimension | 256 |
| MLP layer number | 2 |
| Sample batch size | 4 |
| Replay buffer size | 20% of training |
| Validation frequency (episodes) | 25 |

## Experiment Results

We train the policy for 50, 000 episodes. Performance on the validation set containing 16 instances is checked every 25 episodes and the best-performing model is stored. Figure 3 shows the performance on the validation set during training. The best-performing policy is stored and evaluated on the separate evaluation set containing 64 instances.

We conduct a Monte Carlo simulation for the trained end-to-end DQN framework and compare the results with the three baseline methods. The lines shown in Figure 4 represent the average value accumulated over the evaluation instances. Notably, the single-agent baseline yields fewer production outputs and therefore less profit given the same number of training steps. Due to the sharp increase in action space size, we expect this effect to be even more pronounced on larger problem instances.

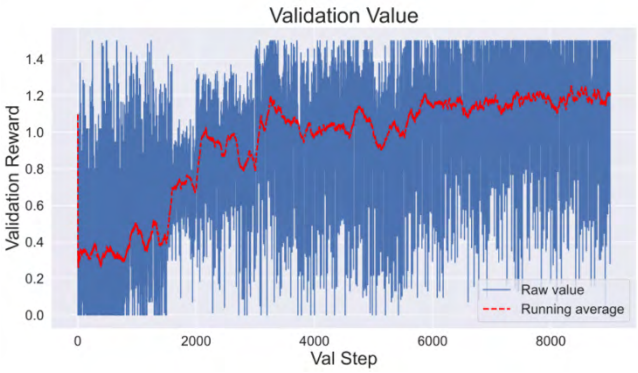

**Figure 3.** Validation performance during training based on the average reward computed from 32 predefined problem instances.

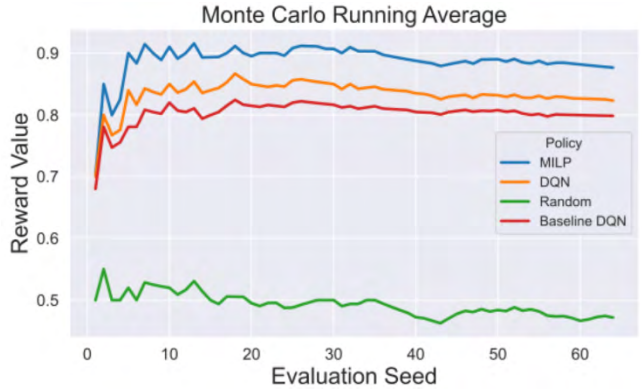

**Figure 4.** Average reward obtained on the evaluation set by the 3 considered methods. Averaged from 10 rounds.

From the box plot in Figure 5, we observe that our method constructs optimal solutions in 60.9% of cases and schedules with at most one task missing in 98.4% of cases. The random policy constructs solutions that, on average, only meet half of the production quantity compared to the optimal solution. Our framework leads to

solutions whose quality is clearly an improvement over the random baseline.

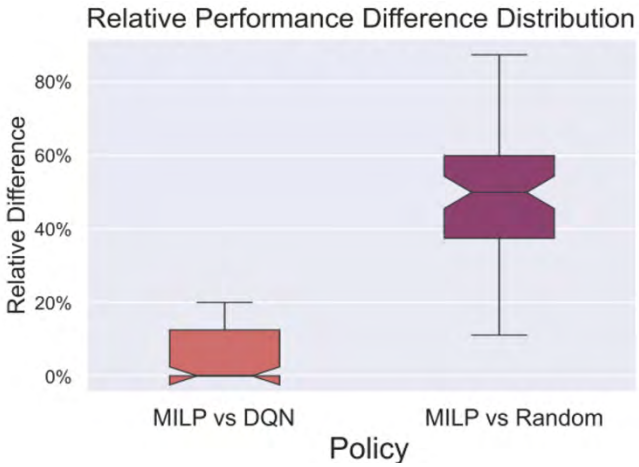

**Figure 5.** Evaluation performance comparing the MILP against the trained policy and a uniform random policy.

The Gantt charts in Figures 6 to 8 showcase the batch schedules constructed by the three methods using the problem instance on which the MILP scheduling method obtains the median performance among all problem instances.

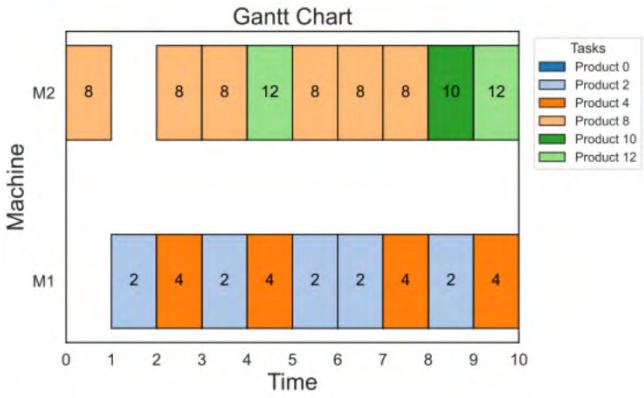

**Figure 6.** MILP scheduling plan on the median problem instance as a Gantt chart. Optimal solution.

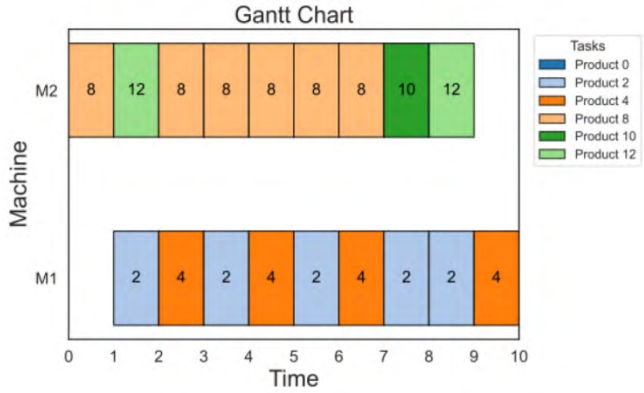

**Figure 7.** Scheduling plan output by our method on the median problem instance.

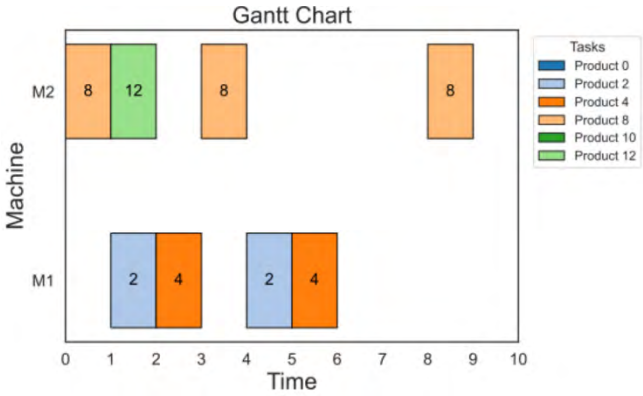

**Figure 8.** Scheduling plan output by uniform random action choices on the median problem instance.

## CONCLUSION

In this work, we addressed the batch process scheduling problem using a deep reinforcement learning method. We formulated it as a Markov decision process and proposed an end-to-end DQN framework underpinned by a GNN encoder, in which multiple agents collaboratively control manufacturing machines to process tasks and construct work sequences to maximise final production quantity. Preliminary results on small-scale instances with up to 13 nodes demonstrate strong performance, with the trained agents achieving high-quality solutions in 98.4% of the evaluation scenarios and reaching optimality in 60.9% of scenarios.

In future research, we aim to leverage the generalisation ability of GNNs to train and evaluate our model on graph topologies with different sizes and characteristics. Our goal is to demonstrate the scalability of our framework to problem instances that are too large to be solved optimally using a MILP formulation but are amenable to a learning-based approach that can produce outputs quickly.

## ABSTRACT

The pipeline transportation and distribution process of natural gas, from production sources to end consumers, can be divided into three stages: upstream production and supply, midstream storage and pipeline transportation, and downstream distribution and end-use. In the optimization of natural gas pipeline networks, considering the full life cycle, multiple uncertainties in planning, design, operation, and maintenance often affect the efficiency and quality of model optimization. This study addresses the uncertainty in end-user demand during the operation of natural gas pipeline net-works and investigates a scheduling method that simultaneously meets user demand while achieving coordinated optimization of operational costs and carbon emissions. Based on one year of historical demand data, a normal distribution is fitted to characterize the demand, and several representative scenarios with corresponding probabilities are extracted through clustering to capture demand uncertainty. A two-stage stochastic programming model is developed. In the first stage, the basic operational strategy of the pipeline network is determined, while in the second stage, flow, pressure, and compressor power are adjusted according to each demand scenario. The model prioritizes minimizing operational costs and employs the ε-constraint method to transform the carbon emission objective into a carbon emission cap. By systematically varying the value of ε, the Pareto frontier between cost and carbon emissions is delineated. Furthermore, nonlinear constraints are addressed using a combination of piecewise linearization and McCormick re-laxation. The proposed model is implemented in a real-world case study in China using Python and the Gurobi solver. Results demonstrate that, compared to conventional methods, the proposed approach effectively reduce carbon emissions by 34.96%, 42.35%, and 36.84% in high, medium, and low demand scenarios. The method provides clear optimization solutions and supports in-depth analysis of results, thereby enhancing data management capabilities of pipeline systems. The model systematically accounts for uncertainties in natural gas demand, offering valuable research support and practical references for scheduling decisions in the natural gas pipeline industry.

## INTRODUCTION

According to the latest statistics from the American Gas Association, natural gas has accounted for 25% of the global energy supply, particularly demonstrating significant application advantages in fields such as power generation, industrial manufacturing, and urban gas utilization [1].

As the "main artery" of the energy transmission system, the scientific nature of natural gas pipeline network planning and design, as well as the quality of operational efficiency, directly relate to national energy security, market stability, and people's livelihood protection [2]. he modern pipeline transportation system, by establishing a nationwide transmission and distribution network, has achieved efficient matching between resource supply

and market demand, providing stable and reliable gas supply assurance for various users including industrial and civil sectors [3]. Systematic pipeline network optimization design and intelligent dispatch management can reduce gas transmission losses and operational costs by up to 33.77% [4], significantly enhancing the market competitiveness of natural gas supply; it can also effectively reduce carbon emissions resulting from energy waste, thereby providing positive support for achievement of carbon peak and carbon neutrality goals.
