According to the HAZOP analysis report provided by the enterprise, a total of 769 risk scenarios were identified. Among the alarm tag nodes involved in these risk events, some nodes did not have corresponding DCS data available. Consequently, 94 tag variables that were both included in the HAZOP analysis and recorded in the DCS were selected for further analysis. A Time-Series Transformer was applied to these variables for causal discovery, with the significance threshold $\delta$ set to 1.05. In total, 141 causal relationships among the variables were identified, and the resulting causal adjacency matrix is shown in Fig. 2(a). To verify the accuracy of the causal discovery algorithm, the causal relationships among these variables were manually assessed. Together with expert engineers, the production structure of the unit was analyzed to identify causal relationships based on expert knowledge, and the corresponding expert-derived causal neighborhood is illustrated in Fig. 2(b). The two matrix is generated by different ways, so the designator names are not completely same. But labels are corresponded in sequence. Treating the expert-identified causal relationships as the ground truth, a comparison with the data-driven causal matrix shows that the proposed causal discovery algorithm achieves an accuracy of 94.61%. The accuracy was calculated by the similarity

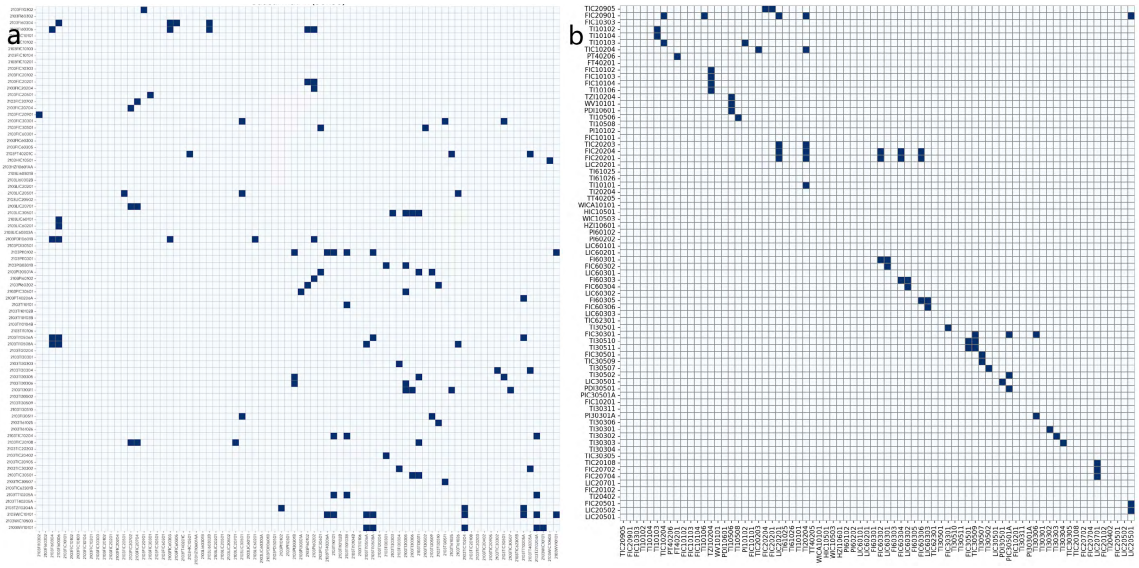

**Figure 2.** Causal adjacency matrix of 94 tag variables. (a) Discovered by Time-Series Transformer. (b) Discovered by expert knowledge

of two adjacent matrix.

Based on the results of causal discovery, the nodes and connections in the adjacency matrix were transformed into nodes and edges of a Bayesian network, forming its structural backbone. Using this backbone, risk events extracted from the HAZOP analysis were inserted into the Bayesian network as risk nodes, resulting in the incorporation of 260 risk scenarios. The complete Bayesian network generated is shown in Fig. 3 and consists of a total of 358 nodes, including 98 alarm tag nodes, 260 event nodes, 62 cause nodes, 61 consequence nodes, and 137 protection layer nodes, with 426 dependency relationships. The proportions of different node types in the Bayesian network are illustrated in Fig. 3.

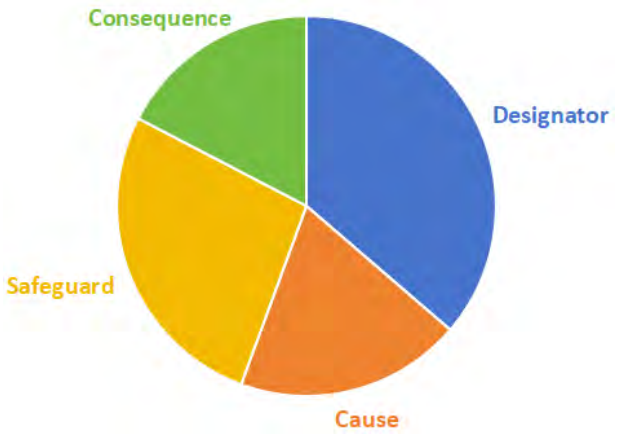

**Figure 3.** Nodes proportions in BN.

Based on the Bayesian network framework established using DCS time-series data and risk events, risk probabilities are matched from the risk database using a Transformer–BERT approach. The cause and consequence nodes extracted from the HAZOP analysis table can be fully and accurately associated with their corresponding probabilities. In contrast, the failure probabilities of protection layer nodes need to be matched from the risk database, with a matching accuracy of over 80%. For some protection measures, accurate and precise failure probabilities cannot be obtained from the risk database. However, this level of uncertainty is acceptable, as subsequent parameter learning is performed using actual operational data. These operational data include DCS time-series data of critical variables as well as fault records from real plant operations.

The final BN auto-constructed is shown in Fig.4, where the yellow nodes stand for hazardous causes, gray for protection layers, red for consequences, and blue for designators. This BN can be used for both forward risk inference and backward root cause tracing. Since the FCC unit considered in this case study is relatively new and no severe accident events have occurred, unplanned shutdowns are used as representative risk scenarios for analysis and validation. Taking the low–low reactor temperature interlock feed cut-off event as an example, the inference result was shown in Fig. 5. Backward risk tracing indicates that the event may have been caused by changes in feed flow rate, an increase in reactor nozzle pressure, or a failure-open condition of WICA10201. The most probable cause is lower feed flow rate, which is further caused by an increase in reactor nozzle pressure. These inferred causes are consistent with those identified in the corresponding accident analysis report.

## 5. CONCLUSION

**Figure 4.** Auto-constructerd BN of FCC unit.

**Figure 5.** Risk evolution inferred by part of the BN.

This paper presents an automated framework for constructing Bayesian causal networks to enable dynamic risk assessment in complex chemical processes. By integrating time-series Transformer–based causal discovery with multi-source risk knowledge from HAZOP reports and reliability databases, the proposed approach effectively eliminates the heavy reliance on manual modeling and expert-driven network construction in conventional Bayesian network–based risk assessment.

The proposed method automatically identifies causal structures from DCS time-series data, systematically embeds risk causes, consequences, and protection layers extracted from HAZOP analyses, and assigns node probabilities through semantic matching using Sentence-BERT. Combined with Bayesian parameter learning based on real operational data, the resulting network is able to continuously adapt to process dynamics and reflect real-time risk evolution.

A case study on an industrial fluid catalytic cracking unit demonstrates that the proposed framework can accurately construct a large-scale Bayesian causal network and support both forward risk prediction and backward root cause diagnosis. The results confirm that the method significantly reduces modeling effort while providing a comprehensive and reliable representation of dynamic risk propagation in chemical plants. Overall, this work offers a practical and scalable solution for automated dynamic risk assessment and has strong potential for industrial safety management applications.

## ABSTRACT

Electrochemical reduction of $CO_2$ ($ERCO_2$) in gas diffusion electrode (GDE)-based electrolyzers represents a potential strategy for global decarbonization, achieving simultaneously the valorization of this abundant carbon resource. While significant progress has been achieved in enhancing $CO_2$ conversion in these systems, further advances are required to enable their practical implementation at the industrial scale. Physics-based simulations offer a powerful tool to guide the optimization of design and operating parameters as well as for the efficient scale-up of $CO_2$ electrolyzers. In this work, we have developed a three-dimensional multiphysics model of the cathodic compartment of a GDE electrolyzer for $ERCO_2$ to formate. For that purpose, the software COMSOL Multiphysics has been used. The model is experimentally validated, confirming its accuracy at reproducing current density and Faradaic efficiency at cathode potentials in the range -1.2 V and -1.7 V. Moreover, kinetic parameters are fitted to experimental data performing several parametric sweeps to minimize discrepancies between simulated and measured current densities. We obtain charge transfer coefficients ($\alpha_{c,k}$) of 0.07 and 0.34, together with exchange current densities ($i_{0,k}$) of 30 $mA \cdot cm^{-2}$ and $10^{-4}$ $mA \cdot cm^{-2}$ for $ERCO_2$ and the competing hydrogen evolution reaction, respectively. Finally, the model is used to predict formate concentration under varying applied potential conditions. Collectively, our three-dimensional multiphysics model reliably predicts $CO_2$ conversion to formate, thus representing a useful tool for guiding system optimization and scale-up. Moreover, the systematic methodology followed for developing the model can be readily extended to the design and analysis of other electrochemical cells beyond $CO_2$-to-formate conversion.

## INTRODUCTION

Anthropogenic $CO_2$ emissions have triggered severe environmental concerns and represent a serious concern worldwide. Hence, there is an urge to implement actions that alleviate these emissions and develop alternative pathways for $CO_2$ utilization. [1-3] In this context, carbon capture and utilization (CCU) is recognized as a potential strategy for curbing energy and industry-related emissions. [4, 5]

Electrochemical reduction of $CO_2$ ($ERCO_2$) represents a promising CCU technology for $CO_2$ conversion into value-added products and fuels. [4, 6, 7] Thereby, $ERCO_2$ aligns with circular economy by enhancing the sustainability of industrial processes using waste $CO_2$ as a raw material. [5, 7]

The application prospects of $ERCO_2$ stem from its appealing advantages, including (i) mild operating conditions (room temperature and pressure), (ii) use of non-toxic green electrolytes, (iii) obtention of various carbon-based product (e.g., carbon monoxide, formic acid, ethanol, etc.) by controlling the reaction conditions, (iv) simplicity of electrochemical systems, (v) process repeatability, (vi) scalability, and (vii) possibility of integrating with low-carbon energy sources (e.g., solar, wind, geothermical, etc.) photovoltaics. [2, 4, 6]

From the different products that can be derived from $ERCO_2$, formate ($HCOO^-$) has received special attention due to its industrial relevance and possible use as fuel source. Hence, significant research efforts have been devoted in recent years to convert $CO_2$ into $HCOO^-$, thus advancing toward large-scale implementation. [7, 8] This progress has been mainly focused on the electrolyzer configuration, catalyst, electrode fabrication and optimizing reaction conditions. In this sense, different cathode configurations have been proposed to enhance electrolyzer performance and ensure closer alignment to industrial requirements (i.e., operating at current densities higher than 200 $mA{\cdot}cm^{-2}$). [2, 5, 7] In this regard, gas diffusion electrodes (GDEs) exhibit outstanding performance, since they alleviate mass transfer limitations. Particularly, GDEs provide a three-phase boundary (gas-liquid-solid), thus facilitating the accessibility of $CO_2$ to the catalyst surface. GDEs comprise two layers: (i) the gas diffusion layer (GDL), which acts as a porous support that promotes $CO_2$ mass transport, and (ii) the catalyst layer (CL), which is deposited onto the GDL and is the component of the GDE where the electrochemical reactions occur. [3, 5, 7]

Optimizing the performance of GDE electrolyzers requires rationalizing the effect of multiple process, operation and design variables. Hence, addressing this complex investigation through a trial-and-error approach could result impractical. [9, 10] Physics-based modeling provides fundamental understanding about the phenomena underlying $ERCO_2$; hence, it can guide electrolyzer optimization prior to their fabrication. Several one- and two-dimensional models of GDE electrolyzers have been developed, which have provided important insights so far. [10, 11] Nevertheless, advancing electrolyzers design and scale-up calls for gaining a more realistic understanding of the system performance so that currently relevant issues, such as the effect of flow distributors, $CO_2$ partial pressure in the feed or pH, could be reliably addressed.

In this study, a three-dimensional multiphysics model is developed for the cathodic compartment of a GDE electrolyzer for $ERCO_2$ to $HCOO^-$. The model has been first validated by comparing simulation predictions of current density and Faradaic efficiency with experimental data of our previous work. Moreover, the kinetic parameters of the involved electrochemical reactions ($ERCO_2$ and hydrogen evolution reaction) have been obtained. Finally, the model is used to predict formate concentration under varying potential conditions. Overall, the developed model provides a powerful framework for gaining insights into the different phenomena underlying electrochemical $CO_2$ valorization and represents a useful tool for guiding optimization and scale-up of GDE-electrolyzers.

# MODEL DEVELOPMENT

## System description

The cathodic compartment of the GDE-electrolyzer modeled in this study derives from the work of Díaz-Sainz et al. as illustrated in Figure 1. [12] In this system, gaseous $CO_2$ and 0.5M KCl + 0.45M aqueous $KHCO_3$ solution are fed through the cathode gas and catholyte channels, respectively. $CO_2$ flows through the GDL into the CL, where it meets the electrolyte and dissolves in it. The $ERCO_2$ and the competing hydrogen evolution reaction (HER) take place in the CL, yielding the desired $HCOO^-$ (eq. 1) and $H_2$ (eq. 2), respectively:

$$CO_2 + 2e^- \rightarrow HCOO^- + OH^- \ (E_0 = -0.02\ vs.RHE) \quad (1)$$

$$2H^+ + 2e^- \rightarrow H_2 \ (E_0 = 0\ V\ vs.RHE) \quad (2)$$

Subsequently, the electrolyte along with $HCOO^-$ and unreacted $CO_2$ exit the cell through the catholyte outlet.

In addition to the electrochemical reactions, homogeneous reactions take place in the electrolyte:

$$CO_{2(aq)} + H_2O \leftrightarrow H^+ + HCO_3^- \quad (3)$$

$$HCO_3^- \leftrightarrow H^+ + CO_3^{2-} \quad (4)$$

$$CO_{2(aq)} + OH^- \leftrightarrow HCO_3^- \quad (5)$$

$$HCO_3^- + OH^- \leftrightarrow H_2O + CO_3^{2-} \quad (6)$$

$$H_2O \leftrightarrow H^+ + OH^- \quad (7)$$

These reactions are fast, and thus, they are considered as equilibrium reactions. They balance the concentration of $H^+$, $OH^-$ and carbon-containing species. [13]

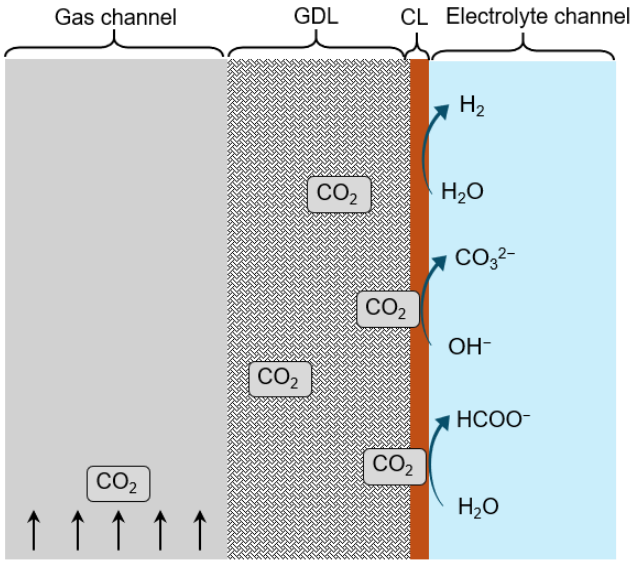

**Figure 1.** Schematic diagram of the $ERCO_2$ to $HCOO^-$ process modeled in this work.

As seen from Figure 1, this study explicitly models

four distinct domains, namely: gas and catholyte channels, GDL and CL. The cell dimensions and operating conditions have been included in Table 1:

**Table 1:** Model parameters for cell geometry and operating conditions.

| Parameter | Value | Unit |
|---|---|---|
| Cell length and width | 30.2 | mm |
| GDL thickness | 325 | μm |
| CL thickness | 15 | μm |
| Gas and catholyte channels thickness | 2.2 | mm |
| Temperature | 298.15 | K |
| Pressure | 1 | atm |
| Feed gas flow rate | 200 | ml·min$^{-1}$ |
| Catholyte flow rate per geometric surface area | 0.57 | ml·min$^{-1}$·cm$^{-2}$ |
| Cathode applied potential | -1.2 to -1.7 | V (vs. Ag/AgCl) |

## Model assumptions

The following assumptions are considered in the developed model:

- The system operates at steady state and isothermal (298.15 K) conditions
- Fluid flow remains in the laminar regime, with the gas phase treated as weakly compressible and the liquid phase as incompressible flow
- The physical properties of GDL and CL are isotropic with constant porosity and permeability.
- Zero-slip and no-species flux are applied to the side walls of the cell
- Kinetics of electrochemical reactions are described by Butler-Volmer equations

## Governing equations

The governing equations for modeling ERCO$_2$ to HCOO$^-$ in a GDE-electrolyzer include both transport equations and electrochemical reaction kinetics. A brief description of these equations is provided below.

### Transport equations

The transport equations include mass, momentum and charge as follows. In these equations, EC (electrolyte channel), CG (gas channel), GDL (gas diffusion layer), and CL (catalyst layer) denote the domains where they are applied.

$$\nabla \cdot (\rho_g u_g) = 0 \,(\mathrm{GC}) \tag{8}$$

$$\nabla \cdot (\rho u) = 0 \,(\mathrm{EC}) \tag{9}$$

$$\rho_g(u_g \nabla) = \nabla p_g + \mu_g\left(\nabla u_g + (\nabla u_g)^T\right) - \frac{2}{3}\mu_g(\nabla u_g)(GC) \tag{10}$$

$$\rho(u\,\nabla)u = \nabla p + \mu(\nabla u + (\nabla u)^T)\,(EC) \tag{11}$$

$$\frac{\rho_g}{\varepsilon}u_g \cdot \nabla\frac{u_g}{\varepsilon} = -\nabla p_g + \nabla \cdot \left[\frac{\mu_g}{\varepsilon}\left(\nabla u_g + (\nabla u_g)^T\right) - \frac{2}{3}\mu_g(\nabla u_g)I\right] - \frac{\mu_g}{k}u_g(GDL/CL) \tag{12}$$

$$\nabla \cdot n_i = 0\,(EC/GC) \tag{13}$$

$$\nabla \cdot n_i = R_i\,(GDL/CL) \tag{14}$$

$$n_i = -D_i\nabla C_i + Z_i F\frac{D_i}{RT}C_i\nabla\varphi_l + C_i u\,(EL/CL) \tag{15}$$

$$\nabla \cdot i = 0\,(GDL/CL) \tag{16}$$

where $\rho, \mu, u$ and p are the density, viscosity, velocity and pressure of the electrolyte, whereas $\rho_g, \mu_g, u_g$ and $p_g$ represent the density, viscosity, velocity and pressure of the gaseous stream; $n_i$, $D_i$ and $C_i$ are the total mass flux, diffusivity and local concentration of species i ($CO_2$, $HCOO^-$, $H_2$, $H_2O$, $H^+$, $OH^-$); $\varphi_l$ is the electrolyte potential; *i* represents the current density of species; F denotes the Faraday's constant; $Z_i$ is the electron transfer number; R is the gas constant and T the temperature.

Gas-phase transport is modeled as the sum of convection and diffusion. Diffusion is driven by gradients in species mass fraction and mixture molar mass, and it is governed by an effective diffusivity. This diffusivity combines Stefan–Maxwell diffusion (multicomponent gas interactions) and Knudsen diffusion (pore-scale effects), whose resistances are added in parallel.

$$n_i = j_i + \rho_i u_g \tag{17}$$

$$j_i = -\rho_g D_i^{eff}\left(\nabla\omega_i + \omega_i\frac{\nabla M_n}{M_n}\right) \tag{18}$$

$$\frac{1}{D_i} = \frac{1}{D_i^m} + \frac{1}{D_i^k} \tag{19}$$

$$D_i^m = \frac{1-\omega_i}{\sum_{n\neq i}\frac{y_n}{D_{in}}} \tag{20}$$

$$D_i^k = \frac{2r_{p,m}}{3}\sqrt{\frac{8RT}{\pi M_i}} \tag{21}$$

where $n_i$ is the total mass flux of species i, $j_i$ is the diffusive mass flux of species i, $\rho_i$ is the mass density of species i, $u_g$ is the average mass velocity of the gas mixture, $\rho_g$ is the density of the gas mixture, $\omega_i$ is the mass fraction of species i, $D_i^{eff}$ is the effective diffusion coefficient of species i, $M_i$ is the molar mass of species i, $M_n$ is the average molar mass of the gas mixture, $D_i$ is the overall diffusion coefficient of species i, $D_i^m$ is the Stefan–Maxwell diffusivity, and $D_i^k$ is the Knudsen diffusivity.

### Electrochemical kinetics

The electrochemical kinetic reactions occurring at the cathode (ERCO$_2$ to HCOO$^-$ and HER) are modeled through the widely used Butler-Volmer equations. Particularly, concentration-dependent and concentration-

independent Butler-Volmer equations have been considered for $ERCO_2$ and HER, respectively:

$$i_{HCOO^-} = -i_{0,HCOO-}\left(\frac{c_{CO_2,aq}}{c^{ref}_{CO_2,aq}}\right)^{\gamma} exp\left(-\frac{\alpha_{c,ERCO2}F}{RT}\eta_{ERCO_2}\right) \quad (22)$$

$$i_{HER} = -i_{0,HER}\, exp\left(-\frac{\alpha_{c,HER}F}{RT}\eta_{HER}\right) \quad (23)$$

$$n_i = \varphi_s - \varphi_l - (U^0_k - \frac{2.303}{F}\mathrm{pH}) \quad (24)$$

$$R_k = \frac{\nu_k i_k}{n_k F} \quad (25)$$

$$FE = \frac{i_k}{i_{total}} \times 100 \quad (26)$$

$$i_{total} = \sum_k i_k = i_{HCOO^-} + \mathrm{i_{HER}} \quad (27)$$

where $i_{0,k}$, $\alpha_{c,k}$ and $\eta_k$ are the exchange current density, charge transfer coefficient and activation overpotential for reaction k; $c_{CO_2,aq}$ is the local $CO_2$ concentration; $c^{ref}_{CO_2,aq}$ represents the reference concentration of $CO_2$ (1M); $\gamma$ is the rate order of $CO_2$ to obtain $HCOO^-$; $U^0_k$ is the reduction potential of reaction k; $\varphi_s$ denotes the solid potential; $\varphi_l$ is the electrolyte potential; $\nu_k$ represents the stoichiometric coefficient of the species; $n_k$ is the number of participating electrons; $i_{total}$ is the total current density.

### $CO_2$ absorption

At the GDL-CL interface, gaseous $CO_2$ and liquid electrolyte meet. Hence, $CO_2$ is absorbed into the electrolyte, which is described as follows:

$$R_{PT,CO_2} = a_V k_{GL,CO_2} M_{CO_2}(H_{CO_2} p_G y_{CO_2} - C_{CO_2(l)}) \quad (28)$$

where $a_V$ is the specific interfacial area, $k_{GL,CO_2}$ is the gas-to-liquid mass transfer coefficient, $H_{CO_2}$ represents the Henry's law constant, $y_{CO_2}$ is the mole fraction of gaseous $CO_2$ and $C_{CO_2(l)}$ is the concentration of dissolved $CO_2$ in the electrolyte.

## Numerical method

The previous equations are solved at steady-state in COMSOL Multiphysics 6.2. Particularly, the "Free and porous media flow, Brinkman", "Transport of concentrated species", "Transport of diluted species", and "Secondary current distribution" physics interfaces are selected to account for the different phenomena underlying $ERCO_2$. A physics-controlled mesh was used; the resulting mesh contains 42844 boundary and 219785 domain elements, with an average element quality close to unity. The model is solved using MUMPS solver with a relative tolerance of $5\times10^{-4}$ through a segregated approach.

To enhance model's convergence, the stationary solver was run in three sequenced steps. First, a "Current distribution and initialization" step is performed. Second, fluid flow is solved since it is not affected by other interfaces of the model. Then, species transport coupled to flow and current distribution are computed simultaneously to derived the final results. Finally, parametric sweeps are conducted for exploring the influence of several operating conditions on cell performance.

## Results and discussion

### Model validation and parametric estimation

Our previous work on the design of filter-press reactors for $ERCO_2$ to $HCOO^-$ is considered for obtaining the kinetic parameters of the involved electrochemical reactions. [12] Starting from literature-based initial values [3, 4, 6], a trial-and-error method is applied by performing parametric sweeps in COMSOL Multiphysics. In particular, the kinetic parameters for $ERCO_2$ and HER are iteratively modified, and the computational results are compared with the experimental data. These parameters are refined to minimize discrepancies between simulated and experimentally measured current densities and Faradaic efficiencies. Table 2 gathers the kinetic parameters (namely charge transfer coefficient, $\alpha_c$ and exchange current density, $i_0$) that have been obtained for $ERCO_2$ and HER. These values align closely with previously reported kinetic parameters for the involved electrochemical reactions.

**Table 2:** Electrochemical kinetic parameters.

| Reaction | Parameter | Value | Unit |
|---|---|---|---|
| $ERCO_2$ | $\alpha_c$ | 0.07 | - |
| | $i_0$ | 30 | $mA{\cdot}cm^{-2}$ |
| HER | $\alpha_c$ | 0.34 | - |
| | $i_0$ | $10^{-4}$ | $mA{\cdot}cm^{-2}$ |

The kinetic parameters derived for $ERCO_2$ and HER lead to successful model validation, as evidenced from Figure 2 which illustrates the simulated and experimental current density and Faradaic efficiency for varying cathode potential. Thereby, simulation results exhibit good agreement to experimental data for potentials within the range of -1.2 V to -1.7 V, where $CO_2$ electrolyzers for $HCOO^-$ typically operate, as experimentally demonstrated. Particularly, the deviation between experimental and modeled current density and Faradaic efficiency is below 3%, which demonstrates the reliability of the developed model for capturing the phenomena underlying $ERCO_2$.

### Electrochemical production of $HCOO^-$

The validated model is used to investigate species distribution in the electrolyzer and predict $HCOO^-$ concentration at the system outlet when applying different cathode potentials. Figure 3 depicts 2D contours of $HCOO^-$ concentration within the electrode and catholyte regions at cathode potentials of -1.2 and -1.7 V. At both potentials, the highest $HCOO^-$ concentration is localized near the edges of the electrode surface. Under an applied

potential of -1.2 V, $HCOO^-$ concentration remains uniform at low values in the catholyte. Conversely, increasing the cathode potential to -1.7V results in a pronounced concentration gradient across the cell width, and significantly higher $HCOO^-$ concentration in the catholyte. This behaviour reflects enhanced electroreduction kinetics at more negative applied potentials.

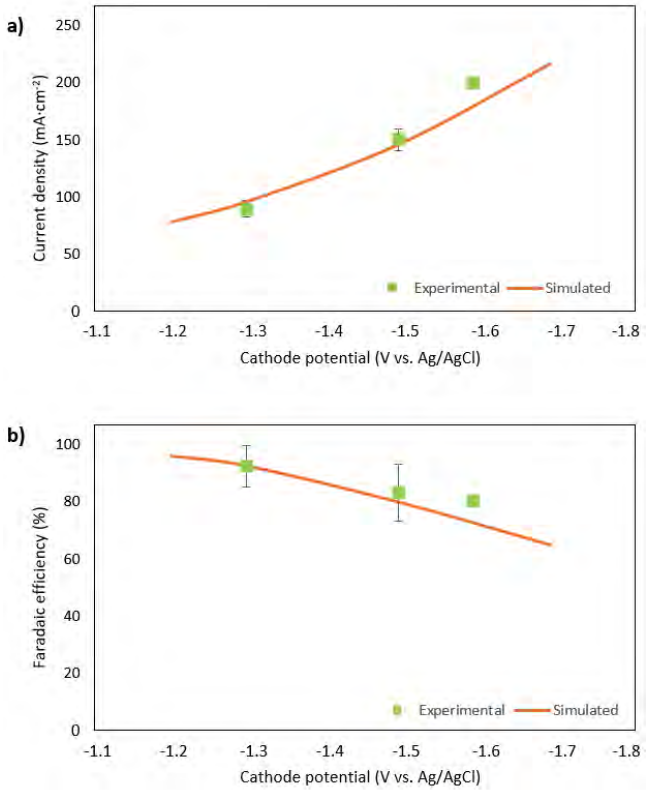

**Figure 2.** Experimental and simulated results for (a) current density and (b) Faradaic efficiency.

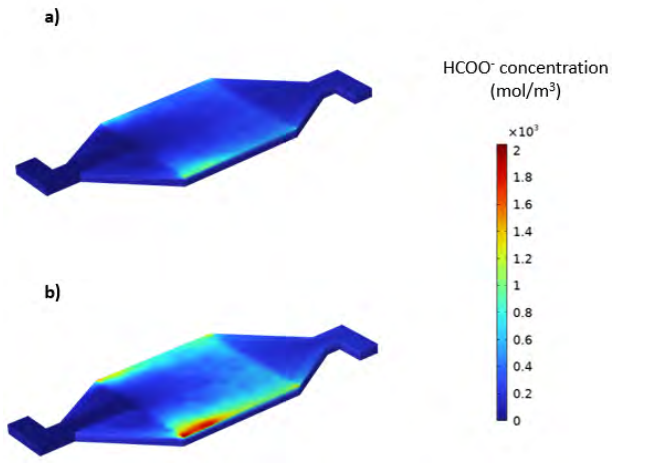

**Figure 3.** Distribution of $HCOO^-$ concentration in the CL and catholyte at two applied cathode potentials: (a) -1.2V, and (b) -1.7V.

Finally, the model is exploited to predict $HCOO^-$ concentration at the system outlet for different applied cathode potentials (Figure 4). It can be easily noticed that there is a strong dependence of $HCOO^-$ production on the applied potential. Particularly, $HCOO^-$ concentration increases from 2 to 3.7 $g{\cdot}L^{-1}$ when the cathode potential varies in the range -1.2V - -1.7V, representing approximately a two-fold increase. While negative potentials favor $CO_2$ conversion they entail increased energy consumption and enhancement of side reactions. Hence, predicting $HCOO^-$ concentration at various cathode potentials can guide the optimization of the operating conditions to achieve a trade-off between the desired concentration of the target product and overall system efficiency.

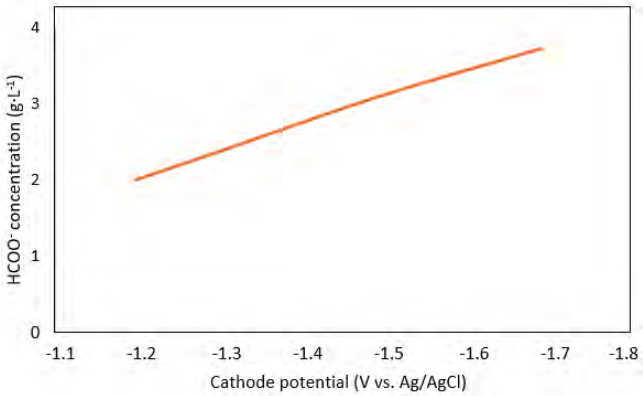

**Figure 4.** $HCOO^-$ concentration at the system outlet.

## CONCLUSION

This study introduces a three-dimensional multiphysics model of the cathodic compartment of a GDE electrolyzer for $ERCO_2$ to $HCOO^-$. The model reliably reproduces experimental observations, since deviations lower than 3% are reported for current density and Faradaic efficiency toward $HCOO^-$ at different applied potentials. Additionally, the three-dimensional model provides insights into the distribution of the involved species in the electrolyzer and enables prediction of $HCOO^-$ concentration at the system outlet under varying cathode potentials. Hence, the developed model can be used to systematically investigate the effect of several design and operating variables on the system performance, including $CO_2$ partial pressure in the feed, inlet flow rate, or the geometry of flow distributors. Moreover, it represents a useful tool for guiding system optimization and scale-up. Additionally, the systematic methodology followed for developing the model can be readily extended to the design and analysis of other electrochemical cells beyond $CO_2$-to-formate conversion.

## ABSTRACT

Multiscale models provide a powerful framework to link bioprocess operation conditions with polymer microstructure, yet their predictive capability for polymer attributes such as chain length distributions (CLDs) remains limited. In this work, an advanced multiscale modeling framework for the microbial production of poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) in *Cupriavidus necator* is presented, targeting the quantitative prediction of polymer microstructure. The model consistently integrates a structured macroscopic kinetic description of substrate uptake, biomass growth, and copolymer accumulation with an explicitly formulated microscopic polymerization model resolving initiation, propagation, termination, and depolymerization reactions of living and dead chains. A central contribution of this study is the quantitative calibration of the polymerization kinetics based on experimental size-exclusion chromatography (SEC) data. Polymerization rate constants were identified by fitting simulated CLDs to measurements obtained at multiple diagnostic time points during fed-batch cultivations using fructose and propionic acid as carbon sources. Parameter estimation was performed using a hybrid multi-start optimization strategy combining simulated annealing with Gauss–Newton refinement. Compared to literature-based parameter sets, the optimized model accurately reproduces both the temporal evolution of the weight-average molecular weight and the full CLD shape, including the emergence of high-molecular-weight tails. The results demonstrate that explicit polymerization modeling combined with parameter identification is essential for quantitatively linking process dynamics to PHBV microstructure. The proposed framework provides a sophisticated basis for model-based optimization of feed strategies and supports quality-by-design approaches for sustainable biopolymer production.

**Keywords**: Modelling and Simulations, Polymers, Optimization, Multiscale Modelling, Process Design

## INTRODUCTION

Microbial polyhydroxyalkanoates (PHAs) are biodegradable and bio-based polymers that represent a sustainable alternative to fossil-based plastics [1]. Among them, the copolymer poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) is of particular interest due to its enhanced flexibility, lower melting temperature, and reduced crystallinity compared to the homopolymer poly(3-hydroxybutyrate) (PHB) [2, 3]. These characteristics improve processability and broaden the application range from packaging to agricultural and biomedical materials. However, despite these advantages, the microbial production of PHAs remains expensive compared to petroleum-based polymers, with reported production costs for PHAs typically exceeding 2.0 US$/kg, compared to average market prices of approximately 1.5 US$/kg for conventional plastics such as polypropylene, creating a strong need for improved process design and optimization strategies [4, 5].

Research on PHBV production should not only focus on maximizing polymer yield at the process level but also

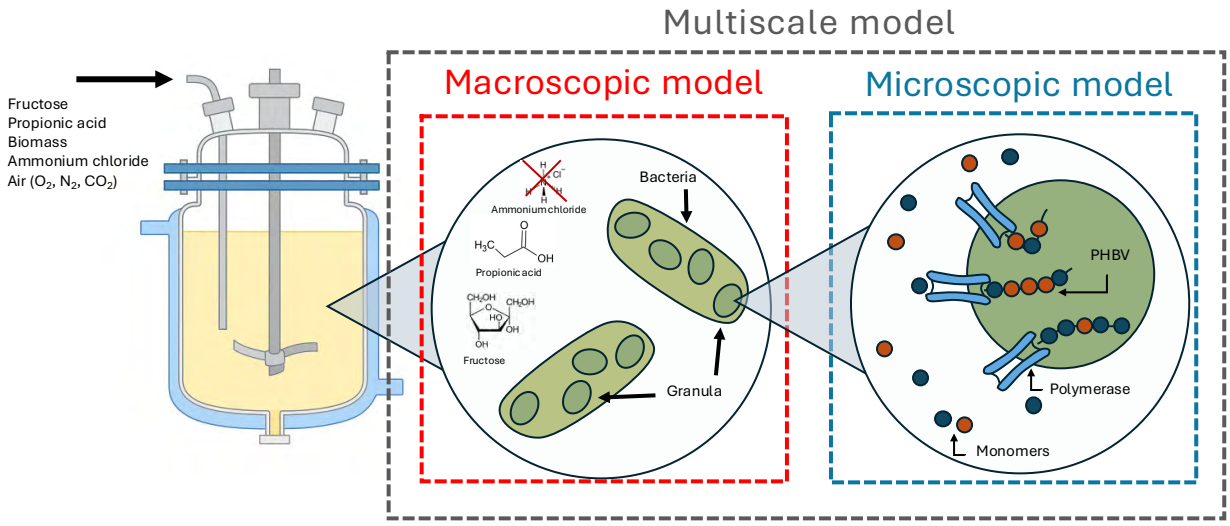

**Figure 1**: Schematic illustration of the multiscale modeling framework for PHBV production in a bioreactor. The macroscopic model (red box) describes reactor-scale dynamics, including substrates (fructose, propionic acid, ammonium chloride), biomass growth and product formation. The microscopic model (blue box) represents intracellular polymerization processes, where monomers are converted into PHBV by polymerases and stored within granules. Coupling both scales enables a consistent description of process dynamics and polymer structure evolution. Adapted from [11].

on tailoring end-use properties, which are determined by polymer quality attributes such as the chain length distribution (CLD), weight-average molecular weight ($M_w$), and polydispersity index (PDI). While molecular averages are commonly reported, they provide only limited insight into the underlying polymer microstructure. In contrast, the detailed information given in the full CLD strongly influences material properties such as mechanical strength and thermal stability. Accurate prediction of CLDs is therefore essential for enabling quality-by-design (QbD) approaches in biopolymer production [6]. Figure 1 provides an overview of the considered fed-batch process and the associated multiscale modeling framework, linking macroscopic dynamics with intracellular polymerization mechanisms.

Previous kinetic models of PHBV production successfully describe biomass growth, substrate consumption, and overall polymer accumulation; however, the polymer is described only by its total concentration, which limits the prediction of polymer quality properties [7]. To overcome this limitation, multiscale modeling approaches have been proposed that couple macroscopic process kinetics with microscopic polymerization models. A first multiscale framework for PHB demonstrated that cultivation conditions can be systematically linked to evolving CLDs by integrating process kinetics with polymerization modeling [8].

In contrast to PHB, PHBV production involves copolymerization of two monomer species, hydroxybutyrate (HB) and hydroxyvalerate (HV), whose relative incorporation depends on metabolic regulation and feed strategy. The use of propionic acid as a precursor for HV formation introduces additional complexity due to inhibitory effects on biomass growth and altered monomer availability. As a result, PHBV production exhibits a strong coupling between macroscopic process conditions and polymer microstructure, which poses additional challenges for predictive modeling.

The present work builds upon an existing multiscale PHBV modeling framework [9] and advances it towards quantitative prediction of polymer microstructure. The proposed approach provides an explicit formulation of the microscopic polymerization model, incorporating living and dead chain dynamics, monomer pools, and multiscale coupling. It also integrates these elements consistently with an updated macroscopic kinetic description within a single simulation environment. In this study, fructose and propionic acid are used as carbon sources, and the polymerization kinetics are quantitatively calibrated by identifying rate constants through fitting simulated chain length distributions to size-exclusion chromatography (SEC) data. This combined model formulation and parameter identification enables improved prediction of molecular weight evolution and CLD shape and establishes a consistent link between process dynamics and polymer quality.

## MODEL FRAMEWORK

The multiscale modeling framework combines a macroscopic description of reactor-scale process dynamics with a microscopic representation of intracellular polymerization mechanisms. An overview of the considered process and the interaction between both modeling levels is shown in Figure 1.

The macroscopic kinetics of substrate uptake, biomass growth, and PHBV accumulation are based on the updated structured kinetic model proposed by Kok et al. [10], which refines the original formulation introduced by Duvigneau et al. [7]. The model describes the temporal evolution of key process variables, including fructose, propionic acid, ammonium chloride, biomass, and polymer concentrations. It explicitly accounts for $CO_2$-dependent metabolic activity, inhibitory effects of propionic acid on biomass growth, and steric limitations arising from intracellular polymer accumulation in granulas. These mechanisms allow the model to capture characteristic features of fed-batch PHBV production under varying substrate availability. For clarity, the macroscopic balance equations are not explicitly repeated and are adopted from the validated formulations reported in Kok et al. [10] and Duvigneau et al. [7].

The microscopic model resolves the intracellular polymerization of hydroxybutyrate (HB) and hydroxyvalerate (HV) monomers into PHBV chains. The polymerization kinetics and the associated multiscale coupling are implemented using the commercial software package Predici [12], which provides a mechanistic description of initiation, propagation, termination, and depolymerization reactions. The model explicitly tracks living and dead polymer chains as a function of their chain length, thereby enabling the direct simulation of chain length distributions.

### Microscopic polymerization model

Living polymer chains terminated with either HB or HV are denoted as $LPHB_i$ and $LPHV_i$, respectively, where i represents the chain length and the last capital letter (B or V) corresponds to the terminal monomer (HB or HV) in the chain. Their temporal evolution is governed by initiation, propagation via monomer addition, and chain termination. The corresponding population balance equations read

$$\frac{d[LPHB_i]}{dt} = \delta_{\{i,1\}} k_{ini}[HB_{syn}] + k_{m2}[HB_{poly}]([LPHB_{i-1}] + [LPHV_{i-1}]) - k_{m2}([HB_{poly}] + [HV_{poly}])[LPHB_i] - k_c[LPHB_i] \quad (1)$$

$$\frac{d[LPHV_i]}{dt} = \delta_{\{i,1\}} k_{ini}[HV_{syn}] + k_{m2}[HV_{poly}]([LPHB_{i-1}] + [LPHV_{i-1}]) - k_{m2}([HB_{poly}] + [HV_{poly}])[LPHV_i] - k_c[LPHV_i] \quad (2)$$

Here, $\delta_{i,1}$ denotes the Kronecker delta accounting for chain initiation at i=1. Living chains grow by monomer addition with rate $k_{m2}$ and are shifted from active to dead (inactive) population with rate $k_c$. Dead polymer chains, denoted as $DPHB_i$ and $DPHV_i$, are formed via change of living chains and subsequently shortened by depolymerization with rate $k_{dep}$. Their dynamics are described by

$$\frac{d[DPHB_i]}{dt} = k_c[LPHB_i] - k_{dep}[DPHB_i] + k_{dep} f_{HB}([DPHB_{i+1}] + [DPHV_{i+1}]) \quad (3)$$

$$\frac{d[DPHV_i]}{dt} = k_c[LPHV_i] - k_{dep}[DPHV_i] + k_{dep} f_{HV}([DPHB_{i+1}] + [DPHV_{i+1}]) \quad (4)$$

Since the microscopic model tracks only the terminal monomer unit of each chain, the identity of the newly exposed terminal unit after a depolymerization step is inferred statistically. The relative fractions of HB and HV as penultimate monomers are assumed to be proportional to the HB/HV composition predicted by the macroscopic model,

$$f_{HB} = \frac{c_{HB}}{c_{HB}+c_{HV}} \quad (5)$$

$$f_{HV} = \frac{c_{HV}}{c_{HB}+c_{HV}} \quad (6)$$

This approximation allows HB-HB, HB-HV, HV-HB and HV-HV terminal combinations to occur during depolymerization without explicit sequence tracking.

The intracellular pools of polymer-forming monomers $HB_{poly}$ and $HV_{poly}$ are consumed during initiation and propagation and replenished by the macroscopic monomer formation rates $M_{HB}^{+}$ and $M_{HV}^{+}$, yielding

$$\frac{d[HB_{poly}]}{dt} = -k_{m1}[HB_{poly}] - k_{m2}[HB_{poly}] \sum_{i=1}^{\infty}([LPHB_i] + [LPHV_i]) + M_{HB}^{+} \quad (7)$$

$$\frac{d[HV_{poly}]}{dt} = -k_{m1}[HV_{poly}] - k_{m2}[HV_{poly}] \sum_{i=1}^{\infty}([LPHB_i] + [LPHV_i]) + M_{HV}^{+} \quad (8)$$

The monomer formation rates are defined in [8] and are adapted for both monomers in the present article. The monomer-synthase complexes are formed reversibly prior to chain initiation and are governed by

$$\frac{d[HB_{syn}]}{dt} = k_{m1}[HB_{poly}] - k_{ini}[HB_{syn}] \quad (9)$$

$$\frac{d[HV_{syn}]}{dt} = k_{m1}[HV_{poly}] - k_{ini}[HV_{syn}] \quad (10)$$

### Multiscale coupling

To ensure consistency between the macroscopic and microscopic descriptions, both model layers are coupled via a mass-conservation constraint on the total HB and HV monomer mass [8]. At each time point, the polymerized monomer mass in the microscopic model is required to match the monomer mass predicted by the macroscopic kinetics. Instead of solving the resulting differential–algebraic system explicitly, a coupling strategy is employed. Here, the monomer formation rates $M_{HB}^{+}$ and

$M_{HV}^{+}$ supplied to the polymerization module are dynamically adjusted such that the microscopic polymer mass follows the macroscopic target.

A key advance of the present work is the consistent implementation of the entire multiscale workflow within a single simulation environment. Both the macroscopic process model, the polymerization kinetics, and the coupling strategy are implemented directly in Predici, enabling numerically robust dynamic simulations and providing a unified basis for subsequent parameter estimation and model validation.

## PARAMETER ESTIMATION AND VALIDATION

A central novelty of this work is the explicit parameter identification for the polymerization kinetics. Literature-based rate constants adopted from PHB studies proved insufficient to reproduce experimentally observed PHBV chain length distributions (CLDs) [9]. Therefore, rate constants for initiation, propagation, termination, and degradation were identified directly from experimental size-exclusion chromatography (SEC) data measured at multiple sampling times during the fed-batch process.

The parameter estimation problem was formulated as a minimization of the deviation between simulated and experimental CLDs. Prior to error evaluation, both experimental and simulated CLDs were normalized to their respective maxima, and the simulated distributions were interpolated onto the experimental molar-mass grid. At each sampling time $t_k$, the discrepancy was quantified using the root mean square error (RMSE),

$$RMSE(t_k) = \sqrt{\frac{1}{N}\sum_{j=1}^{N}\left(\widetilde{w}_{sim}\left(M_j^{exp}, t_k\right) - \widetilde{w}_{exp}\left(M_j^{exp}, t_k\right)\right)^2}, \quad (11)$$

where $\widetilde{w}_{sim}$ and $\widetilde{w}_{exp}$ denote the normalized weight-based CLDs of simulation and experiment, respectively, evaluated at the experimental molar-mass points $M_j^{exp}$.

To obtain a single scalar performance measure over the entire process, the RMSE was averaged over time,

$$\langle RMSE \rangle = \frac{1}{t_f - t_0}\int_{t_0}^{t_f} RMSE(t)dt, \quad (12)$$

and evaluated numerically using the available sampling times.

A hybrid multi-start optimization strategy combining simulated annealing with local Gauss-Newton refinement was employed to ensure robust convergence and avoid trapping in local minima. Model performance was assessed by comparing simulated and experimental CLDs as well as derived quantities such as the weight-average molecular weight and the polydispersity index. The resulting parameter set reproduces both the detailed CLD shapes and the average CLD-derived values, considering experimental uncertainty caused by sample preparation, storage time, and possible impurities.

## RESULTS

Figure 2 compares experimental and simulated chain length distributions (CLDs) at 18 h and 36 h of the fed-batch cultivation. Using literature-based polymerization parameters, the model underestimates both, the shift of the distribution towards higher molecular weights and the overall distribution width. In particular, the high-molecular-weight region is insufficiently captured, indicating an imbalance between propagation, termination, and degradation kinetics. By contrast, the optimized parameter set reproduces the experimentally observed CLD shapes with good agreement at both sampling times. This includes not only the position of the main peak but also the emergence of a pronounced high-molecular-weight tail at 36 h, demonstrating that the temporal evolution of polymerization dynamics is captured more accurately.

The improved agreement highlights the sensitivity of CLDs to polymerization rate constants and underlines that parameter values derived from PHB systems cannot be transferred directly to PHBV without adjustment. The copolymerization of hydroxybutyrate (HB) and hydroxyvalerate (HV), combined with the influence of propionic acid on monomer availability, leads to altered growth and termination behavior that must be reflected at the polymerization level.

Figure 3 shows the corresponding time courses of the weight-average molecular weight ($M_w$) and the polydispersity index (PDI). The optimized parameter set reproduces both the magnitude and temporal evolution of $M_w$ significantly better than the literature-based parameters. In particular, the increase in $M_w$ during the later stages of cultivation is captured consistently, reflecting the accumulation of longer polymer chains observed experimentally. Experimental PDI values exhibit comparatively large scatter, which can be attributed to uncertainties associated with SEC measurements, sample preparation, storage effects, and potential impurities. Nevertheless, the simulated PDI remains within a physically plausible range and follows the experimentally observed trend.

To quantitatively assess the improvement achieved by parameter optimization, the deviation between simulated and experimental CLDs was evaluated using the root mean square error (RMSE). Figure 4 compares the time-resolved RMSE for the literature-based (BASIC) and optimized (OPT) parameter sets. While both simulations capture the overall temporal trend, the optimized parameter set consistently exhibits lower RMSE values over the course of the cultivation. The time-averaged RMSE is

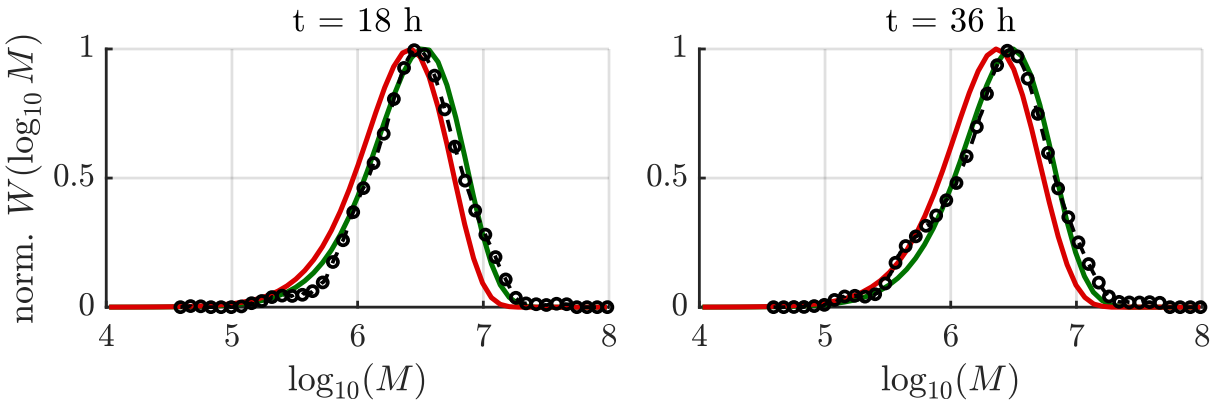

**Figure 2**: Comparison of experimental and simulated chain length distributions at 18 h and 36 h. Experiment: black, dashed with markers; basic model: red; optimized model: dark green.

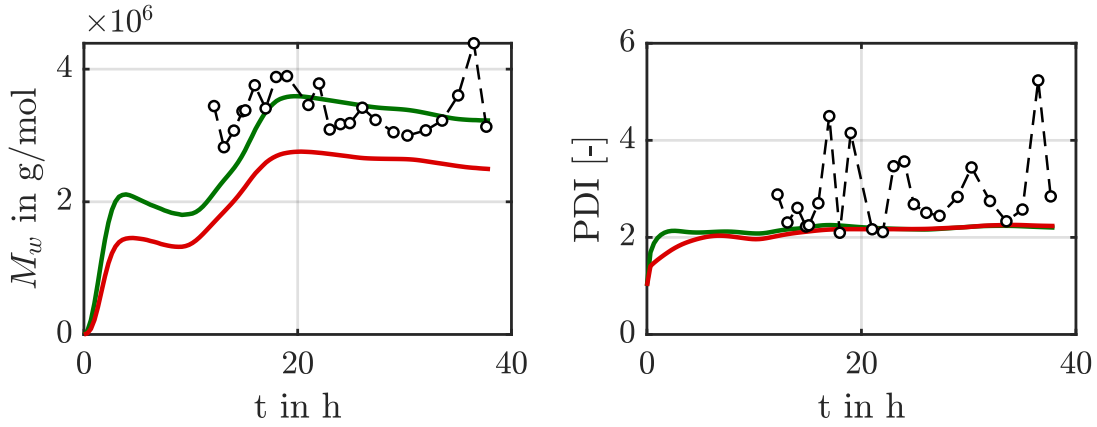

**Figure 3**: Time courses of $M_W$ (left) and PDI (right). Experiment: black, dashed with markers; basic model: red; optimized model: dark green.

reduced from 0.088 for the BASIC parameter set to 0.058 for the optimized case, corresponding to a relative error reduction of approximately 34%. This quantitative improvement confirms that the enhanced agreement observed in the CLD comparisons is not only visual but persists over the entire process duration.

**Table 1:** Comparison between the original and updated parameter set

| Parameter | Unit | Original value | Updated value |
|---|---|---|---|
| $k_{ini}$ | [$h^{-1}$] | 6.3 x $10^3$ | 1.26 x $10^4$ |
| $k_{m1}$ | [$h^{-1}$] | 1.1 x $10^{-4}$ | 5.16 x $10^{-5}$ |
| $k_{m2}$ | [L $h^{-1}$ $mol^{-1}$] | 8.6 x $10^6$ | 3.58 x $10^7$ |
| $k_c$ | [$h^{-1}$] | 1.40 | 8.26 |
| $k_{deg}$ | [$h^{-1}$] | 83 | 6.85 x $10^2$ |

The identified polymerization parameters are summarized in Table 1, comparing literature-based values [13] with the optimized parameter set. The changes in initiation, propagation, termination, and degradation rate constants reflect the altered kinetics required to reproduce PHBV copolymerization under propionic-acid-based feeding conditions.

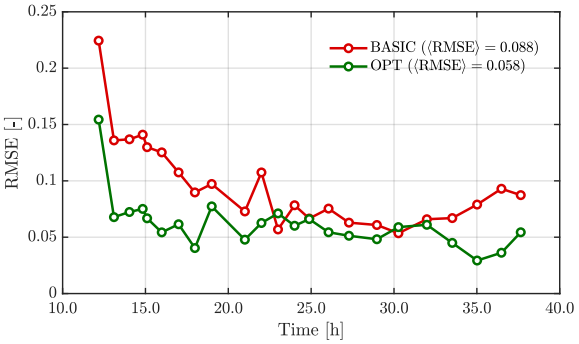

**Figure 4:** Time-resolved RMSE between simulated and experimental chain length distributions for the polymerization parameter sets. The legend indicates the time-averaged RMSE.

Overall, these results demonstrate that explicit parameter optimization at the polymerization level is essential for achieving quantitative agreement between simulated and experimental polymer microstructure. While macroscopic kinetics determine the overall monomer supply, the polymerization parameters govern how this supply is translated into chain length distributions and molecular averages. By reproducing both CLD shapes and derived quantities such as $M_w$, PDI, and RMSE, the proposed multiscale framework establishes a consistent and quantitative link between process conditions and polymer quality.

## CONCLUSION AND OUTLOOK

This study builds upon a previously published multiscale PHBV modeling framework [9] and extends it towards quantitative prediction of both process dynamics and polymer microstructure by explicitly formulating the intracellular polymerization model and calibrating its kinetics. The proposed framework provides a mechanistic description of living and dead chain dynamics, monomer pools, and depolymerization. It also refines the polymerization rate constants by directly fitting simulated chain length distributions to experimental data. As a result, the predictive accuracy for the weight-average molecular weight and the overall CLD shape is substantially improved.

The established framework enables *in-silico* exploration of feeding strategies for tailoring PHBV quality and provides a consistent basis for investigating continuous and semi-continuous process scenarios. Such capabilities are particularly relevant for scale-up, where feed composition and timing can be systematically adjusted to steer polymer composition and molecular properties. Moreover, the modeling approach is not restricted to PHBV and can be extended to other copolymers as well as mixed-substrate fermentations, thereby broadening its applicability in industrial biotechnology.

Overall, this work advances the integration of bioprocess modeling and polymer science and supports quality-by-design approaches for sustainable biopolymer production. Future research should focus on open-loop model validation and the development of advanced control strategies for polymer quality. In this context, surrogate modeling approaches provide a promising pathway to reduce model complexity while preserving essential process dynamics, thereby enabling efficient model-based optimization and control [11]. These steps would further enhance the industrial relevance of the proposed framework and contribute to establishing biopolymers as competitive alternatives to conventional plastics.

## ACKNOWLEDGEMENTS

## ABSTRACT

Hybrid process models are increasingly used for real-time decision support in dynamic operations, where models must remain reliable under changing operating conditions. In such settings, models are often required to extrapolate beyond previously observed batch trajectories, yet conventional validation strategies may fail to reveal weaknesses in extrapolative behavior. This work investigates the effect of hybrid model structure on extrapolative performance using a pilot-scale batch crystallizer as a test case. A structured set of mechanistic and hybrid models is evaluated using nested batchwise leave-one-out cross-validation (NBLOOCV), in which entire batches are withheld to assess extrapolation across operating regimes. For this specific application, the results show that hybrid models employing simple linear correction terms consistently outperform more flexible neural network–based formulations under extrapolation, despite comparable training performance. For the studied process, the findings highlight the importance of validation strategies that reflect intended model use and demonstrate that modest, physically consistent hybridization provides a robust and interpretable basis for operational decision support.

## 1. INTRODUCTION

Process models are widely used in chemical and biochemical engineering to support monitoring, prediction, optimization, and operational decision making. Such models are particularly useful in equilibrium-based separation processes, as the evolution of interdependent states can be difficult to predict. In real-time batch separations, models are not used to reconstruct historical trajectories but to support time-sensitive decisions under uncertainty, such as when to intervene or adjust operational parameters. In this context, a model's practical value is determined not only by its average predictive accuracy, but by its stability and reliability when operating conditions deviate from those previously observed.

Mechanistic models provide a natural starting point for such applications, as they encode mass and energy balances and offer transparent extrapolation behavior. However, mechanistic descriptions of pilot- and industrial-scale equipment are often incomplete due to unmodeled effects, uncertain parameters, and simplifying assumptions [1]. Hybrid modeling approaches seek to address these limitations by augmenting mechanistic models with data-driven components to improve predictive performance.

Recent advances in machine learning have accelerated interest in neural network–based (NN) hybrid models for batch separation processes, because they can flexibly approximate complex discrepancies between models and processes [2]. However, some hybrid model structures can yield performance worse than baseline, necessitating screening procedures to compare them [3]. Additionally, such methods must be applied carefully, as NN-based models can overfit to training trajectories [4], and it is a known challenge to ensure good extrapolation [1, 2]. Poor screening and poor extrapolation performance can lead to model failure when models are used to predict future trajectories under operating conditions that differ from those previously observed.

Whether such failure modes are revealed depends on the validation strategy used during model development. Conventional cross-validation approaches that use validation data to guide hyperparameter selection are well-suited when training and deployment data are

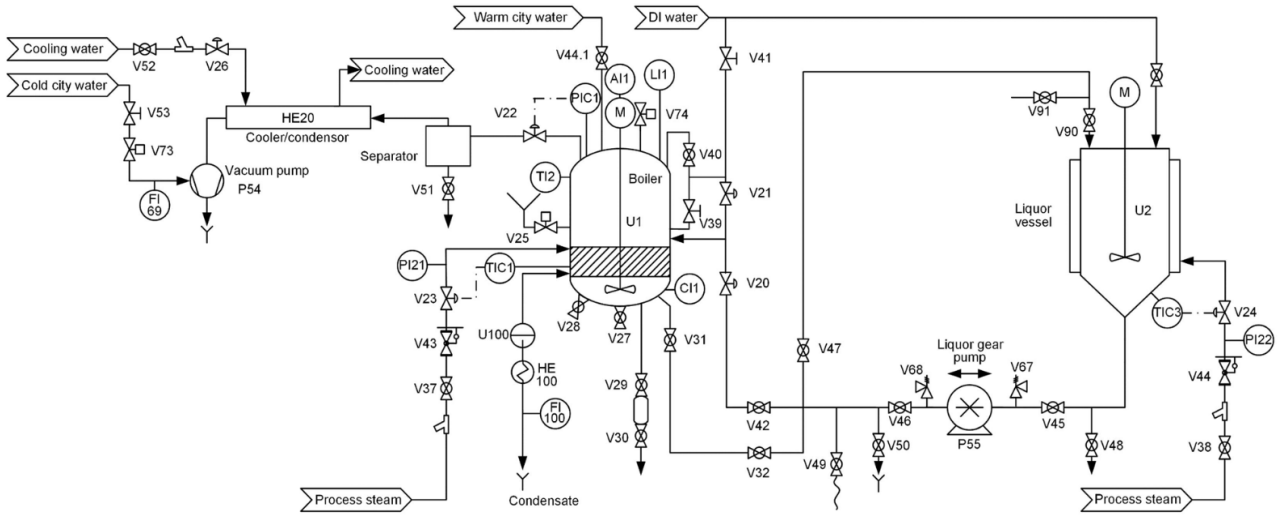

**Figure** 1. Process and Instrumentation diagram for the pilot-scale batch crystallizer.

drawn from similar distributions. However, when models are intended for extrapolation, which is common in low-data settings, these strategies may overestimate robustness [5]. Reporting validation performance on data that has influenced model selection leads to optimistic bias, an issue highlighted by Varma and Simon (2006), who showed that nested cross-validation is required to obtain unbiased generalization estimates [5].

In batch process modelling, segmenting a batch for both training and validation may yield a similar effect. To address this, this work employs nested batchwise leave-one-out cross-validation (NBLOOCV), in which entire batches are withheld as independent test cases. This extends the nested cross-validation framework of Varma and Simon to batch processes, ensuring that performance metrics reflect a model's generalization ability.

The objective of this study is to use a pilot-scale evaporative crystallizer as a case study to examine how different hybrid model structures behave under extrapolation. Pilot-scale batch crystallization provides a controlled yet industrially relevant setting in which operator interventions, unmeasured disturbances, and limited batch data jointly challenge model robustness. The work investigates how linear, nonlinear, and neural network–based correction terms interact with a mechanistic model when evaluated using NBLOOCV, and how these interactions affect trajectory prediction and downstream estimates of crystallization onset.

By focusing on model behavior under extrapolation rather than interpolation performance, this study aims to clarify when increased model flexibility improves predictive utility—and when it instead introduces instability that undermines operational trust.

## 2. METHODOLOGY

At the Technical University of Denmark, a batch crystallizer is routinely used to crystallize citric acid in water for educational purposes. A process and instrumentation diagram of this unit is shown in Figure 1. The crystallization tank is equipped with a temperature, weight, pressure, and conductivity sensor. The steam supply is equipped with a pressure sensor.

For operation, an initial mass of 150-200 kg of approximately 50% w/w citric acid solution is added to the crystallizer tank. A vacuum is pulled, reducing vessel pressure to ~0.15 bar; steam at ~1-2 bar gauge is supplied; and agitation is engaged to maximize evaporation rate. These must be continuously adjusted by the operator due to foaming and overflow risks. Every 20 minutes, samples are taken from the V28 valve, and titration is used to determine the citric acid concentration. Evaporation is continued until crystallization occurs, indicated by a sharp decrease in conductivity. Agitation is stopped, and crystallization is allowed to proceed, whereafter the separation is considered complete.

This batch crystallization process is difficult to describe using simple mechanistic models alone. Evaporation rates and heat transfer are affected by unmeasured disturbances, operator interventions, and equipment-specific effects, motivating the use of hybrid modelling. The process exhibits substantial batch-to-batch variability due to differences in initial conditions, steam and vacuum pressure profiles, and operator actions, resulting in non-identical trajectories that closely resemble variability observed in industrial batch operations. This setting is therefore deliberately chosen to reflect conditions under which hybrid models are most likely to be deployed in practice, but also most vulnerable to failure if validation is insufficient.

Data from seven batches of this operation were collected. The batch operation was segmented into the post-start-up operational phase. Using results from at-line samples, the initial conditions were established as

Table 1: Overview of mechanistic and hybrid model structures

| Model Group | Evaporation Rate Term | Heat Source Term |
|---|---|---|
| Mechanistic | $r_{\text{evap}} = k_{\text{evap}}\left(p^{(\text{sat})}(T) \cdot x_w - p_{\text{vessel}}\right)$ | $Q_{\text{in}} = \text{UA}\,(T_{\text{steam}} - T)$ |
| Linear Correction | $r_{\text{evap}} = f_{\text{lin}}(\text{T}, x_w) \cdot k_{\text{evap}}\left(p^{(\text{sat})}(T) \cdot x_w - p_{\text{vessel}}\right)$ | $Q_{\text{in}} = g_{\text{lin}}(\text{T}, x_w) \cdot\ \text{UA}\,(T_{\text{steam}} - T)$ |
| NN Correction | $r_{\text{evap}} = f_{\text{NN}}(\text{T}, x_w) \cdot k_{\text{evap}}\left(p^{(\text{sat})}(T) \cdot x_w - p_{\text{vessel}}\right)$ | $Q_{\text{in}} = g_{\text{NN}}(\text{T}, x_w) \cdot\ \text{UA}\,(T_{\text{steam}} - T)$ |
| Structural | $r_{\text{evap}} = k_{\text{evap}}\left(f_{\text{poly}}(T) \cdot x_w - p_{\text{vessel}}\right)$ | $Q_{\text{in}} = \text{UA}\left(g_{\text{poly}}(p_{\text{steam}}) - T\right)$ |
| Full NN Term | $r_{\text{evap}} = f_{\text{NN}}(T, x_w, p_{\text{steam}}, p_{\text{vessel}})$ | $Q_{\text{in}} = g_{\text{NN}}(T, x_w, p_{\text{steam}})$ |

the temperature, mass, and citric acid concentration at the time of the first sample. The time until crystallization is between 45 and 90 minutes at this point.

## 2.1 Mechanistic Modelling

A mechanistic model for the evaporation rate, $r_{\text{evap}}$, and temperature $T$, change can be expressed as,

$$\frac{dm}{dt} = r_{\text{evap}} = k_{\text{evap}}\left(p^{(\text{sat})}(T) \cdot x_w - p_{\text{vessel}}\right), \tag{1}$$

$$\frac{dT}{dt} = \frac{Q_{\text{in}} - r_{\text{evap}} \cdot \Delta H_{\text{vap}}}{m \cdot C_p}, \tag{2}$$

where the evaporation rate depends on the difference between the liquid's partial pressure, determined by saturated vapor pressure $p^{(\text{sat})}(T)$, and the molar water fraction $x_w$, and the vessel pressure $p_{\text{vessel}}$, scaled by an empirical coefficient $k_{\text{evap}}$. The temperature change is given by the heat input $Q_{\text{in}}$ minus the energy required for evaporation: $r_{\text{evap}} \cdot \Delta H_{\text{vap}}$. An Antoine relationship is used to determine the saturated vapor pressure, $\log \text{p}^{(\text{sat})}(T) = A + B/(T - C)$ where $A, B$, and $C$ are experimentally determined for a given solution. The heat balance is fitted using a linear driving force $Q_{\text{in}} = \text{UA}\,(T_{\text{steam}} - T)$, where UA is the overall heat transfer coefficient and $T_{\text{steam}}$ is the steam temperature, which may be determined from the measured steam pressure assuming saturated steam. Additionally, Eqn. 1 may be augmented, replacing $x_w$ by water activity $a_w$, to more accurately describe the observed relationship of $p^{(\text{sat})}(T)$ and $x_w$ in low water fraction solutions. $a_w = 1 - k_{a_w} \cdot (1 - x_w)^2$, where $k_{a_w}$ is empirically found.

### Determining Crystallization Onset

To determine when crystallization will occur, the expected concentration of citric acid (CA) is continuously calculated. The concentration of saturated anhydrous citric acid in water as a function of temperature in °C has been determined empirically by,

$$c_{\text{CA, sat}} = 0.246 \cdot T + 59.17, \tag{3}$$

for temperatures greater than 40 °C. During operation, crystallization is not observed at this saturated concentration but instead requires a degree of supersaturation, which is not known in advance and will be determined from the data. In each fold, the training batches will be used to fit an offset to Eqn. 3, yielding the supersaturation curve. This will be used to predict the time of crystallization for the held-out batch.

## 2.2 Introducing Data-Driven Components

The mechanistic model will be augmented with data-driven components to improve predictive performance. An overview of the different structures is presented in Table 1, and includes:

- Correction models: the mechanistic model is corrected using a learned multiplicative factor. Both linear and NN-based correction factors are tested.
- Feature learning: Antoine parameters and steam pressure-temperature relationship are learned.
- Full NN: the entire term is approximated by a NN.

Besides models shown in Table 1, additional mechanistic and corrective hybrid models were evaluated, including models with:

- A heat loss term: $Q_{\text{net}} = Q_{\text{in}} - \text{UA}_{\text{loss}}(T - 25°\text{C})$
- Antoine values for saturated citric acid solution [1]
- Water activity substitute in Eqn. 1.

These variants reflect increasing levels of physical fidelity and parameter uncertainty.

## 2.3 Nested Batchwise Leave-one-out Cross-Validation

To evaluate model performance under extrapolative conditions, nested batchwise leave-one-out cross-validation (NBLOOCV) is employed. A schematic overview of the procedure is shown in Figure 2. In NBLOOCV, one complete batch is withheld as the outer-loop test set, while all remaining batches are used for model training and inner-loop validation. Hyperparameter tuning and model selection are performed exclusively within the inner loop, ensuring that the test batch remains fully independent.

This validation structure reflects how hybrid models are intended to be used in real-time batch operation. In practice, a model structure and its associated hyperparameters are selected using historical batches, trained on all available data, and then deployed to predict the trajectory of a future batch. NBLOOCV mirrors this setting by treating each batch as an indivisible unit and

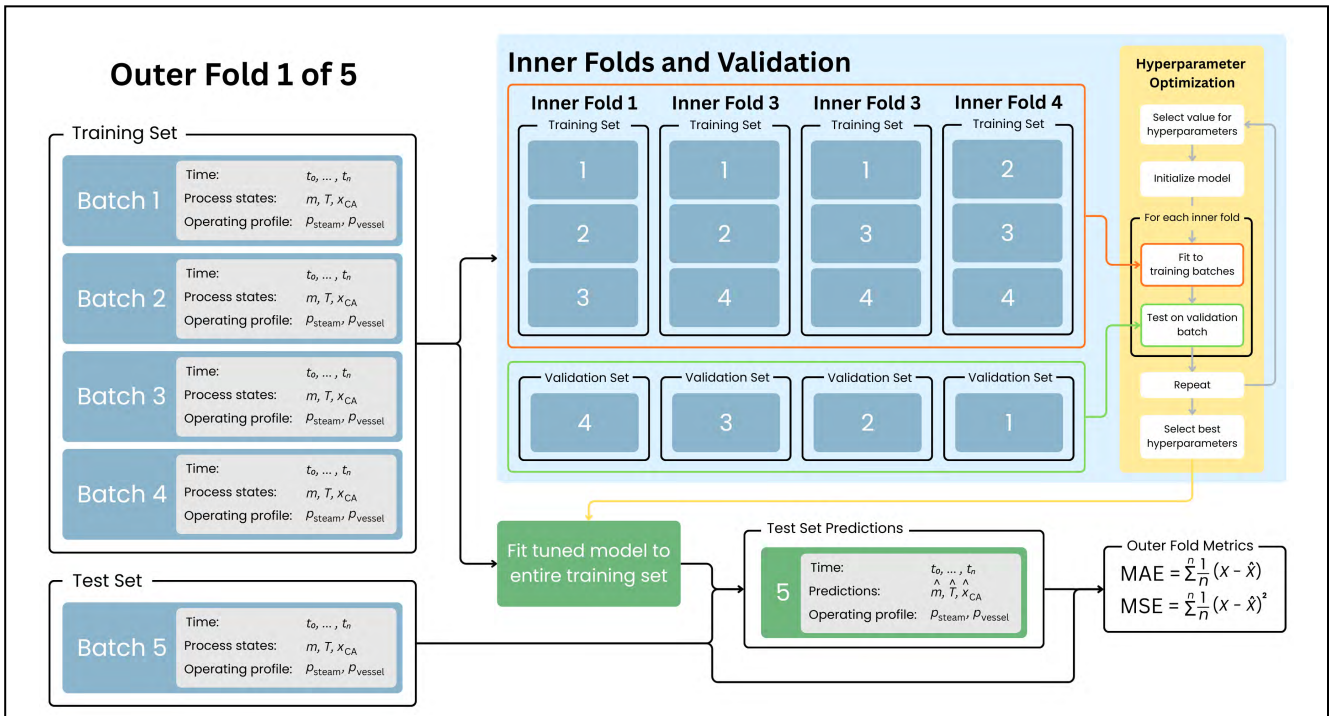

**Figure** 2. Schematic of the nested batchwise leave-one-out cross-validation (NBLOOCV) for a case of five total

evaluating performance on a completely unseen batch.

Within each outer fold, the remaining batches are further split using batchwise leave-one-out cross-validation in the inner loop. Here, one batch is used for validation, while the remaining batches are used for training; this procedure is repeated for all available training batches. The model structure and hyperparameters that yield the best average inner-loop performance are selected, retrained on all inner-loop batches, and evaluated on the withheld outer-loop test batch. This yields an unbiased estimate of performance on an independent batch.

Because batch operating conditions can differ substantially, evaluation on a single held-out batch may produce high-variance estimates of generalization error. NBLOOCV mitigates this by repeating the procedure such that each batch serves once as the independent test batch, after which performance metrics are aggregated across outer folds. As more batches become available, the framework can be extended to leave-*n*-out cross-validation to reduce computational cost while preserving test-set independence.

NBLOOCV is not required in all settings. When training and deployment data are drawn from similar operating regimes, conventional cross-validation provides meaningful estimates of generalization error. However, in low-data settings where future batches deviate from historical trajectories, validation performance can substantially overestimate robustness if the same data influence both model selection and evaluation. This mirrors pilot- and industrial-scale batch operations, where limited data and batch-to-batch variability make extrapolation unavoidable.

By withholding entire batches in the outer loop, NBLOOCV deliberately evaluates extrapolative predictions. As a result, performance metrics obtained using NBLOOCV reflect a model's ability to generalize across operating regimes, rather than its ability to interpolate within previously observed batch trajectories.

## 2.4 Model Training

Model training is performed using a staged optimization strategy that promotes numerical stability and efficient convergence. Initially, time-differenced residual minimization is performed on the mass and temperature gradients to obtain initial parameter estimates. Next, a Nelder–Mead optimization is performed using the full trajectory and initial conditions to refine the parameter values and the correction term parameters.

For NN-based models, the training is instead performed with gradient-based methods: Adam optimization is used for 150 epochs with a learning rate of $2.5 \cdot 10^{-3}$ and L-BFGS optimization for 25 epochs using a learning rate of 1.0. Unified NN models were trained that jointly predict both evaporation and heat input within a single network, such that the functions $f$ and $g$ in Table 1 are represented by one neural network. All model structures were evaluated both with a learned component applied to a single model term while retaining the baseline mechanistic term for the remaining term, and with learned components applied to both terms.

Hyperparameter search was performed using a

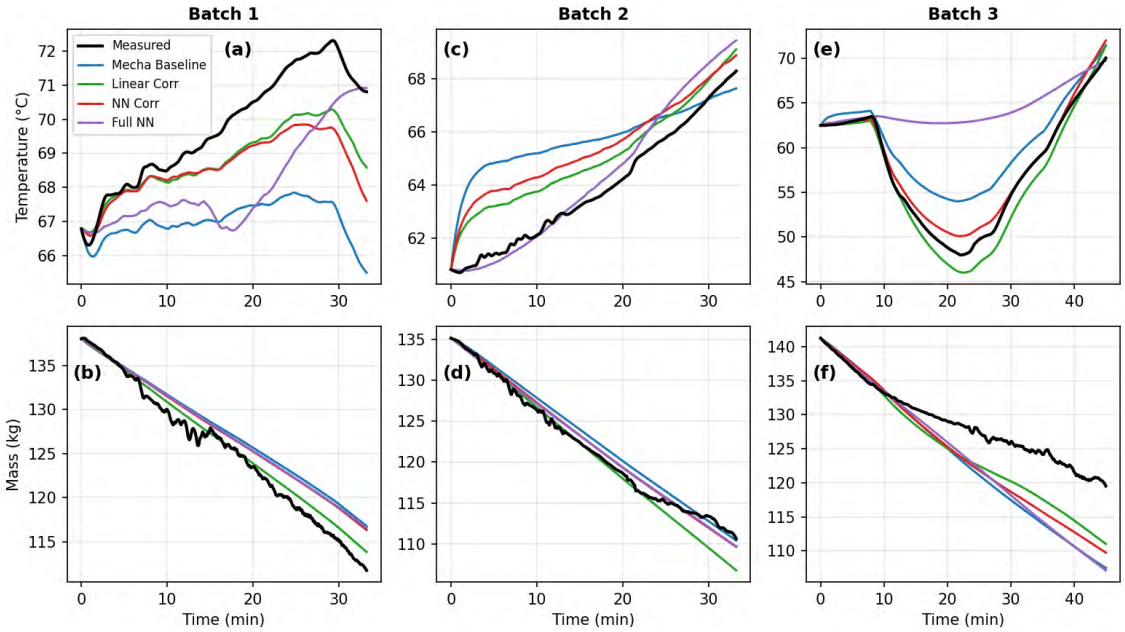

**Figure** 3. Example batches and the prediction of various hybrid models given the initial conditions.

Bayesian Tree-structured Parzen estimator optimizing the number of hidden layers: $\{1, 2\}$, the number of neurons per hidden layer: $\{2, 8\}$, and the weight decay: $\{10^{-5}, 10^{-2}\}$. The $\tanh$ activation function was used. The optimization metric for Nelder-Mead and gradient-based methods was $\sqrt{T_{\text{norm}}^2 + m_{\text{norm}}^2}$, where $T_{\text{norm}}$ and $m_{\text{norm}}$ are the normalized temperature and mass, respectively, based on the approximate means of batches, 70 °C and 120 kg.

## 3. RESULTS & DISCUSSION

Table 2 shows the predictive performance of representative models from each model class, evaluated using NBLOOCV. Training and outer-fold test losses are reported.

The computational cost of NBLOOCV varies substantially across model classes. For example, the linear correction models require on the order of 10 seconds per outer fold, while NN correction and full NN models require on the order of 10–30 minutes per outer fold. These costs are not directly comparable because the linear correction cost reflects a single training run, whereas NN costs include 10 iterations of inner-loop hyperparameter search. With 7 outer folds, the full NBLOOCV procedure for NN-based models takes on the order of 2–3 hours in total.

The mechanistic model using Antoine parameters for water serves as a simple baseline. The mechanistic model incorporating literature values for citric acid-water and water activity already performs worse, indicating that the Antoine parameters for pure water are more representative of the observed dynamics.

The linear correction models performed best in cross-validation across all explored model types. The NN correction models perform worse than the linear correction model but achieve lower average error than the baseline, albeit with higher variance. The full NN models perform worse again with even higher variance. The worst-performing cross-validation models are feature learning models, which perform notably worse than other model types.

In Figure 3, three of the seven batches and their trajectories predicted by select mechanistic and hybrid models are shown. The trajectories are not presented as evidence of strong absolute predictive accuracy, but to illustrate how model structure governs extrapolative behavior. Qualitatively similar trajectories are predicted by the mechanistic and corrected models for temperature, where the linearly corrected model is typically closest to the observed trajectories. The full NN-based models typically do not produce a qualitative match to the evolution of temperature. All models predict a constant decrease in mass, although some deviations are observed that none of the models successfully predict. The relevant distinction is therefore not which model performs best in an absolute sense, but that linear corrections fail in a physically consistent manner while NN-based models can deviate sharply and without physical justification.

### 3.1 Model Structure and Trajectory Fidelity

The strong performance of linearly corrected hybrid models suggests that the underlying mechanistic model already captures the dominant process dynamics, requiring only modest adjustments to account for unmodeled effects. This further implies that the discrepancy between the mechanistic model and the process exhibits a

Table 2: Averaged $R^2$ and losses for the select models of all structures. The outer fold test reports a standard deviation.

| Model Type and Description | Tunable Parameters | Training | | Outer Fold Test | |
|---|---|---|---|---|---|

*Data-driven parameters + mechanistic parameters, **Span of parameters as a result of the per-fold hyperparameter running.

similar functional structure across operating regimes, resulting in comparable training and cross-validation performance.

In contrast, both the neural-network correction model and the fully data-driven NN achieve lower training error but substantially worse cross-validation performance. Because batches differ in operating conditions and trajectory evolution, held-out folds frequently require extrapolation beyond the training regime. For NN-based models, this leads to noticeable degradation in certain batches, lowering outer-fold metrics and resulting in high fold-to-fold variance. This implies that when extrapolation is required, fully data-driven models lack structural constraints to guide their behavior, increasing the likelihood of large prediction errors.

More generally, nonlinear correction terms are not constrained to preserve the functional relationships learned during training when applied outside the data range. As a result, corrections that improve fit within the training regime may scale differently or alter their functional behavior under extrapolation, leading to inconsistent interactions with the mechanistic model and deviations from physically plausible trends.

A similar effect is observed in feature-learning model structures. Although polynomial regressions represent only a modest increase in complexity relative to linear models, their behavior remains highly dependent on the training data used to estimate coefficients. When evaluated outside the training regime, small fitting deviations can be amplified by nonlinearity. While these models are more constrained than neural networks, their embedding within nonlinear relations—such as exponential Antoine-type expressions—can still lead to large extrapolation error. Notably, the feature-learning model that kept the mechanistic evaporation term and learned only the heat input $Q_{\text{in}}$ performed similarly to NN correction models, indicating improved stability when learned components are confined to well-conditioned substructures.

Taken together, these results show that NBLOOCV effectively exposes extrapolation-induced failure modes that remain hidden under conventional validation strategies. These failures are consistent with a low-data, high-variability batch setting, in which flexible models are insufficiently constrained during extrapolation.

## 3.2 Predicting Crystallization Onset

Having established how model structure influences extrapolative robustness, crystallization onset prediction is used here as a downstream test of trajectory reliability, rather than as a standalone modeling objective. Using the linearly corrected hybrid model, a mean supersaturation offset of 3.8% w/w beyond the saturation curve was estimated from training batches and applied to predict crystallization onset in held-out batches. For all but one batch, the onset was predicted within 10 minutes (approximately 16% relative error). One batch (Figures 3e and 3f) exhibited delayed crystallization at lower temperatures, suggesting that the assumed supersaturation offset is invalid at low temperatures.

The purely mechanistic model achieved comparable accuracy (RMSE 8.6 min versus 6.7 min for the linear hybrid), indicating that the dominant process dynamics are already captured mechanistically. The hybrid model's advantage lies primarily in more consistent trajectory prediction across batches. The results show that when trajectory prediction is robust across batches—as enforced by NBLOOCV—simple hybrid corrections can translate into modest but reliable improvements in event timing.

## 3.3 Practical Considerations for Hybrid Model Design

The appropriate design of a hybrid model is inherently tied to its intended use. In real-time batch-process applications, models should support time-sensitive operational decisions under uncertainty. In this context, reliability, stability across operating regimes, and predictable failure modes are often more important than minimizing average prediction error.

The results of this study illustrate how these considerations directly influence hybrid model design. Hybrid models employing simple, structurally consistent correction terms modify mechanistic behavior in a predictable manner and therefore exhibit stable extrapolative behavior across varying batch conditions. This stability is essential when models are used during operation rather than for retrospective analysis. In contrast, hybrid models

incorporating nonlinear correction terms or fully data-driven components exhibit regime-dependent behavior, as reflected in poorer, more variable performance across NBLOOCV outer folds. While such models may perform well under specific conditions, their responses outside the training regime are less constrained, increasing the risk of misleading predictions when operators rely on the model most.

Models that occasionally produce large, unexpected errors can undermine trust and limit adoption, even when average performance appears strong. In contrast, models whose behavior aligns with physical intuition are easier to validate and act upon. The linearly corrected hybrid models evaluated here exemplify this trade-off, yielding reliable improvements over the mechanistic baseline without introducing unstable extrapolation.

Finally, the remaining limits in predictive accuracy indicate that not all errors should be addressed by increasing model complexity. Batch-to-batch variations in evaporation behavior and variability in crystallization onset reflect unmeasured disturbances and intrinsic process variability that cannot be resolved from available data. In such cases, increasing model complexity risks degrading robustness. For real-time applications, these uncertainties may be addressed more naturally through adaptive techniques or by communicating predictions as ranges rather than as point estimates.

Although demonstrated on a single crystallizer, the findings are expected to generalize to other batch separation processes characterized by limited data and batch-to-batch variability, such as chromatographic separation. In these settings, the same tension between flexibility and extrapolative robustness arises, and the case for modest, physically consistent hybridization is similarly desired.

## 4. CONCLUSION

This study examined how the validation strategy influences the selection of hybrid model structures in a case-study pilot-scale crystallizer. Nested batchwise leave-one-out cross-validation (NBLOOCV) was used to test extrapolation across batch trajectories. Here, hybrid models with simple linear correction terms consistently outperformed neural network–based models, which exhibited unstable behavior despite strong training performance. These results demonstrate that increased model flexibility does not guarantee improved predictive power when extrapolating.

The findings indicate that the hybrid model structure should be selected based on the intended operational use, particularly whether extrapolation across batches is required. For real-time applications, models must behave predictably when conditions deviate from historical data. NBLOOCV provides a practical mechanism for identifying extrapolation-induced failure modes during hybrid model selection. In the case studied, simple, linear hybrid corrections provide a robust foundation for operational decision support.

## ABSTRACT

Near-infrared (NIR) sorting systems in waste sorting plants operate under multiple settings, creating distinct input–output relationships that challenge predictive modeling. Conventional neural networks, such as multilayer perceptron (MLP), often suffer from catastrophic forgetting under continual training, limiting reliability across settings. This study evaluates Kolmogorov–Arnold Networks (KAN) for continual regression modeling of multi-setting NIR systems. KAN assign nonlinear transformations to network edges using localized spline grids, enabling structural isolation between input regions. We introduce controlled input-space manipulations (shifting successive settings to adjacent or non-overlapping grid regions) and compare KAN performance with MLPs of comparable parameter count. We also examine single-input versus multi-input configurations to assess dimensionality effects. Results show that KANs with sufficient input-space separation maintain previously learned knowledge with perfect resistance to forgetting, whereas overlapping inputs induce interference. MLP forgetting depends on learning rate and training duration and cannot be fully avoided without additional methods. Single-input KANs achieve comparable accuracy to multi-input models in this system, suggesting limited benefit from additional inputs. These findings demonstrate that KAN's structural locality, combined with controlled input-space alignment, provides a practical and robust approach for continual learning in industrial NIR systems.

## INTRODUCTION

Near-infrared (NIR) sorting systems in waste sorting plants operate under multiple parameter settings to accommodate variations in material composition, throughput, and product quality. These setting changes induce distinct input–output relationships, making reliable output prediction across operating conditions essential for disturbance detection, quality monitoring, and advanced control applications.

Classical models for waste sorting equipment typically rely on linear or split-factor formulations with a small number of dominant inputs [1, 2]. While interpretable, their limited expressiveness restricts their ability to capture nonlinear and setting-dependent behavior. Data-driven models, including multilayer perceptron (MLP), have demonstrated improved predictive accuracy by learning nonlinear relationships directly from data [3].

In industrial practice, however, data from different operating settings often become available sequentially, while historical data may be inaccessible or impractical to reuse. Under such continual learning conditions, neural networks such as MLP are prone to catastrophic forgetting [4], where training on new settings degrades performance on previously learned ones [5]. This behavior limits their reliability for long-term deployment in adaptive industrial systems.

Kolmogorov–Arnold Networks (KAN) have recently been proposed as an alternative neural architecture that assigns nonlinear transformations to network edges rather than nodes. Owing to their localized, grid-based parameterization, KAN may reduce interference between learned representations when trained sequentially. Initial evidence from synthetic benchmarks suggests that KAN

can better preserve previously learned functional components under certain continual learning scenarios [6]. Whether these properties extend to real-world industrial regression tasks remains an open question.

Motivated by these observations, this work investigates continual regression modeling for multi-setting NIR sorting systems using KAN. To explicitly examine the role of input-space structure in catastrophic forgetting. In addition, the study evaluates whether KAN can maintain predictive performance under reduced-input configurations, reflecting practical constraints in industrial modeling.

The contributions of this paper are summarized by the following research questions:

**RQ1:** How does input-space separation affect catastrophic forgetting in Kolmogorov–Arnold Networks under continual training?

**RQ2:** To what extent does KAN retain predictive performance on previously learned settings compared to MLP under identical sequential training protocols?

**RQ3:** Can KAN achieve comparable or superior prediction accuracy using a reduced set of input features compared to multi-input configurations?

# METHOD

## Problem Definition and Data Description

A NIR sorting unit is an optical-based separation system that exploits differences in infrared spectral absorption to distinguish between material types. During operation, the NIR unit periodically measures the spectral absorption, position, and surface area of materials transported on a conveyor belt. Based on the configured operating setting, air jets located at the end of the belt are actuated to divert materials into different output bins. As a result, the NIR sorting unit also functions as a material surface flow meter. Measurements from two subsequent units provides inflow and outflow of upstream unit.

The modeling task considered in this work is to predict the outflow of the NIR unit for a given inflow under different operating settings. Each flow stream consists of 11 material types. To limit scope and ensure clarity, this study focuses on predicting the outflow of a single target material, noting that the proposed methodology is directly extensible to other material fractions.

Inflow and outflow data were collected from the NIR unit and downstream processing equipment in an European waste sorting plant over approximately ten days equivalent of continuous operation. During this period, the system operated under two distinct settings. Setting A was active for the majority of the operating time, while Setting B was active for approximately three days. Measurements were recorded at a sampling interval of one minute, resulting in datasets of size 10, 187 and 3, 771 for Settings A (Dataset A) and B (Dataset B), respectively. The box plot of each dataset is presented in Figure 1.

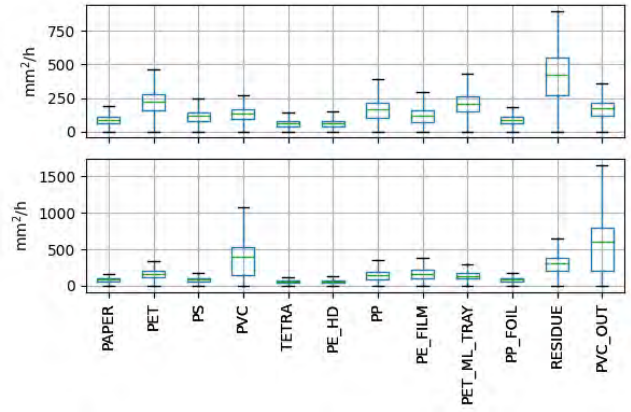

**Figure 1.** Flow Distribution in Dataset A (Top) and Dataset B (Bottom).

## Continual Learning

To emulate a continual learning scenario, the model is trained sequentially on data from different operating settings. In the first phase ($P_1$), training is performed using Dataset A. In the second phase ($P_2$), the model is further trained on Dataset B without access to Dataset A. This setup reflects practical industrial constraints, where historical data may be unavailable when new operating conditions are introduced.

For each setting, the available data are randomly split into 70% for training, 15% for validation, and 15% for hold-out testing. The validation set is used exclusively for early stopping to mitigate overfitting with Patience of 20 steps and Max Steps of 500. Each training is repeated over five independent runs with different random seeds to account for stochastic variability in initialization and training. Model performance is evaluated on the hold-out test sets of all settings after each phase.

Prediction accuracy is quantified using coefficient of determination ($R^2$) for straightforward interpretation of predictive performance and forgetting behavior.

## Kolmogorov Arnold Network

Kolmogorov Arnold Networks are a class of neural architectures inspired by the Kolmogorov-Arnold representation theorem, which states that any continuous multivariate function can be expressed as a finite sum of univariate functions composed with affine transformations. In contrast to MLP, where nonlinearity is applied at the nodes and edges are linear, KAN assign nonlinear transformations to the edges while nodes perform simple summation. See [6] for architectural illustrations.

Each edge in a KAN is parameterized by a learnable univariate function, typically represented using spline-based basis functions defined over a finite grid. These spline functions are locally supported, meaning that

parameter updates primarily affect specific regions of the input space determined by the grid structure and spline order $k$. As a result, changes induced by new training data may remain confined to localized subsets of parameters.

This parameter locality contrasts with the globally shared weights in MLP and provides a structural mechanism by which KAN may reduce interference between sequentially learned tasks. In continual learning settings, such locality suggests that learning new operating conditions could have a limited impact on previously learned input-output mappings, motivating the investigation of KAN for multi-setting industrial regression problems.

## Input-Space Manipulation Strategies

To leverage KAN's grid-based parameter locality in resisting catastrophic forgetting, this study introduces deliberate input-space manipulation strategies. The objective is to control how data from different operating settings occupy the input domain and, consequently, how they align with the spline grids of the KAN model. These manipulations are introduced solely as an experimental mechanism inspired by synthetic continual learning benchmarks and are not assumed to arise naturally in industrial NIR data.

Specifically, multiple input-shifting configurations are examined. In all shifted cases, the input features of Dataset B are translated by a fixed offset relative to Dataset A. Shifts of 2000, 4000, and 6000 mm$^2$/h are evaluated for spline orders $k$=1 and $k$=2, corresponding to different degrees of separation between the input regions associated with successive training phases. A baseline configuration with no input shift is also included for reference.

For all configurations, the grid width is chosen such that each dataset predominantly occupies a single grid region (i.e., 2000 mm$^2$ per region). Grid knot positions are fixed, while the grid range and number of knots vary according to the applied input shift. This ensures that changes in forgetting behavior can be attributed to controlled input-space separation rather than adaptive grid refinement.

By comparing these configurations, the study systematically evaluates how increasing degrees of input-space separation affect catastrophic forgetting behavior in KAN under continual training.

## Experimental Design

### Effect of Input-Space Separation in KAN

The combinations of input shift magnitude and spline order $k$, together with their corresponding grid configurations, are summarized in Table 1. Across all cases, a consistent KAN architecture and training configuration is employed to isolate the effect of input-space separation. Specifically, all models use a single-layer KAN with width of [11, 1], a zero base-function, and fixed spline scaling and bias terms (i.e., spline scale and bias are not trainable).

**Table 1:** Input Space Manipulation Cases and The Corresponding KAN architecture.

| Shift (mm$^2$/h) | 0 | 2000 | 4000 | 6000 |
|---|---|---|---|---|
| Case k=1 | K1S0 | K1S1 | K1S2 | K1S3 |
| Case k=2 | - | K2S1 | K2S2 | K2S3 |
| Grid | 1 | 2 | 3 | 4 |
| Max Grid | 2000 | 4000 | 6000 | 8000 |

### KAN vs MLP under Continual Training

To address RQ2, MLPs are trained under the same continual learning protocol as KANs and evaluated for resistance to catastrophic forgetting. Because MLPs do not exhibit inherent parameter locality, multiple MLP models are trained using different learning rates during the second training phase ($L_{P_2}$) to examine the effect of learning rate on forgetting behavior and to identify the best achievable performance under this constraint.

To ensure a fair comparison of model capacity, MLP architectures with approximately matched numbers of trainable parameters ($n_{\mathrm{PAR}}$) are used. In particular, an MLP with structure of [11, 4, 1] is evaluated and compared against the KAN configuration exhibiting the strongest forgetting resilience identified in RQ1 (denoted KAN-K1S2). All MLPs are trained using the original input space, as input shifting is not expected to induce parameter modularity in standard MLP architectures.

### Reduced-Input vs Multi-Input Configurations

To address RQ3, the predictive performance of KANs under reduced input dimensionality is examined. Two reduced-input KAN models, using a single dominant input and spline orders $k$=1 and $k$=2 (denoted KAN-K1RI and KAN-K2RI), are trained under the same continual learning protocol. Their performance is compared against the best-performing multi-input KAN models for the corresponding spline orders to assess whether comparable accuracy and forgetting resilience can be achieved with fewer input features.

### Forgetting Metrics

Forgetting is quantified by measuring the change in predictive performance on the initial operating setting after training on a new setting. Specifically, the coefficient of determination $R^2$ on the test set of Dataset A is evaluated before and after Phase 2 training. The difference between these values is used as the primary metric.

Models exhibiting a strongly negative $R^2$ on Dataset A after Phase 2 are classified as having undergone catastrophic forgetting and are labeled as "Forgetful". Models maintaining near-identical $R^2$ values before and after

**Table 2:** Input Space Manipulation Results.

| Case | K1S0 | K1S1 | K1S2 | K1S3 | K2S1 | K2S2 | K2S3 |
|---|---|---|---|---|---|---|---|
| $S_{P_1}$ | 29±4 | 28±3 | 27±4 | 27±4 | 87±18 | 77±23 | 110±50 |
| $S_{P_2}$ | 56±15 | 45±19 | 60±22 | 64±26 | 68±8 | 66±20 | 50±18 |
| $R^2_{A,P_2}$ | 0.76 ±0.00 | -2.99 ±0.10 | 0.93 ±0.00 | 0.93 ±0.00 | -456.05 ±14.49 | 0.72 ±0.06 | 0.93 ±0.00 |
| $R^2_{B,P_2}$ | 0.96 ±0.00 | 0.96 ±0.00 | 0.96 ±0.00 | 0.96 ±0.00 | 0.97 ±0.00 | 0.97 ±0.00 | 0.97 ±0.00 |
| $\Delta R^2_A$ | -0.17 ±0.00 | Forgetful | Resilient | Resilient | Forgetful | -0.21 ±0.06 | Resilient |

Phase 2 are classified as “Resilient”.

# RESULTS AND DISCUSSIONS

## Effect of Input-Space Separation

Table 2 summarizes the results of the input-space separation experiments. All configurations triggered early stopping in both Phase 1 and Phase 2, indicating stable convergence under the continual training protocol. Across all cases, predictive performance on the newly learned setting (Dataset B) remained high, with second-phase coefficients of determination ($R^2_{B,P_2}$) exceeding 96%. In contrast, performance retention on the previously learned setting (Dataset A) varied substantially across configurations.

Complete resilience to catastrophic forgetting is observed in cases K1S2, K1S3, and K2S3, where the coefficient of determination on Dataset A remains unchanged after Phase 2 training. In contrast, cases K1S1 and K2S1 exhibit complete forgetting, characterized by a severe degradation in $R^2_{A,P_2}$. The baseline cases K1S0 and K2S2 demonstrate partial resilience, retaining some predictive capability on Dataset A but with a noticeable reduction in performance.

These results indicate that catastrophic forgetting in KANs is strongly governed by the degree of overlap between input regions learned in successive training phases. When the input space of the new setting overlaps with, or is insufficiently separated from, the previously learned region, parameter updates propagate to shared spline basis functions, leading to interference and forgetting. Conversely, shifting the input space by at least $k$ grid lengths from the boundary of the previously occupied region consistently prevents forgetting.

This behavior can be explained by the local support of spline basis functions in KAN. For a spline of order $k$, each spline basis function spans $k$+1 adjacent grid intervals. Consequently, basis functions located near grid boundaries influence neighboring regions outside the immediate input domain. If new training data falls within $k$ grid intervals of a previously learned region, shared spline coefficients are updated, inducing forgetting. Ensuring a separation of at least $k$ grid lengths guarantees that new data activates a disjoint set of spline basis functions, thereby preserving previously learned mappings.

These findings are consistent with observations reported by [7] and [8], who showed that architectures with localized or region-specific activations exhibit task-specific feature detectors. When the activation regions associated with different tasks do not overlap, earlier knowledge remains intact; when overlap occurs, forgetting increases proportionally to the extent of shared activation. In this context, KAN’s spline-based edge functions act as localized feature detectors whose spatial separation directly governs forgetting behavior.

## KAN vs MLP under Continual Training

Table 3 compares the forgetting behavior of MLPs under varying second-phase learning rates with that of a KAN model of comparable parameter count. For MLPs, reducing the second-phase learning rate resulted in smaller $\Delta R^2_A$ values, indicating slower forgetting; however, this was accompanied by a decline in second-phase test performance on data B ($R^2_{B,P_2}$). Early stopping was not triggered for any MLP configuration, implying continued parameter updates throughout the second training phase.

Despite learning-rate tuning, none of the MLP configurations fully avoided catastrophic forgetting. Instead, forgetting was mitigated only by slowing the optimization process, confirming that forgetting in MLPs is governed by optimization duration over shared parameters.

KAN achieved the highest $R^2_{B,P_2}$ while maintaining a comparable $R^2_{A,P_2}$ to the best-performing MLP, with substantially lower result variability. This indicates that KAN’s improved forgetting resilience arises from its localized spline-based representations rather than from optimization hyperparameters.

It is acknowledged that several established techniques such as regularization-based methods, replay strategies, or parameter-isolation approaches can further improve forgetting resilience in MLPs. However, learning-rate control was deliberately selected here to

isolate the effect of optimization dynamics alone, without introducing additional mechanisms that explicitly modify the network structure or training data. This ensures a fair comparison focused on intrinsic architectural differences between MLP and KAN.

**Table 3:** KAN vs MLP in Continual Learning Results.

| Case | K1S2 | MLP1 | MLP2 | MLP3 |
|---|---|---|---|---|
| $L_{P_2}$ | 1 | $1x10^{-4}$ | $2x10^{-5}$ | $1x10^{-6}$ |
| $n_{\mathrm{PAR}}$ | 44 | 53 | 53 | 53 |
| $S_{P_1}$ | 27±4 | 323±167 | 323±167 | 323±167 |
| $S_{P_2}$ | 60±22 | 500±0 | 500±0 | 500±0 |
| $R^2_{A,P_2}$ | 0.93 ±0.00 | 0.54 ±0.05 | 0.89 ±0.02 | 0.93 ±0.00 |
| $R^2_{B,P_2}$ | 0.96 ±0.00 | 0.95 ±0.00 | 0.92 ±0.01 | 0.90 ±0.00 |
| $\Delta R^2_A$ | Resilient | -0.38 ±0.05 | -0.04 ±0.02 | Resilient |

## Input Dimensionality Analysis

Table 4 summarizes the input dimensionality analysis. Across both $k$=1 and $k$=2, multi-input KAN models consistently achieve slightly higher R2 values than their single-input counterparts; however, the performance gap remains marginal.

This indicates that interactions between multiple material inputs contribute only weakly to predictive performance in the studied setting. Single-input models with $k$=2 exhibit a small but consistent improvement over $k$=1, suggesting the presence of mild nonlinear correlations in the input–output relationship.

Given the negligible accuracy gain from additional inputs and higher model complexity, a single-input KAN with $k$=1 emerges as the most effective configuration, delivering comparable predictive accuracy with substantially fewer trainable parameters and reduced model complexity.

**Table 4:** Input Dimensionality Analysis Result.

| Case | K1S2 | K2S3 | K1RI | K2RI |
|---|---|---|---|---|
| $n_{\mathrm{INPUT}}$ | 11 | 11 | 1 | 1 |
| $n_{\mathrm{PAR}}$ | 44 | 66 | 4 | 6 |
| $S_{P_1}$ | 27±4 | 110±50 | 20±0 | 22±1 |
| $S_{P_2}$ | 60±22 | 50±18 | 26±7 | 22±2 |
| $R^2_{A,P_2}$ | 0.93 ±0.00 | 0.93 ±0.00 | 0.92 ±0.00 | 0.92 ±0.00 |
| $R^2_{B,P_2}$ | 0.96 ±0.00 | 0.97 ±0.00 | 0.96 ±0.00 | 0.97 ±0.00 |
| $\Delta R^2_A$ | Resilient | Resilient | Resilient | Resilient |

## Practical Implications for Industrial Modeling

From a practical perspective, the proposed input-space shifting strategy offers a simple yet effective mechanism for maintaining predictive accuracy across multiple operating settings without requiring access to historical data.

The results of this study suggest that, when using KANs, deliberate alignment of new operating data to previously unused regions of the input space can substantially mitigate catastrophic forgetting. This enables long-term model reuse across settings using a single model instance, reducing maintenance effort and simplifying deployment. Moreover, the strategy is purely on data-level and does not require architectural modification or specialized continual learning algorithms, making it attractive for industrial adoption.

## Limitations

Several limitations of the proposed approach should be acknowledged i.e.:

- The input-space manipulation strategy operates exclusively at the input level and explicitly exploits the localized grid structure of shallow KAN. As network depth increases, interactions between layers may reduce the degree of effective parameter locality, potentially diminishing the strength of input-space separation.
- The strategy relies on deliberate and controlled input transformations, which may not always align with naturally occurring process variations. While suitable for controlled modeling scenarios, its applicability to systems with complex, high-dimensional, or poorly bounded input spaces requires further investigation.
- Finally, the present study focuses on a single real-world system and a limited number of operating settings. While sufficient for mechanism validation, broader conclusions regarding generalization across domains should be drawn cautiously.

## Future Work

The following are several directions for future research emerge from this work:

- Extending the experimental setup to deep KAN would allow assessment of forgetting resilience in deep KAN.
- Evaluating the proposed mechanism on other architectures that employ localized representations, such as radial basis function models, would help determine whether the observed behavior is specific to KANs or reflects a broader architectural principle.
- Embedding shallow KAN as base layer of MLP and applying input-space separation might enhance the forgetting resilience of the resulting complex

model.

- Combining input-space manipulation with complementary continual learning techniques, such as replay buffers or regularization-based methods, may further enhance robustness while maintaining feasibility.

## CONCLUSION

Shifting input regions by at least $k$ grid lengths prevent catastrophic forgetting in KAN, while overlapping or insufficiently separated regions cause interference in spline coefficients. This demonstrates that KAN's local-support spline functions can be systematically exploited to retain prior knowledge in continual training.

KAN maintains high accuracy on both old and new settings, whereas MLP forgetting depends on learning rate and training duration and cannot be fully avoided without additional techniques. This shows that KAN's structural locality is key to its superior continual learning performance.

Multi-input KAN models offer only marginal gains over single-input models, indicating minimal effect from multi-material interactions. Single-input KAN with $k$=1 achieves comparable accuracy with fewer parameters, making it the most efficient choice for practical deployment.

Together, the results demonstrate that Kolmogorov–Arnold Networks provide an effective and robust framework for continual learning in multi-setting NIR systems, highlighting its practical suitability for industrial deployment where both adaptability and model reliability are critical.

# Renewables to X: Micro-Reactor Pathways towards Methanol and Dimethyl Ether Production

## ABSTRACT

Renewable-to-X products such as methanol (MeOH) and dimethyl ether (DME) offer scalable, carbon-neutral options for decentralized chemical production. Microreactors, with superior heat and mass transfer, provide more controllable reaction environments. This improved control enhances selectivity and conversion, making microreactors particularly well suited for intensifying $CO_2$/CO hydrogenation within a Power to X framework for synthetic products. However, an assessment of MeOH and DME synthesis routes under microreactor operation is still lacking. To address this gap, a microreactor-scale model was developed where two reactor configurations were analyzed: i) parallel configuration, in which MeOH synthesis and subsequent dehydration to DME take place in the same reactor, and ii) series configuration, in which MeOH synthesis is carried out in the first reactor, followed by MeOH dehydration to DME in a second reactor. To capture realistic process behavior, the simulations incorporated non-isothermal, non-isobaric operation and fugacity-based reaction rates. The comparison reveals that reaction decoupling in the series configuration enables higher overall conversion of MeOH to DME, while the parallel route is constrained by strong kinetic and thermal coupling between hydrogenation, dehydration, and water formation. Despite requiring fewer unit operations, the parallel route yields mixed MeOH–DME product streams, whereas the series pathway favors higher DME productivity. The results highlight a fundamental trade-off between process intensification and conversion efficiency in microreactor-based Renewable-to-X systems.

## INTRODUCTION

Renewable-to-X processes enable the conversion of $CO_2$- and CO-derived synthesis gas into liquid chemical energy carriers such as methanol (MeOH) and dimethyl ether (DME), which are relevant target products for decentralized Power-to-X systems [1]. DME synthesis can be produced through different process configurations that vary in reaction coupling, heat management, and handling of intermediate species, leading to distinct reactor and process performance characteristics. DME can be produced either in parallel, where MeOH synthesis and dehydration proceed concurrently from synthesis gas in a single reactor [2], or in series of reactors, in which MeOH is first formed and then dehydrated to DME in a downstream reactor stage [3].

Microreactor technology offers intensified heat and mass transfer, narrow residence time distributions, and improved temperature control [4], which are advantageous for kinetically coupled reaction networks such as $CO_2$/CO hydrogenation and MeOH dehydration. These characteristics enable systematic investigation of reaction pathway integration and separation under well-defined operating conditions. While microreactors have been widely applied for reaction intensification studies, comparative analyses of alternative DME synthesis routes under consistent microreactor-scale conditions remain limited.

This work addresses this gap by developing a unified microreactor modeling framework for two alternative DME production routes: (i) DME synthesis via parallel MeOH formation and dehydration reactions within a single microreactor, and (ii) DME synthesis via MeOH production followed by dehydration in a second

microreactor. Identical kinetic descriptions and operating conditions are employed to enable a consistent, side-by-side assessment of conversion, selectivity, and reactor performance, providing a quantitative basis for evaluating pathway selection in Renewable-to-X process design.

# METHOD AND MODELS

## Microreactor geometry and operating conditions

The investigated system was a tubular microreactor operated under steady-state conditions. Two reactor volumes were considered, namely 4 mL and 16 mL, corresponding to reactor lengths of 3.16 m and 12.63 m, respectively, at a constant inner diameter of 1.27 mm. The feed flow rate into the system varied between 0.5 and 10 mL/in, depending on the syringe pump configuration. The catalyst was modeled as a thin porous layer uniformly coated on the reactor wall with a thickness of 20 µm. Effective catalyst bulk densities were specified according to the reaction system under consideration: 440 kg/m$^3$ for MeOH synthesis [5], 693.96 kg/m$^3$ for MeOH dehydration to DME [2], and 1019 kg/m$^3$ for DME synthesis [6], based on reported experimental and apparent density data.

## Flow model and species balances

Axial plug flow was assumed, neglecting radial gradients in concentration and temperature due to the small reactor diameter. Species balances were formulated following the approach of Nestler et al. [7], accounting for convective transport and heterogeneous catalytic reactions. For each species *i*, the molar flow rate variation along the axial coordinate *z* was given by Eq. 1.

$$\frac{d\dot{n}}{dz} = A_R \rho_{\text{cat}} \sum_j \nu_{i,j} \cdot r_j \quad (1)$$

In this Eq. 1 $A_R$ is the reactor cross-sectional area, $\rho_{\text{cat}}$ is the catalyst bulk density, $\nu_{i,j}$ is the stoichiometric coefficient, and $r_j$ is the reaction rate of reaction *j*.

## Reaction kinetics

Reaction kinetics were described using established literature models for MeOH synthesis, MeOH dehydration (DME production in series configuration), and DME synthesis in parallel configuration, enabling a consistent and mechanistically grounded comparison of alternative pathways. All kinetic expressions were implemented in terms of fugacities to account for non-ideal gas-phase behavior, as described by the Peng–Robinson equation of state [8].

## Methanol synthesis in series configuration

MeOH synthesis was described by reaction network as presented in Eq. 2. It consisted of CO hydrogenation, reverse water–gas shift reaction and $CO_2$ hydrogenation.

$$\begin{aligned} \mathrm{CO} + 2H_2 &\rightleftarrows \mathrm{CH_3OH} \\ \mathrm{CO_2} + 2H_2 &\rightleftarrows \mathrm{CO} + H_2O \\ \mathrm{CO_2} + 3H_2 &\rightleftarrows \mathrm{CH_3OH} + \mathrm{H_2}O \end{aligned} \quad (2)$$

MeOH synthesis from CO/$CO_2$ and $H_2$ was modeled using the kinetic formulation proposed by Park et al. [9], which builds upon Langmuir–Hinshelwood–Hougen–Watson expressions originally developed by Graaf et al. [10]. The model accounts for parallel hydrogenation of CO and $CO_2$ as well as the reverse water-gas shift reaction, incorporating competitive adsorption of reactants and products on Cu/ZnO/$Al_2O_3$ catalysts. Reaction rates are formulated as functions of species fugacities, ensuring thermodynamic consistency under elevated pressures. Temperature-dependent equilibrium constants and kinetic parameters were taken from Park et al. [9], while adsorption constants were adopted from Graaf et al. [10].

## DME synthesis (methanol dehydration) in series configuration

In the series configuration, MeOH is dehydrated over an acidic catalyst, typically γ-$Al_2O_3$, according to Eq. 3.

$$2\mathrm{CH_3OH} \rightleftarrows \mathrm{CH_3OCH_3} + \mathrm{H_2O} \quad (3)$$

The kinetics of MeOH dehydration to DME were described using the model developed by Berčič and Levec [11]. Their original formulation expresses the reaction rate as a function of species concentrations, which is strictly valid for ideal reaction mixtures. Since non-ideal gas-phase behavior is considered in this work, the kinetic expression was reformulated in terms of partial pressures. At relatively low pressures, fugacities can be approximated by partial pressures, enabling a consistent transformation using the ideal gas relation $C_i = P_i/RT$ [12], [13]. The resulting pressure-based rate expression was implemented, while kinetic and adsorption constants were adopted from the original work [11]. The equilibrium constant for MeOH dehydration was evaluated using a temperature-dependent correlation from the literature [14].

## DME synthesis in parallel configuration

In the parallel DME synthesis route, MeOH synthesis reactions (Eq.1-3) and MeOH dehydration (Eq.4) take place simultaneously within a single reactor over a bifunctional catalyst. This configuration provides a thermodynamic advantage compared to standalone MeOH synthesis, as continuous consumption of MeOH shifts the equilibrium toward higher overall conversion [15].

For the parallel route, the kinetic model proposed by Behloul et al. [6] was employed. The model combines MeOH formation and dehydration kinetics within a unified framework, accounting for reaction coupling and shared

intermediate species. No additional empirical coupling terms were introduced; instead, the interaction between hydrogenation and dehydration reactions emerges naturally through shared species, adsorption terms, and reaction enthalpies.

At each axial discretization step, local temperature, pressure, and composition were used to evaluate fugacities, kinetic rate constants, and adsorption terms. Reaction rates were then coupled to the species and energy balances, enabling fully coupled simulation of mass transfer, heat effects, and reaction kinetics along the reactor length. Identical kinetic formulations were applied across all microreactor configurations to ensure that observed differences in performance arise solely from pathway selection and reactor configuration.

### Energy balance

An axial energy balance was formulated following the methodology of Nestler [7], extended to include external cooling. The energy balance accounts for reaction enthalpies, sensible heat effects, and heat exchange with the reactor surroundings. Reaction enthalpies were evaluated using Kirchhoff's law with temperature-dependent heat capacities [16]. At each axial discretization step, reaction rates, enthalpy changes, and temperature were updated consistently for all reaction networks.

### Thermodynamic model

Non-ideal gas behavior was described using the Peng–Robinson equation of state [8]. For each component, temperature-dependent attractive and repulsive parameters were computed from critical properties and acentric factors. Mixture parameters were obtained using classical van der Waals mixing rules with binary interaction parameters. At each axial position, the cubic Peng–Robinson equation was solved to determine the mixture compressibility factor, selecting the largest real root corresponding to the gas phase. Fugacity coefficients were then calculated and used to evaluate component fugacities in the kinetic rate expressions.

### Pressure drop model

Pressure drop along the microreactor was calculated using the model proposed by Hessel for microchannels [17]. Local losses were neglected, and the pressure drop was expressed as a function of friction factor, channel length, hydraulic diameter, and fluid velocity. The formulation was adapted to use dynamic viscosity instead of density to account for strong temperature dependence. Gas-phase viscosity was calculated using the Chapman–Enskog [18] method for low-pressure cases, while for the high-pressure cases the viscosity was calculated using the method developed by Chung et al. [19].

## CASE STUDY

The simulation study consisted of a sensitivity analysis of two different pathways. For the MeOH and parallel DME configuration, the reactor temperature varied from 210 to 260 °C with 5 °C increments, and the pressure varied from 50 to 90 bar with 5 bar increments. The inlet volumetric flow rate varied between 0.5 and 10 mL/min with a step size of 0.5 mL/min. For the DME production in series reactor configuration, the temperature range was shifted to 290–360 °C in 5 °C increments, and the reactor pressure was fixed at 2.1 bar; the inlet flow rate corresponded to the MeOH outlet stream from the MeOH reactor simulation. The temperature and pressure ranges were chosen in accordance to the ranges at which the kinetic models were developed. Three different synthesis gas compositions were investigated, with $H_2$:$CO_2$:CO ratios of 0.8:0.2:0, 0.8:0.15:0.05, and 0.7:0.2:0.1. For the DME production in the series configuration, the feed composition was fixed at a MeOH:DME:$H_2O$ ratio of 0.96:0.01:0.03. The feed compositions chosen were the most studied ones in literature. All simulations were conducted for reactor volumes of 4 mL and 16 mL to assess scale effects, reflecting the capacities of the available modules.

### Series reactions configuration

The simulation results are presented for each process to examine the effects of operating conditions, reactor size, and process configuration on conversion and product formation. For the methanol reactor system the cases with the highest methanol output in terms of mmol/h and the highest methanol molar fraction in the outlet were discussed.

#### Methanol synthesis

For MeOH synthesis, the 16 mL reactor consistently outperformed the 4 mL configuration in both reactant conversion and MeOH production rate across the investigated operating conditions. The highest MeOH concentration at the outlet, 14.2 mol%, was achieved at 255 °C, 90 bar, 0.5 mL/min, with a $H_2$:$CO_2$:CO feed ratio of 0.7:0.2:0.1. The highest total MeOH output, 68.9 mmol/h, was achieved with a $H_2$:$CO_2$:CO feed ratio of 0.8:0.15:0.05 at 260 °C, 90bar, and 10 mL/min.

Although the feed ratio 0.7:0.2:0.1 delivered the highest outlet MeOH fraction (14.2 mol%) at low flow (0.5 mL/min), this primarily reflects long residence time and does not indicate production capacity. Therefore, the ratio 0.8:0.15:0.05, which yielded the maximum MeOH molar output (68.9 mmol/h) at high throughput (10 mL/min), was selected for further analysis as it represents the relevant design point from a productivity perspective. Figure 1 shows the effect of temperature (Figure 1a) and inlet flow rate (Figure 1b) on MeOH synthesis performance for the 16 mL reactor operated at 90 bar with a $H_2$:$CO_2$:CO feed ratio of 0.8:0.15:0.05.

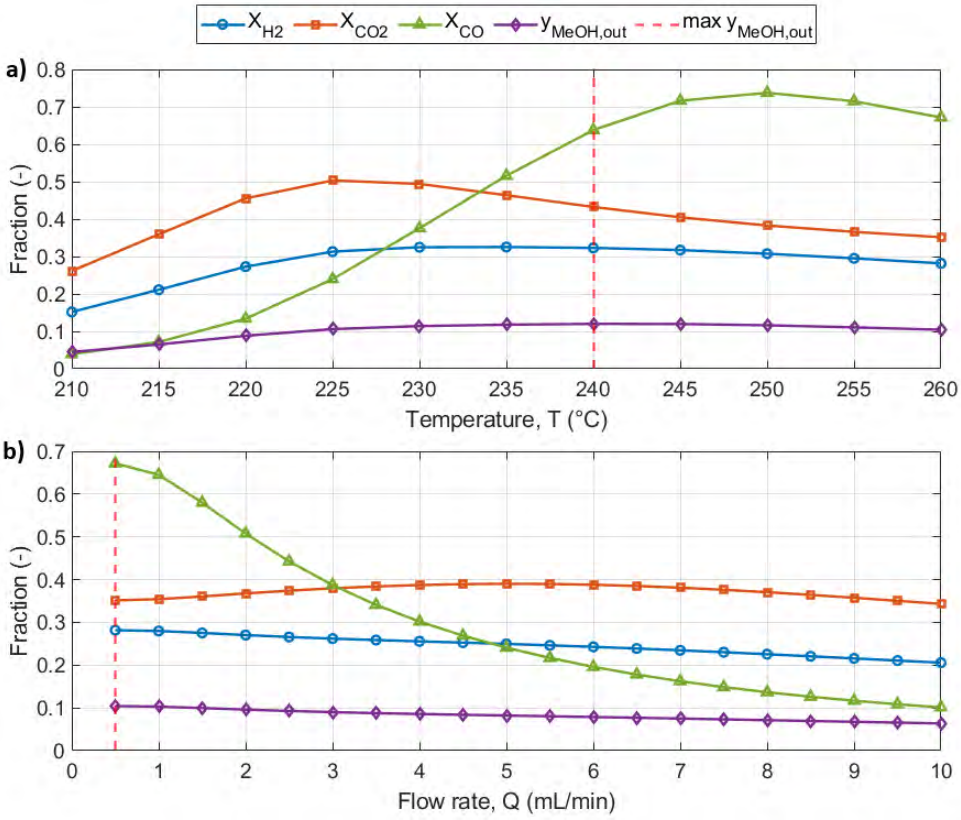

**Figure** 1. Effect of a) temperature, and b) inlet flow rate on reactant conversion and MeOH production for MeOH synthesis

For the temperature sensitivity analysis (Figure 1a), the inlet flow rate was fixed at 0.5 mL/min. Under these conditions, the maximum MeOH outlet fraction of 12.0% was obtained at 240 °C, resulting in a MeOH output of 6.1 mmol/h.

The flow rate sensitivity analysis (Figure 1b) was conducted at a fixed temperature of 260 °C, as the highest possible MeOH output was achieved at that temperature. The highest $H_2$ and CO conversions were observed at the lowest inlet flow rate of 0.5 mL/min. $CO_2$ conversion reached its maximum value of 39.0% at an intermediate flow rate of 5 mL/min. Although reactant conversions decreased with increasing inlet flow rate, the maximum MeOH production rate of 68.9 mmol/h was obtained at 10 mL/min, corresponding to $CO_2$ and CO conversions of 34.3% and 10.1%, respectively, and a MeOH outlet fraction of approximately 6.3 mol%. Although the MeOH outlet fraction under high-throughput operation (6.3 mol%) is substantially lower than the maxima observed at low flow rates (12.0–14.2 mol%), the corresponding MeOH production rate is more than an order of magnitude higher, increasing from approximately 6.1 mmol/h to 68.9 mmol/h.

Figure 2 shows the axial molar fraction values of species as well as the molar flow rate of the product for the MeOH synthesis reactor for the configurations that yield the highest molar MeOH flow rate (Figure 2a) and the configuration yielding a MeOH fraction of 12% (Figure 2b).

Figure 2a shows that in the case of maximum MeOH output, the reaction does not approach equilibrium, as indicated by the still relatively steep increase in MeOH flow and MeOH mol%. It can also be seen that CO mol% remains relatively unchanged from input to output, suggesting that most MeOH is produced from $CO_2$. Figure 2b shows a different trend: MeOH production begins to slow after 5 m. The mol% of CO starts to decrease after 4 m of reactor length, while the amount of $CO_2$ begins to increase. At 4 m of reactor length, the amount of water in the system remains approximately constant even though MeOH mol% continues to increase, indicating that the reverse water-gas shift reaction starts to consume water to produce hydrogen and $CO_2$, which also explains the increasing amount of $CO_2$ in the reactor.

## DME synthesis

Based on the MeOH reactor performance at maximum MeOH output (68.9 mmol/h), the DME synthesis pathway is evaluated using the corresponding MeOH-rich outlet stream as feed. Figure 3 shows the effect of

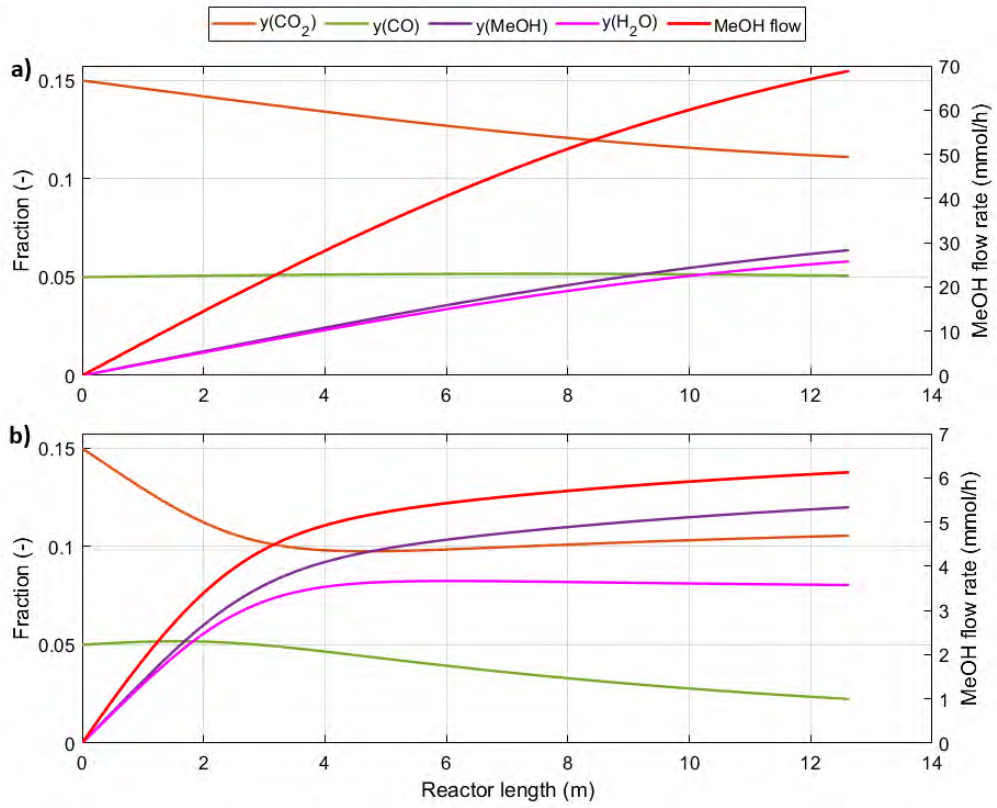

**Figure** 2. Species mol% and MeOH flow rate based on reactor length for a) the case for maximum MeOH output and b) the case for maximum mol% of MeOH in output

temperature on MeOH conversion and DME outlet fraction for DME synthesis pathway in series operated at 2.1 bar with reactor volumes of 4 mL and 16 mL.

For both reactor sizes, increasing the temperature from 290 to 360 °C resulted in a monotonic increase in MeOH conversion and DME formation, indicating that MeOH dehydration is strongly temperature-activated under the investigated conditions. In the 4 mL reactor, operation at 360 °C resulted in a MeOH conversion of 49.70%, corresponding to a DME production rate of 17.83 mmol/h. In the 16 mL reactor, operation at 360 °C led to a MeOH conversion of 87.37%, with a corresponding maximum DME production rate of 30.80 mmol/h. The substantially higher conversion and DME output achieved in the 16 mL reactor highlight the strong influence of reactor volume on DME production in series configuration performance.

Figure 4 presents axial species concentration profiles for this configuration to assess reactor utilization.

MeOH is rapidly consumed near the reactor inlet, with its molar fraction decreasing sharply in the initial portion of the reactor, indicating fast dehydration kinetics under these conditions. Correspondingly, the molar fractions of DME and water increase steeply at short reactor lengths and approach asymptotic values further downstream.

Beyond approximately the first 6 m of reactor length, the molar fractions of DME and water change only slightly, while MeOH approaches a low residual level. This behavior indicates that the dehydration reaction is mainly completed within the upstream section of the reactor, and that additional reactor length contributes minimally to further DME formation under the selected operating conditions.

## Parallel reactions configuration

For DME synthesis in parallel configuration, as before, the 16 mL reactor consistently outperformed the 4 mL configuration in both reactant conversion and DME production rate across the investigated operating conditions. The best results were achieved at the highest investigated pressure of 90 bar using a $H_2$:$CO_2$:CO feed ratio of 0.7:0.2:0.1. Figure 5 shows the effect of temperature (Figure 5a) and inlet flow rate (Figure 5b) on DME synthesis performance for the 16 mL reactor operated at 90 bar with a $H_2$:$CO_2$:CO feed ratio of 0.7:0.2:0.1.

In the temperature sensitivity analysis (Figure 5a), the inlet flow rate was fixed at 0.5 mL/min. Under these conditions, the maximum $H_2$ conversion of 51.4% was obtained at 255 °C, along with the highest $CO_2$ conversion

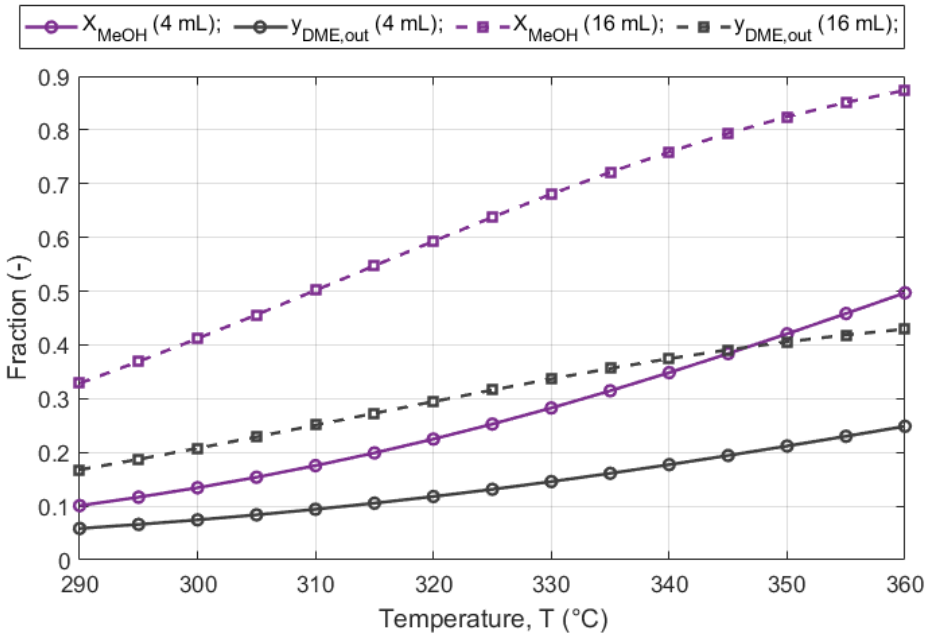

**Figure** 3. Effect of temperature on MeOH conversion and DME outlet fraction for DME synthesis in series configuration

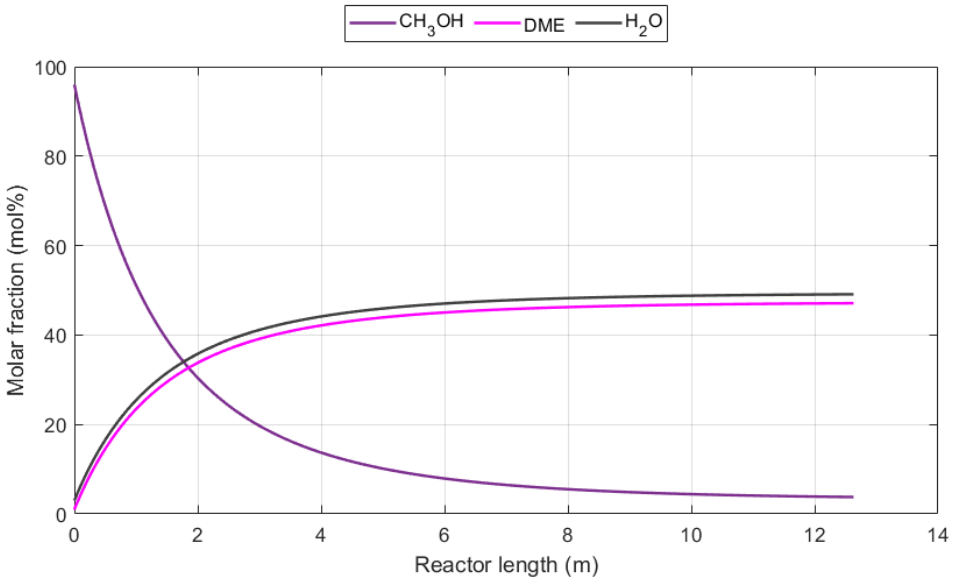

**Figure** 4. Axial molar fraction profiles of MeOH, DME, and water

of 29.2% and CO conversion of 92.3%. The DME outlet fraction peaked at 9.1 mol% (3.3 mol% MeOH) at the same temperature of 255 °C, reaching an output of 3.92 mmol/h.

The flow-rate sensitivity analysis shown in Figure 5b was conducted at a fixed temperature of 260 °C. The highest conversions and the highest DME fraction were achieved at the lowest inlet flow rate. The configuration with the maximum DME production rate (8.48 mmol/h) occurred at an inlet flow rate of 2.5 mL/min and temperature of 260 °C, but resulted in a substantially lower DME fraction of 3.4 mol% (4.3 mol% MeOH).

Figure 6 shows the axial molar fraction values of species and the molar flow rate of the product for the DME synthesis reactor for the configurations that yield the highest molar DME flow rate (Figure 6a) and the configuration yielding a DME fraction of 9.1 mol% (Figure 6b).

In Figure 6a, which corresponds to the highest DME

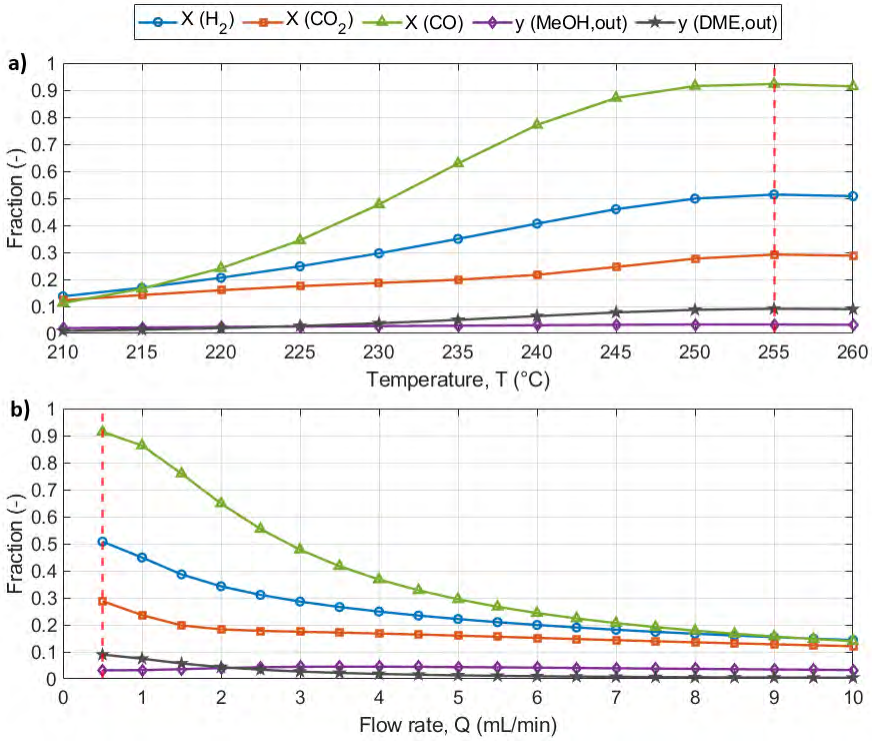

**Figure** 5. Effect of a) temperature, and b) inlet flow rate on reactant conversion and DME production

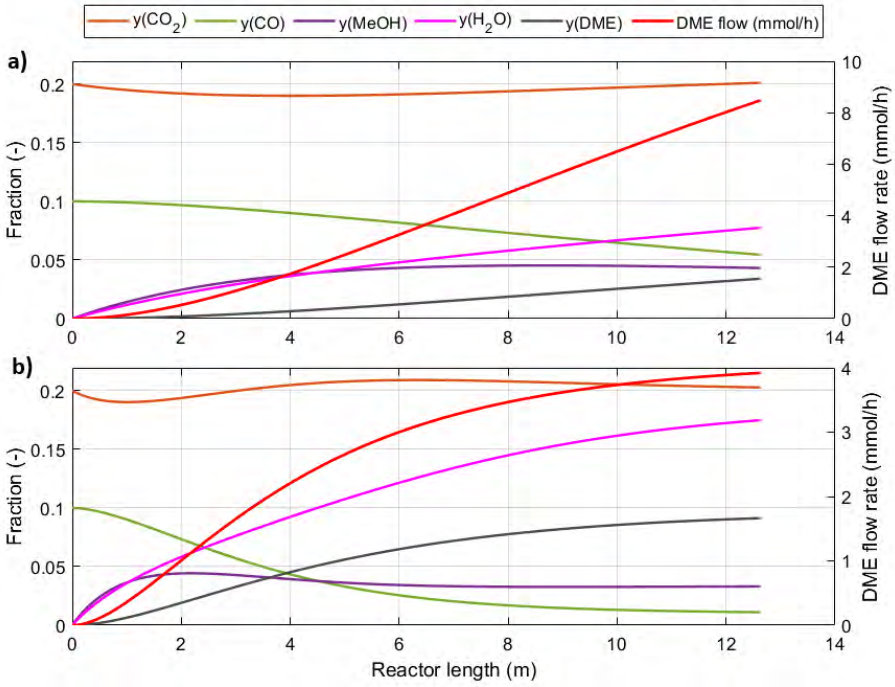

**Figure** 6. Species mol% and DME flow rate based on reactor length for a) the case for maximum DME output flow rate and b) the case for maximum mol% fraction of DME in output

outlet, it is shown that at the start (up to 2 m), $CO_2$ is being consumed to produce MeOH, with MeOH dehydration beginning after 2 m. After 2 m of reactor length, the CO mol% starts to decrease while $CO_2$ mol% starts to increase, indicating that CO is now being utilized to produce MeOH. Although MeOH is being consumed to produce DME, its value remains slightly above 4 mol%. At the reactor output, it can be seen that reactions are still

occurring, as indicated by the continued steep increase in water and DME mol%.

Figure 6b shows a different trend, as the DME mol% at the end of the reactor slowly stops increasing, which is also evident from the DME flow line. The MeOH mol% indicates that MeOH is predominantly produced up to 2 m of reactor length, after which it is consumed until reaching an equilibrium between production and consumption at around 8 m of reactor length.

### Comparison of parallel and series DME production configuration

In the DME route with parallel configuration, where MeOH synthesis and dehydration occur simultaneously in a single reactor, the highest DME outlet fraction was achieved at low volumetric flow rate. At 255 °C, 90 bar, and 0.5 mL/min, the DME mole fraction in the outlet stream reached approximately 9.1 mol%, while the corresponding DME production rate (3.92 mmol/h) remained limited due to the low throughput. Increasing the inlet flow rate resulted in a higher amount of DME produced, with a maximum of approximately 8.5 mmol/h observed at 260 °C and 2.5 mL/min; however, this increase was accompanied by a substantial decrease in the DME fraction to 3.3 mol%.

In contrast, the series route, consisting of a MeOH synthesis reactor followed by an intermediate separation step and a downstream dehydration reactor operated at 2.1 bar, achieved significantly higher DME production. In the dehydration stage, MeOH conversion increased monotonically with temperature, reaching approximately 87% at 360 °C in the 16 mL reactor. Under these conditions, the maximum DME production rate reached approximately 31 mmol/h, about 3.5–4 times higher than the maximum value obtained in the parallel route for the same reactor volume.

The observed difference in performance can be attributed to reaction decoupling in the series configuration allowing the best operating conditions for both reactions. The dehydration reactor is more efficient when operating at elevated temperature and low pressure, conditions that strongly favor MeOH conversion to DME, while MeOH production reaction favor high pressure and peak temperature. In the parallel route, MeOH synthesis, dehydration, and water formation occur simultaneously within a single reactor, causing excess water produced from the MeOH synthesis reaction to further inhibit the MeOH dehydration reaction to DME.

## CONCLUSIONS

A microreactor modeling framework was used to evaluate parallel and series production routes for MeOH and DME under identical reactor-scale assumptions. The series configuration consisting of a MeOH synthesis reactor followed by an intermediate separation step and a downstream dehydration reactor, enabled independent optimization of MeOH formation and MeOH dehydration. In the 16 mL reactor, this separation allowed high MeOH availability at the inlet of the dehydration stage, resulting in MeOH conversions of approximately 87% and a maximum DME production rate of about 31 mmol/h at elevated dehydration temperature and low pressure. In contrast, the parallel route integrates MeOH synthesis and dehydration within a single microreactor, resulting in the simultaneous presence of MeOH and DME in the outlet stream. While this configuration achieved a maximum DME production rate of approximately 8.5 mmol/h, the highest outlet DME mole fraction of about 9% was obtained only at low throughput, where MeOH conversion to DME was favored over absolute production rate. At higher flow rates, increased MeOH slip limited the extent of dehydration, leading to lower DME-to-MeOH ratios despite higher total throughput. Overall, while the parallel route offers a more compact process with a single reactor and no intermediate separation, the series reactors route demonstrates substantially higher DME productivity due to optimized and independent operation of each reaction step.

This study represents an initial step toward the optimal configuration and operation of dimethyl ether (DME) production in a microreactor environment. A kinetic model of the process was developed to a level suitable for validation against laboratory experiments. Once validated, the model can be embedded in a superstructure-based optimization framework (e.g., GAMS) to identify the optimal reactor and separation network topology, as well as the associated operating variables, for DME production. To enable mathematical programming, the governing dynamic model (ODE/DAE/PDE, depending on the chosen reactor representation) can be discretized into a finite-dimensional algebraic form using direct transcription methods such as orthogonal collocation (e.g., collocation on finite elements), resulting in a MINLP formulation.

## ABSTRACT

This work proposes a parsimonious dynamic filtration model for superheated steam containing paper-derived dust, suitable for parameter identification, prediction, and future optimization under limited observability. The model is based on Darcy's law, with the total resistance expressed as the sum of the intrinsic filter resistance and a time-dependent fouling contribution. Experimental data obtained from a dedicated superheated-steam filtration setup were used for parameter estimation and model validation under a single operating condition. Assuming a linear dust dosing rate, the model yields limited agreement with experimental data ($R^2$ = 0.24). By estimating the time-varying solid loading through minimization of the sum of squared errors between measured and predicted pressure drop, the agreement improves significantly ($R^2$ = 0.94). This demonstrates that uncertainties in the dust dosing rate strongly affect pressure drop predictions. The proposed model provides a foundation for extending the analysis to broader process conditions, enabling statistical characterization of fitted parameters, integration with a filter cleaning model, and the development of optimization strategies for long-term, energy-efficient operation of closed-loop superheated steam drying systems.

**Keywords**: Gas filtration model, superheated steam filtration, cake filtration, fouling model, paper industry

## INTRODUCTION

We live in an era where greenhouse gas emissions must be drastically reduced. Much of these emissions result from industrial energy use. In 2023, the European Union's top three energy-consuming industries were chemical and petrochemical, non-metallic, and paper, pulp, and printing [1]. In paper manufacturing, the drying step accounts for about 70% of total energy consumption, highlighting a clear opportunity for efficiency improvements [2]. Superheated steam drying (SHSD) offers a promising alternative to conventional air drying, potentially reducing energy demand by 70% and $CO_2$ emissions by 88% [2].

During SHSD, dust released from the paper contaminates the circulating steam, which can reduce process efficiency and cause operational issues in closed-loop systems. Effective control of these contaminants is therefore essential. Filtration showed potential as a separation method due to its high efficiency for fine particles, operational flexibility, and well-established technology. To support the industry in developing a long-term, energy-efficient filtration process, a filtration model should first be developed, which can later be coupled with a filter cleaning model to guide optimization strategies.

Filtration is a commonly used and extensively studied separation process. Numerous researchers have contributed to the modeling of filtration dynamics, with a focus on the filter performance with fouling development. One of the most recognized models in this field is the Hermia model, introduced in the 1980s [3]. This model describes fouling mechanisms associated with different pore-blocking behaviors and has gained popularity due to its simplicity and ease of application. The model was originally developed for constant-pressure filtration. Later, it was extended to constant-flux operation [4]. Under constant flux, the flow rate remains fixed, with the fouling manifesting as increases in resistance and, consequently, pressure drop. The pressure drop evolution can be expressed as:

$$\frac{d(\Delta P)}{dt} = K\Delta P^n \quad (1)$$

ΔP represents the transmembrane pressure drop over the filter, $t$ is the filtration time, $K$ is the blocking constant, which is typically determined by fitting the model to experimental data, and $n$ is an exponent that defines the prevailing fouling mechanism (e.g., complete blocking, standard blocking, intermediate blocking, or cake filtration). Cake filtration is characterized by a linear increase in pressure drop. In contrast, intermediate, standard, and complete blocking exhibit nonlinear, concave-up pressure drop increases, with progressively steeper slopes from intermediate to standard blocking and the steepest increase observed for complete blocking [5].

Although widely used, the Hermia model has limitations. As it is fundamentally empirical, it does not capture the physical mechanisms.

In contrast to the Hermia model, other filtration models exhibit significantly greater complexity. An example is the model developed by Köry et al., which describes dead-end cake filtration using poroelasticity theory [6]. This approach accounts for the compressibility of both the filter medium and the growing cake layer. To capture these effects, dimensionless parameters are introduced that depend on specific material properties, such as elastic moduli and the permeability–strain relationship. As a result, the model requires detailed material characterization, which makes its application challenging in typical industrial settings due to the complexity and difficulty of obtaining such data.

Other models provide a balance between simplicity and physical insight, offering moderate complexity. One such model is that developed by Saleem et al., which extends Darcy's law to porous filtration systems [7]. The resulting expression includes two additive resistance terms: one representing the flow resistance of the filter medium, characterized by its permeability ($B_m$) and thickness ($L_m$), and the other representing the resistance of the deposited cake layer, characterized by its permeability ($B_c$) and thickness ($L_c$). Both terms scale with the fluid viscosity ($\mu$) and filtration velocity ($u$).

$$\Delta P = \frac{1}{B_m}\mu L_m u + \frac{1}{B_c}\mu L_c u \tag{2}$$

While this model features a reasonable level of complexity and improves upon purely empirical formulations, it does not account for the wide range of operational conditions typically encountered in industrial processes. As a result, there remains a need for a moderate-complexity model that integrates physics-based principles with empirical flexibility, enabling practical implementation in industrial settings. Such a model should be based on parameters that are both physically meaningful and experimentally accessible, enabling accurate predictions under varying process conditions to support design and operational decision-making, particularly for superheated steam applications.

The novelty of this study lies in addressing this need for a superheated steam filtration model, where high temperatures and dynamic particle behavior introduce additional challenges.

The goal of the present work is to develop a parsimonious dynamic model for the dead-end filtration of superheated steam containing paper-like solid particles. The model integrates physically based formulations with empirical calibration to describe filtration behavior under the investigated operating condition. The framework can later be extended to a broader range of operating conditions, with the model refined using empirical correlations derived from statistical analysis of the fitted parameters, coupled with a filter-cleaning model, and ultimately used to support dynamic optimization and model-based control frameworks for industrial applications, aiming to reduce energy consumption and operational costs.

## METHODOLOGY

### Filtration model development

Darcy's equation describes the volumetric flow ($Q$, in m³/s) through a filter material over the effective filter area ($A$, in m). It states that the flow is proportional to the transmembrane pressure drop ($\Delta P$, in Pa), which acts as the driving force, and is inversely proportional to the total filter resistance ($R_t$, in m$^{-1}$) and the fluid viscosity ($\mu$, in Pa·s):

$$\frac{Q}{A} = \frac{\Delta P}{\mu R_t} \tag{3}$$

Due to the low penetration of the filter material, it is expected that the filtration is done at the surface of the filter, also known as cake filtration. For this reason, the total resistance is the sum of the filter resistance ($R_f$, in m$^{-1}$) and cake resistance ($R_c$, in m$^{-1}$):

$$R_t = R_c + R_f \tag{4}$$

The resistance of the cake can be written as the specific resistance ($\alpha$, in m$^{-2}$) multiplied by the cake thickness ($l$, in m):

$$R_c = \alpha\, l \tag{5}$$

The specific resistance is a material-dependent parameter that can, in principle, be estimated using the Carman–Kozeny equation. This equation considers the solid's specific surface area, the void fraction, and the Kozeny constant. However, given the objective of developing a model with parameters that are easily measurable for practical implementation, the specific resistance is determined from experiment.

The cake thickness is dependent on the deposited dust mass, the effective filter area, and the density of the dust cake. For a given mass, a larger filter area or a higher dust density results in a thinner cake. Assuming uniform

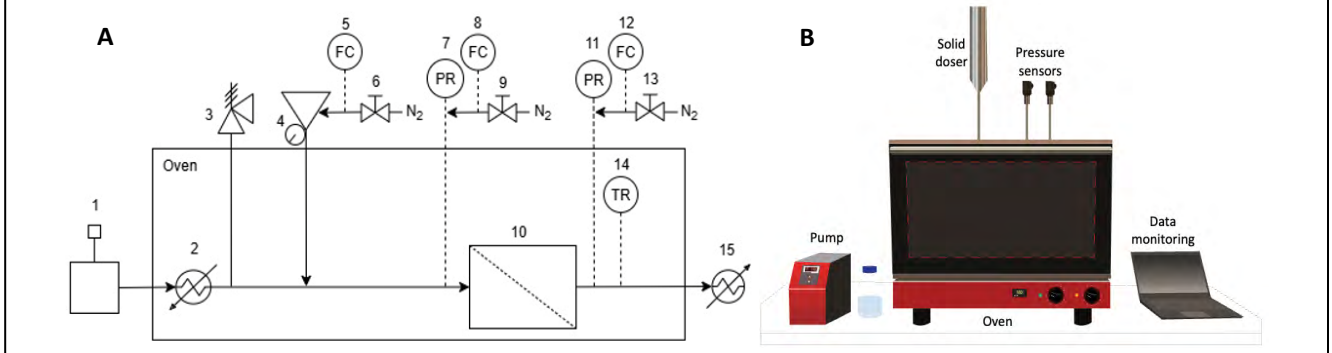

**Figure 2.** A- Piping and Instrumentation diagram of the set up where: 1 Pump; 2 Heating element; 3 Pressure relief; 4 Dust doser; 5, 8, 12 N2 flow controller (FC); 6,9,13 N2 gate valve; 7, 11 Pressure recorder (PR); 12 Dead-end filter in tri clamp; 14 Temperature recorder (TR); 15 Condenser. B- Overview of the main components of the system.

deposition, the cake thickness increases proportionally with the accumulated dust mass over time, reflecting the growth of the dust layer on the filter surface. The cake thickness as a function of time is given by:

$$l(t) = \frac{Q\, C_f\, t}{A\, \rho_c} = \frac{\dot{M}\, t}{A\, \rho_c} \quad (6)$$

with $C_f$ [kg/m³] is the foulant concentration in the fluid, $t$ [s] is the filtration time, $\rho_c$ is the cake density [kg/m³], and $\dot{M} = \frac{dM}{dt}$ is the mass flow into the filter [kg/s].

By substituting equations 6, 5, and 4 in equation 3 and rewriting, the pressure drop is expressed as:

$$\Delta P\,(t) = \frac{Q}{A}\mu(\alpha\frac{M\,(t)}{A\,\rho_c} + R_f) \quad (7)$$

From Equation 7, the fitting parameters, filter resistance and specific cake resistance, were calibrated based on experimental data. The remaining variables were determined or measured, with further details provided in the next section.

A schematic is provided below to aid in visualizing the system. Dust-laden steam enters from the left-hand side and passes through the filter, where solid particles are retained, forming a cake layer. The filter acts as a resistive barrier, represented in the model by the filter resistance term. The total pressure drop across the system is the sum of the resistances contributed by the filter and the accumulated cake layer.

The main assumptions for the development of the filtration model are the following:

- Gas flow is well distributed;
- Uniform and incompressible cake and filter;
- No gradients within the filter;
- Cake filtration is the dominant mechanism;
- Solids do not influence the fluid viscosity;
- No condensation or leakages of steam;
- No chemical reactions;

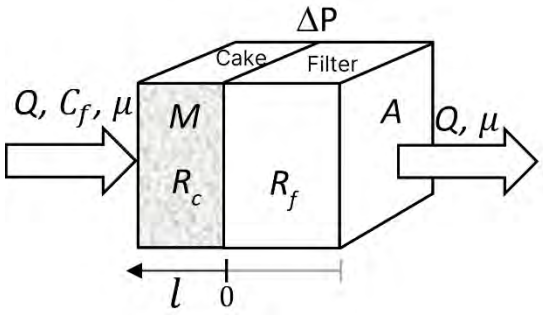

**Figure 1.** Diagram of the filtration mechanism.

## Experimental investigation

Experimental studies were conducted to adjust the fitting parameters in the filtration model, namely the specific resistance and the filter resistance. The setup consisted of the production of superheated steam, dosing of solid particles, filtration of the dusty-laden steam, and the monitoring of the system, especially the temperature and the pressure drop across the filter. It was located inside an oven to avoid the condensation of the steam. Figure 2 shows the schematic of the filtration system.

The filter used was a Polytetrafluoroethylene (PTFE) filter, chosen for its ability to withstand high temperatures and its low dust adhesion, which ensures better long-term performance [8]. It had a surface area of 0.0028 m² and was mounted in the setup using a tri-clamp system, allowing for easy assembly and preventing leakage in the filtration section.

Nitrogen was used to prevent steam from entering the solid doser and to assist in transporting the solids at a flow rate of 3.5 l/min. The pressure sensors, connected to the system via capillaries and located outside the oven, were supplied with 0.05 l/min nitrogen per sensor

to prevent steam condensation, since they could not withstand the oven temperature.

The parameters in equation 7 were obtained through a combination of measurements, calculations, and calibration. Thermophysical properties of the gas phase were evaluated at local temperature and atmospheric pressure using the CoolProp library [9]. Temperature-dependent gas densities were used to determine the volumetric flow rates of nitrogen and steam. The dynamic viscosity of each pure gas was evaluated using Sutherland's law and combined into a mixture viscosity using a composition-dependent mixing rule. The effect of dust particles was not considered in the fluid properties.

The density of the filter cake was determined experimentally using a volumetric method, in which the dust was placed in a volumetric flask and gently compacted to reduce interparticle voids before weighing. This approach is based on the expected low void fraction of the cake resulting from the assumption that there is a uniform and distributed deposition of particles during filtration.

The pressure drop across the filter was measured directly using upstream and downstream sensors. The total mass was determined at the end of each run by weighing the clean filter and the filter after filtration. Cellulose fibers were used as the dust to mimic paper-like particulate matter. The cumulative deposited mass at any time, $M(t)$, and the total deposited mass, $M_{\max}$, were initially assumed based on a linear dosing profile. The actual time-dependent dosing was then reconstructed using an inverse estimation approach by minimizing the sum of squared errors between the pressure drop predicted by the model and the experimental measurements.

The fitting parameters were determined in two steps. First, the filter resistance, $R_f$, was obtained under steam filtration conditions. Second, the specific cake resistance, $\alpha$, was obtained during the dust filtration phase using the filter resistance previously obtained.

Model validation was performed by comparing measured pressure drop data with the output of the calibrated filtration model. Four independent filtration experiments were conducted under identical operating conditions: a process temperature of 160 °C, a water pump flow rate of 5 ml/min, and an average mass of solids retained in the filter of 7.5 g. Two runs were used exclusively to construct the experimental reference, obtained by averaging their pressure drop profiles. The remaining two runs were used for model calibration.

## RESULTS AND DISCUSSION

### Model validation

The filtration system was used to assess the performance of the calibrated model by comparing its predictions with the experimental data. Table 1 presents the process conditions and the parameters used for the pressure drop predictions.

Some degree of variability is inherent to the experimental setup and should be considered when assessing reproducibility. The fabric filter material is not perfectly identical between experiments, and small variations in its structure may occur. In addition, the permeate flux and gas viscosity depend on the system temperature; although the temperature was maintained within a narrow range, minor fluctuations were observed. Small variations in the water pump operation may also lead to slight deviations in the steam flow rate. These factors can introduce limited experimental variability and are considered potential sources of deviation between repeated runs.

Using the average filter resistance and specific cake resistance, together with the remaining operational parameters calibrated from the experimental runs, the filtration model was used to predict the pressure drop, as shown in Figure 3. The solid addition was assumed to occur linearly over time, resulting in a linear pressure drop trend for the fitted model.

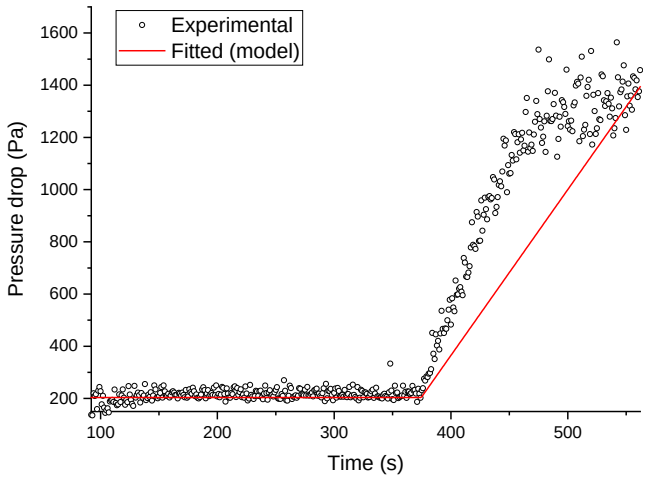

**Figure 3.** Comparison between experimental data and fitted model predictions assuming linear solid dosing.

From Figure 3, two main regions can be identified: a superheated steam filtration region (up to approximately 375 s) and a dust filtration region (from 375 s onward). During the steam filtration stage, the model predicts the pressure drop well in comparison with the experimental data. Deviations observed at the beginning and end of this region are attributed to experimental limitations, mainly the time required to reach equilibrium in the steam production. The coefficient of determination ($R^2$) was evaluated for the steam filtration region by comparing the squared residuals between experimental and modeled pressure drop values to the variance of the experimental data. In this regime, the experimental pressure drop remains nearly constant, as no fouling occurs. Because the variance of the experimental data is very low, even small deviations between the model and experimental result in

negative $R^2$ values, indicating that $R^2$ is not a suitable performance metric here. Instead, model performance was assessed using the root-mean-square error (RMSE), which yielded 24 Pa.

In the dust filtration region, the experimental data show a clear linear increase in pressure drop up to approximately 450 s. Beyond this point, the slope gradually decreases, and the pressure drop approaches a quasi-steady value. The fitted model predictions, which assume linear dust dosing, do not accurately capture the pressure drop increase during this transient phase. The $R^2$ in the dust filtration region is 0.25. However, the model successfully predicts the final pressure drop level. Experimental investigations indicate that the solid mass retained in the filter is measured only at the end of each run, while the dust dosing rate is difficult to control and not constant over time. This uncertainty represents a challenge for predicting the pressure drop evolution.

This behavior is also likely to be observed in industrial settings. Although operating conditions are controlled to ensure steady production, variations in foulant concentration are expected due to upstream fluctuations, changes in raw materials, or transient operating conditions. Similarly, the flow rate of the filtered steam is generally maintained around a target value but may exhibit small variations. Together, these variations can influence the pressure drop evolution across the filter.

Given the known process parameters (Table 1) and the experimental pressure drop profile, the dust dosing profile $M(t)$ was estimated by minimizing the sum of squared errors (SSE) between model predictions and experimental data:

$$SSE = \sum_{i=1}^{n} [\Delta P_{model}(t_i, M(t_i)) - \Delta P_{exp}(t_i)]^2 \qquad (8)$$

The dosing profile was obtained using the L-BFGS-B algorithm, subject to constraints: (i) non-decreasing dust mass, (ii) bounds $M(t)$ between zero and the total measured dust mass $M_{\max}$, and (iii) the final accumulated mass is the measured dust mass. The resulting profile represents the dust accumulation that best matches the filtration model with the measured pressure drop data. The resulting dust dosing profile is shown in Figure 4.

By using the adjusted dust dosing profile, a comparison between the experimental data and the fitted model predictions was performed, as shown in Figure 5A. A significantly improved accuracy is obtained, with a $R^2$ of 0.94, which is evident in the parity plot presented in Figure 5B.

The parity plot also highlights larger deviations at the extremities of the run, particularly around the transition points. The highest spread is observed in the region where the maximum dust mass ($M_{\max}$) is accumulated in the filter.

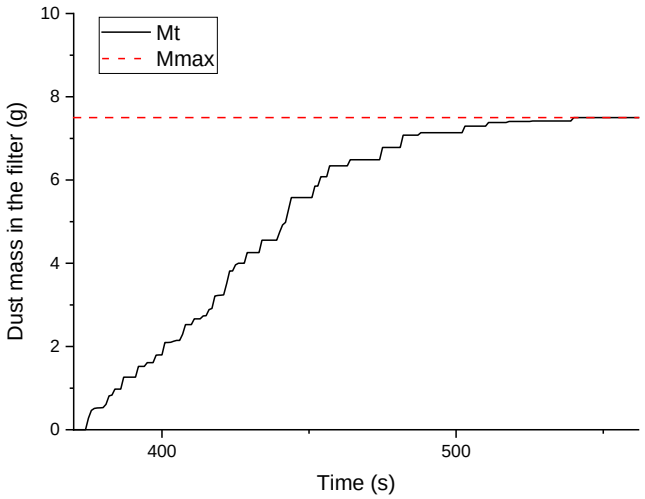

**Figure 4.** Dust dosing profile obtained by minimizing the sum of squared errors between experimental data and model predictions.

At higher dust loadings, the filter cake is subjected to increased compressive stresses, which can modify its internal structure and, consequently, its transport properties, including permeability and porosity [10]. Furthermore, high dust accumulation may promote local compaction, cracking, and channeling within the cake, resulting in non-uniform permeability and flux redistribution across the filter. These structural variations can induce flow instabilities and transient pressure fluctuations, contributing to the increased scatter observed in the experimental data at high dust loadings.

## CONCLUSIONS & OUTLOOK

Overall, the validation suggests that the model provides a reasonable prediction of the system, while also indicating areas where improvements could be made. Accounting for potential effects such as cake compressibility and possible time-dependent variations in filter and specific cake resistance may further enhance predictive accuracy. Additionally, maintaining a fully consistent solid dosing profile, where only the final point, but not the full path, is controlled, introduces variability that affects model performance.

As no models for the filtration of superheated steam containing paper-like dust have been reported, this model provides a useful starting point for exploring this field and guiding future development. With validation under a single operating condition, the next step is to extend the model to a broader range of process scenarios, using statistical analysis of the fitted parameters to capture the influence of varying conditions. The filtration model will then be coupled with a filter-cleaning model to capture system performance over time. With this framework in place, a sensitivity analysis will be performed to identify the parameters and operational factors with the

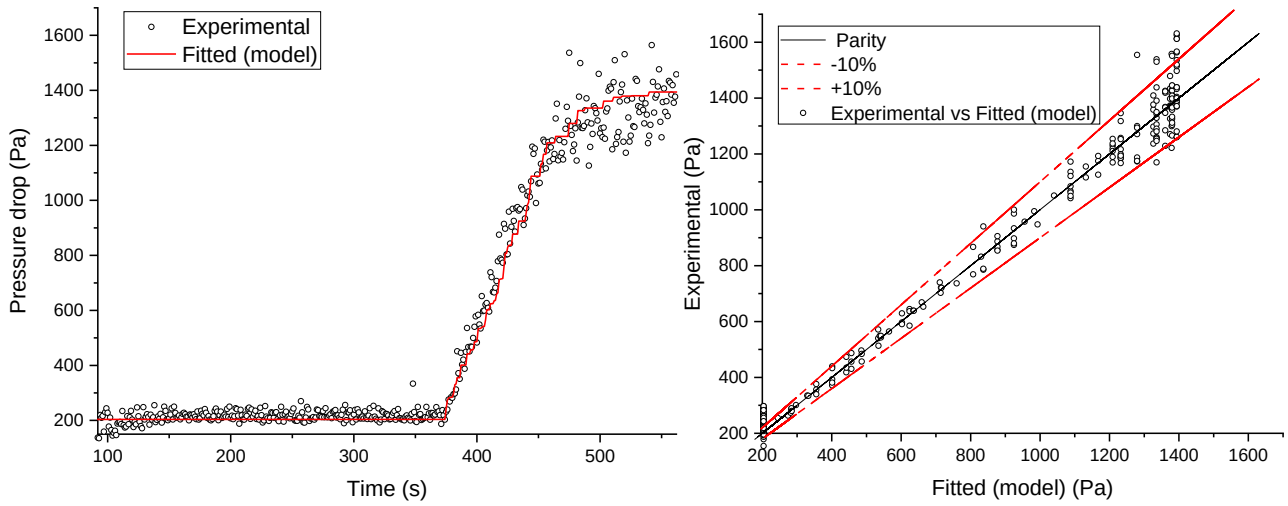

**Figure 5.** A- Comparison between experimental data and fitted model predictions assuming an adjusted solid dosing profile. B- Parity plot comparing experimental data and fitted model predictions, including ±10% deviation.

greatest impact on the process. These insights will guide the development of a dynamic optimization and model-based control strategies that account for variability and uncertainty in operation, such as fluctuations in solid loading or particle composition, supporting energy-efficient and cost-effective industrial applications. The proposed structure is compatible and commonly used in Computer-Aided Process Engineering.

## ABSTRACT

Catalyst deactivation significantly affects reactor performance, process efficiency, and economic viability in chemical processes. The precise estimation of kinetic and deactivation parameters in transient tubular reactors is essential but remains challenging due to strong parameter correlations, nonlinear dynamics, and limited prior knowledge of parameter values. Model-based Design of Experiments techniques for improving parameter precision (MBDoE-PP) has been shown to enhance parameter identifiability by optimally designing informative transient experiments even when catalyst deactivation occurs. However, MBDoE-PP is highly sensitive to parameter misspecification and can lead to suboptimal or infeasible solutions under model uncertainty, in which is the typical case in reaction systems exhibiting catalyst deactivation. In this work, a robust MBDoE framework for parameter precision (RMBDoE-PP) is proposed to explicitly account for process-model parameter mismatch (PMPM) during the experimental design stage. In the framework, stochastic sampling is used to evaluate metrics of the Fisher Information Matrix (FIM) and the experimental design is carried out considering a worst-case scenario, where the globally least informative parameter corresponding to the minimum information content across the uncertainty domain is identified. The performance of MBDoE-PP and RMBDoE-PP is assessed in the sequential closed-loop experimental design framework under varying levels of PMPM. Results demonstrate that RMBDoE-PP consistently yields tighter confidence intervals and more accurate parameter estimates with fewer experimental runs, confirming its superior robustness for deactivation kinetics.

## 1. INTRODUCTION

Catalysts are essential to chemical manufacturing and are extensively used across industrial processes, where they are typically operated over long time horizons. In practice, effective catalyst screening and selection require not only high initial activity but also a quantitative understanding of catalyst stability and deactivation behavior under realistic operating conditions. Catalyst deactivation, defined as the gradual loss of catalytic activity with time on stream, is an inevitable phenomenon that poses significant challenges to process operation and optimization, often leading to reduced productivity and adverse economic impacts [1][2]. Industrial decisions regarding catalyst selection, utilization, and replacement scheduling therefore strongly depend on the accurate quantification and prediction of catalyst activity evolution. Reliable identification of deactivation behavior enables optimized catalyst usage, avoids premature disposal or excessive replacement, reduces catalyst waste, and ultimately improves process profitability.

However, catalyst activity cannot be directly measured, and the identification of deactivation kinetics is inherently complex [3]. This complexity arises from the time-varying nature of catalyst deactivation, uncertainty in reaction kinetics, strong parameter correlations, and limited prior knowledge of model parameters and

operating conditions. Dynamic mechanistic models are commonly employed to describe and predict reactor behavior in the presence of catalyst deactivation, but the development of reliable deactivation models remains challenging. To improve parameter identifiability while reducing experimental effort, transient reactor operation has been increasingly explored which can generate rich time-dependent data without the need to wait for steady-state conditions, thereby reducing experimental time and preventing information loss.

Model-Based Design of Experiments for parameter precision (MBDoE-PP) provides a systematic framework for addressing these challenges by optimally designing experiments to maximize information and reduce the number of experiments needed for model identification [4]. In pevious studies the effectiveness of MBDoE-PP under transient conditions was clearly demonstrated, but in systems where catalyst deactivation was not significantin [5]. In our recent work, MBDoE-PP has been shown to be a powerful approach for accurately identifying deactivation kinetics, but, the effectiveness of MBDoE-PP critically depends on the quality of the starting parameter estimates used during the experimental design stage [6]. When a significant process-model parameter mismatch (PMPM) is present, or when little or no prior knowledge on parameters is available, experimental designs optimized at incorrect nominal values may be poorly informative, leading to slow convergence and unreliable parameter [7]. To address these limitations, a robust Model-Based Design of Experiments (RMBDoE-PP) framework is adopted in this work. Robust experimental design approaches aim to identify experimental conditions that maintain satisfactory performance over a range of plausible parameter values, rather than relying on the assumption that nominal parameter estimates are accurate [8]. However, designs based on expected information may be biased by a few highly informative parameter realisations, masking poor performance elsewhere. The proposed RMBDoE-PP addresses this limitation by targeting robustness, considering the worst-case scenarios, ensuring reliable information content regardless of initial parameter guesses. In this study, MBDoE-PP and RMBDoE-PP are investigated and compared for the design of transient experiments in a tubular reactor with catalyst deactivation.

## 2. METHODOLOGY

The reactor model consists of a system of dynamic partial differential and algebraic equations (DAE) characterized by a set of estimated parameters $\theta$, state variables $\boldsymbol{x}(\boldsymbol{t})$ and the time varying controls $u(t)$ and time invariant controls $w(t)$, which can be used to predict the behaviour of the reactor system. The model enables the prediction of experimentally measurable values $\hat{\mathbf{y}}$:

$$f\left(\dot{\boldsymbol{x}}(\boldsymbol{t}), \boldsymbol{x}(\boldsymbol{t}), \boldsymbol{u}(\boldsymbol{t}), \boldsymbol{w}, \theta, t\right) = 0 \quad (1)$$

$$\hat{\mathbf{y}}(\boldsymbol{t}) = \boldsymbol{g}\left(\boldsymbol{x}(\boldsymbol{t})\right) \quad (2)$$

The Fisher Information Matrix (FIM) for a sample point in the design space can be expressed as follows [9][10]:

$$FIM_t = Q_t^T \cdot {\Sigma_y}^{-1} \cdot Q_t \ = [V_\theta]^{-1} \quad (3)$$

where $Q_t$ is the matrix of sensitivities whose $q_{ij}$ element can be defined as

$$q_{ij} = \frac{\partial \hat{y}_i}{\partial \theta_j} \quad (4)$$

and $V_\theta$ is the variance-covariance matrix of model parameters, ${\Sigma_y}^{-1}$ is the inverse matrix of measurement errors $\Sigma_y$ which can be defined as

$$\Sigma_y = \begin{bmatrix} {\sigma_1}^2 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & {\sigma_y}^2 \end{bmatrix} \quad (5)$$

where $\sigma_i$ is the standard deviation of measurement error for the $i_{th}$ response.

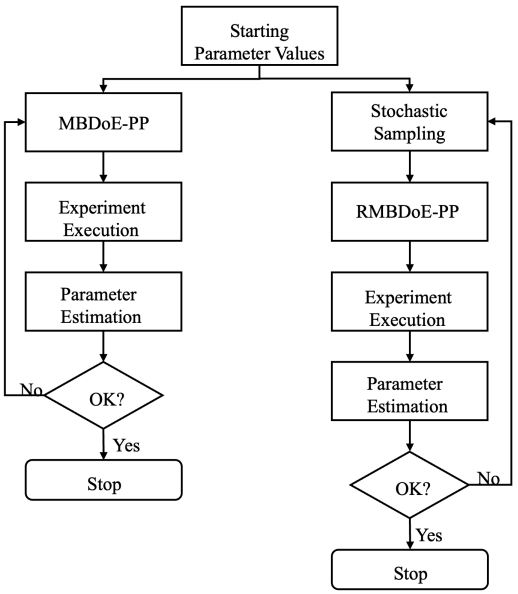

**Figure 1.** The Model Validation Procedure of MBDoE-PP and RMBDoE-PP.

Figure 1 illustrates the iterative model validation and experimental design workflow adopted for both MBDoE-PP and RMBDoE-PP frameworks. In the presence of limited or no prior knowledge of the model parameters, the same set of initial parameter guesses is used to initialise both design strategies. At each iteration, optimal experimental conditions are first determined based on the current parameter information and subsequently applied to a worst-case scenario, which is assumed to represent the true operating conditions of the real

system. In-silico experimental data are then generated by simulating the model responses under additive random measurement noise. Parameter estimation is performed using the generated data, and the resulting estimates are evaluated through a set of statistical model adequacy and parameter significance tests. The iterative procedure is repeated until predefined precision and identifiability criteria are satisfied, at which point the identification process is terminated.

This iterative framework follows the general philosophy employed in [11][12], where successive experiments are designed based on information gained from previous iterations. More recent studies, such as [13], further developed feedback-based experimental design strategies by explicitly incorporating updated parameter knowledge into subsequent design steps. In the present work, this iterative structure is combined with an A-optimality criterion, which aims to minimise the trace of the parameter variance–covariance matrix [9], equivalently maximising the integrated trace of the Fisher Information Matrix over the experimental horizon, thereby improving overall parameter estimation robustness.

## 2.1 Standard MBDoE-PP formulation

For MBDoE-PP, the experimental design problem is formulated as an optimization task where the objective is to determine the optimal time-invariant input variables, denoted as $w(t)$, that maximize the integrated trace of the Fisher Information Matrix (FIM). The trace of the FIM, which is the sum of its diagonal elements, serves as a crucial metric for evaluating the information gained from an experiment, particularly in scenarios where frequent sampling is implemented. This metric provides an effective means of assessing the overall sensitivity of the system to variations in its parameters, ensuring that the designed experiment captures maximal information for parameter estimation. The trace of the FIM can also be leveraged for the dynamic assessment of information gain under the assumption of a constant sampling time interval $\Delta t$. By integrating the trace of the FIM over the duration of the experiment, a cumulative measure of information can be obtained [14]

$$\varphi^{opt}_{MBDoE-PP} = \arg\max_{\varphi} \left\{ \int_0^{t_h} tr(FIM) dt \right\} \tag{6}$$

where $\varphi^{opt}$ is the optimal experimental design vector, containing all the decision variables that can be manipulated during a dynamic experiment. The design accounts for the time-dependent nature of the system's response and allows for an optimal design strategy that ensures the greatest reduction in parameter uncertainty. By optimizing the criterion objective (6), the design ensures that the chosen experimental conditions provide the most informative dataset possible, enhancing the precision and reliability of parameter estimation.

## 2.2 Determination of the worst-case scenario

Worst-case (minimax) experimental design seeks to optimise performance under the most adverse parameter realisation within a predefined uncertainty set [6]. In this study, a worst-case scenario is explicitly constructed to assess the robustness of MBDoE-PP under parameter uncertainty. A parameter domain $\boldsymbol{\Theta}$ is defined to represent plausible model parameters, and multiple initial guesses are selected within this domain to compute corresponding MBDoE-PP optimal experimental conditions. For each design, a stochastic simulation is employed as an evaluation tool, where model parameters are uniformly sampled within $\boldsymbol{\Theta}$ and the cumulative information metric is assessed under fixed experimental conditions. The worst-case scenario is defined as the parameter yielding the globally minimum cumulative information across all evaluated MBDoE-PP designs and is adopted as the true value for subsequent analysis. This formulation provides a conservative and systematic benchmark for assessing the robustness of experimental design strategies under adverse operating conditions.

## 2.3 RMBDoE

RMBDoE extends MBDoE-PP framework by explicitly accounting for process model parameter mismatch (PMPM) in the optimization. Instead of solving the MBDoE optimization problem based on a local FIM evaluation computed at a nominal parameter set, RMBDoE considers a distribution of FIM metric values based on the expected variability in the parameter space $\boldsymbol{\Theta}$. To obtain the distribution, a stochastic simulation is employed and embedded in the MBDoE optimization, where multiple random samples of parameter sets are drawn from a distribution centered around nominal parameter values with a specified variance to reflect the expected uncertainty range. Each sampled parameter set is then used to compute the FIM metric for a given experimental design. Here the objective of RMBDoE is formulated to optimize experimental conditions such that the ratio between the mean of the integral of the FIM trace ($\mu_I$) over the corresponding standard deviation ($\sigma_I$) across all sampled parameter sets is maximised:

$$\varphi^{opt}_{RMBDoE-PP} = \arg\max_{\varphi} \left( \frac{\mu_I}{\sigma_I} \right) \tag{7}$$

with

$$\mu_I = \frac{\sum_{i=1}^{N_s} \left[ \int_0^{t_h} tr(FIM) dt \right]_i}{N_s} \tag{8}$$

$$\sigma_I = \sqrt{\frac{1}{N_s} \sum_{i=1}^{N_s} \left( \left[ \int_0^{t_h} tr(FIM) dt \right]_i - \mu_I \right)^2}$$

and where $N_s$ is the number of scenarios used in the embedded stochastic simulation. The geometrical interpretation of criterion (7) is that the model-based design optimization is seeking an optimal set of experimental

conditions generating a flat and high information surface in the parameter space $\boldsymbol{\Theta}$ so that the design can be insensitive to parametric uncertainty.

## 2.4 Parameter Estimation

The estimation of model parameters is performed using the maximum likelihood estimation (MLE) method, which ensures that the chosen parameters maximize the probability of observing the collected experimental data [15]. The parameter estimation performance is assessed by using a $\chi^2$ lack-of-fit test which provides a quantitative measure of the agreement between the model predictions and the observed experimental data,

$$\chi^2 = \sum_{i=1}^{N_{exp}} \sum_{j=1}^{N_M} \frac{(y_{ij} - \hat{y}_{ij})^2}{\sigma_{ij}^2} \tag{9}$$

and a standard parameter *t*-value test to assess parameter precision, with *t*-values $t_i$ calculated from

$$t_i = \frac{\hat{\theta}_i}{\sqrt{v_{ii}}} \tag{10}$$

where $v_{ii}$ is the variance of the $i_{th}$ parameter (i.e. the $i_{th}$ diagonal element of the parameter variance-covariance matrix). The *t*-value for each parameter is tested against a tabulated reference value related to a Student's t-distribution. The quality of each experimental design is assessed based on the statistical reliability of the fitted model and estimated parameters. $\chi^2$ test and t-value test are the two key tests used for evaluation of parameter estimates: (1) the $\chi^2$ test is used to assess how well the model provides an adequate representation of the experimental data, by comparing the computed $\chi^2$ with the reference value $\chi^2_{\text{ref}}$. If the $\chi^2$ result from designed experiments is lower than $\chi^2_{\text{ref}}$, the kinetic model provides a statistically adequate fit to the simulated experimental data, otherwise, the model is considered inadequate for describing the observed behavior; (2) the t-value test indicates the confidence interval in each parameter estimate and all the *t*-values of model parameters must exceed a critical reference *t*-value to be considered statistically significant.

# 3. CASE STUDY

The optimal design of transient dynamic experiments in a tubular reactor with catalyst deactivation using MBDoE-PP is illustrated through a case study on the oxidation of o-xylene to phthalic anhydride[16]. The reaction takes place in a gas phase tubular reactor which is packed with decaying catalyst particles and where a cooling jacket is positioned around the reactor, as shown in Figure 2. The same experimental setup is also used in other kinetic modelling studies[17][18].

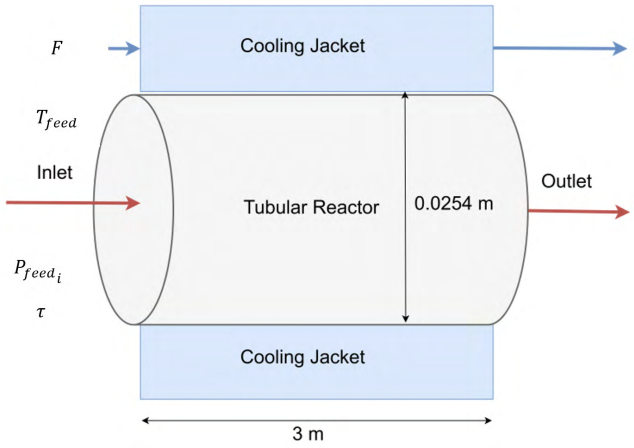

**Figure 2.** Sketch of the experimental system and typical dynamic response for the tubular reactor with cooling jacket operating in transient state. The set of inputs u is defined by the following designed variables: i) initial concentration of the reactants $P_{feed_i}$; ii) residence time $\tau$; iii) feed temperature of cooling fluid $T_{feed}$ and iv) coolant flowrate in the cooling jacket $F$.

The mass balance of the system is defined as

$$\frac{\partial C_i}{\partial t} = -v_g * \frac{\partial C_i}{\partial z} + \varepsilon * D_z * \frac{\partial^2 C_i}{\partial z^2} + \varepsilon * D_r * \left(\frac{\partial^2 C_i}{\partial r^2} + \frac{1}{r}\frac{\partial C_i}{\partial r}\right) + v_i * \rho_b * R_{rxn} \; z \in [0, L], r \in [0, R] \tag{11}$$

$$R_{rxn} = A * e^{-\frac{E}{RT}} * (RT)^2 * C_A * C_B$$

$$z \in (0, L), r \in (0, R) \tag{12}$$

The tubular reactor is non-isothermal, but it is assumed that heat losses can be neglected and that the heat of reaction goes into the bulk fluid phase rather than into heating up the catalyst particles. The energy balance in the gas phase accounts for the axial convection heat transport, the axial and radial dispersion energy, and the heat generated or consumed by the chemical reaction as reported below.

$$\rho_f * C_{pf} * \frac{\partial T}{\partial t} = -\rho_f * C_p * v_g * \frac{\partial T}{\partial z} + k_z * \frac{\partial^2 T}{\partial z^2} + k_r\left(\frac{\partial^2 T}{\partial r^2} + \frac{1}{r}\frac{\partial T}{\partial r}\right) + \rho_b R_{rxn}(-\Delta H) \tag{13}$$

$$z \in (0, L), r \in (0, R)$$

To address the high correlation, a reparameterization of the original Arrhenius equation including a reference temperature is needed[19] to minimize the correlation between the two kinetic parameters as follows:

$$k = A_{ref} * e^{-\frac{E}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)} \tag{14}$$

$$A_{ref} = A * e^{-\frac{E}{RT_{ref}}} \tag{15}$$

As the reaction occurs in the gas phase and assumes ideal gas behavior, the ideal gas law is applied, and the

$RT$ term is incorporated into the expressions for the molar concentration or partial pressure of each component.

$$R_{rxn} = k * (RT)^2 * C_A * C_B \quad (16)$$

The Levenspiel's Deactivation Kinetic Model (LDKM) is selected to represent the loss of catalyst activity (a) overtime[20]. It is assumed that the catalyst activity changes along with the radius and the length, but it is assumed to be the same for all of the components which can be expressed as

$$-\frac{da}{dt} = \psi_d * a \quad (17)$$

$$R_{rxn_{DM1}} = k_{DM1} * (RT)^2 * C_A * C_B * a \quad (18)$$

In Equation 17, $\psi_d$ is assumed to be the deactivation parameter that needs to be estimated.

In this study, the gPROMS modelling environment is used for simulation, optimization as well as for parameter estimation and to optimally design dynamic experiments [21]. The mathematical model of the reactor system is established assuming that the measurable variables are the concentrations of each component at the outlet ($C_{out,i}$). Upper and lower bounds on experimental conditions defining the experimental design space are shown in Table 1.

**Table 1.** Definition of the experimental design space

| Manipulated Variables | Lower Bound | Upper Bound |
|---|---|---|
| $F$ | $0.08\,\frac{kg}{s}$ | $0.12\,\frac{kg}{s}$ |
| $\tau$ | $2.74\ s$ | $4.10\ s$ |
| $T_{feed}$ | $570\ K$ | $625\ K$ |
| $P_{feed,A}$ | $0.880\ kPa$ | $1.32\ kPa$ |

The experimental design vector variables are implemented using a time-invariant input function within a fixed time interval. Four experimental conditions are manipulated simultaneously within this framework to evaluate their combined effects on the system's information which allow for the interaction between conditions to be captured, enhancing the sensitivity of the design. In MBDoE it is assumed that a very frequent sampling in time is possible, i.e. $n_{sp}$ = 361 sampling points can be collected within a fixed time horizon of $\tau_{horizon} = 3hrs$. The experimental data is generated in-silico by assuming that are corrupted by a normally distributed noise with a zero mean and $\Sigma_y = \begin{bmatrix} 0.002 & 0 & 0 \\ 0 & 0.4 & 0 \\ 0 & 0 & 0.02 \end{bmatrix}$. This level of noise amounts to about 10% error on the average values of $C_{out,i}$.

The predefined model parameter domain Θ is defined as [0.5, 1.5]. The estimated parameters are the ratio between the reference value $\theta_{ref_i}$ of parameters and the estimated one as

$$\hat{\theta}_{ratio_i} = \frac{\hat{\theta}_i}{\theta_{ref_i}} \quad (19)$$

where $\hat{\theta}_i$ is the *i*-th parameter [*i*=1, 2, 3], $\hat{\theta}_1$ is the estimated activation energy, $\hat{\theta}_2$ is the estimated Arrhenius constant and $\hat{\theta}_3$ is the deactivation parameter through equations (14-17). To identify the potential worst-case scenario, MBDoE-PP evaluations are performed for multiple initial parameter guesses to identify the respectively optimal experimental conditions (Table 2). Stochastic simulation is then used to evaluate the information distribution over the predefined parameter domain (Figure 3), and the set of parameters yielding the minimum information level are identified as the worst-case scenario. MBDoE-PP seeks to maximize the integral of the trace FIM, optimizing input profiles under the assumption of fixed nominal parameters. In contrast, RMBDoE-PP maximizes the ratio of the mean to standard deviation of the FIM across a parameter distribution here assumed as $\pm 20\%$ of its initial guess, reducing information loss due to poor initial guesses. Once the designed experiment is executed under the optimized input conditions, parameter estimation is performed using the newly acquired data to update the model. The two optimal experimental design approaches, MBDoE-PP and RMBDoE-PP, are compared in terms of statistical tests ( $\chi^2$ test to assess the lack-of-fit and t-test to evaluate the precision in parameter estimates, see Section 2.4 for details).

# 4. RESULT

## 4.1 Identification of the worst-case scenario

MBDoE-PP optimisations were conducted using multiple sets of initial parameter guesses, resulting in a corresponding set of optimal experimental conditions, which are summarised in Table 2. The column denotes the initial guesses for the three kinetic parameters. A single value indicates identical initial guesses for all parameters, while the grouped column "0.5; 0.6; 0.7" corresponds to multiple starting points that yields the same optimal experimental design. For each optimal design, a fixed set of 50 parameters uniformly sampled over the predefined parameter domain were generated to ensure a consistent evaluation framework across all designs. These parameters were used to compute the cumulative information metric under the respective optimal experimental conditions.

The resulting information distributions are presented in Figure 3, which illustrate the variation in information content as a function of parameter realisation and experimental design. From these distributions, the globally worst-case scenario was defined where the

parameter has the minimum cumulative information across all evaluated designs and parameter samples was identified.

These determined true parameter values $\hat{\theta}_{ratio_i} = (1.43, 1.20, 1.19)$ are used to represent the true system for subsequent in-silico experiment execution and parameter estimation studies. Selecting the true value in this manner ensures that subsequent analyses are conducted under the most adverse yet admissible conditions for MBDoE-PP, thereby providing a conservative and meaningful basis for assessing estimation performance and robustness.

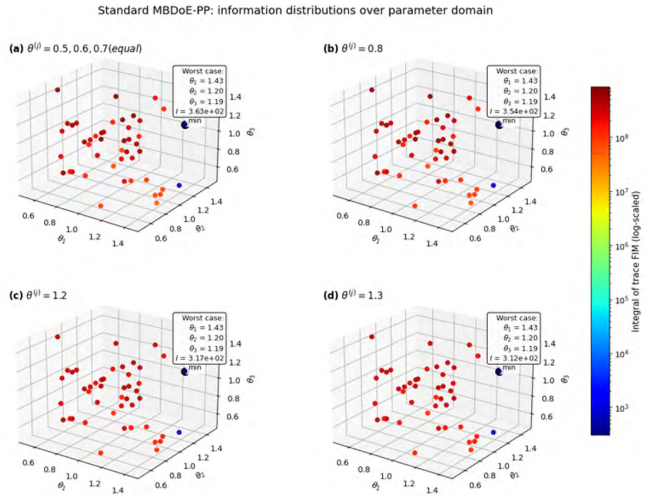

**Figure 3.** The MBDoE-PP information ditribution over parameter domian $\boldsymbol{\Theta}$

**Table 2.** The optimal experimental conditions computed by MBDoE-PP under different starting parameter values.

| Design variable | MBDoE-PP Starting Parameter Value | | | |
|---|---|---|---|---|
| | $\mathbf{0.5; 0.6; 0.7}$ | $\mathbf{0.8}$ | $\mathbf{1.2}$ | $\mathbf{1.3}$ |
| $F\ (\frac{kg}{s})$ | 0.12 | 0.12 | 0.12 | 0.12 |
| $\tau\ (s)$ | 4.10 | 4.10 | 4.10 | 4.10 |
| $T_{feed}(10^2K)$ | 5.70 | 5.73 | 5.84 | 5.86 |
| $P_{feed,A}\ (kPa)$ | 1.32 | 1.32 | 1.32 | 1.32 |

## 4.2 MBDoE-PP and RMBDoE-PP

The guessed parameter vector $(1, 1, 1)$ is selected to initialise both MBDoE-PP and RMBDoE-PP at the center point of the predefined domain. Figure 4 illustrates the initial guessed values for both MBDoE techniques, the parameter uncertainty domain considered in the RMBDoE-PP formulation, and the location of the identified worst-case true value. In the robust design, parametric uncertainty is explicitly represented by a hyper-rectangular domain defined as $\pm 20\%$ around the nominal values, shown as the cubic region in the parameter space. Within this domain, 50 parameter realisations are uniformly sampled and used to evaluate the cumulative information metric under the corresponding optimal experimental conditions shown in Table 3.

The sampled parameter points within the cube represent admissible uncertainty scenarios accounted for during the robust design stage. In contrast, the identified worst-case true value lies outside the predefined uncertainty domain. This point corresponds to the globally minimum information obtained from the stochastic evaluation of all MBDoE-PP designs and therefore represents the most adverse possible parameter set for parameter estimation.

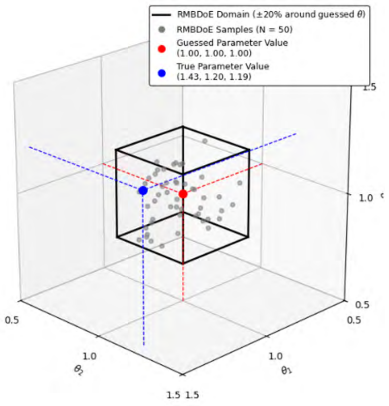

**Figure 4.** Guessed parameter values for both MBDoE-PP techniques and the true parameter value to represent the real system.

**Table 3.** Optimal experimental conditions computed by MBDoE-PP and RMBDoE-PP.

| | MBDoE-PP | RMBDoE-PP |
|---|---|---|
| $F\ (\frac{kg}{s})$ | 0.12 | 0.08 |
| $\tau\ (s)$ | 4.10 | 2.74 |
| $T_{feed}(10^2K)$ | 5.70 | 6.07 |
| $P_{feed,A}\ (kPa)$ | 1.32 | 0.88 |

## 4.3 Parameter Estimation

The results of the $\chi^2$ test and statistical test results for both MBDoE-PP techniques are shown in Table 4, confirm good model-data agreement, with all total $\chi^2$ values falling below the reference value of $1.16 * 10^3$, indicating satisfactory model–data agreement. Despite this overall adequacy, significant differences are observed in the quality of parameter estimation between the two design strategies. Under the standard MBDoE-PP framework, parameter estimation performance is poor: none of the parameters are estimated with satisfactory precision. The estimation of activation energy ($\hat{\theta}_1$) converges to its lower bound, and the estimation of the deactivation parameter ($\hat{\theta}_3$) exhibits poor precision. The estimation of Arrhenius constant ($\hat{\theta}_2$) fails to reach the reference t-value,

**Table 4.** Kinetic and deactivation parameter estimation results from MBDoE-PP and RMBDoE-PP in the presence of PMPM in terms of estimated values and a-posteriori statistics. Superscript asterisk (∗) indicates t-value failing the t-test and (∗∗) indicates that the parameter lies on the bounds and is excluded from the statistical analysis.

| | **Param. estimate + conf. interval (95%)** | ***t*-values ($t_{ref} = 1.65$)** | $\chi^2(\chi^2_{ref} = 1.16 * 10^3)$ |
|---|---|---|---|
| **MBDoE-PP** | $\hat{\theta} = \begin{bmatrix} 0^{**} \\ 3.87 \pm 3.02 \\ 5.62 * 10^{-7^*} \pm 1.24 * 10^2 \end{bmatrix}$ | $\begin{bmatrix} * \\ 1.28^* \\ 4.52 * 10^{-9^*} \end{bmatrix}$ | $1.00 * 10^3$ |
| **RMBDoE-PP** | $\hat{\theta} = \begin{bmatrix} 1.34 \pm 8.71 * 10^{-2} \\ 1.14 \pm 6.17 * 10^{-2} \\ 2.10 \pm 1.05 \end{bmatrix}$ | $\begin{bmatrix} 1.53 * 10^1 \\ 1.85 * 10^1 \\ 1.98 \end{bmatrix}$ | $1.08 * 10^3$ |

indicating poor precision achieved under the optimal experimental conditions.

In contrast, the RMBDoE-PP framework yields substantially better estimation performance. The kinetic parameters are estimated with narrow confidence intervals and *t*-values are well above the reference value, demonstrating statistically significant and reliable identification. The two kinetic parameters remain highly correlated (the correlation coefficient is 0.99), but both parameters are estimated with high precision and statistically significant t-values. This behaviour is consistent with the use of an A-optimality criterion, which prioritises overall parameter precision rather than minimising parameter correlations. The deactivation parameter also exhibits good precision, with its *t*-value exceeding the significance threshold and low correlation realised with the kinetic parameters ($\hat{\theta}_1$) and ($\hat{\theta}_1$), -0.26 and -0.16, respectively. This suggests that RMBDoE-PP markedly enhances robustness against PMPM with the catalyst deactivation.

### 4.4 CPU Time

The CPU time required by both MBDoE techniques are here compared. For the standard MBDoE-PP approach, the optimization step requires 4.86 minutes, followed by 3.38 minutes for parameter estimation. In contrast, the RMBDoE-PP approach incurs a substantially higher computational cost, with 27.88 hours ($1.67 \times 10^3$ minutes) required for the robust optimisation step and 7.40 minutes for parameter estimation.

These results highlight a clear trade-off between computational effort and parameter estimation quality. While RMBDoE-PP achieves substantially higher parameter precision within the first iteration, this improvement comes at the expense of a significantly increased computational burden. Conversely, standard MBDoE-PP requires considerably less CPU time but yields negligible parameter precision in the first iteration, implying that multiple additional iterations and experiments would be required to reach comparable levels of precision. Consequently, the overall experimental and computational burden associated with standard MBDoE-PP may increase substantially when high parameter precision is desired.

## 5. CONCLUSION AND FUTURE WORK

The accurate modelling of tubular reactor operated under transient conditions with catalyst deactivation requires reliable estimation of both kinetic and deactivation parameters. In this work, standard MBDoE-PP and RMBDoE-PP are assessed under the presence of process-model parameter mismatch (PMPM). A worst-case scenario is identified and considered in the study in which the “true” system is defined as the parameter point generating the lowest information among all standard MBDoE-PP designs within a predefined parameter domain.

Under the worst-case scenario, standard MBDoE-PP exhibits poor parameter estimation performance, with low statistical significance and limited precision, indicating practical non-identifiability of some model parameters. In contrast, RMBDoE, which accounts for the PMPM, delivers substantially improved parameter estimates, achieving acceptable precision despite the presence of PMPM and limited prior information. These results demonstrate the advantage of incorporating parameter uncertainty directly into the experimental design stage when robustness against worst-case scenarios is required. However, the study highlights a clear trade-off between computational cost and estimation robustness and confirms the importance of robust design strategies for dynamic reactor systems affected by catalyst deactivation. Future work will focus on the development of hybrid design frameworks that combine standard MBDoE-PP and RMBDoE-PP, aiming to balance computational efficiency with robustness by adaptively integrating information gained during the experiment design and parameter estimation process.

## ABSTRACT

Direct Air Capture (DAC) is recognised as a critical climate mitigation technology necessary for achieving global net-zero emissions by balancing difficult-to-avoid emissions. Despite its importance, the commercial deployment of DAC technology is currently challenged by the substantial energy demands and resultant extremely high operational costs associated with handling the low atmospheric $CO_2$ concentration. This study aims to address these two challenges through dynamic process modelling, simulation and rigorous multi-objective optimisation of a solid sorbent-based temperature vacuum swing adsorption (S-TVSA) cycle. The system utilises an advanced amine-functionalized sorbent, selected for its favourable low-temperature regeneration kinetics.A technical performance assessment was conducted using a first-principle mathematical model to accurately simulate mass and heat transfer in the adsorbent beds. To improve system viability, a multi-objective optimisation with NSGA-II in MATLAB was performed, maximising $CO_2$ productivity and minimising energy demand. The optimisation targeted key parameters like adsorption/desorption time, temperature, and pressure. The Pareto frontier shows trade-offs, identifying optimal points that minimise $W_{eq}$ and energy use. These results provide a pathway to reduce energy costs and enhance the economic viability of solid-sorbent DAC technology.

**Keywords**: Direct air capture, amine-functionalised sorbent, process modelling, performance evaluation, Process optimisation, temperature vacuum swing adsorption

## 1. INTRODUCTION

A significant driver of climate change is the rapidly rising atmospheric concentration of greenhouse gases including $CO_2$ [1]. Atmospheric $CO_2$ levels have increased from 280 ppm in the pre-industrial era to 425 ppm in 2025 [2]. As a result, global temperatures have risen, posing a threat to the environment. To limit the temperature rise to 1.5–2°C, achieving net-zero $CO_2$ emissions by 2050 is essential [3].

Solid-based direct air capture (DAC) technology plays a key role in meeting net-zero targets [4]. However, the diluted atmospheric $CO_2$ concentration poses challenges for meeting energy demand and for the cost of $CO_2$ extraction, as large volumes of air must be processed to extract a significant amount of $CO_2$ [1, 4, 5].

Previous studies [1, 5] demonstrated that a steam-assisted temperature-vacuum swing adsorption (S-TVSA) process can achieve high-purity $CO_2$ (≥ 95%) from ambient air. In S-TVSA, $CO_2$ is initially adsorbed onto an adsorbent under ambient conditions. Subsequently, the pressure is reduced, and steam is used to increase the temperature, releasing $CO_2$. The process alternates between adsorption and regeneration to capture $CO_2$. Designing these processes is complex due to the nonlinear mass and heat transfer within the adsorbent column [19]. Operational decisions, such as cycle step durations, temperatures, pressures, and flow rates, directly influence performance metrics. This study aims to optimise these operational parameters to maximise productivity, reduce energy consumption, and ensure high $CO_2$ purity. This study utilises 3-aminopropylmethyldiethoxysilane-functionalized nanofibrilated cellulose (APDES-NFC), an advanced amine- functionalized sorbent due to its (i) favourable low temperature kinetics and (ii) reliable performance in the presence of moisture [1, 5].

## 2. METHODOLOGY

### 2.1 Model development

#### 2.1.1 Adsorption Equilibrium

The co-adsorption of $CO_2$ and $H_2O$ on the APDES-NFC surface was modelled using a combination of the modified Toth isotherm for $CO_2$ and the Guggenheim-Anderson-de Boer (GAB) isotherm for $H_2O$. The modified Toth isotherm model is defined as:

$$q_{co_2}(T, p_{co_2}, q_{H_2O}) = n_s(T, q_{H_2O}) \frac{b(T, q_{H_2O}).\, p_{co_2}}{[1 + (b(T, q_{H_2O}).\, p_{co_2})^{t(T)}]^{1/t(T)}} \quad (1)$$

$$n_s(T, q_{H_2O}) = \left[ n_{s_0} \exp\left[ \chi \left( 1 - \frac{T}{T_0} \right) \right] \right] . \left[ \frac{1}{1 - \gamma_{q_{H_2O}}} \right] \quad (2)$$

$$b(T, q_{H_2O}) = \left[ b_0 \exp\left[ \frac{\Delta H_0}{RT_0} \left( \frac{T}{T_0} - 1 \right) \right] \right] . \left[ 1 + \beta_{q_{H_2O}} \right] \quad (3)$$

$$t(T) = t_0 + \alpha \left( 1 - \frac{T_0}{T} \right) \quad (4)$$

Where $q_{co_2}$ is specific adsorbed amount of $CO_2$ (mol/kg), $n_s$ is the saturation capacity of $CO_2$ (mol/kg), $p_{co_2}$ is $CO_2$ partial pressure (kPa), $b_0$ is the adsorption equilibrium constant (kPa). The GAB isotherm model is defined as:

$$q_{H_2O}(x) = c_m \frac{c_G K_{ads} x}{(1 - K_{ads} x)(1 + (c_G - 1) K_{ads} x)} \quad (5)$$

**Table 1** GAB and Modified Toth isotherm fitted parameters [1, 5]

| | |
|---|---|
| GAB isotherm | |
| $c_m$ (mol/kg) | 36.4800 |
| $c_G$ | 0.1489 |
| $K_{ads}$ | 0.5751 |
| Modified Toth isotherm | |
| $n_{s0}$ (mol/kg) | 2.3800 |
| $b_0$(kPa$^{-1}$) | 70.7000 |
| $t_0$ | 0.4148 |
| $T_0$ (K) | 296.0000 |
| $\Delta H_0$ (kJ/mol) | -57.0470 |
| $\alpha$ | -1.6060 |
| $\chi$ | 0.0000 |
| $\gamma$ (kg/mol) | 0.0061 |
| $\beta$ (kg/mol) | 28.907 |

#### 2.1.2 Model development of fixed-bed adsorption

The key assumptions are as follows:

- 1-D model in axial direction
- Solid and gas phases are in thermal equilibrium
- Mass transfer rate described using the linear driving force (LDF) model
- Pressure drop was described using Ergun equation
- Heat and mass transfer coefficients were assumed to be constant
- Heat capacities and heat of adsorption were assumed to be constant
- Only $CO_2$ and $H_2O$ are adsorbed by the solid adsorbent.

The mass and energy balance of the fixed-bed adsorption column is described as follows:

Mass Balance

$$\epsilon_t \frac{\partial c_i}{\partial t} + \frac{\partial}{\partial z}(v c_i) + (1 - \epsilon_b)\rho_p \frac{\partial q_i}{\partial t} = 0 \quad i = 1, \ldots, n \quad (6)$$

LDF

$$\frac{\partial q_i}{\partial t} = k_i (q_i^* - q_i) \;\; i = 1, \ldots, n \quad (7)$$

Energy balance

$$\left(\epsilon_t C_g + \rho_b C_s + \rho_b C_{ads}\right) \frac{\partial T}{\partial t} - \epsilon_t \frac{\partial P}{\partial t} + v C_g \frac{\partial T}{\partial z} + \rho_b \sum_{j=1}^{n} \Delta H_j \frac{\partial q_j}{\partial t} = -\frac{4 h_L}{d_{in}} (T - T_w) \quad (8)$$

Wall Energy Balance

$$\frac{\partial T_w}{\partial t} = \frac{2}{C_w (r_{out}^2 - r_{in}^2)} [h_L r_{in} (T - T_w) - h_w r_{out} (T_w - T_{amb})] \quad (9)$$

### 2.2 Process simulation of the TVSA cycle

Figure 1 shows the steam-assisted temperature-vacuum swing adsorption (S-TVSA) cycle. The cycle consists of four steps: (1) adsorption, where a fan blows atmospheric air (mostly $N_2$ and $O_2$) at $T_L$ and $p_H$ through a packed column until $CO_2$ saturation; (2) blowdown, where the inlet is closed, and the column is evacuated to pressure $p_L$ using a vacuum pump, releasing air back into the atmosphere; (3) heating, where heat at $T_H$ is transferred via an external jacket, with the gaseous stream mainly

being air released back; and (4) desorption, with a steam purge providing additional temperature and vacuum swings[1].

**Table 2** Adsorption Column specifications

| Column | |
|---|---|
| Column length L (m) | 0.0100 |
| Inner diameter (m) | 0.0800 |
| Outer diameter (m) | 0.0820 |
| Bed density (kg/m$^3$) | 55.4000 |
| Particle size (m) | 0.0075 |
| Wall heat capacity (J/kg/K) | 513.0000 |
| Solid heat capacity (J/kg/K) | 2070.0000 |
| Fluid Heat transfer coefficient (W/m$^2$/K) | 3.0000 |
| Wall Heat transfer coefficient (W/m$^2$/K) | 26.0000 |
| $CO_2$ heat of adsorption (kJ/mol) | -57.0000 |
| $H_2O$ heat of adsorption (kJ/mol) | -49.0000 |
| $CO_2$ Heat capacity (J/K/mol) | 42.4600 |
| $H_2O$ Heat capacity (J/K/mol) | 73.1000 |
| $CO_2$ Mass transfer coefficient (1/s) | 0.0002 |
| $H_2O$ Mass transfer coefficient (1/s) | 0.0020 |

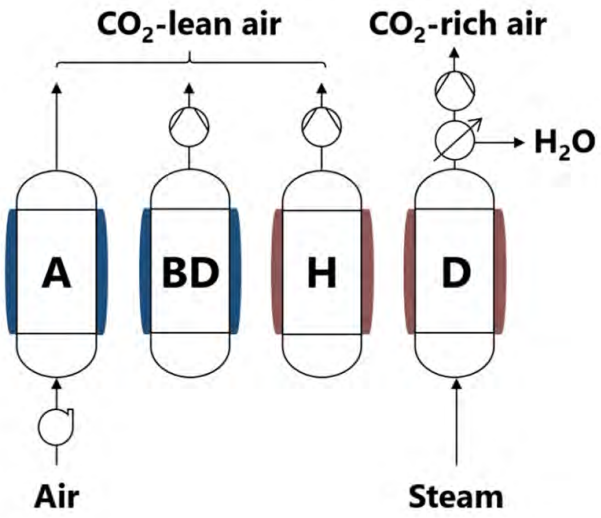

**Figure 1**. S-TVSA cycle [1]

The boundary conditions for each step is reported in Table 3.

**Table 3** S-TVSA boundary conditions[1, 5]

| Step | Time (s) | Boundary condition |
|---|---|---|
| Adsorption | 13, 772 | $pI_{Z=L} = p_H$ |
| | | $uI_{Z=0} = u_{air}$ |
| | | $TI_{Z=0} = T_{air}$ |
| | | $y_i I_{Z=0} = y_{i,air}$ |
| Blowdown | 30 | $pI_{Z=L} = p(t)$ |
| | | $uI_{Z=0} = 0$ |
| | | $\frac{\partial T}{\partial z} I_{Z=0} = 0$ |
| | | $\frac{\partial y_i}{\partial z} I_{Z=0} = 0$ |
| Heating | 704 | $pI_{Z=L} = p_L$ (0.05 bar) |
| | | $uI_{Z=0} = 0$ |
| | | $\frac{\partial T}{\partial z} I_{Z=0} = 0$ |
| | | $\frac{\partial y_i}{\partial z} I_{Z=0} = 0$ |
| Desorption | 30, 000 | $pI_{Z=L} = p_L$ |
| | | $uI_{Z=0} = u_{steam}$ |
| | | $TI_{Z=0} = T_{steam}$ |
| | | $y_i I_{Z=0} = y_{i,steam}$ |

## 2.3 Performance assessment of S-TVSA

### 2.3.1 Key Performance Indicators

The performance of the adsorption process was assessed using four key indicators: $CO_2$ Purity, $CO_2$ productivity, thermal energy use, and electrical energy use. The $CO_2$ Purity in the desorption step is defined as:

$$Pu_{CO_2}(\text{mol\%}) = 100 \times \frac{n_{CO_2}^{prod}}{n_{CO_2}^{prod} + n_{H_2O}^{prod} + n_{N_2}^{prod}} \quad (10)$$

Where $n_i^{prod}$ is the number of moles of component $i$ produced from the desorption step. $CO_2$ productivity is defined as the capture rate per unit volume of the adsorption bed over the duration of a complete cycle. The $CO_2$ productivity is defined as:

$$Pr_{CO_2}(kg/m^3/day) = \frac{m_{CO_2}^{prod}}{V_{bed} \cdot t_{cycle}} \quad (11)$$

Where $m_{CO_2}^{prod}$ is the mass $CO_2$ produced during the desorption step (kg), $V_{bed}$ is the adsorption bed volume (m$^3$), and $t_{cycle}$ is the cycle time (s). Thermal energy consumption comprises the jacket heating required during the heating and desorption steps and the heat supplied

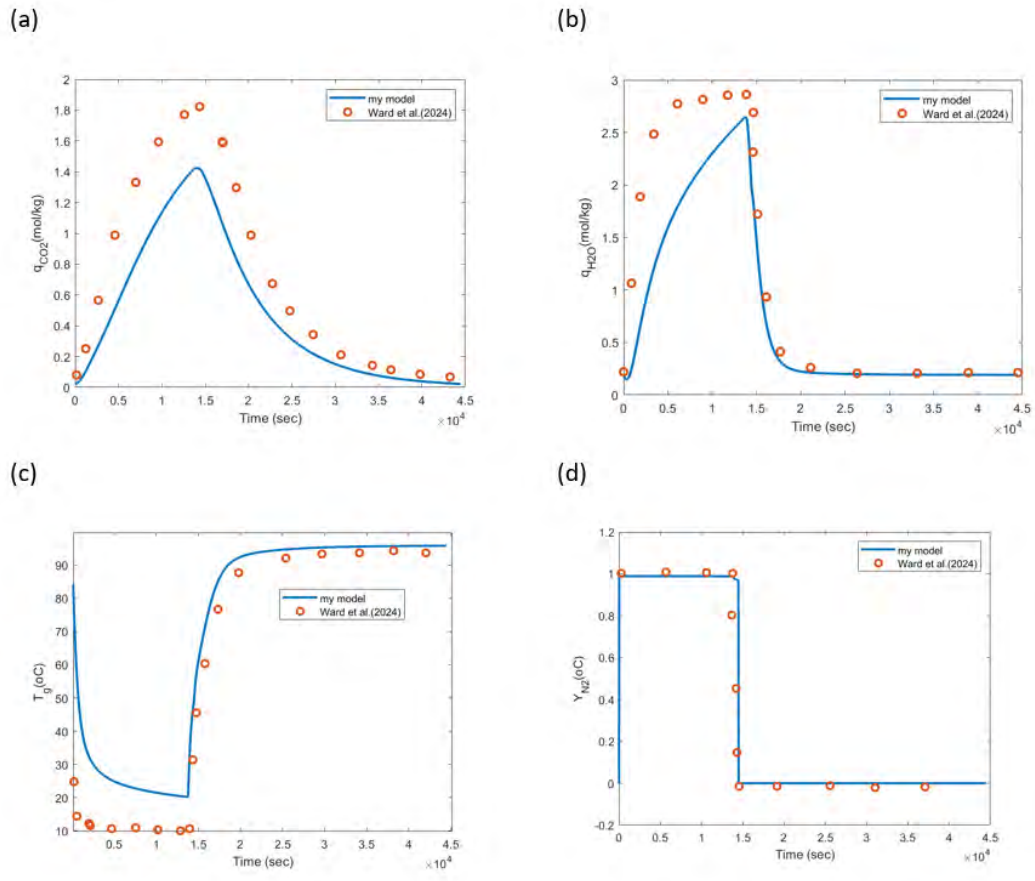

**Figure 2:** TVSA Cycle performance compared with Ward et al[5]. (a) $CO_2$ loading (b) $H_2O$ loading (c) gas temperature ($T_g$)(d) $N_2$ composition

by the steam during the desorption step. The specific thermal consumption ($Q_{therm}$) is defined:

$$Q_{therm}(MJ/kg) = \frac{Q_{heat}^{Jacket} + Q_{des}^{jacket} + Q_{des}^{steam}}{m_{CO_2}^{prod}} \quad (12)$$

Where $Q_i^{Jacket}$ is the heat (MJ) required in the jacket for step $i$, and $Q_{des}^{steam}$ is the heat (MJ) supplied by the stream during the desorption step. The electrical energy consumption includes the energy required to operate the compressor during both adsorption and desorption steps, as well as the energy required for the vacuum pump to create and maintain a vacuum during the blowdown and heating stages. The electrical energy consumption is defined as:

$$E_{elec}(MJ/kg) = \frac{E_{ads} + E_{bd} + E_{heat} + E_{des}}{m_{CO_2}^{prod}} \quad (13)$$

Where $E_i$ is the electrical energy (MJ) consumption of step $i$. To facilitate representing the total energy duty of the capture process as a single value for process optimisation, we use the concept of specific equivalent work to combine electrical and thermal energy consumption. The specific equivalent work is defined as:

$$W_{eq}(MJ/kg) = E_{elec} + \eta_{turb}\left(1 - \frac{T_L}{T_H}\right) \quad (14)$$

Where $\eta_{turb}$ is the turbine isentropic efficiency of a hypothetical turbine undertaking the conversion between electrical and thermal work. $\eta_{turb}$ was assumed to be 75%.

### 2.3.2 Process optimisation

The solid-based DAC performance was optimised by maximising system productivity and minimising energy use. $CO_2$ productivity quantifies the system volume required to achieve a specified $CO_2$ capture rate, thereby affecting the land footprint. Since DAC must be deployed globally for a significant climate impact, high productivity minimises land use. The aim is to minimise energy consumption in a steam-assisted DAC process. The multi-objective optimisation was formulated as follows:

$$\min_{\theta}[-Pr_{CO_2} + \phi, W_{eq} + \phi] \quad (15)$$

$$s.t\ \theta_L \leq \theta \leq \theta_U$$

$$\phi = 0.25 \times [\max(0, 95 - Pu_{CO_2})]^2$$

Where $\theta$ is the vector of the operating variables, $\theta_L$ and $\theta_U$ are the lower and upper operating variable limits (see Table 4). A constraint was imposed on the $CO_2$ purity, requiring a minimum of 95%. $\phi$ is the penalty function.

**Table 4** Lower and upper limits

| Parameter | Lower Limit | Upper Limit |
|---|---|---|
| $t_{ads}$(s) | 10, 000.000 | 20, 000.000 |
| $t_{heat}$(s) | 500.000 | 1, 500.000 |
| $t_{des}$(s) | 20, 000.000 | 40, 000.000 |
| $p_L$(bar) | 0.050 | 0.500 |
| $T_{des}$(°C) | 80.000 | 100.000 |
| $v_s$(m/s) | 0.001 | 0.005 |
| $v_f$(m/s) | 0.005 | 0.010 |

We deployed the NSGA-II algorithm from MATLAB's Global Optimization Toolbox as the gamultiobj function, running for 100 generations with a population of 140. It was initialized with 140 operating points and their key performance indicators, determined by quasi-random Sobol sampling within bounds in Table 4.

# 3. RESULTS

## 3.1 TVSA Cycle performance

The behaviour of the S-TVSA cycle was analysed through $CO_2$ and $H_2O$ loading profiles in comparision with Ward et al.[5]. Figure 2(a) shows $CO_2$ loading increasing during the adsorption phase (13, 772 s) at 20 °C and 1 bar.

Figure 2(b) presents $H_2O$ loading, indicating sorbent stability under humid conditions, which is crucial for DAC applications. Thermal dynamics are shown in Figure 2(c), with the gas temperature ($T_g$) rising to approximately 95 °C during heating and desorption, driven by steam injection and external heating. Figure 2(d) tracks $N_2$, which evacuates rapidly during blowdown and desorption, maintaining high $CO_2$ purity.

## 3.2 Energy consumption

The assessment (Figure 3) shows thermal energy (Q_thermal) as the dominant component of total energy, accounting for jacket heating and steam regeneration (7.04 MJ/kg). Electrical energy (0.37 MJ/kg) primarily powers blowers and vacuum pumps across various phases. The Specific Equivalent Work ($W_{eq}$) determined is 7.41 MJ/kg.

## 3.3 Process optimisation

The optimisation results, generated using the NSGA-II algorithm with 100 generations and a population of 140, are summarised in the Pareto Curve (Figure 4). The results demonstrate a clear trade-off between $CO_2$ productivity and energy consumption. Initial points derived via Sobol sequence sampling within the bounds helped identify an optimal operating window that balances throughput with energy efficiency. The optimal solution yielded a productivity range of 32.6-33.4kg/m$^3$/day. The corresponding energy requirement for the optimal points ranges from 7.0 to 7.6 MJ/kg.

The multi-objective optimisation reveals a key link between the S-TVSA cycle's physical performance and the economic viability of solid-based DAC. The Pareto front marks the 'best possible' performance. Increasing $CO_2$ productivity raises specific work ($W_{eq}$) and reduces adsorbent bed volume ($V_{bed}$), lowering capital costs and land requirements. The 33.4 kg/m³/day point boosts productivity and cuts CAPEX; the 7.0 MJ/kg point minimises OPEX by reducing thermal energy ($Q_{thermal}$).

Thermal energy far exceeds electrical energy, making the heat source critical. Waste heat or low-cost geothermal energy for the heating and desorption steps could greatly lower OPEX, favouring high-productivity points.

# 4. CONCLUSION

This study developed and validated a robust fixed-bed model and an S-TVSA cycle for solid-sorbent-based DAC. The process optimisation with NSGA-II revealed that thermal energy is the main factor driving the energy penalty. Key findings include:

- APDES-NFC demonstrates reliable co-adsorption of $CO_2$ and $H_2O$, making it suitable for environments with varying humidity.
- $Q_{thermal}$ is the dominant factor in $W_{eq}$, necessitating advanced regeneration strategies or materials with higher working capacities.
- Optimal solutions achieved $CO_2$ productivity between 32.6 and 33.4 kg/m$^3$/day. The corresponding specific equivalent work is between 7.0 to 7.6 MJ/kg. This provides a pathway to balancing the trade-off between plant size (CAPEX) and energy demand (OPEX).
- Findings indicate that solid-sorbent DAC's economic feasibility largely relies on low-carbon, low-cost thermal energy for desorption.

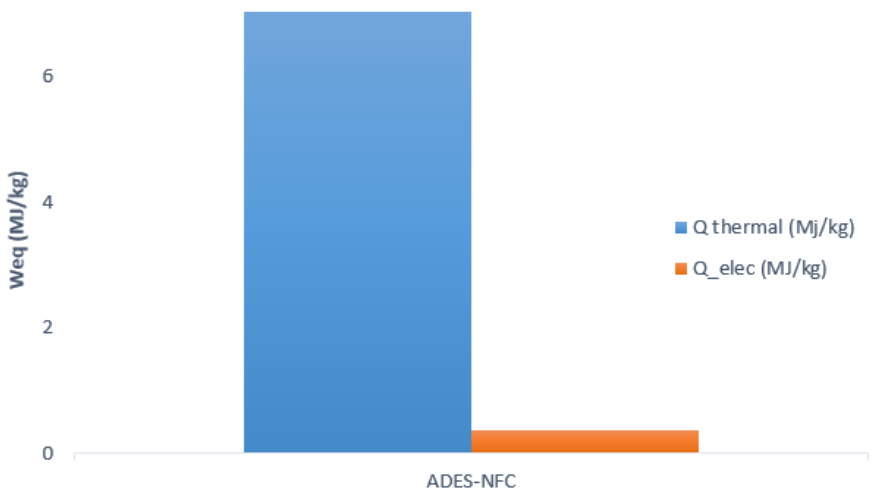

**Figure 3.** Specific equivalent work

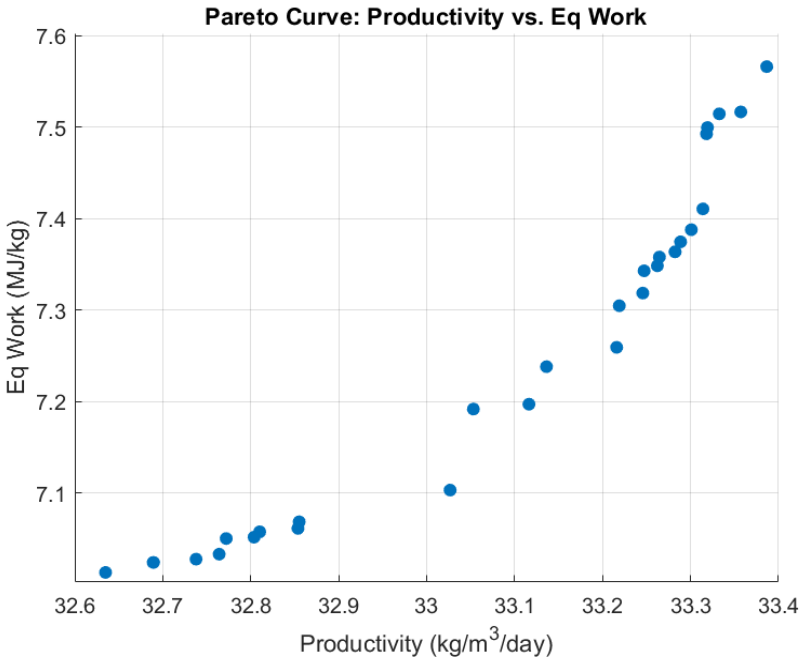

**Figure 4.** Pareto Curve

Future work will focus on a detailed parametric analysis and the impact of water-enhanced amine-functionalised adsorbents on the DAC performance.

## ABSTRACT

Stochastic gene regulatory networks exhibit complex dynamics that require efficient methods for parameter inference and uncertainty quantification. In this work, we propose a surrogate modelling framework that combines a partial integro-differential equation (PIDE) formulation with polynomial chaos expansions (PCE) to efficiently approximate the stochastic dynamics of gene expression models under parametric uncertainty. The approach represents the time evolution of low-order statistical moments as polynomial functions of uncertain kinetic parameters, enabling fast evaluations and tractable inference. The method is demonstrated on a self-regulating gene network, achieving accurate parameter estimation and a reduction of approximately two orders of magnitude in computational cost compared to direct PIDE-based optimisation.

**Keywords**: Surrogate Model, Modelling and Simulations, Optimization

## INTRODUCTION

Stochasticity is an inherent feature of cellular processes, playing a crucial role in various biological phenomena. A prominent example is gene expression, where small numbers of DNA and regulatory molecules lead to pronounced stochastic effects [1]. These fluctuations contribute to the significant cell-to-cell variability observed even in genetically identical cell populations, influencing key processes such as differentiation, phenotypic switching, adaptation, and evolution [1-3]. Advanced single-cell microscopy techniques, combined with mathematical models for single-gene expression, have led to essential insights into elucidating the sources of intrinsic noise in cells [4]. At the same time, they have highlighted new challenges for quantitative modelling, particularly in statistical inference and uncertainty quantification.

Stochastic gene expression is commonly modelled as a reaction network governed by the chemical master equation (CME) [5]. Despite its simple formulation, the CME is generally intractable and exact analytical solutions exist only for a few simple systems. On the other hand, the stochastic simulation algorithm (SSA) provides a numerical approximation of the CME solution. However, stochastic simulations are computationally demanding, making systematic analysis challenging. As an alternative to computing full probability distributions using the CME or its approximations, such systems are often analysed through low-order statistical moments of mRNA or protein abundance [6].

Gene regulatory network (GRN) models are necessarily approximations of biological reality and are therefore affected by multiple sources of uncertainty. In many practical applications, model parameters are only approximately known, as direct experimental measurements of kinetic reaction rates are difficult to obtain. Moreover, even when reliable estimates are available, *in vivo* parameters may be influenced by a multitude of cellular and environmental factors, leading to significant parametric variability [7]. Furthermore, incomplete knowledge of network topology and reaction mechanisms can introduce structural uncertainty, while the intrinsic randomness of molecular interactions gives rise to aleatory variability. If not properly accounted for, these effects can substantially impact model predictions and lead to misleading interpretations in biological applications.

In this work, we combine an efficient partial integro-differential equation (PIDE) framework for modelling stochastic gene regulatory networks with polynomial chaos expansion (PCE) for uncertainty quantification under

parametric uncertainty. The PCE represents the statistical moments of the system as polynomial functions of the model parameters, enabling fast moment evaluation. We demonstrate the effectiveness of the PCE-based approach on a positive autoregulation model by estimating all kinetic parameters of the network. Compared to standard stochastic simulation–based methods, the proposed framework achieves up to a 100-fold reduction in computational cost, making it particularly suitable for inference and uncertainty quantification analyses.

# METHODS

## PIDE Model

We consider a gene regulatory network comprising n genes $\boldsymbol{G} = \{\mathrm{DNA}_1, \ldots, \mathrm{DNA}_n\}$, each responsible for the synthesis of a distinct protein type $\boldsymbol{X} = \{X_1, \ldots, X_n\}$ through their respective messenger RNAs $\boldsymbol{M} = \{\mathrm{mRNA}_1, \ldots, \mathrm{mRNA}_n\}$, following the central dogma. The number of molecules of mRNA and proteins is represented by vectors, $\boldsymbol{m}, \boldsymbol{x} \in R^n$, where $\boldsymbol{m} = (m_1, \ldots, m_n)$ and $\boldsymbol{x} = (x_1, \ldots, x_n)$, respectively. A schematic representation of the gene network is shown in Figure 1.

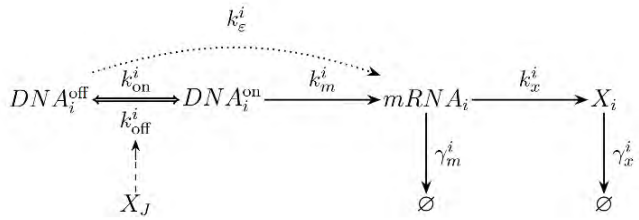

**Figure 1.** Schematic representation of the gene expression model.

Each gene switches between an active $DNA_i^{on}$ and an inactive $DNA_i^{off}$ state. In the active state, mRNA is transcribed at a rate $k_m^i$ and translated into a protein at a rate $k_x^i$. A gene is activated at a rate $k_{on}^i$ and inactivates at a rate $k_{off}^i$, with an additional leakage transcription rate $k_\varepsilon^i$. mRNA and protein degrade at rates $\gamma_m^i$ and $\gamma_x^i$, respectively. Under the assumption of protein-burst condition, the time evolution of the protein probability density function can be described by the following PIDE [4]:

$$\frac{\partial p}{\partial t}(t, \boldsymbol{x}) = \sum_{i=1}^{n} \frac{\partial}{\partial x_i}\left[\gamma_x^i x_i p(t, \boldsymbol{x})\right] + \sum_{i=1}^{n}\left(k_m^i \int_0^{x_i} \beta_i(x_i - y_i) c_i(\boldsymbol{y}_i) p(t, \boldsymbol{y}_i) \mathrm{d}\, y_i\right) \quad (2)$$

$$p(0, \boldsymbol{x}) = p_0(\boldsymbol{x}).$$

The burst condition is represented by $\beta_i$, with

$$\beta_i(x_i - y_i) = \omega_i(x_i - y_i) - \delta(x_i - y_i), \quad (3)$$

where $\boldsymbol{y}_i$ is obtained from $\mathbf{x}$ by replacing its $i$-th component by $y_i$. Additionally, burst size is modelled by an exponential distribution, such that

$$\omega_i(x_i - y_i) = \frac{1}{b_i} \exp\left(-\frac{(x_i - y_i)}{b_i}\right), \quad (4)$$

where $b_i = \frac{k^i{}_x}{\gamma^i{}_m}$. The initial condition $p_0(x)$ is a probability density function assumed to be normally distributed. Here, the function $c_i(x)$ represents the regulatory control of a gene $i$ by other proteins in the network, and it is typically modelled using Hill functions

$$\rho_{ij(x_i)} = \frac{x_j^{H_{ij}}}{x_j^{H_{ij}} + K_{ij}^{H_{ij}}}, \quad (5)$$

where $H_{ij}$ is the Hill coefficient indicating the cooperativity in the regulation, and $K_{ij}$ is the corresponding Hill constant. In the case of regulation by a single protein, the transcription rate is proportional to the fraction of active promoter, expressed as:

$$c_i(x_j) = \left[1 - \rho_i(x_j)\right] + \rho_i(x_j)\varepsilon_i. \quad (6)$$

Here $\varepsilon_i$ is the leakage constant from the inactive promoter. The effect of multiple proteins regulating a gene can be modelled by combining individual Hill functions using logical operations [4].

The PIDE is solved numerically using SELANSI, which computes the solution via an efficient and scalable semi-Lagrangian method, providing the temporal evolution of the protein probability density function [5]. The PIDE approach provides an accurate and computationally efficient approximation of the chemical master equation (CME) solution compared to the standard Gillespie stochastic simulation algorithm. A computational mesh consisting of 5000 time points and 1200 spatial nodes is employed.

## Polynomial Chaos Expansion

PCE is a spectral method for uncertainty quantification that represents random variables as expansions in orthogonal polynomial bases for which stochastic information is available [6]. The PCE expansion of a random variable $u$ can be described as:

$$u(\theta) = \sum_{j=0}^{L} u_j \boldsymbol{\Phi}_j(\theta), \quad (7)$$

where $L$ is the total number of polynomial terms up to a degree $d$, $\boldsymbol{\Phi}_j(\theta)$ are multivariate orthogonal polynomials in the random variable $\theta$, $u_j$ the PCE coefficients, and $j$ is a multi-index. The choice of the polynomial family follows the Askey scheme and depends on the probability distributions of the input parameters. Although classical PCE assumes standard distributions, the approach can be extended to arbitrary input measures. The PCE coefficients

are computed using a non-intrusive regression-based approach. The underlying model is evaluated at a finite set of sampling points in the parameter space, and the coefficients are obtained by solving an ordinary least-squares problem using the corresponding model evaluations.

### Moment-based PCE

Since tracking the full probability distribution is computationally expensive, a surrogate model tracking the moments of the gene circuit is constructed. To this end, the first $k$ raw moments are computed by integrating the probability density obtained from the PIDE formulation at selected time instants

$$M_i = \int x^k p(x) dx. \tag{8}$$

Each moment $M_i(t, \boldsymbol{\theta})$ is then represented as a polynomial chaos expansion in the parametric space. Specifically, the $i$-th moment is approximated as

$$M_i(t, \boldsymbol{\theta}) \approx \sum_{j=0}^{L} m_{i,j}(t)\, \boldsymbol{\Phi}_j(\boldsymbol{\theta}), \tag{9}$$

Where $m_{i,j}$ are the corresponding deterministic PCE coefficients.

## RESULTS

### Moment-based PCE

In this case study, we consider a single-gene circuit with self-regulation, in which feedback arises from the binding of the protein encoded by the gene to its own regulatory regions. This is

$$\rho_{1(x_1)} = \frac{x_1^{H_{11}}}{x_1^{H_{11}} + K_1^{H_{11}}}, \tag{10}$$

and $H_{11}$ has a negative sign because positive self-regulation is considered. The network dynamics are governed by the transcription rate $k_m$, the translation rate $k_x$, and the mRNA and protein degradation rates $\gamma_m$ and $\gamma_x$. However, since the mean burst size is given by $b_1 = k_x/\gamma_m, k_x$ and $\gamma_m$ are not independently identifiable. Consequently, only three independent network parameters can be estimated, namely $k_m$, $k_x$ and $\gamma_x$. These parameters are assumed to be uncertain and are modelled as independent normally distributed random variables with $N\sim(\mu, (0.1\mu)^2)$. Their mean values used in the simulations are listed in Table 1, and the PIDE solutions corresponding to the nominal values are shown in Figure 2.

Simulation data are normalised to the interval $[0, 1]$ to facilitate the PCE construction by avoiding large differences in numerical magnitude between data points. The corresponding probability density functions are normalised consistently. The first five raw moments of protein expression are computed from the distributions obtained via the PIDE stochastic model and used as training data for the surrogate.

**Table 1:** Kinetic parameters used in the PIDE simulation.

| Parameter | Description | Value |
|---|---|---|
| $k_m$ | Translation rate | 8 |
| $k_x$ | Transcription rate | 400 |
| $\gamma_m$ | mRNA degradation rate | 60 |
| $\gamma_x$ | Protein degradation rate | 1 |
| $H_{11}$ | Hill coefficient | 4 |
| $K_1$ | Hill constant | 20 |
| $\varepsilon_1$ | Leakage constant | 0.15 |

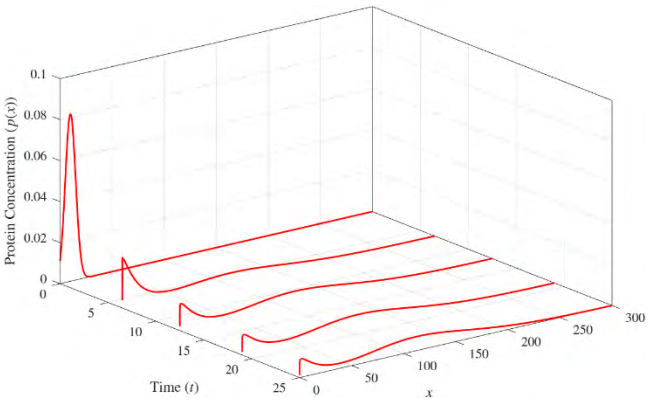

**Figure 2:** Time evolution of PIDE simulation with nominal values. Bimodal behaviour characteristic of positive autoregulation is observed.

A second-order PCE is employed, with an experimental design consisting of 300 model evaluations and their corresponding moments. Based on the assumed distributions of the uncertain parameters, the polynomial basis is chosen as a set of normalised Hermite polynomials. The surrogate is fitted to snapshot data collected at 10 discrete time steps, and the PCE coefficients are computed using the least angle regression (LAR) algorithm, as implemented in UQLab [8]. The choice of the polynomial degree, the size of the experimental design, and the regression algorithm may vary depending on the level of accuracy required. In practice, these choices involve a trade-off between computational cost and surrogate performance. In the present case, the generation of the training samples represents the most computationally expensive step and requires approximately 20 minutes of CPU time. Once trained, however, the PCE surrogate provides an efficient representation of the model response over the entire parameter space, enabling rapid evaluations. Moreover, key statistical quantities such as the mean, variance, and Sobol sensitivity indices can be obtained directly from the PCE coefficients at negligible additional cost.

Parity plots shown in Figure 3 demonstrate strong

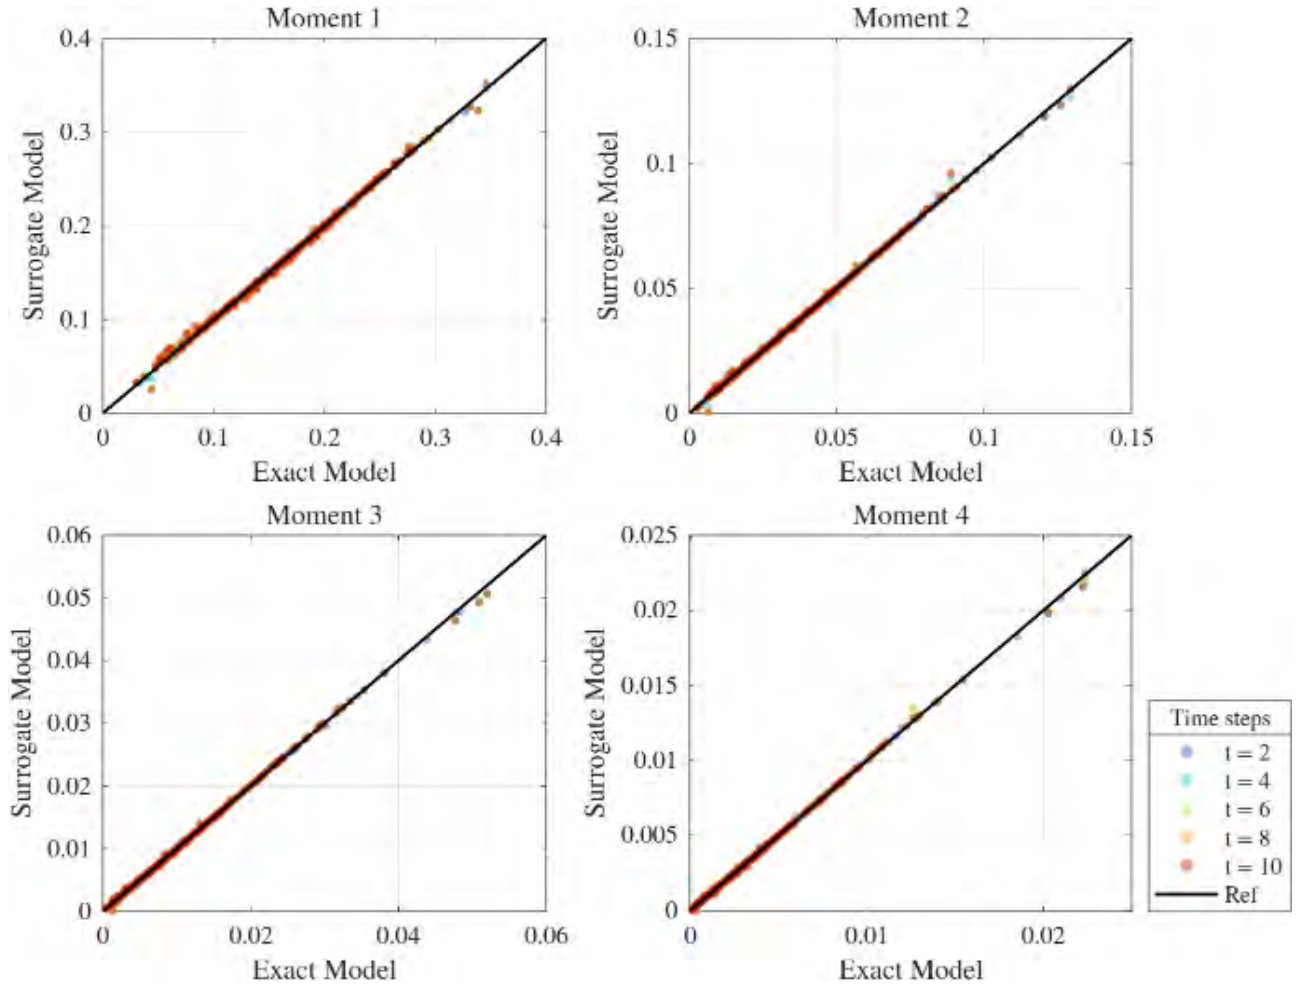

**Figure 3.** Parity plots comparing the first four moments predicted by the PCE surrogate (dots) against the validation dataset (continuous line). A second-order PCE constructed from 300 training samples is used. The zeroth moment is omitted for clarity, and selected data points at representative time instants are shown.

agreement between the moments predicted by the PCE surrogate and those obtained from the validation dataset across all considered time points. In particular, data points closely follow the identity line for the first four moments, indicating that the surrogate accurately captures both the magnitude and temporal evolution of the stochastic moment dynamics.

To quantitatively assess the accuracy of the PCE surrogate, leave-one-out (LOO) cross-validation errors, modified LOO errors, and root-mean-square errors (RMSE) were evaluated at all time points. Since the zeroth moment is identically equal to 1, it was excluded from the error analysis. Considering only moments of order greater than zero, the surrogate errors remained low throughout the simulation, with the global RMSE staying below $1.5 \times 10^{-3}$. The largest contribution to the total error arose from the first moment, whose RMSE increased at early times and then stabilised at approximately $1.5 \times 10^{-3}$, while the remaining moments were predicted more accurately, with RMSE values below $1.0 \times 10^{-4}$. Small deviations are observed only in a limited number of cases, with the first moment contributing most to the total error due to its comparatively larger variability. Nevertheless, the remaining moments are reproduced with very high accuracy, and the overall results confirm that the surrogate provides an accurate approximation of the moment dynamics over the entire time horizon. Further improvements may be achieved through alternative sampling strategies, different regression techniques for computing the PCE coefficients, or larger experimental designs.

Moment-based approaches provide an efficient alternative for characterising stochastic dynamics by representing the system through the evolution of its moments [9]. By focusing on their dynamics, these methods enable the quantification of fluctuations over time while substantially reducing computational cost compared to full distribution-based analyses, as will be demonstrated

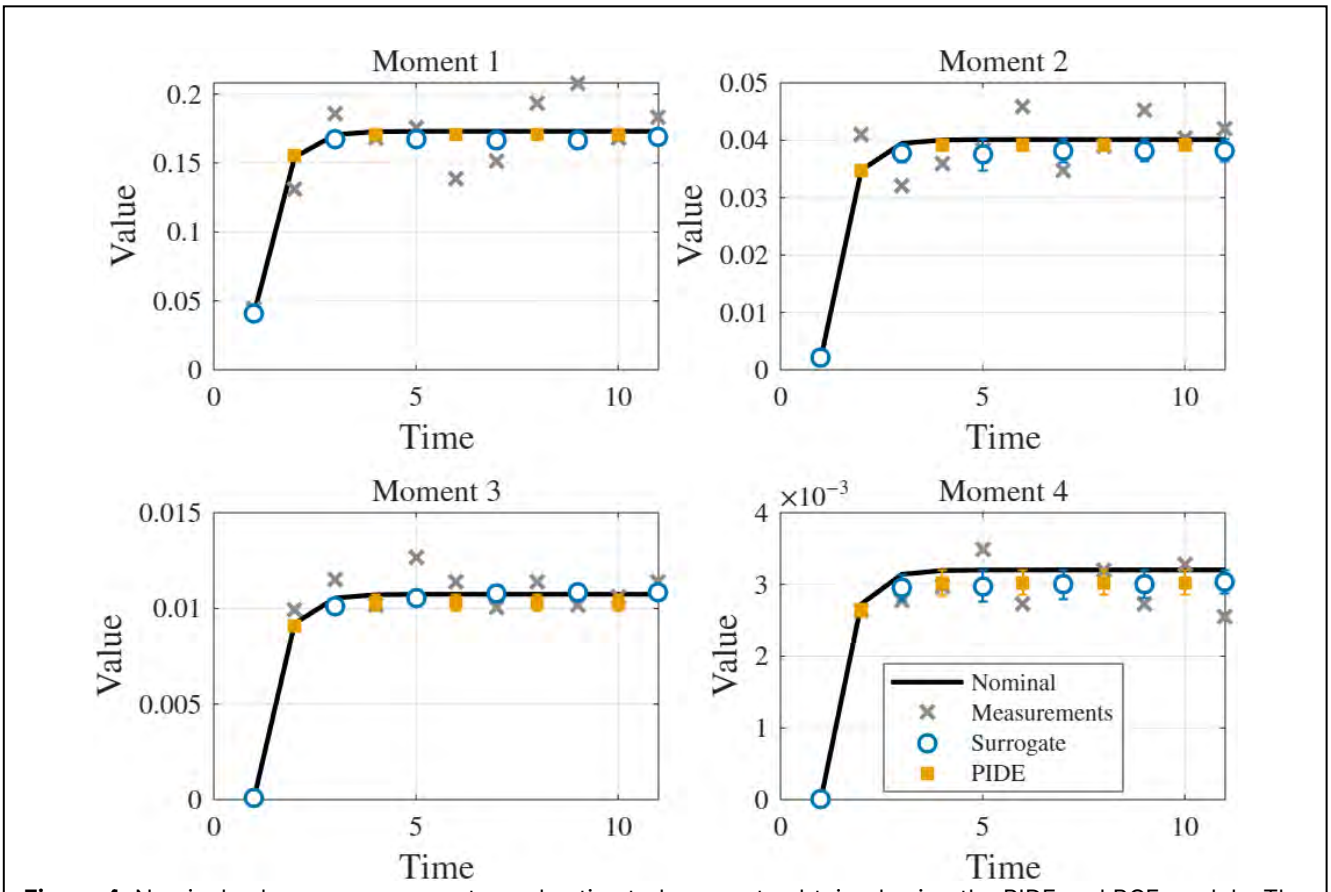

**Figure 4:** Nominal values, measurements, and estimated moments obtained using the PIDE and PCE models. The zeroth moment is omitted for clarity, and 10 data snapshots are considered.

in the following section.

## Parameter Inference

Following the validation of the PCE surrogate, it is employed to estimate the model parameters using a multi-start optimisation strategy. Randomised initial guesses within predefined parameter bounds are used in a constrained optimisation algorithm to minimise a weighted least-squares objective. Noisy measurements are generated from the moment dynamics, assuming 10% multiplicative Gaussian noise. The PCE surrogate enables rapid evaluation of the forward model, making the multi-start procedure computationally feasible while jointly estimating all kinetic parameters of the regulatory network. The parameter set yielding the lowest objective value across all optimisation runs is selected as the final estimate.

Under 10% relative noise, the PCE surrogate accurately captures the underlying moment dynamics. The estimated parameters reproduce the temporal evolution of the measured moments and remain in close agreement with the reference PIDE solution, as shown in Figure 4.

Table 2 summarises the estimated parameters and their relative errors obtained with the PIDE and PCE models, while the resulting probability density functions simulated using the optimised parameters are shown in Figure 5.

**Table 2:** Estimated parameters and relative errors from the PIDE and PCE model.

| Param. | PIDE | PCE | Rel. Error PIDE | Rel. Error PCE |
|---|---|---|---|---|
| $k_m$ | 8.92 | 8.34 | 11.5% | 4.2% |
| $k_x$ | 385.4 | 367.3 | 3.6% | 8.1% |
| $\gamma_x$ | 1.086 | 1.14 | 8.6% | 14.0% |

While the PIDE approach yields accurate parameter estimates with relative errors below 12%, the surrogate-based inference exhibits moderate deviations for some parameters, particularly those associated with stronger coupling and reduced practical identifiability. Nevertheless, the parameter estimates obtained with the PCE surrogate remain within acceptable accuracy and successfully reproduce the temporal evolution of the observed moments. Moreover, the probability density functions reconstructed using the parameters inferred from the PCE surrogate closely match those obtained with the reference PIDE model and the nominal parameter set despite parameter deviations.

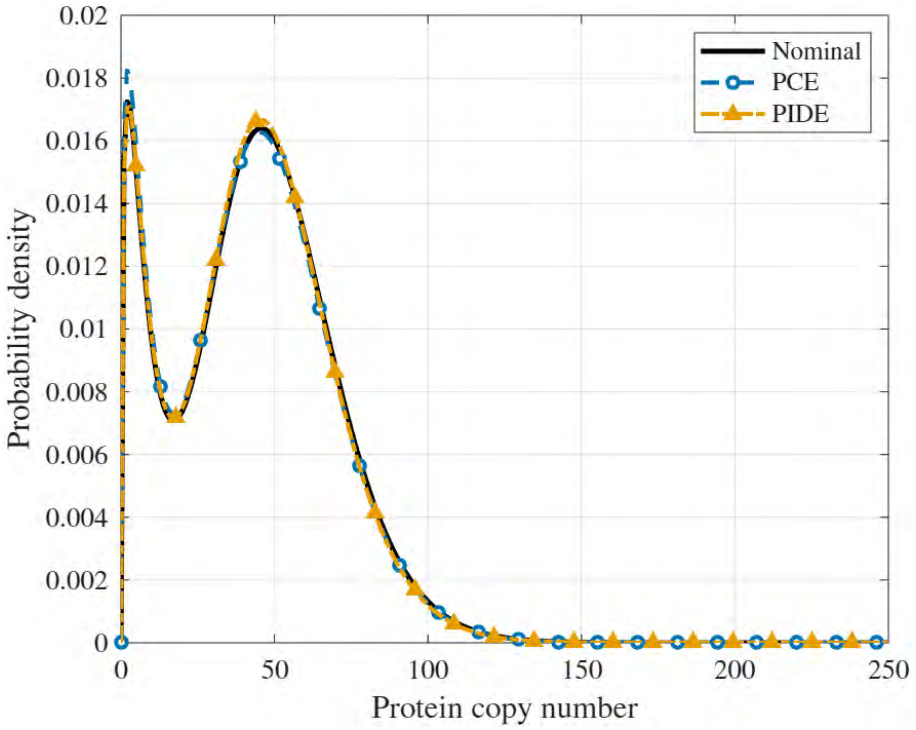

**Figure 5:** Probability density functions obtained using the optimised parameters for the PIDE and PCE models. The PCE-based estimates closely match the reference PIDE solution and preserve the multimodal structure of the distribution.

Beyond accuracy, the use of the PCE surrogate provides substantial computational advantages. For a multi-start optimisation with 20 initial guesses and parallel execution, the total optimisation time using the PCE surrogate was 1.8 minutes, compared to 180.9 minutes when relying on the PIDE model, corresponding to an approximately 100-fold reduction in computational cost. Once constructed, the surrogate can be readily employed for both forward and inverse uncertainty quantification tasks. Furthermore, the non-intrusive nature of the surrogate modelling approach facilitates the inclusion of multiple uncertain parameters, making the proposed framework well-suited for efficient inference and uncertainty quantification in stochastic gene regulatory networks.

## CONCLUSIONS AND FUTURE RESEARCH

In this work, we develop a surrogate modelling framework for uncertainty quantification in stochastic gene regulatory networks. The proposed approach combines PIDE-based simulations for computing probability density functions with Polynomial Chaos Expansions (PCE) to construct an efficient surrogate model. The central idea is to represent the time evolution of statistical moments as functions of uncertain input parameters.

The effectiveness of the proposed method is demonstrated using a one-dimensional self-regulating gene network as a case study. This system is selected for its conceptual simplicity while still exhibiting bimodal behaviour depending on the uncertain input parameters. Despite its low dimensionality, the example highlights that accurate joint inference of all kinetic parameters can be achieved with a substantial reduction in computational cost. These computational gains are expected to become even more pronounced for more complex gene regulatory networks involving multiple interacting genes.

Future research directions include extending the proposed framework to more advanced uncertainty quantification tasks, such as Bayesian parameter inference, and to larger gene regulatory networks with multiple uncertain parameters. Additional reductions in training cost may be achieved through more efficient sampling strategies and improved experimental design.

# Practical Identifiability and Optimal Experiment Design for Hybrid Cybernetic Models: An *E.Coli* Case Study

**Stylianos Floros, Satyajeet S. Bhonsale, Simen Akkermans, Jan F.M. Van Impe***

BioTeC+ Chemical & Biochemical Process Technology & Control, KU Leuven, Ghent, Belgium
* Corresponding Author: jan.vanimpe@kuleuven.be.

## ABSTRACT

Developing predictive, high-resolution microbial models that retain mechanistic insight remains a central challenge in biochemical engineering. This paper addresses the challenge of preserving metabolic information while ensuring model accuracy and proper statistical definition. It employs the Hybrid Cybernetic Modelling (HCM) approach to integrate metabolic regulation with genome-scale information, and dynamically predict *E.Coli* phenotypes. The main aim of this work is to explore HCM's parameter identifiability to advance its accuracy and robustness for a limited set of data. To bypass the computational burden of computing the elementary flux modes, the opt-yield Flux Balance Analysis (opt-yield FBA) is employed to identify a physiologically relevant set of yield-maximising metabolic pathways. Metabolic Yield Analysis (MYA) then reduces this to four key pathways which capture 99% of the original metabolic yield space. The cybernetic model is formulated where "artificial enzymes" are allocated among these key competing pathways, based on a return-on-investment criterion. Initial parameter estimates are derived through non-linear least squares regression for an *in silico* data set of biomass, glucose and acetate concentration. Practical identifiability analysis is employed to explore parameter estimates. Specifically, profile likelihood & sensitivity analysis results lead to model reduction by eliminating the combined acetate-biomass producing pathway. To further improve parameter uncertainty, Optimal Experiment Design (OED) is used to obtain an additional informative experiment. Finally, the calibrated model is validated against a new artificial dataset.

**Keywords**: Metabolic Engineering, Cybernetic Model, Practical Identifiability, Optimal Experiment Design

## INTRODUCTION

Mathematical modelling of intracellular processes is gaining popularity towards developing metabolic and biochemical engineering applications [1]. Recent breakthroughs suggest the formulation of multi-scale modelling approaches that avail of mechanistic information for intracellular metabolism, towards accurately describing changes in microbial communities.

Typically, such models adopt a "grey-box" structure. Specifically, population-based models that come with a form of Ordinary Differential Equations (ODEs) are directly informed by mechanistic models (e.g. Genome-scale Models (GEMs)) for intracellular metabolism [2]. When parametrised, they are calibrated based on limited experimental data to offer informative predictions for bioprocesses.

However, the systematic employment of such models is often hindered by parameter identifiability issues. Many reasons lead to excess parameter uncertainty, which hinders the causal link between intracellular metabolism and extracellular phenotype [3]. As a result, this poses a major threat to the fundamental understanding of complex biological phenomena.

This paper aims to advance the understanding of parameter identifiability in multi-scale models. It employs the Hybrid Cybernetic Model (HCM) to capture temporal changes of biomass, acetate and glucose concentrations within an E.Coli case study [4]. It performs practical identifiability and sensitivity analysis to further explore the estimated parameters' relationship with model inputs/outputs. The study further proceeds with model reduction and Optimal Experiment Design (OED), towards expanding the knowledge on HCM's responses.

# MATERIALS & METHODS

## Case Study Design

This study chooses *Escherichia Coli str. K-12* as a model organism for *in silico* experimentation. First, an artificial data set is generated based on *E.Coli* metabolism. The *in silico* environment resembles a bio-reactor that operates under batch-ideal conditions. This assumption serves as the basis for all subsequent modelling and analysis.

## Dynamic - Flux Balance Analysis

To simulate the temporal changes in cellular biomass production, metabolite consumption and secretion, the *e_coli_core* GEM for *E.Coli K-12* is selected [5].

Dynamic-Flux Balance Analysis (d-FBA) further aids in generating the artificial data set. The initial conditions of the *in silico* experiment are: 0.001 $\mathrm{gDW/L}$ biomass, 10 $\mathrm{mmol/L}$ glucose and 0.35 $\mathrm{mmol/L}$ acetate. To impose glucose availability as an *in silico* constraint for cellular uptake of glucose, a Michaelis-Menten expression is used:

$$V_{glc} = -V_{max} \cdot \frac{S}{K_s+S} \tag{1}$$

where $V_{glc}$, $V_{max}$ are the actual and maximum specific uptake rate ($\mathrm{mmol/gDW*h}$), equal to 10, and $K_s$ is the half-maximum saturation constant ($\mathrm{mmol/L}$), equal to 5. Oxygen uptake was further constrained (-2, +1000) $\mathrm{mmol/gDW*h}$ to enable secretion of both acetate and biomass. The sampling interval is 1 $\mathrm{hour}$, and the simulation lasts for 36 $\mathrm{hours}$, until complete depletion of substrate.

## Hybrid Cybernetic Model

The HCM is a dynamic approach for metabolic modelling, initially presented by [4]. It comes as a set of ODEs, which stem from GEM networks. It incorporates a regulatory process on internal metabolism by using "artificial enzymes" and cybernetic variables [6]. This approach describes the cellular attempt to make optimal use of its resources, among competing pathways, in response to extracellular nutrient availability.

## Extracellular Metabolite Balance

The extracellular metabolite balance is given by the following Equations:

$$\frac{dm_{ex}}{dt} = S \cdot Z^T \cdot \mathbb{I} \cdot v \cdot r \cdot c \tag{2}$$

$$r_i = k_i^{max} \cdot e_{rel,i} \cdot \left(\frac{s}{K_i+s}\right) \tag{3}$$

where $m_{ex}(\mathrm{mmol/L})$ denotes the extracellular metabolite concentration and $r(\mathrm{mmol/gDW*h})$ is a vector for all pathway specific uptake rates, $S$ $(n_{metabolites}$ x $n_{reactions})$ is the GEM stoichiometric matrix, $Z$ $(n_{reactions}$ x $n_{pathways})$ extracts key yielding pathways from $S$, $c$ $(\mathrm{gDW/L})$ is the biomass concentration, $v$ [-] is a vector for all pathways cybernetic enzyme activity, $k_i^{max}$ $(\mathrm{mmol/gDW*h})$ is the maximum specific uptake rate, $e_{rel}$ [-] is the relative enzyme level for every pathway, $s$ $(\mathrm{mmol/L})$ is the substrate concentration and $K$ $(\mathrm{mmol/L})$ is the half-maximum saturation constant.

## Biomass Balance

The biomass concentration is given by:

$$\frac{dc}{dt} = \mu \cdot c \tag{4}$$

where $\mu$ $(1/h)$ is the total specific growth rate, given by the weighted sum of all fluxes.

## Enzyme Balance

As stated, key "artificial enzymes" are allocated to every reaction of the network's metabolic pathways and catalyse substrate conversion. The relative enzyme balance is:

$$\frac{de_{rel}}{dt} = a + (\mathbb{I} \cdot u \cdot r_{e,rel}) - (\mathbb{I} \cdot \beta + \mu) \cdot e_{rel} \tag{5}$$

$$r_{e,rel,i} = k_{e,i} \cdot \left(\frac{s}{K_i+s}\right) \tag{6}$$

where $a$ $(1/h)$ and $\beta$ $(1/h)$ are the enzymatic constitutive synthesis and degradation rate, respectively. Moreover, $u$ $(-)$ is the cybernetic variable for enzyme synthesis, $\mathbb{I}$ is the identity matrix, $r_{e,rel}$ $(1/h)$ is the specific enzyme synthesis rate and $k_{e,i}$ $(1/h)$ is the maximum enzyme synthesis rate.

## Cybernetic Laws

The allocated enzymes are themselves governed by two cybernetic variables, $u$ and $v$. Both are bounded [0, 1] and are determined through optimal control theory [7]. Therefore, two cybernetic laws are formulated:

$$u = \frac{p_i}{\sum p_i} \tag{7}$$

$$v = \frac{p_i}{\max(p_i)} \tag{8}$$

Specifically, $u$ regulates enzyme synthesis by following the "Matching Law ", and $v$ regulates enzyme activity by following the "Proportional Law". For both cybernetic variables, the cellular metabolic goal $p$ is defined as follows:

$$p_i = f \cdot r_i \tag{9}$$

Where $f$ $(-)$ is the substrate's number of carbon atoms, and $r$ is each pathway's specific uptake rate.

## Pathway Matrix - Z

The *e_coli_core* GEM contains 72 metabolites and 95 reactions; the stoichiometric matrix $S$ is of size [72 x 95]. To reduce the total pathways, and therefore parameters, a key-pathway identification routine takes place.

## Opt-yield Flux Balance Analysis

An opt-yield FBA algorithm was employed to identify a physiologically relevant set of yield-maximising metabolic pathways [8]. Yield is defined as the ratio of product formation rate ($r_p$) to substrate uptake rate ($r_s$). In short, opt-yield FBA transforms the nonlinear fractional objective of yield $\left(Y = \frac{r_p}{r_s}\right)$, into a linear one $(r_p - Y_{temp} \bullet r_s)$, by introducing a $Y_{temp}$ temporary yield, and optimises the latter iteratively until the maximal yield is found. The algorithm was applied to the *e_coli_core* GEM under aerobic conditions, and bound glucose (-10, -0.1) $mmol/gDW*h$ to compute the yield space for biomass and acetate, having glucose as substrate.

### Metabolic Yield Analysis

Subsequently, MYA was used to reduce the opt-yield FBA pathways to a minimal set that covers 99% of the original convex yield space. A bottom-up approach was used select the minimum number of biochemical pathways, by sequentially comparing the spanned convex hull volume between the reduced and original yield space [9]. The minimal number of pathways is used for formulating the HCM through the $Z$ matrix.

## Parameter Estimation

For the HCM, 5 unknown parameters $(k^{max}, K, a, \beta, k_e)$ exist. Every unknown parameter vector has size equal to the number of columns (i.e., minimal pathways) of $Z$. Values for $a$, $\beta$, and $k_e$ are selected from the literature [6-8].

### Nonlinear Least Squares Regression

Model parameters $k^{max}$ and $K$ were estimated with least squares regression, minimising the sum of squares errors between model predictions and in silico data for biomass, glucose and acetate concentrations. The objective function was defined as:

$$LSE(\theta) = \sum_i^N \left(y_{sampled,i} - y_{model,t}(\theta)\right)^2 \quad (10)$$

where $\theta$ denotes the vector of unknown parameters, $y_{sampled}$ represents the measured data, and $y_{model}(\theta)$ the model predictions. To assess the goodness of fit, the Mean Squared Error (MSE) was used:

$$MSE = \frac{1}{n_{sampled} - n_\theta} \bullet LSE(\theta) \quad (11)$$

Here, $n$ signifies either the number of sampled data or parameters.

### Parameter Identifiability

To evaluate parameter practical identifiability, we employed the profile likelihood approach [10, 11]. For each parameter $\theta$, the profile likelihood $\chi^2_{PL}(\theta_i)$ was computed by re-optimising all other parameters while keeping $\theta_i$ fixed at a series of values:

$$\chi^2_{PL} = \min\left[\chi^2(\theta)\right] \quad (12)$$

where, $\chi^2(\theta) = LSE(\theta)$ under the assumption of normally distributed residuals. The likelihood-based confidence interval (CI) at level $\alpha$ was defined by the threshold:

$$\Delta_\alpha = \chi^2(\alpha, df = 1) \quad (13)$$

where $\alpha$ is the quantile of the $\chi^2$ distribution with $df$ degrees of freedom. A parameter was considered practically non-identifiable if its profile likelihood remained below $\Delta_\alpha$ in either the increasing or decreasing direction, indicating an infinitely extended confidence bound in that direction. CIs were extracted from the parameter values were $\chi^2_{PL}$ crossed the threshold $\Delta_\alpha$.

### Local Sensitivity Analysis

All parameters were examined for their influence on model output via local sensitivity analysis. The sensitivity matrix $S$ was computed numerically as:

$$S_{i,j} = \frac{\partial y_i}{\partial \theta_j} \quad (14)$$

Parameters with consistently low sensitivity and flat profile likelihoods were considered for model reduction.

## Optimal Experiment Design

To reduce parameter uncertainty, OED was performed using the Modified E-optimality criterion [12]. The Fischer Information Matrix (FIM) was approximated from local sensitivities, evaluated at the nominal parameter estimates:

$$FIM(\theta) = \sum_{k=1}^{N_t} S(\theta, t_k)^T \bullet Q^{-1} \bullet S(\theta, t_k) \quad (15)$$

Where $S(\theta, t_k) = \partial y/\partial\theta|_{t_k}$ is the sensitivity matrix at time $t_k$, and $Q$ is the covariance matrix of measurement errors. The modified E-optimality criterion aims to minimise the condition number of the FIM, which is equivalent to minimising the ratio of the largest to the smallest eigenvalue:

$$E_{criterion} = \min\left[\frac{\lambda_{max(FIM(\theta))}}{\lambda_{min(FIM(\theta))}}\right] \quad (16)$$

An additional *in silico* experiment was designed by solving this optimisation problem under feasible operational bounds, yielding an informative input profile (e.g., a time-varying substrate feed) that was simulated to generate new data for re-estimation.

## Numerical Simulations

All computations were performed in Spyder v6 IDE virtual environment, using the Python 3.10.6 programming language. A numerical simulation for the whole pipeline lasts approximately 7 hours and 15 minutes.

## RESULTS & DISCUSSION

### Yield Space

The opt-yield FBA results in 22 physiologically relevant metabolic pathways, which together span the - acetate/biomass over glucose - yield space. Then, MYA identifies 4 pathways containing 99% of the original convex hull. From these, 2 identified pathways correspond to high-yield acetate and biomass production (pathway 1 & 2, respectively), where a third one represents a no-growth state of complete respiration process.

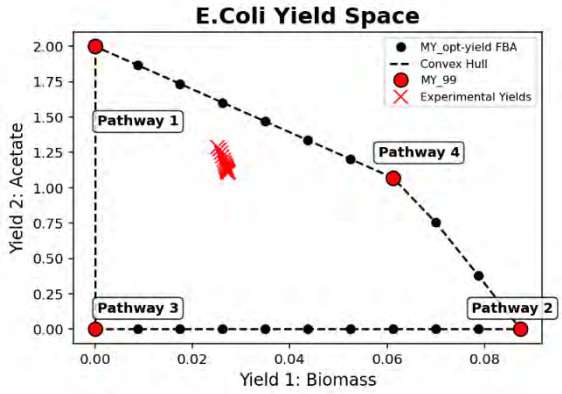

**Figure 1.** Opt-yield FBA and MYA convex yield space.

With pathway 4, which contains a set of intra-extracellular reaction fluxes for combined acetate & biomass secretion. All four are forming a Z-matrix and include all the necessary knowledge towards describing trade-offs between growth and by-product formation.

### HCM – 4 Pathways

#### Model Fit

The HCM accurately reproduces the batch dynamics of biomass growth, glucose uptake and acetate secretion, while preserving metabolic mechanistic interpretability. Model predictions achieve a low MSE for all measured states (Table 1). Meanwhile, cybernetic variables allocate enzyme activity in a physiologically consistent way; growth-oriented pathways dominate during high glucose, and acetate-reassimilation pathways dominate for low carbon conditions.

**Table 1:** Optimal parameter values, HCM (4 paths).

| Pathway | $k_{max}$ (mmol/gDW*h) | K (mmol/L) | MSE |
|---|---|---|---|
| 1 | 0.715 | 1.404 | 0.002 |
| 2 | 0.717 | 6.798 | |
| 3 | 0.587 | 5.257 | |
| 4 | 0.100 | 10.00 | |

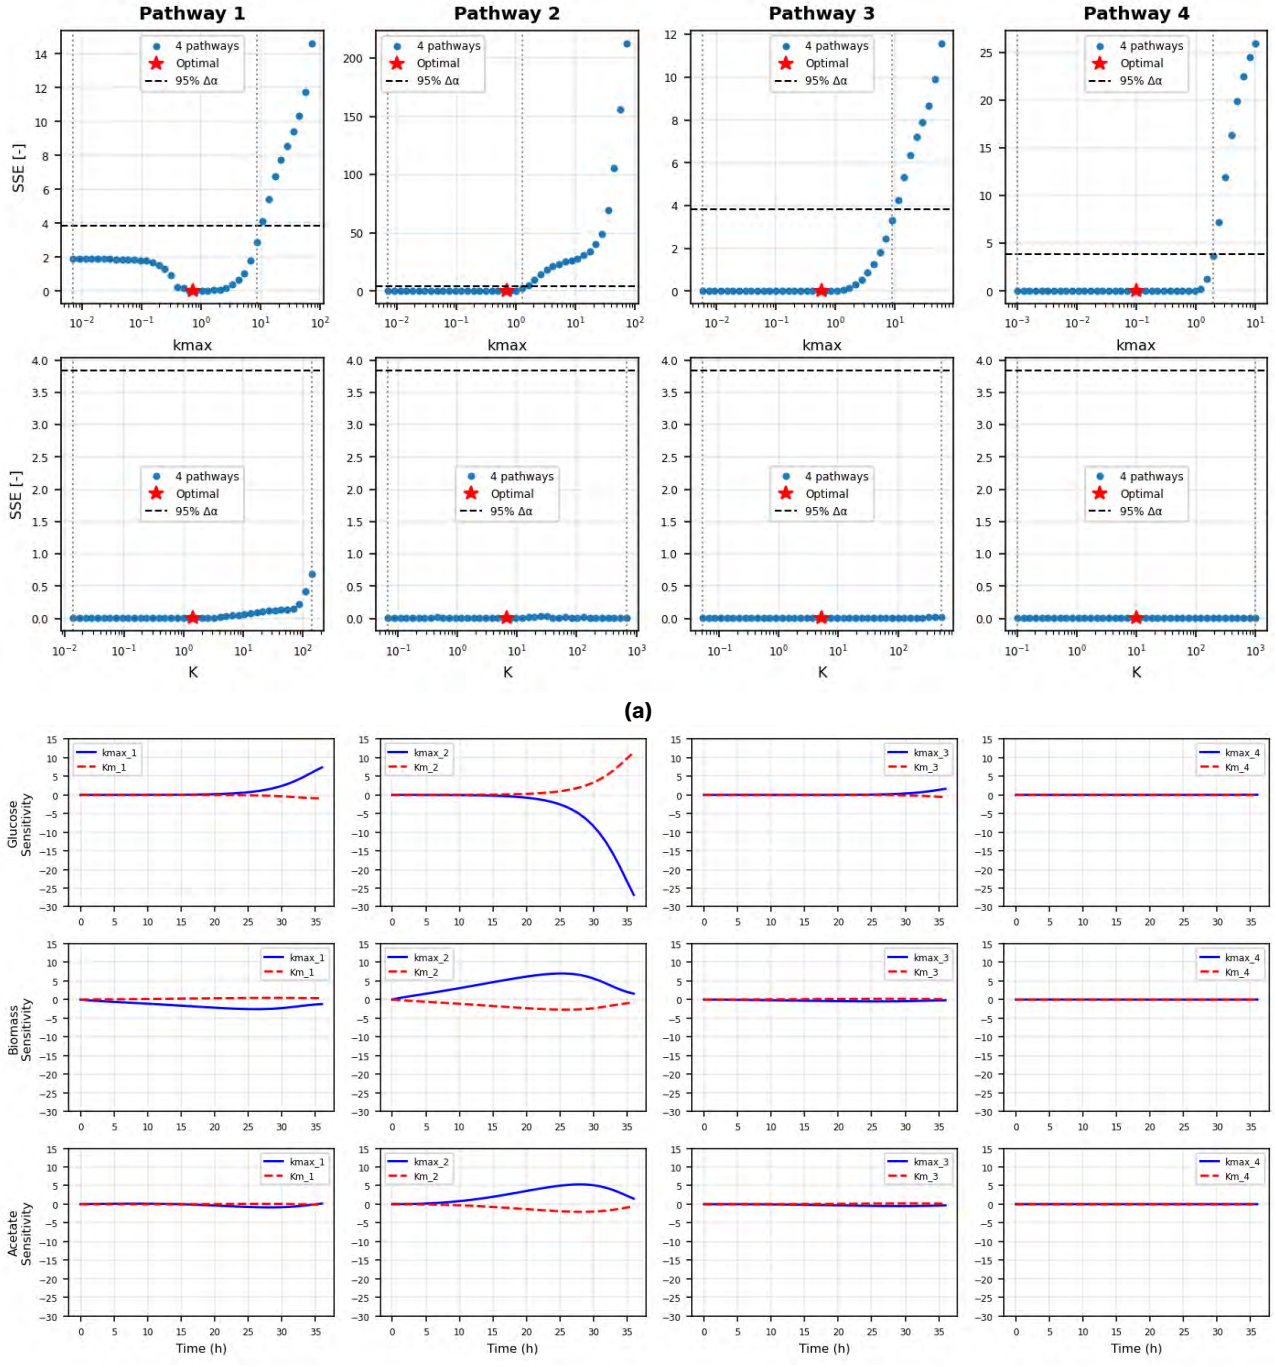

**Figure 3:** Parameter identifiability and sensitivity results, of HCM, for optimal parameters **(Table 1)**. **(a)** Profile Likelihoods. **(b)** Normalised sensitivity profiles: impact of perturbed parameter on model outputs.

Within all pathways, the 4th stands out; it is least sensitive to substrate concentration, has a low exchange rate constant ($K_4$ = 10, $k_4^{max}$=0.1), while pathway enzyme synthesis and activity are approaching 0 over time.

## Identifiability & Sensitivity Analysis

Profile likelihoods and local sensitivities reveal that not all pathway-specific uptake parameters are practically identifiable with the initial experiment, motivating the need for model reduction and additional input data. Similar identifiability issues have been reported for large kinetic and population-balance models, where flat profile likelihoods indicate over-parametrisation and the need for targeted experiments through OED [10, 12].

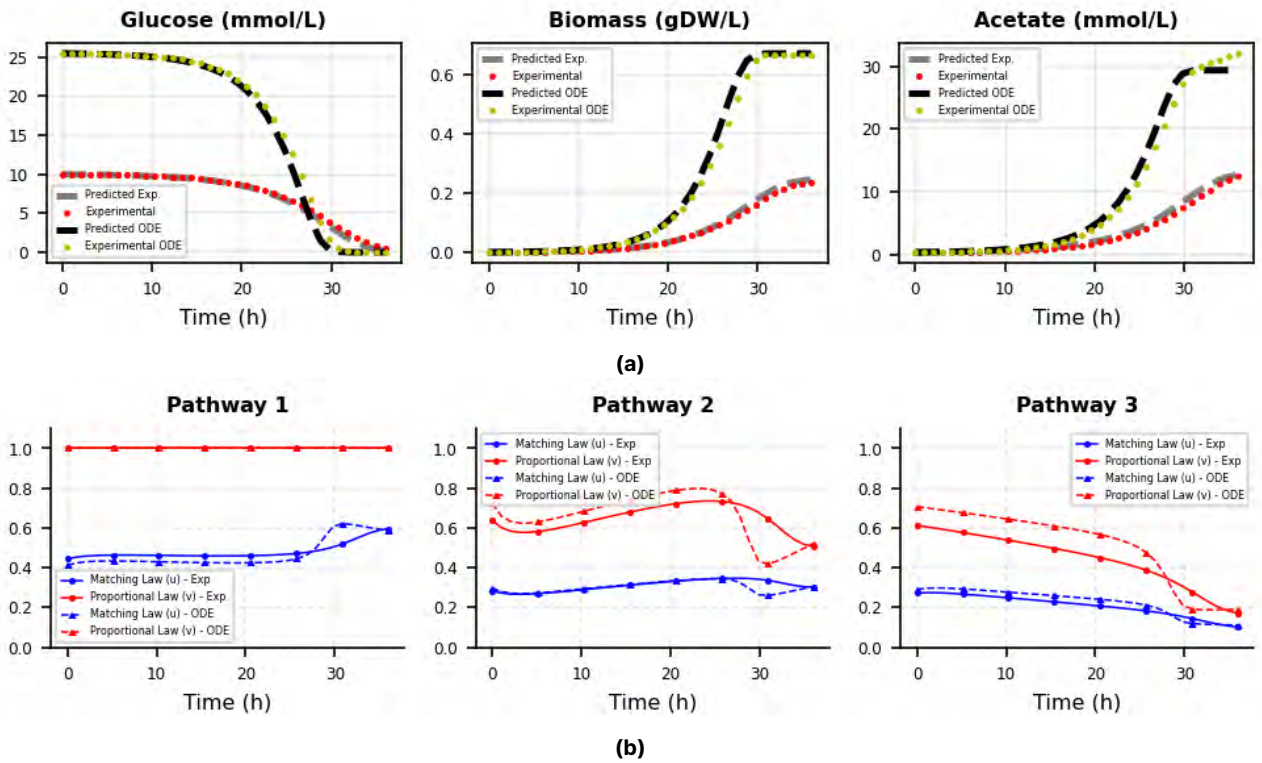

**Figure 4:** Model fit of ODE-enriched HCM for 3 pathways. **(a)** HCM predictions for glucose, biomass and acetate states, using optimal parameters **(Table 2)**. **(b)** Simulated cybernetic variables (u, v) for model's fit.

## HCM – 3 Pathways

### Model Reduction & OED

Model reduction from 4 to 3 pathways is motivated by the combined flat profile likelihoods ($K_4$, Figure 3a) and low local sensitivities ($k^4_{max}$, $K_4$ Figure 3b) for the acetate-biomass co-producing route, indicating practical non-identifiability and limited influence on measured outputs. Removing this pathway promises a more contained model structure, with chances of parameter identifiability [13].

Furthermore, on the structurally reduced 3-pathway HCM, OED is employed using the modified E-criterion to improve the conditioning of the FIM matrix. Specifically, it aims to target FIM directions that are poorly informed by the initial dataset. OED results in an optimal initial glucose concentration (i.e., 25.47 g/L), thus dFBA is performed again to design this new input, yielding a more differentiated activation of the 3 remaining pathways, over time.

**Table 2:** Optimal parameter values, ODE-HCM (4 paths).

| Pathway | $k_{max}$ (mmol/gDW*h) | K (mmol/L) | MSE |
|---|---|---|---|
| 1 | 0.826 | 1.730 | 1e-4 |
| 2 | 0.666 | 4.823 | |
| 3 | 0.660 | 5.303 | |

### Model Fit

In the joint estimation for the merged dataset, the 3-pathway HCM seem to play a complementary role. The high-yield, glucose-to-biomass route dominates early growth and remains highly activated throughout the experiment. Additionally, acetate overflow and respiration pathways are initially active, but their enzymatic promotion and activity are decreasing proportionally with time (i.e., substrate depletion) (Figure 3). This synergy leads to a very low MSE (Table 2) while maintaining physiologically plausible values for six estimated parameters.

### Identifiability & Sensitivity Analysis

Model reduction, by itself, improves the practical identifiability of maximum exchange rate constants for pathways 1 and 2, since both profiles cross the $\Delta\alpha$ threshold. However, it only induces a slight change of slope for the rest of the parameters, with partial or unsuccessful crossing of the threshold, still indicating practical non-identifiability for $k^3_{max}$, $K_1$, $K_2$ and $K_3$ (Figure 5a). The OED experiment induces a clear curve across the 95% CI for three parameters, notably making $K_2$ practically identifiable. The 95% CI of previously identifiable parameters become narrower, but the kinetic parameters that belong to pathway 3 and $K_1$ remain practically non-identifiable.

Multiple reasons may contribute to this result. For example, the lack of sufficient/informative data could

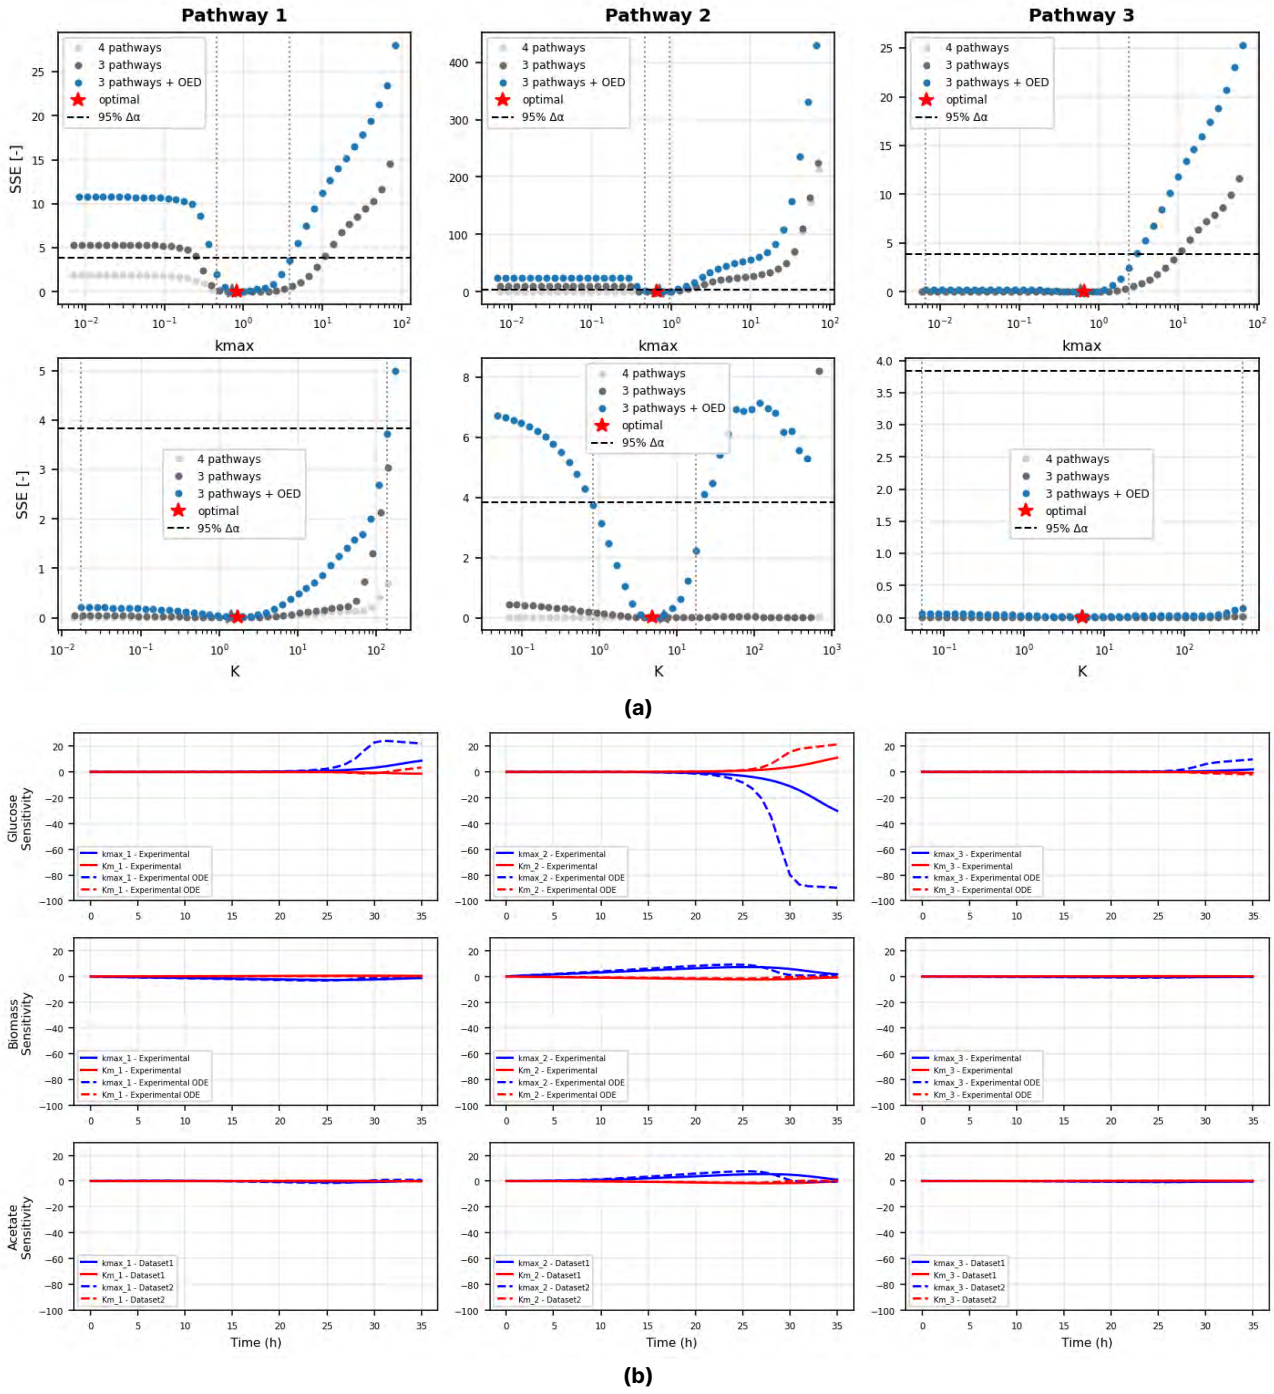

**Figure 5:** Parameter identifiability & sensitivity results; ODE-assisted HCM, for optimal parameters **(Table 2)**. **(a)** Profile Likelihoods, **(b)** Normalised sensitivity profiles; impact of perturbed parameters on model outputs.

lead to incomplete parameter identifiability. As local sensitivities show (Figure 5b), the OED dataset improves the sensitivity of model output over parameter perturbations mostly for pathway 2. However, it didn't succeed in separating the profiles for the pathway 1 & 2. This could require more measurements (e.g. $CO_2$ for pathway 3), or an acetate-driven OED design is needed to improve pathway contributions between 1 & 2. Additionally, if one revisits the HCM Michaelis-Menten formulation for pathway exchange rate, it is of intuitive understanding that the $k_{max}$ and K parameters are countering each other during the profile likelihood analysis. Specifically, when the K value becomes too low, the parameter is negligible towards the value of $k_{max}$; thus, the parameter is not

informed by the data. On the other hand, when $K$ achieves a large value, substrate concentration is negligible, thus only the $\frac{k_{max}}{K}$ ratio can be identifiable. It is therefore a matter of proper experiment design, as well as inclusion of multiple measurements, to achieve a practically identifiable profile for the K parameters, as the $K_2$ profile likelihood signifies.

## CONCLUSIONS

The proposed workflow shows that HCMs can be systematically reduced and still capture microbial metabolic dynamics. Combining methods like opt-yield FBA, MYA and profile likelihood analysis yields a statistically well-defined 3-pathway HCM that retains almost all the original yield space. A modified E-criterion provides an additional informative experiment that improves confidence bounds, measurement sensitivity and parameters' practical identifiability. Together, these steps showcase how integrated analysis enables the reliable employment of mechanistic models for robust prediction and control of microbial bioprocesses.

## ABSTRACT

Predictive modeling of surfactant properties is constrained by limited experimental datasets, a common challenge in specialty chemical development where property measurements require specialized equipment and significant time investment. In this study, we address data scarcity through a semi-supervised generative augmentation framework that leverages both labeled and unlabeled molecular data for surface tension prediction. We implemented a two-stage variational autoencoder (VAE) training strategy using a curated database of 600 non-ionic surfactants. First, 461 unlabeled surfactant structures were used for VAE pre-training to learn latent representations capturing molecular connectivity patterns and amphiphilic relationships. Second, 125 molecules with surface tension measurements were used for fine-tuning to embed property-structure relationships. Our stratified generation framework produces surfactants matching target property distributions (Wasserstein distance = 0.030, KS statistic = 0.152) through stratified sampling and multi-criteria filtering, achieving 88.5% structural validity. We systematically evaluated augmentation effectiveness across seven levels (×1.25 to ×5) using graph convolutional networks with five random seeds per level. Results show optimal performance at ×3 augmentation (375 training molecules), where test $R^2$ improved from 0.60 (baseline, 125 molecules) to 0.78 (+28%), with RMSE decreasing to 0.056 mN/m. Multi-seed analysis demonstrates stable and reproducible training (test $R^2$ = 0.776 ± 0.030). This framework achieves performance equivalent to tripling the experimental dataset, providing a practical and scalable approach for specialty chemical property prediction where structural data is abundant but property labels are scarce.

**Keywords**: surfactants, surface tension, data augmentation, VAE, GCN, semi-supervised learning

## 1. INTRODUCTION

Surfactants are amphiphilic molecules central to formulation chemistry, with applications spanning detergents, cosmetics, pharmaceuticals, and enhanced oil recovery.[1] Their interfacial properties, particularly surface tension at the critical micelle concentration (CMC), directly govern product performance. However, experimental characterization requires specialized tensiometer equipment and careful measurement protocols, [2] creating a bottleneck in surfactant discovery, where thousands of candidate molecules might be considered, but only dozens can be practically tested.

Machine learning offers a pathway to accelerate surfactant discovery by predicting properties from molecular structure.[3-5] Graph convolutional networks (GCNs) have demonstrated strong performance in molecular property prediction tasks.[6] However, these models require substantial training data to learn robust structure-property relationships, conflicting with the reality of specialty chemical development where experimental datasets are typically small (<200 molecules) due to measurement costs and domain specificity.

Data augmentation addresses this limitation by synthetically expanding training sets. While traditional augmentation in computer vision leverages known invariances, [7, 8] molecular augmentation requires generating chemically valid structures with properties matching

target distributions. Generative models, particularly variational autoencoders (VAEs), offer a principled approach by learning continuous latent representations enabling controlled generation of novel structures.[7, 9] When coupled with property prediction, VAEs can generate molecules matching specific property targets.[10] However, training effective molecular VAEs requires substantial data, presenting a fundamental challenge for small experimental datasets.

We address this through semi-supervised learning, leveraging the asymmetry between structural data availability (abundant) and property measurements (scarce). Our approach uses unlabeled surfactant structures to pre-train a molecular VAE, learning valid connectivity patterns, then fine-tunes on property-labeled molecules to embed structure-property relationships. This enables generation of synthetic training data that is both chemically valid and property-relevant.

In this work, we present a systematic evaluation of semi-supervised generative augmentation for non-ionic surfactant surface tension prediction. We demonstrate that intelligent augmentation can improve predictive performance equivalent to tripling the experimental dataset, while identifying fundamental limitations in generating molecules at property extremes and providing comprehensive validation through chemical space analysis and multi-seed evaluation. Our analysis reveals why intermediate augmentation levels show instability and provides guidelines for optimal augmentation strategies. Figure 1 summarizes the proposed semi-supervised augmentation workflow, including two-stage VAE training, stratified generation, and multi-seed GCN retraining.

## 2. METHODS

Figure 1 provides an overview of the full pipeline. Briefly, a baseline GCN is trained on labeled data and used as a property oracle to pseudo-label VAE-generated molecules; stratified augmentation sets are then constructed and used to retrain GCN models under multiple random seeds.

### 2.1 Dataset and Preprocessing

We curated a database of 600 unique non-ionic surfactant molecules from literature sources.[1, 3, 5, 11, 12] Of these, 139 molecules had experimentally measured surface tension, while 461 had only structural information (SMILES strings). Surface tension measurements ranged from 18.0 to 47.5 mN/m. All values were normalized to [0, 1] using min-max scaling.[13]

The 139 labeled molecules were randomly split (seed =2024) into training (125 molecules, 90%) and test (14 molecules. 10%) sets. The split achieved good property distribution balance, with training set mean of 0.460 (std=0.179) and test set mean of 0.471 (std=0.123) in normalized units. All molecules were validated for chemical correctness using RDKit (2024.9.6), [14] and SMILES were canonicalized. The test set was held out for all experiments and used only for final evaluation.

### 2.2 Baseline GCN model

Our surface-tension baseline is a molecular GCN regressor built on graph representations $G = (V, E)$, with atoms as nodes and bonds as edges.[15] Atom states are initialized from RDKit-derived descriptors capturing local chemistry (e.g., elemental identity and bonding environment). The network updates these states through two GraphConv layers (256 channels) using neighborhood aggregation with learnable weights and ReLU nonlinearities, enabling information to propagate across the molecular structure. Node embeddings are then summarized via global mean pooling to yield a fixed-dimensional molecular fingerprint. This pooled representation is mapped to the final prediction by a compact fully connected regressor (256→256→1) that outputs the normalized surface tension. Training employed early stopping using validation RMSE for checkpoint selection, and performance was reported using $R^2$, RMSE, and MAE on the held-out experimental test set.

### 2.3 Semi-supervised VAE training

A VAE was used to learn a continuous generative representation of non-ionic surfactant structures from their SMILES-based encoding. Training followed a two-stage strategy to exploit the larger pool of unlabeled structures. In Stage 1, the VAE was pre-trained on the 461 unlabeled molecules to learn a chemically plausible latent manifold. In Stage 2, the model was fine-tuned on the 125 labeled training molecules to align the latent space with the labeled domain used for surface-tension learning. The fine-tuned VAE parameters were saved and reused for all subsequent generation experiments.

### 2.4 Stratified latent-space generation and filtering

Generation operates exclusively through the VAE decoder: latent vectors z ~ $\mathcal{N}$(0, I) are sampled directly without an encoder pass and decoded to candidate SELFIES strings. To construct a property-relevant synthetic pool, we performed **stratified latent-space generation** using the fine-tuned VAE coupled to the baseline GCN as a property oracle. The target surface-tension distribution was first estimated from the **training labels** by binning normalized surface tension into **10 intervals** and computing the empirical proportion in each bin. Synthetic generation then proceeded iteratively: latent

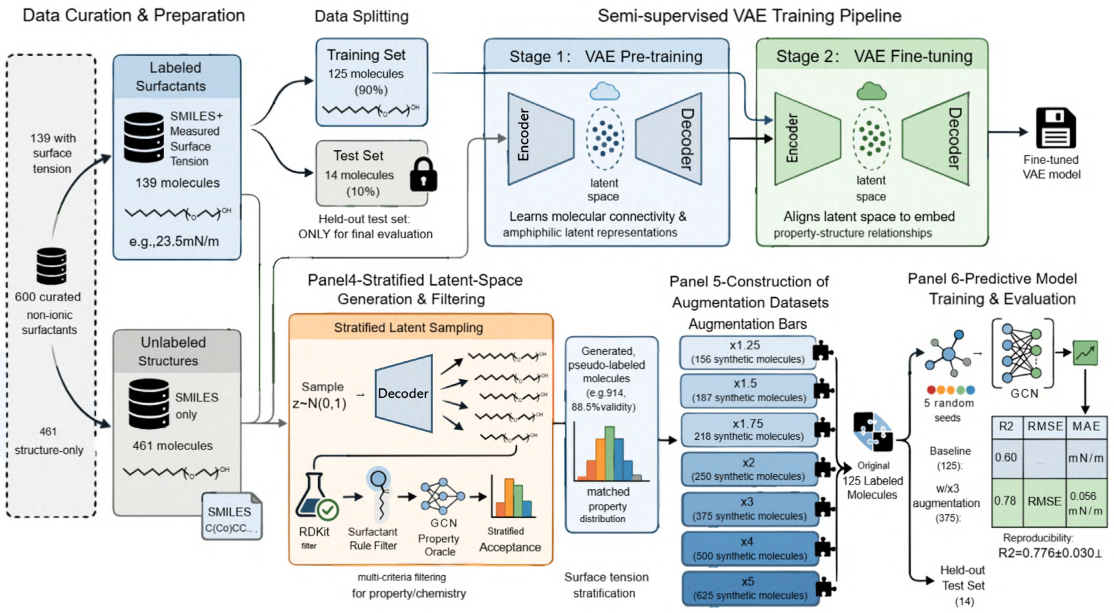

**Figure 1. Semi-supervised generative augmentation pipeline for surface-tension prediction.** Labeled surfactants (n=139) are split into training (n=125) and held-out test (n=14). A VAE is pre-trained on unlabeled structures (n=461) and fine-tuned on the labeled training set. Synthetic molecules are generated via stratified latent sampling, filtered for chemical validity and surfactant plausibility, and pseudo-labeled using a baseline GCN predictor. Stratified, independent augmentation sets (×1.25–×5) are constructed from the pseudo-labeled pool and combined with the labeled training data to retrain GCN models across five random seeds; performance is reported on the fixed experimental test set. Note that Panel 4 (Stratified Latent Sampling) uses only the VAE decoder: latent vectors z are sampled directly from $\mathcal{N}(0,I)$ and decoded into candidate molecules; the encoder is not used during generation.

vectors $z \sim \mathcal{N}(0, I)$ were sampled, decoded to candidate molecules, converted from SELFIES to SMILES, and filtered by RDKit sanitization and radical checks; candidates were then assigned a predicted surface tension using the trained GCN, and accepted only if their prediction fell into a bin that had not yet reached its target quota.

To improve coverage of underfilled bins (particularly near the distribution tails), generation used a **multi-phase adaptive strategy** with increasing sampling temperature and targeted sampling around previously successful latent regions for difficult bins. In addition, a surfactant-specific quality filter was applied during acceptance using a rule-based evaluator that screens for a plausible hydrophobic tail, presence of hydrophilic head groups, and basic structural stability heuristics, with a minimum surfactant score threshold applied during generation.

In the final generation run, the procedure targeted 1000 molecules but accepted **914** after reaching the maximum attempt budget; the RDKit-valid fraction among decoded candidates was **88.5%**, and the generated pseudo-label distribution closely matched the training distribution (Wasserstein distance **0.0298**). Generated molecules spanned predicted normalized surface tension from **0.002 to 0.799**.

## 2.5 Augmentation construction and retraining protocol

From the pseudo-labeled generated pool (SMILES, Prediction), we constructed augmentation datasets at seven levels (×1.25–×5) using independent stratified sampling. For each level, generated molecules were partitioned into bins defined by the training-label quartiles of normalized surface tension, and molecules were sampled from each bin in proportion to the empirical bin frequencies of the real training set. If a bin contained fewer generated candidates than required, all available candidates were retained and the remaining quota was filled by sampling from the residual pool. Each augmentation level was generated with a deterministic level-specific seed to ensure reproducibility while keeping levels non-nested.

For each augmentation level, the synthetic subset was concatenated with the 125 labeled training molecules (using pseudo-labels for synthetic samples), and a GCN was retrained using the baseline hyperparameters. Robustness was assessed across five random seeds (42, 104, 2021, 2024, 4592) with early stopping based on validation RMSE; results are reported as mean ± standard

deviation of test $R^2$, RMSE, and MAE on the unchanged experimental test set.

## 3. RESULTS AND DISCUSSION

### 3.1 Baseline GCN performance

Using only the labeled training set (125 molecules), the baseline GCN achieved a test $R^2$ of 0.599 with RMSE = 0.075 and MAE = 0.052 in normalized units (Table 1). The gap between training and test performance (train $R^2 = 0.868$) highlights the limited generalization achievable with small labeled datasets and motivates the use of generative augmentation.

**Table 1:** Baseline GCN performance on surface tension normalized.

| data | $R^2$ | RMSE | MAE |
|---|---|---|---|
| train | 0.868 | 0.065 | 0.046 |
| test | 0.599 | 0.075 | 0.052 |

### 3.2 Generated dataset validity and distribution matching.

The semi-supervised VAE generation pipeline produced 914 accepted molecules after RDKit validation and rule-based surfactant filtering, corresponding to an overall structural validity of 88.5%.

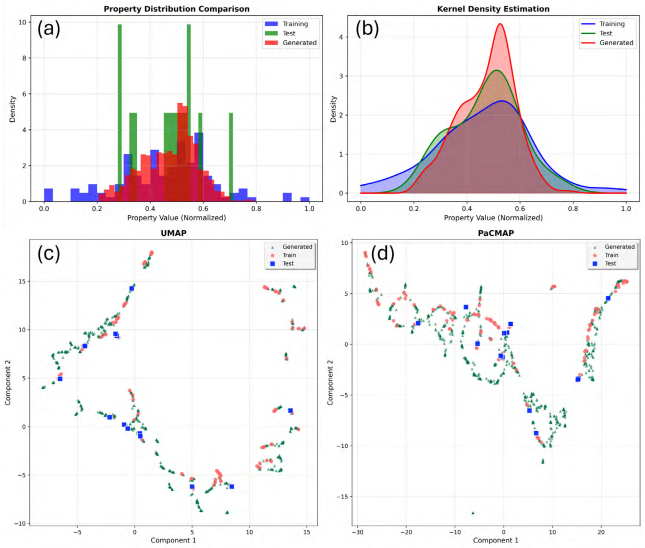

**Figure 2.** Generated data validity, distribution matching, and chemical-space coverage. (a) Normalized surface-tension distributions for training, test, and generated (pseudo-labeled) molecules. (b) Kernel density estimates showing close agreement between generated and empirical distributions. (c) UMAP and (d) PaCMAP projections illustrating that generated samples overlap the empirical domain while modestly expanding chemical-space coverage.

The pseudo-labeled surface-tension distribution of the generated pool closely matched the empirical training distribution (Wasserstein distance = 0.0298; KS statistic = 0.152), indicating that stratified sampling successfully controls property coverage (Figure 2a-b). The chemical space projections in (Figure 2c-d) reveal that VAE-generated molecules predominantly occupy regions already covered by the training data, with modest expansion into adjacent chemical space. This behavior reflects the fine-tuning strategy employed in Stage 2 of VAE training, where the model learns to generate structures similar to the 125 labeled surfactants used for property embedding. While this ensures generated molecules remain within the interpolation regime of the oracle GCN (reducing extrapolation error in pseudo-labeling), it also limits the framework's ability to discover truly novel surfactant chemotypes or explore underrepresented regions of structure-property space.

The narrower spread of the generated distribution visible in Figure 2a-b warrants discussion in the context of VAE mode collapse. Mode collapse in VAEs occurs when the decoder maps only a restricted region of the latent space, producing low-diversity outputs concentrated near the distribution mean and underrepresenting the tails. In our case, however, the reduced spread is primarily a consequence of two deliberate design choices rather than pathological collapse: (1) Stage 2 fine-tuning on only 125 labeled surfactants biases the latent manifold toward the well-represented central property region, and (2) the stratified generation strategy explicitly targets the empirical training distribution rather than attempting to extrapolate beyond it. The low Wasserstein distance (0.030) and KS statistic (0.152) confirm that the generated molecules faithfully reproduce the shape and central tendency of the training distribution. That said, we acknowledge that tail regions, corresponding to very low and very high surface tension, remain underrepresented in the generated pool, consistent with limited tail coverage in the fine-tuning data and mild posterior compression in those latent regions. Future work incorporating β-VAE annealing or tail-targeted latent sampling could improve extremal coverage.

UMAP projections (Figure 2c) show that generated molecules form clusters closely aligned with training data, suggesting the VAE successfully learned the manifold of non-ionic surfactant structures. However, the test molecules; which were held out entirely from VAE training; occupy positions slightly separated from the main training cluster, indicating that real chemical diversity extends beyond what the generative model captures. This observation highlights a key limitation: the VAE can densify coverage within known chemical neighborhoods but struggles to generate out-of-distribution molecules that would expand predictive

capabilities into genuinely unexplored territory.

The PaCMAP projection (Figure 2d), which emphasizes global structure preservation, further confirms that generated molecules largely interpolate between existing training examples rather than extrapolating to new regions. This interpolative behavior is generally desirable for augmentation in small-data regimes, as it reduces the risk of generating unrealistic molecules or introducing covariate shift that degrades model performance. However, it also means that this augmentation approach is most effective for improving prediction accuracy within the existing property range and chemical domain, rather than enabling discovery of surfactants with properties beyond those already measured experimentally.

## 3.3 Augmentation level controls predictive performance.

We evaluated seven augmentation levels (×1.25–×5) under five random seeds per level. Performance improved substantially with moderate augmentation and peaked at ×3, where the model achieved mean test $R^2 = 0.776 \pm 0.030$ and RMSE $= 0.0559 \pm 0.0039$ (Figure 3; Table 2).

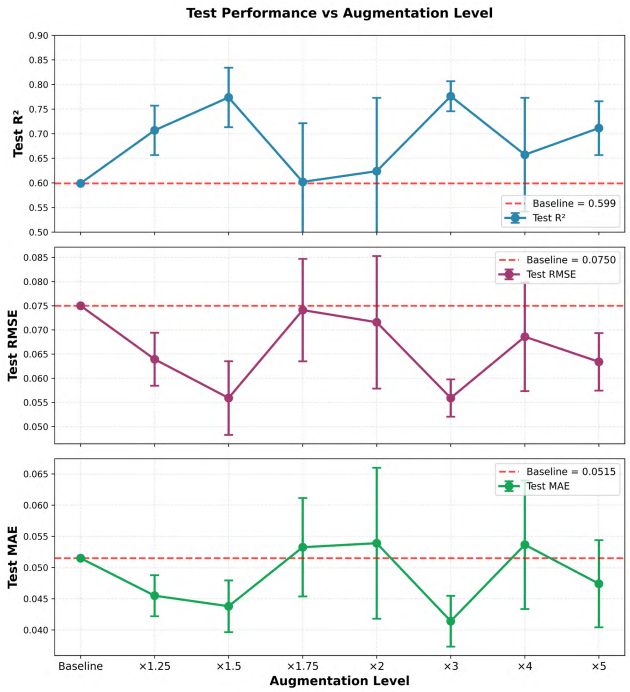

**Figure 3.** Test performance as a function of augmentation level. Mean ± standard deviation across five random seeds for test (top) R², (middle) RMSE, and (bottom) MAE for augmentation levels ×1.25–×5. Dashed lines indicate the baseline performance trained on labeled data only.

Relative to the baseline, ×3 augmentation increases $R^2$ by 0.177 (≈29%) and reduces RMSE by ≈25%, indicating that adding pseudo-labeled samples can substantially improve generalization. Performance was non-monotonic across augmentation levels, with intermediate levels (e.g., ×1.75–×2) exhibiting increased variance and lower mean test $R^2$, suggesting that beyond a certain point, augmentation may introduce pseudo-label noise and/or distributional drift that offsets gains from larger sample size.

**Table 2:** Test performance across augmentation levels (mean ± std over 5 seeds). RMSE is reported in MinMax-scaled units.

| Level | Train size | Test R2 | Test RMSE |
|---|---|---|---|
| Baseline | 125 | 0.599 | 0.075 |
| X1.25 | 156 | 0.707 ± 0.050 | 0.064 ± 0.005 |
| X1.5 | 187 | 0.774 ± 0.060 | 0.056 ± 0.008 |
| X1.75 | 218 | 0.602 ± 0.119 | 0.074 ± 0.011 |
| X2 | 250 | 0.624 ± 0.149 | 0.072 ± 0.014 |
| X3 | 375 | 0.776 ± 0.030 | 0.056 ± 0.004 |
| X4 | 500 | 0.657 ± 0.116 | 0.069 ± 0.011 |
| X5 | 625 | 0.711 ± 0.055 | 0.063 ± 0.006 |

## 3.4 Reproducibility and Understanding Augmentation Limits.

At the optimal ×3 level, test performance was consistent across seeds with relatively small dispersion in test RMSE and MAE (Figure 4). This indicates that the observed gains are not driven by a favorable random split or initialization, supporting the stability of the proposed augmentation framework under training stochasticity.

The non-monotonic relationship between augmentation level and predictive performance reveals fundamental trade-offs in generative augmentation strategies. While the optimal ×3 level demonstrates clear benefits, intermediate levels (×1.75–×2) exhibit performance instability with increased variance and occasional drops below baseline. This behavior suggests a transition regime where competing effects interact: modest augmentation provides insufficient regularization benefit to overcome pseudo-label noise, while the synthetic samples have not yet achieved the diversity and coverage necessary to meaningfully expand the training distribution.

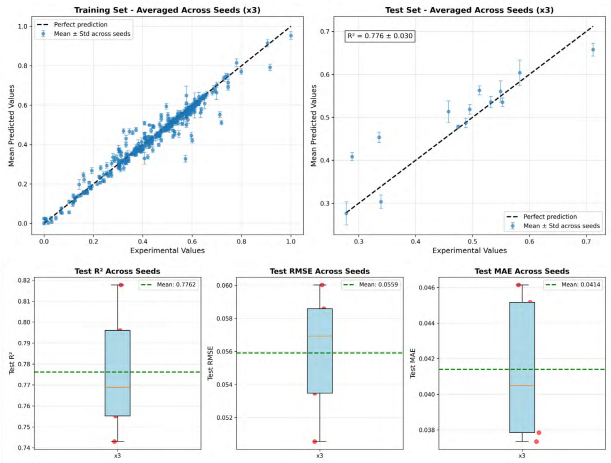

**Figure 4.** Reproducibility and uncertainty at the optimal augmentation level (×3). Top: parity plots for training and test sets using the mean prediction across five random seeds; error bars indicate ±1 standard deviation across seeds for each molecule. Bottom: seed-to-seed distributions of test $R^2$, RMSE, and MAE, demonstrating that the ×3 performance gain is robust to random initialization and training stochasticity.

At higher augmentation levels (×4–×5), performance stabilizes but does not surpass the ×3 optimum, indicating saturation or degradation from excessive reliance on pseudo-labeled data. This decline likely stems from error propagation in the oracle-based labeling process. The baseline GCN used for pseudo-labeling has inherent prediction uncertainty (test RMSE = 0.075), which compounds when generating labels for hundreds of synthetic molecules. As augmentation increases, the ratio of noisy pseudo-labels to ground-truth labels grows, eventually dominating the training signal and limiting model refinement. Additionally, the stratified generation strategy prioritizes distribution matching over tail-region accuracy, meaning molecules with extreme surface tension values are under–represented and potentially less reliable as training examples. This explains why augmentation benefits plateau rather than continue scaling linearly with dataset size.

The existence of an optimal intermediate augmentation level has practical implications for deployment: practitioners should systematically evaluate multiple augmentation ratios rather than maximizing synthetic data volume. Our multi-seed evaluation framework provides a template for identifying stable operating points where gains are reproducible across training stochasticity. Furthermore, the instability at intermediate levels suggests that augmentation strategies should either commit to minimal augmentation (×1.25–×1.5) for conservative noise control or move directly to higher levels (×3+) where increased sample diversity compensates for label uncertainty.

## 3.5 Practical Implications for Surfactant Discovery and Development

From a practical standpoint, achieving test $R^2$ = 0.78 with ×3 augmentation (375 total training samples: 125 real + 250 synthetic) represents performance equivalent to collecting approximately 250 additional experimental measurements; a substantial cost and time savings. Surface tension measurements via pendant drop or Wilhelmy plate methods typically require 2-4 hours per molecule including sample preparation, equilibration, and replicate measurements, translating to approximately 500-1000 person-hours or several months of laboratory work. The generative augmentation framework described here enables this performance gain using only computational resources (VAE training and GCN inference), which can be completed in hours on standard hardware.

This efficiency gain is particularly valuable in industrial surfactant development contexts where candidate molecules are continuously evaluated for specific applications. For example, formulation chemists might screen hundreds of potential surfactant structures in silico before selecting a subset for experimental validation. By training predictive models with augmented data, initial screening accuracy improves, reducing the number of false positives that proceed to costly synthesis and testing. The ×3 augmentation level identified in this work provides a practical guideline: for every 100 experimentally characterized molecules, generating 200 high-quality synthetic samples via stratified VAE sampling can enhance model performance by approximately 30% in $R^2$ while maintaining prediction stability.

However, several important limitations and boundary conditions constrain the applicability of this approach. First, augmentation effectiveness depends critically on the quality and diversity of the unlabeled structural data used for VAE pre-training. In our case, 461 unlabeled non-ionic surfactants provided sufficient coverage to learn valid molecular patterns, but domains with narrower structural diversity may require larger unlabeled pools or alternative generative architectures. Second, the approach assumes that the oracle model (baseline GCN) captures relevant structure-property relationships despite limited training data. If the baseline model has systematic biases or poor calibration in certain property regions, these errors will propagate through pseudo-labeling and potentially amplify during augmentation. Third, the framework is most effective for properties with smooth structure-property landscapes where interpolation is reliable; highly discontinuous properties or those governed by subtle molecular features may benefit less from density-based augmentation.

The stratified generation strategy is essential for maintaining distribution balance and should be adapted

to the specific property distribution of interest. For surfactant surface tension, which exhibits near-Gaussian behavior across our dataset, quartile-based stratification proved sufficient. Applications targeting skewed distributions or multimodal properties may require adaptive binning strategies or importance sampling to ensure adequate coverage of tail regions. Additionally, practitioners should validate that generated molecules satisfy domain-specific chemical rules—our surfactant-specific quality filter prevented generation of implausible structures, but similar heuristics would need to be developed for other molecular families.

Finally, while this work focused on single-property prediction (surface tension), the framework generalizes naturally to multi-property optimization scenarios common in formulation chemistry, where surfactants must simultaneously satisfy constraints on CMC, foaming behavior, biodegradability, and cost. By training the VAE on molecules with diverse property measurements and conditioning generation on multi-objective targets, the augmentation strategy could support more holistic molecular design workflows. This extension represents a promising direction for future research, particularly in specialty chemical domains where property trade-offs are critical and experimental data remains scarce.

## CONCLUSION

We presented a semi-supervised generative augmentation framework for predicting surfactant surface tension from limited experimental data, demonstrating that intelligent data augmentation can overcome key bottlenecks in specialty chemical property prediction. By leveraging 461 unlabeled surfactant structures for VAE pre-training and 125 labeled molecules for fine-tuning, we generated 914 high-quality synthetic training samples (88.5% structural validity) that closely matched the target property distribution (Wasserstein distance = 0.030). Systematic evaluation across seven augmentation levels revealed optimal performance at ×3 augmentation, where test $R^2$ improved from 0.60 to 0.78 (+28% relative gain) with RMSE decreasing to 0.056, performance equivalent to tripling the experimental dataset.

Our multi-seed analysis confirmed that these gains are reproducible across random initialization ($R^2$ = 0.776 ± 0.030), establishing the stability of the approach. Chemical space analysis revealed that generated molecules primarily densify regions near existing training data rather than exploring entirely novel chemical space, which proves advantageous for interpolative prediction but limits extrapolation capabilities. The non-monotonic performance curve identified a critical trade-off between pseudo-label noise and sample diversity, with intermediate augmentation levels showing instability and diminishing returns at high augmentation ratios beyond ×3.

From a practical perspective, this framework provides a scalable and cost-effective approach to improve predictive models in data-scarce domains. Achieving high-quality predictions without collecting hundreds of additional experimental measurements addresses a fundamental challenge in specialty chemical development, where measurement costs and time constraints limit dataset sizes. The stratified generation strategy and multi-seed evaluation protocol offer a replicable template for applying generative augmentation to other molecular property prediction tasks where structural data is abundant but property labels are scarce.

Future work should focus on three key directions: (1) developing diversity-promoting generation strategies to expand chemical space coverage beyond interpolation, potentially through active learning or physics-guided sampling; (2) extending the framework to multi-property prediction scenarios where molecules must satisfy multiple constraints simultaneously; and (3) investigating transfer learning approaches where VAEs pre-trained on large unlabeled datasets can be rapidly adapted to new property targets with minimal labeled data. Additionally, integrating uncertainty quantification into the pseudo-labeling process could improve robustness by weighting synthetic samples based on oracle confidence, potentially addressing the performance degradation observed at high augmentation levels.

This work demonstrates that semi-supervised generative augmentation is a practical and effective strategy for molecular property prediction in small-data regimes, offering a promising pathway to accelerate discovery in specialty chemical domains where experimental data acquisition remains a significant bottleneck.

## ABSTRACT

The rapid electrification of the energy and transport sectors has increased the demand for efficient thermal management of Lithium-Ion Batteries (LIBs). LIBs operate optimally within a narrow temperature range (15–40 °C), effective Battery Thermal Management Systems (BTMS) are essential to prevent accelerated aging and performance degradation. Immersion cooling using dielectric fluids has emerged as a promising solution; however, a systematic comparison of their thermal and hydraulic performance remains limited. This study evaluates six dielectric fluids—Silicone Oil, Mineral Oil, Sunflower Oil, AmpCoolAC-100, E5-TM410, and Deionized Water—using Computational Fluid Dynamics (CFD) simulations of a lithium-ion battery pack composed of 32 fully immersed 18650 cells. The analysis focuses on key thermophysical properties, particularly the Prandtl number and thermal diffusivity, as criteria for coolant selection. The results demonstrate a strong correlation between cooling performance and the Prandtl number. Fluids with lower Prandtl numbers provide superior heat dissipation and lower hydraulic losses. Deionized water exhibited the best overall performance, maintaining maximum cell temperatures at 31.04 °C under a 2 LPM flow rate and achieving up to 31.33% better cooling than silicone oil. In contrast, high-viscosity oils showed poor thermal performance and significantly higher pressure drops. This work establishes the Prandtl number as a critical and reliable parameter for selecting dielectric fluids in immersion-based BTMS, highlighting deionized water as the most effective coolant among those evaluated.

## INTRODUCTION

The urgent need for innovative solutions lowering the environmental impact of energy and transport sectors is leading to an unprecedentedly fast adoption rate of electrification [1]. Consequently, Lithium-Ion Batteries (LIBs) have been extensively adopted, whose choice is mainly driven by their high energy density (reaching 300 Wh/kg), efficiency (as high as 98%), lifetime (8-10 years) [2]. Lithium-ion batteries (LIBs) have established themselves as the primary energy storage technology for electric vehicles (EVs), grid-scale systems, and high-performance electronics due to their high power density, energy density, and extended cycle life. Despite these advantages, LIBs are highly sensitive to temperature, with their performance, safety, and reliability depending heavily on maintaining a narrow operational range, typically between 15°C and 40°C [3]. Operating outside these limits—specifically during high-current charging or rapid discharging—can result in accelerated aging, capacity degradation, and dangerous thermal runaway events [4].

To address these challenges, Battery Thermal Management Systems (BTMS) are employed to regulate peak temperatures and ensure uniform temperature distribution across individual cells and entire modules [3]. While conventional cooling strategies, such as forced air cooling and indirect liquid cooling, an emerging and highly effective alternative is direct liquid immersion cooling, where battery cells are submerged in an electrically non-conductive dielectric fluid [5].

While current literature has explored various categories of liquids—such as hydrofluoroethers, hydrocarbons, silicone oils, and esters—most studies focus on testing specific commercial products rather than establishing a systematic selection framework. For instance, research on deionized water (DELC-1) has shown temperature rise below 2.2 °C during 3C discharge with minimal parasitic power consumption [11]. Other studies highlight the "thermal buffer" created by low-boiling fluids like 3M Novec 7000, which utilizes latent heat to maintain cell temperatures near 34 °C even under aggressive 10C cycling [4].

This project aims to conduct a rigorous computational fluid dynamics (CFD) analysis of the thermal management of a lithium-ion battery pack. The study will focus on evaluating the cooling behavior of various dielectric fluids. The goal is to identify the best fluid that ensures the best cooling of the cells. Unlike other studies that analyze dielectric fluids without a robust foundation, this project adopts a strategic selection approach. It prioritizes comparative analysis of the thermophysical properties of different dielectric fluids to identify the most option for the thermal management of lithium-ion battery packs. This study is based on a previously reported cell pack geometry, which will allow us to validate existing simulation models or, alternatively, propose concrete improvements for cooling.

# METHODOLOGY

## Governing Equations

The numerical model of the battery pack cooling system is based on the fundamental principles of mass, momentum, and energy conservation, which are governed by the following equations. The fluid is considered to be an incompressible, Newtonian flow, and the thermal properties of the fluids are assumed to be constant.

The mass conservation equation, Eq. (1), describes how mass is conserved within the system.

$$\partial p/\partial t + \nabla \bullet (\rho v) = 0 \quad (1)$$

The momentum conservation equation, also known as the Navier-Stokes equation, Eq. (2), describes the motion of a fluid. It relates the forces acting on the fluid, such as pressure and viscosity, to changes in its velocity.

$$\rho(\partial v/\partial t + v \bullet \nabla v) = -\nabla P + \mu \nabla^2 v + \rho g \quad (2)$$

Finally, the energy conservation equation, Eq. (3) is utilized to model the thermal behavior of the system where $S_T$ is heat generation of battery pack. This equation is crucial for understanding the heat transfer between the batteries and the dielectric fluid.

$$\rho Cp(\partial T/\partial t + v \bullet \nabla T) = -\nabla \bullet (k \nabla T) + S_T \quad (3)$$

## Model-Geometry

The present study investigated the thermal performance of a Li-ion battery pack cooled by immersion in different dielectric fluids. A numerical model was developed and simulated using the commercial software ANSYS FLUENT. The model geometry, Figure 1, based on the work [6], consisted of a pack of 32 18650-type cells arranged with a 4 mm spacing in a total immersion cooling system. The manifold for the cooling system was designed with three inlets and three outlets, each featuring a diameter of 15 mm and a height of 25 mm.

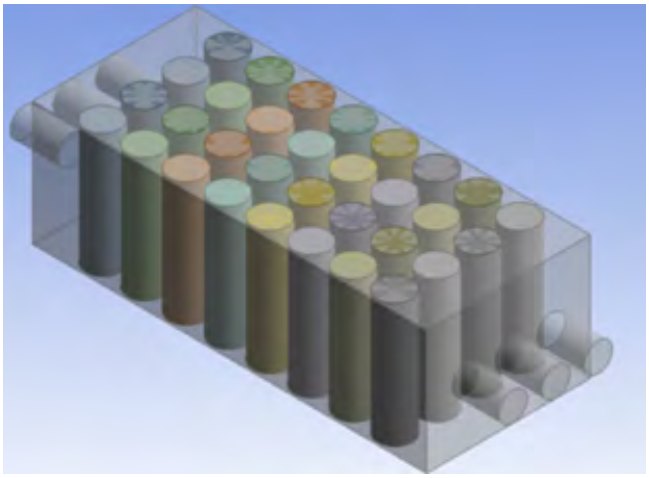

**Figure 1.** Geometry of pack Li-ion batteries analyzed.

## Mesh Sensitivity Analysis

A mesh sensitivity analysis was conducted using the E5-TM410 dielectric fluid. The purpose of this analysis was to determine the best mesh density, balancing computational cost with solution accuracy. We focused on a range of mesh sizes between 1.55 mm and 3.75 mm, as this range consistently demonstrated stable and reliable behavior, thus justifying its selection for the rest of the study.

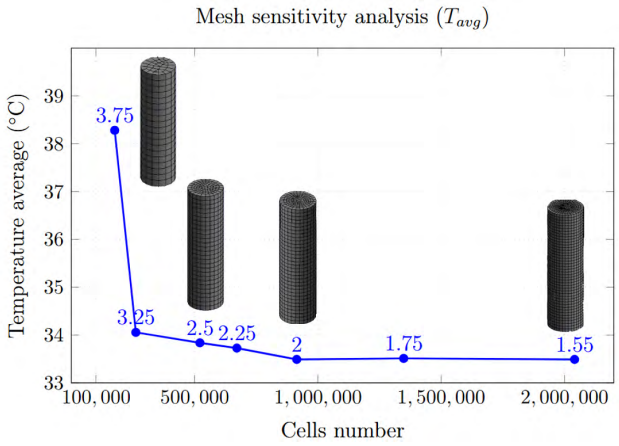

**Figure 2.** Mesh sensitivity analysis showing the battery temperature average as a function of mesh cell count.

**Table 1.** Thermal properties of dielectric fluids

| Fluid | Viscosity (kg/m s) | Density (kg/m$^3$) | Cp (J/kg K) | K (W/m K) | Reference |
|---|---|---|---|---|---|
| **Deionized water (DW)** | 0.0009982 | 998.2 | 4182 | 0.6 | [7] |
| **Sunflower (SF)** | 0.035672 | 910 | 1800 | 0.175 | [8] |
| **AmpCool AC-100 (AC)** | 0.00799646 | 811 | 2203.2 | 0.1373 | [7] |
| **E5-TM410 (E5)** | 0.015617 | 805 | 2100 | 0.14 | [6] |
| **Mineral oil (MO)** | 0.05152 | 920 | 1900 | 0.13 | [7] |

As shown in Figure 2, the maximum battery temperature approaches an asymptotic value beyond a cell count of approximately 700, 000, indicating a stable, mesh-independent solution. Based on these findings, a mesh size of 2.0 mm was selected for the full study, as it provided an optimal balance. The corresponding mesh, consisting of 914, 140 cells, yielded accurate results without the excessive computational burden of finer meshes. The error analysis further confirmed this choice, showing a maximum error of 14.3% for the coarsest mesh (3.75 mm). Notably, the error stabilized at zero for both the 2 mm and 1.55 mm meshes.

## Dielectric Fluids Selection

To ensure a rigorous selection of dielectric fluids, we began by analyzing their thermophysical properties to determine their capacity for heat removal from the battery cells. We evaluated the properties of six fluids reported in different studies like their optimal fluids see Table 1, focusing initially on viscosity. The initial hypothesis was that a fluid with high viscosity would impede heat removal from the batteries, even with a powerful pumping system, which would also be costly. This preliminary analysis led us to conclude that a low viscosity is a critical requirement. A similar analysis was performed for density. Subsequently, we focused on two others crucial thermophysical properties: heat capacity (Cp) and thermal conductivity (k). For a fluid to be a coolant, it must possess high values for both Cp and k, as these properties directly influence its ability to exchange heat with another body.

The relationship between these properties was further explored through two dimensionless parameters: the Prandtl number (*Pr*), as defined in Eq. (4), and thermal diffusivity (α), shown in equation Eq. (5). The analysis revealed that high thermal diffusivity is desirable for effective cooling. Conversely, a low Prandtl number is also indicative of a coolant. This is because a fluid with both high diffusivity and low viscosity will have a low Prandtl number, which correlates with superior cooling performance.

$$Pr = \frac{\mu}{\alpha} \tag{4}$$

$$\alpha = \frac{k}{Cp\rho} \tag{5}$$

Table 2 shows the Prandtl number (Pr) and thermal diffusivity values for the previously selected dielectric fluids. These values reveal a clear hierarchy, with deionized water exhibiting the lowest Pr number (Pr ≈ 7), and silicone oil presenting the highest (Pr ≈ 8808). This significant difference in Pr suggests a wide range of potential cooling performance. Based on this trend, we simulated the six fluids to validate the hypothesis. If the Prandtl number serves as a reliable indicator of cooling performance, we expect the cooling efficiency of the fluids to follow the same order as their Pr ranking.

**Table 2.** Prandtl number ranking of dielectrics fluids.

| Fluid | α (m$^2$/s) | Pr | Ranking |
|---|---|---|---|
| Deionized water | $1.44\times10^{-7}$ | 6.96 | 1 |
| AmpCool AC-100 | $7.68\times10^{-8}$ | 128.32 | 2 |
| E5-TM410 | $8.28\times10^{-8}$ | 234.26 | 3 |
| Sunflower | $1.07\times10^{-7}$ | 366.91 | 4 |
| Mineral oil | $7.44\times10^{-8}$ | 752.98 | 5 |
| Silicone oil | $1.13\times10^{-7}$ | 8807.95 | 6 |

## Boundary Conditions

The simulation was initialized under transient conditions with a time step of 720 seconds and was terminated once convergence was achieved. Heat generation was modeled using Eq. (6), within a numerical domain previously analyzed [6].

$$Q_b = 0.0013t^3 - 0.97t^2 + 143.12t + 293016 = 0 \tag{6}$$

The thermal properties of the batteries, presented in Table 3, were considered constant throughout the simulation. To accurately represent the thermal behavior of the cells, a thermal conductivity matrix was incorporated. This approach accounted for the anisotropic nature of

the material by specifying thermal conductivity in the axial ($k_{zz}$=19.03), radial ($k_{yy}$=1.07), and tangential ($k_{xx}$=19.03) directions, effectively modeling the thermal conductivity tensor.

**Table 3.** Properties of the Battery Pack Simulation

| Thermal property | Value |
|---|---|
| Density (kg/m$^3$) | 2055.1 |
| Specific heat (J/kg K) | 1129.95 |
| Thermal conductivity (W/m K) | Anisotropic |

**Table 4.** Boundary conditions of the fluids.

| Boundary Conditions | Value |
|---|---|
| Inlet Temperature (°C) | 25 |
| Volumetric Flow Rates | 2, 3, 4 and 5 |
| Wall Slip Condition | Non-Slip |

The boundary conditions for the fluids, as detailed in Table 4, were applied to the six fluids analyzed in this study. The investigation was conducted at four different volumetric flow rates (LPM) to evaluate the influence of fluid velocity on battery cooling. The thermophysical properties for each fluid are listed in Table 1.

# RESULTS

## Model Validation

As shown in Figure 3, the simulated maximum and average temperatures exhibit excellent agreement with the values reported in the reference article [6]. The maximum temperature data showed a maximum error of 2.25% at a flow rate of 5 LPM, while the minimum error was 0.49% at 3 LPM. Similarly, the average temperature data demonstrated a comparable trend, with a maximum error of 1.3% and a minimum error of 0.35%.

All percentage errors are well within the acceptable range for this type of analysis, these results successfully validate the numerical model against the published reference data.

Figure 4 presents the simulation results for the six dielectric fluids, clearly indicating deionized water delivered the best cooling performance. It maintained the maximum battery temperature within the optimal Li-ion operating range (15°C–40°C) across all volumetric flow rates, achieving a value of 30.04°C even at the lowest flow of 2 LPM. In contrast, silicone oil was the least effective, only maintaining a temperature within the safe range at the highest flow rate of 5 LPM (39.3°C).

As demonstrated, deionized water (DW) was the only coolant capable of maintaining the battery temperature within the desired operational range across all tested volumetric flow rates. In contrast, the other fluids—E5-TM410, AmpCoolAC-100, Sunflower oil, and mineral oil—only maintained temperatures within the acceptable range at higher volumetric flow rates of 4 and 5 LPM. Furthermore, even under these conditions, they operated at the upper thermal limit of the range, rendering them less reliable due to the heightened risk of temperature fluctuations exceeding the safe operational threshold.

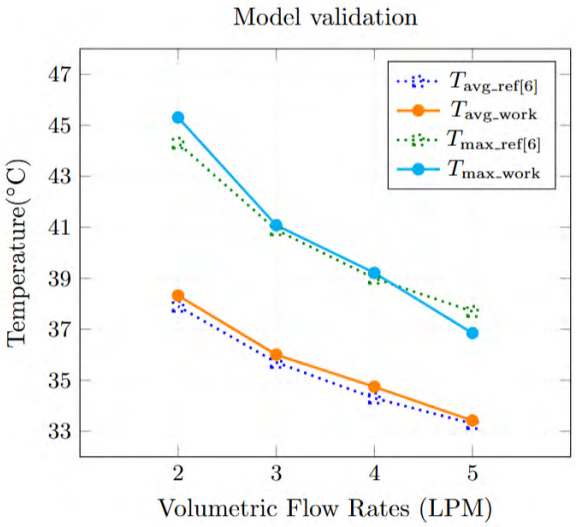

**Figure 3.** Thermal behavior of batteries using the E5-TM410 fluid for model validation.

Thermal Behavior of the Dielectric Fluids

At a reduced flow rate of 2 LPM, the performance difference among the coolants became more pronounced. Silicone oil exhibited the most significant thermal deviation, exceeding the maximum temperature limit by 17.7% (47.11°C), followed by mineral oil (14.66%, 45.86°C), sunflower oil (13.38%, 45.35°C), E5-TM410 (13.26%, 45.30°C), and AmpCoolAC-100 (11.76%, 44.71°C). Given that all tested fluids exceeded the safe operational threshold at this flow rate, it is deemed unsuitable for operation. In contrast, a flow rate of 5 LPM is recommended, as it maintained all fluids within the prescribed temperature range. Consequently, silicone oil was identified as the least effective coolant, maintaining the battery within the operational range only at the maximum flow rate of 5 LPM. These findings unequivocally designate silicone oil as unsuitable for this battery cooling application under most operational flow conditions.

The distribution of temperature within the battery pack provides direct insight into the effectiveness of heat transfer between the dielectric fluids and the batteries. As previously analyzed, deionized water provides superior cooling performance compared to silicone oil. These findings are further supported by the thermal behavior observed at a flow rate of 5 LPM, as illustrated in Figure 5a-c. The results compare the temperature profiles of three dielectric fluids selected to represent the top, median, and bottom rankings of the proposed methodology.

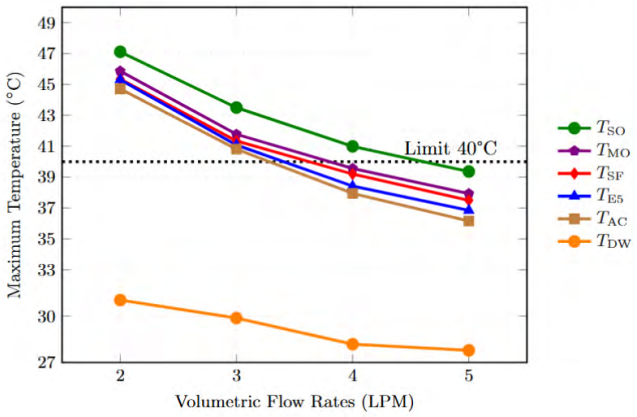

**Figure 4.** Relationship between the volumetric flow rate (LPM) and the maximum battery temperature for the different dielectric fluids.

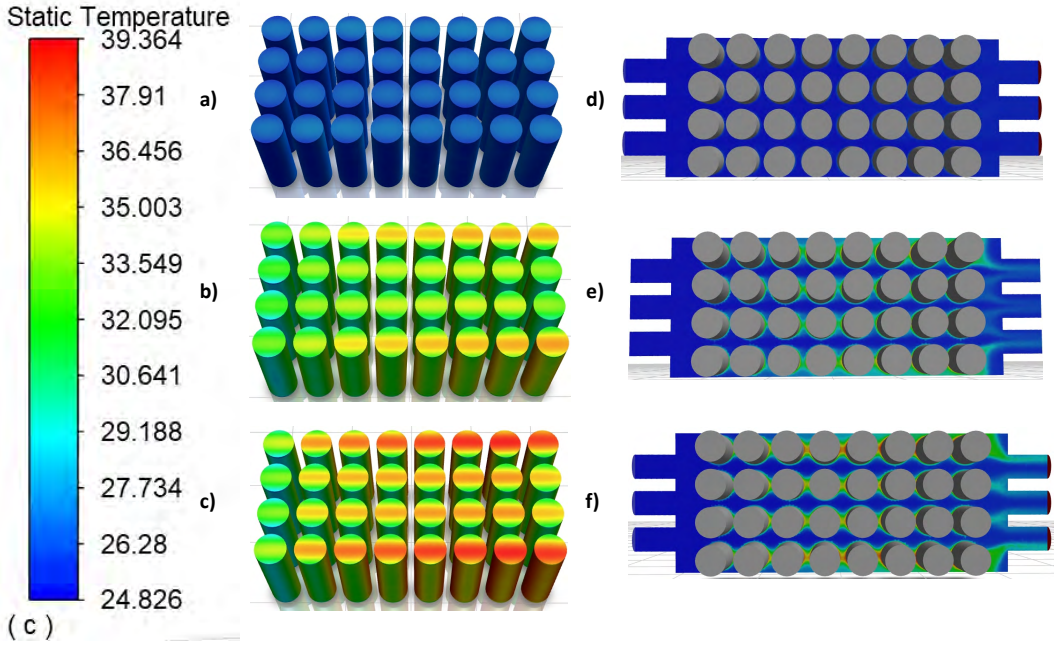

**Figure 5.** Comparison of the thermal distribution within the battery pack for three representative coolants selected through the proposed methodology: (a) deionized water (top-ranked), (b) E5-TM410 fluid (intermediate performance), and (c) silicone oil (lowest-ranked). Panels (a–c) show the temperature distribution across the battery cells, while panels (d–f) illustrate the corresponding temperature fields of the coolant flow within the pack for (d) deionized water, (e) E5-TM410, and (f) silicone oil.

Notably, the highest battery temperature was recorded when using silicone oil, confirming its lower performance relative to the other candidates. A closer inspection of an individual cell reveals evident anisotropic thermal diffusion. This phenomenon is a direct consequence of the simulated thermal conductivity varying with direction (radial, axial, and tangential).

The overall temperature distribution across the battery pack is non-uniform. Higher temperatures are consistently observed in the downstream and peripheral cells in the six fluids. Achieving a uniform temperature is critical for prolonging the cycle life of each cell. Thermal non-uniformity can lead to the premature degradation and eventual failure of individual cells, which necessitates the costly replacement of the entire battery pack.

To mitigate this issue, the implementation of a system that promotes a more uniform thermal distribution is essential. A potential solution is the use of turbulence promoters, which can disrupt the boundary layer and enhance heat transfer throughout the pack of batteries.

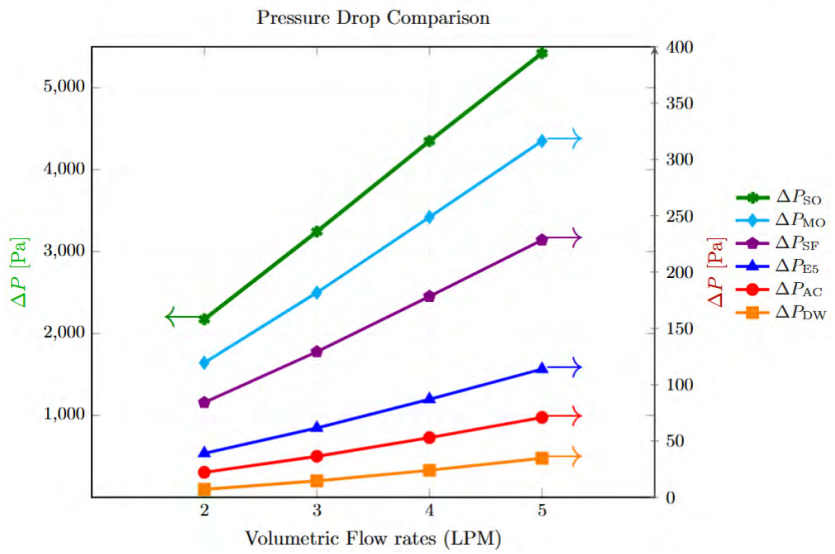

**Figure 6.** Pressure Drop comparison: Silicone Oil (left axis) vs. Others fluids (right axis).

These promoters could help transition the flow from a laminar to a turbulent regime, improving cooling efficiency at the implemented volumetric flow rates. The implementation of turbulence promoters is deemed necessary for this simulation. Promoters enhance fluid velocity and disrupt the boundary layer, which facilitates more effective heat removal from the batteries. This is crucial because, without them, the fluid's capacity to absorb heat diminishes as it flows through the pack, leading to higher temperatures in the downstream and peripheral cells.

This behavior is corroborated by the fluid temperature distribution shown in Figure 5d-f. The figure indicates that fluid temperature is significantly higher in the downstream cells compared to the inlet. This can be attributed to the fluid's initial momentum and impact with the first row of batteries, which promotes local turbulence and more effective cooling. As the fluid progresses, its momentum is dissipated and its heat absorption capacity diminishes, resulting in a less efficient heat exchange with the subsequent cells.

Further evidence for this behavior is provided by the fluid outlet temperatures at a flow rate of 5 LPM, the higher outlet temperatures observed in the more viscous fluids, such as silicone oil (26.34°C), mineral oil (26.01°C) and sunflower (26.02°C), particularly at low volumetric flow rates, indicate a less efficient heat exchange. This suggests that the longer residence time of these fluids in the battery pack allows for a greater increase in temperature as they absorb heat, which is less effective for overall thermal management.

The pressure drop across the battery pack, detailed in Figure 6, exhibits a direct correlation with fluid viscosity. As expected, the highly viscous silicone oil (μ= 0.96 kg/m·s) produced the most significant pressure drop, measuring 5422.29 Pa at 5 LPM—a value approximately 156 times greater than that of deionized water. Mineral oil (μ= 0.05 kg/ms), the second most viscous fluid, followed with a pressure drop of 331.42 Pa, which is about 9.12 times that of water. This substantial difference underscores the profound impact of even incremental viscosity increases on hydraulic resistance. The remaining fluids exhibited progressively lower pressure drops: sunflower oil at 228.4 Pa (6.58x DW), E5-TM410 at 113.83 Pa (3.2x DW), and AmpCoolAC-100 at 70.9 Pa (2.04x DW).

This behavior is a direct consequence of increased internal fluid friction and flow resistance at higher viscosities and volumetric flow rates. A high-pressure drop is a critical design drawback, as it necessitates a more powerful pumping system, thereby increasing the auxiliary energy consumption and reducing the net energy available for vehicle propulsion. While a turbulent flow regime—potentially enhanced by turbulence promoters—is desirable for improved cooling performance, its implementation would further exacerbate the pressure drop. Therefore, a strategic balance must be struck. It is suggested that turbulence promoters are most effectively deployed with low-viscosity fluids. This approach would enhance heat transfer while maintaining the associated pressure drop at a manageable level, avoiding the excessive energy costs incurred with high-viscosity coolants like silicone oil.

## Hypothesis Validation

The simulation results validate the initial hypothesis that the Prandtl number (Pr) is a good parameter for selecting effective dielectric cooling fluids. As illustrated in Figure 4, the cooling performance of the fluids exhibits a strong inverse correlation with their Prandtl number. Deionized water, possessing the lowest Pr, delivered the best cooling performance, followed in descending order

of performance by AmpCoolAC-100, E5-TM410, Sunflower oil, mineral oil, and finally, silicone oil with the highest Pr. This trend is further corroborated by the data in Figure 7. At a flow rate of 5 LPM, silicone oil (Pr ≈ 8807.95) reached a maximum battery temperature of 39.3°C, approaching the upper safe operating limit, whereas deionized water (Pr ≈ 6.96) maintained temperatures well within the optimal range.

This analysis confirms that the Prandtl number effectively integrates the influence of key thermophysical properties, as it is defined as the ratio of momentum diffusivity (kinematic viscosity, μ) to thermal diffusivity (α), where α is itself a function of thermal conductivity (k), density (ρ), and specific heat (Cp). While high thermal conductivity and specific heat capacity are crucial for effective heat transfer, they are insufficient if not considered in conjunction with viscosity. Fluids with favorable k and Cp values but high viscosity will exhibit a high Prandtl number, which significantly impedes heat transfer by restricting fluid flow. This underscores the necessity of a balanced thermophysical profile, where high thermal diffusivity (enabling rapid heat propagation) is coupled with low viscosity (ensuring efficient flow) for superior thermal management.

Furthermore, a quantitative analysis was conducted to compare the cooling system of each dielectric fluid against the top-performing coolant, deionized water. This comparison was based on the average battery temperatures recorded at a flow rate of 5 LPM. The results demonstrate that deionized water provides superior cooling, outperforming silicone oil by 31.33%, mineral oil by 28.75%, sunflower oil by 25.45%, E5-TM410 by 24.73%, and AmpCoolAC-100 by 22.42%.

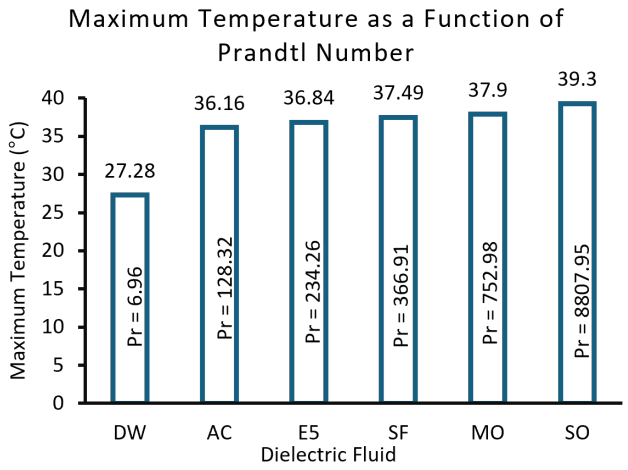

**Figure 7.** Comparison of Coolants: Maximum Temperature as a Function of Prandtl Number

Finally, the simulation results robustly support the hypothesis that a low Prandtl number and high thermal diffusivity are optimal for battery cooling. Deionized water is unequivocally the superior coolant among those tested, as it simultaneously excels in minimizing the maximum battery temperature, ensuring thermal uniformity, and operating with the highest hydraulic efficiency.

## CONCLUSION

The analysis of the battery pack's thermal management through immersion in different dielectric fluids has conclusively validated the hypothesis that the thermophysical properties of the fluids, particularly the Prandtl number (Pr), are decisive for cooling. The simulation results confirmed that deionized water, with the lowest Prandtl number, provided the most superior cooling performance, maintaining maximum battery temperatures within the safe operational range of 20-40°C and outperforming silicone oil by 31.33%.

Furthermore, the analysis of pressure drop revealed a key disadvantage of the more viscous fluids. The high pressure drop observed in silicone oil implies a greater energy demand for the pumping system, which compromises the vehicle's overall energy efficiency. In contrast, deionized water achieved exceptional cooling with minimal pressure drop, positioning it as the most promising option for a high-performance and energy-efficient thermal management system.

The uniform thermal management of battery packs is critical for maintaining their performance and lifespan. In a further work, a key area for improvement lies in achieving a more uniform temperature distribution across the battery cells. We propose the implementation of turbulence promoters, cooling fins integrated into the battery cells, or a combined arrangement of both within the cooling channels. These promoters are designed to alter the fluid's flow patterns, transitioning from a laminar to a more turbulent regime. This change in flow behavior enhances the convective heat transfer coefficient, leading to a more effective heat exchange and, ultimately, a more uniform and efficient cooling of the batteries.

## ABSTRACT

As greenhouse gas emissions accelerate global warming, new capture and storage technologies are essential for reducing the industrial $CO_2$ concentration in the atmosphere. This study addresses the urgent need for greenhouse gas capture technologies by developing a detailed dynamic mathematical model for Chemical Looping Process with Integrated Combustion and $CO_2$ capture (CL-ICCC). In the CL-ICCC process configuration, $CO_2$ capture is integrated into the chemical looping combustion system, resulting in a higher-purity, more efficient process. In this work Cu/CuO oxygen carrier material and $CaO/CaCO_3$ sorbent materials were considered in a fixed bed reactor as solid phase to investigate Oxidation and Reduction/Calcination processes under different operating conditions. The simulation results were compared with experimental results from the literature. In case of the oxidation process, a sensitivity study was performed to investigate the behavior of the process for variation of different operating parameters under dynamic conditions: gas composition, initial gas temperature and solid phase mass composition. In the case of reduction/calcination, multiple fuel type and solid composition were investigated.

**Keywords**: Carbon Dioxide Capture, Chemical Looping, Fixed-Bed Reactor, Hydrogen generation, Sensitivity Study

## INTRODUCTION

In the last years, the level of greenhouse gases (GHG) increased drastically, accelerating the process of global warming by raising the average temperature. [1] To create a pollution-free world, it is impossible to minimize all major pollution sources, such as industrial, transportation or agricultural GHG emissions. New GHG capture technologies, specifically $CO_2$ capture methods, that can have a negative, reducing effect on overall greenhouse gas levels are the solution. [2] Chemical Looping Combustion (CLC) is one of these new types of solutions and it can be adapted in multiple ways. The main purpose is to reduce GHG level in flue gas after the industrial processes. The working principle of the process is very simple: the process uses two different reactors: an Air Reactor (AR) where an oxidation process takes place between a metal or metal-oxide (known as Oxygen Carrier (OC)) and a Fuel Reactor (FR) where the combustion process can be performed in the absence of air. [3-5] An upgraded version of CLC process is the Chemical Looping with Integrated Combustion and $CO_2$ Capture (CL-ICCC) process. In this case the $CO_2$, which will be captured, is generated during the main process and that can increase the efficiency of the plant, also minimizing the climate change effect. [6] However, the products of the CL-ICCC process can be stored and used as raw materials for different processes, depending on the market and the plant operating profile. The main products of the CL-ICCC plant are pure $H_2$, $CO_2$ gas and electric power via steam. [7-9] The flowsheet of the presented, complex chemical process can be seen in Figure 1. All chemical processes take place in a single fixed-bed reactor. A complex valve system, illustrated in Figure 1, is included to switch between the different gaseous raw materials. In this study a copper-based OC, more specifically Cu/CuO material is used. For the $CO_2$ capture process the Ca-based compound is an optimal and efficient choice from an economic point of view. [9] The main objective

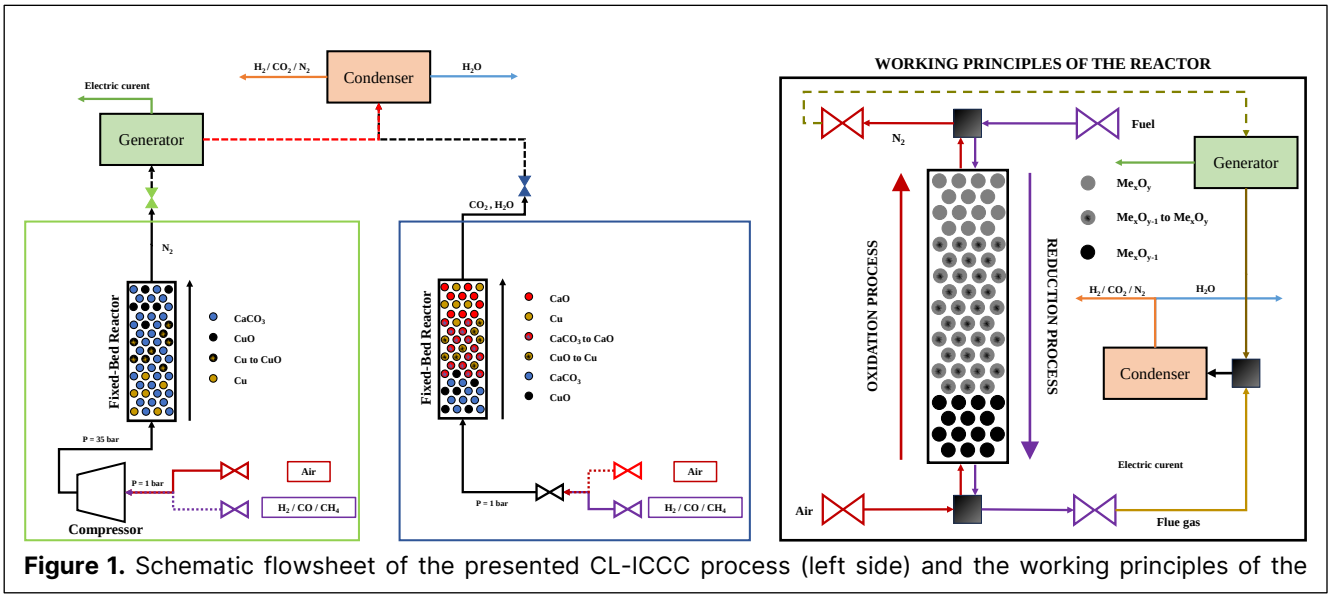

**Figure 1.** Schematic flowsheet of the presented CL-ICCC process (left side) and the working principles of the

of this work is to develop a dynamic mathematical model of the entire CL-ICCC process which can be divided into three different parts.

## Carbonation process (A)

The $H_2$ synthesis occurs based on the reaction equations (1) – (3). At the same time the in-situ $CO_2$ capture takes place. As output of the system, the gaseous phase contains a significant quantity of $H_2$ gas, high-pressure steam, with fuel traces. The chemical process is performed in Fixed-Bed Reactors via Steam Enhanced Reforming (SER) and Water Gas Shift (WGS) processes [9, 10].

$$CH_4 + H_2O \rightarrow CO + 3\,H_2 \quad (1)$$

$$CO + H_2O \rightarrow CO_2 + H_2 \quad (2)$$

$$CH_4 + 2\,H_2O \rightarrow CO_2 + 4\,H_2 \quad (3)$$

$$CaO + CO_2 \rightarrow CaCO_3 \quad (4)$$

## Oxidation (Regeneration) process (B)

The regeneration of the OC material (according to the equation 5) takes place in the oxidation process. The OC capability and type have a high influence on the efficiency of the carbonation process [11, 12]. During the chemical process, the oxidation stage generates a high amount of energy, and the excess energy can be used in steam generation, according to the scientific work of J. R. Fernández et al. [9].

$$2\,Cu + O_2 \rightarrow 2\,CuO \quad (5)$$

## Calcination (reduction) process (C)

During the calcination process, the $CO_2$ gas is generated via two different ways: from the decomposition of the calcium carbonate, which was generated during the carbonation process and from the reaction between syngas and OC material [7, 11, 13]. The reactions described in equations:

$$4\,CuO + CH_4 \rightarrow 4\,Cu + CO_2 + 2\,H_2O \quad (6)$$

$$CuO + H_2 \rightarrow Cu + H_2O \quad (7)$$

$$CuO + CO \rightarrow Cu + CO_2 \quad (8)$$

$$CaCO_3 \rightarrow CaO + CO_2 \quad (9)$$

After the calcination process, the reactor remains at elevated temperature, due to the excess heat generated during the reduction stage and not consumed in the calcination. To improve overall efficiency, syngas synthesis can be performed immediately after the reduction, supplying fuel for subsequent or parallel reduction cycles.

# MATERIALS AND METHODOLOGY OF THE RESEARCH

The aim of this study was to develop a dynamic mathematical model describing stages B and C, with emphasis on model validation and sensitivity analysis of key operating parameters. Although $CO_2$ capture and storage processes are well documented in the literature, differences arise in the choice of oxygen carrier and $CO_2$ sorbent, as well as in the level of model detail. J. R. Fernández et al. proposed several models for the same industrial process; however, their pseudo-homogeneous formulations simplify the temperature profile and provide only limited description of gas–solid interactions. [7-10, 12]

In stage B, a critical parameter is the stability of the solid phase under high-temperature and high-pressure conditions. Reactor temperatures may exceed 1000 °C and pressures approach 35 bar, emphasizing the need for appropriately selected support materials. To simulate the chemical process, the initial step involved validating

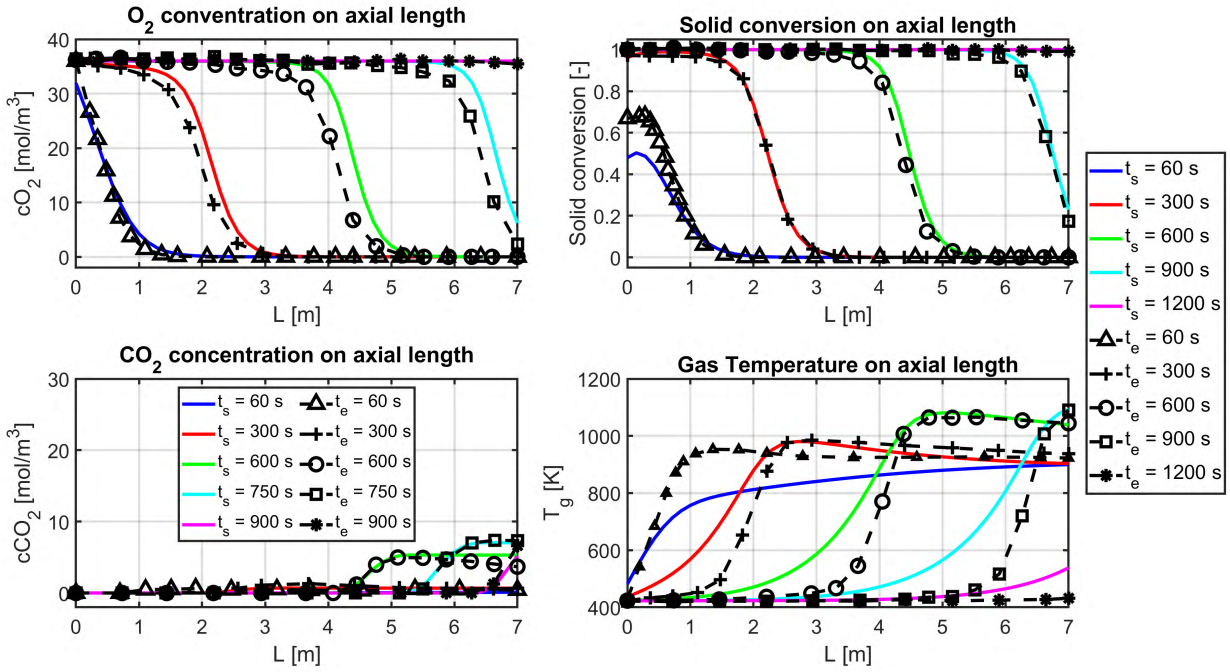

**Figure 2.** Validation diagrams of the stage B process (solid composition: Cu:Ca = 0.28:0.23) (simulated results vs.

the reaction kinetics under various conditions using experimental data from the literature. F. García-Labiano et al. conducted a comprehensive kinetic study on copper-based oxygen carriers, through first-order kinetic model, was chose for this work. [14]

**Table 1.** Kinetical parameters of Stage B and Stage C. [14, 15]

| Parameters | U.M. | Values |
|---|---|---|
| Stage B | | |
| $\rho_{m,Cu}$ | kmol/m$^3$ | 140.252 |
| $L_{Cu}$ | m | $4 \cdot 10^{-10}$ |
| $k_{0,ox}$ | m/s | $4.7 \cdot 10^{-6}$ |
| $E_{a,ox}$ | kJ/mol | 15 |
| Stage C | | |
| $\rho_{m,CuO}$ | kmol/m$^3$ | 80.402 |
| $L_{CuO}$ | m | $2.3 \cdot 10^{-10}$ |
| $k_{0,H_2}$ | m/s | $1 \cdot 10^{-4}$ |
| $E_{a,H_2}$ | kJ/mol | 33 |
| $k_{0,CO}$ | m/s | $5.9 \cdot 10^{-6}$ |
| $E_{a,CO}$ | kJ/mol | 14 |
| $k_{0,CH_4}$ | m/s | $4.5 \cdot 10^{-4}$ |
| $E_{a,CH_4}$ | kJ/mol | 60 |
| $k_{0,red}$ | kmol/(m$^3$ • s) | 252 015 |
| $E_{a,red}$ | kJ/mol | 91.7 |

Although the previous studies provided a solid theoretical foundation, several literature sources indicate that the oxidation process is more accurately represented by a second-order kinetic model. In this formulation, key parameters include the oxygen-carrier layer thickness ($L_{Cu}$) and its density ($\rho_{m,Cu}$), as shown in equation (10) and (11):

$$\upsilon_{p_{ox}} = \frac{dX}{dt} = \frac{2}{\tau} \cdot (1 - X_{ox})^{0.5} \quad (10)$$

$$\tau = \frac{L_{Cu} \cdot \rho_{m,Cu}}{b \cdot k_{ox} \cdot C_g^n} \quad (11)$$

$$k_{ox} = k_{0,ox} \cdot e^{\left(-\frac{E_{a,ox}}{RT}\right)} \quad (12)$$

where $X_{ox}$ is the conversion of the solid component, $b$ is the stoichiometric factor of reaction, $k_{ox}$ is the chemical reaction rate constant of the oxidation process [m/s], $C_g$ is the gas component concentration in the reactor chamber [kmol/m$^3$], $n$ is the reaction order, $\tau$ is the necessary time to complete the solid conversion [s], $R$ is the gas constant [J/mol•K]. The reaction rate constant is calculated by the Arrhenius equation (12).

For calcination, additional parameters have been defined in the literature to account for temperature effects, maximum conversion, and the equilibrium $CO_2$ concentration in the system, as expressed in equation (13) and (14):

$$\upsilon_{p_{cal}} = \frac{dX_{cal}}{dt} = k_{cal} \cdot (1 - X_{cal})^{\frac{2}{3}} \cdot \left(c_{CO_2,eq} - c_{CO_2}\right) \quad (13)$$

$$c_{CO_2,eq} = \frac{5.045 \cdot 10^8}{T} \cdot \exp\left(-\frac{20474}{T}\right) \quad (14)$$

$$k_{cal} = k_{0,cal} \cdot e^{\left(-\frac{E_{a,cal}}{RT}\right)} \quad (15)$$

where $X_{cal}$ is the conversion of the solid component in the calcination process, $k_{cal}$ is the chemical reaction rate constant [kmol/(m³•s)], $c_{CO_2}$ is the $CO_2$ concentration in the reactor chamber [kmol/m³], $c_{CO_2,eq}$ is the equilibrium concentration of the $CO_2$ gas, calculated by equation (14), according to J. M. Alarcón et al. [13] The reaction rate constant is evaluated using the Arrhenius equation (15). The full set of kinetic parameters used in this work is summarized in Table 1.

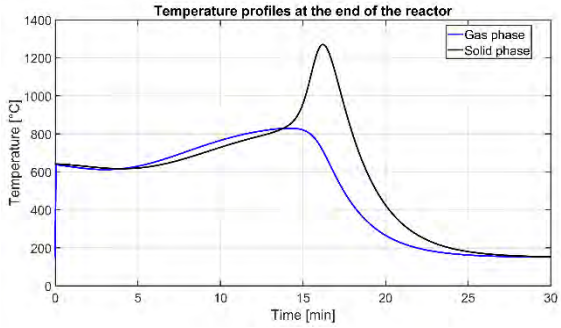

**Figure 3.** Temperature profiles at reactor exit are in a steady state regime.

For the model development, the governing equations were formulated using standard mass and energy balance relationships, consistent with established literature. In stage B, J. R. Fernandez et al. proposed two alternative modelling approaches, noting that the elevated temperatures reached during oxidation may induce partial calcination. [12] To examine this effect, they developed two different models: one model when the calcination reaction is not considered during the process and an other model when it is considered. In this study, the mathematical model was performed based on the second case. The components mass balance equations are presented via equations (16) – (22):

$$\varepsilon\frac{dm_{Cu}}{dt} = -(1-\varepsilon)\bullet\eta\bullet v_{p_{ox}}\bullet m_{Cu} \quad (16)$$

$$\varepsilon\frac{dm_{CuO}}{dt} = (1-\varepsilon)\bullet\eta\bullet v_{p_{ox}}\bullet m_{Cu}\bullet\frac{M_{CuO}}{M_{Cu}} \quad (17)$$

$$\varepsilon\frac{dm_{CaCO_3}}{dt} = -(1-\varepsilon)\bullet v_{p_{cal}}\bullet m_{CaCO_3} \quad (18)$$

$$\varepsilon\frac{dm_{CaO}}{dt} = -(1-\varepsilon)\bullet v_{p_{cal}}\bullet m_{CaO}\bullet\frac{M_{CaO}}{M_{CaCO_3}} \quad (19)$$

$$\varepsilon\frac{dc_{O_2}}{dt} = -w_g\bullet\frac{dc_{O_2}}{dz} - \frac{(1-\varepsilon)\bullet\eta\bullet v_{p_{ox}}\bullet m_{Cu}}{2\bullet M_{Cu}\bullet A\bullet dz} \quad (20)$$

$$\varepsilon\frac{dc_{N_2}}{dt} = -w_g\bullet\frac{dc_{N_2}}{dz} \quad (21)$$

$$\varepsilon\frac{dc_{CO_2}}{dt} = -w_g\bullet\frac{dc_{CO_2}}{dz} + \frac{(1-\varepsilon)\bullet v_{p_{cal}}\bullet m_{CaO}}{M_{CaCO_3}\bullet A\bullet dz} \quad (22)$$

where $m_j$ is the mass of the *j* component in the solid bed (*j* = Cu, CuO, CaO, $CaCO_3$) [kg], $\eta$ is an efficiency factor of the chemical reaction, $\varepsilon$ is the solid bed porosity, $c_i$ is the concentration of the *i* components in the reactor (*i* = $O_2$, $N_2$, $CO_2$) [kmol/m³], $M_j$ is the molecular weight of the *j* component [kg/kmol], $w_g$ is the velocity of the gas flow [m/s], $A$ is the cross section of the reactor [m²], $dz$ is the length of a section of the reactor (the reactor length was divide into 50 equal spaces).

The energy balance equations describe the conventional heat exchange between the solid and gaseous phases, according to the plug flow reactor operating principles. The balance equations are presented below:

$$\varepsilon\frac{dT_g}{dt} = -w_g\bullet\frac{dT_g}{dz} - \frac{K_T\bullet A_T\bullet(T_g-T_s)}{c_{p_g}\bullet\rho_g\bullet A\bullet dz} \quad (23)$$

$$\varepsilon\frac{dT_s}{dt} = \frac{K_T\bullet A_T\bullet(T_g-T_s)}{c_{p_s}\bullet\rho_s\bullet A\bullet dz} - \sum\frac{(1-\varepsilon)\bullet\eta\bullet\Delta H_x\bullet v_{p_x}\bullet m_j}{b\bullet M_j\bullet c_{p_s}\bullet\rho_s\bullet A\bullet dz} \quad (24)$$

where $T_s$ is the temperature of the solid bed [K], $T_g$ is the temperature of the gaseous phase [K], $K_T$ is the heat transfer coefficient [W/m²K], $A_T$ is the surface area where the heat exchange process takes place [m²], $c_{p_s}$ and $c_{p_g}$ are the specific heat capacity for the gaseous and solid phases [J/kgK], $\rho_s$ and $\rho_g$ are the density of the gaseous and solid phases [kg/m³], $x$ is an indicator for the processes during the interpretation of the energy balance equations ($x$ = oxidation or calcination).

**Table 2.** Process operating parameters.

| Parameters | Values |
|---|---|
| Stage B | |
| Initial gas temperature [$T_{g,0}$] | 423 K |
| Initial solid temperature [$T_{s,0}$] | 923 K |
| Pressure [$P$] | 35 bar |
| Inlet mass flow velocity [$Q_s$] | 21 kg/m²s |
| Process effectiveness [$\eta$] | 0.3 |
| Inlet $O_2$ concentration [$c_{O_{2_{in}}}$] | 3.6 % |
| Particle size [$d_p$] | 10 mm |
| Porosity [$\varepsilon$] | 0.5 |
| Solid phase density [$\rho_s$] | 3400 kg/m³ |
| Cu weight fraction [$\rho_{Cu}$] | 950 kg/m³ |
| $CaCO_3$ weight fraction [$\rho_{CaCO_3}$] | 750 kg/m³ |
| Stage C | |
| Initial gas temperature [$T_{g,0}$] | 973 K |
| Initial solid temperature [$T_{s,0}$] | 973 K |
| Pressure [$P$] | 1 atm |
| Inlet molar flow velocity [$Q_s$] | 1 kmol/s |
| Process effectiveness [$\eta$] | 0.8 |
| Inlet fuel gas concentration [$c_{i_{in}}$] | 75 % |
| Particle size [$d_p$] | 5 mm |
| Porosity [$\varepsilon$] | 0.5 |
| Solid phase density [$\rho_s$] | 2330 kg/m³ |

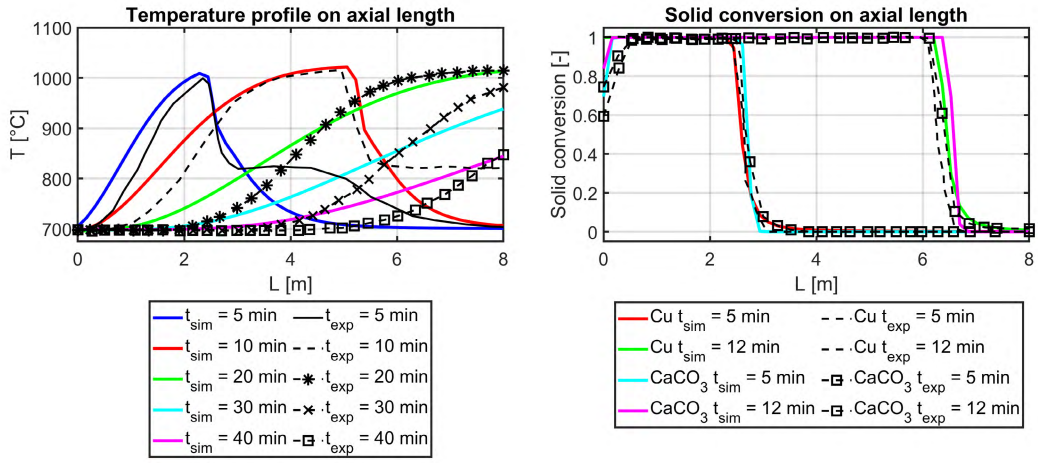

**Figure 4.** Validation diagrams of the stage C during $H_2$ process (solid composition: Cu:Ca = 0.3:0.15) (simulated results vs. experimental results)
From left to right: 1. Gas temperature profile on axial length; 2. Solid conversion on axial length;

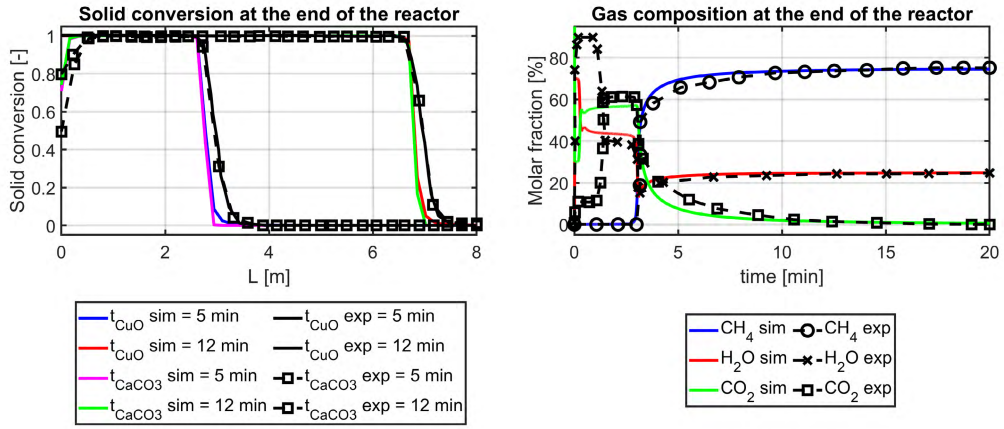

**Figure 5.** Validation diagrams of the stage C during CO and $CH_4$ process (solid composition: Cu:Ca = 0.3:0.21). (simulated results vs. experimental results)

For the calcination processes, the defined equations are the same, the differences come from the direction of the chemical reactions, from the raw material to the product, according to the reaction equations (6 - 9). The developed mathematical model is also operating in adiabatic conditions, where the energy for the calcination process is generated in situ via the reduction processes. The mass and energy balance equations are described below:

$$\varepsilon \frac{dm_j}{dt} = \pm (1-\varepsilon) \bullet \eta \bullet \upsilon_{p_{red}} \bullet m_j \quad (25)$$

$$\varepsilon \frac{dc_i}{dt} = -w_g \bullet \frac{dc_i}{dz} \pm \frac{(1-\varepsilon) \bullet \eta \bullet \upsilon_{p_{red}} \bullet m_j}{b \bullet M_j \bullet A \bullet dz} \quad (26)$$

$$\varepsilon \frac{dT_g}{dt} = -w_g \bullet \frac{dT_g}{dz} - \frac{K_T \bullet A_T \bullet (T_g - T_s)}{c_{p_g} \bullet \rho_g \bullet A \bullet dz} \quad (27)$$

$$\varepsilon \frac{dT_s}{dt} = \frac{K_T \bullet A_T \bullet (T_g - T_s)}{c_{p_s} \bullet \rho_s \bullet A \bullet dz} - \sum \frac{(1-\varepsilon) \bullet \eta \bullet \Delta H_x \bullet \upsilon_{px} \bullet m_j}{b \bullet M_j \bullet c_{p_s} \bullet \rho_s \bullet A \bullet dz} \quad (28)$$

where $i$ = $H_2$, $H_2O$, CO, $CO_2$, $CH_4$.

The model simulation was performed in MATLAB/Simulink, the used solver was 'ode15s'. The operating parameters (Table 2) were chosen based on multiple literature sources. [8, 12, 13]

## DYNAMIC SIMULATIONS' RESULTS AND DISCUSSION

### Dynamic simulation and sensitivity study of stage B

The dynamic mathematic simulation was conducted to evaluate the systems' behavior under realistic operating conditions. The oxidation reaction concluded at approximately 15 minutes, after which the system began to cool due to heat transfer between the fresh gas stream and the oxidized solid phase. Owing to the elevated temperature, a minor extent of $CaCO_3$ decomposition occurred, by the calcination process. Since the minimum

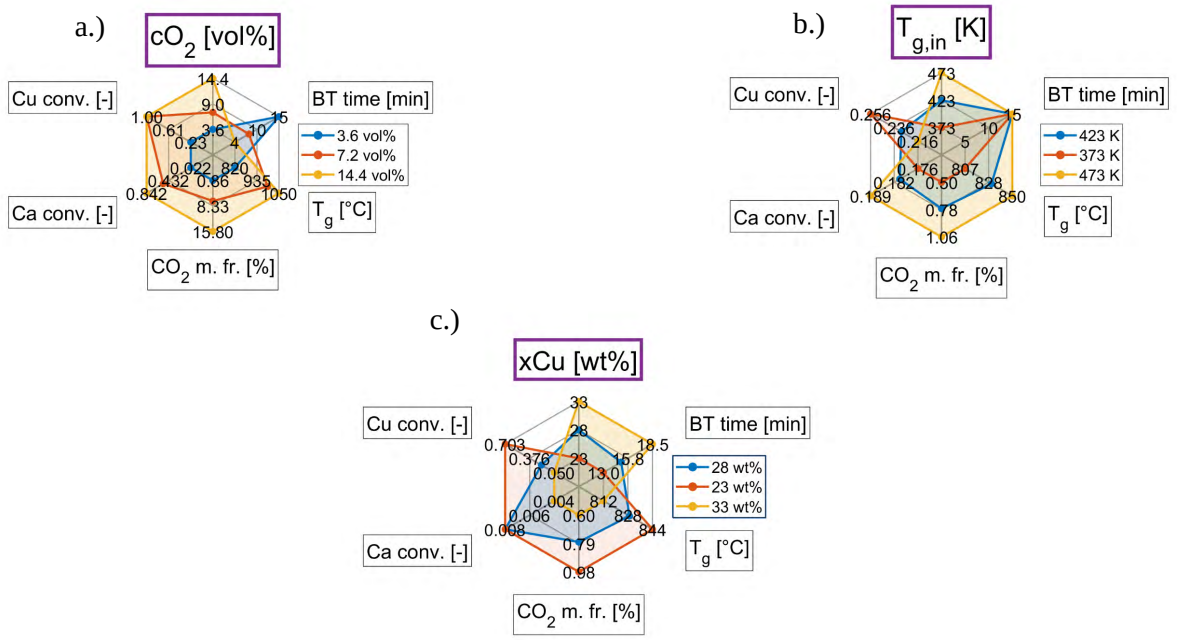

**Figure 6.** Spider web diagrams of the sensitivity study of the stage B (BT time is Breakthrough time): a.) Variation of gas composition [3.6 – 14.4 vol%]; b.) Variation of the initial gas temperature [373 – 473 K]; c.) Variation of the mass composition of the solid bed [23 – 33 wt% Cu];

temperature of the calcination exceeds 973 K, the peak temperature reached during stage B surpassed and threshold. The oxygen carrier achieved complete conversion at around 15 minutes, marking the breakthrough point. Beyond this point, the $O_2$ concentration returned to its initial level, signaling the end of the chemical reaction.

The steady state of the system within the reactor can be evaluated at two levels: the chemical composition and temperature. Figure 3 illustrates the temperature profiles of the solid and gas phases from the beginning to the breakthrough point. The temperature difference in the system is significant: the oxidation reaction generates a large amount of energy, and this energy is transferred to the gaseous phase to warm up the gas mixture to the operating temperature. After the breakthrough point, the temperature in the solid phase rises, caused by the excess heat from the oxidation process at the end of the undesired calcination process.

To investigate the system's response to variation in operating conditions, sensitivity analysis was performed. Three key parameters were examined: gas composition, initial gas temperature and mass difference in the case of Cu after 5 minutes on 2.5 m examination point. Based on the results, the hydrogen level can generate a non-favorable system behavior. The increase in $O_2$ concentration has a significant effect on system behavior, as illustrated in Figure 6. Higher hydrogen levels accelerate the reaction rate, resulting in shorter breakthrough times and an earlier appearance of the breakthrough curves. This intensified reaction also causes a significant temperature increase. At 14.4 vol% $O_2$, the peak gas-phase temperature is approximately 1, 050 °C, which is about 30% higher than under the reference operating conditions. At this point, the $CO_2$ concentration increases to 15.8 %, and the overall conversion of the Ca-based sorbent reaches 0.842 after 5 minutes at 2.5 m axial length. These conditions are undesirable, because the primary objective is to fully oxidize the oxygen carrier, while preserving the chemical integrity of the calcium-containing material. A lower initial gas temperature generates more desired results by higher Cu conversion and significantly lower Ca conversion. This phenomenon is caused by the temperature differences between the gas and the solid phase. The solid composition is also an important aspect of the system design and has significant impact on multiple evaluated parameters. A lower Cu composition in the solid bed causes a higher peak temperature, a shorter reaction time and a higher $CO_2$ level at the end of the reactor. The results indicate to estimate an optimized operating time, to decrease the appearance of the calcination in the oxidation process and maximize the Cu conversion.

## Dynamic simulation of stage C

In the stage C, the chemical reaction is dictated by the composition of the fuel gas. Although the theoretical optimum operates with syngas ratio $CO:H_2$ = 1:3, trace alkanes (specifically $CH_4$) may be present due to valve malfunction or post-breakthrough operations. In order to develop a well-defined mathematical model, it is necessary to consider every case and perform three different

operating mods. Each operating mode was performed in isolated conditions, during the simulation steam was added to the pure fuel gas to create an inert atmosphere. The simulations were performed using the model equations (24-29), and the reactor was considered as an adiabatic system (perfectly isolated), which reduces the number of thermodynamic phenomena in the system.

The $H_2$ process was simulated for 80 minutes to evaluate the solid conversion, the gas composition and the temperature profiles. The breakthrough point occurred at 15 minutes when the solid phase reaches the maximum conversion level and the system reached its peak temperature. The process started with preheated gaseous phase at 973 K, which was also the temperature of the solid phase. After the fuel gas was introduced into the reactor chamber, an initial fluctuation of the gas composition occurred.

The CO process simulation duration was 30 minutes, and the breakthrough point was achieved in 12 minutes. During the process, significant amount of the $CO_2$ was detected, by the oxidation of the CO gas from syngas and from the calcination process for dissociation of the $CaCO_3$. In contrast with the $H_2$ solution, the reaction heat which comes from the CO oxidation process is much higher. The highest temperature obtained during the CO simulation was close to 1, 250°C, compared to 875°C obtained during the $H_2$ process.

With the $CH_4$ fuel gas, the simulation was performed under 20 minutes, and the end of the chemical reaction was nearly 3 minutes, which is almost 10 times shorter than the operating time of the $H_2$ simulation. The conversion of the $CaCO_3$ did not reach the maximum conversion level, which could be achieved by increasing the gas composition or the gas stream flow rate.

In the case of the $H_2$ model, the simulation results were validated for multiple mass composition by the experimental data provided by J. M. Alarcón et al. [13]

## CONCLUSION

In this work, multiple mathematical models were developed successfully under dynamical operating conditions for the oxidation and calcination/reduction processes. The validation process was performed by experimental data presented in literature. During the validation process, the developed model accurately predicted the gas composition and the temperature profile at the end of the reactor, as well as the axial length and solid conversion. However, a sensitivity study was performed to examine the response of the oxidation process under dynamic operating conditions. Specifically, the elevated $O_2$ concentration (14.4 vol%) in the fuel gas stream indicates an undesirable calcination process. During the oxidation on an elevated peak temperature (1050°C) can produce the same unfavorable phenomenon: 0.189 Ca conversion after 5 minutes at 2.5 m axial length.

The calcination process is highly influenced by the composition and type of the fuel used. In the case of $H_2$ reduction, the peak temperature of the system was 875°C, while in the CO calcination, the value of the peak temperature was 1250°C. The $CH_4$ reduction process was performed under 3 minutes due to the large amount of energy generated via fuel gas. In practice, these three calcination types take place simultaniously in the reactor chamber in, complicates the modeling process.

## ABSTRACT

Styrene is mainly produced by dehydrogenating ethylbenzene over an iron oxide-based catalyst. The reaction is endothermic and thermodynamically limited when operated in conventional catalytic fixed-bed reactors. This makes the styrene production process a conversion-selectivity trade-off, where different objectives must be compromised. In this work, a one-dimensional reactor model accounting for changes in molar flowrate, temperature, and pressure is used to predict the performance of a membrane reactor. Three main hydrogen flux profiles were assumed along the reactor axial direction: constant, linearly increasing, and linearly decreasing. It is found that the styrene yield and selectivity in a membrane reactor operated with a linearly decreasing hydrogen flux profile are higher than those with constant or linearly increasing hydrogen flux profiles in both isothermal and nonisothermal cases. It is also observed that the styrene yield and selectivity of the membrane reactor operated with a linearly decreasing hydrogen flux can be enhanced by improving the membrane's average hydrogen permeability. The influence of nonlinearity in the hydrogen flux equation is marginal and observed mainly at the reactor inlet. The improvement is due to enhanced hydrogen permeation, which is observed to be better for the linearly decreasing hydrogen profile than for the constant, linearly increasing hydrogen flux profile. When a permeation section is included in the reactor at the point where maximum hydrogen production is observed, the styrene yield is better than that of the completely permeated catalytic reactor.

## INTRODUCTION

Styrene is a crucial component for manufacturing high-performance polymers. It is mainly produced via the dehydrogenation reaction of ethylbenzene catalyzed by iron-oxide based catalyst. The reaction is endothermic and thermodynamically limited when operated in conventional fixed-bed reactors. This turns the process of styrene production into a conversion-selectivity problem where different objectives must be compromised.

Several researchers studied the kinetics of ethylbenzene dehydrogenation and its interactions with other chemicals. For instance, the influence of the presence of $CO_2$ in the reactor catalyzed by $Fe_2O_3$ supported on $Al_2O_3$ was addressed by Mimura and Saito, while the impact of the presence of steam in the reactor when ethylbenzene is dehydrogenated was studied by Zhu et al. via dynamic experiments in the presence of a potassium-promoted iron oxide-based catalyst [1, 2]. Rossetti et al. studied the causes of the deactivation of a commercial catalyst used for the dehydrogenation of ethylbenzene to styrene [3]. Lee and Froment studied the kinetics of the dehydrogenation of ethylbenzene to styrene catalyzed by a commercial iron oxide catalyst in a fundamental way, whereas Hossain M et al. studied the kinetics on a mesoporous alumina-supported iron catalyst [4, 5].

To improve styrene yield and selectivity, various reactor configurations have been proposed in the literature.

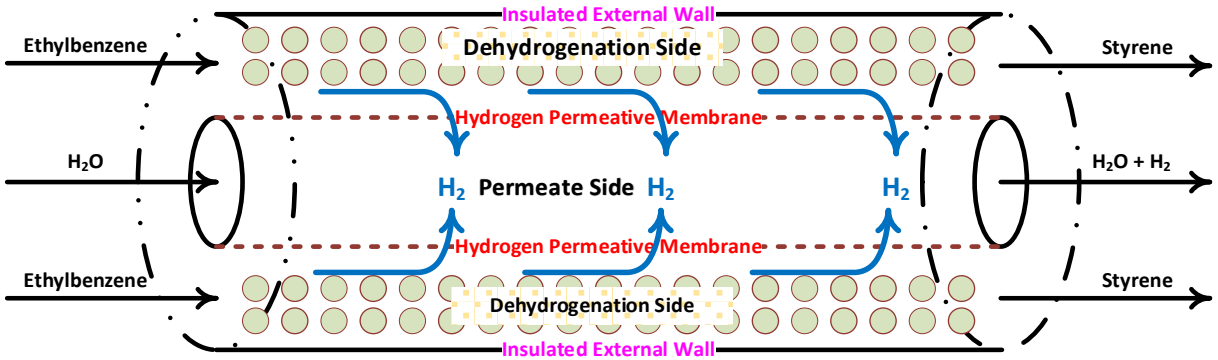

**Figure 1:** Cocurrent configuration of the catalytic fixed bed membrane reactor operating dehydrogenation of ethylbenzene.

For example, catalytic membrane reactors were used for the dehydrogenation of ethylbenzene to styrene, with the reaction integrated with either a sweep gas on the permeate side or with another hydrogenation reaction, such as the hydrogenation of nitrobenzene to aniline [6, 7]. Both 1D and 2D reactor mathematical models were used to describe and optimize the performance of the newly configured membrane reactors [8]. In catalytic membrane reactors, it is observed that styrene yield and selectivity were significantly improved compared to conventional fixed-bed reactors.

The performance of membrane reactors that enhance the selectivity and yield of a desired species is influenced by several parameters, among them the hydrogen permeation policy. So far, the hydrogen flux profile in membrane reactors has been estimated using Sievert's law, in which the driving force is the difference in hydrogen partial pressures between the reaction and permeate sides. The assessment of the various hydrogen permeation profiles and their impacts on reactor performance has not yet been addressed in the literature. The concept of nonuniform distribution has been already implemented in problems related to the catalyst activity within catalyst pellets and heat exchange in nonadiabatic catalytic reactors. Consequently, the main goal of this manuscript is to address the variation in hydrogen flux along the axial direction of a membrane reactor used to dehydrogenate ethylbenzene to styrene and to assess reactor performance. This will surely help reduce membrane reactor construction costs, as these costs are directly related to hydrogen permeability. Additionally, this study shed light on the problem of optimal hydrogen policy leading to the construction of optimally efficient catalytic membrane reactors.

## KINETICS AND REACTION RATE LAWS

The reaction network of ethylbenzene dehydrogenation on a commercial iron oxide catalyst is composed of the following set of stoichiometric equations:

$$C_6H_5C_2H_5 \Leftrightarrow C_6H_5C_2H_3 + H_2 \quad [1]$$

$$C_6H_5C_2H_5 \rightarrow C_6H_6 + C_2H_4 \quad [2]$$

$$C_6H_5C_2H_5 + H_2 \rightarrow C_6H_5CH_3 + CH_4 \quad [3]$$

$$C_6H_5C_2H_3 + 2H_2 \rightarrow C_6H_5CH_3 + CH_4 \quad [4]$$

Two types of chemical reactions occur within the reactor: thermal and catalytic reactions, and neither can be neglected. The thermal reactions, following a radical mechanism, happen in the reactor free zone and are described by reactions [1], [2], and [3]. On the other hand, the catalytic reactions are described by reactions [1], [2], [3], and [4], which take place at the catalyst surface. The kinetic laws of thermal reactions based on molecular mechanisms and catalytic reactions based on intrinsic Hougen-Watson kinetic models are given by Lee and Froment [4].

## REACTOR CONFIGURATION

The schematic diagram of the cocurrent configuration of a catalytic membrane reactor is depicted in Figure 1. The reactor is assumed to have a concentric configuration with an outer and an inner side. The outer side of the reactor is packed with a commercial iron oxide catalyst, catalyzing the dehydrogenation reaction of ethylbenzene to styrene. The reaction network is complex, leading to net endothermicity in conventional fixed-bed reactors. Benzene, toluene, and ethylene are produced as byproducts within the reactor. In conventional fixed bed reactors, hydrogen production and net endothermicity limit ethylbenzene conversion, styrene yield, and selectivity.

The external wall on the inner side of the reactor is fabricated to be hydrogen-permeable. It allows hydrogen produced on the dehydrogenation side to infiltrate to the permeate side, where pure steam is used to purge out the diffused hydrogen. Additionally, the permeate side may be used for in-situ heat exchange with the reaction side,

assisting in shifting the reaction's thermodynamic limitation. In-situ hydrogen permeation from the reaction side to the permeate side can significantly enhance the conversion and yield of ethylbenzene and styrene compared to conventional catalytic fixed-bed reactors. The external wall of the reactor on the reaction side is assumed to be perfectly insulated, preventing significant heat transfer between the reactor and its surroundings.

## REACTOR MATHEMATICAL MODELLING

The mathematical model governing the performance of the catalytic membrane reactor is deduced considering the following assumptions:

1. Steady state operation
2. Ideal gas behavior on both sides of the reactor.
3. Ideal plug flow behavior.
4. Pseudo-homogeneous reactor model, i.e., neglect the transport effect between the reacting fluid and the catalyst pellets.
5. Neglecting the effect of catalyst deactivation.
6. A highly selective membrane reactor allowing only hydrogen to penetrate to the permeate side.
7. Adiabatic external wall of the membrane reactor
8. Pressure drop within the reaction side is correlated using Ergun's equation.

The reactor model equations on the reaction side of the catalytic membrane reactor may be mathematically presented as follows:

### Mole balance equation on the reaction side:

$$\frac{dn_i}{dz} = \sum_{j=1}^{3} \upsilon_{ij}\, r_j^t A_c \varepsilon + \sum_{j=1}^{4} \upsilon_{ij}\, r_j^t \rho_s A_c (1-\varepsilon) - 2\pi R_3 \omega_i J_i(z) \quad [5]$$

### Energy balance equation on the reaction side:

$$\frac{dT}{dz} = \frac{\begin{bmatrix} \sum_{j=1}^{3} \upsilon_{ij} r_j^t A_c \varepsilon [-\Delta H(T)]_j^t \\ + \sum_{j=1}^{4} \upsilon_{ij} r_j^t \rho_s A_c (1-\varepsilon) [-\Delta H(T)]_j \\ - \sum_{i=1}^{n} 2\pi R_3 \omega_i J_i(z) \int_{T'}^{T} C_{pi} dT + 2\pi R_3 U(T'-T) \end{bmatrix}}{\sum_{i=1}^{n} n_i C_{pi}} \quad [6]$$

### Ergun's equation on the reaction side:

$$\frac{dP}{dz} = -\frac{G}{\rho g_c D_p}\left(\frac{1-\varepsilon}{\varepsilon^3}\right)\left[\frac{(1-\varepsilon)\mu}{D_p} 1.75G\right] \quad [7]$$

On the permeate side, the model equations may be stated as follows:

### Mole balance equation on the permeate side:

$$\frac{dn_i'}{dz} = 2\pi R_3 \omega_i J_i(z) \quad [8]$$

### Energy balance equation on the permeate side:

$$\frac{dT'}{dz} = \frac{\sum_{i=1}^{n} 2\pi R_3 \omega_i J_i(z) \int_{T'}^{T} C_{pi} dT - 2\pi R_3 U(T'-T)}{\sum_{i=1}^{n} n_i' C_{pi}'} \quad [9]$$

The boundary condition for the cocurrent flow configuration on both sides of the membrane reactor is defined at the reactor inlet as follows:

At $z = 0$:

$$n_i = n_{i0} \quad T = T_0 \quad P = P_0 \quad n_i' = n_{i0}' \quad T' = T_0' \quad [10]$$

In Eqs. [5], [6], [8], and [9], the Greek letter "$\omega_i$" was introduced to make the derived model usable for both a conventional fixed bed reactor and a membrane catalytic reactor. If "$\omega_i = 0$" the model predicts the performance of the conventional fixed bed reactor, while "$\omega_i = 1$" the performance of the catalytic membrane reactor is predicted.

The set of reactor model equations forms an initial-value problem (IVP) that must be solved numerically using a suitable numerical method. In this work, a finite element orthogonal collocation technique is implemented using a predefined number of points per interval, thereby transforming the system of differential equations into a set of nonlinear algebraic equations. The set of algebraic equations has been solved using the "fsolve" MATLAB subroutine.

## REACTOR PERFORMANCE MEASURE

The reactor performance indexes considered in this study are ethylbenzene conversion, styrene yield, and styrene selectivity. They are all estimated using the following equations:

$$x_{EB} = \frac{n_{EB,0} - n_{EB}}{n_{EB,0}} \quad [11]$$

$$Y_{ST} = \frac{n_{ST} - n_{ST,0}}{n_{EB,0}} \quad [12]$$

$$S_{ST} = \frac{n_{ST} - n_{ST,0}}{n_{EB,0} - n_{EB}} \quad [13]$$

These performance measures are generally conflicting; maximizing one leads to minimizing the others. As a result, multi-objective optimization problems that combine these measures might be considered at later stages of this study.

## PROBLEM MATHEMATICAL FORMULATION

This study aims to investigate and assess the impact of implementing different hydrogen-permeation policies on the performance of a membrane reactor used for the dehydrogenation of ethylbenzene to styrene. The molar flux profile in the reactor model equation is given by the term $J_i(z)$ and it is defined only for hydrogen. The following mathematical model predicting the molar hydrogen flux as a function of axial distance is implemented in the reactor model equations:

$$J_{H_2}(z) = az^{\alpha} + b \quad [14]$$

The parameters "a" and "b" in the above equation

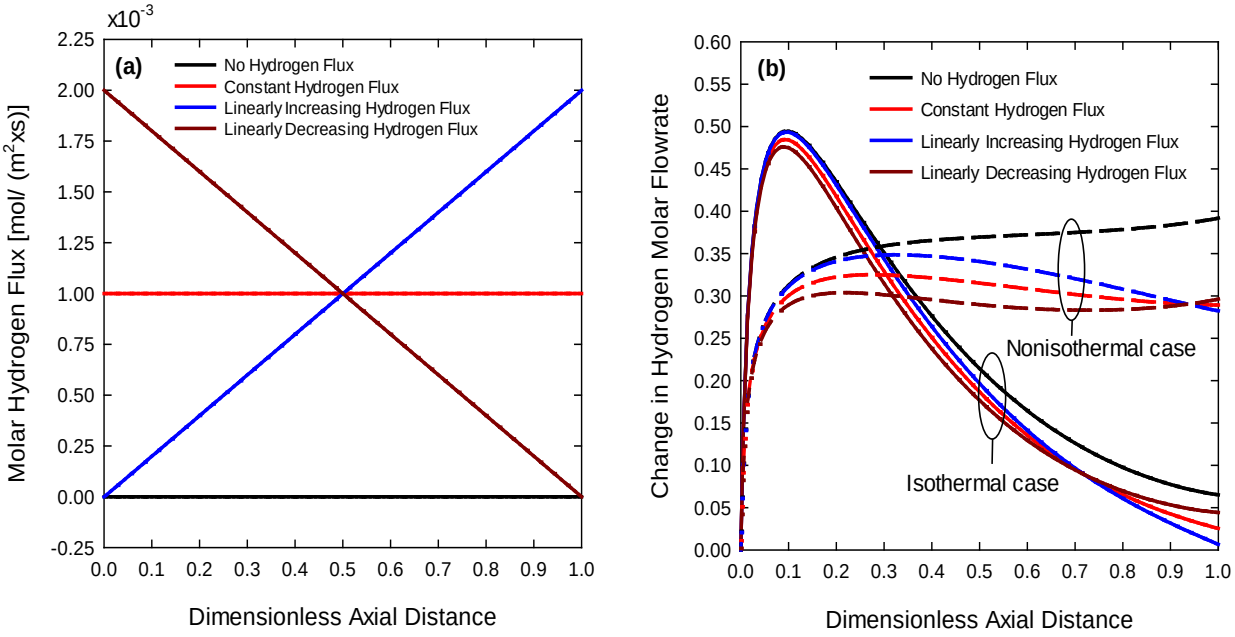

**Figure 2:** (a) hydrogen flux profiles implemented in the cocurrent configuration of the membrane reactor with an average permeability of $1.0\times10^{-3}$ mol/(m²×s). (b) change in hydrogen molar flowrates for both isothermal and nonisothermal cases.

have the units of mol/($m^{\alpha+2}$×s) and mol/(m²×s), respectively. Adjusting "α" in the above model provides a variety of linear and nonlinear distributions, i.e., α=0 is constant, α=1 is linear, and α≠1 is nonlinear. Three types of monotonic hydrogen fluxes may be defined: constant hydrogen flux, an increasing molar flux set to zero at the reactor feeding point, and a decreasing molar flux set to zero at the reactor exit. Consequently, the hydrogen molar flux is given for α≠1 as a function of the dimensionless distance $\zeta = \frac{z}{L}$ as follows:

Constant hydrogen flux:

$$J_{H_2}(z) = J_{ave} = \bar{J} \qquad [15]$$

Monotonically increasing hydrogen flux for $0 \le \zeta \le 1$ and $\zeta_1 < \zeta_2$ :

$$J_{H_2}(\zeta) = \frac{(1+\alpha)(\zeta_2-\zeta_1)\bar{J}(\zeta^\alpha-\zeta_1^\alpha)}{\zeta_2(\zeta_2^\alpha-\zeta_1^\alpha)-\alpha\zeta_1^\alpha(\zeta_2-\zeta_1)} \qquad [16]$$

Monotonically decreasing hydrogen flux for $0 \le \zeta \le 1$ and $\zeta_1 < \zeta_2$ :

$$J_{H_2}(\zeta) = \frac{(1+\alpha)(\zeta_2-\zeta_1)\bar{J}(\zeta^\alpha-\zeta_2^\alpha)}{\zeta_1(\zeta_2^\alpha-\zeta_1^\alpha)-\alpha\zeta_2^\alpha(\zeta_2-\zeta_1)} \qquad [17]$$

In the above molar flux models, the average membrane permeability in the above equations is defined as:

$$J_{ave} = \bar{J} = \frac{1}{L}\int_0^L J_{H_2}(z)dz = \int_0^1 J_{H_2}(\zeta)d\zeta \qquad [18]$$

In this study, the influence of average membrane permeability, nonlinearity, and hydrogen flux on the performance of the catalytic membrane reactor is examined primarily under isothermal conditions. The behavior of the membrane reactor under adiabatic, nonisothermal operating conditions is also presented to extend the conclusions. The focus is mainly on the isothermal condition, as establishing net endothermicity in the nonisothermal reactor will influence reaction kinetics and equilibrium conversion. Hence, the assessment of reactor performance will also be affected by temperature variations.

## REACTOR OPERATING CONDITIONS

The geometric parameters and operating conditions used to simulate the performance of the catalytic membrane reactor are summarized in Table 1.

These parameters were kept constant while varying the trajectories of the molar hydrogen flux along the reactor axial distance and accounting for changes in related parameters, such as membrane permeability and the nonlinearity of the hydrogen flux profiles.

## RESULTS AND DISCUSSION

In this study, the three basic molar hydrogen flux profiles considered, i.e., constant, linearly increasing, and linearly decreasing profiles, are shown in Figure 2a. For the constant molar hydrogen flux profile, the average molar hydrogen flux is maintained along the reactor, unlike the linearly increasing hydrogen flux profile, where the maximum permeability is observed at the reactor exit, or the linearly decreasing hydrogen flux profile, where the maximum permeability is observed at the reactor inlet.

In Figure 2b, the changes in the hydrogen molar flowrate defined as the difference in hydrogen molar flowrate to the ethylbenzene fed, are plotted along the axial distance of the reactor for the conventional fixed reactor, and the catalytic membrane reactor operated isothermally and nonisothermally. The maximum reduction in hydrogen on the reaction side of the membrane reactor occurs with a linearly decreasing hydrogen flux, followed by a linearly increasing hydrogen flux, and then a constant hydrogen flux profile. This observation is consistent whether the membrane reactor is operated isothermally or nonisothermally.

The influence of the application of the linear molar hydrogen flux profiles on the styrene yield and selectivity to styrene is depicted in Figure 3. In Figure 3a, the styrene yield is plotted as a function of the reactor axial distance for both the conventional catalytic fixed reactor and the catalytic membrane reactor, operated with three

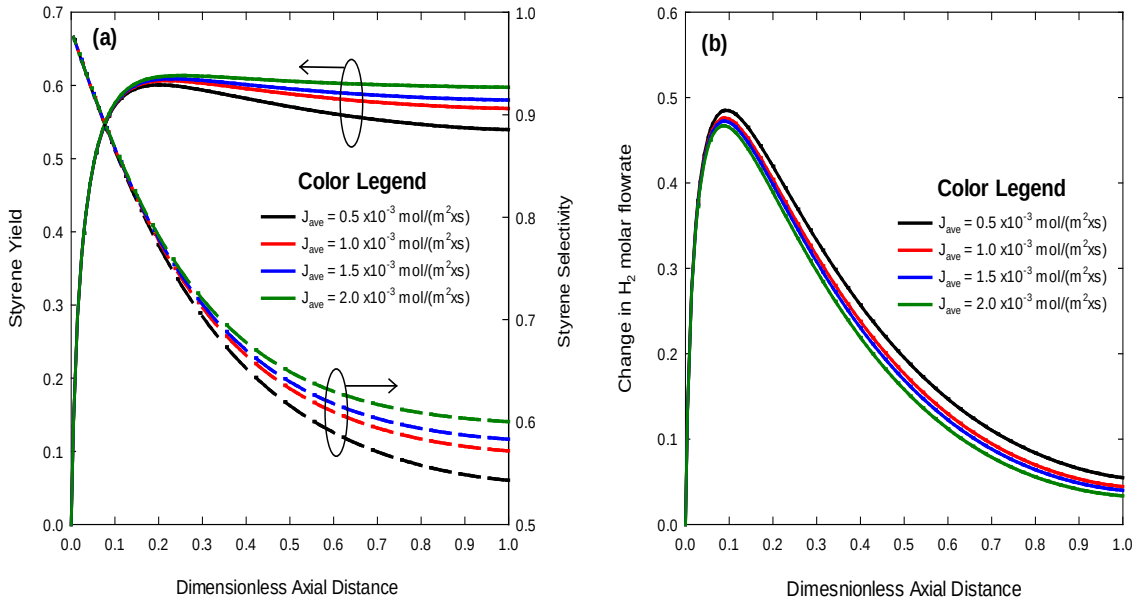

**Figure 4:** Influence of the average permeability of hydrogen on (a) styrene yield and selectivity to styrene and (b) change in hydrogen molar flowrate along the dimensionless axial distance of the reactor for the linearly decreasing hydrogen flux case.

different molar hydrogen flux profiles. It is found that the catalytic membrane reactor outperforms the conventional fixed-bed reactor, and the membrane reactor with a linearly decreasing hydrogen molar flux performs better than those with linearly increasing or constant hydrogen flux profiles.

This is because hydrogen permeation is significantly enhanced when linearly decreasing hydrogen flux profiles are used. The styrene selectivity along the reactor axial direction is plotted in Figure 3b. It is also observed that the performance of the catalytic membrane reactor with a linearly decreasing hydrogen molar profile exceeds that of conventional catalytic fixed reactors and of catalytic membrane reactors with linearly increasing or constant hydrogen flux profiles.

The effect of changing the average membrane permeability is assessed for a linearly decreasing hydrogen flux profile in Figure 4, where styrene yield, styrene selectivity, and change in hydrogen molar flowrate are plotted along the reactor axial distance. The values of $0.5\times10^{-3}$, $1.0\times10^{-3}$, $1.5\times10^{-3}$, and $2.0\times10^{-3}$ mol/(m$^2$×s) were chosen to evaluate the performance of the membrane reactor under a linearly decreasing molar flux profile.

In Figure 4a, both the styrene yield and the styrene selectivity are plotted as a function of membrane reactor length for all four values of membrane permeability. It is found that as permeability increases, both the overall styrene yield and the styrene selectivity increase from ~0.53 to ~0.60. This refers to the permeation of hydrogen whose molar flow rate change is plotted along the axial distance of the membrane reactor in Figure 4b. It is shown that as membrane permeability increases, the hydrogen flowrate decreases on the reaction side, thereby enhancing both the styrene yield and selectivity to styrene

The effect of nonlinearity in the creasing flux equation is depicted in Figure 5. For α=0.3, α=1.0, and α=2.0, three nonlinearly decreasing hydrogen flux profiles are plotted along the reactor axial distance in Figure 5a. It is observed that increasing the value of "α" increases permeability at the reactor inlet, and it is higher for α=0.3 than for α=1.0 or α=2.0.

In Figure 5b, both the styrene yield and the change in hydrogen molar flowrate are plotted as a function of the reactor dimensionless distance for α=0.3, α=1.0, and α=2.0. It is found that as the value of "α" decreases, the styrene yield enhances at the reactor inlet, where the hydrogen flux is significant due to the decrease in the hydrogen molar flowrate. This suggests that when ethylbenzene is dehydrogenated in a catalytic membrane reactor, the maximum permeation should occur at the reactor inlet, where the hydrogen molar flow rate is high.

The impact of introducing a permeation section in an existing fixed bed reactor is also assessed in this study. Linearly decreasing hydrogen flux profiles with an average hydrogen molar flow rate of $3.0\times10^{-3}$ mol/(m$^2$×s) are sketched along the reactor dimensionless axial distance

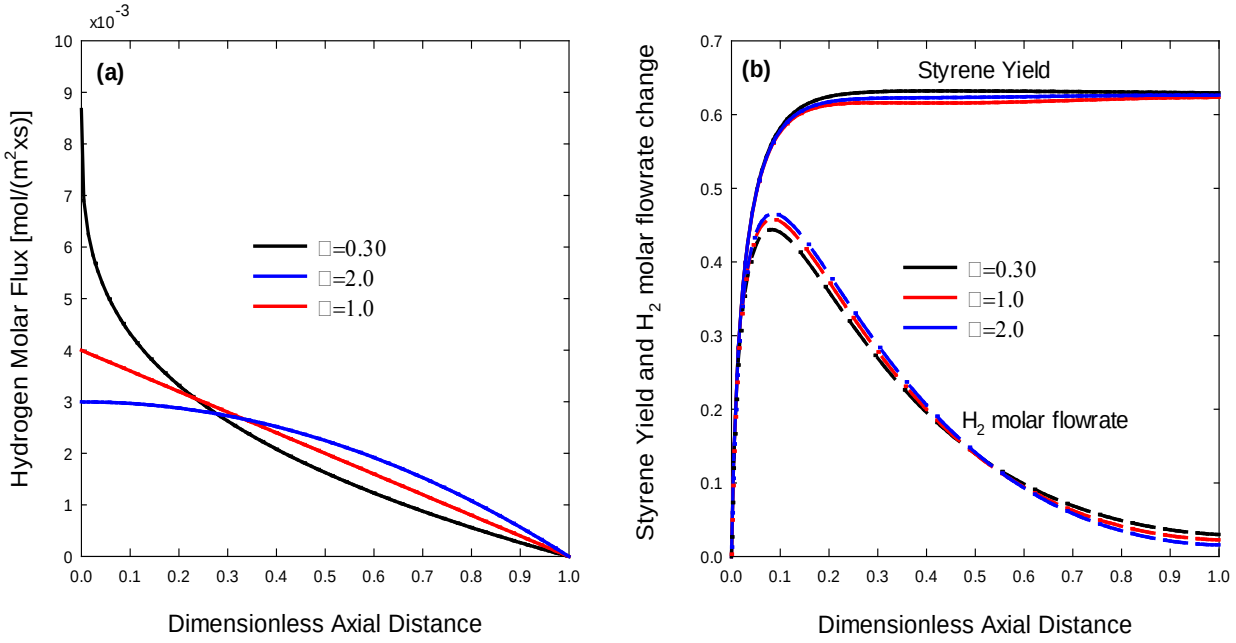

**Figure 5**: Influence of the nonlinearity in the hydrogen permeation model on (a) hydrogen flux, (b) styrene yield, and change in hydrogen molar flowrate along the dimensionless axial distance of the reactor for the linearly decreasing hydrogen flux case.

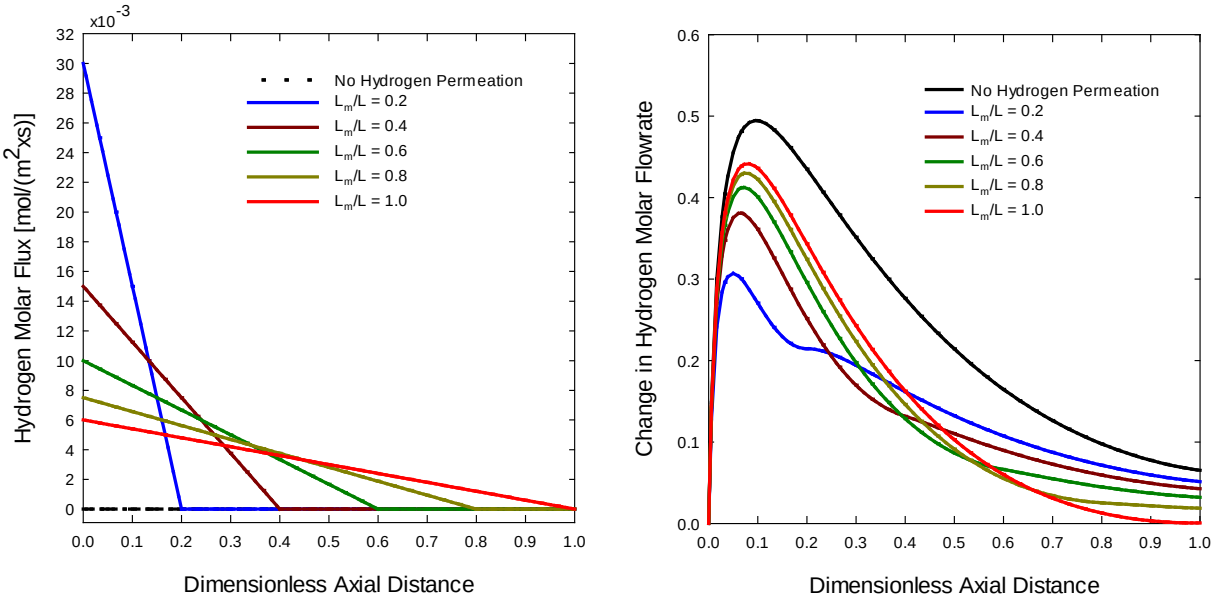

**Figure 6:** (a) decreasing hydrogen molar flux profiles applied at different fractions of the reactor length, (b) the corresponding change in hydrogen molar flowrate along the reactor axial distance.

in Figure 6a.

As the permeation fraction varies between 0.0 (non-permeable reactor) and 1.0 (Fully permeable reactor), a significant reduction in the hydrogen molar flow rate is observed, as shown in Figure 6b, compared to the conventional fixed bed reactor. The hydrogen molar flow rate increases at the beginning of the reactor due to the dehydrogenation of ethylbenzene, then falls after reaching a maximum at which the rate of hydrogen production is balanced by the rate of hydrogen permeation.

This shows that there is an optimal length when maximizing styrene production is the goal. The optimal

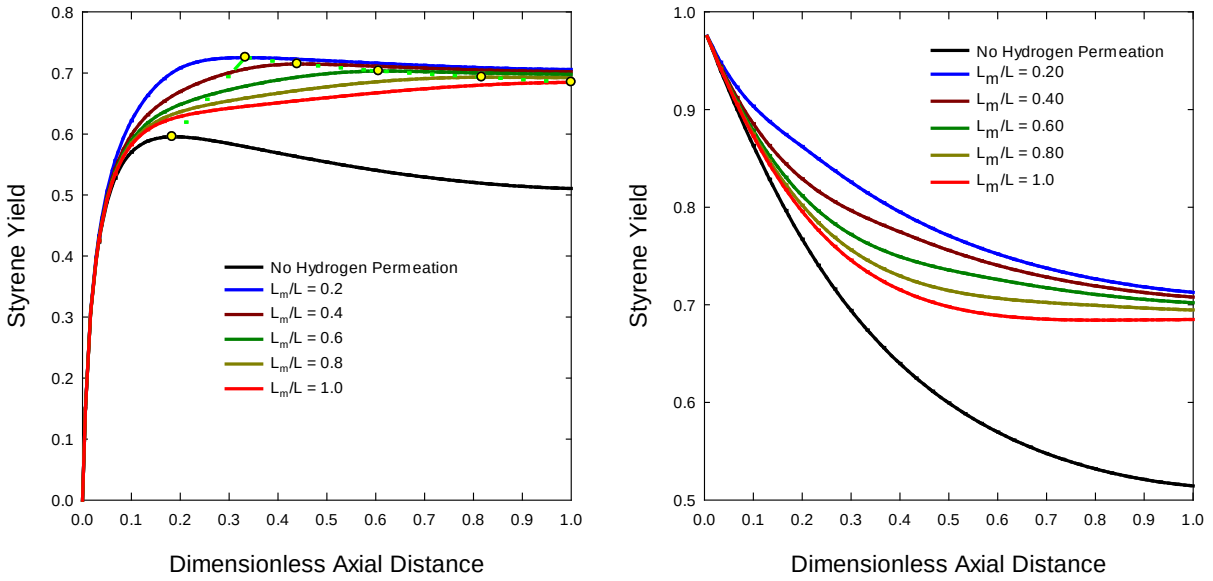

**Figure 7**: (a) styrene yield and (b) tyrene selectivity along the reactor axial distance for different fractions of the permeation section.

reactor fractional length is shown in Figure 7a by the light green curve, and a summary of the computed optimal reactor fractional length is given in Table 2. Based on the results summarized in Table 2, increasing the fraction of the permeation section within the reactor while maintaining the same average hydrogen permeation rate shifts the optimal reactor length to the right, improving yield. In general, the presence of a nonpermeating section in the reactor is detrimental, as it causes styrene to react with residual hydrogen to produce toluene. This unpleasant effect becomes more pronounced as the permeation section within the reactor is shortened. However, when a permeation section is placed around the point of maximum hydrogen production, the styrene yield in the reactor improves.

For instance, when the permeation section is placed within the first 20% of the reactor length, the predicted styrene yield is 0.73, the highest among all the trials considered. As far as styrene selectivity is concerned, it improves as the fraction of the reactor's permeation section increases.

**Table 2:** Summary of the optimal reactor length required to maximize styrene yield

| Applied fraction of the permeation section | Optimal Reactor fractional length | Maximum styrene yield | Comment |
|---|---|---|---|
| 0 | 0.18 | 0.60 | No Permeation |
| 0.20 | 0.33 | 0.73 | -- |
| 0.40 | 0.44 | 0.71 | -- |
| 0.60 | 0.61 | 0.70 | -- |
| 0.80 | 0.82 | 0.69 | -- |
| 1.0 | 1.00 | 0.68 | Fully Permeated reactor |

## CONCLUSION AND RECOMMENDATIONS

The computational analysis of the impact of applying theoretical molar hydrogen profiles on the performance of a catalytic membrane reactor used for the dehydrogenation of ethylbenzene to styrene has been conducted using a one-dimensional reactor model that accounts for changes in molar flowrate, temperature, and

pressure on both the reaction and permeate sides. Three main molar hydrogen profiles are tested, namely constant, linearly increasing, and linearly decreasing profiles, and the performance of the catalytic membrane reactor is assessed via styrene yield and selectivity to styrene. It is found that the reactor should be designed to achieve a maximum hydrogen permeation rate at the inlet section, thereby enhancing styrene yield and selectivity. This can be achieved by applying linearly decreasing molar hydrogen profiles, which are more attractive than constant or linearly increasing hydrogen permeation profiles. Yet, with linearly decreasing hydrogen permeation profiles, the reactor's performance can be further enhanced by adopting a shell-and-tube configuration, which increases the available surface area for hydrogen permeation. Hydrogen membranes with linearly decreasing hydrogen profiles can be fabricated by correlating the palladium distribution with the hydrogen permeation rate. The steam feeding strategy on the permeate side might also be used to adjust the permeation rate of existing membranes to match the linear hydrogen flux observed in this work. The application of these results can significantly promote the use of hydrogen membranes with varying permeabilities in chemical reactors, thereby reducing construction costs. In addition, the results here shed light on the optimal hydrogen flux trajectory required to maximize the styrene yield and selectivity. Adding a permeation section around the point where maximum hydrogen is observed is preferable and yields higher conversion than a completely permeable reactor.

## NOMENCLATURE:

$A_c$: reactor cross-sectional area, [m$^2$].
$D_p$: diameter of the catalyst pellet, [m].
$G$: mass velocity of the reacting mixture, [Kg/(m$^2$×s)].
$J_i(z)$: molar flux of species i along the axial distance of the reactor, [mol/(m$^2$×s)].
$J_{ave} or \bar{J}$: average molar flux of species i, [mol/(m$^2$×s)].
$n_i$: molar flowrate of species i in the reaction side of the reactor, [mol/s].
$L$: reactor length, [m].
$P$: Pressure in the reaction side of the reactor, [K].
$r_j^c$: catalytic reaction rate of j reaction, [mol/(Kg×s)].
$r_j^t$: thermal reaction rate of j reaction, [mol/(m$^3$×s)].
$T$: Temperature on the reaction side of the reactor, [K].
$T'$: Temperature on the permeate side of the reactor, [K].
$U$: overall heat transfer coefficient, [J/(m$^2$×K×s)].
$z$: reactor axial distance, [m].
$\zeta$: dimensionless reactor axial distance, [-].
$\mu$: Viscosity of the reacting mixture, [Pa×s].

## ABSTRACT

This work presents a data-driven surrogate modeling framework for predicting distillation behavior assuming an infinite number of stages and distillation limits informed by residue-curve topology and pinch-point feasibility analysis. The framework provides a direct mapping from feed composition and distillate-to-feed ratio (D/F) to distillate and bottom product compositions, making it suitable for flowsheet synthesis and optimization applications. The approach combines three components: a classifier that identifies feasible singular-point splits, a boundary regression model that predicts D/F limits separating pure- and mixed-product operating regimes, and a neural network that interpolates product compositions in the intermediate regime. The method is demonstrated for the ternary system ethanol, benzene, and water at 1 atm using data generated from rigorous vapor–liquid–liquid equilibrium analysis. Results show that the framework provides reliable predictions for pure splits while retaining smooth interpolation behavior in the mixed regime.

**Keywords**: Distillation, Surrogate Model, Machine Learning, Process Design, Modelling and Simulations

## INTRODUCTION

Modeling distillation behavior of multicomponent systems is central to conceptual process design. Cumbersome process simulations based on equilibrium stage models are computationally demanding, prone to numerical failure, and require numerous specifications. They are therefore typically avoided in early design phases in favor of shortcut models that focus on the general feasibility of a split rather than detailed apparatus design. Shortcut models typically assume an infinite number of theoretical stages and target the minimum energy demand for pinched separations, e.g., the Underwood method for constant relative volatilities or the rectification body method for general nonideal mixtures [1]. Such shortcuts require prespecified products for which feasibility is determined. In many applications such as flowsheet synthesis, a mapping from feed and split specifications (e.g. distillate-to-feed ratio ($D/F$)) to product composition is required instead.

If such a mapping is required, one could rely on heuristics to suggest preferred column products [2] or wrap existing shortcut models inside iterative loops that adjust product specifications until material balances and split specifications are met [3]. Heuristics often restrict the design space, for example by excluding non-sharp splits [2], while iterative loops can be slow and may fail to converge, particularly in nonideal and azeotropic settings [3]. Ryll et al. [4] propose direct mapping from feed specifications and $D/F$ to product compositions under infinite-stages and total reflux (∞/∞) assumptions; however, these methods are geometric, work only for discrete pressures, and are limited to four components [5] [6].

In this work, we address these limitations by proposing a data-driven surrogate model for distillation columns assuming an infinite number of stages and operating under general distillation limits defined by residue-curve behavior at total reflux and pinch point-based feasibility limits. The key objective is a deterministic, direct mapping from the molar feed composition and molar $D/F$ to the distillate and bottom molar compositions for *a priori* defined systems of any vapor–liquid equilibrium (VLE) topology. Accordingly, these models serve as tailor-made surrogates for feasibility studies in conceptual process design, intended for flowsheet synthesis and machine learning (ML)-based process optimization, where a

large number of process alternatives have to be screened before optimizing the column parameters (e.g., number of stages, reflux ratio) in detail.

Data-driven surrogate models have been used successfully for distillation column design and optimization, including neural network-based [7-9] and Gaussian process-based [10, 11] models for different column configurations. Further, Panofen et al. [12] have recently proposed a surrogate model of distillation boundaries in azeotropic multicomponent mixtures. However, data-driven surrogates are always tailor-made for, and thus limited to one specific task. To the best of our knowledge, no surrogate currently exists for predicting distillation column products at the limiting cases of an infinite number of stages and distillation boundaries informed by residue-curve topology and pinch-point feasibility analysis. We close this gap with the present work.

We present results for ternary systems, although the methodology is in principle not limited and can be extended to multicomponent systems when sufficient computational power is available during training. The resulting surrogate model can be used in any flowsheet synthesis problem. Because the applied ML-based models evaluate quickly and robustly, it is particularly suited for optimization methods that identify flowsheet concepts, such as superstructure optimization and ML-based flowsheet design [3], where numerous flowsheet evaluations are needed.

## METHODOLOGY

### Overview

The objective is a direct and deterministic mapping from feed composition and $D/F$ to the corresponding product compositions,

$$(\boldsymbol{z}, D/F) \rightarrow (\boldsymbol{x}, \boldsymbol{y}), \tag{1}$$

where $\boldsymbol{z} = (z_1, z_2, \ldots, z_n)$ denotes the mole fractions of the feed an $n$-component mixture with $\sum_{i=1}^{n} z_i = 1$, $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)$ the distillate's mole fractions, and $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)$ the bottom product's mole fractions.

The training data for this mapping are generated using the Automated Process Synthesis (APS) Tool v1.0 [2], which performs thermodynamically rigorous VLE analysis of multicomponent mixtures. The APS Tool identifies azeotropes, distillation regions, and feasible singular-point splits, that is, separations involving pure components or azeotropes, using general distillation limits defined by residue-curve topology and continuation-based pinch-branch calculations. Residue curves characterize separation behavior in the total reflux limit, whereas pinch lines describe the limiting behavior of reversible columns operated at finite reflux. A split is considered feasible if it is admissible under either limiting case. Consequently, the feasible split set identified by the APS Tool represents the outer envelope of thermodynamically admissible separations for a given feed.

In the present work, these identified limiting singular-point splits are used as anchors for surrogate modeling. Once the limiting products are known, the separation behavior between them can be represented in terms of $D/F$, without explicitly distinguishing the underlying reflux mechanism.

A straightforward approach to learning the mapping in Eq. (1) would be to train a sufficiently large neural network directly on input—output data. While feasible, this approach was found to exhibit inconsistent accuracy in predicting azeotropic compositions and occasionally produced slightly impure product compositions in cases where a pure-product split is expected.

To address these limitations, we propose embedding the neural network into a structured hierarchical learning framework that leverages knowledge on distillation theory to guide the training process and enhance physical interpretability. The overall structure of the proposed framework is illustrated in Figure 1.

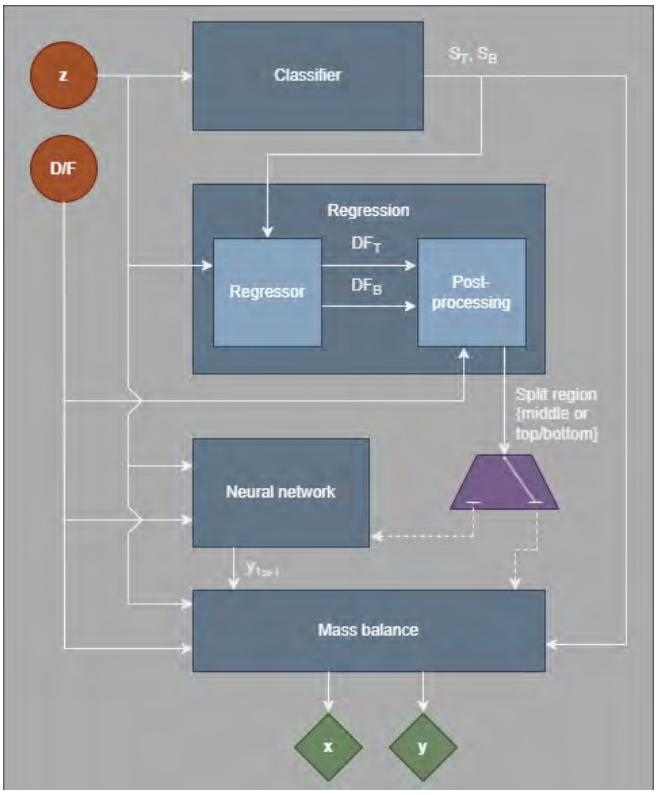

**Figure 1.** Hierarchical surrogate framework integrating data-driven models for predicting distillation behavior.

At the beginning of the pipeline, two learning tasks are introduced to extract physically interpretable information about the separation before predicting the compositions $(\boldsymbol{x}, \boldsymbol{y})$. The first task is a classification problem

that determines, based on $\boldsymbol{z}$, which singular points in the VLE act as unstable and stable nodes of the distillation lines governing the splits. The second task is a boundary regression that predicts the limiting $D/F$ values associated with attainable singular-point separations for given feed composition $\boldsymbol{z}$ and singular points determined in the classifier.

In certain cases, the product compositions can be determined directly from the outcomes of these two tasks. For example, when separation to a pure singular-point product is feasible at a given $D/F$, the corresponding distillate or bottom compositions coincide with the composition of that singular point. Only for $D/F$ values that do not admit a pure singular-point split, is the neural network used to predict the product compositions.

Both the classifier and the boundary regressor are entirely data-driven, with the required labels obtained and stored during the data-generation process. Overall, the proposed hierarchical framework effectively *distills* VLE knowledge into a data-driven surrogate model that is computationally efficient, numerically stable, and well-suited for flowsheet synthesis and ML-based process synthesis.

## Data generation and representation

The training data are derived from rigorous VLE analyses performed with the MATLAB-based APS Tool. The proposed framework approximates these results while preserving physical interpretability and numerical robustness. Rather than relying on repeated evaluations with the APS Tool, physically meaningful separations are extracted from the tool's thermodynamic analyses and combined with material-balance calculations to determine the $D/F$ value corresponding to a particular product split. This information can then be embedded into predictive models that accept $D/F$ as an explicit input and can be evaluated efficiently in a Python-based environment.

First, a separation system is defined by specifying pure-component properties, such as Antoine equation parameters, together with a binary activity coefficient model. Based on this thermodynamic description, the singular points of the system are identified. The finite set of thermodynamically admissible singular points as top products is denoted as $\boldsymbol{S_T} = \{s_{T,1}, s_{T,2}, \dots, s_{T,K}, \varnothing_T\}$, and the corresponding set for bottom products by $\boldsymbol{S_B} = \{s_{B,1}, s_{B,2}, \dots, s_{B,K}, \varnothing_B\}$, where $\varnothing_T$ and $\varnothing_B$ denote the absence of a feasible pure distillate or pure bottom split, respectively.

Feed compositions $\boldsymbol{z}$ are then systematically sampled over the composition simplex. The evaluated feeds evenly cover the simplex, as studies on surrogate models show that such coverage reduces error and delivers large speedups when embedded later in flowsheet optimization [12]. For each feed composition, a one-hot encoding is assigned to indicate which elements of $S_T$ and $S_B$ correspond to feasible top and bottom splits, respectively. In addition, the corresponding product compositions $\boldsymbol{y}$ and $\boldsymbol{x}$ for the pure split at the maximum achievable yield are provided.

The APS Tool may identify multiple competing singular points for a given feed composition, for example near distillation boundaries where more than one pure top or bottom product is theoretically feasible. In such cases, expert judgment is applied to select the most appropriate split.

Once the singular-points splits have been identified, two critical values of $D/F$ are defined for each feed composition: $DF_T$, the maximum $D/F$ at which a pure distillate is achievable, and $DF_B$, the minimum $D/F$ at which a pure bottom product is achievable. These values are calculated from a component-wise molar balance,

$$z_i = y_i(D/F) + x_i(1 - D/F). \tag{2}$$

The resulting values partition the operating space into three regimes:

Top: $0 < D/F \leq DF_T$,

Middle: $DF_T < D/F < DF_B$

Bottom: $DF_B \leq D/F < 1$.

If no pure distillate split exists for a given feed, $DF_T$ is set to zero, and if no pure bottom split $DF_B$ is set to one. This information constitutes the complete dataset required to train the classifier and boundary regressor.

To train the neural network, additional data are generated to capture the relationship outlined in Eq. (1). For singular-point splits, product compositions are computed for pure-product yields $Y_i$ ranging from $Y_i$ =0.01 to the maximum feasible yield. An example of such data points for a single feed composition in a ternary mixture of ethanol, benzene, and water at 1 atm is illustrated in Figure 2.

The feed selected in Figure 2 corresponds to a separation governed by residue-curve topology, such that the intermediate operating points remain consistent with the distillation boundary associated with the total-reflux limit. Data points corresponding to a pure bottom split (orange circles) represent the bottom operating regime at high $D/F$ values ($D/F$ = 0.78-0.99), whereas points associated with a top split with a minimum ternary azeotrope (red squares) represent the top operating regime at low $D/F$ values ($D/F$ = 0.003-0.33).

Data for the middle operating regime are generated by interpolating between the limiting pure splits. When a feed admits both a pure distillate and bottom product, intermediate compositions are sampled along the discretized binary line connecting the corresponding pure-split product compositions, as indicated by the green diamonds in Figure 2. For each sampled composition, the corresponding $D/F$ is computed using Eq. (2).

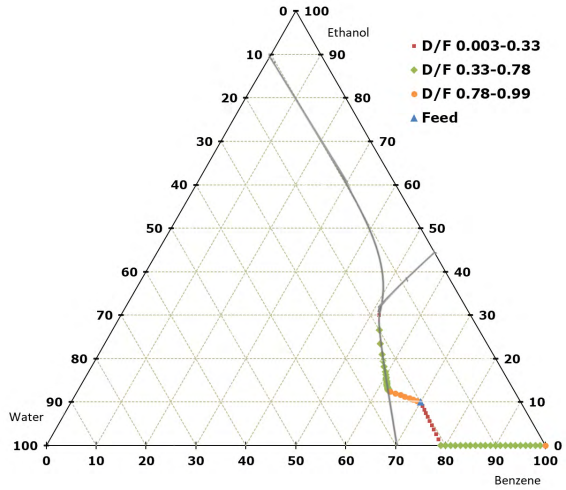

**Figure 2.** Example data points for ternary system collected using APS Tool [2]. Separation behavior falls within limits of residue-curve topology.

Figure 3 illustrates a case in which the selected feed admits feasible operating points associated with pinch-line feasibility. In this case, some middle-regime data points extend beyond the residue-curve-based distillation boundary, reflecting admissible separations under reversible-column limits. Both types of behavior are retained in the training dataset and treated as physically admissible by the surrogate framework.

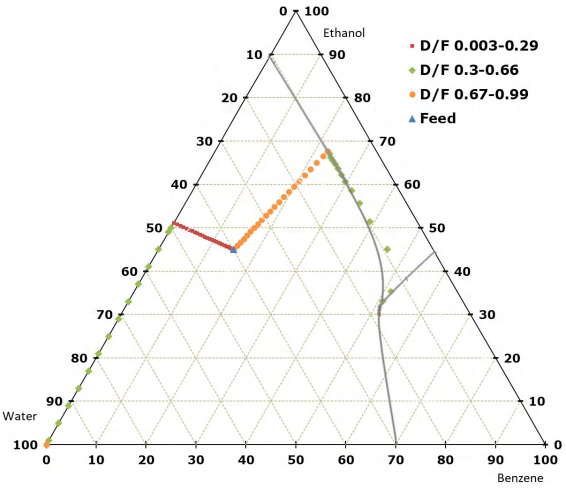

**Figure 3.** Example data points for ternary system collected using APS Tool [2]. Separation behavior falls within limits of pinch-line feasibility analysis.

Moreover, due to the geometry of the distillation boundaries and pinch-points limits, the resulting $D/F$ values along these interpolation paths do not necessarily vary monotonically. This further motivates the use of a neural network to learn the relationship between $D/F$ and product composition in the middle regime. In addition, numerical convergence issues may arise in rigorous VLE calculations for certain intermediate operating points, motivating the development of a surrogate model capable of delivering robust predictions across the full operating range.

## Singular point split classification

The first ML task addresses the identification of singular-points for a given feed composition. The input to this task is the reduced feed composition vector $\tilde{\boldsymbol{z}} = (z_1, z_2, \dots, z_{n-1})$ for an $n$-component system. The output is a one-hot encoded vector over the predefined sets $S_T$.and $S_B$, indicating which singular points correspond to the top and bottom splits, respectively, for the given feed compositions.

The model employs a histogram-based gradient boosting classifier implemented in the *scikit-learn* library in Python. This method constructs an ensemble of decision trees sequentially, where each tree is trained to correct misclassifications of the current ensemble. The histogram-based discretization of the input space improves numerical robustness and computational efficiency while preserving the ability to represent nonlinear decision boundaries in the composition simplex.

The trained classifier yields a discrete and interpretable mapping from $\tilde{\boldsymbol{z}}$ to $S_T$.and $S_B$ within the training domain.

## Operating regime prediction via boundary regression

The regression task is formulated as a boundary regression problem. Two continuous regression models are trained to predict the functions $\widehat{DF}_T = f_T(\tilde{\boldsymbol{z}}, S_T, S_B)$ and $\widehat{DF}_B = f_B(\tilde{\boldsymbol{z}}, S_T, S_B)$. The operating regime for a queried $D/F$ value is then obtained by comparison with these predicted boundaries.

Explicit constraints are enforced to ensure physically consistent predictions, including clamping predicted ratios to the interval [0, 1] and enforcing the condition $\widehat{DF}_T \geq \widehat{DF}_B$. The regression models are implemented using histogram-based gradient boosting regressors from the *scikit-learn* library, which efficiently capture nonlinear boundary surfaces over the composition simplex while remaining numerically robust.

## Neural network for impure product splits

For operating points in the middle regime, product compositions are predicted using a feed-forward neural network implemented in Python with *PyTorch*. The network is trained as a regression model that maps $\boldsymbol{z}$ and $D/F$ to the distillate compositions $\tilde{\boldsymbol{y}} = (y_1, y_2, \dots, y_{n-1})$. The remaining $y_n$ and corresponding bottom compositions $\boldsymbol{x}$ are computed from an overall material balance.

## Product composition reconstruction

The final product compositions are predicted using a hybrid reconstruction strategy that combines analytical material balances and the neural network prediction. In the top and bottom regimes, product compositions are computed using Eq. (2) consistent with the corresponding limiting pure split. For operating points in the middle regime, the neural network is used to predict product compositions.

To ensure physical feasibility, all predicted compositions are postprocessed to satisfy component-wise material constraints. For a given $D/F$, the distillate mole fractions must satisfy

$$y_i \leq \min\left(1, \frac{z_i}{D/F}\right), \tag{3}$$

reflecting that a distillate stream cannot be in excess of its availability in the feed. If necessary, the predicted distillate vector is projected onto the feasible composition simplex under these caps, ensuring nonnegativity and a unit sum. Once a feasible distillate composition is obtained, the bottom composition is computed from the overall material balance (see Eq. (2)).

## EXAMPLE CASE STUDY

The proposed framework is demonstrated using the ternary mixture of ethanol, benzene, and water at 1 atm, modeled using the Non-Random Two-Liquid (NRTL) $g^E$-model [13] with parameters taken from Aspen Plus [14]. The mixture exhibits a liquid-liquid phase split and four minimum azeotropes (three binary, one ternary; two homogeneous, two heterogeneous). The set $S_B$ comprises pure bottom splits yielding ethanol, benzene, or water, as well as the absence of a pure bottom split. Since all feasible compositions admit a top split with the ternary minimum azeotrope, the set $S_T$ contains only a single option and yielding a trivial classification task.

Data for split classification and operating regime prediction are generated with approximately 124, 000 feed compositions samples across the VLE simplex. The samples are drawn from a structured grid with component mole fractions in the range $0.002 \leq z_i \leq 0.996$. To avoid artificial grid-induced artifacts and improve generalization, small Gaussian perturbations with standard deviations of $\sigma = 0.0003$ are added to the sampled compositions. This stochastic smoothing prevents the classifier and regression models from memorizing grid-aligned decision boundaries and encourages learning of physically meaningful, continuous separation surfaces in the composition space.

A comparatively high sampling density is used for classification and boundary regression tasks because these models must resolve sharp transitions between distillation regions and accurately capture singular-point behavior near curved distillation boundaries. In addition, generating training data for pure splits is computationally efficient, as it requires only the identification of limiting separation behavior, rather than singular points across the entire operating range.

In contrast, training data for the neural network are generated using feed compositions in the range of $0.02 \leq z_i \leq 0.96$. For middle-regime splits, product compositions are generated along the binary line connecting the pure bottom split and the bottom composition associated with the pure distillate split, as described above and outlined in Figures 2 and 3. These compositions are sampled in increments of $\Delta z_i = \pm 0.01$. In total, approximately 293, 000 data points are generated for neural network training.

## Results

### Classifier

The pure-split classification model was evaluated on 4, 851 validation feed compositions that were not used in the training dataset, with component mole fractions in the range $0.01 \leq z_i \leq 0.98$. The results of the evaluation are shown in Figure 4, which shows the predicted pure bottom split for each feed composition $\boldsymbol{z}$ selected from the admissible set $S_B$.

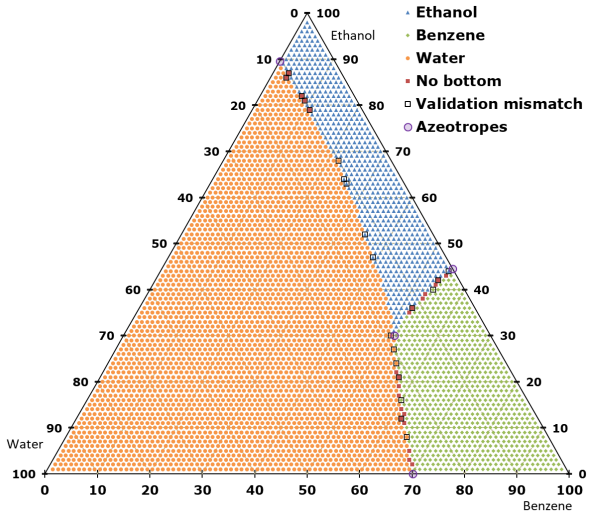

**Figure 4.** Validation run for singular-point split classification.

Of the analyzed feed compositions, only 21 showed mismatches with the expected splits. Notably, all of these cases occur at distillation boundaries separating feasible pure splits. In eight cases, the model predicted an incorrect pure bottom component, while in the remaining 13 cases it incorrectly classified whether a pure bottom split exists at the boundary point. Further improvements could be achieved by increasing the training density or applying additional weighting for feed compositions near distillation boundaries. In addition, incorporating confidence

measures based on the consistency of predictions in a local neighborhood of the composition space could enable the use of fallback strategies or alternative predictors when the model encounters uncertain splits.

## Regression

The operating regime regression model was evaluated using the same validation set by comparing queried $D/F$ values against the predicted $DF_T$ and $DF_B$ boundaries. The predicted $DF_T$ values exhibited a mean absolute error of $|\varepsilon_T|$ = 0.0039 with a standard deviation of $\sigma_T$ = 0.0056, with a maximum observed error of $\varepsilon_T$ = 0.0178. The prediction error for $DF_B$ was slightly greater, with a mean absolute error of $|\varepsilon_B|$ = 0.0062 and a standard deviation of $\sigma_B$ = 0.0129. The two largest errors, $\varepsilon_B$ = 0.277 and $\varepsilon_B$ = 0.194, occurred for feed compositions where the bottom split was misclassified by the singular-point classifier, with ethanol predicted as the bottom product instead of water. Both cases lie near distillation boundaries, underscoring the sensitivity of the regression task to accurate split classification near these regions. While this suggests that additional fine-tuning of the classifier could reduce such errors, alternative strategies for improving the regression model could also be explored, including the use of different regression architectures or uncertainty-aware regression formulations.

## Neural Network

The neural network is trained using mini-batch gradient descent with the Adam optimizer and a mean-squared-error (MSE) loss function. Key modeling choices, including data normalization, loss formulation, validation strategy, optimization settings, and stopping criteria, were systematically evaluated. A randomized train–validation split with a fixed random seed and early stopping based on validation loss were selected to balance accuracy and generalization. Among the tested configurations, a network with three hidden layers of 32 neurons each achieved the best validation performance, with an MSE of $2.36 \times 10^{-5}$.

## Overall model

The full predictive framework was evaluated using representative feed compositions by first generating reference product compositions and the corresponding $D/F$ values using the APS Tool. Figure 5 illustrates four representative cases. The first three feed compositions (cases (a)-(c)) were selected for their location within distinct distillation regions, for which a pure bottom split is expected. The fourth (case (d)) was chosen because it represents a composition for which the singular-point classifier produced a mismatch. The APS Tool-derived $D/F$ values were provided as inputs to the hybrid surrogate and neural network models, and the resulting product compositions were compared against the APS reference data.

Although the hybrid surrogate and standalone neural network show similar overall agreement with the APS Tool data in cases (a)-(c), closer inspection reveals qualitative and quantitative differences in performance. In particular, for cases (a) and (b), the standalone network fails to correctly reproduce the expected pure-bottom product splits at high $D/F$ values where thermodynamics dictates a pure split. The hybrid surrogate successfully predicts the compositions of these pure splits, as pure-split compositions are enforced by construction.

These discrepancies are reflected in the error statistics summarized in Table 1, which report the mean absolute error of the predicted product composition vectors relative to the APS Tool reference, evaluated across all components simultaneously and averaged over all considered $D/F$ values for each split.

**Table 1:** Comparison of prediction errors between hybrid surrogate and neural network for representative feed compositions.

| | Prediction error (mean ± std. dev.) | |
|---|---|---|
| **Case study** | **Surrogate model** | **Neural network** |
| (a) | $4.17\times10^{-4}$ | $3.57\times10^{-3}$ |
| | $\pm2.82\times10^{-3}$ | $\pm2.54\times10^{-2}$ |
| (b) | $3.32\times10^{-5}$ | $1.69\times10^{-3}$ |
| | $\pm1.58\times10^{-4}$ | $\pm1.15\times10^{-2}$ |
| (c) | $8.56\times10^{-5}$ | $3.23\times10^{-4}$ |
| | $\pm7.11\times10^{-4}$ | $\pm7.59\times10^{-4}$ |
| (d) | $1.26\times10^{-1}$ | $1.10\times10^{-2}$ |
| | $\pm2.83\times10^{-1}$ | $\pm2.53\times10^{-2}$ |

For cases (a)-(c), the hybrid surrogate achieves lower mean errors, on the order of $10^{-5}$-$10^{-4}$, compared with $10^{-4}$-$10^{-3}$ for the neural network, and shows substantially lower variability. In particular, the standard deviations of the surrogate predictions remain less than $3\times10^{-3}$, whereas the neural network exhibits standard deviations exceeding $1\times10^{-2}$ for all splits. These differences also arise from the tendency of the neural network to produce inconsistent predictions of the ternary azeotrope composition, whereas the hybrid surrogate enforces exact singular-point compositions.

For the feed corresponding to the classifier mismatch (case (d)), errors show the opposite trend. The neural network exhibits a lower mean error than the hybrid surrogate, whose errors increase substantially due to the incorrect pure-split classification of ethanol instead of water, as seen in Figure 5. In this case, the surrogate predictions trend toward the misclassified bottom split, whereas the neural network captures a smooth transition toward the correct split. This behavior suggests that additional uncertainty-aware handling near classification boundaries could further improve the hybrid framework.

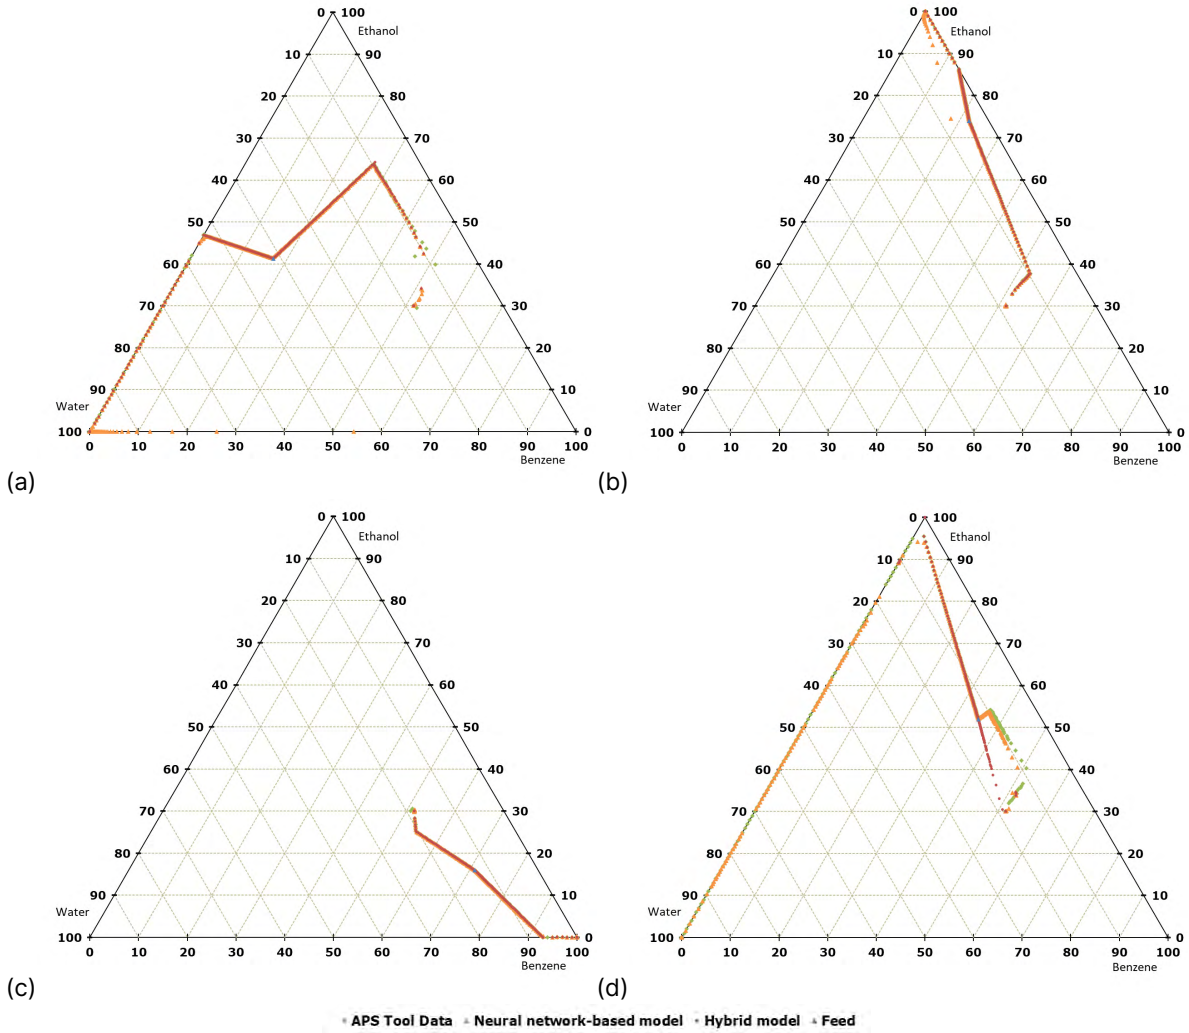

**Figure 5.** Hybrid surrogate vs. neural network-based product predictions for four feed compositions from different distillation regions

Nonetheless, due to its consistency and accuracy in predicting pure splits and its physically constrained behavior across operating regimes, the proposed hybrid surrogate provides a more reliable overall predictor than a purely neural network-based approach.

## CONCLUSION

This work presents a structured, data-driven surrogate modeling framework for predicting distillation behavior under infinite-stage assumptions, operating within distillation limits informed by residue-curve behavior at total reflux and pinch point-based feasibility analysis. The framework provides a direct and deterministic mapping from feed composition and distillate-to-feed ratio to product compositions, making it well-suited for flowsheet synthesis and optimization applications in early conceptual design that require repeated and robust column evaluations. By decomposing the overall problem into a singular-point split classification task, an operating regime boundary regression, and a neural network-based predictor for impure splits, the approach combines physical interpretability with numerical robustness and computational efficiency.

The results demonstrate that the proposed framework reliably predicts feasible pure splits and operating regimes across the example ternary composition space of ethanol, benzene, and water. In particular, the combination of the classifier and regime regression outperforms a purely neural network-based predictor for pure splits, where exact reproduction of singular-point compositions is essential. The neural network, on the other hand, is well-suited for interpolating product compositions in the middle regime between limiting pure splits, as well as for feed compositions associated with greater uncertainty in the feasible bottom split. This hybrid

structure allows each modeling component to be applied where it is most effective, resulting in improved consistency and physical fidelity.

While the current implementation represents a significant step toward practical surrogate models for nonideal distillation systems, several opportunities for further improvement remain. The accuracy of the regime boundary predictions could be further refined, and the data generation workflow should be streamlined to reduce manual intervention and computational effort. In addition, the present framework is limited to fixed-pressure operation. Extending the model to include pressure as an additional input would require expanded training data and, in the case of azeotropic singular points, prediction of pressure-dependent azeotrope compositions. A longer-term objective is the development of a more general surrogate model that incorporates thermodynamic descriptors as inputs, enabling application to previously unseen chemical systems.

## ABSTRACT

Activity coefficients are key thermodynamic quantities for describing phase equilibria, but their experimental determination entails laborious and costly phase-equilibrium measurements, making predictive approaches highly desirable. The potential of machine learning for such predictions has received growing attention as an alternative to physics-based models that require experimental data or expensive calculations for parameterization. We propose a physics-informed edge-enhanced graph attention network (PEGAT) to predict activity coefficients in multicomponent mixtures, where each molecule is encoded as a graph in which the nodes correspond to atoms and the edges to chemical bonds. The excess Gibbs free energy of the mixture is predicted using the proposed model, including a nonlinear transformation in the final layer to ensure that the excess Gibbs free energy vanishes for pure components. To further enforce thermodynamic consistency, the relevant activity coefficients are obtained via the Gibbs–Duhem relation. Unlike machine-learning models developed primarily for binary systems, the proposed framework is directly applicable to arbitrary multicomponent mixtures. The PEGAT model is evaluated using a mixed dataset comprising both binary and ternary mixture data and demonstrates high predictive accuracy. Further validation on representative mixtures shows close agreement between predicted and reference activity coefficients. The results confirm that improved thermodynamic consistency can be achieved by embedding hard physical constraints into the graph neural network architecture. However, they also highlight that unphysical behaviors may still be predicted despite these constraints.

**Keywords**: Machine Learning, Graph Neural Network, Activity Coefficients, Physics-informed, Thermodynamic consistency

## INTRODUCTION

Activity coefficients are fundamental thermodynamic quantities that can describe phase equilibria and reaction kinetics by accounting for non-ideal interactions through the chemical potentials of liquid mixtures [1]. The accurate prediction of activity coefficients is therefore essential for reliable modelling of vapor–liquid, liquid–liquid, and solid–liquid equilibria, as well as for assessing reaction feasibility in non-ideal liquid phases. Inaccurate activity-coefficient predictions can lead to erroneous estimates of phase behavior, such as spurious phase separation or miscibility gaps, which may ultimately result in infeasible process designs.

However, the experimental determination of activity coefficients is typically laborious, time-consuming, and costly, particularly for multicomponent mixtures where composition space grows combinatorially. Such experimental efforts are often impractical during early-stage molecular and/or process design, where the rapid evaluation of the properties of a large number of candidate mixtures and process conditions is required. Consequently, predictive thermodynamic models for activity coefficients play a central role in computer-aided mixture and blend design (CAM$^{b}$D) frameworks and in process design, enabling the efficient exploration of mixture

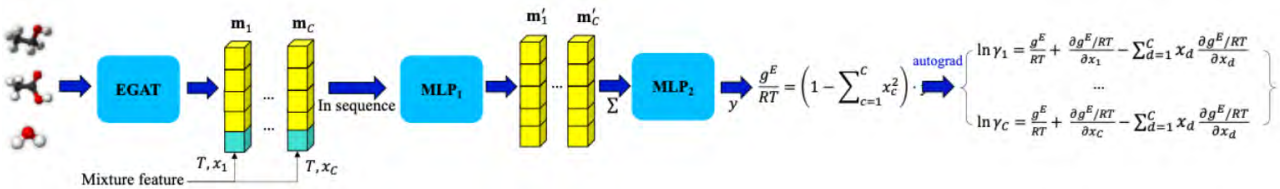

**Figure 1.** Schematic illustration of the proposed PEGAT model architecture. The edge-featured graph attention network (EGAT) converts molecules into latent space embeddings, followed by multi-layer perceptrons (MLPs) to capture the inherent nonlinearity. The derivatives with respect to composition are obtained through automatic differentiation (*Autograd* library).

space and/or informed optimization of process operating conditions [2].

A variety of thermodynamic models based on different physical principles have been developed for activity coefficient prediction, including local composition models such as NRTL [3], group-contribution approaches such as UNIFAC [4] and SAFT-γ Mie [5], and quantum chemical approaches exemplified by COSMO-RS [6]. Although these models have been successfully applied to a wide range of systems, their applicability is often limited by the availability of interaction parameters and the computational cost / effort required in modelling systems that fall outside of existing parameter sets. For instance, both UNIFAC and SAFT-γ Mie models rely on predefined group definitions and associated parameters, which restrict their use for molecules containing novel functional groups or lacking reliable parameterization. For COSMO-type models, costly quantum chemical calculations are required to generate the $\sigma$-profile data of new compounds. These limit the applicability of the methods for large-scale screening and early-stage process design. Overall, the transferability and generalization of these models to new mixtures, particularly those involving novel compounds or novel mixtures, remains limited.

Recently, supervised learning approaches have been widely leveraged to predict properties by learning structure–property relationships [7]. For example, Sanchez Medina et al. [8] trained a graph neural network (GNN) to predict infinite dilution activity coefficients at 298.15 K and achieved competitive performance compared to the UNIFAC and COSMO-RS methods. Winter et al. [9] employed a transformer model for binary activity coefficient prediction from SMILES for a temperature range from 273.15 to 598.15 K. Qin et al. [10] developed several SolvGNN models by adding hydrogen bonding features to capture intermolecular interactions and trained separate models for activity coefficients in binary and ternary mixtures, based on datasets generated from COSMO-RS at 298.15 K.

However, due to their black-box nature, machine learning models do not inherently guarantee the thermodynamic consistency of the predictions. To overcome this limitation, embedding physical knowledge is essential. Combining machine learning models with existing thermodynamic models has been attempted [11], but while effective, this approach is limited by the accuracy of the chosen thermodynamic model. Instead, Rittig et al. [12] developed a physics-informed GNN model for binary mixtures by imposing a Gibbs-Duhem penalty when training with a synthetic dataset at 298.15 K [10]. The model was later refined by embedding the Gibbs-Duhem relation as a hard constraint to obtain the activity coefficients in binary mixtures with the same dataset [13]. Specht et al. [14] proposed a hard-constraint neural network, called HANNA, trained on experimental data for binary mixtures at multiple temperatures. HANNA uses a pretrained model to convert a SMILES representation into a latent space and enforces thermodynamic consistency by incorporating the Gibbs-Duhem relation into the model as well as applying a nonlinear transformation to ensure that the predicted activity coefficients recover the correct behavior in the pure-component limit. HANNA was later improved by introducing a geometric projection method to represent the interactions between component pairs [14], thereby allowing the model to map the Gibbs excess free energy $g^{\mathrm{E}}$ trained from binary mixture data into multicomponent space. Nevertheless, such projections neglect the presence of higher-order interactions among the components when calculating the pairwise interactions.

Motivated by these earlier works, this paper proposes a physics-informed edge-enhanced graph attention network (PEGAT) model for thermodynamically consistent activity coefficient prediction. Rather than relying on a projection step, the PEGAT is designed to handle mixtures with an arbitrary number of components and to predict the overall Gibbs excess free energy directly. The corresponding activity coefficients are then computed using the Gibbs-Duhem relation. This formulation enables the model to be trained on heterogeneous, multi-source datasets that include not only binary mixtures but also higher-order multicomponent systems, with a potential to enhancing the model's generalisation capability.

# METHODOLOGY

The proposed PEGAT model architecture in Figure 1 implements an edge-featured graph attention network (EGAT) submodule to convert graphs into latent embeddings. These embeddings are further processed by two multi-layer perceptrons (MLPs) to predict the overall Gibbs excess free energy $g^{\mathrm{E}}$ and finally the activity coefficients as $\ln \gamma_c$. Details of the model can be found below.

## Data Preparation

For the purpose of developing the model architecture, a synthetic dataset of activity coefficient values derived from COSMO-RS calculations is used [10], including 280, 000 binary and 160, 000 ternary mixture datapoints. The dataset is split into training (70%), validation (20%) and test (10%) subsets. Each molecule in a mixture is converted from a SMILES string into a graph $G = (V, E)$ using the *RDKit* package [15]. The nodes $v_i \in V$ represent the atoms in a molecule, and the edges $e_{ij} \in E$ describe the chemical bonds between atom $i$ and $j$. With one-hot encoding, a 77-dimensional feature vector is generated for each node (Table 1) and a 16-dimensional feature vector for each edge (Table 2).

## EGAT Module

Unlike other message-passing GNN models, the PEGAT model introduces an attention mechanism to update the node and edge features for obtaining a better representation. After a transformation through simple networks, each node $v_i \in V$ is associated with an initial atomic feature vector $\mathbf{h}_i^0 \in \mathbb{R}^h$ and each edge $e_{ij} \in E$ is associated with an initial bond feature vector $\mathbf{e}_{ij}^0 \in \mathbb{R}^e$.

At the $l^{\text{th}}$ layer and $n^{\text{th}}$ attention head in EGAT, the unnormalised attention score between node $i$ and node $j$, $s_{ij}^{l,n}$, is defined by incorporating the edge feature as follows:

$$s_{ij}^{l,n} = \mathrm{LeakyReLU}(\boldsymbol{\beta}^T[\mathbf{W}_h^n \mathbf{h}_i^l \parallel \mathbf{W}_h^n \mathbf{h}_j^l \parallel \mathbf{W}_e^n \mathbf{e}_{ij}^l]) \quad (1)$$

where $\mathbf{W}_h^n$ and $\mathbf{W}_e^n$ are learnable linear transformations for node and edge features at the $n^{\text{th}}$ attention head. The $\parallel$ refers to vector concatenation and $\boldsymbol{\beta}^T$ is the attention vector. The attention coefficients are obtained via softmax:

$$a_{ij}^{l,n} = \frac{\exp(s_{ij}^{l,n})}{\sum_{k \in \mathcal{N}_i} \exp(s_{ik}^{l,n})} \quad (2)$$

where $\mathcal{N}_i$ is the number of nodes that are connected to node $i$. The node feature is then updated via aggregating the neighbors in all the attention heads:

$$\mathbf{h}_i^{l+1} = \frac{1}{N} \sum_{n=1}^{N} \mathrm{LeakyReLU}\left(\sum_{j \in \mathcal{N}_i} a_{ij}^{l,n} \mathbf{W}_h^n \mathbf{h}_j^l\right) \quad (3)$$

where $N$ is the total number of attention heads. Similarly, the edge feature vector for edge $(i, j)$ at the $(l+1)^{\text{th}}$ layer is updated with the adjacent node features:

$$\mathbf{e}_{ij}^{l+1} = \mathrm{LeakyReLU}(\mathbf{W}_e^0[\mathbf{h}_i^l \parallel \mathbf{h}_j^l \parallel \mathbf{e}_{ij}^l]) \quad (4)$$

where $\mathbf{W}_e^0$ is a different linear transformation for updating the edge. Such EGAT transformation is applied to each molecule $c$ in the mixture to obtain the final representation $h_{i,c}^L$ for each node at $L^{\text{th}}$ layer, the embedding of the molecule $c$ then formulated by summing up:

$$\mathbf{m}_c = \sum_{i \in I^c} h_{i,c}^L, c = 1, \ldots, C \quad (5)$$

where $c$ represent the component in the mixture and $I^c$ is the set of nodes in molecule $c$.

## Thermodynamically Consistent Prediction

In addition to the structure feature vectors of all components, $\boldsymbol{m}_c, c = 1, \ldots, C$, the temperature and composition (mole fraction of each component, $x_c$) are added to the component input vectors which are individually converted via the first MLP, given by:

$$\mathbf{m}_c' = \mathrm{MLP}_1([\mathbf{m}_c \parallel T \parallel x_c]), c = 1, \ldots, C \quad (6)$$

The $\mathrm{MLP}_1$ is defined with three layers whose dimensions

are $[513, 256, 64]$. The SiLU activation function is used to eliminate gradient vanishing in the model. Through $\mathrm{MLP}_1$, the molecule embedding is now updated by capturing the temperature and respective composition information. The updated molecule representations are summed up to define the overall mixture before inputting into a second MLP, $\mathrm{MLP}_2$, to obtain an initial scalar prediction $y$:

$$y = \mathrm{MLP}_2\left(\sum_{c=1}^{C} \mathbf{m}_c'\right) \tag{7}$$

Similar to $\mathrm{MLP}_1$, the $\mathrm{MLP}_2$ is defined as three layers of $[64, 256, 1]$. Also, SiLU is implemented as activation function here. The $\mathrm{MLP}_2$ is converting the mixture representation into desired scalar output. While to ensure that $g^{\mathrm{E}}$ is zero for a pure component, a composition-dependent coefficient is introduced to obtain $g^{\mathrm{E}}$:

$$\frac{g^{\mathrm{E}}}{RT} = \left(1 - \sum_{c=1}^{C} x_c^2\right) \cdot y \tag{8}$$

Lastly, the logarithm of the activity coefficient for each component $c$, $\ln \gamma_c$ is obtained through the GD relation:

$$\ln \gamma_c = \frac{g^{\mathrm{E}}}{RT} + \frac{\partial g^{\mathrm{E}}/RT}{\partial x_c} - \sum_{d=1}^{C} x_d \frac{\partial g^{\mathrm{E}}/RT}{\partial x_d}, c = 1, \ldots, C \tag{9}$$

Through these hard constraints, the GNN model now rigorously satisfies thermodynamic consistency, not only in terms of the Gibbs–Duhem relation, but also in terms of the limiting activity coefficients of pure components.

## Model Training

The loss function $\mathcal{L}$ is taken as the mean squared error (MSE) for the logarithm of the activity coefficients:

$$\mathcal{L} = \frac{1}{N_p} \sum_{i=1}^{N_p} (\ln \gamma_i - \ln \tilde{\gamma}_i)^2 \tag{10}$$

where $N_p$ refers to the total number of data points used in training. The PEGAT model is developed using the *DGL* package [16]. The Adam optimizer is used, with a batch size of 512, a learning rate of 0.001 and 200 epochs. The hyperparameters, including the learning rate, attention layers and number of neurons, are tuned with *optuna* [17]. With current settings, it takes around 3 hours to train this model on Windows11 using Intel(R) Xeon(R) Gold 6226R CPU @ 2.90GHz with 64GB RAM for data generation and NVIDIA RTX A4000 GPU with 16GB RAM for model training and evaluation.

**Table 3:** Performance evaluation of the PEGAT model on training, validation, and test datasets

| Dataset | RMSE | MAE | $R^2$ |
|---|---|---|---|
| Training | 0.0665 | 0.0361 | 0.9922 |

# RESULTS AND DISCUSSION

## Overall Performance

The model is further evaluated on the binary dataset and the ternary dataset, respectively. The metric scores indicate that the model has comparable performance on these two datasets. For the ternary dataset, the RMSE is even smaller than those for binary mixtures. Given that the ternary dataset is smaller than the binary dataset, this indicates that the model enhances capturing the $g^{\mathrm{E}}$ function and activity coefficients in ternary mixtures from binary mixture data, contributing to the applicability of the model to ternary mixtures.

## Performance on Binary Mixtures

Figure 2 compares the predicted $g^{\mathrm{E}}$, $\ln \gamma_1$, and $\ln \gamma_2$ values with available data [10] for two binary mixtures of acrolein-benzene and chloroform-hexane from the test dataset, at 298.15 K and 1 atm. The predicted $g^{\mathrm{E}}$ values for both mixtures in Figures 2(a, c) approach zero as the mixture composition approaches one of the two pure components, which is also consistent with the findings in [14]. Moreover, the imposed hard constraint (Eq. 7) guarantees the consistency of the behavior of the excess Gibbs free energy function, which is seen in Figures 2(b, d) where the respective $\ln \gamma_i$ becomes zero. Regarding the $\ln \gamma_i$ predictions, the model is in good agreement with the datapoints but is found to be of variable quality between points. Specifically, while the Gibbs–Duhem relation is satisfied at each value of $x_1$, the overall dependence on $x_1$ is sometimes unexpected. While the overall behavior of the curves for the acrolein-benzene mixture in Figure 2(a) is in agreement with the trend in the COSMO-RS data, including a maximum in $\ln \gamma_1$, multiple plateaus are observed between datapoints for the chloroform-hexane mixture in Figure 2(d). This latter behavior is unphysical and arises from the differentiation of the data-driven $g^{\mathrm{E}}$ model, as no constraints have been imposed on behavior of the derivatives during model training or in the model itself. This highlights one of the challenges in developing physically meaningful data-driven models.

## Performance on Ternary Mixtures

Figure 3 compares the predicted $g^{\mathrm{E}}$ and $\ln \gamma_i$ values now for two ternary mixtures of cyclohexane-ethanol-methanol (CEM) and water-ethanol-benzene (WEB) from the test dataset, also at 298.15 K and 1 atm. For simplicity, the relative compositions of two of the components are set to $x_{\mathrm{ethanol}}{:}\,x_{\mathrm{methanol}} = 2{:}1$ in mixture CEM and $x_{\mathrm{ethanol}}{:}\,x_{\mathrm{benzene}} = 1{:}2$ in mixture WEB. Given that at most 5 datapoints are available for any given ternary mixture in the training dataset and the information relating to these specific ternary mixtures is limited, we use the COSMO-SAC [18] instead to generate the data for the

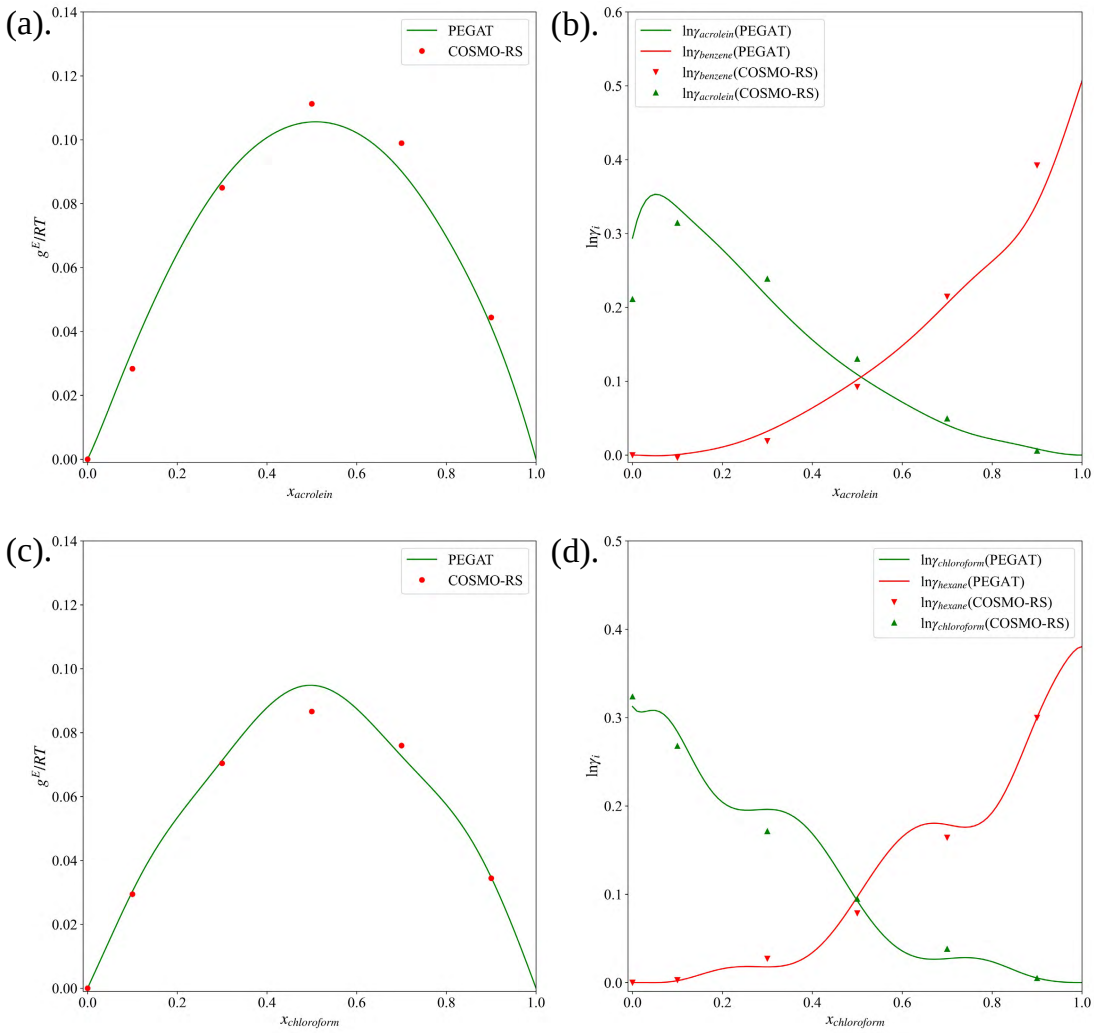

**Figure 2:** Calculated $g^{\mathrm{E}}$, $\ln\gamma_1$ and $\ln\gamma_2$ values for two binary mixtures at $T = 298.15$ K and $P = 1$ atm as a function the mole fraction $x_1$. The curves are predictions with the proposed models and the symbols are values from the dataset of COSMO-RS calculations (a) $g^{\mathrm{E}}$ for acrolein (1)-benzene (2); (b) $\ln\gamma_1$ and $\ln\gamma_2$ values for acrolein (1)-benzene (2); (c) $g^{\mathrm{E}}$ for chloroform (1)-hexane (2); (d) $\ln\gamma_1$ and $\ln\gamma_2$ values for chloroform (1) -hexane (2).

plots as reference. To evaluate 100 data points for generating the diagrams, the PEGAT model takes only 0.05 seconds. While for the COSMO-SAC model, it can take up to 1.7 seconds if the $\sigma$-profiles have already existed; or otherwise, to hours if the $\sigma$-profiles need to be generated from beginning. This shows a significant reduction in computational expense with the proposed method. While it should be noted that the PEGAT model is trained based on the dataset from COSMO-RS and it is different from COSMO-SAC. Nevertheless, good quality fits are observed in Figures 3(a, c) for $g^{\mathrm{E}}$, with the overall behavior following the trends in the data and good overall quantitative agreement, especially when $x_{\mathrm{cyclohexane}}$ and $x_{\mathrm{water}}$ approach 0 or 1. Furthermore, from Figures 3(b, d), the model demonstrates good agreement with the $\ln\gamma_i$ data at intermediate compositions, despite some deviations close to the 0 and 1 limits. Given the small amount of ternary mixture data used in training, this satisfactory performance confirms the value of combining binary and ternary data in model development. This can be helpful in enhancing performance for multicomponent mixtures, where generating a training dataset is challenging due to the large sampling space induced by the combinatorial explosion of possible components and compositions.

## CONCLUSIONS AND FUTURE WORK

We have proposed a PEGAT model for the prediction of activity coefficients in multicomponent mixtures. The proposed model includes an EGAT module to convert molecular graphs into latent space embeddings. The edge-aware attention mechanism captures the interactions between atoms within the molecules. This is followed by a sequence of two MLPs that result in a

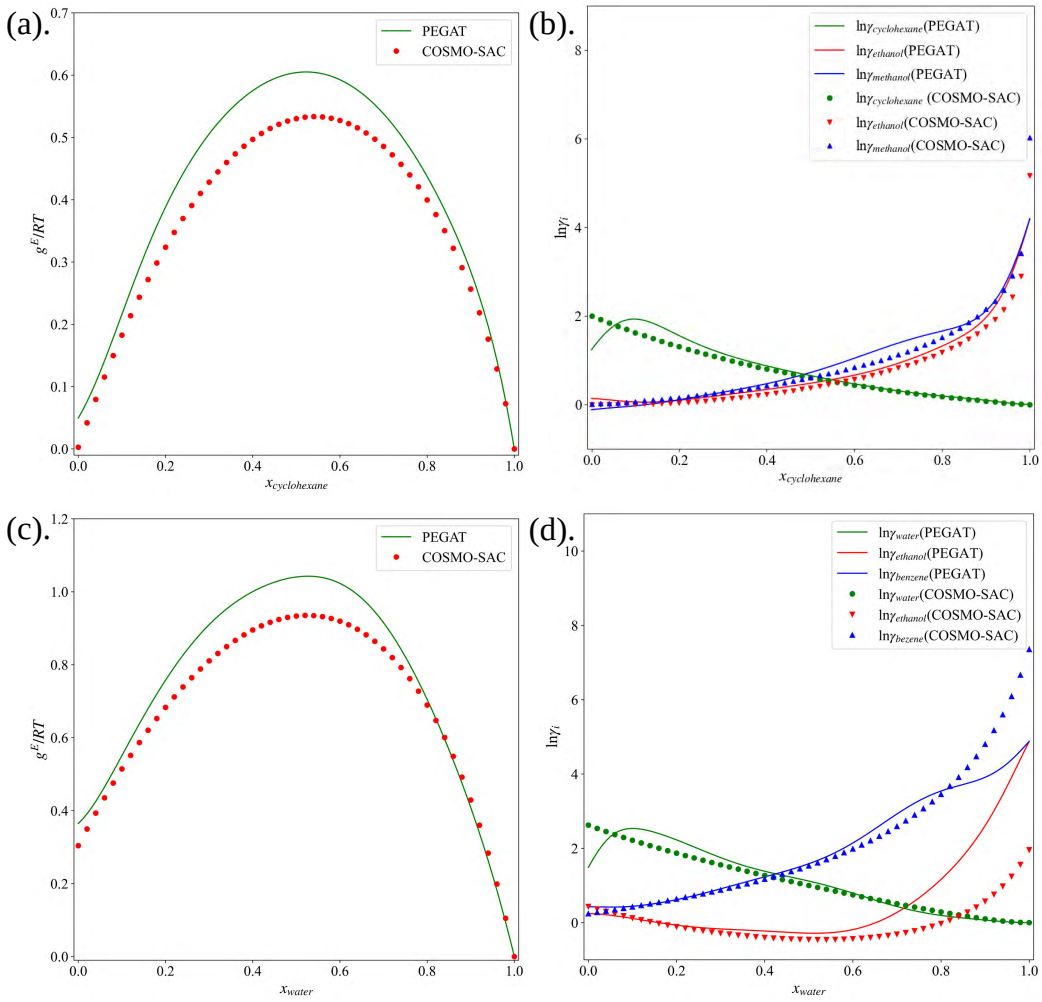

**Figure 3.** Values of $g^{\mathrm{E}}$ and $\ln\gamma_i$ for ternary mixtures at $T = 298.15$ K and $P = 1$ atm as a function of of the mole fraction of one components. The curves show the calculations with the proposed model and the symbols the COSMO-RS data (a) $g^{\mathrm{E}}$ and (b) $\ln\gamma_i$ for cyclohexane-ethanol-methanol with $x_{\mathrm{ethanol}}{:}\,x_{\mathrm{methanol}} = 2{:}1$; (c) $g^{\mathrm{E}}$ and (d) $\ln\gamma_i$ for water-ethanol-benzene with $x_{\mathrm{ethanol}}{:}\,x_{\mathrm{benzene}} = 1{:}2$.

prediction of the scalar excess Gibbs free energy. Thanks to a nonlinear transformation, $g^{\mathrm{E}}$ is guaranteed to approach zero for pure components, as is consistent with physical behavior. Then the activity coefficients are obtained via the Gibbs-Duhem relations by computing the derivatives of $g^{\mathrm{E}}$ with respect to compositions. These hard constraints ensure thermodynamic consistency in the predictions. Furthermore, the model is designed for mixtures with any number of components, which enables the use of a mixed dataset of binary and ternary mixture data for training. This architecture enhances the model's ability to learn from binary mixtures and extend to ternary mixtures, reducing the demand for expensive sampling. While good quality predictions are obtained, the interpolation behavior of the models can sometimes be unphysical due to use of derivatives for evaluation, highlighting the need to impose additional thermodynamic consistency requirements. In the future, more complex mixtures, such as quaternary mixtures, need to be furthermore validated to illustrate the potential of such model. The proposed model can be trained with experimental data and compared to existing thermodynamic models to demonstrate model's ability. Other alternative machine learning models, such as graph transformers, can be implemented to enhance learning both interactions within and between molecules for physical interpretability. The model could also be extended to include pressure as an input.

## ABSTRACT

Despite the growing economic importance of the fragrance industry, perfume formulation remains largely guided by empirical knowledge and iterative trial-and-error approaches. The structured design of fragrances, typically organised into top, middle, and base notes through the blending of perfume raw materials, is therefore time-consuming, costly, and difficult to generalise. Existing computational approaches have begun to address this challenge, but are commonly limited to small ingredient sets or require extensive sensory data that are not always available. This work proposes a computer-aided optimisation framework for Eau de Parfum formulation that simultaneously maximises perceived olfactory intensity and minimises formulation cost. The resulting optimisation problem is formulated to preserve the structural balance of top, middle, and base notes inherent to the perfume pyramid. Application of the framework to a fruity–floral Eau de Parfum formulation demonstrates a substantial increase in perceived intensity alongside a reduction in total formulation cost of approximately 64%. The proposed approach is intended as a decision-support tool for perfumers, enabling rapid exploration of cost–intensity trade-offs once a candidate ingredient set has been defined. The framework offers a step towards more systematic, data-driven perfume engineering and provides a foundation for future extensions incorporating ingredient selection and sensory constraints.

## INTRODUCTION

In 2017, the global Flavours and Fragrances industry was valued at over 26 billion US dollars, with projections indicating that it will exceed 36 billion US dollars by 2029 [1]. This industry spans a wide range of products, including fine fragrances, shampoos, candles, detergents, and fabric softeners [2]. Despite this sustained economic growth and the increasing interest in perfume engineering as a formal discipline, the literature still reports a notable lack of innovative, scientifically grounded tools for perfume formulation [3]. As a result, the design of fragrances remains largely dependent on empirical expertise and iterative trial-and-error procedures, which are time-consuming, costly, and difficult to generalise [4], [5]. Perfumes are complex mixtures of volatile compounds, typically dissolved in ethanol, water, or other carrier matrices, and are conventionally structured into top, middle, and base notes. In perfumery, the term notes refers to layers of scent that evaporate at different rates and collectively define the temporal evolution of a fragrance. Top notes consist of highly volatile compounds that dominate the initial sensory impression but dissipate rapidly. Middle notes, often described as the “heart” of the perfume, emerge shortly after application and establish its core olfactory character. Base notes comprise low-volatility compounds that persist for several hours and frequently act as fixatives by retarding the evaporation of more volatile constituents. The persistence and perceived intensity of each note are governed by

thermodynamic behaviour, mass-transfer phenomena, and psychophysical response mechanisms [2]. Carles conceptualised the perfumes structure as a pyramid divided into top, middle, and base notes, proposing typical proportions of 15–25%, 30–40%, and 45–55%, respectively [6]. These proportions were postulated to govern perfume tenacity, that is, the balanced evolution of odour intensity during evaporation.

The top, middle, and base notes described above are achieved by blending chemical ingredients known as perfume raw materials (PRMs), each contributing specific olfactory and volatilisation characteristics to the overall composition. Perfumers typically rely on experience-based heuristics to select and combine these PRMs, refining formulations through repeated sensory evaluation until the desired olfactory profile is achieved. This empirical methodology limits reproducibility and scalability, particularly given that modern cosmetic products often comprise more than 15 ingredients and may include up to 50 PRMs.

In recent years, several studies have tried to address these limitations through computational and data-driven approaches. Rodrigues et al. developed a machine learning-driven framework linking molecular structure to human olfactory perception, combining generative neural networks, odour-intensity prediction, thermodynamic modelling, and optimisation to reproduce target olfactory experiences from experimental data [3]. Viena Santana et al. proposed a systematic computational strategy for perfume formulation, employing deep learning trained on high-fidelity simulations alongside a meta-heuristic optimisation scheme to design compositions that achieve a desired odour spectrum while minimising undesirable notes [7]. Similarly, Zhang et al. introduced an optimisation-based framework for cosmetic formulation using a hierarchy of sensorial and product-property models, combined with iterative model substitution and generalised disjunctive programming, and demonstrated its applicability through a perfume design case study [8].

Despite their conceptual advances, these approaches suffer from several limitations. They typically focus on formulations containing a small number of PRMs (often three to four ingredients) or investigate the evaporation or performance of individual PRMs in isolation. Moreover, their application generally requires prior knowledge of odour detection thresholds for each ingredient, which are not always available or reliable. These constraints significantly limit their applicability to real-world cosmetic formulations, which are considerably more complex. Moreover, to the best of the authors' knowledge, the literature does not currently report any work aimed at mathematically optimising commercial perfume formulation.

In this work, an alternative optimisation framework for perfume formulation is proposed. Each PRM is characterised by its own odour intensity, reflecting differences in sensory experience between compounds. Consequently, two PRMs present at the same concentration will not necessarily be perceived at the same intensity level. The perceived odour strength is modelled explicitly in terms of olfactory intensity, based on a sigmoidal relationship between sensory response and the logarithm of stimulus concentration, consistent with established psychophysical models such as Hill's law, and the strongest-component model is employed to evaluate the overall intensity of the formulation [9], [10]. The approach integrates molecular property prediction, olfactory intensity modelling, and constrained numerical optimisation within a unified workflow. PRMs are characterised according to olfactory note classification, vapour–liquid equilibrium behaviour, intrinsic odour intensity, and economic cost, allowing for a quantitative assessment of their contribution to overall perfume performance. Olfactory intensities are computed from predicted gas-phase concentrations using established psychophysical models, while cost considerations are incorporated through a normalised economic metric. Crucially, the optimisation problem is formulated to preserve the structural balance of top, middle, and base notes inherent to the perfume pyramid, as illustrated in Figure 1, enabling the rational design of realistic Eau de Parfum formulations with industrial relevance.

## METHOLOGY

The workflow of the current work is summarised in Figure 1. The proposed workflow begins with the selection of fragrance molecules, followed by the collection of key molecular characteristics, including olfactory note classification and economic information. These data were found through web scraping. In particular, molecules identifiers, molecular weights ($MW_i$), note type and character were found on Scent Tree, OQEMA Flavour & Fragrance Ingredients and The Good Scent Company. Commercial pricing data for each molecule were retrieved from Sigma-Aldrich, FluoroChem, Perfumer's Apprentice, and Pell Wall. To incorporate economic considerations, the cost per mole of each molecule was normalised between $10^{-3}$ and 1, generating a dimensionless cost metric suitable for inclusion in the optimisation problem. Moreover, parameters needed to characterise PRMs intensities were retrieved by Wakayama et al [9]. The selected molecules were then combined into fragrance formulations following a predefined Eau de Parfum composition, comprising 75 wt% ethanol, 20 wt% PRMs, and 5 wt% water. In this study, the initial composition was defined to mimic a realistic fragrance pyramid, wherein molecules are categorised as top, middle, or base notes. Each molecule was initially assigned a weight fraction corresponding to its contribution to the total perfume

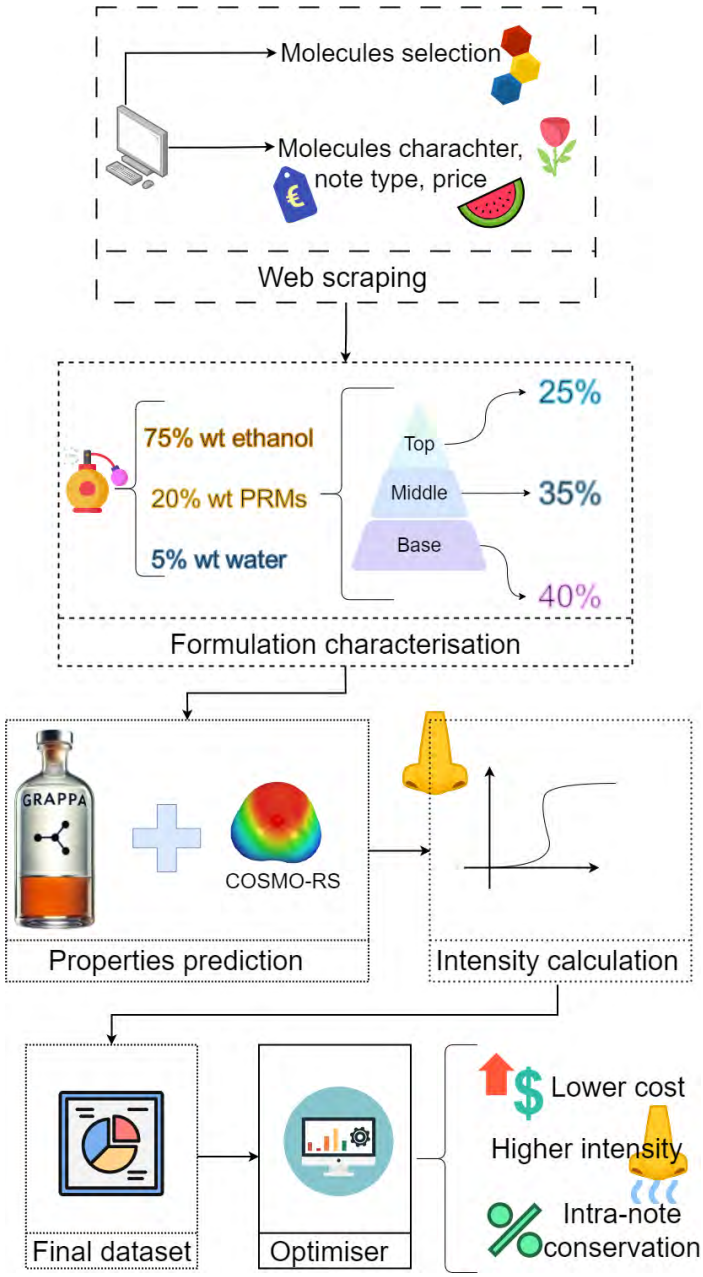

**Figure 1.** Schematic overview of the workflow adopted in this study. The process begins with web scraping to select and characterise PRMs. The selected molecules are then assembled into an Eau de Parfum formulation following predefined note-distribution constraints. Once the formulation is defined, relevant vapour–liquid equilibrium properties are predicted and used to calculate olfactory intensities. Finally, the molar fractions of the PRMs are optimised to maximise fragrance intensity while minimising formulation cost and preserving the relative proportions of top, middle, and base notes.

fraction. The relative distribution of weight fractions within each note category was determined to preserve intranote balance, reflecting the perfumer's approach of proportionally blending molecules within top, middle, and base notes to achieve the characteristic volatility and olfactory structure of the formulation (e.g. among 20%wt PRMs, 25% wt of top notes, 35% wt of middle notes and 40% wt of base notes)

Once the formulation is fully characterised, its vapour-liquid equilibrium properties were predicted. Activity coefficients ($\gamma_i$) at 36 °C (corresponding to human skin temperature) were calculated using COSMOTherm [11] (version 24.00), while vapour pressures ($P_i^0$) were estimated using GRAPPA [12]. COSMOTherm was

**Table 1:** Characterisation of the formulation developed for the current work, along with optimisation results. First, molecule identifiers and notes are reported. Then, activity coefficients, normalised costs, initial molar fraction and intensities are presented. Finally, optimised molar fractions and intensities are presented.

additionally employed to predict the pure-component densities of PRMs at ambient temperature, allowing all cost data to be expressed on a consistent molar basis, as supplier prices can be reported either by mass or by volume.

## Optimisation problem formulation

The contribution of each molecule was quantified through its intensity $\Psi_i$:

$$\Psi_i = \frac{I_{max,i}}{1+e^{(-X_i - C_i D_i)}} \quad (1)$$

Where $X_i$ is the logarithm of the concentration of the ith PRM in the gas phase (µg/L air) and $I_{max,i}$, $C_i$, and $D_i$ are parameters specific to each PRM: $I_{max,i}$ is the odour intensity at saturated gas concentration, $C_i$ is the value of $X_i$ when $\Psi_i$ is $I_{max,i}/2$, and $D_i$ is the steepness of the function. These parameters were retrieved by Wakayama et al [9]. Considering the ideal gas law, $X_i = {P_i}/{RT}$, where $P_i$ (Pa) is the equilibrium partial pressure, R is the ideal gas constant (L Pa $K^{-1}$ $mol^{-1}$), and T is the temperature (K). From Raoult's law $P_i = \gamma_i x_i P_i^0$, where $x_i$ is the ith molecule molar fraction. Therefore, $X_i$ is a function of the $x_i$ as follows:

$$\mathrm{X}_i = \log\left(\frac{\gamma_i x_i P_i^0}{RT}\, MW_i\, 10^3\right) \quad (2)$$

The objective function was defined as a weighted combination of total perceptual intensity and economic cost:

$$x_i^* = argmin\left(-\sum_{i=1}^{N} \Psi_i(x_i) + \lambda \sum_{i=1}^{N} c_i\, x_i\right) \quad (3)$$

Where $c_i$ is the normalised cost of the molecule and $\lambda$ is a tunable parameter balancing the importance of cost minimisation against intensity maximisation. In this case, $\lambda = 1$. The optimisation was subject to multiple equality constraints to ensure the structural integrity of the perfume formulation. Specifically, the sum of molar fractions within each note category (top, middle and base) was constrained to match the initial total fraction of that note type, reflecting the intranote balance inherent to the perfume pyramid:

$$\sum_{i \in Top} x_i = \sum_{i \in Top} x_i^0 = 0.0183, \quad (4)$$

$$\sum_{i \in Middle} x_i = \sum_{i \in Middle} x_i^0 = 0.0200 \quad (5)$$

$$\sum_{i \in Base} x_i = \sum_{i \in Base} x_i^0 = 0.0216 \quad (6)$$

The rationale for these constraints is as follows. The

initial molar fractions $x_i^0$ are derived from the target weight fractions of the perfume pyramid by converting each molecule's assigned weight fraction using its molecular weight and density. Consequently, the sums $\sum_{i\in Top} x_i^0$, $\sum_{i\in Middle} x_i^0$, and $\sum_{i\in Base} x_i^0$ encode the desired note-category proportions at the molar level. Enforcing Equations (4)–(6) as equality constraints during optimisation ensures that the total molar amount of each note category remains unchanged. The optimiser may therefore freely redistribute molar fractions among molecules within a note category, favouring those with higher intensity or lower cost, while the total molar amount of each note category, and hence the overall molar proportion of top, middle, and base notes in the Eau de Parfum, is held constant.

Additionally, target intensity constraints were imposed for specific olfactory categories, such as floral and fruity molecules, to ensure the final composition retained desired sensory characteristics:

$$\sum_{i\in Floral} \Psi_i(x_i) = \Psi_{Floral}^{target}, \quad (7)$$

$$\sum_{i\in Fruit} \Psi_i(x_i) = \Psi_{Fruit}^{target} \quad (8)$$

Where $\Psi_{Floral}^{target} = 0.4$ and $\Psi_{Fruity}^{target} = 60$. It is important to note that, from a psychophysical perspective, olfactory intensities are not strictly additive, and summing individual component intensities does not represent the true perceptual intensity of a fragrance. Nevertheless, the use of summed intensities is an easy and convenient mathematical construct within the optimisation framework, enabling the enforcement of compositional constraints on specific olfactory families. The optimisation problem was solved numerically using the Sequential Least Squares Programming (SLSQP) algorithm implemented in SciPy optimize minimize. $x_i$ bounds ranged from $10^{-6}$ to $10^{-2}$. Given the low concentration regime, infinite dilution conditions were assumed; accordingly, variations in $\mathrm{X}_i$ in Equation (2) arise solely from changes in $x_i$, while $\gamma_i$ is kept constant.

Convergence was monitored using a $10^{-6}$ tolerance on the objective function, and the final solution was verified by computing the molar fractions of each note type to confirm they remained conserved within a $10^{-6}$ difference, thereby ensuring that the perfume pyramid structure was maintained.

## RESULTS

Table 1 compares the initial and optimised compositions of the fragrance formulation in terms of molar fraction and olfactory intensity. A clear redistribution of material is observed following optimisation, reflecting the objective function, which maximises the sum of olfactory intensities while reducing economic cost. Molecules characterised by high initial intensities ($\Psi_i^0$) and relatively low normalised costs are preferentially selected and assigned increased molar fractions. In particular, Ethyl 2-methylbutyrate, Diphenyloxide, Linalool, and Hexyl salicylate exhibit substantial increases in molar fraction and corresponding olfactory intensity after optimisation. Among these, Ethyl 2-methylbutyrate emerges as a dominant contributor, with its optimised intensity ($\Psi_i^{opt} \approx 39.2$) significantly exceeding its initial value, while remaining economically efficient. Under the strongest component model, the perceived intensity of a perfume is governed primarily by the molecule with the highest individual intensity contribution. According to this criterion, the optimised formulation is strongly dominated by Ethyl 2-methylbutyrate, whose intensity far exceeds that of all other components. Compared to the initial formulation, where the maximum individual intensity is substantially lower, the optimisation therefore leads to a pronounced increase in overall perceived perfume intensity.

Conversely, several molecules are effectively excluded from the optimised formulation, with their molar fractions reduced to the imposed lower bound. This behaviour is particularly evident for compounds exhibiting extremely low initial intensities, such as Benzyl butyrate, Phenirat, Alpha-amylcinnamaldehyde, Ethyl linalool, Methyl dihydrojasmonate, and Benzyl salicylate. Despite some of these molecules having moderate or even low normalised costs, their negligible olfactory contributions render their inclusion unjustifiable within the optimisation framework. In addition, molecules associated with comparatively high costs and modest intensities, such as Benzyl tert-butanol and Isoamyl acetate, are strongly penalised and largely removed from the formulation. In addition to the objective function, explicit constraints were imposed on the summed olfactory intensities of fruity and floral components, as defined in Equations (7) and (8). The target floral and fruity intensities were set to $\Psi_{Floral}^{target}$ = 0.4 and $\Psi_{Fruit}^{target}$ = 60, respectively, compared to initial summed values of approximately 0.21 for floral notes and 39.6 for fruity notes. Following optimisation, both constraints are satisfied exactly, with optimised floral and fruity intensities of 0.400 and 60.0, respectively.

Under this formulation, the total summed intensity increases from 39.8 in the initial composition to 60.4 after optimisation. However, the actual perceived intensity of the perfume remains governed by the strongest component model and is therefore dominated by Ethyl 2-methylbutyrate.

Beyond sensory performance, the optimisation yields a substantial economic benefit. The total normalised cost of the formulation (calculated as $\sum_{i=1}^{N} c_i x_i$) is reduced from 0.00762 in the initial composition to 0.00279 after optimisation, corresponding to a cost reduction of approximately 64%. Importantly, this reduction is achieved simultaneously with an increase in overall perceived intensity, as dictated by the strongest component

model. Lastly, the influence of the cost–intensity trade-off parameter λ in the objective function was also examined. For the results presented above, λ = 1 was used, corresponding to equal weighting of intensity maximisation and cost minimisation. When λ was set to 0, such that only olfactory intensity was maximised, the optimiser selected a substantially larger number of molecules, including high-cost components. Although this intensity-only optimisation still reduced the total normalised cost from approximately 0.007 to 0.005, the reduction was markedly smaller than in the λ = 1 case. This comparison highlights that λ acts as a tunable formulation parameter, allowing the optimisation to prioritise either maximal intensity or economic efficiency depending on the desired design objective. The sensitivity of the optimisation to λ was further explored by increasing its value to 100, thereby strongly prioritising cost minimisation. In this specific case, no substantial changes in the optimised formulation were observed relative to the λ = 1 solution. This behaviour arises from the limited number of candidate components and, more importantly, from the presence of strict compositional constraints, including the perfume pyramid structure and the imposed floral and fruity intensity targets. These constraints must be satisfied simultaneously, which necessarily enforces the inclusion of certain molecules regardless of the cost penalty applied. This outcome reflects a limitation of the formulation space defined by the modeller rather than a failure of the optimisation strategy itself. In practical perfumery, expert knowledge would guide the initial selection and balancing of ingredients, preventing excessive dominance of individual components while ensuring that structural and sensory requirements are met without reliance on extreme parameter tuning.

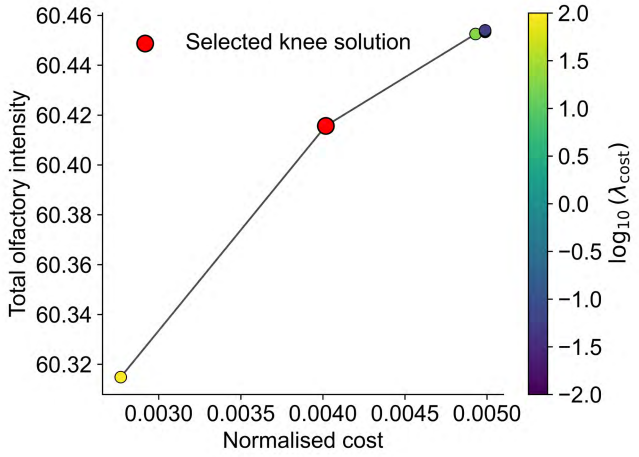

**Figure 2.** Pareto front: intensity–cost trade-off.

## Pareto Front results

To further investigate the trade-off between olfactory performance and formulation cost, a Pareto-front analysis was performed by sweeping the cost regularisation parameter, $\lambda_{\text{cost}}$, over a logarithmically spaced grid and solving the constrained optimisation problem for each value.

In addition to the original note-fraction constraints (Equations (7)-(8)), soft constraints were introduced on the total floral and fruit intensities, allowing them to vary within 0.8–1.5 times their respective initial values. The resulting solutions define Pareto curves describing the compromise between total olfactory intensity and normalised cost.

An automatic knee-selection criterion based on the normalised intensity–cost trade-off was then applied to identify an optimal balance between performance and cost. The selected solution ($\lambda_{\text{cost}} \approx 43.3$) yields a substantial increase in total intensity (from ≈ 39.8 to ≈ 60.4) alongside a marked reduction in normalised cost (from ≈ 0.0071 to ≈ 0.0040), while satisfying all constraints exactly. The floral and fruit intensities increase from 0.21 to 0.51 and from 39.6 to 59.9, respectively. This Pareto-selected formulation closely aligns with the previously reported optimisation case corresponding to λ = 100, both in terms of the selected molecules (seven components are retained with non-negligible contributions) and the overall composition profile, with most remaining components pushed towards their lower bounds. Moreover, inspection of the Pareto front indicates diminishing returns in total intensity for normalised costs above approximately 0.003–0.004, suggesting that further cost increases yield only marginal performance gains.

## CONCLUSIONS AND PERSPECTIVES

In this work, a systematic optimisation framework for Eau de Parfum formulation has been proposed, aimed at simultaneously maximising olfactory intensity and minimising economic cost. By coupling physicochemical property prediction, intensity modelling, and constrained numerical optimisation, the methodology provides a quantitative tool capable of redistributing PRMs in a cost-efficient manner while preserving the structural integrity of the fragrance pyramid. The results demonstrate that significant gains in perceived intensity can be achieved alongside substantial reductions in formulation cost, highlighting the potential of optimisation-based approaches to support perfume engineering and formulation design. It should be emphasised that, in the present study, fragrance molecules were initially selected in a simplified manner, based primarily on their fruity and floral character, with olfactory intensities computed a posteriori. This led to a pronounced imbalance in intrinsic intensity across the candidate set, whereby a small number of molecules exhibited markedly higher intensity contributions than others. As a consequence, the optimiser was naturally driven towards selecting and amplifying

these dominant components, in accordance with both the objective function and the model of olfactory perception. While this behaviour is fully consistent with the mathematical formulation of the problem, it does not reflect the typical workflow of a professional perfumer, who would usually pre-select ingredients with broadly comparable olfactory strength in order to achieve a balanced sensory profile. From this perspective, the proposed framework is not intended to replace the creative expertise of the perfumer, but rather to act as a decision-support tool that accelerates and rationalises the formulation process. When applied to a candidate set already curated by a perfumer, based on experience, artistic intent, and desired olfactory balance, the optimisation tool can rapidly identify cost–intensity trade-offs and suggest optimal molar fractions that respect both sensory constraints and economic targets. In this sense, the methodology offers a means to formalise and streamline stages of formulation refinement that are traditionally addressed through iterative trial-and-error experimentation. Future work will focus on extending the optimisation framework to include a preliminary selection stage, in which candidate molecules are dynamically pooled and screened based on their intensity-to-cost ratios. Such an approach would enable the optimiser not only to determine optimal molar fractions, but also to identify the most promising subset of ingredients from a larger candidate library. The integration of molecule selection and composition optimisation within a unified framework would represent a significant step towards fully computer-aided perfume formulation, with the potential to further enhance efficiency, reduce development costs, and support innovation in fragrance design.

## ABSTRACT

Heat exchangers frequently suffer from fouling, which is the accumulation of unwanted deposits on heat-transfer surfaces. This issue reduces thermal performance, increases pressure drop, and raises energy use and operating costs. Predicting fouling resistance remains challenging in process engineering, yet it is important for monitoring, maintenance planning, and mitigation actions that reduce economic losses and environmental impacts. Symbolic regression (SR) is a machine learning approach that searches for an explicit mathematical expression that best represents the relationship between process inputs and a target output. Unlike many black-box models, SR can capture nonlinear behavior while producing compact, interpretable equations that are easier to deploy and analyze in industrial settings. In this work, a methodology to rapidly obtain algebraic models for fouling resistance in industrial heat exchangers using SR was proposed. Plant measurements of hot- and cold-side flow rates and inlet/outlet temperatures were transformed into dimensionless numbers, which were used as model inputs to predict fouling resistance. SR was applied to operational data from industrial heat exchangers, achieving coefficients of determination ($R^2$) above 0.95 and 0.87 for the training and validation datasets, respectively, with low prediction errors. A selected equation was then transferred to a second industrial heat exchanger by re-estimating a reduced set of parameters using plant data. Validation on data not used during parameter estimation showed that the adapted model maintained high predictive accuracy, with $R^2$ values of 0.96 and 0.91 for training and validation, respectively. Overall, the proposed approach provided an efficient and interpretable framework for fouling resistance modeling and supported practical deployment across similar units.

## INTRODUCTION

Heat exchangers are key units in chemical processing, energy systems, and oil refining, where they enable efficient heat recovery and thermal integration. However, their performance is strongly affected by fouling, defined as the unwanted accumulation of solid or semi-solid material on heat transfer surfaces, which introduces an additional thermal resistance and progressively degrades heat transfer efficiency [1–3]. In refinery preheat trains, fouling leads to increased fuel consumption, higher greenhouse gas emissions, elevated pressure drops, and significant economic penalties due to throughput reduction and maintenance interventions [2, 4, 5]. Despite decades of research and industrial experience, fouling remains one of the most persistent and costly operational challenges in heat exchanger networks, with surveys indicating that more than 90% of industrial heat exchangers experience fouling during operation [1, 3, 6].

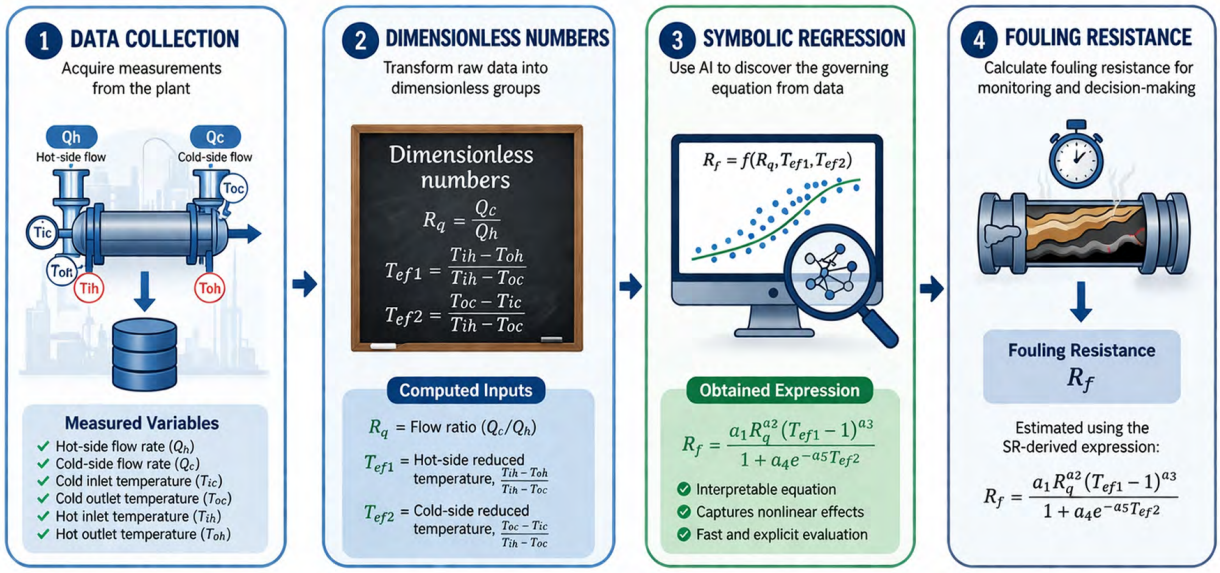

**Figure 1:** SR-based methodology proposed in this work to obtain expressions to calculate the fouling resistance.

The impact of fouling on heat exchanger performance is commonly quantified through the fouling resistance, which represents the additional thermal resistance introduced by the deposited layer and directly affects the overall heat transfer coefficient [1, 3, 7]. Fouling resistance is not constant over time and can exhibit markedly different temporal behaviors, including linear growth, asymptotic behavior, falling-rate trends, or oscillatory patterns, depending on the nature of the deposits, operating conditions, and dominant fouling mechanisms [1, 6, 8]. Multiple mechanisms may act simultaneously, including crystallization fouling, chemical reaction fouling, particulate deposition, corrosion, and ageing of deposits, resulting in highly complex and system-specific fouling dynamics [1, 5, 6]. This complexity makes fouling resistance difficult to predict reliably, particularly under industrial conditions where temperature, flow velocity, fluid composition, and shear stress vary along the length of the exchanger [4, 7, 9].

To model fouling resistance, a wide range of approaches has been proposed in the literature, spanning from empirical correlations to semi-empirical and physically motivated models [5, 7, 9]. Early models introduced the concept of competing deposition and removal mechanisms, expressing the net fouling rate as the difference between deposition and suppression terms [5, 7]. Building on this idea, threshold fouling models were developed to identify operating conditions under which deposition is balanced by removal, leading to negligible fouling rates [4, 5, 9]. These models have been widely adopted due to their relative simplicity and their ability to capture key trends observed in laboratory experiments. However, their predictive accuracy often deteriorates when applied to industrial systems, especially refineries, as the fitted parameters are strongly dependent on crude composition, exchanger geometry, and operating regime [5, 7, 10].

More advanced modeling approaches include deterministic and distributed models that explicitly account for local transport phenomena, reaction kinetics, and the dynamic interaction between fouling growth and heat transfer [2, 7, 9]. Such models have shown improved agreement with industrial data and can capture spatial variations of fouling resistance along the exchanger length [2, 7]. Computational fluid dynamics (CFD) has further enhanced mechanistic understanding by resolving local temperature, velocity, and concentration fields, offering insight into early stage fouling and induction periods [8, 9]. Nevertheless, these high-fidelity models are computationally intensive, require extensive parameterization, and are often impractical for routine monitoring, optimization, or real-time decision support in industrial environments [7–9].

As a result, fouling resistance modeling faces a fundamental trade-off between physical fidelity, computational tractability, and practical applicability. Empirical and semi-empirical models are easy to deploy but lack robustness and transferability, while detailed mechanistic models offer insight at the expense of complexity and computational cost [5, 7, 9, 10]. Moreover, many existing approaches rely on fouling resistance values inferred indirectly from heat balance calculations, embedding additional uncertainty associated with measurement noise and modeling assumptions [7, 9].

Machine learning (ML) has emerged as a powerful modeling paradigm in chemical and process engineering, particularly for systems where first-principles models are difficult to derive, computationally expensive, or affected by structural uncertainty. ML-based surrogate and data-driven models can learn complex nonlinear relationships directly from process data, enabling fast prediction, efficient optimization, and real-time decision support without explicit mechanistic formulations [11–13]. Compared to traditional empirical correlations, machine learning models can integrate large numbers of input variables, capture high-order interactions, and remain effective under noisy or partially observed conditions, which are common in industrial environments [11, 12]. As a result, ML approaches have been successfully applied to process modeling, optimization, monitoring, and fault detection across a wide range of chemical engineering applications, demonstrating significant gains in accuracy and computational efficiency over conventional modeling strategies [11–13].

In the context of heat exchangers, machine learning has shown promise for modeling fouling resistance. Artificial neural networks (ANNs) and deep learning models have been employed to predict fouling resistance directly from measurable process variables such as temperatures, flow rates, and pressure drops, achieving high predictive accuracy even under noisy conditions [14, 15]. These data-driven approaches bypass the need for detailed fouling mechanism identification and can be trained using either experimental data or high-fidelity simulation data, making them attractive for industrial deployment [14, 15]. Moreover, ML-based fouling models have demonstrated scalability across operating regimes and exchanger configurations, supporting their use in monitoring, maintenance planning, and performance optimization of heat exchanger systems [12, 14, 15]. However, many existing ML approaches rely on complex black-box models, which can limit interpretability and hinder trust and adoption in industrial decision-making.

Building on the broader adoption of ML in chemical engineering, symbolic regression (SR) has gained attention as a way to retain the predictive power of data-driven models while producing explicit, readable equations rather than opaque black-box predictors [16, 17]. SR searches over a space of mathematical expressions (e.g., combinations of process variables, constants, and operators) to identify compact formulas that balance accuracy and complexity, often using evolutionary or program-search strategies to evolve candidate models toward parsimonious structures [16, 17]. This is particularly attractive in process systems engineering because the resulting expressions are straightforward to audit, differentiate, and embed in simulation, optimization, and control workflows, and they can serve as interpretable surrogates or as corrective closures to improve mechanistic models [18]. Recent chemical-engineering studies highlight SR as a practical bridge between data and physics: it can recover compact relationships consistent with underlying transport/kinetic behavior and can be used to distill complex learned representations into deployable algebraic forms without sacrificing much accuracy [19, 20].

This work aims to address the limitations of existing fouling resistance modeling approaches by developing an accurate, interpretable, and transferable data-driven model suitable for industrial applications. Building on the strengths of ML while explicitly mitigating the drawbacks associated with black-box models, a SR–based framework was proposed to identify compact algebraic expressions that relate fouling resistance to operating conditions expressed through physically meaningful variables and dimensionless groups. The specific contributions of this study are: (i) the formulation of a symbolic regression methodology tailored to fouling resistance modeling using industrial heat exchanger data; (ii) the demonstration that the resulting symbolic models achieve high predictive accuracy while remaining transparent and easy to deploy; and (iii) the validation of the model's transferability by adapting it to a second industrial heat exchanger with minimal parameter re-estimation. By combining interpretability, computational efficiency, and practical relevance, the proposed approach provides a robust alternative for fouling monitoring, analysis, and decision support in heat exchanger operation.

# METHODOLOGY

## Data acquisition and preprocessing

The dataset used in this work was obtained from two industrial shell-and-tube heat exchangers operating under normal refinery conditions. For each unit, routinely measured operating variables were collected over extended periods of operation. The available measurements include the hot-side fluid flow rate ($Q_h$), cold-side fluid flow rate ($Q_c$), cold-fluid inlet temperature ($T_{ic}$), hot-fluid inlet temperature ($T_{ih}$), cold-fluid outlet temperature ($T_{oc}$), and hot-fluid outlet temperature ($T_{oh}$). These variables are typically available in industrial control systems and were selected to ensure that the proposed modeling framework relies exclusively on standard plant measurements.

Prior to model development, the datasets were screened to remove missing values and outliers associated with sensor faults or transient shutdown conditions. The resulting datasets were then divided into training and validation subsets, ensuring that both heat exchangers were represented in each subset. This strategy was adopted to assess not only predictive accuracy, but also the transferability of the identified models across different units.

## Dimensionless variable formulation

To reduce scale effects and improve generalization, the measured variables were transformed into a set of dimensionless groups derived from energy balance considerations. In particular, the following dimensionless variables were defined:

$$R_q = \frac{Q_c}{Q_h} \quad (1)$$

$$T_{ef1} = \frac{T_{ih} - T_{oh}}{T_{ih} - T_{oc}} \quad (2)$$

$$T_{ef2} = \frac{T_{oc} - T_{ic}}{T_{ih} - T_{oc}} \quad (3)$$

These quantities capture the relative flow distribution and thermal effectiveness of the heat exchanger in a compact, normalized form. The use of dimensionless variables also facilitated comparison between exchangers of different sizes, operating ranges, and absolute flow rates. The fouling resistance, $R_f$, was treated as the target variable and was calculated from the model proposed by Liporace and Oliveira [21].

## Symbolic regression framework

SR was used to discover an explicit algebraic relationship between fouling resistance $R_f$ and the dimensionless variables $(R_q, T_{ef1}, T_{ef2})$. The workflow implemented in this study is summarized in Fig. 1, which outlines: (i) acquisition of plant measurements, (ii) computation of dimensionless groups, (iii) SR search for an analytical expression, and (iv) evaluation of $R_f$ using the discovered expression. Symbolic regression was performed using the PySR library [22], an open-source framework for equation discovery based on a multi-population evolutionary search with an evolve–simplify–optimize loop for improving candidate expressions and refining numerical constants.

The PySR search was configured with 400 iterations and a population size of 30 candidate expressions. To promote interpretability and numerical stability, the operator set was restricted to common elementary functions. The allowed unary operators were exponential, logarithm, and square. The allowed binary operators were addition, subtraction, multiplication, and division. Candidate equations were evaluated by predictive performance and expression complexity, and the final model was selected to balance accuracy with parsimony, consistent with the goal of obtaining a compact and deployable equation for $R_f$.

# RESULTS AND DISCUSSION

## Application of Symbolic Regression

SR was first applied using data from the first industrial heat exchanger to identify an explicit algebraic relationship between the fouling resistance and the dimensionless variables defined in Methodology section. The resulting expression, denoted as Eq. 4, was selected based on the trade-off between predictive accuracy and model complexity. Table 1 summarizes the performance metrics obtained for this equation, showing coefficients of determination $R^2$ of 0.97 and 0.91 for the training and validation datasets, respectively, together with low mean squared error (MSE) values. These values indicate that the SR model can accurately capture the nonlinear relationship between operating conditions and fouling resistance for the first heat exchanger.

$$R_f = -0.192 T_{ef1} R_q - 0.806 T_{ef1} + \frac{0.806 T_{ef1}}{T_{ef2}} + 0.806 T_{ef2} - 0.943 \quad (4)$$

**Table 1:** Coefficient of determination ($R^2$) and mean squared error (MSE) of Eq. 4 to predict the training and validation sets for the first heat exchanger.

| Dataset | $R^2$ | MSE |
|---|---|---|
| Training | 0.972 | $2.48x10^{-8}$ |
| Validation | 0.910 | $1.43x10^{-7}$ |

Figure 2 compares the measured fouling resistance values with the predictions obtained using Eq. 4. A good agreement between predicted and measured values was observed across the full range of fouling resistance, with no evident systematic bias. The dispersion around the parity line remains limited for both training and validation datasets, indicating that the identified symbolic expression generalizes well and does not suffer from overfitting despite its relatively compact analytical form. This result highlights one of the main advantages of SR, namely its ability to produce parsimonious and interpretable models while maintaining high predictive accuracy.

A second SR model was then identified using data exclusively from the second industrial heat exchanger, resulting in Eq. 5. The predictive performance of this model is reported in Table 2. The obtained $R^2$ values of 0.96 for the training dataset and 0.87 for the validation dataset confirm that SR is also capable of accurately modeling fouling resistance for a different unit operating under distinct conditions. Figure 3 further illustrates the agreement between measured and predicted fouling resistance values for this second heat exchanger, again showing a close alignment along the parity line and limited scatter.

$$R_f = -1.23 R_q - 3.17 T_{ef1} + \frac{1.65}{T_{ef2}} \quad (5)$$

The performance of Eqs. 4 and 5 shows that SR can successfully extract meaningful functional relationships between dimensionless operating variables and fouling resistance directly from industrial data. The identified

models achieved high predictive accuracy without relying on heat exchanger-specific mechanistic assumptions, supporting the applicability of the proposed approach to real industrial systems.

**Table 2:** Coefficient of determination ($R^2$) and mean squared error (MSE) of Eq. 5 to predict the training and validation sets for the second heat exchanger.

| Dataset | $R^2$ | MSE |
|---|---|---|
| Training | 0.958 | $3.56x10^{-8}$ |
| Validation | 0.871 | $1.58x10^{-8}$ |

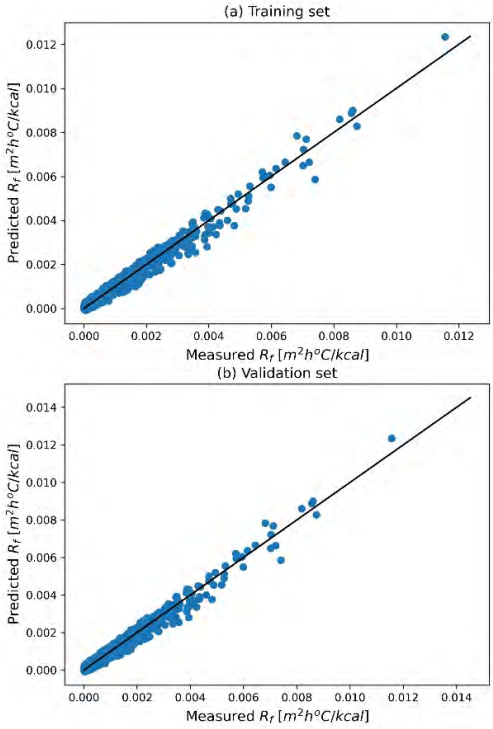

**Figure 2.** Comparison between the measured values of the fouling resistance and the predictions made by the SR model obtained with data from the first heat exchanger.

## Generalization of the Symbolic Regression Equation

To assess the transferability of the SR model, the expression identified using data from the first heat exchanger (Eq. 4) was applied to the second heat exchanger by re-estimating its numerical parameters. Eq. 4 was chosen because of its better performance compared to Eq. 5, as presented in Tables 1 and 2. In this step, the functional structure of the symbolic equation was kept unchanged, and only a reduced set of coefficients was adjusted using plant data from the second unit. Parameter estimation was performed using particle swarm optimization (PSO) implemented with the *pymoo* Python library [23].

The predictive performance of the resulting model, denoted as Eq. 6, is summarized in Table 3. The re-parameterized equation achieved coefficients of determination $R^2$ of 0.96 and 0.91 for the training and validation datasets, respectively, with correspondingly low MSE values. These values are comparable to those obtained when fitting a symbolic regression model directly to data from the second heat exchanger (Table 2), indicating that the symbolic structure of the first heat exchanger was sufficiently flexible to describe fouling behavior across different units after limited recalibration.

$$R_f = -1.55T_{ef1}R_q - 6.79T_{ef1} + \frac{1.64T_{ef1}}{T_{ef2}} - 6.64T_{ef2} + 5.81 \quad (6)$$

.

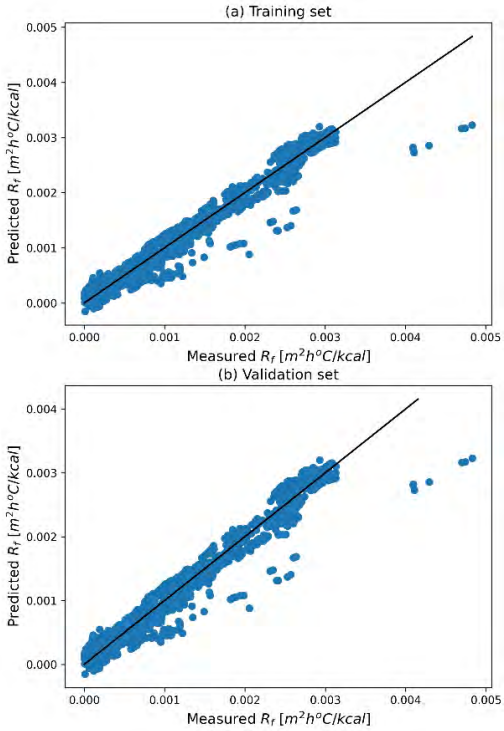

**Figure 3.** Comparison between the measured values of the fouling resistance and the predictions made by the SR model obtained with data from the second heat exchanger.

Figure 4 compares the measured fouling resistance values with the predictions obtained using Eq. 6. This figure presents a strong agreement between measured and predicted values over the full operating range, with no evident systematic deviation. The dispersion around the parity line remains similar to that observed for the heat exchanger-specific symbolic model of Eq. 5, confirming that re-estimating a small number of parameters is sufficient to adapt the model to a new heat exchanger

**Table 3:** Coefficient of determination ($R^2$) and mean squared error (MSE) of Eq. 6 to predict the training and validation sets for the second heat exchanger.

| Dataset | $R^2$ | MSE |

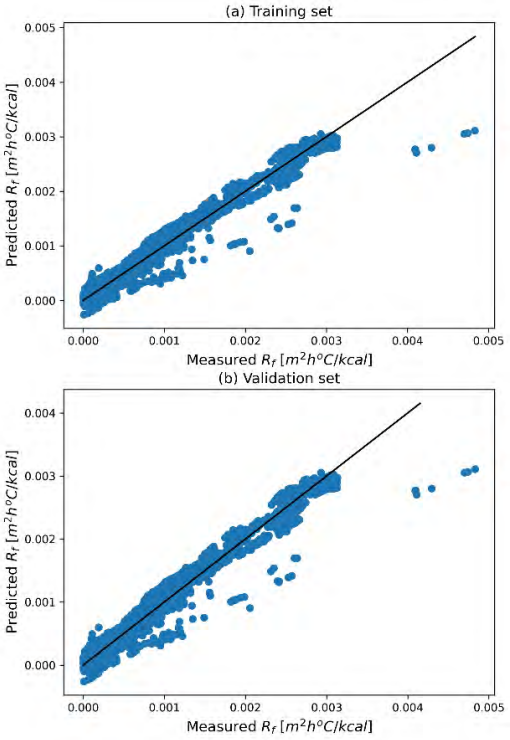

**Figure 4.** Comparison between the measured values of the fouling resistance and the predictions made by the SR model obtained with data from the first heat exchanger after estimating the model parameters with data from the second heat exchanger.

From an industrial perspective, the proposed approach presented a key advantage, which is the ability to obtain structurally transferable equations that can be adapted to new heat exchangers with minimal additional data. Rather than repeating the full SR procedure for each unit, plant engineers can reuse the learned functional form and perform a lightweight parameter estimation step, significantly reducing modeling effort and data requirements. This characteristic makes the proposed approach particularly attractive for large heat exchanger networks, where rapid and consistent fouling modeling across multiple units is essential for monitoring, optimization, and maintenance decision support.

## CONCLUSION

In this work, a SR–based methodology was proposed for modeling fouling resistance in industrial heat exchangers using routinely available plant measurements. By expressing operating conditions through physically meaningful dimensionless variables, the approach enabled the identification of compact and interpretable algebraic equations that accurately described fouling behavior. The analysis of two industrial heat exchangers showed that SR can achieve high predictive accuracy for both training and validation datasets while avoiding the opacity commonly associated with black-box machine learning models. The explicit nature of the resulting expressions facilitates model inspection, interpretation, and direct integration into existing monitoring and analysis workflows.

Beyond predictive performance, the proposed framework was shown to provide transferability across heat exchangers. The symbolic equation identified for one heat exchanger could be successfully adapted to a second exchanger through limited parameter re-estimation, preserving high accuracy without repeating the full model discovery process. This capability highlights the potential of SR as a practical tool for fouling modeling at the plant and network levels, enabling rapid deployment, reduced data requirements, and consistent modeling across multiple units. Overall, the methodology offers a robust and interpretable alternative to conventional empirical correlations and black-box data-driven models, supporting improved fouling monitoring and decision-making in industrial heat exchanger operation.

## ABSTRACT

We present a steady-state, optimization-based techno-economic study of a continuous fluidized temperature-swing adsorption (TSA) system for post-combustion $CO_2$ capture from biomass-derived flue gas, using two adsorption stages and one desorption stage with integrated heat-pump thermal management. The GAMS/CONOPT4 model couples molar and energy balances, Toth adsorption equilibrium, fluidized-bed hydrodynamics and literature cost correlations. Optimization yields $CO_2$ purity of 96% v/v and 95.5% recovery at low, safe pressures with particle Reynolds numbers of 2-11, indicating near-minimum-fluidization operation. The nominal capture cost is 87 USD/ton$CO_2$ with an internal rate of return of 42%; utilities comprise 49% of annualized costs and the adsorption compressor dominates equipment capital. Disabling the heat pump increases modeled capture cost to 124 USD/ton$CO_2$, highlighting the heat pump's decisive role in reducing energy demand and costs. Adding adsorption stages lowers modeled cost further but produces impractically shallow beds, revealing a trade-off between mass-transfer performance and feasible bed geometry. A sensitivity analysis demonstrated a linear positive correlation between electricity cost and capture cost, with capture costs potentially as low as 50 USD/ton$CO_2$ and an internal rate of return as high as 64%. While results demonstrate the technical and economic plausibility of a heat-pump-assisted fluidized TSA under the stated assumptions, the study recommends including flue contaminants, refined heat-exchanger and pressure-drop models, and experimental validation for scale-up.

## INTRODUCTION

The 2015 Paris Agreement, ratified by 196 countries, established the ambitious objective of constraining global mean temperature rise to 1.5 °C through rapid reductions in greenhouse gas emissions — a target that demands substantial technological and policy effort [1]. Within the broader decarbonization agenda, carbon capture and storage (CCS) technologies are frequently identified as essential pathways to reduce emissions from hard-to-abate sectors [2]. In particular, bioenergy with carbon capture and storage (BECCS) has attracted attention because it can deliver net negative $CO_2$ emissions by capturing and permanently storing carbon that was originally sequestered from the atmosphere during biomass growth [3].

Despite this promise, most optimization studies addressing BECCS have concentrated on linear, system-level representations of spatial and temporal networks (plants, feedstock supply, and transport logistics), while paying limited attention to the internal operational dynamics of individual capture units [3, 4]. High-fidelity, process-level simulation and optimization can reveal critical interactions among process variables, energy flows, and equipment design that are necessary to bring emerging capture technologies from laboratory concepts to

industrially robust, cost-competitive systems. One such emerging technology is temperature-swing adsorption (TSA) implemented in a fluidized configuration, where a moving solid adsorbent circulates counter-current to an upward flow of $CO_2$-rich flue gas. Solid sorbents as binder-free zeolite 13X offer attractive properties for this application, including high $CO_2$ selectivity and reduced regeneration energy compared with many alternative materials [5, 6, 7]. Process-level optimization studies of TSA processes are comparatively rare in the literature and typically restricted to small-scale demonstrations that lack process cost estimates [8].

The authors' previous work on optimization of a simulated fluidized TSA process yielded interesting and potentially cost-saving insights while delivering a capture process cost estimate of about 84 USD/ton$CO_2$ [7]. However, that work relied on the heavy hypothesis of stage-wise mass-transfer equilibrium reached, and it lacked proper energy management between heat exchangers. Therefore, this study aims to improve on that previous work of an optimization-based process scale-up through developing a guidelines framework via in silico simulations.

This objective also aligns with the Sustainable Development Goals set by the United Nations for 2030 [9], including:

- 7: Affordable and Clean Energy
- 9: Industry, Innovation and Infrastructure
- 11: Sustainable Cities and Communities
- 12: Responsible Consumption and Production
- 13: Climate Action.

## MATERIALS AND METHODS

The fluidized-bed TSA system simulated and optimized in this study was described in the authors' previous work [5, 6, 7]. It consists of two multi-stage fluidized columns – one for adsorption and another for desorption – with continuous adsorbent recirculation between them. The desorption column has a heat exchanger at the gas stream in its bottom, and each fluidized bed in each column also has a dedicated heat exchanger to optimize local temperature. The recirculating solid adsorbent also passes through a heat exchanger between the columns. Part of the gas desorbed in the desorption column is purged and recovered, and the rest is used as stripping gas recycled to the desorption column.

The number of adsorption stages was optimized based on $CO_2$ purity targets and design efficiency considerations. Our initial simulations indicated that only two adsorption stages and a single desorption stage could obtain $CO_2$ at over 90% v/v purity, a common benchmark in the field [10]. As will be discussed, adding more stages result in impractically wide and shallow adsorption beds.

A compressor is used at the bottom of each column to propel the gas upwards. A heat pump connects the solid-stream heat exchanger between columns to the desorption bed heat exchanger.

Table 1 presents the hypotheses for the process modeling, while Table 2 presents the values and units for several parameters. Figure 1 presents the process schematics, including adsorption and desorption stages, heat exchangers, compressors, the heat pump and main process streams.

| Labor, storage and transport costs neglected |
| Heat exchangers pressure drop neglected |

The Marshall & Swift index, which adjusts equipment prices for inflation, was estimated as 2500 after extrapolation from values reported in the literature [12, 13, 14]. The monthly adsorbent loss was increased from 10% in our previous work [7] to 30% in this study to account for both mechanical losses and adsorption sites deactivation due to impurities. The flue gas molar flow was left as a variable to be fitted. The flue gas and the captured $CO_2$ molar compositions have also been changed from the authors' last work [7], which should be taken into consideration when comparing the cost estimates.

The process model couples molar and energy balances for each gaseous species in every stage of the adsorber with balances for the external heat-exchange loops, and it explicitly incorporates the thermodynamics of adsorption and the fluid dynamics characteristic of

fluidized beds. Adsorption equilibrium within each stage is represented by the Toth isotherm [19], using parameter values taken from prior experimental characterization [6]; the heterogeneity parameter for $N_2$ is fixed at unity and treated as temperature-independent for the present simulations. Mass and energy conservation equations are complemented by algebraic constraints representing thermodynamic relations, fluid dynamic closures, equipment efficiencies and cost correlations; together these expressions define the nonlinear constrained optimization problem.

**Table 2:** List of parameters for the fluidized TSA simulation.

| Parameter description | Parameter value |
|---|---|
| Flue gas temperature | 318.16 K |
| Flue gas pressure | 1.01325 bar |
| Flue gas molar composition | 10% v/v $CO_2$ and 90% v/v $N_2$ |
| $CO_2$ max molar concentration after adsorption | 0.5% v/v [5, 6, 7] |
| $CO_2$ min molar concentration after desorption | 96% v/v |
| Zeolite 13XBF specific heat | 920 J/kg.K [6] |
| Zeolite 13XBF bulk density | 1287 kg/m$^3$ [6] |
| Zeolite 13XBF spheric particle diameter | 0.5 mm [5, 6, 7] |
| Compressors efficiency | 72% [11] |
| Overall transfer coefficient in each heat exchanger | 200 W/m$^2$.K [11] |
| Marshall & Swift inflation index | 2500 [12, 13, 14] |
| Work hours per year | 8000 h/year [14] |
| Plant lifetime | 20 years |
| Interest rate | 10% |
| Cold water cost | 0.506 USD/GJ [15, 16] |
| Steam cost | 25.3 USD/GJ [15, 16] |
| Electricity cost | 20.0 USD/GJ |
| Zeolite 13XBF cost | 2 USD/kg |
| Adsorbent monthly losses | 30% |
| Start-up cost | 10% of fixed capital [14] |
| $CO_2$ market price | 120 USD/ton$CO_2$ |
| Carbon credit | 60 USD/ton$CO_2$ [17] |
| Max column diameter | 3.048 m [18] |
| Column height/diameter min ratio | 1 |

The efficiency of $CO_2$ mass transfer between solid and gas, defined in Equation 1 (where $q$ is the amount of gas adsorbed), was estimated by an empirical correlation found via in silico adsorption simulations, as shown in Equation 2 [20]. In Equation 2, $u$ is the gas velocity, $u_{mf}$ is the minimum fluidization velocity, $S/G$ is the ratio between solid and gas mass flows, $\tau_S$ is the solid mean residence time and $T$ is the temperature. The efficiency of $N_2$ mass transfer was left as a variable $\in [0, 1]$ to be fitted. The fixed capital investment (FCI) consisted in literature correlations for equipment cost for columns, heat exchangers, compressors and the heat pump [18, 21].

The heat pump is modeled as an auxiliary energy-recovery unit that redirects thermal energy from the solid-cooling heat exchanger between columns into useful heat for regeneration at the desorption stage [26]. Its required output heat duty is linked to the process heat demand, while the electrical power consumption is computed from a temperature-dependent coefficient of performance ($COP > 1$) as shown in Equation 3, where $\lambda$ is the heat pump efficiency, $Q_{out}$ is the heat output of the heat pump, $W$ is the electric work supplied to the heat pump, $T_{des}$ is the desorption stage temperature, and $T_{Sout}$ is the outlet solid temperature at the heat exchanger between columns.

$$\eta_{i,j} = \frac{q_{i,j} - q_{i,j+1}}{q_{i,j}^{(Eq)} - q_{i,j+1}}, i = \mathrm{CO_2}, \mathrm{N_2}, j = \text{stage} \quad (1)$$

$$\eta_{\mathrm{CO2}} = 1 - 0.1018 \left(\frac{u}{u_{mf}}\right)^{3.298} \left(\frac{S}{G}\right)^{0.1105} \left(\frac{\tau_S}{60\ \mathrm{s}}\right)^{-0.3055} \left(\frac{T}{300\ \mathrm{K}}\right)^{-0.7377} \quad (2)$$

$$COP = \frac{Q_{out}}{W} = \lambda\left(\frac{T_{des}+5}{(T_{des}+5)-(T_{Sout}-5)}\right) \quad (3)$$

The entire model (mass, energy, Toth equations, process economics and auxiliary relations) was encoded in GAMS (GAMS Software GmbH, release 52.5.0) and solved with the nonlinear programming solver CONOPT4 [22]. The formulation comprises 249 constraints (including inequality constraints) and 207 variables, with 58 definitional constraints – constraints which can be written as *a=f(b, c, d, ...)* and are solved separately after the problem is optimized. The optimization objective is the minimization of annualized process cost normalized by the annual mass of $CO_2$ captured.

Because the formulation is nonlinear, solver performance depended strongly on variable initializations and bounds [23]. To promote convergence we enforced physically meaningful upper and lower bounds and initial guesses on pressures, temperatures, gas properties and Toth parameters (set to their theoretical minima and maxima where applicable), and supplied strictly positive initial guesses for variables that would otherwise produce undefined expressions if equal to null.

## RESULTS AND DISCUSSION

Tables 3 and 4 present the optimized values of main variables. The optimization resulted in no adsorption stage having a heat exchanger, with their thermal loads being automatically set to null. The external heat exchanger at the bottom of the desorption column was also

unnecessary to the optimized process.

**Table 3:** Optimized values of main global variables.

| Variable | Optimized value |
|---|---|
| Flue gas flow | 94 mol/s (7602 $Nm^3/h$) |
| Flue gas pressure | 2.13 bar |
| Adsorbent flow | 10.5 kg/s |
| Stripping gas flow | 3.17 mol/s |
| Stripping gas temperature | 465 K |
| Stripping gas pressure | 1.11 bar |
| Recovered gas flow | 9.4 mol/s |
| $CO_2$ recovery | 95.5% |
| Internal rate of return | 42% |
| Capture cost | 87 USD/ton$CO_2$ |
| Heat pump *COP* | 2.0 |
| Heat pump efficiency | 62% |
| Heat pump electric work | 663.4 kW |

**Table 4:** Optimized values of variables per stage.

| Variable | Adsorption bottom stage | Adsorption top stage | Desorption stage |
|---|---|---|---|
| Pressure | 2.09 bar | 1.94 bar | 1.01 bar |
| Temperature | 371 K | 352 K | 465 K |
| $CO_2$ efficiency | 73% | 60% | 92% |
| Porosity | 0.49 $m^3/m^3$ | 0.53 $m^3/m^3$ | 0.42 $m^3/m^3$ |
| Minimum porosity | 0.42 $m^3/m^3$ | 0.42 $m^3/m^3$ | 0.42 $m^3/m^3$ |
| Velocity | 0.19 m/s | 0.25 m/s | 0.10 m/s |
| Minimum velocity | 0.12 m/s | 0.12 m/s | 0.10 m/s |
| Density | 1.94 $kg/m^3$ | 1.86 $kg/m^3$ | 1.14 $kg/m^3$ |
| Dynamic viscosity | 0.0000217 Pa.s | 0.0000209 Pa.s | 0.0000257 Pa.s |
| Solid residence time | 485 s | 1651 s | 189 s |
| Bed height | 0.54 m | 2.51 m | 1.25 m |
| Bed diameter | 3.048 m | 2.62 m | 1.25 m |
| Stage heat | 0 W | 0 W | +142 kW |

The particle Reynolds numbers predicted for both adsorption and desorption stages remain low, ranging from approximately 2 to 11. These values confirm that the solids are readily fluidized and that the column operates close to minimum fluidization conditions, particularly in the desorption section. They also imply that viscous dissipation and inertial effects contribute comparably to the pressure losses associated with gas flow through the particulate phase. Under such conditions, a purely Stokesian drag description is inadequate, and inclusion of both viscous and kinetic terms in the Ergun formulation is therefore warranted [24].

The minimum fluidization porosity calculated from the semi-empirical Ergun correlation is approximately 0.42, in close agreement with the value of 0.43 reported in earlier work [8] and well within the typical 0.40–0.45 range expected for nearly spherical particles [24]. Superficial gas velocities fall within values commonly reported for industrial adsorption operations [25], and the optimized pressure levels across stages further indicate that TSA systems can be designed to operate safely at relatively low pressures.

The findings in this work further support claims that capturing $CO_2$ at purities greater than 90% is physically as well as economically feasible [10]. Low $CO_2$ mass transfer efficiencies in the adsorption stages indicate the optimal operating point is a compromise between the mass transfer process and economic parameters.

The objective function value, the $CO_2$ capture cost per mass unit, was optimized at 87 USD/ton$CO_2$, a value similar to that previously reported by the authors [7] – which shows that the economies derived from the efficient thermal management by the heat pump must be approximately similar to the increased costs of rejecting the strong stage-wise equilibrium hypothesis. Increasing the number of stages in adsorption resulted in decreased capture costs (to ≈76 USD/ton$CO_2$) while producing mathematically sound but practically unfeasible beds (of a few centimeters high or less).

In order to evaluate the improvement brought about by the energy management through the heat pump installation, the same process with the same constraints and same initial guess was optimized while setting variable $Q_{out}$ to null. The resulting capture cost was 124 USD/ton$CO_2$, indicating that the heat pump reduced costs by 37 USD/ton$CO_2$ (or about 30%) and is therefore essential if the fluidized TSA technology is to find commercial success in the CCS field.

Figure 2 below shows the annualized costs of equipment, adsorbent and utilities. It is evident that utilities are still the main cost drivers for the fluidized TSA $CO_2$ capture system, comprising approximately half of the total annualized cost. However, that is down from 76% of our previous estimates [7]. Regarding equipment, the most expensive fixed capital investment is the adsorption compressor, nearly twice as expensive as its desorption counterpart.

A sensitivity analysis with respect to the effect of the electricity cost parameter on the capture cost yielded the correlation shown in Figure 3 below. The same initial guesses, parameters and constraints were used in each simulated process optimization. We observe that the overall capture cost increases linearly in a strong correlation with the electricity cost. It also noteworthy that if such electricity cost reduces by one order of magnitude

from the parameter value used in Table 2, the $CO_2$ capture cost may be reduced to 50 USD/ton$CO_2$, which suggests that this technology's economic feasibility may depend on regional utilities availability price.

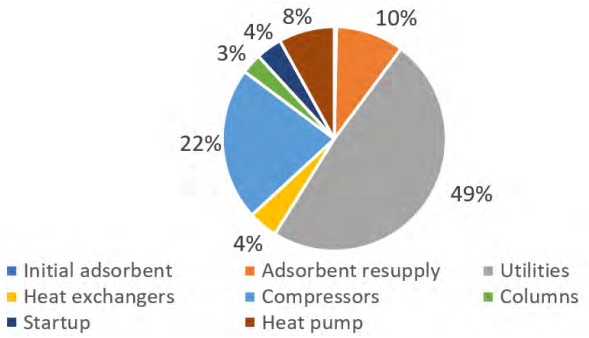

**Figure 2.** TSA annualized costs distribution.

The optimized capture costs obtained in this study, spanning approximately 50–87 USD/ton$CO_2$, lie within the range reported for several CCS technologies [2, 7] and are substantially lower than typical costs associated with direct air capture [2, 7]. Although these values remain higher than those reported for mature amine-based absorption processes [7], the corresponding economic performance is encouraging. In particular, the optimized annual internal rate of return reaches about 42% for the nominal case at 87 USD/ton$CO_2$ and increases to 64% at the lower-cost end of the electricity cost range. These results indicate that, despite its current developmental stage, fluidized TSA presents a level of economic attractiveness that justifies continued investigation, detailed modeling, and experimental validation.

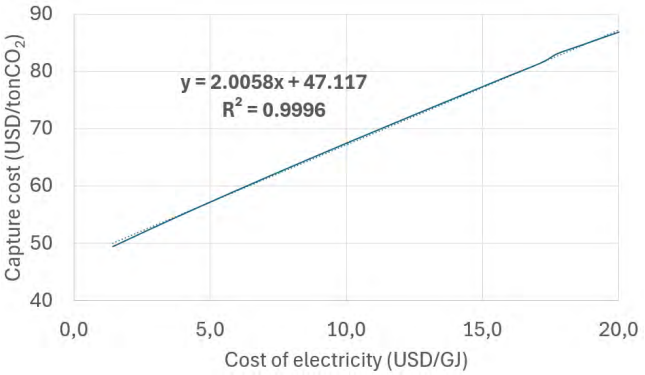

**Figure 3.** Sensitivity analysis of electricity cost on capture process cost.

## CONCLUSION

A continuous fluidized TSA with two adsorption stages and one desorption stage can reach 96% $CO_2$ purity and 95.5% $CO_2$ recovery while operating at low, safe pressures and near minimum-fluidization hydrodynamics. The optimized nominal capture cost is about 87 USD/ton$CO_2$, with an internal rate of return of 42%, numbers that imply the concept is both physically feasible and economically promising. A sensitivity analysis resulted in a positive strongly linear relation between electricity and capture costs, with the optimized value potentially as low as 50 USD/ton$CO_2$.

A central technical and economic finding is that active thermal management via the heat pump is essential: removing the heat pump from the model raises the optimized capture cost from 87 to 124 USD/ton$CO_2$. The optimization also reveals trade-offs and practical constraints: mass-transfer efficiencies in adsorption stages are low, so the economic optimum is a compromise between increasing contact and the rising equipment and utility costs that follow. Increasing the number of adsorption stages can further reduce modeled capture costs (to ≈76 USD/ton$CO_2$) but the resulting optimal bed geometries become practically infeasible (very shallow beds).

In summary, this simulation study supports the physical and economic plausibility of a heat-pump-assisted, fluidized continuous TSA system for post-combustion $CO_2$ capture; further model refinement plus experimental validation is necessary before strong scale-up claims can be made.

Future developments in this work may include adding other costs, considering the effect of flue gas contamination, or enhancing heat exchangers modelling.

## ACKNOWLEDGEMENTS

This study was financed by Brazil's National Council for Scientific and Technological Development – CNPq, scholarship 153526/2024-6, through the INCT project CAPICUA 406710/2022-8. This study was also financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – Finance Code 001. We gratefully acknowledge support of the RCGI – Research Centre for Greenhouse Gas Innovation, hosted by the University of São Paulo (USP) and sponsored by FAPESP – São Paulo Research Foundation (2014/50279-4 and 2020/15230-5) and by Shell Brasil. We also thank the strategic and important support given by ANP (Brazil's National Oil, Natural Gas and Biofuels Agency) through the R&D levy regulation.

## ABSTRACT

Ethanol derived from biomass is a promising renewable fuel; however, its long-term use as a gasoline additive is becoming increasingly uncertain due to the rise of electric vehicles and alternative propulsion technologies. This trend motivates the exploration of higher-value applications for ethanol, particularly in the food and pharmaceutical sectors, where product safety is critical. A key challenge in ethanol purification is breaking the ethanol–water azeotrope, as conventional entrainers such as ethylene glycol or glycerol can leave residual traces that limit ethanol's use in sensitive markets. Magnesium chloride ($MgCl_2$) offers an effective alternative, enabling high-purity ethanol without introducing hazardous organic residues, while exhibiting favorable hygroscopic properties and operational reliability. Simulating this system is challenging due to strong non-ideal and electrolyte interactions in phase equilibrium. Conducting a rigorous controllability analysis is also difficult; therefore, within an Integrated Design and Control (IDC) framework, accurate approximations are essential for successful implementation. This work presents a multi-objective optimization of a $MgCl_2$-based ethanol dehydration column, simultaneously minimizing the Total Annual Cost (*TAC*) and the open-loop controllability criterion ($A_\gamma + \gamma_{sm}$). The optimization integrates Aspen Plus® with Python and employs validated surrogate cost models for the preconcentrator and salt concentrator processes. Dynamic boundaries ensure product purity by maintaining the ethanol/water feed below the salt feed. The *ASF* (Achievement Scalarizing Function) solution achieved a 64.33% improvement in controllability with a 13.37% increase in *TAC* relative to the reference case reported in the literature, illustrating the trade-off between economic and control objectives. This study demonstrates that incorporating simplified controllability metrics into multi-objective optimization enables the efficient and practical design of complex systems, providing a viable approach for managing cost–control trade-offs in processes with challenging dynamics.

**Keywords**: Magnesium Chloride, Ethanol Dehydration, Multi-objective Optimization, Surrogate Models, Aspen Plus - Python

## INTRODUCTION

Ethanol produced from biomass has long been considered a promising renewable fuel, particularly as an additive in gasoline blends to reduce emissions and partially replace fossil fuels. However, the increasing adoption of electric and hydrogen mobility technologies, along with global decarbonization goals, may reduce the long-term demand for traditional liquid fuels, thereby affecting ethanol consumption [1]. Market studies indicate that ethanol demand is closely tied to gasoline and that, without supportive blending policies or mandates (such as E10, E15, or E85), its use could decline despite ongoing technological advancements [2]. Nevertheless, the future of ethanol is not predetermined; its role will continue to be shaped by regulatory frameworks, and significant opportunities exist for diversification as a chemical feedstock and within integrated biorefinery platforms, opening pathways to new applications in a low-carbon economy [3]. This transition underscores the need to explore

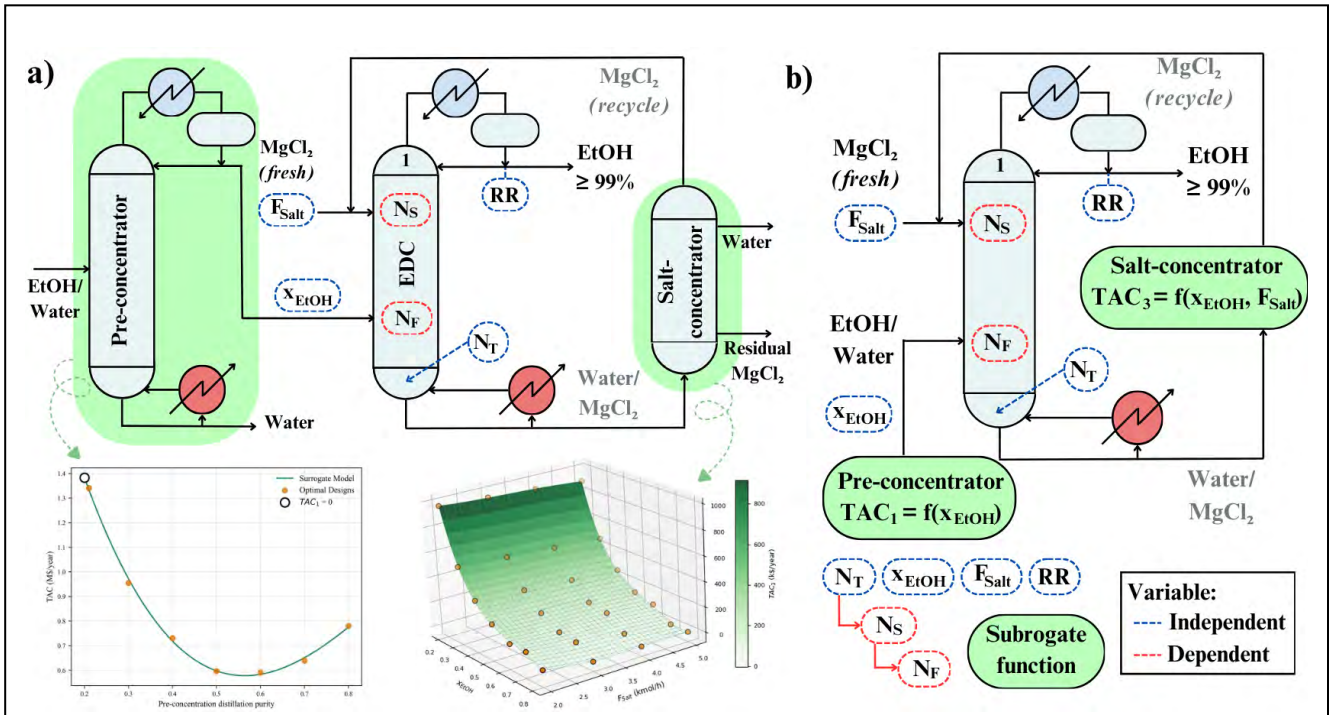

**Figure 1:** a) Actual extractive distillation process, including the mapping of the surrogate model variables used to derive Eqs. 2 and 3. b) Scheme to be optimized, in which the surrogate models replace the corresponding unit operations and variables for the optimization and their evaluation sequence.

alternative high-value uses of ethanol, particularly in the food and pharmaceutical industries, where stringent safety and quality requirements are paramount.

Ethanol with a purity exceeding 95 vol% is suitable for applications in the pharmaceutical, cosmetic, solvent, and chemical industries [4]. Conventional distillation is inherently limited to purities near the azeotropic composition, and achieving higher purities requires substantial energy input due to the reduced driving force as the azeotrope is approached. To address this limitation, several intensified separation strategies have been reported in the literature, including reactive distillation using ethylene oxide to remove water via ethylene glycol formation [5], and azeotropic distillation employing entrainers such as benzene [6]. Among these alternatives, extractive distillation has emerged as a well-established and widely implemented industrial process for producing anhydrous ethanol. This approach typically relies on high-boiling solvents (e.g. ethylene glycol and glycerol) to modify the relative volatility of the ethanol–water system, thereby enabling high-purity ethanol production [7]. However, the use of conventional extractive agents may result in residual traces in the final product, potentially limiting its suitability for sensitive applications such as the food and pharmaceutical industries.

In contrast, magnesium chloride ($MgCl_2$) has proven effective for producing high-purity ethanol without posing health risks, even at trace levels [8]. Additionally, $MgCl_2$ exhibits favorable hygroscopic properties and presents fewer operational challenges compared to alternative salts (*e.g.* $CaCl_2$) [9]. More recently, Herrera Velázquez et al. [10] optimized an $MgCl_2$-based extractive dehydration column by minimizing the Total Annual Cost ($TAC$), using surrogate models to represent the preconcentration and salt concentration processes. However, extractive distillation systems are inherently thermodynamically complex and involve more degrees of freedom than conventional distillation, which significantly complicates their control. In this context, previous studies have shown that improvements in controllability often conflict with economic performance metrics such as ($TAC$) [11], highlighting the need to explicitly incorporate control considerations during the process design stage.

Simulating these systems is challenging due to the strong non-ideal and electrolytic interactions present in phase equilibrium, which make dynamic-state simulations particularly difficult. In this context, obtaining controllability approximations from the steady-state conditions can be very useful for conducting such analyses. The Integrated Design and Control (IDC) propose designing the process and its controller simultaneously, thereby overcoming the traditional separation between process design and control [12]. This conventional separation can be suboptimal, as it often neglects the dynamic behavior of $u(t)$, where $u$ is the dynamic model, and its controllability is unknown. Although controller design is not addressed in this work, understanding controllability behavior from the early design stages is fundamental.

Open-loop analysis provides a reliable approximation, since a well-designed process naturally facilitates control, whereas advanced control cannot fully compensate for an inadequate design.

Dynamic controllability analysis during stochastic optimization is computationally intensive because it involves nested optimization. As an alternative, open-loop controllability can be evaluated using first-order transfer function models and Singular Value Decomposition ($SVD$). The condition number $\gamma^*$ is evaluated across a frequency range ($10^2$ $rad/h$), and system performance is quantified using the parameter $A_\gamma + \gamma_{sm}$, which represents the area under the condition number curve and penalizes noise amplification [13]. This approach is feasible because time constants can be estimated from steady-state data using the equations of Skogestad and Morari [14]. Employing approximate first-order models simplifies and generalizes the system analysis, allowing relevant controllability information to be obtained during the optimization process without requiring additional rigorous steps.

# METHODOLOGY

## Case Study

The extractive distillation scheme is shown in Figure 1. Figure 1a represents the real scheme, while Figure 1b shows the simplified scheme used in this work. The system feed is $500$ $kmol/h$ with an ethanol ($EtOH$) concentration of $20\,\%$ $mol$. The feed to the extractive distillation column ($EDC$), however, depends on the value of $x_{EtOH}$, as the study evaluates whether water is removed in the preconcentrator or extracted in the $EDC$. The $EDC$ is simulated in Aspen Plus® V12 using the APV140VLE-IG databank to estimate the dissociation reaction parameters (Eq. 1) required by the E-NRTL activity coefficient model. The column operates at a pressure of $1.2$ $atm$, with a stage pressure drop of $0.05$ $kPa$.

$$MgCl_2 \rightarrow Mg^{++} + 2Cl^- \tag{1}$$

The E-NRTL model parameters were fitted using equilibrium data reported by Zeng [8] and are summarized in Table 1.

**Table 1:** Electrolyte pair parameters.

| | | | |
|---|---|---|---|
| Ethanol (1) - Water (2) | $\alpha_{m_1,m_2}$ | $\tau_{m_1,m_2}$ | $\tau_{m_2,m_1}$ |
| | 0.3000 | −0.1893 | 1.8224 |
| Ethanol (1) - $\boldsymbol{MgCl_2}$ (ca) | $\alpha_{ca,m_1}$ | $\tau_{m_1,ca}$ | $\tau_{ca,m_1}$ |

| | 0.2000 | 7.8720 | −4.1470 |

For the preconcentration and salt concentration process, surrogate models are used to provide the data required for the economic analysis. These units are represented with surrogate models because they correspond to well-established and optimized process configurations under the operating conditions considered, while also significantly reducing the computational complexity of the overall optimization problem. The surrogate model for the preconcentrator is defined in Eq. 2 and depends on the ethanol purity, as its primary purpose is to deliver the feed to the $EDC$ at the specified ethanol composition, $x_{EtOH}$.

$$\begin{aligned} TAC_1[M\$/year] \approx f(x_{EtOH}) &= -4.1959x_{EtOH}^3 \\ &+ 11.6440x_{EtOH}^2 \\ &- 9.1315x_{EtOH} + 2.7769 \end{aligned} \tag{2}$$

$$0.2 < x_{EtOH} \leq 0.8$$

Eq. 2 is defined over the range $0.2 < x_{EtOH} \leq 0.8$, with the additional constraint that when $x_{EtOH} = 0.2$, the associated cost $TAC_1 = 0$. Under these conditions, a preconcentration unit is not required, since the ethanol composition already matches that of the feed to the separation system. This lower limit is based on the typical ethanol concentration found in the water/ethanol mixture at the outlet of a biomass fermentation reactor [16, 17].

Consequently, the maximum ethanol purity that can be fed to the extractive distillation column is $x_{EtOH} = 0.8$, which remains below the azeotropic composition. Eq. 2 depends solely on the purity of the $EtOH$, as it is a conventional distillation scheme. The surrogate model is adjusted based on optimized schemes for discretized ethanol purities (Figure 1a). Therefore, for any given $EtOH$ purity used to evaluate the preconcentrator cost, the model ensures that the design corresponds to the optimal configuration for that specific $x_{EtOH}$ [10]. Eq. 3 presents the surrogate model for the salt concentrator located downstream of the $EDC$.

$$\begin{aligned} TAC_3[k\$/year] \approx f(x_{EtOH}, F_{Salt}) = \\ -8236x_{EtOH} + 534F_{Salt} + 9043x_{EtOH}^2 \\ -2374x_{EtOH}F_{Salt} + 9043F_{Salt}^2 + 71.53x_{EtOH}^3 \\ +7490x_{EtOH}^2F_{Salt} + 144.5x_{EtOH}F_{Salt}^2 \\ +77.52F_{Salt}^3 - 3382x_{EtOH}^4 - 9382x_{EtOH}^3F_{Salt} \\ -356.5x_{EtOH}^2F_{Salt}^2 + 1.927x_{EtOH}F_{Salt}^3 \\ -11.97F_{Salt}^4 + 4033x_{EtOH}^4F_{Salt} + 216x_{EtOH}^3F_{Salt}^2 \\ +8.697x_{EtOH}^2F_{Salt}^3 - 0.831x_{EtOH}F_{Salt}^4 \\ + 0.7047F_{Salt}^5 + 2158 \end{aligned} \tag{3}$$

$$0.2 \leq x_{EtOH} \leq 0.8;\ 2 < F_{Salt}[kmol/h] \leq 5$$

This model is a function of the $x_{EtOH}$, and the fresh salt flow rate, $F_{Salt}$. The dependence on $x_{EtOH}$ arises because the amount of water to be removed is determined by the $EtOH$ concentration entering the system. Additionally, the salt flow rate directly affects both the

thermodynamic behavior of the unit and the required water removal, since a certain amount of water is needed to dissolve the solid salt (approximately $2\,\%\,mol$ relative to the total salt mixture). Both surrogate models are taken from Herrera Velázquez et al. [10]. The optimization variables for this problem are the ethanol fraction at the outlet of the preconcentrator and the inlet of the $EDC$ ($x_{EtOH}$), the salt flow rate $F_{Salt}$, the total number of stages ($N_T$), the salt feed stage ($N_S$), the ethanol-water feed stage ($N_F$), and the reflux ratio ($RR$). The variables will be solved sequentially as shown in Figure 1b.

## Mathematical Treatment

The problem is formulated as a Multi-Objective Optimization ($MOO$) problem where the objective functions are $TAC$ and $A_\gamma + \gamma_{sm}$, as shown in Eq. 4.

$$\min\left(TAC, A_\gamma + \gamma_{sm}\right) = f(x_{EtOH}, F_{Salt}, N_T, N_s, N_F, RR)$$
$$s.t.\, Conv = 0;\; P_{EtOH} \geq 99\,\%\,mol \tag{4}$$

$Conv$ is a convergence constraint; if it is not met, a penalty value is assigned to each objective function. The distillate flow rate is set at $100\ kmol/h$, and the purity constraint is set to be greater than $99\,\%\,mol$ for the ethanol ($P_{EtOH}$); if this is not met, a penalty value is assigned. The optimization bounds are presented in Table 2.

**Table 2:** Optimization Bounds.

| ***Variables*** | ***Boundaries*** $[\boldsymbol{lower}, \boldsymbol{upper}]$ |
|---|---|
| $x_{EtOH}$ | $[0.2, 0.8]$ |
| $F_{Salt}\ [kmol/h]$ | $[2, 5]$ |
| $N_T$ | $[15, 50]$ |
| $N_S$ | $[2, (2/3)N_T]$ |
| $N_F$ | $[N_S + 2, N_T - 1]$ |
| $RR$ | $[0.2, 10]$ |

To ensure product purity, dynamic boundaries were applied to the feed stage positions, guaranteeing that the ethanol/water mixture is always fed below the salt. The variables were normalized following the method reported by Herrera Velázquez et al. [10] using Eq. 5.

$$VN_i = \left(B_{upper} - V_i\right)/\left(B_{upper} - B_{lower}\right) \tag{5}$$

Where $VN_i$ is the normalized value of the variable $V_i$, and $B_{upper}$ and $B_{lower}$ are the upper and the lower bounds of variable $i$, respectively. The $TAC_2$ associated to the $EDC$ is calculated as indicated in Eq. 6, and the overall $TAC$ is calculated as shown in Eq. 7.

$$TAC_2\left[\frac{\$}{year}\right] = C_{Vapor} + C_{Cooling} + \frac{\left(\frac{CEPCI_{2022}}{CEPCI_{2001}}\right)\left(C_{Shell} + C_{Plates} + C_{Reboiler} + C_{Condenser}\right)}{Recovery\ time\ (Years)} \tag{6}$$

$$TAC\left[\frac{\$}{year}\right] = (1x10^6)TAC_1 + TAC_2 + (1,000)TAC_3 \tag{7}$$

With respect to open-loop controllability, a sensitivity analysis indicates that the considered disturbances have a negligible effect on the gains of both the preconcentrator and the salt concentrator. Consequently, these units are excluded from the controllability objective function, which is therefore applied exclusively to the $EDC$.

For the calculation of $A_\gamma + \gamma_{sm}$, the transfer function matrix $G_j(s)$ is calculated as indicated in Eq. 8. $P_{EtOH,j}$ and $P_{W,j}$ (Water) represent the purities achieved for the design at iteration $j$. $P_{EtOH,RR_j}$ and $P_{W,RR_j}$ correspond to the purities obtained by applying a positive perturbation of $0.5\%$ to the $RR$. Similarly, $P_{EtOH,Q_{H,j}}$ and $P_{W,Q_{H,j}}$ represent the purities obtained by applying a positive perturbation of $0.5\%$ to the heat duty ($Q_H$). Each disturbance is evaluated through independent simulations, resulting in a total of three simulations per iteration $j$: (1) to verify that the design satisfies the constraints, (2) to apply a perturbation to $RR$ and (3) to apply a perturbation to $Q_H$.

$$G_j(s) = \begin{bmatrix} \frac{\left(\frac{P_{EtOH,RR_j} - P_{EtOH,j}}{0.0025}\right)}{1 + \tau_{1,1}\, s} & \frac{\left(\frac{P_{EtOH,Q_{H,j}} - P_{EtOH,j}}{0.0025}\right)}{1 + \tau_{1,2}\, s} \\ \frac{\left(\frac{P_{W,RR_j} - P_{W,j}}{0.0025}\right)}{1 + \tau_{2,1}\, s} & \frac{\left(\frac{P_{W,Q_{H,j}} - P_{W,j}}{0.0025}\right)}{1 + \tau_{2,2}\, s} \end{bmatrix} \tag{8}$$

For $\tau$, they are calculated as indicated in Eq. (9-12).

$$\tau_{1,1} = \frac{\sum_{k=2}^{N_T-1} H_{L,k}\left(x_{EtOH,RR_j,k} - x_{EtOH,k}\right)}{F_{D,RR_j}\left(P_{EtOH,RR_j} - P_{EtOH,j}\right) + F_{B,RR_j}\left(P_{W,RR_j} - P_{W,j}\right)} \tag{9}$$

$$\tau_{2,1} = \frac{\sum_{k=2}^{N_T-1} H_{L,k}\left(x_{W,RR_j,k} - x_{W,k}\right)}{F_{D,RR_j}\left(P_{EtOH,RR_j} - P_{EtOH,j}\right) + F_{B,RR_j}\left(P_{W,RR_j} - P_{W,j}\right)} \tag{10}$$

$$\tau_{1,2} = \frac{\sum_{k=2}^{N_T-1} H_{L,k}\left(x_{EtOH,Q_{H,j},k} - x_{EtOH,k}\right)}{F_{D,Q_{H,j}}\left(P_{EtOH,Q_{H,j}} - P_{EtOH,j}\right) + F_{B,Q_{H,j}}\left(P_{W,Q_{H,j}} - P_{W,j}\right)} \tag{11}$$

$$\tau_{2,2} = \frac{\sum_{k=2}^{N_T-1} H_{L,k}\left(x_{W,Q_{H,j},k} - x_{W,k}\right)}{F_{D,Q_{H,j}}\left(P_{EtOH,Q_{H,j}} - P_{EtOH,j}\right) + F_{B,Q_{H,j}}\left(P_{W,Q_{H,j}} - P_{W,j}\right)} \tag{12}$$

Where $x_{EtOH,k}$ and $x_{W,k}$ are the mole fractions of ethanol and water, respectively, at stage $k$. $F_{D,RR_j}$ and $F_{B,RR_j}$ are the distillate and bottom flow rates, respectively, for iteration $j$ under the perturbation of $RR$. Similarly, $F_{D,Q_{H,j}}$ and $F_{B,Q_{H,j}}$ are the distillate and bottom flow rates for iteration $j$ under the perturbation of $Q_H$. Finally, $H_{L,K}$ represents the liquid holdup at stage $k$. The $G_j(s)$ from Eq. (8) is then converted to the frequency domain ($s = \omega j$) and

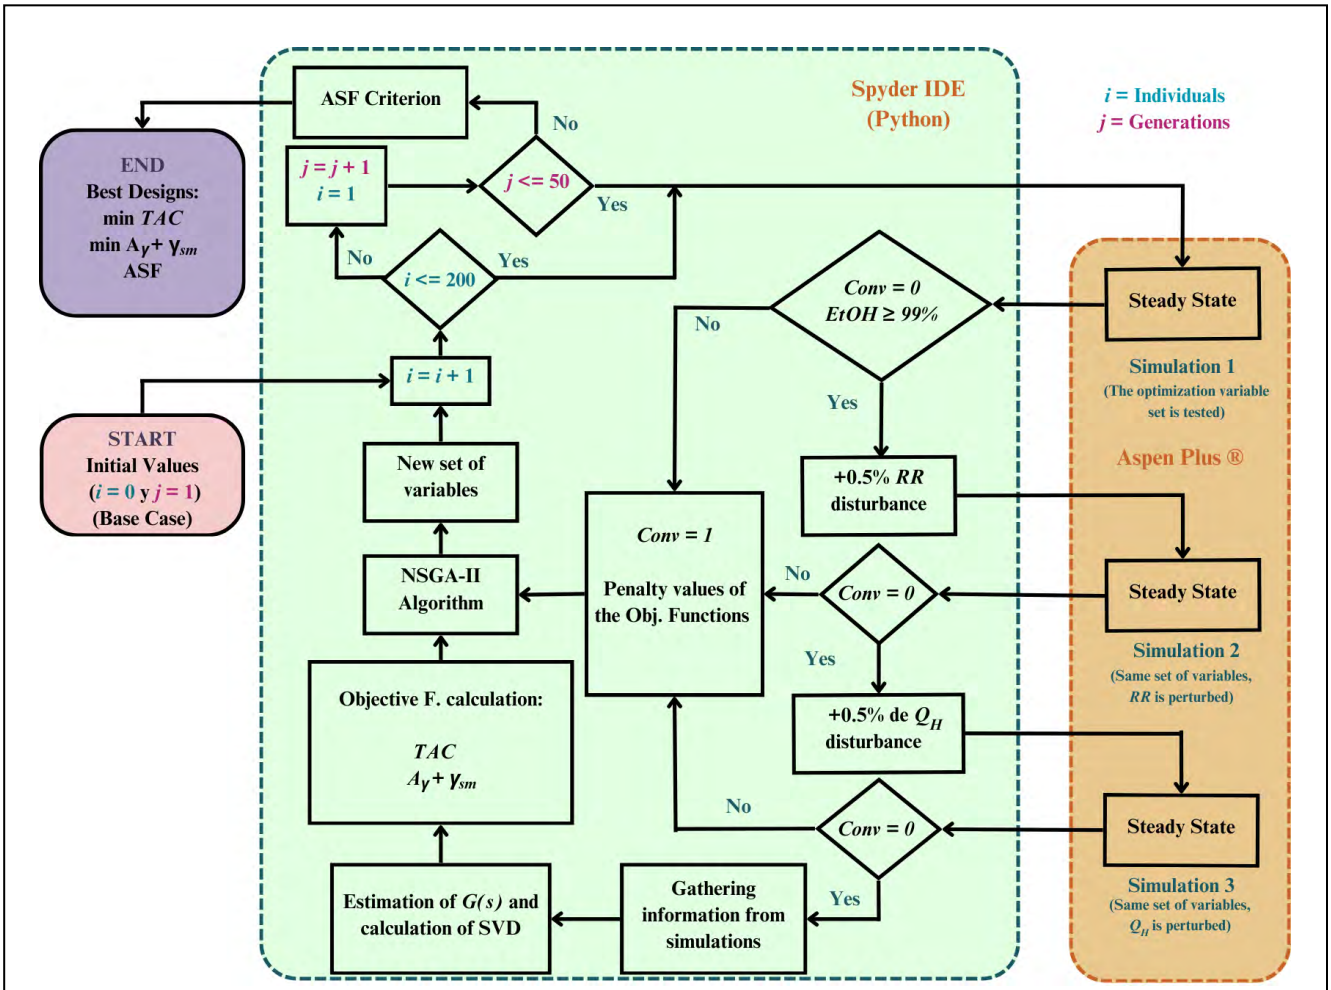

**Figure 2.** Flowchart of the mathematical model optimized for *EDC* with the NSGA-II algorithm.

the DVS of its $\gamma^*$, are evaluated over the frequency range from $10^{-4}$ $rad/h$ to $10^{2}$ $rad/h$. Numerical integration is subsequently performed using Eq. 13 and the trapezoidal method. This equation is discussed in detail in Herrera Velázquez et al. [15].

$$A_\gamma + \gamma_{sm} = \frac{\int_{\log a}^{\log b} \log(\gamma^*)\, d(\log \omega)}{\log b - \log a} + \int_{\log a}^{\log b} \Delta log(\omega)\, |\gamma'_{i+1} - \gamma'_i|\, d(\log \omega) \qquad (13)$$

$$\gamma'_{i+1} - \gamma'_i = \frac{log[\gamma^*(\omega_{i+1})] - log[\gamma^*(\omega_i)]}{log(\omega_{i+1}) - log(\omega_i)} - \frac{log[\gamma^*(\omega_i)] - log[\gamma^*(\omega_{i-1})]}{log(\omega_i) - log(\omega_{i-1})}$$

Where $b$ and $a$ are the upper and lower limits of the evaluated frequency range, respectively. The model was optimized using the NSGA-II algorithm [18], with 50 generations of 200 individuals each. Figure 2 shows the complete optimization process. The algorithm was implemented in Spyder IDE 5.2.2 and executed on an Intel® Xeon® W-3235 CPU at 3.30 GHz with 48 GB of RAM.

## RESULTS

The execution time for the optimization was 9.79 hours. A total of $4,359$ designs $(43.59\ \%)$ satisfy the purity and convergence constraints. The summarized results are shown in Table 3. The criterion $A_\gamma + \gamma_{sm}$ is not reported for the reference case because, under the methodology described, the perturbation applied to the $RR$ does not converge $(Conv = 1)$. Figure 3 shows the Pareto front obtained after the optimization process, highlighting the most relevant solutions $(\min TAC, \min A_\gamma + \gamma_{sm}, ASF)$. Figure 4 presents the distribution of partial costs $(TAC_1, TAC_2\ and\ TAC_3)$ within the overall $TAC$ for all solutions, as well as for the reference design.

Figure 5 shows the values of condition number $(\gamma^*)$ and the minimum singular values $(\sigma_*)$ derived from the control estimates obtained using Eq. (8–12). Due to the difference in orders of magnitude, the trajectories of $\gamma^*$ cannot be clearly observed; however, $\sigma_*$ enables the identification of relevant differences in this analysis. The behavior of $\sigma_*$ is consistent with expectations for each

solution, with the $\min TAC$ solution exhibiting the poorest performance. This trade-off highlights the inherently multi-objective nature of the problem.

**Table 3:** Summary of results of MOO.

| *Variables* | *Ref. Des.* [10] | $\min TAC$ | $\min A_\gamma + \gamma_{sm}$ | *ASF* |

## CONCLUSIONS

Compared to the reference design, the $ASF$ solution (close to the utopian point) shows a $13.37\%$ increase in $TAC$. However, from a controllability perspective, the reference case exhibits high sensitivity to perturbations in the reflux ratio ($RR$), as evidence by convergence difficulties in the simulation, suggesting unstable dynamic behavior. This result confirms the inherent trade-off between cost and controllability in the problem. A total of 89 non-dominated solutions were identified, forming the Pareto front and reflecting the multi-objective nature of the system. Most of these solutions, except for the $\min A_\gamma + \gamma_{sm}$ solution, use an $EDC$ feed consisting of an ethanol-water mixture with $70\%$ mol ethanol. This finding differs from what is commonly reported in the literature, where compositions close to the azeotrope are typically preferred. In this case study, however, feeding at a lower purity is more economical due the dominant contribution of the preconcentrator to the $TAC$, which amounts for more than $50\%$ of the cost in all evaluated designs.

In contrast, the solution corresponding to the $\min A_\gamma + \gamma_{sm}$ proposes a feed with $80\%$ mol ethanol, which coincides with the upper limit considered in the surrogate

model of the preconcetrator. This behavior can be explained by the relationship between feed composition and internal column flows, which directly influence the time constants used in controllability estimation. Higher ethanol purity reduces the amount of water entering the $EDC$, thereby modifying the system dynamics and improving controllability. For $\min A_\gamma + \gamma_{sm}$ solution, the salt concentrator has a negligible impact ($TAC_3 < 1,000$ \$/$yr$), as salt recovery satisfies the water requirements for recirculation without incurring significant additional costs.

Finally, incorporating a controllability criterion based on simplified models within a $MOO$ framework provides a practical approach for designing complex systems such as the $MgCl_2$-based $EDC$, particularly when full dynamic modeling is difficult to implement. Evaluating controllability using first-order transfer functions and open-loop $SVD$ analysis yields quantitative indicators of dynamic behavior, enabling the identification of sensitive and robust configurations. In this study, an indirect relationship between controllability and $TAC$ is observed, supporting a more comprehensive analysis of the trade-off between economic performance and operability. This approach enables the generation of Pareto fronts that facilitate the selection of robust and economically viable designs in systems with complex dynamics.

## ABSTRACT

Building a robust calibration curve is essential for accurate quantification of multicomponent mixtures. Matrix effects can distort the proportional relationship between the analyte concentration and instrumental response. In addition, classical machine learning models do not inherently incorporate simple physical constraints, such as the requirement that a zero response must correspond to a zero concentration, which can result in non-zero predictions. To address this limitations, prior-induced calibration models were proposed that inherently embed this physical constraint into the model architecture. A dataset was generated for ethanol electrooxidation products using headspace gas-chromatography-mass spectrometry (HS-GC-MS). Multiple linear regression (MLR), polynomial regression and artificial neural network (ANN) models were trained to investigate the effects of model complexity and the incorporation of physical information on predictive performance. Model selection and complexity were assessed using Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC). The prior-induced polynomial regression model achieved improved predictive accuracy while maintaining low model complexity, whereas the ANN provided comparable accuracy but was strongly penalized due to its substantially higher complexity.

## INTRODUCTION

Accurate quantification of individual species in multicomponent mixtures is essential for reliable chemical analysis, process monitoring and optimization of operating parameters on selectivity and conversion, which is critical for both batch studies and reactor design. Matrix effects and competitive partitioning among analytes complicate accurate quantification by altering the linear relationship between the analyte concentration and the response [1]. In such systems, the measured peak area is not solely proportional to the analyte concentration but is also influenced by the concentrations of the co-existing components, since each composition defines a new vapor–liquid equilibrium governed by non-ideal intermolecular interactions. To overcome this, an appropriate calibration model is required to accurately resolve the concentration of each component [2]. A calibration curve is a regression model between the known concentrations of analytes and its response obtained from an analytical instrument, which allows the prediction of the concentration of an unknown mixture [3].

Matrix effects have been addressed using calibration models, including linear and non-linear models such as MLR, principal component analysis, partial least squares (PLS), and ANNs [4]. Veiga-del-Baño et al. built LC–MS/MS and GC–MS/MS calibration models using linear, weighted linear, and polynomial regression, and reported that the weighted linear model had the best performance compared the other models [5]. Also, to identify adequate calibration models, Chen et al. investigated six different linear and non-linear calibration equations and reported that most real calibration curves exhibit measurable non-linearity, with non-linear models often outperforming linear models in terms of fitting and prediction [6]. Matrix effects were addressed by developing a calibration curve using PLS model to quantify volatile compounds in wine, where single internal standard

calibration failed to correct matrix effects [7]. Campmajó et al. used PLS to quantify peanut and hazelnut adulteration in almond products with prediction errors below 6.1% and no observable matrix effects [8]. Brusamarello et al. compared PLS and ANN models on UV–Vis spectra for soybean biodiesel quantification, finding that the ANN model achieved higher predictive accuracy for complex reaction mixtures [9]. Gholivand et al. addressed strong serum matrix effects in voltammetric analysis by calibrating PLS models in blank serum and applying baseline and alignment corrections, allowing reliable simultaneous determination of five electroactive alkaloids [10].

Classical machine learning algorithms cannot inherently incorporate simple physical constraints, such as the condition that in the absence of a given species, the corresponding peak area should be zero. As a result, such models may produce non-zero predictions even when the input peak area is zero. This issue can be addressed by applying a rule-based correction layer that forces the output to zero whenever the input value is zero or by manipulating the dataset by augmenting the training dataset with zero-concentration samples, however, this could introduce bias into the model. Alternatively, the model can be designed to inherently learn this constraint. In this case, the model cannot violate the physical boundary condition, as the physical information is enforced by design. Moreover, embedding this constraint reduces the effective model complexity and improves robustness near the detection limit.

This work aims to develop an data-driven calibration model for quantification of ethanol oxidation products while capturing the nonlinear relationships arising from matrix effects. The model also incorporates a simple physical prior: the principle that a zero peak area corresponds to zero concentration to increase prediction accuracy further. There are two models proposed: Prior-informed polynomial regression and prior-informed branched ANN model. The predictive performances of these models are compared with those of MLR, polynomial regression, and feed forward ANN. The model complexities are assessed using AIC and BIC.

# METHODOLOGY

## Chemicals

Ethanol (>99%) was purchased from Fisher Scientific (Hampton, NH, USA). Acetaldehyde (>99.5%), acetic acid (>99.9%), ethyl acetate (>99.7%), and 1-propanol (>99.9%) were obtained from Sigma-Aldrich (St. Louis, MO, USA). All chemicals were of analytical grade and used as received without further purification. Ultrapure water (resistivity ≥18.2 MΩ·cm) was used for all solution preparations

## Method

Headspace gas chromatography–mass spectrometry (HS–GC–MS) was utilized to generate a dataset of standard solutions. Analyses were performed using an Agilent 8890 GC coupled to a 5977C MS and an 8697 HS. Chromatographic separation was achieved using an Agilent J&W HP-5 capillary column (30 m × 0.25 mm × 0.50 µm). Helium was used as the carrier gas at a constant flow rate of 2 mL $min^{-1}$. The GC inlet temperature was set to 250 °C, and a split injection mode with a split ratio of 100:1 was applied. The oven temperature was maintained isothermally at 35 °C for 5 min, which was sufficient to achieve complete elution and baseline separation of all target compounds. Headspace conditions were set to 70 °C for the oven, 80 °C for the loop, and 90 °C for the transfer line. Samples were equilibrated in the headspace oven for 10 min prior to injection, and the injection duration was 0.5 min. The mass spectrometer was operated in electron impact (EI) ionization mode at an ionization energy of 70 eV. The source and quadruple temperatures were set to 230 °C and 150 °C, respectively. Initial method development and peak identification were carried out in full-scan mode (m/z 30–80) to verify peak identity and chromatographic separation. Subsequently, selected ion monitoring (SIM) mode was employed to improve sensitivity and quantitative performance. The monitored ions and corresponding retention time windows for each analyte are summarized in Table 1:

**Table 1:** Retention time windows and quantifier m/z values used for SIM mode for each component.

| Component | Time Segments | m/z |
|---|---|---|
| Acetaldehyde | -1.20 | 29 |
| Ethanol | 1.20-1.48 | 31 |
| 1-propanol | 1.48-1.80 | 31 |
| Ethyl acetate | 1.80- | 43 |

## Sample preparation & data acquisition

Standard mixtures were prepared to generate calibration and simulated reaction datasets. All solutions were transferred into 20 mL headspace vials and salted with 3.20 g of sodium chloride per vial to enhance analyte partitioning into the headspace. The vials were immediately sealed with Teflon/silicone crimp caps prior to analysis. Standard mixtures containing 1-propanol as an internal standard (IS) were prepared, with individual analyte concentrations varied between 50 and 1000 mg $L^{-1}$ across four concentration levels. A full factorial experimental design was employed to generate all possible combinations of species. For each combination, four calibration standards were prepared. The concentration range was divided into four equal intervals, and Latin hypercube sampling was used to assign one concentration value from each interval to every species present in a given mixture. The sampled concentration values were rounded for accurate and practical pipetting. Solutions

containing only acetic acid were excluded from the HS–GC–MS dataset. Due to its significantly lower volatility, acetic acid was quantified separately using ion chromatography (IC), as acetic acid is the only ionic species among the target analytes. Nevertheless, acetic acid was included in all standard mixtures, as its presence can influence vapor–liquid equilibrium and thereby affect the headspace partitioning behavior of the volatile components. For mixtures containing all analytes, simulated electrooxidation samples were generated by assuming a representative bioethanol feed concentration of approximately 2 M. Random selectivities toward products were applied, which yielded 12 simulated electrooxidation samples and a total of 64 calibration samples. The peak area of each analyte was extracted and normalized to the peak area of the internal standard. These normalized peak areas were used as input variables for model training, while the corresponding known concentrations served as output variables.

## Model Development

To analyze the effects of increasing model complexity and prior-induced model architectures on prediction accuracy and model training, 5 different models were trained: MLR, polynomial regression, ANN, prior-induced polynomial regression, and prior-induced branched ANN. The MLR model was used as the baseline for comparison with the more complex models. Polynomial regression and ANN models were also included to enable direct comparison with the prior-induced models. All models were evaluated using 5-fold cross-validation, and MAE and RMSE were used as metrics to compare predictive performance. Model complexities were additionally assessed using the AIC an BIC.

### Baseline calibration models

MLR model was employed as a baseline model due to its simplicity, interpretability, and widespread use in chemometrics. The MLR model is expressed as:

$$\hat{y} = \mathbf{X}\beta \tag{1}$$

Where $\hat{y}$ denotes the predicted output vector, $\mathbf{X}$ is the input matrix, $\beta$ is the regression coefficients. Polynomial regression and ANN models were also developed to consider potential nonlinear relationships between normalized areas and analyte concentrations, and for comparison with the proposed prior-induced models. Polynomial model extends the linear model by applying a polynomial feature expansion $\mathbf{\Phi}(.)$ of a degree 2:

$$\hat{y} = \mathbf{\Phi}(\mathbf{X})^{\mathrm{T}}\beta \tag{2}$$

Despite the nonlinear transformation of the inputs, the model is still linear with respect to the parameters, $\beta$. ANNs were used as a flexible nonlinear models capable of capturing complex interactions among variables. The general expression for a feedforward ANN with $L$ layers is given by:

$$\hat{y} = \boldsymbol{W}_L\sigma_{L-1}\left(\boldsymbol{W}_{L-1}\sigma_{L-2}\left(\ldots\sigma_1(\boldsymbol{W}_1\mathbf{X})\right)\right) \tag{3}$$

Where $\boldsymbol{W}_L$ represents the weight matrices (including bias terms) of layer $L, \sigma_L$ denotes the activation function of the corresponding layer.

Linear and polynomial regression models were implemented using the scikit-learn library (version 1.7.2), while prior-induced polynomial regression and ANN models were developed using PyTorch (version 2.5.1) in Python. All models were trained and evaluated using 5-fold cross-validation to ensure robust performance assessment. For all models, normalized peak areas were used as input variables, yielding a total of 3 input features. Each model predicts 3 outputs, corresponding to the concentrations of the respective species. All input and output variables were normalized in the range 0-1. ANN training employed the mean squared error (MSE) as the loss function. Hyperparameters of the ANN models were selected using a manual exploration strategy to identify an optimized network architecture and training configuration considering dataset size. For this, a nested cross-validation strategy was adopted, where hyperparameter optimization was conducted using an additional 5-fold cross-validation within the training set of each k-fold. The activation functions evaluated included the rectified linear unit (ReLU) and the hyperbolic tangent (tanh). The number of hidden layers was varied between 1 and 3, and the number of neurons per layer ranged from 3 to 36. Model training was performed using the Adam optimizer, with learning rates manually explored in the range of $10^{-4}$ and $10^{-2}$. Xavier weight initialization were applied to enhance training stability and convergence.

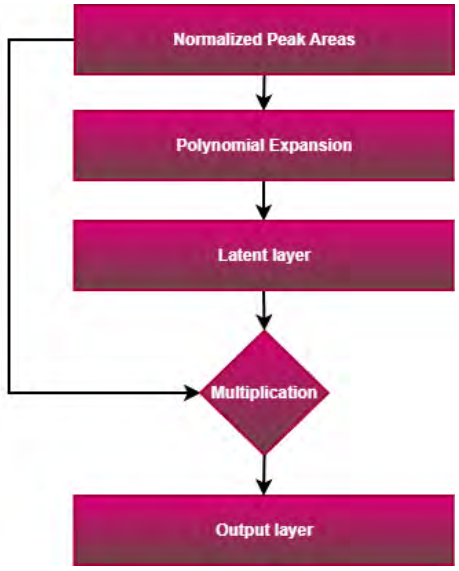

**Figure 1.** Physical prior-induced polynomial regression workflow.

## Integration of physical prior

The prior-induced polynomial regression model was implemented in PyTorch using 3 input layers in the input layer. Polynomial feature expansion was applied to the inputs in the first layer. This layer was followed by the formation of intermediate terms. Then, these intermediate terms were multiplied with the input layer and linearly mapped to the output layer, yielding the final outputs. The resulting architecture is visualized in the Figure 1. Model training was performed using the MSE loss function and the Adam optimizer, with a fixed learning rate of $10^{-3}$.

The ANN model was constructed following a similar prior-integration strategy, in which the original input variables were multiplied with the intermediate terms. To make ANN specialized for each of the output, the ANN architecture was partitioned into 3 separate sub-branches, each corresponding to an individual output. The model incorporates a shared base layer to capture common features across all outputs, followed by dedicated branch layers, which aims output-wise refinement and increased predictive performance. This branched ANN architecture, which balanced the shared information and output-specific modelling with an incorporation of physical prior is illustrated in the Figure 2.

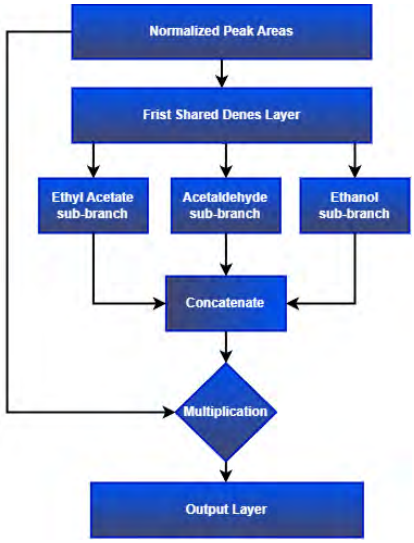

**Figure 2.** Physical prior-induced sub-branched ANN model.

## Model Evaluation Criteria

AIC and BIC are widely used model selection criteria in machine learning that balances goodness of fit against model complexity. The two criteria differ in the way model complexity is penalized. In this study, both metrics were used to evaluate the proposed models in order to avoid selection of unnecessarily complex calibration models. For regression models, AIC is [11]:

$$AIC = n \bullet \ln\left(\frac{RSS}{n}\right) + 2k \quad (1)$$

Where $n$ is the total number of data points used for fitting, and $k$ is the number of parameters, which penalizes the model complexity. The first term in the equation indicates goodness of fit, and $RSS$ is the residual sum of squares, and calculated across all components since there are 3 outputs:

$$RSS = \sum_{i=1}^{n} \sum_{j=1}^{3} \left(y_{ij} - \hat{y}_{ij}\right)^2 \quad (2)$$

In this case, AIC is calculated fold-wise and average of the 5-fold is reported to compare the models.

BIC is derived from Bayesian probability theory, and used for model selection [12]. It balances likelihood with a sample-size penalty. Like AIC, the first term evaluates the goodness of fit. BIC penalizes the number of parameters more strongly than AIC with the multiplication of $\ln(n)$ in the second term, which promotes simpler models.

$$BIC = n \bullet \ln\left(\frac{RSS}{n}\right) + k \bullet \ln(n) \quad (3)$$

For ANNs, BIC strictly limits the number of variables and favors linear models like polynomial regression with a low degree.

# RESULTS & DISCUSSION

Figure 3 shows the relationship between concentration and the response behaviour of each analyte, where the primary y-axis is normalized area and the secondary y-axis corresponds to the raw peak area. The application of an internal standard has a very clear effect mitigating fluctuations between injections and instrumental variability, and improves stability and robustness significantly. However, Figure 3 also reveals that application of internal standard is not sufficient to explain relation with a perfectly linear trend, as there is still noticeable response variability.

## Baseline Model Performance

Averaged over 5-fold cross-validation, MLR model yields a component-wise MAE and RMSE values of 29.26 and 35.40 for ethanol, 45.16 and 55.55 for acetaldehyde, and 49.75 and 58.00 for ethyl acetate. These results serve as a baseline for comparison with more flexible calibration models.

Parity plots for the test results of each k-fold obtained using the MLR model are shown in Figure 4 for each component separately. A clear model bias is observed in all plots, where predictions are above the parity line in the center of the range and below the parity line at the extremes. In addition, the MLR model produces non-zero predictions at zero concentration, this phenomenon is particularly evident for ethyl acetate predictions.

Standard polynomial regression with a second degree expansion results in a significant improvement in both metrics. The component-wise MAE and RMSE values are given in Table 2. The significant improvement in prediction accuracy indicates that the calibration model benefits from incorporating nonlinear relationships between the response and analyte concentrations.

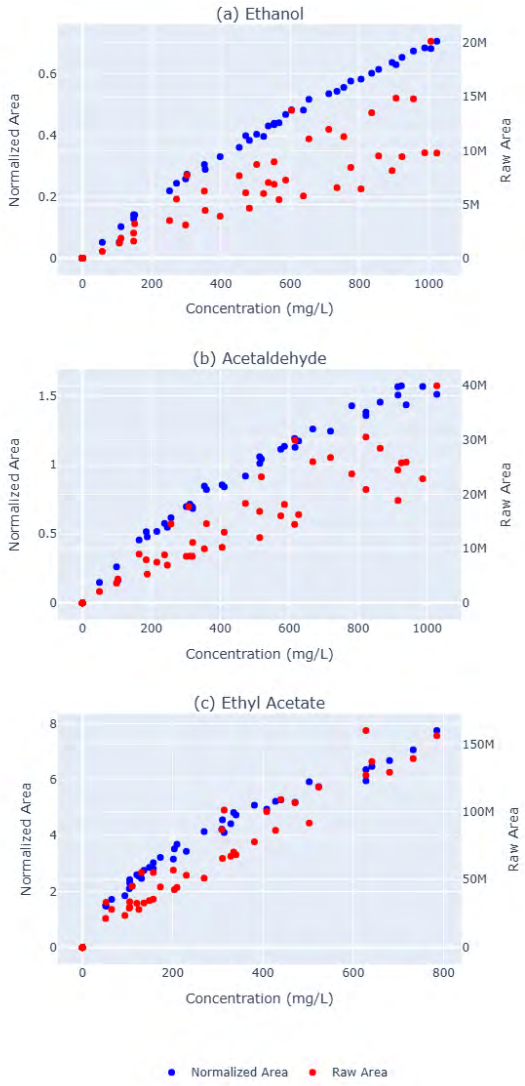

**Figure 3.** Standard concentrations and raw and internal standard normalized peak areas for (a) ethanol, (b) acetaldehyde, and (c) ethyl acetate.

The ANN model also exhibits predictive performance similar to polynomial regression. As shown in Table 3, the ANN yields a slightly higher MAE and RMSE for acetaldehyde, while achieving a nearly 10% decrease in MAE and RMSE for ethyl acetate. Overall, both polynomial regression and ANN outperform the MLR model, which indicates the importance of incorporating nonlinear relationships between the input variables and analyte concentrations.

**Table 2:** Component-wise MAE and RMSE for test set predictions, averaged over 5-fold cross-validation, obtained using polynomial regression.

| Component | MAE | RMSE |
|---|---|---|
| Ethanol | 10.11 | 15.03 |
| Acetaldehyde | 18.30 | 29.92 |
| Ethyl acetate | 15.17 | 23.89 |

**Table 3:** Component-wise MAE and RMSE for test set predictions, averaged over 5-fold cross-validation, obtained using ANN.

| Component | MAE | RMSE |
|---|---|---|
| Ethanol | 10.30 | 14.50 |
| Acetaldehyde | 19.08 | 30.46 |
| Ethyl acetate | 13.50 | 20.81 |

**Table 4:** Component-wise MAE and RMSE for test set predictions, averaged over 5-fold cross-validation, obtained using prior-induced polynomial regression.

| Component | MAE | RMSE |
|---|---|---|
| Ethanol | 7.50 | 12.55 |
| Acetaldehyde | 18.56 | 33.18 |
| Ethyl acetate | 12.04 | 20.50 |

**Table 5:** Component-wise MAE and RMSE for test set predictions, averaged over 5-fold cross-validation, obtained using polynomial regression prior-induced branched ANN model.

| Component | MAE | RMSE |
|---|---|---|
| Ethanol | 7.98 | 13.45 |
| Acetaldehyde | 17.37 | 29.85 |
| Ethyl acetate | 12.84 | 23.50 |

**Table 6:** Number of parameters, k, AIC, and BIC values for each model.

| Model | k | AIC | BIC |
|---|---|---|---|
| MLR | 12 | 332 | 352 |
| Polynomial regression | 30 | 302 | 352 |
| Fully connected ANN | 115 | 475 | 545 |
| Prior-induced polynomial regression | 30 | 316 | 370 |
| Prior-induced branched ANN | 155 | 665 | 803 |

## Prior-Induced Models

The prior-induced polynomial regression and branched ANN models were evaluated using the same validation procedure as the baseline models. Incorporating prior information into the polynomial regression framework results in improved prediction accuracy for ethanol and ethyl acetate, while it yields comparable performance for acetaldehyde across both error metrics.

The component-wise MAE and RMSE values obtained using this model are summarized in Table 4.

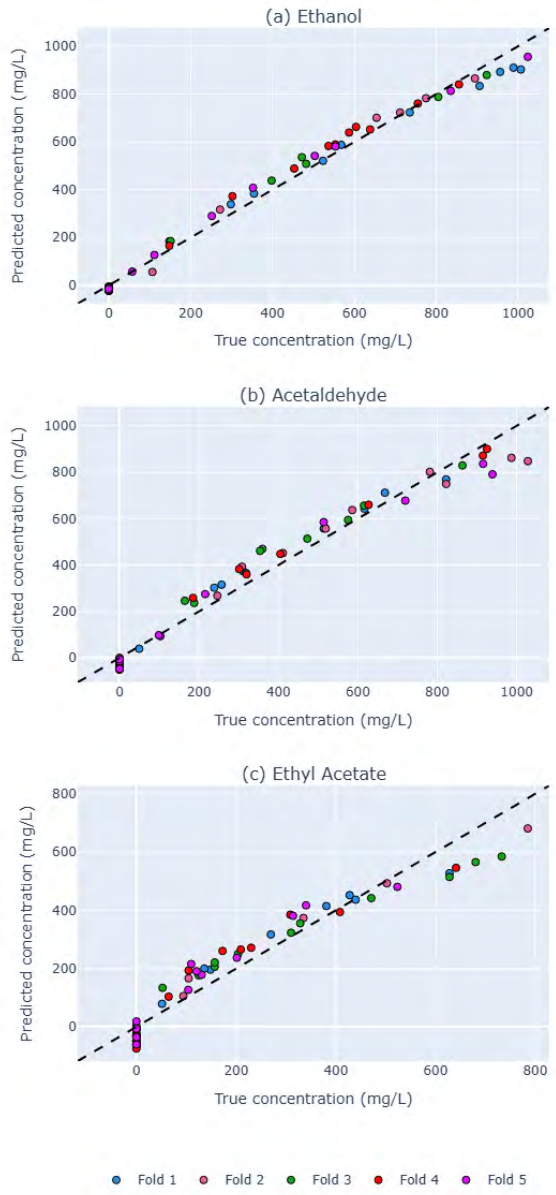

**Figure 4.** Parity plots for the test set of each k-fold using MLR for (a) ethanol, (b) acetaldehyde, and (c) ethyl acetate.

The prior-induced branched ANN model demonstrates consistent improvement across all metrics compared the fully connected ANN model, however, when it is compared with prior-induced polynomial regression model, branched ANN achieves slightly better prediction accuracy for acetaldehyde, while having marginally higher errors for ethanol and ethyl acetate. These results suggest that embedding prior knowledge into the network enhances predictive performance, while still having an efficient training process.

## Model Complexity

Table 6 compares AIC and BIC values obtained for MLR, polynomial regression, fully connected ANN, and their prior-induced counterparts. Both AIC and BIC evaluate model performance by balancing goodness of fit against model complexity through an explicit penalty on the number of parameters. Among all evaluated models standard polynomial regression exhibits the lowest AIC and one of the lowest BIC values, which indicates that the improvement in predictive performance justifies the additional complexity relative to the MLR baseline. The fully connected ANN and prior-induced ANN results in substantially higher AIC and BIC, showing that large number of trainable parameters in ANNs are strongly penalized. The prior-induced polynomial regression has slightly increased AIC and BIC compared to standard polynomial regression. Since both models contain the same number of trainable parameters, this increase can be attributed to a higher RSS for the prior-induced formulation.

When all models are considered, ANN-based models do not yield proportional improvements in prediction accuracy despite their increased complexity, while the prior-induced polynomial regression model achieves predictive performance close to the ANN-based models, while having AIC and BIC comparable to MLR model, which makes it a good alternative in this specific use-case. However, both prior-induced polynomial regression model and branched-ANN model can provide efficient frameworks for incorporating physical prior information into calibration models for similar or more complex systems affected by matrix effects.

## CONCLUSION

In conclusion, data-driven calibration models were developed for the accurate quantitative analysis of ethanol electrooxidation products using HS–GC–MS calibration data. MLR, polynomial regression, and fully-connected ANN were employed as baseline calibration models, while prior-induced polynomial regression and ANN models were developed by incorporating a simple physical constraint: The principle that a zero response corresponds to zero analyte concentration. Both polynomial regression and ANN models substantially outperformed the MLR baseline, achieving approximately 60–70% reductions in component-wise MAE and RMSE. Polynomial regression exhibited slightly better performance in acetaldehyde prediction, whereas ANN yielded marginally lower MAE and RMSE for ethyl acetate. Incorporation of prior information with polynomial regression further reduced MAE and RMSE by approximately 20–25% for ethanol and acetaldehyde. The prior-induced branched ANN achieved predictive accuracy comparable to that of the prior-induced polynomial regression model. However, both fully connected and branched ANN models

exhibited AIC and BIC values approximately twice those of the polynomial models, indicating that the ANN architectures are overly complex for the present problem. Overall, the proposed methodology demonstrates strong potential for application to more complex solution systems by effectively integrating prior physical knowledge and nonlinear relationships into model training.

## ABSTRACT

This study develops a multi-objective computer-aided process engineering (CAPE) framework to evaluate integrated sugarcane-based agro-industrial systems combining a high-yield cultivar, Haru-no-Ougi, and the "Inversion Process, " which reverses the conventional order of sugar crystallization and ethanol fermentation through selective fermentation of reducing sugars. The in-house CAPE tool SugaNol integrates agricultural, industrial, and environmental (life cycle assessment) models to simulate productivity, energy balance, greenhouse-gas (GHG) emissions, and relative economic performance on a per-hectare basis. Four scenarios were analyzed: NiF8–Conventional, KY01-2044–Conventional, Haru-no-Ougi–Conventional, and Haru-no-Ougi–Inversion Process. Simulation results showed that the combined Haru-no-Ougi and Inversion Process system increased total energy-equivalent productivity by approximately 40-45% compared with the baseline NiF8 system. Life cycle GHG emissions were reduced by 4–11%, while relative economic performance improved by approximately 35-40% due to enhanced ethanol and electricity co-production. These results demonstrate that CAPE-based multi-objective simulation enables holistic assessment and design of agro-industrial systems by explicitly linking crop traits and process design, providing a quantitative basis for sustainable sugar–ethanol–energy system design.

**Keywords**: Computer-Aided Process Engineering (CAPE), Life Cycle Assessment (LCA), Agro-Industrial Symbiosis, Bagasse Utilization, Sustainable Sugar–Ethanol–Energy Systems

## INTRODUCTION

Sugarcane (*Saccharum* spp.) has historically been cultivated primarily for sugar production; however, in the era of global decarbonization and resource circularity, it is increasingly recognized as a promising feedstock for integrated agro-industrial systems producing sugar, ethanol, and electricity. Its unique combination of high biomass productivity and sugar accumulation makes it one of the few crops capable of providing both food and energy from the same land area [1-3]. Consequently, sugarcane-based industries play a central role in achieving carbon neutrality and the development of circular bioeconomies in tropical and subtropical regions.

Nevertheless, recent breeding strategies aimed at yield improvement have revealed a significant trade-off between total cane yield and sucrose content [3]. The conventional Japanese cultivar NiF8 exhibits a moderate cane yield (60-70 t ha$^{-1}$) with high sucrose content (13-14%), whereas the high-biomass cultivar KY01-2044 achieves a much higher cane yield (90-100 t ha$^{-1}$) but at the expense of lower sucrose (9-10%). As a result, despite increased biomass productivity, sugar yield per unit land area is reduced by on the order of 10% compared with conventional cultivars. Such compositional trade-offs necessitate process-system innovations that valorize both sugars and lignocellulosic residues to improve overall system efficiency.

A new high-yield Japanese cultivar, Haru-no-Ougi, was developed through breeding to overcome this

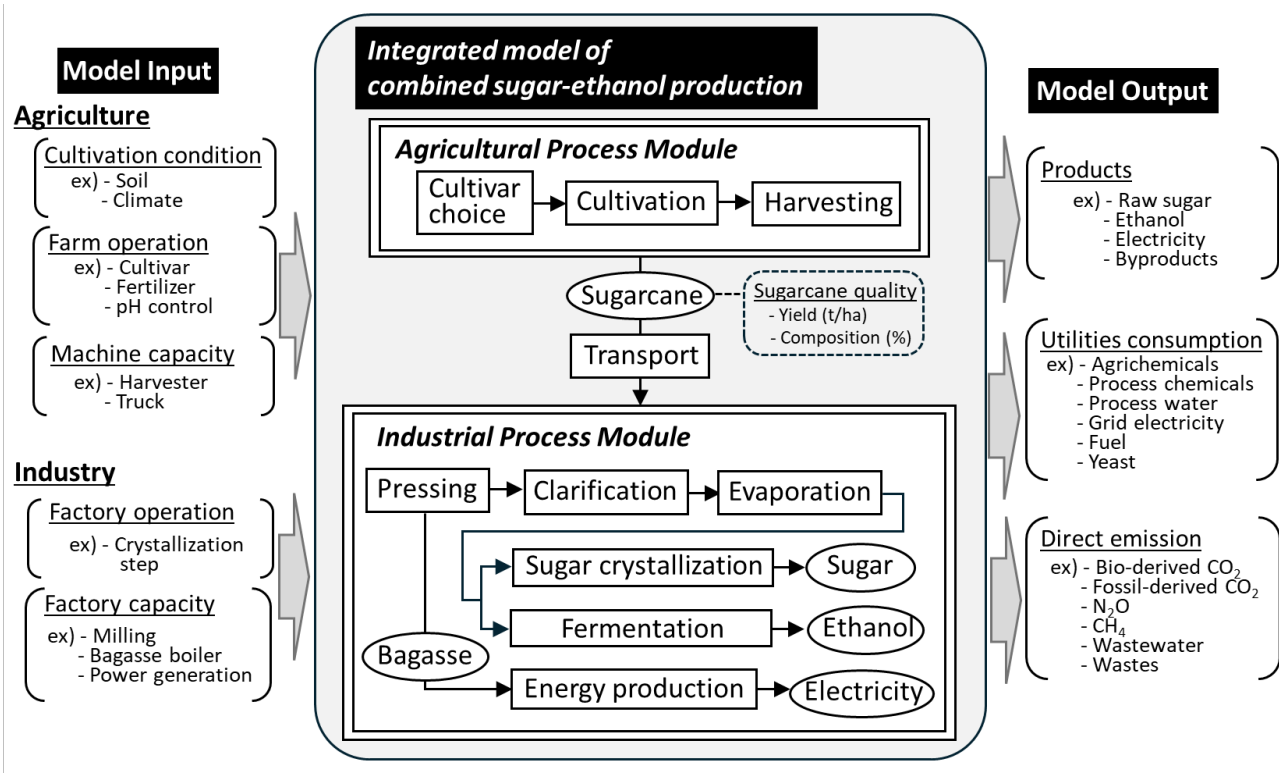

**Figure 1.** Integrated CAPE framework "SugaNol" linking agricultural, industrial, and environmental (LCA) models for sugarcane-based systems.

limitation [4]. It combines high cane yield (100-120 t ha$^{-1}$) with moderate-high sucrose content (11-12%) and increased fiber content (14-15%), enabling both efficient sugar crystallization and enhanced cogeneration from bagasse. To maximize the benefits of this cultivar, however, the industrial process configuration must be optimized in an integrated manner [2].

To address this challenge, the "Inversion Process" was introduced by [3, 5, 6] as a novel industrial scheme that reverses the conventional sugar–ethanol production sequence. Rather than crystallizing sucrose first and fermenting residual molasses, this approach selectively ferments reducing sugars (glucose and fructose) using invertase-defective yeast before crystallization. By removing inhibitory reducing sugars early, the process achieves higher sucrose purity, better crystallization efficiency, and greater ethanol yield, contributing to improved energy integration.

Despite these technological advances, a comprehensive evaluation integrating both agricultural and industrial performance remains limited [7]. Conventional life cycle assessment (LCA) and process optimization studies often focus on either cultivation or factory operation in isolation. Therefore, this study aims to establish an integrated Computer-Aided Process Engineering (CAPE) framework that couples agricultural, industrial, and environmental models to evaluate and optimize sugarcane-based agro-industrial systems.

The objective of this research is to apply the CAPE-based multi-objective simulation framework to the high-yield cultivar Haru-no-Ougi combined with the Inversion Process. The framework quantifies agricultural and industrial productivity, life cycle greenhouse-gas (GHG) emissions, and the associated economic performance on a per-hectare basis to identify synergistic solutions that simultaneously enhance food, fuel, and energy production toward carbon neutrality.

## METHODOLOGY

### Integrated CAPE Simulation Framework

An integrated CAPE framework was developed using the in-house Excel-based simulation tool *SugaNol*, originally introduced by Ouchida *et al.* [8]. The tool integrates three sub-models—agricultural, industrial, and environmental (LCA)—within a single platform to allow mass and energy balance consistency between field and factory operations. Figure 1 illustrates the overall structure of the integrated CAPE framework, linking agricultural production, industrial processing, and life cycle assessment within a unified simulation platform.

The simulation workflow begins with agricultural data (yield, composition) and propagates through process simulation to calculate product yields, energy use,

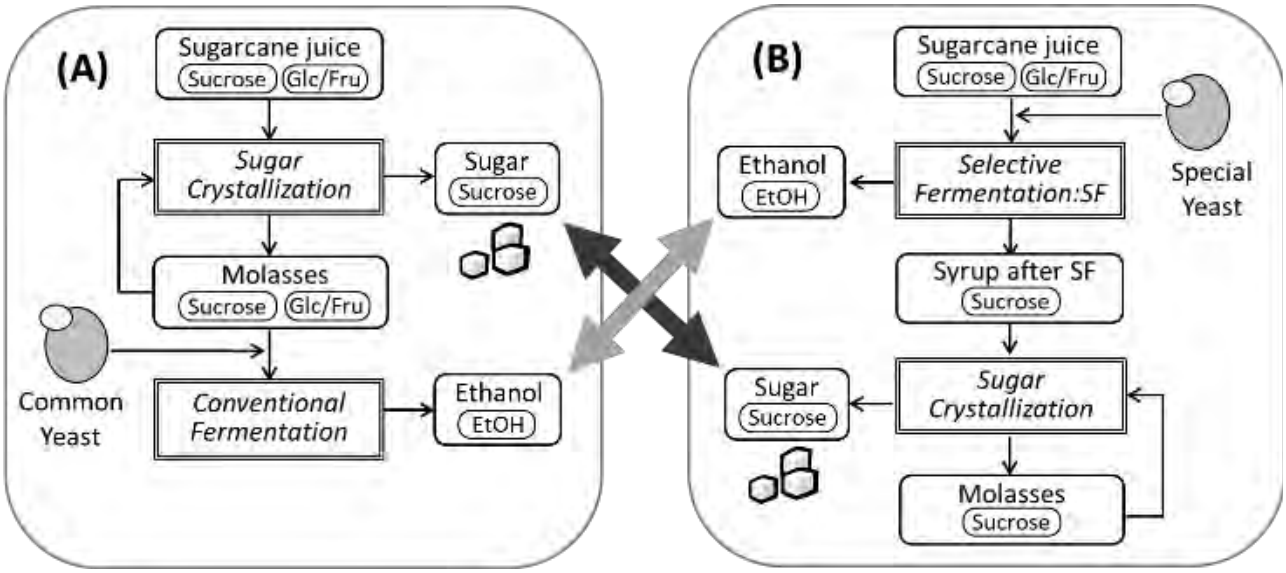

**Figure 2.** Process flow comparison between (A) the Conventional Process and (B) the Inversion Process for integrated sugar and ethanol production.

and emissions. The environmental model subsequently evaluates life cycle impacts and provides feedback for comparative multi-objective evaluation. All results are normalized to the functional unit of 1 ha of field.

## Agricultural Model

The agricultural model represents field operations and compositional characteristics of different cultivars. It considers inputs of fertilizers (N, P, K), compost, pesticides, irrigation water, and fuel consumption for tillage, planting, harvesting, and transport. Outputs include cane yield and stalk composition (sucrose, reducing sugars, fiber, and moisture).

Three cultivars were simulated:
(1) NiF8 (baseline, conventional yield and high sucrose),
(2) KY01-2044 (high-yield, high-fiber), and
(3) Haru-no-Ougi (high-yield, moderate-high sucrose).

Agronomic input coefficients were derived from field trials in Kyushu, Japan, adjusted for energy and emissions factors based on the Japanese LCA database IDEA v3.5.1. [9]. Table 1 summarizes the cane yield and composition of the three cultivars used as primary inputs for the simulations.

**Table 1:** Yield and compositional characteristics of sugarcane cultivars (NiF8, KY01-2044, and Haru-no-Ougi).

| | NiF8 | KY01-2044 | Haru-no-Ougi |
|---|---|---|---|
| | Conventional | High-yield | High-yield |
| Yield[t/ha] | 67.1 | 93.5 | 107.3 |
| Sucrose[%] | 13.5 | 9.3 | 11.8 |
| Glc & Fru[%] | 0.6 | 1.2 | 0.4 |
| Fiber[%] | 12.3 | 14.0 | 14.8 |

The model assumes that all cultivars are cultivated under identical management practices to isolate genetic and compositional effects. Fertilizer rates were 150, 60, and 180 kg $ha^{-1}$ for N, $P_2O_5$, and $K_2O$, respectively. Diesel fuel for agricultural machinery was set at 45 L $ha^{-1}$, and irrigation energy was assumed negligible under rain-fed conditions [7, 8].

## Industrial Process Model

The industrial model simulates two process configurations: (a) Conventional Process – sugar crystallization followed by molasses fermentation; (b) Inversion Process – selective fermentation of reducing sugars before sucrose crystallization [3]. Mass and energy balances were solved across clarification, crystallization, fermentation, distillation, and cogeneration units. Steam and power demands were met through bagasse combustion in high-pressure boilers (boiler efficiency: 90%). Surplus electricity was exported to the grid. Fermentation efficiency was fixed at 85%, and sucrose crystallization recovery at 95%.

In the Inversion Process, glucose and fructose—natural inhibitors of sucrose crystallization—were selectively fermented to ethanol prior to crystallization using an invertase-defective yeast [5, 6]. This configuration improved energy balance and ethanol yield without sacrificing sugar quality. Figure 2 schematically compares the Conventional Process and the Inversion Process configurations considered in this study.

## Life Cycle Assessment (LCA)

The environmental impact model calculates life cycle greenhouse-gas (LC-GHG) emissions on a cradle-to-gate basis, focusing on emissions from sugarcane

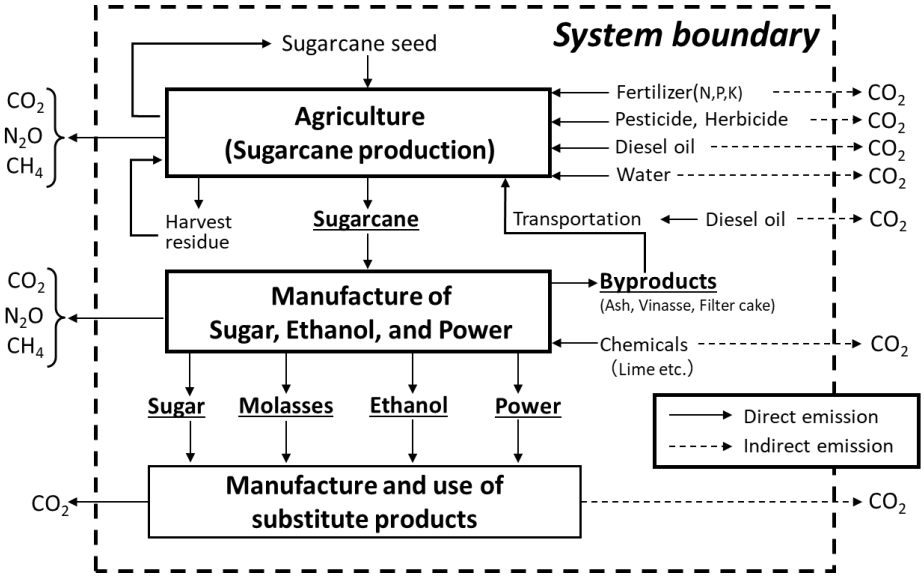

**Figure 3.** Life cycle assessment (LCA) system boundary for the integrated sugarcane-based agro-industrial system (cradle to gate).

cultivation through industrial processing. The system boundary encompasses agricultural production, transportation of sugarcane, and the production of sugar, ethanol, and electricity. The functional unit was defined as the "use of 1 ha of field." Figure 3 shows the system boundary of the life cycle assessment.

Input data included fertilizers, pesticides, compost, and fuel in agriculture, as well as materials, fuel, electricity, and auxiliary chemicals in factory operations. Both direct emissions from agricultural and industrial processes and indirect emissions associated with upstream production of inputs were accounted for. Background inventory data were obtained from the Japanese LCA database IDEA v3.5.1. [9]

Only the climate-change impact category was considered in this study. The greenhouse gases considered were $CO_2$, $CH_4$, and $N_2O$. Life cycle GHG emissions were calculated using 100-year global warming potentials (GWP100) from the IPCC Fourth Assessment Report ($CO_2$ = 1, $CH_4$ = 25, $N_2O$ = 298) and expressed as LC-GHG emissions [kg $CO_2$ eq $ha^{-1}$] [10].

## RESULTS AND DISCUSSION

### Simulation Results on Productivity and Life Cycle GHG Emissions

Four simulation cases were analyzed:

(1) NiF8 – Conventional Process (baseline),

(2) KY01-2044 – Conventional Process,

(3) Haru-no-Ougi – Conventional Process, and

(4) Haru-no-Ougi – Inversion Process.

Figure 4 compares the production of sugar, ethanol, and electricity, as well as life cycle GHG emissions, across the four simulated scenarios.

For Case (1), the baseline configuration using NiF8 under the conventional process produced 8.3 t sugar $ha^{-1}$ and 0.35 kL ethanol $ha^{-1}$, with 348 kWh $ha^{-1}$ surplus power and LC-GHG emissions of 3.94 t $CO_2$ eq $ha^{-1}$.

In Case (2), where the high-biomass cultivar KY01-2044 was processed using the conventional process, ethanol production increased to 0.80 kL $ha^{-1}$ (+126%) and electricity generation to 469 kWh $ha^{-1}$, while LC-GHG emissions were reduced by approximately 11%. However, the lower sucrose content of this cultivar resulted in a reduced sugar yield of 7.5 t $ha^{-1}$, confirming the yield–composition trade-off.

Case (3), corresponding to Haru-no-Ougi under the conventional process, achieved the highest sugar yield (11.4 t $ha^{-1}$) together with substantial ethanol co-production (0.43 kL $ha^{-1}$) and 669 kWh $ha^{-1}$ surplus electricity, although total LC-GHG emissions were slightly higher (4.66 t $CO_2$ eq $ha^{-1}$) due to increased industrial energy demand.

In Case (4), which combines Haru-no-Ougi with the Inversion Process, the system delivered 11.6 t sugar $ha^{-1}$ and 0.35 kL ethanol $ha^{-1}$ with complete energy self-sufficiency and LC-GHG emissions of 4.47 t $CO_2$ eq $ha^{-1}$ (–4% relative to Case (3)). When evaluated in energy-equivalent terms (sugar + ethanol), productivity per hectare increased by approximately 45% compared with the Case (1) baseline, demonstrating the synergistic benefit of integrating high-yield cultivars with process innovation.

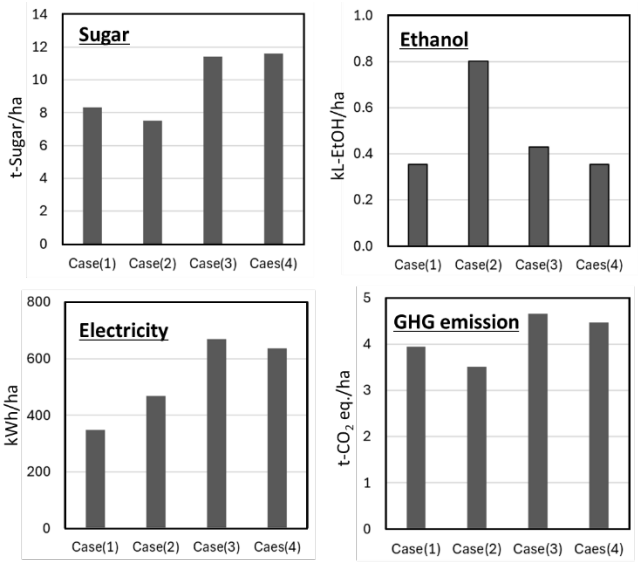

**Figure 4.** Comparison of sugar, ethanol, electricity production, and life cycle GHG emissions among four simulated scenarios.

## Discussion: Environmental Impact and Bagasse Utilization

LC-GHG emissions ranged from 3.5 to 4.7 t $CO_2$ eq $ha^{-1}$ among the four cases. Improvements in the Inversion Process stem primarily from enhanced ethanol yield and efficient steam integration. The higher emissions in Haru-no-Ougi–Conventional reflect the increased throughput and energy demand, but these are offset when normalized per unit of energy-equivalent output.

In this simulation, all surplus bagasse was assumed to be combusted in factory boilers for electricity generation. Alternative utilization routes, however, have been explored in previous studies using simulation-based approaches [11]. Corradini *et al.* clarified through process-system simulation that torrefaction—a mild pyrolysis process at 250–300 °C—can convert bagasse into a solid carbon-rich product with improved energy density and stability. Previous studies have also reported that biochar derived from thermochemical conversion can enhance soil fertility, improve water retention, and promote long-term carbon sequestration when applied to agricultural fields [12, 13]. Although detailed calculations for torrefaction-based bagasse recycling were not conducted in this study, these findings suggest that integrating such utilization pathways could further reduce LC-GHG emissions through additional carbon storage and reduced upstream inputs.

Overall, these results indicate that bagasse utilization strategies play a critical role in determining the environmental performance of sugarcane-based agro-industrial systems. While electricity generation via direct combustion represents a practical baseline configuration, simulation-based assessments highlight the potential of alternative pathways to support deeper decarbonization when integrated with agricultural and industrial system design.

## Discussion: Economic Evaluation and Multi-Objective Assessment

A simplified economic evaluation was conducted on a relative basis using representative unit prices of 100 JPY $kg^{-1}$ for sugar, 70 JPY $L^{-1}$ for ethanol, and 15 JPY $kWh^{-1}$ for electricity. These values were applied consistently across all cases to compare revenue structures on a per-hectare basis. The resulting relative economic performance of the four cases, normalized to the Case (1) baseline, is summarized in Table 2.

**Table 2:** Relative economic performance of the four simulated scenarios normalized to the Case (1) baseline.

| Case | Cultivar & Process | Sugar revenue | Ethanol revenue | Electricity revenue | Total revenue |
|---|---|---|---|---|---|
| (1) | NiF8 & Conv. | 100 | 100 | 100 | 100 |
| (2) | KY01-2044 & Conv. | 90 | 226 | 135 | 95 |
| (3) | Haru-no-Ougi & Conv. | 137 | 122 | 192 | 137 |
| (4) | Haru-no-Ougi & Inversion process | 140 | 100 | 182 | 139 |

In Case (2), based on the high-yield cultivar KY01-2044, sugar production decreased compared with the baseline, while ethanol and electricity outputs increased substantially. This case represents a configuration that sacrifices sugar production in favor of fuel and energy generation. As summarized in Table 2, the total economic performance of Case (2) was approximately 5% lower than that of the Case (1) baseline, indicating that increased fuel revenue did not fully compensate for reduced sugar output.

In contrast, Cases (3) and (4), based on the high-yield cultivar Haru-no-Ougi, achieved significantly higher sugar production together with increased electricity generation. These cases illustrate a configuration that balances sugar and power production rather than prioritizing fuel output. Table 2 shows that the total economic performance increased by approximately 35–40% relative to the baseline, reflecting the combined effects of higher cane yield, improved sucrose recovery, and enhanced bagasse utilization.

Case (4), which combines Haru-no-Ougi with the Inversion Process, further shifts the product balance toward sugar maximization. Although ethanol production was slightly reduced due to decreased molasses formation, this configuration achieved the highest overall economic performance among the four cases.

Rather than performing numerical optimization, the CAPE model was used to conduct a multi-objective assessment of trade-offs among productivity, life cycle GHG emissions, and economic performance. This comparative evaluation demonstrates that scenarios integrating Haru-no-Ougi with the Inversion Process achieve a balanced improvement across multiple performance indicators, without sacrificing sugar productivity or environmental performance.

The results further demonstrate that multi-objective evaluation can effectively identify system-level synergies even in the absence of formal optimization. By simultaneously considering agricultural yield, industrial output, environmental impact, and economic implications, the CAPE framework provides a quantitative basis for informed decision-making in agro-industrial system design. This approach is consistent with the "Design for Sustainability" concept proposed in the literature [14], which emphasizes the integrated evaluation of technical, economic, and environmental dimensions within a unified modeling framework.

## CONCLUSIONS

This study developed a multi-objective CAPE-based simulation framework for integrated sugarcane-based agro-industrial systems. By coupling agricultural, industrial, and environmental models, the framework enables system-wide comparative evaluation of productivity, energy performance, life cycle GHG emissions, and relative economic performance.

Simulation results confirmed that combining the high-yield cultivar Haru-no-Ougi with the Inversion Process increased total energy-equivalent productivity by approximately 40–45% relative to the conventional NiF8 system. Life cycle GHG emissions were reduced by 4–11%, while relative economic performance improved by up to approximately 40%, depending on the balance between sugar, ethanol, and electricity production. The case-by-case comparison clarified distinct system roles, ranging from fuel-oriented configurations to designs prioritizing sugar maximization through improved sucrose recovery.

Rather than relying on numerical optimization, this study demonstrated that multi-objective CAPE-based assessment can identify system-level synergies and support design choices aligned with regional priorities. Overall, the proposed framework illustrates how modelling and simulation can bridge crop breeding and process design, providing a quantitative basis for data-driven strategies toward carbon-neutral and resource-efficient agro-industrial symbioses.

# Towards the Decarbonization of a Conventional Ammonia Plant by the Gradual Incorporation of Green Hydrogen and Air-Separated Nitrogen

**João Fortunato, Diogo A. C. Narciso*, and Henrique A. Matos**

Centro de Recursos Naturais e Ambiente, Departamento de Engenharia Química, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais 1, 1049-001 Lisboa, Portugal

## ABSTRACT

As economies advance towards decarbonization, industry follows suit. The ammonia ($NH_3$) sector heavily relies on the energy- and carbon-intensive Haber-Bosch (HB) process, which accounts for nearly 2% of global $CO_2$ emissions due to its reliance on fossil fuels. Emerging technologies are paving the way for fully renewable $NH_3$ production, although the most mature green process still relies on the HB process, entirely replacing fossil fuels with electrolytic green hydrogen ($H_2$). This work introduces the first developments towards the gradual incorporation of green $H_2$ and air-separated nitrogen ($N_2$) into a conventional $NH_3$ production plant. Using *Aspen Plus® V14* for modelling and simulation of Steam Methane Reforming (SMR), different scenarios incorporating 0 to 40 % of these alternative feedstocks were analyzed. An economic objective function is used in each scenario's optimization. To improve green $H_2$ incorporation and ensure operational constraints were met, the simulations used an adapted SMR section proposed in previous work. Preliminary results in the development of this methodology indicate that at 40 % green $H_2$ and 40 % air-separated $N_2$ incorporations, a 29.4 % reduction in carbon emissions was achieved, along with 30.1 % natural gas savings and a 35 % decreased in conventional operational costs (without green $H_2$ and air-separated $N_2$ costs) compared to the base case, where no alternative feedstocks were used. At current market prices, in the same scenario, incorporating alternative feedstocks can increase total operational costs by 52 %.

## INTRODUCTION

At the beginning of the 20th century, agriculture faced increasing pressure to secure a reliable source of nitrogen to enable higher food production for a rapidly growing population. Nitrogen is an essential nutrient for crop growth, and until then, it was obtained mainly from limited natural sources. In 1909, Fritz Haber achieved the fixation of atmospheric nitrogen ($N_2$) by synthesizing ammonia ($NH_3$) through its reaction with hydrogen ($H_2$) using an iron-based catalyst, Equation (1). Years later, in 1913, Carl Bosch successfully scaled up ammonia synthesis for industrial application, giving rise to what is now known as the Haber-Bosch (HB) process. This breakthrough is widely regarded as one of the most important technological developments in human history. [1]

$$N_2 + 3\,H_2 \rightleftharpoons 2\,NH_3 \quad (1)$$

Ammonia is the second-most-produced chemical globally, with 85 % of its output used in the nitrogen-based fertilizer industry, including urea and ammonium nitrate. It is estimated that almost half of the world's population relies directly on these fertilizers for food production. Besides agriculture, ammonia has diverse uses, including pharmaceuticals, textiles, explosives manufacturing, and deNOx technologies. [2, 3]

Given its global significance and extensive production scale, the Haber-Bosch (HB) process accounts for approximately 2 % of the world's total energy consumption and contributes between 1 % and 2 % to worldwide carbon dioxide ($CO_2$) emissions. [1] This considerable environmental footprint primarily stems from its substantial

reliance on fossil fuels, which serve as feedstocks for hydrogen production and process heat. Currently, around 75 % of global ammonia synthesis is derived from light hydrocarbons such as natural gas and naphtha, whereas the remaining 25 % originates from heavy hydrocarbons, including coal and Heavy Fuel Oil (HFO). In the European context, nearly all ammonia manufacturing facilities operate exclusively on natural gas, producing hydrogen via Steam Methane Reforming (SMR). [2, 3] This manufacturing route is regarded as the Best Available Technology, owing to its superior energy efficiencies, reduced emissions, and lower capital investment.

Driven by policies aimed at achieving carbon neutrality and energy independence, the ammonia industry is increasingly exploring decarbonization pathways. In the European Union (EU), the Renewable Energy Directive III stipulates that by 2030, 42 % of the hydrogen used in industrial processes must be derived from renewable sources. To align with these regulations and targets, the ammonia sector has intensified efforts to develop alternative synthesis technologies that transcend the conventional HB process, striving for a more decentralized, flexible, and energy-efficient production. The emerging routes under investigation are designed to facilitate the complete integration of renewable energy sources and encompass electrochemical, electrocatalytic, and photocatalytic methods for ammonia synthesis. Nevertheless, most of these technological approaches remain at early stages of development and are distant from commercial deployment. [4]

Currently, the most mature technology for green $NH_3$ production is based on electrifying the HB process, in which SMR is replaced by water electrolysis as the hydrogen source and an Air Separation Unit as the nitrogen source. By supplying renewable electricity to the process, green $NH_3$ can be produced. However, operating the HB process within the inherent variability of renewable energy sources, particularly solar and wind, remains a significant challenge. Numerous studies have addressed the issues related to fluctuating energy supply and, consequently, hydrogen production. Under such conditions, the operation of the HB process often requires hydrogen storage in buffer tanks and/or the use of energy storage systems such as batteries. Therefore, producing fully green $NH_3$ remains costly due to expensive infrastructure, high energy prices, and logistical challenges stemming from the underdeveloped electrolyser market. [4]

The $NH_3$ industry is consequently striving to balance economic competitiveness with the attainment of decarbonization targets, ideally leveraging existing capital investments in current infrastructure. As examples, Fertiberia and Yara are major players in the European ammonia industry, which has begun incorporating green hydrogen into its conventional plants. Inspired by the operating procedures at a real-life plant, a previous work addressed the incorporation of green hydrogen into a conventional, methane-fed $NH_3$ plant. [5] The authors pointed out that overheating in some equipment limits green $H_2$ integration and proposed a new SMR configuration to prevent it. With an adapted SMR, a maximum green hydrogen incorporation of 60 % can be achieved, although lower fractions may lead to issues with equipment load reduction. [5]

Building on the previous study, this work explores the simultaneous use of green $H_2$ and air-separated $N_2$ as alternative feedstocks in the SMR section of a conventional ammonia plant.

## METHODOLOGY

As part of a conventional ammonia plant with an annual capacity of around 200 kton, an SMR section was modeled in *Aspen Plus® V14*, as shown in **Figure 1**.

### SMR Section

The SMR section relies on natural gas, steam, and atmospheric air consumption to produce a synthesis gas mixture of $H_2$ and $N_2$. The process natural gas is first purified by hydrodesulfurization to remove sulphur compounds and prevent catalyst poisoning. This stream is then heated, mixed with process steam, and fed into a pre-reforming section, where the heavier hydrocarbons in natural gas are converted into methane ($CH_4$). Following this step, the reforming process begins in the primary reformer, Ref-I, where $CH_4$ reacts with steam to produce $H_2$, carbon monoxide (CO), and $CO_2$, Equations (2) and (3).

$$CH_4 + H_2O \rightleftharpoons CO + 3\ H_2 \quad (2)$$

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad (3)$$

The gas mixture is mixed with compressed hot atmospheric air and fed into a secondary reformer, Ref-II, where $CH_4$ conversion is completed. The atmospheric air supplied in this unit must ensure the right amount of $N_2$ for ammonia synthesis, as well as the oxygen ($O_2$) needed for $CH_4$ partial and total oxidation, Equations (4) and (5).

$$CH_4 + 0.5\ O_2 \rightleftharpoons CO + 2\ H_2 \quad (4)$$

$$CH_4 + 2\ O_2 \rightleftharpoons CO_2 + 2\ H_2O \quad (5)$$

The mixture is then cooled, and CO is converted in a two-stage process: a high-temperature shift (HT) followed by a low-temperature shift (LT) according to the stoichiometry in Equation (3). $CO_2$ is removed from the process stream by scrubbing the mixture with an ammonia solution. To ensure that the syngas mixture produced does not contain oxygen-containing compounds, the unconverted CO fraction and the final traces of $CO_2$ are subjected to a methanation step, in which $CH_4$ and water

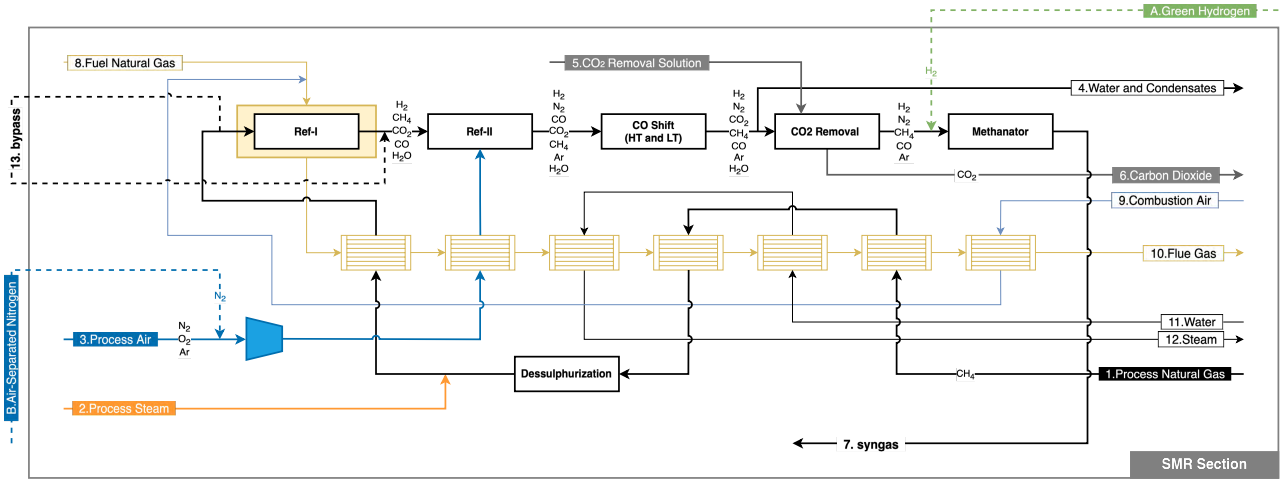

**Figure 1:** Simplified schematics of the SMR section model developed. The grey box contains the conventional SMR configuration; outside the box are represented the adapted SMR configuration (stream 13, a Ref-I Bypass proposed in [5,6]), stream A (green hydrogen incorporation), and stream B (air-separated nitrogen incorporation).

are produced.

The water is ultimately eliminated using molecular sieve adsorbers, allowing $CH_4$ and the Argon (Ar) introduced with atmospheric air to proceed to $NH_3$ synthesis as inert chemicals. The gas mixture obtained is then composed of $H_2$ and $N_2$ in a 3:1 molar ratio, with traces of $CH_4$ and Ar.

In addition to the main process line, the SMR section encompasses an auxiliary line that utilizes natural gas as fuel through combustion with air. The heat generated from this combustion process is employed to supply energy for reforming reactions (as described in Ref-I), to pre-heat various streams such as process natural gas and combustion air, and to generate steam.

Since the integration of alternative feedstocks is considered within the SMR section and the objective remains to produce equivalent flow rates of $H_2$ and $N_2$, the $NH_3$ synthesis process is not addressed in this analysis. Ultimately, incorporating green $H_2$ and air-separated $N_2$ could reduce the inert chemical fraction in the syngas stream, thereby decreasing inert component accumulation in the $NH_3$ synthesis loop and reducing purge fractions. Those additional advantages at $NH_3$ synthesis are not addressed in this work.

## Green Hydrogen Incorporation

The incorporation of green $H_2$ was modeled as a pure stream ($xH_2$ = 1). The injection point into the process was positioned immediately prior to the methanation step, where the production of gry hydrogen (from $CH_4$ reforming) is completed. The study did not include modeling of the water electrolysis process used for green hydrogen production.

Green $H_2$ incorporation reduces grey $H_2$ production, thereby decreasing $CH_4$ reforming and helping achieve potential decarbonization. The extent of this alternative feedstock's incorporation is quantified by the Green Hydrogen Incorporation fraction (GHI), defined as the ratio of green $H_2$ in the total $H_2$ supply to NH3 synthesis (grey + green).

## Air-Separated Nitrogen Incorporation

The incorporation of air-separated $N_2$ was treated similarly to green $H_2$, considering it as a pure stream ($xN_2$ = 1). This stream was intended to simulate the nitrogen-rich output typically produced by a well-established Air Separation Unit (ASU) technology, although the process itself was not explicitly modeled.

Air-separated $N_2$ incorporation decreases the requirement for atmospheric air, as the $N_2$ flow rate in syngas must stay constant to maintain consistent $NH_3$ production. The extent of incorporation of this alternative feedstock was quantified using the Air-Separated Nitrogen Incorporation fraction (SNI), which is defined as the ratio of $N_2$ incorporated relative to the total $N_2$ supplied for $NH_3$ synthesis (including both direct air supply and air separation).

## Economic Optimization

Taking the green $H_2$ and air-separated $N_2$ incorporations as independent parameters in this framework, the main goal of this work is to explore how the SMR process can be operated to accommodate multiple combinations of these two key parameters. Building a thorough understanding of how SMR operation can be adapted in this context is vital to map the transition from the classic HB process towards partly or fully green $NH_3$ manufacture, while achieving the best economic performance. This

transition will only be considered in future work.

To achieve the first goal above, the process flowsheet model was configured and optimized as a function of green $H_2$ and air-separated $N_2$ incorporations using the Optimization tool in *Aspen Plus® V14* software. The optimization considers a set of manipulated variables listed in **Table 1**. These variables translate into different stream flow rates that may be adjusted by valves and their respective control, ensuring the optimal operation under different fractions of alternative feedstock incorporation.

**Table 1:** List of manipulated variables considered.

| Variable | Lower Bound | Upper Bound | [Unit] |
|---|---|---|---|
| Process Natural Gas | 0 | 19 | ton/hr |
| Process Steam | 0 | 60 | ton/hr |
| Process Air | 0 | 2 000 | kmol/hr |
| Fuel Natural Gas | 0 | 5 | ton/hr |
| Combustion Air | 0 | 140 | ton/hr |
| $CO_2$ Removal Solution | 0 | 150 | ton/hr |
| Ref-I Bypass Fraction | 0 | 1 | - |

**Table 2:** List of constraints considered.

| Equality Constraint | Value | [Unit] |
|---|---|---|
| Steam/Carbon in Ref-I | 3 | mol/mol |
| H2 in Syngas Stream | 3 000 | kmol/hr |
| Combustion Air to Fuel | 20 | ton/ton |
| H2 to N2 at Syngas Stream | 3 | mol/mol |
| **Inequality Constraint** | **Value** | **[Unit]** |
| CO2 Content after Removal | ≤ 0.01 | %mol |
| Q (Ref-I) + Q (Fired-Box) | ≤ 0 | MW |
| Ref-II Outlet Temperature | ≤ 921 | ºC |

In earlier works [5, 6], the authors introduced a Ref-I Bypass to enable the redistribution of $CH_4$ reforming reactions between primary and secondary reformers. They found that operating with the Ref-I Bypass can increase the fraction of green $H_2$ while keeping the Ref-II outlet temperature stable. The overheating problem in the Ref-II unit was identified in the same study when the Ref-I Bypass was not used and was observed to worsen as the GHI fraction rises. Due to its demonstrated effectiveness, the Ref-I Bypass Fraction is listed as a variable in **Table 1**.

The optimal solution must also satisfy the operational constraints listed in **Table 2**. A constraint is included to avoid overheating of Ref-IIThe problem is subsequently formulated to minimize the operational costs associated with the SMR section. For that purpose, a set of economic parameters (**Table 3**) is employed to estimate the costs of raw material streams (including alternative feedstocks), electricity consumption, thermal energy use and production, as well as taxes related to $CO_2$ emissions.

**Table 3:** Main economic parameters considered.

| Economic Parameter | Value | [Unit] |
|---|---|---|
| Natural Gas | 490 | $/ton |
| Process Steam | 37 | $/ton |
| Electricity | 77 | $/MWh |
| $CO_2$ Emission Tax | 83 | $/ton |
| Green $H_2$ | 5 000 | $/ton |
| Air-Separated $N_2$ | 50 | $/ton |

The objective function integrates all economic factors to minimize the Operational Net Cost (ONC), Equation (6).

$$\text{minimize } f(x) = \text{ONC} \tag{6}$$

The optimization problem was then solved, incorporating both alternative feedstocks from 0 to 40 % (0 < GHI < 40% and 0 < SNI < 40%) in intervals of 10%.

## RESULTS

### The Base Case

The base case is defined as the SMR operation with no alternative feedstock incorporated. This simulates a conventional $NH_3$ plant that operates entirely on natural gas and atmospheric air (GHI = SNI = 0%), with a non-adapted configuration (Ref-I Bypass Fraction = 0). **Table 4** lists some important consumption rates and indicators obtained for the base case.

**Table 4:** Results obtained for the base case (GHI = SNI = 0 %).

| | Value | [Unit] |
|---|---|---|
| Natural Gas Consumption | 20.8 | ton/hr |
| Atmospheric Air Consumption | 39.2 | ton/hr |
| Ref-II Outlet Temperature | 920 | ºC |
| $CO_2$ Emissions | 54.5 | ton/hr |
| ONC | 14.5 | k$/hr |
| $CO_2$ Emission per kg of $H_2$ | 9.1 | kg/kg |
| ONC per kg of $H_2$ | 2.4 | $/kg |

### Alternative Feedstock Incorporation

From the base case, the incorporation of alternative feedstock was considered. Specifically, the incorporation of green $H_2$ raises concerns about overheating in the Ref-II unit [6]. **Figure 2** shows the outlet stream temperature

of this unit, demonstrating compliance with its constraint.

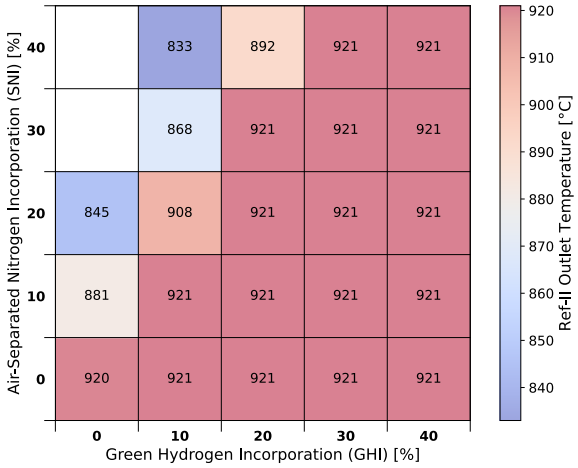

**Figure 2:** Matrix of Ref-II Outlet Temperature as a function of GHI and SNI (0 - 40 %; blank cells indicate no feasible solution was found).

As air-separated nitrogen incorporation increases, the results show that it has the opposite effect on Ref-II outlet temperature than hydrogen incorporation. This is especially evident when no green $H_2$ is considered (GHI = 0 %) and suggests that its incorporation may help control this temperature, thereby enabling higher green $H_2$ incorporation than previously reported [6]. Although the incorporation of green $H_2$ tends to increase the Ref-II outlet temperature, this temperature is kept constant at the base case value by activating the Ref-I Bypass. Therefore, the effect of increasing green $H_2$ is reflected not in overheating of this unit but in an increasing Ref-I Bypass fraction. **Figure 3** shows the Ref-I Bypass fraction required to comply with that limit.

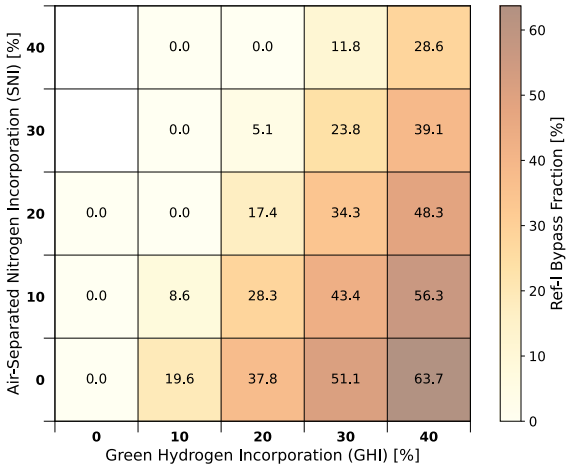

**Figure 3:** Matrix of Ref-I Bypass Fraction as a function of GHI and SNI (0 - 40 %; blank cells indicate no feasible solution was found).

Although the Ref-I Bypass operation is an important step toward greater green $H_2$ incorporation, it naturally reduces Ref-I load, as part of it is diverted by the bypass. A previous study considered a limit of 60 % on the reduction of Ref-I nominal capacity. Applying the same criteria in this work would make it impossible to achieve GHI values of 30 % and 40 % if no air-separated $N_2$ is considered. As SNI increases, the required Ref-I Bypass fraction is lower, which means not reporting such a sharp reduction in Ref-I load. This way, GHI of 30 % and 40 % are possible when SNI of 10 % and 40 %, respectively, are applied. Therefore, the results show that simultaneous incorporation of both alternative feedstocks can, in fact, enable higher green $H_2$ incorporation, contributing to greater decarbonization and deeper natural gas savings.

**Figure 4** illustrates the Total Decarbonization extent achieved through both alternative feedstock incorporation. This indicator represents the relative difference in $CO_2$ emissions for each case compared to the previous base case. Included in $CO_2$ emissions are those captured in the $CO_2$ Removal Section, as well as emissions from flue gas generated by burning natural gas for energy production.

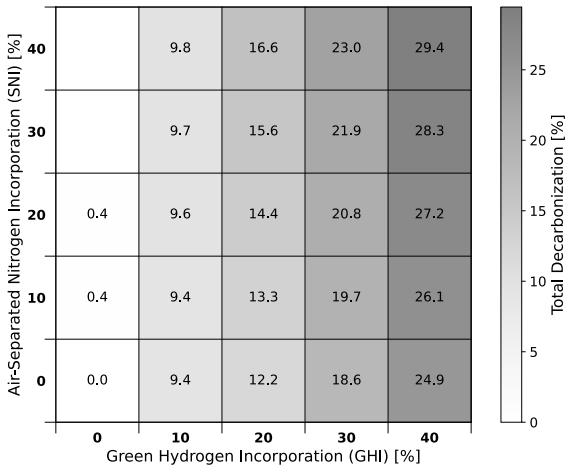

**Figure 4:** Matrix of Total Decarbonization as a function of GHI and SNI (0 - 40 %; blank cells indicate no feasible solution was found).

The decarbonization values achieved are notably significant, especially when green hydrogen is incorporated. These values arise from the reduced use of grey $H_2$ and the corresponding decrease in $CH_4$ required for both reforming and combustion, thereby substantiating the reported decarbonization levels. With respect to air-separated nitrogen, its influence is minor at low green hydrogen incorporation fractions (GHI < 10%), but it can contribute substantially to additional decarbonization at higher GHI values.

The reduction in natural consumption is quantified through Natural Gas Savings, which measures the

savings in natural gas (both as feedstock and fuel) reported relative to the base case. The results are presented in **Figure 5**.

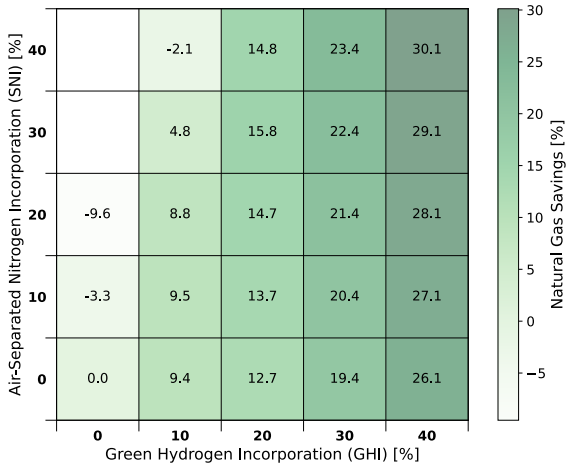

**Figure 5:** Matrix of Natural Gas Savings as a function of GHI and SNI (0 - 40 %; blank cells indicate no feasible solution was found).

Reducing natural gas consumption is a crucial consideration for the plant's economics, particularly given that, in the base case, natural gas costs account for approximately 70 % of total operational expenses. The economics obtained are reported in **Figure 6**.

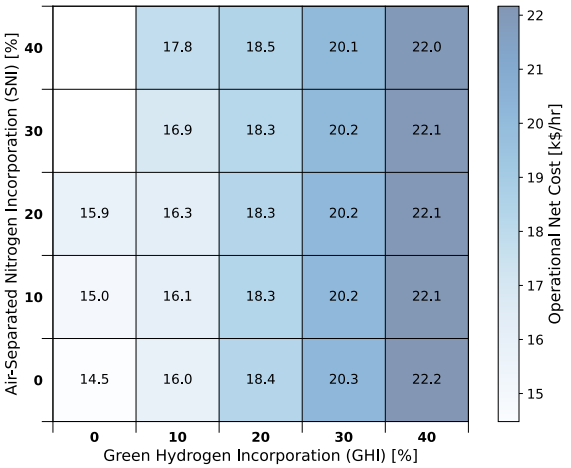

**Figure 6:** Matrix of ONC as a function of GHI and SNI (0 - 40 %; blank cells indicate no feasible solution was found).

Combining the effects of natural gas savings and the reduction in $CO_2$ emission taxes enabled by the extent of decarbonization, it would be expected that a cheaper operation would result as alternative feedstock incorporation is considered. Nevertheless, significant increases in operational costs are reported due to the cost of alternative feedstock considered. This is especially noted for green $H_2$, whose price is way higher than that of air-separated $N_2$. For instance, in the most decarbonized scenario, with GHI and SNI at 40 %, green $H_2$ expenses account for more than 50 % of total operating costs, while air-separation accounts for less than 3 %. Green $H_2$ may only be economically attractive once its production cost falls to around 2.4 $ per kilogram, at which point it becomes competitive with grey $H_2$ production.

## CONCLUSIONS AND FUTURE WORK

The incorporation of green $H_2$ and air-separated $N_2$ into a conventional $NH_3$ plant was investigated using a model developed in *Aspen Plus® V14*. Incorporating green $H_2$ makes a greater contribution to natural gas savings and to the extent of SMR process decarbonization. Although its contribution is limited, air-separated $N_2$ can be significant in enabling broader control of the Ref-II outlet temperature.

Building on the previously proposed Ref-I Bypass operation, it was shown that higher GHI fractions can be achieved by considering a minimum fraction of air-separated $N_2$.

Despite technical viability, incorporating both alternative feedstocks ($H_2$ and $N_2$) increases SMR operational costs, mainly due to the cost of green $H_2$ considered. The threshold could be reached with a green $H_2$ cost of around 2.4 $ per kilogram, at which point it becomes competitive with grey $H_2$ production.

As these are preliminary results, future research may include exploring alternative feedstock compositions, varying injection points, or modifying the flowsheet to facilitate more flexible operation of the SMR process under the proposed conditions and to achieve greater decarbonization. Given the substantial costs involved, subsequent studies might also incorporate an economic analysis of green $H_2$ production costs to assess their impact on the economics of retrofitted $NH_3$ plants.

# Hybrid Modeling of Wastewater Treatment Dynamics Using Hammerstein-Wiener Structures

**Arne Tirez[a], Niels Stevens[a], Dominik Bongartz[a], and José Matias Assumpcao[b]**

## ABSTRACT

The zero-pollution ambition of the European Union requires improvements in wastewater treatment to meet increasingly stringent regulations at achievable cost. One promising approach consists in model-based optimal control. However, wastewater treatment plants involve highly nonlinear and time-varying processes, making existing mechanistic models such as the Benchmark Simulation Model no.1 (BSM1) challenging for direct use in online control. Therefore, this study explores a hybrid modeling approach using the Hammerstein-Wiener (HW) structure. The proposed model combines a mechanistic steady-state model, derived from BSM1, with a data-driven approximation of the system dynamics, incorporating low-order linear dynamic models. In this work, the HW model was used as a surrogate for BSM1. The HW surrogate model attained coefficients of determination ($R^2$) often exceeding 0.95 across key water quality indicators, such as total nitrogen and ammonium concentration. This accuracy was found to be substantially better than that of a First-Order-Plus Dead-Time model as conventional low-order linear model, demonstrating the usefulness of the HW structure in capturing key nonlinearities.

## INTRODUCTION

New regulation is imposing increasingly stringent requirements on wastewater treatment to tackle emerging sources of urban pollution and address societal challenges like the energy transition and climate neutrality [1]. One approach towards meeting these requirements consists in model-based methods, and in particular model-based optimal control. However, accurate and computationally tractable modeling of wastewater treatment dynamics remains a challenge.

In the 80s, the Activated Sludge Model no.1 (ASM1) became the first accepted mechanistic model across the industry, giving insights into the dynamic behavior of the carbon and nitrogen removal of activated sludge systems. Several versions have since been developed to target specific biological processes, such as phosphorus recovery and anaerobic digestion [2].

Due to the success of the ASM1 and its variants, mechanistic models are still used in wastewater treatment plants (WWTPs) because of the process insight and predictive capabilities they provide in plant design and operation optimization. The Benchmark Simulation Model No. 1 (BSM1) [3] is the industry standard for benchmarking and control application. Conversely, dynamic black-box models (a.k.a. data-driven models) are the most effective in the presence of a high volume of data. However, they have limited interpretability, large data requirements, and are unreliable in extrapolation [4].

A promising intermediate approach is hybrid modeling, which has already been successfully applied to certain aspects of wastewater treatment where some parameters, such as micropollutant concentration, colloid charge, and pathogen abundance, are hard or expensive to measure with sufficient precision [5]. By using data-driven surrogates for these complex variables, hybrid models offer a robust solution for real-time monitoring and process control. For instance, Gaublomme et al. [6] used hybrid models for solution-diffusion processes in membrane processes. Wang et al. [7] created an integrated framework to improve forecasting of salinity and dissolved oxygen with hybrid models. Nordstrand & Dutta [8] achieved a more robust and flexible control of capacitive-deionisation desalination processes by applying the

hybrid linear-state-space dynamic Langmuir model. Tomperi et al. [9] used a series-connected ARMAX model to estimate effluent COD concentration in full-scale industrial WWTPs.

Despite the fact that current hybrid models offer significant predictive capacity, they often face a trade-off between computational complexity and integration into real-time control and optimization frameworks. A critical gap remains in identifying hybrid structures that are complex enough to capture wastewater dynamics but simple enough to be used efficiently in mathematical optimization [10–12].

In this work, we address this by utilizing Hammerstein–Wiener (HW) models. These models constitute a class of block-structured dynamic models that represent systems as a linear dynamic block embedded between two nonlinear static transformations [13]. Specifically, we aim at using a mechanistic steady-state model as nonlinear static block, combined with a data-driven low-order dynamic block. We hypothesize that this hybrid model structure is well-suited for WWTP for two reasons: First, many dynamics observed in WWTP pilot plants can be effectively described as first-order models [2]. Second, by including a mechanistic model as static block, we can capture nonlinearities in the gains and represents steady states accurately. In this work, we use BSM1 both to derive the static block, and as a high-fidelity representation of the true system (cf. Figure 1).

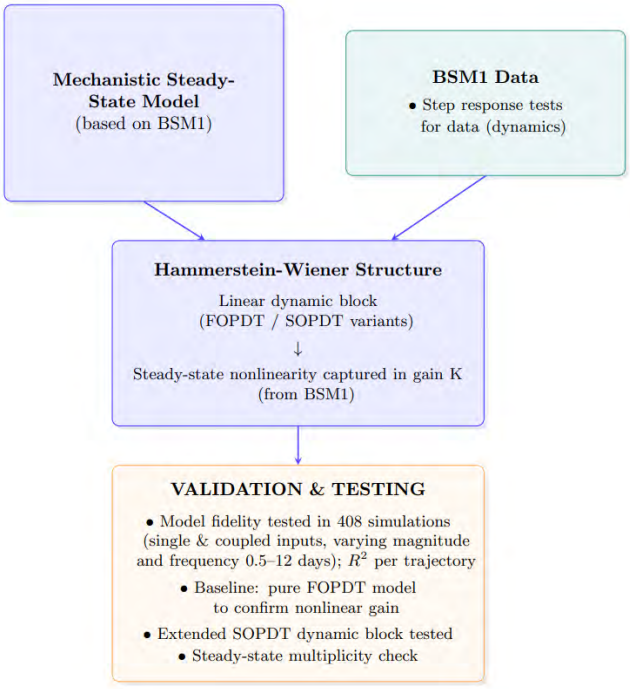

**Figure 1.** Simplified Flowsheet of Methodology

Our contribution lies in the development of a hybrid HW model that aims to strike a balance between accuracy and computational efficiency for real-time applications. In the following, we first describe the structure of the model as well as the experiments used for fitting the data-driven blocks. Then we evaluate the accuracy of the model in a number of validation experiments. Finally, we compare it to a first-order-plus-dead-time model as conventional, linear model to assess the benefit of retaining the nonlinear mechanistic part.

# METHODOLOGY

## BSM1 Model

The base model configuration of BSM1 consists of an activated sludge unit for biological wastewater treatment, followed by a circular secondary settler for separating treated water from sludge. The model consists of 205 differential equations and a minimum of 65 algebraic equations, depending on the specific implementation, and has 28 individual control handles [14]. The BSM1 reflects the standard design of many real-world secondary treatment stages in WWTPs. BSM1 provides standardized simulation environments to evaluate control strategies in SIMULINK.

In this work, we use the BSM1 in two ways: 1. We use a steady-state version of it within the HW structure as described below. 2. We use the full dynamic BSM1 as virtual plant, i.e., to generate data for the identification of the dynamic part of the HW structure, and as well as the ground truth for evaluating the accuracy of the HW model.

## Hammerstein-Wiener Model

The Hammerstein-Wiener model is commonly used in nonlinear dynamic system identification. As illustrated in Figure 2, it is constructed from a linear block between two static nonlinear transformations.

**Figure 2.** Hammerstein-Wiener Structure

The formulation for a Hammerstein-Wiener model is presented in Equation (1)-(4) provided by Wills et al. [13]:

$$w(t) = f_H(u(t)), \forall t \in [t_0, t_f] \quad (1)$$

$$\dot{x}(t) = Ax(t) + Bw(t), \forall t \in [t_0, t_f] \quad (2)$$

$$z(t) = Cx(t) + Dw(t), \forall t \in [t_0, t_f] \quad (3)$$

$$y(t) = f_W(z(t)), \qquad \forall t \in [t_0, t_f] \quad (4)$$

Here, $f_H: \mathbb{R}^{n_u} \to \mathbb{R}^{n_w}$ represents the Hammerstein function for the input nonlinearity and $f_W: R^{n_z} \to R^{n_y}$ the

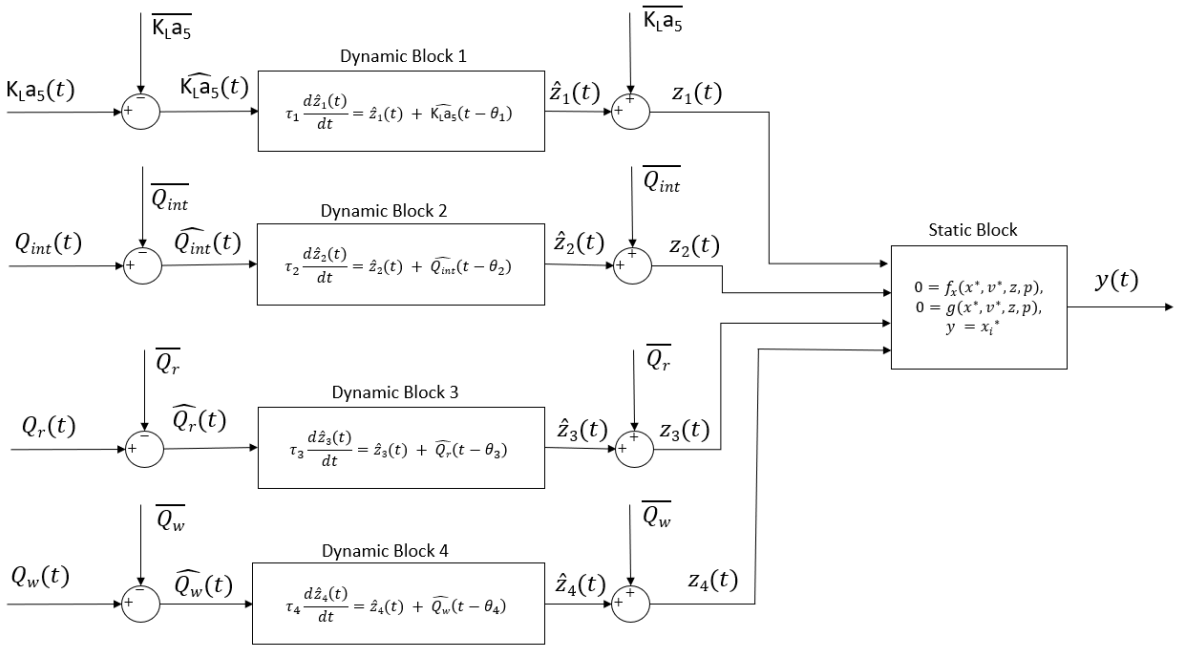

**Figure 3.** Hammerstein-Wiener surrogate model. $y(t)$ can be any of the 17 outputs in Table 1; the same model structure must be run separately for each output

Wiener function for the output nonlinearity. The inputs of the system are represented as $u: [t_0, t_f] \rightarrow \mathbb{R}^{n_u}$, while the inputs to the linear time-invariant (LTI) system are denoted by $w: [t_0, t_f] \rightarrow \mathbb{R}^{n_w}$. The system states are given by $x: [t_0, t_f] \rightarrow \mathbb{R}^{n_x}$, and the outputs of the LTI system are described by $z: [t_0, t_f] \rightarrow \mathbb{R}^{n_z}$. Finally, the overall system outputs are expressed as $y: [t_0, t_f] \rightarrow \mathbb{R}^{n_y}$.

Hammerstein-Wiener models can also be observed as two simpler variants: the Hammerstein model uses a nonlinear-then-linear (N-L) structure, and the Wiener model follows a linear-then-nonlinear (L-N) structure.

## Hybrid modeling Approach

The HW model developed is inspired by the Wiener structure (linear-then-nonlinear) and takes 4 inputs: aeration intensity in the 5th aeration tank $(K_L a_5)$, internal recycle flow $(Q_{int})$, sludge recycle flow $(Q_r)$, and waste sludge flow $(Q_w)$. This selection was based on the most common control handles of a WWTP. Furthermore, aeration intensity and internal recycle flow have a built-in PID controller in BSM1, which provide a ground for control comparison. The modeled outputs are the effluent variables of secondary clarifier in BSM1, which can be found in Table 1. The resulting HW model architecture is shown in Figure 3.

Note that, to capture the distinct system dynamics of each variable, we developed a series of Multi-Input Single-Output (MISO) structures, where a dedicated HW model is trained for each specific effluent output. This is because the time constants $\tau_i$ and dead times $\theta_i$ of the FOPDT models in Equation (7) only captures the relation between a single input and output. Therefore, different outputs will require different parameter values. For example, ammonium concentrations and active heterotrophic biomass are affected differently by an increase in aeration intensity.

### Parallel Linear Dynamic Blocks

The input entering each linear dynamic block $i$ is defined as a deviation form by subtracting the nominal operating point from the actual input value:

$$\hat{u}_i(t) = u_i(t) - \overline{u}_i, (6)$$

where $\hat{u}_i(t)$ is the deviation input, the actual input $u_i(t)$, and nominal operating point $\overline{u}_i$. The linear block models only the time-dependence of the effect of input $u_i$ on the output $y$, and consists of a FOPDT model with unit gain:

$$\tau_i \frac{d\hat{z}_i(t)}{dt} = -\hat{z}_i(t) + \hat{u}_i(t - \theta_i), \qquad (7)$$

where $\hat{z}_i(t)$ is the internal state (output) of the $i^{th}$ block, $\hat{u}_i(t)$ is the input, $\tau_i$ is the time constant, and $\theta_i$ is the dead time. The output $\hat{z}_i$ thus represents the same physical quantity as $\hat{u}_i$, but delayed in a way that represents the response *dynamics* of the overall output of the HW model (i.e., the output of the nonlinear block, $y$).

The parameters of each dynamic block $i$ are only the time constant $\tau_i$ and time delay $\theta_i$, which are determined from multiple step responses and validated against response signals from the ground truth system, where in each case the best fitting parameters are chosen based

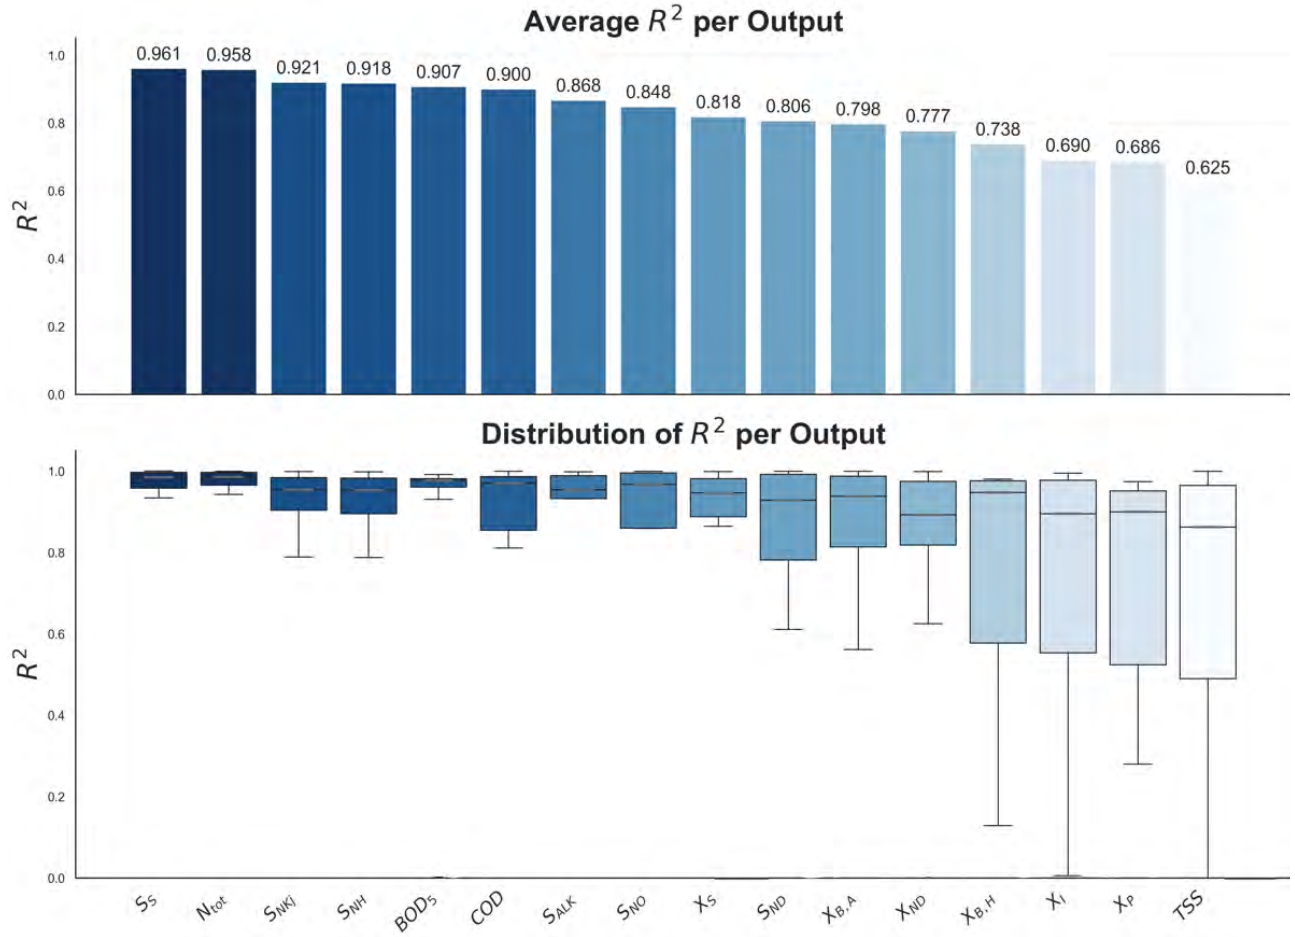

**Figure 4:** Predictive performance of the HW model across water quality outputs. Averages and distributions are computed over all time points of the 408 validation simulations.

on the coefficient of determination ($R^2$). The underlying assumption is that $\tau_i$ and $\theta_i$ stay rather constant across a wide operating range (i.e., that the main nonlinearity is in the gains). Moreover, it is assumed that the interaction between inputs in terms of dynamics can be ignored (superposition principle).

Finally, the operation point value is added to the dynamic block output to finalize the signal that flows into the nonlinear block:

$$z_i(t) = \hat{z}_i(t) + \overline{z}_i \quad (8)$$

where, $z_i(t)$ is the nominal term, $\hat{z}_i(t)$ is the deviation, and $\overline{z}_i = \overline{u}_i$ is the nominal operating point.

This modeling approach was used to enable dynamic prediction without introducing excessive model complexity, and much smaller data requirements than full black-box models. These smaller data requirements are enabled by the superposition principle of linear differential equations.

## Nonlinear Static Block

This block consists of a steady-state model derived from the BSM1 equation set. Since the original BSM1 is implemented in Simulink, which limits the efficient computation of steady-states, we developed a standalone version in CasADi using the equations from [14]. This new model version allows for the calculation of steady states at a significantly lower computational cost. Note that, because the inputs are transformed based on their dynamic relationship with the output (captured via time constants and dead times), the steady-state block's solution represents a quasi-steady state, meaning the approximate response of the output to time-dependent input changes. The HW model is considered to be at a true steady state only when $u(t) = z(t)$, indicating the system has fully settled following input perturbations.

To compute the steady states, the BSM1, which is a nonlinear DAE, was converted into an algebraic system as follows. Let $x(t) \in \mathbb{R}^{n_x}$ denote the differential states, $v(t) \in \mathbb{R}^{n_v}$ the algebraic states, $z(t) \in \mathbb{R}^{n_z}$ the inputs, for which we here use the inputs transformed by the linear blocks rather than the actual external inputs to the system, and $p \in \mathbb{R}^{n_p}$ the model parameters. The BSM1 equations are

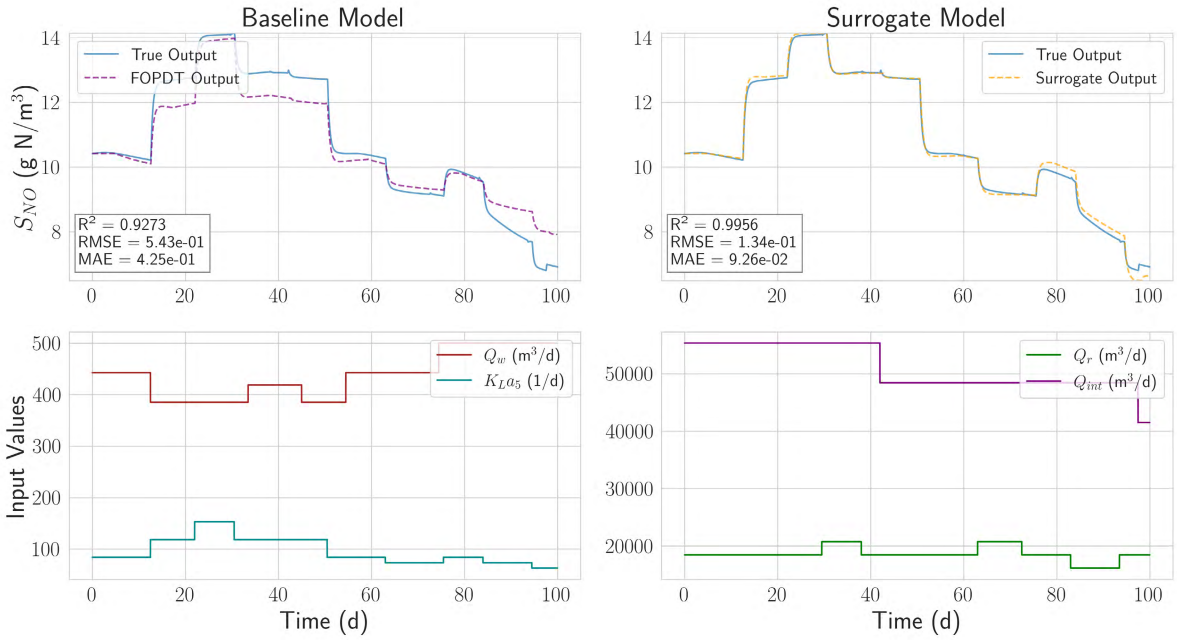

**Figure 5.** Comparison of a FOPDT baseline model (top left, dashed purple) against the proposed HW smodel (right, dashed orange) for nitrate and nitrite concentration, both in comparison to the BSM1 as ground truth (solid blue). The inputs are shown in the bottom left and right plots. Despite being shown in different figures, they were applied simultaneously to the models but were plotted on different graph because of the order of magnitude for the inputs.

$$\dot{x}(t) = f_x(x(t), v(t), z(t), p), (9)$$

$$0 = g(x(t), v(t), z(t), p), (10)$$

where $f_x$ defines the differential equations (bioreactor, clarifier, and sensors), and $g$ defines the algebraic equations (clarifier mappings and output connections). Computing the steady states reduces to solving the system

$$0 = f_x(x^*, v^*, z, p), (11)$$

$$0 = g(x^*, v^*, z, p), (12)$$

where $(x^*,\ v^*)$ represent the steady-state values for the differential and algebraic variables, respectively. The effluent concentration $i$ can be extracted from $x^*$:

$$y = x_i^* \ (15)$$

The fact that only one output can be extracted for solving the steady state model (as described above) is a limitation of the proposed structure.

## Model Training and Validation

All data was sampled at 15 minute intervals. This was an upper limit of sampling time for the regression to capture the fastest dynamic in the system. For the training data, step responses were applied to the ground truth BSM1, starting from different operating points. Given the linear dynamic models used, all inputs were varied separately to fit the respective blocks. For each input, 20 points evenly spaced across the feasible range of input values were used as initial operating points as well as final points of the input steps. From these 20 step responses per input, a FOPDT model was fitted to every input-output combination through least-squares regression, resulting in 20 parameters sets $(K_i, \tau_i, \theta_i)$ per output (i.e., one per input for every output). The gains $K_i$ were then discarded, since this they are not used in the HW model.

The validation dataset was generated utilizing a Pseudorandom Multilevel Sequence (PRMS) with Pseudorandom Frequency Modulation (PRFM) as input signal. The multilevel amplitudes varied across different experiments: some only covered the training space, while other extrapolated beyond the training space while remaining within the physical operating bounds of the plant. . The frequency modulation was varied from a $1/(0.5\ \text{days})$ to $1/(12\ \text{days})$ across experiments. This was designed to validate all aspects of the model, including extrapolation capabilities, accuracy under fast and slow dynamics, and ability to predict steady states. The data was generated with the same sampling rate as the training data. In total, 408 output trajectories were generated by applying the described inputs signals.

Model validation was performed in two steps; first the best among the 20 best parameter sets per input-output combination was selected based on the coefficient of determination $(R^2)$, which was computed along

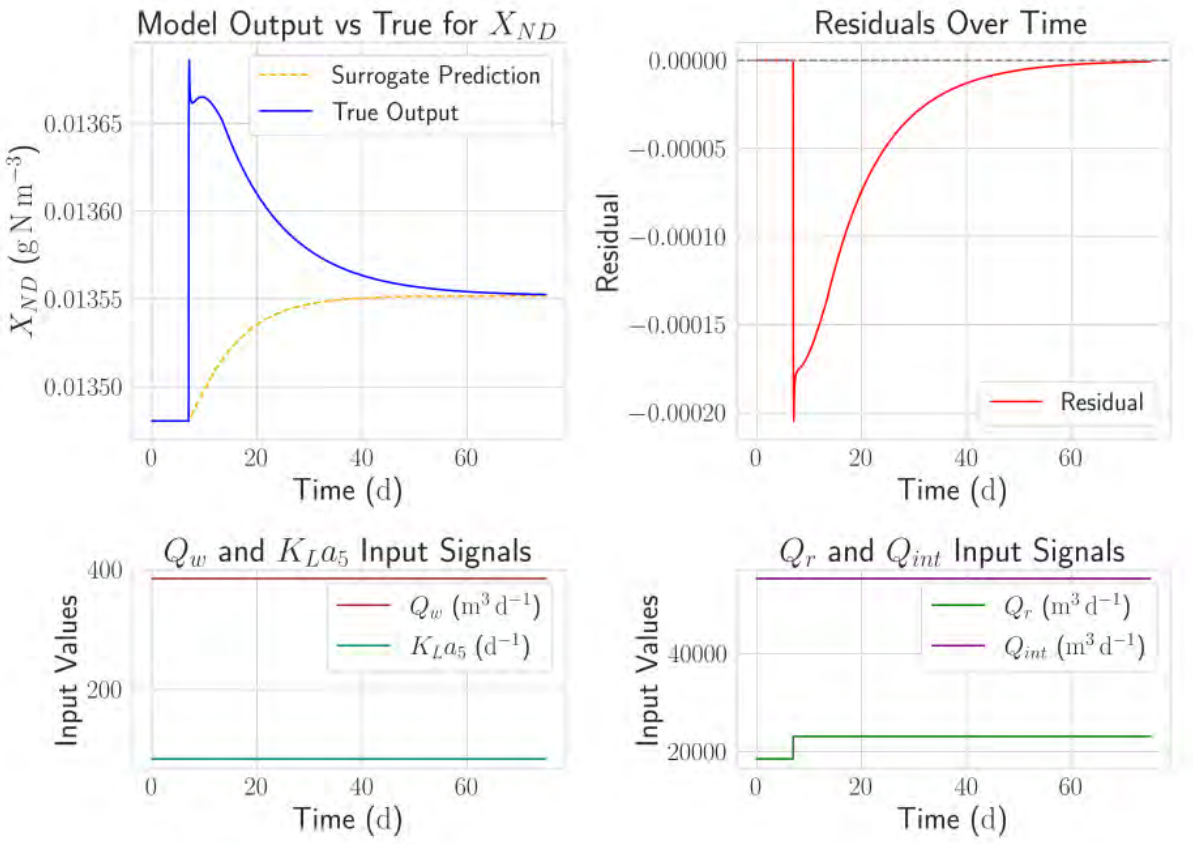

**Figure 6.** The particulate biodegradable organic nitrogen concentration cannot be captured by the proposed HW model with first-order dynamics because of its complex transient behavior.

the output trajectory. Afterwards, these best parameters were specified in the model.

In the second step of model validation (considered evaluation), the HW model's fidelity was tested. For each simulation the coefficient of determination ($R^2$) was captured for the whole trajectory of the simulation.

To evaluate the benefit of capturing the nonlinear gain through the mechanistic model in the HW structure, a pure FOPDT model was also developed as conventional low-order linear model. It was fitted to a step response where the final value was the upper bound of the training input range. As an extension, a HW model with a Second Order Plus Dead Time (SOPDT) function in its dynamic blocks was designed to consult test if an extra parameter in the structure leads to better predictive capabilities.

Although the BSM1 exhibits a unique steady state, the nonlinear blocks of the HW structure could introduce artificial steady-state multiplicity. To verify the reliability of the proposed model, we performed a multiplicity analysis using Latin Hypercube Sampling (LHS) to generate different initial guesses to the steady-state solver, ensuring the HW model maintains a unique, physically consistent mapping across the operational space.

## RESULTS & DISCUSSION

Across all 408 validation simulations, the average $R^2$ for the outputs, as seen in Figure 4, achieved consistently high values, often exceeding 0.9, indicating accurate replication of both steady-state and dynamic behavior. The most important results from these experiments were the good predictive performance ($R^2 > 0.9$) across key water quality indicators such as readily biodegradable substrate ($S_s$), total nitrogen ($N_{tot}$), Kjeldahl nitrogen ($S_{NKj}$), and ammonium ($S_{NH}$), as well as Biochemical Oxygen Demand ($BOD_5$) and Chemical Oxygen Demand ($COD$). Lower-performing outputs were linked to specific limitations, particularly input-output relationships exhibiting complex nonlinear dynamics beyond FOPDT approximation. An example for such a case is shown in Figure 6.

The HW model achieved substantially better accuracy than the pure FOPDT model in the validation simulation: the HW model consistently attained higher

coefficients of determination ($R^2$) for the whole trajectory of a simulation, often exceeding 0.90 whereas the FOPDT model yielded noticeably lower $R^2$ values. An example is shown in Figure 5. Preliminary experiments indicated that extending the HW model's linear blocks to second-order (SOPDT) dynamics yielded negligible improvements in predictive accuracy over the first-order structure.

Steady-state multiplicity analysis confirmed the presence of multiple equilibria in roughly 10% of tested conditions. These multiplicities were concentrated in specific input regions, most notably when the wastage sludge flow $Q_w$ dropped below $300\ \mathrm{m^3 d^{-1}}$. This confirms that in operating regimes where multiplicity is present the HW model is not reliable.

Comparing the HW model to traditional linear hybrid structures, such as ARMAX, highlights the potential advantages of the our approach. For instance, while an ARMAX model achieved an $R^2 \approx 0.67$ for effluent COD in a specific industrial WWTP [9], our results suggest that augmenting low-order dynamics with nonlinear static map can further enhance predictive capabilities by capturing the system's inherent nonlinearities more effectively.

## CONCLUSION

This work demonstrates that a hybrid Hammerstein–Wiener model can effectively approximate the dynamics of key outputs in a wastewater treatment process by combining mechanistic steady-state modeling with data-driven linear dynamic blocks. This separation enables reasonably accurate dynamic prediction without introducing excessive model complexity, and much smaller data requirements than full black-box models. Moreover, the HW model retains the gain of the original rigorous model which is useful for control and optimization applications. The linear dynamics of the HW model can be an advantage also because they can be exploited algorithmically in optimization algorithms [15]. These properties make the Hammerstein–Wiener framework particularly well suited for integration into DRTO or NMPC and allow operation with online optimization crucial for WWTPs that operate under increasingly strict regulatory constraints.

**Table 1:** Inputs and outputs of Hammerstein-Wiener model

| Symbol | Description | Unit |
|---|---|---|
| $K_{La5}$ | Oxygen transfer coefficient in reactor | $\mathrm{d^{-1}}$ |
| $Q_{\mathrm{int}}$ | Internal recycle flow rate | $\mathrm{m^3\,d^{-1}}$ |
| $Q_r$ | Return sludge flow rate | $\mathrm{m^3\,d^{-1}}$ |
| $Q_w$ | Waste sludge flow rate | $\mathrm{m^3\,d^{-1}}$ |
| $N_{\mathrm{tot}}$ | Total nitrogen in effluent | $\mathrm{g\,m^{-3}}$ |
| $\mathrm{COD_{tot}}$ | Total chemical oxygen demand in effluent | $\mathrm{g\,m^{-3}}$ |
| $S_{\mathrm{NH}}$ | Ammonium nitrogen in effluent | $\mathrm{g\,m^{-3}}$ |
| $\mathrm{TSS}$ | Total suspended solids | $\mathrm{g\,m^{-3}}$ |
| $\mathrm{BOD_5}$ | 5-day biochemical oxygen demand in effluent | $\mathrm{g\,m^{-3}}$ |
| $S_I$ | Soluble inert organic matter | $\mathrm{g\,m^{-3}}$ |
| $S_S$ | Readily biodegradable substrate | $\mathrm{g\,m^{-3}}$ |
| $X_I$ | Particulate inert organic matter | $\mathrm{g\,m^{-3}}$ |
| $X_S$ | Slowly biodegradable substrate | $\mathrm{g\,m^{-3}}$ |
| $X_{B,H}$ | Active heterotrophic biomass | $\mathrm{g\,m^{-3}}$ |
| $X_{B,A}$ | Active autotrophic biomass | $\mathrm{g\,m^{-3}}$ |
| $X_P$ | Particulate products from biomass decay | $\mathrm{g\,m^{-3}}$ |
| $S_O$ | Dissolved oxygen | $\mathrm{g\,m^{-3}}$ |
| $S_{NO}$ | Nitrate and nitrite nitrogen | $\mathrm{g\,m^{-3}}$ |
| $S_{ND}$ | Soluble biodegradable organic nitrogen | $\mathrm{g\,m^{-3}}$ |
| $X_{ND}$ | Particulate biodegradable organic nitrogen | $\mathrm{g\,m^{-3}}$ |
| $S_{\mathrm{ALK}}$ | Alkalinity | $\mathrm{mmol\,L^{-1}}$ |

## ABSTRACT

Pyrolysis is an emerging green pathway to produce bulk chemicals and sustainable fuels. However, pyrolysis oil requires stabilisation via hydrotreatment, and this process generates an aqueous waste containing alcohols (mainly methanol and ethanol), carboxylic acids, and some ketones. To increase the economic sustainability of biofuels production, there is increasing interest in recovering these valuable chemicals from water. Reliable thermodynamics are necessary to address the separation and design of equipment to fractionate such complex mixtures, with multiple azeotropes and non-idealities. The Non-Random Two-Liquids (NRTL) models in both Aspen Plus V12.0 and COFE V3.7, a license-free software released by AmsterChem, do not accurately reproduce the equilibrium measurements of most of the binary and ternary mixtures involving water, a $C_1$-$C_4$ alcohol, and a light carboxylic acid. This work aims to retune the activity-based model to improve the NRTL model predictivity, using experimental data retrieved from NIST ThermoData Engine V10.1. The regression is performed in Aspen Plus V12 using the Maximum Likelihood algorithm. The resulting re-parametrised NRTL shows improved accuracy and reliability compared to the existing models. For all investigated binary and ternary mixtures, the Average Relative Deviation (ARD) is lower than 20%, and for 75% of them, ARD is lower than 10%. The ARD in the prediction of vapour phase composition drops from 16.0% and 12.1% of the original COFE and Aspen Plus models, respectively, down to 7.0%.

**Keywords**: pyrolysis, water phase valorisation, NRTL model, VLE model re-parametrisation, Aspen Plus, COCO-COFE

## INTRODUCTION

Pyrolysis oil offers a valuable solution to the circular economy, as it allows valorisation of waste, including lignocellulosic biomass and plastics. It represents a renewable fuel for transport and power generation, and it can be used as a feedstock to produce valuable chemicals [1]. However, raw pyrolysis oils are chemically and physically unstable. A stabilisation is necessary to reduce acidity and reactive components (mainly carbonyls and carboxylic acids). The stabilisation process includes the following steps [2]:

1. Selective hydrogenation at mild temperatures (200-250°C). The obtained product is called Stabilised Pyrolysis Oil (SPO);
2. Deoxygenation at high temperature (350°C). The obtained product is called Stabilised Deoxygenated Pyrolysis Oil (SDPO);
3. Final hydrogenation (refinement step at 425°C) to produce Hydrogenated Pyrolysis Oil (HPO), which meets the specifications for blending with conventional fuels.

This stabilisation process generates a substantial amount of aqueous stream, which is currently treated as waste. This water stream contains methanol and ethanol in the order of 2 wt%-6 wt%, and minor concentrations of higher alcohols, $C_1$-$C_4$ carboxylic acids, and light esters.

In FUEL-UP [3], a research project funded by the European Commission, we aim to design a process to isolate the chemicals embodied in the aqueous phase and

exploit them as intermediates to generate biofuels, biochemicals, and pharmaceutical products.

Reliable thermodynamics are necessary to design, model, and optimise a process to fractionate such complex mixtures, characterised by multiple azeotropes. Among available Vapour-Liquid Equilibrium (VLE) models, the Non-Random Two-Liquid (NRTL) activity model is often used to characterise thermodynamic equilibrium in azeotropic systems. In this context, the reliability of existing models for multi-component mixtures can be checked by verifying their accuracy in predicting the VLE of binary and ternary mixture data available in the literature.

In this work, a statistical analysis is carried out to check the reliability of default NRTL models in both Aspen Plus V12.0 [4] and COCO-COFE V3.7 [5], a license-free process simulator, in predicting vapor-liquid equilibrium data for all possible combinations of mixtures involving the 14 compounds which are present in the water stream to be valorised in concentrations equal or higher than 0.1%. For the Aspen model, research on available interaction coefficients is enabled among all existing databanks. When available, APV121 VLE-IG database is selected, in accordance with the Aspen Plus default template.

NRTL combined with ideal gas law is considered instead of more accurate gas phase models where the gas phase is described by means of an equation of state, such as NRTL-RK. This choice is done for the sake of consistency in the model accuracy comparison, as this more advanced option to combine the NRTL model with an equation of state to describe the vapor phase is not available in COCO-COFE. Using NTRL in the liquid phase and ideal gas law in the gas phase can be justified considering that water-alcohol mixtures exhibit significantly stronger non-idealities in the liquid phase compared to the vapor phase and that the target separation process is to be carried out at atmospheric pressure.

After verifying the insufficient predictability of both existing Aspen Plus and COCO-COFE models, NRTL binary interaction coefficients are re-fitted in AspenPlus for all mixtures showing an Average Relative Deviation (ARD) > 10%. The model tuned in this work is used as the thermodynamic framework for the design and optimisation of a multi-step distillation process to recover alcohols, in particular methanol and ethanol, at the highest possible purity from pyrolysis oil aqueous waste. The process design and evaluation of Key Performance Indicators for this process are discussed in a separate contribution, entitled “Process design for the recovery of valuable organic compounds from pyrolysis oil aqueous phase”.

## AQUEOUS STREAM CHARACTERISATION

10 litres of both SPO and SDPO have been collected and delivered to SINTEF by the Biomass Technology Group (BTG), a company specialised in converting biomass into sustainable biofuels located in the Netherlands. The composition of these streams has been analysed in SINTEF using the Gas Chromatography-Flame Ionisation Detector (GC-FID) technique. 14 different species were identified, and their concentration was measured after calibration following the Standard Operating Procedure (SOP). Peaks of unidentified species were combined with the peaks of the closest species in the chromatogram. For simplicity, alcohols heavier than $C_5$ were lumped into pentanol, and carboxylic acids higher than $C_4$ were lumped into butyric acid.

The composition of SPO and SDPO aqueous phases ($SPO_{Aq}$ and $SDPO_{Aq}$, respectively) is shown in Table 1. Noteworthily, the measured concentrations of the compounds detected with the GC cover 85% and 95% of the mass balance for $SPO_{Aq}$ and $SDPO_{Aq}$, respectively.

All organics are highly diluted in water (concentration < 5 wt%). The species present in the highest concentrations are alcohols, in particular methanol, ethanol, and pentanol. All other compounds, including carboxylic acids, acetates, ketones, and furans, have individual concentrations below 0.8 wt%.

**Table 1:** Composition of SPO and SDPO aqueous streams (wt %).

| Component | Symbol | $SPO_{Aq}$ | $SDPO_{Aq}$ |
|---|---|---|---|
| Water | H2O | 72.50% | 89.90% |
| Methanol | MEOH | 4.95% | 0.33% |
| Ethanol | EtOH | 2.70% | 1.85% |
| 1-Propanol | 1-PrOH | 0.32% | 0.55% |
| Butanol | BuOH | 0.13% | 0.03% |
| Formic acid | FoAc | 0.05% | 0.05% |
| Acetic acid | AcAc | 0.22% | 0.00% |

| Methyl acetate | MeA | 0.25% | 0.00% |
| Ethyl acetate | EtA | 0.59% | 0.49% |
| Acetone | Acet | 0.05% | 0.08% |
| Isopropanol | 2-PrOH | 0.20% | 0.10% |
| Propionic acid | PrAr | 0.23% | 0.47% |
| Butyric acid | BuAc | 0.37% | 0.50% |
| Pentanol | PeOH | 1.91% | 0.87% |
| TOTAL | - | 84.70% | 95.41% |

## METHODOLOGY

### Experimental data overview

The reliability of the existing Aspen Plus V12.0 and COFE v3.7 models is checked by verifying their accuracy

in predicting the VLE of binary and ternary mixtures data available in the literature. Experimental data for model evaluation are retrieved from NIST ThermoData Engine version 10.1, considering all possible binary and ternary combinations among the compounds listed in Table 1.

Since the target process is to be operated at atmospheric pressure, the analysis considers all isobaric data collected at atmospheric pressure and isothermal data in a pressure range 80-120 kPa for the other mixtures. In the selection process, all data failing to pass the thermodynamic consistency test are disregarded. All collected data are then plotted in Excel in the form of a Temperature-composition chart to identify and remove any remaining outliers.

A statistical analysis is performed on the remaining data to obtain insight into how many independent measurements are available for each analysed mixture and into what share of the liquid composition range is covered by experiments. An overview of experimental data availability is provided in Table 2 and Table 3. Liquid composition ranges shown in the tables include all the components present in the mixture. Data availability is significantly larger for binary mixtures.

**Table 2:** Statistical analysis on experimental data availability on binary mixtures from NIST ThermoData Engine V10.1.

| Indicator | Value |
|---|---|
| N° of mix. with available data | 76 / 105 |
| **Covered composition range** | |
| Liquid Composition <1% - >99% (mol) | 21% |
| Liquid Composition <5% - >95% (mol) | 68% |
| Liquid Composition <10% - >90% (mol) | 90% |
| **Number of experimental data** | |
| N data > 100 | 21% |
| N data > 50 | 43% |
| N data > 20 | 75% |
| N data >10 | 88% |

**Table 3:** Statistical analysis on experimental data availability on ternary mixtures from NIST ThermoData Engine V10.1.

| Indicator | Value |
|---|---|
| N° of mix. with available data | 31/455 |
| **Covered composition range** | |
| Liquid Composition <1% - >99% (mol) | 7% |
| Liquid Composition <5% - >95% (mol) | 23% |
| Liquid Composition <10% - >90% (mol) | 52% |
| **Number of experimental data** | |
| N data > 100 | 19% |
| N data > 50 | 52% |
| N data > 20 | 77% |
| N data >10 | 90% |

## Statistical analysis for model evaluation

Average Relative Deviation (ARD) is used as the statistical indicator to evaluate the model performance, as shown in expression (1), where *z* stands for a generic property (T, P, vapor composition), and *i* stands for the generic experimental measurement.

$$ARD = \frac{1}{N_{data}} \sum_{i=1}^{N_{data}} \left| \frac{z_{i,mod} - z_{i,exp}}{z_{i,exp}} \right| \quad (1)$$

For isothermal binary data, a VLE problem at fixed temperature and liquid composition is solved. Therefore, the ARD is calculated for pressure and vapor composition. Conversely, for isobaric data, pressure and liquid composition are fixed, and ARD is checked for temperature and vapor composition. For ternary data, the system has an additional degree of freedom according to the Gibbs phase rule, therefore both temperature and pressure are assigned, and the ARD is calculated for vapor phase composition only.

For a given mixture, the model predictability is considered satisfactory if the obtained average ARD is lower than 10%. These mixtures are coloured in green. Mixtures showing ARD higher than 10% but lower than 20% are coloured in yellow. This condition indicates that the model is still able to provide a reasonable description of the system equilibrium, but there is room for improvement through coefficient regression. Finally, mixtures showing ARD > 20% are coloured in red. This condition indicates that the current model is unsuitable for VLE prediction.

## Regression procedure

NRTL binary interaction coefficients are regressed in AspenPlus V12.0 using the Aspen Plus regression tool for all mixtures showing ARD > 10% in both default models. Default values from the Aspen model are kept for all the other mixtures, as the Aspen model shows better predictability compared to the COFE one.

The generic expression of activity coefficient ($\gamma_{ij}$) in the NRTL model [6] is shown in expressions (2) to (3), where *j, k*, and *m* represent a generic component in a mixture, and *n* is the total number of components.

$\tau_{ij}$ is defined according to expressions (4) and (5) in Aspen Plus and COCO-COFE, respectively.

$$\ln(\gamma_i) = \frac{\sum_{j=1}^{n} x_j \cdot \tau_{ji} \cdot G_{ji}}{\sum_{k=1}^{n} x_k \cdot G_{ki}} + \sum_{j=1}^{n} \frac{x_j \cdot G_{ij}}{\sum_{k=1}^{n} x_k \cdot G_{kj}} \cdot \left( \tau_{ij} - \frac{\sum_{m=1}^{n} x_m \cdot \tau_{:mj} \cdot G_{mj}}{\sum_{k=1}^{n} x_k \cdot G_{kj}} \right) \quad (2)$$

$$G_{ij} = \exp(-\alpha_{ij} \cdot \tau_{ij}) \quad (3)$$

$$\tau_{ij}(\text{Aspen}) = A_{ij} + \frac{B_{ij}}{T} \quad (4)$$

$$\tau_{ij}(\text{COFE}) = \frac{g_{ij} - g_{ij,T} \cdot \left(1 - \frac{T}{T_{ref}}\right)}{T} \quad (5)$$

COFE-compliant coefficients can be easily retrieved from the corresponding Aspen-compliant coefficients

using expressions (6) and (7), where Tref is set equal to 298.15 K.

$$g_{ij} = B_{ij} + A_{ij} \cdot T_{ref} \quad (6)$$

$$g_{ij,T} = \mathrm{A_{ij}} \cdot T_{ref} \quad (7)$$

The regression is performed following the same procedure adopted in Gilardi et al. [7]. Both temperature-independent ($A_{ij}$) and temperature-dependent ($B_{ij}$) coefficients (see expression (4)) are regressed, while the non-randomness factor ($\alpha_{ij}$) is fixed at a value of 0.3. The regression is performed using the Modified-Barker algorithm, which means that the system solves a VLE at fixed temperature and liquid composition for isobaric data, and at fixed pressure and liquid composition for isothermal data. Each regression is repeated for 10 iterations to ensure the global minimum is reached, rather than just a local minimum. Overall, 108 parameters are re-fitted, improving the VLE prediction for 27 different mixtures.

## RESULTS

The results of the COFE and Aspen Plus models evaluation for every single mixture are gathered in Figure 1 to Figure 2, and Figure 3 to Figure 4, respectively. A summary of the model reliability assessment results is shown in Table 4.

**Table 4:** Summary of Key Performance Indicators from the evaluation of both COFE and Aspen Plus default models.

| KPI | Original COFE | Original Aspen |
|---|---|---|
| ARD-composition (%) | 16.01 | 12.08 |
| ARD-Temperature (%) | 3.02 | 1.53 |
| ARD – Pressure (%) | 8.27 | 4.24 |
| “Green” mixtures | 36 | 62 |
| “Yellow” mixtures | 39 | 31 |
| “Red” mixtures | 32 | 14 |

The average ARD among all binary mixtures is 14.7% and 9.2% for the two models, respectively, while the average ARD among ternary mixtures is 19.1% and 12.5%. The results show that the Aspen Plus model outperforms the COFE model, but there is still a relevant number of mixtures for which the ARD is >20% (14), which makes it unsuitable for accurate process modelling of waste-water stream valorisation from pyrolysis oil stabilisation.

**Figure 4.** Results of the default Aspen Plus V12.0 NRTL model evaluation for ternary mixtures: Average Relative Deviation on vapor composition (ARD Y).

An improvement of the current Aspen Plus model is achieved in this work through interaction parameters re-fitting for all 45 mixtures coloured in red and yellow in Figure 3 and Figure 4. The list of the re-fitted coefficients is available in Table 5. The results of the re-fitted model evaluation are gathered in Figure 5 and Figure 6 for binary and ternary mixtures, respectively.

The kPIs of the re-parametrised model are summarised in Table 6.

**Table 6**: Summary of Key Performance Indicators from the evaluation of both COFE and Aspen Plus default models.

| KPI | Re-fitted model |
|---|---|
| ARD-composition (%) | 6.96 |
| ARD-Temperature (%) | 0.89 |
| ARD – Pressure (%) | 2.01 |
| “Green” mixtures | 80 |
| “Yellow” mixtures | 27 |
| “Red” mixtures | 0 |

The re-fitted NRTL model shows a significantly improved capability to reproduce experimental VLE data. Indeed, for all investigated binary and ternary mixtures, the ARD is < 20%. Temperature versus composition plots (both boiling point and dew point curves) are drawn to check the model smoothness. For all binary mixtures of interest, a smooth trend is obtained throughout the whole composition range. As a conclusion. the re-fitted model can be considered sufficiently accurate for process design and optimisation purposes.

## CONCLUSIONS

Using experimental data available in NIST ThermoData Engine collected at atmospheric pressure, a NRTL model has been re-parametrised to improve the VLE characterisation in strongly non-ideal mixtures containing water and short-chain alcohols, esters and carboxylic acids.

This model can be successfully used to improve the thermodynamic modelling of a wide range of both conventional and bio-based processes, including the recovery of diluted chemicals from fermentation broth, extraction and separation products for biochemicals upconcentration, Fischer esterification, vinegar production, and organics recovery and valorisation from wastewater in pyrolysis and hydrothermal liquefaction.

## ACKNOWLEDGEMENTS

The present work received co-funding from FUEL-UP project, part of the European Union’s Horizon Europe Research and Innovation Programme under Grant Agreement N° 101136123.

The authors express their gratitude to BTG (Netherlands) for their precious contribution concerning feedstock supply and to Avecom (Belgium) for their support and cooperation in sample analysis.

The authors are also thankful to Rune Myrstad (SINTEF) and Camilla Otterlei (SINTEF) for their substantial contribution to sample analytics.

## ABSTRACT

The growing integration of renewable energy sources such as solar and wind power has intensified the demand for advanced energy storage technologies. Lithium–air (Li–$O_2$) batteries are particularly attractive due to their exceptionally high theoretical specific energy, which surpasses that of the conventional lithium-ion system. However, their practical application is hindered by poor reversibility during discharge, primarily due to the formation and decomposition of lithium peroxide ($Li_2O_2$), which causes cathode passivation and capacity fading. Since the electrochemical performance of Li–$O_2$ batteries is strongly influenced by the morphology, size, and spatial distribution of $Li_2O_2$ crystals, understanding the mechanisms governing their nucleation and growth is critical. To address this challenge, this work proposes a computational framework based on population balance modeling (PBM) to describe $Li_2O_2$ crystallization dynamics during battery discharge. The framework integrates population, mass, and energy balances, allowing the coupled analysis of electrochemical kinetics, supersaturation effects, and the evolution of crystal size distributions. Compared with continuum-scale and phase-field models, the PBM approach offers reduced computational cost while naturally accounting for particle size distributions and linking microscopic crystallization phenomena to macroscopic battery performance and degradation. Although simplified assumptions were adopted in this initial formulation, the framework successfully captures the essential discharge behavior of Li–$O_2$ systems. As such, it provides a robust foundation for future model refinements incorporating additional physicochemical mechanisms and more detailed electrochemical and transport phenomena.

## INTRODUCTION

Renewable energy sources represent a promising alternative to mitigate environmental issues associated with conventional fossil-based systems. In addition to their role in reducing greenhouse gas emissions, renewables have become increasingly cost-competitive in electricity generation. According to the International Renewable Energy Agency [1], solar photovoltaic (PV) and onshore wind technologies are significantly more economical than fossil fuel–based alternatives with costs approximately 41% and 53% lower than conventional options, respectively [2]. Despite their advantages, sources such as solar and wind are inherently intermittent. Solar power generation is constrained to daylight hours, while wind energy availability is dependent on geographic and meteorological conditions [3]. This intermittency is a challenge to the reliable and continuous supply of electricity that motivates the development of integrated energy systems capable of storing excess energy and delivering it on demand. In this context, electrochemical energy storage technologies, particularly batteries, have emerged as a viable solution to enable the large-scale integration of renewables. Notably, the cost of battery technologies has decreased more than 90% since 2010, highlighting their growing viability [2].

Rechargeable lithium-ion batteries have become the dominant energy storage technology for mobile app-

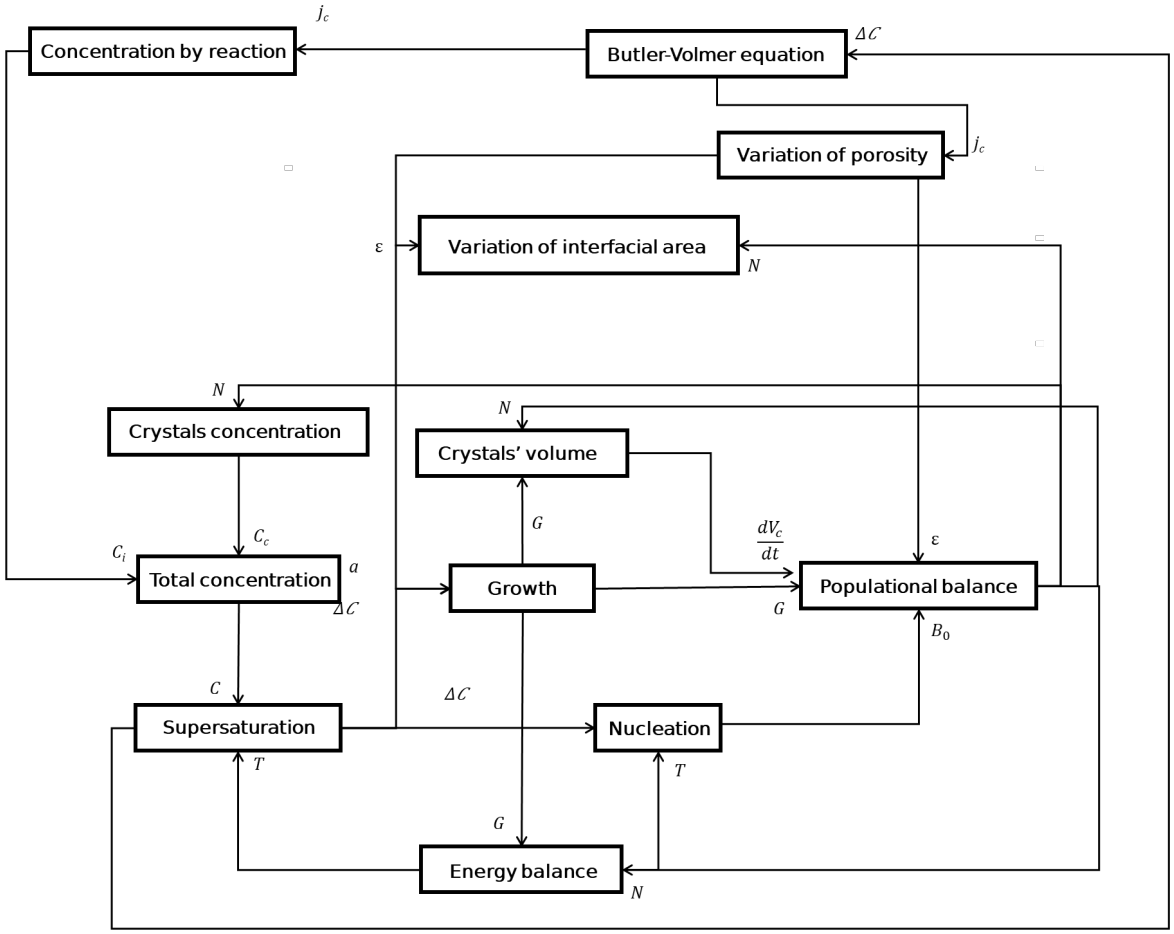

**Figure 1.** Information flow to model the discharge product involved in the $Li_2$-$O_2$ battery.

lications, largely due to their high energy density [4]. Despite these advantages, the energy density of lithium-ion batteries is approaching its theoretical limit and remains insufficient to fully meet the growing global demand for large-scale storage. In this context, lithium–air (Li–$O_2$) batteries have attracted attention because of their high theoretical specific energy, reported to reach approximately 3500 W.h/kg [5]. Nevertheless, this value is unlikely to be achieved in practical systems due to fundamental challenges [6].

In lithium–oxygen (Li–$O_2$) batteries, the overall reversible electrochemical reaction is governed by the formation and decomposition of lithium peroxide ($Li_2O_2$), in contrast to the intercalation-based mechanism of conventional lithium-ion batteries [7]. The morphology and accumulation of the $Li_2O_2$ discharge product are critical factors influencing the performance and reversibility of Li–$O_2$ cells. Specifically, $Li_2O_2$ formation and decomposition at the cathode directly affect round-trip efficiency, rate capability, and long-term cycling stability [8]. Studies have demonstrated that the insulating $Li_2O_2$ can deposit in diverse morphologies, including thin films and complex toroidal structures, depending on operating conditions [9]. Since the crystallization form of $Li_2O_2$ governs electron transport pathways and reaction accessibility during charging, controlling its morphology is essential. Consequently, a detailed understanding of how process variables influence $Li_2O_2$ nucleation, growth, and morphology is essential for optimizing battery capacity and achieving stable, reversible Li–$O_2$ operation.

Motivated by the influence of $Li_2O_2$ crystallization in the performance of Li–$O_2$ batteries, previous theoretical studies based on experimental observations have examined the formation of discharge products during battery operation [10-12]. In earlier work by the authors, a population balance–based model was applied to analyze $Li_2O_2$ deposition during discharge, and the resulting trends and performance-related implications were discussed [13]. The present study, however, addresses a distinct and complementary objective. Rather than focusing on the interpretation of modeling outcomes, this work provides a detailed exposition of the population balance modeling framework itself, including the governing equations, assumptions, numerical implementation, and coupling with

electrochemical variables. By systematically elucidating the structure and rationale of the model, this contribution establishes a reproducible simulation platform for $Li_2O_2$ crystallization, with direct applicability to other battery systems in which crystallization processes are crucial. As such, the novelty of this work lies in the formalization and clarification of the modeling methodology, enabling its reliable application and future expansion to more complex electrochemical energy storage systems.

## LI-O2 CRYSTALLIZATION MODELLING

Crystallization produces solid particles with a distribution of sizes, commonly described by the crystal size distribution (CSD). In Li–$O_2$ batteries, the evolution of the CSD during discharge is governed by the coupled effects of electrochemical kinetics, mass and energy transport, and particle population dynamics. These phenomena are captured through an integrated modeling framework that accounts for $Li_2O_2$ saturation, nucleation, and crystal growth (Figure 1). Accordingly, the following sections detail the core components of the model, including the characterization of $Li_2O_2$ crystals, mass and energy balances coupled with electrochemical kinetics, the population balance formulation, and the expressions adopted for saturation, nucleation, and growth rates.

### Characteristics of Li2O2 crystals

The external geometry of a crystal can be characterized by its characteristic length (L), the surface areas of its facets, and the angles between them. In modeling applications, these geometric attributes are conveniently represented through shape factors, which provide a compact description of crystal morphology. Shape factors are commonly defined with respect to crystal volume and surface area, as expressed by the volume-based and area-based shape factors (Equations 1 and 2), respectively [14]. These dimensionless parameters relate the characteristic length of a crystal to its corresponding volume and surface area. In the case of lithium peroxide, experimental observations indicate that the discharge product typically forms disk-like structures, such as toroids or oblate spheroids. Consequently, the associated shape factors are functions of the aspect ratio between the disk diameter and thickness, which governs the effective morphology of $Li_2O_2$ crystals [15].

$$V_c = k_V L^3 \tag{1}$$

$$A_c = k_a L^2 \tag{2}$$

### Mass balance of $Li_2O_2$ crystals and kinetics

The material balance of $Li_2O_2$ crystals during battery discharge is formulated by accounting for the temporal accumulation of solid discharge products within the cathode. Equation 3 quantifies the total mass of $Li_2O_2$ as obtained from the distribution of insoluble crystals in the system and Equation 4 describes the evolution of crystal volume as a function of particle growth. To close the mass balance, the rate of $Li_2O_2$ formation must be linked to the underlying electrochemical processes. Lithium peroxide is generated through the cathodic oxygen reduction reaction, and its formation rate is evaluated using the Butler–Volmer formulation (Equation 5). This expression captures the dependence of the reaction rate on the applied overpotential as well as on the concentrations of the reactants ($O_2$ and $Li^+$) and the discharge product ($Li_2O_2$). Based on the calculated cathodic reaction rate, the resulting variations in $Li_2O_2$ concentration, electrode porosity, and electrochemically active interfacial area are subsequently determined (Equations 6–8). Finally, the effective suspension volume of the system (Vsusp) is estimated from the geometric dimensions of the cathode (radius and thickness) in combination with the evolving porosity (Equation 9) [16].

$$C_c(t) = k_V \rho_c \int_0^\infty N(L,t) L^3 dL \tag{3}$$

$$\frac{dV_c}{dt} = -3k_V \int_0^\infty G(L,t) N(L,t) L^2 dL \tag{4}$$

$$\frac{j_c}{nF} = k_{ano} \Delta C exp\left[\frac{(1-\beta)nF}{RT}\eta_c\right] - k_c (C_{Li})^2 C_{O_2} exp\left[\frac{-\beta nF}{RT}\eta_c\right] \tag{5}$$

$$\frac{\partial C_i}{\partial t} = -\frac{a j_c MM}{2F} \tag{6}$$

$$\frac{\partial \varepsilon}{\partial t} = \frac{a j_c MM}{2F\rho_c} \tag{7}$$

$$ae = ae_0 \left[1 - \left(\frac{k_v \int_0^\infty N L^3 dL}{V_{susp}\varepsilon_0}\right)\right]^p \tag{8}$$

$$V_{susp} = \pi r_{el}{}^2 esp\, \varepsilon \tag{9}$$

### Energy balance

The energy balance describes the heat transfer processes occurring within the system and is expressed by Equation 10. Two primary contributions are considered in this formulation. The first accounts for the thermal effects associated with crystallization and $Li_2O_2$ formation, represented by the crystallization enthalpy. The second term represents heat exchange with the surroundings. In the present model, heat dissipation to the environment is assumed to occur via forced air convection, characterized by an average overall heat transfer coefficient of 30 W $m^{-2}$ $K^{-1}$ [17].

$$\rho_e c_{p_e} \frac{dT}{dt} = \left(-3\Delta H_c \rho_c k_V \int_0^\infty G(L,t)N(L,t)L^2 dL\right) - UA_T(T - T_s) \quad (10)$$

## Populational Balance

The general population balance equation (PBE) employed in this work was previously derived and reported by the authors in an earlier study (Equation 11) [18].

$$\frac{\partial N_\xi}{\partial t} + \frac{\partial}{\partial x} \bullet (U_o N_\xi) + \frac{\partial}{\partial \xi} \bullet (\dot{\xi} N_\xi) = h_\xi \quad (11)$$

Building on this formulation, several assumptions were adopted to tailor the population balance description to Li–$O_2$ battery systems. Crystal size is characterized using a single linear dimension, namely the characteristic length L, resulting in a univariate population balance (ξ=L). The system is modeled under transient operating conditions, reflecting the time-dependent nature of battery discharge. The control volume is defined as the cathode surface, which constitutes the primary site of $Li_2O_2$ nucleation and growth. Accordingly, the corresponding term in the PBE accounts for temporal changes in particle volume within the electrode domain. Particle transport within the phase volume is assumed to be governed solely by the linear crystal growth rate, while birth and death processes associated with discrete events are neglected ($h_\xi$ =0). Under these assumptions, the population balance for $Li_2O_2$ crystallization reduces to the batch crystallizer formulation expressed in Equation 12, yielding a partial differential equation that depends on both particle size and time, N(L, t). Two boundary conditions are required to close the system: the first, N(0, t), represents the nucleation flux (Equation 13), while the second, N(L, 0), corresponds to the initial seed crystal size distribution. The resulting PBE is solved numerically using the method of classes, in which the size domain is discretized into finite intervals, transforming the PDE into a system of ordinary differential equations with established numerical solution procedures (Equations 14–16).

$$\frac{\partial N}{\partial t} + \frac{\partial (GN)}{\partial L} + N\frac{\partial V}{V \partial t} = 0 \quad (12)$$

$$N(0,t) = \frac{B_0(t)}{G(0,t)} \quad (13)$$

$$\frac{dN_1}{dt} + \frac{1}{V_{susp}}\frac{dV_c}{dt}N_1 + \frac{G(L_1)}{2\Delta c_1}N_1 + \frac{G(L_1)}{2\Delta c_2}N_2 = B_0 \quad (14)$$

$$\frac{dN_i}{dt} + \frac{1}{V_{susp}}\frac{dV_c}{dt}N_i + \frac{G(L_i)}{2\Delta c_{i+1}}N_{i+1} + \frac{G(L_i) - G(L_{i-1})}{2\Delta c_i}N_i - \frac{G(L_{i-1})}{2\Delta c_{i-1}}N_{i-1} = 0 \quad (15)$$

$$\frac{dN_N}{dt} + \frac{1}{V_{susp}}\frac{dV_c}{dt}N_N - \frac{G(L_{N-1})}{2\Delta c_N}N_N - \frac{G(L_{N-1})}{2\Delta c_{N-1}}N_{N-1} = 0 \quad (16)$$

## Crystal saturation

A solution is defined as saturated when thermodynamic equilibrium is established between a dissolved species and its corresponding solid phase, indicating that the maximum solute concentration permitted under given conditions has been reached. Saturation is therefore an intrinsic property of the solute–solvent system and is strongly dependent on temperature [19]. In most cases, solubility increases with temperature; however, certain systems exhibit weak temperature dependence or even a decrease in solubility as temperature rises. In contrast, supersaturation arises when the solute concentration in the solution exceeds its equilibrium saturation value. The degree of supersaturation (ΔC) is quantified as the difference between the actual solute concentration (C) and the equilibrium saturation concentration (C∗), as defined in Equation 17. Supersaturated systems are thermodynamically unstable and provide the driving force for nucleation and crystal growth, making supersaturation important in crystallization processes.

$$\Delta C = C - C^* \quad (17)$$

## Nucleation rate (B0)

Nucleation refers to the formation of stable crystal embryos from a supersaturated solution, marking the onset of a new solid phase. In this work, the nucleation rate of $Li_2O_2$ is modeled using classical nucleation theory [20]. For disk-shaped nuclei, the free energy of formation is evaluated by considering a critical nucleus size that ensures thermodynamic stability and sustained growth (Equation 18) [9]. The corresponding surface energy (γ) is estimated using the correlation given in Equation 19 [19]. On this basis, the nucleation rate expression (Equation 20) is formulated as a function of the Zeldovich factor (Equation 21), the diffusion coefficient of $Li_2O_2$ in the electrolyte (Equation 25), and the density of active nucleation sites (x0) The parameter x0 must be estimated for the system and represents one of the principal sources of uncertainty in the model. Accordingly, its influence on the predicted crystallization behavior is examined in detail in the previous work [13].

$$G_{crit} = \frac{\gamma^2 a^4}{2k_b T \ln(dC/C^*)} \quad (18)$$

$$\gamma = 0.414\, k_b T \ln(dC/C^*)\left(\frac{dC * Na}{MM_{Li_2O_2}}\right)^{2/3} \quad (19)$$

$$B_0 = D_l a_D^{-2} Z x_0 \exp\left(\frac{-G_{crit}}{k_b T}\right) \quad (20)$$

$$Z = \frac{[G_{crit}/(3\pi k_b T)]^{0.5}}{n_{crit}} \quad (21)$$

## Growth rate (G)

The crystal growth rate, G, is defined as the temporal rate of change of the characteristic crystal length, dL/dt and is evaluated using the expression given in Equation 22. To account for the interplay between electrochemical reaction kinetics and mass transport limitations, an effectiveness factor for $Li_2O_2$ growth, ηr, is introduced and calculated according to Equation 23. This factor quantifies the relative contributions of reaction-controlled and diffusion-controlled growth regimes. Low values of effectiveness indicate dominance of the electrochemical reaction rate constant ($k_c$), whereas values approaching unity signify growth primarily limited by mass transfer, characterized by the mass transfer coefficient (kd). The coefficient kd is determined using Equation 24, as described in the literature [21-22]. The parameter θ represents the ratio of the operating current density to the limiting current density, with the latter corresponding to conditions under which reactant depletion in the electrolyte or membrane induces concentration polarization and constrains mass transport [23]. Finally, the diffusivity of disk-shaped $Li_2O_2$ crystals, $D_l$, is calculated using Equation 25 [24], which is derived from the linear regime observed in the early-time response of the curve obtained from intermittent potentiostatic titration experiments. The constant ksl corresponds to the slope of this linear relationship.

$$G = \frac{k_a k_c MM}{3\rho_c k_V}\eta_r(\Delta C)^{j_l} \quad (22)$$

$$\eta_r = \frac{1}{\frac{k_c}{k_d}(\Delta C) + 1} \quad (23)$$

$$k_d = \frac{I_c K_R RT}{8F^3(C_{Li_2O_2}/MM)^2 D_l\, \theta\, ae\, esp} \quad (24)$$

$$D_l = \left(\frac{\pi}{36}\right)\left(\frac{k_{sl}\, L}{Q}\right)^2 \quad (25)$$

## COMPUTATIONAL IMPLEMENTATION

The computational implementation of the proposed modeling framework follows the information flow illustrated in Figure 1, integrating all key components required to describe crystallization phenomena in battery systems. The system of ordinary differential equations resulting from the discretized population balance formulation was solved using the *solve_ivp* routine from the SciPy library, employing the implicit multistep Backward Differentiation Formula (BDF) method. This solver was selected for its robustness and numerical stability when handling stiff systems arising from the strong coupling between crystallization kinetics and electrochemical processes.

The discretization of the particle size domain required by the method of classes is inherently system-dependent and must be defined according to the characteristic crystal sizes, growth kinetics, and operating conditions of the electrochemical system under investigation. Both the extent of the size domain and the class width should therefore be chosen to adequately resolve the evolution of the crystal size distribution. In the present implementation, and consistent with the methodology established in the authors' previous work, the size domain was discretized using a uniformly spaced mesh spanning from 0 to 10 μm, with a class width of 0.05 μm. This discretization was shown to be appropriate for capturing the order of magnitude and temporal evolution of $Li_2O_2$ crystal growth during battery discharge. A uniform mesh was adopted because the population dynamics are governed exclusively by continuous nucleation and growth processes, with no contribution from discrete birth or death events.

The integral terms appearing in the mass and energy balance equations were evaluated using the *integrate.quad* function from the SciPy library, ensuring accurate numerical integration over the discretized size domain. Following implementation, the model outputs were systematically compared against selected response variables to verify numerical consistency and proper coupling among the governing equations, thereby validating the computational methodology employed in this study.

## CONCLUSION

In this work, a population balance–based modeling framework was developed to describe the crystallization occurring during the discharge of Li–$O_2$ batteries. To enable an adequate formulation, several simplifying assumptions were adopted, which limit the quantitative accuracy of the model and its ability to capture highly complex operating scenarios, such as variable discharge currents, electrolyte compositions, or detailed electrode architectures. A key strength of the proposed approach lies in its ability to naturally account for crystal size distributions and morphological effects while maintaining a relatively low computational cost. By bridging microscopic crystallization mechanisms with macroscopic battery performance indicators, the framework provides physically meaningful insights without requiring excessively complex formulations. As such, it offers an accessible and flexible modeling platform for investigating crystallization-driven limitations in metal–air batteries. This study represents a step toward the systematic application of population balance modeling to Li–$O_2$ batteries, with a particular emphasis on formalizing and clarifying the

governing equations and numerical implementation. Future work may extend the present framework by incorporating additional mechanisms, such as side reactions, electrolyte-dependent effects, dynamic operating conditions, and alternative electrode designs. These developments would further enhance the predictive capability.

## Symbology

$a_e$ = interfacial area.
$a_D$ = length scale of liquid $Li_2O_2$.
$A_C$ = surface area of the crystals.
$A_T$ = thermal exchange area.
$B_0$ (t)= nucleation function.
$c_p$ = specific heat.
C = concentration.
C* = equilibrium saturation concentration
ΔC = supersaturation.
$D_l$= diffusivity constant of crystals.
esp = electrode thickness.
F = Faraday constant.
$G^{crit}$ = critical formation energy of crystal nuclei.
G(L, t) = crystal growth function.
$h_\xi$ = jump function (discrete events).
$H_c$ = heat of formation.
$I_c$ = current applied to the system.
$j_c$ = interfacial transfer current density.
$j_l$ = kinetic order of the growth law.
$k_a$ = constant to obtain the crystal surface area.
$k_{ano}$ = anodic kinetic constant.
$k_b$ = Boltzmann constant.
$k_c$ = cathodic kinetic constant.
$k_d$= mass transfer coefficient.
$k_{sl}$= diffusivity constant of the Li2O2 crystal.
$k_v$= constant to obtain the volume of the crystal.
$K_r$ = electrolyte conductivity.
L = characteristic length.
MM = molar mass.
n = number of electrons in the reaction.
$n_{crit}$ = critical nucleus size.
N = total number density.
$N_A$ = Avogadro's number.
Q = battery capacity.
rel= electrode radius.
R = universal gas constant.
t = discharge time.
T = temperature.
U = overall heat transfer coefficient.
$U_o$ = crystals velocity.
$x_0$ = nucleation site density.
$V_c$= volume of the crystals.
$V_{susp}$= effective volume of the system.
Z = Zeldovish factor.
ξ = internal coordinate vector of the PB.
ε = electrode porosity.
$\rho_c$ = specific mass of Li2O2 crystals.
$\rho_e$= specific mass of the electrolyte.
$\eta_r$= effectiveness factor.
$\eta_c$= overpotential.
γ= surface energy.
θ = ratio of current density to limiting current density.

## ABSTRACT

The growing global energy demand and the need to reduce dependence on fossil fuels have intensified efforts toward developing renewable alternatives. Among these, biodiesel and ethanol emerged as viable and sustainable fuel sources. In this context, the use of palm oil and ethanol as raw materials represents a promising production route, due to their availability, high productivity per unit of cultivated area, and renewable characteristics. However, ethanolic transesterification still faces challenges, such as lower productivity compared to methanolic processes and higher energy consumption due to reaction characteristics that impact the whole process. Bearing this in mind, this work aims to develop process simulations in Aspen Plus to optimize biodiesel production from palm oil and ethanol, coupled with an energy integration analysis. The process was divided into three main stages: (i) feed preparation, (ii) transesterification reaction, and (iii) separation and purification of biodiesel and glycerin. The key operational parameters evaluated were temperature, pressure, and ethanol:palm oil molar ratio, important factors to ensure reaction efficiency and biodiesel quality. Additionally, energy integration was performed using the Pinch Analysis method, which enabled the identification of major energy demands and potential opportunities for process improvement. Overall, the proposed simulation framework contributes to enhancing the competitiveness of biodiesel production through ethanolysis, reinforcing its role as a sustainable and viable alternative within the global energy mix.

## INTRODUCTION

Energy is essential in modern lifestyles and global demand has increased rapidly due to rising consumption. At present, fossil fuels such as petroleum, diesel, coal, and natural gas are widely used for power generation and mechanical energy [1]. However, the growing reliance on fossil fuels is a major concern because of their finite availability and significant environmental impacts [2]. Non-renewable energy sources dominate the global energy mix, and their combustion releases large quantities of greenhouse gases, including carbon dioxide and methane [3]. In addition, fossil fuel extraction and transportation often cause substantial environmental damage, such as habitat degradation, oil spills, and water pollution [4].

Biofuels have emerged as promising and sustainable alternatives that are derived from organic materials (plant biomass and agricultural residues) [2]. Among them, bioethanol and biodiesel show strong potential for integration into the global energy system [5]. Driven by rising oil prices and growing concerns over climate change, research into renewable biofuel technologies has intensified. Biofuels can reduce net carbon dioxide emissions because it is partially offset by the carbon dioxide absorbed by plants during growth, forming a near-closed carbon cycle. In addition to environmental benefits, biofuels reduce dependence on imported fossil fuels, enhance energy security, and create new opportunities for agricultural development and rural economic growth [6].

Palm oil and ethanol are promising biofuel feedstocks due to their high availability, renewable nature, and strong potential for sustainable large-scale energy production. Biodiesel, produced as monoalkyl esters from

vegetable oils or animal fats through transesterification with alcohol in the presence of a catalyst, can substitute conventional diesel fuels. The suitability of vegetable oil feedstocks for biodiesel production depends on regional soil and climatic conditions, with palm oil standing out for its high yields and efficiency [7]. Consequently, the palm oil sector supports food and biomass demands while ensuring economic decarbonization [8]. Ethanol is one of the most established and scalable biofuels globally, benefiting from mature production technologies [1]. Furthermore, the utilization of palm oil residues and ethanol-based pathways enhances sustainability by converting agricultural and processing wastes into biofuels, thereby improving resource efficiency and reducing environ–mental impacts.

Despite the advantages of ethanol as a renewable and less toxic alcohol derived from biomass, its application in biodiesel production remains technically challenging. Comparative studies indicate that ethanolic transesterification achieves lower conversions than methanolic routes, requiring higher reaction temperatures, longer reaction times, and higher alcohol-to-oil molar ratio [9-10]. These process characteristics increase overall energy consumption and reduce productivity, largely due to ethanol's higher polarity, steric hindrance, and reduced catalyst activity [11].

Therefore, this study focuses on the development of detailed process simulations using Aspen Plus to evaluate and optimize biodiesel production from palm oil via ethanolic transesterification, alongside a comprehensive energy integration analysis. The same framework is applied to the methanolic transesterification to compare the more sustainable process to a conventional one. Thereby, this work improves the technical feasibility of ethanol-based biodiesel production by systematically assessing process performance and energy efficiency, strengthening its potential as a sustainable and competitive fuel option.

## PROCESS DESCRIPTION

This work models two biodiesel production routes in Aspen Plus V14, based on palm oil transesterification using sodium hydroxide as catalyst with short-chain alcohols: methanolysis and ethanolysis. In both cases, the plant was simulated with a production capacity of 1000 kg/h of biodiesel. The flowsheets were constructed to enable a consistent comparison of reaction performance, alcohol recovery, separation requirements, and energy demand. Both routes follow the same process structure, feed basis, and product specifications, with changes limited to the alcohol identity and dosage and the downstream separation steps required for alcohol recycling and product purification. Figure 1 shows the flowsheet of the biodiesel plant. The palm oil feed was represented using the triglyceride composition listed in Table 1. Phase equilibria and activity coefficients were calculated using the NRTL property method.

**Table 1:** Palm oil composition used to define the feed stream.

| Fatty Acid | Palm Oil |
|---|---|
| Dyglyceride | 5.20. |
| Triglyceride | 94.80 |
| Triunsaturated | |
| OOO | 4.40 |
| OOL | 0.58 |
| Total | 4.98 |
| Monosaturated | |
| PLO | 9.68 |
| POO | 23.26 |
| OOS | 2.24 |
| Total | 35.18 |
| Disaturated | |
| MPL | 2.20 |
| PPL | 9.23 |
| PPO | 29.62 |
| POS | 4.90 |
| Total | 45.95 |
| Trisaturated | |
| MMM | 0.42 |
| MMP | 1.70 |
| PPP | 5.51 |
| PPS | 1.06 |
| Total | 8.69 |

The selected alcohol (methanol or ethanol) and palm oil feeds were combined and sent to a transesterification reactor operating with an alcohol-to-palm oil molar ratio of 6:1 and 1% NaOH catalyst (based on the oil feed) [12]. In the reactor, triglycerides were converted to fatty acid alkyl esters (FAAE) as the main product, namely FAME (fatty acid ethyl ester) in the methanolysis route and FAEE in the ethanolysis route, with glycerol formed as the byproduct. The transesterification reactor was modeled in Aspen Plus as a continuous stirred-tank reactor (CSTR). The reaction system and kinetic parameters were taken from Narváez et al. (2015) [13] and applied to both alcohols in the comparative assessment.

Conversion was calculated using Eq. (1), defined as the ratio of fatty acid alkyl esters (FAAE) to three times the initial triacylglyceride (TAG) amount on a molar basis. For ethanolysis, FAAE corresponds to FAEE, whereas for methanolysis it corresponds to FAME.

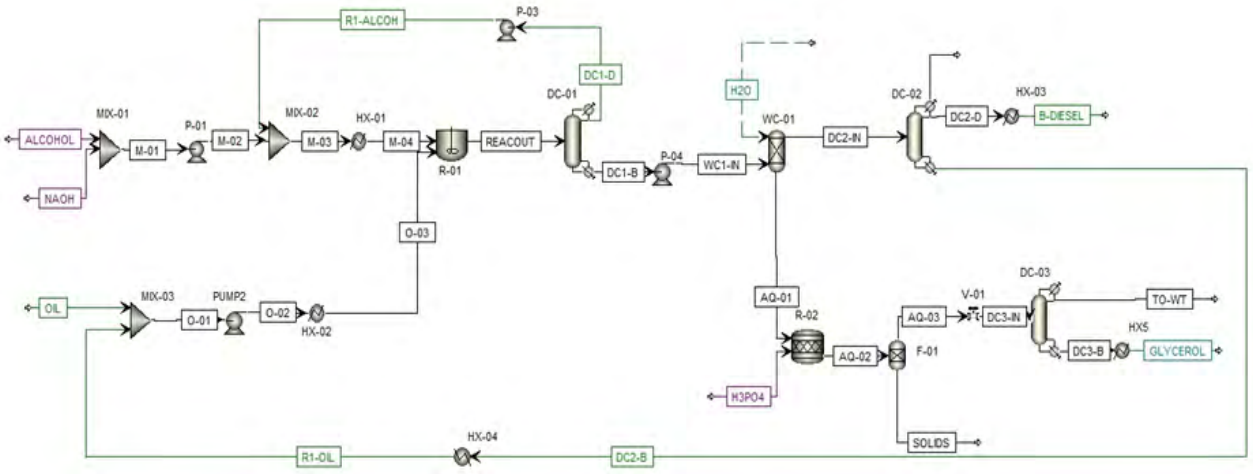

**Figure 1.** Process flowsheet used to evaluate methanolic and ethanolic transesterification routes for biodiesel production

$$Conversion\ (\%) = \frac{FAAE}{(3 * TAG)} . 100 \quad 1)$$

The reactor effluent was then sent to the first separation unit, a distillation column (DC-01), which was specified to recover unreacted alcohol in the destilled stream. The alcohol-rich distillate was recycled to the reactor. The bottom stream from DC-01 was routed to the washing column (WC-01), where water was used as the washing medium to promote phase splitting into an aqueous phase and an organic phase. The aqueous phase was withdrawn as the bottom product and contained residual alcohol, NaOH, produced glycerol, and residual water. The organic phase was removed as the top stream, consisting mainly of biodiesel (FAAE) and unreacted glycerides (tri-, di-, and monoglycerides), and was sent to the subsequent separation column (DC-02). DC-02 was simulated for the purpose of purifying biodiesel in the distillate stream. The bottom stream, rich in unreacted glycerydes, was then recycled to the reactor.

The aqueous bottom stream from WC-01 was directed to a neutralization step to remove the homogeneous catalyst. Neutralization was modeled as a stoichiometric reactor (RSTOIC) considering the reaction between NaOH and phosphoric acid 20% w/w ($H_3PO_4$), producing inorganic salts. These solids were removed in a filtration unit (FILTER). The clarified aqueous phase was then fed to a distillation column for glycerol purification. Detailed operating specifications and performance indicators for each unit are reported in the Results and Discussion section.

## RESULTS AND DISCUSSION

### Process Results

This section compares the methanolysis and ethanolysis routes by adopting an excess-alcohol strategy as the starting point and then examining how the alcohol identity affects reaction performance, separation behavior, and overall process requirements. In addition to biodiesel formation, particular attention is given to the remaining unreacted glycerides in each route, since their accumulation directly reflects incomplete conversion and losses of valuable feedstock. The mass of unreacted glycerides is therefore quantified and discussed along with the role of recycling these streams back to the reactor, which increases overall feed utilization and supports higher biodiesel yields at the plant level. All stream data for the methanol and ethanol routes will be presented in an Excel spreadsheet, which will be made available as supplementary material.

A biodiesel production rate of 1000 kg/h was imposed as a design basis. Aspen Plus Design Spec was used to calculate the required fresh feeds of palm oil and pure alcohol so that, after mixing with the recycle streams, the overall alcohol-to-palm oil molar ratio entering the reactor remained at 6:1. In the methanolysis route, the reactor was operated at 50 °C with a residence time of 80 min [14], achieving a conversion of 96.35%. In the ethanolysis route, the reactor was operated at 70 °C with a residence time of 60 min [13], achieving a conversion of 96.42%.

The distillation columns were designed using a sequential modeling strategy in Aspen Plus. A shortcut model (DSTWU) was first employed to establish an initial design and provide starting estimates for key variables. The columns were then implemented in a rigorous framework using RadFrac, and separation targets were met through the Design Spec tool. Next, a sensitivity analysis was performed to identify the number of stages and the feed stage for each column, aiming to minimize reboiler

energy consumption while maintaining the required separation performance. Finally, hydraulic checks were carried out and column hydraulics were adjusted as needed to ensure that all stages operated within acceptable ranges. Table 2 and 3 summarizes the main design and operating parameters adopted for the distillation columns in the simulated flowsheets.

**Table 2:** Distillation column specifications used in the Aspen Plus V14 simulations for the methanolysis route.

| | DC-01 | DC-02 | DC-03 |
|---|---|---|---|
| Purpose | Alcohol recovery | Biodiesel purification | Glycerol purification |

| Feed stage | 2 | 2 | 2 |
| Reflux ratio (molar) | 2.00 | 1.70 | 2.00 |
| D:F (molar) | 0.38 | 0.98 | 0.82 |
| Operating Pressure (bar) | 0.20 | 0.10 | 0.10 |

**Table 3:** Distillation column specifications used in the Aspen Plus V14 simulations for the ethanolysis route.

| | DC-01 | DC-02 | DC-03 |
|---|---|---|---|
| Purpose | Alcohol recovery | Biodiesel purification | Glycerol purification |
| Number of stages | 23 | 20 | 5 |
| Feed stage | 2 | 2 | 2 |
| Reflux ratio (molar) | 2.53 | 0.38 | 2.00 |
| D:F (molar) | 0.44 | 0.96 | 0.92 |
| Operating Pressure (bar) | 0.20 | 0.10 | 0.10 |

The table reports, for each column, the molar reflux ratio, the distillate-to-feed ratio, the total number of equilibrium stages, and the feed stage location. These parameters are used to describe the separation strategy applied in each column and to support the comparison of column configurations between the methanolysis and ethanolysis routes. DC-01 specifications indicate that alcohol recovery is the main separation step distinguishing the two routes. Ethanolysis required a markedly higher column complexity, with 23 stages and a molar reflux ratio of 2.53, whereas methanolysis achieved the same task with 10 stages and a reflux ratio of 2.00, at the same operating pressure (0.20 bar). This higher separation effort is consistent with the ethanol–water azeotropic constraint in the presence of water, which limits alcohol dehydration by conventional distillation and increases the reflux and staging needed to meet recycle requirements. As a direct consequence, the ethanolysis configuration is expected to demand higher condenser and reboiler loads due to increased internal vapor and liquid traffic, which is reflected in the overall utility consumption of the separation section.

The bottom stream from the DC-01 distillation column was pumped to the washing column (WC-01). WC-01 was specified using an Aspen Plus Design Spec to determine the required water flow rate such that 90% of the residual alcohol was recovered in the aqueous phase withdrawn as the bottom product. The top stream from WC-01 was sent to DC-02, which was modeled with a partial condenser to achieve a biodiesel distillate with a molar purity of 99%. Notably, DC-02 adopted different stage and reflux configurations in the two routes, reflecting distinct separation strategies. The purified biodiesel was then cooled to 35 °C prior to storage and packaging.

In methanolysis, biodiesel purification was achieved with fewer stages (11) but a higher molar reflux ratio (1.70), whereas ethanolysis required more stages (20) but operated at a much lower reflux ratio (0.38). This contrast indicates a trade-off between column complexity and internal reflux demand: increasing the number of stages tends to reduce the reflux needed to meet a given distillate purity, but it increases column height and, consequently, capital requirements. Conversely, operating with fewer stages can be compensated by higher reflux, which increases internal vapor and liquid traffic and typically raises condenser and reboiler duties, increasing operating costs. These route-dependent designs suggest that the alcohol identity, along with the associated phase behavior in the separation section, shifts the balance between capital-lean and energy-lean configurations for achieving the same biodiesel specification.

The bottom stream from WC-01 was sent to the neutralization reactor. The required $H_3PO_4$ feed rate was calculated using the Aspen Plus calculator tool based on the NaOH molar flow rate in the WC-01 bottom stream, ensuring stoichiometric neutralization of the dissolved catalyst. Neutralization produces sodium phosphate salts, which were removed in a filtration unit prior to sending the clarified stream to the glycerol purification section. The resulting aqueous stream was then processed in DC-03 to concentrate and purify glycerol, completing the liquid-phase treatment train associated with catalyst removal and byproduct recovery. In contrast to DC-01 and DC-02, glycerol purification exhibited similar column requirements in both routes, indicating that the main process differences are concentrated in the alcohol recovery and biodiesel purification steps rather than in the final glycerol finishing section. With the separation tasks defined, the next section evaluates how these route-dependent column configurations translate into utility consumption and opportunities for heat integration.

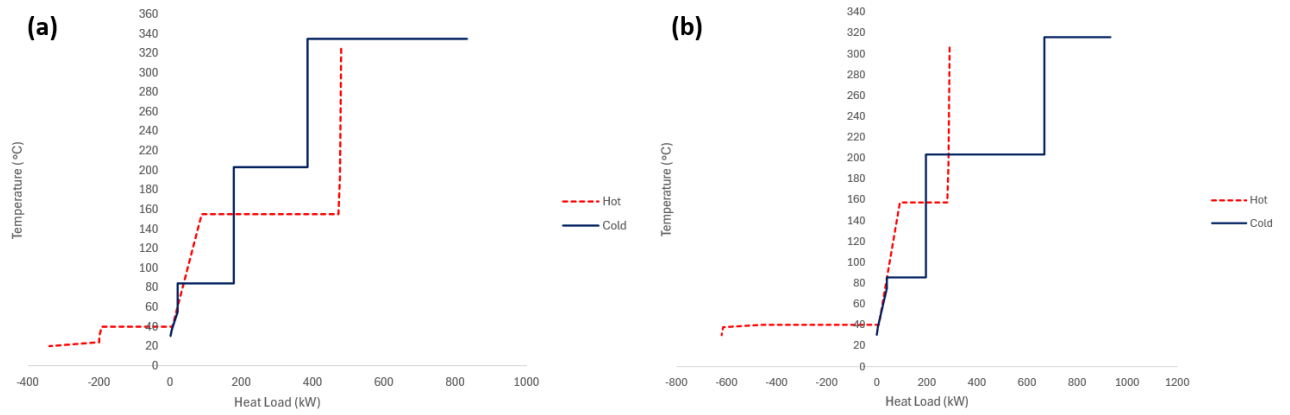

**Figure 2.** Composite curves for both evaluated scenarios. (a): methanolic route; (b): ethanolic route.

## Energy Integration

Heat integration was evaluated in both scenarios (using methanol and ethanol) to investigate whether the choice of the primary alcohol in the transesterification reaction could provide energetic advantages. By applying the concepts of the pinch analysis, it is possible to identify opportunities for heat recovery and utilization between hot and cold utilities while respecting thermodynamic limits. A $\Delta T_{min}$ = 10 °C was adopted for initial insights. Focus was given to the existing heat exchangers and distillation columns, the main energy consumers in continuous biodiesel plants [15]. Also, it is assumed that there are no restrictions in energy exchange among all process streams.

Overall, the outcomes were similar in both cases. The pinch temperatures were determined as being 36.5 °C and 38.2 °C for the methanol and ethanol scenarios, respectively. It means that it is likely to have a similar profile in the heat cascade between them. Also, such low values of pinch temperatures indicate that the energy bottleneck occurs near the cold end of the process; in other words, the process is well integrated as the temperature intervals and heat capacities are similar throughout the process. In the methanol case, it was calculated a total heat recovery of 819 kW which comprehends the totality of the availability of the hot utilities; the same happens in the ethanol case, where the total heat recovery is 910.9 kW – the totality of the hot utilities of this specific case (Figure 2). The high energy consumption of the conventional biodiesel production and pinch points are similar to the findings in Plesu et al. (2015) [16].

As can also be observed, the ethanolic route has a higher energy demand. That's mainly because of two key factors: 1) the ethanol flow rate and molar proportion ethanol:oil in the feed stream is higher compared to the methanol; 2) the optimal temperature of the transesterification step for the ethanolic route was determined as 70 °C, which is 40% compared to the methanolic approach and thus promoting a slightly increase in utility demand.

## CONCLUSION

This work developed a computational framework to simulate and compare methanolic and ethanolic biodiesel production routes from palm oil, with integrated energy analysis. Both routes achieved similarly high conversions (≈96%), indicating that ethanolysis is technically comparable to the conventional methanolysis process. The main differences between the routes were found in the separation section, particularly in alcohol recovery and biodiesel purification. While the ethanolic route required more energy input due to the challenging ethanol–water separation, these differences were subtle overall. The pinch analysis revealed similar thermal profiles, with effective utilization of available heat in each scenario.

These results indicate that the technical gap between methanolic and ethanolic biodiesel production is narrower than expected. Consequently, targeted improvements in separation design, alcohol recovery strategies, and process intensification will enhance the technical feasibility of ethanolysis. Given the renewable nature of ethanol, further investigation of the ethanolic route is essential to advance biodiesel production toward more sustainable configurations.

## DIGITAL SUPPLEMENTARY MATERIAL

A spreadsheet containing the complete stream data for both the methanolic and ethanolic routes is provided as digital supplementary material and is accessible via hyperlink, as referenced in the Results and Discussion section: Stream data for the methanolic and ethanolic transesterification routes

## ABSTRACT

The pharmaceutical sector is essential for ensuring universal access to medicines, demanding efficient supply chains that deliver drugs at optimal prices with minimal delays and shortages. Pharmaceutical supply chains (PSCs) face significant challenges, including strict quality controls, government regulations, drug perishability, high R&D costs, and complex transportation requirements. The sector is undergoing a shift, driven by the rise of pharmaceutical components in emerging markets, unpredictable demand, and reduced R&D investments by major companies, which struggle to compete with generic pharmaceutical brands. Post-pandemic challenges and geopolitical risks have further exposed vulnerabilities in PSCs, leading to frequent supply disruptions, product shortages, and unreliable transportation. The increasing focus on regionalization highlights the need for more resilient supply chains to manage disruptions effectively. PSCs must incorporate robustness to address uncertainties and disruptions, which can be internal, such as operational, financial, and quality risks, or external, including supply, demand, and environmental uncertainties. While recent research emphasizes the importance of integrating these uncertainties into decision-making tools, the field still lacks comprehensive solutions for PSC optimization. Previous studies have used heuristic and metaheuristic algorithms to address individual uncertainties and disruptions, providing feasible solutions with lower computational effort. However, a more holistic approach is required. This work introduces a new tool based on a Meta-heuristic algorithm, which evaluates the robustness of PSCs under multiple uncertainties and disruptions. The tool enables the development of what-if scenarios, helping decision-makers improve supply chain robustness and adaptability in the face of several risks

## INTRODUCTION

An essential role of pharmaceuticals is to provide stability and sustainability to any healthcare system, being one of the key areas of a country's economy. Ensuring demand satisfaction for pharmaceutical products and having a perfect service level with acceptable costs is crucial for every country. In top of that, pharmaceutical drugs gather special characteristics, like extensive and complex production processes, product perishability, intensive investment in R&D activities, and stringent transportation conditions that only create harder conditions for companies to achieve the desired service level.

For this reason, pharmaceutical supply chains (PSCs) need to guarantee a ceaseless flow of products throughout all stages and respond quickly and efficiently to possible changes and disruptions. Over the years, they became more complex, globalized, and subject to more strict safety procedures, quality controls, and regulations from governments and insurers. It is imperial to develop strategies that account for all these factors when managing and designing a network.

Furthermore, a good balance between all the factors and trade-offs affecting the performance of the PSC is

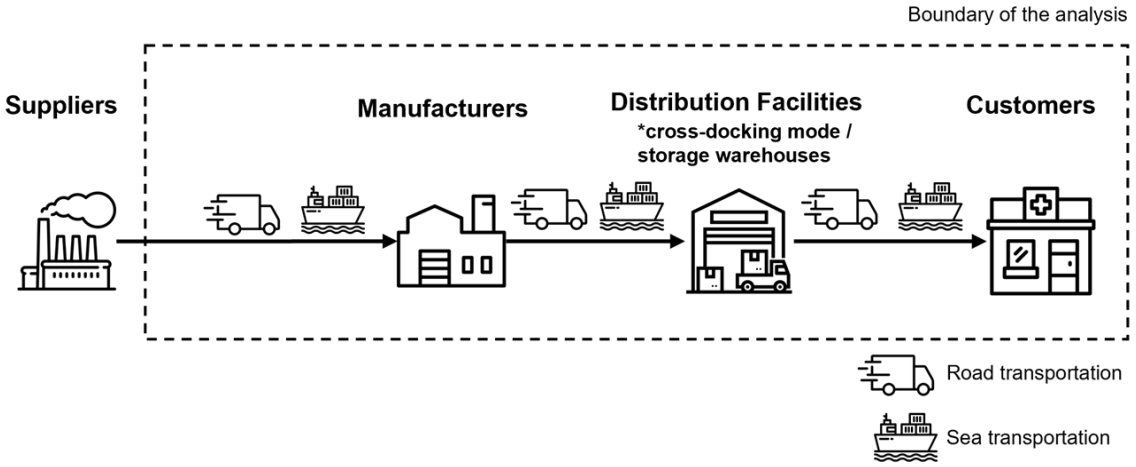

**Figure 1**. Pharmaceutical supply chain

essential, from resource allocation to inventory management and the location of entities.

Nowadays, the pharmaceutical sector is under a paradigm shift. The growing of pharmaceutical components in emerging countries and the unpredictability of markets is creating an additional layer for companies to account for and exposes them to more vulnerabilities. Moreover, the decrease of new pharmaceutical drugs by research-based companies due to reductions in R&D investment, price pressures, and the shortening of patent lives is making it difficult for these companies to maintain their performance and compete with generic pharmaceutical enterprises [1]. Drug shortages are also increasing due to supply, demand, and regulatory issues, which are also affecting the price and the production of its main components [2]. More recently, the impacts of the COVID-19 pandemic also affected this sector, as the world's main suppliers restricted production to domestic, and started to move to self-sufficiency and decentralized models [3].

All these challenges have a high degree of uncertainty associated with them, making the task of designing and operating an effective and responsive supply chain even more difficult.

While deterministic models have traditionally provided a baseline for pharmaceutical supply chain (PSC) design, they often fail to capture the inherent volatility of real-world operations, leading to vulnerable networks and ineffective strategies. In contrast, the metaheuristic approach proposed in this work allows for the integration of multiple uncertainties—such as raw material supply and transportation network disruptions—simultaneously. This provides decision-makers with the ability to develop "what-if" scenarios and assess the resistance of specific network entities, identifying a clear need for increased redundancy and decentralization as strategies to thrive under severe uncertainty.

Recent research shows that the field of optimizing PSC network design is still missing focus. The transition toward uncertainty-aware optimization is supported by a growing body of literature that identifies uncertainty quantification as a core requirement for process engineering. [1, 4] highlight that while the pharmaceutical sector has been extensively studied, most research still focuses on inventory models rather than the global optimization of network design under uncertainty.

In the last years, approaches based on Heuristics and Metaheuristics algorithms have been applied, since they allow the discovery of a good feasible solution with less computational effort than exact methods. Operational risks and their inherent uncertainties, encountered in customer demand, costs, and the capacity of facilities have been addressed in a large scale by the literature [5, 6, 7]. Particularly, [6, 7] have demonstrated the efficiency of hybrid metaheuristics in solving multi-objective PSC problems, proving that non-exact approaches can provide high-quality solutions for NP-hard network configurations. Furthermore, [8] emphasizes how deterministic models significantly underestimate risks in post-pandemic landscapes. Additionally, some authors have also been able to quantify the resilience of a network and model the effect of disruptions on production [4] and suppliers [9]. On top of that, disruptions in the transportation network were studied by Roshan [10], that developed a model for re-routing planning in the event of natural disasters.

By building on these foundations, this work addresses the existing research gap in simultaneous multi-uncertainty assessment through an adaptable Simulated Annealing algorithm. In the last years, approaches based on Heuristics and Metaheuristics algorithms have been applied, since they allow the discovery of a good and feasible solution for complex problems within a lower computational effort.

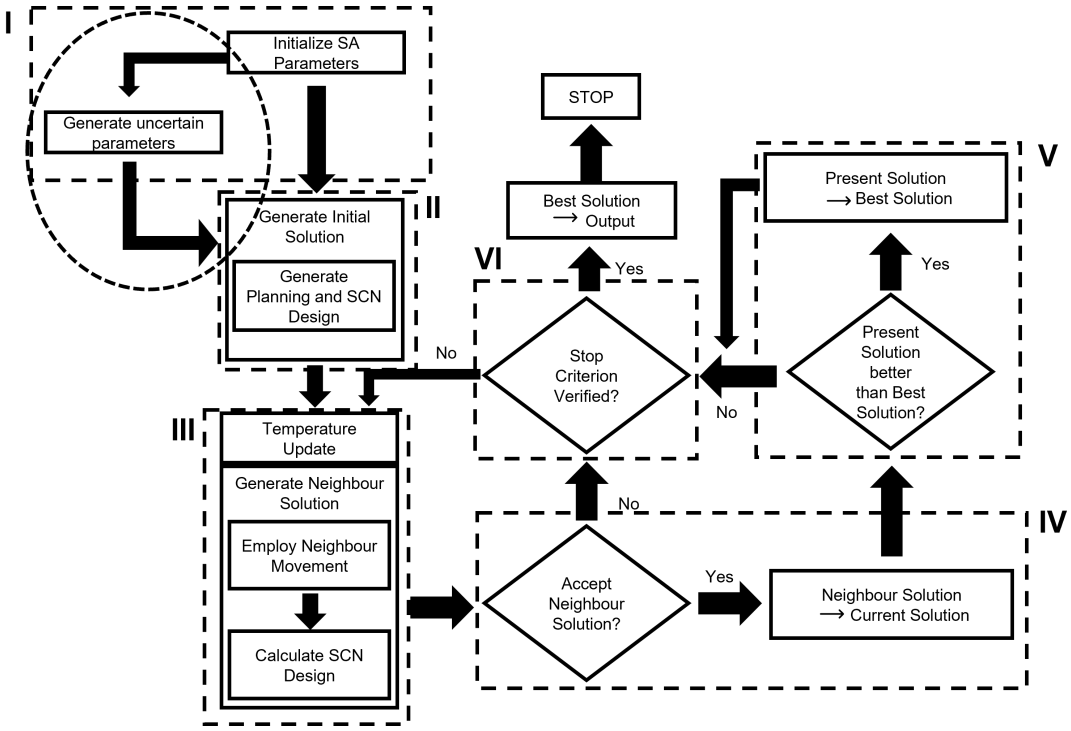

**Figure 2.** SA algorithm under uncertainty

## PROBLEM CHARACTERIZATION

This work characterizes a design and planning of a global pharmaceutical supply chain (PSC) with 4-levels, shown in Figure 1.

The concerned PSC is defined by 4 stages: suppliers, manufacturers, distribution centers (DCs) and markets. Raw materials are delivered to factories by suppliers. After production, the final products are transported to distribution facilities, and from those to markets to satisfy demand. The distribution facilities can operate in a cross-docking mode, or function as typical warehouses and accommodate inventory of final products, that can also exist at the factories. The transportation between different levels is carried out using unimodal transportation, by road, or intermodal transportation, considering road and sea. In the latter, products are first transported from the origin entity to a seaport, where they are transshipped to a ship. Subsequently, they are transported to another seaport and finally to the end destination by road. Each entity has a seaport assigned, that works in a cross-docking mode. Supply, production levels, materials flow across entities and material storage handling are limited between specific bounds. Additionally, uncertainty is considered in some parameters of the problem, namely in production capacity. A possible disruption on the transportation network is also taken into account.

The aim of the problem is to define the PSC design over uncertainty alongside minimizing the total network cost. For that reason, the cost of factories and DCs installation, operational, storage, labor, transportation, and raw material are considered. Transportation costs include variable costs, arising from the distances travelled, contracted (fleet outsourced) and handling costs at the seaports.

From a strategic view, the entities are chosen from a set of potential locations. At a tactical level, the supply and production quantities, in addition to the materials flow within the network are determined.

At the same time, by studying this problem, it is possible to assess the severity of the impact of uncertainty across the multiple levels of the supply chain and understand the degree of robustness of the PSC that results from it.

## METHODOLOGY

The Simulated Annealing (SA) algorithm is extended from its traditional form [11] to consider uncertainties in the design of the pharmaceutical supply chain. The SA algorithm under uncertainty considers 6 main steps, as shown in Fig. 2. The inclusion of uncertainty is defined at Procedure I, circled in dashes.

Procedure I is the key novelty in the algorithm, hence it is the only procedure highlighted and explained in more detail. This procedure is related with the initialization of the algorithm and determination of the parameters tainted with uncertainty. They are computed in the following way:

**Uncertainty Generation Characterization.** For each parameter that can be uncertain or disrupted, generate an arbitrary number $x \in [0,1]$. Considering the disruption ($pd$) or uncertainty probability ($pu$) of each of those parameters:

- If $x < pd/pu$, the parameter changes to a new value.
- If $x \geq pd/pu$, the value of the parameter remains the same.

After those parameters are settled, the algorithm is initiated, and moves to the next procedure, in order to find a compromise solution.

## CASE STUDY

A real case study of a global supply chain from a pharmaceutical company that produces and delivers vaccines all over the world is explored.

The pharmaceutical company in question can install entities across 9 different locations. There are five possible manufacturing sites dedicated to the production of vaccines: U.S (Pennsylvania), Canada (Toronto), Europe (France), Asia (India) and Africa (Kenya). These manufacturers, when installed, receive the required raw materials from a supplier of the same region. Distribution centres can be installed in every location that contains a market, such as U.S (Pennsylvania), Canada (Toronto), Europe (France), Asia (India), Latin America (Brazil), Middle East (Israel), Eurasia (Russia) and Australia. In addition, each of these regions has a seaport that can be used for transportation purposes.

The aim of the case-study unfolds in two ways. 1) to determine which is the network design of the PSC capable of satisfying the total markets' demand with minimum cost, in terms of location, number of entities, and materials allocation. 2) analyse the impact of some uncertainties in the design and its costs, identifying which entities are robust. For that purpose, a baseline scenario and two additional ones are explored considering different types of uncertainty. The scenarios characterization is detailed in Table **1**, followed by the uncertainty or disruption probability associated to each of them, in Table 2.

An exploratory analysis was performed for the algorithm parametrization using: initial temperature ($T_0$), number of iterations at the same temperature (NIST) and cooling rate (α). The best values found were $T_0$ = 7500, NIST = 50 and α = 0.95. As a way of not falling in local minimums with higher network costs, an outer loop was added to the algorithm. For each run, the SA algorithm restarts its process 7 times, returning the solution with minimum costs encountered.

**Table 1:** Scenarios' characterization.

| Scenario | Description |
|---|---|
| **A**: No Uncertainty | All the parameters of the PSC are considered deterministic. |
| **B**: Production Capacity | The maximum production capacity level of each manufacturer can decrease or maintain its original value. |
| **C**: Disruption on the transportation network | Some of the routes used for transportation between factories and DCs, and DCs and markets from the same region can suffer a disruption and become unavailable |

**Table 2:** Scenarios' characterization.

| Scenario | Disruption/ Uncertainty Probability (pd, pu) |
|---|---|
| **A**: No Uncertainty | Baseline |
| **B**: Production Capacity | $pu_{production} = 0.3$ |
| **C**: Disruption on the transportation network | $pd_{transport} = 0.3$ |

## RESULT ANALYSIS

The algorithm was performed 100 times for each scenario, and the solutions were analyzed considering their total network cost, general topology, and main characteristics of the supply chain regarding number, location of entities and possible reasons for the designs. The scenario **A** is deterministic and defined as the baseline. Therefore, all the remaining scenarios are compared with the baseline. The computational time required for an individual run in each of the scenarios addressed is displayed in Table 3.

**Table 3:** Time for each run in all scenarios.

| Scenario | Time for each run (CPU s) |
|---|---|
| **A**: No Uncertainty | 602 |
| **B**: Production Capacity | 802 |
| **C**: Disruption on the transportation network | 750 |

### Scenario A – Baseline - Deterministic

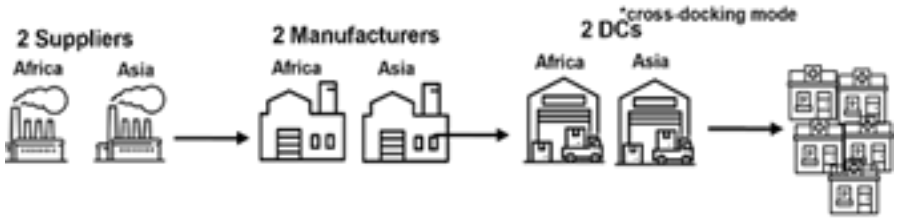

**Figure 3.** Baseline SCP configuration

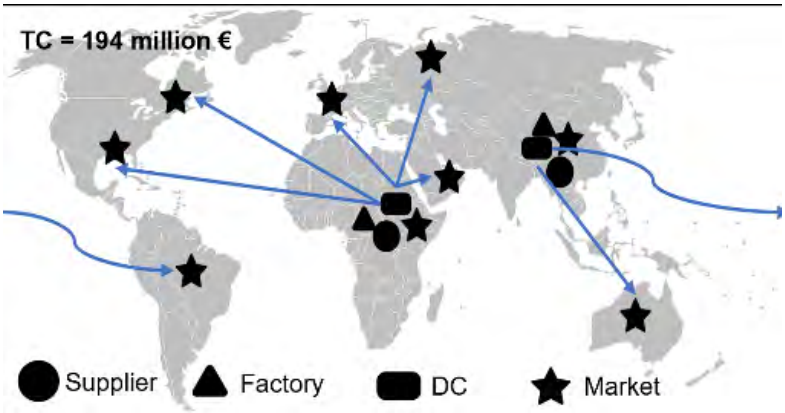

**Figure 4.** – Baseline SCP Locations

The PSC characterization of scenario **A** in terms of network configuration for the minimum cost solution is shown in Figure 3, corresponding to a total cost of 190 million €.

Regarding the network design most of the solutions shared the same overall structure, only differing in a small secondary part of the chain, such in some transfers of small quantities of vaccines between entities. Figure 3 illustrates the common topology for Baseline Scenario's solutions. The PSC is composed by two suppliers, two factories and two DCs functioning in a cross-docking mode, located both in Asia and Africa. Africa is the biggest supplier, producer, and distributor of vaccines, shipping them to its nearest markets, just like Asia, as shown in Figure 4.

These locations are among the ones with the lowest entity and transport related costs, not to mention that Asia is the region with the lowest overall costs. Their central location regarding other markets, and low costs justify the decision for the installation of entities.

## Uncertainty behavior and impact on the PSC total cost and configuration

The results related with the cost, number, location and topology were explored and the most common topologies were characterized.

### Scenario B

As can be seen in Figure 5, Scenario **B** requires an additional factory installed in Europe to satisfy the demand, due to capacity reduction of production in the factories used originally in Scenario **A**. As a result, the European supplier is also included in the PSC. The location for the factory comes from the fact that Europe is the third cheapest region to set up and operate a factory after Asia and Africa. Moreover, the PSC network for this scenario is composed by 6 DCs, resulting in a PSC with more entities. More DCs were necessary apart from the ones in Asia and Africa, for all solutions. The additional DCs were normally installed in Latin America, Middle East, Europe, or/and Eurasia. These results are justified by cheapest labour and seaport usage related costs of these 6 regions. Furthermore, these regions are among those with markets with higher demands. With the additional factory, and DCs the total cost of the PSC increased significantly to 220 million €.

### Scenario C

The comparison with the baseline topology (Figure 3) shows that all solutions from Scenario C had similar topologies to the Baseline. The main difference is the instalation of two additional DCs. Given that Asia and Africa are the dominant regions for the installation of factories and DCs, it is logical that a blockage in one of the unimodal paths of these regions causes a change in the functioning of the chain since part of the vaccines need to be distributed by a different DC. Nevertheless, the solutions from this scenario had the least impact in terms of

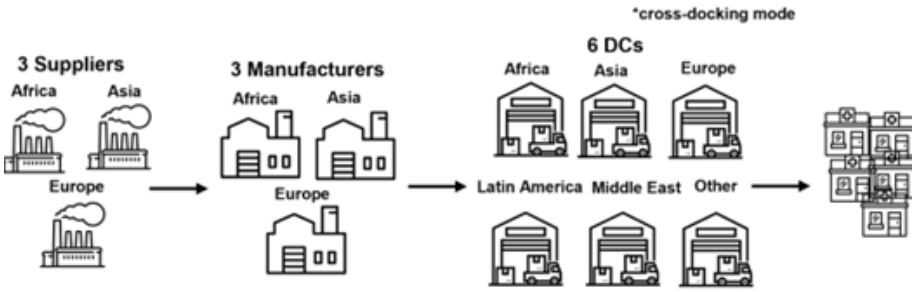

**Figure 5.** - Scenario B PSC configuration

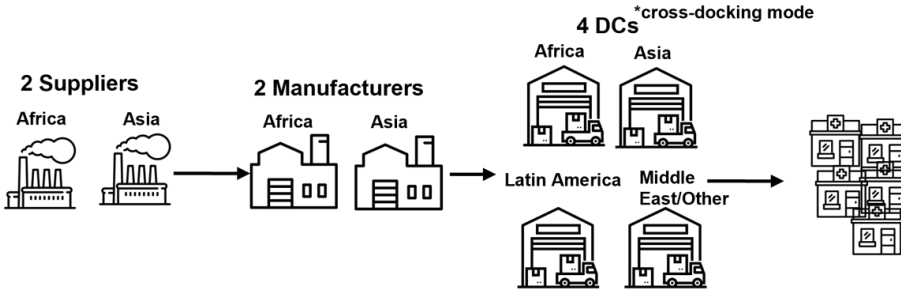

**Figure** 6. – Scenario **C** PSC configuration

costs. The least cost solution was comparable to the Baseline Scenario, implying that the instalation of additional DC higher costs is compensated by the supression of longer transportation and consequently lower transportation costs.

## Some additional considerations

The results demonstrate that, as the severity of the uncertainty increases, costs also increase. However, this was not always the case, for Scenario **C**, indicating that the location where uncertainty is experienced may play an important role in the impact on the chain.

Given that Asia and Africa are the dominant regions for the installation of factories and DCs, it is logical that a decrease in the quantity of vaccines manufactured, or a blockage in one of the unimodal paths of these regions causes a major change in the functioning of the chain, and consequently higher costs, since part of the vaccines need to be produced in a new factory or even distributed by a different DC.

The effect of uncertainty on the PSC topology lead to more decentralized networks, requiring more entities, mainly DCs. This way, they get closer to the markets, with the DCs being able to satisfy their own local markets, instead of having two larger central DCs in Asia and Africa, as in the Baseline Scenario **A**, delivering vaccines to all markets. When comparing all the topologies, it is shown that a part of scenario **A** PSC is able to be robust and withstand both the production capacities uncertainty and the disruption. Asia and Africa continued to be the main regions for the supply and production of vaccines. Even with uncertainty, new entities emerge as common across the analysis, such as the use of a DC in Latin America and/or Middle East. The use of these entities brought additional costs, but a higher agility to the network, in case of uncertainty. Hence, it constitutes a trade-off that should be carefully studied.

# CONCLUSIONS

Throughout this work, a type of uncertainty and disruption with consequences on a global PSC were explored in terms of their impact in the total network costs and its topology, in order to provide information for decision makers to create resilient and informed decisions when faced with uncertain future situations across the pharmaceutical sector.

To achieve this goal, a meta-heuristic (SA) tool able to consider different types of uncertainty and disruption was developed. To compare the severity of the uncertainty and the disruption, the algorithm explored a deterministic scenario (baseline), followed by two additional uncertain scenarios. A case study was provided for that purpose.

The results showed that the SA algorithm was able to address the inclusion of different disturbances on a PSC. It was concluded that uncertainty on the production capacity of manufacturers imposed the biggest impact on network costs, simultaneously with the larger changes on the PSC topology. The entities through which the majority of products were produced and distributed were able to withstand all the disturbances studied, being

considered the most robust. Furthermore, it was also noticeable a tendency for SC decentralization with increasing severity of uncertainty, as more local entities closer to markets tended to be installed.

As future works, deeper development of the algorithm should be made, by testing new rules for the search of the initial and neighbor solutions, in order to provide more efficient and effective solutions. Moreover, more types of uncertainties could be explored. Additional measures to quantify robustness and resilience, flexibility on the supply chain may be also explored in the future. Finally, the proposed problem could aim to incorporate sustainability and social issues, as their association with the economic part of a company is becoming inseparable.

## ABSTRACT

Process modelling is essential to improve carbon capture unit design. However, depending on the modelling decisions made, such as the thermodynamic model and calculation method, the results obtained may vary significantly, hindering reliable process design. Nevertheless, studies that decouple the effects of thermodynamic packages and model approximations on simulation results are not well established. This contribution focuses on clarifying these effects and providing guidelines for the simulation of a $CO_2$ capture process with monoethanolamine (MEA) at different liquid-to-gas (L/G) ratios and $CO_2$ partial pressures in Aspen Plus. The calculations are validated with eight pilot campaign runs. The analysis reveals that the use of rate-based with kinetic reactions significantly improves the accuracy of the simulations. This approach, combined with the ENRTL-RK thermodynamic model, using Peng-Robinson for the vapor phase, provides the best performance, with average deviations below 3% in terms of $CO_2$ capture efficiency and energy requirements. On the other hand, strategies to improve convergence success in closed-loop simulations include replacing a single heat exchanger with two heater blocks, and a calculator block to automate mass-balance calculations and account for losses.

**Keywords**: Climate Change, Carbon Capture Utilization Storage (CCUS), Post Combustion Carbon Capture (PCC), Monoethanolamine (MEA), Aspen Plus Simulation

## INTRODUCTION

The recent thirtieth conference of the parties (COP30) in Belém, Brazil, acknowledged the likelihood of overshooting the 1.5°C set during the Paris Agreement [1]. To limit global warming to 1.5°C requires rapid and deep emissions reductions of greenhouse gas (GHG) emissions such as carbon dioxide ($CO_2$) [2]. One of the key technologies that can curb these emissions, also reported in the Industrial Carbon Management (ICM) by the EU, is Carbon Capture, Utilization and Storage (CCUS) [3]. As the deployment of CCUS accelerates globally, rigorous process modelling becomes central to designing efficient and reliable $CO_2$ capture systems. Among different $CO_2$ capture technologies, the most mature and adaptable system at both pilot and industrial scale is post-combustion capture with monoethanolamine (MEA) [4].

Despite extensive literature on MEA capture systems, the bibliography on this topic remains fragmented and many results differ from one another. The main reason for these discrepancies is related to the choice of thermodynamic models, calculation methods (model complexity) and closed-loop convergence challenges. Most published works omit these details that matter in practice.

To address this gap, we investigate the independent effects and interactions between two different thermodynamic packages and calculation methods and document convergence tactics that enable stable solutions. The novelty of this study lies in the decoupling of thermodynamic models from calculation methods, along with the development of modelling strategies that facilitate convergence.

Specifically, the study compares the new unsymmetric electrolyte NRTL model (ENRTL-RK) for liquid with the Peng–Robinson Equation of State (EOS) for vapor phase, with ENRTL-RK combined with the Perturbed-Chain Statistical Association Fluid Theory (PC-SAFT). Furthermore, different degrees of model complexity,

such as equilibrium-stage, rate-based modelling, and chemical reactions are also revised to check their impact on Key Performance Indicators (KPIs). These KPIs include $CO_2$ capture efficiency (%) and thermal energy requirement (MJ/kg $CO_2$). Flowsheet convergence tips are also described to help in achieving closed-loop simulation convergence success.

The goal is to provide practical guidelines to follow when modelling post-combustion $CO_2$ capture processes using chemical absorption, especially at varying liquid-to-gas (L/G) ratios and $CO_2$ partial pressures.

## PILOT PLANT SPECIFICATIONS

In this work, the pilot plant at the University of Kaiserslautern reported in [5] has been used for the validation of the process model developed in this work. The absorber and stripper column internals and the range of operating conditions are reported in Table 1. One of the parameters analyzed in this pilot plant was the variation in the L/G ratio while maintaining a constant gas flow rate. Two series of experiments were used for comparison: one with a low $CO_2$ partial pressure of 54 mbar (cases A1–A6) and another with a higher $CO_2$ partial pressure of 102 mbar (cases A7–12). In this work, eight of these experiments, covering both low and high $CO_2$ partial pressures and L/G ratios, were validated.

### Key performance indicators

To validate the model using the experimental data from the pilot plant, two KPIs were defined, namely the $CO_2$ capture efficiency ($\eta_{cap}$) and thermal energy requirement ($e_{req}$). The following equations (1 – 3), based on the work of [6] were used to calculate these KPIs.

$$\dot{m}_{CO2,abs} = \dot{m}_{CO2,in} - \dot{m}_{CO2,out} \quad (1)$$

$$\eta_{cap} = \frac{\dot{m}_{CO2,abs}}{\dot{m}_{CO2,in}} \bullet 100 \quad (2)$$

$$e_{req} = \frac{\dot{Q}_{reb}}{\dot{m}_{CO2,abs}} \quad (3)$$

Here, $\dot{m}_{CO2,abs}$ is the absorbed $CO_2$ mass flow, $\dot{m}_{CO2,in}$ and $\dot{m}_{CO2,out}$ are the mass flow rates of $CO_2$ in the flue gas entering and exiting the absorber in kg/h, respectively, and $\dot{Q}_{reb}$ is the reboiler duty in MJ/h.

### Model validation

The deviations between the experimental data and simulations results are given by the relative error ($\varepsilon$) and the percentage average absolute relative deviation ($\%AARD$). Equations (4 – 5) are used to calculate these deviations.

$$\varepsilon = \frac{x_{sim} - x_{exp}}{x_{exp}} \bullet 100 \quad (4)$$

$$\%AARD = \frac{\sum_1^n |\varepsilon|}{n} \quad (5)$$

where, $x_{sim}$ is the simulation result, $x_{exp}$ is the experimental value, and $n$ is the number of data points.

## METHODOLOGY

### Process flowsheet

Aspen Plus v14 was used to build the flowsheet and simulate the MEA-based $CO_2$ capture process as depicted in Figure 1. The flue gas enters the bottom of the absorber while the lean solvent is introduced at the top. After absorption, the solvent is loaded with $CO_2$ and becomes the rich solvent. The rich solvent stream exits from the bottom of the absorber and is pumped through the heater block (half-heat exchanger), to finally enter the stripper, where the process is reversed. Following the stripper, the lean amine stream exits at the bottom and enters the second heater block (which acts as a cooler). This lean amine stream is mixed with the MEA and water makeups which are necessary to account for losses.

In the simulation, it is possible to use a single rigorous heat exchanger (HeatX) model to pre-heat the rich solvent and cool the lean solvent stream. However, for a closed-loop system, this approach creates two nested convergence loops: one for the HeatX block and the second one for the solvent recycle loop. This increases model complexity, making it prone to convergence issues, mostly related to temperature crossovers. To avoid this, two heater blocks connected using a heat stream are used instead of the single HeatX model [7]. In addition, for maintaining overall mass (material) balance, a calculator block is created in order to close the recycle solvent loop. This facilitates the convergence of the recycle stream by ensuring mass balances are accurate through the calculation of the required MEA and $H_2O$ makeup streams.

### Thermodynamic method and reactions

One of the most fundamental aspects to consider during process modelling is the choice of the thermodynamic method. This is because an incorrect decision of the thermodynamic package can lead to erroneous results in the simulation.

In this study, two slightly different thermodynamic methods are compared. The first uses the Electrolyte Non-Random Two-Liquid (ENRTL-RK) property method with the Peng–Robinson (PR) EOS to compute liquid and vapor properties, respectively [8]. This model was recently used by [9] and found to provide good predictions of the experimental data. The second thermodynamic package also uses the ENRTL-RK to calculate liquid phase properties but applies the PC-SAFT EOS for the calculation of the vapor phase fugacity coefficients [10].

For both property methods, the pure and binary parameters have been regressed or validated against available experimental data [8, 10]. Moreover, the following

chemical equilibrium reactions (equations (6 – 10)) were considered.

$$2H_2O \leftrightarrow OH^- + H_3O^+ \quad (6)$$

$$H_2O + HCO_3^- \leftrightarrow CO_3^{2-} + H_3O^+ \quad (7)$$

$$2H_2O + CO_2 \leftrightarrow HCO_3^- + H_3O^+ \quad (8)$$

$$H_2O + MEACOO^- \leftrightarrow MEA + HCO_3^- \quad (9)$$

$$H_2O + MEAH^+ \leftrightarrow MEA + H_3O^+ \quad (10)$$

Equilibrium constants of reactions (6)–(10) for both thermodynamic packages were calculated using the Gibbs free energy change described by equation (11).

$$\ln(K_j) = -\frac{\Delta G^o_{i,j}}{RT} \quad (11)$$

Here, $K_j$ denotes the chemical equilibrium constant, $\Delta G^o_{i,j}$ is the standard free energy of formation of component $i$, $R$ is the universal gas constant, and $T$ is the temperature in Kelvin.

On the other hand, carbamate and hydrolysis reactions are typically expressed as kinetically controlled reactions, given by equations (12 – 13). Kinetic constants for these reactions can be found in [10].

$$MEA + CO_2 + H_2O \rightarrow MEACOO^- + H_3O^+ \quad (12)$$

$$MEACOO^- + H_3O^+ \rightarrow MEA + CO_2 + H_2O \quad (13)$$

## Equilibrium-stage modelling

The Aspen Plus RadFrac block allows two calculation methods: equilibrium and rate-based modelling. Furthermore, in both methods it is possible to consider equilibrium or kinetic reactions in the liquid phase.

In this work, equilibrium-stage modelling was the first approach used, setting the number of stages to 20 for both columns. This approach assumes perfect mixing and does not take into account mass-transfer. Nonetheless, it is recommended as a first step because it facilitates the convergence of the closed-loop simulation, producing initial column estimates (such as temperature and composition) that are useful when moving to the more advanced rate-based modelling. Additionally, for the same equilibrium model, different model complexities regarding reaction information can still be applied, as reported in [11].

The first model used in this paper was the equilibrium-stage with chemical equilibrium reactions (EQ). Then, after successful convergence of the closed-loop simulation, the complexity can be increased to equilibrium-stage using kinetic reactions (EK). Nonetheless, when switching to EK model, data for liquid holdup or liquid residence time is required. In this contribution, the liquid holdup values reported by [12] were used. After successful convergence of the EK model, the columns can then be switched to rate-based modelling to account for mass transfer phenomena.

## Rate-based modelling

In reality, the previous equilibrium-stage assumptions are never satisfied because of the highly non-ideal behavior of $CO_2$ capture systems. To address these limitations, the rate-based model is also tested. The rate-based model accounts for both mass and heat transfer. The mass transfer is explained by the two-film theory (Figure 2), which uses the Maxwell-Stefan approach [13].

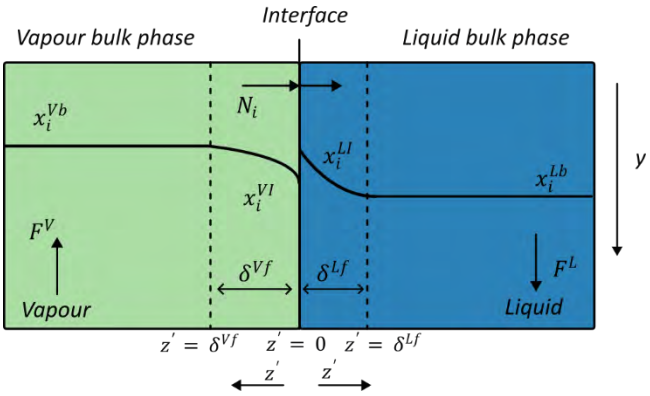

**Figure 2.** Two-film theory (model) for a packing segment adapted from [13].

Similar to equilibrium modelling, rate-based models also accept two approaches to define chemical reactions. The first one is rate-based model with chemical equilibrium reactions (RE), while the second one uses also the rate-based model but with kinetic (RK) and film reactions. This last model is considered the most complex.

In rate-based modelling, the column geometry must be specified for both absorber and stripper. To this end, data presented in Table 1 is utilized to replicate the pilot plant that will be used for validation. On the other hand, Table 2 reports the model parameters used for the rate-based model, which are common for the two thermodynamic models used in this work. For the liquid, vapor mass transfer, and interfacial area factor, the correlation by [14] is used. The heat transfer has been modeled using [15] and the liquid holdup was calculated by [16]. Additionally, the liquid film was discretized into 5 points and the reaction condition factor was set to 0.9 as suggested by [17].

Combining equilibrium-stage and rate-based modelling, along with equilibrium and rate-limiting kinetic reactions, and two thermodynamic packages, a total of eight different calculation models were tested.

**Table 1:** The main pilot plant specifications [5].

| Parameter | Data | Unit |
|---|---|---|
| Flue gas source | Natural gas burner | (-) |
| $CO_2$ concentration in the flue gas | 3–14 | (vol%) |
| Liquid flow rate | 20–350 | (kg/h) |
| Flue gas flow rate | 30–100 | (kg/h) |
| Liquid load in the absorber | 2–28.5 | ($m^3/(m^2h)$) |
| Electrical heat duty of evaporator | 0–30 | (kW) |
| Absorber pressure | Atmospheric pressure | (bar) |
| Stripper pressure | 1.0–2.5 | (bar) |
| | Absorber Geometry | |
| Total height of packing in absorber | 4.25 | (m) |
| Column internal diameter | 0.125 | (m) |
| Type of packing | BX 500 | (-) |
| | Stripper Geometry | |
| Total height of packing in stripper | 2.55 | (m) |
| Column internal diameter | 0.125 | (m) |
| Type of packing | BX 500 | (-) |

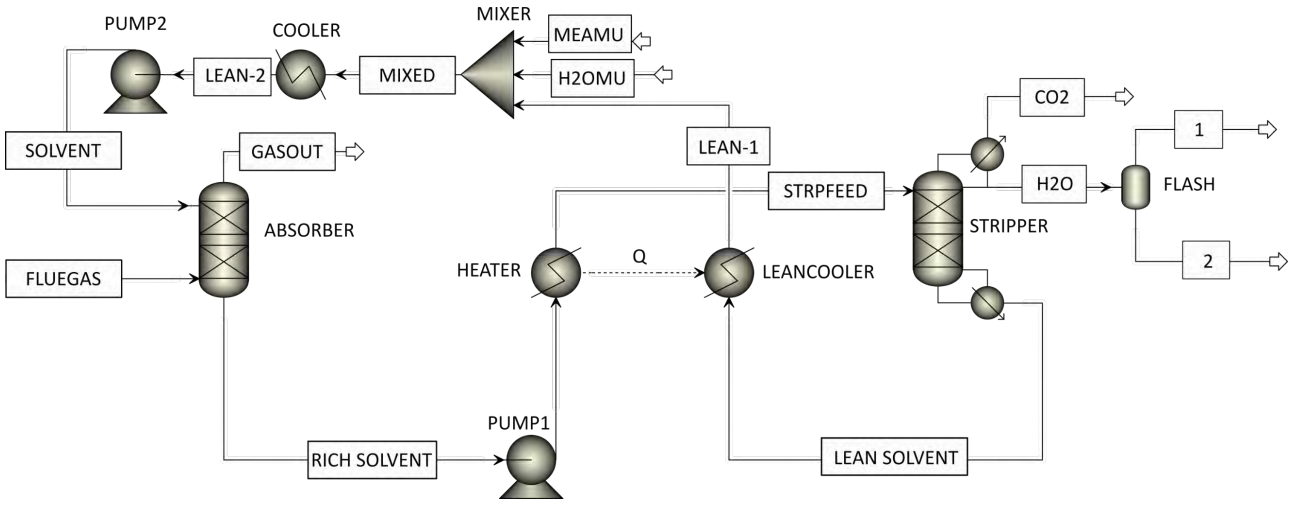

**Figure 1.** Process flowsheet of MEA $CO_2$ capture process.

**Table 2:** Rate-based model parameters used.

| Parameter | Specification |
|---|---|
| Number of segments | 20 |
| Flow model | Mixed |
| Mass transfer coefficient method | Brf-85 |
| Heat transfer coefficient method | Chilton and Colburn |
| Interfacial area method | Brf-85 |
| Interfacial area factor | 1 |
| Liquid holdup correlation | Brf-92 |
| Reaction condition factor | 0.9 |
| Film discretization ratio | 5 |

## RESULTS AND DISCUSSION

### Effect of thermodynamic and model complexity

The process modelling results of the eight runs carried out at the University of Kaiserslautern are evaluated. The $CO_2$ capture efficiency (%) and the thermal energy requirement (MJ/kg $CO_2$) are the two KPIs evaluated and compared for the four different model complexities.

A summary of the %AARD in all KPIs for these models is given in Table 3. Both thermodynamic models predict the KPIs with an AARD of less than 10%. Among the KPIs, the thermal energy requirement is the one that can

be most accurately predicted. Nonetheless, some differences arise regarding the use of different model complexities. Including kinetically-controlled reactions significantly impact the results when using rate-based models. As an example, for the ENRTL-RK with Peng–Robinson, the model predicts the $CO_2$ capture efficiency and thermal energy with an AARD of 9.23% and 7.96%, respectively, when using rate-based model with equilibrium reactions (RE), but improves to 2.46% and 2.84%, respectively, when including kinetic reactions (RK). When using ENRTL-RK with PC-SAFT, the same pattern is noticed, but with minor improvements, especially for thermal energy requirement.

Lastly, the incorporation of mass-transfer kinetics also has a significant influence on the results, particularly when using ENRTL-RK with Peng–Robinson. Switching from equilibrium to rate-based model, when already considering kinetically controlled reactions (i.e., from EK to RK), improves predictions of $CO_2$ capture efficiency from 8.31% to 2.46%. Likewise, using PC-SAFT for the same KPI, the deviations decrease from 7.97% to 5.46%. For the thermal energy requirement, predictions improve by 61% (i.e., from 7.23% in EK to 2.84% in RK) when using Peng–Robinson and by 8% (from 7.05% to 6.47%) if using PC-SAFT.

These results highlight the fact that when thermodynamic binary parameters from both models have been properly validated against experimental data (heat capacity, density), they play a minor role compared with model complexity. In this case, where the same property method was used to calculate liquid properties (ENRTL-RK), the choice of different EOS for the vapor phase did not alter the results significantly, achieving minor differences in %AARD between Peng–Robinson and PC-SAFT for the same model complexity. However, for the same thermodynamic model, %AARD changed significantly when moving from classic equilibrium-stage model to the more advanced rate-based model with kinetic reactions.

## Effect of L/G ratio and $CO_2$ partial pressure

After checking the average patterns from the two KPIs, this subsection examines these KPIs for each run analyzing the impact of the L/G ratio and $CO_2$ partial pressure. Figure 3 depicts the relative errors of the calculated $CO_2$ capture efficiency at low (A1, A4, A5, and A6) and high (A9, A10, A11, and A12) $CO_2$ partial pressure across various L/G ratios using the two thermodynamic methods.

It is apparent from Figure 3 that both thermodynamic methods perform well and are comparable to each other, although slight differences arise. At both, low and high $CO_2$ partial pressures and L/G ratios, the two thermodynamic models overestimate experimental results by 5–11% when using chemical equilibrium reactions (EQ and RE). However, when using kinetically-controlled reactions (RK, crimson-red) PC-SAFT underestimates experimental results by 1–11%, whereas, with Peng–Robinson, simulation results either underestimate or overestimate experimental values in the range of (-5%)–2%, showing excellent agreement with the data at high $CO_2$ partial pressures. Switching the mass-transfer model to EK (light blue), results in overestimation of the calculations by 0–11% for both thermodynamic packages.

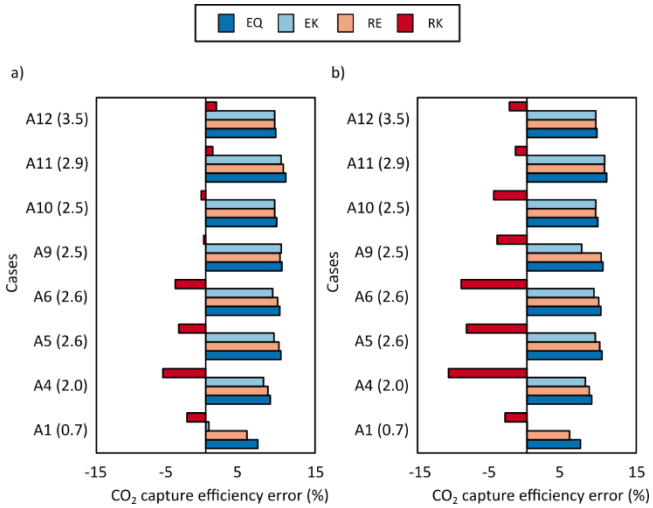

**Figure 3.** Relative error (%) for $CO_2$ capture efficiency using: (a) ENRTL-RK with Peng–Robinson and (b) ENRTL-RK with PC-SAFT. L/G ratio value in brackets.

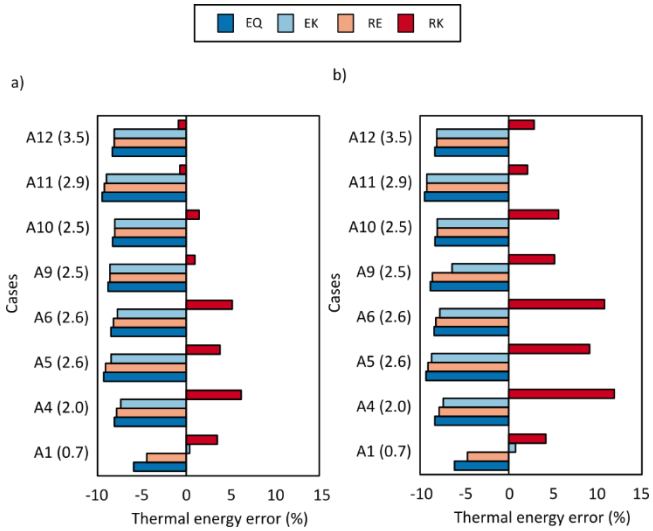

**Figure 4.** Relative error (%) for thermal energy requirement using: (a) ENRTL-RK with Peng–Robinson and (b) ENRTL-RK with PC-SAFT. L/G ratio value in brackets.

Figure 4 illustrates the relative errors of the calculated thermal energy requirement for both low and high $CO_2$ partial pressures and L/G ratios. As shown in the figure, the differences between the results using the two thermodynamic models are comparatively small, with the

**Table 3:** % AARD between the pilot plant data based on 8 runs and the process modelling results using different model complexities and two thermodynamic methods.

| Thermodynamic method | Model complexity | $CO_2$ capture efficiency (%) | Thermal energy requirement ($MJ/kgCO_2$) |
|---|---|---|---|
| ENRTL-RK Peng–Robinson | EQ | 9.66 | 8.35 |
| | EK | 8.31 | 7.23 |
| | RE | 9.23 | 7.96 |
| | RK | 2.46 | 2.84 |
| ENRTL-RK PC-SAFT | EQ | 9.68 | 8.39 |
| | EK | 7.97 | 7.05 |
| | RE | 9.25 | 7.98 |
| | RK | 5.46 | 6.47 |

exception of the RK model.

Interestingly, when using chemical equilibrium reactions (EQ and RE) the calculated values consistently underestimate the thermal energy requirement in the range of (-9%)–(-4%), irrespective of the mass-transfer method. Conversely, using kinetically-controlled reactions (RK, crimson-red) with PC-SAFT clearly over-predicts the experimental results in the range of 2–12%.

This also happens when using Peng–Robinson with kinetic reactions (crimson-red), but in these cases the thermal energy has more modest overestimations, with overall deviations between (-1%)–6%.

Additionally, it can be seen that the results using PC-SAFT for RK (crimson-red) overestimate the experimental values compared to Peng–Robinson at both low and high $CO_2$ partial pressure values (Figure 4). This result was also evident in Figure 3 when predicting $CO_2$ capture efficiency, yet, in that case, the deviations were causing an underprediction. The analysis shows that the differences between the two thermodynamic models is comparatively small at low $CO_2$ partial pressure and L/G ratio between 0.7 and 2.6.

However, at high $CO_2$ partial pressure and L/G >2.5 the choice of the EOS for the vapor phase (Peng–Robinson) affects the results, particularly in rate-based model with kinetic reactions.

## CONCLUSIONS

The purpose of the present contribution is to provide a framework for accurately simulating a post-combustion $CO_2$ capture process using MEA by evaluating the effects of thermodynamic models and mass transfer methods, under different modelling decisions and chemical reactions assumptions.

During process modelling, two strategies were identified to facilitate convergence of closed-loop simulations. The first strategy consisted of replacing a rigorous heat exchanger with two heater blocks connected by a heat stream. The second strategy consisted of using a calculator block to automate the computation of solvent and co-solvent (water) makeup, thereby maintaining material balance in the system automatically.

The two thermodynamic models used were based on the ENRTL-RK method for liquid phase properties, but differing on how vapor phase properties are calculated (Peng–Robinson vs PC-SAFT).

The results indicated that both thermodynamic methods yielded an %AARD below 10% in all cases, showing comparable results in most mass transfer approaches. However, the use of the rigorous RK model revealed that ENRTL-RK with Peng-Robinson was superior to ENRTL-RK using PC-SAFT, reducing average deviation by approximately 50% for both KPIs.

For the computational cost, both equilibrium-stage and rate-based simulations exhibit acceptable performance for isolated runs, in the order of 1.0-2.0s (EQ; the simplest) and 11.0-22s (RK, the most complex) using a 13$^{th}$ Gen Intel(R) Core i7-1355U and 16.0 GB RAM machine. While this difference might seem small in practice, it can become relevant when the process model is embedded within an optimization framework potentially requiring the evaluation of thousands of solutions. Furthermore, the rate-based model provides greater accuracy, yet it requires additional data such as column internals (tray or packing specifications) and reliable mass transfer correlations, which might not always be available in practice. Hence, modellers may select simplified approaches in contexts where deviations on the order of 10% are deemed acceptable.

The current process model was validated using experimental data from a single pilot-plant operating under post-combustion conditions representative of gas-fired and coal-fired power plants. Although the validation considers a reasonably broad range of L/G ratios (0.7-3.5) and inlet $CO_2$ compositions ($CO_2$ partial pressures, 54-102 mbar), the applicability to other pilot plants or to op-

erating conditions outside this range cannot be guaranteed. Therefore, this should be regarded as a limitation of the present study.

Nevertheless, the results obtained here provide useful insight into the model performance within the tested domain. In particular, for the cases analysed, the Peng-Robinson equation of state for the gas phase showed better performance at L/G ratios above 2.5, suggesting that it may be a more suitable option for plants operating under similar conditions. The combination of this model within the rate-based with kinetic equations framework assures very good accuracy for the KPIs studied, particularly at higher $CO_2$ partial pressures. Still, extrapolation to other systems should be carried out with caution. For reliable application to different pilot plants or operating windows, the thermodynamic model should be assessed and, if necessary, fit using experimental data representative of the corresponding conditions. Even in that case, real-world systems may deviate from the assumptions made in the model. This is because the predictive accuracy depends on the quality and availability of data for parameters such as mass transfer coefficients and kinetic constants, which might not always be available in practice.

In conclusion, the results presented in this paper may be used as practical guidelines for the accurate design of post-combustion $CO_2$ capture systems using rate-based models with kinetic reactions, adaptable to various L/G ratios and $CO_2$ partial pressures.

## ABSTRACT

The use of green hydrogen to reduce iron ore is a promising approach to drastically decrease $CO_2$ emissions in the steel industry. To enable the rapid adoption of this technology, it is essential to start from the fundamentals, namely understanding the intrinsic kinetics of iron oxide reduction. In this work, a kinetic investigation was conducted in a PBR-like system using both pure and commercial iron oxide powders under a wide range of operating conditions. The thermal conductivity of the outlet gas was measured and innovatively correlated with the extent of solid reduction through a rigorous mathematical procedure. To simulate the reduction process and determine the kinetic parameters, a deterministic axial dispersion model was developed in conjunction with a dynamic multistep shrinking core model. The model incorporates the particle size distribution of the solid into the mass balance and includes a reaction-front control mechanism to ensure physical consistency during kinetic parameter estimation. The model successfully reproduced all experimental data, confirming that the controlling mechanisms were predominantly chemical, internal diffusion, or mixed, depending on the type of solid material used. Furthermore, the model not only demonstrates excellent predictive capabilities through the validation of kinetic parameters but also provides new insights into the key phenomena governing iron oxide reduction.

**Keywords**: hydrogen, direct reduced iron, green ironmaking, TCD, SCM, deterministic kinetic modelling

## INTRODUCTION

The steel industry is one of the most carbon-intensive sectors in the world, with estimated $CO_2$ emissions of 1.85 - 2.6 tons per ton of steel produced [1]. This is largely due to the dominance of the blast furnace–basic oxygen furnace route, which is based on the combustion of coke to generate carbon monoxide (CO), the most important reducing agent in the high-temperature chemical reduction of iron ores [2]. Various alternative processes have been developed in recent decades, e.g., direct reduction (DR), in which CO and hydrogen ($H_2$) gas mixtures are used to reduce iron ores at lower temperatures [3]. DR processes promise significant reductions in emissions, especially when hydrogen is used as the sole reducing agent [4]. However, the technological transition to hydrogen-based reduction faces challenges related to the availability of hydrogen, energy requirements and reactor customization. The reduction of iron oxides follows a multi-step reversible reaction sequence from hematite ($Fe_2O_3$) to magnetite ($Fe_3O_4$), wüstite (FeO) and finally metallic iron [5]. The reaction network is displayed in Table 1.

**Table 1:** Reactive network.

| | Reactions |
|---|---|
| 1) | $3Fe_2O_3 + H_2\,(CO) \rightleftharpoons 2Fe_3O_4 + H_2O\,(CO_2)$ |
| 2) | $Fe_3O_4 + H_2\,(CO) \rightleftharpoons 3FeO + H_2O\,(CO_2)$ |
| 3) | $FeO + H_2\,(CO) \rightleftharpoons Fe + H_2O\,(CO_2)$ |

The role of water vapor is particularly crucial during the second and third reduction steps in controlling the local thermodynamic equilibrium. A wide range of experimental methods have been used to investigate $H_2$-based reduction, including thermogravimetric analysis [6], gas

phase analyses [7] and morphological characterizations [8]. The current findings in this field remain largely inconsistent, primarily because several distinct rate-determining steps have been identified. Depending on the specific reduction stages and experimental conditions, these mechanisms range from chemical kinetics and intraparticle diffusion to hybrid regimes [9]. Consequently, the diversity of theoretical and practical methodologies has led to a significant divergence in reported kinetic parameters.

This discrepancy is mainly attributed to the varied experimental setups employed, as well as the fundamental characteristics of the reducing agents and solid materials. Literature reviews show that while some researchers estimated kinetic constants using samples with high gangue content [10] others utilized high-purity materials synthesized in situ [11]. Furthermore, fluctuations in particle geometry, scale, and physical attributes—such as density and porosity—further complicate the reliable assessment of published activation energies. As a result, deriving definitive intrinsic kinetic parameters solely from existing literature remains a significant challenge. These studies show a large variability in the reported kinetic parameters with activation energies between 18 kJ/mol and 246 kJ/mol [12], with results influenced by the solid materials, the experimental procedure as well as the mathematical approach taken to determine the parameters [13]. To overcome this inconsistency, a rigorous and innovative approach is followed in the present work. The reduction degree of the iron oxide sample in the experiment was determined using an innovative mathematical method by measuring the thermal conductivity of the reactor's outlet gases, which allows for an accurate tracking of the reaction progress. The experimental data were analyzed and interpreted through a detailed mathematical model based on an axial dispersion model coupled with a multi-stage dynamic shrinking core model (dSCM); furthermore, the model accounts for the particle size distribution of the powders [14].

## MATERIALS AND METHOD

### Experimental Setup

The iron oxide samples used in the reduction studies were high purity hematite powders (purity >96 %) from Sigma-Aldrich and commercial samples of pellets used in BFs, and DR shaft furnaces provided by steelmaking companies. Pure hematite has an average particle diameter below 5 µm, while the commercial materials were produced by crushing and sieving pellets to achieve a fine particle size distribution (< 50 µm). The chemical composition of the commercial material is reported in Table 2.

**Table 2:** BF and DRI pellets chemical compositions.

| | Fe [%] | FeO [%] | $Al_2O_3$ [%] | CaO [%] | MgO [%] | MnO [%] | $SiO_2$ [%] |
|---|---|---|---|---|---|---|---|
| BF | 64.9 | 0.15 | 0.34 | 1.04 | 0.39 | 0.15 | 5 |
| DRI | 66.9 | 0.69 | 0.43 | 0.99 | 0.28 | 0.05 | 1.7 |

The experiments were carried out under isothermal conditions using an Autochem 2910 device containing a thermal conductivity detector (TCD) for real-time analysis of the gas phase composition with high temporal resolution. The setup of the experimental system is shown in Figure 1. The reactor used was a straight glass tube with a length of approximately 190 mm and a radius of 11 mm, housed in a compact electric furnace that facilitated accurate thermal control (heating ramp: 10 °C/min). The powdered sample (30-200 mg) was positioned on a quartz disc supported by a layer of quartz wool.

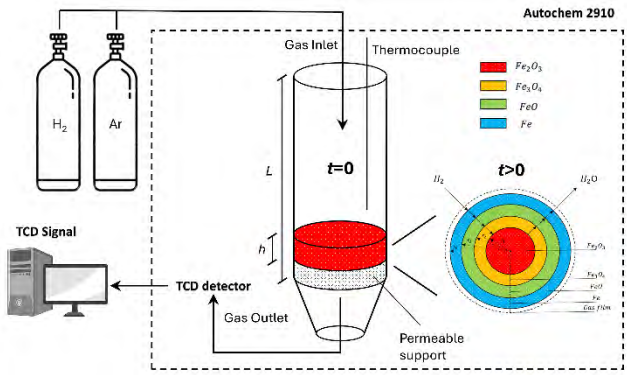

**Figure 1.** Schematic of the reactor experimental setup.

A wide range of operating parameters — including temperature, sample mass, total gas flow rate and hydrogen concentration — were systematically varied to investigate their effects on the reduction. The solid samples were characterized using several analytical techniques: X-ray diffraction (XRD) to identify chemical phases tracking the reduction process, light scattering to determine particle size distribution, nitrogen adsorption to assess porosity and specific surface area, and scanning electron microscopy (SEM) to evaluate surface morphology.

### TCD Signal interpretation

Analyzing the thermal conductivity signal during iron oxide reduction is challenging because it reflects not only the conductivity difference between reference and exhaust gases but also the structural characteristics of the Wheatstone bridge. Despite this complexity, the high sensitivity of the data enables a detailed interpretation of the reduction process. Changes in signal slope are correlated with different reaction phases and indicate shifts in kinetic or thermodynamic regimes caused by the depletion of dominant solid species. An example of TCD results of pure hematite reduction is displayed in Figure 2.

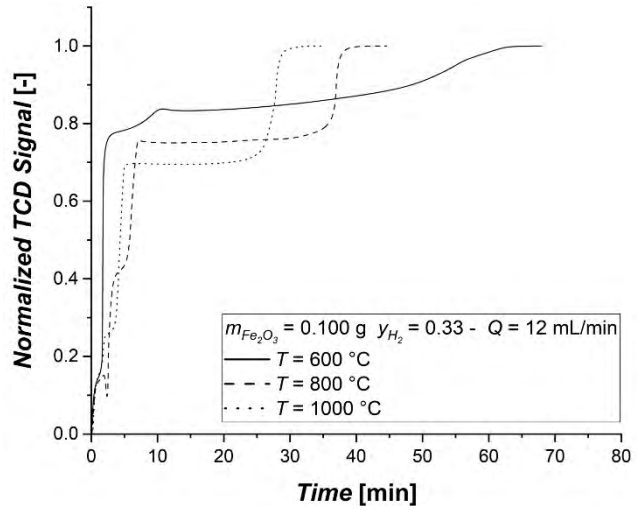

**Figure 2.** Examples of normalized TCD signals of pure hematite reduction at different operating temperatures.

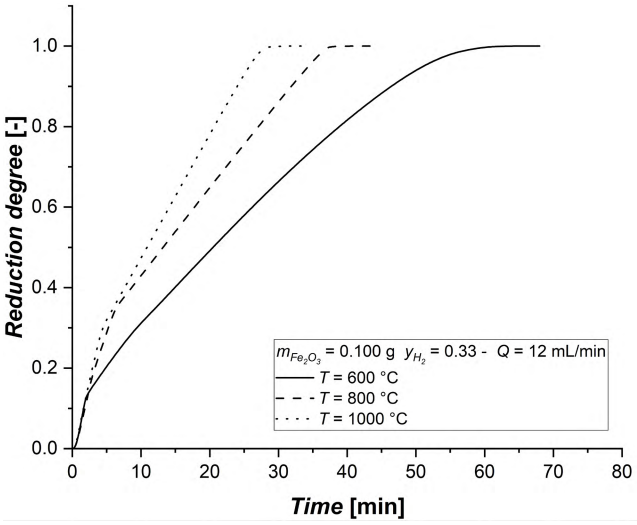

**Figure 3.** Examples of reduction degrees obtained from TCD signals of pure hematite reduction.

To validate these interpretations, stop-tests were performed at selected reaction times, and XRD analysis confirmed a direct correlation between the signal and the solid conversion. However, simulating the signal itself is complex because it is strongly affected by hydrogen concentration and reactor fluid dynamics. To overcome this, an alternative approach was developed to correlate the gas-derived signal with an indirect estimate of the overall reduction degree. The method involves deterministic mathematical operations: normalization, complement transformation, cumulative integration using the trapezoidal method, and correction by subtracting a blank signal obtained under identical conditions. This correction eliminates overestimation caused by axial dispersion and dilution effects, isolating the actual hydrogen consumption by the chemical reaction.

The processed signal can then be compared with the global reduction degree of the solid sample and used to estimate kinetic parameters for multistage iron oxide reduction. The key innovation lies in correlating highly accurate gas-phase measurements with solid conversion in heterogeneous reactions, enabling robust kinetic modeling and deeper physic-chemical interpretation of the reduction process. An example of reduction degrees obtained from TCD signals is displayed in Figure 3 from the same experiments used in Figure 2.

## First principle mathematical model

To describe the experimental data, a mathematical model was developed that describes the gas–solid interaction during reduction. This model includes kinetic and thermodynamic evaluation as well as the fluid dynamics of the empty and non-empty reactor. It also includes a refined solid-phase mass balance that considers the particle size distribution and closely tracks the progression of the reaction from. The model couples an axial dispersion model with a dSCM, which is enhanced by a product layer. At each time step, the governing equations are selected dynamically depending on the number of active reaction fronts [13]. he temporal and spatial evolution of the molar content of the individual oxides is described along the axial coordinates $z_1$ and $z_2$ (i.e., the fixed-bed axial coordinate). The reactor is divided into a non-reactive inlet zone and a reactive fixed-bed region. The initial molar oxygen content $n_0$ is calculated based on the mass of the sample. The mass balance of the solid phase, which determines the degree of conversion $X_j$, is given by

$$\frac{\partial X_j(t,z_2)}{\partial t} = \frac{r_j(t,z_2)}{n_0 \cdot a_j} \tag{1}$$

where $a_j$ is the stoichiometric oxygen content of the oxide $j$. The overall degree of reduction of the solid is therefore calculated by

$$X(t,z_2) = \sum_j^3 a_j \bullet X_j(t,z_2) \tag{2}$$

The local reduction rate $r_j$ is expressed

$$r_j(t,z_2)\big|_f = \sum_{n=1}^{N} x_n \bullet \frac{P}{R_g T} \frac{3}{r_n^0} \frac{1}{A_j(t,z_2,r_n^0)\big|_f} \cdot R_j(t,z_2,r_n^0)\big|_f \tag{3}$$

$$R_j(t,z_2,r_n^0)\big|_f = \left( \frac{N_j(t,z_2,r_n^0)\big|_f}{W(t,z_2,r_n^0)\big|_f} - y_{\mathrm{H_2},j,\mathrm{eq}}(t,z_2) \right) \tag{4}$$

where $P$ is the pressure, $R_g$ is the universal gas constant and $y_{\mathrm{H_2},j,\mathrm{eq}}$ is the equilibrium molar fraction of hydrogen for the reaction $j$ resulting from the local gas composition and the reaction-specific equilibrium constant $K_j$.

$$y_{\mathrm{H_2},j,\mathrm{eq}}(t,z_2) = \frac{1}{1+K_j} \cdot \left( y_{\mathrm{H_2},j}(t,z_2) + y_{\mathrm{H_2O},j}(t,z_2) \right) \tag{5}$$

The overall reaction rate is calculated by averaging the rates across the particle size classes, weighted by the initial radius $r_n^0$ and the mass fraction $x_n$. The key

parameters of the model include $N_j$ and $W$, which correspond respectively to the kinetic resistance, the effective reaction rate and the total resistance. These terms evolve dynamically with the number of active reaction fronts, which is determined for each layer of the bed at each time step. A transition function $f$ controls the number of active reaction fronts.

$$\begin{cases} X_1(t,z_2)=0 \implies f=1\ j=1 \\ X_1(t,z_2)<1 \wedge X_2(t,z_2)=0 \implies f=2\ j=1,2 \\ X_1(t,z_2)<1 \wedge X_2(t,z_2)<1 \wedge\ <0\ X_3(t,z_2)<1 \implies f=3\ j=1,2,3 \\ X_1(t,z_2)=1\ \wedge X_2(t,z_2)<1 \wedge X_3(t,z_2)<1 \implies f=2\ j=2,3 \\ X_1(t,z_2)=1\ \wedge X_2(t,z_2)=1 \wedge X_3(t,z_2)<1 \implies f=1\ j=3 \\ X_1(t,z_2)=1 \wedge X_2(t,z_2)=1 \wedge X_3(t,z_2)=1 \implies f=0 \end{cases} \quad (6)$$

$N_j$ and $W$ are calculated using the parameters $A_j, B_j$ and $F$, which represent kinetic resistances, intraparticle diffusion resistances and external diffusion resistances, respectively. These correlations are described below in the case of three active fronts of reactions, two fronts of reactions and a single front.

$$\begin{aligned} N_1(t,z_2,r_n^0)|_3 &= (A_1A_2A_3)\cdot y_{\mathrm{H_2},1} + (A_2(B_3+F))\cdot y_{\mathrm{H_2},3,eq} \\ &+(A_1A_3B_2 + A_1A_3(B_3+F) + A_1B_2(B_3+F))\cdot y_{\mathrm{H_2},2,\mathrm{eq}} \\ &+(A_3B_1(A_2+B_2) + A_3B_1(A_2+B_2) + B_1(A_2+B_2)(B_3+F) \\ &+A_2A_3B_2 + A_2A_3(B_3+F) + A_2B_2(B_3+F))\cdot y_{\mathrm{H_2},1,\mathrm{eq}} \end{aligned} \quad (7)$$

$$\begin{aligned} N_2(t,z_2,r_n^0)|_3 &= (A_2A_3(A_1+B_1))\cdot y_{H_2,2} + (A_2(A_1+B_1) \\ &(B_3+F))\cdot y_{\mathrm{H_2},3,\mathrm{eq}} + (A_3(A_1+B_1)(B_3+F) + B_2(A_1+B_1) \\ &(B_3+F) + A_3B_2(A_1+B_1))\cdot y_{\mathrm{H_2},2,\mathrm{eq}} + (A_2A_3B_2 + A_2A_3B_2 \\ &+A_2B_2(B_3+F) + A_2A_3(B_3+F))\cdot y_{\mathrm{H_2},1,\mathrm{eq}} \end{aligned} \quad (8)$$

$$\begin{aligned} N_3(t,z_2,r_n^0)|_3 &= [A_3(A_1+B_1)(A_2+B_2) + A_2A_3B_2]\cdot y_{\mathrm{H_2},3} \\ &+[(A_1+B_1)(A_2+B_2)(B_3+F) + A_2B_2(B_3+F)]\cdot y_{\mathrm{H_2},3,\mathrm{eq}} \\ &+[A_3(A_1+B_1)(B_3+F)]\cdot y_{H_2,2,eq} + [A_2A_3(B_3+F)]\cdot y_{\mathrm{H_2},1,\mathrm{eq}} \end{aligned} \quad (9)$$

$$\begin{aligned} W(t,z_2,r_n^0)|_3 &= ((A_1+B_1)\cdot(A_3(A_2+B_2+B_3+F) \\ &+(A_2+B_2)\cdot(B_3+F)) + A_2(A_3(B_2+B_3+F) \\ &+B_2(B_3+F)))\cdot y_{\mathrm{H_2},1,\mathrm{eq}} \end{aligned} \quad (10)$$

$$\begin{aligned} N_2(t,z_2,r_n^0)|_2 &= (A_2A_3)\cdot y_{\mathrm{H_2},2} + [A_2(B_3+F)]\cdot y_{\mathrm{H_2},3,\mathrm{eq}} \\ &+[A_2B_1 + (A_3+B_2)(B_3+F)]\cdot y_{\mathrm{H_2},2,\mathrm{eq}} \end{aligned} \quad (11)$$

$$W(t,z_2,r_n^0)|_2 = A_3(A_2+B_2+B_3+F) + (A_2+B_2)\cdot(B_3+F) \quad (12)$$

$$N_3(t,z_2)|_1 = y_{\mathrm{H_2},3}(t,z_2) - y_{\mathrm{H_2},3,\mathrm{eq}}(t,z_2) \quad (13)$$

$$W(t,z_2,r_n^0)|_1 = \frac{A_3+B_3+F}{A_3} \quad (14)$$

The analytical formulations of $A_j, B_j$, and $F$ are defined as follows

$$A_j(t,z_2)\big|_f = \frac{1}{\left(1-X_j(t,z_2)\right)^{\frac{2}{3}}}\cdot\frac{1}{k_j\cdot\left(1+\frac{1}{K_j}\right)} \quad (15)$$

$$B_j(t,z_2,r_n^0)\big|_f = \frac{\left(1-X_{j+1}(t,z_2)\right)^{\frac{1}{3}}-\left(1-X_j(t,z_2)\right)^{\frac{1}{3}}}{\left(1-X_j(t,z_2)\right)^{\frac{1}{3}}\cdot\left(1-X_{j+1}(t,z_2)\right)^{\frac{1}{3}}}\cdot\frac{r_n^0}{D_j} \quad (16)$$

$$F = \frac{1}{H} \quad (17)$$

where $k_j$ is the kinetic constant, $D_j$ is the intraparticle diffusion coefficient and $H$ is the external mass transfer coefficient. The kinetic parameters were determined by fitting experimental reduction data using the linearized Arrhenius equation, while the thermodynamic and diffusion parameters were obtained from established theoretical and empirical expressions [13].

The gas phase dynamics are modelled by tracking changes in species concentrations over time. The equation for the gas species $i$ is

$$\frac{\partial c_i(t,z_1)}{\partial t} = -\frac{u}{L-h}\cdot\frac{\partial c_i(t,z_1)}{\partial z_1} + \frac{D_z}{(L-h)^2}\cdot\frac{\partial^2 c_i(t,z_1)}{\partial {z_1}^2} \quad (18)$$

$$\frac{\partial c_i(t,z_2)}{\partial t} = -\frac{u}{h}\cdot\frac{\partial c_i(t,z_2)}{\partial z_2} + \frac{\partial^2 c_i(t,z_2)}{\partial {z_2}^2} + (1-\varepsilon)\cdot\sum_{j|_f}^{3}\nu_{i,j}\cdot r_j(t,z_2) \quad (19)$$

here, $c_i$ is the concentration of the species $i$ ($H_2$ or $H_2O$), $\nu_{i,j}$ are stoichiometric coefficients, and $\varepsilon$ is the initial porosity of the bed, measured via nitrogen physisorption. The relevant parameters are the bed height $h$, superficial velocity $u$ and the axial dispersion coefficient $D_z$. The bed height used corresponds to the theoretical height calculated based on the sample density and reactor geometry, while the axial dispersion coefficient was determined through fluid dynamics studies**.** The evaluation of the residence time distributions of the experimental setup enabled the evaluation of the Peclet number and of the axial dispersion coefficient $D_z$.

The boundary conditions of the PDE system are defined at the reactor inlet ($z_1$ = 0), at the outlet of the empty zone ($z_1$ = 1), at the inlet of the reactive bed ($z_2$ = 0) and at the system outlet ($z_2$ = 1).

$$c_i(t,z_1)\big|_{z_1=0} = c_{i,\mathrm{in}}\ \left.\frac{\partial c_i(t,z_1)}{\partial z_1}\right|_{z_1=1} = 0 \quad (20)$$

$$c_i(t,z_2)\big|_{z_2=0} = c_i(t,z_1)\big|_{z_1=1}\ \left.\frac{\partial c_i(t,z_2)}{\partial z_2}\right|_{z_2=1} = 0 \quad (21)$$

A detailed assessment was performed to identify which phenomena could be safely neglected in the kinetic modelling of hydrogen-based iron oxide reduction under controlled laboratory conditions. The analysis indicates that external mass transfer limitations can be neglected due to the very fine particle size used in the experiments. A detailed evaluation of the external mass transfer coefficient under different operating conditions confirmed values of $H$ high enough to rule out significant resistance compared to other mechanisms in the dynamic shrinking core model. Similarly, thermal effects were assessed to verify the assumption of negligible temperature gradients within the particles. Despite the endothermic nature of the reduction reactions, the use of small beds of fine particles combined with strong external heating ensures nearly uniform temperature. Theoretical estimates of intraparticle temperature differences under worst-case conditions showed variations below 2 K for all oxides involved, supporting the assumption of isothermal behavior. These findings justify focusing on chemical and internal diffusion control while excluding external diffusion and thermal gradients from the kinetic model.

The mathematical model was implemented in Matlab 2025b to simulate the reduction process and estimate kinetic parameters. The system of partial differential equations was solved using the finite difference method, applying a backward scheme for first-order spatial derivatives and a centered scheme for second-order derivatives. The reactor's two axial coordinates were discretized into 20 nodes each, generating a system of ordinary differential equations solved with ode15s, a variable-step, variable-order solver based on numerical differentiation formulas (orders 1–5).

Parameter estimation was carried out using patternsearch, a deterministic, derivative-free optimization algorithm that explores the solution space through an adaptive grid (pattern). This approach ensures robustness in handling complex, nonlinear systems without requiring gradient information.

The objective function minimized the deviation between experimental data and the simulated average conversion of the thin layer over time ($\bar{X}_s$), expressed as:

$$O = \sum_s^S \left( \frac{X_{\text{meas},s} - \bar{X}_s}{X_{\text{meas},s}} \right)^2 \quad (21)$$

This formulation guarantees accurate fitting of experimental results, enabling reliable estimation of kinetic parameters for multistage iron oxide reduction.

## RESULTS

The interpretation of the TCD response is inherently challenging. This difficulty stems not only from the conductivity contrast between the reference and outlet gas streams, but also from the specific physical layout and internal configuration of the detector. By applying a rigorous mathematical treatment, it was possible to link the processed signal directly to the conversion progress of the reacting solid. The operating conditions examined in this work include temperature, reducing-gas composition, volumetric flow rate, and the solid-sample loading in the reactor, as well as the type of solid employed, namely pure hematite and industrial samples used in BF and DRI processes. In total, 17 experiments were carried out for each type of solid sample, extensively varying all the different operating conditions.

Among all factors influencing the reduction of iron oxides, temperature is one of the most influential. The reason lies in the strong correlations that temperature has with both the reaction kinetics and the thermodynamics of the reduction process, as well as with diffusion-related phenomena. Figure 4 highlights how temperature affects the overall reduction degree over time. Panel (a) presents tests performed on pure hematite beds, whereas panel (b) and (c) displays results obtained from the reduction of compact BF and DRI powder respectively.

A key observation is the marked decrease in the total reduction time as temperature increases, reflecting the enhanced reaction rate. The data indicate that the conversion of hematite to magnetite occurs rapidly—within approximately 4 minutes—in all experiments. Some of them show a distinct change in the slope of the conversion curve at approximately 0.11 signals the completion of the hematite-to-magnetite transition. Further slope variations are more subtle, as the reductions of $Fe_3O_4$ and FeO overlap significantly. Consequently, a conversion value near 0.3 cannot be uniquely associated with the full reduction of magnetite. In these experiments, the height of the bed plays a crucial role in determining the reaction pathway. The water vapor formation introduces thermodynamic constraints deeper in the bed, observed as a noticeable slope break around a conversion of 0.2-0.3, identifying the approximation to the end of magnetite reduction and the initial stages of FeO formation.

The kinetic parameters for pure hematite were previously derived in an earlier study [14], whereas the parameters reported in Table 3 were obtained from the experiments performed on the commercial materials.

**Table 3:** Activation energy and pre-exponential factor estimated from BF and DRI powder.

| Reactions | $E_a$ [kJ/mol] | $k_{j,\text{ref}}$ [m/s] |
|---|---|---|
| $Fe_2O_3 \rightleftharpoons Fe_3O_4$ | $61 \pm 3$ | $2.8 \cdot 10^{-1} \pm 6 \cdot 10^{-2}$ |
| $Fe_3O_4 \rightleftharpoons FeO$ | $37 \pm 2$ | $2.4 \cdot 10^{-3} \pm 9 \cdot 10^{-5}$ |
| $FeO \rightleftharpoons Fe$ | $27 \pm 1$ | $2.6 \cdot 10^{-3} \pm 6 \cdot 10^{-5}$ |

Figure 5 compares simulated and measured conversion values through reduction degree parity plots of all the different datasets: pure (a) BF (b) and DRI (c).

The plots show strong agreement between model predictions and experimental measurements, with most data points falling within a ±10% deviation. This consistency is further supported by the corresponding $R^2$ values. The robustness of the kinetic parameters was additionally confirmed by applying them to a broader set of reduction experiments involving hematite fixed beds.

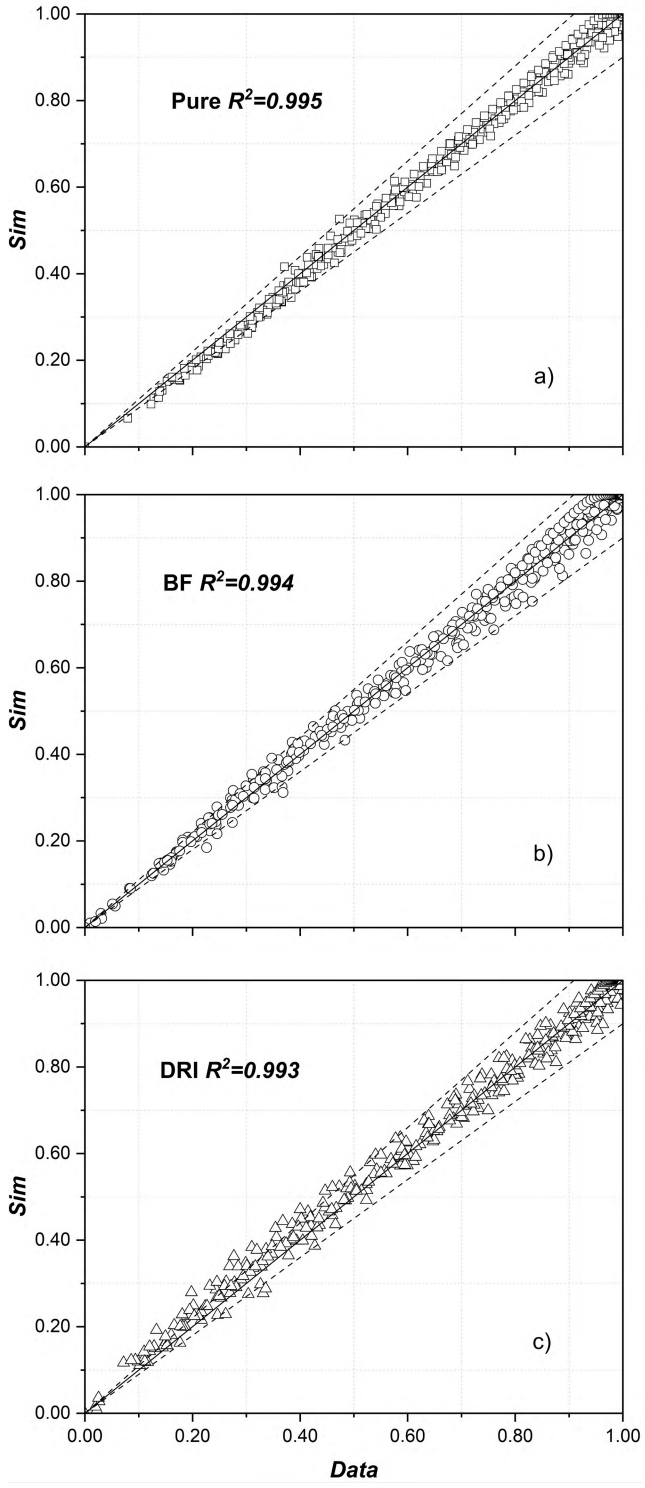

**Figure 5.** Reduction degree parity plots for a) pure hematite; b) BF; c) DRI.

## CONCLUSIONS

This work has presented a comprehensive experimental and modelling investigation of the hydrogen-based reduction of iron oxide powders, with the aim of estimating the kinetic parameters of the reactions involved. In this study, the reduction of pure hematite, BF, and DRI powders in a fixed-bed reactor was examined under a wide range of operating conditions, including different temperatures, total volumetric flow rates, hydrogen contents in the feed gas, and solid sample loadings. The experiments were performed in a fixed-bed reactor equipped with a thermal conductivity detector, enabling fast and accurate gas-phase analysis.

The TCD signal was processed using a mathematical approach capable of correlating the thermal-conductivity response of the off-gas to the reduction degree of the sample. This indirect measurement strategy was rigorously validated through complementary analytical techniques, including morphological, chemical, structural, and granulometric characterization of the solids.

A novel mathematical modeling framework was developed, integrating a dynamic multi-front shrinking core formulation with a variable number of reaction interfaces and an axial dispersion description to accurately represent the behavior of the experimental system. The model dynamically tracks the sequential reduction reactions and their spatial evolution within the bed, enabling a detailed description of the reduction process under varying thermodynamic conditions. Numerical simulations showed excellent agreement with the experimental results over a wide range of operating conditions, demonstrating the predictive capability of the framework.

In parallel, a novel methodology based on thermal conductivity detector signal analysis was developed to determine the reduction degree directly from off-gas measurements. Through a deterministic signal-processing procedure, the evolution of the reaction could be continuously monitored, providing a robust and reproducible alternative to conventional gravimetric approaches for studying hydrogen-based reduction systems.

Importantly, the model proved capable of consistently describing the reduction behavior of different iron-bearing materials, including pure iron oxides, blast furnace materials, and direct reduced iron systems. Overall, the results demonstrate that the developed methodology—combining rigorous experimentation, advanced gas-phase diagnostics, solid-phase characterization, and physically grounded modeling—provides a robust and versatile framework for interpreting the dynamics of hydrogen-based iron oxide reduction.

## ABSTRACT

The identification of predictive mathematical model structures (i.e. set of model equations) is essential for the development of digital twin models of chemical reactor systems. Recent work demonstrated the use of artificial neural networks (ANNs) for kinetic model recognition in a conceptual batch reaction experimental system. In practical chemical processes, however, system behaviour is governed not only by reaction kinetics but also by reactor hydrodynamics and system thermodynamics. While a very recent study incorporated hydrodynamic effects, this work integrates the three aspects: reaction kinetics, reactor hydrodynamics, and system thermodynamics, to develop a general reactor modelling recognition framework. The framework, which comprises three modules: 1) model generator module; 2) data generation module; and 3) ANN classifier module, was applied to a case study of benzoic acid esterification in a Taylor vortex flow reactor system. Analysing the framework's sensitivity, results showed that ANN performance in classification deteriorates under increasing measurement noise but can be improved by increasing the number of simulated experiments. Further results show that extensive hyperparameter optimisation of ANN architectures provides no benefit over a fixed ANN architecture. This study highlights the potential of ANN-based frameworks for reactor model recognition while underscoring the dominant role of experimental design and data quality over network hyperparameter tuning.

**Keywords**: Modelling, Machine Learning, Optimization, Modelling and Simulations, Process Operations, Hybrid modelling, Artificial neural networks, Taylor vortex flow reactor

## 1.0 INTRODUCTION

Digital twin (DT) technology is transforming the way chemical and pharmaceutical processes are designed, monitored, and optimised [1 - 3]. A digital twin combines real-time data from a physical process with predictive computational models to enable autonomous operation and closed-loop optimisation [2]. In pharmaceutical manufacturing, DTs play a central role in accelerating process development, ensuring consistent product quality, and supporting regulatory compliance.

Despite the rapid rise of data-driven and machine learning (ML)-based digital twins, their adoption in safety-critical industries such as pharmaceuticals has been hindered by concerns about reliability, interpretability, and robustness [4]. Purely data-driven models can capture system trends efficiently but often fail to extrapolate beyond the training domain, leading to unsafe or suboptimal operation when process conditions change. To overcome these limitations, hybrid digital twins—which combine the computational efficiency of ML with the physical interpretability of first-principles models—have gained increasing attention [5-7].

Within this context, model identification remains a crucial step. Reliable digital twins require high-fidelity process models capable of representing reaction kinetics, reactor hydrodynamics, and thermodynamic interactions [8]. Recent research has demonstrated the use of artificial neural networks (ANNs) for rapid kinetic model recognition and optimal experimental design, particularly in batch reactor systems [9, 10]. However, these studies often neglected hydrodynamic and thermal effects whose representation is critical in nonisothermal flow reactors, which are increasingly central to pharmaceutical

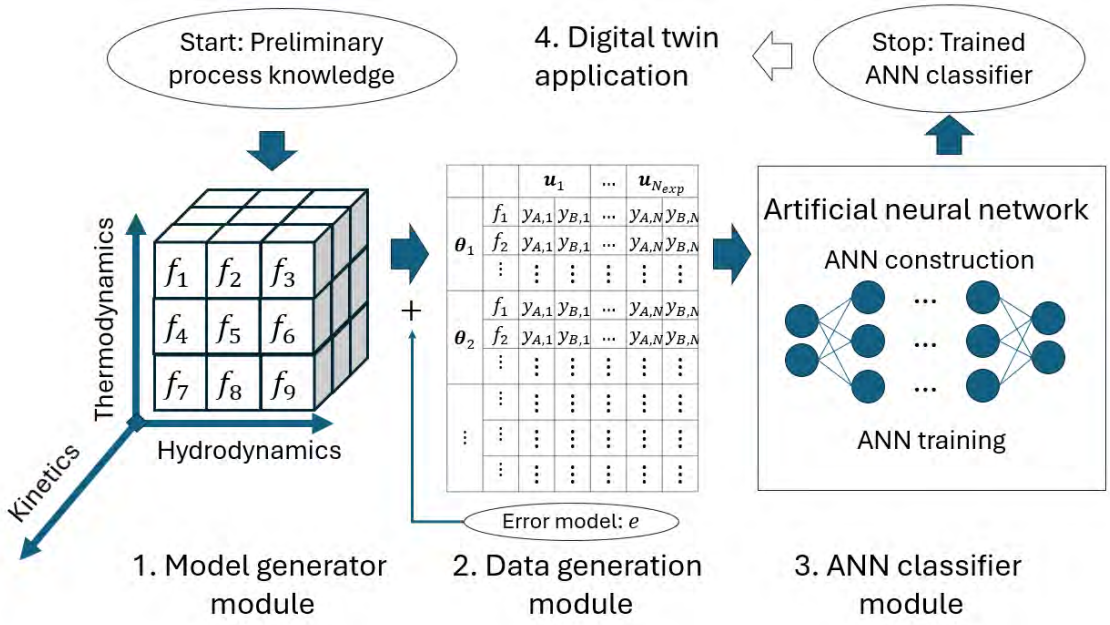

**Figure 1:** ANN hybrid modelling framework with 3-dimensional physics-based model generator

scale-up.

The present work extends previous ANN-based frameworks [9–11] by incorporating hydrodynamics and thermodynamics explicitly into the model recognition process. The extended framework is subsequently evaluated with respect to data quality and ANN architectural complexity to assess its scientific robustness and computational efficiency. The proposed framework identifies the most suitable reactor model structure among a library of possible configurations including kinetics, hydrodynamics, and energy interactions. This hybrid approach enables fast yet physically grounded model recognition — a key requirement for reliable DT implementation.

## 2.0 METHODOLOGY

The proposed hybrid framework comprises three interconnected modules (Fig. 1): 1. Model Generator Module, 2. Data Generation Module, and 3. ANN Classifier Module, for subsequent application as a digital twin.

### 2.1 Model Generator Module

The model generator defines the library of possible reactor models, organised as a three-dimensional tensor. Each axis of this tensor corresponds to a distinct modelling domain:

- Reaction Kinetics: Alternative rate-law formulations capturing alternative mechanistic hypotheses;
- Reactor Hydrodynamics: Different reactor flow models, considering in this work continuously stirred tank reactor (CSTR) and plug flow reactor (PFR) representations;
- System Thermodynamics: Alternative energy balance assumptions—adiabatic and isothermal operations.

Each model structure $i$ is generally described by a system of differential and algebraic equations that can be written as:

$$\boldsymbol{f}_i(\boldsymbol{x}, \dot{\boldsymbol{x}}, \boldsymbol{u}, \theta, \tau) = \boldsymbol{0}$$
$$\boldsymbol{y} = \boldsymbol{g}(\boldsymbol{x}) \quad (1)$$

where $\boldsymbol{x} \in \mathcal{X} \subseteq \mathbb{R}^{n_x}$: vector of state variables (e.g., concentrations and temperatures), $\dot{\boldsymbol{x}} \in \dot{\mathcal{X}} \subseteq \mathbb{R}^{n_x}$: vector of time derivatives of the state variables; $\boldsymbol{u} \in \mathcal{U} \subseteq \mathbb{R}^{n_u}$: vector of control/input variables (e.g., inlet temperature, stream flow rates and composition in flow reaction systems); $\theta \in \boldsymbol{\Theta} \subseteq \mathbb{R}^{n_\theta}$: vector of model parameters (e.g., reaction Arrhenius parameters); $\tau$: space time variable; $\boldsymbol{y} \in \boldsymbol{\mathcal{Y}} \subseteq \mathbb{R}^{n_y}$: vector of measured variables.

### 2.2 Data Generation Module

The data generation module produces synthetic datasets by simulating each model structure over the defined parameter and design spaces, following three main features:

- Parameter Space Sampling: Kinetic parameter sets $\{\dots, \theta_i, \dots\}$ are sampled from the feasible space of model parameters [9] using Latin hypercube

sampling (LHS) to ensure space-filling coverage.

- Experimental Design Space Sampling: Operating conditions $\boldsymbol{u}_i = [\boldsymbol{c}_0, T, \tau]$, denoting feed concentrations, temperature, and residence time, respectively are randomly designed using the Latin hypercube sampling technique from the experimental design space $\boldsymbol{\varphi}$ before employing the models to simulate the experimental conditions.
- Noise Modelling: to assess the impact of data quality on model identification Gaussian noise ($e$) with zero mean and relative variance $\omega$ has been varied between 0.01 and 0.1, and added to model outputs $\hat{\boldsymbol{y}}$ to mimic measurement uncertainty in real experiments, i.e.,

$$e = \mathcal{N}[0, \sigma^2 = (\omega y)^2] \quad (2)$$

The simulated data comprise model outputs and their labels, which serve as training and validation data set for ANN classifiers.

## 2.3 ANN Classifier Module

The third module performs model recognition using ANNs trained to classify which model structure best represents the test data. Two ANN architectures are considered:

- ANNfix: Fixed network structure comprising 3 hidden layers with 160 nodes per layer
- ANNopt: Hyperparameter-optimised network, varying the number of hidden layers ($n_h$ = 1 – 5) and the number of nodes per layer ($n$ = 32-256)

The ANN classification transformation can be described as:

$$p_i = \phi_{N_L}(\dots \phi_1(\boldsymbol{w}^T \boldsymbol{y} + \boldsymbol{b}) \dots); \forall i = [1, 2, \dots, N_m] \quad (3)$$

where $p_i$ is the probability of ANN selection calculated for Model $f_i$; $\boldsymbol{w}$ and $\boldsymbol{b}$ are the weights and biases in ANN nodes respectively; $\phi_1$ is the activation function of layer 1. For classification, SoftMax activation function is used in Layer $N_L$ while ReLU activation function is used in all the preceding layers [12]. ANN parameters $\boldsymbol{w}$ and $\boldsymbol{b}$ are estimated from model training using standard backpropagation with categorical cross-entropy as the objective function. Classification accuracy $\mathrm{Acc}_{\Psi_{\mathrm{test}}}$—the proportion of correctly identified model structures in the test dataset, expressed in Eq. (4)—serves as the primary performance metric.

$$\mathrm{Acc}_{\Psi_{\mathrm{test}}} = \frac{N_{\Psi_{\mathrm{test}} \wedge \hat{l}_i = l_i}}{N_{\Psi_{\mathrm{test}}}} \cdot 100\% \quad (4)$$

where $N_{\Psi_{\mathrm{test}}}$ is the number of samples in the test dataset; $N_{\Psi_{\mathrm{test}} \wedge \hat{l}_i = l_i}$ is the number of test samples where the model label has been correctly classified.

# 3.0 CASE STUDY

The synthesis case study considered in this work is related to benzoic acid esterification [13] in a Taylor vortex reactor (TVR). In this esterification reaction, benzoic acid (BA) reacts with ethanol (EtOH) to produce water (W) and ethylbenzoate (EB) in a single reaction shown in Eq. 5. This reaction can be described using two rival reaction kinetics shown in equations M1 and M2, providing two options along the kinetic submodel dimension [13]

$$BA + EtOH \rightarrow W + EB \quad (5)$$

$$k_1 c_{BA} c_{EtOH} \quad (M1)$$

$$\frac{k_1 c_{BA} c_{EtOH}}{(1 + K_W c_W)^2} \quad (M2)$$

where: $k_1 = \exp\left(-KP_1 - \frac{KP_2 \times 10000}{RT}\left[\frac{1}{T} - \frac{1}{T_{ref}}\right]\right)$;

$$T_{ref} = 378.15\ K \quad (6)$$

Thus, $\boldsymbol{u} = [c_{BA}(0), T, F_{total}]$; $\hat{\boldsymbol{y}} = [c_{BA}, c_{EtOH}, c_W, c_{EB}, T]$ and $\theta = [KP_1, KP_2, K_W]$.

A TVR of 10 mL volume with 9.5 and 10.2 $mm$ in annulus inner and outer diameters is employed. Because of its rotating concentric cylinders (inner rotor and outer stator as shown in Fig. 2), the TVR offers mixing conditions that can vary from continuously stirred tank reactor (CSTR) (Eq. R1) to plug flow reactor (PFR) (Eq. R2) [14], so that a trained ANN within the hybrid framework will be able to recognise the prevailing hydrodynamics from experimental data.

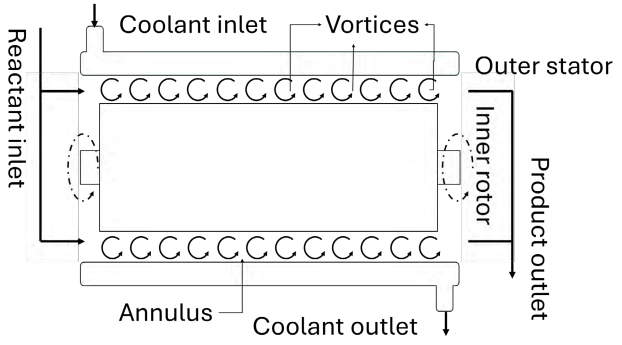

**Figure 2.** Axial cross section of a Taylor vortex reactor

Only this two hydrodynamics are considered in this work, yielding two options along the reactor submodel dimension.

$$c_i = c_{i0} + \frac{V}{F_{total}} \upsilon_i r; \quad (R1)$$

$$\frac{dc_i}{dV} = F_{total} \upsilon_i r; \quad (R2)$$

The reactor temperature profile expressed using the energy balance reported in Eq. (7) [15] can vary from an isothermal thermodynamic operation (Eq. D1), where the

reaction system temperature is controlled and under a constant temperature to an adiabatic thermodynamic operation (Eq. D2), where the reaction system temperature is uncontrolled and influenced by the reaction heat. These two operating modes provides the options along the thermodynamic submodel dimension.

$$dH = Q + W_s \tag{7}$$

where $dH$ is the enthalpy change; $Q$ is the heat transferred and $W_s$ the shaft work impacted on the system.

$$T = constant \tag{D1}$$

$$Q = 0 \tag{D2}$$

Using these three submodel dimensions, 8 candidate models $(f_1, f_2, \dots, f_8)$ can be generated as shown in Table 1.

**Table 1:** The set of candidate models $\boldsymbol{f} = [f_1, f_2, \dots, f_8]$ obtained from the model generator.

| | $D1$ | | $D2$ | |
|---|---|---|---|---|
| | $R1$ | $R2$ | $R1$ | $R2$ |
| $M1$ | $f_1 = (M1, R1, D1)$ | $f_3 = (M1, R2, D1)$ | $f_5 = (M1, R1, D2)$ | $f_7 = (M1, R2, D2)$ |
| $M2$ | $f_2 = (M2, R1, D1)$ | $f_4 = (M2, R2, D1)$ | $f_6 = (M2, R1, D2)$ | $f_8 = (M2, R2, D2)$ |

## 4.0 RESULTS AND DISCUSSION

Table 2 shows the experimental design for benzoic acid esterification where the reported kinetic models are valid.

**Table 2:** Benzoic acid experimental design space with three design variables and their lower and upper limits

| Limits | $c_{BA}(0)$ (M) | $T$ $(K)$ | $F_{total}$ $(\mu L/min)$ |
|---|---|---|---|
| Lower | 1.0 | 373.0 | 20.0 |
| Upper | 1.5 | 393.0 | 40.0 |

The impacts of three factors on the ANN classification performance are investigated: number of experiments, noise level and ANN architecture settings. In the number of experiments, five simulated experiment numbers were employed: 1 to 5, each experiment corresponding to five responses (= 4 exit chemical concentrations + 1 exit temperature). Fig. 3 shows the distribution of the 5 experiments within the experimental design space.

Two levels of constant relative noise were investigated: low (=0.01) and high (=0.1) noise level. In the ANN architecture settings, ANNfix and ANNopt were investigated. The Python optimiser package HyperOpt was employed for ANNopt. HyperOpt optimised the ANN layers and nodes along with their weights and biases during the training.

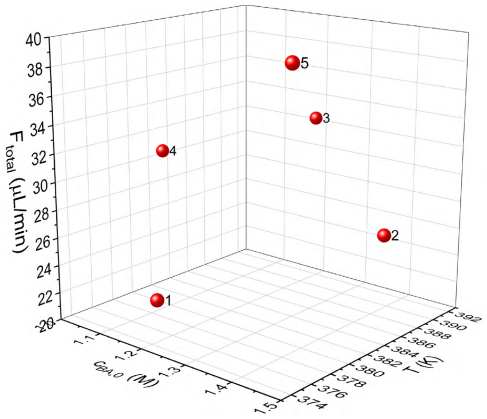

**Figure 3.** Distribution of 5 experiments designed using LHS in the experimental design space

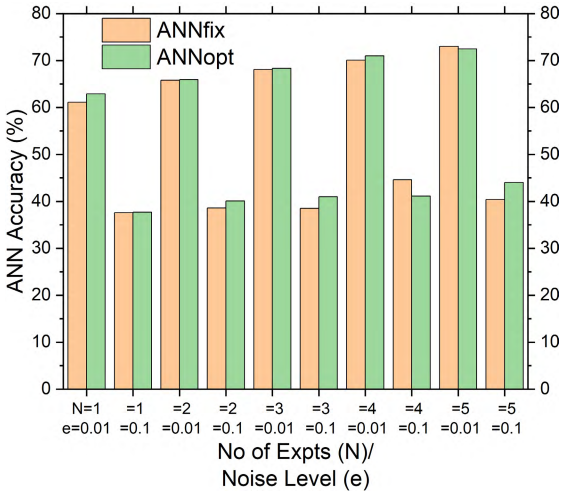

**Figure 4.** Comparison of the performance of the ANN network on the test dataset for the two different ANN architectures (ANNfix and ANNopt) for number of experiments between 1 and 5 and level of noise of 0.01 and 0.1.

Each of the 8 models in the model library was simulated using 1, 000 samples from the kinetic parameter space shown in Table 3. The model simulated responses in concentrations and temperature were subsequently corrupted randomly from a Gaussian distribution with a constant relative variance equalled to the level of noise.

**Table 3:** Benzoic acid esterification kinetic parameter space [13]

| $KP_1$ | $KP_2$ | $K_W$ |
|---|---|---|
| $16.7 \pm 0.02$ | $5.93 \pm 0.20$ | $0.27 \pm 0.10$ |

The resulting in-silico data, split into training, validation and testing datasets in the ratio: 3:1:1, are fed into the ANN network. The ANN performance on the test dataset using the accuracy metric is shown in Fig. 4.

Results show that there is no significant difference between the performances of ANNfix and ANNopt in terms of global classification accuracy for the same number of experiments and level of noise. For example, when $N_{exp} = 5$ and noise level = 0.01, ANNfix achieved an accuracy of 73.0% while ANNopt achieved a slightly lower accuracy of 72.5%. At the lower number of experiments when $N_{exp} = 1$ and noise level = 0.01, ANNfix achieved an accuracy of 61.1% while ANNopt achieved only slightly a higher accuracy of 62.9%, a marginal increment not substantial enough to offset the required computational cost (86.0 seconds VS 6.7 seconds of ANNfix) and largely due to the stochastic shuffling of the datasets. Both architectures have the SoftMax activation function in the last layer required for the classification task. The input into the layer has been calculated using the trained prior network parameters and the last layer can still perform the classification, regardless of the network architectures. Further investigation confirmed that, provided the number of nodes per hidden layer in ANNfix was greater or equal to the input features, the hyperparameter optimisation employed in ANNopt did not confer a performance advantage over ANNfix. In the investigation at $N_{exp} = 20$ and $0.01$ noise level, ANNfix achieved 86.3% while ANNopt achieved 86.9%. Similarly, a change in the design technique did not influence this trend. Using the full factorial design at 2 levels in the experimental design space, yielding 8 experiments from the corners in Fig. 3, ANNfix achieved 79.9% ANN classification accuracy but ANNopt performed about 2% worse at 78.1% accuracy.Different from the ANN architecture settings, other factors such as the noise level and number of experiments influence the network performance. For example, while ANNfix at a small level of noise (0.01) achieved an ANN performance of 61.1% with a single experiment, the same network architecture only achieved a performance of 37.6% at the higher noise level of 0.1. The same trend applies to ANNopt considering a single experiment, achieving 62.9% at 0.01 small noise level and 37.7% at 0.1 large noise level. By increasing the number of experiments to 2, both architectures improved in ANN performance to 65.8% and 65.9% at 0.01 noise level and to 38.6% and 40.1% at 0.1 noise level for ANNfix and ANNopt, respectively. The same trend can be observed by increasing the number of experiments further until, $N_{exp} = 5$, which has the highest ANN accuracy for both small and large noise levels in both ANN architectures. Increasing number of experiments increases the performance of the ANN while increasing noise level deteriorates the ANN performance.

The classification accuracy is illustrated graphically in Fig. 5 using the confusion matrices with two scenarios: Scenario 1 and Scenario 2. Scenario 1 corresponds to $N_{exp} = 5$ and 0.01 noise level where the achieved classification accuracy was 73.0% and Scenario 2 corresponds to $N_{exp} = 1$ and 0.1 noise level where the accuracy was 37.6 %, both considered using ANNfix architecture. The candidate models are labelled as in Table 4.

**Table 4:** The 8 candidate models: labels and components

| Model Labels | Model components |
|---|---|
| Model 0 | M1, R1, and D1 |
| Model 1 | M2, R1, and D1 |
| Model 2 | M1, R2, and D1 |
| Model 3 | M2, R2, and D1 |
| Model 4 | M1, R1, and D2 |
| Model 5 | M2, R1, and D2 |
| Model 6 | M1, R2, and D2 |
| Model 7 | M2, R2, and D2 |

The small noise in Scenario 1 only gives rise to classification confusion among alternative thermodynamic models (D1: isothermal and D2: adiabatic). For example, 76 out of 191 test datasets originating from Model 0 (kinetic M1, CSTR hydrodynamic R1 and isothermal thermodynamic D1) were wrongly classified as M2 (kinetic M1, CSTR hydrodynamic R1 and adiabatic thermodynamic D2). In a few instances data sets originating from a model with a CSTR hydrodynamic sub model were wrongly classified as PFR (Actual Model 2 and Predicted Model 7) or data sets originating from a model with kinetic M1 were wrongly classified as kinetic M2 (Actual Model 7 and Predicted Model 6).

In Scenario 2 with larger noise level, confusion in the ANN network classification extends beyond just one model label to multiple model labels. For example, test datasets originating from Model 0 are being wrongly classified as Model 1 (2), Model 2 (45), Model 3 (17), Model 4 (1), Model 5 (16) and Model 7 (11). Only Model 6 (kinetic M1, PFR hydrodynamic R2 and Adiabatic thermodynamic D2) was not wrongly predicted.

As a trend, the ANN performance decreases with increasing noise in the training data. At 0.01 noise variance and five simulated experiments, both ANNfix and ANNopt achieved comparable classification accuracies—73.0% and 72.5%, respectively. As noise increased to 0.1, accuracies fell below 60%, highlighting the detrimental impact of experimental uncertainty on model recognition.

Contrary to expectations [16, 17], extensive hyperparameter optimisation (ANNopt) did not improve classification performance over the fixed network (ANNfix). This suggests that data quality and diversity exert a stronger influence on model recognition accuracy than ANN complexity.

Increasing the number of simulated experiments substantially improved classification accuracy, even

under high-noise conditions. This reinforces the critical role of experimental design in ensuring model identifiability and supports the use of optimised designs in physical experimentation.

The framework provides a robust computational foundation for experimental studies in flow reactors, particularly TVRs, where mixing and thermal effects interact strongly. The ability to recognise between hydrodynamic and kinetic models rapidly can inform both reactor design and digital twin development for scale-up.

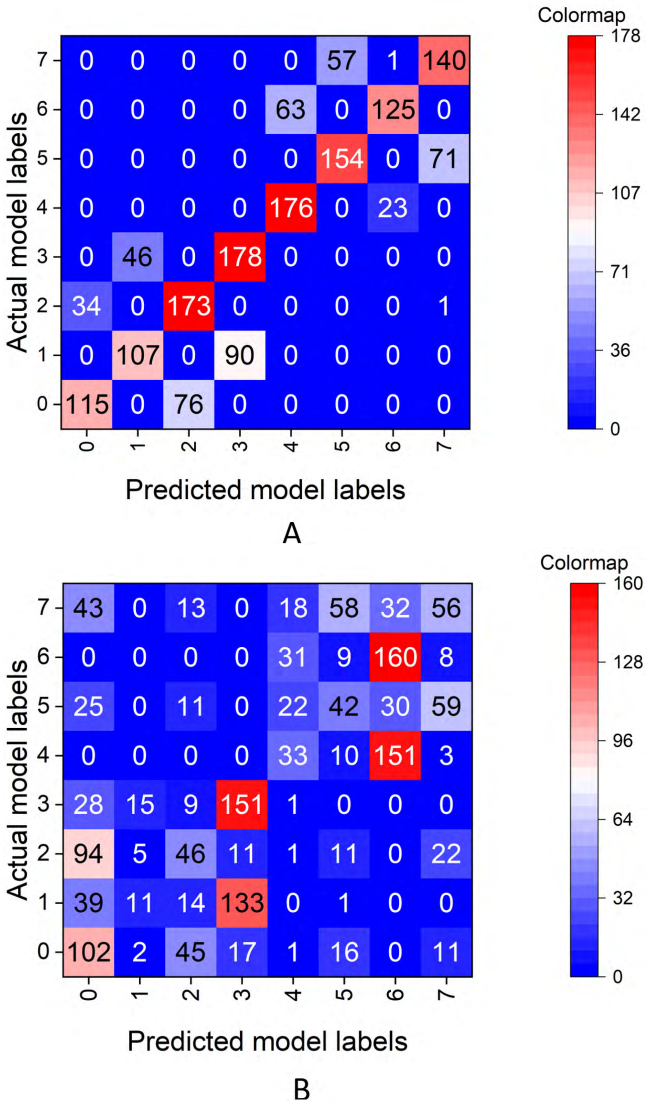

**Figure 5.** ANN test classification shown as confusion matrices. A) Scenario 1 ($N_{exp} = 5$, 0.01 noise level, 73.0 % accuracy); B) Scenario 2 ($N_{exp} = 1$, 0.1 noise level, 37.6 % accuracy; Model 0 (M1, R1, D1), Model 1 (M2, R1, D1), Model 2 (M1, R2, D1), Model 3 (M2, R2, D1), Model 4 (M1, R1, D2), Model 5 (M2, R1, D2), Model 6 (M1, R2, D2) and Model 6 (M2, R2, D2).

## 5.0 CONCLUSIONS

This study presents a hybrid digital twin framework for reactor model recognition integrating reaction kinetics, hydrodynamics, and thermodynamics. The framework combines first-principles modelling with ANN classification to achieve fast, data-driven yet physically meaningful model identification in a flow reactor system. Simulated results related to a case study of benzoic acid esterification in a Taylor vortex reactor show that ANN classification performance is highly sensitive to data noise but less dependent on network hyperparameters. Also, increasing the number of designed experiments mitigates noise effects and enhances model recognition accuracy. Hydrodynamic and thermal model inclusion improves the generality of the digital twin and its interpretability.

This work highlights the importance of combining physics-based and data-driven approaches in reactor model identification and provides a foundation for hybrid digital twin development in chemical and pharmaceutical manufacturing. Future work will therefore focus on the extension of the model library and the integration with the physical system.

# PREDICTING FLOW REGIMES IN A WIPED FILM EVAPORATOR USING THE VOLUME OF FLUID METHOD

## ABSTRACT

To produce complex injectable formulations, it is imperative that the contents of the formulation are not damaged during processing. Some formulations require the removal of excess solvent often through evaporation. Wiped Film Evaporators can be applied for these scenarios, since they can operate at relatively low temperatures with mass transfer being promoted through a large surface area. This is created by wiping the liquid against the inner heated wall of the equipment, with the proper operation requiring, as much as possible, a stable and continuous liquid film. In some cases, however, depending on operating conditions or physical properties of the materials, film ruptures and wetting/de-wetting dynamics are observed, and in more severe situations the liquid is dispersed in isolated globules and drops. These are undesirable situations of operation, where it is not possible to guarantee an optimal and homogenous heat and mass transfer. In this work, Computational Fluid Dynamic (CFD) simulations are used to predict a map relating operating conditions to these different flow regimes. From this fundamental knowledge, it is possible to infer operatory windows for a given task and ultimately develop a reliable model for process scale-up.

**Keywords**: Computational Fluid Dynamics, Wiped Film Evaporator, Pharmaceutical Formulations

## INTRODUCTION

Downstream processing of complex liquid pharmaceutical formulations requires a careful choice of equipment and operating conditions to avoid product damage. Such is the case of lipid nanoparticles and polymer nanoparticles, often produced as dilute suspensions, from which excess solvent must be removed under operating conditions that must not degrade the drug-charged particles [1-3]. The equipment here considered is a Wiped Film Evaporator (WFE), able to promote solvent evaporation at relatively low temperatures and shear rates.

In a WFE (Figure 1), the liquid is fed to a rotating plate that ejects it against the stationary heated wall of the main vessel. The liquid is then spread along the wall in a downwards helical pathway through spinning vertical blades (wipers), whose tip may have different geometries. The WFE under study has three wipers with tilted grooves that wipe the liquid upwards thus forcing it to rotate more in its helical path and have a longer residence time within the equipment. During operation, the evaporated solvent leaves the equipment upwards, while the concentrated liquid flows downwards and is collected at the bottom.

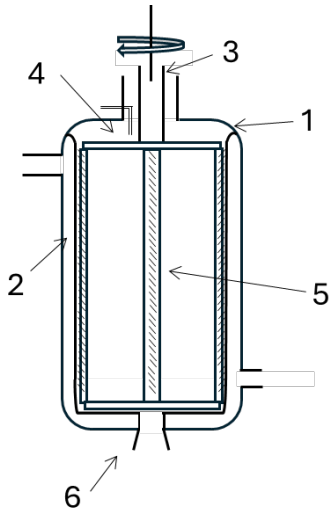

**Figure 1.** Schematic representation of a Wiped Film Evaporator. 1-main vessel; 2-heating jacket; 3-rotor; 4–feeding plate; 5- rotating wiper.

By adjusting inlet flowrate, temperature and/or rotating speed, one can in principle achieve an operating state with a reasonable evaporation rate, without exposing the mixture to excessive temperatures and wiping it gently enough, so that the suspended nanoparticles don't get damaged to the point of spilling their content. Achieving this desired state can be challenging. In some instances, other states apart from a stable wiped film are observed, such as the de-wetting of the inner wall or the formation of droplet streams instead of a constant film. These undesired flows are shown in Figure 2 and have already been reported in previous works regarding the study of WFE [4].

In this work, we present a CFD study aiming at identifying these different flow regimes using the Volume of Fluid model, well known by its ability to track complex gas-liquid interfaces. A simplified 2D version of the real flow is resolved, thus allowing to perform tens of simulations in the flowrate × rotation speed space.

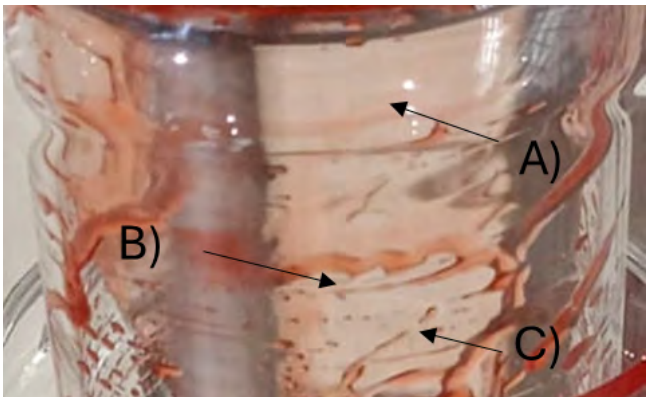

**Figure 2.** Image of our lab-scale WFE, highlighting the presence of 3 regimes: A–continuous film; B–film rupture into droplets; C–droplets.

## CFD MODELLING

### Model assumptions

The model used to simulate the film formation on the evaporator was a transient-state, laminar and multiphase model. To model the dynamic between liquid and gas, a Volume of Fluid (VoF) method was chosen. The VoF method is a commonly used technique that instead of solving momentum equations for each phase, it tracks the fraction of a phase in any given cell, in this case the volumetric fraction of liquid (α). The properties of the fluid are then calculated in each finite volume as a function of α, such as shown in Equation 1 for density. The sharp interface definition, which is of the highest interest in this case, is modeled through Equation 2, where $F_\sigma$ represents the surface tension forces, $k$ the curvature of the interface and σ the surface tension between both fluids. $F_\sigma$ is added to the momentum balance and is what allows the VoF method to capture interface dynamics with great precision, given that the mesh chosen has enough finite volumes.

$$\rho = \alpha\rho_{liquid} + (1 - \alpha)\rho_{gas} \quad (1)$$

$$F_\sigma = \sigma k \nabla\alpha \quad (2)$$

Since the objective is to study the interface, a cross-section cut of the WFE was considered, thus the simulations carried out were 2D simulations. The cross section chosen is assumed to be around the middle of the equipment, where the fluid profiles should be well developed. This dimensional simplification drastically reduces computational time and can still give a good approximation of the regime in the WFE, although the lack of gravity is noticeable and will be discussed further in the next sections. The geometry used is present in Figure 3, along with the chosen boundaries.

During WFE operation, the rotating wipers can leave the rotor frame and move out, towards the inner wall, due to the centrifugal force [5]. Thus, since they are not fixed in any given position, to model the presence of the wipers, a porosity model was used. The porosity zone is presented in Figure 3 also. The chosen porosity model was the Darcy-Forchheimer equation, but only the viscous resistance was considered, since the Reynolds numbers of the simulations to study correspond mainly to laminar flows. The value used for viscous resistance coefficient was $4\times10^7\ m^{-2}$.

In this first approach, only the momentum transfer was considered, as for the time being it is only of interest to determine if the models can predict the scenarios of continuous film, film break or droplets. For the simulations considered, the liquid phase has the physical properties of water, while the gas was considered to have those of air. The model is solved with all velocities being relative to the spinning blades, as if blades were stationary and the inner wall was sliding (at the same speed of the blades and in the opposite direction). The relative velocities are reverted to absolute ones in the post processing of the simulation results.

In this 2D model it is not possible to directly manipulate the flow rates for the liquid entering the cavity, therefore the parameters to manipulate are the inlet velocity ($U_{in}$), inlet thickness of the fluid (ε), as well as the velocity of the sliding wall ($U_{wall}$). The values of $U_{wall}$ are calculated based on the equivalent rotating wall velocity. To approximate to flowrate values, in the following sections, the product of ε and $U_{in}$, $\varepsilon U_{in}$, will be considered for the global dynamic profile analysis.

### Boundary Conditions

The inlet water velocity is a fixed value and although dependant on the scenario studied, its values are always related to those of $U_{wall}$. For scenario A the water enters the cavity fully wetting the sliding wall, with a parabolic

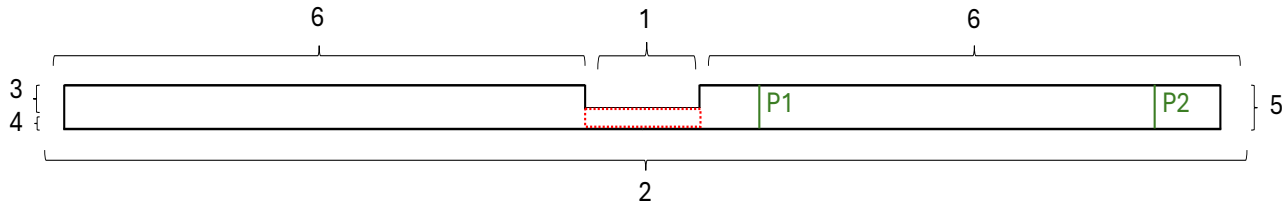

**Figure 3.** Cavity geometry and its boundaries. 1-resting blade; 2-sliding wall; 3-air inlet; 4-water inlet; 5-outlet; 6-back outlet. The dashed red line represents the porous media, and the green lines represent the P1 and P1 points.

velocity profile that increases the closer it is to the sliding wall, with $U_{wall}$ being its maximum value. On the other hand, in scenario B it is assumed that the water enters diagonally relative to the sliding wall, approximately 2 *mm* above said wall, and with less kinetic energy than it. The velocity profile in this scenario B is a linear velocity, that is dependant on $U_{wall}$. Both scenarios were created to study: the water entering has an already established, well-defined profile for scenario A, while for scenario B studies the initial feed of liquid in the WFE, and how the difference of kinetic energy between feed and sliding wall may influence the flow pattern.

The air inlet and back outlet allow for air to leave but does not allow backflow. The outlet on the right side of the cavity has a similar boundary condition, allowing for matter to leave, but blocking backflows. The inner sliding wall has a fixed velocity, due to the exchange of reference with the rotating wiper. Thus, the wiper boundary has a no slip condition for velocity.

For the pressure, in the outlets the pressure was fixed as the atmospheric pressure, while the remaining boundaries were calculated depending on the flow on the cells near that boundary.

On the volumetric fraction side, it is important to note that for the inner sliding wall, a boundary condition that fixes the contact angle for water-air-glass was chosen, in order to better describe the interaction of the fluids with this wall, and to create more realistic and sharper droplets, in the cases where they appear.

For the face of the front and back of the cavity, a special boundary condition was chosen to not solve the momentum equation in the axial direction, thus making this a proper 2D simulation.

### Meshing

The chosen mesh for this simulation corresponds to a rectangular cavity, with a height of 4 *mm*, and a width corresponding to a third of the perimeter of the evaporator, totaling 12 *cm*. The number of cells is around 33 000. From previous studies, it is imperative that in the gap between the resting blade and the inner wall, which is 2 *mm*, at least 16 cells are present, to capture the interface sharply [6]. In this study, a minimum of 28 cells were used to describe the gap, and for the cases where the feed height is smaller, more cells were used.

The simulations were conducted using the *openFOAM®* v2412 software, on a workstation equipped with an AMD Ryzen Threadripper™ PRO 7995WX, and 256 Gb of RAM. Post processing was carried out on the paraView software, along with using the Python™ pyVista package.

## SIMULATION RESULTS AND DISCUSSION

As referred above, two scenarios where studied: A – a scenario where the inlet flow is parallel to the sliding wall, the inlet velocity was kept constant and ε varied between a defined range (Figure 4A and 4B); B – another one where ε has a fixed value, but the inlet velocity value varies, and its position is so that water enters diagonally to the sliding wall (Figure 4C). For scenario A, a range of $U_{wall}$ and $\varepsilon$ used were as follows: $U_{wall}$ = [0.48; 0.64; 0.80; 0.96] *m/s*, and ε = [0.25; 0.5; 1.0 1.5; 2.0] *mm*, while for scenario B the range of $U_{wall}$ used was the same as A, while the inlet thickness was a fixed value of ε = [0.25] *mm*. Furthermore, in scenario B the inlet velocity $U_{in}$ varied based on the sliding mesh linear velocity by factors of [25; 50; 75; 100] *%*. The tests were conducted until the liquid thickness at positions P1 and P2 (see Figure 3), 2 *cm* after reaching the porous media and 1 *cm* before the main outlet, were considered constant, as well as analyzing the match between inlet and outlets flows. If both analyzes are constant, it is assumed that the simulation has achieved a steady state. The simulation time required to achieve a steady state varies according to the values of $U_{wall}$ and ε. For the cases where droplets formed, the thickness was not evaluated, but rather the periodicity of the droplet formation. For cases where full film was formed, the convergence of the thickness analysed at P1 and P2 varies for each simulation condition, being as low as 0.17s (Scenario A, $U_{wall}$ = 0.96 *m/s*; ε = 0.25 *mm*), and as high as 0.52s (Scenario A, $U_{wall}$ = 0.64 *m/s*; $\varepsilon$ = 0.25 *mm*), for example.

The CPU Clocktime for each simulation varied according to the value of $\varepsilon$, since smaller values of ε required finer meshes. The range of clocktimes was between [1650;2500] *s* per each second of results obtained.

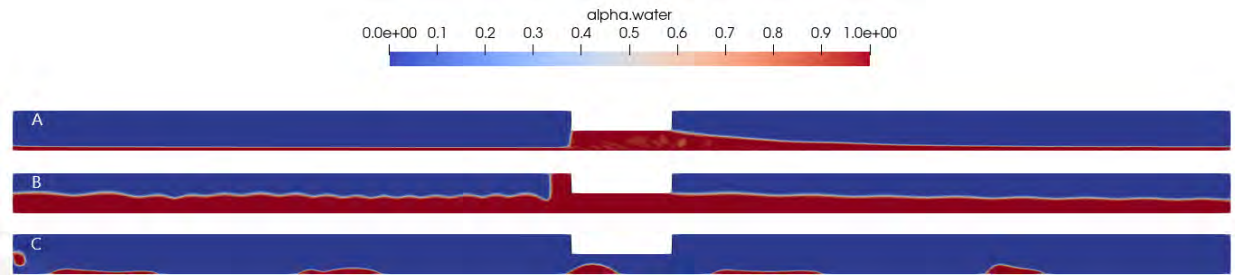

**Figure 4.** 2D representation of the fields of water volumetric fraction, showing examples of the different types of liquid film profiles identified during the simulations. A – Fully formed film (Scenario A, $U_{wall}$ = 0.64 m/s, ε = 0.5 mm); B – Film with overflow (Scenario B, $U_{wall}$ = 0.48 m/s, ε = 2.0 mm); C – Droplets (Scenario B, $U_{wall}$ = 0.64 m/s, $U_{in}$ = 0.32 m/s).

In each simulation the wetting behaviour of the liquid in the inner wall was analysed, to understand if it would fit one of the three categories at the main outlet: droplets, intermediate state from droplets to film, and finally a fully formed film. The simulations for scenario A showed full films and a different category, which was film overflowing form the cavity, while for scenario B the results varied between droplets and full film. An example of each of those cases are presented in Figure 4. To note that the characteristic "bow-wave" is formed in front of the blade, are visible in in those cases as well. The global analysis of the dynamic profile for the batch of simulations conducted is organized in the plots of Figures 5 and 6. Based on those results, it possible to identify some patterns for both scenarios. For scenario A, in the cases where $\varepsilon U_{in}$ are higher seem to lead more to the formation of liquid overflow, while for the cases where $\varepsilon U_{in}$ is smaller tendentiously lead to clear thin formed films. These phenomena can be interpreted as: the thinner films suffer less disruption from the porous media, meaning that they are less wiped by the rotating blade. Antithetical, the thicker films offer a larger liquid mass to be wiped by the blade, creating bigger bow waves in the front of the blade, and making so more liquid accumulates in that bow wave. This conclusion can also be corroborated by the $\alpha$ profiles shown in Figure 4. To overcome this, it is necessary to augment the values of $U_{wall}$ for a given $\varepsilon U_{in}$, similarly to what happened for cases like $U_{wall}$ = [0.80; 0.96] $m/s$, and $\varepsilon U_{in} \approx$ [0.75:1] $m^2/s$, for example.

For Scenario B, meant to replicate the first passage of the liquid in the WFE, it is possible to see that for lower values of $U_{in}$, meaning lower inlet flow, it is not possible to develop a clear film right from the start. The droplets turn to complete film by augmenting the inlet flow, and it is possible to analyze that lower sliding wall velocities, like $U_{wall}$ = 0.48 $m/s$, can not produce complete films from this diagonal feed but instead will produce pulses of droplets. This can be interpreted as follows: since the inlet liquid lacks kinetic energy compared to the scenario where it enters already wetting the wall and with a well-defined velocity profile, it is important to have a sliding wall that can provide enough kinetic energy to fully spread the liquid so that it forms a film.

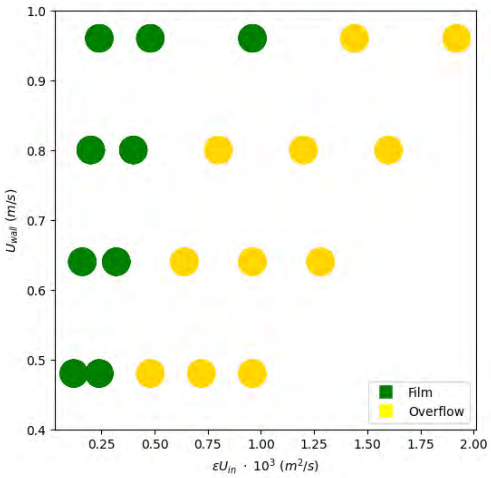

**Figure 5.** Flow regime map for the simulations of Scenario A.

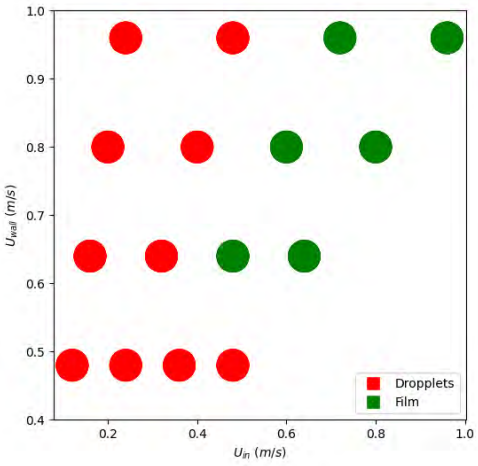

**Figure 6.** Flow regime map for the simulations of Scenario B.

Despite the promising results shown for the higher values of $U_{wall}$, working in a range of [0.80:0.96] *m/s*, or even above, may not be of interest to treat more sensitive pharmaceutical formulations. Furthermore, it is important to note that, the smaller the value of $U_{wall}$, the more noticeable the effects of gravity should be felt by the liquid in the real evaporator, since the gravitational force pulling downwards needs to be overcome by the centrifugal force the wiper combs spreading the fluid continuously. Without gravity, it is possible to identify the formation of droplets with considerable thickness and width, and the amount of liquid pushed in the bow wave also increased due to the lack of gravitational force, enabling it to accumulate. These phenomena can be seen on Figure 4B and 4C and should not be discard when analyzing the results. The larger droplets appear mostly in cases were the difference in kinetic velocity between $U_{wall}$ and $U_{in}$ is higher, and these cases were categorized as droplets. It was known that the initial assumptions would limit the model capability of replicating every aspect of the original equipment, nonetheless the computational speed reduction gained, as well as the sharp interface description demonstrated that there is value in these more elementary simulations.

To be able compare these results to a lab-scale evaporator, an auxiliary technology to determine film thickness inside the WFE would be necessary, such a high-speed image capturing equipment.

## CONCLUSIONS AND FUTURE WORKS

From these simpler cases solved, it is possible to determine that the VoF method can describe the phenomena registered when operating a WFE for lower ranges of sliding wall velocity, initial film thickness and lower initial kinetic energy. The porosity model proved to be capable of retard the fluid movement enough to generate regimes that differ from the simple continuous film, and even creating the classic bow wave in front of the blade. The frame of reference exchange also proved viable, meaning that in future simulations it may be a useful alternative to the more conventional modelling approaches.

A range of operatory sliding wall velocities was also defined as best to be avoided, since there was fluid rupture and droplet formation for those cases. In spite of the simplifications used in the modeling step, this work proved that it is still possible to attain valuable information from this 2D simulations, and the creation of this first map of flow regimes will be most useful for future works, be it fully developed 3D models, or even for equipment scale-up.

Using this work as a base, the next step is to naturally transition to a more complex 3D model of the equipment, where gravity will play a crucial role in describing the dynamic behaviour of the film. It would also be an interesting complementary work to acquire high speed imaging inside a WFE to better identify the cases of film rupture, to then calibrate the 3D model. It would also be of interest to refine the porosity model or verify experimentally if the parameters can be optimized to match the effect that the wipers have on the fluid, be it interface definition or residence time.

## ACKNOWLEDGEMENTS

The authors have the pleasure of acknowledging the support from “CiNTech - Technological Hub for Innovation, Translation and Industrialization of Complex Injectables Drugs” (reference:7131), in the scope of PRR – Recovery and Resilience Plan and by the Next Generation EU European Funds. ## ABSTRACT

Fouling is a persistent issue in industrial heat-transfer equipment, increasing energy demand and reducing efficiency. This is also true in the dairy industry where falling-film evaporators are central to powder production. Most dynamic models, however, neglect gradual fouling, limiting predictive accuracy during extended operation. As a result, model-based control can become unreliable when fouling becomes significant. The dynamic models by Bojnourd et al. [1] are widely used but assume clean-surface operation. While this captures short-term thermal behavior, it cannot represent the progressive decline in heat-transfer performance caused by fouling. Díaz-Ovalle et al. [2] introduced a fouling-layer model that explicitly describes the growth of a fouling deposit over time. Building on this concept, the present work incorporates a simple dynamic fouling model for falling-film evaporators and validates it using industrial data from a four-effect evaporator using thermal vapor recompression. Two fouling-modelling strategies are evaluated: a mechanistic fouling layer model and an empirical model describing the observed loss in heat-transfer efficiency. The fouling layer model substantially reduces prediction error, demonstrating that it captures the dominant fouling behavior. Although the empirical model fits all observed discrepancies, it lacks predictive capability and therefore cannot be applied for model-based prediction or control.

**Keywords**: Fouling dynamics, Falling-film evaporator, Dynamic modelling, Dairy industry

## 1. INTRODUCTION

The dairy industry uses drying to extend product shelf life and reduce transportation costs [3]. Dairy powder production relies on two main unit operations: falling-film evaporation and spray drying [4]. Spray drying is the most energy-intensive step, followed by falling-film evaporation. To lower overall operating expenditures, a falling-film evaporator is typically used beforehand to remove part of the water content [4]. In a falling-film evaporator, the liquid feed flows as a thin film through multiple vertical tubes, with hot steam applied on the other side. Water evaporates from the film, and a concentrated liquid exits the tubes, as illustrated in Figure 1. Optimizing the overall drying process requires maximizing the solids content at the evaporator outlet. Higher concentrations, however, increase the risk of fouling, a well-known challenge in evaporation systems. Fouling refers to the unwanted accumulation of deposits in process equipment, typically consisting of minerals, organic matter, and biological growth [5], as illustrated in Figure 2. Fouling reduces heat-transfer efficiency, which increases energy consumption and cleaning costs [2]. In thermal treatment of dairy products, fouling is caused by multiple interacting reactions, making the mechanisms difficult to capture [7]. The main reactions are protein agglomeration and salt precipitation. The initial protein agglomeration forms a monolayer on the heating surface in a slow "induction period," during which heat transfer is not significantly affected [8]. After the induction period, the fouling layer grows more rapidly on the protein layer surface.

This study uses industrial data from a four-effect evaporator with thermal vapor recompression (TVR) to develop and validate a simple model of fouling behavior. Validation includes estimating the fouling parameters incorporated in the model.

## 2. METHODOLOGY

### 2.1 Industrial case study

The available data for the 4-effect TVR evaporator is summarized in Table 1. Measurements are

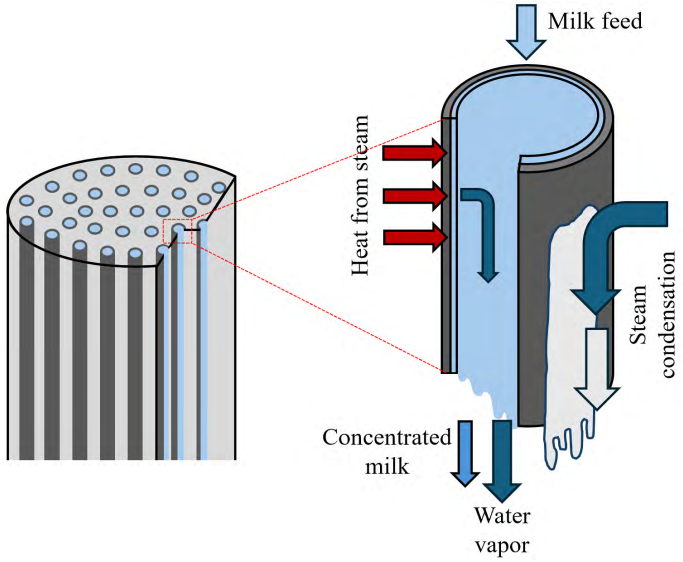

**Figure 1.** Basic principles of a falling-film evaporator.

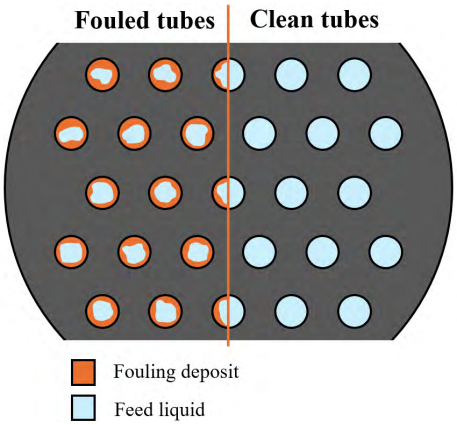

**Figure 2**. Illustration of fouling deposits in evaporator tubes.

recorded every 60 seconds. While the system's power consumption is also monitored, it is not required for simulation because both vapor and steam temperatures are measured, which are sufficient to model energy balances. Table 1 lists the measured variables, their descriptions, and units for both the industrial data and the simulation.

**Table 1:** Available data for a 4-effect TVR evaporator with data collected every 60 sec.

| Symbol | Description | Unit |
|---|---|---|
| $F_{in}$ | Feed flow | kg/h |
| $x_{in}$ | Feed mass fraction | w/w% |
| $T_{steam}$ | Steam temperature | °C |
| $T_{vapor}$ | Vapor temperature | °C |
| $F_{out}$ | Outlet flow | kg/h |
| $x_{out}$ | Outlet mass fraction | w/w% |

To ensure mass balance consistency, the industrial data are reconciled by accounting for a systematic bias in the feed concentration, $x_{in}$, and reducing measurement noise using a weighted least-squares method:

$$\min_{\hat{z}} \sum_{n=1}^{N} \sum_{k=0}^{K} \left( \frac{\hat{z}_{n,k} - z_{n,k}}{\sigma_n} \right)^2 \quad (1)$$

Subject to the mass balance constraint:

$$\hat{F}_{in} \cdot \hat{x}_{in} - \hat{F}_{out} \cdot \hat{x}_{out} = 0 \quad (2)$$

where $z = [F_{in}, x_{in}, F_{out}, x_{out}]$ are measured values, $\hat{z} = [\hat{F}_{in}, \hat{x}_{in}, \hat{F}_{out}, \hat{x}_{out}]$ are reconciled values and $\sigma_n$ is the standard deviation for each variable in a steady state region. $N$ and $K$ are the number of variables and measurements, respectively. This reconciliation ensures a consistent mass balance even with sensor calibration errors or other systematic biases.

## 2.2 MATHEMATICAL MODELS

The evaporator dynamics are modeled using lumped models in both radial and axial directions, following Bojnourd et al. [1]. These models fit industrial data reasonably well when fouling is negligible. The mathematical description is divided into a base model, assuming no fouling, and a fouling layer model, incorporating fouling effects based on literature [2].

### Base Model

The base model is governed by the following ODEs:

$$\frac{dF_{out}}{dt} = \frac{1}{\tau(1-\alpha)}(F_{in} - F_{out} - F_e) - \frac{\alpha}{1-\alpha}\frac{dF_{in}}{dt} \quad (3)$$

$$\frac{dx_{out}}{dt} = \frac{F_{in}(x_{in}-x_{av}) - F_{out}(x_{out}-x_{av}) + F_e x_{av}}{\tau(1-\alpha)F_{av}} - \frac{\alpha}{1-\alpha}\frac{dx_{in}}{dt} \quad (4)$$

Here, $F_{out}, F_{in}$ and $F_e$ are the outlet, feed and evaporated mass flows respectively. $x_{in}$ and $x_{out}$ are inlet and outlet solid mass fraction. $t$ is time, $\tau$ is residence time and $\alpha$ is an averaging parameter used to define $x_{av}$ and $F_{av}$ in Equations (5) and (6).

$$F_{av} = \alpha F_{in} + (1-\alpha)F_{out} \quad (5)$$

$$x_{av} = \alpha x_{in} + (1-\alpha)x_{out} \quad (6)$$

The evaporated flow, $F_e$, is defined through the heat transfer from the steam to the liquid as shown by equation (7).

$$F_e = \frac{U \cdot A \cdot (T_{steam} - T_{vapor})}{H_{vap}(T_{vapor})} \quad (7)$$

Where $U$ is the overall heat transfer coefficient across the tube, $A$ is the surface area of the tubes, $T_{steam}$ and $T_{vapor}$ are the temperatures on the steam side of the tube and inside the tubes respectively. The heat of vaporization, $H_{vap}(T)$, is based on pure water and described using a fourth order polynomial based on experimental data.

The unknowns in the base model are $U, A, \tau$. The value $U \cdot A$ can be estimated using a pseudo steady-state approximation over the first 20 minutes of operation:

$$UA_{base} = \text{mean}\left(\frac{H_{vap}(T_{vapor}[1:20]) \cdot (F_{in}[1:20] - F_{out}[1:20])}{T_{steam}[1:20] - T_{vapor}[1:20]}\right) \quad (8)$$

When no fouling is present this value is expected to fit the whole dataset. The final unknown parameter, the residence time $\tau$, is theoretically expected to vary with changes in the flow within the system; however, it was observed through fitting $\tau$ that a value of 60 s was reasonable for all mass flows in the data. This constant value is used in all simulations.

### Empirical Fouling Model

When fouling occurs, the heat transfer decreases because the fouling layer has lower thermal conductivity than the tube material. A pseudo steady-state approximation is used over 5-minute intervals to estimate the effective heat transfer coefficient. This is done to reduce noise.

$$UA = \frac{H_{vap}(T_{vapor}) \cdot (F_{in} - F_{out})}{T_{steam} - T_{vapor}} \quad (9)$$

This approach helps to quantify the reduction in heat transfer due to fouling.

### Fouling Layer Model

A detailed fouling mechanism involves multiple reactions. The fouling layer model is based on the work by Díaz-Ovalle et al. [2], however the model is simplified heavily due to the many unknown parameters. The model is based on the fouling layer thickness, $\delta$, growing over time, resulting in a decreased heat transfer coefficient.

$$\frac{d\delta}{dt} = \frac{k_d k_f}{U_C Re} \exp\left(-\frac{E}{R} \cdot \frac{k_f + \delta U_C}{k_f T_{steam} + T_{vapor} U_C}\right) - k_r \delta \quad (10)$$

Here the first term describes a deposition rate, dependent on the fouling parameters, flow regime and the temperatures in the system. The second term describes a removal rate, only dependent on the current fouling thickness and the parameter $k_r$, which is the rate of fouling layer removal. $k_d$ describes the deposition rate, with $k_f$ being the thermal conductivity of the fouling layer, $Re$ is the Reynold number of the system, $E$ is the activation energy of the overall fouling reaction and $R$ is the universal gas constant. The corrected heat transfer coefficient, $U_C$, is defined in Equation (11).

$$U_C = \left(U_0^{-1} + \frac{\delta}{k_f}\right)^{-1} \quad (11)$$

Where $U_0 = UA_{base}/A$ is the initial heat transfer coefficient where fouling is not present. Only the ratio $\delta/k_f$ appears in $U_C$, resulting in $\delta$ and $k_f$ are not being uniquely identifiable and they may scale together unless one of their magnitudes is known. For solid proteins the thermal conductivity is between 0.1-0.3 W/(m K) [9, 10] which is assumed for the fouling layer. The ODEs for the flow and solid mass fractions are identical to Equations (3) and (4) with the evaporated mass flow now being described with $U_C$ as shown by Equation (13).

$$F_e = \frac{U_C \cdot A \cdot (T_{steam} - T_{vapor})}{H_{vap}(T_{vapor})} \quad (13)$$

Initial simulations indicated that, within the fouling layer model, both the temperatures and the corrected heat transfer coefficient $U_C$ could be treated as constant, since their variation had a negligible effect on the results. The fouling layer model is simplified and defined through three constant parameters $K_{\text{pre}}, K_{\text{exp}}$, and $k_r$.

$$\frac{d\delta}{dt} = K_{pre} \cdot \exp(-K_{exp} \cdot \delta) - k_r \delta \quad (14)$$

$$K_{pre} = \frac{k_d k_f}{U_C Re} \cdot \exp\left(-\frac{Ek_f}{R(k_f T_{steam} + T_{vapor} U_C)}\right) \quad (15)$$

$$K_{exp} = \frac{E \cdot U_C}{R(k_f T_{steam} + T_{vapor} U_C)} \quad (16)$$

The output data are used to determine these fouling parameters, along with the surface area, which is also unknown for the specific evaporator configuration. The fouling model is applied only when fouling is actively reducing heat transfer. Therefore, the simulation is divided into two segments: an induction period, during which the base model is used, and the post-induction period, where the fouling model is applied.

The induction period is determined by calculating the needed $UA$ from Equation (9) and determining when the heat transfer decreases by 1% from the baseline in Equation (8). To ensure robustness, this decrease must persist for at least five consecutive measurements before the induction time is assigned.

## 3. SIMULATION RESULTS AND DISCUSSION

The initial conditions for the outlet flow and solid mass fraction are defined based on the first measurement. In all simulations, a value of $\alpha = 0.5$ is used, however, the exact value was found to have little influence on the simulation results [1]. Other constant parameters include a residence time of $\tau = 60\,\mathrm{s}$, and a thermal conductivity of the fouling layer of $k_f = 0.2 \frac{\mathrm{W}}{\mathrm{m\,K}}$. All results are presented as normalized values, normalized to the maximum value of measured data in each subplot.

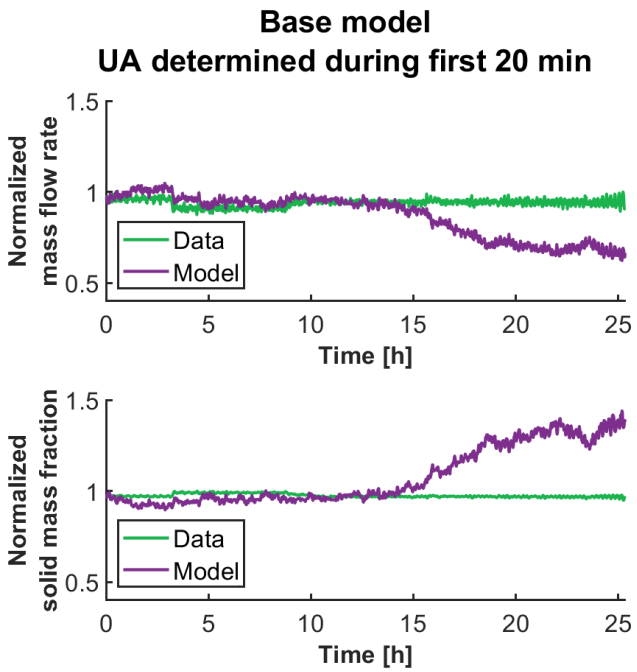

**Figure 3.** Simulation using base model.

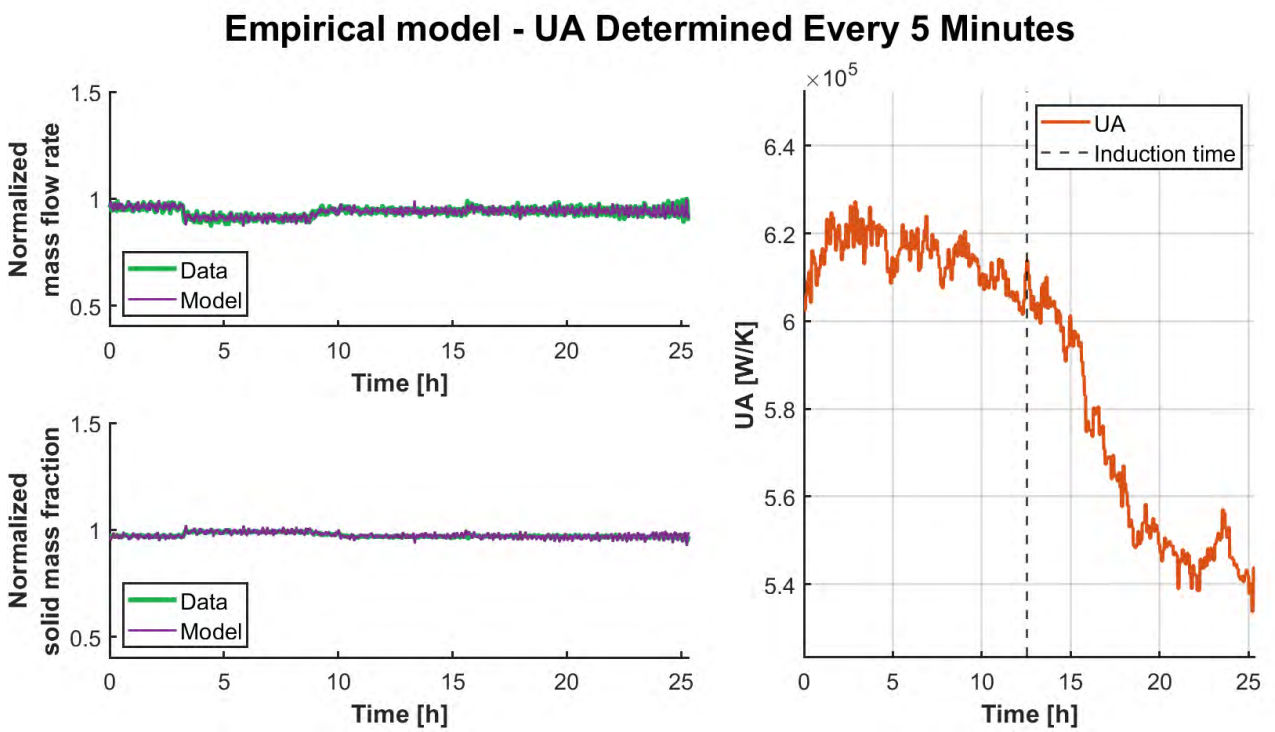

**Figure 4.** Simulation using empirical model, correcting the heat transfer coefficient $UA$.

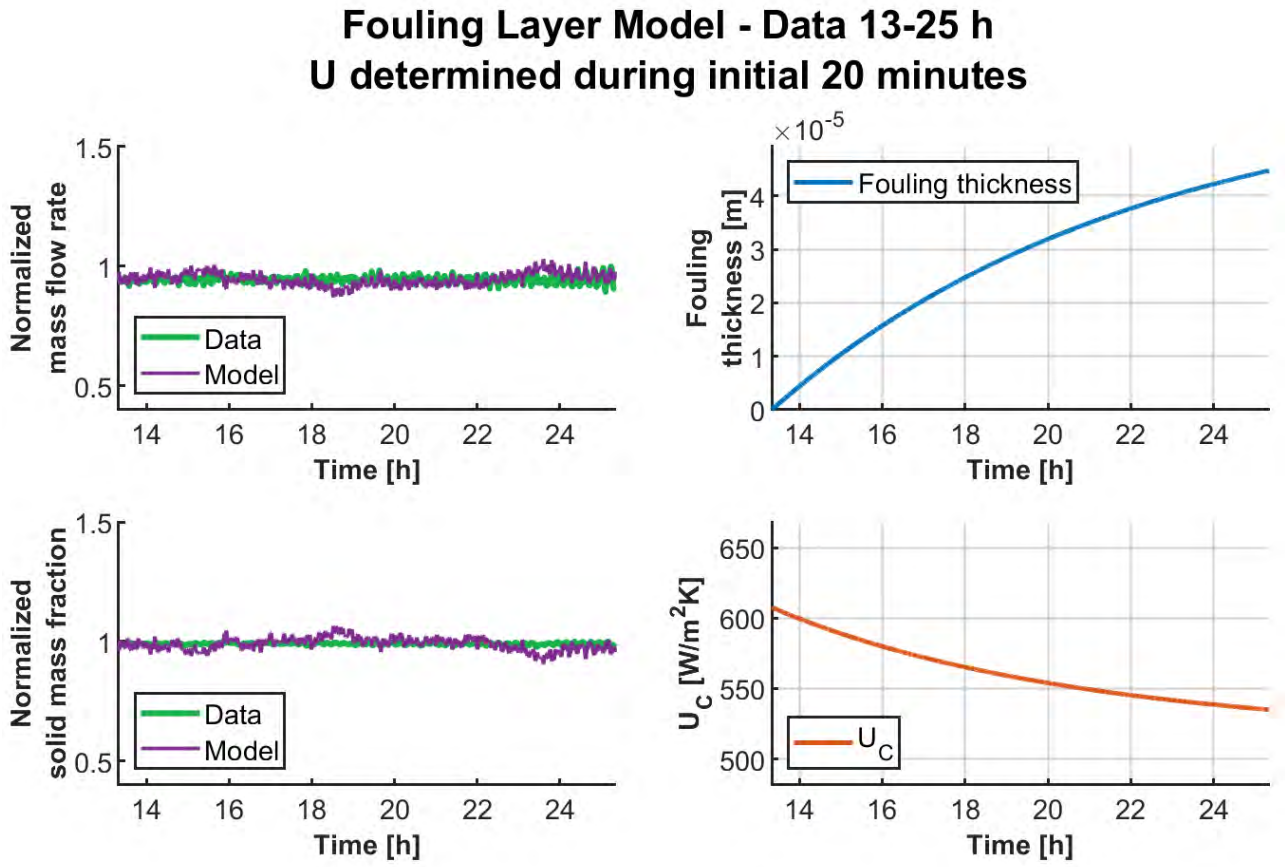

**Figure 5.** Simulation using fouling layer model on fouling data after the induction period.

The initial simulations using the base model, shown in Figure 3, illustrate the model's limited predictive capability. During the induction period, $t = [0, 13]$ h, the base model provides a reasonable fit. After approximately 12 hours, the model predictions increasingly deviate from the measured data. The empirical approach presented in Figure 4 shows a relatively constant overall heat transfer coefficient ($UA$) up to 12 hours, after which a noticeable decrease in heat transfer occurs. This decline correlates with the discrepancies observed in the base model predictions.

**Table 2:** 95% CI of the fouling parameters estimated for hour 13-25.

| Parameter | Estimated value: 95% CI | Unit |
|---|---|---|
| $A$ | $1000 \pm 294$ | m$^2$ |
| $K_{pre}$ | $[1.90 \pm 0.56] \cdot 10^{-9}$ | m/s |
| $K_{exp}$ | $[5.14 \pm 2.02] \cdot 10^{-2}$ | 1/m |
| $k_r$ | $[3.16 \pm 0.27] \cdot 10^{-5}$ | 1/s |

**Table 3:** Fouling parameters estimated for 8 runs, with the surface area fixed at 500 m$^2$.

| Parameter | Estimated value: 95% CI | Unit |
|---|---|---|
| $K_{pre}$ | $9.55\ (+0.46/-0.44) \cdot 10^{-10}$ | m/s |
| $K_{exp}$ | $4.12\ (+1.0/-0.81) \cdot 10^{4}$ | 1/m |
| $k_r$ | $1.02\ (+17/-0.96) \cdot 10^{-6}$ | 1/s |

The data from hours 13 to 25 are simulated in Figure 5 using the fouling model. The unknown parameter vector $p = [A, K_{pre}, K_{exp}, k_r]$ is fitted to the output data using a minimizing function. The 95% confidence intervals (CI) of the optimal parameters are presented in Table 2.The simulation results shown in Figure 5 indicate that the simplified fouling layer model, employing constant parameters, fits the experimental data well. The parameter estimation was performed using a statistical approach, yielding a cross-correlation matrix shown in Figure 6. This analysis reveals a strong correlation between the surface area $A$ and the parameters $K_{pre}$.

Furthermore, the simulations demonstrated that different initial conditions could lead to different parameter sets while producing the same total error. To mitigate the

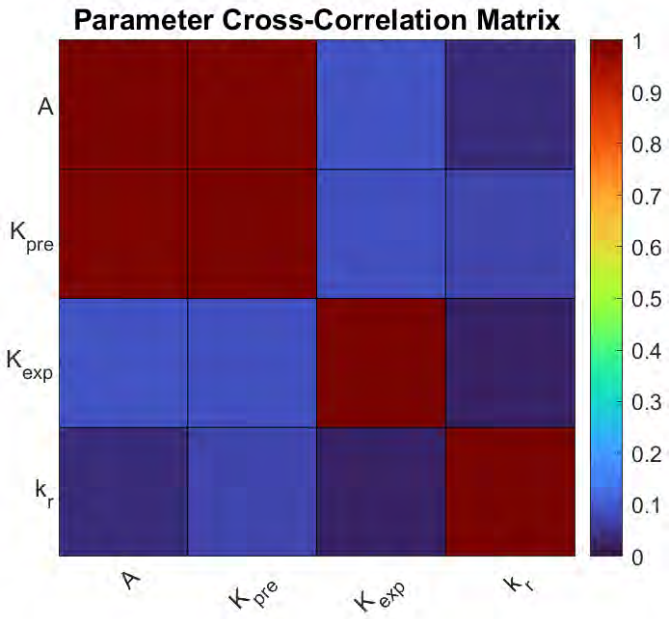

**Figure 6.** Parameter cross correlation matrix.

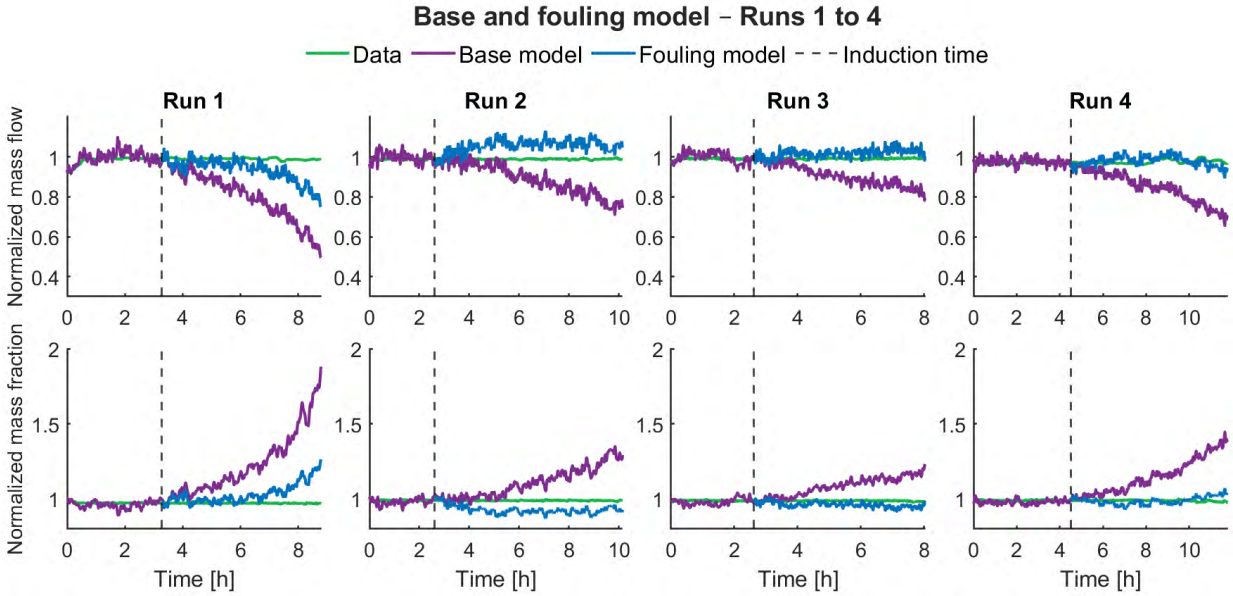

**Figure 7.** Simulation of run 1-4 using the optimal parameters in Table 3.

issue of multiple parameter solutions, the surface area is fixed at $A = 500\ \mathrm{m}^2$ for an extended parameter estimation.

A more global parameter estimation is performed using data from eight runs with the same feed type, each consisting of approximately 600 operational measurements. For all runs, the error between the model predictions and the measured data is included in a global optimization procedure. The data from the eight runs are distributed seasonally throughout the year and correspond to different durations of initial cleaning. This approach is adopted to evaluate the robustness of the estimated fouling parameters. The resulting parameter values are presented in Table 3, where the confidence intervals are asymmetric because the parameters were estimated on a logarithmic scale.

These parameters are applied in the simulation shown in Figure 7, where the fouling model becomes active after the induction period. The maximum relative error and the average relative error are calculated for all eight runs and are presented in Figure 8. The results clearly demonstrate that the use of the fouling model significantly reduces the prediction errors compared to the

base model, with the exception of run 5, for which both models perform equally well. using the fouling model compared with the base model. Runs 6-8 show behavior very similar to runs 1-4 and are therefore omitted.

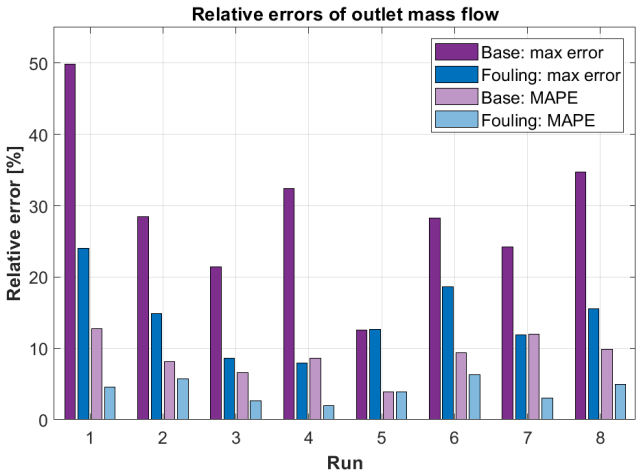

**Figure 8.** The maximum and average relative errors obtained using the fouling model compared with the base model.

The parameters estimated from individual runs generally exhibit substantial variability, particularly for the parameter $K_{exp}$ which can span several orders of magnitude. In contrast, the value of $K_{pre}$ and $k_r$ show less variation. This variability in the fouling parameters may be attributed to changes in feed composition due to seasonal variations and/or differences in the operating conditions of the evaporator resulting from variations in cleaning procedures. The induction time was not observed to depend on the duration of the cleaning process.

## FUTURE APPLICATION

The primary motivation for employing a simple model is to facilitate its use in process control of evaporator systems, where fouling significantly influences system behavior. Model predictive control (MPC) requires models that can reliably predict future system dynamics. A more accurate fouling model could improve control performance by enabling faster and more appropriate system responses.

The model is sensitive to parameter variations, particularly when only limited measurements are available, which can lead to uncertainty and non-unique solutions during early fouling, reducing control robustness. To address this, model parameters for different milk types could be systematically mapped and analyzed under varying feed compositions. This approach may provide a deeper physical understanding of fouling behavior and allow control sequences to anticipate fouling layer growth without estimating parameters for each individual run.

## CONCLUSION

It has been shown that incorporating a simple fouling model in the dynamic operation of a four-effect falling-film evaporator leads to a substantial improvement in overall model performance.

The fouling layer model was shown to significantly improve predictive accuracy, reducing model errors by a factor of two or more in most cases. Using data from eight operational runs with the surface area fixed at 500 m², the fouling parameters were estimated as $K_{pre} = 9.55 \cdot 10^{-10}$ m/s, $K_{exp} = 4.12 \cdot 10^{4}$ 1/m and $k_r = 1.02 \cdot 10^{-6}$ 1/s, with $k_r$ having a rather large confidence interval.

Although the model is sensitive to parameter variations, and the estimated parameter values can vary by several orders of magnitude due to seasonal changes in feed composition and differences in cleaning conditions, the inclusion of fouling dynamics consistently results in a substantially better fit than a model that neglects fouling altogether. These results demonstrate that even a simplified, physically motivated fouling model can provide robust improvements in predictive performance, supporting its applicability for both simulation and control-oriented applications in evaporator systems.

## ABSTRACT

Slug flow in multiphase production systems is a critical challenge in the oil and gas industry, characterized by complex and oscillatory dynamics, e.g., limit cycles. First-principle (FP) models often employ physics simplification, such as a virtual valve for the slug formation. To capture complex physics poorly modeled by FP models, hybrid models combine data-driven techniques and physical knowledge, such as the architecture known as universal differential equation (UDE). This work aims to employ a hybrid model based on neural networks to enhance the modeling of multiphase oil production systems. In the UDE model, a neural network is embedded within the structure of the FP differential equations. To demonstrate the feasibility of the methodology, the model was trained based on synthetic data, employing parameters estimated from OLGA simulations. Since the system faces oscillatory behavior, we trained the UDE in two stages: the first one employs smooth collocation on data to obtain an estimation of the derivatives. The results show that the two-stage strategy was successful in addressing the resolution of an oscillatory system. In the second stage, the algorithm reached a scaled MSE of 0.009 in 502 iterations. For the testing phase, using 20%, 40%, 60%, and 80% valve openings, the scaled MSE reported was 0.088. For the 100% valve opening, outside of the training part, the MSE reported was 0.039, showing a good extrapolation capacity.

## INTRODUCTION

After early works of machine learning (ML) in the 1990s in process systems engineering (PSE) [1], ML in the PSE field has experienced a growing interest due to the greater computational power available, simultaneously with the development of novel algorithms. This legacy was further employed to enhance first-principles (FP) models, which, in general, employ simplifying assumptions in their formulation. Therefore, research dedicated to incorporating physics into ML has attracted the attention of the scientific and engineering community in recent years, under the name physics-informed machine learning (PIML) [2], a class of hybrid models.

The advantages of hybrid models include improving the interpretability of neural network architectures [3]. Furthermore, ML can update the FP model based on new data. For instance, providing new terms in an equation if physics is partially known [4]. Machine learning is generally a good interpolator, but its results outside the data domain may fail and become unsatisfactory. On the other hand, when PIML is appropriately designed and trained, it can gain the capacity to extrapolate [5]. A third benefit of integrating physics into machine learning is promoting data parsimony: the data collection can be simple, but not simpler than required [5]. Therefore, the junction of the two fields can accelerate discovery in the field of science and engineering and enforce known physics.

The oil and gas industry faces various financial, operational, and environmental constraints. As a result, it is essential to develop dynamic models that account for complex behaviors to improve control, monitoring, and

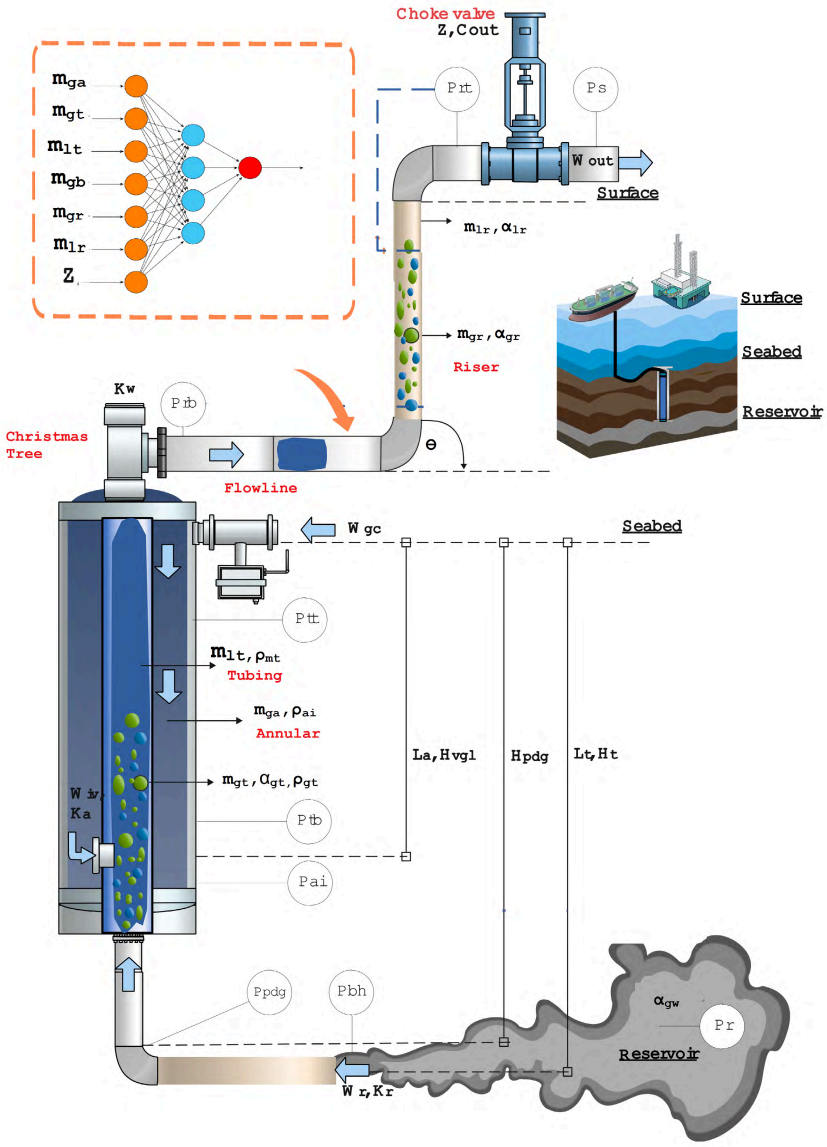

**Figure 1.** Neural Fast Offshore Model. Adapted from [11].

optimization. Neural networks can approximate the dynamic models, the so-called neural ordinary differential equations (NODEs). NODEs are designed by parametrizing the derivative of the hidden state using NNs. Then, it can be solved employing the adjoint method, which involves set of differential equations solved backward in time [6]. Physical constraints, also known as inductive bias, can be combined with the NODE in a universal differential equations (UDE) model [7]. In the oil and gas field, hybrid models combined with neural networks were performed by Kittelsen et al. [8], who employed physics-informed neural networks (PINNs) as a surrogate model for controlling gas-lift wells. However, PINNs need to consider the knowledge of the model in advance. In this sense, Faria et al. [9] developed a UDE model for gas-lift wells; however, the work aimed to replace algebraic equations with NNs for parameter estimation, without considering slug flow.

One significant challenge encountered by the industry is slug flow in multiphase flows. This phenomenon occurs when accumulated liquid obstructs the passage of gas. When the gas builds sufficient pressure, it can push the accumulated liquid, leading to sudden oscillations between liquid and gas flows. Additionally, the connections and angles between flowlines and risers can exacerbate this problem. Diehl et al. [10] developed a model that accounts for the reservoir, the gas-lift annulus, the production column, and the flowline-riser set. The authors employed a virtual valve to represent the point at which severe slug flow forms. The model has been used in several

works, for anti-slug PI control [11], for pressure estimation comparing Kalman filters and NN [12], and for transfer learning using recurrent networks [13].

Despite the model being validated in real production systems under some considerations, it is necessary to address a parameter estimation problem, which depends on the system conditions. Although simple, the model requires specific knowledge of the well to be tuned. Therefore, extending the model to other wells is a cumbersome task. Furthermore, the model assumes that the slug can be modeled based on a few parameters, considering that it occurs basically due to a virtual valve. For this reason, the long-term dynamics are particularly difficult to model, encouraging the use of more general tools, such as machine learning [13]. Therefore, we hypothesize that this virtual valve term, can be approximated by an NN embedded in a differential equation, with both first-principle and data-driven models working in tandem in the UDE scheme.

Apio et al. [12] compared the Kalman filter and NN for predicting downhole pressure measurements in slug flow. They conclude that NNs offer superior performance, but they failed outside the conditions of training. In that paper, just one choke condition was employed. In a recent work, Luz et al. [13] proposed a transfer learning approach to handle slug flows by using an NN trained over synthetic data. However, both works assume a pure black-box model to handle the system's complexity. In contrast, this work aims to employ universal differential equations to enhance the modeling of multiphase oil production systems under multiple choke conditions. Thus, we preserve the physical structure of the mass-balance model while letting the neural component capture unmodeled physics of the slugs.

This work is divided as follows: in the Methodology section, we describe the FP model used to generate the data and demonstrate the UDE model; in the next section, we present and discuss the UDE results. The final remarks and future works are presented in the Conclusions section.

## METHODOLOGY

### Description of the system

The multiphase production system model presented by Diehl et al. [10], referred to the Fast Offshore Wells Model (FOWM), was employed. The dynamic model is shown in Eqs. (1) to (6). The mass balance in the annulus, $m_{\mathrm{ga}}$, is obtained from the mass flow rate of gas injected into the annulus $(W_{\mathrm{gc}})$ and the gas flow entering the tubing, $W_{\mathrm{iv}}$. In the tubing — Eq. (2), the gas balance also considers the production flow from the reservoir $(W_{\mathrm{r}})$ and the gas flow at the wellhead $(W_{\mathrm{whg}})$. The liquid flow rate in the tubing is derived in a similar manner — Eq. (3). $\alpha_{\mathrm{gw}}$ is the gas fraction in the tubing, whereas $E$ represents the mass fraction of gas that bypasses the slug in the subsea production line. The bubble formation through the slug — Eq. (4) — is modeled based on $W_{\mathrm{g}}$, which corresponds to the flow through the virtual valve. In the riser, Eqs. (5) and (6), besides the upstream flows, the mass balance also accounts for $W_{\mathrm{lout}}$ and $W_{\mathrm{gout}}$, which are, respectively, the liquid and gas flow rates through the surface choke valve.

$$\frac{\mathrm{d}m_{\mathrm{ga}}}{\mathrm{d}t} = W_{\mathrm{gc}} - W_{\mathrm{iv}} \tag{1}$$

$$\frac{\mathrm{d}m_{\mathrm{gt}}}{\mathrm{d}t} = W_{\mathrm{r}}\,\alpha_{\mathrm{gw}} + W_{\mathrm{iv}} - W_{\mathrm{whg}} \tag{2}$$

$$\frac{\mathrm{d}m_{\mathrm{lt}}}{\mathrm{d}t} = W_{\mathrm{r}}(1-\alpha_{\mathrm{gw}}) - W_{\mathrm{whl}} \tag{3}$$

$$\frac{\mathrm{d}m_{\mathrm{gb}}}{\mathrm{d}t} = (1-E)\,W_{\mathrm{whg}} - W_{\mathrm{g}} \tag{4}$$

$$\frac{\mathrm{d}m_{\mathrm{gr}}}{\mathrm{d}t} = E\,W_{\mathrm{whg}} + W_{\mathrm{g}} - W_{\mathrm{gout}} \tag{5}$$

$$\frac{\mathrm{d}m_{\mathrm{lr}}}{\mathrm{d}t} = W_{\mathrm{whl}} - W_{\mathrm{lout}} \tag{6}$$

The mass flow rates are modeled as shown in Eqs. (7) – (13). $K_a$ is the flow coefficient between the annulus and the tubing in Eq. (7). $K_r$ is a Vogel-type coefficient proportional to the reservoir contribution to the flow in the tubing in Eq. (8), whereas $K_w$ represents the flow coefficient at the wellhead in Eqs. (9) and (10). The gas density in the annulus is denoted by $\rho_{ai}$. The gas mass fraction in the tubing is represented by $\alpha_{gt}$, whereas $\alpha_{gr}$ and $\alpha_{lr}$, denote, respectively, the gas and liquid mass fractions in the subsea production line. The constants $C_g$ and $C_{\mathrm{out}}$ correspond to the virtual valve coefficient and the choke coefficient, respectively. The choke opening is defined by the fraction $z$. The pressures in the reservoir (bottomhole) and in the gravitational separator at the topside processing plant are represented by $P_r$ and $P_s$, respectively.

$$W_{iv} = K_a\sqrt{\rho_{ai}(P_{ai} - P_{tb})} \tag{7}$$

$$W_{\mathrm{r}} = K_r\left[1 - 0.2\left(\frac{P_{bh}}{P_r}\right) - 0.8\left(\frac{P_{bh}}{P_r}\right)^2\right] \tag{8}$$

$$W_{\mathrm{whg}} = K_w\sqrt{\rho_L(P_{tt} - P_{rb})}\,\alpha_{gt} \tag{9}$$

$$W_{\mathrm{whl}} = K_w\sqrt{\rho_L(P_{tt} - P_{rb})}\,(1-\alpha_{gt}) \tag{10}$$

$$W_{\mathrm{g}} = C_g(P_{eb} - P_{rb}) \tag{11}$$

$$W_{\mathrm{gout}} = \alpha_{gr}\,C_{\mathrm{out}}\,z\sqrt{\rho_L(P_{rt} - P_s)} \tag{12}$$

$$W_{\mathrm{lout}} = \alpha_{lr}\,C_{\mathrm{out}}\,z\sqrt{\rho_L(P_{rt} - P_s)} \tag{13}$$

In addition to the density and gas fractions already described, the FOWM model also considers the following pressures: $P_{ai}$, pressure at the gas injection point from the annulus to the tubing; $P_{tb}$, pressure at the gas injection point on the tubing side; $P_{bh}$, bottomhole pressure; $P_{pdg}$,

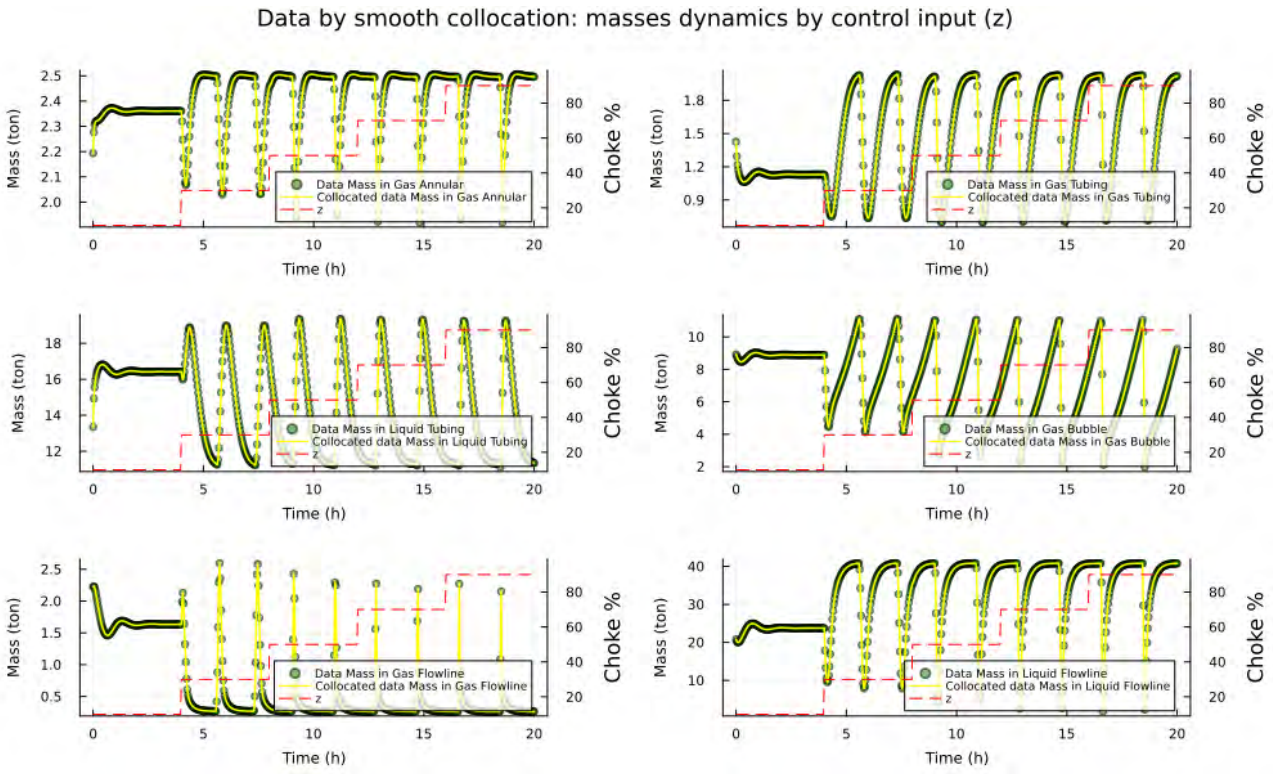

**Figure 2.** Results of interpolating data by cubic splines in the first-stage of training.

pressure at the PDG (Permanent Downhole Gauge); $P_r$, reservoir pressure near the bottom; $P_{tt}$, pressure at the tubing top; $P_{rb}$, pressure in the flowline upstream of the bubble point; $P_{eb}$, pressure at the bubble point; $P_{rt}$, pressure at the riser top. The described relations are represented in Eqs. (14) – (21):

$$P_{ai} = \left(\frac{RT}{V_a M} + \frac{gL_a}{V_a}\right) m_{ga} \tag{14}$$

$$P_{tb} = P_{tt} + \rho_{mt} g H_{vgl} \tag{15}$$

$$P_{bh} = P_{pdg} + \rho_{mres} g\left(H_t - H_{pdg}\right) \tag{16}$$

$$P_{pdg} = P_{tb} + \rho_{mres} g\left(H_{pdg} - H_{vgl}\right) \tag{17}$$

$$P_{tt} = \frac{\rho_{gt} RT}{M} \tag{18}$$

$$P_{rb} = P_{rt} + \frac{(m_{lr} + m_{L,still}) g \sin(\vartheta)}{A_{ss}} \tag{19}$$

$$P_{eb} = \frac{m_{gb} RT}{M V_{eb}} \tag{20}$$

$$P_{rt} = \frac{m_{gr} RT}{M}\left(\omega_u V_{ss} - \frac{m_{lr} + m_{L,still}}{\rho_L}\right) \tag{21}$$

The auxiliary variables used to compute gas density and mass fractions are given in Eqs. (22) – (25).

$$\rho_{ai} = \frac{M P_{ai}}{RT} \tag{22}$$

$$\alpha_{gt} = \frac{m_{gt}}{m_{gt} + m_{lt}} \tag{23}$$

$$\alpha_{gr} = \frac{m_{gr}}{m_{gr} + m_{lr}} \tag{24}$$

$$\alpha_{lr} = 1 - \alpha_{gr} \tag{25}$$

In the model, $T$ denotes the average temperature along the production system, $M$ represents the gas molecular weight, $R$ is the universal gas constant, and $g$ is the gravitational acceleration. The annulus is characterized by its volume $V_a$ and length $L_a$. The mixture density in the tubing, $\rho_{mt}$, is computed from the fluid properties in this section, whereas the corresponding gas density, $\rho_{gt}$, is obtained separately. The mixture density in the reservoir, $\rho_{mres}$, is assumed constant. The vertical distances from the wellhead to key points of the system are: $H_{\text{vgl}}$ to the gas-lift valve, $H_{\text{pdg}}$ to the PDG sensor, and $H_t$ to the bottomhole. The average riser inclination is denoted by $\vartheta$.

The minimum liquid mass in the subsea line is represented by $m_{L,\,\text{still}}$, and the gas bubble volume by $V_{eb}$. An auxiliary parameter, $\omega_u$, is introduced to help locate the bubble. The cross-sectional area of the subsea line, $A_{ss}$, and its total volume are computed based on the pipeline geometry. Additionally, the volume of the gas-lift annulus is determined through standard geometric relationships. The production system parameters were tuned to

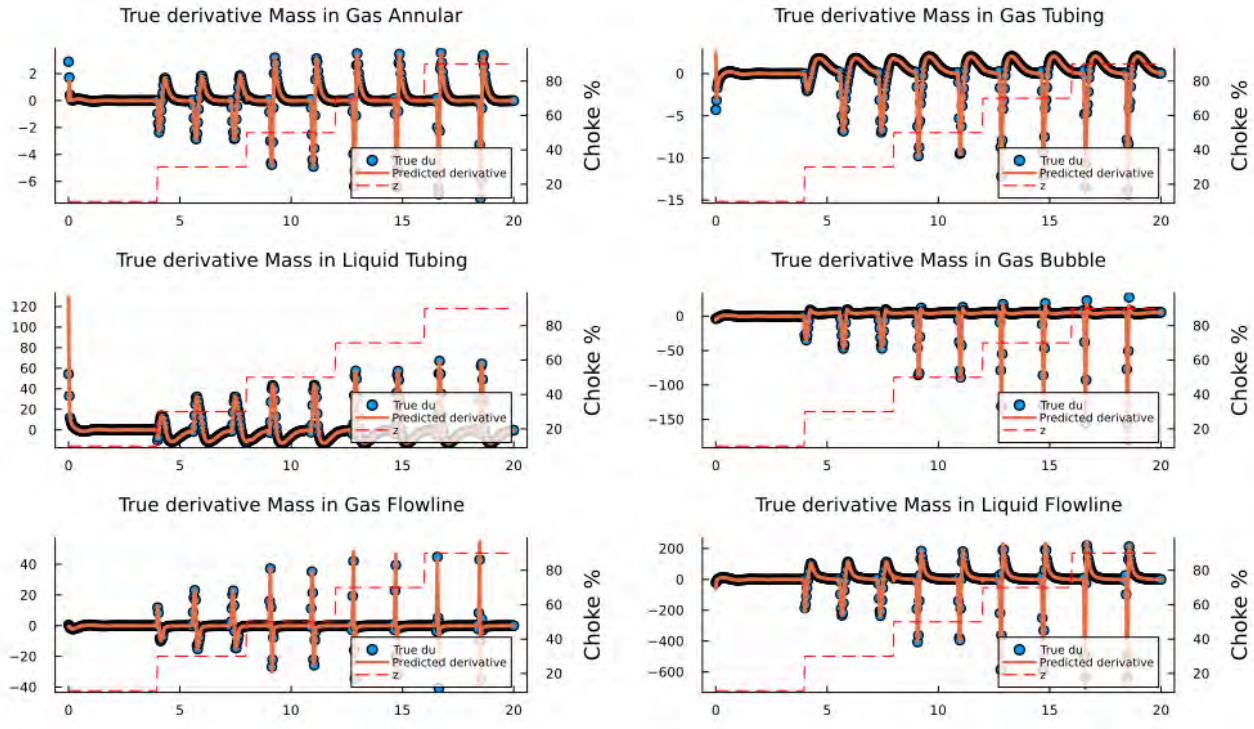

**Figure 3.** Predicted derivatives by the smooth colocation against data for each of the mass holdups.

reproduce real wells based on OLGA simulations, as listed in Table 1.

**Table 1:** Parameters from a real production well.

| Parameter (Unit) | Unit |
|---|---|
| $\rho_L(kg/m^3)$ | 900 |
| $P_r(bar)$ | 225 |
| $P_s(bar)$ | 10 |

| $\omega_u$ | 2.780 |

The remaining geometric and mixture relations are given in Equations (26) – (32).

$$\rho_{mt} = \frac{m_{gt}+m_{lt}}{V_t} \tag{26}$$

$$\rho_{gt} = \frac{m_{gt}}{V_{gt}} \tag{27}$$

$$V_{gt} = V_t - \frac{m_{lt}}{\rho_L} \tag{28}$$

$$A_{ss} = \frac{\pi D_{ss}^2}{4} \tag{29}$$

$$V_{ss} = \frac{\pi D_{ss}^2}{4}\left(L_r + L_{fl}\right) \tag{30}$$

$$V_a = \frac{\pi D_a^2 L_a}{4} \tag{31}$$

$$V_t = \frac{\pi D_t^2 L_t}{4} \tag{32}$$

## Modeling by Universal Differential Equations

This study uses a hybrid physics-informed machine learning approach to model and predict the dynamic

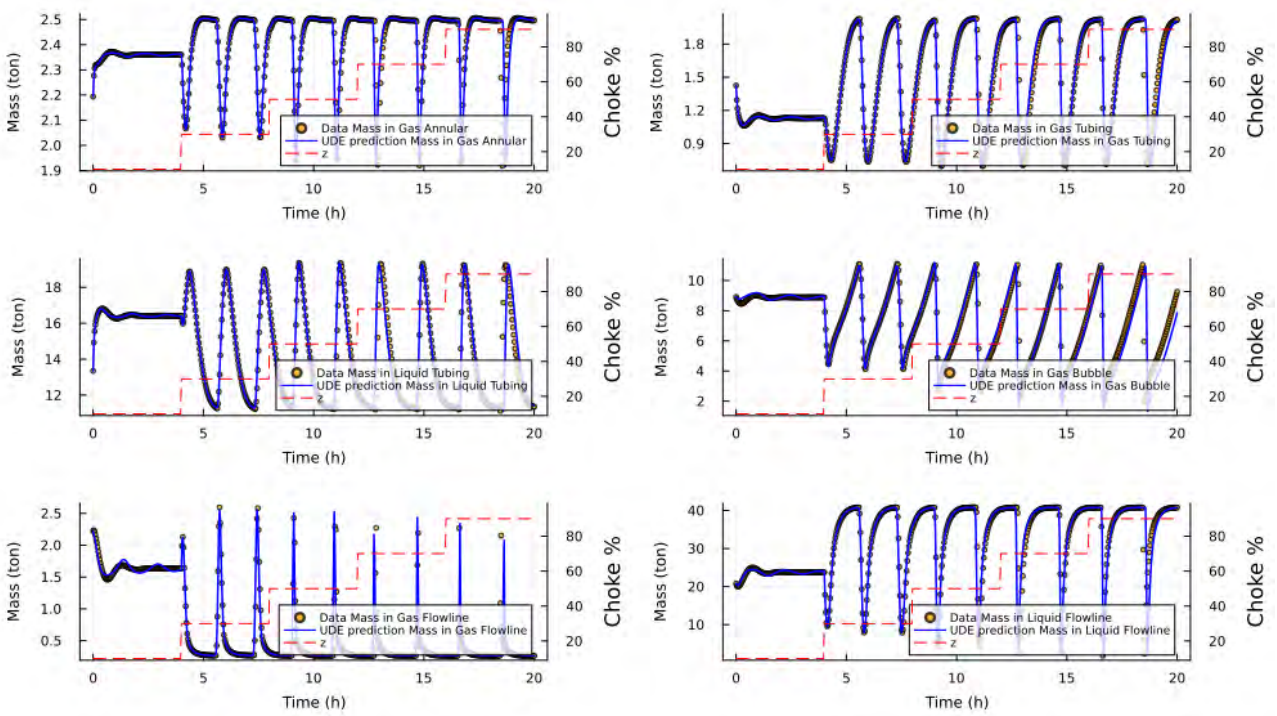

**Figure 4.** The initial UDE estimation of each of the mass holdups after the finishing the first-stage of training. The initial estimations are represented against data in different choke openings (z).

behavior of a multiphase oil production system. The methodology handles the complexity of simplified terms through a data-driven method. The data source comes from the simulation performed with the FOWM model described in the previous section. This work employs UDE, i.e., a neural network is embedded into the structure of the FOWM differential equations, replacing the virtual valve flow in Eqs. (4) and (5), as illustrated in Fig. 1. The neural network receives the six differential states, in addition to the choke valve opening (z), as inputs to a 3-layer hidden topology with 7 neurons each, using radial basis function (RBF) as the activation function. The virtual valve flow rate is considered as the output. The choke valve opening was varied from 10% to 90%, considering a 20% increment. The gas-lift flow rate was considered constant at 80, 000 m³/d. Training was performed using data from a 20-hour simulation of well operation, with a 1-minute time step. For the testing phase, the valve was considered with openings from 20% to 80%, using the same increment, to test generalization within the trained range, and at 100% to verify extrapolation capability.

Since the system exhibits oscillatory behavior, the UDE was trained in two stages: the first uses smooth data collocation to obtain an estimate of the derivatives, which will feed the UDE. In this work, we have access to the data of the states, but not to its derivatives. Therefore, we proceed to its estimation employing smooth collocation. There are several methods available to smooth the noisy data, including kernel-smoothing methods and piecewise interpolation. In this work, cubic splines were chosen instead of a kernel-based method because the data exhibit many oscillations. The second method would lead to discarding data when peaks are present. Once the data are interpolated, it is possible to compute the derivatives locally and then minimize the error between these derivatives and the UDE derivative outputs, as stated in Eq. (33). The $\theta$ represents the parameters of the NN, while the indexes $i$ and $j$ are, respectively, the states and the sample time. The superscript $\widehat{\mathrm{m}_i}$ represents the prediction of the state $i$ by the UDE, the $\widetilde{\ }$ represents the derivative estimation by the interpolation method, while the variables are marked accordingly to represent the data.

$$\mathrm{MSE}_{\mathrm{deriv}}(\theta) = \frac{1}{\mathrm{MN}} \sum_{i,\mathrm{j}=1}^{\mathrm{M},N} \left\| \frac{\widehat{\mathrm{dm}_i(\theta,\mathrm{j})}}{\mathrm{dt}} - \frac{\widetilde{\mathrm{dm}_i(\mathrm{j})}}{\mathrm{dt}} \right\|^2 \quad (33)$$

This avoids a high computational cost in the initial phase, since it is not necessary to repeatedly solve the differential equation during the coarse tuning of the UDE parameters. The backpropagation process is employed to find an initial $\theta$.

The incremental strategy provides a reasonable starting point for the second stage, the training of the complete UDE model, which involves backpropagation

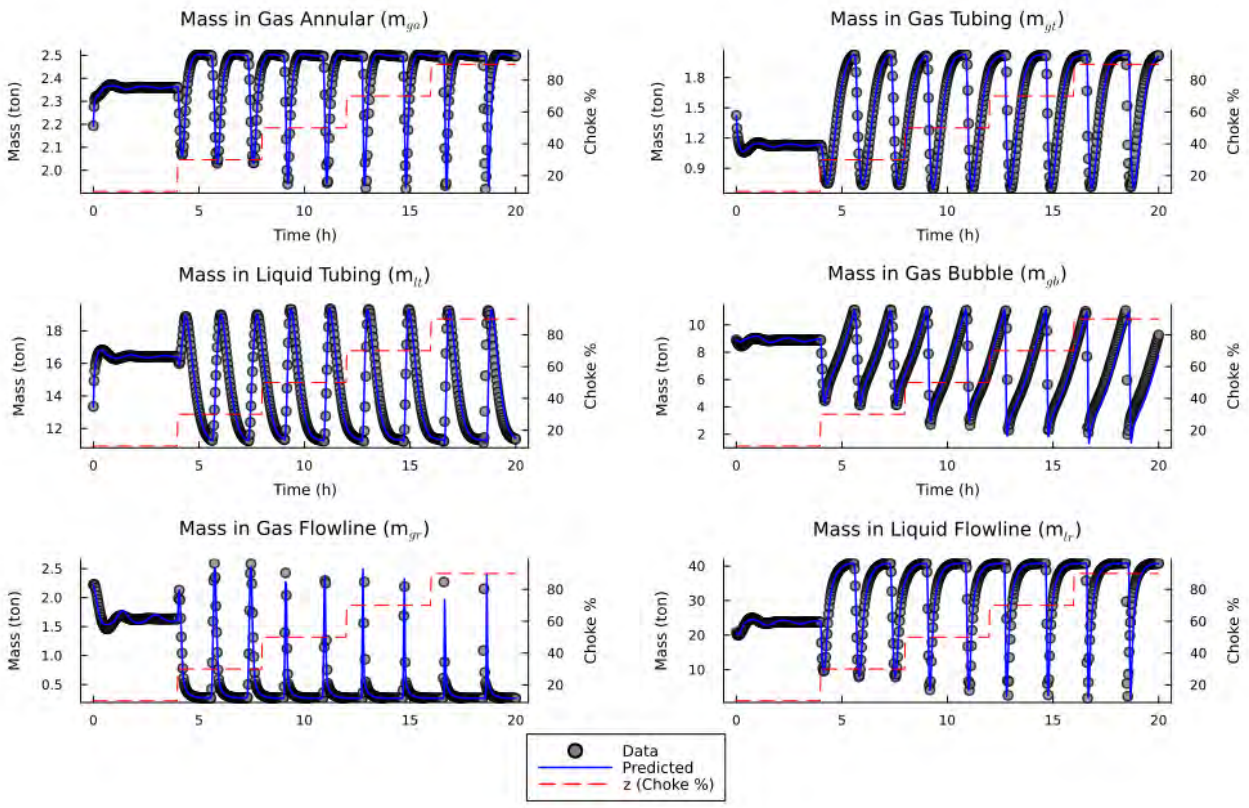

**Figure 5.** The UDE predictions of each of the mass holdups after the finishing the second-stage of training. The predictions are represented against data in different choke openings (z).

and solving the differential equation simultaneously. The objective function involves minimizing the mean squared error (MSE) between the predicted and expected (scaled) values of the states (mass holdup), Eq. (34).

$$\mathrm{MSE}_{\mathrm{state}}(\theta) = \frac{1}{\mathrm{MN}} \sum_{i,\mathrm{j}=1}^{\mathrm{M},N} \left\| \frac{\widehat{\mathrm{m_i}(\theta,\mathrm{j})}}{\max(\mathrm{m}_i^{data}) - \min(\mathrm{m}_i^{data})} - \frac{\mathrm{m}_i^{data}(\mathrm{j})}{\max(\mathrm{m}_i^{data}) - \min(\mathrm{m}_i^{data})} \right\|^2 \quad (34)$$

The first phase was limited to a maximum of 10, 000 iterations, and the second to a maximum of 5, 000 iterations using the ADAM algorithm, followed by 1, 000 iterations with the LBFGS algorithm. Early stopping was used to interrupt training if no improvement was observed after 500 iterations. The code was developed using the Scientific Machine Learning package of the Julia language.

## RESULTS AND DISCUSSION

The results of the first stage (smooth data collocation) with cubic splines interpolation are shown in Fig. 2 for the state variables and in Fig. 3 for their time derivatives. Since the data are noise-free simulation data, the piecewise polynomials pass through all data points. The results of the initially estimated UDE are shown in Fig. 4, where the derivatives minimization was able to reasonably predict the state data. The MSE of the derivatives were 205.39, while the scaled MSE was 0.0099. This enables fast convergence, in which the first stage only performs a coarse adjustment, while the full network training constitutes the fine-tuning, when the computational cost is higher. In the literature, this is considered a recommendation for complex systems. Huang et al. [14] trained a UDE for wastewater process employing smooth collocation followed by direct UDE training in a stiff system. As the authors stated, the stiffness may arise not only from the system itself but also from the introduction of the NN, leading to a numerical stiffness. By using this incremental strategy, it is possible to circumvent the instability hurdle at the beginning of training, providing smooth gradients to the second stage, in which the differential equation is solved simultaneously with the backpropagation process. Furthermore, this strategy can minimize the computational overhead.

Therefore, with a reasonably good initial estimate, the model can capture the dynamics present in the slugging system, as shown in Fig. 5. In this second stage, the

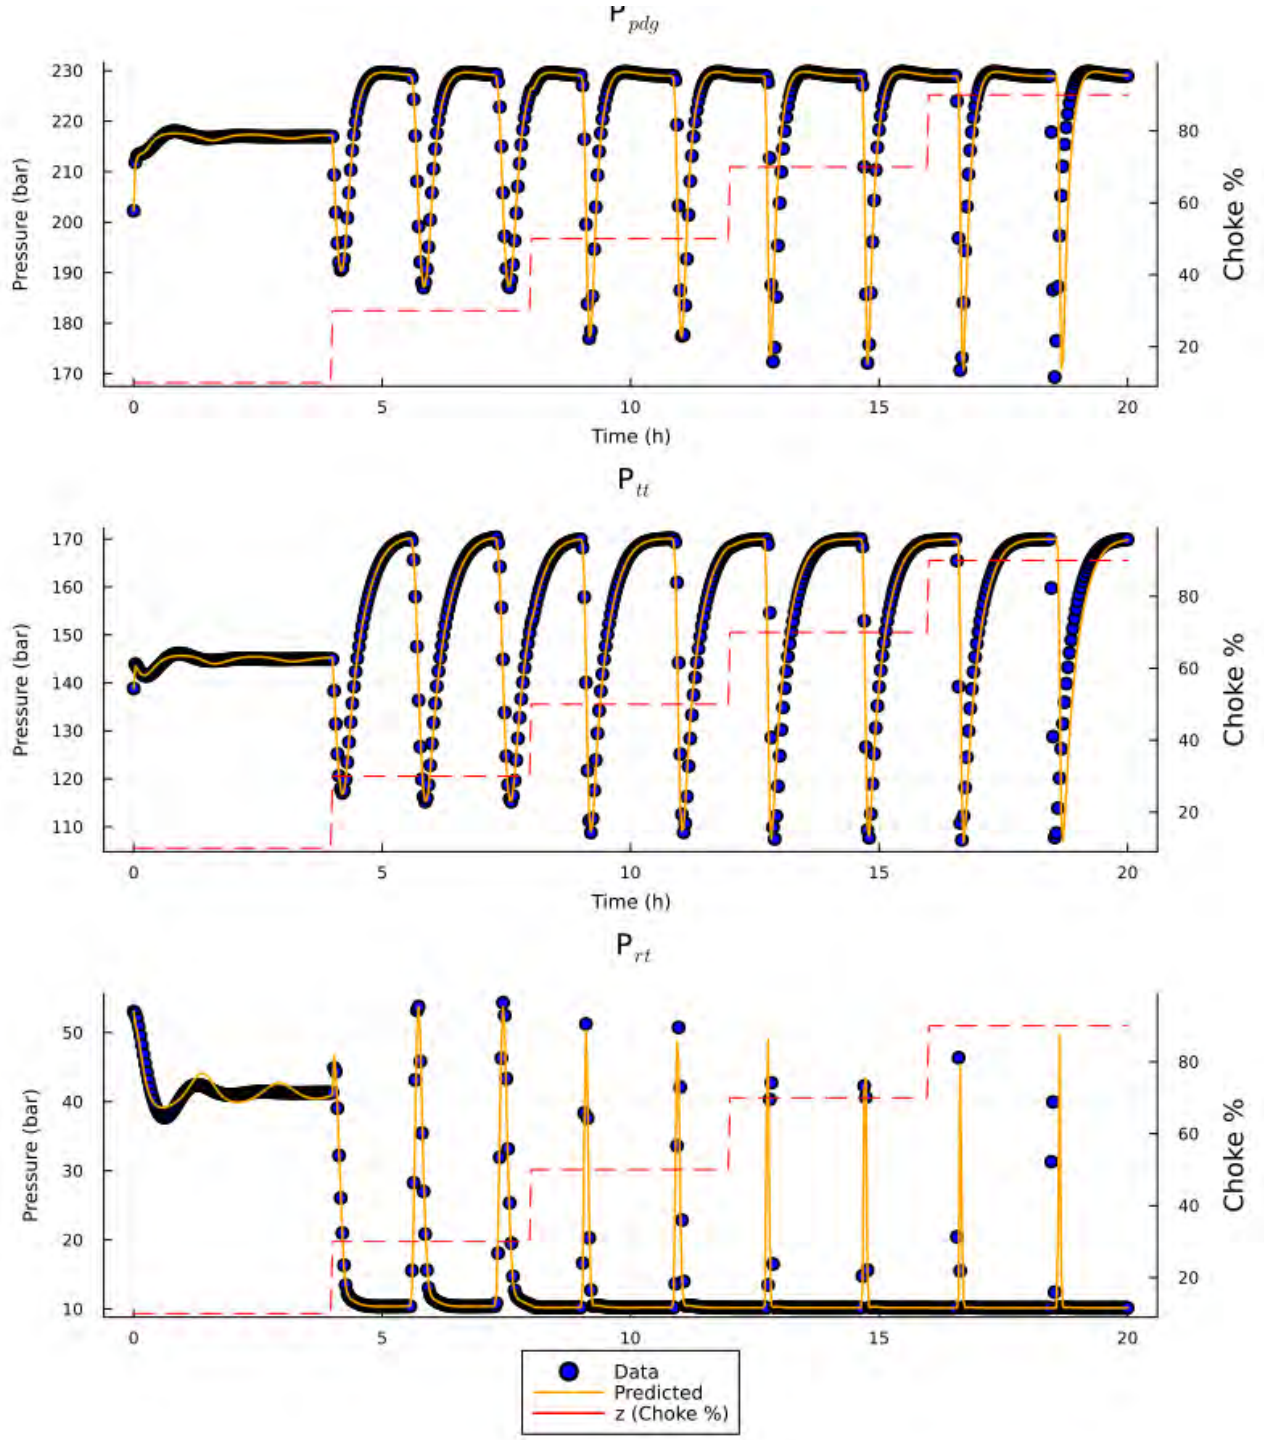

**Figure 6.** Pressure predictions by the UDE after the finishing the second-stage of training. The predictions are represented against data in different choke openings (z).

algorithm achieved a mean squared error of 0.0092 (in scaled units) after 505 iterations. During this phase, the algorithm explored regions in which the MSE increased, but it stopped after a small decrease of the MSE found based on the first stage. . It is worth noting that without the pre-training stage, network convergence is impossible due to the inherent numerical instability of hybrid models and the tendency to form local minima. We tried to bypass the pre-training step, but it failed to converge in all cases. It should be noted that the oscillations

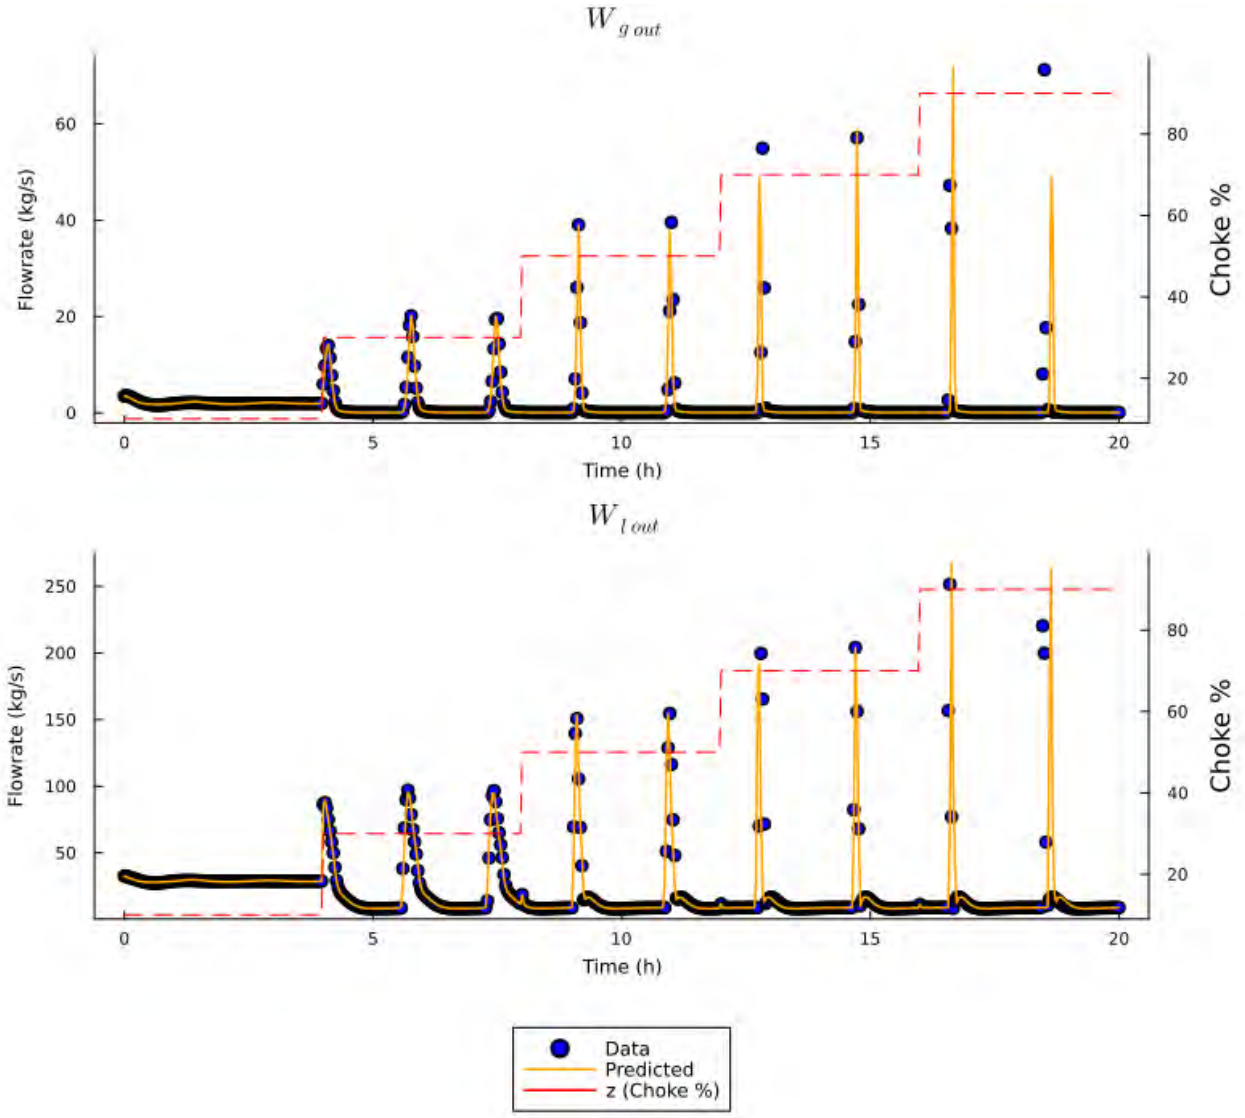

**Figure 7.** Flow rates predictions by the UDE after the finishing the second-stage of training. The predictions are represented against data in different choke openings (z).

increase as the choke is more opened. The NN can capture the trend as well, suggesting that it can generalize considering exogenous inputs.

Comparisons of pressures at the PDG location, at the tubing top, and across the choke are shown in Fig. 6. It can be observed that the pressures computed by the UDE model are accurate, as with a reasonable state estimate, they are calculated directly from Eqs. (17), (18), and (21). In real production systems, these are the measurements usually available, and they can be used as indicators of the model's quality. The model can be extended to consider production data from the plant.

Similarly, the predicted flow rates are shown in Fig. 7. The results suggest that universal differential equations can be applied to systems whose physics is poorly known. Compared to the transfer learning approach based on LSTM networks [12], the proposed UDE formulation does not rely on a purely black-box architecture. Instead, it also considers the governing mass-balance equations, thus, it enables extrapolation of the choke openings in the slug regime. Since the flow rates are usually not measured in the oil platforms, this has led to the development of virtual flow meters in recent works. With our model, it tackles the problem in a two-fold way: by predicting the pressures for anti-slug control and by acting as a virtual flow meter, which is vital for maximizing productivity. With a good prediction of the pressures, a control for suppressing slug regimes can be developed based on the UDE model, as demonstrated by using FP FOWM in [12].

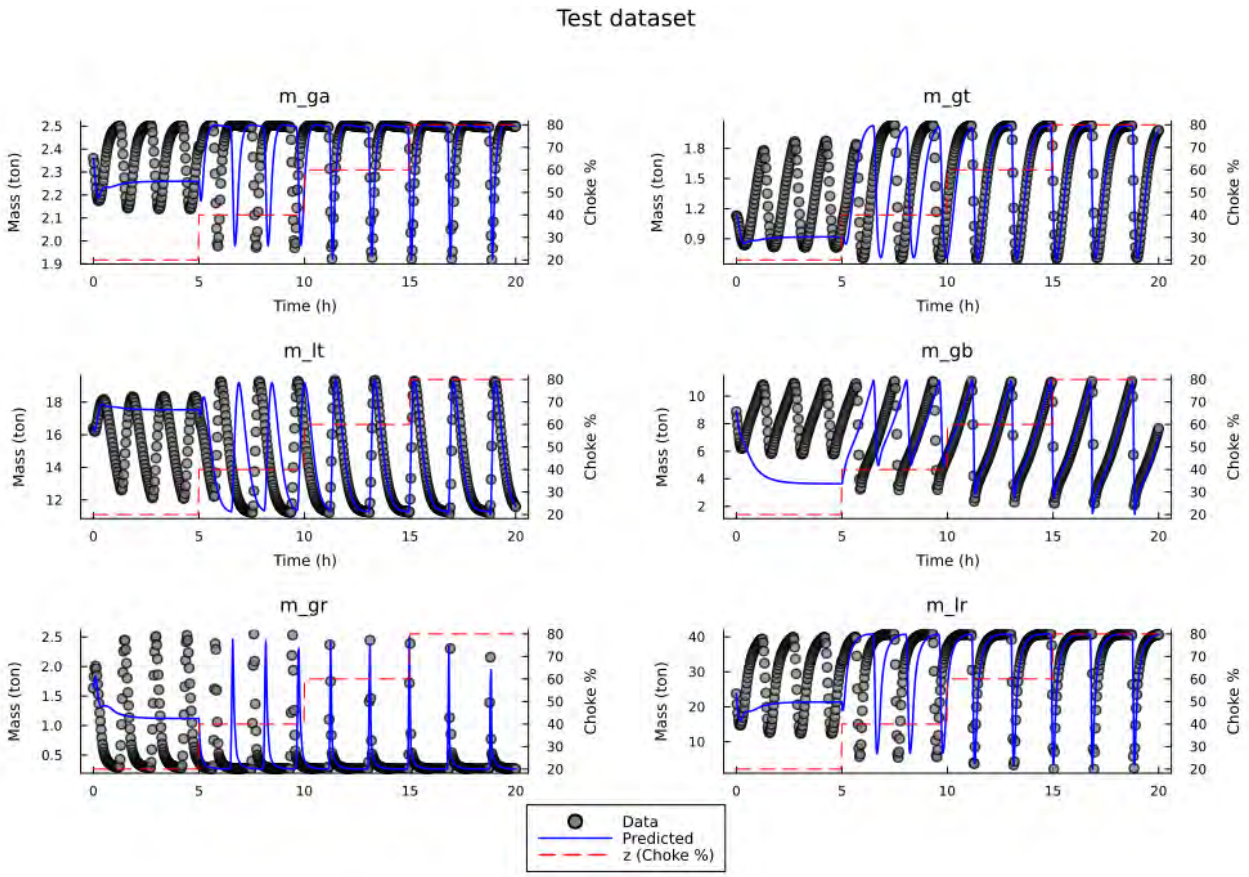

**Figure 8.** Test predictions by the UDE. The predictions are represented against data in different choke openings (z).

As discussed in previous work [12, 13], using a simple NN when changing choke scenarios can compromise its predictive capacity. This justifies the use of more complex ML strategies, such as transfer learning [13] or UDE modeling as in this work. However, previous works were based solely on pressure measurements, without accounting for the advantages of flow rate evaluation. Moreover, Luz et al. [13] conducted 1000 simulations to enable the NN to capture the underlying patterns. Results in the literature suggest that using physical priors can reduce the data requirement [2, 5], but more studies are needed to verify this claim in our context.

The results for the prediction on the test set are shown in Fig. 8. The test set considers interpolation between 20% and 80% choke opening, with a 20% increment. The reported scaled MSE was 0.088. The main limitation identified occurs in the prediction at 20% opening, in the transition region associated with a bifurcation. In this range, the errors are higher, and a local minimum is reached, inherited from the knowledge before the bifurcation. The results suggest that, for limit cycles, training over the transition region should be refined; once the oscillations are established, the model can capture the long-term dynamics.

On the other hand, for the extrapolation at 100% opening, the achieved scaled MSE was 0.039. As illustrated in Fig. 9, the UDE was able to adequately reproduce the trends of the states, suggesting that the model incorporated useful knowledge of the underlying physics even outside the exact training range.

As a main limitation of the work, we should note that, to apply to real data, only pressure measurements are available. In theory, one could use the MSE between the pressure measurements and the predictions in the UDE model, just changing Eq. (34). However, it should be noted that this would implying in skipping the first stage of training, as in Eq. (33). One suggestion would be to use the training of the adjusted FOWM data as warm up and apply transfer learning over the real data.

## CONCLUSION

In this work, we proposed a universal differential equation (UDE) formulation for modeling slug-flow dynamics in offshore wells, using the Fast Offshore Wells

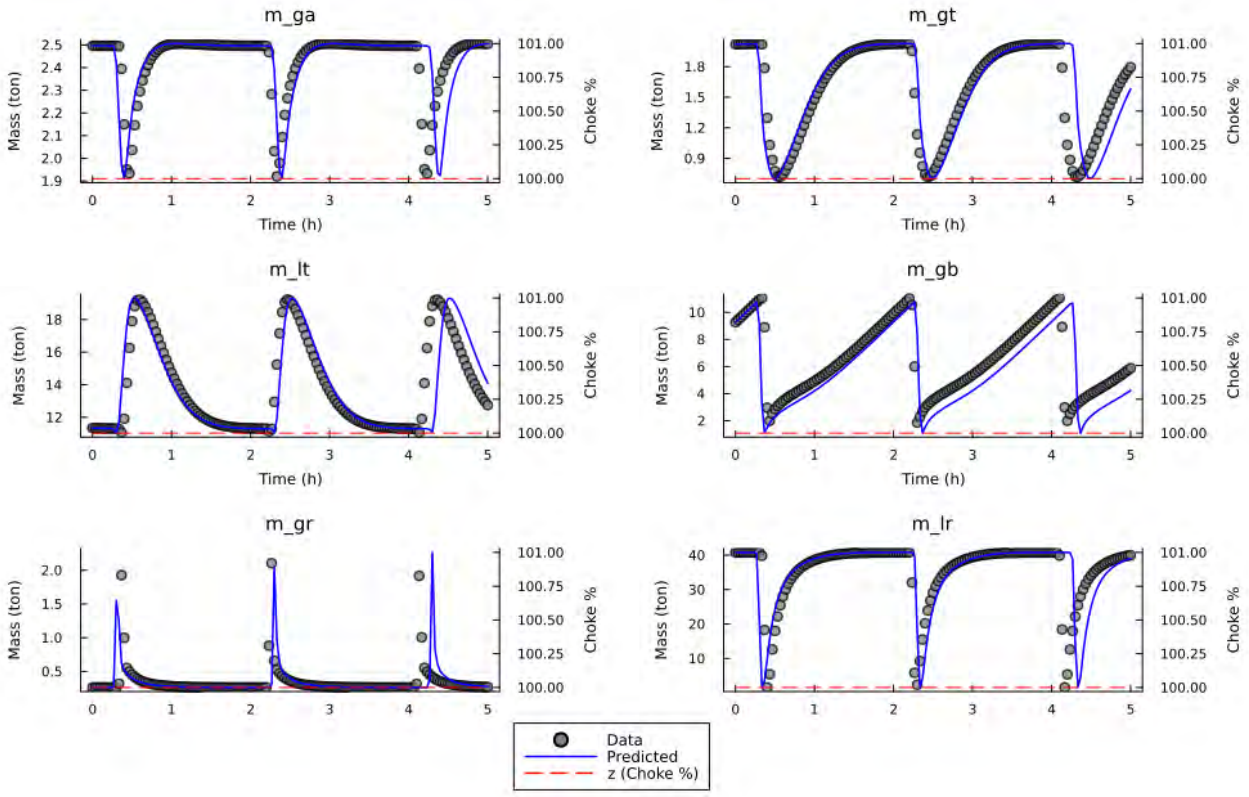

**Figure 9.** Extrapolation predictions by the UDE. The predictions are represented against data in different choke openings (z).

Model (FOWM) as the physical backbone. A neural network was embedded into the mass-balance equations by replacing the virtual valve flow term, allowing the model to capture unmodeled slugging physics while preserving the overall state-space structure.

A two-stage training strategy based on data collocation was employed to address numerical instability in the hybrid model. In the first stage, cubic splines were used to obtain local derivative estimates, which were used to get an initial estimate of the NN parameters. This step provided a suitable initialization for the second stage, in which the full UDE was trained by solving the differential equations and minimizing the mean squared error between the predicted and scaled state trajectories. The proposed approach achieved a scaled MSE of 0.0092 on the training scenarios and 0.088 on interpolation tests with choke openings between 20% and 80%. For the extrapolation case at 100% opening, the scaled MSE was 0.039, and the UDE was able to reproduce the mass holdup trends.

These results indicate that UDE-based hybrid models represent a feasible and promising possibility for modeling multiphase production systems. The methodology can be applied to other systems in the limit-cycle as well, especially when physics is partially known. Future work will focus on validating the methodology against high-fidelity simulators and field data, while incorporating the considerations of using only available measurements. Furthermore, future work should discuss in more detail the stability of the hybrid models.

## ABSTRACT

Reliable data for the standard enthalpies and Gibbs free energies of formation, $\Delta H_f^\circ$ and $\Delta G_f^\circ$, are essential for process synthesis, energy integration, and lost-work analysis. However, many biomass-derived compounds lack reliable thermodynamic property data, limiting optimization of energy and carbon utilization in biomass conversion processes. This study proposes a composition-based method to estimate $\Delta H_f^\circ$ and $\Delta G_f^\circ$ for compounds containing carbon, hydrogen, and oxygen. The method exploits widely available heats of combustion data and establishes a linear correlation between the enthalpy and Gibbs free energy of combustion, $\Delta H_C$ and $\Delta G_C$, using tabulated organic compounds. The applicability of this relationship to biomass-derived compounds is tested using published data for cellulose, starch, and glucose. Thornton's correlation between heat of combustion and oxygen demand is then incorporated to derive simple expressions for estimating formation properties directly from elemental composition. The results show that the proposed framework provides sufficiently accurate estimates for conceptual thermodynamic analysis, enabling rapid evaluation of reaction enthalpies, minimum work requirements, equilibrium constants, and reaction driving forces. The method is therefore well suited for early-stage process synthesis and screening of biomass conversion pathways.

## INTRODUCTION

The optimization of energy utilization in industrial processes involving reacting systems requires reliable values of the standard heats of formation, $\Delta H_f^\circ$, of all reacting components [1]. A complementary and more fundamental measure of process efficiency is the extent to which the chemical potential of the feed streams, together with process workflows, is conserved in the chemical potentials of the product streams. Any deviation from this ideal corresponds to lost work arising from irreversibilities associated with chemical reaction, separation, heat transfer, and mixing. Quantification and targeting of this lost work require accurate values of the standard Gibbs free energies of formation, $\Delta G_f^\circ$, for all compounds appearing in the feed and product streams [2].

Conversion of biomass feedstocks into chemicals and fuels represents a key pathway toward improving the sustainability of the chemical industry. From a thermodynamic perspective, knowledge of the Gibbs free energy of biomass feedstocks is essential for evaluating how efficiently chemical potential in the feed, together with supplied work, is transferred to the product streams. This information is required to quantify minimum work requirements, assess unavoidable irreversibilities, and determine how closely a process can approach its thermodynamically imposed limits on energy use and $CO_2$ emissions. A representative example is the conversion of lignocellulosic biomass to bioethanol, for which accurate Gibbs free energy data are necessary to distinguish fundamental thermodynamic constraints from inefficiencies arising from process structure and operation [3].

Such analyses and optimizations have been significantly hindered by the scarcity of reliable thermodynamic data for biomaterials, as well as by inconsistencies among reported values arising from differences in experimental methods, thermodynamic models, and sample characteristics [4-5]. In the case of cellulose, the wide range of reported thermodynamic properties may partly reflect its historically low economic value, as it was predominantly combusted rather than utilized as a chemical feedstock, reducing the incentive for detailed thermodynamic characterization. More recently, however, large quantities of underutilized lignocellulosic residues have become attractive as renewable feedstocks, motivating renewed interest in their thermodynamic properties [6-7].

Compounding this challenge, many biomass-derived compounds, including cellulose and xylan, exhibit polymorphism, with multiple allomorphs differing in crystallinity and molecular structure [5, 8]. These structural variations give rise to corresponding differences in thermodynamic properties and are further complicated by the inherently amorphous and heterogeneous nature of components such as lignin. Collectively, these gaps and uncertainties in thermodynamic property data constrain rigorous process optimization, $CO_2$ utilization studies, and the development of reliable life cycle and techno-economic analyses for biomass conversion processes. More critically, they preclude the application of lost-work and exergy-based targeting methods, which are central to early-stage process synthesis and the identification of fundamentally efficient process structures.

While values of $\Delta H_f^\circ$ for biomass-derived compounds are generally absent from standard thermodynamic tables, heats of combustion, $\Delta H_C$, have been reported for many biocompounds and bio-feedstocks (9-10). These reported values often exhibit substantial variability, which may be attributed to differences in elemental composition, crystallinity, and moisture content of the samples (10-11). If the elemental composition of a compound is known, $\Delta H_f^\circ$ can be calculated from the measured value of $\Delta H_C$ using the appropriate combustion stoichiometry.

In contrast, the determination of $\Delta G_f^\circ$ is considerably more challenging, as neither $\Delta G_f^\circ$ nor the Gibbs free energy of combustion, $\Delta G_C$, can be measured directly. In some cases, reaction equilibrium measurements may be used to estimate $\Delta G_f^\circ$; however, this approach is not feasible for many biomass-derived compounds. An alternative route is provided by the Third Law of Thermodynamics, which requires knowledge of the compound's heat capacity from 0 to 298 K. For biomass materials, such data are rarely available and typically rely on a combination of assumptions and indirect measurements.

In this paper, a method is proposed for estimating $\Delta G_C$ for a general organic compound of the form $\mathrm{C}_x\mathrm{H}_y\mathrm{O}_z$ based on its heat of combustion, $\Delta H_C$. The approach is based on the observation of a linear correlation between $\Delta H_C$ and $\Delta G_C$ across a wide range of organic compound families, including alkanes, alkenes, alcohols, ketones, aldehydes, and carboxylic acids. We hypothesize that this linear relationship, established for organic compounds composed of carbon, hydrogen, and oxygen, also holds for biomass-derived compounds. This hypothesis is tested using published values of $\Delta H_C, \Delta H_f^\circ$, and $\Delta G_f^\circ$ for compounds such as cellulose, starch, xylan, and glucose. It is shown that the reported biomass data lie slightly above the correlation obtained for general organic compounds but nevertheless obey the same linear relationship to a good approximation. Consequently, for any compound of the form $\mathrm{C}_x\mathrm{H}_y\mathrm{O}_z$, we proposed that the value of $\Delta G_C$ may be estimated from the measured $\Delta H_C$, from which $\Delta G_f^\circ$ can be calculated directly using reaction stoichiometry.

The method is further extended by incorporating the linear relationship between $\Delta \mathrm{H}_c$ and oxygen demand proposed by Thornton, yielding a simple linear relationship between $\Delta G_f^\circ$ and the elemental C:H:O ratio of the compound. This framework provides a practical basis for lost-work targeting in processes that convert one organic or biomass-derived compound into another, enabling early identification of minimum work requirements and unavoidable irreversibilities prior to detailed flowsheet development. Moreover, it enables estimation of reaction enthalpies, Gibbs free energies, equilibrium constants, and their temperature dependence for reactions involving organic and biomass compounds. These estimates offer high-level insight into minimum energy and work requirements and reaction driving forces, giving an understanding of the overall thermodynamic difficulty and energy operating costs of biomass conversion processes.

## METHODS

### Analysis of Enthalpy and Gibbs Free Energy of Tabulated Organic Compounds

To maintain a consistent thermodynamic basis, data for organic compounds were obtained from the NIST Chemistry WebBook [12]. For each compound, the database provides the standard heat of formation, $\Delta H_f^\circ$, in the appropriate standard state, together with the standard molar entropy, $S^\circ$, at 298.15 K. These quantities were used to calculate the standard entropy of formation, $\Delta S_f^\circ$, relative to the elements in their standard states at 298.15 K and 1 atm, and subsequently the standard Gibbs free energy of formation, $\Delta G_f^\circ$, on the same basis.

The formation of a general organic compound of the form $\mathrm{C_xH_yO_z}$ from its constituent elements is described

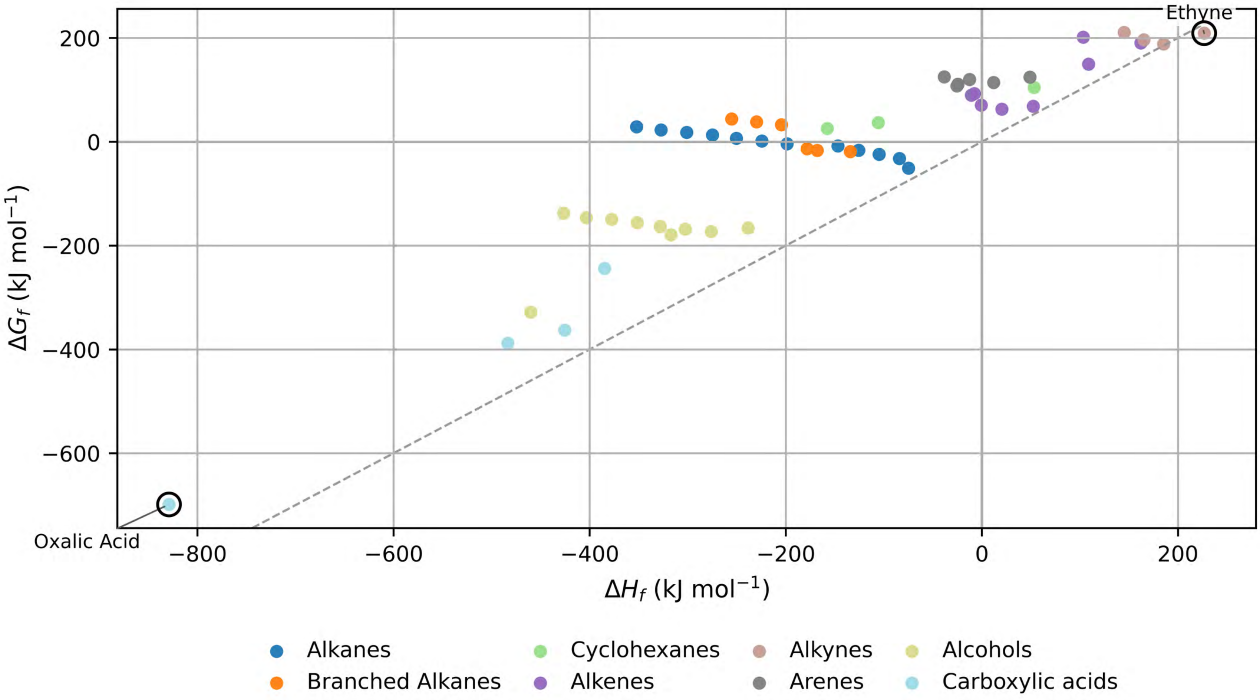

**Figure 1.** Standard Gibbs free energy of formation, $\Delta G_f^\circ$, versus standard heat of formation, $\Delta H_f^\circ$, for organic compounds grouped by chemical family (kJ mol$^{-1}$). The dotted line represents 45° line corresponding to $\Delta G_f^\circ = \Delta H_f^\circ$. Data extracted from NIST WebBook [12] and listed in Table S1.

by Eq.1.

$$xC(s) + \frac{y}{2}H_2(g) + \frac{z}{2}O_2(g) = C_xH_yO_z \quad (1)$$

The standard entropy of formation for each compound was calculated following Eq.2. Then standard Gibbs free energy of formation was obtained from Eq. (3), with $T = 298.15\ K$ and entropy expressed in kJ mol$^{-1}$ K$^{-1}$.

$$\Delta S_F^0 = S^0_{C_xH_yO_z} - xS_C^0 - \frac{y}{2}S^0_{H_2} - \frac{z}{2}S^0_{O_2} \quad (2)$$

$$\Delta G_F^0(C_xH_yO_z) = \Delta H_F^0(C_xH_yO_z) - T\Delta S_F^0 \quad (3)$$

Thermodynamic data for 53 organic compounds were extracted from the NIST WebBook. The compounds span a range of chemical families, including alkanes, alkenes, alcohols, and carboxylic acids. The values of $\Delta H_f^\circ, S^\circ$, and the calculated $\Delta G_f^\circ$ are listed in Table S1 of the Supplementary Material. A plot of $\Delta G_f^\circ$ versus $\Delta H_f^\circ$ for these compounds is shown in Fig. 1.

Although the data exhibit scatter, clear trends are observed within individual chemical families. For example, oxalic acid exhibits one of the lowest values of $\Delta G_f^\circ$, indicating that its formation from the elements is both highly exothermic and strongly spontaneous. In contrast, ethyne exhibits a large positive $\Delta H_f^\circ$ and a correspondingly large positive $\Delta G_f^\circ$, implying that its formation from the elements is highly endothermic and would require the input of approximately 200 kJ mol$^{-1}$ of work.

Sempuga et al. [13] introduced a useful representation of thermodynamic feasibility by plotting $\Delta G$ versus $\Delta H$, in which the axes correspond to reaction work and energy requirements, respectively. In this representation, compounds lying in the upper-right and lower-left quadrants are particularly attractive for thermocatalytic processes, as the temperature of the heat flow associated with the reaction may carry sufficient equivalent work to drive chemical conversion.

To evaluate combustion thermodynamics, the conversion of carbon dioxide and liquid water to a general organic compound $C_xH_yO_z$ and oxygen was considered:

$$xCO_2 + \frac{y}{2}H_2O(l) = C_xH_yO_z + \left(x + \frac{y}{4} - \frac{z}{2}\right)O_2 \quad (4)$$

This reaction corresponds to the photosynthetic production of organic matter and is equivalent to the reverse of the combustion reaction. When water is in the liquid phase, the heat of combustion corresponds to the higher heating value (HHV) of the compound.

The $\Delta G_C$ and $\Delta H_C$ were calculated from Eqs. (5) and (6).

$$-\Delta G_C = \Delta G_F(C_xH_yO_z) + \left(x + \frac{y}{4} - \frac{z}{2}\right)\Delta G_F(O_2) - x\Delta G_F(CO_2) - \frac{y}{2}\Delta G_F(H_2O) \quad (5)$$

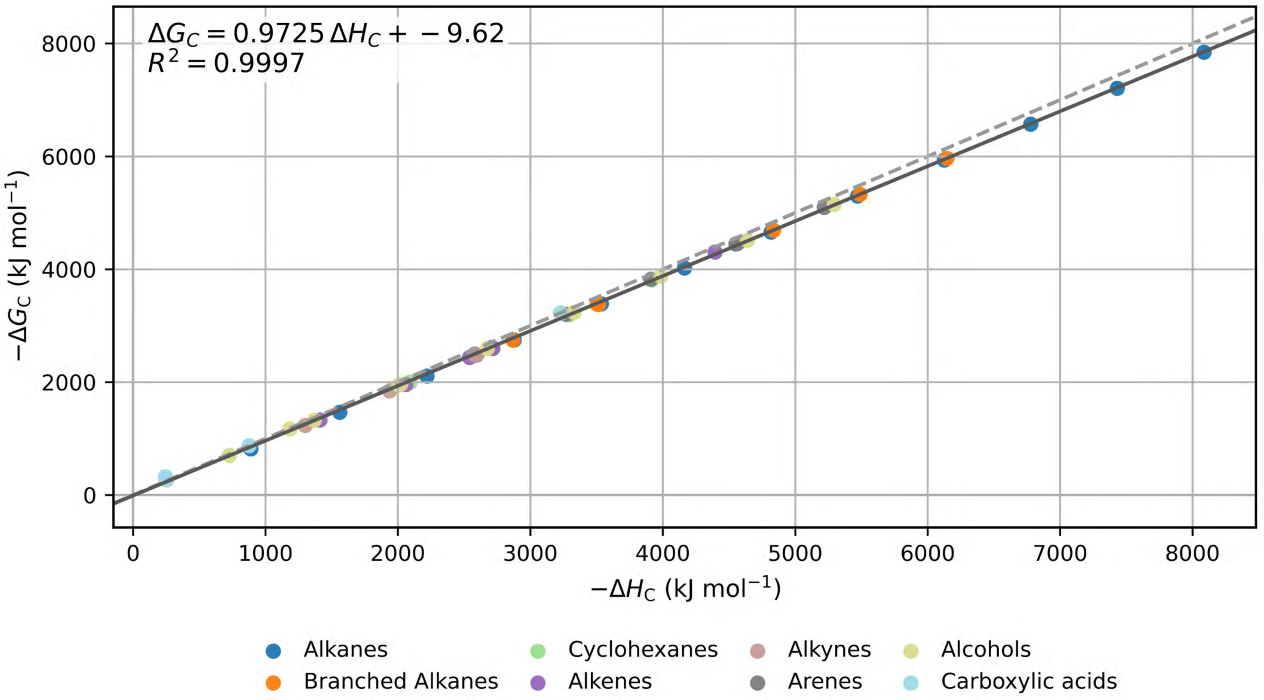

**Figure 2.** $-\Delta G_C$ versus $-\Delta H_C$.for organic compounds grouped by chemical family. The dotted line represents the 45° line corresponding to $\Delta G_C = \Delta H_C$; the solid line shows the linear regression given by Eq. (7).

$$-\Delta H_C = \Delta H_F(C_xH_yO_z) + \left(x + \frac{y}{4} - \frac{z}{2}\right)\Delta H_F(O_2) - x\Delta H_F(CO_2) - \frac{y}{2}\Delta H_F(H_2O) \quad (6)$$

Using the values of $\Delta G_f^\circ$ and $\Delta H_f^\circ$ obtained from Eqs. (2) and (3), the quantities $-\Delta G_C$ and $-\Delta H_C$ were calculated for the 53 organic compounds in the dataset, represented in Table S2. A plot of $-\Delta G_C$ and $-\Delta H_C$ is shown in Figure 2. The data collapse onto a linear relationship of the form in Eq. (7) where $\Delta G_C$ and $\Delta H_C$ are expressed in kJ mol$^{-1}$. The regression coefficient $R = 0.9997$ indicates the linear model in Eq. (7) gives a very good fit.

$$\Delta G_C = 0.9725\Delta H_C - 9.62 \quad (7)$$

From Fig. 2 it is evident that, for the set of organic compounds studied, which span a wide range of elemental C:H:O ratios, there exists a strong linear relationship between $\Delta G_C$ and $\Delta H_C$. The slope is close to unity, and the intercept is small relative to the magnitude of the combustion energies, which typically lie in the hundreds to thousands of kJ mol$^{-1}$.

This simplified examination of organic compounds holds a mean average percent error, MAPE, of 1.71% with a mean average error, MAE, of 24.53 kJ/mol, proving there is very nominal error with this estimation.

## Hypothesis

Based on the observed linear correlation in Fig. 2, it is hypothesized that that relationship described by Eq. (7) applies generally to compounds in the form $C_xH_yO_z$. Accordingly, the Gibbs free energy of combustion, $\Delta G_C$, for any biomass-derived compound containing only carbon, hydrogen and oxygen may be estimated directly from its measured heat of combustion, $\Delta H_C$. Given the elemental C:H:O ratios and estimated value of $\Delta G_C$, the standard Gibbs free energy of formation, $\Delta G_f^\circ$, may then be calculated using Eq. (5), and the corresponding heat of formation, $\Delta H_f^\circ$, using Eq. (6).

## Hypothesis Testing

To test the hypothesis that the linear relationship between the Gibbs free energy of combustion, $\Delta G_C$, and the heat of combustion, $\Delta H_C$, applies to biomass-derived compounds of the form $C_xH_yO_z$, published thermodynamic data for cellulose, starch, and glucose were examined. In particular, data for several allomorphic forms of cellulose with chemical formula $C_6H_{10}O_5$, reported by Ioelovich [14], were used. In this work, values of the standard heat of formation, $\Delta H_f^\circ$, were derived from measured heats of combustion, $\Delta H_C$. In addition, published values of $\Delta H_f^\circ$ and $\Delta G_f^\circ$ for α-D-glucose and potato starch

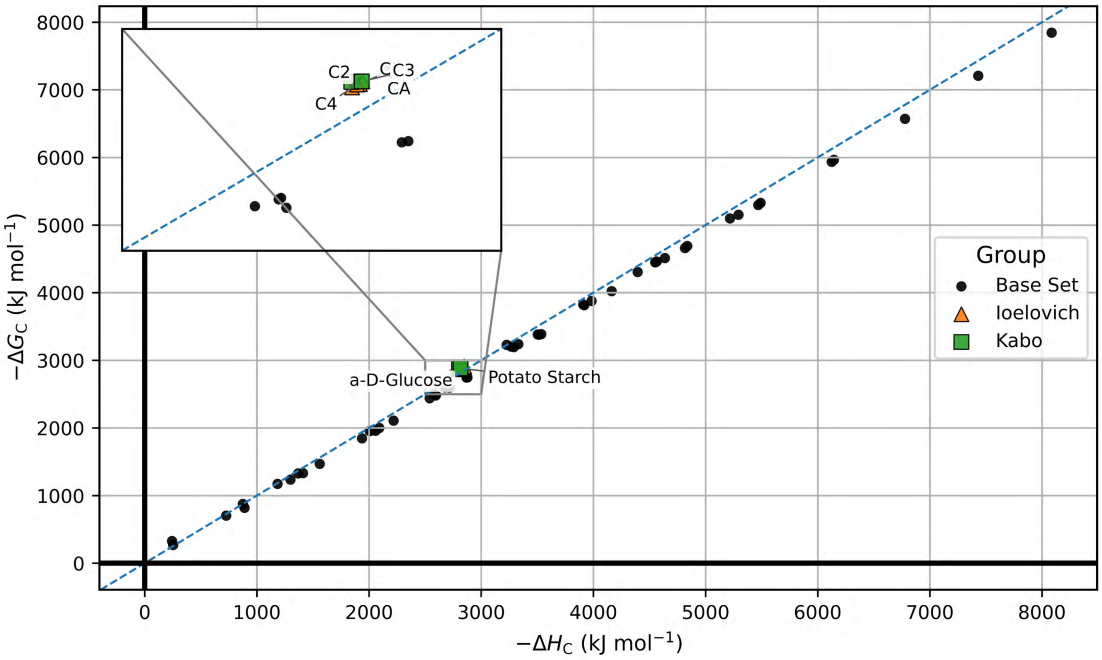

**Figure 3.** Comparison of $-\Delta G_C^*$ and $-\Delta H_C^*$ for biomass-derived compounds from references [14, 15] with $-\Delta G_C$ versus $-\Delta H_C$ for 53 organic compounds from the NIST database. The dotted line represents the 45° line corresponding to $\Delta G_C = \Delta H_C$.

reported by Kabo et al. [15] were included in the test. The thermodynamic data used in this analysis are summarized in Tables 1 and 2.

**Table 1.** $\Delta G_f^\circ$ and $\Delta H_f^\circ$ of formation of cellulose allomorphs as determined by Ioelovich [14].

| Cellulose Allomorph | $-\Delta H_f^\circ$ (kJ mol$^{-1}$) | $-\Delta G_f^\circ$ (kJ mol$^{-1}$) |
|---|---|---|
| CI | 979.6 | 676.4 |
| CII | 986.9 | 683.7 |
| CIII | 973.2 | 670.0 |
| CIV | 980.4 | 677.2 |
| CA | 942.4 | 642.6 |

**Table 2.** $\Delta G_f^\circ$ and $\Delta H_f^\circ$ of formation of glucose and starch as reported by Kabo *et al.* [15].

| Compound | Formula | $-\Delta H_f^\circ$ (kJ mol$^{-1}$) | $-\Delta G_f^\circ$ (kJ mol$^{-1}$) |
|---|---|---|---|
| α-D-Glucose | $C_6H_{12}O_6$ | 1273.7 | 908.6 |
| Potato Starch | $C_6H_{10}O_5$ | 974.1 | 670.4 |

Using the tabulated values of $\Delta H_f^\circ$ and $\Delta G_f^\circ$ from Tables 1 and 2, $\Delta H_C$ and $\Delta G_C$ were calculated using Eqs. (5) and (6). These calculated quantities are denoted as $-\Delta H_C^*$ and $-\Delta G_C^*$, respectively, and are listed in Table 3.

**Table 3.** $-\Delta H_C^*$ and $-\Delta G_C^*$ for cellulose allomorphs, glucose, and starch derived from published formation data [14, 15].

| Compound | Formula | $-\Delta H_C^*$ (kJ mol$^{-1}$) | $-\Delta G_C^*$ (kJ mol$^{-1}$) |
|---|---|---|---|
| CI Cellulose | $C_6H_{10}O_5$ | 2813.6 | 2875.5 |
| CII Cellulose | $C_6H_{10}O_5$ | 2803.3 | 2868.16 |
| CIII Cellulose | $C_6H_{10}O_5$ | 2817.0 | 2881.9 |
| CIV Cellulose | $C_6H_{10}O_5$ | 2809.8 | 2874.7 |
| Amorphous Cellulose | $C_6H_{10}O_5$ | 2847.8 | 2909.3 |
| α-D-Glucose | $C_6H_{12}O_6$ | 2802.34 | 2880.40 |
| Potato Starch | $C_6H_{10}O_5$ | 2816.11 | 2881.46 |

The values of $-\Delta H_C^*$ and $-\Delta G_C^*$ for the biomass-derived compounds were combined with the 53 organic-compound data points obtained from the NIST WebBook and plotted together in Fig. 3. Both the biomass-derived data and the tabulated organic compounds lie close to the linear relationship described by Eq. (7); although all the biomass-derived data points lie above the trendline. The deviation from the line is generally less than 100 kJ mol$^{-1}$, which is small relative to the absolute magnitudes of the combustion energies.

This level of agreement indicates that, for the purposes of conceptual thermodynamic analysis and early-

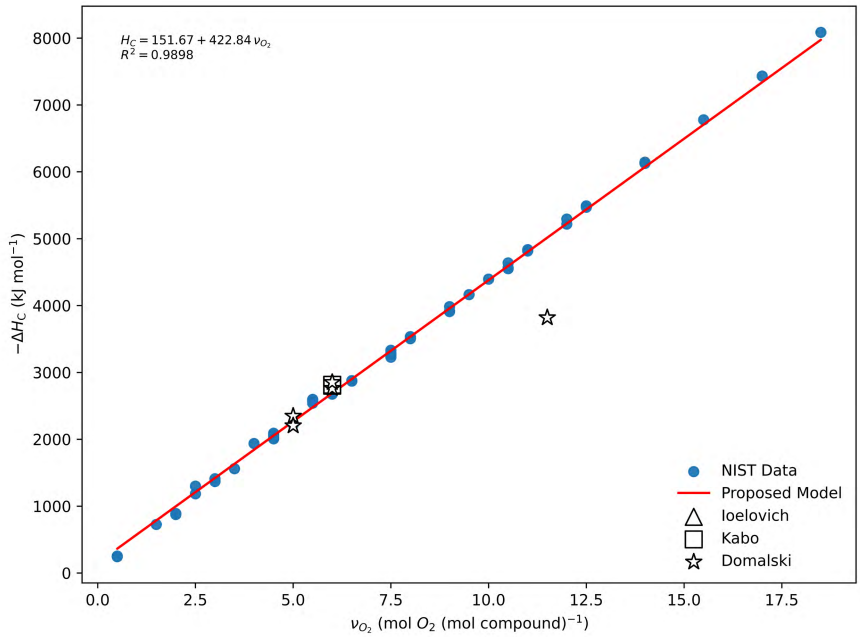

**Figure 4.** -Heat of combustion, -$\Delta H_C$, versus oxygen demand, $\nu_{O_2}$, for organic and biomass-derived compounds. Circles denote NIST data, triangles Ioelovich data [14], squares Kabo *et al.* data [15], and stars Domalski *et al* [17]. The solid line corresponds to the linear regression.

stage process synthesis, the proposed linear relationship provides sufficiently accurate estimates of $\Delta G_C$ from $\Delta H_C$. On this basis, it can be concluded that the hypothesis holds: thus, the value of $\Delta G_C$ for biomass-derived compounds of the form $C_xH_yO_z$ can be calculated from $\Delta H_C$ using Eq. (7). It then follows that the value of $\Delta G_f^\circ$ can be calculated using Eq. (5).

## Thornton's Model

Thornton proposed that, for an organic compound of the form $C_xH_yO_z$, the heat of combustion is directly related to the amount of oxygen consumed during combustion [16]. He observed that the heat released per unit mass of oxygen consumed is approximately constant at about 13.1 MJ kg$^{-1}$ $O_2$, leading to the linear relationship where $\nu_{O_2} = \left(x + \frac{y}{4} - \frac{z}{2}\right)$ is the stoichiometric oxygen demand for complete combustion, as defined in Eq. (4).

$$-\Delta H_C^T = \theta_0 + k_{O_2}\nu_{O_2} \quad (8)$$

The experimentally derived values of $\Delta H_C$ were plotted against oxygen demand for three datasets: organic compounds from NIST WebBook, cellulose allomorphs from Ioelovich [14] and starch and glucose from Kabo *et al.* [15]. These results are shown in Fig. 4. A linear regression by least squares was conducted on the data using Python's *sklearn.linear_model* package.

Regression of the combined dataset yields an excellent fit with $R^2 = 0.9898$ in the form of Eq. (9). The fitted slope of 422.84 kJ mol$^{-1}$ $O_2$ agrees well with Thornton's estimate of approximately 460 kJ mol$^{-1}$ $O_2$, confirming the applicability of the model to both organic and biomass-derived compounds.

$$-\Delta H_C^T = 151.67 + 422.84\left(x + \frac{y}{4} - \frac{z}{2}\right) \quad (9)$$

Eq. (9) implies that compounds with identical elemental composition will exhibit the same heat of combustion. Accordingly, all cellulose allomorphs examined by Ioelovich [14], which share the formula $C_6H_{10}O_5$, are predicted to have identical $\Delta H_C$. Although starch and glucose differ chemically, their oxygen demand is identical to that of cellulose and therefore fall at the same point in Fig. 4.

Using Eq. (9), the predicted heat of combustion for all seven bio compounds is $-\Delta H_C^T = 2688.72$ kJ mol$^{-1}$. Comparison with the calculated values $-\Delta H_C^*$ derived from formation data (Table 3) is shown in Table 4. Deviations are on the order of 4-5%, indicating that Thornton's model provides sufficient accuracy for conceptual thermodynamic analysis.

The mean absolute percentage error corresponds to a mean absolute error of 78.82 kJ mol$^{-1}$. For compounds with large combustion energies, this results in small percentage errors. For compounds with lower $\Delta H_C$, percentage errors increase. For example, oxalic acid ($(COOH)_2$) exhibits a 48.9% error, whereas 1-4-dimethylbenzene ($C_8H_{10}$) shows an error of only 0.85%. This indicates that

the proposed framework is most suitable for biomass-derived and other high-molecular-weight organic compounds.

**Table 4.** Comparison calculated heats of combustion, $-\Delta H_C^*$, with Thornton-model predictions $-\Delta H_C^T$.

| Compound | $-\Delta H_C^*$ (kJ mol$^{-1}$) | $-\Delta H_C^T$ (kJ mol$^{-1}$) | Percent Error (%) |
|---|---|---|---|
| CI | 2813.6 | 2688.72 | 4.44 |
| CII | 2803.3 | 2688.72 | 4.09 |
| CIII | 2817.0 | 2688.72 | 4.55 |
| CIV | 2809.8 | 2688.72 | 4.31 |
| CA | 2847.8 | 2688.72 | 5.59 |
| α-D-Glucose | 2802.34 | 2688.72 | 4.05 |
| Potato Starch | 2816.11 | 2688.72 | 4.52 |

## Comparing HHV Data from Domalski *et al.* with Thornton Model

The applicability of Thornton's model to biomaterials was further examined using biomass compounds for which only higher heating values (HHV) are available. Domalski *et al.* [17] reported HHV values for several biomass-derived compounds (Table 5). These values were converted to heats of combustion using molecular weights derived from elemental composition, assuming pure components.

**Table 5.** HHV and chemical composition of select biomass compounds from Domalski *et al* [17].

| Compound | Formula | HHV (BTU lb$^{-1}$) |
|---|---|---|
| Cellulose | $C_6H_{10}O_5$ | 7325 |
| Lignin | $C_{10}H_{12}O_3$ | 9111 |
| Starch | $C_6H_{10}O_5$ | 7560 |
| Xylan | $C_5H_8O_4$ | 7637 |
| Hemicellulose | $C_5H_8O_4$ | 7170 |

When plotted in Fig. 4, all compounds except lignin follow the Thornton correlation closely. Using the nominal formula $C_{10}H_{12}O_3$, the Thornton model predicts $-\Delta H_C^T = 5014$ kJ mol$^{-1}$, whereas Domalski *et al.* report a value equivalent to 3819 kJ mol$^{-1}$. The deviation for lignin could be attributed to its structural complexity and compositional heterogeneity, leading to $\nu_{O_2}$ not being estimated correctly.

## Relationship between $\Delta H_f^\circ, \Delta G_f^\circ$ and Oxygen Demand

By combining the linear relationship between $\Delta G_C$ and $\Delta H_C$ established in Eq. (7) with Thornton's oxygen-demand model Eq. (9), a simple framework is obtained for estimating the standard heats and Gibbs free energies of formation of organic and biomass-derived compounds of the form $C_xH_yO_z$.

Combining Eq. (6) and (9), the standard heat of formation may be expressed directly as a function of elemental composition:

$$\Delta H_F^0 = 151.67 + 29.33x - 37.21y - 211.42z \quad (10)$$

Similarly, combining Eqs. (7) and (9) yields an expression for the Gibbs free energy of combustion:

$$-\Delta G_C = 137.88 + 411.21x + 102.8y - 205.6z \quad (11)$$

Substitution of Eq. (11) into the combustion-free-energy balance, Eq. (5), allows the standard Gibbs free energy of formation to be estimated as:

$$\Delta G_F^0 = 147.5 + 16.65x - 15.77y - 205.6z \quad (12)$$

The units of enthalpy and Gibbs free energy are kJ mol$^{-1}$. Eqs (10) and (12) therefore provide a closed, composition-based method for estimating both $\Delta H_F^0$ and $\Delta G_F^0$ for any compound containing only carbon, hydrogen and oxygen.

## Estimation of Enthalpy and Gibbs Free Energy of Reaction

Once formation properties are known, enthalpies of reaction, $\Delta H_{rxn}$ and Gibbs free energy of reaction, $\Delta G_{rxn}$ can be estimated for reactions between any organic or biomass-derived compounds. Consider the anaerobic conversion of reaction $C_{x1}H_{y1}O_{z1}$ to a product $C_{x2}H_{y2}O_{z2}$. Writing the reaction in terms of carbon dioxide and liquid water balance yields, in which $\nu_{O_{2,i}}$ is defined in Eq. (14):

$$C_{x1}H_{y1}O_{z1} + \left(\frac{\nu_{O_{2,1}}}{\nu_{O_{2,2}}}x_2 - x_1\right)CO_2 + \frac{1}{2}\left(\frac{\nu_{O_{2,1}}}{\nu_{O_{2,2}}}y_2 - y_1\right)H_2O = \frac{\nu_{O_{2,1}}}{\nu_{O_{2,2}}}C_{x2}H_{y2}O_{z2} \quad (13)$$

$$\nu_{O_{2,i}} = \left(x_i + \frac{y_i}{4} - \frac{z_i}{2}\right) \quad (14)$$

This can then be used to determine $\Delta H_{rxn}$ and $\Delta G_{rxn}$ by the following Eqs:

$$\Delta H_{rxn} = -\Delta H_{C,1} + \frac{z_1 - 2x_1 - \frac{y_1}{2}}{z_2 - 2x_2 - \frac{y_2}{2}}\Delta H_{C,2} \quad (15)$$

$$\Delta G_{rxn} = -\Delta G_{C,1} + \frac{z_1 - 2x_1 - \frac{y_1}{2}}{z_2 - 2x_2 - \frac{y_2}{2}}\Delta G_{C,2} \quad (16)$$

## Connection to Process Synthesis and Estimation of Minimum Operating Costs

For a process exchanging a quantity of heat $Q_0$ at ambient temperature $T_0$ and work $W$ with its surroundings, we can show that:

$$\Delta H_{rxn} = Q_0 + W \quad (17)$$

For a reversible process, the minimum reversible work, $W_{rev}$, requirement is given by Eq. (18) while for a real, irreversible process, Eq. (19) holds:

$$W_{rev} = \Delta G_{rxn} \quad (18)$$

$$W = W_{rev} + W_{lost} \quad (19)$$

Thus, estimates of $\Delta G_{rxn}$ provide direct insight into the minimum work requirements for a process and allow for estimation of irreversibilities if the work consumption of an actual process is known. In electrochemical and electrically driven processes, where operating costs are typically dominated by electricity consumption, the minimum operating cost can be calculated from the cost of a quantity of electricity $\Delta G_{rxn}$. Large deviations between actual work input and $\Delta G_{rxn}$ indicate significant losses arising from reaction pathways, or equipment design and operation.

### Chemical Reaction Equilibrium Analysis

The equilibrium constant at temperature $T_0$ is given by:

$$K_{eq}(T_0) = \exp\left(\frac{\Delta G_{rxn}(T_0)}{RT_0}\right) \quad (20)$$

Accordingly, Eq. (16) may be used to estimate equilibrium constants for reactions involving organic and biomass-derived compounds. The temperature dependence of $K_{eq}(T)$ can then be evaluated using the Gibbs-Helmholtz equation, with $\Delta H_{rxn}$ obtained from Eq. (15).

### Scope and Use

The simplified composition-based estimation of $\Delta H_F^0$ and $\Delta G_F^0$ developed here is particularly valuable for early-stage process analysis and synthesis. It enables rapid assessment of reaction driving forces, equilibrium limitations, minimum work requirements and potential operating costs before detailed kinetic, separation, and flowsheet models are available. The only information that is required is the elemental composition of the components.

## DISCUSSION

A central contribution of the proposed methodology is the establishment of a method for estimating $\Delta H_f^o$ and $\Delta G_f^o$ for biomass-derived compounds of the form $C_xH_yO_z$. At present, reported thermodynamic properties for biomass materials span wide ranges, reflecting differences in feedstock origin, crystallinity, polymorphism, moisture content, and experimental methodology. While such variability is important for detailed material characterization, it complicates early-stage techno-economic and thermodynamic analyses, where the objective is to assess feasibility, energy requirements, and fundamental limits rather than to resolve fine material distinctions. For many other biomass-derived compounds, reliable values of Gibbs free energy of formation are simply unavailable due to the difficulty of direct measurement. The framework proposed here provides a physically grounded reference point that is sufficiently accurate for conceptual analysis of heat and work requirements.

From a process systems perspective, the ability to estimate both $\Delta H_f^\circ$ and $\Delta G_f^\circ$ on a consistent basis is particularly valuable. Many process analysis tasks, including energy integration, lost-work analysis, reaction screening, and equilibrium assessment, require at least one of these properties. When different compounds within a flowsheet rely on inconsistent data sources or assumptions, the resulting calculations can be internally inconsistent and misleading. By expressing formation properties directly in terms of elemental composition, the proposed approach enables thermodynamically consistent calculations across all compounds in a system, facilitating reliable comparison of alternative process pathways.

The integration of the linear correlation between $\Delta H_C$ and $\Delta G_C$ with Thornton's oxygen-demand model provides a clear physical basis for the method. The strong linearity observed across a broad set of organic compounds, and its extension to biomass-derived materials, supports the hypothesis that combustion thermodynamics are dominated by elemental composition rather than molecular structure at a first-order level. The deviations observed for complex materials such as lignin highlight important practical considerations, most notably sample heterogeneity and hydration, but do not undermine the utility of the approach for early-stage analysis. Indeed, the ability to flag possible inconsistencies in experimental measurements could aid in identifying issues related to sample heterogeneity, incomplete drying, or other experimental issues.

From the standpoint of process synthesis and optimization, the principal value of the methodology lies in its connection to minimum work requirements and reaction driving forces. Estimates of $\Delta G_{\mathrm{rxn}}$ provide direct insight into reversible work limits, equilibrium constants, and the magnitude of unavoidable irreversibilities. In electrically driven and electrochemical processes, where operating costs are dominated by electricity consumption, these estimates translate directly into lower bounds on operating cost. Conversely, large discrepancies between actual work input and estimated $\Delta G_{\mathrm{rxn}}$ signal opportunities for improved reaction pathways, flowsheets or equipment design. In this sense, the proposed framework enables lost-work targeting for biomass systems that would otherwise be inaccessible due to missing thermodynamic data.

The methodology is subject to several limitations that define its intended scope of applicability. It is formulated for compounds containing only carbon, hydrogen, and oxygen, and does not explicitly account for nitrogen, sulphur, or other heteroatoms. The linear correlation observed between $\Delta G_C$ and $\Delta H_C$ in Fig. 2 is therefore expected to apply primarily to CHO compounds. In addition, the method does not distinguish between structural isomers or polymorphs, assigning identical thermodynamic properties to compounds with the same elemental

composition. While this limits its use for detailed materials characterization, it may be appropriate for early-stage process synthesis and conceptual thermodynamic analysis, where such distinctions typically have a limited impact on feasibility assessments and comparative process screening.

## CONCLUSION

A composition-based methodology has been developed for estimating $\Delta H_f^\circ$ and $\Delta G_f^\circ$ of biomass-derived compounds containing C, H and O. By combining an observed linear relationship between the $\Delta H_C$ and $\Delta G_C$ with Thornton's oxygen-demand model, the approach enables consistent estimation of formation properties using widely available combustion data. Validation against published data for cellulose, starch, glucose, and related compounds indicates that the method provides sufficient accuracy for conceptual thermodynamic analysis.

The proposed framework supports early-stage process synthesis and screening by enabling rapid estimation of reaction enthalpies, minimum work requirements, equilibrium constants, and reaction driving forces in systems where reliable thermodynamic data are otherwise unavailable. While the method is limited to CHO compounds and does not account for structural or polymorphic effects, it provides a practical and internally consistent basis for evaluating the thermodynamic feasibility of biomass conversion and $CO_2$ utilization pathways prior to detailed flowsheet development.

## ABSTRACT

Waste incineration with combined heat and power (CHP) supplies electricity and heat to cities and industrial clusters but remains a significant source of greenhouse gas emissions. This work develops an optimization-based, system-level decarbonization framework for an integrated waste-to-energy and chemical production cluster under operational, societal, and economic constraints. The framework is applied to a real-world case study including a municipal waste incineration plant, an energy utility system, and multiple chemical production units. A layered decarbonization strategy is implemented. First, energy efficiency is enhanced through waste heat valorization using heat pumps. Second, coordination between industrial actors is improved through solid waste storage management and operational alignment of heat and power supply with demand. Third, alternative feedstocks are introduced to reduce fossil-based inputs. Within the work material and heat-stream inventories are collected, and the required chemical synthesis pathways are modeled using Aspen Plus. The integrated system is optimized within the OSMOSE framework using a multi-period mixed-integer linear programming formulation that minimizes the annualized total cost while accounting for seasonal heat demand and electricity price variability. The results show that waste-heat upgrading alone enables fossil emission reductions of up to 22% while improving overall system profitability. More broadly, up to 80% of fossil-based Scope 1 and Scope 2 $CO_2$ emissions can be reduced through energy efficiency improvements, system integration, and feedstock substitution prior to carbon capture deployment. To address the remaining hard-to-avoid emissions and enable net-negative operation, post-combustion carbon capture options are evaluated in combination with solid oxide electrolysis cells (SOEC).

**Keywords**: Industrial symbiosis, Waste valorization, Waste heat, Carbon capture, Process integration

## INTRODUCTION

In Switzerland, the most common practice for treating municipal solid waste is incineration. Approximately 30 waste incineration plants are currently in operation, treating about 4 Mt/yr of waste and accounting for roughly 5% of national $CO_2$ emissions [1]. A large share of these facilities is connected to district heating networks, while a smaller number directly supplies steam to nearby industrial zones. Although this configuration reduces additional fossil fuel combustion for steam generation and residential heating, current systems often fail to fully exploit the efficiency potential of the existing infrastructure. As a result, significant opportunities remain for optimization, particularly through improved valorization of industrial condensate using heat pumps and enhanced coordination between actors to further reduce fossil fuel use. In addition, waste can be used as a feedstock for the production of basic chemicals for nearby industries, extending industrial symbiosis beyond energy exchange to include material flows. This can further reduce the fossil dependency of the chemical sector, which is currently estimated to rely on fossil-based feedstocks for approximately 95% of its raw material input.

This work provides a system-level analysis involving multiple actors, combining process modeling, integration,

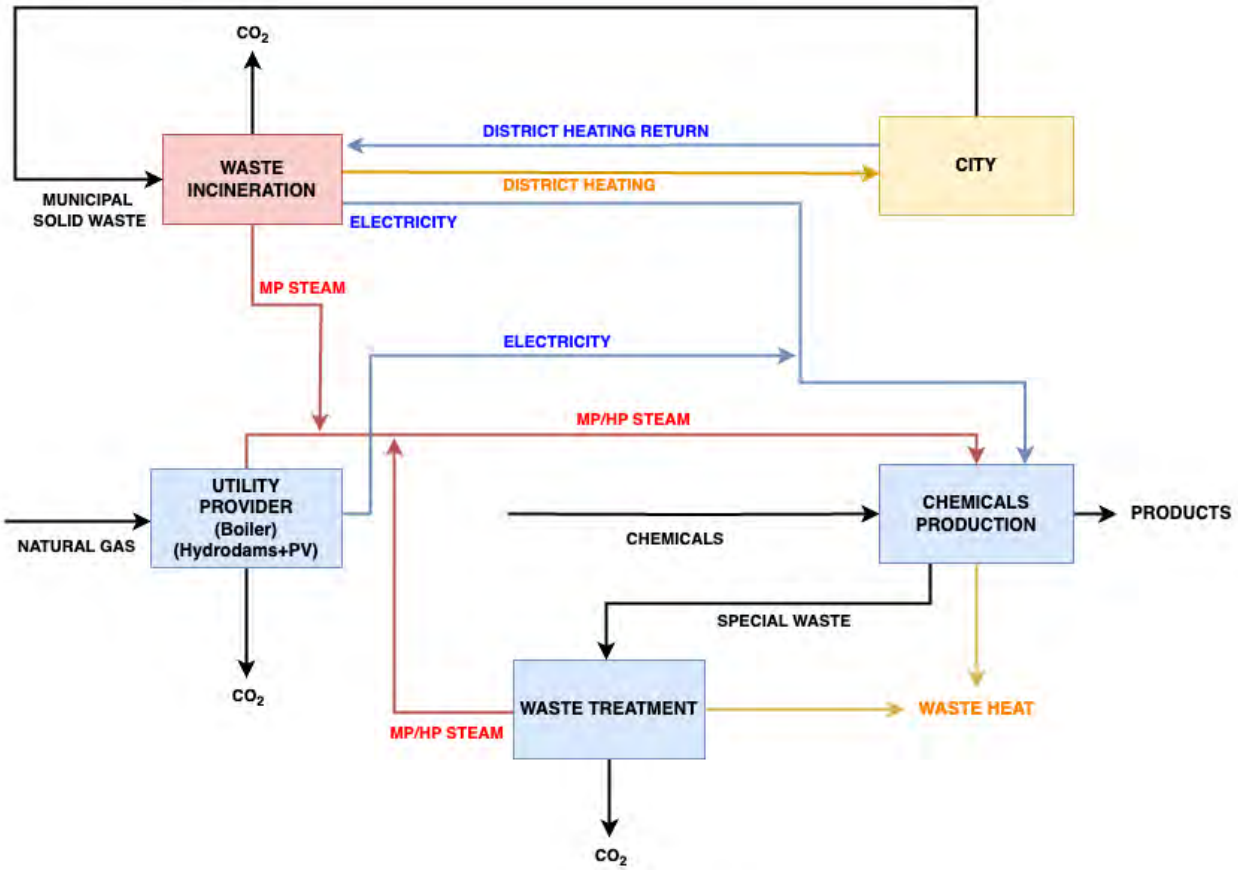

**Figure 1.** System boundary and energy–material interactions between system actors

and optimization to improve energy efficiency and reduce fossil-based emissions while explicitly accounting for economic constraints. A layered decarbonization approach is adopted, prioritizing measures that are easier to implement and adapt in industrial practice, thereby reducing reliance on and challenges associated with large-scale carbon capture deployment.

## METHODS

### System Boundary and Actors

Within the defined system boundaries shown in Figure 1, several industrial actors are considered. The first is the waste-to-energy (WtE) plant, which treats municipal solid waste (MSW) and supplies energy in the form of medium-pressure (MP) steam and electricity to the chemical processes, as well as hot water to the district heating network. The second actor is the utility company, which provides heat, power, and special waste treatment services to the chemical processes. Its available assets within the system include a natural gas boiler for the production of MP and high-pressure (HP) steam, waste incineration units capable of supplying MP and HP steam, and renewable power generation units, including hydropower dams and photovoltaic (PV) fields. The third actor consists of the chemical production units, which require electricity, steam, and basic chemical feedstocks, and produce high-value chemicals for the market. These units also benefit from cooling services provided by the utility company, generating low-grade waste heat that can be upgraded and valorized within the system. The final actor is the city, which requires heat for most of the year due to local climatic conditions, supplies municipal solid waste to the WtE plant, and acts as a net importer of electricity, with limited photovoltaic installations and hydropower capacity.

Although a certain degree of industrial symbiosis already exists between these actors, their current level of coordination remains far from optimal. As a result, significant opportunities for improving energy efficiency and reducing fossil-based carbon emissions remain unexploited. This work addresses these gaps by strengthening existing energy distribution and material exchange links and introducing new integration pathways within the system. The coordination of actors is optimized using a system-level approach to achieve the decarbonization objectives outlined above.

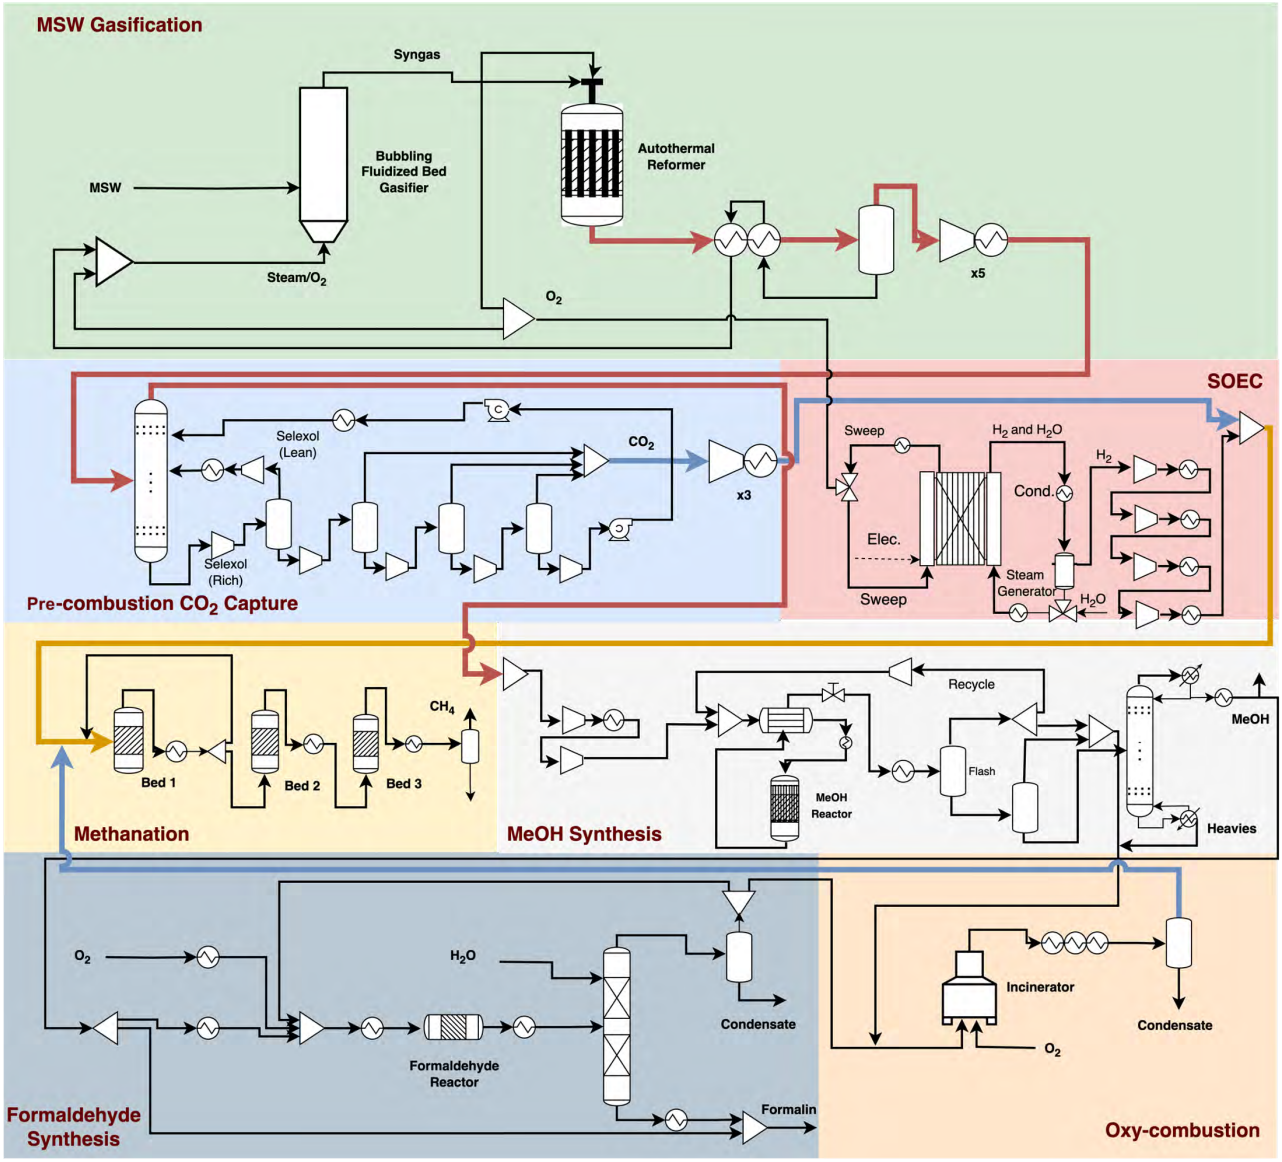

**Figure 2.** Superstructure of chemical synthesis pathways considered in the study, including municipal solid waste gasification for syngas production, pre-combustion carbon dioxide capture, $H_2$ production with SOEC, oxy-combustion for $CO_2$ capture, and downstream synthesis of methanol, formaldehyde, and synthetic natural gas.

## Energy Demand and Supply in the System

In the current reference state of the system, approximately 67% of the total heat demand for the chemical processes is supplied as MP steam, while the remaining demand is covered by HP steam. Around half of the MP steam demand is met by the WtE facility, with the remainder supplied by the NG boiler operated by the utility company. For HP steam, the dominant share is provided by the incineration of special waste, accounting for approximately 80% of the supply, while the remaining share is supplied by the NG boiler. All heat demand of the city is covered by the WtE facility and represents approximately one fifth of the heat demand of the chemical processes.

In terms of power distribution, approximately 40% of the electricity consumed by the utility company and the chemical processes is supplied by the WtE facility. Around 8% is generated by PV installations, while the remaining share is provided by hydropower dams, with the possibility of electricity injection into the grid in the case of excess generation.

As a consequence of the current heat and power generation and distribution, approximately 65% of the total $CO_2$ emissions originate from the WtE facility, of which about half corresponds to biogenic carbon. Around 25% of the $CO_2$ emissions are associated with the incineration

of special waste, while the remaining 10% result from the combustion of natural gas for steam supply.

## Process Modeling of Chemical Pathways

MSW can be valorized beyond direct incineration by converting it into syngas for the production of basic chemicals and by recovering high-grade heat for industrial applications. In this context, this study considers a superstructure of chemical synthesis pathways that enables the integrated valorization of material and energy streams within the overall system, as shown in Figure 2.

For the gasification of MSW, a model of bubbling fluidized gasifier using oxy-steam as the gasification agent, operated at 750 °C and 1 bar was used based on the study of Sebastiani et al. [2]. The chemical properties of the waste used is given in Table 1.

**Table 1.** Proximate and ultimate analysis of MSW (fuel as received)[2]

| Composition | | MSW |
|---|---|---|
| Proximate Analysis [%] | M | 14.6 |
| | FC | 8.90 |
| | VM | 64.7 |
| | Ash | 11.8 |
| Ultimate Analysis [%] | C | 41.8 |
| | H | 5.05 |
| | N | 3.02 |
| | O | 23.4 |
| Net calorific value [MJ/kg] | | 19.9 |

The produced syngas passes through an adiabatic autothermal reformer and is subsequently cooled to condense water. The resulting syngas is processed in an selexol-based carbon capture unit operating at 30 bar with 90% capture efficiency, adjusting the composition to the stoichiometric number (SN) of slightly above 2.0 required for methanol synthesis [3]. The resulting syngas after the upgrading has a molar composition of 68.3% $H_2$, 31.3% CO, 0.4% $CO_2$.

$$SN = (x_{H_2} - x_{CO_2})/(x_{CO} + x_{CO_2})$$

The methanol synthesis process is operated isothermally at 210 °C and 90 bar, based on Lurgi's MegaMethanol® technology, achieving a mass yield of 95.8% [4]. The produced methanol can either be used as a base chemical within the system or converted to formaldehyde via the Formox® process, which is based on the catalytic oxidation of methanol [5]. The reaction is operated at 250 °C and 1 bar. Following formaldehyde production, the product is mixed with methanol and water to obtain a formalin solution with a composition of 38% formaldehyde, 14% methanol, and 48% water on a molar basis.

The $CO_2$ captured during syngas upgrading and from the oxy-combustion of purge streams is utilized in a methanation process coupled with SOEC, following the approach proposed by Flórez-Orrego et al [6].

## Definition of Decarbonization Options

Following the layered decarbonization strategy, five system configurations are defined and analyzed. Each configuration progressively extends the level of integration, flexibility, and decarbonization options considered in the optimization framework.

- **Base**: The base configuration represents the reference system as defined in the previous sections, without additional flexibility or decarbonization measures.
- **A**: In this configuration, waste heat available from chemical synthesis processes and special waste incineration is valorized through the integration of decentralized and centralized steam-generating heat pumps. WtE is operated considering historical trends.
- **B**: Building on Configuration A, the waste-to-energy (WtE) facility is allowed for operational flexibility through the management of seasonal solid waste storage. The facility can adjust the allocation between steam, electricity, and district heating production in response to the demands of other system actors
- **C:** In addition to the features of Configuration B, waste heat from chemical synthesis and special waste treatment is further upgraded via heat pumps and allowed to supply the district heating network, thereby introducing competition with district heating generated by the WtE facility.
- **D**: The final configuration extends Configuration C by integrating a municipal solid waste (MSW) gasifier. The produced syngas is used as a feedstock for the synthesis of basic chemicals (i.e., methanol and formalin) at the chemical site. In addition, pre-combustion $CO_2$ captured from the gasification process is combined with hydrogen produced by a solid oxide electrolysis cell (SOEC) to increase chemical yields or enable the production of synthetic natural gas.

Each configuration is also evaluated with the integration of post-combustion carbon capture based on MEA for the capture of all the remaining $CO_2$ emissions within the system boundaries. Configurations including carbon capture are denoted by a prime symbol (') throughout this study.

## Optimization Framework and Problem Formulation

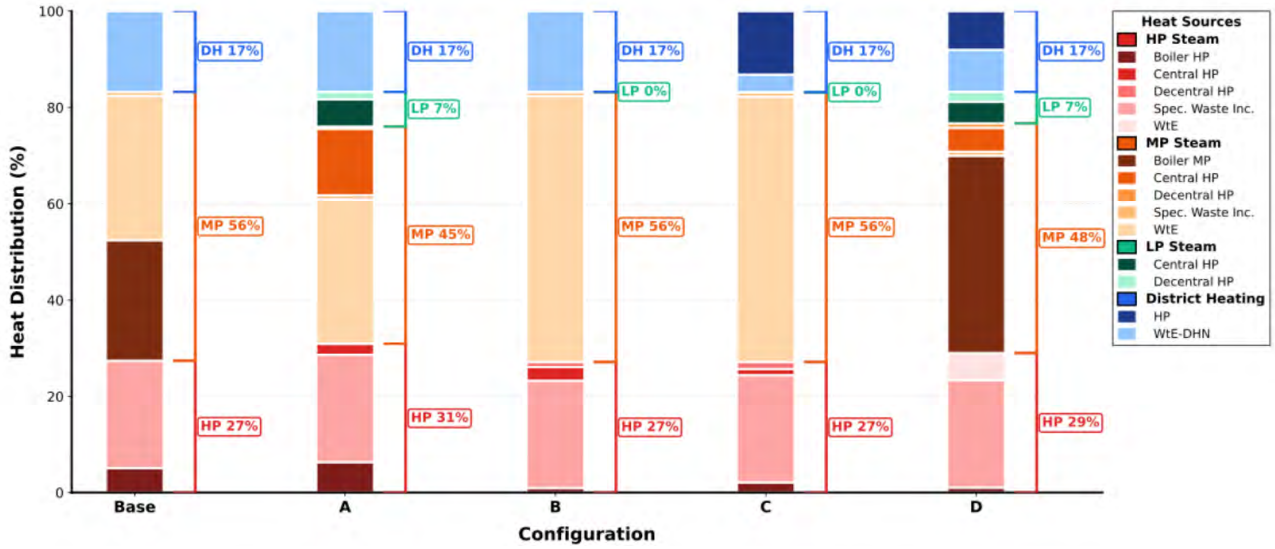

**Figure 3a.** Heat distribution by steam pressure level and heat source across the different decarbonization configurations.

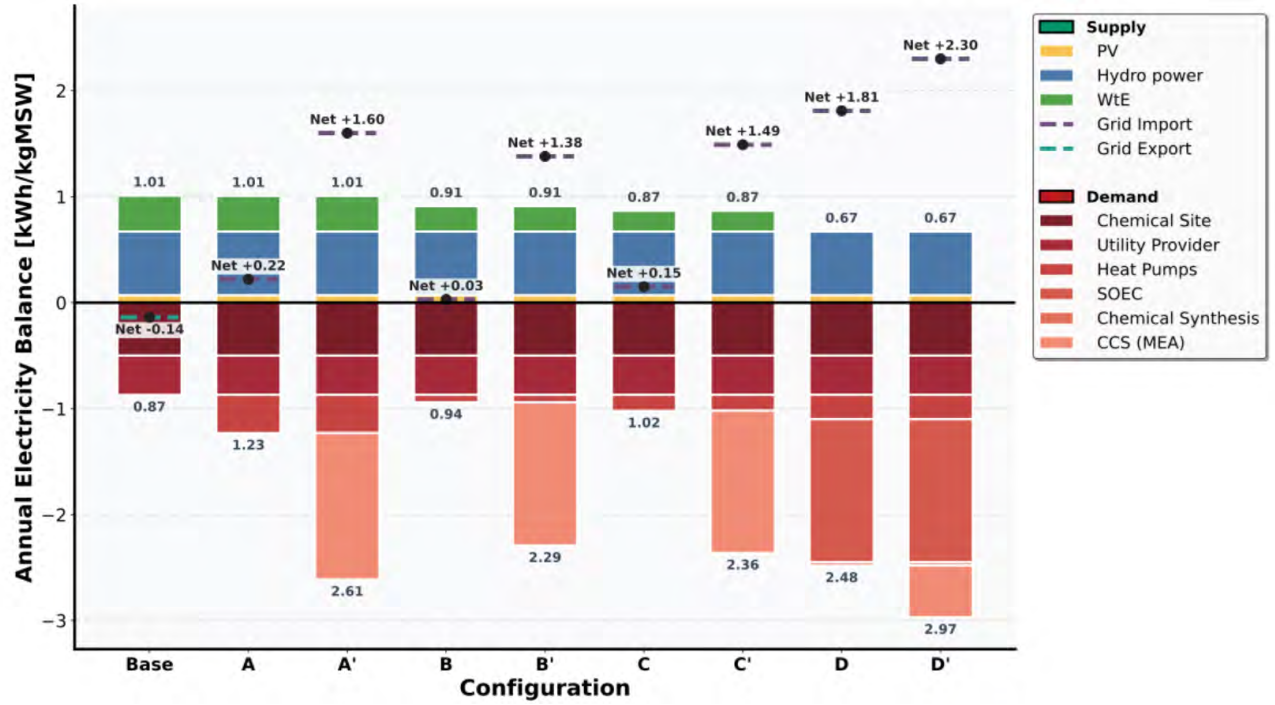

**Figure 3b.** Annual electricity balance of the integrated system across the different decarbonization configurations, showing electricity supply and demand contributions.

The proposed configurations are integrated and optimized within the OSMOSE Lua platform to identify cost-optimal operating conditions for the superstructure, as defined by the objective function presented below [7].

$$\min Cost_{tot} = \sum_{u \epsilon Units} \left[ \sum_{t \epsilon Time} [(Cop1_u \bullet Y_{u,t} + Cop2_u \bullet M_{u,t}) \Delta t + Cinv1_u \bullet Y_u + Cinv2_u \bullet M_u] \right]$$

- $Cop1_u$ [EUR/h]: fixed operating cost of unit u,
- $Cop2_u$ [EUR/kWh or EUR/kg]: variable operating cost of unit u,
- $Y_{u,t}$ [-]: integer variable standing for the activation of the unit u at a time t,
- $M_{u,t}$ [kg/h or kW]: continuous variable standing for the load of the unit u at a time t,

- $Cinv1_u$ [EUR/y]: fixed annualized cost of unit u,
- $Cinv2_u$ [EUR/kWh or EUR/kg]: variable annualized cost of unit u,
- $Y_u$ [-]: integer variable for the activation of the unit u, maximum value of $Y_{u,t}$,
- $M_u$ [kg/y or kWh/y]: maximum load of the unit.

The problem is solved using a multi-period formulation with 10 representative clusters, capturing steam demand of chemical processes, district heating requirements, MSW supply to WtE, and electricity/natural gas prices based on the Swiss spot market [8]. The electricity supply is considered to be fully decarbonized based on the real-case arrangements defined within the system boundaries. A Scope 2 emission factor of 0.05 $kgCO_2$/kWh is applied to the natural gas supply.

## RESULTS AND DISCUSSION

This section presents and discusses the results of the OSMOSE optimization framework for the different configurations, focusing on energy distribution, fossil $CO_2$ emissions, and the resulting economic trade-offs.

### Energy Distribution and Electricity Demand

The heat distribution within the system for each configuration is shown in Figure 3a. In Configuration A, where only heat pump integration is introduced at temperature levels of 40 °C and 70 °C, the boiler supplying MP steam is no longer required. In contrast, the HP boiler remains in operation due to the higher temperature lift required. As a result, approximately 90% of the available waste heat is upgraded to LP and MP steam levels, while only about 10% is upgraded to HP steam, primarily during periods of low electricity spot prices.

In Configuration C, when the WtE facility is allowed to better align its operation with the other system actors and waste heat can be supplied to the district heating network, it becomes the sole provider of MP steam. At the same time, its direct contribution to district heating is reduced by approximately 80%. Given the high coefficient of performance of the heat pumps supplying the district heating network (COP = 4.3), the system favors cascading heat through the chemical processes while using the available waste heat primarily for meeting the city's heating demand. As a result, only about 18% of the available waste heat is utilized for steam generation.

Finally, in Configuration D, the system enables the production of synthetic natural gas, and the heat released from syngas cooling, exothermic methanol and formaldehyde synthesis, and purge stream combustion is recovered and reused for steam generation for the gasifier and the SOEC. As a consequence, the contribution of waste treatment to steam supply is reduced and the MP boiler is reactivated. In this configuration, approximately 60% of the upgraded waste heat is allocated to steam generation, while only about half of the city's heating demand is supplied via heat pumps.

As shown in Figure 3b, at its current electricity generation capacity the system is not able to remain fully self-sufficient and therefore requires electricity imports across all configurations. In Configuration A, the installation of heat pumps leads to an increase in electricity consumption of 0.36 $kWh_{EE}$/kgMSW. However, when improved alignment between system actors is introduced in Configuration B, the system reaches near self-sufficiency, with electricity imports limited to only 0.03 $kWh_{EE}$/kgMSW. The highest electricity consumption and imports are observed in Configuration D, as the SOEC installation requires 1.35 $kWh_{EE}$/kgMSW and electricity generation from the WtE turbine is no longer available. As the heat demand of the MEA carbon capture unit is electrified, electricity consumption increases by up to 1.38 $kWh_{EE}$/kgMSW in Configuration B′. In contrast, this increase is limited to 0.49 $kWh_{EE}$/kgMSW in Configuration D′, since a larger fraction of the carbon contained in the MSW is retained within chemical products, thereby reducing the required size of the MEA carbon capture unit

### $CO_2$ Emissions Performance

With the integration of heat pumps leading to the significant reduction in boiler usage, as illustrated in Figure 3a, net fossil emissions decrease by 17% in Configuration A, as shown in Figure 4a. Improved alignment between system actors and cascading of heat through the chemical processes before heating the city further extend the reduction in fossil emissions to 22% compared to the base case.

The remaining fossil $CO_2$ emissions consist of approximately 60% originating from MSW incineration and 40% from the incineration of special waste generated by the chemical processes; however, the system remains far from achieving carbon neutrality. In Configuration D, the valorization of waste as a feedstock for basic chemical production reduces net emissions to 0.23 $kgCO_2$/kgMSW. However, due to the combustion of synthetic natural gas, fossil $CO_2$ originating from the MSW is released again into the environment. Therefore, the integration of post-combustion carbon capture is required to achieve net negative emissions. With the deployment of MEA-based carbon capture and assuming that all remaining residual $CO_2$ is captured and permanently stored, the system can reach net negative emissions of −0.5 $kgCO_2$/kgMSW.

### Economic Performance and Cost Trade-offs

The breakdown of marginal operating and capital expenditures for all configurations is shown in Figure 4b. Across Configurations A–C, optimization of the existing

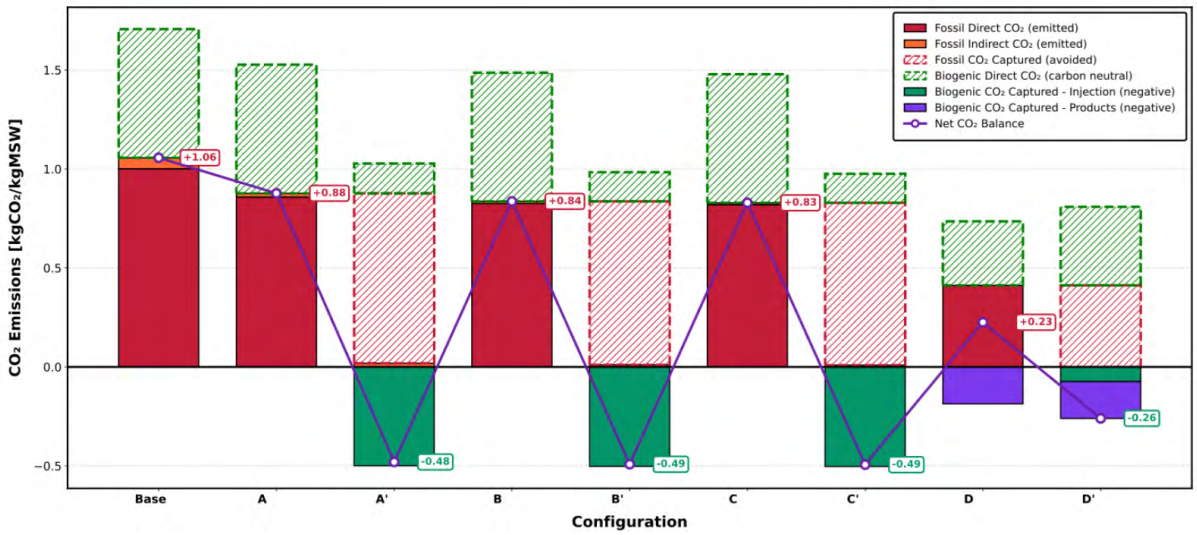

**Figure 4.a.** Breakdown of fossil and biogenic $CO_2$ emissions, captured $CO_2$, and net $CO_2$ balance across the different decarbonization configurations, normalized per kg MSW.

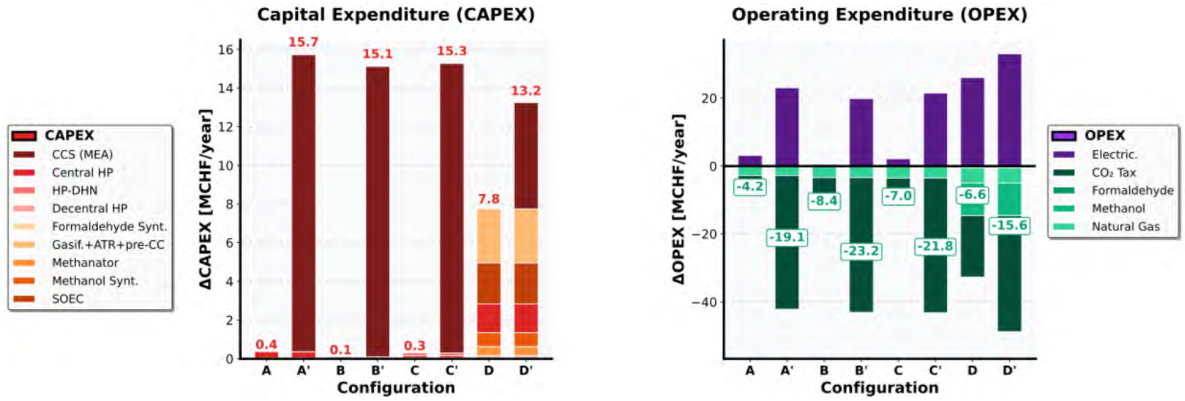

**Figure 4.b.** Breakdown of annualized capital expenditure (CAPEX) and operating expenditure (OPEX) across the different decarbonization configurations.

infrastructure combined with the installation of heat pump solutions requires limited capital investment and yields annual savings of up to 8.3 MCHF/year, with the maximum savings observed in Configuration B. In contrast, Configuration D results in a net loss of 2.2 MCHF/year. Although savings from avoided $CO_2$ taxes and additional revenues from methanol and synthetic natural gas exports exceed the required capital investments, the high cost of electricity imports ultimately leads to an overall net loss.

The integration of CCS technologies results in only a limited reduction in profitability for Configuration A'-C', amounting to approximately 0.2 MCHF/year, considering an average annual electricity spot price of 0.08 CHF/kWh and a conservative carbon price of 85 CHF/t$CO_2$ captured.

## CONCLUSIONS

This work has demonstrated a systemic analysis of a real-world case study involving multiple actors within a symbiotic relationship, including a waste incineration facility, a utility company, a cluster of chemical industries, and the city. The analysis aimed to reduce fossil $CO_2$ emissions while concerning economic profitability through the combined use of process modeling, integration, and optimization methodologies.

The results showed that as a short-term solution, integration of heat pump technologies, optimizing the steam supply levels through means of heat cascading can lead to moderate reductions in fossil $CO_2$ emissions while providing significant economic benefits. However, these measures are followed by increase in electricity consumption, highlighting the need for adequate preparation of national electricity infrastructures in case of

mass adaptation.

While cost-effective and easily adoptable technologies are desirable, they fail on their own to achieve net-zero/negative operation. The findings of this work show the benefit of a layered decarbonization approach for a decarbonization pathway, in which energy efficiency and heat integration measures are prioritized before introducing capital intensive solutions. In the longer term, full defossilization requires a transition toward alternative renewable feedstocks and explicit consideration of carbon circularity to avoid burden shifting across sectors.

## ABSTRACT

Energy Baselines (EnBs) provide a reference for evaluating Energy Key Performance Indicators (eKPIs), and their establishment is mandated under ISO 50001. Since eKPIs are typically defined per functional unit, such as product, recipe or recipe phase, EnBs should not be averaged across heterogeneous operating conditions but instead be defined in a context-specific manner. This requires detailed mechanistic models or sufficiently rich operational data for statistical approaches, both of which are often unavailable in highly flexible, semi-continuous production systems.This paper proposes a four-stage framework for the automated generation of surrogate EnBs to address this gap. In the first stage, the relevant training data space is defined, including non-influenceable variables (e.g., equipment deviations), design parameters (e.g., material properties), and adaptable recipe parameters (e.g., operating conditions and control actions). In the second stage, these parameters are systematically varied to automatically generate a labelled dataset representing process dynamics and energy behavior. The third stage trains and evaluates candidate surrogate models using the PRESTO recommendation framework, followed by a global sensitivity analysis based on Sobol indices to identify the dominant drivers of energy performance.The framework is demonstrated using a stirred tank reactor at laboratory (2 L) scale. The results show that Random Forest surrogates provide reliable performance across a wide operating range and that recipe parameters, particularly mixer rotational speed, dominate energy efficiency. Future work will address scalability to other equipment types and reactive processes.

## INTRODUCTION

Energy efficiency has become a central objective in the design and operation of chemical and biochemical production systems, driven by economic pressure, regulatory requirements, and sustainability targets [1]. Energy Management Systems (EnMS), standardized under ISO 50001, provide a structured framework for monitoring, evaluating, and improving energy performance [2]. Central to an EnMS is the definition of Energy Key Performance Indicators (eKPIs) together with appropriate Energy Baselines (EnBs), which serve as reference points for performance assessment, deviation detection, and verification of energy savings [2, 3].

In industrial practice, eKPIs are commonly expressed per functional unit, such as product [4], batch, recipe, or recipe phase [3]. This is particularly relevant for batch and semi-continuous processes, where production is governed by structured recipes as formalized in the ANSI/ISA-88 standard [5]. Consequently, meaningful EnBs must reflect the operational context in which the eKPIs are evaluated [3]. Averaging energy performance across heterogeneous recipes or operating modes can lead to misleading conclusions and conflicts ISO 50006 principles [6].

These challenges are particularly pronounced in flexible and modular production systems, where frequent reconfiguration, short production campaigns, and evolving system configurations limit the availability of sufficiently rich historical operating data. To address this, this work proposes a four-stage workflow for generating surrogate, context-specific EnBs based on systematically generated recipe-based process data and demonstrates its applicability using stirred-tank reactor case study.

## FUNDAMENTALS

### Energy Baselines and Energy Performance Indicators

EnBs and energy performance indicators (EnPIs) are fundamental elements of EnMS. ISO 50001 [2] defines EnBs as quantitative reference points against which changes in energy performance are assessed, while ISO 50006 provides guidance on their consistent establishment with respect to variables that significantly influence energy performance.

ISO 50006 distinguishes between influenceable parameters, defined as measurable factors whose values can change and that have a significant influence on energy performance [3, 6], and non-influenceable parameters, defined as measurable factors whose values are fixed or nearly fixed over the period under review but still significantly affect energy performance [4, 6].

### Recipe-Based Operation

Batch and semi-continuous processes are typically operated using recipes, as formalized in the ANSI/ISA-88 [5]. Recipes describe the sequence of operations, setpoints, control actions, and phase transitions required to produce a given product [7]. In modular plants, recipes play an even more prominent role, as the same equipment modules may be reused across different products and operating modes.

### Surrogate Modeling

Surrogate models are widely used to approximate complex process behavior when detailed mechanistic models are computationally expensive or difficult to maintain [8, 9]. In the context of energy systems, surrogate models have been applied for energy performance analysis, optimization, and decision support [4]. Common surrogate techniques include regression models, Gaussian processes, and ensemble methods such as Random Forest [10].

## PROBLEM DEFINITION AND SCOPE

Conventional approaches to EnBs definition typically assume a stable operating context or rely on averaging energy performance across multiple operating conditions [6]. In recipe-driven batch systems, such averaging is inappropriate, as different recipes and recipe phases can exhibit fundamentally different energy behavior. Applying a single baseline across heterogeneous recipes may therefore mask inefficiencies and lead to misleading energy related performance assessments.

These limitations are further amplified in highly flexible and modular production systems, where frequent reconfiguration, and ongoing system evolution prevent the accumulation of sufficiently rich historical operating data. As a result, purely data-driven EnBs approaches become impractical, while the development and maintenance of detailed mechanistic energy models that capture non-influenceable effects are often costly. Despite the growing use of surrogate models for energy performance analysis, existing approaches rarely explicitly account for recipe-based operation and typically rely on historical plant data collected under fixed operating modes.

To address this gap, this work focuses on the generation of surrogate EnBs models using systematically generated simulation data from structured recipe execution. Deterministic process models are executed repeatedly under varying parameter realizations, with particular emphasis on recipe parameters.

## FRAMEWORK FOR ENERGY BASELINES SURROGATE GENERATION

This section presents a four-stage framework for the generation of surrogate EnBs models using recipe-based simulation data. The framework is designed to address the lack of sufficiently rich operational data and the limited applicability of conventional EnBs approaches in highly flexible, semi-continuous production systems. Rather than replacing detailed mechanistic models, the proposed framework leverages such models as high-fidelity data generators to derive computationally efficient and interpretable surrogate EnBs representations.

### I. Definition of the Training Data Space

The first stage focuses on the systematic identification and definition of the training data space for the EnBs surrogate model. As EnBs are inherently dependent on the operating context, it is essential to explicitly characterize the dimensions along which energy performance may vary. To this end, the parameter space [11] is structured into state variables describing the instantaneous dynamic condition of the system, model parameters representing physical and structural characteristics such as material properties and equipment geometry, recipe parameters capturing adaptable operational decisions including setpoints, phase durations, and control actions, input variables corresponding to external operational inputs, and output variables comprising energy-related quantities and derived eKPIs.

For each free parameter, appropriate bounds and probability distributions are defined, enabling a systematic exploration of feasible operating scenarios and ensuring that the generated dataset adequately represents the expected process dynamics and corresponding energy behavior. This structured definition of the training data space provides a consistent basis for generating representative simulation data to train reduced-order surrogate models for EnBs definition and analysis. While the framework includes all parameter categories as

potential dimensions of the training data space, individual studies may fix selected subsets depending on the analysis objective and system scope.

### II. Automated Data Generation

In the second stage, the defined parameter space is systematically explored to generate labelled process data in an automated manner. All free parameters identified in Stage I are varied and combined according to their respective probability distributions, while the underlying process model is executed repeatedly using different parameter realizations. The simulations are carried out in gPROMS, with automated execution, parameter variation, and data extraction orchestrated via Python-based workflows. In particular, recipe parameters are explicitly varied, enabling the same recipe structure to be evaluated under a wide range of operating conditions.

Each simulation run yields a labelled data point comprising sampled input parameters and corresponding energy-related outputs. As the deterministic, noise-free process model is computationally expensive, the resulting dataset serves as a controlled reference for training surrogate models, enabling efficient EnBs evaluation, comparison across operating contexts, and sensitivity analysis without reliance on historical plant data.

A stratified sampling strategy is employed to ensure representative coverage of the feasible operating domain, resulting in a total of *N* simulation runs. The generated dataset represents idealized system behavior without measurement noise or structural model mismatch and is therefore intended for surrogate model development rather than direct representation of real plant variability.

While this provides a controlled benchmark for methodological development, it may lead to optimistic surrogate performance compared to real plant conditions. In practical applications, measurement noise, sensor uncertainty, and model–plant mismatch may affect predictive accuracy. Future work should therefore consider noise-augmented datasets and validation against measured plant data to ensure robustness.

### III. Surrogate Model Training and Selection

In the third stage, the generated dataset is used to train candidate surrogate models for approximating the EnBs. The objective of the surrogate models is to capture the functional mapping between the selected input parameters and the resulting eKPIs. To enable a systematic and reproducible model selection, the PRESTO (Predictive REcommendation of Surrogate models To approximate and Optimize) [12] framework is employed. PRESTO assesses candidate models based on the characteristics of the dataset and the modeling task and recommends suitable surrogate structures accordingly.

The dataset is divided into training and test subsets using a fixed split to enable unbiased evaluation of predictive performance. All candidate surrogate models are trained using identical input parameter sets and evaluated on the same test data. Hyperparameters are not exhaustively optimized but are retained at default or PRESTO-recommended values to ensure a consistent and reproducible comparison. The objective of this stage is therefore comparative model screening rather than exhaustive surrogate tuning.

While this ensures a fair and reproducible comparison, it may disadvantage models sensitive to hyperparameter selection. Therefore, the reported performance reflects comparative behavior under standardized settings rather than maximum achievable accuracy.

### IV. Global Sensitivity Analysis

The final stage focuses on improving the interpretability of the surrogate EnBs model and identifying the most influential parameters governing energy performance. To this end, a global sensitivity analysis [13] based on Sobol indices is conducted using the trained surrogate model. Both first-order ($S_1$) and total-order ($S_T$) Sobol indices are computed to quantify the individual contributions of each parameter as well as their combined interaction effects on the variability of the eKPIs. This analysis enables the identification of dominant parameters, the differentiation between influenceable and non-influenceable drivers of energy performance, and the assessment of the relative importance of recipe parameters in comparison to model parameters. Sobol indices are computed using surrogate model predictions rather than direct evaluations of the mechanistic model and may therefore be affected by approximation errors, particularly in regions with limited training data or lower predictive accuracy. While the high fidelity of the selected surrogate mitigates this effect, the results should be interpreted with consideration of potential surrogate-induced bias.

## CASE STUDY: STIRRED TANK REACTOR

A stirred tank reactor (STR) having a total volume of 2 L is considered as the case study for process data generation. Figure 1 shows a schematic of the STR used in this study. The reactor is equipped with a thermal jacket for temperature control and inlet streams for reactants. Here, red and black colors highlight energy and mass streams, respectively, while the reactor dimensions are indicated in grey color.

The case study is intentionally selected as a structurally simple and well-understood system in order to isolate and demonstrate the proposed recipe-based EnBs surrogates generation framework without introducing additional complexity from reaction kinetics or phase behavior. In reactive systems, additional complexities are expected due to nonlinear coupling between mass and

energy balances, reaction heat effects, and concentration-dependent dynamics. These factors may increase model stiffness and introduce multiple operating regimes, requiring denser sampling and potentially more expressive surrogate structures. Nevertheless, the proposed framework remains applicable in principle and provides a foundation for such extensions. This allows the methodological aspects related to recipe execution, energy flows, and operating-context variability to be analyzed in a transparent manner.

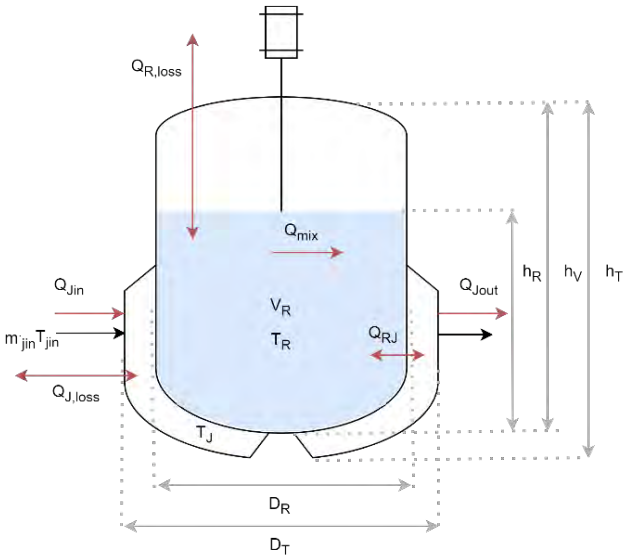

**Figure 1.** Schematic of the stirred tank reactor

The following assumptions are adopted to simplify the system modeling. Thermophysical fluid properties, such as density and heat capacity, are assumed to be constant and independent of temperature. The reactor contents are considered perfectly mixed, ensuring a spatially uniform temperature within each control volume. Reactor fouling and surface deposition effects are neglected, and the overall heat-transfer coefficient is therefore assumed to remain constant.

As the system contains only water, the reactor temperature dynamics are governed by the balance between heat transfer from the jacket, heat losses to the environment, and agitation-related heat input. The jacket temperature dynamics are described by the balance between the inlet enthalpy flow, heat exchange with the reactor, and heat losses to the environment:

$$\frac{dT_R}{dt} = \frac{1}{\rho_R V_R c_{pR}}(U_K A_{RJ}(T_J - T_R) + U_{RE}A_{RE}(T_{amb} - T_R) + Q_{mix}) \quad (1)$$

The reactor–jacket heat transfer area and reactor height are given by:

$$A_{RJ} = \pi D_R h_R + \frac{\pi D_R^2}{4} \quad (2)$$

$$h_R = \frac{4V_R}{\pi D_R^2} \quad (3)$$

$$A_{RE} = \frac{\pi D_R^2}{4} \quad (4)$$

The agitation-induced heat input is modeled via an empirical power correlation:

$$Q_{mix} = N_P \rho_R N^3 D_s^5 \quad (5)$$

$$N_P = \frac{3.26}{Re^{0.287}}; Re = \frac{\rho_R N D_s^2}{\mu_R} < 10^4 \quad (6)$$

$$N_P = \frac{0.484}{Re^{0.079}}; Re = \frac{\rho_R N D_s^2}{\mu_R} \geq 10^4 \quad (7)$$

The jacket temperature dynamics are described as and the jacket–environment heat transfer area is given by:

$$\frac{dT_J}{dt} = \frac{1}{\rho_J V_J c_{pJ}}(\dot{m}_{Jin} c_{pJ}(T_{Jin} - T_J) - U_K A_{RJ}(T_J - T_R) + U_{JE}A_{JE}(T_{amb} - T_J)) \quad (8)$$

$$A_{JE} = \pi D_T h_v + \frac{\pi D_T^2}{4} \quad (9)$$

A PI temperature control loop with sensor and actuator dynamics is implemented. The measured reactor temperature evolves according to:

$$\frac{dT_{Rmeas}}{dt} = \frac{(T_R - T_{Rmeas})}{\tau_s} \quad (10)$$

$$e = -(T_{sp} - T_{Rmeas}) \quad (11)$$

$$\frac{dI}{dt} = \frac{e}{t_i} \quad (12)$$

$$m_{Junsat} = K_c (e + I) \quad (13)$$

$$m_{Jclamped} = Max(m_{Jmin}, Min(m_{Junsat}, m_{Jmax})) \quad (14)$$

$$\frac{dm_J}{dt} = \frac{m_{Jclamped} - m_J}{\tau_v} \quad (15)$$

The reactor energy balance accounts for heat transfer between the reactor and the surrounding jacket, characterized by the overall heat-transfer coefficient $U_K$ and the reactor–jacket heat-transfer area $A_{RJ}$, as well as heat losses to the environment and agitation-related heat input. The quantities $\rho_R, c_{p,R}$, and $T_R$ denote the density, specific heat capacity, and temperature of the reactor contents, respectively, while $\rho_J, c_{p,J}, V_J$, and $T_J$ describe the corresponding properties of the jacket. The thermal input to the jacket is represented by the inlet mass flow rate $\dot{m}_{J,in}$ and inlet temperature $T_{J,in}$, which together

determine the enthalpy flow driving the jacket temperature dynamics. Geometric parameters include the reactor volume $V_R$, reactor diameter $D_R$, impeller diameter $D_s$, and characteristic heights $h_R$ and $h_v$, which define the relevant heat-transfer areas. Agitation is characterized by the impeller speed $N$, power number $N_P$, and Reynolds number $Re$, with $\mu_R$ denoting the dynamic viscosity of the reactor fluid. The PI controller is defined by the temperature setpoint $T_{sp}$, controller gain $K_c$, integral time constant $t_i$, and actuator time constant $\tau_v$, with the jacket mass flow constrained between $m_{J,\min}$ and $m_{J,\max}$.

In this work, several eKPIs are considered, with a particular focus on thermal energy performance. The reactor heat exchange duty ($Q_{RJ}$) quantifies the useful heat transferred between the reactor and the jacket. Heat losses are captured by two additional indicators, the reactor heat loss ($Q_{R,loss}$), describing heat dissipated from the reactor to the environment, and the jacket heat loss ($Q_{J,loss}$), representing losses from the jacket to the surroundings. Based on these quantities, the thermal efficiency ($\eta$) is calculated as defined in Eq. (19), expressing the share of useful thermal energy relative to the total supplied heat, including unavoidable losses.

$$Q_{RJ} = U_K A_R (T_\mathrm{J} - T_\mathrm{R}) \tag{16}$$

$$Q_{R,loss} = U_\mathrm{RE} A_R (T_\mathrm{R} - T_{amb}) \tag{17}$$

$$Q_{J,loss} = U_\mathrm{JE} A_R (T_\mathrm{J} - T_{amb}) \tag{18}$$

$$\eta = \frac{Q_{RJ}}{Q_{RJ} + Q_{Jloss} + Q_{Rloss}} \cdot 100 \tag{19}$$

Here, the quantities $A_{RJ}, A_{RE}$, and $A_{JE}$ correspond to the reactor–jacket, reactor–environment, and jacket–environment heat-transfer areas, respectively. $U_K, U_{RE}$, and $U_{JE}$ are the associated heat-transfer coefficients.

While these eKPIs quantify instantaneous or batch-level energy performance, they are not directly used as EnBs. Instead, EnBs are defined in this work as expected reference values of the selected eKPIs under a specified operating context, including recipe parameters, system state, and relevant model parameters. To this end, the trained surrogate model provides a functional mapping from the operating context to the corresponding eKPIs, thereby serving as a context-dependent EnBs model. For this system, the parameter space is systematically explored. State, model, input, and recipe parameters are summarized in Table 1, while additional derived parameters include $N_P, Re, Q_{mix}, h_R, A_{RE}, A_{RJ}, A_{JE}, e, \dot{m}_{J,unsat}$, and $\dot{m}_{J,clamped}$. Parameters that directly affect the eKPIs and can be actively controlled ($T_{sp,preheat}, N_{mix,sp}$, etc.) are classified as influenceable. In contrast, design-specific parameters that influence the eKPIs only indirectly, through their impact on system properties or process dynamics, are considered non-influenceable. Based on the explored parameter space, simulation data are generated and used for training surrogates that provide operationally meaningful reference values for energy performance assessment.

The reactor operation is defined by a deterministic batch recipe composed of sequential phases:

1. Preheating: The jacket temperature is set to a predefined value to condition the reactor.
2. Mixing: The agitator operates at a specified rotational speed for a defined duration.
3. Heating: The reactor temperature is increased to a target setpoint via jacket control.

**Table 1:** Parameter Space Exploration.

| Category | Parameters | Influenceability |
|---|---|---|
| State variables | $T_R$ | Influenceable |

| | $t_{heat}$ | Influenceable |
| | $t_{batch}$ | Influenceable |

While the recipe structure and phase sequence remain unchanged across simulations, recipe parameters, including temperature setpoints, mixing speed, and phase durations, are treated as stochastic variables. The recipe is executed repeatedly while varying selected influenceable parameters, including temperature setpoints, mixing intensity, and phase durations. This design isolates the effect of recipe-level variability on eKPIs without introducing interference from structural influences.

Parameter bounds and probability distributions are defined a priori to ensure physically meaningful and operationally feasible scenarios. The process model is executed for each sampled parameter set, generating a diverse set of operating conditions.

A stratified sampling strategy ensures representative coverage of the operating domain. In this case study, 10 full batch simulations were performed. Each simulation produced approximately 662 time-step observations across four phases, resulting in 6, 621 input–output pairs. The dataset was split into training (80%) and test (20%) sets using a fixed random seed. Despite the limited number of batch simulations, the time-resolved data provides a sufficiently rich sample set for surrogate model training. The dataset is not used directly as an EnBs but to train a surrogate model that predicts expected energy performance under a given operating context. These predictions define context-specific EnBs, against which observed or simulated eKPIs are compared to assess performance deviations.

## RESULTS

Multiple surrogate models, including artificial neural networks (ANN), extreme learning machines (ELM), Gaussian process regression (GPR), multivariate adaptive regression splines (MARS), radial basis function networks (RBFN), Random Forests (RF), and support vector regression (SVR), are evaluated using the PRESTO framework. The PRESTO variant proposed by Williams et al. [12] is excluded due to limitations associated with the high data volume required for reliable training. All remaining models are trained using identical input sets comprising all state, model, input, and recipe parameters, while excluding the output variables $T_R, T_J, Q_{RJ}, Q_{R,\text{loss}}, Q_{J,\text{loss}}$, and $\eta$.

Input features are standardized prior to training for models sensitive to feature magnitude (ELM, SVR, ANN, GPR, RBFN), using parameters derived from the training dataset and consistently applied to the test data. For RF and MARS, unscaled inputs are used, as these methods are invariant to monotonic transformations. Figure 2 compares the predictive performance of the trained models for the representative output $Q_{Jloss}$.

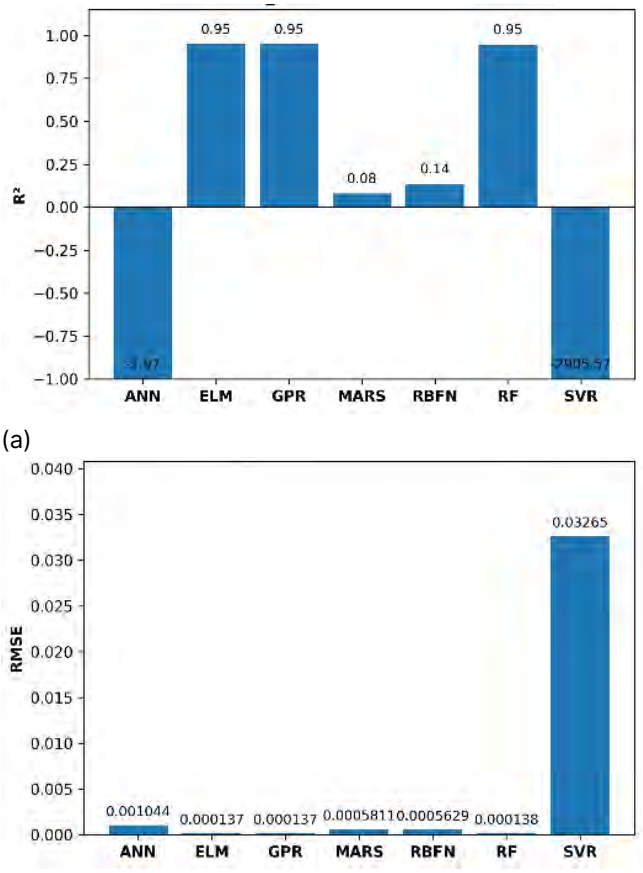

**Figure 2** Performance comparison of candidate surrogate models (a) $R^2$, (b) RMSE

Among the evaluated candidates, the RF model consistently exhibits superior predictive accuracy and robustness and is therefore selected for all subsequent analyses. SVR exhibits poor predictive performance for outputs with small magnitudes (~$10^{-1}$), as the ε-insensitive loss (ε = 0.1) is comparable to the target scale, causing many deviations to fall within the ε-tube and thus not contribute to model learning. ANN similarly exhibit unstable convergence behavior despite input standardization, likely due to the high dimensionality of the input space and the absence of dedicated hyperparameter tuning, leading to ill-conditioned optimization and unstable gradient updates. No additional data normalization or architectural tuning was applied to ensure a consistent and unbiased comparison across surrogates.

Figure 3 presents parity plots comparing RF predictions with reference values obtained from process simulations for all considered outputs and eKPIs. Across all outputs, the surrogate model achieves coefficients of determination $(R^2)$ close to unity and low root-mean-square errors (RMSE), indicating accurate representation of nonlinear relationships over the explored operating space. Minor deviations occur primarily near the boundaries of the parameter ranges or for outputs with limited

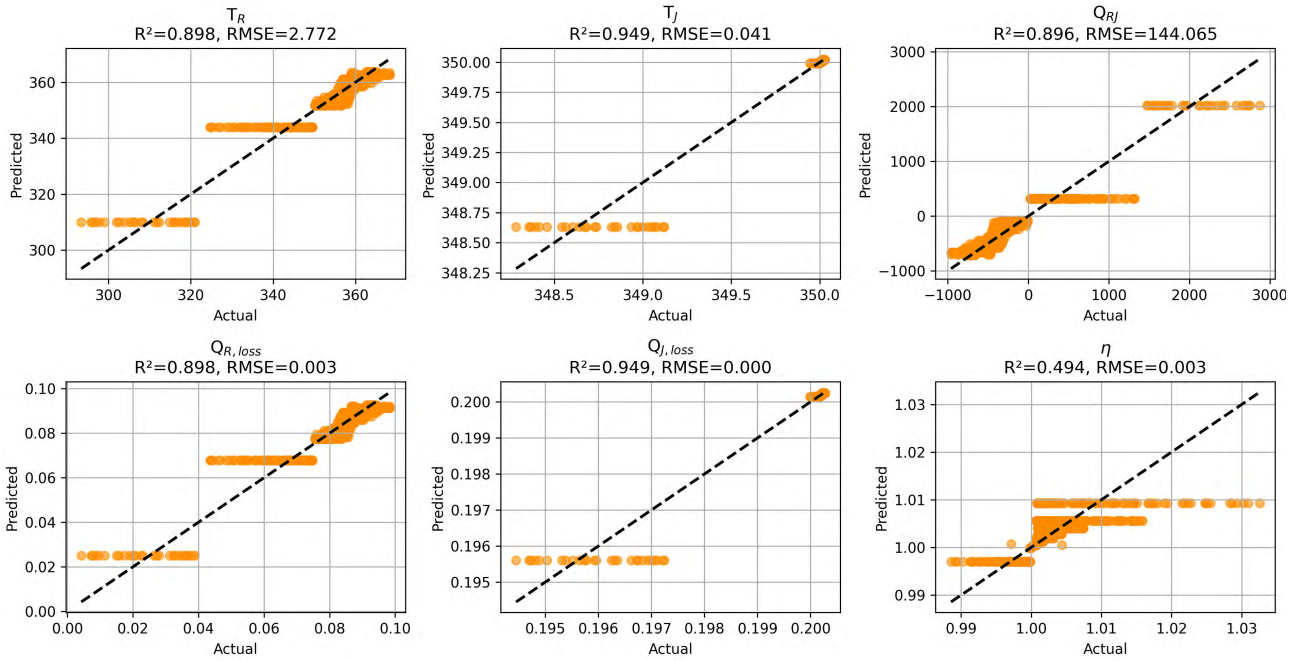

**Figure 3.** Parity plots of predicted versus simulated values for all output variables and eKPIs using the Random Forest surrogate model

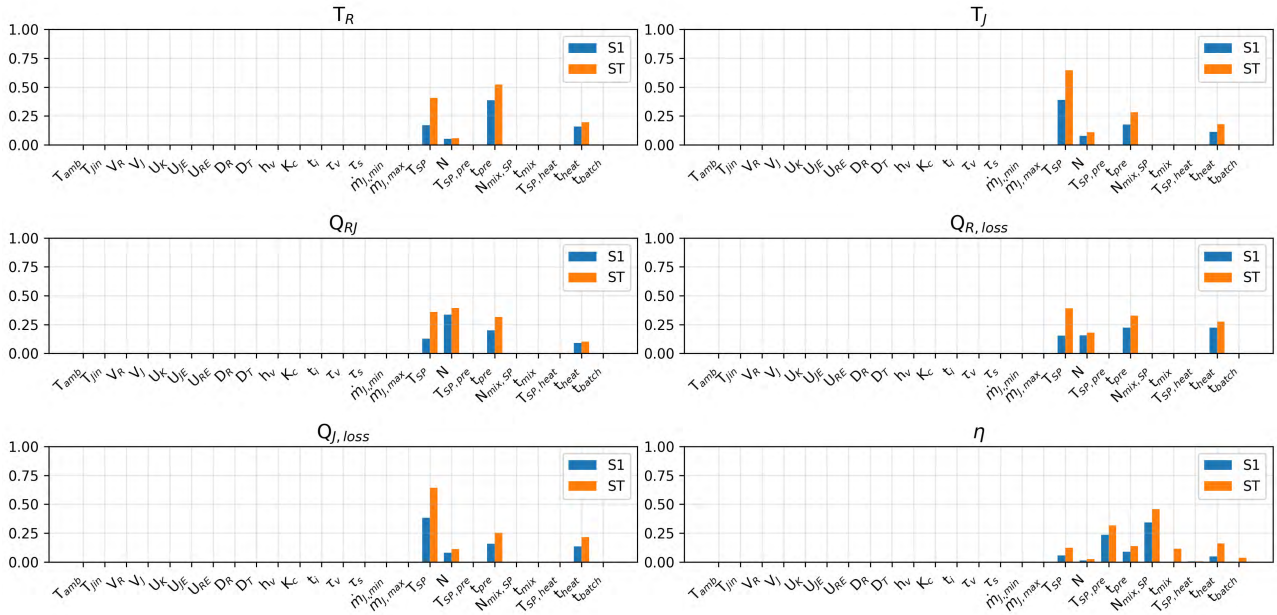

**Figure 4.** Global Sensitivity Analysis Using Sobol Indices

variability, where small absolute errors appear more pronounced. These results confirm that the trained RF surrogate is suitable for representing recipe-dependent EnBs and is subsequently used for global sensitivity analysis and performance assessment.

Figure 4 summarizes the first-order ($S_1$) and total-order ($S_T$) Sobol indices for the outputs $T_R, T_J, Q_{RJ}, Q_{R,loss}, Q_{J,loss}$, and $\eta$. While the first-order index quantifies the independent contribution of each parameter, the total-order index additionally captures interaction effects. Across all outputs, only a small number of parameters significantly influence the results, while most parameters have a negligible impact on energy-related behavior within the studied ranges.

For both reactor temperature ($T_R$) and jacket temperature ($T_J$), dominant sensitivities are associated with temperature setpoints, phase definitions, and reactor–jacket heat-transfer capability. This is physically con-

sistent, as temperature evolution in a non-reactive system is governed by thermal driving forces and heat transfer rates. The gap between total- and first-order indices indicates strong interaction effects, particularly between setpoints, heat-transfer capacity, and phase durations, shaping transient heating behavior.

The reactor–jacket heat transfer $Q_{RJ}$ is primarily influenced by parameters determining the driving force and transfer rate, notably heat-transfer capability and recipe-dependent temperature differences and durations. The observation that $S_T$ exceeds $S_1$ for key parameters confirms the presence of coupled effects, where both temperature response dynamics and phase durations govern heat transfer.

Loss-related outputs are most sensitive to temperature gradients, heat-loss coefficients, and phase durations, reflecting their dependence on both temperature differences and residence time. Interaction effects, particularly between setpoints and batch duration, further influence cumulative losses.

The mixing-related energy $Q_{mix}$ exhibits sensitivity almost exclusively to recipe parameters associated with mixing intensity and mixing duration, while thermodynamic and structural parameters remain negligible. This behavior is consistent with physical expectations for a recipe-controlled agitation input and confirms that the surrogate-based sensitivity analysis preserves the intended separation between mechanical energy input and thermal exchange mechanisms in the adopted lumped, non-reactive formulation.

In contrast, the efficiency $\eta$ displays the broadest sensitivity profile, with multiple contributing parameters and total-order indices that often exceed the corresponding first-order indices. As a KPI aggregating heat transfer and losses, it is strongly influenced by interactions between recipe parameters and system characteristics. Consequently, changes in operational decisions such as heating targets or phase durations can influence efficiency to a similar extent as variations in equipment-related parameters, underscoring the need for recipe-aware EnBs in batch and modular systems.

## CONCLUSION AND OUTLOOK

This work demonstrates the feasibility of a four-stage framework for generating surrogate EnBs models from systematically generated recipe-based simulated data. By combining structured parameter space definition, automated data generation, surrogate modeling, and global sensitivity analysis, the framework enables EnBs definition without reliance on historical data.

Among the evaluated surrogate modeling approaches, Random Forests are found to be particularly well suited for the investigated case study, providing high predictive accuracy and compatibility with global sensitivity analysis. However, the optimal surrogate model choice is expected to depend on the characteristics of the underlying process, the dimensionality of the parameter space, and the structure of the available data.

The results show that recipe parameters, most notably mixing rotational speed, dominate the variability of energy-related outputs and eKPIs, while equipment-related parameters primarily influence system behavior through interaction effects. This provides quantitative justification for defining EnBs that are explicitly conditioned on recipe context, as aggregation across heterogeneous operating regimes can obscure meaningful performance differences. At the same time, the proposed approach should be understood as a model-based EnBs support tool whose validity depends on the adequacy of the underlying mechanistic model and requires validation against metered process data before deployment in operational EnMS.

Future work will focus on extending the framework to systems with increased modeling complexity, including reactive processes and coupled mass–energy interactions, as well as validating surrogate-based EnBs against measured process data to enable ISO-compliant energy performance assessment.

## ABSTRACT

Liquefied natural gas (LNG) plays a key role in the energy transition, but its production is often limited by the high $CO_2$ content of some reservoirs, which increases operating costs and solidification risks. This study evaluates the dual-pressure low-temperature cryogenic distillation process applied to a recently discovered gas field with a high $CO_2$ content (25%) for LNG production. The critical properties of the gas streams and the process operating conditions were analyzed using Aspen Plus v14. The results indicate that reducing the $CO_2$ concentration throughout the column is essential to prevent solid formation by maintaining a fluid composition with a freezing temperature below the operating temperature of the stages. It was also observed that the reflux affects LNG purity and freezing temperature in all stages. Furthermore, the adoption of a low-pressure separator upstream of the distillation proved crucial to producing condensates within commercial specifications. The work extends the understanding of the dual-pressure low-temperature cryogenic distillation to the 25% $CO_2$ range and highlights the potential of cryogenic distillation to enable LNG production in fields with high $CO_2$ content.

## INTRODUCTION

The energy transition from fossil fuels to renewable energy depends on the role of natural gas (NG) in mitigating the limitations of renewable energy. For example, the strong dependence on climate conditions, the weak structure to satisfy the high energy demand of cities during specific periods of the day, and the need to develop new technologies to store the energy supplied by the environment are among the key issues in this context [1]. NG alleviates these problems since it presents a competitive cost in comparison to oil [2] and has a lower greenhouse gas (GHG) emissions potential than coal [3]. In the past ten years, production of dry NG around the world has been increasing, supported by an increasing NG consumption in electricity generation [4]. As a result, the share of NG has practically remained constant (22% - 23%) despite the rise of renewable energy [5]. Together, these factors highlight the importance of NG in the energy mix.

One option for transporting NG is liquefaction, which reduces its volume by a factor of 600. This situation gives liquified natural gas (LNG) some notable advantages in NG supply. For instance, small quantities of LNG offer high NG availability and can be economically stored in tanks when a higher-than-needed supply is available. Additionally, LNG can be transported for long distances, which sometimes can be unfeasible with pipelines [6-8].

One of the main challenges in LNG processing is the high $CO_2$ content (15%-80% by mole) in some gas fields, which increases operating costs and poses a risk of solidification during processing, encompassing many technical challenges [6-8]. In the last ten years, companies have developed gas production projects in fields with high $CO_2$ content. For instance, gas production has been developed in the LaBarge field in Wyoming (USA) and in fields located in Southeast Asia (Malaysia, Indonesia, Vietnam, and the southern Gulf of Thailand) [7-12].

Similarly, some stakeholders have been evaluating the production potential in regions such as the Otway Basin (Southeast coast of Australia), the Kwanza Basin (Angola), and the Santos Basin (Brazil) [13-15]. This situation highlights the importance of innovation in producing LNG from those fields.

This work aims to evaluate the dual-pressure low-temperature distillation process for producing LNG from a recently discovered field with high $CO_2$ content. The process was simulated in Aspen Plus v14, and the results highlight the limitations and operational parameters to avoid solids formation and critical conditions.

## MATERIALS AND METHODS

### Data collection

The composition and operating conditions of a recently discovered gas field are shown in Table 1.

**Table 1:** Composition and operating conditions of the feed gas

| Feed composition | Mole % |
|---|---|
| $C_1$ | 64.06 |
| $C_{2+}$ | 10.33 |
| $CO_2$ | 25 |
| $H_2S$ | 0.01 |
| $N_2$ | 0.60 |
| Flowrate (MMscfd) | 1 |
| Pressure (bar) | 70 |
| Temperature (°C) | 30 |

### Process simulation

The process was simulated in Aspen Plus v14, to achieve an LNG production of 0.0096 MMTPA (million metric tons per annum), with a lower heating value (LHV) of 900.47 BTU/scf (British Thermal Unit per standard cubic foot of gas). To develop the simulation, the following aspects were considered: selection of the thermodynamic model, estimation of the pseudocritical temperatures of the streams, determination of the operating conditions of units, and sensitivity analysis.

#### Thermodynamic model

As the components can be considered all nonpolar, including $H_2S$ because of its weak electronegativity, the most appropriate thermodynamic package to estimate the physical properties of the streams throughout the overall process corresponds to an Equation of State (EoS) [16-17]. The three main EoS considered in this study were: Peng-Robinson (PR), Soave-Redlich-Kwong (SRK), and Perturbed Chain Statistical Associating Fluid Theory (PC-SAFT). Results of equilibrium data for every EoS were compared to experimental data collected at the solid-vapor, liquid-vapor, and solid-liquid equilibria region for different alkane-$CO_2$ binary systems [18-25]. Finally, the PR EoS proved to be the thermodynamic model with the best fit to experimental data. This situation is explored in Figure 1, where the results of the selected EoS are compared with data reported by Wei *et al.* [25].

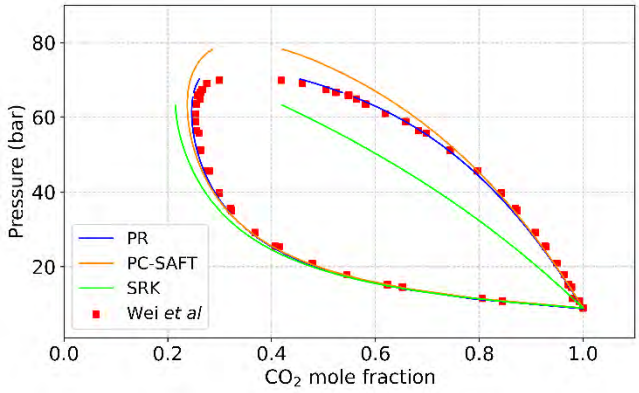

**Figure 1.** Validation of the Peng-Robinson Equation of State on the vapor-liquid equilibrium region of the $C_1$-$CO_2$ binary system at -43 °C

#### Pseudocritical temperatures

The critical point of a gas mixture is the temperature and pressure at which the distinction between the gas and liquid phases disappears. Under this condition, the dew point and bubble point curves converge to a single point in the pressure vs. temperature phase diagram [26].

Critical properties are not usually measured for hydrocarbon mixtures; instead, they are estimated as pseudocritical properties from correlations and depend strongly on gas composition [6, 26]. Once critical conditions are reached, measuring those properties in vapor and liquid becomes too difficult [27-28]. To ensure the accuracy of the results, the authors have defined that pseudocritical conditions constitute an operational limit in the simulation. This is illustrated in Figure 2, where the pseudocritical temperature of the process gas feed was estimated by varying the $CO_2$ content (25-65%) and the $C_{2+}$ content (2-10%).

#### Operating conditions of units

The process is divided into two stages: condensate production (Figure 3) and dual-pressure, low-temperature distillation (Figure 4). First, the reservoir gas feeds the high-pressure separator HG-SEP, which operates at 70 bar and 30 °C. Then, the bottom product flows to the low-pressure separator LP-SEP, whose conditions can be optimized to achieve a Reid vapor pressure (RVP) between 0.69 and 0.82 bar at stream LKO-02 (based on a commercial specification for the liquid knock-out stream [29]). Both operations were simulated using a *Flash2* model.

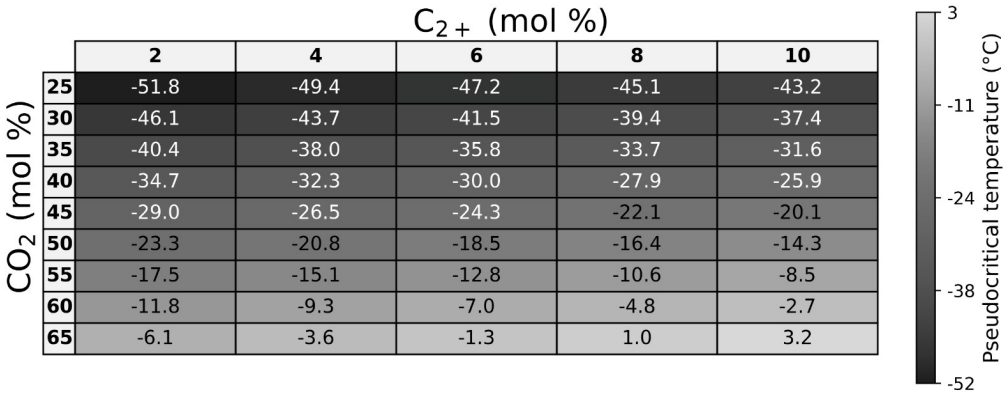

**Figure 2.** Estimation of the pseudocritical temperature for different compositions of gas feed.

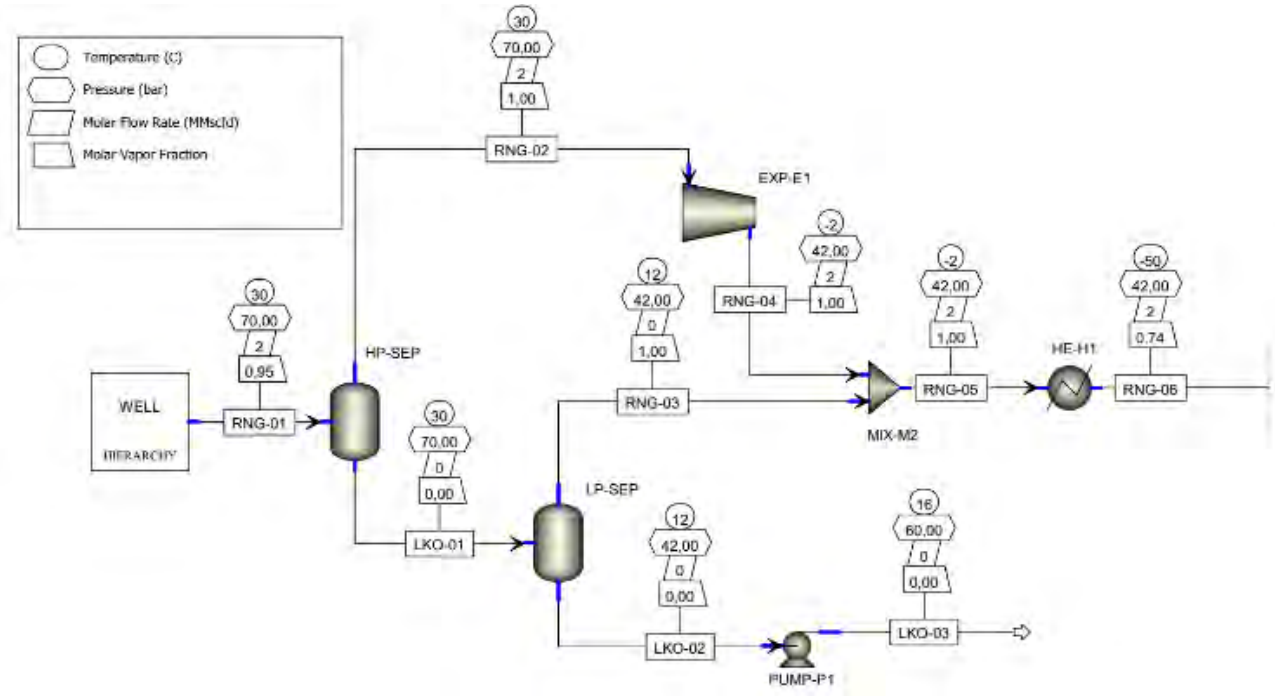

**Figure 3.** Setup of the condensate separation step.

At the same time, the top product of HP-SEP is directed towards the expander EXP-E1 (*Compr* model set as turbine), reducing its pressure to 42 bar. After the expansion, the stream is mixed with the top product of the LP-SEP and then cooled in the Heater model HE-H1, preparing it for the next step.

In the dual-pressure, low-temperature distillation stage (Figure 4), the gas stream RNG-06 feeds column COL-D1 (*RadFrac* model). This first column operates at 42 bar and a temperature range of -82 °C to -16 °C, producing an overhead product with approximately 80 mol% of methane. This distillate is then divided into two streams: one feeds the bottom of column COL-D2 (*RadFrac* model) directly, and the other (RNG-09) passes through the heater HE-H2 before heading to COL-D2. The second column operates at 39 bar and a temperature range of -89 °C to -84 °C. The bottom product is recycled to COL-D1, passing through *Pump* model PUMP-P2 to increase the stream pressure to 42 bar. As the $CO_2$ solid formation depends on the increase in $CO_2$ concentration [6], an additional outlet stream was considered in the column stage with a higher $CO_2$ concentration. As a result, a rich methane stream is produced at the top of COL-D2 (greater than 99 mol%). Likewise, a rich methane stream is produced at the bottom of COL-D1 (approximately 90 mol%).

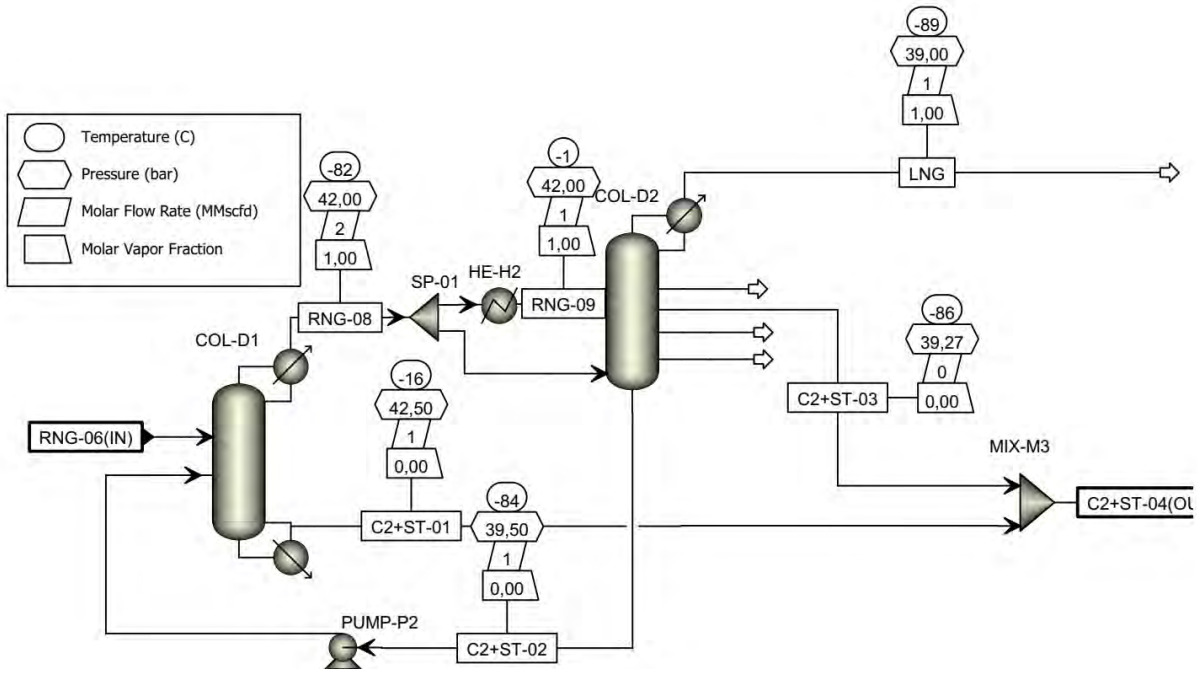

**Figure 4.** Setup of the dual-pressure, low-temperature distillation step.

## Sensitivity analysis

The present study conducted two sensitivity analysis: one evaluating the operating conditions of the LP-SEP and another assessing those of COL-D2.

The project aims to produce a liquid condensate stream for sale to oil refineries, so the main objective of the first stage is to produce a liquid stream from the LP-SEP that meets commercial requirements. In this work, the Reid vapor pressure in LKO-03 (Figure 3) is used to measure its volatility. The Reid vapor pressure is defined as the vapor pressure of a liquid sample measured in a chamber at 37.8 °C, according to the D323 method of the American Society for Testing and Materials (ASTM) [30]. Usually, the Reid vapor pressure of a mixture is lower than its true vapor pressure, so crude stabilization systems can be designed to achieve a specified value to avoid the vaporization of volatile compounds [29].

On the other hand, the main variable used to assess LNG produced in the second stage of the process is $CO_2$ content, which is expected to be below 50 ppmv. This low concentration is only possible by operating COL-D2 at cryogenic temperatures ranging from -160 °C to -56 °C [7-8]. This means a challenge since the high concentrations of $CO_2$ in some stages of the column can lead to solids formation and to a proximity to the pseudocritical temperature [6, 17, 27, 28].

To evaluate operating conditions in COL-D2, this work examined the molar reflux ratio at the top and its potential impact on the freezing temperature in stages with higher $CO_2$ concentrations. Thus, the variable $\Delta T_F$ was defined as the difference between the stage temperature and the freezing temperature of the mixture, mathematically expressed as:

$$\Delta T_{Fi} = T_i - FT_i \quad (1)$$

where $T_i$ is the temperature of the column at stage $i$, and $FT_i$ corresponds to the mixture's freezing temperature at that stage. Additionally, the minimum reflux ratio is specified to achieve a $CO_2$ content below 50 ppmv, as LNG production is required to meet all specifications. In this context, $\Delta T_{Fi}$ works as an indicator of the safety margin between the freezing and operating temperature. This way, the research focuses on the operating parameters to avoid potential risks during the process.

# RESULTS AND DISCUSSION

## Condensate separation step

The operating conditions in LP-SEP were defined to achieve a commercial Reid vapor pressure between 0.76 and 0.80 bar. However, the separator pressure was also determined by the outlet pressure at EXP-E1, since a pressure difference between RNG-03 and RNG-04 could imply a problem before entering HE-H1. Similarly, the outlet pressure at EXP-E1 must support the LNG production in the next stage. Consequently, the operating pressure of LP-SEP was fixed, and only the effect of temperature on the Reid vapor pressure of LKO-03 was evaluated. The sensitivity of Reid vapor pressure to the temperature in LP-SEP is illustrated in Figure 5.

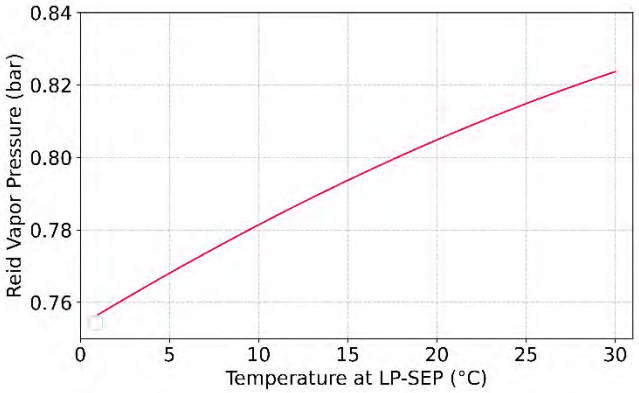

**Figure 5.** Reid vapor pressure of the condensate stream as a function of temperature at LP-SEP.

The increase in Reid vapor pressure in LKO-03, along with the corresponding temperature rise at LP-SEP, is due to two factors. First, the solubility of methane in light hydrocarbons (between $C_4$ and $C_{10}$), which increases strongly with the pressure rise and with the high content of such hydrocarbons [31]. Second, the solubility of $CO_2$ in hydrocarbon mixtures, which increases with temperature [17]. Both factors contribute to the presence of methane and $CO_2$ (volatile compounds) in LKO-03, reducing the boiling point of the stream and increasing its vapor pressure [32]. For example, the molar fraction of $CO_2$ plus the molar fraction of methane in LKO-03 ranged between 30 and 40% across the different temperatures.

Downstream, the top product of LP-SEP and the outlet stream RNG-04 from EXP-E1 are mixed in MIX-M2 (*Mixer* model), whose outlet constitutes stream RNG-05. This stream was then cooled in HE-H1, setting the outlet temperature between the freezing and pseudocritical points, -42 °C and -68 °C, respectively. This procedure avoids the solids formation without reaching the pseudocritical limit [6].

## Dual-pressure, low-temperature distillation stage

The RNG-06 stream enters COL-D1, which at the same time is fed by a reflux stream. The composition profiles of methane and $CO_2$ are illustrated in Figure 6.

The top product in COL-D1 reached a molar fraction of approximately 95% of methane. This result is similar to that calculated by Anaugraha *et al.* [8], who estimated a methane molar fraction of 88% in the Natuna gas field, and 99% in the Bojonegoro gas field. In the same way, Pellegrini *et al.* [7] estimated a methane molar fraction between 85% and 92%. The reflux was determined to feed the column at the tenth stage, reducing the temperature and the $CO_2$ concentration. This configuration avoids the solids formation because the reflux stream has a methane molar fraction of approximately 90%. The temperature profile, the pseudocritical temperature, and the freezing temperature throughout each stage in COL-D1 are presented in Figure 7.

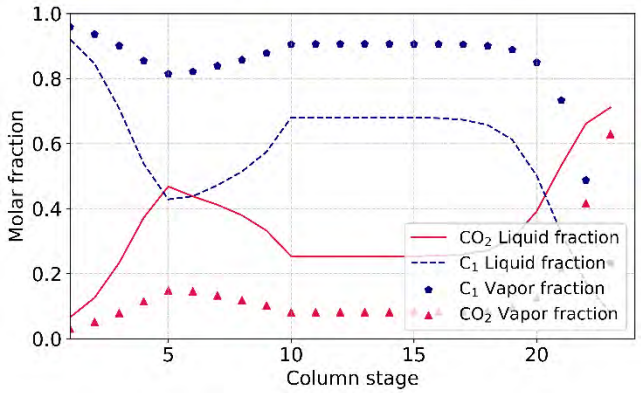

**Figure 6.** Compositions profile in COL-D1

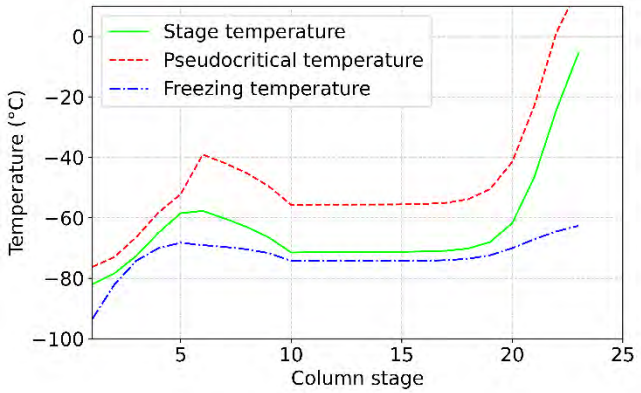

**Figure 7.** Temperature profile in COL-D1

The rich methane stream produced at the top of COL-D1 feeds COL-D2, whose methane and $CO_2$ composition profiles are shown in Figure 8.

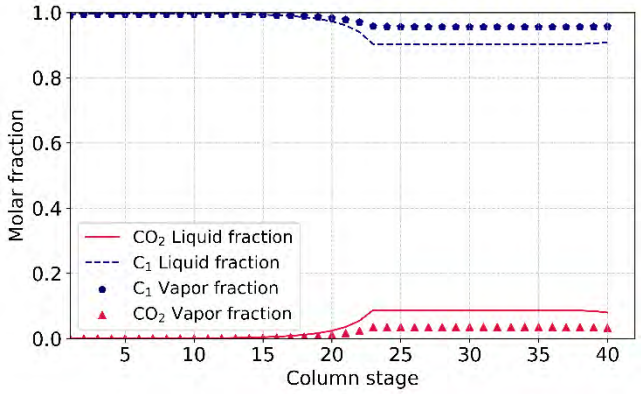

**Figure 8.** Compositions profile in COL-D2

As suggested by Anaugraha *et al.* [8] and Pellegrini *et al.* [7], the dual-pressure, low-temperature distillation presents the potential to produce natural gas with a minimum fraction of $CO_2$ content. However, the low temperatures and high operating pressure pose a risk of solid

formation. Figure 9 shows the freezing, pseudocritical and operating temperatures throughout the entire column COL-D2. This approach aligns with practices presented in GPSA [6] by considering solid formation and critical conditions as limits of the operational window.

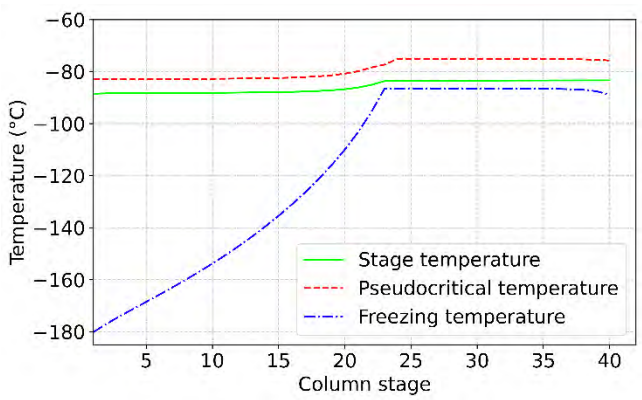

**Figure 9.** Temperature profile in COL-D2

It is important to notice in what stages the higher risk of solids formation can occur. In the case of this study the stages where the freezing temperature is close to the operating temperature are the 22nd, 23rd, and 24th. These stages have $CO_2$ and methane mole fractions of about 8.7% and 90.3%, respectively. In this context, the mixture at such stages behaves as a $C_1$-$CO_2$ binary system. These results align with the experimental data measured by ZareNezhad [21] and GPSA [33], reporting that the high increase in freezing temperature occurs with a $CO_2$ molar fraction between 6 and 10%.

Several authors report possible solutions for this cumbersome situation. Lastari [34] proposed an approach based on the Ryan/Holmes process by adding light hydrocarbons ($C_{4+}$), affecting the $CO_2$ solubility and concentrations. The GPSA [6], highlighted hydrocarbons addition led to a temperature rise in the overhead product, an increase in the relative volatility between methane and $CO_2$, and a rise in critical pressure, allowing higher-pressure operation. The Controlled-Freeze Zone (CFZ) developed by ExxonMobil promotes the $CO_2$ freezing in an open area of the column so that it can be dissolved and removed in the stripping section [35]. Pellegrini *et al.* [7] proposed the dual-pressure low-temperature distillation process to separate the methane from the $CO_2$. The high pressures in both columns and the recycling of methane-rich streams can prevent $CO_2$ solid formation despite the low temperatures.

In dual-pressure, low-temperature distillation, the low-pressure column COL-D2 serves as the final stage of methane purification. In this context, this work proposed an auxiliary outlet stream at stage 23 that can be mixed with the bottom product of COL-D1 to reduce $CO_2$ concentration. This scheme guarantees a methane recovery at distillate higher than 95%, which is similar to the results reported by Anaugraha *et al* [8] and Lastari [34], as shown in Table 2.

**Table 2:** Hydrocarbon recovery during LNG production

| Hydrocarbon recovery (% mol/mol) | This work | Anaugraha | Lastari |
|---|---|---|---|
| $C_1$ (top) | 95.8% | 87.8% - 99.9% | 99.9% |
| $C_{2+}$ (top) | <0.1% | 1.6% | 0.22% |
| $CO_2$ (bottom) | 99.9% | 98.5% - 99.9% | 99.9% |

Furthermore, the research analyses the operating conditions in COL-D2. Thus, the impact of the molar reflux ratio that flows from the condenser on the $\Delta T_F$ variable on stages 22 and 24 is illustrated in Figure 10.

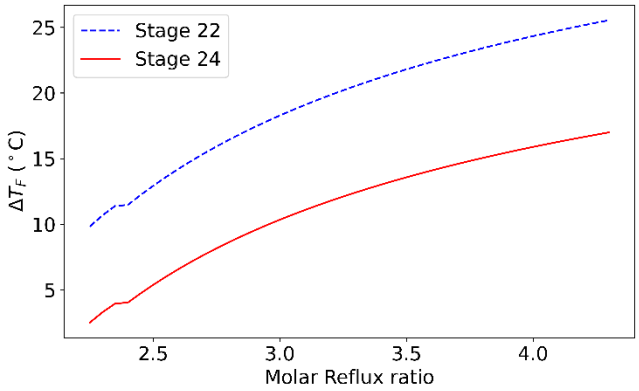

**Figure 10.** Molar reflux ratio effect on $\Delta T_F$ parameter on COL-D2

The safety margin between the operating temperature and freezing temperature increases as the molar reflux ratio in COL-D2 increases. This can be explained by the rise in methane concentration, driven by the higher reflux rate, which in turn reduces $CO_2$ concentration throughout the column. This affects solid-liquid and solid-vapor equilibria, reducing the freezing temperature at all stages.

## CONCLUSIONS

The results show that the dual-pressure, low-temperature distillation process is a promising approach for LNG production in $CO_2$-rich gas fields. This product has a methane molar fraction of up to 99.1% and a $CO_2$ content lower than 50 ppmv. Reducing the $CO_2$ content at certain stages of the low-pressure column can prevent the formation of solids. This can be achieved by considering an outlet stream at the stage, increasing the column reflux rate, and adding light hydrocarbon streams. Additionally, the presence of a separator upstream of the distillation stage is key to producing a liquid stream of light hydrocarbons that meets the commercial requirement of an

Reid vapor pressure between 0.76 and 0.80 bar.

## ACKNOWLEDGEMENTS

We gratefully acknowledge PETRONAS Petróleo Brasil Ltda. (PPBL) for their funding and support, as well as ANP (Brazil's National Oil, Natural Gas, and Biofuels Agency) for assistance through the R&D levy regulation (Project #25186-8). We also thank EQS – Sustainable Energy and Chemistry Laboratory, PQGe – Chemical Processes and Business Management Laboratory, the Center for Energy and Petroleum Studies (CEPETRO), and the School of Chemical Engineering (FEQ) at the University of Campinas (UNICAMP), Brazil. ## ABSTRACT

Biological systems are governed by coupled interactions between intracellular metabolism and bioreactor operation that span multiple time scales. Constraint-based metabolic models are widely used to describe intracellular metabolism, but repeatedly solving the optimization problem at each time step in dynamic models introduces numerical challenges related to infeasibility and computational efficiency. This work presents a multi-scale modeling framework that integrates genome-scale, constraint-based metabolic models with dynamic bioreactor simulations. Intracellular metabolism is described using positive flux variables in a parsimonious flux balance analysis, and the resulting embedded optimization problem is replaced by a neural network surrogate. The surrogate provides a smooth approximation of the embedded optimization mapping and eliminates repeated linear program solves during simulation. The approach is demonstrated for fed-batch fermentation of *Escherichia coli*, in which the surrogate model yields intracellular fluxes under substrate-limited conditions, whereas the underlying linear program would otherwise be infeasible. The framework provides a continuous representation of intracellular metabolism suitable for dynamic simulation of genome-scale models in bioreactor configurations.

**Keywords**: Machine Learning, Multiscale Modelling, Modelling and Simulations, Surrogate Model, Dynamic Modelling

## INTRODUCTION

Biological systems are governed by coupled interactions between cellular metabolism and process operation. These interactions span multiple time scales, from the rapid kinetics of intracellular reactions to the slower dynamics of bioreactor processes. Enzymatic reactions typically occur on the order of milliseconds, transcription and translation evolve over seconds to minutes, and bioreactor-scale phenomena develop over hours to days [1]. Modeling such systems requires a consistent representation of processes across these time scales [1, 2].

Constraint-based metabolic models are widely used to describe intracellular metabolism [3, 4] and are commonly embedded in dynamic reactor simulations through dynamic flux balance analysis (dFBA) [5-7]. This formulation links genome-scale metabolism with extracellular mass balances. Numerical challenges arise when the optimization problem approaches infeasible regions, for example, when maintenance requirements cannot be satisfied [5, 6, 8]. Changes in active constraints induce a piecewise-defined dependence of intracellular fluxes on extracellular conditions, potentially leading to infeasibility in substrate-limited regions [9].

In this work, a multi-scale modeling framework is presented that integrates genome-scale, constraint-based metabolic models with dynamic bioreactor simulations by replacing the embedded optimization problem with a neural network surrogate [10]. The framework consists of three coupled components. A reactor model describing flow, mixing, and volume dynamics. An extracellular reaction model defining mass balances for substrates, biomass, and products, and a kinetic cell model providing intracellular metabolic fluxes as functions of

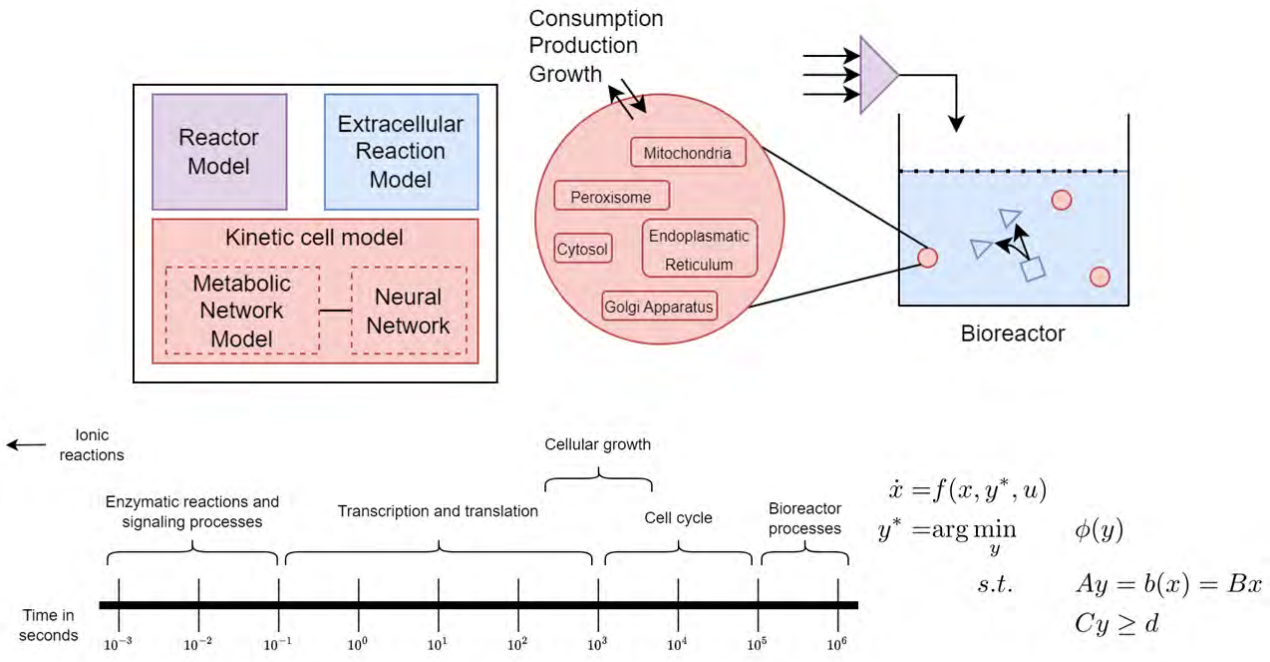

**Figure 1.** Overview of the multi-scale modelling framework linking intracellular metabolism to bioreactor dynamics. The upper panel shows the model structure, comprising the reactor model, the extracellular reaction model, and the kinetic cell model. The kinetic cell model describes intracellular metabolism using a constraint-based metabolic network formulation that a neural network surrogate can approximate [10,11]. The lower panel illustrates the wide separation of time scales in biological and process phenomena, ranging from picoseconds for ionic reactions to days for reactor operation [1]. Together, the three submodels capture the interaction between substrate consumption, product formation, and cellular growth across multiple time scales.

the extracellular conditions, as shown in Figure 1. Before surrogate replacement, the multi-scale model is expressed as a coupled dynamic optimization problem. Extracellular states evolve according to dynamic mass balances, whereas intracellular fluxes are obtained by solving an optimization problem subject to stoichiometric constraints, flux bounds, and a biological objective. Intracellular metabolism is assumed to operate in a quasi-steady state relative to the reactor dynamics, reflecting the separation of time scales between fast metabolic reactions and slower process-level phenomena [1, 5, 7].

The formulation is demonstrated using fed-batch fermentation of *Escherichia coli* with the genome-scale model iCH360 [3]. The coupled formulation links genome-scale metabolic models with reactor-scale dynamics within a single differentiable model.

The paper is structured as follows. The Method section presents the multi-scale modeling formulation, including the reactor model, extracellular mass balances, and kinetic cell model, as well as a description of the constraint-based metabolic formulation and the neural network surrogate model. The Results section presents simulation results for fed-batch fermentation of *E. coli* and a sensitivity analysis, followed by a discussion of model behavior and limitations, and a brief conclusion.

## METHOD

### Dynamic modeling

The multi-scale metabolic system is described by a set of ordinary differential equations coupled with optimal intracellular reaction rates. The extracellular dynamics depend on optimal rates obtained from an embedded optimization problem, or a surrogate model. The coupled system is written as,

$$\dot{x} = f(x, y^*, u) \tag{1a}$$
$$y^*(x) = y^* = \arg\min_y \quad \phi(y) \tag{1b}$$
$$s.t. \quad Ay = b(x) = Bx \tag{1c}$$
$$Cy \geq 0 \tag{1d}$$

$x$ denotes the extracellular state variables, $y^*$ is the optimal rates, as a function of the extracellular conditions, and $u$ is the manipulated inputs. A surrogate representation may replace the embedded optimization problem in Equation (1b-1d) without altering the structure of the

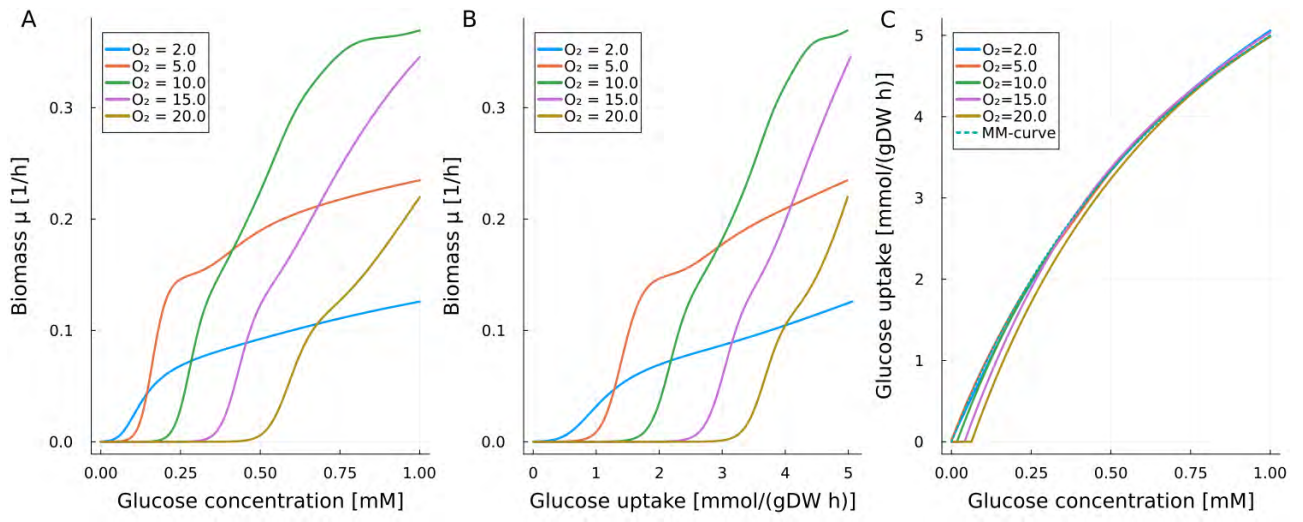

**Figure 2.** Surrogate model predictions of intracellular metabolism for the *E. coli* genome scale metabolic model. Biomass growth rate as a function of extracellular glucose concentration (A) for different fixed oxygen uptake rates, with growth decreasing as glucose availability is reduced. Biomass growth rate as a function of glucose uptake rate (B) at fixed oxygen uptake rate. Glucose uptake rate as a function of extracellular glucose concentration (C), with uptake decreasing towards zero at low glucose concentrations. The dotted line in (C) shows a Michaelis-Menten curve for comparison with $V_{max} = 10$ and $K_m = 1.0$.

remaining submodels.

## Reactor modeling

The reactor model is modelled as a fed-batch system.

$$\dot{V} = e^T F_{in} \tag{2a}$$
$$\dot{n}_e = C_{in} F_{in} + R^*_{ext}(c_e)V, \quad c_e = \frac{n_e}{V} \tag{2b}$$
$$\dot{n}_X = R^*_X(c_e)V, \qquad c_X = \frac{n_X}{V} \tag{2c}$$
$$R^*_{ext}(c_e) = \nu^T_{ext} r^*(c_e) \tag{2d}$$
$$R^*_X(c_e) = \nu^T_X r^*(c_e) \tag{2e}$$
$$r^*(c_e) = \mu^*(c_e) c_X \tag{2f}$$

$V$ is the volume, $F_{in}$ is the inlet flow rate, $n_e$ is the mole amount of extracellular species, $C_{in}$ denotes inlet concentration. The vector $R^*_{ext}(c_e)$ represents the extracellular production and consumption rates, obtained from the intracellular model. $n_X$ is the amount of biomass, and $R^*_X(c_e)$ is the production rate of biomass. $\nu_{ext}$ and $\nu_X$ are the stoichiometric matrices, $r^*(c_e)$ is the reaction rate vector, and $\mu^*(c_e)$ is the flux per unit of biomass and is a function of the extracellular concentration.

## Constraint-based modeling

Flux balance analysis assumes that intracellular metabolism operates at steady-state and computes a flux distribution consistent with stoichiometric constraints and the specified objective [3, 12]. To account for changing extracellular conditions, uptake rates are fixed as functions of extracellular concentrations, denoted $\bar{\mu}_{in}(c_e)$. Embedding FBA within the reactor model yields a dFBA formulation [5, 12]. Intracellular reactions are assumed to equilibrate instantaneously relative to reactor-scale dynamics [5, 7]. The FBA problem is reformulated using positive forward and reverse fluxes to ensure directional consistency.

$$\mu^*(c_e) = \mu^* = \min_{\mu} \quad c^T(\mu^+ - \mu^-) \tag{3a}$$
$$s.t. \quad R_c = \nu_c^T(\mu^+ - \mu^-) = 0 \tag{3b}$$
$$0 \le \mu^+ \le \mu^+_{max} \tag{3c}$$
$$0 \le \mu^- \le \mu^-_{max} \tag{3d}$$
$$\mu^+_{in} - \mu^-_{in} = \bar{\mu}_{in}(c_e) \tag{3e}$$

$\mu$ is the vector of fluxes, decomposed into forward and reverse components, $\mu^+$ and $\mu^-$. The vector $c$ defines the linear objective function, the matrix $\nu_c$ is the intracellular stoichiometric matrix, and the constraint $R_c = 0$ enforces steady-state balances for intracellular metabolites. The vectors $\mu^+_{max}$ and $\mu^-_{max}$ define the upper bounds for the forward and reverse fluxes. The FBA solution is generally non-unique, as the steady-state stoichiometric constraints define a high-dimensional feasible set [7, 13]. Linear optimization selects a single point from the optimal face, so parsimonious FBA (pFBA) is applied to identify flux distributions with minimal total flux, while maintaining the optimal growth rate $z^*_{FBA}$ [14]. The pFBA optimization problem is defined as,

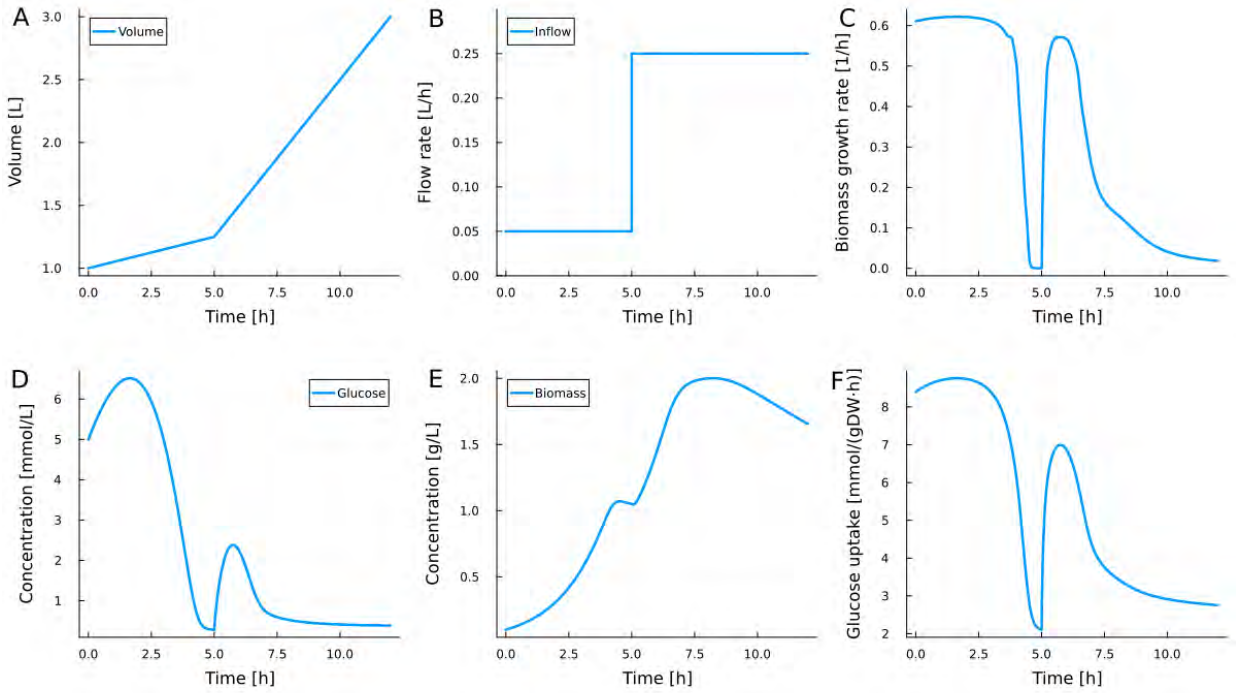

**Figure 3.** Dynamic fed-batch simulation of *E. coli* using the proposed multi-scale modeling framework with a neural network surrogate model. The reactor volume (A) increases over time in response to the feed profile (B). Biomass growth rates (C) are initially high and subsequently decrease as extracellular glucose (D) is consumed. This results in biomass accumulation (E), while glucose uptake rates (F) decrease but remain non-zero due to the continuous glucose feed. Glucose uptake follows a Michaelis-Menten dependence on extracellular concentration. Biomass growth ceases before complete substrate depletion when substrate uptake is insufficient to sustain growth. Oxygen uptake is kept constant at 15 mmol/(gDW h).

$$\mu^*(c_e) = \mu^* = \min_{\mu} \quad \sum_{i=1}^{n_\mu} \mu_i^+ + \mu_i^- \tag{4a}$$

$$s.t. \quad R_c = \nu_c^T(\mu^+ - \mu^-) = 0 \tag{4b}$$

$$0 \le \mu^+ \le \mu_{max}^+ \tag{4c}$$

$$0 \le \mu^- \le \mu_{max}^- \tag{4d}$$

$$\mu_{in}^+ - \mu_{in}^- = \bar{\mu}_{in}(c_e) \tag{4e}$$

$$\mu_X = z_{FBA}^* \tag{4f}$$

$n_\mu$ is the total number of reactions, and $\mu_X$ is the biomass growth flux.

## Surrogate modeling

During dynamic simulation, substrate depletion may render the linear program infeasible or lead to discontinuous flux trajectories [8]. To obtain a smooth representation of intracellular fluxes, a neural network surrogate is used to approximate the pFBA solution map [9, 10]. The coupled system with the surrogate model can then be written as,

$$\dot{x} = f(x, y^*, u) \tag{5a}$$

$$y^*(x) = y^* = NN(\theta) \tag{5b}$$

$NN(\theta)$ is the trained neural network parameterized by $\theta$. The surrogate model is trained on sampled uptake rates and the corresponding optimal flux distributions obtained from pFBA. In regions where the original pFBA formulation becomes infeasible, feasibility is maintained by introducing slack variables [15]. The surrogate is trained to approximate the resulting relaxed solution map, with fluxes decreasing smoothly towards zero. The surrogate model thus provides a smooth approximation of the optimal flux distribution within the sampled training region.

Training data consist of non-negative parsimonious fluxes. The surrogate is implemented in Julia [16] using Flux.jl [17, 18] and was trained using an NVIDIA H100 GPU and an AMD EPYC 9354 CPU. Training was performed on 40.401 pFBA solutions, each consisting of 349 intracellular fluxes. The pFBA solutions were generated from a uniform grid sampling over glucose and oxygen uptake rates from 0-20 mmol/(gDW h) with a step size of 0.1. The model was trained for approximately 15.000 epochs with early stopping.

Figure 2 shows surrogate model predictions of intracellular metabolism in *E. coli* under various conditions.

Panel A presents how the biomass growth rate changes as a function of the extracellular glucose concentration. In the low-substrate regions shown, growth decreases as glucose availability decreases and approaches zero. Higher oxygen uptake rates (15 and 20 mmol/(gDW h)) have not plateaued and can sustain higher biomass growth at higher glucose concentrations. Panel B shows the predicted biomass growth rate as a function of glucose uptake rate at a fixed oxygen uptake rate. Panel C shows the predicted glucose uptake rate as a function of extracellular glucose concentration. Uptake decreases smoothly towards zero as glucose concentration decreases and approximates the Michaelis-Menten kinetic equation (dotted line for comparison). When there is not enough glucose available for a fixed oxygen uptake, the glucose uptake rate smoothly approaches zero. Under fermentation conditions, neither the substrate nor oxygen uptake is fixed, but instead adapts to an optimum at the conditions the cell is in.

Figure 3 shows a dynamic fed-batch simulation of *E. coli* using the multi-scale modeling framework with the neural network surrogate. Panels A and B show the reactor volume and inflow, with a step increase in the inflow rate after 5 hours. Panel C shows the growth rate predicted by the surrogate model, while panels D and E show the glucose and biomass concentration in the bioreactor. Initially, the biomass concentration increases at a maximum rate under a fixed oxygen uptake. As the glucose concentration decreases, both the growth rate and glucose uptake shown in panel F decline. Following the step change in inflow, the reactor volume and glucose concentration increase, thereby increasing substrate availability. As a result, the glucose uptake, biomass growth rate, and biomass concentration increase. Once biomass accumulation is sufficient to take up more substrate than is supplied to the bioreactor, glucose concentration and biomass growth rate decrease. Here, the biomass concentration decreases due to dilution, while the total amount of biomass in the reactor continues to increase until the biomass growth rate is zero. At the step change, the non-surrogate model would have encountered an infeasible solution, and the simulation would have been terminated before additional feed [7].

Surrogate and pFBA flux predictions are compared in Figure 4 at glucose and oxygen uptake rates of 10 mmol/(gDW h). Panel A compares the total absolute intracellular flux, summed across all reactions, and the surrogate, which slightly underpredicts the sum of fluxes. Panel B shows the total flux related to glycolysis, specifically, the glycolysis reactions in Figure 5. In both cases, the surrogate reproduces the magnitude of the fluxes. Panels C and D show the parity plot comparing per-reaction flux predictions. Panel C includes all reactions, while Panel D consists of the glycolysis reactions in Figure 5. The low residuals and linear correlation between the surrogate and the pFBA flux predictions indicate a good fit for individual reactions.

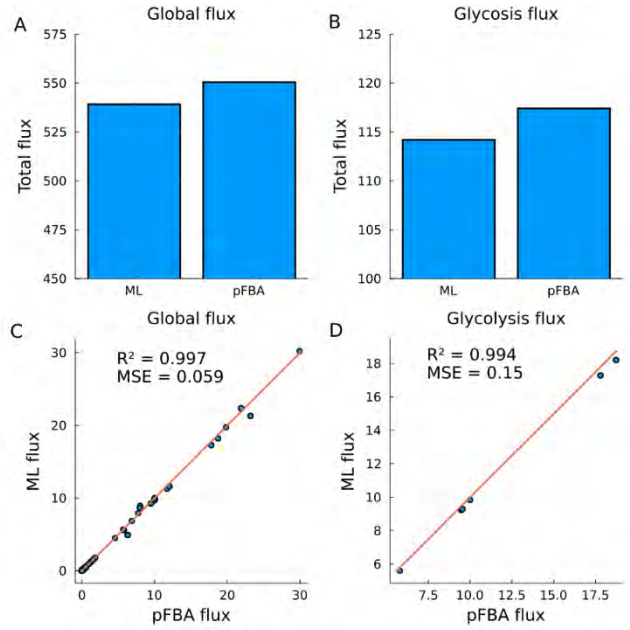

**Figure 4.** Comparison of surrogate and pFBA flux predictions using the *E. coli* genome-scale model. (A) Total absolute intracellular flux magnitude and (B) total glycolysis flux magnitude predicted by the surrogate and the pFBA at fixed glucose and oxygen uptake rates. (C-D) Per reaction flux comparison between surrogate and pFBA for the full network and the glycolysis pathway.

Results

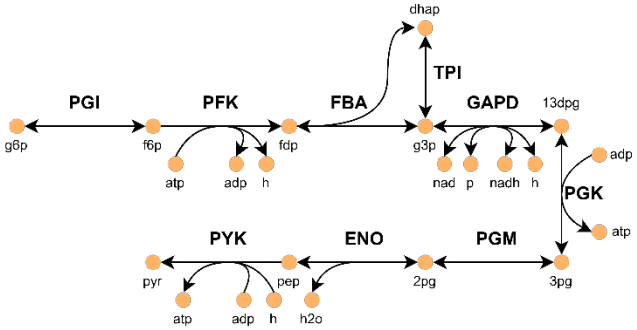

**Figure 5.** Graphical overview of the condensed glycolysis reactions used in Figure 4 (B, D). The enzyme abbreviations are in bold, and the yellow dots are intracellular species.

It should be noted that the uptake rates used in Figures 3 and 4 are included in the surrogate training data. The surrogate model should be applied only within the region of the input space covered by the training data, as it does not explicitly enforce mass-balance constraints or upper and lower bounds. Instead, the surrogate model reproduces empirical relationships observed during training.

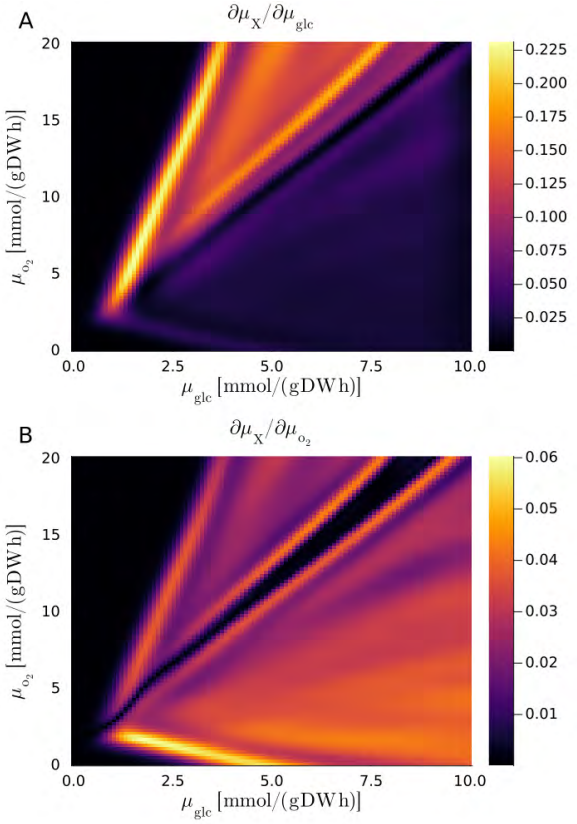

**Figure 6.** Sensitivity of the surrogate predicted biomass production rate $\mu_X$ with respect to glucose uptake, $\mu_{glc}$, and oxygen uptake, $\mu_{o_2}$.

Figure 6 shows sensitivity measures for the surrogate intracellular metabolism across the glucose and oxygen uptake range. Panel A shows the partial derivative of the biomass production rate with respect to glucose uptake, $\partial\mu_X/\partial\mu_{glc}$. High sensitivity is observed along a narrow diagonal region, where concurrent increases in glucose and oxygen uptake lead to increased biomass production. Sensitivity decreases outside this region and approaches zero in low-uptake or oxygen-limited regions. Panel B shows the partial derivative of the biomass production rate with respect to oxygen uptake, $\partial\mu_X/\partial\mu_{o_2}$. Similar regions are observed, however, the overall magnitude of the oxygen sensitivity is lower and more broadly distributed than that of glucose sensitivity.

## DISCUSSION

In the iCH360 model, there is a minimum energetic requirement through the non-growth-associated maintenance reaction [3, 13]. At sufficiently low substrate uptake rates, this requirement cannot be met, and the pFBA problem becomes infeasible [8]. To have training samples, slack variables are introduced, and the surrogate constitutes a relaxed pFBA solution in these regions. The surrogate was trained using glucose and oxygen uptake rates as inputs, assuming Michaelis-Menten uptake kinetics without inhibition [1]. Mass-balance constraints and flux bounds are not explicitly enforced and are reflected only through the training data. Additional inputs, such as mineral uptake or alternative substrates, would require retraining [10, 19]. However, this retraining is performed offline and does not affect computational cost during simulation.

For the iCH360 model, solving the pFBA problem requires approximately 2.33 ms in Julia, where two linear programs are solved sequentially using Gurobi at fixed glucose and oxygen uptake rates. A classical FBA formulation requires approximately 120 $\mu$s. In contrast, the surrogate model predicts via a forward pass consisting of matrix-vector multiplications and nonlinear activation functions, in approximately 60 $\mu$s. This is 39 times faster than the pFBA-based formulation, and twice as fast as the classical FBA formulation.

The genome-scale model contains 349 intracellular fluxes, all of which were included in the training and validation datasets. Deviations between surrogate and pFBA predictions were generally small. The largest discrepancy between the pFBA solution and the surrogate prediction was observed for the hydrogen exchange reaction. Here, an absolute difference of 1.75 mmol/(gDW h), approximately 8%, was observed at a fixed glucose and oxygen uptake rate of 10 mmol/(gDW h). Increasing training coverage, adding more data points, or employing more advanced machine learning methods may reduce discrepancies [10, 19].

When implemented in Julia [16] using Flux.jl [17, 18], automatic differentiation is used to compute Jacobians and Hessians of intracellular fluxes with respect to states and parameters. State and parameter sensitivities are directly accessible through the formulation as well as for Julia's differential equation solvers. These sensitivities may be used in gradient-based state estimation and control [9].

## CONCLUSION

This work extends dynamic FBA by replacing the embedded linear optimization problem with a surrogate model of intracellular metabolism. By approximating the parsimonious FBA solution, the surrogate enables dynamic simulations in operating regions, where the original optimization problem may become infeasible. The surrogate produces continuous intracellular flux trajectories and eliminates repeated optimization solves during simulation. Extension to additional substrates and operating conditions can be achieved through offline retraining. The surrogate provides a computationally efficient basis for integration into control frameworks to optimize fermentation processes.

## ABSTRACT

Capacitive Deionization (CDI) is an emerging electrochemical technology for energy-efficient brackish water desalination. However, the rigorous design and scale-up of CDI systems are frequently hindered by the complexity of validating predictive models. The coupling of electrochemical double-layer kinetics with macroscopic mass transport often leads to structural parameter correlations, where multiple combinations of kinetic rates yield indistinguishable effluent trajectories. This paper addresses these challenges by proposing a simulation-driven Model-Based Design of Experiments (MBDoE) framework. We develop and implement a reduced-order Dynamic Langmuir (DL) model within the gPROMS platform, designed to capture cyclic adsorption-desorption dynamics with high computational efficiency. Sensitivity analysis reveals that information content is highly transient, concentrated primarily in the short time windows following voltage switching, and that the effluent concentration is significantly more sensitive to desorption kinetics than adsorption. Fisher Information Matrix (FIM) analysis of baseline experimental data confirms a strong negative correlation between kinetic parameters, resulting in a poorly conditioned estimation problem. To resolve this, a large-scale in-silico screening of the experimental design space—spanning inlet concentration, flow rate, and cell volume—is conducted using a D-optimality criterion. The simulation results demonstrate that operating at low flow rates and large effective cell volumes maximizes parameter identifiability by enhancing the separation of dynamic signatures. This work illustrates the critical role of dynamic simulation in guiding experimental strategy, minimizing trial-and-error effort, and improving the robustness of process models.

**Keywords**: Desalination, Capacitive Deionization, Modelling and Simulation, System Identification, Design of Experiment

## 1. INTRODUCTION

Freshwater scarcity is a growing global constraint, driving the demand for reliable and energy-efficient desalination technologies. Capacitive Deionization (CDI) has emerged as a promising alternative to reverse osmosis, particularly for the treatment of low-to-moderate salinity brackish water [1]. The technology operates on the principle of electrosorption, where dissolved ions are removed from a feed stream by applying a low voltage across porous carbon electrodes, storing them in electrical double layers (EDLs) [2]. Unlike steady-state membrane processes, CDI is inherently dynamic and cyclic, alternating between a charging or purification phase and a discharging or regeneration phase.

The optimization of CDI cycles—balancing salt removal, energy consumption, and water recovery—requires robust predictive models. However, the modelling of CDI systems presents a significant fidelity-cost challenge [3]. High-fidelity models, such as those based on Poisson-Nernst-Planck (PNP) equations or modified Donnan theory, offer detailed resolution of pore-scale electrochemistry but are often computationally prohibitive for real-time control or extensive design screening [4]. Conversely, simple equivalent-circuit models (RC circuits) are computationally inexpensive but lack mechanistic insight into mass transfer limitations, making them poor tools for process scale-up.

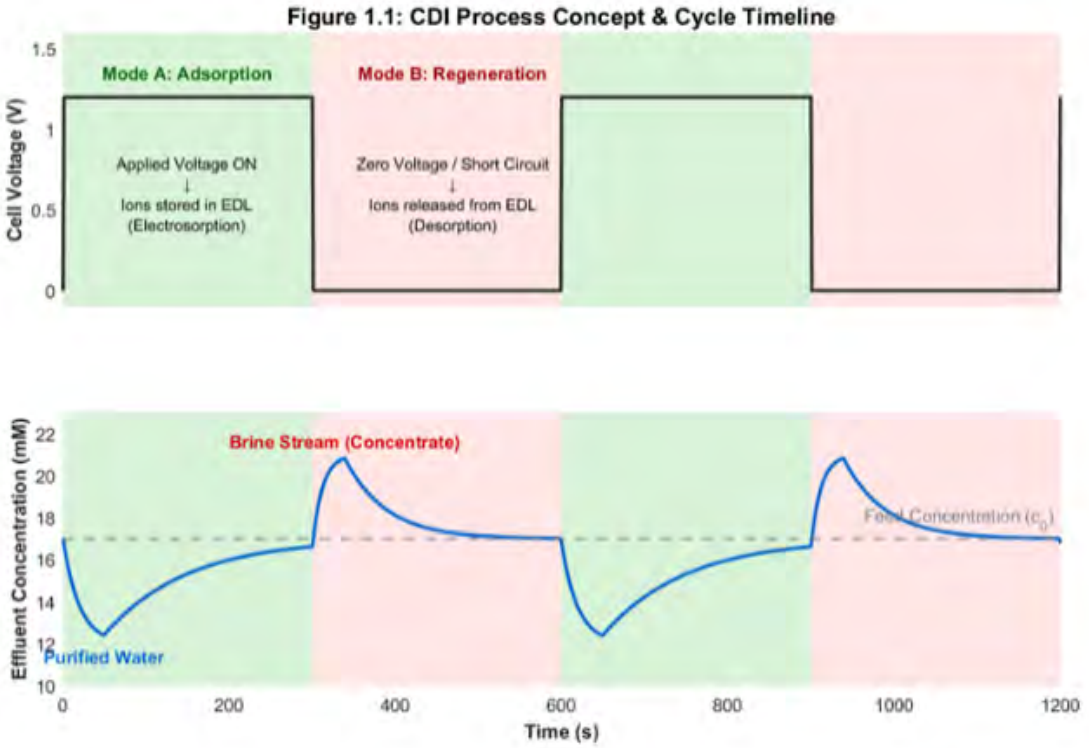

**Figure 1.** Ideal CDI process concept and timeline

An intermediate class of models, such as the Dynamic Langmuir (DL) model, offers a compelling compromise by describing the macroscopic adsorption dynamics with a compact set of parameters [5]. Yet, even simplified mechanistic models face the challenge of parameter identifiability. The coupling of reaction kinetics with fluid dynamics in a flow-through cell often leads to strong correlations between parameters. For instance, a faster adsorption rate might be mathematically indistinguishable from a different mass transfer coefficient under certain flow conditions. Standard experimental approaches, which often rely on normal one by one sweeps, is hard to generate data that can decouple these effects, leading to models with large predictive uncertainties [6].

Figure 1 shows the ideal CDI process concept and the adsorption regeneration cycle timeline. The top panel shows the applied cell voltage profile, which changes between a charging step (Mode A) where a constant voltage is applied to drive absorption, and a regeneration step (Mode B) where the voltage is removed or reversed. The bottom panel shows the corresponding effluent concentration response (blue line) relative to the constant feed concentration. During Mode A, ion removal causes the effluent concentration to drop, producing purified water. Conversely, in Mode B, the release of stored ions creates a concentration peak, resulting in a concentrated brine stream. These transient responses highlight why understanding dynamics and cycling is important to both system operation and model development.

Calibrating mechanistic models for CDI is challenging because different combinations of kinetic and transport parameters often yield indistinguishable effluent profiles, leading to poor parameter identifiability [7]. Traditional experimental design strategies, which typically rely on intuition or broad factorial sweeps, are often inefficient at resolving these correlations and can result in high experimental costs without reducing parameter uncertainty.

To address this, we employ Model-Based Design of Experiments (MBDoE) [8, 9]. Unlike classical design approaches that aim for broad empirical coverage, MBDoE uses the mechanistic model itself to quantitatively predict the information content of future experiments [10]. By analyzing dynamic sensitivities and the Fisher Information Matrix (FIM), MBDoE identifies specific operating windows, such as precise flow rates or cycle timings, that maximize the sensitivity of the measured outputs to the target parameters. This approach guides the selection of experimental conditions to decouple correlated parameters and minimize the variance of estimates with the least possible experimental effort [11]. Similar work in electrodialysis successfully minimise the number of trials and resources required for model identification [12].

This paper uses modelling and simulation as a tool

to solve this experimental design problem. We propose a MBDoE framework to systematically identify operating conditions that maximize the information content of collected data.

## 2. METHODOLOGY: MODELLING AND SIMULATION FRAMEWORK

### 2.1 The Dynamic Langmuir (DL) Model

To enable the rapid, repeated simulations required for extensive design screening ($N > 1000$ runs), we adopt a reduced version of the Dynamic Langmuir model. The original DL framework describes ion removal as a competitive adsorption process on voltage-induced sites.

The full kinetic description typically depends on the real-time free ion concentration inside the cell, $c(t)$. However, in this work, a key simplification to improve structural identifiability and computational speed was introduced [13]: It assume that for the purpose of the adsorption driving force, the cell concentration can be approximated by the constant inlet concentration, i.e., $c(t) \approx c_0$ in the kinetic rate term. This assumption transforms the nonlinear adsorption dynamics into a linear Ordinary Differential Equation (ODE) for the adsorbed concentration state, $c_{ads}$ (mM)[14]:

$$\frac{dc_{ads}}{dt} = K_a - K_b c_{ads} \tag{1}$$

Here, $K_a$ (mM/s) represents an effective adsorption rate that lumps together the site availability, voltage dependence, and feed concentration effects.$K_b$ ($s^{-1}$) represents the effective desorption or relaxation rate constant.

The macroscopic mass balance for the cell is modelled as a Continuous Stirred Tank Reactor (CSTR). The change in free ion concentration $c$ (mM) is driven by the net removal of ions to the electrode (adsorption sink) and the convective transport through the cell [14]:

$$\frac{dc}{dt} = -\frac{dc_{ads}}{dt} + \frac{Q}{V}(c_0 - c) \tag{2}$$

where $Q$ is the volumetric flow rate (mL/s) and $V$ is the effective free cell volume (mL). This structure retains the essential dynamic features of CDI, which is the rapid drop during charging and the concentration overshoot during regeneration, while reducing the estimation problem to two primary kinetic parameters, $\theta = [K_a, K_b]^T$.

### 2.2 Model-Based Design of Experiments (MBDoE) Formulation

The objective of the MBDoE framework is to determine the experimental design vector $\varphi = [c_0, Q, V]^T$ that minimizes the statistical uncertainty of the estimated parameters $\theta$.

**Sensitivity Analysis:** The foundation of the analysis is the dynamic local sensitivity matrix $Q(t)$, which quantifies the influence of parameters on the measured output $y(t) = [c(t), c_{ads}(t)]^T$:

$$Q_{ij}(t) = \frac{\partial y_i(t)}{\partial \theta_j} \tag{3}$$

In this study, sensitivities were computed using a finite-difference perturbation method ( $\delta = 1\%$ ) implemented directly within the simulator. Large sensitivity values indicate that the output is strongly responsive to the parameter, implying that the data contains significant information for estimation.

**Fisher Information Matrix (FIM):** To aggregate this information over the duration of a dynamic experiment ($T$), we compute the cumulative Fisher Information Matrix, $H(\theta)$. Assuming Gaussian measurement noise with variance $\sigma^2$, the FIM is defined as [8]:

$$H(\theta) = \frac{1}{\sigma^2}\int_0^T Q(t)^T Q(t) dt \tag{4}$$

The inverse of the FIM approximates the parameter covariance matrix ($Cov(\theta) \approx H^{-1}$). Therefore, "maximizing" the FIM corresponds to minimizing the variance and covariance of the parameters.

**D-Optimality Criterion:** Since the FIM is a matrix, a scalar metric is required for optimization. We employ the **D-optimality criterion**, which maximizes the determinant of the FIM [8]:

$$\Phi_D(\varphi) = \log\det\big(H(\varphi)\big) \tag{5}$$

Geometrically, maximizing the determinant minimizes the volume of the joint confidence ellipsoid in the parameter space. This is particularly critical in CDI modeling, where parameters are often highly correlated; D-optimality specifically penalizes designs that result in flattened, elongated confidence regions.

### 2.3 Implementation in gPROMS

The simulation framework was implemented in gPROMS ModelBuilder. The architecture was designed for scalability, consisting of two layers:

**Unit Model:** A rigorous dynamic model of a single CDI cell solving the mass balance and kinetic equations (Eqs. 1-2) under a cyclic voltage schedule].

**Manager Model:** A high-level wrapper that instantiates an array of unit models. This allows for the simultaneous execution of a full-factorial Design of Experiments (DoE) grid.

This architecture enabled the screening of $N_{exp} = 1000$ virtual experiments in a single simulation job, ensuring consistency across initial conditions and solver settings.

## 3. RESULTS AND DISCUSSION

### 3.1 Dynamic Behaviour and Sensitivity Analysis

The reduced model was first evaluated under baseline conditions ($c_0 = 17$ mM, $Q = 1$ mL/s, $V = 10$ mL) to establish the dynamic characteristics of the system. . The simulation successfully reproduces the classic CDI response: upon voltage application, the effluent concentration drops sharply as ions are electrosorbed, followed by a gradual saturation. During regeneration (voltage removal), a concentration peak (overshoot) is observed as stored ions are released back into the bulk

The agreement between the model predictions using the estimated parameters and the measured data is illustrated in Figure 2 The solid line represents the simulated effluent concentration, while the symbols with error bars denote the experimental measurements and their standard deviations based on the estimated variance model. The figure shows that the model captures both the rapid initial decrease in effluent concentration during adsorption and the subsequent recovery and slight overshoot during regeneration. All measured points lie within the ±1σ confidence bands, and no systematic deviation can be observed over time.

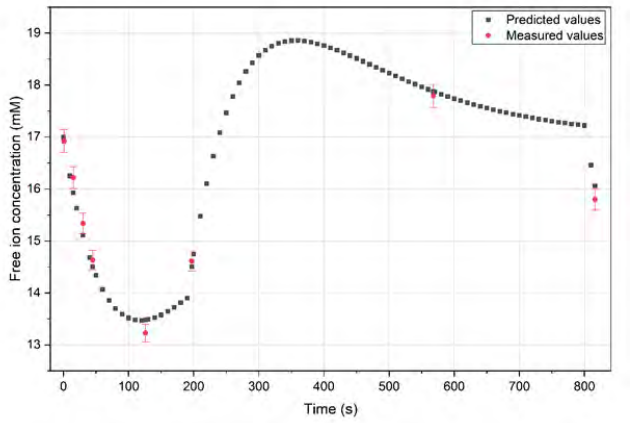

**Figure 2.** Comparison between measured and model-predicted effluent concentration c for the sample experiment

A critical finding from the sensitivity analysis is the disparity in parameter influence. The sensitivity of the effluent concentration to the desorption rate ($K_b$) is approximately an order of magnitude larger than that to the adsorption rate ($K_a$). Specifically, sensitivity to $K_b$ peaks at values around $3 \times 10^2$, while sensitivity to $K_a$ remains within $\pm 20$.

Furthermore, the information content is highly localized in time. The sensitivity profiles exhibit sharp peaks immediately following the voltage switching events (charging and discharging steps) and decay to near zero during the steady-state phases. This temporal analysis suggests that measurements taken during the transient "switching windows" are exponentially more valuable than those taken at steady state. It confirms that dynamic operation is not just a feature of CDI but a necessity for accurate model calibration.

### 3.2 Parameter Estimation and Identifiability Issues

Using experimental data from a single charging cycle taken from literature, the kinetic parameters were estimated as $K_a \approx 0.0814$ mM/s and $K_b \approx 0.0071$ s$^{-1}$. While the model achieved a statistically valid fit (passing $\chi^2$ and lack-of-fit tests), the FIM analysis reveals severe underlying identifiability issues.

The cumulative FIM at the end of the experiment showed a condition number of approximately $2.4 \times 10^2$, indicating a highly ill-conditioned estimation problem. The off-diagonal element of the covariance matrix revealed a correlation coefficient between $K_a$ and $K_b$ of $\rho \approx -0.83$. This indicates a strong negative correlation between Ka and Kb: an increase in one parameter can be partially compensated by a decrease in the other while still producing similar model responses. Geometrically, the confidence region in the $(K_a, K_b)$-plane is expected to be an elongated ellipse with a major axis tilted away from the coordinate axes.

Geometrically, this strong negative correlation results in a highly elongated joint confidence ellipse. This implies that $K_a$ and $K_b$ are coupled: an error in estimating the adsorption rate can be compensated by a proportional error in the desorption rate, leaving the model prediction largely unchanged. This "parameter compensation" effect is a primary cause of poor model predictive capability when operating conditions change.

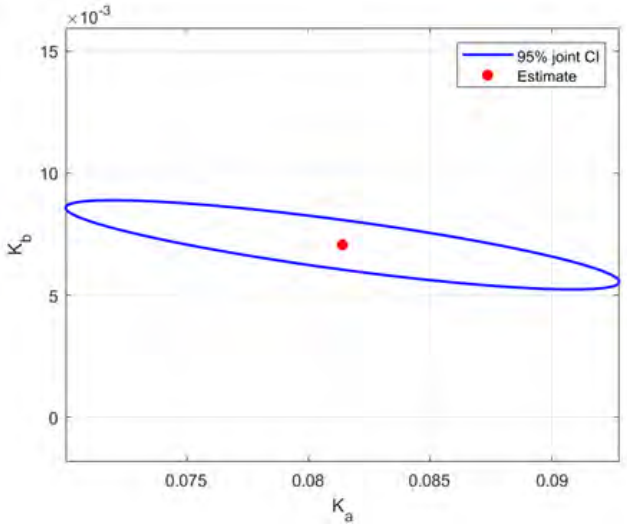

**Figure 3.** Joint 95% confidence region for the kinetic parameters $K_a$and $K_b$

**Table 1.** Estimated kinetic and variance-model parameters for the experiment data

| Parameter | Final value | Initial guess | Std. dev. | 95% CI lower | 95% CI upper | t-value |
|---|---|---|---|---|---|---|
| $K_a$ [units] | 0.0814 | 0.0976 | 0.0046 | 0.059 | 0.119 | 6.82 |
| $K_b$ [$s^{-1}$] | 0.00706 | 0.00880 | 0.00075 | 0.00530 | 0.00919 | 3.68 |
| $\omega$ [–] | 0.0130 | 0.0100 | 0.0049 | 0.0093 | 0.0185 | 1.10 |

Table 1 summarises the final parameter estimates, together with their standard deviations and 95% confidence intervals as reported by gPROMS. Starting from the literature-based initial guesses, the optimisation converged to slightly lower values for both kinetic parameters: $K_a$ decreases from 0.0976 to approximately 0.081, while $K_b$ decreases from 0.0088 to around 0.0071. These shifts indicate that the originally assumed rates moderately overestimated both the adsorption and desorption kinetics for the dataset considered.

## 3.3 Optimal Design Screening via Simulation

To break this parameter correlation, the simulation framework was used to screen the design space for conditions that maximize the D-optimality score. A full-factorial grid was evaluated:

- Inlet concentration $c_0 \in [0.1, 100]$ mM
- Flow rate $Q \in [0.05, 5.0]$ mL/s
- Cell volume $V \in [1, 100]$ mL.

The analysis of the resulting 1000 design points (Figure 4) yields three key insights for process engineering:

**Invariance to Concentration:** The D-optimality score showed negligible sensitivity to the inlet concentration $c_0$. This is consistent with the linear structure of the reduced model, suggesting that experimenters have flexibility in choosing $c_0$ based on safety or material constraints without compromising information quality.

**Dominance of Flow Rate:** The flow rate $Q$ emerged as the most critical design factor, showing a strong negative correlation with the D-score ($r \approx -0.68$). Reducing the flow rate from 5.0 mL/s to 0.05 mL/s improved the determinant of the FIM by nearly a factor of three. Physically, lower flow rates increase the residence time of fluid in the cell. This allows the kinetic signature of the adsorption process to manifest more clearly against the background of convective transport, effectively "amplifying" the signal of the kinetic parameters.

**Benefit of Cell Volume:** Larger cell volumes were found to improve identifiability ($r \approx +0.31$). Similar to flow rate, a larger volume stretches the characteristic time of the mass balance, enhancing the separation of adsorption and desorption dynamic modes.

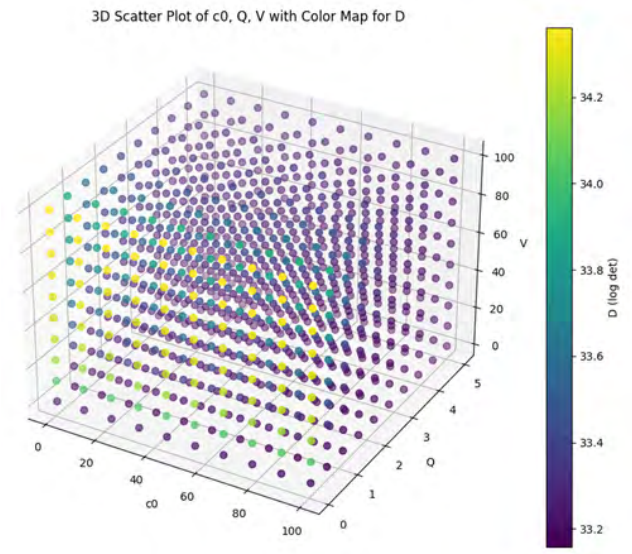

**Figure 4.** Three-dimensional scatter plot of the DOE design space $(c_0, Q, V)$ coloured by the final D-criterion $D_{\log}(t_f)$, indicating the regions of highest and lowest information content for estimating $K_a$ and $K_b$.

## 3.4 Recommended Design Strategy

Based on these simulation results, the optimal strategy for characterizing CDI kinetics is to operate at the **lowest feasible flow rate** and using a **larger effective cell volume**. The "worst-case" design was identified as a high-flow, small-volume configuration ( $D_{log} \approx 33.16$ ), while the "best-case" design was a low-flow, large-volume configuration ($D_{log} \approx 34.36$). By shifting experiments to this optimal region, researchers can significantly reduce the volume of the parameter confidence ellipsoid, decoupling the kinetic rates and ensuring a more robust model calibration.

# 4. CONCLUSION

This study demonstrates the power of modelling and simulation as a core pillar of Computer Aided Process Engineering (CAPE) for emerging water technologies. By formulating a reduced-order dynamic model for Capacitive Deionization and integrating it with a rigorous MBDoE framework, we successfully quantified the information content of experimental data.

The simulation results highlight that "standard"

experimental conditions often yield poor parameter identifiability due to intrinsic correlations between adsorption and desorption kinetics. However, by using the model to navigate the design space, we identified that operating regimes with high residence times (low flow, large volume) maximize the D-optimality criterion. This approach moves beyond trial-and-error experimentation, providing a systematic workflow to minimize experimental effort while maximizing the reliability of process models. Future work will extend this framework to include multi-objective optimization, incorporating energy consumption and thermodynamic efficiency into the design criteria.

## ABSTRACT

Liquefied Natural Gas (LNG) plays a strategic role in the global energy transition, as it represents a less carbon-intensive alternative to coal. Separation of $CO_2$ from raw natural gas is a critical step for meeting LNG specifications and enabling Enhanced Oil Recovery (EOR) in offshore fields. However, high $CO_2$ concentrations and formation of a $CO_2$ ethane azeotrope increase the process complexity, often requiring extractive distillation with heavier hydrocarbons. Severe limitations are faced in offshore environments due to their weight, volume and high energy consumption. Due to that, Process Intensification (PI) seeks to enhance heat and mass transfer efficiency, potentially reducing equipment volume and weight. Rotating Packed Beds (RPB) have demonstrated significant potential for intensifying LNG purification by using centrifugal forces to drive liquid through a porous medium in contact with a gas stream. Experimental measurements of total pressure drop, and local liquid holdup are feasible in pilot-scale units, although typically requiring specialized equipment and instrumentation. Consequently, modeling approaches based on mass, momentum, and energy balances have been widely proposed in the literature to estimate the hydrodynamic behavior of RPB systems. While Computational Fluid Dynamics (CFD) models can provide detailed insights into equipment behavior, they are often computationally expensive for parametric studies and design optimization. In this context, this work proposes a one-dimensional model in cylindrical coordinates to analyze fluid flow in an RPB for natural gas/$CO_2$ separation process. The governing equations are formulated and validated against experimental data for pressure drop, interfacial velocity, and liquid holdup along the RPB radius.

## INTRODUCTION

Liquefied Natural Gas (LNG) plays a strategic role in the global energy transition, as it is a less carbon-intensive alternative to coal. The growing need to reduce greenhouse gas emissions, coupled with the search for greater efficiency in oil exploration, has driven the application of Enhanced Oil Recovery (EOR) techniques in offshore fields. In these projects, the separation of $CO_2$ from raw natural gas is a critical step, both to meet LNG quality specifications and to enable the reinjection of $CO_2$ as a miscible displacement fluid.

However, many natural gas fields have high levels of carbon dioxide ($CO_2$), which makes commercial exploration unfeasible. One problem related to removal of $CO_2$ from raw natural gas is the significant hydrocarbon losses due to the formation of an azeotrope with ethane, which reduces overall efficiency of the process and the economic viability of LNG production. One way of reducing the loss of light carbon components due to the azeotrope formed may be to use a third component and subsequent fractionation using a low temperature distillation process, such as the use of compounds with 4 or more carbons, as reported in [1].

However, conventional separation methods, such as traditional cryogenic distillation columns, have significant limitations in offshore environments: high energy consumption, especially in mixtures with a high $CO_2$ content;

weight and volume of the equipment, restrictive factors on offshore platforms; operational complexity due to variations in load and gas composition.

One way of reducing the equipment volume is to intensify heat and mass transfer processes, with the aim of improving the efficiency of the mixing and transfer processes [2], which can reduce required volumes to a scale of 10 to 100 times and are interesting in environments with limited space.

For the case of intensifying the separation of $CO_2$ from the hydrocarbon stream, the application of a rotating packed bed (RPB) has demonstrated potential in the literature. In this method, a liquid stream is injected into the inner surface of the packing, while the packing is rotated, forcing the liquid to travel to the outer surface. A gas stream can be injected either at the outer casing (counter-current) or at the same location as the liquid inlet (co-current).

To understand and estimate separation efficiencies, experimental data or/and simulation and modeling of the transport phenomena inside the system have been carried out. Measurement of total pressure drop [3–5] and local liquid holdup [6, 7] are possible with pilot plant systems, although requiring specialized equipment. Due to that, modelling of the system based on mass, momentum and energy balances are proposed in the literature to estimate the system's behavior. For that, simplified models [8–12] can be solved to understand locally the process dynamics, which can include pressures, flow velocities and compositions across the packing. Moreover, Computational Fluid Dynamics (CFD) models can also be used to address different packing geometries [13–15], although often requiring more computational resources [16–18], but providing an insight in liquid distribution inside the packing, since it is difficult to take internal measurements during operation.

In this context, distillation using RPBs has emerged as a promising technology to overcome the economic barriers to LNG production in offshore wells and to understand the system behavior, a simpler 1D model in cylindrical coordinates are proposed to analyze the fluid flow, heat, and mass transfer in an RPB for the LNG/$CO_2$ separation process. Based on that, governing equations are described for modeling the process, and it is compared with available experimental data for pressure drop, interfacial velocity, and liquid holdup.

# MATERIALS AND METHODS

## Rotating packed bed

Rotating packed beds can be operated in co-current or counter-current, with typical rotations between 500 and 2500 RPM, with the packed bed being made of foams, spheres, wire meshes or other geometries and rotated vertically or horizontally. In the counter-current approach, liquid is inserted at the inner radius from the packing material and is driven to the outer radius due to the created gravitational field and gas flows in opposite direction. A schematic representation of the system is given in Figure 1. By increasing the liquid velocity, as compared to stationary packed beds, turbulence is intensified, which improves mass transfer coefficients inside the liquid. This effect is made possible by using packing elements that can simultaneously combine high surface area, promote low pressure drop and efficient liquid distribution [19].

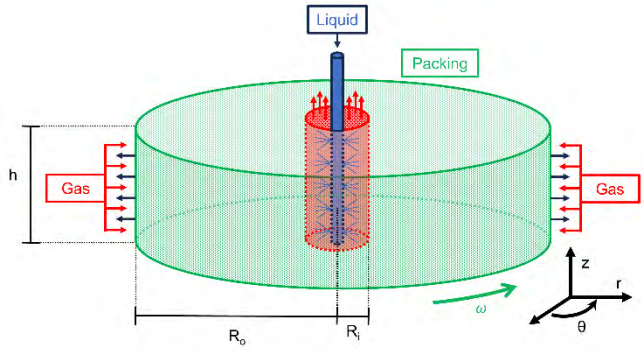

**Figure 1.** Schematic representation of a horizontal Rotating Packed Bed (RPB) system operating in a counter-current mode.

## Hydrodynamic model

A counter-current gas-liquid RPB operating horizontally was assumed. For modelling the two-phase (gas, liquid) behavior, mass and r-component momentum balances are written in cylindrical coordinates, respectively, in Equation (1) and (2). Equation (3) was added to account for the presence of more phases, with all k-th volume fractions being equal to one. Gravitational force in the z-axis were disregarded, following similar approaches from the literature [20, 21].

$$\frac{1}{\alpha_k}\frac{\partial \alpha_k}{\partial r} + \frac{1}{u_{r,k}}\frac{\partial u_{r,k}}{\partial r} + \frac{1}{P}\frac{\partial P}{\partial r} = -\frac{1}{r} \quad (1)$$

$$\alpha_k \rho_k u_{r,k}\frac{\partial u_{r,k}}{\partial r} + \alpha_k \frac{\partial P}{\partial r} - 2\mu_k\left(\frac{1}{r}\frac{\partial u_{r,k}}{\partial r}\right) = \frac{\alpha_k \rho_k u_{\theta,k}^2}{r} + M_{r,k} \quad (2)$$

$$\sum_{k=0}^{n} \alpha_k = 1 \quad (3)$$

$\alpha_k$ represents the volume fraction with subindices k-th, representing the two phases (k – gas, liquid), $P$ is the local pressure [Pa], which followed the ideal gas law, $\rho_k$ is the density [kg/m$^3$], $\mu_k$ is the viscosity [Pa.s] $u_{r,k}$ is the area averaged radial velocity and $u_{\theta,k}$ is the tangential velocity of the k-th phase [m/s] and $M_{r,k}$ represents the momentum exchange between the phases. Assuming a solid body rotation, tangential velocities can be written in terms of radius and rotation velocity ($\omega$), as $u_{\theta,k} = \omega r$.

In the modelling, simplifying hypotheses were assumed, such as steady-state operation, one-dimensional flow (velocity varies only in r component), no mass transfer occurs (only the hydrodynamic model is being developed) and excluded secondary velocity derivatives. The model was solved considering initial value problems, where conditions were set at the inner radius ($R_i$) and the equations were numerically integrated up to the outer radius of the packing material ($R_o$). Integrations were solved using the implicit Radau method, which is recommended for stiff-problems, available in Scipy library.

## Interaction forces

During the flow of the gas and liquid phases through the voids of the solid packing material, the liquid often flows above the solid surface, partially wetting the surface and applying a force between at the solid boundary ($f_{LS}$). Gas flows in the center of the void section, forming an interface between liquid and solid. Due to velocities at the interface being the same, momentum is transferred at the interface due to the drag force between gas and liquid ($f_{GL}$). Also, gas momentum can be transferred directly to the solid ($f_{GS}$) through the liquid film, due to the tortuosity inside the packing material. As a result, momentum transfer to the liquid ($M_{r,L}$) and gas ($M_{r,G}$) are written, respectively, by Equations (4) and (5) [20].

$$M_{r,L} = f_{GL} - f_{LS} \tag{4}$$

$$M_{r,G} = -f_{GL} - f_{GS} \tag{5}$$

To calculate the interaction forces $f_{LS}$, $f_{GS}$ and $f_{GI}$, different models are proposed in the literature. For studying the hydrodynamic behavior of a descending cocurrent gas-liquid flow through a trickle bed reactor, composed of packed spheres, Attou et al. (1999) [20] have used Equations (6), (7), (8) and (9), assuming that all solid surfaces were covered with liquid. For the model it was considered that the Ergun parameters are: $E_{\mu,LS} = E_{\mu,GS} = E_{\mu,GL} = 180$ and $E_{\rho,LS} = E_{\rho,GS} = E_{\rho,GL} = 1.8$

$$f_{LS} = E_{\mu,LS}\frac{(1-\epsilon)^2}{(1-\alpha_g)^3\epsilon^3 d_p^2}\mu_l w_l + E_{\rho,LS}\frac{1-\epsilon}{(1-\alpha_g)^3\epsilon^3 d_p}\rho_l w_l|w_l| \tag{6}$$

$$f_{GS} = \alpha_g\left(E_{\mu,GS}\frac{(1-\alpha_g\epsilon)^2}{\alpha_g{}^3\epsilon^3 d_p^2}\left(\frac{1-\epsilon}{1-\alpha_g\epsilon}\right)^{\frac{2}{3}}\mu_g w_g + E_{\rho,GS}\frac{(1-\alpha_g\epsilon)}{\alpha_g{}^3\epsilon^3 d_p}\left(\frac{1-\epsilon}{1-\alpha_g\epsilon}\right)^{\frac{1}{3}}\rho_g w_g|w_g|\right) \tag{7}$$

$$f_{GL} = \alpha_g\left(E_{\mu,GL}\frac{(1-\alpha_g\epsilon)^2}{\alpha_g{}^3\epsilon^3 d_p^2}\left(\frac{1-\epsilon}{1-\alpha_g\epsilon}\right)^{\frac{2}{3}}\mu_g w_r + E_{\rho,GL}\frac{(1-\alpha_g\epsilon)}{\alpha_g{}^3\epsilon^3 d_p}\left(\frac{1-\epsilon}{1-\alpha_g\epsilon}\right)^{\frac{1}{3}}\rho_g w_r|w_r|\right) \tag{8}$$

$$w_r = w_g - \left(\frac{\alpha_g}{1-\alpha_g}\right)w_l \tag{9}$$

Where $\epsilon$ is the packed bed porosity, $d_p$ the diameter of the packing material [m], $w$ is the superficial velocity [m/s], defined as $w_k = \epsilon u_k$. To account for a partial surface wettability ($f_e$), Lappalainen et al. (2008) [22] modified to include this effect in the interaction forces, as given by Equations (10) and (11).

$$M_{r,L} = f_e(f_{GL} - f_{LS}) \tag{10}$$

$$M_{r,G} = -f_e f_{GL} - (1 - f_e) f_{GS} \tag{11}$$

In addition to that, Ergun parameters were changed to account for the different tortuosity in the packing. Ergun parameters are then modified according to Equations (12) and (13).

$$E_{\mu,i} = 72T_i^{\,2} \tag{12}$$

$$E_{\rho,i} = 0.4554T_i^{\,3} \tag{13}$$

With specific tortuosity ($T_i$) for the gas and liquid phase, being given respectively, by Equations (14) and (15), with $T_0 = 1.58$ being obtained for the tortuosity in an empty bed and the parameters $A = 3.592$ and $B = 1.14$ obtained by optimization.

$$T_G = \frac{T_o + 1}{2} + \alpha_g\left(\frac{T_0 + 1}{2} - 1\right) \tag{14}$$

$$T_L = T_o A^{\alpha_g{}^B} \tag{15}$$

Lu et al. (2018) [23] modified the flow resistance model of Kolodziej et al. (2009) [24] to account for a packing bed made of wire meshes, resulting in interaction forces being given by Equations (16), (17) and (18).

$$f_{LS} = \alpha_l\epsilon\left(4(f_{app} + f_t)\frac{\rho_l|w_l|\epsilon\tau^3}{2d_w(\alpha_l\epsilon)^3\cos^3\theta}\right)w_l \tag{16}$$

$$f_{GS} = \alpha_g\epsilon\left(4(f_{app} + f_t)\frac{\rho_g|w_g|(1-\alpha_g\epsilon)\tau^3}{2d_w(\alpha_g\epsilon)^3\cos^3\theta}\right)w_g \tag{17}$$

$$f_{GL} = \alpha_g\epsilon\left(4(f_{app} + f_t)\frac{\rho_g|w_g - w_l|(1-\alpha_g\epsilon)\tau^3}{2d_w'(\alpha_g\epsilon)^3\cos^3\theta}\right)(w_g - w_l) \tag{18}$$

In which $f_{app}$ is the corrected Fanning friction factor for non-developed laminar flows and $f_t$ is the Fanning friction factor for turbulent flows, $\tau$ is the bed tortuosity factor, $\theta$ is the angle between the bed axis and flow direction and $d_w$ is the diameter of the packed wires [m], which are given for each phase and detailed elsewhere [23].

## Wetting efficiency

For the surface efficiency coverage ($f_e$), the model developed by Lu et al. (2018) [23] used the correlation provided by Onda et al. (1968) [25], as detailed in Equation (19).

$$f_e = 1 - e^{\left(-1.45\left(\frac{\sigma_c}{\sigma}\right)^{0.75} Re_l^{0.1} We_l^{0.2} Fr_l^{-0.05}\right)} \quad (19)$$

In which $Re_l = \rho_l u_l / a_s \mu_l$ is the Reynolds number of the liquid, $We_l = \rho_l u_l^2 / a_s \sigma$ is the Weber number, $Fr_l = a_s u_l^2 / g_c$ is the Froude number and centrifugal acceleration is given by $g_c = r\omega^2$. $\sigma = 0.072$ is the surface tension of the liquid, which was assumed as water [N/m] and $\sigma_c = 0.06$ is the critical surface tension in glass media. $v_l$ is the liquid velocity [m/s] and $a_s$ is the specific surface area of the dry packing media [1/m].

Lappalainen et al. (2008)[22] fitted a correlation from literature data for $Re_l, Ga_g = \rho_g^2 g d_p^3 \epsilon^3 / (\mu_g (1-\epsilon)^2)$ being the Galileo number, $Fr_g = u_g / \sqrt{g d_p}$ being the Froude number and $E\ddot{o} = \rho_l g d_p^2 \epsilon^2 / (\sigma (1-\epsilon)^2)$ being the modified Eötvos number, resulting in Equation (20).

$$f_e = 0.335 Re_l^{0.185} E\ddot{o}^{-0.188} Ga_g^{0.027} \left(1 + Fr_g\right)^{-0.014} \quad (20)$$

## RESULTS AND DISCUSSION

For the model verification, experimental and simulation results obtained in the literature were compared with the current implementations using the three interaction forces of Attou et al. (1999) [20], Lappalainen et al. (2008) [22] and Lu et al. (2018) [23], with necessary parameters extracted from the sources. Attou et al. (1999) [20] and Lappalainen et al. (2008) [22] were developed for modelling the hydrodynamic behavior in a trickle bed reactor, composed of packed solid spheres, and Lu et al. (2018) [23] focused in modelling the flow inside a porous foam media. Comparisons were made in terms of pressure drop through the rotating media, liquid holdup, gas and liquid velocities. Experimental data from Sandilya et al. (2001), with parameters highlighted in Table 1, were used in the developed model, while varying two gas flow rates (2000 and 6000 cm³/s) and two rotations (950 and 1410). Another setup case from Lu et al. (2018) [23] was also tested using the different interaction forces.

### Pressure drop

By comparing the pressure results obtained by the proposed model for gas flow rates in the range of 2000 cm³/s and 6000 cm³/s, as observed respectively in Figures 2 and 3. It is possible to note similar estimations for the pressure by using the interaction model of Lappalainen et al. (2008) [22] and Lu et al. (2018) [23], at the gas flow rate of 2000 cm³/s, which are somewhat close to the experimental data of Sandilya et al. (2001) [26], while Attou et al. (1999) [20] overpredicts pressure drop, with a relative difference of more than 72 % (950 rpm), which could be explained by considering that the whole solid surface is covered by liquid, resulting in a slightly higher pressure drop. When a higher gas flow rates of 6000 cm³/s are used, the three interaction force models predict higher values for pressure losses and the force models proposed in Lu et al. (2018) [23] and Lappalainen et al. (2008) [22] results in a value closer to the experimental data, with a maximum relative difference of 33 % (950 rpm). However, it is observed that higher rotation speeds increase pressure drop.

**Table 1: Specification of the packing material used in the experimental setup and flow rates**.

| Var. | Description | [26] | [27] |
|---|---|---|---|
| $R_i$ | Inner radius (mm) | 30 | 35 |
| $R_o$ | Outer radius (mm) | 155 | 160 |
| $h$ | Bed height (mm) | 22 | 10 |
| $d_p$ | Diameter pore (mm) | 0.25 | 7.6 |
| $a_s$ | Specific media area (1/m) | 2196 | 786 |
| $\epsilon$ | Porosity (-) | 0.91 | 0.953 |
| $Q_g$ | Gas flow rate (cm³/s) | 2000; 6000 | 2.0 |
| $Q_l$ | Liquid flow rate (cm³/s) | 14.3 | 17.5 |
| $\omega$ | Rotation speed (rpm) | 950; 1410 | 600; 917; 1200 |

By comparing the pressure results obtained by the proposed model for lower gas flow rates (2.0 cm³/s), as observed in Figure 4, it is possible to note that the three different interaction force models give a similar behavior for the different imposed rotations and result in differences lower than 0.2% with the correlation proposed in Sandilya et al. (2001) [26]. Moreover, it is observed that higher pressure losses as higher rotation speeds are employed and results are similar for the estimation from Equation (21), which is the correlation proposed by Sandilya et al. (2001) [26].

$$\Delta P_{RPB} = \frac{150(1-\epsilon)^2 \mu}{{d_p}^2 \epsilon^3} \left(\frac{Q_g}{2\pi h}\right) \ln\left(\frac{R_o}{R_i}\right) + \frac{1.75(1-\epsilon)\rho_g}{d_p \epsilon^3} \left(\frac{Q_g}{2\pi h}\right)^2 \left(\frac{1}{R_i} - \frac{1}{R_o}\right) + \frac{1}{2}\rho_g \omega^2 (R_i^2 - R_o^2) \quad (21)$$

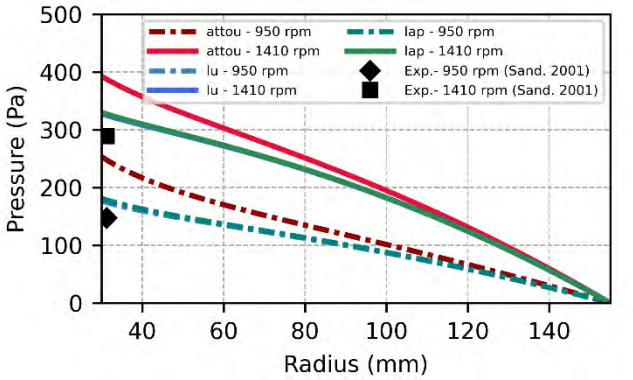

**Figure 2.** Relative pressures across the packing media, with atmospheric pressure condition being placed at the outer radius, for a gas flow rate of 2000 $cm^3/s$ and liquid flow rate of 14.3 $cm^3/s$, and pressure obtained with the experimental data from Sandilya et al. (2001) [26].

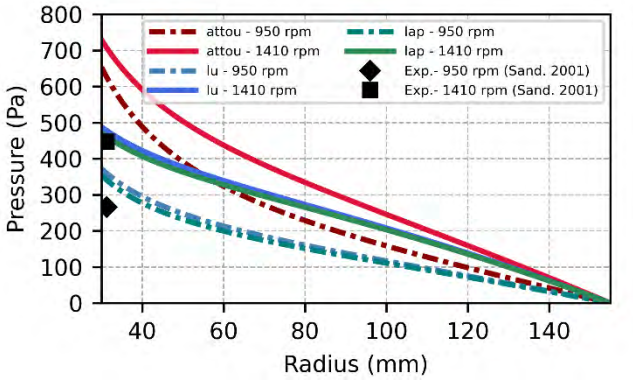

**Figure 3.** Relative pressures across the packing media, with atmospheric pressure condition being placed at the outer radius, for a gas flow rate of 6000 $cm^3/s$ and liquid flow rate of 14.3 $cm^3/s$, and pressure obtained with the experimental data from Sandilya et al. (2001) [26].

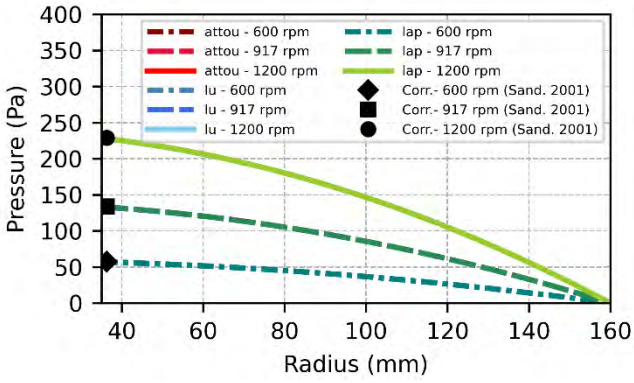

**Figure 4.** Relative pressures across the packing media, with atmospheric pressure condition being placed at the outer radius, for a gas flow rate of 2.0 $cm^3/s$ and liquid flow rate of 17.5 $cm^3/s$, and pressure obtained with the correlation from Sandilya et al. (2001) [26].

## Liquid holdup

Using a packed bed with inner radius of 35 mm and outer radius of 160 mm, with specific surface area of 786 1/m and porosity of 0.953, with rotations varying from 25 to 170 rad/s, Burns et al. (2000)[28] evaluated the liquid retained ($\epsilon_l$) in the porous foam media and correlated that based on the rotation and the superficial liquid velocity, as observed in Equation (22).

$$\epsilon_l = 0.034\left(\frac{r\omega^2}{100}\right)^{-0,38}\left(\frac{w_l}{0.01}\right)^{0.62} \quad (22)$$

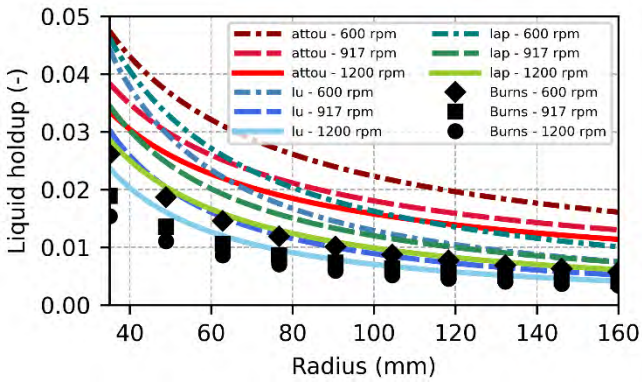

**Figure 5.** Comparison of liquid holdup obtained for three force interaction models across the packing media for the packed bed configuration used by Lu et al. (2018) [23], and experimental correlation obtained by Burns et al. (2000)[28].

By using similar packed bed configuration and process parameters, the three force models were compared with the correlation in Equation (22), as shown in Figure 5. It is possible to observe that for this case, that the interaction proposed by Attou et al. (1999) [20] resulted in higher liquid holdup, with a relative difference of 186% (1200 rpm), Lu et al. (2018) [23] predicted lower liquid holdups, with a relative difference of 81% (1200 rpm), and the model proposed by Lappalainen et al. (2008) [22] fell in the middle between the two models, with a relative difference of 33% (1200 rpm).

However, when higher gas flow rates are employed, such as the ones used in the experiment of Sandilya et al. (2001) with gas flow rate of 6000 $cm^3/s$, it is possible to observe lower liquid retentions obtained by using the model of Lu et al. (2018) [23], with close behavior than the other two interaction models, with a relative difference of 125% (950 rpm), as observed in Figure 6. Moreover, it is noticed that for all cases, higher rotations of the RPB ended up decreasing the liquid holdup and as the liquid traveled inside the packed media to the outer radius, lower local liquid retention is also observed, possibly due to the increase in surface area.

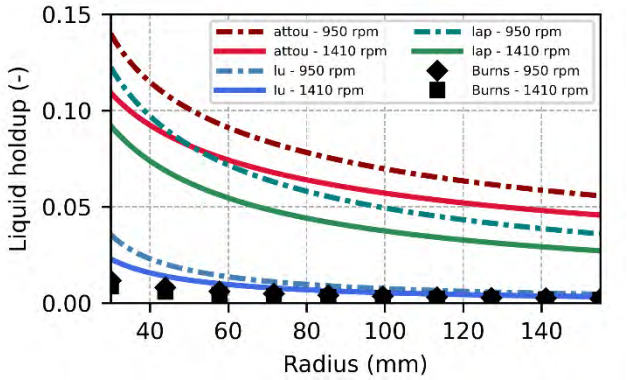

**Figure 6.** Comparison of liquid holdup obtained for three force interaction models across the packing media for the packed bed configuration used by Sandilya et al. (2001) [26] with gas flow rate of 6000 $cm^3/s$ and liquid flow rate of 14.3 $cm^3/s$ and experimental correlation obtained by Burns et al. (2000)[28].

## Gas velocity

Radial gas velocities inside the packing bed were extracted for the configuration used by Sandilya et al. (2001) [26] with gas flow rate of 6000 $cm^3/s$ with the three interaction force models, as shown in Figure 7. It is possible to observe an increase in gas velocity ($u_g$) as it travels to the center of the packed bed, an independent behavior of the rotation, as reported also in the literature.

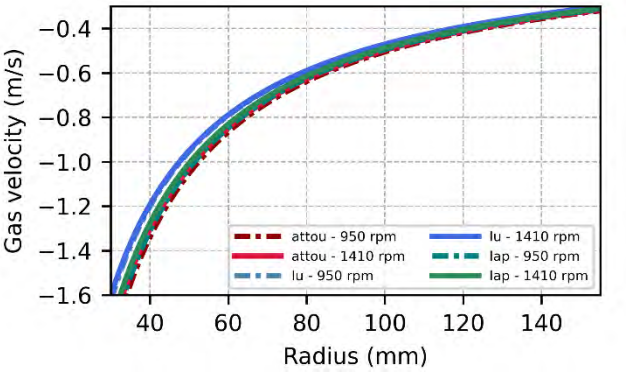

**Figure 7.** Comparison of radial gas velocities obtained for three force interaction models across the packing media for the packed bed configuration used by Sandilya et al. (2001) [26] with gas flow rate of 6000 $cm^3/s$ and liquid flow rate of 14.3 $cm^3/s$.

## Liquid velocity

Radial liquid velocities inside the packing bed were extracted for the three tested force models using the packed bed configuration of Lu et al. (2018) [23] with results shown in Figure 8. It is observed that the force model proposed by Attou et al. (1999) [20] predicts lower interstitial liquid velocities and tends to reduce the velocity as liquid travels to the outer radius of the RPB. For Lu et al. (2018) [23], higher velocities are observed, but with an increase in velocity as liquid travels the outward of the packing material. For Lappalainen et al. (2008) [22], lower and constant velocity were observed.

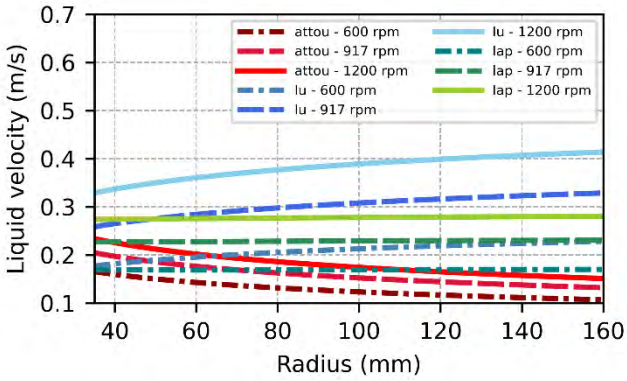

**Figure 8.** Comparison of radial liquid velocities obtained for three force interaction models across the packing media for the packed bed configuration used by Lu et al. (2018) [23].

When higher gas flow rates (6000 $cm^3/s$) are used, with configuration used by Sandilya et al. (2001) with the three interaction force models, as shown in Figure 9, liquid velocities for Attou et al. (1999) [20] and Lappalainen et al. (2008) [22] have similar values, whereas for Lu et al. (2018) [23], higher liquid velocities are observed, which still increases as liquid is driven outward from the packed bed.

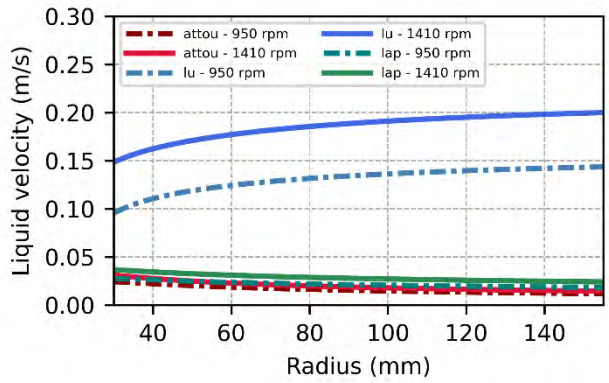

**Figure 9.** Comparison of radial liquid velocities obtained for three force interaction models across the packing media for the packed bed configuration used by Sandilya et al. (2001) [26] with gas flow rate of 6000 $cm^3/s$ and liquid flow rate of 14.3 $cm^3/s$.

# CONCLUSIONS AND OUTLOOKS

Based on the mass and momentum balance presented in this study, pressure, velocity and volume fractions were obtained for a gas-liquid RPB working at counter-current condition. To model the interaction between

the gas-liquid system with the solid packing material, three interaction force models were analyzed for different operating conditions and compared to available experimental data.

For the pressure losses across the bed material and operating at lower gas flow rates, similar predicted values were obtained for the different force models. However, for higher gas flow rates, differences were observed, with Lu et al. (2018) [23] and Lappalainen et al. (2008) [22] models obtaining closer values to the correlation.

For the liquid holdup estimation, it is observed that Lu et al. (2018) [23] model predicts closer values to the Burns et al. (2000)[28] correlation. When using the three force models, slightly differences were observed for gas velocities. Moreover, rotation did not have an effect in altering the gas velocities across the packed media, as reported also in the literature.

For liquid velocities, higher values were observed for the model proposed by Lu et al. (2018) [23], with lower values observed for the Attou et al. (1999) [20] model. When gas flow rates increase, similar behavior occurs for the liquid velocity.

Although the force model proposed by Attou et al. (1999) [20] and Lappalainen et al. (2008) [22] were focused in the flow behavior inside a sphere packed reactor, it could be observed good agreement with the experimental data for rotating packed beds with higher porosity medias, such as the one developed by Lu et al. (2018) [23], which used force models focused in flow around wire meshes.

Based on the presented study, it is possible to see that the hydrodynamic model for the RPB flow was successfully implemented, and further comparisons with experimental data and CFD simulations results are expected to occur. Moreover, it is possible to further develop the model to account for mass and heat transfer in the distillation of LNG/$CO_2$ streams, to obtain characteristic sizes and operational conditions for the equipment.

## ACKNOWLEDGEMENTS

We gratefully acknowledge PETRONAS Petróleo Brasil Ltda. (PPBL) for their funding and support, as well as ANP (Brazil's National Oil, Natural Gas, and Biofuels Agency) for assistance through the R&D levy regulation (Project #25186-8). We also thank EQS – Sustainable Energy and Chemistry Laboratory, PQGe – Chemical Processes and Business Management Laboratory, the Center for Energy and Petroleum Studies (CEPETRO), and the School of Chemical Engineering (FEQ) at the University of Campinas (UNICAMP), Brazil. This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – Finance Code 001.

## ABSTRACT

The valorization of lignocellulosic biomass represents a key pathway toward sustainable chemical production, as it enables the development of circular economy products with reduced dependence on fossil resources. Among the platform molecules derived from biomass, furfural stands out as a versatile intermediate that can be transformed into several high-value chemicals, such as furfuryl alcohol, 2-methylfuran, tetrahydrofurfuryl alcohol, furan, tetrahydrofuran, and maleic anhydride. In this work, an integrated biorefinery scheme for producing the main furfural derivatives is proposed and evaluated through process simulation and sustainability metrics. The process was modeled in Aspen Plus V14, using furfural obtained from lignocellulosic biomass (corn stover) as raw material, following hydrogenation and oxidation routes. The process is multi-product, meaning that the main furfural derivatives are produced simultaneously within the same plant. This was achieved by implementing splitters that work at 50% capacity in the division of raw materials. The mass and energy balances from the simulation were used to evaluate environmental, economic, energy, and efficiency performance using a set of indicators. Economic data were obtained from Aspen Economics, yielding a total capital cost of 7.65 MUSD and a total annual cost of 1.93 MUSD/year. The environmental assessment resulted in an EI99 of approximately $2.0\times10^{8}$ mPt/year, mainly influenced by hydrogen consumption and carbon monoxide emissions. From an efficiency perspective, the process shows favorable performance, with an MLI of 0.07 and an MCI of 69%, indicating high material efficiency despite the inherent complexity of multi-stage hydrogenation and oxidation pathways. Overall, the results demonstrate the technical and sustainability potential of an integrated furfural-based biorefinery, while highlighting opportunities for further improvement through process integration and hydrogen recovery.

**Keywords**: Furfural, Furfuryl alcohol, Biomass, Biorefinery, Performance Indexes

## INTRODUCTION

### Background

Sustainability, the need to generate circular economy products, furfural as a high-value product from biomass, a biorefinery scheme to produce all components for different applications, furfural as a versatile platform, explaining each of the products to be obtained.

The valorization of biomass as a sustainable alternative to its fossil counterpart, to create sustainable and profitable processes, is of great importance since lignocellulosic biomass is the only source that fixes carbon, is especially abundant, relatively inexpensive, and has great potential to be transformed into high-value bio-based chemicals. Due to this great economic advantage offered by using biomass as a starting point for the creation of a complete process, process design is relevant to identifying the appropriate kinetic and thermodynamic conditions.

The concept of biorefinery has become popular in recent years, as it involves the general concept of a plant that processes raw materials from biomass and converts them into a platform product, from which products with higher market value can subsequently be extracted, but

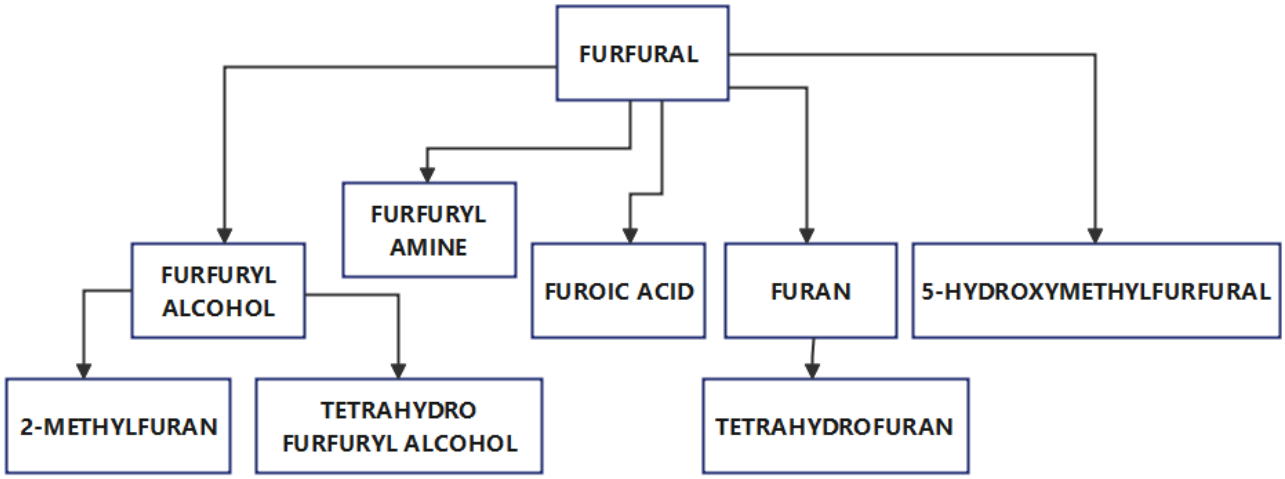

**Figure 1.** Primary products derived from the direct transformation of furfural [1].

which now have a more sustainable origin as they come from biomass.

This study considered integrated biorefinery processes by combining different processes to produce various products of interest. This was achieved by integrating mass and energy flows for the processing of furfural by-products, which can improve process efficiency in terms of yield, raw materials, and energy consumption, reducing waste generation and promoting economic and environmental performance. Since process integration provides a broader view of the use of products and by-products, through simple processes such as oxidation or hydrogenation, we can obtain a new product derived from the biorefinery. It is important to note that in previous cases, such as that carried out by Kabwe et al. (2025), scenarios are studied where production focuses only on some furfural derivatives. In this study, we carried out a multi-product process, meaning that all the main furfural derivatives are produced simultaneously within the same plant. This was achieved through the implementation of splitters that operate at 50% capacity and manage to divide the product flows that feed another sub-process.

## The Chemistry of furfural and its derivatives

The chemistry of furfural and its derivatives is well developed. The main transformation of furfural is through hydrogenation and oxidation, resulting in primary families of derivatives that are more profitable than furfural, as most of them already have an established market, as can be seen in Figure 1. The different compounds obtained are widely used as solvents, transportation fuels, gasoline additives, lubricants, resins, addictive and decolorizing agents, and flavor enhancers for food and beverages.

### Furfuryl alcohol

Among the main furfuryl derivatives, furfuryl alcohol is the most established, due to its broad market with applications in the chemical industry, specifically in pharmaceuticals, polymers, and resin manufacturing. It is also an important chemical intermediate for the manufacture of fragrances [1].

### 2-Methylfuran

In addition to the production of furfuryl alcohol, alternative furfural derivatives of interest that show market potential include 2-methylfuran (MF), which is currently the focus of research because it is an alternative to fossil fuels. Since MF has physicochemical characteristics like gasoline, its implementation in internal combustion engines is a potential field of application [2].

### Tetrahydrofurfuryl

Tetrahydrofurfuryl alcohol is a promising source of organic chemicals that are currently produced from fossil fuels [3].

### Furan

Furan is commercially produced from furfural by decarbonylation, where the loss of carbon monoxide directly yields furan. From a general chemical perspective, furan is a 5-membered heterocyclic unsaturated ring compound containing oxygen; therefore, it is the basic ring structure found in all kinds of industrially important products [4].

### Tetrahydrofuran

Tetrahydrofuran has established itself as an excellent solvent, with high volatility, a low freezing point, and

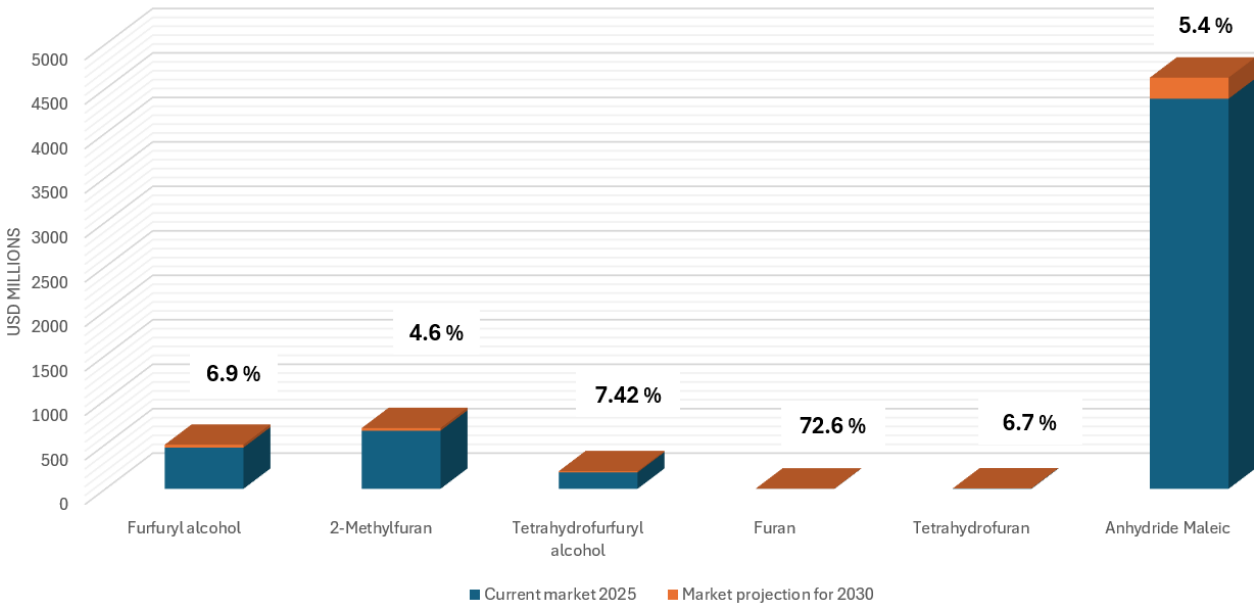

**Figure 2.** Growth projections for the main furfural derivatives for 2030 [8-13].

the ability to dissolve both polar and non-polar compounds. The applications of tetrahydrofuran are diverse, ranging from the production of polymer coatings and adhesives to pharmaceutical chemistry, where its presence reflects the use of a clean solvent that can be easily separated from the desired products [5]. Currently, THF is produced industrially from petroleum-derived intermediates, involving the hydrogenation of maleic anhydride or the dehydration of 1, 4-butanediol. Bio-based THF can be produced by direct catalytic hydrogenation of furfural or using furan as an intermediate, achieving typical yields of 52–100% [6].

### Maleic anhydride

Finally, maleic anhydride is the anhydrous form of maleic acid and is currently produced on an industrial scale from fossil fuels, but there is another route for obtaining it from furan. Its main applications are in the pharmaceutical industry and in the manufacture of polyester resins. The largest percentage of maleic anhydride produced in the United States is used in the manufacture of polyester resins (52%). These applications are diverse, ranging from their use in reinforced plastics for automobiles, boats, and construction panels, among others [7]. However, the market for maleic anhydride resins is undoubtedly growing year after year, hence the importance of finding a new biosustainable production mechanism.

## Market for the main furfural derivates

The market for furfural derivatives, as shown in Figure 2, has become even more important than that for furfural itself as a base product, because it is these transformed compounds that truly capture the greatest economic and technological value in industrial chains. While furfural is mainly used as a chemical platform and specialized solvent, its derivatives find direct and massive applications in resins, fuels, additives, polymers, coatings, and high-performance materials. This means that demand is driven more by the end markets for these derivatives than by the consumption of furfural itself, shifting the focus from simple intermediate production to the integration of higher value-added conversion processes. In this sense, furfural increasingly functions as a strategic “building block” within a biorefinery, while the real economic and growth engine of the sector lies in the diversification and expansion of its derivatives in larger-scale, higher-margin industrial markets.

Based on this, several researchers have focused their attention on conducting techno-economic analyses of furfural derivatives to compare production costs with prices established for different scenarios, such as Kabwe et al. (2025), who evaluated different scenarios for the conversion of furfural products, depending on the product of interest and the conditions established.

# CASE STUDY

## Furfural production

The background to furfural production is the design and optimization of a multi-product biorefinery aimed at obtaining furanic compounds proposed by Caceres-Barrera et al. (2024) from lignocellulosic biomass, using corn stover as the main raw material. The proposed process is based on a pretreatment that allows the biomass to be

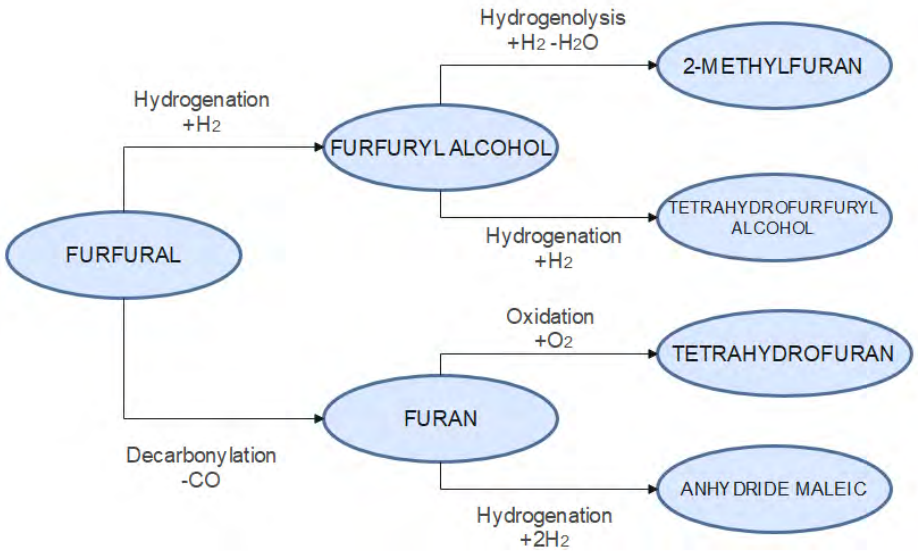

**Figure 3.** The main production routes for furfural derivatives.

broken down and the constituent sugars to be released, especially the pentoses from hemicellulose, which are subsequently converted into furfural through dehydration reactions. The design strategically integrates the reaction and separation stages to maximize the recovery of furfural and other valuable products such as HMF, levulinic acid, and γ-valerolactone. It is here that we segment the production route and take the final stream of the furfural product as feedstock for the biorefinery proposed in this study.

## Process description

The production process was modeled in the Aspen Plus V14 process simulation tool using the diagram shown in Figure 3 to obtain mass and energy balances. The data retrieved from the simulation was used to perform multi-objective optimization using the mathematical model we constructed to estimate the quantity produced of each furfural derivative, maximizing profit. Assuming that the amount of furfural is fixed and predetermined (i.e., fixed plant size) retrieved from the article published by Cáceres-Barrera et al. (2024) [14].

The main production routes for furfural derivatives, as shown in Figure 3, are hydrogenation and oxidation. The reaction kinetics for each of the routes are shown in Table 1.

Finally, the process modeled in Aspen Plus follows the methodology shown in Figure 4. The process mainly consists of six reactive zones for obtaining the main products derived from furfural. The production of 2-Methylfuran includes an additional separation process through a distillation column for the purification of 2-Methylfuran. The maleic anhydride production process includes a purification process through an absorber to include a solvent that separates water from maleic anhydride, which is then obtained through a distillation column.

**Table 1:** The reaction kinetics.

| Kinetics | Reference |
|---|---|
| $C_5H_4O_2 + H_2 \rightarrow C_5H_6O_2$ | [15] |
| $C_5H_4O_2 + 2H_2 \rightarrow C_5H_6O + H_2O$ | [15] |
| $C_5H_4O_2 + 4H_2 \rightarrow C_5H_{10}O_2$ | [16] |
| $C_5H_4O_2 \rightarrow C_4H_4O + CO$ | [17] |
| $C_4H_4O + 2H_2 \rightarrow C_4H_8O_2$ | [18] |
| $C_4H_4O + \frac{3}{2}O_2 \rightarrow C_2H_2O_3 + H_2O$ | [17] |

## Optimization

The production process for the main furfural derivatives presents a suitable case for optimization, with the analysis of the process's economic, environmental, and safety properties serving as the objective function. This can be explained through the design parameters involved in the process that directly impact economic, environmental, and safety indicators. It is important to note that to achieve a process with a positive environmental impact, it is necessary to consider various external variables, such as the chosen solvent. To achieve a design with high recovery of the main furfural derivatives, low environmental impact, low operating costs, and safety, it is necessary to have an appropriate design for the separation and purification units of the main products. Likewise, the choice of the solvent used to purify maleic

anhydride and the appropriate operating conditions play a significant role in the process.

In this project, the objective function involves indicators and metrics necessary for optimizing the production process of the main furfural products, which are described below.

## Eco-indicator 99 (EI99)

The advantages of incorporating EI99 in sustainability evaluations are manifold. Firstly, it offers a thorough perspective on the environmental performance of a product or system, enabling decision-makers to prioritize actions and investments in areas with the most substantial impacts. EI99 covers a broad spectrum of environmental categories, aligning with the multidimensional approach of the UN's 2030 Agenda that seeks to tackle interconnected global challenges. Eco-indicator 99 is one of the most widely used environmental impact estimation methods and consists of a quantitative analysis of the life cycle evaluated from beginning to end. The calculation is performed using Eq. (1). Where ω represents the damage weight factor (Pts/kg), Ci represents the impact value for each of the categories i, and α is the value of subcategory j (kg/year). This methodology accounts for the origin of raw material in processing and degradation. It is based on standard ecological indicators, which are numbers that express the total environmental burden of a product or a process. The higher the value of the indicator, the greater the environmental impact. Therefore, the best scenario is the lowest possible EI99.

$$EI99 = \sum_i \sum_j \omega \bullet C_i \bullet \alpha_j \quad (1)$$

## Total annual cost (TAC)

Assessing the overall yearly expenses of a process is crucial within a sustainability framework. The evaluation of total annual costs is essential for various compelling reasons. Firstly, by quantifying these costs, organizations and policymakers can comprehensively grasp the environmental, social, and economic implications of their actions. Sustainability goes beyond minimizing immediate expenditure; it requires an evaluation of long-term consequences. Considering the comprehensive cost, which includes direct and indirect financial expenses, environmental impacts, social implications, and potential externalities, allows stakeholders to make well-informed decisions considering the entirety of sustainability factors. This approach fosters transparency and accountability, as it enables a clear evaluation of trade-offs between short-term economic gains and long-term sustainability objectives. The TAC assumes the annualization of the investment cost of the main process equipment over a 10-year amortization period. To calculate it, Eq. (2) is used. Where $C_{TM,i}$ is the capital cost of the equipment in dollars ($), $r$ represents the payback period in years, and $C_{ut,j}$ is the cost of cooling and heating services, in dollars per year ($/year). The objective function evaluates the lowest annual cost of the process while considering the utilities used by the plant and various units. The best scenario is a total annual cost as low as possible to recover the investment.

$$TAC = \frac{\sum_{i=1}^{n} C_{TM,i}}{r} + \sum_{j=1}^{n} C_{ut,j} \quad (2)$$

## Individual risk (IR)

The Individual Risk (IR) metric is crucial for sustainability because it evaluates the likelihood of accidents or harmful events affecting individuals, thus supporting the design of safer industrial processes. By quantifying potential risks to human health and safety, IR ensures that processes prioritize safety, reducing the chance of incidents that could harm people or damage the environment [19]. This focus on minimizing risks aligns with the broader goals of sustainability, including regulatory compliance and social responsibility. Moreover, IR supports Sustainable Development Goals (SDGs) such as Good Health and Well-being (SDG 3) and Decent Work and Economic Growth (SDG 8) by promoting safe working conditions and protecting human health, which are essential components of sustainable development [19]. The IR identifies the risk that a person faces based on his position, including the likelihood of an accident resulting in death or serious injury. The IR is defined as shown in Eq. (3). Where, $f_i$ represents the recurrence that one accident will occur, and $P_{x,y}$ is the likelihood that the accident will occur in a particular location.

$$IR = IR = \sum f_i P_{x,y} \quad (3)$$

In the methodology of this project, the instantaneous and continuous risk analysis was performed for each of the equipment involved in the $CO_2$ capture process that is in contact with the solvent of interest. Catastrophic events such as Boiling Liquid Expanding Vapor Explosion (BLEVE), Unconfined Vapor Cloud Explosion (UVCE), Jet Fire, Flash fire, and toxic explosion were evaluated using specific mathematical models for each case reported in the literature. The ideal scenario is the one with the lowest individual risk index (IR), as it would be a less risky process.

## The objective function

In this study, the objective function encompasses three key areas: environmental, economic, and process safety. It is hoped that this work will contribute to selecting the optimal production route for the main furfural derivatives or to a specific analysis of a product of individual interest. Similar studies have been previously reported by Sanchez-Ramirez et al. [20] and Romero-Garcia et al.[21] for carbon capture cases, but a similar methodology is applied. Therefore, based on this prior information regarding the indicators, the general mathematical

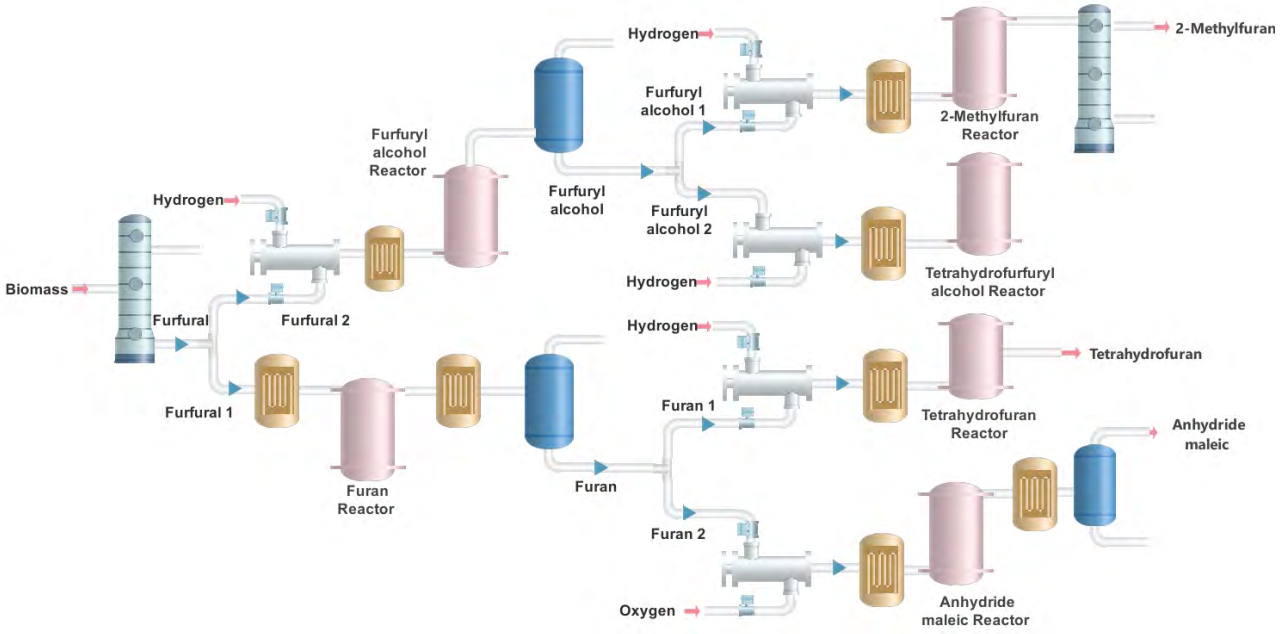

**Figure 4.** Process simulation diagram.

expression for the objective function, and the respective decision variables involved in the optimization process, are shown below in Equation (4).

$$Min\ [EI99, \mathrm{TAC}, \mathrm{IR}\ ] = f\left(N_{i,j,k}, NF_{i,j}, D_{i,j,k}, DBP, RR, Q\right) \quad (4)$$

For the variables related to the capture process $N_{i,j,k}$ represents the number of stages, $NF_{i,j}$ represents the feed stage, $D_{i,j,k}$ represents the diameter where the i is specified for distillation column, absorber j and de k corresponds to the desorber. DBP represents the solvent feed flow in the absorber, RR represents re reflux ratio and Q the reboiler duty, both in the desorber column.

The proposed model involves a significant number of variables that must be optimized to achieve an optimal design and operating conditions, with the goal of minimizing various performance metrics and maximizing the recovery of the main products of market interest. The implementation of the global optimization approach involved linking Aspen Plus with Microsoft Excel. To initiate the optimization process, the design variables were specified in Microsoft Excel using the stochastic optimization algorithm, Differential Evolution with Tabu List (DETL). During the optimization process, a vector of decision variables is created from Excel to Aspen; in Aspen, the process is evaluated under the parameters of the decision vector, then it is assessed whether the combination of variables is feasible; if not, the algorithm generates a new combination, the resulting data is returned from Aspen Plus and stored in Excel, to apply constraints based on the desired purities or flows, evaluating the previously mentioned indicators, to minimize the objective function and find the optimal process design.

The parameters considered for the DETL method are: population size of 120 individuals, 1, 000 generations, a tabu list size of 60, a tabu radius of 0.0001, a crossover rate of 0.9, and a mutation rate of 0.3. These parameters have been shown to work exceptionally well with nonlinear problems, yielding excellent results.

## RESULTS

### Analysis of the 3D Pareto Fronts

The scatter plot represents the system's solution space, highlighting the variability among the evaluated indicators. The blue points show all possible configurations, while the orange points represent the smoothed trend of the system's behavior. A nonlinear relationship is observed among the indicators, confirming the existence of a trade-off between them and the multi-objective nature of the problem.

### Optimal Design

Table 2 provides a summary of the optimal design for the main purification units in the furfural production process; the optimal design is achieved when the objective functions are in equilibrium with one another and the trade-offs between the objectives are balanced.

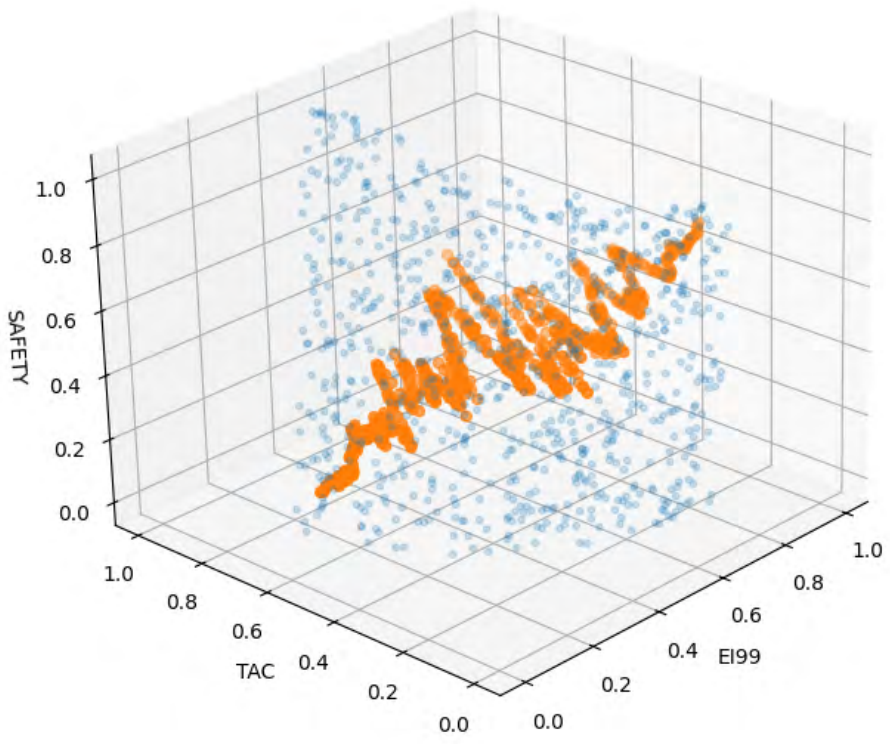

**Figure 5.** Pareto fronts between the Total annual cost (TAC), Ecoindicator 99 (EI99) and Safety.

**Table 2:** Design parameters for the best scenario.

It is possible to observe the impact of certain design parameters on process performance. In the case of the absorption unit, the solvent temperature plays an important role in achieving the adsorption of maleic anhydride and its subsequent separation, thus directly affecting the recovery efficiency of this main product. Furthermore, the reflux ratio is directly related to energy requirements. The higher the reflux ratio, the greater the energy requirements for capture. Regarding the analysis of sustainability indices, it is observed that the lowest EI99 is achieved when lower amounts of energy are used in the process, which is largely related to equipment sizes; this trend is related to the process topology.Energy efficiency

Figure 6 highlights an important perspective on efficiency by comparing the production rate (kg/h) with the energy consumption rate (MJ/h) for each component. It is evident that not all processes use energy with the same efficiency: for example, FURAN and FOL achieve relatively high production with low to moderate energy consumption, indicating efficient performance, while THF and THFA consume more energy without a proportional increase in production, making them less efficient. This contrast becomes more pronounced with MF and, especially, with MA, where energy consumption is significantly higher despite having production levels similar to those

of other components, revealing energy-intensive processes. Overall, the graph demonstrates that higher energy consumption does not necessarily translate to higher production, underscoring the importance of evaluating and optimizing energy efficiency in process design.

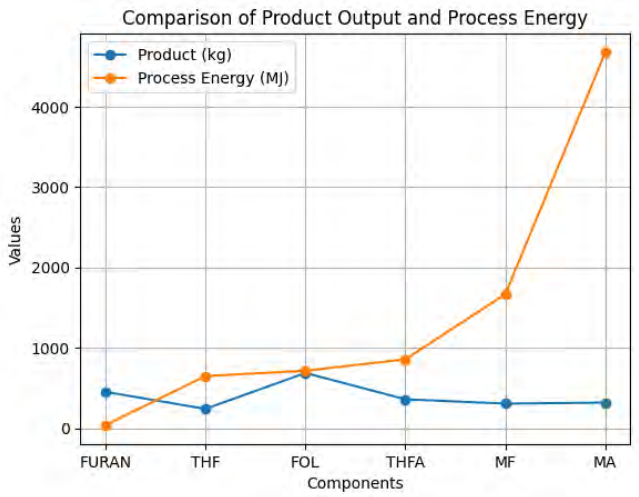

**Figure 6.** Energy efficiency.

## CONCLUSIONS

This study proposes the design and optimization of a production plant for the main furfural derivatives. Simultaneous production is achieved through the implementation of flow separators for the main streams of first-generation furfural products, thereby enabling the simultaneous production of six of the main derivatives. The evaluation of metrics related to environmental impact, economic assessment, and process safety provides a broader perspective on how different variables can affect the sustainability of the process. Finally, the implementation of the multi-objective optimization algorithm provides a broader perspective on process control, with the objective function being to minimize these economic, environmental, and safety aspects of the process; this aims to achieve the optimal design that meets the established constraints and serves as the starting point for its implementation or scaling.

In conclusion, this work creates an opportunity for future research on the main furfural production routes. Considering the sustainability framework, there is significant potential for process improvement and adaptation, specifically regarding the implementation of new production routes based on this work or the implementation of a new solvent to recover maleic anhydride from the process.

## ABSTRACT

Copper refining via electrolysis is a core metallurgical process that takes place in tankhouses, subject to strict temporal, spatial, and operational constraints. The efficiency and stability of this process depend critically on the coordinated scheduling of crane operations responsible for handling anodes, cathodes, and auxiliary tasks. In industrial practice, crane scheduling must simultaneously satisfy long-term production targets and short-term operational feasibility, while respecting process-dependent timing constraints imposed by electrochemical parameters. Inefficient or inconsistent schedules can lead to process delays, suboptimal resource utilization, and degraded electrolysis performance, ultimately affecting product quality and operational stability. This paper presents a modeling approach for optimizing tankhouse operations. The uniqueness of this case lies in the broad range of constraints, including human capacity, energy restrictions, metallurgical rules, and logistical specifications. The model operates on three levels, starting with generalized schedule optimization and culminating in the detailed optimization of crane movements and cathode stripping machine operations. Although the focus is on the specific use case of tankhouse operations within metallurgical production, the model can be adapted and fine-tuned for a wide range of scheduling applications. Additionally, we discuss the challenges encountered when integrating the model into existing production processes and outline directions for further work.

## INTRODUCTION

Every year, Aurubis produces 1.1–1.2 million metric tons of copper cathodes with an extremely high copper content, at a minimum of 99.99% purity [2].

To achieve this material purity, the anodes undergo an electrolysis process in the tankhouse as the final step [1]. The quality of the resulting cathodes depends on the duration and electricity levels during the electrolysis process. Therefore, timely processing of all groups is one of the main priorities.

The current setup includes several groups of different types of cathodes, some of which share electrical circuits, as well as cranes that transfer cathodes from the electrolyte bath to the copper stripping machines. These cranes are tasked with several operations, including lifting, transporting, and positioning both cathodes and anodes in and out of the electrolyte cells. These operations require high precision to avoid damaging the delicate metal deposits and to ensure the safe handling of heavy materials. The exchange process must be executed in a sequential manner, where each crane handles one anode or cathode at a time, often under strict timing constraints.

One of the main modeling challenges is the scalability of the model. In the production environment, operators aim to receive optimized results as quickly as possible, without sacrificing the operational details. Therefore, addressing the problem in the traditional MILP fashion might be quite tricky and lead to a rapid increase in variables [3]. However, other approaches often disregard essential operational rules, making them unsuitable for industrial settings.

In this paper, we describe a model that is feasible within our industrial setting, while keeping the parameters flexible to accommodate a broader range of applications. This balance between computational efficiency and operational accuracy is crucial for practical implementation in real-world production environments.

### Problem setup

The key elements of the tankhouse setup are cathode and anode stripping machines and cranes which operate on groups of electrolyte cells. Each group contains

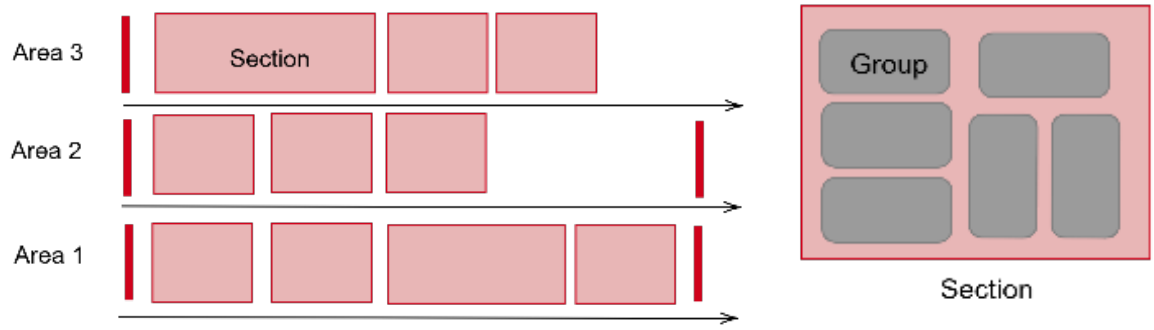

**Figure 1.** Schematic depiction of initial positions of cranes (in bold red) in the tankhouse layout (left) and a zoomed-in depiction of the example group layout in a section (right).

5-20 cells of cathodes/anodes. In addition, several groups are combined into section which share one electrical circuit. Further there are several tankhouse areas – lanes on which specific numbers of cranes operate. Some areas have one crane, whereas some have two, which causes the problem of tracking the distance between cranes and ensuring that the cranes do not intersect or collide.

### The Cathode-Anode Exchange Process

During the copper refining process, metal ions are reduced and deposited onto a cathode in an electrolyte bath. The anode, typically made of a material like impure copper, supplies the metal ions that dissolve into the electrolyte. This process unfolds as follows: the anode gradually dissolves to provide metal ions to the electrolyte solution, which are then deposited on the cathode [1].

Therefore, cathodes must be exchanged regularly to remove the deposited metal, while a fresh cathode is placed in the cell. The anode also needs to be replaced, but the rate at which the anode is consumed, and the frequency of replacement are different from those of the cathode. In this paper, we assume that in one cycle (lifespan of one anode) there are two cathode changes followed by one cathode and anode change.

Typical operations in the tankhouse involve removing the spent anodes and replacing them with new ones while simultaneously removing the deposited cathodes. The sequence of operations consists of the following key steps:

- Lifting: The crane is responsible for lifting the spent anode and moving it from the electrolyte cell to the storage area.
- New Anodes Placement: Once the old anode is removed, the crane places a new anode into the electrolyte cell to continue the refining process.
- Lifting the Deposited Cathodes: The crane then lifts the cathode, which has the refined metal deposits, and moves it to a cathode stripping machine.
- Depositing the Refined Cathodes: After lifting, the crane transports the cathodes to a processing area for further refining or packaging.

Furthermore, the tankhouse operation is designed to be continuous and needs to maintain a constant flow of materials. Thus, it's important to create a schedule of operations that can be repeated indefinitely, accounting for more frequent change of the cathodes than the anodes as well as provide a model to support daily planning operations to optimize crane movements.

## FIRST STAGE: CYCLIC OPERATION SCHEDULING MODEL

### Problem Description

We consider a cyclic scheduling problem for repetitive operations on groups of cells. Each group consists of several cells and belongs to one of the areas (Figure 1). Over a finite planning horizon of $D$ days, a schedule is created that is assumed to repeat indefinitely.

Each group must undergo three operations, denoted $O_1, O_2$ and $O_3$ (corresponding to two cathode changes and an anode change as described in previous section) which must always be executed in the fixed cyclic order:

$$O_1 \to O_2 \to O_3 \to O_1 \to \cdots$$

The time intervals between consecutive operations are fixed. Let $\delta_{ij}$ denote the number of days between $O_i$ and $O_j$. These spacings, $\delta_{12}, \delta_{23}, \delta_{31}$, must be respected exactly, including across the boundary of the planning horizon.

Since the plan is cyclic, groups do not need to start

with $O_1$. Instead, each group may start at any operation in the sequence, which introduces a phase shift that is decided by the optimization model.

The main goal is to balance the daily workload, which is defined as the number of cells processed per day. Optionally, an additional balancing requirement can be imposed to ensure that the daily workload is also approximately balanced between the areas and groups (Figure 1). This ensures a more uniform utilization of resources and helps prevent operational bottlenecks across the planning horizon.

## Model Formulation

The model uses the following sets:

- $\mathcal{G}$: set of groups
- $\mathcal{D} = \{1, \dots, D\}$: set of days in the planning horizon
- $\mathcal{O} = \{O_1, O_2, O_3\}$: set of operation types

The parameters of the model are:

- $c_g \in \mathbb{N}$: number of cells in group $g$
- $s_g \in \{A_1, A_2, A_3\}$: area of group $g$
- $\delta_{ij} \in \mathbb{N}$: fixed number of days between operation $i$ and its successor $j$
- $D \in \mathbb{N}$: length of the cyclic planning horizon

Binary decision variables are defined as:

$$x(g,d,o) = \begin{cases} 1, \text{ if group } g \text{ performs operation } o \text{ on day } d \\ 0, \text{ else,} \end{cases} \forall g \in \mathcal{G}, d \in \mathcal{D}, o \in \mathcal{O}$$

To model the cyclic phase choice, additional binary variables are introduced:

$$y(g,o) = = \begin{cases} 1, \text{ if group } g \text{ starts its cycle with operation } o \\ 0, \text{ else,} \end{cases} g \in \mathcal{G}, o \in \mathcal{O}$$

The model is completed with the following constraints:

- Phase selection: Each group must select exactly one starting operation:

$$\sum_{o \in \mathcal{O}} y(g,o) = 1, \forall\, g \in \mathcal{G}.$$

- At most one operation per group per day:

$$\sum_{o \in \mathcal{O}} x(g,d,o) \leq 1, \forall g \in \mathcal{G}, d \in \mathcal{D}.$$

- Cyclic sequence and spacing constraints: If a group performs operation $i$ on day $d$, it must perform the successor operation $j$ exactly $\delta_{ij}$ days later, where the day index is computed modulo $D$.This enforces the fixed sequence $O_1 \to O_2 \to O_3 \to O_1$ and ensures consistency under cyclic repetition. In the mixed-integer linear formulation, these implications are implemented using precomputed feasible day pairs or standard linearization techniques.

The total workload on day d is defined as the sum of the cells processed by all groups on that day:

$$W_d = \sum_{g \in \mathcal{G}, o \in \mathcal{O}} c_g x(g,d,o), \forall d \in \mathcal{D}.$$

Let $\bar{W}$ denote the average daily workload over the planning horizon. To obtain a balanced plan using linear objective, the model minimizes the sum of absolute deviations of the daily workload from this average.

This is achieved using linear constraints that relate $W_d$ and $\bar{W}$ to the deviation variables $z_d$:

$$z_d \geq W_d - \bar{W}, \forall d \in \mathcal{D}.$$

$$z_d \geq -(W_d - \bar{W}), \forall d \in \mathcal{D}.$$

Then the objective function is given by

$$\min \sum_{\forall d \in \mathcal{D}} z_d.$$

If area balancing is activated, additional deviation terms are introduced to penalize differences between area workloads on each day. Analogously one can introduce deviation variables and constraints to add to the objective function balancing per section or specific group, if required.

## Key Challenges and assumptions

The main challenges of the proposed model are:

- Representing cyclic time dependencies using modulo arithmetic.
- Allowing flexible starting phases while enforcing a strict operation sequence.
- Maintaining a linear formulation for solver efficiency.
- Ensuring scalability as the number of groups and planning days increases.

The proposed mixed-integer linear model generates cyclic operation schedules with fixed sequencing and exact inter-operation spacing. By allowing flexible phase shifts, the model achieves balanced daily workloads and can optionally balance workloads between spatial sections. The formulation is suitable for standard MILP solvers and can be extended to incorporate additional operational constraints.

In this setup, the time between each operation $\delta_{ij}$ is the same for each group. However, depending on the specific properties and composition of anodes, they can vary. This can be modelled by introducing $\Delta = \delta_{ij}(g)$, for

each group $g$. Consequently, the plan is executed with a periodicity equal to the Least Common Multiple (LCM) of all cycle durations. This extension increases the model's flexibility, while also introducing additional computational complexity due to the longer effective planning cycle.

## SECOND STAGE: DAILY PROCESSING OPTIMIZATION

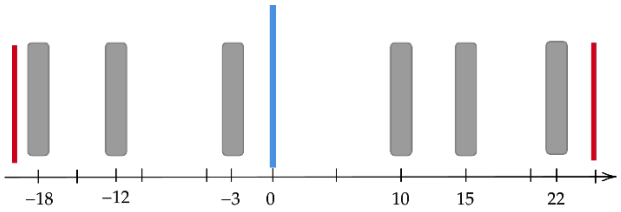

**Figure 2.** Schematic depiction of an area with two cranes (red), 6 groups to be processed (in grey) and a cathode machine (position 0, in blue).

### Problem Description

We consider now a planning on a daily level. We aim to model the process given in section The Cathode-Anode Exchange Process. The problem can be summarized as follows: a set of groups must be processed using one or more overhead cranes and a single cathode stripping machine. Each group consists of multiple identical cells that must be transported individually from the group location to the machine, processed, and returned. The objective is to determine an optimal processing sequence that minimizes the total completion time (makespan) of all groups.

We set the following assumptions in our modeling setup:

- Each group contains between 5 and 20 cells.
- All cells within a group are assumed to be co-located at a fixed position for modeling simplicity.
- Groups are located at different distances to the left or right of the machine.
- Cranes move along a shared rail and cannot intersect or pass each other.
- Exact timing of individual movements is not critical; instead, the focus is on optimizing the processing sequence in a realistic manner.

Given these properties, the problem is modeled as a sequencing and assignment problem at the group level, where the processing time of each group is derived from the number of cells and the travel distance to the machine.

### Model Formulation

The main bottleneck is efficient utilization of a cathode machine, since in our setup we consider only one cathode machine per plant, shared between cranes and areas which is used 3 times per cell every cycle. Following this we focus in our model on crane movement from group to cathode machine and back, excluding movement of the crane to the anode machine during anode operation ($O_3$) from the schedule.

Further, in this paper we do not focus on sections (Figure 1) which represent shared electrical circuit, since we do not aim to optimize shutdown time in our case. However, we remark that our model could be easily extended to this objective. Therefore, we schedule operation on group level considering only varying number of cells per group and ignoring to which section which group belongs (Figure 2).

The formulation employs a discrete-event-based approach to capture the interactions between cranes and jobs – operations performed in a specific group.

The cranes are modeled as parallel machines with sequencing decisions. Crane interference is handled by enforcing spatially consistent processing orders, reflecting the fact that cranes move on a single rail and cannot cross.

The model uses the following sets:

- $\mathcal{J}$: set of jobs
- $\mathcal{C}$: set of cranes
- $\mathcal{T}$: set of time slots
- The parameters of the model are:
- $P_InitialInventory(j)$: the initial number of cells in the group represented by job $j$
- $P_CathodeProcessingSpeed(t, j, c)$: processing speed of job $j$ on crane $c$ during time $t$. This parameter is 0 if job belongs to an area which is not covered by crane $c$.
- $P_Location(j)$: x-coordinate location of job $j$ on the rail.

Binary decision variables are defined as:

$$BV_JobAssignCrane(j,c) = \begin{cases} 1, \text{if job j is assigned to crane } c \\ 0, \text{else,} \end{cases} \forall j \in \mathcal{J}, c \in \mathcal{C},$$

$$BV_JobCraneProcess(t,j,c) = \begin{cases} 1, \text{if job j is being processed at time t} \\ 0, \text{else,} \end{cases} \forall j \in \mathcal{J}, c \in \mathcal{C}, \text{t} \in \mathcal{T},$$

$$BV_RemainingCells(t,j) = \begin{cases} 1, \text{if job j has remaining cells at time t} \\ 0, \text{else,} \end{cases} \forall j \in \mathcal{J}, \text{t} \in \mathcal{T},$$

$$BV_BothActive(t,j,j') = \begin{cases} 1, \text{if job j and job j' are scheduled at time t} \\ 0, \text{else,} \end{cases} \forall j,j' \in \mathcal{J}, t \in \mathcal{T}$$

$$BV_JobLeft(t,j,j') = \begin{cases} 1, \text{if job } j \text{ is left to job } j' \text{ at time } t \\ 0, \text{else,} \end{cases} \forall j,j' \in \mathcal{J}, \text{t} \in \mathcal{T}$$

And the continuous decision variables:

- $V_Inventory(t,j)$: the inventory of cells for job $j$ at time $t$
- $V_CellsProcessingAmount(t,j,c)$: the number of cells processed for job $j$ by crane $c$ at time $t$.
- The model aims to minimize an objective related to crane idle time or the makespan, i.e., the total time required to complete all jobs:

$$\min T_{max} = \sum_{\text{t}\in\mathcal{T}, j\in\mathcal{J}} t \bullet V_Inventory(t,j)$$

- The main constraints are given as follows:
- Each group is assigned to exactly one crane:

$$\sum_{c\in\mathcal{C}} BV_JobAssignCrane(j,c) = 1, \forall j \in \mathcal{J},$$

- At any given time, only one job can be processed on a crane:

$$\sum_{j\in\mathcal{J}} BV_JobCraneProcess(t,j,c) \leq 1, \forall\, t \in \mathcal{T}, c \in \mathcal{C}$$

- A job can only be processed on a crane if it is assigned to that crane:

$$BV_JobCraneProcess(t,j,c) \leq BV_JobAssignCrane(j,c), \forall\, t \in \mathcal{T}, c \in \mathcal{C}, j \in \mathcal{J}$$

- The mass balance given by:

$$V_Inventory(t,j) = V_Inventory(t-1,j) - \sum_{c\in\mathcal{C}} BV_JobCraneProcess(t,j,c), \forall\, t \in \mathcal{T}, c \in \mathcal{C}, j \in \mathcal{J}$$

- Job completeness:

$$\sum_{t\in\mathcal{T}, c\in\mathcal{C}} V_CellsProcessingAmount(t,j,c) = P_InitialInventory(j), j \in \mathcal{J}$$

- Continuous unloading across time slots:

$$BV_JobCraneProcess(t+1,j,c) \leq BV_JobCraneProcess(t,j,c) + 1, \forall\, t \in \mathcal{T}, c \in \mathcal{C}, j \in \mathcal{J}$$

$$BV_JobCraneProcess[t+1,j,c] \leq BV_RemainingCells(t,j), \forall\, t \in \mathcal{T}, c \in \mathcal{C}, j \in \mathcal{J}$$

### Crane Non-Intersection Constraints

Another important constraint necessary is the crane non-intersection constraint. The hanging cranes operate on a single shared rail per area and therefore cannot cross or overtake one another during operation. Rather than explicitly modeling crane trajectories over time, the proposed formulation enforces non-intersection implicitly through sequencing constraints derived from the spatial ordering of groups.

Each group $j \in \mathcal{J}$ is associated with a fixed spatial coordinate $P_Location(j)$, representing its position along the crane rail. Without loss of generality, negative coordinates correspond to positions to the left of the machine, and positive coordinates to positions to the right.

For two groups $j,j' \in \mathcal{J}$, with $P_Location(j) < P_Location(j')$, any schedule in which crane $c_1$ completes processing of group $j$ before crane $c_2$ completes processing of group j' would require the cranes to cross at some point in time. Such schedules are therefore physically infeasible. These constraints are encoded as logical sequencing restrictions and eliminate schedules that would require crane intersection as follows:

$$P_Location(j) + K \leq P_Location(j') + M \bullet (1 - BV_JobLeft(t,j,j')) + M \bullet (1 - BV_BothActive(t,j,j')) \forall j,j' \in \mathcal{J}, \text{t} \in \mathcal{T},$$

where $M > 0$ is a sufficiently large Big-M constant and $K$ is a minimal safety distance between the cranes [4].

### Possible Model Extensions

While this paper presents the simplest objective function, the proposed model can also be adapted to optimize additional factors, such as minimizing electricity usage (e.g., reducing shutdowns per section) or maximizing the throughput of the cathode machines.

Furthermore, in real-world setups, crane movement speeds may vary between areas, and certain groups may have higher processing priorities. These operational nuances can be incorporated into the model using penalty terms and scaling parameters.

The model can also be extended to add further realism, such as accommodating partial group processing, handling heterogeneous crane speeds, and introducing safety buffers for movement and waiting times at the groups and cathode machines.

## RESULTS

### Cyclic schedule

We present now the results of optimizing a cyclic schedule for operations for 24 days. In this example we consider around 3000 cells distributed across 10 groups.

We chose $\delta_{12} = 7, \delta_{23} = 8, \delta_{31} = 9$. We first try to find a schedule which balances the operations across 3 areas, without additional restriction on balancing the operations per group and per day. This results already in

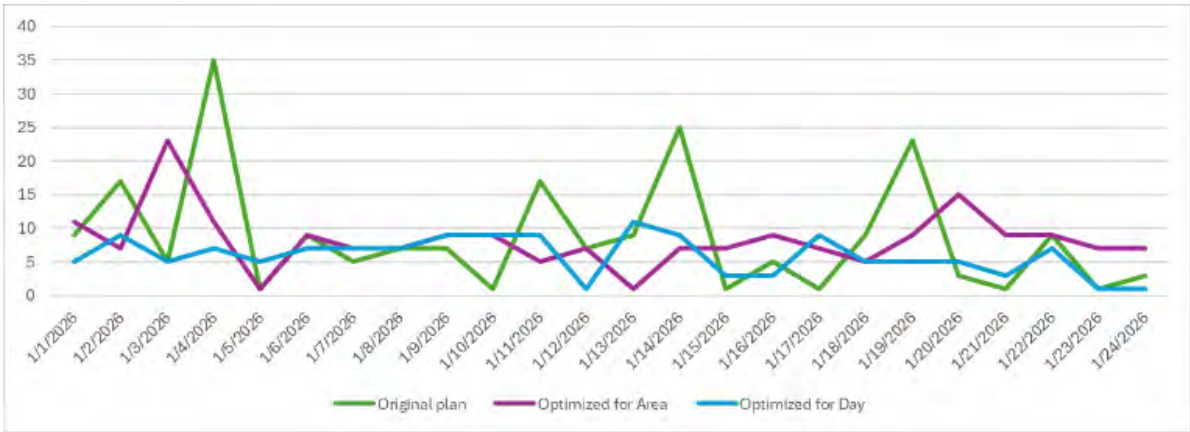

**Figure 3.** Deviation from processed avarage cell amount per day in the original plan (green), optimized plan with prioritized balanced distribution per area (purple), optimized plan with prioritized balancing per day (blue).

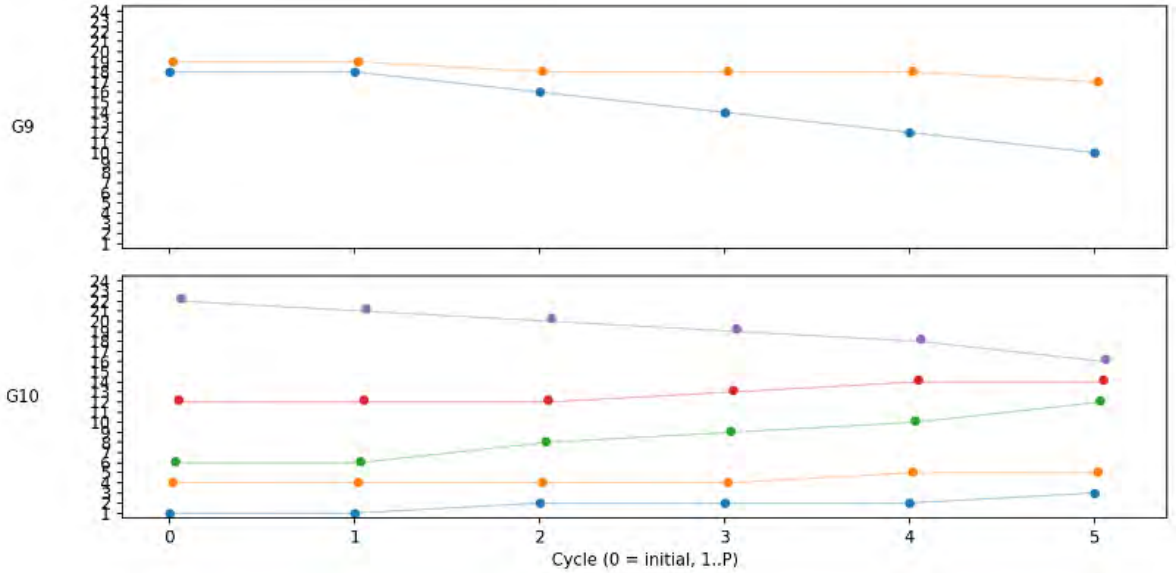

**Figure 4.** Optimized transition plan for group G9, G10 to be completed after P=5 cycles from the 24-day schedule to 21-day schedule.

improvement compared to the base scenario (Figure 3). By additionally minimizing the deviation per day for total amount of cells we achieve even more equal workload.

## Daily schedule

We consider again the example showed on Figure 2: we are given a list of jobs to perform for each group. Each group is located at different position and can be accessed by one of two cranes. The details of each group are summarized in Table 1.

For simplicity we assume that a crane can transport only one cell per time (i.e. $V_CellsProcessingAmount$ is always 0 or 1), there is no additional time required for lifting or putting the cathode into the cell. We aim to omit crane intersections but allow multiple cranes to stay at the cathode machine (located at 0) to mimic the queuing. In practice, would add some crane movements to free up the space in post-processing.

**Table 1:** Groups to be scheduled with their location w.r.t. cathode machine (position 0) and number of cells.

| Group | Location | # Cells |
|---|---|---|
| 1 | 22 | 10 |
| 2 | 15 | 15 |
| 3 | -12 | 12 |
| 4 | 10 | 16 |
| 5 | -18 | 16 |
| 6 | -3 | 16 |

The obtained results for this example are shown on Figures 5-7. The crane movement plot visually depicts the movement of the cranes across the rail system during the entire scheduling horizon. It can be observed that the crane movements are synchronized to avoid overlapping tasks and minimize the overall travel time. This is

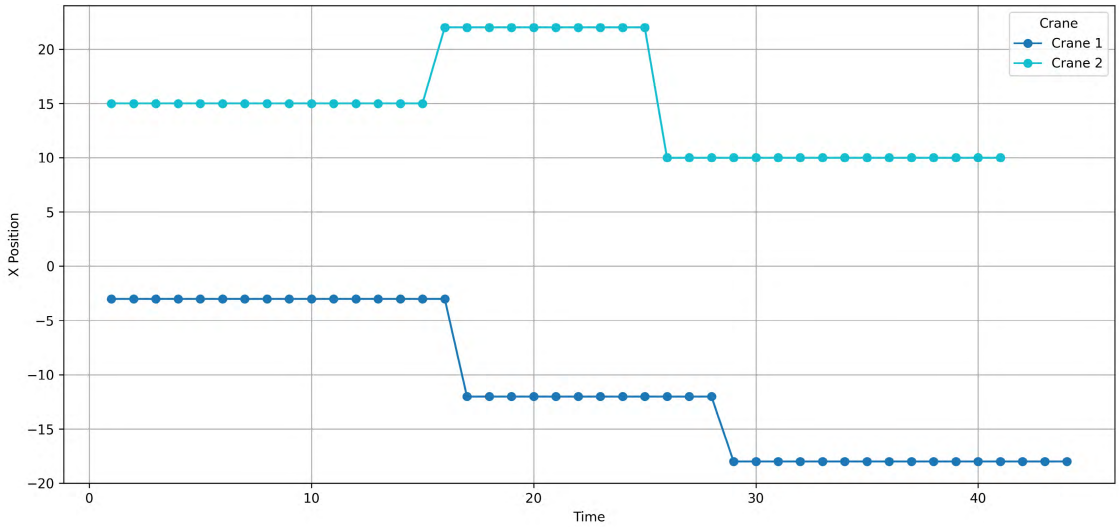

**Figure 5.** Crane movement with regards to the groups.

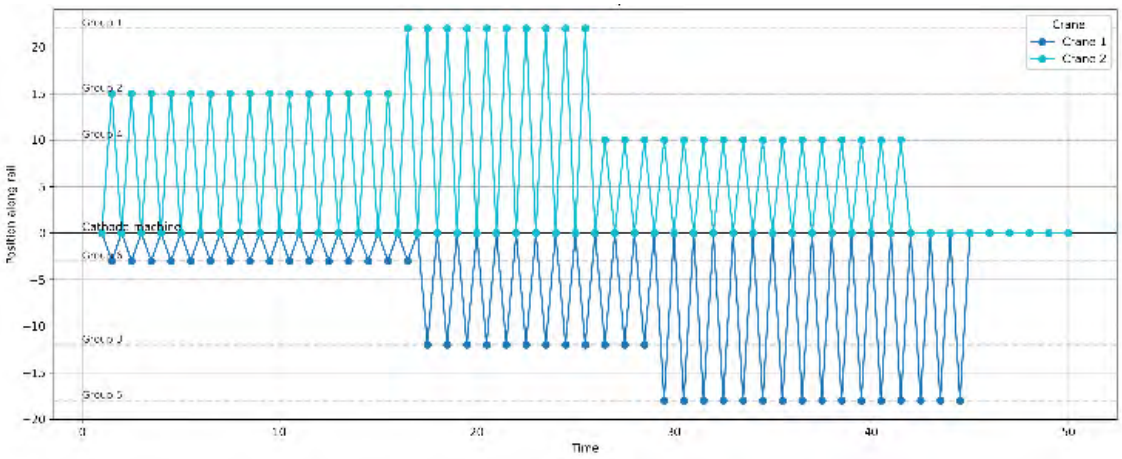

**Figure 6.** Crane movement with regards to the groups.

achieved by enforcing the non-interference constraints, which ensure that cranes do not cross paths or perform operations at the same location at the same time. The plot also shows how crane movements are efficiently scheduled, maximizing their utilization while respecting the available space and minimizing idle times.

On Figure 6 we show more detailed movement trajectory of each of the cranes to illustrate the active no-intersection condition and repeated travelling to cathode machine to return used and bring new cathodes.

Figure 7 provides a time-based visualization of the schedule, which shows the systematic distribution of job processing across time, ensuring that all jobs are completed within the required timeframe.

## FUTURE WORK

While the results obtained from the optimization model discussed in previous sections are promising, an intriguing question arose during the project regarding the practical implementation of the optimized plan, particularly in terms of minimizing disruptions to an existing operational schedule. Specifically, the challenge lies in determining how to transition from the current, potentially suboptimal, schedule to the optimized plan while ensuring minimal disturbances to ongoing operations.

Further, depending on the anode availability and electricity prices the duration of the cycle can be increased or reduced from the modelled X-days. Therefore, the same question arises: how one would transition optimally (maybe within several cycles) from X-day plan to Y-day plan and from X day plan to the optimized X day plan.

A straightforward solution would be to employ linear interpolation, as illustrated in Figure 4. This approach would allow for a smooth transition between schedules

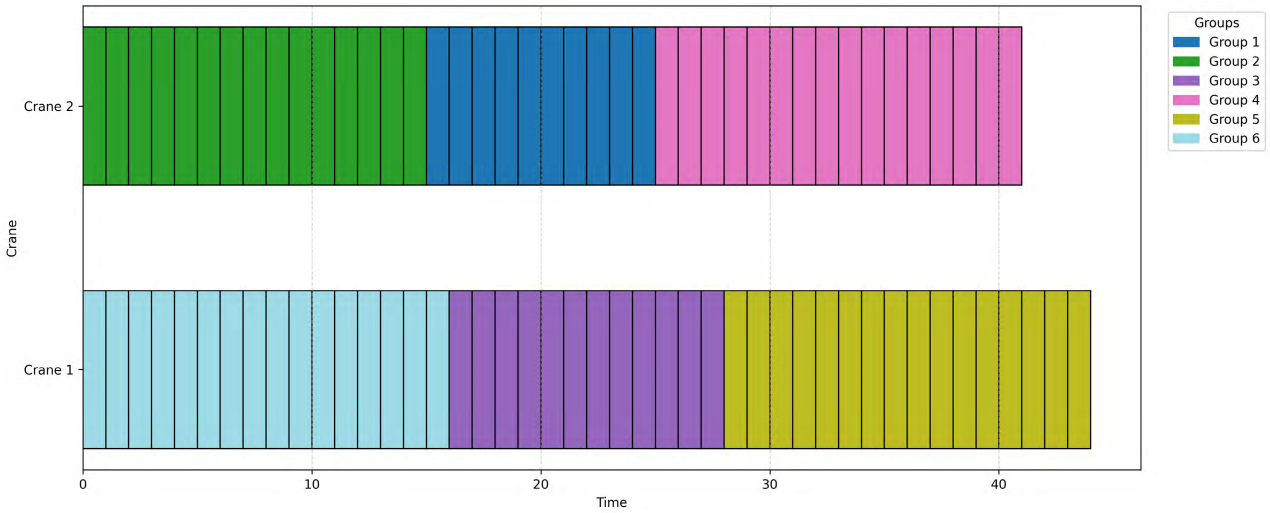

**Figure 7.** Job processing timeline for each of the cranes.

by gradually adjusting the start times and job assignments. However, while this method is simple, it may not fully capture the complexities of crane operations and job sequencing, especially under dynamic constraints.

In future work, we aim to explore more sophisticated techniques for these transitions. Possible approaches include the use of rolling horizon optimization, adaptive scheduling methods, or real-time re-optimization strategies, which would enable the system to adjust dynamically to changes in operational conditions, such as equipment availability and energy price fluctuations. These methods could potentially provide more robust solutions that balance operational efficiency with flexibility, ensuring smoother transitions between different scheduling plans.

## CONCLUSION

This paper presents an optimization model for scheduling crane operations in copper refining tankhouses, addressing complex constraints such as metallurgical rules and operational feasibility. Despite the complexity of the problem, the model successfully integrates key operational parameters, ensuring minimal disruptions to existing processes while maximizing resource utilization and electrolysis efficiency. The results, demonstrated through optimized schedules, show potential for improving operational throughput and reducing downtime within the tankhouse.

## ACKNOWLEDGEMENTS

The authors would like to express their gratitude to their colleagues from the production team at Aurubis for their valuable collaboration and insights throughout this project.

## ABSTRACT

Carbon dioxide hydrogenation to produce methane, as an energy carrier or raw material, has great potential for the chemical industry. Since methanation reaction is strongly exothermic and sensitive to diffusion, radial flow reactors represent a clear solution thanks to their low pressure drop and effective heat removal. A two-dimensional mixing cell network (MCN) approach to model the carbon dioxide methanation in a radial flow reactor is proposed. The reaction is catalyzed by a bifunctional Ni–Ce zeolite 13X supported catalyst, combining catalytic and adsorption functions. This contribution outlines the ongoing work, starting from a straightforward MCN pseudo-homogeneous approach comparing it with a tubular packed bed reactor. Both methanation kinetics and water adsorption have been successfully implemented in both models, setting feasibility for further improvements. Future developments will be necessary aiming to aid the design of units employing Ni–Ce/13X catalysts.

**Keywords**: Radial Flow Reactor, Methanation, Sorption-Enhanced, Mixing Cell Network, Carbon Dioxide Utilization

## 1. INTRODUCTION

The decarbonization of energy- and carbon-intensive sectors is pushing for the development of Power-to-Gas routes, in which renewable hydrogen is combined with carbon dioxide to produce synthetic natural gas (SNG). $CO_2$ methanation is an attractive pathway for the wide availability of catalytic materials and the production of grid-compatible fuel [1]. The reaction is reported below:

$$CO_2 + 4H_2 \rightleftarrows CH_4 + 2H_2O \quad (1)$$

$$\Delta_r H^0_{298K} = -165\ kJ/mol \quad (2)$$

As revealed, it occurs with a decrease in the number of moles and with the release of energy and is therefore thermodynamically favored by high pressures and low temperatures.

Many catalytic materials are available, differing from each other in the active phase, the support or the promoter [2]. Nonetheless, nickel is widely accepted to be fairly accessible balancing catalytic properties and application costs [3]. Furthermore, in recent research it was shown that using both physical mixture of catalyst and sorbent [4] and sorbent material as support for a catalyst [3] would improve the conversion of $CO_2$ by adsorbing water, exploiting Le Chatelier's principle. For these reasons, a bifunctional material made of Ni–Ce supported on zeolite 13X is implemented in the model discussed in this paper.

Different commercialized methanation technologies, like the TREMP Topsøe [5], are already common and employ packed bed reactors to produce SNG. However, as methanation is strongly exothermic an efficient heat removal is needed to avoid hot spot formation and to favor the thermodynamics of the reaction. Researchers suggested employing radial flow packed bed reactors, to enhance heat removal, to reduce the costs coming from using higher pressure to favor the thermodynamics [6]. In a radial reactor the catalyst is constrained between two perforated cylindrical metal screens enclosed in an outer shell which forms with the outer screen an annuls. The flow of the gas in a radial reactor can be centrifugal (CF) or centripetal (CP) and co-current (π-type) or counter-current (Z-type). There are four different

configurations of radial reactors, depending on how the flow is arranged, that are the CF flow Z-type, the CP flow Z-type, the CF flow π-type and the CP flow π-type [7]. In general, radial reactors are the favored solution when it comes to the scale up and when addressing the heat management and pressure drops [7].

Many strategies were adopted to model radial reactors, the majority of which were model based on the assumption that this type of reactor would behave similarly to a tubular packed bed reactor [8, 9]. However, in recent research, radial reactors were described as a matrix of interconnected CSTRs, each one representing a portion of the particle bed [10].

In the present paper the modelling of sorption enhanced methanation in a radial reactor is discussed. The radial reactor is modelled following a mixing cell network (MCN) approach, the kinetic is modelled for the bifunctional catalyst according to recent literature, accounting for the water adsorption. The results obtained from the radial reactor model will be compared to that of a tubular PBR.

## 2. MODELING

In this study the sorption enhanced methanation is modeled by developing and implementing a radial bed reactor adopting a pseudo-homogeneous mass balance. In the MCN the reactor is split into a matrix of interconnected tanks, each one representing the effect of a portion of the particulate bed. Figure 1 is a representation of the generic cell of the system. Figure 2 depicts the 2D MCN grid to model the radial reactor.

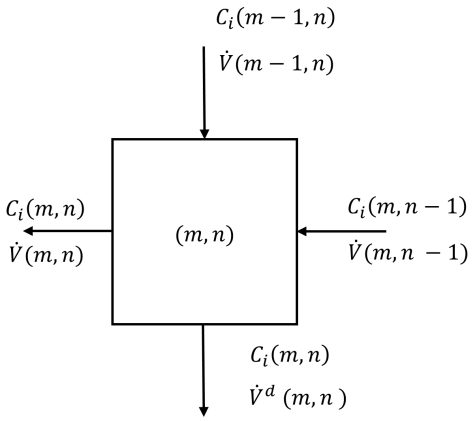

**Figure 1.** Schematic representation of the generic cell; m is the row index, n is the column index.

As a comparison the same reaction is also modelled in a packed bed reactor (PBR). The following assumptions were made:

- Ideal gas law applies.
- No side reactions are considered.
- Reactors are isothermal.
- A pseudo-homogenous mass balance was assumed.
- The model is written in dynamic form.
- Axial dispersion was assumed for PBR.
- Pressure drops for the radial reactor were neglected [11].
- A linear driving force (LDF) model is used to describe the adsorption rate [12].
- The reaction is assumed to be catalyzed by the bifunctional catalyst 5%Ni2.5%Ce13X [3].
- The outlet from each cell splits equally and the splitting is described by the ratio between the outlet volumetric flow rates from the cell.

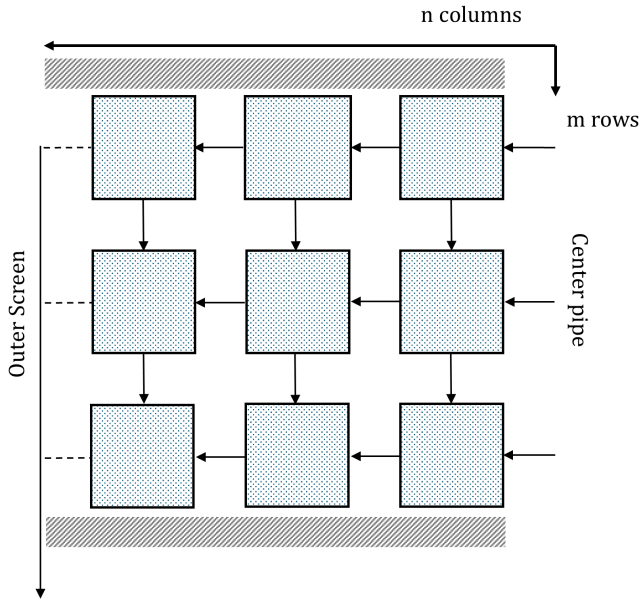

**Figure 2.** Schematic depiction of the 2D mixed cell network grid used for RFR.

### Mass balance

For the MCN the mass balance equations are non-linear algebraic equations obtained by considering as a control volume the single cell. The general form of the dynamic mass balance in the gas phase for the generic (m, n) cell can be written as follows:

$$\overbrace{\varepsilon_B \frac{dC_i(m,n)}{dt} V_{cell}}^{Accumulation} = \overbrace{C_i(m,n-1)\dot{V}(m,n-1) + C_i(m-1,n)\dot{V}(m-1,n)}^{Inlet} -$$

$$\underbrace{\left(C_i(m,n)\dot{V}(m,n) + C_i(m,n)\dot{V}^d(m,n)\right)}_{Outlet} + \underbrace{\rho_b \nu_i r_C(m,n)\, V_{cell}}_{Reaction} \quad (3)$$

Here, $C_i$ is the concentration of the i-th component in the gas phase, $\varepsilon_B$ is the bed void degree, $V_{cell}$ is the volume of the single cell, V (dotted) is the volumetric flow rate, $\rho_b$ is the catalyst bulk density, ν is the stoichiometric coefficient of the i-th component and $r_c$ is the rate of the catalyzed reaction.

## Kinetics and adsorption

For the methanation of $CO_2$ the kinetic was implemented grounding on previous studies [13, 14]. According to Koschany et al. for Ni-based catalyst, it was suggested that the rate of the catalyzed reaction was [14]:

$$r_c = \frac{k(C_{H_2} C_{CO_2})^{0.5}(R_{gas}\, T)\left(1 - \frac{C_{CH_4} C_{H_2O}^2}{C_{H_2}^4 C_{CO_2} Keq*(Rgas\, T)^2}\right)}{\left(1 + (R_{gas}\, T)^{0.5}\left(K_{OH}\frac{C_{H_2O}}{C_{H_2}^{0.5}} + K_{H_2} C_{H_2}^{0.5} + K_{mix} C_{CO_2}^{0.5}\right)\right)^2} \quad (4)$$

Where k is the kinetic constant, $R_{gas}$ is the ideal gas constant, T is the temperature, $K_{eq}$ is the equilibrium constant, $K_{OH}$, $K_{H2}$ and $K_{mix}$ are adsorption constants. The kinetic constant is calculated from the modified Arrhenius law, written as follows:

$$k = k_0 exp\left(\frac{E_a}{R}\left(\frac{1}{T_{ref}} - \frac{1}{T}\right)\right) \quad (5)$$

The adsorption constants are computed as:

$$K_x = K_{ref,x} exp\left(\frac{\Delta H_x}{R}\left(\frac{1}{T_{ref}} - \frac{1}{T}\right)\right) \quad (6)$$

The equilibrium constant is calculated with the empirical formula:

$$K_{EQ} = 137\, T^{-3.994}\, exp\left(\frac{158.7\, kJ/mol}{R_{gas}\, T}\right) \quad (7)$$

The mass balance for the sorbent is described adopting a linear driving force model [12]. Therefore, it can be written as follows:

$$\frac{\partial q}{\partial t} = K_{LDF}(q^* - q) \quad (8)$$

Where q is the amount of water adsorbed on zeolite 13X, q* is the equilibrium adsorption capacity of water on zeolite 13X and $K_{LDF}$ is the linear driving force coefficient which takes into accounts internal mass transfer resistances during adsorption. The equilibrium adsorption capacity of water on the sorbent is defined as:

$$q^* = \frac{\rho(T)}{Mm_{H_2O}}\, W(T,P) \quad (9)$$

Where, $Mm_{H2O}$ is the molecular mass of water and ρ(T) is the density of the adsorbed phase expressed as:

$$\rho(T) = \frac{\rho_{20°C}}{1+\beta_{20}(T-298.15K)} \quad (10)$$

Here, the parameter $\rho_{20°C}$ and $\beta_{20}$ are the density and the thermal expansion coefficient of adsorbate at 20°C, respectively.

In eq. 9 W(T, P) is the volumetric adsorption capacity which is expressed according to previous studies [12]:

$$W = W_0\, exp\left[-\left(\frac{A}{E_{ads}}\right)^n\right] \quad (11)$$

$$A = \frac{R_{gas}}{Mm_{H_2O}}\, T\, ln\left(\frac{P_{sat}}{P_{H_2O}}\right) \quad (12)$$

In eq. 11 and 12 W is the adsorption volume, $W_0$ is the maximum adsorption volume, $E_{ads}$ is the characteristic adsorption energy, A is the adsorption potential, $P_{sat}$ is the saturation vapor pressure of water, $P_{H2O}$ is the partial pressure of water and n is the heterogeneity factor of the micropore size distribution [12]. The linear driving force coefficient is computed as:

$$K_{LDF} = \frac{15}{0.5 d_p^2} D_{eff,H2O} \quad (13)$$

Where $d_p$ is the particle diameter and $D_{eff,\ H2O}$ is the water effective diffusivity. Table 1 summarizes the geometrics of the reactor, the parameter set for the catalyst and the specification of the current fed to the reactor in the simulations. Table 2 gathers the values for all the parameters set for equation 4-13 which are kinetic, adsorption and thermodynamic data at reference temperature of 555K.

## RESULTS AND DISCUSSION

### Radial reactor results

The simulations were carried out considering a 10x10 matrix of stirred tank reactors. The initial feeding was fed only to the first tank, and it subsequently split up in the following cells. The application of the mixed cell network led to obtain good first approximation results. Figure 3 reports the outlet gas molar fractions of the participant in the reaction. The breakthrough curve of water is depicted, showing the delayed outlet due to adsorption on zeolite 13X. Figure 4 shows the outlet molar flow rates, in particular the molar flow rate of carbon dioxide, hydrogen and methane variates, it increases for the reactants and decreases for the product. This happens at the water outlet, corresponding to the saturation of the adsorbent, and it is due to the shift of the reaction equilibrium to the reactants side. The variation is subtle due to the high equilibrium constant.

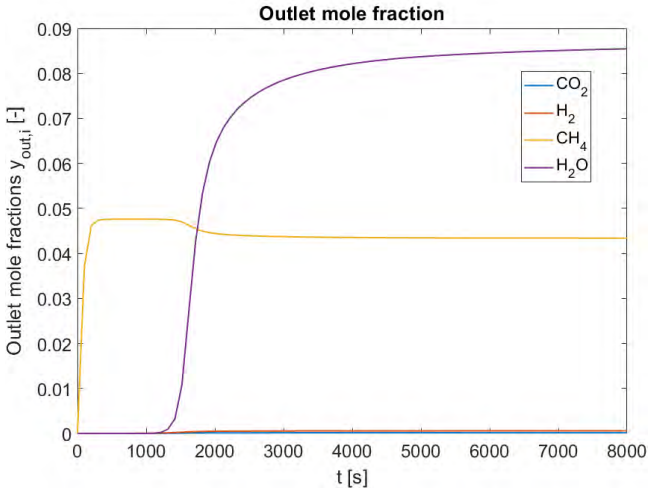

**Figure 3.** Radial flow reactor outlet gas molar fractions of the participant to the reaction versus time, the inert (helium) was excluded for reading pourpose.

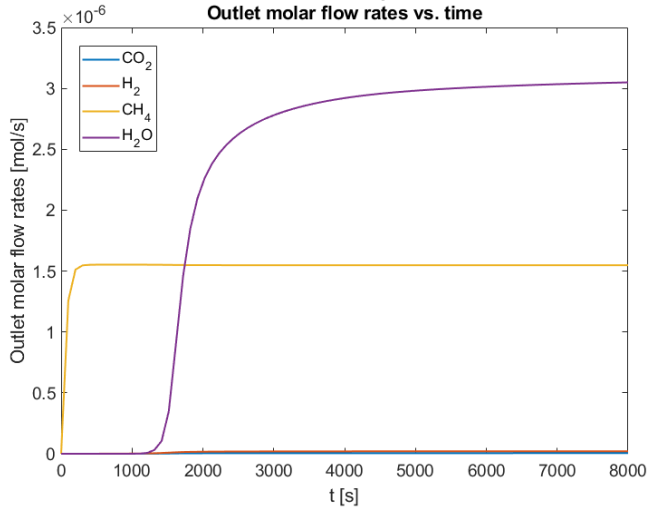

**Figure 4.** Radial flow reactor outlet molar flow rates of the participant to the reaction versus time.

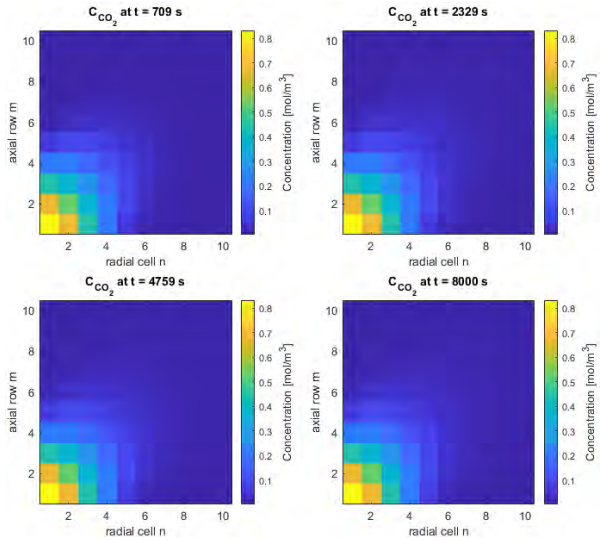

**Figure 5.** Carbon dioxide (limiting reactant) gas phase concentration [mol/m$^3$] in each cell at fixed time instants.

Figure 5 shows the $CO_2$ gas phase concentration in each (m, n) cell at fixed time instants. Since the water is removed from the gas phase the equilibrium is shifted towards the products according to Le Chatelier's principle, therefore the reactants are consumed in the first part of the reactor. Figure 8 shows the development of the breakthrough curve of water. The water starts to appear in the reactor once the zeolite 13X has reached its maximum equilibrium capacity. When the sorbent can no longer retain water, the reaction is not enhanced anymore by adsorption.

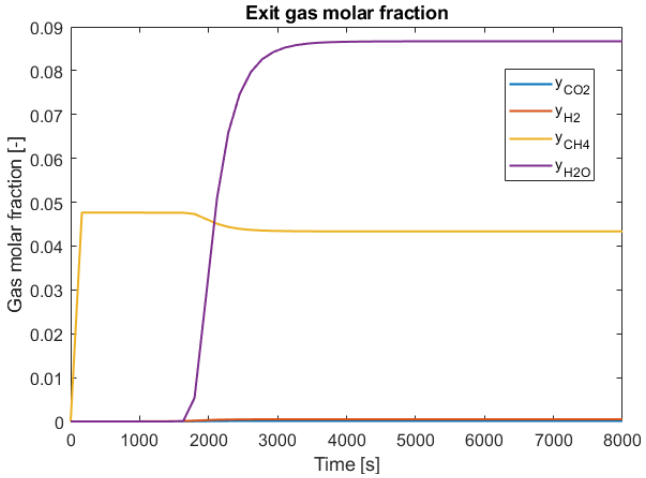

**Figure 6.** Tubular packed bed reactor outlet gas molar fractions versus time.

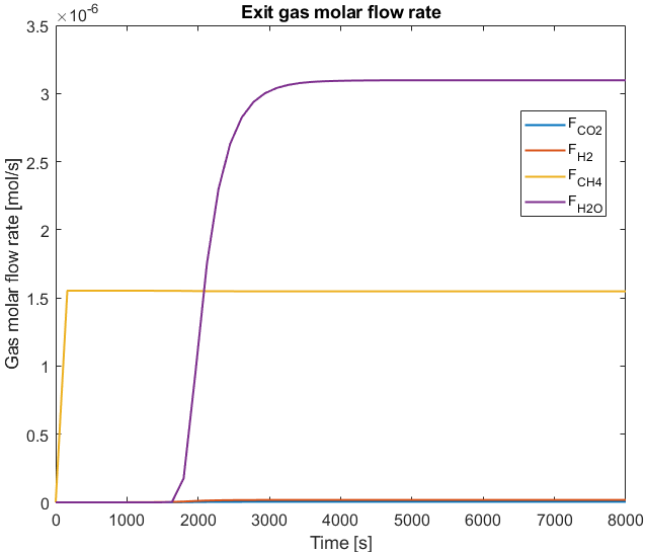

**Figure 7.** Tubular packed bed reactor outlet molar flow rates versus time.

## Comparison with tubular PBR

To better inspect the behaviour of the MCN in a first stage the results can be compared to that of a tubular packed bed reactor of the same volume. This can be done because it is assumed that the reacting gas moves principally in the radial direction. The operation conditions and all the parameters used for the simulation of the radial reactor are the same for the tubular reactor. Figure 6 reports the outlet gas molar fractions for the tubular PBR.

It is possible to observe a slightly longer period of sorption enchantment, before zeolite 13X hits its maximum water uptake. In particular, the shorter period before the exit of water, in figure 3, in the radial reactor can be attributed to a distribution of residence time among the stirred cells due to the effect of the splitting parameter R. Figure 7 reports the outlet molar flow rates from the tubular reactor. Comparing the water breakthrough curves for both (fig. 3 and 6) reactors, it should be noted that in the region at longer times, the reaction should reach a new steady state, as the water is no longer being adsorbed by the zeolite 13X. This behaviour is correctly shown by the simulation in the tubular PBR, as can be seen in figure 6. Indeed, both the molar fraction of water and methane remain constant after the inflection point, where the sorbent has reached its maximum water uptake. However, in the radial reactor, deviations occur, and the steady state is delayed. Thus, the molar fraction of water and methane appear to increase and decrease, respectively (see figure 3). The delayed steady state is likely attributable to the onset of numerical diffusion due to the distribution of residence time among the mixed cells.

## CRITICAL ASPECTS AND FUTURE DEVELOPMENT

Compared to other models available in literature for radial reactors, the mixed cell network avoids the widely spread approximation of assuming it to behave similarly to a tubular reactor. Therefore, the MCN has the potential to better describe a radial reactor with respect to classical plug flow models or axial dispersion models.

Pressure drops and velocity field handling are critical for the correct description of radial flow systems. This means combining the mass balance with a momentum balance and a continuity equation to describe the interaction of the flowing gas with the particle bed. In this study the fluid dynamic description was lumped in the parameter R which represents the splitting ratio between flow rates going out from each cell. Therefore, for future development the fluid dynamic will be addressed by solving the Ergun's equation for the radial coordinate and for the axial coordinate and combining it with continuity equation to obtain a velocity profile which can be coupled with the mass balance.

Another critical aspect is the appearance of internal diffusion limitations, which can be a bottleneck for the methanation reaction [13]. Therefore, an intraparticle mass balance can be implemented in the mixed cell network to account for this phenomenon.

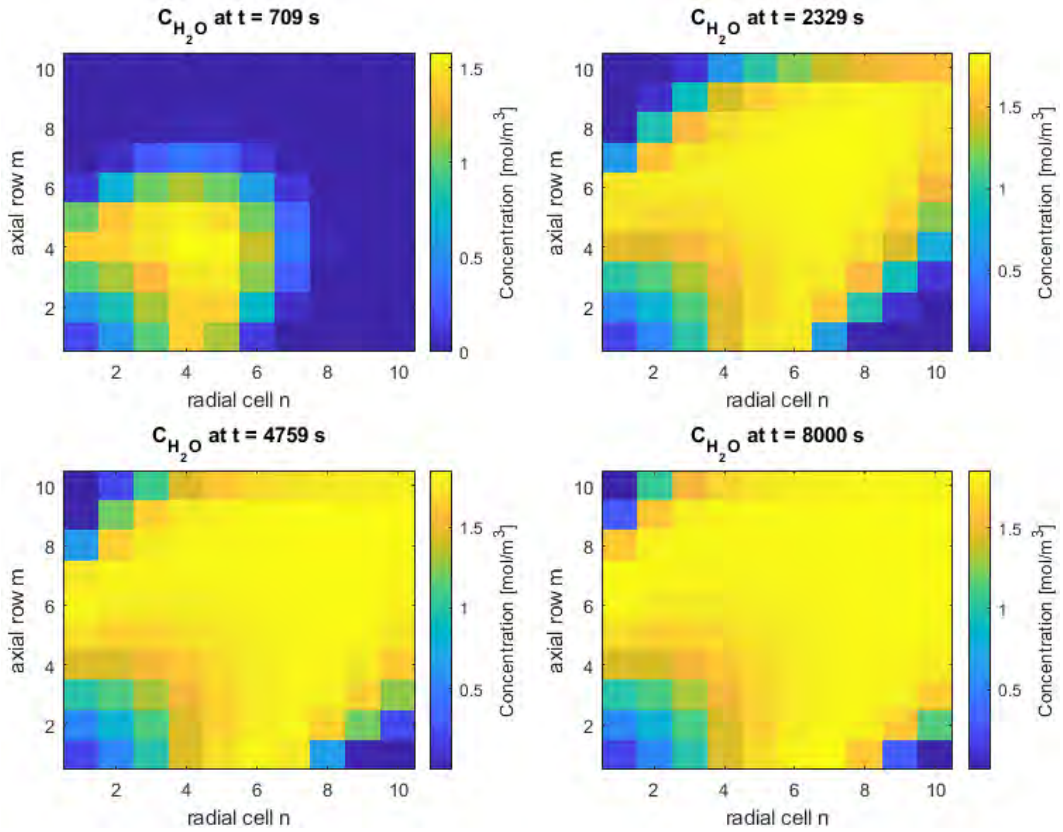

**Figure 8.** Water gas phase concentration [mol/m$^3$] in each cell at fixed time instants.

Methanation reaction is strongly exothermic, and this poses a design challenge when modelling radial reactors. An important future development is the implementation of the dynamic energy balance. Studying the transient of the temperature variation in the reactor is fundamental when trying to avoid hot spots formation as this can easily cause region of over-utilization of the bed and eventual runaways.

## CONCLUSION

This study showed and discussed the modelling of the sorption enhanced methanation in a radial flow reactor system. The foundations of the MCN were presented. The mass balance on each cell and the implementation of the kinetics and adsorption was successfully, showing a good sorption enhancement period. The results fairly agree with that of a tubular PBR, and the difference are attributed to the handling of the fluid dynamics in the radial reactor. Critical aspects of the model and its future development have been highlighted showing good room for improvements implementing intraparticle balances, energy balance and pressure drop handling.

# Dynamic Modeling of a Biomass Fluidized-Bed Gasifier

**Jefferson D. C. Araujo[a]*, Fréderic Marias[a], and Sabine Sochard-Reneaume[a]**

## ABSTRACT

The climate crisis and dependence on fossil fuels make the transition to renewable energy sources imperative, with biomass standing out for promoting decarbonization and circular economy. In this context, fluidized bed gasification emerges as an efficient route for converting waste into syngas, applicable to power and hydrogen generation. Given the variability of real operating conditions, dynamic models are essential to represent coupled fluid dynamic, thermal, and kinetic phenomena over time. In this work, a dynamic phenomenological model was developed using a lumped 0D approach, in which the reactor is divided into two interacting zones represented as continuous stirred-tank reactors (CSTRs): a dense bed, where drying, devolatilization, and heterogeneous reactions occur, and a freeboard, dominated by homogeneous gas-phase reactions. The model was validated against experimental data from a bubbling fluidized bed gasifier, showing good agreement for major syngas species (CO and $H_2$, mean absolute error below 2%), with minor deviations for $CH_4$ due to simplified devolatilization and tar conversion kinetics. Transient simulations revealed strong sensitivity of process performance to particle size and biomass composition. Compared with the reference case (6 mm), reducing particle size to 1 mm enhanced hydrogen gas efficiency, cold gas efficiency, and carbon conversion due to intensified heterogeneous reactions and improved solid–gas heat transfer. Additionally, biomass switching simulations demonstrated that real-time air flow control effectively stabilizes syngas quality under feedstock variability. Overall, the model provides a computationally efficient tool for process optimization, control strategy development, and integration of biomass gasification into flexible and hybrid low-carbon energy systems.

**Keywords**: Gasification, Fluidized-bed, Dynamic modelling, Biomass, Syngas.

## INTRODUCTION

The global climate crisis, intensified by persistent greenhouse gas (GHG) emissions, exposes the structural vulnerability of fossil fuel-based energy systems, whose geopolitical volatility and progressive depletion threaten global energy security. In this context, the Paris Agreement (2015) set ambitious targets to limit global warming to 1.5 °C, requiring a 45% reduction in emissions by 2030 and the achievement of carbon neutrality by 2050 [1].

Biomass emerges as a strategic vector in this transition, combining decarbonisation with circular economy principles by valorising agricultural, forestry and urban waste. The biomass is highly significant in the circular economy for both material products and energy provision, closing nutrient cycles and minimising waste [2].

According to the International Energy Agency's (IEA) Net Zero Emissions by 2050 Scenario, modern bioenergy is expected to triple its contribution, reaching approximately 100 EJ/year by 2050 (up from the current 60 EJ) to supply 15–20% of global energy demand [3].

Among thermochemical conversion routes, gasification stands out for its efficiency in producing syngas (CO + $H_2$), offering versatile applications in power generation, hydrogen production, and processes with the potential for negative emissions. Within this field, fluidized bed gasification is particularly notable due to its operational flexibility in processing heterogeneous biomass feedstocks. This reactor type provides efficient heat transfer and is well-suited for materials with compositional variability. Persistent challenges, though, including biomass moisture management and optimal operating pressure, require further development [4] .

In the case of real energy platforms, however, there

are load variations, fluctuations in fuel composition, and real-time control demands, requiring dynamic models that capture the coupled interactions between fluid dynamic, thermal, and kinetic phenomena over time [5]. While steady-state models are useful for point-in-time analysis, dynamic modeling is essential for design, operational optimization, and integration with hybrid systems. This approach is all the more necessary given the high complexity of thermochemical conversion processes, such as gasification, which involve non-linear parameters and high-dimensional conversion processes. Mathematical models therefore become indispensable tools for designing, optimizing, and intensifying these processes [6]. They make it possible to determine a system's optimal operating conditions, evaluate the impact of different variables on outcomes, and anticipate trade-offs between energy efficiency, thermal stability, and syngas quality. Furthermore, these models can be used for real-time control and optimization, as well as for predicting critical process performance parameters. These capabilities accelerate the technological maturity of processes toward industrial-scale deployment [7].

In this context, the present work aims to develop a numerical tool based on dynamic modeling capable of predicting the behavior of a biomass fluidized-bed gasifier when processing different types of biomass, each with distinct chemical composition, moisture content, and physical properties. The model seeks to capture, in a transient manner, the effects of these variations on the composition and yield of syngas, enabling the evaluation of their influence on process efficiency, operational stability, and the quality of the generated energy product.

# METHODOLOGY

## Model Description

A dynamic phenomenological model was developed to describe biomass gasification in a bubbling fluidized bed reactor, a schematic representation of the system and the boundaries of the domain studied is presented in the Figure 1. The objective of the model is to capture the main hydrodynamic, thermal, and chemical phenomena governing solid conversion and syngas composition under transient operating conditions.

To achieve this, a lumped-parameter approach (0D) was adopted, with the reactor divided into two distinct zones, both modeled as continuous stirred-tank reactors (CSTR). The reactor is divided into a dense bed zone and a freeboard zone, which are dynamically coupled through mass and energy exchanges.

The dense bed represents the fluidized region where gas and solid phases coexist. Biomass particles are introduced into an inert bed material and undergo drying, de-volatilization, char gasification, and partial oxidation re-actions. Gas–solid mass and heat transfer, as well as particle size reduction due to conversion, are explicitly considered in this zone.

The freeboard is modeled as a gas-phase region free of solid particles. Homogeneous gas-phase reactions and heat transfer with the reactor walls are considered. This zone contributes to the homogenization of the product gas composition before it exits the reactor.

The main modeling assumptions are summarized as follows: (i) Zone dense is a Multiphase CSTR (intra-phase homogeneity), (ii) Pressure is constant throughout each zone, (iii) Perfect gas behavior, (iv) Representation of biomass based on immediate and elemental analyses, (v) Layered model for biomass particles, (vi) Simplified thermal representation of walls and (vii) Particle shrinkage is considered, but average particle size is applied, while particle fragmentation is neglected.

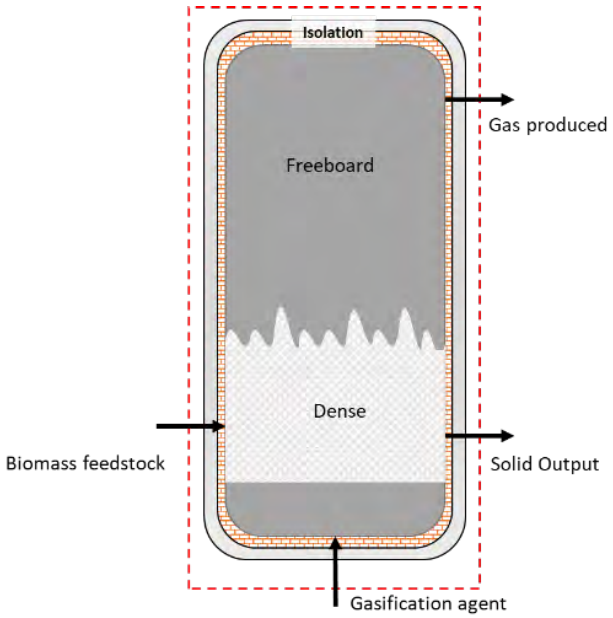

**Figure 1.** Schematic representation of the system – bubblubg fluidized bed reactor.

## Phenomenological model construction

The proposed model considers the main stages of biomass conversion occurring in a bubbling fluidized bed gasifier. These stages include drying, devolatilization, heterogeneous reactions involving the solid char, and homogeneous gas-phase reactions. Each stage is modeled according to its dominant physical and chemical mechanisms and is dynamically coupled through mass and energy balances.

## Drying

Drying describes the removal of moisture from biomass particles as their temperature increases. In the present model, moisture evaporation is driven by heat transfer between the gas and solid phases and occurs prior to devolatilization. The water evaporation rate is described

by an Arrhenius-type expression, dependent on the particle surface temperature and the amount of water contained in the particle, ensuring that the drying process progressively slows down as the available moisture is depleted [8].

## Devolatilization

Devolatilization corresponds to the thermal decomposition of dry biomass, leading to the release of volatile species and the formation of a solid char residue. Devolatilisation is described using a global, lumped approach.

$$C_aH_bO_cN_dS_eCl_f \rightarrow \alpha C_{solide} + \sum \beta_i Gaz_i \quad (1)$$

For a given temperature, the devolatilisation products are represented by a limited number of gaseous and tar species, whose yields are determined by a set of empirical coefficients. Twelve coefficients are calculated: (i) one coefficient related to solid carbon, corresponding to the fixed carbon fraction, (ii) eight coefficients for gaseous species and (iii) three coefficients for tar compounds.

The system is closed using: (i) six atomic balance equations (C, H, O), (ii) three pyrolysis correlations from [9], [10] defining the ratios $CO/CO_2$, $C_6H_6/C_6H_6O$, and $C_6H_6/C_7H_8$, (iii) one gas-to-tar ratio correlation from [11] and (iv) one energy balance equation. This approach allows capturing the main trends of biomass devolatilisation while keeping the model computationally efficient and suitable for dynamic reactor simulations. Once the product distribution coefficients are established, the devolatilisation rate must be determined. This rate depends on the biomass type and is typically modeled using an Arrhenius-type kinetic expression [11].

**Table 1:** The kinetic reaction rates of reactions with carbon.

| Reaction | k(m/s) |
|---|---|
| $C + H_2O \rightarrow CO + H_2$ | $k_1 = 5.714 \cdot T \cdot \exp\left(\frac{-15600}{T}\right)$ |
| $C + CO_2 \rightarrow 2CO$ | $k_2 = 5.89 \cdot 10^2 \cdot T \cdot \exp\left(\frac{-26800}{T}\right)$ |
| $C + \frac{1}{2}O_2 \rightarrow CO$ | $k_3 = 2.30 \cdot T \cdot \exp\left(\frac{-11100}{T}\right)$ |
| $C + O_2 \rightarrow CO_2$ | $k_4 = k_3 \cdot \left(2512 \cdot \exp\left(\frac{-6420}{T}\right)\right)^{-1}$ |

## Heterogeneous reactions

Heterogeneous reactions between char and gaseous species are modeled using a shrinking-core approach [12]. After devolatilization, the particle consists of a uniform reactive char layer surrounding an inert ash core. The entire external surface remains active throughout conversion, with ash contributing neither to reaction nor to internal diffusion resistance. Consequently, gaseous reactants encounter only gas-film resistance, and the particle diameter decreases progressively as char is consumed until only inert ash remains. All gasification and combustion reactions are assumed first-order in gaseous species and occur exclusively at the external char surface, with kinetic constants adopted from surface reaction data [13].

## Homogeneous Reactions

Homogeneous gas-phase reactions play a central role in gasification by converting primary pyrolysis volatiles and heterogeneous reaction products into a more stable syngas composition. These reactions occur throughout the reactor, both in the dense bed and freeboard zones, and involve 16 key gaseous species, including major pyrolysis products (CO, $CO_2$, $H_2$, $H_2O$, $CH_4$), tar surrogates (benzene, toluene, phenol), light hydrocarbons ($C_2H_2$), particulate carbon, and oxidant gases ($O_2$, $N_2$). To balance accuracy and computational efficiency for dynamic reactor-scale simulation, a reduced kinetic scheme comprising 21 global reactions was adopted. The set captures the dominant chemical pathways: thermal cracking, steam and dry reforming, partial and complete oxidation, water–gas shift, and tar reforming/degradation [14-16]. Particular attention was given to tar conversion due to its dual energetic and environmental implications. The complete reaction list with stoichiometry and kinetic parameters is provided in the supplementary material.

## Validation and Case Study

The predictive capability of the proposed model was evaluated by comparing simulation results with experimental data reported in the literature under similar operating conditions. Key process variables, including syngas composition, reactor temperature, and solid conversion, were analyzed. The operating parameters, such as gasifying agent composition, biomass characteristics, and reactor temperature, were adjusted to match the experimental setup.

Following validation, the model was applied as a predictive tool to investigate operational trade-offs associated with biomass gasification. The case study focused on two relevant transient operational scenarios: variation in particle diameter due to conversion and switching between different biomass feedstocks during reactor operation.

The impact of these parameters was evaluated in terms of syngas composition, reactor temperature evolution, and overall energy performance. To quantify process efficiency, several performance indicators were analyzed, including Hot Gas Efficiency (HGE), Cold Gas Efficiency (CGE), and Carbon Conversion Efficiency (CCE).

This combined validation and application approach highlights the capability of the model to support the analysis of transient operating strategies and to provide insights into the optimization of biomass gasification performance.

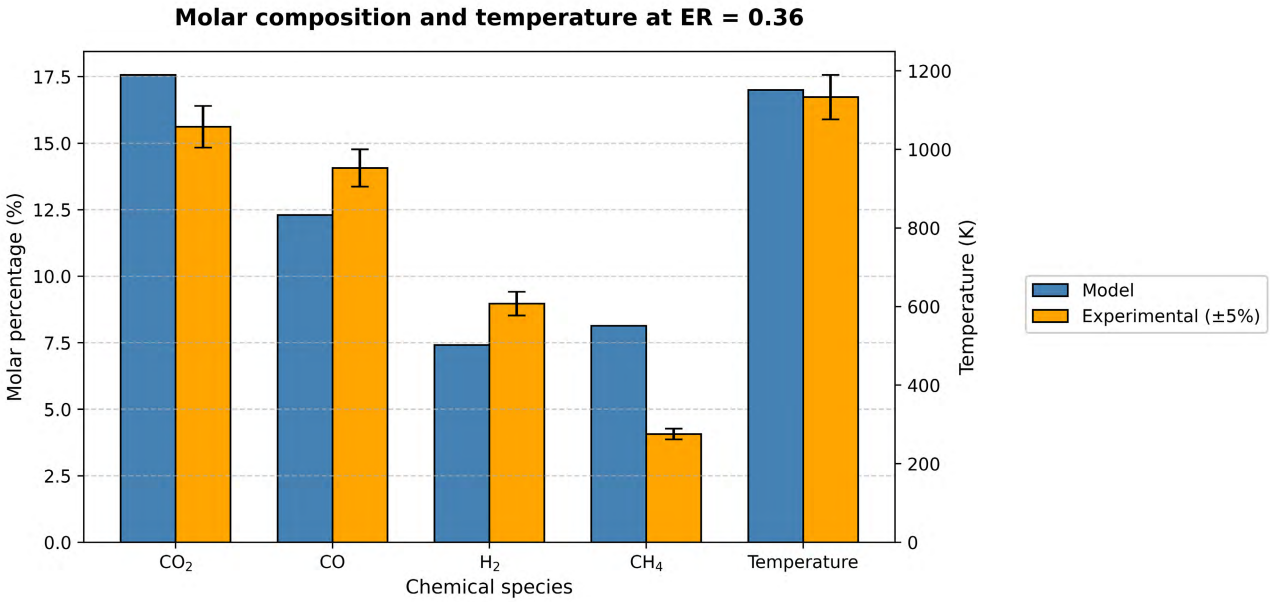

**Figure 2.** Comparison of Predicted and Experimental Gas Composition & Temperature (ER = 0.36)

# RESULTS AND DISCUSSION

## Validation

The model was validated against experimental data from a bubbling fluidized bed gasifier operating at 860 °C with Wood Pellets and air as the gasifying agent [17].Steady-state predictions of syngas composition ($H_2$, CO, $CO_2$, $CH_4$) and bed temperature were compared to measured values. As shown in Figure 2, the model reproduces the main trends of gas composition with a mean absolute error below 2% for $H_2$ and CO, the dominant species governing syngas heating value. A slight overprediction of $CH_4$ (≈4 % error) is observed, attributable to the simplified devolatilization and tar reforming kinetics. Overall, the results confirm the model's capability to predict the main features of biomass gasification steady-state conditions.

# CASE STUDY

## Reference case

Before the transient analysis, the model simulates a complete 48-hour startup sequence, from cold conditions (298 K) to steady-state operation, corresponding to the stabilization duration reported in [17]. The sequence begins with heating the bed to 380°C, followed by gradual feeding of biomass (wood pellets: $d_p$ = 6.0 mm, moisture = 7.9% by weight, LHV = 16.95 MJ·kg$^{-1}$), followed by controlled adjustment of the air flow to achieve the target equivalence ratio (ER = 0.28). This controlled combustion phase drives the thermal increase of the reactor, favoring autothermal conditions, while air flow control will stabilize the composition of the synthesis gas. In 48 h, the system reaches steady-state conditions (CO = 5.03%, $H_2$ = 7.40%, dry basis; carbon conversion efficiency = 68.21%, HGE =59.68 % and CGE = 45.45%), with species variations below 1.0% in 1-hour windows (Figure 3).

The residence time was calculated based on the feed and withdrawal dynamics of the reactive solids in the reactor. In the reference scenario (base case), this parameter was set at 984.4 seconds, corresponding to approximately 16 minutes and 30 seconds. This validated baseline serves as the initial condition for the transient scenarios : (i) particle size (6.0 → 1.0 mm and 6.0 → 10.0 mm) and (ii) biomass switch (wood pellets →woodchips eucalyptus).

Building upon the validated steady-state baseline (48 h startup, $d_p$ = 6.0 mm, residence time = 984.4 s), two transient scenarios were simulated to assess particle size sensitivity: (i) reduction to fine particles ($d_p$ = 1.0 mm) and (ii) increase to coarse particles ($d_p$ = 10.0 mm), as showed in Figure 4. To isolate the intrinsic effect of particle size on conversion kinetics, while maintaining equivalent hydraulic conditions, the solid outlet flow rate was dynamically recalculated at the instant of size change to preserve the reference residence time (984.4 s). This adjustment compensates for the altered bed inventory resulting from particle size variation, ensuring that observed transients reflect purely kinetic and heat/mass transfer effects rather than hydraulic residence time differences. The step-change in particle size was applied at t = 48 h, with biomass composition, flow rate and ER = 0.28 held

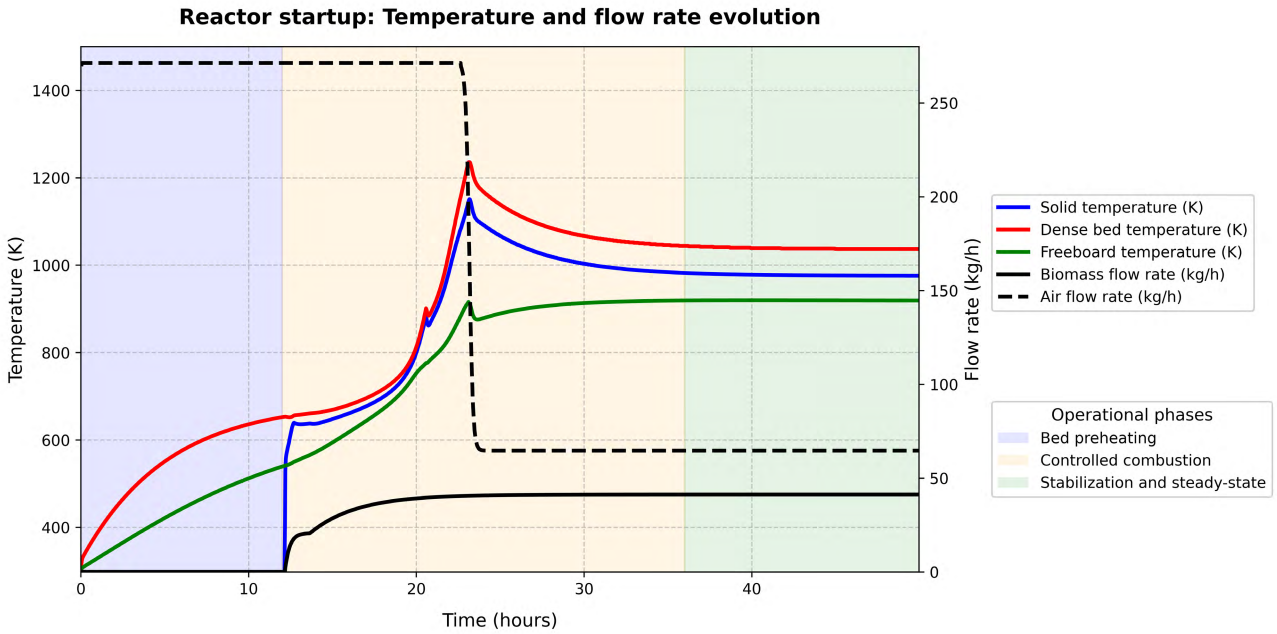

**Figure 3.** Reactor Startup : Temperature and flow rate evolution.

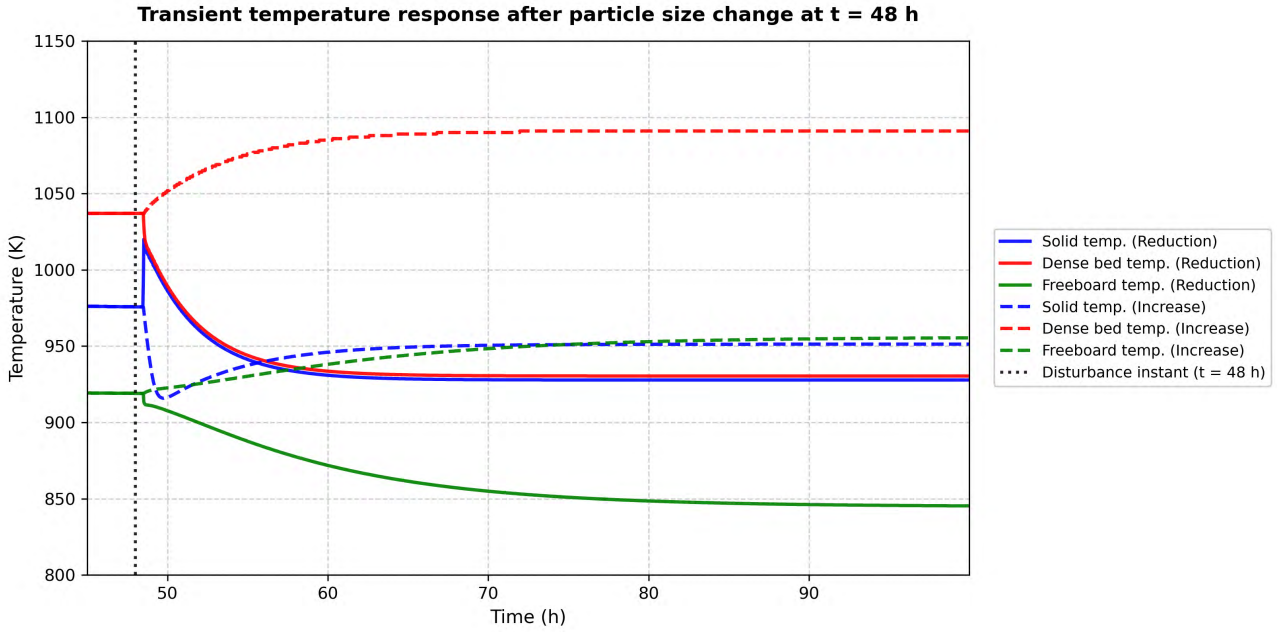

**Figure 4.** Transient temperature response after particle size change at t=48h.

constant throughout.

## Particle size

Particle size strongly influences heat transfer, heterogeneous reaction rates, and overall gasification performance. The reference case (6 mm) represents a balance between reactive surface area and thermal behavior. Reducing particle size increases the specific surface area, enhancing solid–gas convective heat transfer and accelerating endothermic heterogeneous reactions such as steam and $CO_2$ gasification. Conversely, increasing particle size reduces the available reactive surface, limiting heterogeneous conversion and weakening thermal coupling between solid and gas phases.

Compared with the reference case, reducing particle size from 6 mm to 1 mm improves process performance, increasing hydrogen gas efficiency (HGE) from 59.68 % to 69.08 %, cold gas efficiency (CGE) from 45.45 % to 56.25 %, and carbon conversion efficiency (CCE) from 68.21 % to 77.01 %. This enhancement is associated

with intensified heterogeneous reactions (C + $H_2O$ and C + $CO_2$), leading to higher char conversion and improved syngas quality, with CO and $H_2$ concentrations increasing from 5.03 % to 7.93 % and from 7.40 % to 11.24 %, respectively. In contrast, increasing particle size from 6 mm to 10 mm reduces HGE, CGE, and CCE to 54.54 %, 39.63 %, and 63.17 %, respectively, while decreasing CO and $H_2$ concentrations to 3.51 % and 5.24 %. These results confirm the dominant role of particle size in controlling thermal behavior and product distribution in fluidized bed gasifiers, highlighting the advantages of finer biomass particles, despite the additional milling energy requirement.

## Biomass switch

To assess operational flexibility under feedstock variability, a transient scenario was simulated wherein the biomass type was switched from wood pellets to eucalyptus woodchips while maintaining a constant particle diameter (6 mm). The new biomass, characterized in [18], exhibits lower fixed carbon (16.21 wt.% vs. 20.21 wt.%) and same volatile content (79.81 wt.%), which inherently alters devolatilization intensity and char reactivity. To preserve syngas quality despite this compositional shift, the air flow rate was dynamically adjusted to maintain a constant CO/$H_2$ molar ratio, the targeted quality indicator, as showed in Figure 5.

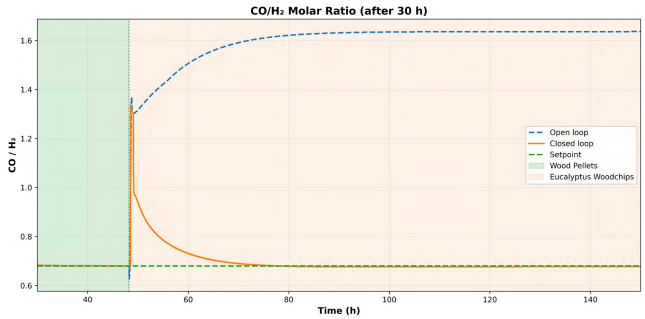

**Figure 5.** CO/$H_2$ molar ratio (after 30h).

Switching from wood pellets to eucalyptus woodchips necessitates dynamic air flow adjustment to maintain syngas quality, as demonstrated by the controlled case (Close loop), as showed in Figure 6. By modulating the air flow rate to stabilize the CO/$H_2$ molar ratio at 0.68, the system maintained consistent syngas composition (CO: 6%, $H_2$: 8.95%) and freeboard temperature (823 K) despite the feedstock change. In contrast, the uncontrolled case (Open loop) exhibited significant deviations, with the CO/$H_2$ ratio increasing to 1.6, CO concentration rising to 12%, $H_2$ to 7.33%, and freeboard temperature reaching 1057 K.

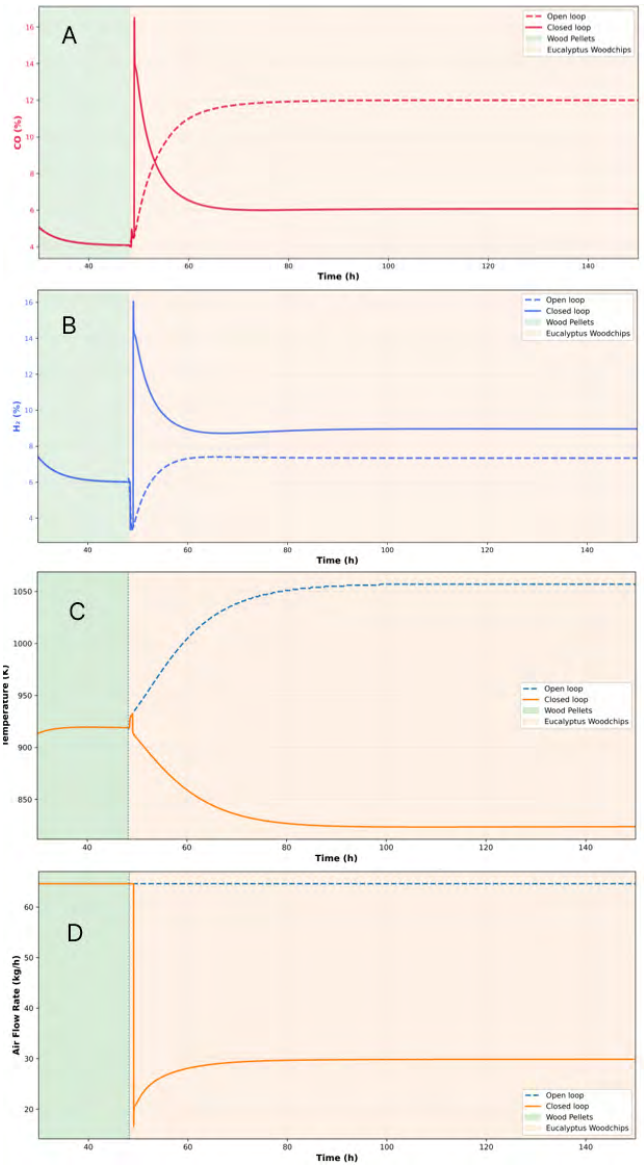

**Figure 6.** Dynamic response of syngas composition, thermal and flow rate behavior: (A) CO concentration, (B) $H_2$ concentration, (C) freeboard temperature and (D) air flow rate under open-loop and closed-loop operation during biomass transition.

This confirms that real-time air flow regulation effectively compensates for biomass-induced variations in reaction kinetics, ensuring operational stability during feedstock transitions. The comparison between Wood Pellets and Woodchips Eucalyptus highlights the strong influence of feedstock properties and process control on gasification performance. When Biomass 2 is operated under controlled conditions, the process shows improved gasification efficiency, with increases in HGC (from 59.7% to 63.61%) and CGC (from 45.46% to 55.37%) while maintaining a stable CO/$H_2$ ratio (0.68). These improvements are achieved with a significantly lower air flow rate, indicating a more efficient and optimized

conversion process. Conversely, when Biomass 2 is operated without control, the system exhibits substantially higher performance indicators (HGC = 85.43%, CGC = 67.44%, CCE = 99.06%), but this is accompanied by a strong increase in the $CO/H_2$ ratio (1.63) and higher air consumption. This suggests that although uncontrolled operation maximizes carbon conversion, it compromises gas quality and process selectivity, demonstrating the critical role of control strategies in balancing conversion efficiency, gas composition, and energy optimization.

## CONCLUSION

This work presents a dynamic model for biomass gasification in bubbling fluidized bed reactors that accurately predicts both steady-state and transient behavior by integrating hydrodynamic, thermal, and kinetic phenomena within a unified framework. Validated against experimental data, the model successfully captures key aspects of biomass conversion, syngas composition, and thermal dynamics, while also simulating realistic operational disturbances such as particle size changes and biomass switching. Results highlight that feedstock properties significantly affect conversion efficiency and syngas quality, but real-time air flow control can effectively compensate for biomass variability, enabling stable operation with heterogeneous feedstocks, a common challenge in industrial settings.

The model's dynamic nature offers a strategic advantage for integrating gasification into hybrid, multi-product energy systems, as it enables analysis of load variations, start-up/shutdown sequences, and transient disturbances critical for coupling with downstream processes like methanation, hydrogen production, and Fischer–Tropsch synthesis. By predicting time-dependent syngas composition, it enhances compatibility with catalytic units, supports digital twin development, and facilitates advanced process control for improved efficiency and reduced environmental impact. Providing a computationally efficient yet physically representative tool, this work advances the design of flexible bioenergy platforms aligned with low-carbon energy transitions, with future extensions envisioned in areal-time control integration for industrial-scale deployment.

## ABSTRACT

Traditional approaches for mechanistic modelling require in-depth understanding of the underlying chemical and physical phenomena to construct reliable and predictive models. However, at early stages of development, limited experimental data, incomplete expert knowledge, and non-observable states often hinder a full understanding of the underlying mechanisms. Symbolic regression (SR) enables systematic model discovery and offers a practical route to addressing these challenges by automating the identification of interpretable model structures and the estimation of associated parameters from available data. However, structural identifiability and observability (SIO), a critical property of such models, is often overlooked in SR, thereby limiting its broader adoption and effective deployment. To address these limitations, this study proposes a comprehensive framework, which leverages scarce prior knowledge in SR and incorporates SIO analysis, offering a potential solution to capture the effects of all state variables and ensure rigorous structure of the resulting models. The proposed strategy is demonstrated on a partially observed sulfide oxidation system, demonstrating how an SIO-assured model can be systematically identified from limited data and incomplete system knowledge. Overall, this work presents a potential pathway for extending model discovery to partially observed systems and enhancing model robustness, thereby positioning SR as an alternative tool with respect to traditional kinetic modeling strategies.

## 1. INTRODUCTION

The availability of robust mathematical models and digital twins constitutes a cornerstone of digital transformation across multiple industries [1, 2]. Mathematical models are essential for both off-line and real-time decision-making and underpin process design, optimization, scale-up, control, operation, and integration [3, 4]. The recent emergence of digitally driven paradigms for process and product quality and environmental sustainability, such as Green-by-Design and Quality-by-Digital-Design frameworks [5-7], has further reinforced the central role of mathematical models, particularly within the pharmaceutical industry. These recent shifts coincide with the broader adoption of continuous manufacturing technologies, collectively driving increased demand for high-quality mathematical models that support design space identification and exploration, start-up and shut down, and control strategies [8, 9]

Traditionally, the development of a mathematical model starts by postulating the inputs and outputs, then constructing the model equations which involve the unknown model parameters to be calibrated using experimental data. Often the underlying phenomena to be modelled are intricate, subject to limited measurements, non-observables, and expert bias. These challenges result in multiple model candidates which may require further benchmarking and discrimination procedures. However, the identification of affective model through the traditional route may demand extensive prior knowledge of

the system and domain expertise, which can be scarce especially for early-stage studies. More importantly, the optimality of the chosen kinetic expression is probably questionable since discrimination is normally restricted to a handful of manually crafted alternatives, while an exhaustive search remains prohibitively labor-intensive. On the contrary, data-driven models (e.g., response surface models, artificial neural networks) dispense with mechanistic assumptions and exhibit superior adaptability to the data supplied, offering accurate predictions within the training space. Nonetheless, they are known to be data-hungry and commonly difficult to extrapolate. In addition, they are operated as opaque black boxes with poor interpretability, which potentially hinders the comprehension of the underlying natural phenomenon.

The emergence of automated model discovery approaches is possibly delivering a way out of this impasse. Through automating the exploration and identification of the most appropriate model over a large combinatorial search space, the demand of human data-science expertise is minimized, thereby dramatically reduces the effort for the determination of the optimal set of model equations. In particular, symbolic regression (SR), a process that discovers parsimonious mathematical expressions from datasets, is a group of the most attractive approaches in automated model discovery. SR refers to the practice not only estimating the numerical coefficients of a pre-defined mathematical expression but also exploring the most appropriate functional forms describing the data [14], which fuses applied mathematics and machine learning to provide deep insights of the underlying relationship between the input, output and state variables with limited prerequisites of the model structure. Therefore, it is greatly beneficial to unveil the unknown governing equations of the systems that manifest complex or nonlinear behaviors. Hence, SR is rapidly becoming a catalyst for advanced model development. For instance, two automated model discovery frameworks (ADoK-S and ADoK-W) were developed for chemical reactions to automatically yield process models utilizing a Python-based deep SR toolbox PySR [11]. SR is also applied to discover the nucleation and growth expressions for a batch crystallization case of potassium sulphate, yielding highly resembling equations as the ones of standard method of moments, confirming the interpretability of the model and the effectiveness of the methodology [10]. Another SR implementation on crystallization process [15] leverages SINDy to obtain the nucleation and growth governing equations, which fitted well with the 1st and 2nd moments data but were not very satisfactory for 0th and 3rd moments, probably due to the invalidity of the inherent assumption of linear combination of the terms in SINDy. In a biological context, the kinetic model of a microbial fermentation was derived through implementing SR, which was then embedded in a multi-objective optimization to maximize cell biomass, protein titre and minimize batch time [10]. Experimental validation showed excellent agreement with model predictions, demonstrating the practical utility of SR in real-world bioprocesses.

SR is an extraordinary tool to uncover concise, predictive equations, yet most studies stop at goodness-of-fit and ignore structural identifiability and observability (SIO). Structural identifiability asks whether the parameters can be uniquely recovered from the observables, while observability determines whether unmeasured states can be uniquely inferred from the observables. Neglecting either property incurs ill-posed models that fit the training data yet yield unreliable predictions [17].

To bridge this gap, we couple PySR with the MATLAB-based toolbox STRIKE-GOLDD and its extension AutoRepar [16]. PySR is selected as the algorithm for model generation in this study due to greater flexibility in the functional forms and better compatibility to unmeasured states compared with SINDy. After PySR proposes a parsimonious model, STRIKE-GOLDD investigates it SIO, and the equations will be reparametrized by AutoRepar if any structural defect is pinpointed. The loop repeats until a structurally sound, data-efficient model is returned.

The resulting workflow furnishes an end-to-end pipeline from raw data to trustworthy equations, requiring minimal prior mechanistic insight and human intervention. We demonstrate its value on a partially observed sulfide-oxidation system [12], which starts from sparse measurements and recovers a compact, identifiable and observable high-fidelity model. By embedding SIO analysis inside SR, the approach offers a rigorous new paradigm for early-stage process development where data are scarce and mechanistic knowledge is limited.

## 2. METHODOLOGY

The proposed holistic framework which integrates the automated model discovery and SIO analysis for chemical reaction systems as shown in Figure 1. Initially, PySR is used to perform SR based on the measured data of the observables ($\boldsymbol{y}$), generating a large set of plausible concentration-time equations $\boldsymbol{y}(t)$. The $\boldsymbol{y}(t)$ with the lowest Akaike information criterion (AIC) is chosen, approximating the concentration evolution of the observed species. Thereafter, the concentration-time expressions for the entire set of state variables $\boldsymbol{x}(t)$ are derived from $\boldsymbol{y}(t)$ applying mass balance and stoichiometry, which allows the numerical computation of derivative values $\dot{\boldsymbol{x}}(t)$. Next, the evaluated $\dot{\boldsymbol{x}}(t)$ values are leveraged in couple with the measured data of $\boldsymbol{y}$ in the SR exploring $\dot{\boldsymbol{y}}(\boldsymbol{x})$ expressions using PySR. It is worth highlighting that $\dot{\boldsymbol{y}}(\boldsymbol{x})$ is the kinetic equations set describing the chemical reaction system. Afterwards, an AIC test is performed to find the top N

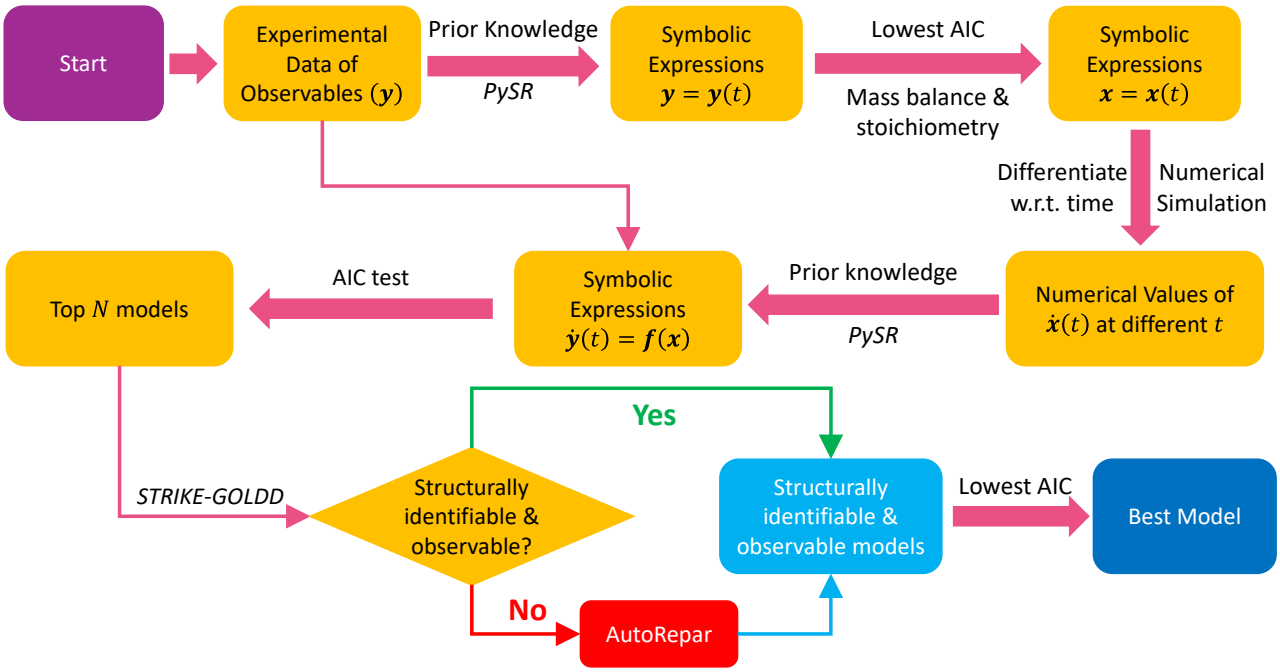

**Figure 1.** Proposed framework which integrates the automated model discovery and SIO analysis for chemical reaction systems.

models best fitting the data. The SIO of these models are scrutinized using STRIKE-GOLDD, while the models with structural defects will be reparametrized by AutoRepar. Eventually, the SIO-assured model with the lowest AIC is selected as the best model. This pipeline delivers models that both fit the data and exhibit rigorous structure, minimizing the requirement of prior mechanistic knowledge and domain expertise, thereby reducing human input to problem specification and data upload.

## 3. CASE STUDY

A sulfide oxidation reaction system [12] is selected as the case study, which involves four species: raw material methyl phenyl sulfide (R), desired product methyl phenyl sulfoxide (D), side-product methyl phenyl sulfone (U) and reactant hydrogen peroxide ($H_2O_2$). The main reaction and the side reaction are presented in Equations 1 and 2, respectively. An experimental study was conducted in [12], providing the concentration-time data of $\mathrm{R}, \mathrm{D}$ and $\mathrm{U}$, as depicted in Figure 2, while the initial concentration of $H_2O_2$ is 2.5 times as the initial concentration of $\mathrm{R}$. The process involves four state variables $\boldsymbol{x} = [\mathrm{R}, \mathrm{D}, \mathrm{U}, H_2O_2]$ and three observables $\boldsymbol{y} = [\mathrm{R}, \mathrm{D}, \mathrm{U}]$. The goal is to find the underlying rate equations of $\mathrm{R}, \mathrm{D}, \mathrm{U}$ and $H_2O_2$ based on the data provided.

$$\mathrm{R} + H_2O_2 \rightarrow \mathrm{D} + H_2O \quad (1)$$

$$\mathrm{D} + H_2O_2 \rightarrow \mathrm{U} + H_2O \quad (2)$$

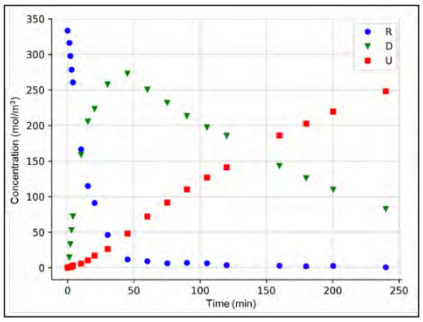

**Figure 2.** Experimental concentration-time data of methyl phenyl sulfide oxidation [12]. R: Methyl phenyl sulfide. D: Methyl phenyl sulfoxide. U: Methyl phenyl sulfone.

### 3.1. Obtain $\boldsymbol{y}(t), \boldsymbol{x}(t)$ and $\dot{\boldsymbol{x}}(t)$

The first step in the workflow is to obtain a concentration-time model for the observables denoted by $\boldsymbol{y}(t)$. Before running SR, it should be noticed that the atomic balance of sulfur can be given by Equation 3, where $\mathrm{R}_{\mathrm{ini}}$ the initial concentration of $\mathrm{R}$. Since $\mathrm{R}_{\mathrm{ini}}$ is a known constant, $\mathrm{U}$ can be treated as a dependent variable, thereby it is only necessary to symbolically regress $\mathrm{R}(t)$ and $\mathrm{D}(t)$. The PySR settings in this step are summarized in Table 1.

$$\mathrm{R}(t) + \mathrm{D}(t) + \mathrm{U}(t) = \mathrm{R}_{\mathrm{ini}} \quad (3)$$

By running SR, a series of mathematical expressions of $\mathrm{R}(t)$ and $\mathrm{D}(t)$ are obtained. In this case, 19 candidates for $\mathrm{R}(t)$ and 17 candidates for $\mathrm{D}(t)$ are identified by PySR, among which the expressions corresponding to the

**Table 1:** PySR settings for the discovery of concentration-time relationships

| Setting | Value | Description |
|---|---|---|
| niterations | 100 | Maximum number of iterations in symbolic regression |

(b)

**Figure 3.** Symbolically regressed reaction rate expressions of: (a) Methyl phenyl sulphide (R), (b) Methyl phenyl sulfoxide (D).

lowest AIC values are selected as the best concentration-time equations (Equations 4 and 5 below).

$$\mathrm{R}(t) = \frac{\exp(8.678)}{t+17.577+0.0732(\exp(0.192t)+t^2)} + \exp(1.469) \tag{4}$$

$$\mathrm{D}(t) = \exp\left(\exp\left(0.645 + \frac{t+114.992}{t+\frac{212.903}{t+1.676}+95.674}\right)\right) - 0.559t - 24.232 \tag{5}$$

With $\mathrm{R}(t)$ and $\mathrm{D}(t)$ determined, the mathematical expression of $\mathrm{U}(t)$ can be readily calculated using Equation 3. To derive $\mathrm{H_2O_2}(t)$, the mass balance can be implemented, deducing that the consumption of $\mathrm{H_2O_2}$ is equal to the sum of the consumption of R and the generation of U, resulting in Equation 6. As the initial concentrations of R ($\mathrm{R_{ini}}$) and $\mathrm{H_2O_2}$ ($\mathrm{H_2O_{2_{ini}}}$) are known, Equation 6 enables the calculation of $\mathrm{H_2O_2}$ value at any given time.

$$\mathrm{H_2O_2}(t) = \mathrm{H_2O_{2_{ini}}} - \left(\mathrm{R_{ini}} - \mathrm{R}(t)\right) - \mathrm{U}(t) \tag{6}$$

Therefore, $\boldsymbol{x}(t) = [\mathrm{R}(t), \mathrm{D}(t), \mathrm{U}(t), \mathrm{H_2O_2}(t)]$ is obtained, which allows the numerical computation of the $\dot{\boldsymbol{x}}(t)$ values at the sampling points, approximating the reaction rates

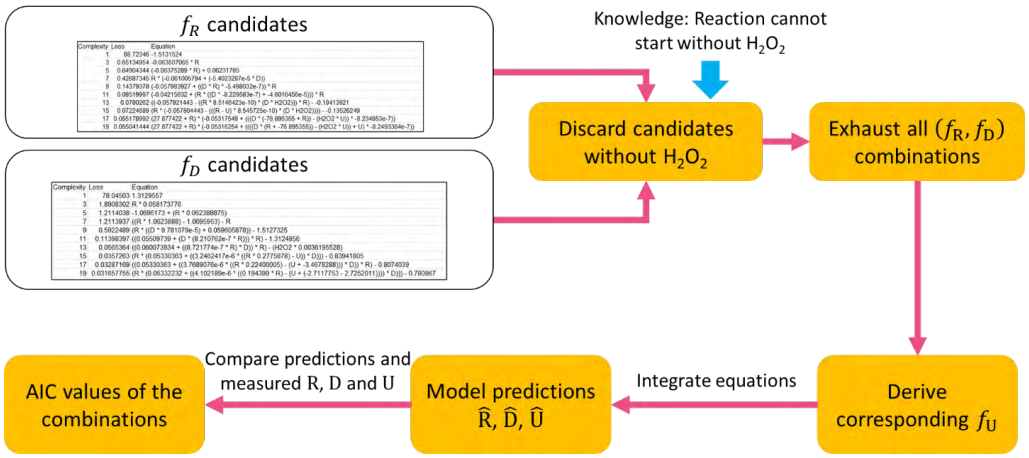

**Figure 4.** Procedure to construct valid rate model candidates and calculate the AIC values.

for each species in the experiment. The measured of $\mathrm{R, D, U}$ data, the simulated $H_2O_2$ values, together with the simulated $\dot{\boldsymbol{x}}(t)$ values at the sampling points, are subsequently used in the next step discovering the $\dot{\boldsymbol{y}}(\boldsymbol{x})$ mathematical expressions.

## 3.2. Derive $\dot{\boldsymbol{y}}(\boldsymbol{x})$

As emphasized in section 3.1, $\mathrm{U}$ and $H_2O_2$ are dependent on $\mathrm{R}$ and $\mathrm{D}$, thus it is only necessary to attain the mathematical expressions $\dot{\mathrm{R}} = f_{\mathrm{R}}(\mathrm{R, D, U}, H_2O_2)$ and $\dot{\mathrm{D}} = f_{\mathrm{D}}(\mathrm{R, D, U}, H_2O_2)$ via SR, which are the reaction rate equations sought in this study. Compared with the settings for seeking the concentration-time relationships (Table 1), the settings for the SR of the reaction rate equations ($f_{\mathrm{R}}$ and $f_{\mathrm{D}}$) apply a deeper search, which raises the maximum number of iterations from 100 to 150 and the population size from 100 to 200. Furthermore, the division operator and the exponential operators are disabled, as they are rarely seen in rate laws. Moreover, the complexity cap is tightened from 30 to 20, reflecting the parsimony of natural kinetics.

Figure 3 presents the resulting $f_{\mathrm{R}}$ and $f_{\mathrm{D}}$ candidates given by SR. Some mathematical expressions do not contain $H_2O_2$ in the terms, violating the knowledge that the reaction cannot start without its existence. Thus, the expressions without $H_2O_2$ are discarded.

Thereafter, an exhaustive mapping is carried out to construct all possible $(f_{\mathrm{R}}, f_{\mathrm{D}})$ combinations from expressions that pass the screening and derive the corresponding $f_{\mathrm{U}}$. The resulting model candidates, consisting ordinary differential equations, are integrated with respect to time, giving the predicted $\hat{\mathrm{R}}, \hat{\mathrm{D}}$ and $\hat{\mathrm{U}}$ at the sampling times. Afterwards, the AIC values are calculated by leveraging the measured data of $\mathrm{R, D}$ and $\mathrm{U}$. This procedure is graphically presented in Figure 4.

## 3.3. SIO Analysis & Best Model Selection

Utilizing the MATLAB-based tool STRIKE-GOLDD, the SIO of the 10 model candidates with the lowest AIC values are analyzed, where the models with structural defects will be reparametrized by AutoRepar to fix this issue. Note that the AIC of the reparametrized models are re-computed, since the number of model parameters have changed. Eventually, the best kinetic model is selected among these SIO-assured models based on the updated AIC values. The rate equations of the best model are given by Equations 7 to 10, with the parameter values presented in Table 2. The SIO of this model is guaranteed, as evidenced by the SIO analysis records presented in Figure 5. Moreover, this model has an outstanding prediction performance as demonstrated in Figure 6. Hence, a high-fidelity and structurally rigorous reaction rate model is obtained in this case study.

$$\dot{\mathrm{R}} = p_1 + (p_2 - p_3 \cdot \mathrm{R} \cdot \mathrm{D} \cdot H_2O_2) \cdot \mathrm{R} \tag{7}$$

$$\dot{\mathrm{D}} = (p_4 + p_5 \cdot \mathrm{R} \cdot \mathrm{D}) \cdot \mathrm{R} - p_6 \cdot H_2O_2 \tag{8}$$

$$\dot{\mathrm{U}} = -(p_1 + (p_2 - p_3 \cdot \mathrm{R} \cdot \mathrm{D} \cdot H_2O_2) \cdot \mathrm{R}) - ((p_4 + p_5 \cdot \mathrm{R} \cdot \mathrm{D}) \cdot \mathrm{R} - p_6 \cdot H_2O_2) \tag{9}$$

$$\dot{H_2O_2} = 2(p_1 + (p_2 - p_3 \cdot \mathrm{R} \cdot \mathrm{D} \cdot H_2O_2) \cdot \mathrm{R}) + ((p_4 + p_5 \cdot \mathrm{R} \cdot \mathrm{D}) \cdot \mathrm{R} - p_6 \cdot H_2O_2) \tag{10}$$

**Table 2:** Parameter estimates of the best rate model

| Parameter | Value | Unit |
|---|---|---|
| $p_1$ | 0.194 | $mol \cdot m^{-3} \cdot min^{-1}$ |
| $p_2$ | $-5.79\times10^{-2}$ | $min^{-1}$ |
| $p_3$ | $-8.51\times10^{-10}$ | $mol^{-3} \cdot m^{-9} \cdot min^{-1}$ |
| $p_4$ | $6.01\times10^{-2}$ | $min^{-1}$ |
| $p_5$ | $8.72\times10^{-7}$ | $mol^{-2} \cdot m^{-6} \cdot min^{-1}$ |
| $p_6$ | $-3.62\times10^{-3}$ | $min^{-1}$ |

## 4. CONCLUSION

An integrated workflow coupling SR with joint SIO analysis is proposed and demonstrated through a partially observed sulfide oxidation case study. By embedding scarce prior knowledge and limited experimental

data, the approach returns a model that simultaneously fits the data and preserves rigorous structure. In contrast to purely data-driven SR pipelines, which often yield non-identifiable or structurally inconsistent models, the proposed framework systematically filters candidates based on identifiability and observability, leading to a substantially reduced and more interpretable model space. Relative to conventional mechanistic model

development, the workflow achieves comparable structural guarantees while requiring markedly less a priori specification, thereby improving robustness and credibility in early-stage process modelling where data and mechanistic insight are both limited.

## ABSTRACT

This work presents the scale-up and detailed analysis, including comparison of relevant key performance indicators (KPIs) and energy analysis, of three innovative technologies for producing biomethane and its subsequent upgrading. The SEMPRE-BIO project tested and validated three different innovative technologies and pilots within the Horizon Europe framework. The three pilots are in Spain (biomethanation of biogas from wastewater treatment fermentation), France (biomethanation of syngas from biomass gasification), and Belgium (purification of biogas from manure anaerobic digestion). The three case studies will be presented and discussed. The analysis will dive into the layout of the optimised process layout of the scale-up plants as well as an exhaustive comparison, presenting advantages, shortcomings and bottlenecks of each technology, accounting for the main KPIs, i.e., electricity and steam demand, consumables including cooling water and others specific to the technologies.

## INTRODUCTION

Biomethane (bio-$CH_4$) is gaining attention for its application as fuel and feedstock in chemical synthesis [1-4]. Currently, replacing natural gas with bio-$CH_4$ is part of the EU's decarbonisation strategy. The implementation of a large and integrated biogas network should increase the EU's energy independence and resilience to market shocks and shortages [5]. Biogas is produced via anaerobic fermentation. It contains mainly wet bio-$CH_4$ and biogenic $CO_2$ (bio-$CO_2$), but, in minor content, also pollutants, such as $NH_3$ and $H_2S$ [5, 6]. As for natural gas, biogas needs purification to meet specifications for use and/or transport. The purification of biogas, i.e., dehydration, cleaning, and removal of bio-$CO_2$, is the most straightforward strategy [7]. Direct biomethanation of biogas [8] or (bio)syngas [9] is becoming appealing to boost bio-$CH_4$ yield and site productivity, but challenges are to be fixed [10]. SEMPRE-BIO project, funded under the EU's Horizon Europe program, aims to secure domestic production of cost-effective bio-$CH_4$. For this reason, pilots for three technologies have been run at different locations using different feedstocks. The general scope is increasing the European portfolio, adding more options for bio-$CH_4$ production and unlocking the biogas economy. The proposed technologies covered either biomethanation with downstream cleaning or biogas purification. For all case studies, the focus was on validating the concepts and debottlenecking their deployment. This work presents the three case studies (CSs), the results from process simulations, and compares the technologies regarding to the most relevant key performance indicators (KPIs).

## MATERIALS AND METHODS

### Case studies presentation

This section presents the case studies (CSs) and the corresponding processes. For each demo site, the block flow diagram (BFD) and model assumptions are reported. All process simulations have been performed in COCO COFE V3.10 using both conventional units and custom-based solutions.

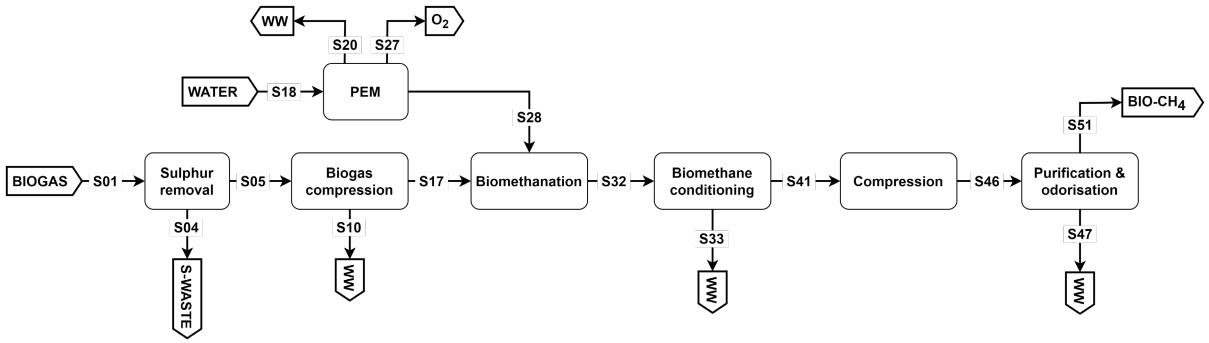

**Figure 1.** CS1 (Spain) - BFD

## Case Study 1 (CS1) - Spain

### Process description

Figure 1 depicts the BFD for the demo site in Spain to validate the direct biomethanation of cleaned biogas. The produced bio-$CH_4$ is expected to meet quality for fuelling public transport vehicles. The raw biogas comes from the fermentation of wastewater treatment sludge. The resulting raw biogas (S01) is desulfurised and the cleaned biogas (S05) compressed to 7 bar(a) and partially dehydrated (S17). The compressed biogas is sent to the biomethanation reactor, where $H_2$ from a proton-exchange membrane (PEM) module (S28) is fed and consumed. The relative ratio between $H_2$ and $CO_2$ is sensitive. The resulting gas mixture (S32), rich in bio-$CH_4$, is post-treated and conditioned to reduce its moisture content below the target value. Bio-$CH_4$ (S41) is compressed to the desired pressure based on storage and final user requirements. For this case, we considered 250 bar(a). The compression further refines the water content in the final product (S51).

### Model assumptions

For the simulation of this case study, the following assumptions have been adopted:

- Redlich-Kwong-Soave (RKS) cubic equation of state has been used to model both the liquid and gas phases.
- The desulphurisation unit has been designed as a splitter with assigned efficiency, whose value has been assigned based on the average value from literature and providers [6, 11].
- Compressors and pumps have been simulated with an assigned total efficiency of 75% (accounting for both mechanical and polytropic factors).
- The PEM electrolyser has been modelled as a simplified unit where cathode and anode reactions occur in a reactor at a fixed conversion of water. The conversion is a function of the operating temperature of the electrolyser. In addition, reaction efficiency has been considered based on the suggested value from the provider (ProPuls). This approach was already adopted in other studies [12, 13].
- Biomethanation reactor has been simulated as a reactor with fixed conversion for the limiting reactant (bio-$CO_2$). The average $CO_2$ conversion for thermophilic bacteria consortia has been retrieved from experimental evidence and the literature [14].

## Case Study 2 (CS2) - France

### Process description

Figure 2 shows the BFD for the demo site in France, for the biomethanation of biosyngas from woody biomass gasification. The chips (S01) are fed to the gasification. Steam is not supplied as the solid presents a high content of moisture, and steam is produced during the heating. The gasification chamber is run at 700-750°C under autothermal conditions. The solid (char) is discharged from the chamber, while the hot raw gas leaves the gasifier (S15). The sensible heat of S15 is recovered to sustain the gasification. The recovered heat is insufficient as gasification is highly endothermic. The remaining energy demand is covered with the combustion of a fraction of the produced biosyngas (S31). The raw biosyngas (S20) is conveyed to a cleaning unit to refine the tars and pollutants content. The cleaned syngas (S22) is split into two streams. One fraction (S31) is pre-mixed with air (S32) and burnt. The remaining (S23) is fed to a biomethanation reactor. Conversely to CS1 (biogas as feed), bio syngas contains $H_2$. Hence, two alternatives for the biomethanation have been considered: with co-feed of extra $H_2$ from an electrolyser (CS2-A) and without supplying outsourced $H_2$ (CS2-B). The resulting gas mixture (S28) is purified to deliver the best purity for bio-$CH_4$ (S30). During the cooling and purification condenses are generated. These streams are sent to wastewater treatment, not been considered in our simulations.

### Model assumptions

For the simulation of this case study, the following assumptions have been adopted:

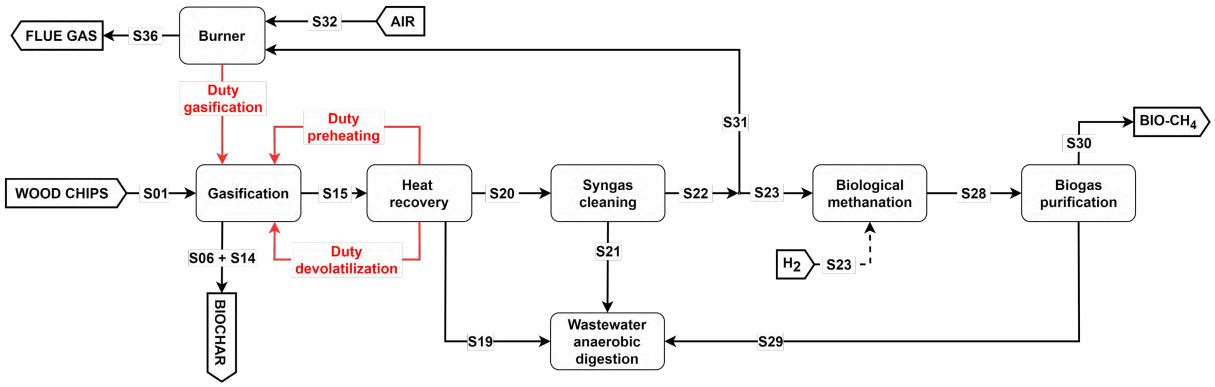

**Figure 2.** CS2 (France) - BFD

- The same equation of state has been used.
- Elemental and proximate analyses are considered to characterise the feedstock (sensitive).
- Gasification involves a complex chemistry with hundred thousand of species and reactions. The thermochemical process has been simulated considering the different steps of gasification, i.e., heating, devolatilization, pyrolysis, tar cracking, tar reforming, and secondary gas-phase lumped reaction. Details on model and preliminary validation are available [15].
- Syngas cleaning and biomethanation reactor have been simulated as for CS1.
- The fraction of burnt biosyngas is adjusted to reach autothermal conditions in the gasifier. Air is the comburent, in 10% excess. The flue gas leaves the burner at 850°C to mimic flame temperature and ensure that heat is supplied to the gasification chamber (operated at 700-750°C).

## Case Study 3 (CS3) - Belgium

### Process description

The process and the refrigeration strategies are described with more details in the paper *"Energy recovery from process purges: steam turbine integration and operation optimisation in biogas upgrading within SEMPRE-BIO project"*, which is the complement of this work. Figure 3 depicts the three process layouts considered in the analysis. The proposed BFDs differ for the "cold box". The remaining part of the process is kept unchanged. Manure (S1-01) is digested, resulting in the slurry digestate (S1-04) and raw biogas (S1-07). The produced biogas is purified from $H_2S$ and $NH_3$, then dehydrated and compressed (S1-19). Its residual moisture is reduced in triethylene glycol (TEG) absorption below 3 ppm vol. Dry biogas (S3-01) leaves the absorber, and a bio-$CH_4$-rich stream, the top of the stripper of TEG regeneration. This stream is post-treated in a membrane to recover part of the bio-$CH_4$. Pure bio-$CH_4$ is recirculated to the stripper. Injecting hot methane as stripping gas in TEG regeneration is an industrial practice to improve TEG purity from 98 to >99.9 wt%, without outsourcing heat. Unrecovered bio-$CH_4$ (S2-34) is burnt to generate steam for the turbines. The dry biogas (S3-01) is cooled and S3-02 conveyed to the cryogenic distillation: part of the bio-$CO_2$ is recovered as pure liquid (>99.99 vol%) from the bottom, while bio-$CH_4$-enriched stream (S3-11 with $CO_2$ ~80 vol%) is sent to a membrane cascade to purified until outlet gas (S4-04) reaches a residue $CO_2$ content below 50 ppm (vol), respecting the specifications for grid injection. The membranes work at ambient temperature. The permeated gas is enriched in $CO_2$ but contains bio-$CH_4$ as $CO_2$ permeation is favoured. Part of the permeate is recycled internally, while the purge (S4-12) is cooled and recycled to the cryogenic distillation. Pure bio-$CH_4$ is cooled and conveyed to the $CH_4$ liquefaction process (S5-01), where the expansion (Joule-Thomson effect) generates the frigories to liquefy part of the bio-$CH_4$ (S5-03). The not liquefied fraction (S5-20) is purged. The purges, S2-34 (from TEG dehydration) and S5-20 (from bio-$CH_4$ liquefaction), are burnt. The combustion of these streams produces heat for steam and power production. Part of the steam is used for the regeneration of TEG solvent (topic of the complementary paper).

### Refrigeration strategies

Figure 3 shows three layouts depicting three alternatives to manage the refrigeration and keep the cold box of the system:

- Option A (single loop): the total cooling demand is covered using a hydrocarbon (HC) mixture as working fluid. The HC blend contains $C_2$-$C_3$ hydrocarbons. The relative ratio of $C_2$-$C_3$ has been tuned to keep the cold box minimum temperature (sensitive).
- Option B (double loop): the same mixture is used

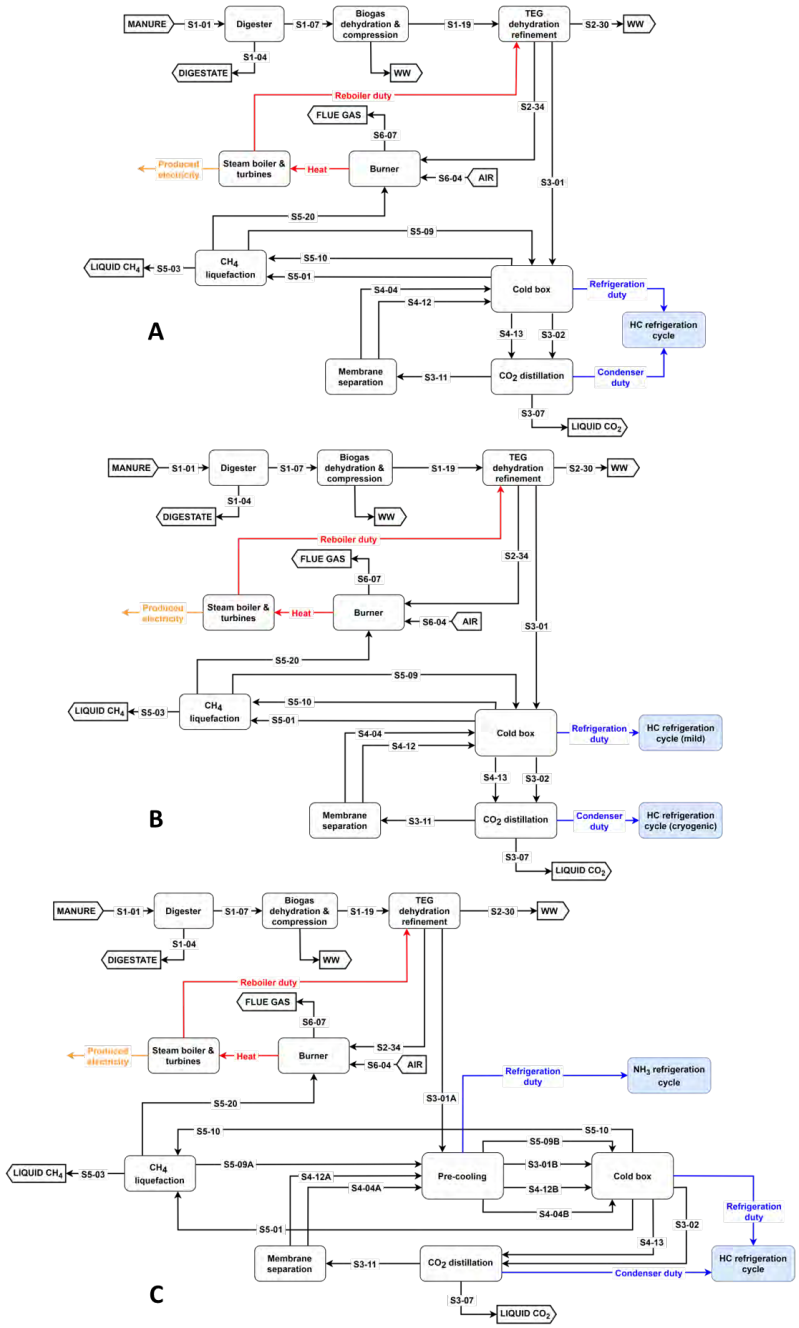

**Figure 3.** CS3 (Belgium) - BFDs

as working fluid but split into two independent mild refrigeration loops. In the first refrigeration loop (named as loop), all warm streams are precooled from ambient temperature (25-30°C) to reach the same intermediate temperature of the gas leaving the top of the cryogenic column. This temperature is sensitive and is not reported. In the second refrigeration loop (named as cryo loop), all the streams are cooled to the final desired temperature (sensitive).

- Option C (double loop with two refrigerants): is like Option B, but all warm streams are pre-cooled to the same intermediate temperature using ammonia for the mild loop. The temperature is reduced to the final target value in a second refrigeration cycle, using the same HC mixture as for options A and B.

## Model assumptions

The following assumptions are considered:

- Biogas flow and volumetric composition are assigned (sensitive).
- The same efficiency for pumps and compressors, $H_2S$ and $NH_3$ removal as for CS1 and CS2.
- The template for TEG has been retrieved from examples and ready-to-use flowsheets available in COCO COFE webpage [16].
- The membranes are modelled as a Python-based custom module integrated within the flowsheet. Permeance and selectivity for an industrial membrane are retrieved from the literature [17].
- Other model assumptions related to the refrigeration cycles and the steam turbine are available in the mentioned work.

## Technology assessment: definition of key performance indicators (KPIs)

The three technologies have been assessed both individually and in comparison. The specific KPIs for each case study (CS) will be discussed in the dedicated section to contrast our results with pieces of evidence from prior literature. This analysis has been carried out to show the consistency of the implemented models. Regarding the comparison of the three technologies, the assessment has been structured to fairly compare them in terms of net production and other relevant indices. The demo sites validate different concepts with different solids starting feedstock, capacity, scale, and target. Hence, their direct comparison through extensive properties would be misleading. In addition, CS1 and CS2 include biomethanation, whereas purification of biogas is the core of CS3. For this reason, the analysis focuses on the net (dry) bio-$CH_4$ production per unit of both dry solid feedstock and volume of dry biogas or biosyngas. Here, biosyngas is considered because CS2 consider gasification of woody biomass and not biogas from solid waste fermentation. Remarkably, both bio-$CH_4$ and the reference solid/gas feedstock are considered on a dry basis. The bio-$CH_4$ purity, electricity demand, and cooling water consumption are other relevant parameters. Remarkably, the PEM electrolyser is considered for both CS1 and CS2A to supply green $H_2$. For these cases, the electrolyser demand is set from the simulation. The average demand for electrolysis is ~56 kWh/$kg_{H2}$, in line with literature and technical reports [18-20]. Regarding cooling water demand, the source is assumed at 20°C and the maximum allowable discharge temperature is set 30°C.

# RESULTS AND DISCUSSION

## Simulation results

This section will show and comment on the results from the simulations. In the first part, each case study will be discussed. Finally, an overview and comparison based on KPIs of the different case studies is addressed.

### CS1 results

The most relevant property of the compressed bio-$CH_4$ is its dew point ($T_{dew}$) at 250 bar(a). This is the storage pressure of the product for end-user usage (fuel for public transport). The dew point is directly proportional to the purity of delivered bio-$CH_4$ and the content of impurities. CS1 can deliver compressed bio-$CH_4$ with a purity of 98.45 vol%. The dew point of the gas mixture has been calculated based on the Redlich-Kwong-Soave model. It corresponds to -60.5°C, meaning that the level of other impurities (moisture, $H_2$, and $CO_2$) is kept below the threshold value. The estimated dew temperature respects the European standard EN 16723-2:2017 for compressed natural gas for the use of Bio-CNG (compressed natural gas) as an automotive fuel stored at 200–250 bar.

### CS2 results

Table 1 summarises the results related to the steam gasification of the woody biomass. The main KPIs are the gas yield, i.e, the amount of dry gas produced per unit of mass of dry solid, the volumetric composition of the syngas (still on a dry basis) limited to $H_2$ and $CH_4$, and the corresponding $H_2/CO_x$, defining the excess of $H_2$ compared to the sum of $CO_2$ and CO. In addition, the analysis considers the tar yield, the energy input, defined as the total amount of heat supply to the gasifier per unit of dry solid, and the heating values (both high and low). The results have been compared to experimental works and review papers referring to steam gasification [20-21]. The mentioned references confirm that the obtained values are aligned with experimental values and ranges for softwood biomass.

**Table 1:** Overview of CS2: KPIs for biomass pyrolysis (all values refer to dry product and feedstock)

| KPI | Value | References |
|---|---|---|
| Gas yield | 1.23 $Nm^3_{syngas}/kg_{solid}$ | [20, 21] |
| $H_2$ content | 50.9 vol% | [20, 21] |
| $CH_4$ content | 6.10 vol% | [20, 21] |
| $H_2/CO_x$ | 1.18 vol/vol | [20, 21] |
| Char yield | 0.25 $kg_{char}/kg_{solid}$ | [20, 21] |
| Tar yield | 17.7 $g_{tar}/kg_{solid}$<br>14.4 $g_{tar}/Nm^3_{syngas}$ | [20, 21] |
| Energy input/ demand | 1.02 $kWh_{th}/kg_{solid}$ or 3.66 $MJ_{th}/kg_{solid}$ | [20, 21] |
| HHW | 12.35 $MJ/Nm^3_{syngas}$ | [20, 21] |
| LHW | 10.60 $MJ/Nm^3_{syngas}$ | [20, 21] |

Finally, Table 2 gathers the main performance of the technology, including the biomethanation process. For CS2, two different configurations have been considered: with (CS2A) and without (CS2B) extra green $H_2$ supplied

to the biomethanation.

Remarkably, the results show that the $H_2$ in the biosyngas is not sufficient to run the biomethanation to full depletion of $CO_x$. Hence, extra $H_2$ boosts the productivity of the system; thus, the purity and concentration of bio-$CH_4$ in the product mixture. The moisture content is still large for transport and use. Therefore, a deep dehydration step should be considered. Beyond this consideration, the analysis highlights the need to combine $H_2$ production with woody biomass gasification.

**Table 2:** Overview of KPIs of CS2 (all values refer to dry bio-$CH_4$ and solid feedstock)

| KPI | CS2A | CS2B |
|---|---|---|
| Productivity | 0.32 $Nm^3_{CH4}/kg_{solid}$ | 0.15 $Nm^3_{CH4}/kg_{solid}$ |
| $H_2$ addition | 1.91 $Nm^3_{H2}/Nm^3_{CH4}$ | Not available |
| $CH_4$ purity | 95.2 vol% | 45.0 vol% |
| Impurities | | |
| $CO_2$ | 0.03 vol% | 30.1 vol% |
| CO | 0.07 vol% | 20.6 vol% |
| $H_2$ | 0.34 vol% | < 100 ppmv |
| $H_2O$ | 4.34 vol% | 4.34 vol% |

## CS3 results

CS3 is the only demo site where direct biogas purification is performed. Compared to alternative processes such as amines [22], the technology validated in CS3 enables the delivery of both pure bio-$CH_4$ and bio-$CO_2$ (purity > 99.99 vol%). This is the main advantage of this new cryogenic system. Other relevant results refer to the integration of boiler and steam turbines, and how the selection of refrigerant and the refrigeration cycle layout affect the energy balance of the system. This paragraph will briefly summarise the main results. More details are reported in *"Energy recovery from process purges: steam turbine integration and operation optimisation in biogas up-grading within SEMPRE-BIO project"*. The analysis showed that keeping the cold box through a refrigeration cycle is energy-demanding. Compression of refrigerants accounts for 34 to 37% of the total electricity demand. The implementation of two independent refrigeration loops (Option B and C) lowers the electricity demand. Using ammonia as a refrigerant in the mild loop (Option C) further drops the electricity demand and valorising waste streams is needed to mitigate the energy demand of the overall process. The simulations highlight that the steam cycle allows for recovering up to 10% of the total electricity demand of the upgrading plant.

## Processes comparison

Table 3 highlights the main results of the global KPIs of the CSs, including all process configurations. Looking at the results, it is possible to draw the following conclusions:

- Woody biomass has the highest gas yield, meaning that it is the feedstock that releases the largest amount of gas (biosyngas) per unit of solid. Gasification indeed is an efficient technology to convert solids into syngas. Unfortunately, the same information is not available for wastewater sludge due to missing data related to the efficiency of the sludge fermentation.
- Apparently, biomethanation of biogas from sludge fermentation is the most productive route. It is worth remarking that for CS1 (but also CS2A), the total productivity is boosted due to the addition of green $H_2$ (in excess to the stoichiometric amount) to run the biomethanation. Conversely, for CS3, the productivity is the net productivity of the system because bio-$CH_4$ is recovered from biogas directly.
- The electricity consumption of the three technologies is completely different. Whenever biomethanation is part of the process, most of the electricity demand is concentrated in the green $H_2$ production. For CS3, the energy demand covers the compression of biogas and the energy for the refrigeration cycles (refrigerant compression). If PEM energy demand is disregarded, CS3 consumes almost 10 times more energy than other options.
- Directly from the previous comment, it is evident that biomethanation is an effective solution to produce bio-$CH_4$ from both biogas and biosyngas. The technology enables a substantial conversion of COx into CH4, thereby breaking the thermodynamic equilibrium and operating the system at thermophilic conditions (milder temperatures, e.g., ~50-55°C). However, despite this advantage, $H_2$ demand is still relevant and represents one of the bottlenecks of the technology.
- Cooling water demand is in the same order of magnitude for all the considered processes. This parameter is less relevant to the present analysis as it highly depends on the operative condition. Anyway, there are no significant differences in electricity demand.

Regarding CS3, it is worth underlining that the electricity demand covers both the refrigeration cycle and the compression of biogas; more in general, the overall electricity demand to deliver both pure pressurised bio-CH4 and bio-CO2 (99.99+ vol% purity). Refrigeration covers from 34 to 37% of the total energy depending on refrigerant and cycle configuration. The process up to bio-CH4 purification, i.e., disregarding liquefaction of bio-CH4, consumes 1.70 $kWh_{el}/Nm^3_{biogas}$ and 0.15 $kWh_{th}/Nm^3_{biogas}$.

**Table 3:** Overview of KPIs of all CSs

| | Solid feed-stock | Biogas/ Biosyngas pro-duced | Bio-$CH_4$ production[1] | Bio-$CH_4$ purity (vol%) | Electricity de-mand (w/o PEM)[2, 3] [$kWh_{el}/Nm^3_{CH4}$] | Cooling Water (CW) demand [$t_{CW}/Nm^3_{CH4}$] |
|---|---|---|---|---|---|---|
| CS1 | Sludge | Not Available | 0.709 $Nm^3_{CH4}/Nm^3_{biogas}$ | 98.5 | 11.9 (0.30) | 0.174 |
| CS2A (extra $H_2$) | Woody biomass | 1.23 $Nm^3_{syngas}/kg_{solid}$ | 0.260 $Nm^3_{CH4}/Nm^3_{biosyngas}$ 0.320 $Nm^3_{CH4}/kg_{solid}$ | 95.2 | 10.1 (0) | 0.523 |
| CS2B (no extra $H_2$) | Woody biomass | As CS2A | 0.122 $Nm^3_{CH4}/Nm^3_{biosyngas}$ 0.150 $Nm^3_{CH4}/kg_{solid}$ | 45.0 | 0 | 0.804 |
| CS3 Option A | Manure | 3.80 $Nm^3_{biogas}/t_{solid}$ | 0.591 $Nm^3_{CH4}/Nm^3_{biogas}$ 0.09 $Nm^3_{CH4}/kg_{solid}$ | 99.99+ | 2.21 | 0.374 |
| Option B | Manure | As Option A | As Option A | As above | 2.15 | 0.207 |
| Option C | Manure | As Option A | As Option A | As above | 2.10 | 0.205 |

[1] Referred to dry biogas/biosyngas
[2] Assuming PEM consuming 56 $kWh_{el}/kg_{H2}$
[3] Energy recovered from turbine is included (only CS3)

Recent literature investigated several amine systems for upgrading biogas [22].

This work reports on average 0.15 $kWh_{el}/Nm^3_{biogas}$ and 0.28 $kWh_{th}/Nm^3_{biogas}$ but neglects the compression and purification of $CO_2$ and bio-$CH_4$. The purity of bio-$CH_4$ is poor, ranging 90-95 vol%; hence, further refinement is needed. This comment holds also for bio-$CO_2$ which can contain acid pollutants ($H_2S$) and degradation products. The purification and compression of $CO_2$ is expensive: values reported in the literature does not represent the actual energy cost for delivering bio-$CH_4$ matching market specification. The analysis is limited to the bulk separation of $CO_2$ from biogas. Moreover, the technology tested in the SEMPRE-BIO project (Cryo Inox's patent) allows for delivering both $CH_4$ and $CO_2$ pure and liquid to ease their transport. $CO_2$ liquefaction is always neglected in articles dealing with the biogas upgrading.

## CONCLUSION AND FUTURE WORK

This work presented the results of the process simulation and comparison for three technologies for bio-$CH_4$ production. The analysis showed that biomethanation of both biogas and biosyngas is a valuable opportunity to convert bio-$CO_2$ into bio-$CH_4$. However, this option is still under investigation and constrained to the availability of cheap green-$H_2$. Despite this potential limitation, it is worth noting that biomethanation can increase overall production of the site. Biogas upgrading is a well-established technology to purify bio-$CH_4$. The SEMPRE-BIO project validates a new option with cryogenic distillation. The analysis showed more efforts should focus on reducing the energy demand. This work is limited to the technical analysis of the three technologies. However, it is important to note that the analysis should be more holistic, accounting for integrated techno-economic and life-cycle assessments to address the economic and environmental aspects. Only a complete analysis encompassing all these aspects allows for leveraging advantage and identifying bottlenecks. This holistic analysis will be finalised later within the project.

## ABSTRACT

Power-to-ammonia (P2A) provides a carbon-free alternative to conventional ammonia production by replacing fossil-based feedstocks with electrolytic hydrogen and nitrogen from air separation. For decentralized P2A systems, pressure swing adsorption (PSA) offers a flexible alternative to cryogenic air separation. However, its industrial implementations are largely proprietary, and open, first-principles models capable of simulating its cyclic, nonlinear transport are scarce in literature. This work presents a first-principles, dynamic, one-dimensional model of a PSA superstructure for nitrogen generation, formulated with thermodynamically consistent equations of state, coupling multicomponent mass, energy, and momentum balances with kinetically limited adsorption on carbon molecular sieves. The resulting system of partial differential-algebraic equations is semi-discretized using the finite volume method, integrated using diagonally implicit Runge-Kutta methods, and cyclic steady states (CSS) are computed via shooting-based solution methods. The framework is implemented in Julia, combining analytical derivatives with automatic differentiation and utilizing sparse linear algebra for efficient solution of the arising large nonlinear systems. The framework is demonstrated on a two-bed PSA cycle for air separation, comparing spatial and temporal discretization strategies, CSS solution methods, and the effects of ideal versus real-gas thermodynamics on predicted nitrogen purity and recovery. The proposed framework establishes an extensible basis for PSA simulation and optimization.

## INTRODUCTION

Conventional ammonia production relies on the famous Haber–Bosch process, combining nitrogen with hydrogen derived from fossil-based syngas. The resulting grey ammonia, of which approximately 80% is used for fertilizer production, accounts for about 4.5% of global industrial $CO_2$ emissions [1]. To mitigate this environmental impact, power-to-ammonia (P2A) has emerged as a carbon-free alternative, replacing fossil-based hydrogen with hydrogen produced by water electrolysis and sourcing nitrogen from atmospheric air. When powered by renewable electricity, P2A enables the production of green ammonia, which can serve both as a carbon-free hydrogen carrier and as a potential maritime fuel.

Nitrogen is traditionally produced by large-scale cryogenic air separation. However, for the smaller and decentralized production units envisioned in P2A systems, pressure swing adsorption (PSA) offers a flexible alternative. PSA achieves high-purity (95%+) nitrogen through cyclic adsorption and desorption of air components on carbon molecular sieves (CMS). Despite its widespread industrial adoption, PSA process design remains largely proprietary, and the open literature, often relying on commercial simulators, offers limited first-principles models capable of simulating its inherently cyclic operation. This limitation is exacerbated by strong multiscale coupling between transport, adsorption kinetics, and thermodynamics, making systematic computation of cyclic steady states (CSS) especially challenging.

Motivated by these gaps, this work develops a first-principles adsorption column model and superstructure for PSA-based nitrogen generation, which, using well-established numerical discretization methods, enables systematic computation of thermodynamically consistent cyclic operation.

## ADSORPTION COLUMN MODEL

We model adsorption columns with fixed beds composed of carbon molecular sieve pellets, specifically the commercial Takeda 3A CMS adsorbent. Parameters describing the adsorbent are given in the digital supplementary material. We model the adsorption column as a cylinder with length $L$ on the axial interval domain $\Omega = [0, L]$. We study a set of components $\mathcal{C} = \{\mathrm{N}_2, \mathrm{O}_2, \mathrm{Ar}\}$ representative of the composition of air (78%, 21%, 1%). To model the adsorption process, the column is treated heterogeneously and divided into a mobile phase and a stationary phase with porosity $\varepsilon$. Accordingly, the column volume $V$ holds the gaseous volume $V_{\mathrm{gas}} = \varepsilon V$, and the ratio between the gaseous and stationary volumes is given by $\varphi = \varepsilon/(1-\varepsilon)$. We denote mobile-phase concentrations by $c = [c_\alpha]_{\alpha\in\mathcal{C}}$, and stationary-phase concentrations by $q = [q_\alpha]_{\alpha\in\mathcal{C}}$. Moreover, we let $u$ denote the pseudo-homogeneous total internal energy density, accounting for both the mobile and stationary phases. The mass and energy balances of the adsorption column are then summarized by a system of one-dimensional transport equations subject to thermodynamic constraints

$$\partial_t c = -\partial_z N + R, \tag{1a}$$

$$\partial_t u = -\partial_z E + Q. \tag{1b}$$

Here, $N = [N_\alpha]_{\alpha\in\mathcal{C}}$ denotes the molar fluxes, $R = [R_\alpha]_{\alpha\in\mathcal{C}}$ the adsorption rates, $E$ the heat flux, and $Q$ the heat transfer rate.

### Thermodynamics

We introduce thermodynamic functions to evaluate bulk gas-phase properties. Assuming local thermodynamic equilibrium, the thermodynamic state is characterized by the local temperature, pressure, and composition of the system. While the composition is distributed between the mobile and stationary phases, the temperature and pressure are common to both phases. A gas phase with temperature $T$, pressure $P$, and moles $n = [n_\alpha]_{\alpha\in\mathcal{C}}$, can be described by thermodynamic functions

- Volume: $\mathcal{V}(T, P, n)$
- Enthalpy: $\mathcal{H}(T, P, n)$
- Internal energy: $\mathcal{U}(T, P, n)$

provided by an equation of state (EOS). The thermodynamic functions satisfy standard identities. In particular, they are related by

$$\mathcal{U}(T, P, n) = \mathcal{H}(T, P, n) - P\,\mathcal{V}(T, P, n). \tag{2}$$

Moreover, the thermodynamic functions are first-order homogeneous in the component moles $n$, i.e.,

$$\mathcal{V}(T, P, \lambda n) = \lambda \mathcal{V}(T, P, n), \qquad \lambda > 0, \tag{3}$$

with analogous relations holding for $\mathcal{H}$ and $\mathcal{U}$. The EOS may be specified by ideal-gas correlations, with or without cubic real-gas modifications.

### Transport

The molar fluxes account for mobile-phase convection and are given by

$$N = \upsilon c, \tag{4}$$

assuming negligible diffusive contributions. Here, $\upsilon$ denotes the interstitial axial velocity. The velocity is related to the pressure gradient through a momentum balance. We employ Ergun's equation

$$-\partial_z P = 150\mu \left(\frac{\varphi}{d_p}\right)^2 \upsilon + 1.75\rho_{\mathrm{gas}} \frac{\varphi}{d_p} \upsilon|\upsilon|. \tag{5}$$

Here, $\mu$ denotes the mobile-phase dynamic viscosity, $d_p$ the effective particle diameter, and

$$\rho_{\mathrm{gas}} = \textstyle\sum_{\alpha\in\mathcal{C}} c_\alpha M_\alpha, \tag{6}$$

the mobile-phase density, which is defined by molar masses $M = [M_\alpha]_{\alpha\in\mathcal{C}}$. We fix the dynamic viscosity to be that of air at ambient conditions and invert (6) to yield an explicit expression for the velocity $\upsilon = \upsilon(\partial_z P, c)$.

The heat flux accounts for mobile-phase convection and is expressed in terms of the enthalpy flux

$$E = \varepsilon \mathcal{H}(T, P, N), \tag{7}$$

neglecting gas- and solid-phase conduction. Here, first-order homogeneity is employed to express the enthalpy flux in terms of the enthalpy function and molar fluxes.

### Adsorption and heat transfer

The adsorption rate $R$ is defined by the stationary-phase mass balances

$$R = -\varphi\, \partial_t q, \tag{8}$$

where the volume ratio $\varphi$ ensures consistent mobile- and stationary-phase volume bases. The stationary-phase mass balances are modeled using the linear driving force (LDF) approximation

$$\partial_t q = \omega \odot (q^* - q), \tag{9}$$

With rate constants $\omega = [\omega_\alpha]_{\alpha\in\mathcal{C}}$ and equilibrium concentrations $q^* = [q^*_\alpha]_{\alpha\in\mathcal{C}}$. They are described by correlations, with parameters provided in the supplementary material.

### Adsorption equilibria

Following [2], we consider the multi-component Langmuir isotherm, which for a given component $\alpha \in \mathcal{C}$ is defined by

$$q^*_\alpha = q_{\max,\alpha} \frac{b_\alpha P_\alpha}{1 + \sum_{\beta\in\mathcal{C}} b_\beta P_\beta}. \tag{10}$$

Here, $q^{\max}_\alpha$ denotes the component's saturation capacity,

$b_\alpha$ its Langmuir parameter, and $P_\alpha$ its partial pressure. The partial pressure is given by $P_\alpha = P c_\alpha / \sum_{\beta \in \mathcal{C}} c_\beta$. The remaining quantities are specified by temperature-dependent correlations

$$q_{\max,\alpha} = k_{1,\alpha} - k_{2,\alpha} T, \tag{11a}$$

$$b_\alpha = k_{3,\alpha} exp\left(\frac{k_{4,\alpha}}{T}\right), \tag{11b}$$

with component-wise constants $k_{i,\alpha}$ for $i = 1, 2, 3, 4$.

### Adsorption rates

For each component $\alpha \in \mathcal{C}$, the adsorption rate constant is defined as

$$\omega_\alpha = \Omega \frac{D_\alpha}{r_p^2}, \tag{12}$$

where $\Omega$ is a geometric factor, $D_\alpha$ denotes the component's effective pore diffusivity, and $r_p$ is the effective particle radius. Assuming effectively spherical particles, we take $\Omega = 15$. The apparent time constant $D_\alpha / r_p^2$ is modeled as a pressure-dependent quantity using the supercritical structural Langmuir model [2]

$$\frac{D_\alpha}{r_p^2} = k_\alpha \sqrt{P_{r,\alpha}} (1 + b_\alpha P_\alpha)^2, \tag{13}$$

where $k_\alpha$ is a kinetic parameter and $P_{r,\alpha} = P_\alpha / P_{c,\alpha}$ denotes the reduced pressure defined by the component's critical pressure $P_{c,\alpha}$. The Langmuir parameter $b_\alpha$ is consistent with the adsorption equilibrium model.

### Heat of adsorption

Neglecting wall effects, the heat transfer rate accounts for the heat of adsorption

$$Q = -(1 - \varepsilon) \sum_{\alpha \in \mathcal{C}} \Delta H_\alpha \, \partial_t q_\alpha, \tag{14}$$

where $\Delta H = [\Delta H_\alpha]_{\alpha \in \mathcal{C}}$ denotes the component-wise heats of adsorption. Note that the heat of adsorption is taken to be negative for exothermic adsorption. Component-wise heats of adsorption are obtained from Clausius-Clapeyron analysis of the equilibrium isotherm [2].

## Thermodynamic constraints

The thermodynamic EOS is enforced through closures that recover the pseudo-homogeneous temperature and pressure fields. We provide constraints on the internal energy and volume.

### Internal energy constraint

The total internal energy density is constrained by enforcing the decomposition into mobile- and stationary-phase contributions

$$u = \varepsilon u_{\text{gas}} + (1 - \varepsilon) u_{\text{stationary}}. \tag{15}$$

Exploiting first-order homogeneity, the mobile-phase internal energy density is given by

$$u_{\text{gas}} = \mathcal{U}(T, P, c). \tag{16}$$

For the stationary phase, the internal energy density is split into its pore-phase and solid-phase contributions $u_{\text{stationary}} = u_{\text{pore}} + u_{\text{solid}}$. The pore-phase internal energy density is similarly given by

$$u_{\text{pore}} = \mathcal{U}(T, P, q). \tag{17}$$

Moreover, the solid-phase internal energy density is defined as

$$u_{\text{solid}} = \rho_{\text{solid}} c_{p,\,\text{solid}} (T - T_{\text{ref}}), \tag{18}$$

where $\rho_{\text{solid}}$ denotes the solid-phase density, $c_{p,\,\text{solid}}$ the heat capacity, and $T_{\text{ref}}$ a reference temperature.

### Volume constraint

The total gas volume comprises the mobile-phase and pore gas volumes. Due to sorption effects, the pore gas volume is not well-described by the EOS. Instead, a volume constraint is enforced on the mobile-phase gas

$$\mathcal{V}(T, P, c) = 1, \tag{19}$$

which, by first-order homogeneity, ensures that the relation $\mathcal{V}(T, P, n) = V_{\text{gas}}$ holds.

## Initial and boundary conditions

The differential mass and energy balances are closed by a set of initial and boundary conditions.

### Initial conditions

Initial conditions are prescribed for the differential states $(c, q, u)$ at time $t = 0$ across the axial domain $z \in \Omega$

$$c(0, z) = c_0(z), \tag{20a}$$

$$q(0, z) = q_0(z), \tag{20b}$$

$$u(0, z) = u_0(z). \tag{20c}$$

From these, consistent initial profiles of the algebraic states $(T, P)$ are subsequently obtained from the thermodynamic constraints (15) and (19).

### Boundary conditions

Boundary conditions are prescribed directly on the boundary fluxes

$$N(t, 0) = N_{\text{in}}(t), \tag{21a}$$

$$E(t, 0) = E_{\text{in}}(t), \tag{21b}$$

$$N(t, L) = N_{\text{out}}(t), \tag{21c}$$

$$E(t, L) = E_{\text{out}}(t). \tag{21d}$$

We employ flow-driven boundary conditions, specifying the upstream flows and downstream pressure. Consequently, the inlet fluxes are defined by

$$N_{\text{in}}(t) = \frac{f_{\text{in}}(t)}{S_{\text{gas}}}, \tag{22a}$$

$$E_{\text{in}}(t) = \varepsilon \frac{h_{\text{in}}(t)}{S_{\text{gas}}}, \tag{22b}$$

where $f_{\text{in}} = [f_{\text{in},\alpha}]_{\alpha \in \mathcal{C}}$ denotes the inlet molar flow rates and $h_{\text{in}} = \mathcal{H}(T_{\text{in}}, P_{\text{in}}, f_{\text{in}})$, the corresponding inlet enthalpy flow, specified by the inlet temperature $T_{\text{in}}$ and pressure $P_{\text{in}}$. Moreover, $S_{\text{gas}} = V_{\text{gas}}/L$ denotes the cross-sectional gas area. At the outlet, the prescribed pressure $P_{\text{out}}(t)$ determines the outlet pressure gradient $\partial_z P(t, L)$ and thus the outlet velocity $v_{\text{out}}(t)$ via the momentum balance (5). To prevent backflow, we adopt a check-valve formulation and determine

$$v_{\text{out}}(t) = \max_{\delta}\{0, v(\partial_z P(t, L), c(t, L))\}, \tag{23}$$

where the smoothed maximum operator is given by $\max_{\delta}\{a, b\} = \left(a + b + \sqrt{(a-b)^2 + \delta}\right)/2$ with $\delta = 10^{-4}$. The outlet fluxes are then defined by

$$N_{\text{out}}(t) = v_{\text{out}}(t) c(t, L), \tag{24a}$$

$$E_{\text{out}}(t) = \varepsilon \mathcal{H}(T(t, L), P(t, L), N_{\text{out}}(t)). \tag{24b}$$

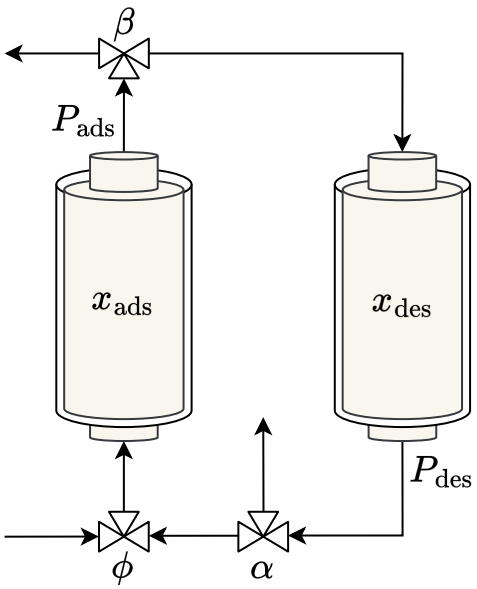

**Figure 1.** Diagram of the two-bed PSA superstructure.

## PSA SUPERSTRUCTURE

The PSA process is simulated by periodically sequencing a set of operating steps (pressurization, adsorption, blowdown, desorption, purge, and pressure equalization) across multiple adsorption beds. In a conventional two-bed PSA configuration, the operating steps are symmetric and may be divided into two complementary half-cycles: an adsorption half-cycle and a desorption half-cycle. While one bed undergoes the adsorption half-cycle, the other simultaneously undergoes the desorption half-cycle. Under this symmetry, it is sufficient to simulate the two-bed interactions across a single half-cycle, with the remaining half-cycle obtained by swapping beds. This motivates the PSA superstructure in [3], as shown in Figure 1. The superstructure defines the interconnections between the adsorption beds through idealized valves and imposed adsorption and desorption pressure levels. We omit the modeling of auxiliary equipment, and set pressure levels via boundary conditions.

### Mathematical formulation

We formulate the PSA superstructure over a half-cycle time horizon $t \in [0, \tau]$. Each bed is represented by an instance of the adsorption column model described previously. For each bed, we denote its differential states by $x = [c; q; u]$ and its algebraic states by $y = [T, P]$. The two beds are distinguished by subscripts indicating whether the bed undergoes adsorption or desorption. The left-most bed in Figure 1 undergoes the adsorption half-cycle, while the right-most bed undergoes the desorption half-cycle.

### Boundary conditions

In the left-most bed, a fraction $\phi(t)$ of the constant feed stream $(f_{\text{in}}, h_{\text{in}})$ enters from the bottom inlet, together with a fraction $\alpha(t)$ of the right-most bed outlet

$$N_{\text{in, ads}}(t) = \phi(t) \frac{f_{\text{in}}}{S_{\text{gas}}} + \alpha(t) N_{\text{out, des}}(t), \tag{25a}$$

$$E_{\text{in, ads}}(t) = \varepsilon \phi(t) \frac{h_{\text{in}}}{S_{\text{gas}}} + \alpha(t) E_{\text{out, des}}(t). \tag{25b}$$

Similarly, a fraction $\beta(t)$ of the left-most bed outlet enters the top inlet of the right-most bed

$$N_{\text{in, des}}(t) = \beta(t) N_{\text{out, ads}}(t), \tag{26a}$$

$$E_{\text{in, des}}(t) = \beta(t) E_{\text{out, ads}}(t). \tag{26b}$$

Here, the outlet fluxes are defined by (24), via the prescribed adsorption pressure $P_{\text{ads}}(t)$ and desorption pressure $P_{\text{des}}(t)$. The superstructure enforces unidirectional flow through the check-valve formulation (23), allowing the half-cycle to be simulated without flow reversal.

### Cyclic steady state

A consistent PSA cycle is obtained from the simulated half-cycle at CSS. Exploiting the symmetry of the two-bed superstructure, the full PSA cycle is recovered by imposing periodic boundary conditions, such that the terminal state of one bed at the end of a half-cycle provides the initial condition for the other bed at the beginning of the subsequent half-cycle, and vice versa. Accordingly, the differential states of the superstructure are required to solve the boundary value problem (BVP)

$$x_{\text{des}}(\tau, L - z) = x_{\text{ads}}(0, z), \tag{27a}$$

$$x_{\text{ads}}(\tau, L - z) = x_{\text{des}}(0, z). \tag{27b}$$

for all $z \in \Omega$, where the axial reversal reflects the flow

configuration of the superstructure. Consistent periodic profiles of the algebraic states are recovered from the thermodynamic constraints as part of the CSS solution.

## NUMERICAL SIMULATION

We simulate the PSA superstructure by discretizing the governing system of PDAEs in space using the method of lines. The resulting semi-discrete system of DAEs is then integrated in time.

### Finite volume discretization

We discretize the axial domain $\Omega$ into $K$ uniform volumes $\Omega_h^k = [z_h^{k-1/2}, z_h^{k+1/2}]$ of length $h = L/K$, and consider a cell-centered finite volume approximation $w_h = [w_h^k]_{k=1}^K$ of a given quantity $w$. For a volume $\Omega_h^k$, we define its midpoint $z_h^k = (k-1/2)h$ and interfaces $z_h^{k\pm1/2} = z_h^k \pm h/2$, and approximate the volume-averaged quantity

$$w_h^k(t) \approx \langle w \rangle_h^k(t) = \frac{1}{h}\int_{z_h^{k-1/2}}^{z_h^{k+1/2}} w(t,z)\,\mathrm{d}z, \tag{28}$$

by midpoint evaluation $w_h^k(t) = w(t, z_h^k)$. Applying the fundamental theorem of calculus and the same midpoint approximation to the volume-averaged mass and energy balances (1), we find that

$$\partial_t c_h^k = -\frac{1}{h}\left(N_h^{k+1/2} - N_h^{k-1/2}\right) + R_h^k, \tag{29a}$$

$$\partial_t u_h^k = -\frac{1}{h}\left(E_h^{k+1/2} - E_h^{k-1/2}\right) + Q_h^k, \tag{29b}$$

where $N_h^{k\pm1/2}$ and $E_h^{k\pm1/2}$ denote the interface molar and heat fluxes, respectively, and where $R_h^k$ and $Q_h^k$ denote the midpoint approximations of (8) and (14)

$$R_h^k = -\varphi\,\partial_t q_h^k, \tag{30a}$$

$$Q_h^k = -(1-\varepsilon)\textstyle\sum_{\alpha\in\mathcal{C}} \Delta H_\alpha (\partial_t q_\alpha)_h^k. \tag{30b}$$

Here, $\partial_t q_h^k = \left[(\partial_t q_\alpha)_h^k\right]_{\alpha\in\mathcal{C}}$ is defined by the midpoint approximations of the LDF approximation

$$\partial_t q_h^k = \omega_h^k \odot \left((q^*)_h^k - q_h^k\right), \tag{31}$$

with $(q^*)_h^k = q^*(T_h^k, P_h^k, c_h^k)$ and $\omega_h^k = \omega(T_h^k, P_h^k, c_h^k)$.

### Numerical fluxes

Since the superstructure enforces unidirectional flow, stability is ensured by prescribing upwind numerical fluxes at the volume interfaces. They are defined as

$$N_h^{k+1/2} = v(\partial_z P_h^{k+1/2}, c_h^k) c_h^k, \tag{32a}$$

$$E_h^{k+1/2} = \varepsilon \mathcal{H}(T_h^k, P_h^k, N_h^{k+1/2}), \tag{32b}$$

where the interface pressure gradient is approximated by $\partial_z P_h^{k+1/2} = (P_h^{k+1} - P_h^k)/h$. This results in a monotone first-order accurate spatial discretization.

### Thermodynamic constraints

The thermodynamic constraints are imposed locally in each finite volume $\Omega_h^k$. Applying the midpoint approximation to the internal energy constraint (15) yields

$$u_h^k = \varepsilon\left(u_{\mathrm{gas}}\right)_h^k + (1-\varepsilon)\left(u_{\mathrm{stationary}}\right)_h^k, \tag{33}$$

with $\left(u_{\mathrm{stationary}}\right)_h^k = \left(u_{\mathrm{solid}}\right)_h^k + \left(u_{\mathrm{pore}}\right)_h^k$. Here, the corresponding phase contributions are given by midpoint evaluation of (16)-(18) as

$$\left(u_{\mathrm{gas}}\right)_h^k = \mathcal{U}(T_h^k, P_h^k, c_h^k), \tag{34a}$$

$$\left(u_{\mathrm{pore}}\right)_h^k = \mathcal{U}(T_h^k, P_h^k, q_h^k), \tag{34b}$$

$$\left(u_{\mathrm{solid}}\right)_h^k = \rho_{\mathrm{solid}} c_{p,\,\mathrm{solid}}\left(T_h^k - T_{\mathrm{ref}}\right). \tag{34c}$$

Similarly, the volume constraint (19) is also enforced by midpoint evaluation

$$\mathcal{V}(T_h^k, P_h^k, c_h^k) = 1. \tag{35}$$

### Initial and boundary conditions

The initial conditions are also discretized by midpoint evaluation

$$c_h^k(0) = c_0(z_h^k), \tag{36a}$$

$$q_h^k(0) = q_0(z_h^k), \tag{36b}$$

$$u_h^k(0) = u_0(z_h^k), \tag{36c}$$

from which the initial algebraic states are recovered by the discrete thermodynamic constraints. The inlet boundary conditions are simply given by the inlet fluxes

$$N_h^{1/2}(t) = N_{\mathrm{in}}(t), \tag{37a}$$

$$E_h^{1/2}(t) = E_{\mathrm{in}}(t), \tag{37b}$$

and the outlet boundary conditions are given by the upwind fluxes

$$N_h^{K+1/2}(t) = v\left(\partial_z P_h^{K+1/2}(t), c_h^K(t)\right) c_h^K(t), \tag{38a}$$

$$E_h^{K+1/2}(t) = \varepsilon \mathcal{H}\left(T_h^K(t), P_h^K(t), N_h^{K+1/2}(t)\right), \tag{38b}$$

Here, the outlet pressure gradient is approximated by $\partial_z P_h^{K+1/2}(t) = \left(P_{\mathrm{out}}(t) - P_h^K(t)\right)/(h/2)$ using the prescribed outlet pressure $P_{\mathrm{out}}(t)$.

### Semi-discrete system

We let $x_h = [c_h; q_h; u_h]$ and $y_h = [T_h; P_h]$ denote the finite-volume discretizations of the differential and algebraic states, respectively. For the two-bed PSA superstructure, the corresponding discretized states of both beds are collected into global differential and algebraic state vectors $\mathbf{x}$ and $\mathbf{y}$. The spatial discretization of the superstructure then yields a semi-discrete system of semi-explicit index-1 DAEs

$$\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{y}, p), \mathbf{x}(0) = \mathbf{x}_0, \tag{39a}$$

$$0 = g(\mathbf{x}, \mathbf{y}, p), \tag{39b}$$

where $\mathbf{x}_0$ is defined by the discretized initial conditions, and $p$ the prescribed boundary conditions.

### Initialization

Before integration, we solve for consistent initial algebraic states $\mathbf{y}(0) = \mathbf{y}_0$ satisfying

$$g(\mathbf{x}_0, \mathbf{y}_0, p) = 0. \tag{40}$$

To this end, we employ Newton's method with backtracking line search, which restricts trial iterates to the feasible domain of the model functions and prevents evaluation at physically inadmissible states.

## Diagonally implicit Runge-Kutta methods

Time integration of (39) is performed using a diagonally implicit Runge-Kutta (DIRK) method [5]. Given states $(\mathbf{x}_n, \mathbf{y}_n)$ at time $t = t_n$, an $s$-stage DIRK method advances to the states $(\mathbf{x}_{n+1}, \mathbf{y}_{n+1})$ at time $t = t_{n+1}$, with step size $h_n = t_{n+1} - t_n$, by computing stage values $(\mathbf{X}_{n,i}, \mathbf{Y}_{n,i})$ satisfying the implicit stage equations

$$\mathbf{X}_{n,i} = \mathbf{x}_n + h_n \sum_{j=1}^{s} a_{i,j} f(\mathbf{X}_{n,j}, \mathbf{Y}_{n,j}, p), \tag{41a}$$

$$0 = g(\mathbf{X}_{n,i}, \mathbf{Y}_{n,i}, p), \tag{41b}$$

defined at stage times $T_{n,i} = t_n + c_i h$, for $i = 1, \dots, s$. The advancing states are found via the stage values using the quadrature rule

$$\mathbf{x}_{n+1} = \mathbf{x}_n + h_n \sum_{i=1}^{s} b_i f(\mathbf{X}_{n,i}, \mathbf{Y}_{n,i}, p), \tag{42a}$$

$$0 = g(\mathbf{x}_{n+1}, \mathbf{y}_{n+1}). \tag{42b}$$

The DIRK method is characterized by a Butcher tableau with coefficients $a = [a_{i,j}]_{i,j=1}^{s}, b = [b_i]_{j=1}^{s}$, and $c = [c_i]_{i=1}^{s}$, where $a_{i,j} = 0$ for $i < j$. In this work, we employ singly-diagonally implicit Runge-Kutta (SDIRK) methods, and in particular explicit first-stage SDIRK (ESDIRK) methods, with constant diagonal coefficients $a_{i,i} = \gamma$ and $a_{1,1} = 0$. We further adopt stiffly accurate schemes where $b_i = a_{s,i}$, such that the final stage directly gives the advancing state. This combination of properties renders stiffly accurate ESDIRK methods particularly efficient. The lower-triangular structure enables sequential solution of the stage equations via Newton's method, while the constant diagonal allows reuse of a single Jacobian factorization across all stages within a time step, making quasi-Newton schemes especially effective. The remaining coefficients are then chosen to ensure high-order accuracy and stability. Step sizes are chosen adaptively, to control the temporal error and to handle transient stiffness arising from changes in boundary conditions. We use PID-based step-size control via embedded error estimates, as described in [5].

# CYCLIC STEADY-STATE SIMULATION

While the previous section describes numerical simulation of a single half-cycle of the PSA superstructure, a physically consistent PSA cycle is obtained only when the half-cycle satisfies the CSS conditions defined by the BVP (27). Using the method-of-lines discretization, the CSS BVP is solved numerically using shooting methods.

## Single shooting

Single shooting aims to solve the BVP by iteratively integrating the semi-discrete DAE system and updating the initial state until CSS is achieved. Using the ESDIRK integrators, we introduce the half-cycle propagator $\Phi$, which, for given initial differential states $\mathbf{x}_0$ and boundary conditions $p$, returns the terminal states $\Phi(\mathbf{x}_0, p)$ at the end of the half cycle via numerical integration over $t \in [0, \tau]$. Additionally, we define the operator $\Pi$, which implements the permutation of the superstructure states that swaps the two beds and applies the axial reversal. The discretized CSS BVP reduces to the fixed-point problem

$$\Pi\Phi(\mathbf{x}, p) = \mathbf{x}, \tag{43}$$

whose solution defines initial states for a consistent PSA cycle. Alternatively, we adopt the residual formulation

$$R(\mathbf{x}) \quad = \Pi\Phi(\mathbf{x}, p) - \mathbf{x}, \tag{44}$$

and seek a solution to $R(\mathbf{x}) = 0$. The fixed-point formulation of single shooting lends itself to simple fixed-point (Picard) iterations and acceleration techniques, such as Anderson acceleration (AA). In contrast, Newton's method may be used to solve the residual formulation.

# IMPLEMENTATION DETAILS

The simulation framework is implemented in the Julia 1.10 language and executed on an Intel Xeon E5-2650 (2.2 GHz) workstation. Model derivatives are computed by combining analytical derivatives of the finite-volume discretization with forward-mode automatic differentiation of the thermodynamic functions provided by `Clapeyron.jl` [6]. Dense linear algebra is performed with Intel MKL-accelerated BLAS, while sparse model Jacobians are assembled explicitly and factorized using sparse direct linear algebra within the Newton schemes used for consistent initialization and ESDIRK time integration. Sensitivities of the half-cycle propagators are computed via staggered direct forward sensitivity analysis of the ESDIRK method and are used in the Newton-based single shooting solver.

## NUMERICAL EXPERIMENTS

We consider simulation of the example two-bed PSA cycle described in Table 1 and shown in Figure 2. The columns are fed dry air at ambient temperature, supplied at constant pressure and flow rate. Column and feed parameters are summarized in Table 2. Studying a converged CSS, we first assess how spatial resolution and thermodynamics affect simulated cycle performance. Using tight integration tolerances, purity and recovery are compared for ideal and real-fluid thermodynamics across increasing finite-volume resolutions. As shown in Table 3, the predicted product purity increases with spatial resolution, whereas the recovery remains essentially unchanged. Differences between ideal and real-fluid thermodynamics are negligible, on the order of 1–2‰, indicating that spatial discretization effects dominate.

The dominant computational task is governed by time integration, and in particular thermodynamic property evaluation. Table 4 compares several ESDIRK schemes from [5] for CSS simulation across error tolerances. While higher-order methods require fewer time steps, their larger stage counts make lower-order schemes slightly faster at loose tolerances. However, higher-order schemes are more efficient at stricter tolerances. It is worth noting that simulation scales linearly in $K$, since we employ sparse linear algebra. Accordingly, since model evaluation is dominated by the thermodynamics, ideal conditions are roughly 30-50% faster to simulate across all spatial resolutions.

Beyond the cost of individual cycle simulations, the computation of the CSS hinges on how efficiently the CSS BVP is solved. Using the 4$^{th}$ order ESDIRK method, Table 5 compares Picard iterations, Anderson acceleration, and Newton-based solution. Newton's method converges in only three iterations with quadratic convergence, achieving a tighter solution tolerance in minutes, whereas Picard and Anderson-accelerated iterations require hundreds of iterations and substantially longer runtimes. The dominant eigenvalue of the propagation operator lies within the integration tolerance of unity, making fixed-point convergence noisy, necessitating tight integration tolerances.

**Table 4:** CSS simulation statistics (EOS=Real, K=80).

| Method | Statistic | Tol=$10^{-2}$ | Tol=$10^{-4}$ | Tol=$10^{-6}$ | Tol=$10^{-8}$ |
|---|---|---|---|---|---|
| **ESDIRK2(1)3L[2]SA** | Steps [#] | 178 | 266 | 1589 | 14542 |
| 2$^{nd}$ order 3 stages | Time [min:sec] | **00:04** | **00:06** | 00:31 | 04:43 |
| **ESDIRK3(2)5L[2]SA** | Steps [#] | 143 | 163 | 282 | 725 |
| 3$^{rd}$ order 5 stages | Time [min:sec] | 00:05 | **00:06** | **00:10** | 00:27 |
| **ESDIRK4(3)7L[2]SA** | Steps [#] | **129** | **144** | **233** | **377** |
| 4$^{th}$ order 7 stages | Time [min:sec] | 00:06 | 00:07 | 00:11 | **00:20** |

**Table 5.** Solver statistics (EOS=Real, K=40, Tol=$10^{-6}$).

| Statistic | **Picard** | **AA** | **Newton** |
|---|---|---|---|
| Iterations [#] | 1123 | 416 | **3** |
| Time [hr:min] | 01:19 | 00:23 | **00:02** |

Finally, the two half-cycles are stitched together to recover the full periodic operation and simulated spatio-temporal composition profiles are shown in Figure 3. The resulting product flow rate of approximately 450 [$m^3$/h] at ambient conditions falls well within the range of small-scale PSA-based air separation units.

## CONCLUSION

This work presented a first-principles, dynamic modeling framework for PSA-based nitrogen generation. Thermodynamically consistent column models, combined with finite-volume discretization and implicit time integration, enable systematic simulation and reliable CSS computation via shooting methods. Numerical experiments show that solver choice strongly affects computational efficiency, with Newton-based methods converging substantially faster than fixed-point approaches. The framework provides a systematic basis for optimization of PSA cycles for nitrogen generation, following [3].

## ABSTRACT

The SEMPRE-BIO project tested and validated three different innovative technologies and pilots within the Horizon Europe framework. One of the pilots is commissioned in Belgium. The proposed technology purifies biogas from manure anaerobic digestion and delivers simultaneously pure biomethane and food-grade $CO_2$, conversely to conventional purification technologies such as absorption and adsorption. Due to the severe cryogenic conditions, energy recovery for purge and waste streams becomes relevant to improve the energy demand of the process. The present work will show an effective solution to reduce the electricity demand of the process. Biomethane slip and other purge stream are valorised in a steam boiler and a two-pressure-level steam turbine to deliver both middle pressure steam as utility in distillation reboilers and produce electricity. The analysis will propose a simple, but rigorous methodology to maximise the steam turbine loop and the net power. The present work is based on solid and concrete assumptions for the design of the steam turbine. The analysis shows that the process allows for recovering up to 12% of the total electricity and around 55% of the total energy demand for the refrigeration loop to preserve the cold box of the bio-$CH_4$/$CO_2$ distillation.

**Keywords**: Turbines, Energy Efficiency, Combustion Heat and Power (CHP), Energy recovery, Biogas upgrade

## INTRODUCTION

Biogas appears as a promising feedstock for combustion heat and power (CHP) applications [1, 2] as well as for replacing fossil methane in chemical production [3]. Biogas is a wet mixture of biomethane (bio-$CH_4$) and biogenic $CO_2$ (bio-$CO_2$) with a variable ratio of the two main components. Generally, bio-$CH_4$ ranges from 45 vol% to 75 vol% [4]. The remaining is mainly wet bio-$CO_2$. Prior to any application and transport, biogas undergoes deep dehydration and purification/upgrading by removing bio-$CO_2$ [5]. In addition, bacteria releases $H_2S$ and $NH_3$ in traces during the anaerobic digestion of biological wastes (food residue, sludges, wastewater, crops, and manure) [4, 5]. These species are harmful and corrosive. Hence, biogas purification is energy intensive [6]. The bulk capture of $CO_2$ and successive dehydration of bio-$CH_4$ consumes heat, cooling water, and electricity [7]. This work will introduce a novel concept for biogas upgrading patented by Cryo Inox S.L. and tested within SEMPRE-BIO, an EU project under the EU's Horizon Europe Program. The site capacity and biogas productivity are sensitive. The analysis shows that valorising side streams covers part of the electricity energy and satisfy the total demand for thermal energy of the plant.

## MATERIALS AND METHODS

### Process block flow diagram (BFD)

Figure 1 depicts the three different process layouts considered in the analysis. The proposed BFDs differ for the "cold box" and how refrigeration is performed. The remaining of the biogas upgrading is kept unchanged. Regardless of the process configuration, manure (S1-01) is digested resulting in the slurry digestate (S1-04) and raw biogas (S1-07). The produced biogas is purified ($H_2S$ and $NH_3$ removal) while dehydration and compression are carried out. The compressed biogas (S1-19) still contains

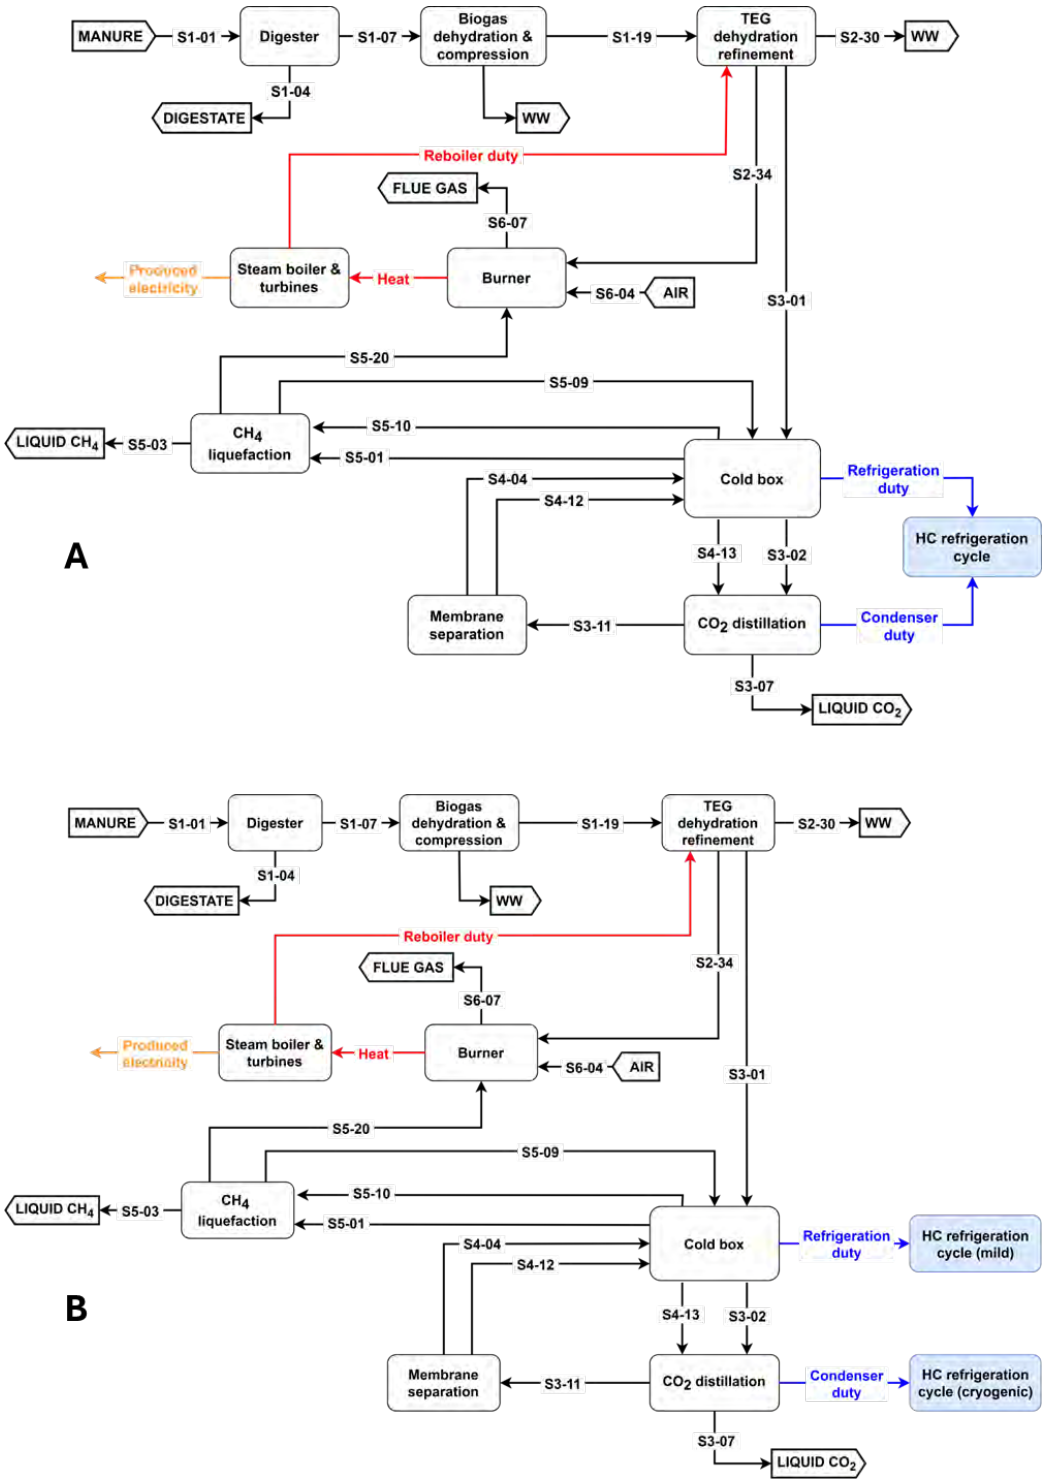

**Figure 1:** Process BFDs for three different configurations of the analysed process. The processes differ for the cold box configuration and how cooling (blue arrows) is managed within the process. The remaining part of the process remains the same. WW stands for wastewater.

a relevant residual moisture. The moisture content is refined through a conventional triethylene glycol (TEG) absorption process to keep the residue water content below 3 ppm (vol). The dry biogas (S3-01) leaves the absorber. As the absorber is run at high pressure and low temperature to abate residue moisture, bio-$CH_4$ and bio-$CO_2$ accumulates in the solvent [8, 9], which are easily released as heat is supplied. TEG regeneration is run

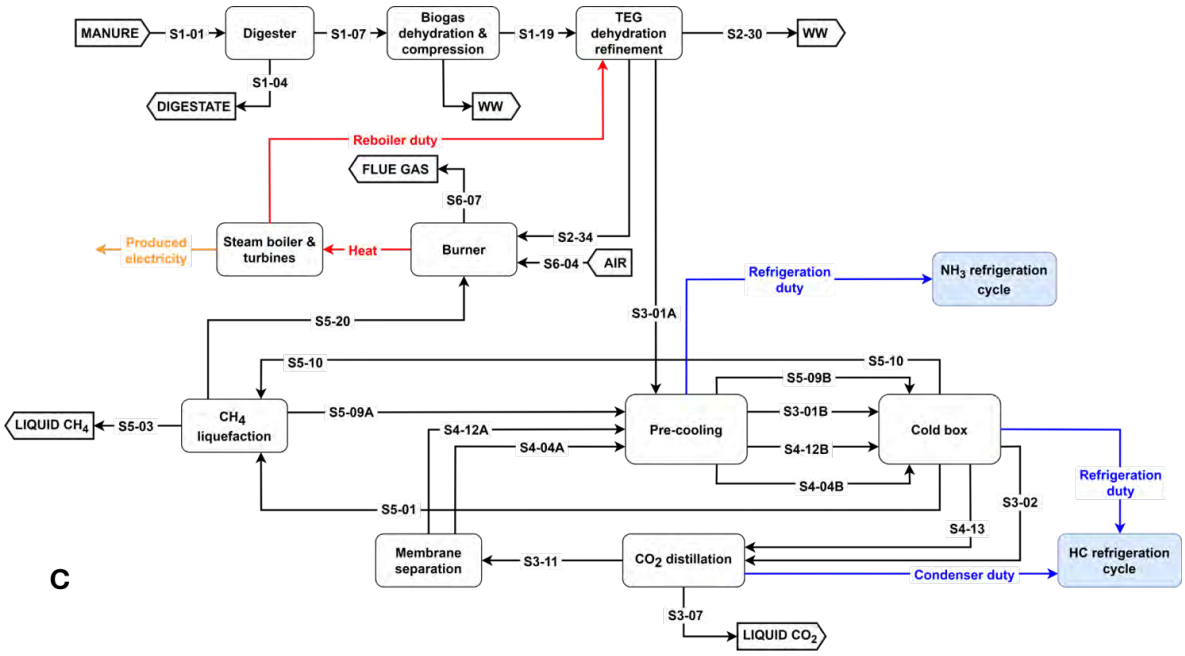

**Figure 1. (continues):**

thermally, and the process require steams. However, the temperature in the reboiler of the TEG regeneration is kept below 207°C to prevent it from degrading. To keep a minimum temperature approach ~10°C and avoid formation of hotspots in the reboiler, steam must be supplied around 219-221°C. A bio-$CH_4$-rich stream is released from the top of the stripper of the TEG regeneration. This stream is post-treated in a membrane to recover part of bio-$CH_4$. Pure methane is recycled back to the stripper after recompression. Injecting hot methane as stripping gas in TEG regeneration column is an industrial practice to increase the TEG purification from 98 to 99.9+ wt%, while lowering the thermal demand for the regeneration and reducing the temperature at the bottom [10, 11]. This is reflected in a minimum TEG degradation and liquid-to-gas ratio in the absorber to reduce the moisture content in the gas phase below 3 ppm (vol). The unrecovered bio-$CH_4$ (S2-34) is a purge and valorised in the burned to deliver steam for the steam turbine.

The dry biogas (S3-01) is cooled, and the resulting cold biogas (S3-02) is conveyed to the cryogenic distillation, whose operating conditions, namely, temperature and pressure, are sensitive. Part of the bio-$CO_2$ is recovered as pure liquid (>99.99 vol%) from the bottom, while bio-$CH_4$-enriched gas stream (S3-11 with $CO_2$ ~80 vol%) is sent to a membrane separation system where residue $CO_2$ selectively permeates and the gas stream is progressively purified until the outlet gas (S4-04) reaches a residue $CO_2$ content below 50 ppm (vol), which respects the specifications for grid injection. The membrane system works at ambient temperature. The permeated gas is enriched in $CO_2$ but still contains bio-$CH_4$ as membrane preferably permeate $CO_2$, but the separation is not sharp. Part of the permeated gas is recycled internally, while the purge (S4-12) is cooled and recycled to the cryogenic distillation to maximise both bio-$CH_4$ recovery and liquid bio-$CO_2$ production. Pure bio-$CH_4$ is cooled and conveyed to $CH_4$ liquefaction process (S5-01) where it is compressed and partially expanded to exploit Joule-Thomson effect and generate the frigories to liquefy part of the bio-$CH_4$ (S5-03). The not liquefied fraction (S5-20) is purged. The purged streams, namely S2-34 (from TEG dehydration) and S5-20 (from bio-$CH_4$ liquefaction), are transferred to a burned where excess air is co-fed. The combustion of purge streams is used to produce heat (steam) and power. Part of the produced steam is used for the regeneration of TEG solvent. The implementation and optimisation of combined steam boiler and turbine is described in the next sections.

## Refrigeration strategies

Figure 1 shows three different layouts depicting three alternatives to manage the refrigeration and keep the cold box of the system. The basic process is described in the previous section, and it is kept equal regardless of the refrigeration strategy and configuration. The cold box satisfies the frigories demand in the cryogenic distillation (bio-$CH_4$ purification through bio-$CO_2$ liquefaction) and liquefaction of purified bio-$CH_4$. For the first, pre-cooling of the dry biogas and reaching cryogenic temperature in the top condenser of the distillation column (condenser duty in Figure 1) are needed. For the latter, cryogenic conditions are required to reduce the inefficiency. Indeed, if frigories are recovered exclusively

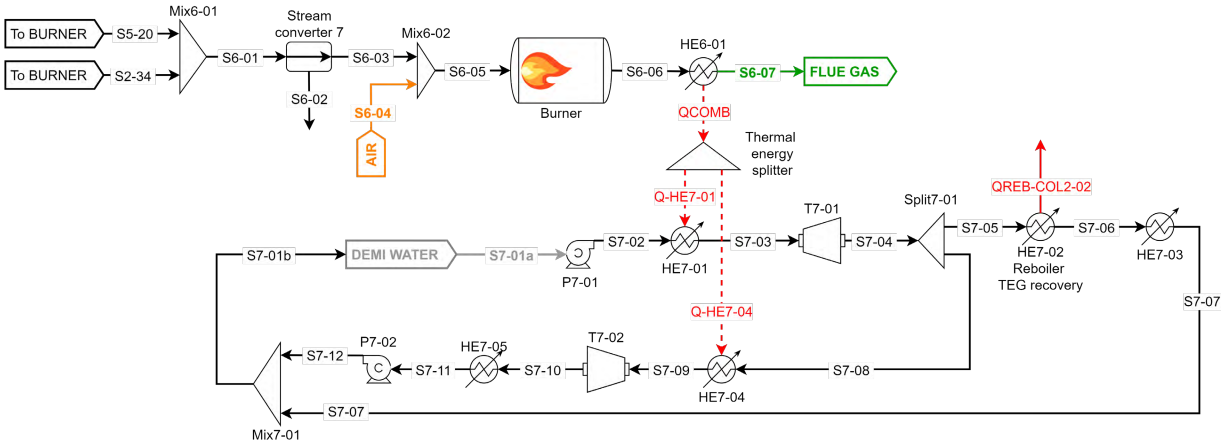

**Figure 2.** Combustion chamber and steam boiler with corresponding dual-pressure steam loop

using the liquefied bio-$CH_4$ without outsourced cooling duty, the net production of liquid bio-$CH_4$ would be reduced. Figure 1 distinguishes between the duty for the condenser of the cryogenic distillation and all the pre-cooling demand distributed around the plant. This distinction will be clarified later. Based on these considerations, three different layouts have been identified:

- Option A (single loop): the total cooling demand is covered using a hydrocarbon (HC) mixture as working fluid. The HC blend contains $C_2$-$C_3$ hydrocarbons. The relative ratio of $C_2$-$C_3$ has been tuned to keep the cold box minimum temperature (sensitive).
- Option B (double loop): the same mixture is used as working fluid but split into two independent refrigeration loops. In the first refrigeration loop (named as mild loop), all warm streams are precooled from ambient temperature (25-30°C) to reach the same intermediate temperature of the gas leaving the top of the cryogenic column. This temperature is sensitive and here not reported. In the second refrigeration loop (named as cryo loop) all the streams are cooled to final desired temperature (sensitive). This option is justified by thermodynamic constraints. Warmer streams allow for having higher outlet temperature of the cooling fluid leaving the evaporator. Conversely, colder streams are more challenging to further refrigerate because of the minimum temperature approach in the condenser heat exchanger. Then, the milder loop would treat a lower amount of gas because the gas from the cryogenic distillation is treated and cooled only in the cryo loop.
- Option C (double loop with two refrigerants): is like Option B, but all warm streams are pre-cooled to the same intermediate temperature using ammonia refrigerant for the mild loop. The temperature is reduced to the final target value in a second refrigeration cycle still using the same HC mixture as for options A and B.

## Steam boiler and turbine

### Process description

Figure 2 depicts the configuration of the burner and a conventional dual-pressure steam turbine system. Cold water (S7-01a) is pumped (P7-01), superheated (HE7-01) and conveyed to the first steam turbine T7-01. Expanded steam leaves the unit and it is split into two flows: S7-05 and S7-08. S7-05 is the steam supplied to the reboiler of the TEG regeneration. The resulting condensed steam (S7-06) is further cooled (HE7-03) and recycled back. The other stream from the split (S7-08) is heated a second time and sent to a second expander (T7-02). The low-pressure steam is then fully condensed (HE7-05), pumped (P7-02) and mixed with S7-07. The total condensed water is then recycled to the main pump (P7-01). This work aims to optimising the steam cycle to maximise the net work recovered from the combustion of bio-$CH_4$ rich purges defined as

$$W_{Net} = W_{T7-01} + W_{T7-02} - W_{P7-01} - W_{P7-02} \quad (1)$$

where W stands for the power generated (for turbines) and consumed (for pump) and consumed (for pump).

### Input data and Degrees of Freedom (DoF) of the optimisation

The combustion of bio-$CH_4$ purges releases 96.04 $kW_{th}$. This is the total energy input to the steam cycle. The steam cycle is designed to deliver 39.12 $kW_{th}$ to the reboiler of the TEG regeneration. As aforementioned, steam should be supplied saturated at 220°C, i.e., at 23.5 bar (absolute). The steam quality is stringent due to TEG thermal stability. The degrees of freedom of the system are: (1) the total flow of water/steam circulating in the cycle (S7-01a), (2) the upper pressure of the steam cycle,

(3) the thermal duty (Q-HE07-01) supplied to the first superheater (HE07-01), and (4) the discharge pressure of the second steam turbine (T7-02). These variables correspond to the optimisation parameters.

The system has been simulated in Aspen Hysys V12 using ASME steam thermodynamic model. The optimisation has been carried out using the sensitivity analysis tool in the simulation environment. For pump and turbines, a global efficiency, i.e., product of polytropic and mechanical efficiency, has been assumed. The following ranges have been investigated for the optimisation parameters:

Total mass flow: 95 – 115 kg/h with a step of 5 kg/h. Our investigation included 98, 107, and 112 kg/h to refine the domain and further optimise the process.

(1) Maximum/upper pressure of the steam cycle: ranges between 60 – 120 bar (absolute), typical for high-efficiency system for heat recovery and electricity production [12, 13]. 10 bar is the considered discretization step. The lower and upper limited has been identified based on steam turbine producers' suggestions and standard, i.e., not customised, units.

(2) Superheater Q-HE7-01 duty: ranges 90 – 96 $kW_{th}$ and energy balances imposes that

$$Q_{HE7-04} = 96.04 - Q_{HE7-01} \quad (2)$$

(3) Discharge pressure of the second turbine T7-02: as been limited to 0.3 – 1.2 bar (absolute) with a step of 0.3 bar. The bottom and upper limits are retrieved from technical reports and producers [14]. It is unlikely to lower the discharge pressure below 30 kPa. It is possible to run the turbine above 1.2 bar absolute, however, this is normally done in district heating and not in steam boiler and turbine loops where the main target is the energy recover.

### Constraints and criteria

The results have been screened and filtered based on the following criteria (checkpoint list) and constraints:

1. The maximum inlet temperature of superheated steam to turbines (S7-03) is 600°C to avoid thermal stress [12, 15], i.e., periodic maintenance, and expensive construction materials [15]. This constraint links the duty to the first superheater (HE07-01) and the total water mass flow circulating in the loop. If the inlet temperature exceeds this threshold, i.e., $T_{S7-03}$ > 600°C, the operating point is unfeasible. The same constraint holds for the steam conveyed to the second steam turbine (T7-02), hence $T_{S7-09}$ < 600°C must be fulfilled.
2. S7-05 is the saturated steam for the reboiler of TEG regeneration. The maximum temperature of the steam is assumed 220°C to keep a minimum temperature approach of ~10°C in the reboiler and the avoid hotspots in the unit as TEG degrades above 207°C. Setting the steam pressure implies that the discharge pressure of T7-01 is 23.5 bar. Moreover, the reboiler duty for the TEG regeneration (QREB-COL02-02) is assigned; indeed

$$m_{S7-04} = \frac{Q_{REB-COL2-02}}{\Delta H_{EV}(T_{sat}, P_{sat}(T_{sat}))} \quad (3.1)$$

$$m_{S7-04} = \frac{39.12}{\Delta H_{EV}(220°C, 23.5\ bar)} \quad (3.2)$$

3. From the previous point it follows that the temperature of the superheated steam leaving the turbine T7-01 (S7-04) could be warmer than the one selected to deliver steam to the TEG reboiler. Hence, the optimal operational point should deliver steam as much as possible to the saturation point to avoid a kind of transfer line heat exchanger to remove the "excess" heat ($Q_{excess}$). This device would increase the inefficiency of the system.
4. The lower pressure of the loop, i.e., discharge pressure of the second turbine T7-02, is an optimisation variable and DoF of the system. The discharge pressure is constrained to the physical state of the steam leaving the unit. If steam starts condensing, the expander cannot be operated. Hence, the discharge pressure is selected as the lowest pressure at which only steam leave the unit, i.e., vapour fraction α = 1. This condition preserves the operation of the turbine while ensuring to recover the maximum work. It is straightforward, that the same condition must be satisfied also at the outlet of first turbine (T7-01). This condition is less stringent, unless to large water mass flow is processed in the cycle.

## RESULTS DISCUSSION

### Steam cycle optimisation

Table 1 gathers the results from the sensitivity analysis performed in Aspen Plus. Several feasible points have been identified; only the optimal one per each tested total mass flow of steam/water in the loop are reported. The optimal points are selected based on the maximum net work recovered from the loop. The trend of net work recovered from the steam cycle is depicted in Figure 3. The results show that the steam cycle can be operated only within a limited domain for the steam/water mass flows in the loop: between 98 kg/h (minimum) and 112 kg/h (maximum). Indeed, below 98 kg/h, the total fluid is too little and the inlet temperature of superheated steam either to the first or to second turbine violates the threshold value of 600°C. Under this condition, the combustion releases an excessive heat. Conversely, above 112 kg/h, the total fluid is too large: the first superheater requires a substantial fraction of the heat released from the combustion, but the remaining heat is insufficient to reheat the steam after the splitter.

**Table 1:** Optimal points for the steam cycle

| Steam flow (kg/h) | P max (bar abs) | P min (bar abs) | $Q_{HE7-01}$ (kW) | $Q_{excess}$ (kW) | Inlet T (°C) T7-01 / T7-02 | Net work (kW) |
|---|---|---|---|---|---|---|
| 95 | - | - | - | - | - | - |
| 98 | 120 | 0.4 | 92.5 | 6.07 | 588 / 588 | 19.11 |
| 100 | 120 | 0.4 | 92.0 | 4.80 | 554 / 573 | 19.10 |
| **105** | **120** | **0.4** | **90.0** | **1.46** | **468 / 566** | **19.04** |
| 107 | 120 | 0.6 | 90.0 | 0.60 | 448 / 526 | 18.34 |
| 110 | 100 | 0.9 | 90.0 | 0.05 | 407 / 487 | 16.64 |
| 112 | 80 | 1.0 | 90.0 | 0.05 | 374 / 472 | 15.26 |
| 115 | - | - | - | - | - | - |

**Table 2:** Comparison of the refrigeration strategies

| Option | $P_{tot}$ (kW) | $P_{tot-net}$ (kW) | Compression refrigerant (kW) | $Compr\%_{tot}$ | Electricity Saving (ES) | $\Delta E_{tot}$ | $\Delta E_{net}$ |
|---|---|---|---|---|---|---|---|
| A | 191.2 | 172.2 | 70.8 | 37.0% | -9.94% | Reference | Reference |
| B | 186.2 | 167.2 | 66.1 (total) | 35.5% | -10.2% | -2.6% | -2.9% |
| C | 181.9 | 162.9 | 61.9 (total) | 34.0% | -10.4% | -4.9% | -5.4% |

This results in incipient condensation of the steam even above the atmospheric pressure (1.2 bar absolute has been considered as the upper limit). In other words, the system experiences a lack of thermal energy. This explanation justifies also the reduction of the upper pressure of the steam loop, which progressively reduces from 120 bar (maximum) to 80 bar. This is the result of the combination of saturation temperature (higher as pressure increases) and latent of vaporization (lower as pressure increases). Figure 3 displays an almost flat profile up 105 kg/h and then a sharp drop of the net work recovered. The average net work recovery is around 19 kW for the flat area. The reduction of the net work is substantial beyond 105 kg/h. Indeed, for an increment of the mass flow from 105 to 112 kg/h (+6.25%), the work recovery falls from 19 kW to 15.3 kW (-19%). The physics behind the system is straightforward and already commented above, when describing the boundaries of the feasible domain to run the steam cycle. The optimal operational point has been selected by globally accounting for the criteria listed and described in the dedicated section. In particular, the steam cycle run with 105 kg/h is considered the best option because of the limited excess heat, meaning that the steam withdrawn after the first expansion is almost close to saturation and no quench is required. In addition, in that configuration, superheated steam is fed to both turbines at milder temperatures, i.e., lower than the maximum allowable one (600°C), lowering the risk of mechanical failure.

## Effect of refrigeration strategies and steam cycle integration in the biogas upgrading

In addition, the system has been analysed in terms of refrigerant demand and total energy demand to identify the best cold box configuration and the benefit associated with the addition of a steam turbine system in the base process. Based on the simulation of the whole process under the different options (Figure 1). The total cooling demand is around 49 $kW_{th}$, split into 19.3 $kW_{th}$ for the condenser at the cryogenic distillation and 29.7 $kW_{th}$ to provide frigories in other sections of the process.

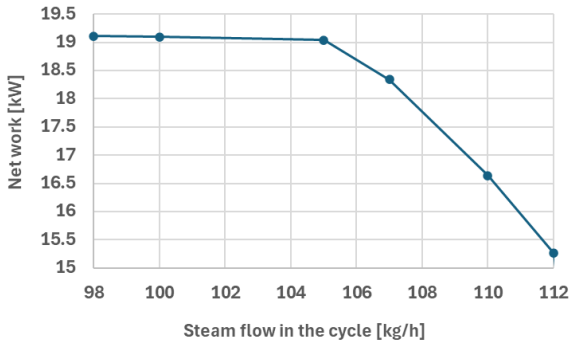

**Figure 3.** Locus of optimal points

Table 2 gathers the results from the simulation. The results show a progressive reduction in the fluid demand and the corresponding compression costs. Hence, the possibility to split the refrigeration into two independent loops is a benefit. Moreover, the possibility to run the mild loop with ammonia as refrigerant improves further the performance. Indeed, the pre-cooling with ammonia and reduces the total electricity demand to operate the refrigeration cycle. At this point, it is worth contextualising the role of the energy recovery and cold box optimisation in the plant for biogas upgrading and liquefaction.

Additional data are necessary to carry out this last assessment. Table 3 resumes the results for all the simulations. The total electricity, in Eq (4), power demand ($P_{tot}$) accounts for compressors and pumps and it has been estimated based on the simulations; while the net power ($P_{tot\text{-}net}$) is defined as the difference between the total power ($P_{tot}$) and the net total power/work recovered from the steam boiler and turbine system ($W_{net}$), as defined in Eq (1). All entities are expressed in kilowatt (kW).

$$P_{tot-net} = P_{tot} - W_{net} \quad (4)$$

It is important to highlight that the previous analysis concluded that the maximum net power ($W_{net}$) recovered from the turbine loop is around 19 kW (Table 1). The analysis considers the following key performance indicators (KPIs):

- Percentage of energy demand of compression of refrigerant(s) on the total electricity demand:

$$Compr\%_{tot} = \frac{W_{refrigerant\ compression}}{P_{tot}} \quad (5)$$

where the numerator is provided in Tables 2 and 3.

- The electricity saving defined as:

$$ES = \frac{W_{net}}{P_{tot}} \quad (6)$$

- Energy reduction factors (both using as reference the total and net power of Option A) calculated as:

$$\Delta E_{tot} = \frac{P_{tot} - P_{tot(option\ A)}}{P_{tot(option\ A)}} \quad (7)$$

$$\Delta E_{net} = \frac{P_{tot-net} - P_{tot-net(option\ A)}}{P_{tot-net(option\ A)}} \quad (8)$$

Table 3 shows that energy demand for the compression of refrigerant(s) represents one of the most substantial energy consumptions for running the purification of biogas. The implementation of a steam turbine enables to cover almost 10% of the total electricity of the system. In addition, Options B and C introduce additional improvements to the benchmark (Option A). These two configurations further reduce the total energy demand thanks to a better layout of the refrigeration loop (Option B) and selection of the refrigerants (Option C). The energy reduction with regards to the benchmark is still limited, but the electricity power demand drops up to -4.9% and –
5.4% if you consider the either the total or the net energy demand as baseline, respectively. Though the energy savings could sound limited, but the steam cycle delivers 100% of the steam demand for the entire process. The end user does not have to burn extra methane or outsource fuel, i.e., biomass waste, to integrate the amount of steam. Beyond the technical aspect and comments related to the energy analysis of the system, it is important to stress that also economic aspects must be considered to identify the best process configuration. However, this is out of the scope of the present paper.

## CONCLUSIONS AND FUTURE WORKS

The paper presented a novel technology for the upgrading of the biogas. Remarkably, the system allows for purifying bio-$CH_4$, while producing bio-$CO_2$ with purity of both products 99.99+ vol%, meeting specs for injection in pipeline (methane) and carbon use, including food and beverage, or permanent storage ($CO_2$). The proposed technology, patented by Cryo Inox, represents an example of full electrification of biogas upgrading. The system includes the bio-$CH_4$ liquefaction. Liquefaction can be considered for small clusters of bio-$CH_4$ producers. Indeed, liquid bio-$CH_4$ can be transported. Hence, the proposed process is ideal whenever natural gas pipelines are far from the biogas site and/or connecting to existing infrastructure is not feasible. The work showed that the recovery and valorisation of waste stream coming from the process becomes relevant to improve the key performance of the system. For instance, the valorisation of purges containing bio-$CH_4$ can be exploited to generate steam and heat. The energy analysis highlighted that the integration of the combustion chamber with a steam boiler and a steam cycle can benefit to the upgrading process. The optimization of the fully integrated steam cycle enables to recover up to 10% of the total electrical energy demand of the system and satisfy 100% of the total thermal energy demand (steam). In addition, the paper also showed the optimisation of the refrigeration strategy, and its configuration have an impact on the overall

**Table 3:** Energy analysis of the three options.

indicators. Three configurations to supply frigories have been investigated: the selection of both the process layout and the proper refrigeration affects the performance. Beyond these technical aspects, it is worth underlining that the analysis should not be limited to "engineering" aspect, i.e., energy recovery and process optimisation, but integrate the economics assessment to identify the best options among the candidates and account for the impact of process configuration on the profitability. This is not included the present work, but it will be investigated within the SEMPRE-BIO project.

## ABSTRACT

This paper presents ProcessSimulator.jl, an open-source process simulation framework built in Julia that combines acausal, equation-oriented modelling with seamless integration of procedural code. The framework leverages ModelingToolkit.jl to enable modular construction of unit operations using symbolic–numeric representations, facilitating the extension of models with advanced thermodynamics, kinetics, and data-driven components. Inspired by the ModuSim concept [3], ProcessSimulator.jl introduces an extensible control-volume abstraction and connector-based composition at the unit-operation level. A steady-state CSTR case study is presented and compared against Aspen Plus, showing good agreement in key variables. The results demonstrate the feasibility of a flexible, open, and composable process simulation paradigm for research and education.

**Keywords**: Process Simulation, Acausal Modeling, Modularisation, Open Source Software, Julia Language

## INTRODUCTION

Process simulation is a central component of process systems engineering, enabling the coupling of thermodynamics, transport, and reaction kinetics across interconnected unit operations for design, optimisation, and control of complex chemical systems. Current simulators have enabled remarkable advances in systems engineering since the 60s, thanks to prebuilt, configurable unit operations and thermophysical models. While prebuilt components are powerful, innovating and designing new processes requires going beyond them. In this sense, commercial simulators enable users to create unconventional unit operations through custom modelling languages. ASPEN Custom Modelling Language and gPROMS Model Builder are powerful tools for achieving this goal. One drawback, however, is that unconventional unit operations often require an interface between the modelling language (declarative), where the conservation laws are written, and a procedural language, where the thermodynamics, kinetics, and other calculation routines, such as those for Deep Learning and modern data-driven tools, are written. This interplay is often far from simple in commercial tooling, since such tooling is often designed to be self-contained.

We believe that reducing the gap and friction in this interplay is critical to the easy integration of emerging, complex process models. One way to achieve this is to run the simulator in a fully featured language that supports seamless interplay between declarative and procedural programming. Addressing these limitations requires a new simulation paradigm grounded in open, high-level, and composable programming frameworks that bridge symbolic and numeric representations at high performance.

Another highly desirable feature for process systems engineering simulators is modularisation at the unit operation level, as it readily enables modelling of non-standard problems. The idea of composing submodels into a unit operation that, when combined, forms a flowsheet has been part of process engineering research and practice since the 90s [1], [2], [3]. The ModuSim concept [3], for example, was proposed in the 90s along these lines. Concretely, the ideas presented in ModuSim are very amenable to the equation-oriented modelling paradigm, which partitions a system or unit operation into small sub-models and assembles them using acausal connectors. The connectors represent boundary

conditions spanning convective and diffusive transport across ports. This can be done at the unit operation level up to the flowsheet level. This is a highly flexible and powerful modelling concept for chemical engineering, especially when easily integrated into procedural code, where thermophysical and transport-property correlations are typically written (calculations that require complex code constructions – for, while, conditionals, data structures).

There exists open-source software for process simulation written in modern, fully featured programming languages built on different modelling concepts. IDAEs PSE [4] is a Python-based process modelling framework and model library for process simulation and optimisation. The software core stack has at its bottom the Pyomo Algebraic Modeling Language. On top, it contains a library of models for common process unit operations and thermophysical properties that can be used to rapidly create process systems. Modularity of unit operations is enabled by the object-oriented nature of the Python language through inheritance and method overloading, but it is not part of the language's inherent modelling philosophy, as it is in the Modelica environment, for example. NeqSim is a Java-based library for process simulation and fluid thermodynamics. It hosts a comprehensive library of unit operations and thermodynamic models, but it does not mention any constructs for extending models from basic elements. OMCHEMSim is an open-source library in OpenModelica supporting implementations of unit operations and thermodynamic models (within the Modelica language). At the moment, however, no open-source software is available for structured acausal network modelling with smooth integration with procedural coding for process and chemical engineering.

In this setting, we present ProcessSimulator.jl, an open-source package that aims to be a modern library for modularising process systems engineering models at the unit-operation level using acausal equation-oriented modelling, with a smooth interface to procedural code. The technologies that enable it are the open-source Julia programming language and the ModelingToolkit.jl (MTK.jl) package [5]. ModelingToolkit.jl is a symbolic-numerical package in Julia that enables the application of the concept of Physical Network Acausal modelling to build complex models by assembling components with connectors. The symbolic constructs of the components enable ModelingToolkit.jl to perform symbolic manipulations, such as automatic index reduction, variable transformation, and problem simplification, to provide the optimal form for a numerical solver.

ModelingToolkit.jl is inspired by the Modelica language and shares the same principles of acausal modelling; however, Modelica is not a fully featured programming language, which makes it difficult to express complex code constructs for efficient thermophysical property calculations. Consequently, attempts to construct a process simulation environment require rewriting thermodynamic calculations in Modelica [6] or using workarounds to access external packages written in other languages. Moreover, because ModelingToolkit is a Julia modelling language that generates Julia code (functions) using metaprogramming, it can be composed efficiently and smoothly with other libraries available in the language. Examples of such compositions are illustrated using the Clapeyron.jl package, which provides libraries for thermodynamic and transport properties.

Built-in compositions in ModelingToolkit.jl are also used to solve the resulting numerical problem, with DifferentialEquations.jl for dynamic simulations and NonlinearSolve.jl for steady-state problems. As in Modelica, there is a separation of concerns – the system is represented in a modelling language and further simplified by an algorithm to best suit the numerical solvers, leaving the modeller with the efforts to do what they know – to model systems.

It is worth noting that ProcessSimulator.jl is still in its early stages, but this publication aims to communicate its philosophy. We believe that with a well-structured philosophy, advancing the software becomes easier, since many other contributors can materialise the philosophy in code, a task that is cumbersome for a single person.

The benefits of creating a process simulator in a language such as Julia using the acausal modelling paradigm are several-fold. It is not only useful for custom and advanced modelling but also for educational purposes. The state of open-source scientific computing is advanced enough to simulate complex models in process and chemical engineering, especially in Julia. Using the freely available latent infrastructure to advance and expand computational tools in chemical engineering is therefore worth pursuing.

On the educational side, acausal-equation-oriented modelling prompts reflection on many important aspects that shape a good engineer - every part of the system must be placed through a rational, conscious decision: a system's degrees of freedom, what to include and what to exclude when modelling it. This is somewhat lost when engineers spend time configuring numerous boxes without a direct understanding of their impact on the model.

## METHODOLOGY

### Previous modularisation methodologies - The ModuSim

The constructs presented here aim to reflect many of the concepts and ideas in the ModuSim concept, using equation-oriented modelling. Both ModuSim and ModelingToolkit use different wording for similar concepts. Similarly, in ProcessSimulator.jl, we introduce additional vocabulary that shares meanings with many concepts in

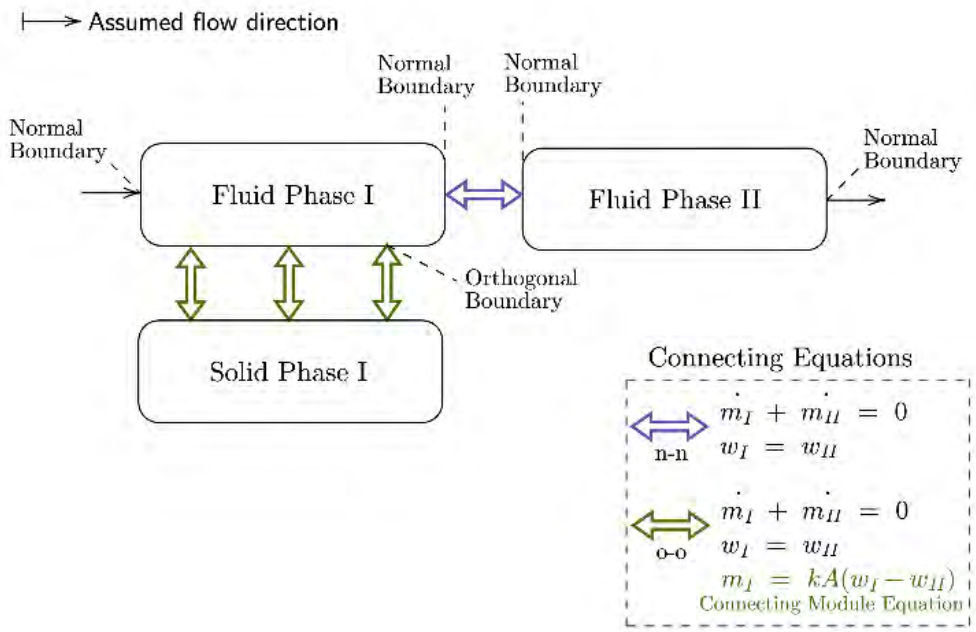

**Figure 1.** The ModuSim modularisation methodology. Adapted from [3].

ModuSim.

In ModuSim notation, there are two classes of main modelling objects: devices and connections. A device is a model object that may have a holdup of extensive quantities and that holds the relationships used to calculate state variables such as temperature, composition, and density. A connection creates equations that, when solved, calculate unknown fluxes from known variables at device boundaries. The ModuSim concept distinguishes between two types of connectors: normal and orthogonal boundaries. Normal boundaries point in the direction of the coordinate system (the direction of the convective flow), and orthogonal boundaries have no specified direction (depends on the potential for transfer in the system). The connection between two devices can only take place through a connector.

## The acausal equation-oriented equivalent of ModuSim in ProcessSimulator.jl

As previously mentioned, the core modelling language in ProcessSimulator.jl is ModelingToolkit.jl (MTK.jl). Therefore, the equivalent ModuSim construction in ProcessSimulator.jl is implemented using MTK.jl.

While ModuSim is chemical-engineering-oriented, the ModelingToolkit.jl notation is generic. Therefore, effort is necessary to translate ModuSim concepts into MTK.jl. MTK.jl also has classes of modelling objects. A component in MTK.jl is a data structure that holds variables, parameters, equations, a name, and potentially other inner components, nested within it. In some sense, a connector in MTK.jl is one special kind of component that also holds variables, parameters and a name. The only difference is that connectors automatically generate equations depending on the type of connection one assigns to their variables. ProcessSimulator.jl uses two types of connector variables from MTK.jl: flow, regular connectors. By tagging a connector variable as flow, whenever two connectors are connected, it creates the equation:

$$w_I + w_{II} = 0 \tag{1}$$

Moreover, the regular connector tag creates the following equation:

$$v_I - v_{II} = 0 \tag{2}$$

Where $w_I, w_{II}, v_I, v_{II}$ are the variables tagged as flow and regular variables from the connectors $I$ and $II$.

It is possible to see that the ModuSim normal-normal (n-n) connecting equations and part of the orthogonal-orthogonal (o-o) are displayed in Figure 1 can be well represented with connector variables through equations (1) and (2). The connecting module equation seen in green on Figure 1 It depends on which types of interaction arise from the two phases in contact. In the Figure, it can, for example, be an adsorbent in contact with a carrier gas during an adsorption separation process. In these lines, the connecting equation can be a linear driving-force mass-transfer equation.

The ModuSim paper has not provided details on how to modularise devices, i.e., what is the minimum set of equations and variables that can be later extended to become conventional or advanced unit operations –

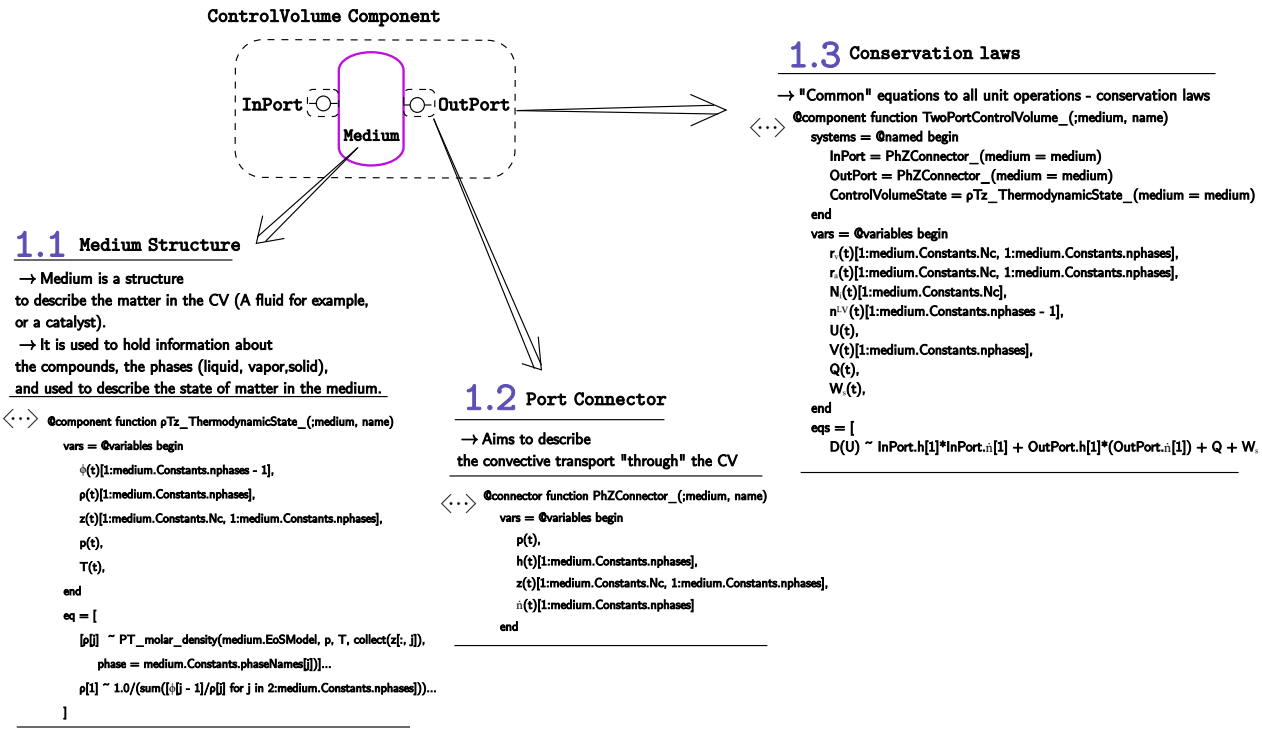

**Figure 2.** The ControlVolume modularisation strategy.

reactors, separators, etc. In ProcessSimulator.jl, we explored this aspect of the modularisation with the ControlVolume component. This is presented in the next section.

## The ControlVolume component

The idea behind the control volume component (in MTK.jl notation) is to provide an extensible component that can be easily transformed into a specific unit operation. To achieve this goal, some reasoning on what the equations are that are common to almost all "conventional" unit operations is required.

To keep it simple, we start by analysing perfectly mixed, multicomponent, non-distributed systems and their governing conservation equations (mole component balance and energy):

$$\frac{d(N_i)}{dt} = \dot{m}_{in} z_{in,i} + \dot{m}_{out} z_{out,i} + \mathrm{r}_{i,V} V + r_{i,A} A \qquad (3)$$

$$\frac{d(\mathrm{U})}{dt} = \dot{m}_{in} h_{in} + \dot{m}_{out} h_{out} + \dot{\mathrm{Q}} + \dot{W} \qquad (4)$$

$V$ is the control volume's volume, A is the control volume's area, U is the control volume internal energy, $h_{in}$ and $h_{out}$ are the inlet and outlet streams' molar enthalpies, $\dot{m}_{in,}$ and $\dot{m}_{out}$ are the overall inlet and outlet molar flow rates, $\dot{\mathrm{Q}}$ is the rate of heat to/from the control volume, $\dot{W}$ is the work rate done on the control volume by the environment. Additionally, $N_i$ is the molar holdup, $z_{in,i}$ and $z_{out,i}$ are the inlet and outlet streams' mole fraction, $\mathrm{r}_{i,V}$ is the volumetric molar rate of generation, all with respect to the $i^{\mathrm{th}}$ component.

In addition to the differential equations representing conservation laws, we need algebraic expressions for each of the terms of the equations, except $N_i$ which is set by an initial condition.

By default, equations for $\mathrm{r}_{i,V}, r_{i,A}, \dot{\mathrm{Q}}, \dot{W}$ are not specified and are left to the user to specify according to the unit operation being modelled. For example, a heated stirred tank can be extended by including the expression $\mathrm{r}_{i,V} = 0, r_{i,A} = 0, \dot{\mathrm{Q}} = Q_0, \dot{W} = W_0$ where $Q_0, W_0$ are real numbers. A heated stirred tank reactor can be extended by replacing zero generation rate by $\mathrm{r}_{i,V} = kinetics(N_i, V, T)$.

All the equations associated with variables marked with the $in$ Subscripts are derived from the control volume's connection to the nearest upstream components. These equations are defined in the ControlVolume using the InPort connector. InPort is of type PhZnConnector because it connects pressure, enthalpy, composition, and flow rate information. Pressure, compositions and enthalpy are regular connector variables – create equations like Equation (2). Flow rate is a flow variable; it yields equations like Equation (1).

When it comes to outlet variables ($out$ subscripts),

only the outlet flow rate ($\dot{m}_{out}$) information depends on downstream equipment. $h_{out}$ is calculated from the control volume's state and "transmitted" downstream. The ControlVolume has an OutPort of type PhZnConnector to transmit information downstream.

While rate laws are unit-operation-specific, thermophysical properties are not. Therefore, in ProcessSimulator.jl, the ControlVolume component encapsulates the "StateComponent". Internally, it calls functions which are used to evaluate its thermophysical properties, i.e.; $\mathrm{U} = internal_{energy(medium,T,\rho,N_i)}, \rho = density(medium, T, P, N_i)$ $h_{out} = enthalpy(medium, T, \rho, N_i)$

Where $medium$ is a structure that holds the information of the thermophysical model and $internal\ energy, density, enthalpy$ are functions to calculate the properties of interest. For density, for example, it typically involves a phase stability check followed by a sequence of other calculations depending on the $medium$ type. All these concepts are illustrated in the Figure 2.

When composing thermodynamic calculations with MTK.jl, direct calls from within those calculations can cause problems. MTK.jl makes extensive use of symbolic manipulation, and tracing symbolic variables through complex code structures leads to a symbolic explosion. To stop tracing, functions of this kind have to be registered. Registration informs MTK.jl that particular calculations should be treated as a single block rather than decomposed. Registering a function in MTK.jl is very simple, allowing users to treat any complex block in the modelling language as an isolated calculation block. If the registered functions are Julia-native, the Julia compiler will perform its optimisations, as it does in any other piece of Julia code, after code generation. This makes the modelling environment extremely flexible, powerful and performant, as discussed before.

Another challenge in chemical and process systems is that phase splitting can occur at any time during numerical simulation; therefore, it must be checked during the simulation. In practice, it means that $h_{out}, \mathrm{U}$ depends on the number of phases present, each phase's composition, and the fraction of each phase. If only one phase exists, it means that the fraction of the others is zero, and their compositions can be assigned to an arbitrary value. Stability checks must be run during simulation and used to detect phase splitting when it occurs.

## RESULTS AND DISCUSSION

To illustrate the modularisation strategy implemented in ProcessSimulator.jl in this work, a steady-state, fixed-volume CSTR reactor simulation is presented.

The reactor has $1\ \mathrm{m}^3$ volume and carry out the reaction between ethylene oxide and water to produce ethylene glycol with all stoichiometric coefficients equal to 1, and the reaction rate given by a power law with a first-order dependency on the concentration of ethylene oxide. The kinetics are expressed in code using the structure `PowerLawReaction` developed in ProcessSimulator.jl:

```
rxn1 = PowerLawReaction(components = components, stoichiometry = Dict("ethylene oxide" => -1.0, "water" => -1.0, "ethylene glycol" => 1.0), order = Dict("ethylene oxide" => 1.0, "water" => 0.0), A = 0.5, Ea = 0.0)
```

The inlet temperature is set to 350.15 K and 5 bar, with a flow rate of 100 mol/s, and an excess of water (60 mol/s of water and 40 mol/s of ethylene oxide). The reactor pressure is set to match the inlet pressure. The inlet specifications are encapsulated in the `Boundary_pTzn` component, which is equivalent to an infinite source of matter that drains at a fixed pressure, temperature, composition, and flow rate. It was not discussed in the methodology, but anyone familiar with common simulators is familiar with the material stream on those. It is the exact same construction. In terms of code, it is wrriten as:

```
@named S1 = Boundary_pTzn(medium = medium, p = 5*101325.0, T = 350.15, z = [0.4, 0.6, 0.0], flowrate = 100.0, flowbasis = :molar)
```

Medium is created using the Clapeyron.jl [7] extension, which is built as part of ProcessSimulator.jl. The details of the thermodynamic model are beyond the scope of this work, but it is correlation-based and based on established literature.

```
components = ["ethylene oxide", "water", "ethylene glycol"]
idealmodel = CompositeModel(components,
 liquid = RackettLiquid,
 gas = ReidIdeal(components, reference_state = :formation),
 saturation = DIPPR101Sat,
 hvap = DIPPR106HVap)
activity = NRTL(components)
model = CompositeModel(components, fluid = idealmodel, liquid = activity)
medium = EoSBased(components = components, eosmodel = model)
```

To create the fixed-volume reactor, we use an extension of the control volume from lines 150 to 174 in https://github.com/SciML/ProcessSimulator.jl/blob/siglephase-approach/src/reactors/CSTR.jl. These are the code implementations of the additional equations that extend the control volume to a reactor.

With this set of specifications, it is easy to demonstrate that no additional specifications are required to fulfil the degrees of freedom, and the outlet flow rates and temperature are then determined by solving the conservation laws, kinetics and additional constraints.

The results for the outlet stream were compared with those obtained in ASPEN V12.1 using the NRTL non-ideal model and the default ideal models. The comparison is shown in Table 1. The largest difference is in the ethylene oxide (EO) mole fraction (about 60%). This is attributed to solver configurations rather than implementation errors, since the other variables show discrepancies smaller than 10% and orders of magnitude much higher than the mole fraction.

**Table 1:** Outlet stream results comparison – ProcessSimulator.jl and ASPEN.

| Property | Unit | Aspen (SI) | ProcessSimulator (SI) | % diff (PS vs Aspen) |
|---|---|---|---|---|
| Temperature | K | 350.15 | 350.15 | 0.0% |
| Pressure | Pa | $5.07 \times 10^5$ | $5.07 \times 10^5$ | 0.0% |
| Liquid molar flow | mol/s | 60.2 | 60.34 | 0.2% |
| Molar enthalpy | J/mol | $-3.94 \times 10^5$ | $-3.55 \times 10^5$ | 9.7% |
| Total mass flow | kg/s | 2.84 | 2.84 | 0.0% |
| Mole frac — EO | — | 0.00355 | 0.00562 | 58.5% |
| Mole frac — $H_2O$ | — | 0.336 | 0.337 | 0.4% |
| Mole frac — EG | — | 0.661 | 0.657 | −0.5% |
| Heat duty | W | $-4.00 \times 10^5$ | $-3.81 \times 10^5$ | 4.8% |

## CONCLUSIONS

ProcessSimulator.jl demonstrates that acausal, symbolic–numeric modelling in Julia provides a flexible and extensible foundation for process simulation. By combining modular unit-operation design with seamless access to procedural thermodynamic and kinetic models, the framework reduces modelling friction and supports advanced custom applications. Although still in early development, the presented philosophy and case study indicate strong potential for future research, industrial prototyping, and education in process systems engineering.

## ABSTRACT

Nanoparticle (NP) synthesis has been extensively studied since the mid-1800s and are utilized across numerous fields due to their unique microscopic properties that collectively yield macroscopic benefits. Of particular interest are silver (Ag) NPs, whose controllable size and morphology impart distinct catalytic, electronic, and optical properties advantageous for environmental and energy-related applications. The theoretical understanding of NP nucleation and growth has advanced considerably starting with classical nucleation theory, evolving into the LaMer model centering on burst nucleation and diffusion-limited growth and resulted in near monodispersed hydrosols. Finke and Watzky later introduced the autocatalytic model considering a slow and continuous nucleation and autocatalytic surface growth not limited by monomer diffusion. However, the precise mechanisms remain the subject of active debate for the different homogeneous and heterogenous nucleation systems. In this study, simulation models for NP population balances are developed using both material balanced and constant number Monte Carlo methods to describe NP formation and growth under diffusion-limited and autocatalytic conditions. Perturbative analysis of the model provides insight into whether NP formation is diffusion-limited or autocatalytic and how addition(s) or subtraction(s) of precursor influence the NP growth mechanism. Perturbative analysis reveals the mean particle size and variance can be tuned by adding or removing precursor molecules during the reaction, although the overall size distribution trend remains consistent. The present study together with new experimental capabilities lays the foundation for a model-based design of experiments to explore the nucleation and growth mechanism of metal nanoparticles.

## INTRODUCTION

The development of nanoparticle (NP) synthesis models began with classical nucleation theory (CNT), progressed through the LaMer diffusion-limited model [1], and later evolved into the autocatalytic Finke–Watzky framework [2]. Early experimental observations, starting in the mid-19th century, established that NPs could form under controlled chemical conditions and exhibit unique properties distinct from bulk materials [3]. As experimental techniques improved, these foundational ideas were extended into population balance modeling (PBM), which captures the dynamic evolution of particle size distributions by accounting for nucleation, growth, and aggregation processes [4].

CNT emerged from pioneering work by Faraday, Ostwald, Zsigmondy, and later Becker and Döring, who formalized nucleation kinetics using population-based equations [5]. CNT successfully explains the energetic barrier to nucleus formation and distinguishes between homogeneous and heterogeneous nucleation. However, it treats nuclei as bulk-like entities and provides limited mechanistic insight into post-nucleation growth and final particle size distributions, leaving important gaps in understanding nanoparticle growth behavior [5].

To address growth and size uniformity, LaMer

introduced a diffusion-limited model describing three distinct stages: monomer accumulation, burst nucleation once a critical concentration is reached, and subsequent growth limited by monomer diffusion. This model explained the formation of near-monodisperse particles and became widely cited as a general framework for nanoparticle synthesis [1]. Nonetheless, because it was developed for sulfur sols and extrapolated to other systems, its applicability, particularly to transition metals, has been questioned, as many systems do not exhibit instantaneous burst nucleation or purely diffusion-limited growth [6].

The autocatalytic Finke–Watzky model challenged the LaMer paradigm by proposing slow, continuous nucleation at low monomer concentrations coupled with rapid autocatalytic surface growth. In this framework, smaller particles grow faster than larger ones, naturally leading to near-monodisperse (or sized focused) distributions without burst nucleation [2]. Subsequent refinements added diffusion driven agglomeration and secondary autocatalytic steps, supported by kinetic studies, microscopy, and simulations, further improving the model's ability to capture experimentally observed nanoparticle growth pathways [7].

Modern approaches integrate the autocatalytic framework with mechanism-enabled PBM to explicitly track particle dispersity throughout nucleation and growth [8]. While this approach has been successful for certain transition metals, evidence from silver nanoparticle and nanowire systems shows that diffusion processes remain important alongside autocatalytic growth and LaMer growth may still be important [7, 9, 14]. Consequently, accurate modeling of silver NP formation requires a hybrid framework that incorporates both autocatalytic surface reactions and diffusion-limited transport, motivating the development of tailored kinetic and population balance models for silver NPs (AgNPs). These computational studies support our experimental efforts to understand the mechanism of Ag NP growth by the polyol process [10-13].

## THEORETICAL OBJECTIVES

The objective of this research is to develop a mechanistic and kinetic understanding of NP nucleation, growth, and particle size distribution (PSD), with particular emphasis on how transient perturbations in reactant concentration can differentiate formation mechanisms. By elucidating not only how NPs form but also how their size and PSD can be controlled, this work aims to enable the rational design of AgNPs for applications in medicine, catalysis, sensing, and related commercial fields [14]. A testable, mechanistic hypothesis is proposed in which nucleation follows first-order kinetics and growth proceeds via second-order autocatalytic kinetics, represented through reaction extents for nucleation ($\xi_0$) and growth ($\xi_{n+1}$, n > 0). This framework (Table 1) allows systematic investigation of how changes in reaction conditions, precursor concentration(s), and additives can be used to manipulate AgNP size and dispersity, providing a foundation for model refinement using empirical data.

**Table 1.** Hypothesized reaction mechanism for NP nucleation and growth.

| Step | Reaction | Rate |
|---|---|---|
| Nucleation | $A \xrightarrow{k_0} C_1$ | $R_0 = \frac{d\xi_0}{dt} = k_0[A]$ |
| Growth | $A + C_n \xrightarrow{k_n} C_{n+1}$ | $R_n = \frac{d\xi_n}{dt} = k_n[A][C_n], \forall\, n \geq 1$ |

The corresponding material balance equations for the different species generating NPs are given in Table 2, assuming a batch reactor system. These predict how the NP concentration changes over time in relation to the precursor and nucleate.

**Table 2.** Species concentration rate over time under reaction mechanism of Table 1.

| Species | Rate |
|---|---|
| Precursor | $\frac{d[A]}{dt} = -k_0[A] - \sum_{n=1}^{\infty} k_n[A][C_n]$ |
| NP Nucleate | $\frac{d[C_1]}{dt} = k_0[A] - k_1[A][C_1]$ |
| NP | $\frac{d[C_n]}{dt} = k_{n-1}[A][C_{n-1}] - k_n[A][C_n], \forall n \geq 2$ |

**Table 3.** Normalized NP species concentrations over time.

| Species | Normalized Rate |
|---|---|
| Precursor | $\frac{dc_A}{d\tau} = -\kappa_0 c_A - c_A \sum_{n=1}^{\infty} \kappa_n c_n$ |
| NP Nucleate | $\frac{dc_1}{d\tau} = \kappa_0 c_A - \kappa_1 c_A c_1$ |
| NP | $\frac{dc_n}{d\tau} = \kappa_{n-1} c_A c_{n-1} - \kappa_n c_A c_n, \forall n \geq 2$ |

Species concentrations are normalized to the initial precursor concentration $[A]_0$, yielding the dimensionless quantities $c_A$ for the precursor and $c_n$ for the nanoparticles. Characteristic times are defined based on the reaction rate constants: the nucleation time $\tau_N$ and the growth time $\tau_G$, normalized to the nucleation and growth rate

constants, respectively, as summarized in Table 3. Normalizations for autocatalytic growth are also provided by:

$$\tau = \frac{t}{\tau_G} \quad , \kappa_0 = \frac{\tau_G}{\tau_N} = \frac{k_0}{[A]_0 k_n} \tag{1}$$

These equations form the foundation of the NP nucleation and growth mechanisms simulated in the two models developed here. To enable versatility across both diffusion-limited and autocatalytic regimes, a diffusion component is incorporated to account for the transport of monomer to the NP surface. The Smoluchowski equation, which characterizes diffusion-limited aggregation [15-18], was originally formulated to describe the collision rate between two colloidal particles. A simplified form of this expression is used here by assuming the precursor is a single Ag atom of unit radius $r_{Ag}$, the NP radius follows a 1/3 power-law dependence on the number of Ag atoms per NP (or $n$), and the diffusion coefficient ($D$):

$$k_{D,n} = 4\pi D r_{Ag} n^{1/3} \tag{2}$$

Here, the effective NP growth rate constant is expressed as the inverse sum of the autocatalytic and diffusion-limited rate constants per Collins-Kimball [16-17].

$$k_{eff,n}^{-1} = k_{D,n}^{-1} + k_{A,n}^{-1} \tag{3}$$

This formulation allows the model to represent purely diffusion-limited growth ($k_{A,n} = 0$), purely autocatalytic growth ($k_{D,n} = 0$), or a combination of both mechanisms. Accordingly, the reaction rates listed in Table 1 can be extended to incorporate diffusion effects by using Equation 3. The rate of precursor diffusion to the NP surface relative to autocatalytic growth rate can be summarized by the Damköhler number (Da).

$$Da_n = \frac{k_{A,n}}{k_{D,n}}, for\ n > 0 \tag{4}$$

Larger Damköhler numbers yield higher autocatalytic growth of NPs relative to diffusive flux of precursor atoms to the NP surface [18]. For this study, we can consider the ratio of the rate constant for the first growth event to the diffusion coefficient, $k_{A,1}/D$, for characterization of varying degrees of diffusion to autocatalytic growth.

## MODELING METHODOLOGY

Two NP nucleation and growth simulation models were developed, a material balanced (or constant volume) model and a constant Number Monte Carlo Model. Both utilize the Metropolis-Hastings Markov Chain Monte Carlo (MCMC) method to nucleate and grow NPs [19-20].

### Material Balanced Monte Carlo Model

A stochastic model for NP formation was implemented in Python using the Metropolis–Hastings MCMC method. The NP formation system can be considered a Markov Chain since the NP reaction rates are predicated on the current concentration of the NPs and precursor [20]. The material balanced NP formation algorithm proceeds in two stages.

For the first stage, nucleation is represented as the initial element, while subsequent elements correspond to autocatalytic growth. Reaction rate constants follow an Arrhenius-like decay reflecting the lower surface area to volume as NP size increases. Alternatively, a power law decay could also be used but Arrhenius-like decay was used for this work.

$$k_{A,n} = k_{A,1} e^{-\lambda n} \tag{5}$$

First, a uniform random number, $N_{R,1}$, between 0 and 1 is selected based on a cumulative normalized vector of reaction rates defined by Equation 6 below:

$$X_n = \frac{\sum_0^i R_n}{\sum_0^T R_n} \tag{6}$$

where T is the maximum size of the NP reaction rate vector. Within the normalized vector of reaction rated $X_n$, an NP size is identified such that:

$$X_{n-1} < N_{R,1} \leq X_n \tag{7}$$

The normalized cumulative vector enables selection of nucleation or NP growth where nucleation dominates at the initial stage, while growth probabilities become more dispersed as particles enlarge.

Second, the accept–reject algorithm determines whether the chosen event occurs. Reaction rates are normalized to the maximum rate per Equation 8:

$$Y_n = \frac{R_n}{\max(R_n)} \tag{8}$$

a second uniform random number, $N_{R,2}$, is drawn and, if it is less than or equal to the normalized rate, the event is accepted. If it is greater, the event is rejected. This ensures particles with higher reaction rates are more likely to grow, while those with lower rates stagnate.

Ultimately, this framework provides mechanistic insight into NP formation and growth. By training the model with experimental data, particle size distributions can be mapped over time using heat maps, contour plots, or other 3-D visualizations. This enables model-based design of experiments to compare classical LaMer and Finke–Watzky autocatalytic models, offering a pathway to control NP size and distribution through mechanistic understanding of nucleation and growth kinetics.

### Adaptability of NP Formation

The material balanced model is extended to incorporate monomer additions and subtractions at defined times during nucleation and growth. Resulting changes in reaction rate constants, surface free energy, and precursor reduction are evaluated to assess their impact on NP formation. NP evolution is tracked through changes in mean particle size and the full-size distribution. Key perturbations include adding precursor atoms during

growth, introducing structure-directing agents ($H_2$), and accounting for ambient oxygen. Incorporating these variations enables the simulation to quantify how each perturbation influences NP formation and growth dynamics, yielding a clearer picture of the underlying mechanism.

Although precursor concentrations are difficult to control experimentally, perturbations observed in experimental data can be used to validate the simulation. Canning et al have used perturbation analysis that nucleation is fast relative to growth [10]. Minute changes in precursor concentration are challenging to monitor in real time, but the model enables controlled virtual experiments that replicate these conditions. By comparing simulation results with measurable experimental perturbations, the robustness and predictive capability of the model can be validated.

The material balanced model, while effective in simulating precursor concentrations, becomes computationally expensive and less practical for large NP sizes, as all precursor and NPs must be explicitly accounted for. To address this limitation, a second approach was developed: the constant Number Monte Carlo model. This framework tracks a fixed number of particles that may nucleate, grow, or leave the system based on probabilities dictated by reaction rates. This approach reduces computational demands and extends functionality, making it more suitable for simulating NP nucleation and growth at larger scales.

## Constant Number Monte Carlo (cNMC) Model

In the constant Number Monte Carlo (cNMC) method, an array of NPs is tracked for nucleation and growth within a simulation box. This approach is analogous to transmission electron microscopy (TEM), where a representative sample slide reveals the NP distribution [21]. In the cNMC model, the number of NPs in the simulation box ($c_N$) remains constant, while the NP mass concentration ($c_M$) increases over time as NPs nucleate and grow. The average volume $\langle v \rangle$ is defined as:

$$\langle v \rangle = \frac{c_M}{c_N} \tag{9}$$

Thus, NP distributions and concentrations must be tracked individually. Assuming normalized precursor and NP concentrations, the initial conditions are defined as:

$$c_{0,(t=0)} = 1, c_{n,(t=0)} = 0 \tag{10}$$

$$c_N = \sum_1^\infty c_n = 0 \tag{11}$$

The NP autocatalytic growth rate and mean growth rate constant are expressed as:

$$r_A = c_0 c_N \frac{\sum_{n=1}^{\infty} k_n c_n}{c_N} \tag{12}$$

Experimentally, TEM measurements of NP size and number yield a similar mean growth rate constant:

$$\langle k_N \rangle = \frac{\sum_{n=1}^{\infty} k_n c_n}{c_N} = \frac{\sum_{n=1}^{N} k_{n(i)}}{N} \tag{13}$$

with nucleation and autocatalytic growth rates defined as

$$r_N = k_0 c_0 \tag{14}$$

$$r_A = c_0 c_N \langle k_N \rangle \tag{15}$$

The simulation box contains N particles representing normalized concentrations $c_N(t)$, with N constant while $c_N$ and $c_M$ evolve. Each Monte Carlo step updates the system by either: (1) nucleation adds an NP of mass 1 to the box and ejects a random NP from the box to maintain a constant N or (2) growth adds one unit of mass ($\delta_v = +1$) to an existing NP in the box. The time increment and NP mass concentration change are given by:

$$\delta t = \frac{1}{r_N + r_G} \tag{16}$$

$$\delta c_M = \frac{c_m \delta v}{N \langle v \rangle} \tag{17}$$

with initial conditions:

$$t = 0, c_0 = 1, c_M = 0, c_N = 0, \langle v \rangle = 0$$

The first event is always nucleation and therefore Equations 14-15 reduce to:

$$\delta t = \frac{1}{k_0} \tag{18}$$

$$\delta c_M = \frac{1}{N} \tag{19}$$

Subsequent events update the mean NP size and growth rate constant:

$$\langle k_n \rangle = \frac{\sum_{i=1}^{N} k_i}{N}, \langle v \rangle = \frac{\sum_{i=1}^{N} v_i}{N} \tag{20}$$

At each step, nucleation or growth is chosen probabilistically. The probabilities are:

$$P_N = \frac{r_N}{r_N + r_G} \tag{21}$$

$$P_G = \frac{r_G}{r_N + r_G} \tag{22}$$

$$P_N + P_G = 1 \tag{23}$$

If growth occurs, an NP is selected based on its relative reaction rate constant. The chosen NP increases in mass by one unit, and system variables are updated in Equations 14-15. This algorithm is repeated until the desired number of iterations is reached, enabling simulation of NP nucleation and growth dynamics under constant particle number constraints.

# RESULTS

Two MCMC models, the material balanced model and the cNMC model, were developed and validated to simulate NP formation and growth. These models generate data to examine how NPs nucleate, grow, and how their size distributions can be manipulated and controlled over time. Both frameworks can be adapted to represent either diffusion-limited LaMer growth, the autocatalytic

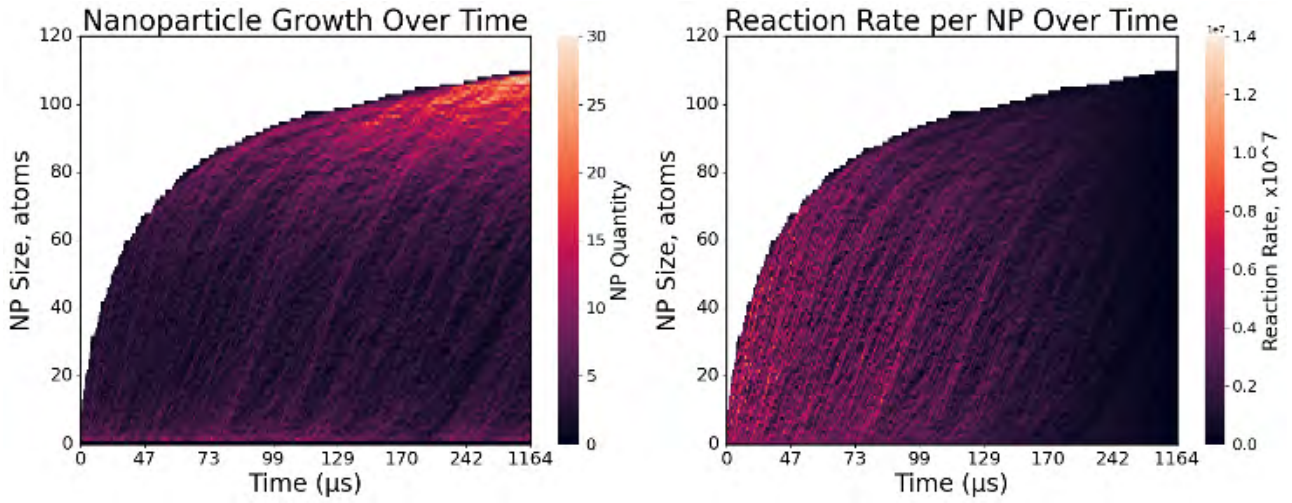

**Figure 1.** Material balanced model simulation of NP formation and growth and reaction rate over time. NP size (left) and reaction rate (right) show convergence of larger NPs at longer time scales (size-focusing) and decreasing reaction rate as precursor atoms are consumed. This simulation was executed assuming a nucleation rate, $k_0 = 100\ \frac{1}{s}$ initial growth rate, $k_1 = 1,000 \frac{1}{Ms}$, successive $k_n$ values following equation 5, $D = 1.0\ \frac{l^2}{s}$, λ = 0.05, and an initial silver concentration population of 50, 000 atoms resulting in $\frac{k_{A,1}}{D} = 1,000\ \frac{1}{l^2 M}$ ($\overline{Da}$=2.51). The simulation time was calculated using the inverse sum of the reaction rates for each step.

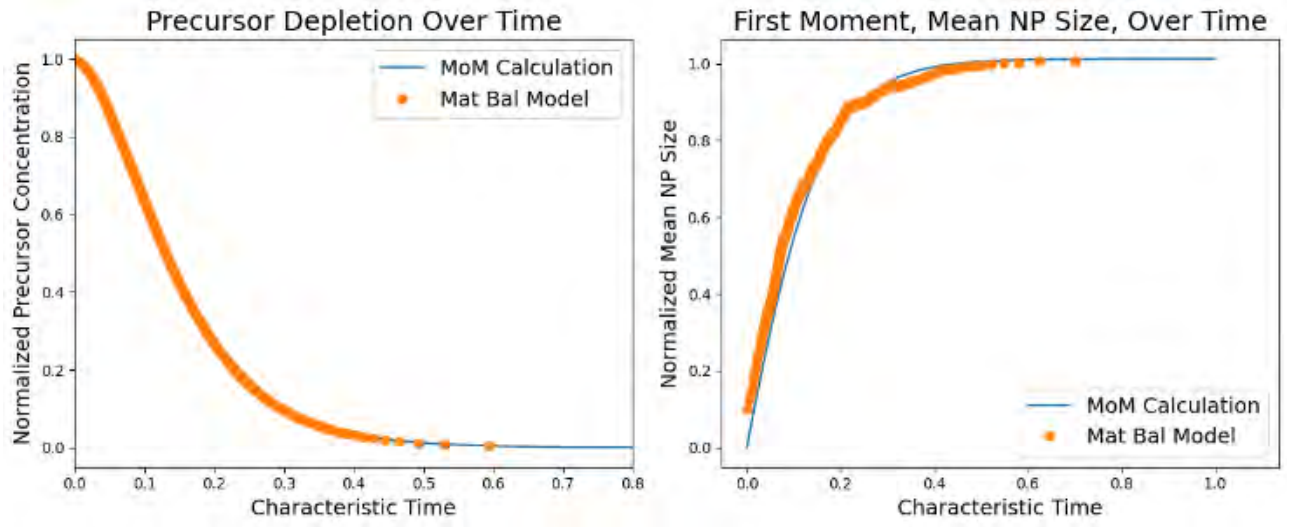

**Figure 2.** MoM validation of the material-balanced model. The material balanced model exhibits alignment with the MoM calculations for both precursor concentration (left) and the first-moment NP mean size (right) over time, demonstrating consistent predictive behavior across the two approaches.

Finke–Watzky mechanism of NP formation, or both. The simulations were performed on Google Colab using a T4 GPU. NP size distributions were tracked in pandas arrays, and three-dimensional heat maps were generated with the seaborn package in Python.

## Material Balanced Monte Carlo Model

The material balanced (constant volume) model was implemented following the Methodology section of the referenced paper and used to simulate nanoparticle formation. This framework is well suited for systems with a finite precursor supply, enabling perturbative analyses in which precursor is added or removed and allowing calculation of NP formation yield. Consistent with literature consensus, reaction rate constants decrease as NP size increases [22]. Figure 1 shows the evolution of particle size distribution and reaction rates over time; the heat-map representation highlights their coupled,

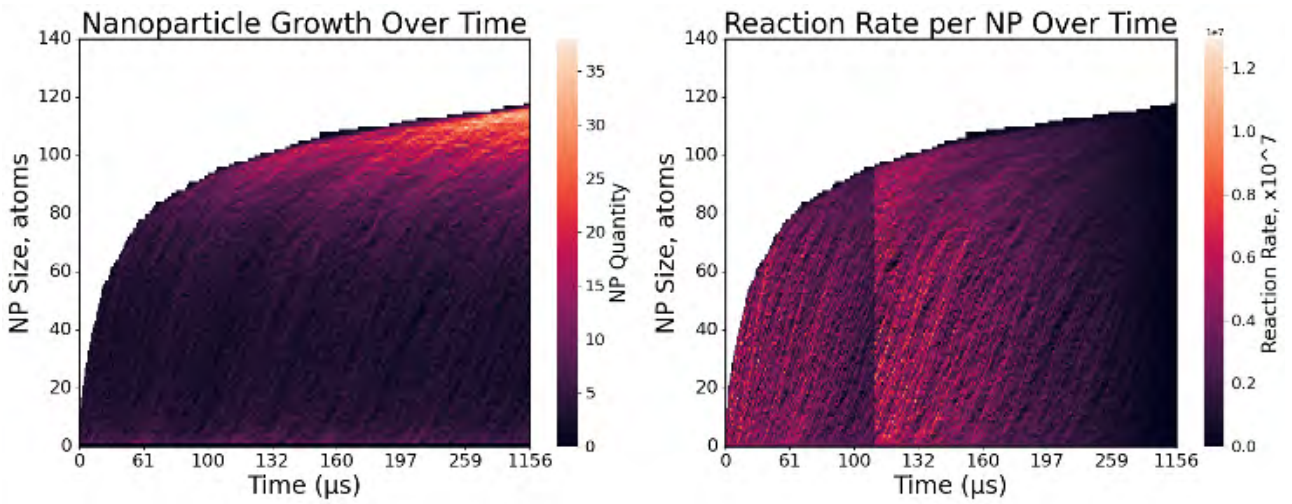

**Figure 3.** Perturbative analysis of NP growth where 25, 000 precursor molecules are added once 50% of the 50, 000 initial precursor molecules have reacted with conditions described in Figure 1. A sudden increase in reaction rate is noted as precursor is injected leading to a larger NP mean size.

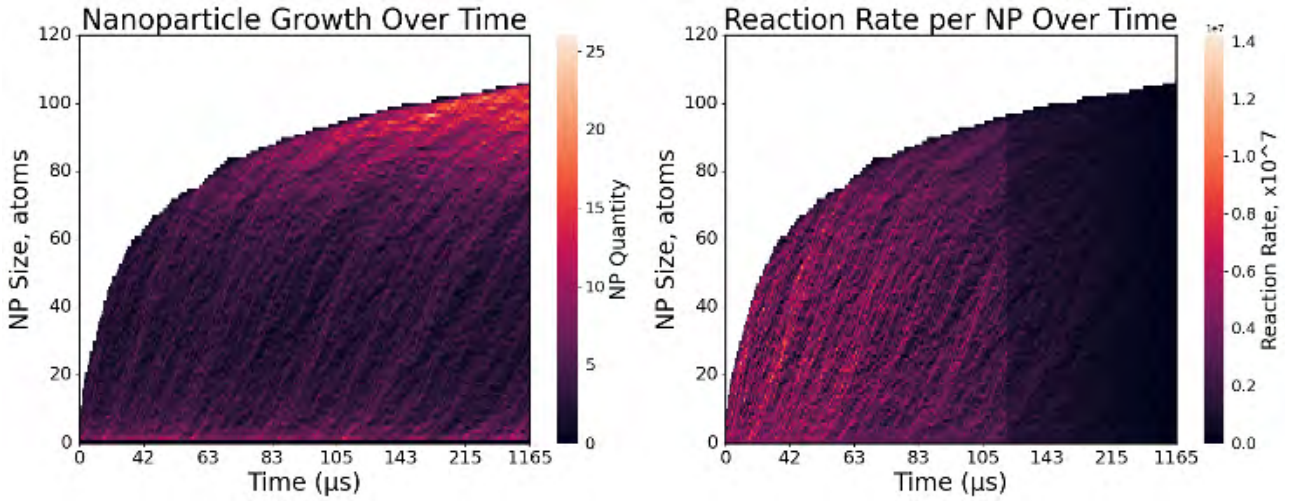

**Figure 4.** Perturbative analysis of NP growth where 10, 000 precursor atoms are subtracted once 50% of the 50, 000 initial precursor molecules have reacted with conditions described in Figure 1.

three-dimensional progression. As illustrated, the population size-focuses toward a mean of 73.75 ± 32.96 Ag atoms.

The material balanced model was validated using a Method of Moments (MoM) simulation for NP generation and results are shown in Figure 2. The normalized precursor concentration exhibits a sigmoidal decay profile where nucleation dominates early, growth accelerates precursor consumption, and depletion slows once precursor is consumed. The NP mean size follows the expected trend as well, increasing as NPs form and then tapering as precursor is exhausted which is in alignment with the MoM simulated mean.

Development and validation of the material balanced model provides the foundation for simulating perturbations to assess their effects on NP mean size and dispersity, which offers insight into the nanoparticle formation and growth mechanism.

## Adaptability of NP Formation

The effect of precursor additions and changes in reaction conditions on NP growth was examined. In one scenario, an additional 50% of precursor was injected once half of the initial precursor had been consumed. As shown in Figure 3, starting with 50, 000 precursor atoms, an extra 25, 000 molecules were introduced after 50% precursor conversion. The reaction rate then increased sharply, evident from the intensified color on the heat map. This behavior occurs because the sudden availability of precursor accelerates growth across all NP sizes

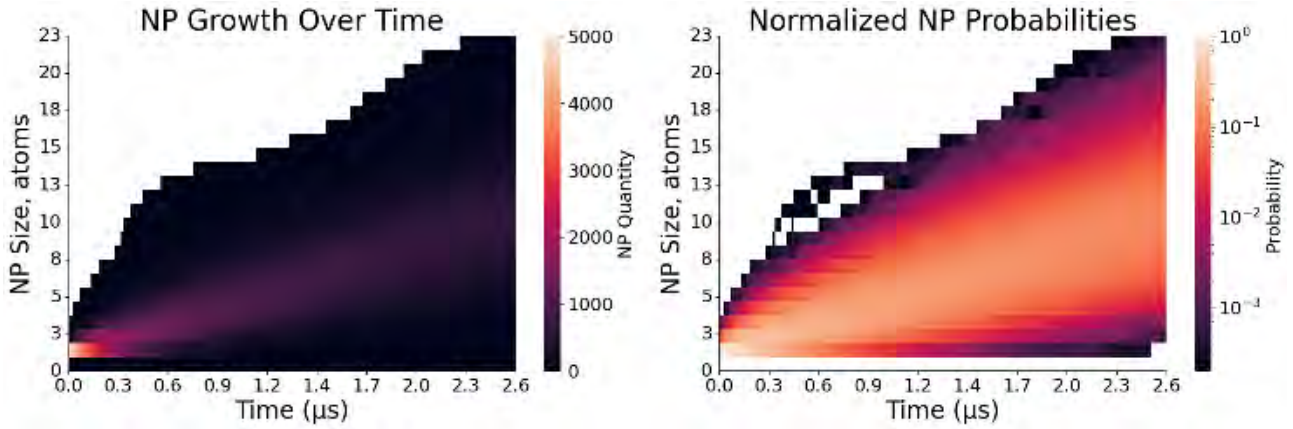

**Figure 5.** cNMC simulation using a 5000-particle box with $k_0$ is 1x10$^{-12}$ and $k_n$ is based on Arrhenius-like Decay (λ = 0.05). NP growth for 50, 000 iterations allows NPs to grow up to ~90 atoms.

simultaneously. In this case, the NPs size focus toward a mean of 82.33 ± 34.39 Ag atoms.

Conversely, we looked at subtracting precursor molecules when 50% of precursor atoms have reacted. Experimentally, this could be achieved by adding a deactivation reagent to the solution where suddenly a fraction of precursors are deactivated and unable to nucleate or add to existing NPs. Figure 4 shows this simulation and, in comparison with Figure 3, shows the reaction rates suddenly decrease once the fraction of precursor molecules are added to the system. In this case, the NPs size focus toward a mean of 67.80 ± 32.50 Ag atoms.

As such, perturbations in the addition or subtraction of precursor atoms during the reaction have a strong influence on the mean and the variance of the final NP size distribution. Adding precursor atoms increases the mean size and variance of the NP population whereas subtraction of the precursor molecules during the reaction lowers the mean size and variance.

Expanding on this point, Table 4 summarizes the relative variation in NP size increases as the diffusion coefficient decreases. In other words, greater resistance to diffusion leads to a more dispersed, or less size-focused, NP population. This increase in dispersity becomes even more pronounced when the system experiences perturbations that add or subtract precursor molecules.

The results in Table 4 show that both diffusion coefficient and precursor perturbations systematically shape NP size evolution. Lower diffusion coefficients produce larger mean NP sizes because restricted mass transport limits precursor delivery to NP surfaces, promoting continued growth of existing particles. At the same time, the normalized standard deviation and polydispersity increase as diffusion slows, yielding broader, less size-focused populations. Additive perturbations suppress dispersity, whereas precursor removal amplifies it, especially at low diffusion. Systems with restricted diffusion are therefore more sensitive to precursor fluctuations, resulting in greater heterogeneity in the final NP size distribution.

**Table 4.** Final NP size and dispersity parameters after precursor perturbations at three diffusion coefficients.

| **Diffusion Coeff** | **0.010** | **0.100** | **1.000** |

## Constant Number Monte Carlo (cNMC) Model

The cNMC model has the advantage that it can grow nanoparticles (NPs) to very large sizes and run for an effectively indefinite simulation time. Since the algorithm

does not impose a finite precursor pool, additional precursor atoms can be introduced into the simulation box as NPs grow. Under the conditions shown here in Figure 5, the mean NP size converges towards a mean of 10.99 ± 2.50 Ag atoms.

Event probabilities indicate nucleation is initially far more likely than growth; however, once NPs form, the probability rapidly shifts toward growth. This behavior is consistent with both the LaMer burst-nucleation picture and the autocatalytic Finke–Watzky mechanism. As NPs enlarge, their total mass increases while the particle concentration ($c_n$) remains constant within the simulation box. The cNMC framework, therefore, provides an alternative approach to simulating NP nucleation and growth that is not constrained by a fixed particle number. Additionally, it is more representative of TEM experiments, where a sample of the reaction mixture is analyzed as a distribution within a finite observation volume.

**Table 5.** Summary of NP size and dispersity parameters obtained from the Constant Number Monte Carlo (cNMC) simulations at varying diffusion coefficients. Increasing diffusion leads to reduced polydispersity and a systematic increase in mean NP size.

| Diffusion Coeff | 0.010 | 0.100 | 1.000 |
|---|---|---|---|
| $k_{A,1}/D$ | 100,000 | 10,000 | 1, 000 |
| Result | | | |
| Mean NP size | 5.87 | 9.32 | 10.76 |
| Std Dev (SD) | 4.47 | 4.53 | 3.09 |
| Norm SD | 0.76 | 0.49 | 0.29 |
| Polydispersity | 1.58 | 1.24 | 1.08 |

As observed in the material balanced model, NP polydispersity decreases with increasing diffusion coefficient. However, in contrast to the material balanced model, the mean NP size increases with greater precursor diffusivity. This difference arises because, in the cNMC model, the simulation box effectively expands as precursor atoms are added during growth. Faster diffusion therefore increases the rate at which precursors reach the NP surface, enabling larger average NP sizes while still narrowing the size distribution. In the material balanced model, by contrast, the simulation box is fixed by the initially supplied precursor, making growth increasingly supply limited as NPs grow and precursors depleate. Together, these frameworks clarify how diffusion-limited and supply limited regimes shape NP growth. Both the material balanced and cNMC models will be used for experimental studies in which simulated size distributions can be directly compared with TEM-derived NP populations to validate mechanistic assumptions about NP formation under various kinetic regimes.

## DISCUSSION

A nanoparticle growth model was proposed (Table 1) incorporating LaMer diffusion-limited growth via the Smoluchowski equation with the Collins–Kimball framework, and implemented along with two formation and growth models using a Metropolis–Hastings MCMC algorithm [19-20]. Both the material balanced and cNMC models were developed to study NP formation under experimental conditions and to accommodate diffusion-limited LaMer [1] and autocatalytic Finke–Watzky [2] mechanisms. Diffusion-limited growth was modeled with Smoluchowski diffusion, while autocatalytic growth followed an Arrhenius-like decay in rate constants, consistent with observations that larger NPs grow more slowly [22]. Although the original autocatalytic framework was designed for iridium, its applicability to diffusion-limited silver systems is uncertain; diffusion remains a critical parameter for AgNP growth [7, 14] and is explicitly included here. Increasing diffusional resistance (i.e., decreasing diffusion coefficient) produces more disperse NPs in both the material balanced and cNMC models.

A perturbative analysis was performed in which precursor molecules were added or removed once 50% of the initial precursor had been consumed. This analysis revealed that subtracting precursor decreased the mean and increased the dispersity of the final NP distribution, while adding precursor caused the reverse. Despite these perturbations, the overall particle size distribution remained relatively consistent, demonstrating the robustness of the modeling framework.

A constant Number Monte Carlo (cNMC) NP growth model was also developed to incorporate both autocatalytic and diffusive components. Event probabilities show that nucleation dominates first, but once NPs begin to form, the likelihood rapidly shifts toward growth. This transition mirrors the mechanistic behavior described by both the LaMer model and the autocatalytic Finke–Watzky framework. As in the material balanced model, increasing diffusion decreases NP dispersity. However, in contrast to the material balanced model, the mean NP size increases with increasing diffusion. This difference arises because the cNMC framework does not impose a finite precursor pool and is not supply limited. Precursor can be continuously added into the simulation box and are therefore not limited by the initial concentration.

Development of these models, with the use of controlled perturbations, provides a powerful framework for understanding how NPs grow and achieve size focusing. These perturbation studies reveal how fluctuations in precursor availability can reshape both the mean and dispersity of the final NP population, offering mechanistic insight into the sensitivity of NP growth pathways. Future work will focus on aligning experimental data with both material balanced and cNMC models to determine how

nucleation and early-stage growth proceed at scales below typical instrumental detection limits and define fundamental NP formation mechanisms. The simulations presented here demonstrate precursor perturbations exert measurable and systematic effects on NP size evolution, underscoring the value of this modeling approach for probing nanoscale processes that are otherwise experimentally inaccessible.

## ABSTRACT

This work presents the conceptual design, rigorous simulation, and multi-objective optimization of an integrated multiproduct biorefinery focused on the sustainable valorization of lignin into catechol and a portfolio of high-value aromatic derivatives, including guaiacol, vanillin, and vanillic acid. The proposed methodology combines a critical review of synthesis pathways and kinetic data with detailed process modeling in Aspen Plus® V14. The process framework begins with lignocellulosic biomass pretreatment via acid hydrolysis, followed by catalytic lignin depolymerization to obtain catechol as a platform intermediate. Subsequently, dedicated reaction and separation sections are designed for the selective conversion of catechol into value-added derivatives, incorporating energy-efficient and thermally integrated separation schemes. A stochastic multi-objective optimization strategy based on Differential Evolution with a Tabu List (DETL) is implemented to simultaneously assess economic and environmental performance indicators. The results demonstrate that lignin can be effectively upgraded into commercially relevant fine chemicals, confirming its strategic role within next-generation biorefineries and reinforcing the transition toward circular, low-emission chemical processes.

**Keywords**: Biorefinery, Catechol, Catechol Derivatives, Process Design, DETL Optimization

## INTRODUCTION

Currently, approximately 80% of global primary energy consumption and nearly 90% of chemical products are derived from fossil-based resources. The extensive exploitation of these resources has led to significant environmental, economic, and social impacts that are increasingly incompatible with the commitments established in the United Nations 2030 Agenda for Sustainable Development [1]. In this context, the development of sustainable chemical production routes capable of reducing greenhouse gas emissions and fossil dependency has become a strategic priority.

Biorefineries have emerged as a promising technological paradigm for converting renewable biomass into fuels, energy carriers, and high-value chemicals. Among the main biomass constituents, lignin represents the most abundant renewable source of aromatic structures [2].

Historically, lignin has been significantly underutilized within the lignocellulosic biorefinery framework, predominantly burned for low-grade heat and power generation [3]. Early techno-economic and life cycle assessments established the fundamental viability of shifting this paradigm. For instance, Montazeri and Eckelman [4] demonstrated the environmental advantages of lignin-derived catechol over its petrochemical counterpart, while Mabrouk et al. [5] confirmed its market competitiveness using olive tree pruning as a primary feedstock.

However, the field has rapidly evolved beyond single-product feasibility. Recent comprehensive reviews, such as John et al. [6], confirm that the current state-of-the-art is shifting toward increasingly integrated and efficient multi-product systems. These studies encompass a diverse range of feedstocks showing that product diversification is fundamental to mitigating economic risks and improving the overall sustainability of the system.

Despite these advances, a critical limitation remains: most studies focus exclusively on the production of a

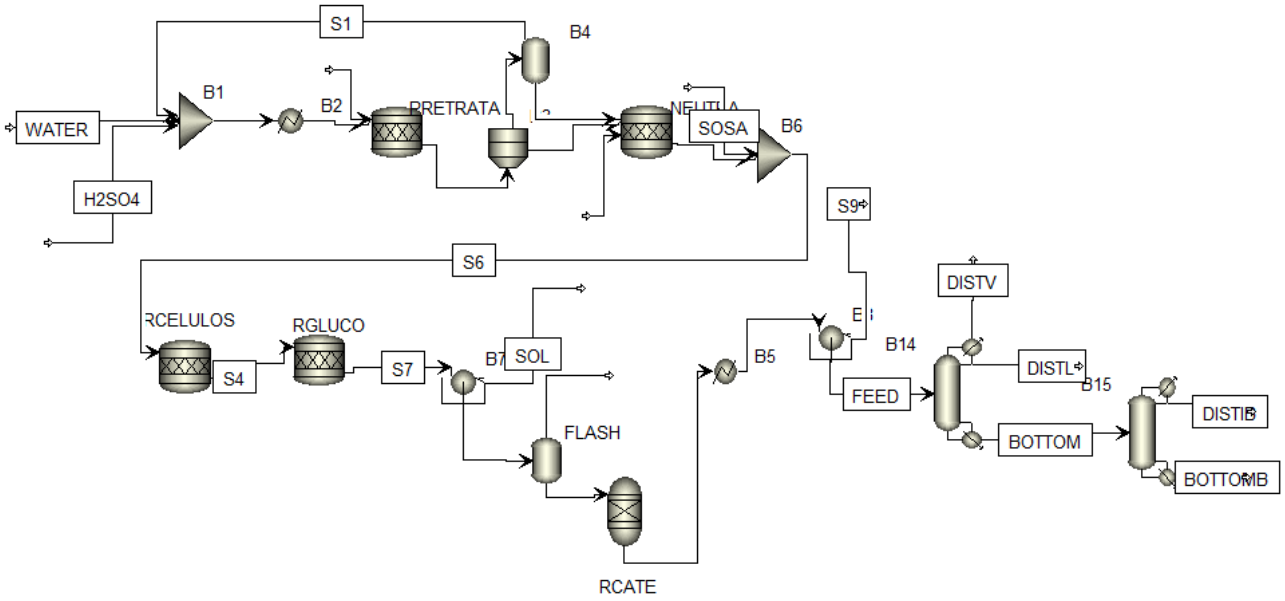

**Figure 1.** Diagram Process of Catechol Production.

single platform molecule. This work addresses this gap by proposing a multiproduct biorefinery where catechol serves as a strategic intermediate for the synthesis of higher value-added products, specifically focusing on the guaiacol pathway and its conversion into vanillin and vanillic acid. The novelty of this contribution lies in the integrated optimization of the entire value chain—from lignocellulosic biomass to purified fine chemicals—under circular economy principles.

By combining rigorous simulation with advanced stochastic optimization, this work provides a robust and scalable framework aligned with Sustainable Development Goals 7 (Affordable and Clean Energy), 9 (Industry, Innovation, and Infrastructure), 12 (Responsible Consumption and Production), and 13 (Climate Action), offering a viable pathway toward a bio-based and low-carbon chemical industry [7].

## METHODOLOGY

The proposed methodology comprises the conceptual design, rigorous simulation, kinetic modeling, and multi-objective optimization of a multiproduct biorefinery aimed at lignin valorization. All process units were modeled using Aspen Plus® V14, ensuring thermodynamic consistency and reliable mass and energy balances.

### Simulation of Catechol Production

A thermodynamic framework based on the Non-Random Two-Liquid (NRTL) activity coefficient model was selected to accurately represent the highly non-ideal behavior of the multicomponent liquid mixtures involved. The process begins with the fractionation of lignocellulosic biomass through dilute-acid hydrolysis, modeled as a continuous reactor operating at temperatures between 140 and 200 °C using sulfuric acid as catalyst. This pretreatment selectively solubilizes hemicellulose into a xylose-rich aqueous stream, while producing a solid fraction primarily composed of cellulose and lignin.

The solid fraction is subsequently processed in a catalytic depolymerization section to break down the lignin macromolecular structure. Cellulose conversion to glucose is simultaneously considered. Due to the limited availability of detailed kinetic data for lignin depolymerization, a yield-based reactor model (RYield) was employed to represent the conversion of solubilized lignin into catechol under high-temperature conditions (300 °C). The resulting product stream is purified through a dedicated separation train consisting of two distillation columns designed to recover catechol with commercial-grade purity.

### Simulation of Guaiacol Pathway

Catechol is further valorized via vapor-phase O-methylation with methanol over an alumina-based catalyst. This reaction system was modeled using a tubular fixed-bed reactor (RPlug), incorporating a kinetic scheme that accounts for both guaiacol formation and the parallel production of veratrole as an undesired byproduct. Reactor operating conditions were selected to maximize selectivity toward guaiacol.

Given the formation of azeotropic mixtures, the

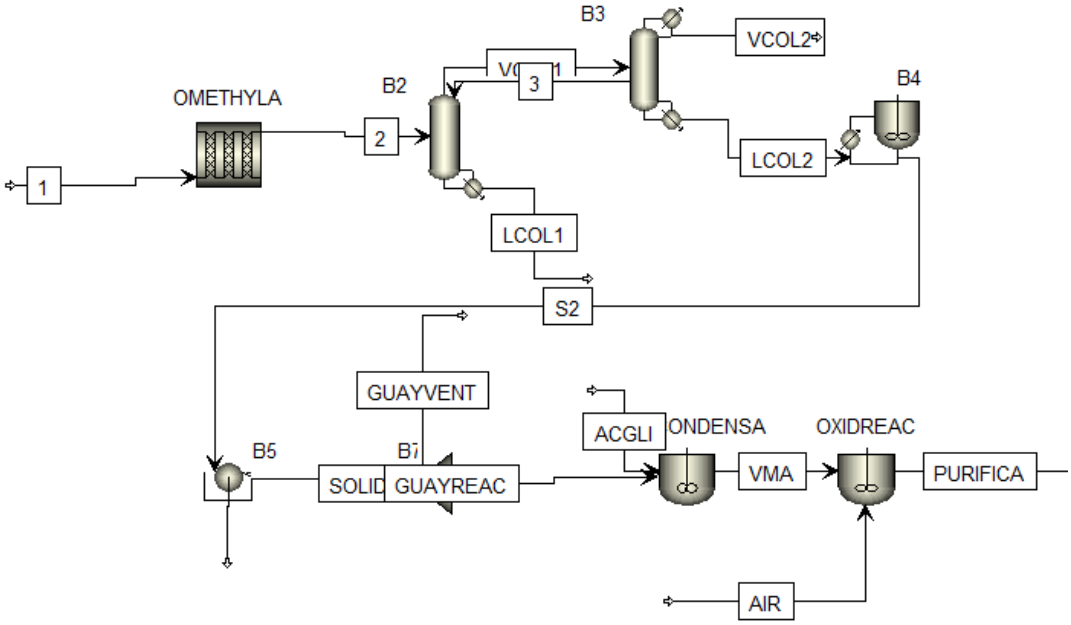

**Figure 2.** Diagram Process of Guaiacol Pathway.

downstream separation was modeled using a hybrid separation strategy combining distillation and melt crystallization within a thermally coupled indirect distillation sequence. This approach significantly reduces energy consumption compared to conventional standalone distillation systems.

For vanillin synthesis, the purified guaiacol stream was conditioned and fed to a liquid-phase reaction section composed of two continuous stirred-tank reactors (CSTRs) arranged in series. In the first reactor, the condensation reaction between guaiacol and glyoxylic acid was carried out in an aqueous basic medium, producing the key intermediate vanillylmandelic acid (VMA).

Finally, the conversion of VMA into the target product was achieved through oxidative decarboxylation in the second CSTR. A continuous bubbled air feed stream was introduced to supply the required oxygen. From a kinetic standpoint, this stage was defined as a system of competitive parallel reactions of zero order with respect to the reactants, favoring vanillin formation (approximately 89%) over over-oxidation to vanillic acid (approximately 11%).

## Optimization of Kinetic Parameters

For the O-methylation reaction system, a first-order kinetic model with respect to each reactant was formulated. The kinetic parameters, including pre-exponential factors and activation energies, were estimated through a stochastic optimization approach using the Differential Evolution with Tabu List (DETL) algorithm. The objective function minimized the global error between simulated and experimental molar flow rates of guaiacol, veratrole, and water, ensuring robust predictive capability.

Process-level optimization was subsequently carried out using the same DETL framework, treating the overall flowsheet as a black-box system. Aspen Plus® acted as the calculation engine, while Microsoft Excel was used to evaluate economic and environmental objective functions. Decision variables included operating temperatures, pressures, flow rates, reflux ratios, and the number of theoretical stages in separation units.

$$C_6H_6O_2 + CH_3OH \rightarrow C_7H_8O_2 + H_2O \quad (1)$$

$$r_1 = k_1 C_A C_B \quad (2)$$

Where $k_1$ is the first-order kinetic constant, $C_A$ is Catechol's molar concentration and $C_B$ is the Methanol's molar concentration.

## Optimization Process

Process optimization is essential due to the inherent complexity of the models, which integrate highly nonlinear and non-convex equations to describe the behavior of kinetic reactors and rigorous separation units. In this work, a stochastic black-box optimization strategy was implemented using the Differential Evolution with a Tabu List (DETL) algorithm, which interacts directly with the simulator without requiring prior knowledge of the internal equations or precise system initialization.

For the execution of this phase, an integrated framework was developed to dynamically link Aspen Plus V14 with Microsoft Excel. In this framework, the simulator

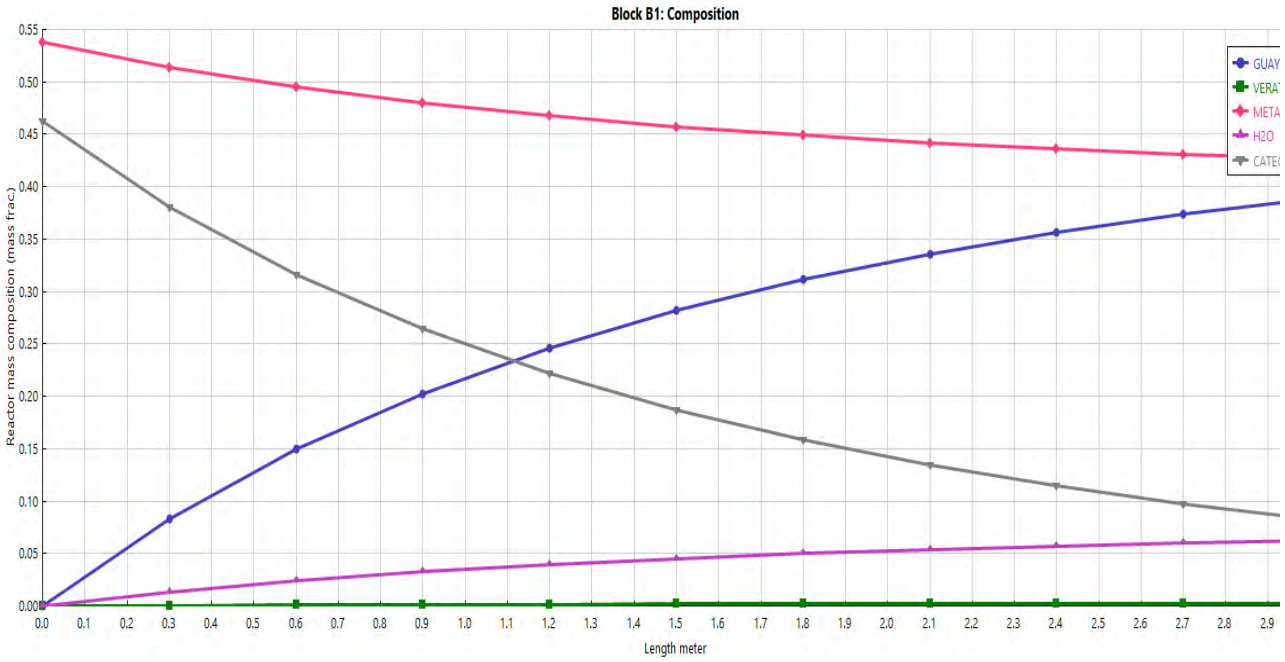

**Figure 3.** O-methylation reactor composition profiles

acts as the computational engine for mass and energy balance calculations for a given set of operating variables, while the spreadsheet centralizes the results to compute the objective functions. The algorithm manages the exploration of the solution space by manipulating key variables such as stream flow rates, operating temperatures and pressures of the equipment, the number of stages, reflux ratios, among others, with the aim of minimizing the objective functions.

## RESULTS

The multi-objective optimization identified operating configurations that simultaneously enhance technical performance, economic viability, and environmental sustainability. Key improvements include significant reductions in energy consumption through optimized reflux ratios and thermally integrated separation schemes, increased selectivity toward high-value derivatives, and a substantial decrease in carbon footprint due to reduced utility demand and improved material efficiency.

The multi-objective optimization ensured a technically and environmentally efficient catechol production stage, establishing a robust foundation prior to its conversion into high-value derivatives. As detailed in the Table 1, the refined design of the separation trains significantly reduces energy consumption and operating costs by configuring 54 stages for Column 1 and 30 stages for Column 2. The implementation of optimized reflux ratios (21.54 and 72.68, respectively) facilitates the recovery of a platform intermediate with commercial-grade purity while minimizing the overall carbon footprint. These results supported the economic and sustainable viability of catechol as a precursor within the proposed biorefinery scheme.

**Table 1:** Catechol Purification Results

| Variable | Column 1 | Column 2 |
|---|---|---|
| Pressure | 1.01 bar | 1.01 bar |
| Number of Stages | 54 | 30 |
| Feed stage | 50 | 13 |
| Distillate rate | 1925.74 kmol/h | 0.682033 kmol/h |
| Bottom Rate | 140.736 kmol/h | 140.054 kmol/h |
| Reflux Ratio | 21.5 | 72.7 |
| Condenser Duty | $-4.7878 \times 10^6$ cal/sec | -175740 cal/sec |
| Reboiler Duty | $4.988 \times 10^6$ cal/sec | 176079 cal/sec |

Table 2 demonstrates a highly efficient material balance for the catechol production stage. The separation train processes a substantial distillate rate in Column 1 to isolate key components, eventually yielding a steady bottom rate of 140.05 kmol/h in Column 2, which corresponds to the purified catechol stream. This optimized flow distribution minimizes waste and ensures that catechol is recovered with the high purity required for its subsequent conversion into high-value derivatives.

**Table 2:** Catechol Production Streams

| Compound | Flow |
|---|---|
| Biomass | 15000 kg/h |
| Xilose | 4602.25 kg/h |
| Glucose | 824.998 kg/h |
| Soluble Lignin | 1375.5 kg/h |
| Methanol | 5928.53 kg/h |
| Catechol | 200 kg/h |

Through the implementation of the DETL stochastic optimization algorithm, the global error objective function was successfully minimized, yielding a set of kinetic parameters that faithfully reproduce the experimental flow profiles. The optimized values for the pre-exponential factors and activation energies regarding the proposed reaction scheme are summarized in Table 3.

**Table 3:** Optimization of Kinetic Parameters Results

| Variable | Value |
|---|---|
| Pre-exponential factor 1 | $5.96x10^{9}$ |
| Activation Energy 1 | 22931.2 cal/mol |
| Pre-exponential factor 2 | $4.08x10^{7}$ |
| Activation Energy 2 | 20052.9 cal/mol |
| Pre-exponential factor 3 | $5.50x10^{7}$ |
| Activation Energy 3 | 23500.5 cal/mol |

**Table 4:** Guaiacol Purification Results

| Variable | Column 1 | Column 2 |
|---|---|---|
| Pressure | 1.01 bar | 1.01 bar |
| Number of Stages | 58 | 20 |
| Feed stage | 15 | 10 |
| Distillate rate | 8.6263 kmol/h | 7.2653 kmol/h |
| Bottom Rate | 0.4553 kmol/h | 1.3609 kmol/h |
| Reflux Ratio | 16.4 | 9.0 |
| Condenser Duty | -554, 992 cal/sec | -178, 723 cal/sec |
| Reboiler Duty | 547, 441 cal/sec | 156, 341 cal/sec |

The integration of thermally coupled demonstrates high technical and economic efficiency for the separation of higher-value derivatives. As shown in the process flowsheet, the effluent from the O-methylation reactor is processed through a sequence of columns where thermal coupling minimizes energy demand. The optimized design, detailed in the Table 4, achieves commercial-grade purity while significantly decreasing operating costs through equipment size reduction and improved heat integration.

Based on the mass balance results presented in the Table 5, a catechol feed of 200 kg/hr is successfully processed to yield 166.66 kg/hr of guaiacol as a primary intermediate. Subsequent condensation and oxidation stages further valorize this stream, resulting in the production of 60.911 kg/hr of vanillin and 7.5284 kg/hr of vanillic acid. The precise control of side-reactions is evidenced by the minimal formation of by-products such as veratrole (1.0286 kg/h), ensuring high selectivity and product purity throughout the integrated biorefinery scheme. These flow rates confirm the robustness of the optimized chemical pathways in maximizing the economic revalorization of lignin-derived platform molecules.

**Table 5:** Guaiacol Pathway streams.

| Compound | Flow |
|---|---|
| Catechol | 200 kg/hr |
| Guaiacol | 166.66 kg/hr |
| Veratrole | 1.0286 kg/h |
| VMA | 68.44 kg/hr |
| Vanillin | 60.911 kg/h |
| Vanillic Acid | 7.5284 kg/h |

These results consolidate the proposed scheme as a viable alternative for next-generation biorefineries focused on the sustainable valorization of lignin, contributing to Sustainable Development Goals (SDGs) 7, 9, 12, and 13 related to clean energy, innovative industry, responsible production, and climate action.

## CONCLUSION

This study demonstrates the technical feasibility of an integrated biorefinery, achieving a high-purity separation of aromatic derivatives through an optimized distillation sequence. Simulation results in Aspen Plus show that the process can recover catechol with a molar purity of 99.99% and a recovery rate of 200 kg/hr, and production of 166.66 kg/hr of Guaiacol, 60.911 kg/hr of vanillin, and 7.52 kg/hr of vanillic acid from the lignin-derived stream.

The energy performance of the process was significantly enhanced through the integrated design, where the total thermal duty of the distillation reboilers was minimized to ensure an efficient resource allocation within the circular economy framework. By combining rigorous simulation with advanced stochastic optimization, this work establishes a robust numerical foundation for further life cycle assessment and process intensification. These findings reinforce the strategic role of biomass-derived aromatics in the transition toward a sustainable and low-carbon chemical industry.

# Integrated Data-Driven Optimisation of LNG Hot Section for Energy Efficiency and Decarbonization

**Aisha Al-Hammadi[a]*, Dr Tareq Al-Ansari[a], Dr Ahmed AlNouss[a], Abdul Aziz Shaikh[a]**

[a] College of Science and Engineering, Hamad Bin Khalifa University (HBKU), Qatar Foundation, Doha, Qatar

## ABSTRACT

In today's competitive LNG market, reducing energy consumption is critical for enhancing both profitability and sustainability. The hot section of the LNG processing, which includes inlet receivers, acid gas removal, and dehydration units, is the most thermally demanding. Previous optimisation methods targeted each unit separately. On the other hand, this work details the development of a data-driven optimisation framework to minimise energy across these interdependent units. Preliminary application of the framework has yielded encouraging results. Utilising HYSYS process simulation data, the study successfully identifies critical operating variables—such as reboiler duty, amine circulation rate, and air-to-furnace stoichiometry—that drive production efficiency and energy consumption. Results indicate that a baseline condensate mass flow of 2, 048.71 kg/h is achieved at a stripper bottom temperature of 137.74 °C, while the AGRU produces sweet gas with 0.18 ppm $H_2S$. Optimisation using Pareto frontier analysis reveals a "knee" point in the SRU at 96.9% recovery efficiency, balancing elemental sulfur production (7, 622.24 kg/h) against heating loads. The findings provide mathematical coefficients for plant control to maximise yield while maintaining strict environmental stack limits.

**Keywords**: Natural Gas, Liquified Natural Gas, Optimization, LNG Optimization, Data-driven optimization, Hot section, Energy Efficiency.

## INTRODUCTION

The liquified natural gas (LNG) industry faces pressure to reduce energy intensity as global markets demand both economic competitiveness and environmental sustainability. The liquefaction process is highly energy-intensive, consuming a significant portion of the feed gas's energy, mainly to power the large compression systems that drive refrigeration cycles. This high energy consumption results in both high operating costs and significant CO2 emissions. For a typical LNG facility, even a small reduction in specific energy consumption results in significant annual savings and reduces the carbon footprint.

LNG production involves two process sections (hot section and cold section). The hot section operates at ambient temperature to pre-treat the feed gas, removing impurities that would otherwise freeze in cryogenic equipment. As shown in Figure 1, the hot section consists of an inlet receiver, a condensate stabilisation unit, an acid gas removal unit (AGRU), and molecular sieves dehydration. The treated gas enters the cold section for liquefaction through different cooling cycles, such as propane pre-cooling and mixed refrigerant cycles, reaching -162 ºC. The hot section accounts for a substantial portion of total plant energy consumption through thermal duties in amine regeneration reboilers, condensate stabilisation columns, and molecular sieve regeneration systems [1].

While research has focused on optimising the cold section (cryogenic liquefaction processes), the hot section has received limited attention. A critical, overlooked characteristic is the high interdependence among the hot-section units. Condensate stabiliser overhead composition affects molecular sieve loading, acid gas removal efficiency influences downstream dehydration requirements, and heat integration opportunities create coupling through the thermal utility system. Despite these interdependencies, traditional optimisation approaches have mainly focused on individual unit operations in isolation, leading to suboptimal overall plant performance.

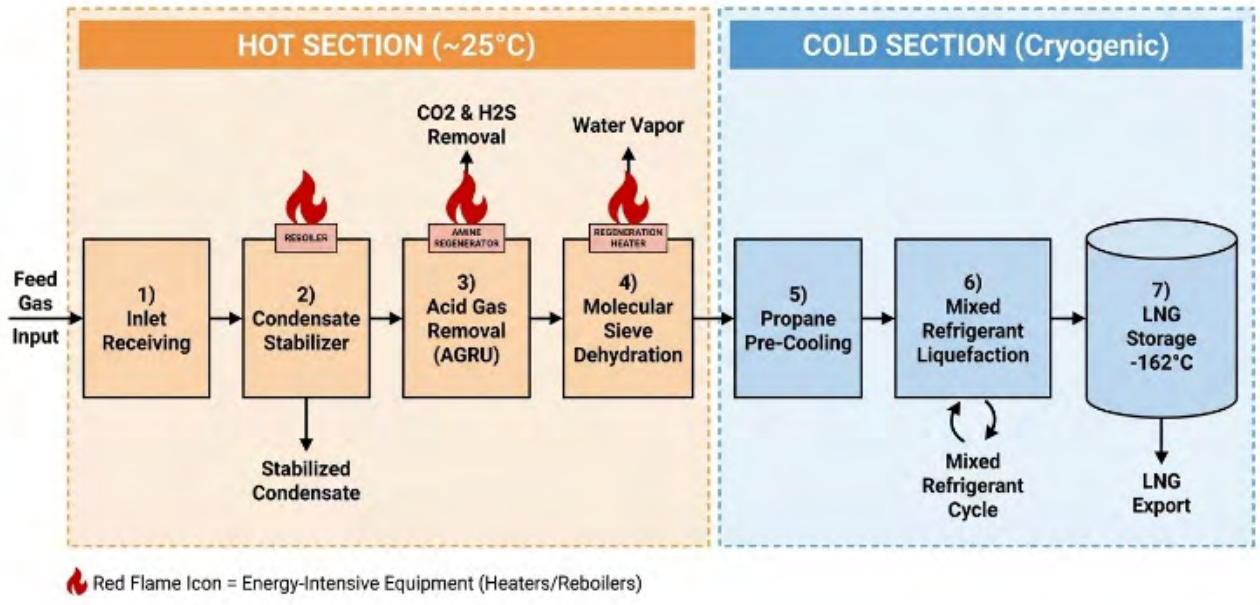

**Figure 1.** LNG plant hot and cold sections configuration.

This work addresses the gap between traditional unit-specific optimisation and the operational reality of interdependent systems. Rather than employing conventional model-based optimisation that requires extensive first-principles modelling, this study develops a data-driven optimisation framework that uses simulation data to identify optimal operating strategies.

## LITERATURE REVIEW

### Hot Section Energy Intensity

The hot section consists of several thermally intensive units. The acid gas removal unit (AGRU), employing amine-based absorption-regeneration cycles, is the most significant energy consumer, with large reboiler duties for solvent regeneration [2]. Condensate stabilisation separates light hydrocarbons from heavier liquids that require significant thermal energy, while molecular sieve dehydration requires periodic regeneration with hot gas at elevated temperatures [1].

These units show significant interdependencies. Feed composition variations affect all units; for instance, changes in CO2 content alter amine circulation requirements and reboiler duty, while variations in heavy hydrocarbon content affect both condensate stabilisation loads and downstream molecular sieve performance. Heat integration opportunities further couple the units through the thermal utility system [3].

### Conventional Optimisation Approaches

LNG process optimisation has historically relied on employing detailed first-principles models in platforms. Chew et al. (2022) developed an AGRU model and optimised operating conditions using a hybrid genetic algorithm and sequential quadratic programming, achieving a 22% reduction in reboiler duty. Shaikh et al. (2022) applied pinch analysis, demonstrating that waste heat recovery could supply a substantial portion of molecular sieve regeneration energy requirements.

First-principles approaches face limitations, such as the burden of extensive model development and calibration, computational expense when optimising large flowsheets, difficulty in translating theoretical optimal solutions into practical operational changes, and a static nature that provides limited guidance for real-time adaptation to changing conditions [4]. Industrial practice often relies on heuristic optimisation based on operational practice, which has limited exploration, difficulty handling variable interactions, and a tendency to underestimate trade-offs.

### Research Contribution

This work addresses critical gaps: (1) limited data-driven optimisation in LNG hot section despite the successful applications in other industries, (2) inadequate consideration of units' interdependencies with most studies addressing individual units separately, and (3) disconnect between academic optimisation and industrial application due to computational complexity and model validation challenges. The primary challenge lies in the competitive nature of the optimisation objectives. For instance, increasing condensate stabilisation to meet

Reid Vapour Pressure (RVP) limits inherently reduces mass yield by vaporising light hydrocarbons. Similarly, the AGRU must balance solvent circulation against regeneration energy, while the SRU requires precise stoichiometric control to prevent $H_2S$ breakthrough. This report quantifies these trade-offs through rigorous sensitivity mapping and optimisation formulation.

The study is conducted using a steady-state HYSYS simulation framework. The methodology followed a four-step process:

1. Baseline Validation: Current plant data for condensate stabilisation, AGRU, and SRU are used to establish the baseline.
2. Framework Analysis: The simulation utilised the Sour-PR and Sulfinol-D fluid packages for accurate phase behaviour and acid gas kinetics.
3. Sensitivity Studies: Operating parameters are varied by ±10% to ±40% to observe the impact on Objective Functions (Mass Flow, Duty, Purity).
4. Optimisation Formulation: Competitive objectives were plotted to identify the Pareto Frontier.

The simulation is based on a high-pressure feed gas arriving at **7, 800 kPa**. Key baseline values extracted from the simulation workbooks are summarised below:

**Table 1:** Key baseline values from simulation

| Parameter | Value |
|---|---|
| Condensate Mass Flowrate | 2, 048.71 kg/h |
| Condensate Stripper Duty | 1, 766, 960 kJ/h |
| Stripper Bottom Temperature | 137.74 °C |
| Sweet Gas Mass Flowrate from AGRU | 412, 312.66 kg/h |
| AGRU Solvent Circulation Rate | 1, 319, 223.78 kg/h |
| AGRU Regenerator Reboiler Duty | $1.81 \times 10^9$ kJ/h |
| AGRU Overall Duty | $2.49 \times 10^9$ kJ/h |
| $CO_2$ Content in AGRU Sweet Gas | 81.5 ppm |
| $H_2S$ Content in AGRU Sweet Gas | 0.18 ppm |
| Lean Solvent Temperature to Absorber | 55 °C |
| $H_2S$ mol% Entering SRU (Acid Gas) | 48.7 mol% |
| $H_2S$ ppm Content from SRU (Stack) | 4.26 ppm |
| SRU Overall Duty | $1.22 \times 10^9$ kJ/h |
| Elemental Sulphur Production | 7, 622.24 kg/h |

## Sensitivity Analysis

Sensitivity curves depict the competitive relationships among production capacity, energy consumption, and product purity across the different units of the LNG hot section.

Figure 2 represents the trade-off between maximising mass flow rate and meeting stabilisation requirements. Reboiler Duty varied within +-20% range to study Condensate Mass Flow and RVP. The curves show a decreasing trend of condensate flow and RVP with increasing reboiler duty.

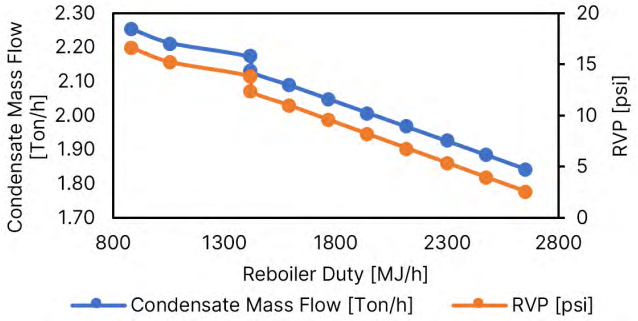

**Figure 2.** Sensitivity analysis of condensate stripper reboiler duty against condensate production and RVP.

Figure 3 shows the effect of decreasing reboiler duty on stripper bottom temperature and its dependence on feed temperature.

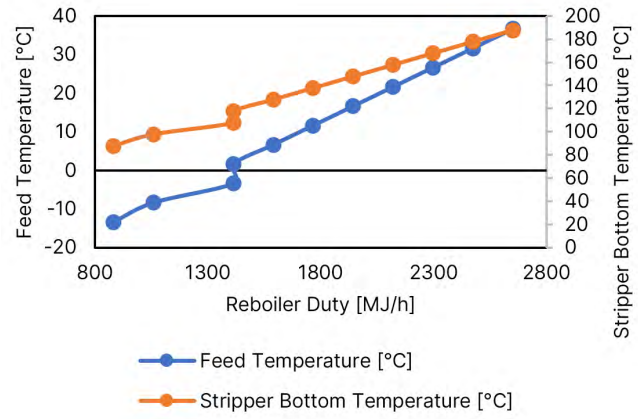

**Figure 3.** Sensitivity analysis of condensate stripper reboiler duty against feed and stripper bottom temperatures.

Sensitivity analysis shows that mass flow is highly sensitive to the stripper bottom temperature. A 10 °C increase in bottom temperature results in a ~2% reduction in mass yield due to the vaporisation of butane into the overhead.

Figures 4 and 5 show the competitive nature of amine circulation; more solvent improves purity but significantly increases pumping and regeneration duty. Amine rate varied within +-20% range to study CO2 content in sweet natural gas, regen, and pump duties.

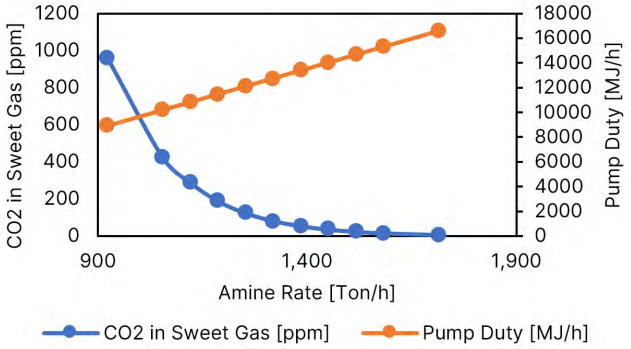

**Figure 4.** Sensitivity analysis of amine circulation against amine pumping duty and CO2 content in sweet natural gas.

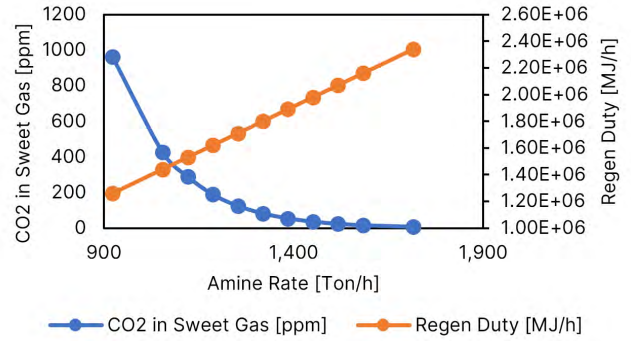

**Figure 5.** Sensitivity analysis of amine circulation against regeneration duty and CO2 content in sweet natural gas.

Similarly, increasing the amine rate enhances H2S removal from natural gas but reduces sweet natural gas production, as illustrated in Figure 6.

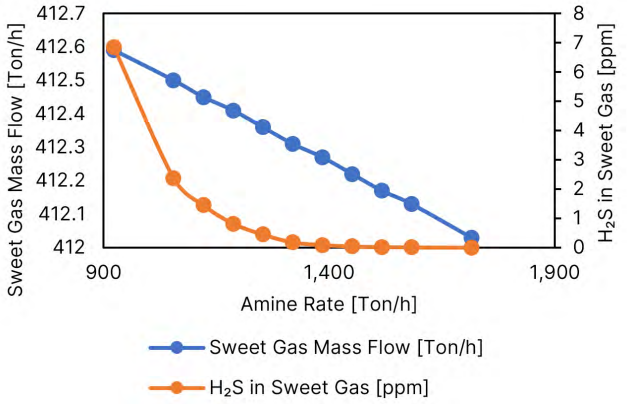

**Figure 6.** Sensitivity analysis of amine circulation against sweet gas flow and CO2 content in sweet natural gas.

The amine circulation rate shows diminishing returns in terms of gas purity. Increasing the rate from 1, 319 to 1, 583 Ton/h improves $H_2S$ removal from 0.18 ppm to 0.01 ppm but increases pumping duty by 20%.

Figure 7 shows the most critical "competitive" parameter in sulfur recovery: the Air/Acid Gas ratio must be precisely balanced to maintain the 2:1 H2S: SO2 stoichiometric ratio. Air flow varied within ±20 % to study H2S content in the stack and sulfur production.

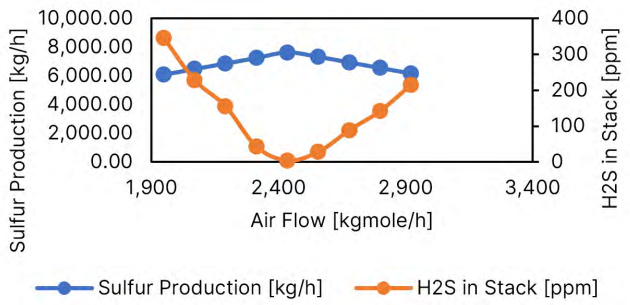

**Figure 7.** Sensitivity analysis of air flow against sulfur production and H2S content in the stack.

Figure 8 represents another critical parameter in sulfur recovery, where recovery efficiency and net heating duty are measured against air flow variation. Recovery efficiency in SRU is calculated as per Eq 1.

$$\eta_{SRU} = \frac{m_{S-produced}}{m_{H_2S-inlet}} \quad \text{Eq 1}$$

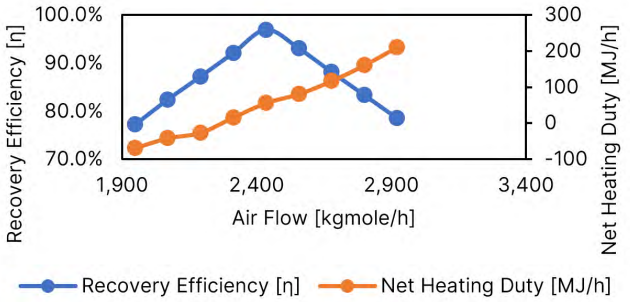

**Figure 8.** Sensitivity analysis of air flow against recovery efficiency and net heating duty.

## Optimization Formulation

The following linear and non-linear optimisation formulations are derived from the sensitivity analysis of simulation data points to achieve the desired optimisation goals.

1. Maximise Field Condensate Mass Flowrate

Objective Function:

$$\boldsymbol{Max\ m_c = C_o + a_1(Q) + a_2(RVP)} \quad \text{Eq 2}$$

Where,

Co = 2457.4

a1 = -0.23

a2 = -0.00313

Subject to:

$$RVP \leq 10\ psi \quad \text{Eq 3}$$

$$T_{bottom} \leq Thermal\ stability\ limit\ of\ hydrocarbons$$

2. Maximise Sweet Gas Mass Flowrate from AGRU

Objective Function:

$$\boldsymbol{Max\ m_{NG} = C_1 + b_1(m_{amine}) + b_2(Duty_{pump}) + b_3(Duty_{regen})}$$ Eq 4

Where,

C1 = 413.24

b1 = 0.0121

b2 = -0.00077

B3 = -3.9x10-6

Subject to:

$H_2S \leq 4\ ppm$ Eq 5

$CO_2 \leq 50\ ppm$ Eq 6

3. Maximise SRU Efficiency

Objective Function:

$$\boldsymbol{Max\ \eta_{SRU} = \frac{m_{S-produced}}{m_{H_2S-inlet}} = C_2 + d_1(m_{Air}) + d_2(Duty_{net})}$$ Eq 7

Where,

C2 = 5.171

d1 = -0.00232

d2 = 6.59x10-6

Subject to:

$H_2S\ in\ stack \leq 270\ ppm$ Eq 8

## OPTIMIZATION RESULTS

The optimisation problems represent critical competitive challenges in the LNG hot section.

For the condensate stabilisation section, the multi-objective optimisation yielded a Pareto Frontier between the condensate production rate and the required reboiler duty, as illustrated in Figure 9. Increasing reboiler duty stabilises the product (lowers RVP) but vaporises more hydrocarbons into the off-gas.

For the acid gas removal section, the multi-objective optimisation yielded a Pareto Frontier between sweet natural gas production and required solvent regeneration duty as illustrated in Figure 10. Increasing regeneration duty purifies the product (lowering CO2 and H2S content) but decreases sweet gas production due to greater absorption.

The most critical competitive optimisation is the SRU recovery efficiency versus external heating load. At a sulfur production rate of 7, 622 kg/h, the unit achieves 96.9% efficiency, as illustrated in Figure 11. Attempting to reach 97.8% recovery requires an additional 16% increase in heater duty, exceeding the energy provided by the Waste Heat Exchanger (1.64E+08 kJ/h).

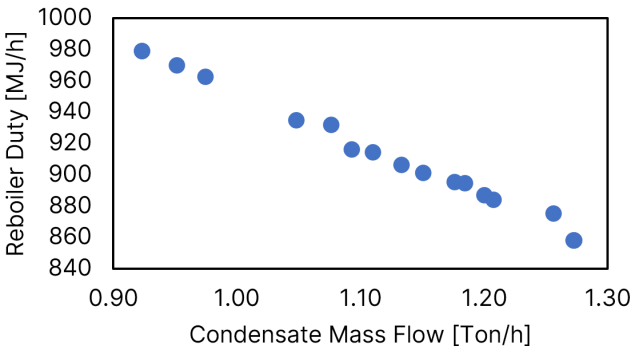

**Figure 9.** Pareto Frontier of condensate production and reboiler duty.

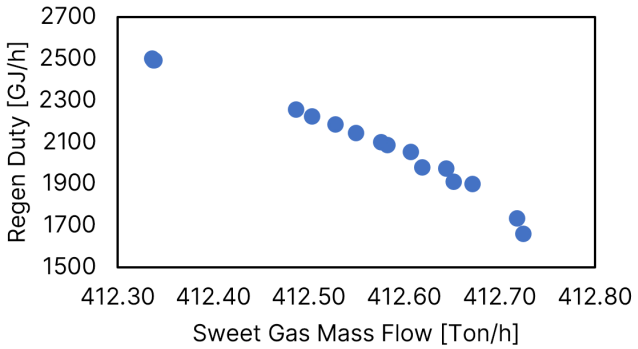

**Figure 10.** Pareto Frontier of condensate production and reboiler duty.

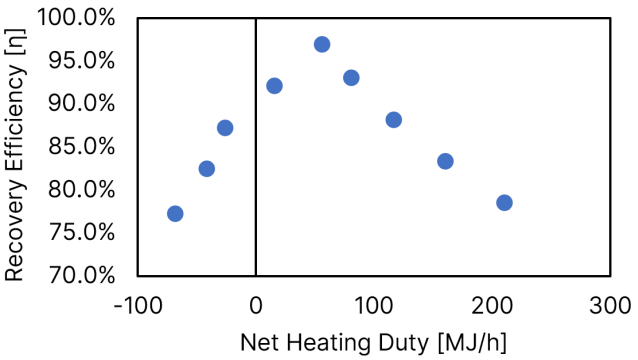

**Figure 11.** Optimisation curve of SRU recovery efficiency and net heating load.

### Comparison with Literature

The achieved 0.18 ppm $H_2S$ in sweet gas is significantly better than the typical 4.0 ppm pipeline limit, indicating the AGRU is conservatively designed. In addition, the 96.9% SRU efficiency is standard for a two-stage Claus unit. To achieve higher rates (99%+), the literature suggests adding a Tail Gas Treatment Unit (TGTU).

## CONCLUSION

Optimising the integrated facility highlights the baseline operating point as the Pareto-optimal knee. Specifically, the Condensate Unit should maintain a bottoms temperature of 137.7 °C to maintain a balance between a 2, 048 kg/h flow rate and a 9.6 psi RVP. AGRU should operate at 1, 319 Ton/h amine rate; further increases lead to excessive reboiler duty without meaningful purity gains. The SRU must be strictly controlled at 2, 435.34 kgmole/h air flow to maintain stack emissions at 4.26 ppm $H_2S$.

## ABSTRACT

Sonochemical reactors are a promising technology in process intensification, offering a sustainable and energy-efficient means of enhancing chemical reactions. By harnessing acoustic cavitation – the formation, oscillation and violent collapse of bubbles in a liquid medium – these systems generate local hotspots that can accelerate reaction kinetics. Despite its potential, efficient design and scale-up of sonochemical reactors remain major challenges, mostly because the cavitation phenomena take place close to the ultrasonic transducer. This work presents a simulation-based framework for the optimization of sonochemical batch reactors by coupling microscopic-level bubble behavior with macroscopic-level reactor performance, focusing on the placement of transducers to maximize reaction activity.

**Keywords**: Batch Process, Modelling and Simulations, Optimization, Sonochemistry, Acoustic Cavitation

## INTRODUCTION

Sonochemistry relies on the phenomenon of acoustic cavitation, i.e. the type of cavitation induced in a liquid medium by ultrasound or acoustic waves [1]. When such a wave propagates through a liquid it causes cavities (bubbles) to form, oscillate and finally collapse [2, 3]. During the rarefaction phase of the wave, cavities form and preexisting bubbles expand, while during the compression phase the bubbles contract. This oscillatory pattern continues until the prevailing conditions drive the bubble into a violent collapse. The result of this process is the creation of localized hotspots, characterized by extreme pressure and temperature, which in turn enhances chemical reactions.

For accurate modeling of sonochemical reactors, several physical phenomena must be considered in combination: wave propagation inside the liquid, bubble dynamics under the ultrasound, heat diffusion from the collapsing bubbles and reaction kinetics. The bubble dynamics were captured using the Keller–Miksis model, accounting for liquid compressibility, while the Helmholtz equation described wave propagation within the reactor, incorporating viscous, thermal, and acoustic damping. Reaction kinetics for the Fenton assisted degradation of cresols were modelled as a pseudo–first-order process governed by Arrhenius temperature dependence.

## BUBBLE DYNAMICS

The dynamic oscillations of a single bubble in a liquid medium under the influence of applied ultrasound can be described based on the fundamental principles of force and energy equilibriums, which are employed to derive the Rayleigh-Plesset equation. Following this, the refinement suggested by Keller and Miksis will be presented to account for more complex phenomena and to provide a more accurate representation of the oscillations and collapse. Finally, the effect of multiple acoustic waves on single-bubble dynamics will be examined.

### Force Equilibrium

A typical cavitation bubble, assumed to pre-exist in the liquid medium, consists of both vapor and gas. Consequently, the total pressure inside the bubble ($p_{in}$) is the sum of the vapor pressure ($p_v$) and the gas pressure ($p_g$).

$$p_{in} = p_v + p_g \tag{1}$$

The vapor pressure is assumed to remain constant, whereas the gas pressure undergoes significant changes and can be approximated as:

$$p_g V_b{}^k = constant \quad (2)$$

where $V_b = {}^4/_3 \pi R^3$ is the volume and $R$ the radius of the bubble. The exponent $k$ represents the heat capacity ratio and the specific value depends on the model approach and the material. In the case of an adiabatic process involving air, the ratio can approximately be:

$$k = \frac{C_p}{C_v} \cong 1.4 \quad (3)$$

For the bubble to expand by $dR$, the work required is $\sigma(8\pi R\, dR)$, where $\sigma$ is the surface tension. Using the above definitions, the force equilibrium on the bubble wall can be expressed as:

$$p_{in}\,(4\pi R^2) = p_b(2\pi R^2) + \sigma(8\pi R) \quad (4)$$

where $p_b$ is the pressure on the bubble wall.

It is assumed that the bubble is oscillating from an equilibrium point with radius $R_0$ and the static ambient pressure is $p_\infty = p_0$. Combining the above equations provides an expression for the pressure on the bubble wall.

$$p_b = \left(p_\infty + \frac{2\sigma}{R_0} - p_v\right)\left(\frac{R}{R_0}\right)^{3k} + p_v - \frac{2\sigma}{R} \quad (5)$$

The effect of the acoustic wave, represented as time dependent variable $p_s(t)$, is incorporated into the ambient pressure term

$$p_\infty = p_0 + p_s(t) \quad (6)$$

In most typical cases the pressure wave is sinusoidal with pressure amplitude of $P_a$ and frequency f, superimposed on hydrodynamic pressure $p_0$:

$$p_s(t) = p_0 - P_a\ sin(2\pi f t) \quad (7)$$

## Energy Equilibrium

The conservation of energy can be described as: the work of the oscillating bubble $W_b$, either positive for expansion or negative for contraction and collapse, must be equal to the work $W_l$ plus kinetic energy $E_k$ required by the liquid volume surrounding the cavity.

$$W_b = W_l + E_k \quad (8)$$

Each of these terms is calculated separately:

$$W_b = p_b \frac{4}{3}\pi\left(R^3(t) - {R_0}^3\right) \quad (9)$$

$$W_l = p_\infty \frac{4}{3}\pi\left(R^3(t) - {R_0}^3\right) \quad (10)$$

$$E_k = 2\pi\rho_L R^3(t)\left(\frac{dR(t)}{dt}\right)^2 \quad (11)$$

## Rayleigh-Plesset

The combination of equations (5)-(11) yields the Rayleigh-Plesset equation, describing the radius of the bubble in respect to time.

$$\frac{3}{2}\left(\frac{dR(t)}{dt}\right)^2 + R(t)\frac{d^2R(t)}{dt^2} = \\ = \frac{1}{\rho_L}\left(p_g + p_v - \frac{2\sigma}{R(t)} - 4\mu\frac{1}{R(t)}\frac{dR(t)}{dt} - p_0 - p_s(t)\right) \quad (12)$$

## Keller-Miksis

The Rayleigh – Plesset equation is foundational for any work done in acoustic cavitation. However, the main assumptions made, that the liquid is incompressible and the bubble remains spherical, are less than accurate for such high-speed phenomenon. To address these limitations, the suggested modifications by Keller and Miksis [4, 5] account mainly for the compressibility of the liquid, as well as effects of viscosity, surface tension and acoustic radiation

$$\left[1 - \frac{1}{3}(3\Lambda + 1)\frac{1}{c_L}\frac{dR(t)}{dt}\right]\frac{3}{2}\left(\frac{dR(t)}{dt}\right)^2 + \\ + \left[1 - (\Lambda + 1)\frac{1}{c_L}\frac{dR(t)}{dt}\right]R(t)\frac{d^2R(t)}{dt^2} = \\ = \left[1 + (1 - \Lambda)\frac{1}{c_L}\frac{dR(t)}{dt} + \frac{R}{c_L}\frac{d}{dt}\right]\frac{p_b - p_\infty}{\rho_L} \quad (12)$$

In the present work the parameter $\Lambda = 0$, referring to the Keller form of the equation.

## Collapse

The analysis of the transient collapse of the oscillating gas filled cavity [6] assumes that the bubble reaches a maximum radius $R_{max}$ just before the violent collapse to a minimum radius $R_{min} \to 0$. The collapse is characterized by the bubble wall reaching its maximum velocity under the assumption of adiabatic compression of the internal gas. As a result, the gas reaches exceedingly high pressures and temperatures during the collapse. The maximum temperature reached during the process can be determined, using the initial temperature $T_0$, by the following relationship [7].

$$T_{max} = T_0\left(\frac{R_{max}}{R_{min}}\right)^{3(\gamma-1)} \quad (13)$$

## Different Wave Sources

A preliminary approach to analyze the effect of multiple wave sources on the single bubble dynamics can be made via simple modifications to the existing model. The equation (7) can be modified to account, for instance, two distinct waves characterized by amplitudes and frequences $P_{a1}, f_1$ and $P_{a2}, f_2$ respectively [8, 9].

$$p_s(t) = p_0 - P_{a1} sin(2\pi f_1 t) - P_{a2}\ sin(2\pi f_2 t) \quad (14)$$

# WAVE PROPAGATION

Analyzing wave propagation in a liquid medium containing dispersed bubble population requires a comprehensive approach. One of the most important parameters

in the cavitation theory is the void fraction $\beta$. It accounts for the total volume occupied by cavities inside the control volume $V$:

$$\beta = \frac{4}{3}\pi R_0^3 n \tag{15}$$

where $n = {}^{N}/_{V}$ is bubble number density and $R_0$ is the equilibrium radius that all bubbles are assumed to have [10].

## Mass Conservation

The conservation of mass for a mixture of liquid and dispersed bubbles is expressed as:

$$\frac{\partial \rho}{\partial t} + \boldsymbol{\nabla} \cdot (\rho \boldsymbol{v}) = 0 \tag{16}$$

where $\boldsymbol{v}$ is the velocity and $\rho$ is the density of the mixture, based on the void fraction

$$\rho = \rho_L(1-\beta) + \rho_g\beta \cong \rho_L(1-\beta) \tag{17}$$

It is apparent that the mixture density approaches the liquid density $\rho_L$, since the gas density $\rho_g$ is negligibly small.

Assuming (a) negligible bubble coalescence and fragmentation, (b) bubbles move at the same velocity as the liquid and (c) the void fraction is of the order of $10^{-4}$ or smaller, the equation for conservation of mass is:

$$\frac{1}{\rho_L}\frac{D\rho_L}{Dt} + \boldsymbol{\nabla} \cdot v = 4\pi R^2 \frac{DR}{Dt} \tag{18}$$

## Energy Conservation

The momentum conservation is ensured via Cauchy relationship:

$$\rho_L\left[\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{v} \cdot \boldsymbol{\nabla}\boldsymbol{v}\right] = \boldsymbol{\nabla} \cdot \bar{\bar{\sigma}} + \boldsymbol{f} \tag{19}$$

Neglecting viscous terms expressed via the stress tensor $\bar{\bar{\sigma}}$ and the body forces given via $\boldsymbol{f}$ term, thereby considering only for pressure forces, the momentum conservation equation is simplified to:

$$\rho_L\left[\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{v} \cdot \boldsymbol{\nabla}\boldsymbol{v}\right] - \boldsymbol{\nabla}p = \boldsymbol{0} \tag{20}$$

## Wave equation

The non-homogeneous wave equation can be derived through the nondimensionalization of the governing mass and momentum conservation equations. Following the work done by Calfisch and al. [11] the non-homogeneous wave equation can be obtained:

$$\frac{1}{{c_L}^2}\frac{\partial^2 p}{\partial t^2} - \nabla \cdot \nabla p - \frac{\partial^2 \beta}{\partial t^2} = 0 \tag{21}$$

It can be proven that the wave propagation in the bubbly liquid is following the Helmholtz's equation

$$\Delta P(t,\boldsymbol{r}) + {k_m}^2 P(t,\boldsymbol{r}) = 0 \tag{22}$$

where the complex wavenumber, a monodisperse bubble population with equilibrium radius $R_0$, for is defined by the relationship:

$${k_m}^2 = \frac{\omega^2}{{c_L}^2}\left(1 + 4\pi \frac{{c_L}^2 \frac{N}{V} R_0}{\omega_0 - \omega^2 + 2ib\omega}\right) \tag{22}$$

The wave number incorporates variables like resonance frequency ($\omega_0$), damping constant ($b$) that accounts for viscous, thermal and acoustic effects and velocity potential ($\Phi$) given by the following relationships:

$$\omega_0 = \frac{p_0}{\rho_L {R_0}^2}\left[Re(\Phi) - \frac{2\sigma}{R_0 p_0}\right] \tag{23}$$

$$b = \frac{2\mu}{\rho_L {R_0}^2} + \frac{p_0}{2\rho_L {R_0}^2} Im(\Phi) + \frac{\omega^2 R_0}{2c_L} \tag{24}$$

$$\Phi = \frac{3\gamma}{1 - 3(\gamma-1)i\frac{Dg}{\omega {R_0}^2}\left[\sqrt{i\frac{\omega {R_0}^2}{Dg}}coth\left(\sqrt{i\frac{\omega {R_0}^2}{Dg}}\right) - 1\right]} \tag{25}$$

# REACTION

Fenton oxidation is a promising method for the degradation of pollutants like phenols. In Fenton process, hydroxyl radicals $OH^-$ are produced from hydrogen peroxide $H_2O_2$ catalyzed by iron Fe(II).

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH\bullet \tag{26}$$

The generated radicals can react effectively with a variety of organic compounds RH.

$$RH + OH\bullet \rightarrow H_2O + R\bullet \rightarrow \textit{further oxidation} \tag{27}$$

$$R\bullet + H_2O_2 \rightarrow ROH + OH\bullet \tag{28}$$

## Batch Reactor

Considering a well-mixed mixture, two areas of interest can be assumed. The first one is where the cavitation takes place, which is essentially the part of the liquid that has elevated temperature due to a bubble collapse, thus an enhanced reaction rate. The second one is the rest of the bulk liquid having an ambient temperature, thus a base reaction rate. The areas are symbolized with $c$ and $B$ respectively. The mass equilibrium for a product with concentration, $C$, may then be written as:

$$\frac{dC}{dt} = \beta r_c + (1-\beta) r_B \tag{29}$$

where $\beta$ is the void fraction and $r$ the rate of the reaction.

## Effective Rate

Although this theory may be applied to different reactions, this work focuses on the degradation of cresols, due to the reaction being well documented under a variety of conditions.

$$C_7H_8O + 17H_2O_2 \rightarrow 7CO_2 + 21H_2O \tag{30}$$

Assuming abundance of $H_2O_2$, a pseudo-first-order reaction rate for the organic compound is given by:

$$r = -kC \tag{31}$$

where the constant k has an Arrhenius dependency of temperature:

$$k = A\exp\left(\frac{E_A}{RT}\right) \quad (32)$$

In the bulk liquid with an ambient temperature $T_0$, the rate constant would be:

$$k_B = A\exp\left(\frac{E_A}{R_g T_0}\right) \quad (33)$$

While in the area affected by cavitation phenomena, heat diffusion in the surrounding liquid must be considered. Thus, the rate constant would be given by the following equation:

$$k_{eff} = \frac{\int_t \int_V k(t,\boldsymbol{r})dVdt}{\int_t \int_V dVdt} \quad (34)$$

By integrating Eq. (29) a more convenient variable for comparison can be derived, hereafter referred to as effective rate $r_{eff}$:

$$-ln\left[\frac{C}{C_0}\right] = \left[\beta k_{eff} + (1-\beta)k_B\right]t \quad (35)$$

where:

$$r_{eff} = \beta k_{eff} + (1-\beta)k_B \quad (36)$$

# SIMULATION DETAILS

## Geometry

The sonochemical reactor is a cylindrical batch reactor, open at the top, with a cylindrical transducer submerged from the top. The ultrasound is introduced into the system from the tip of the transducer.

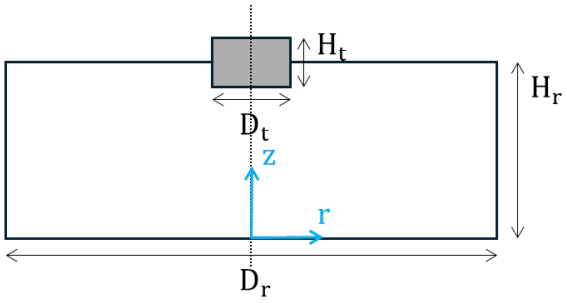

**Figure 1.** Geometric characteristics of the reactor.

The reactor is filled with an aquatic solution. The geometry of the reactor is described in Figure 1 and Table 1

**Table 1.** Geometrical characteristics of the reactor.

| Symbol | Value |
|---|---|
| $D_r$ | 0.5 m |
| $D_t$ | 0.08 m |
| $H_r$ | 0.2 m |
| $H_t$ | 0.1 m |

## Parameters

The liquid medium is water at standard temperature and pressure, thus $T_0 = 298.15$ K and $p_0 = 1.01325 \cdot 10^5$ Pa. The physical properties of water are given in Table 2.

**Table 2.** Physical properties of water.

| Symbol | Value |
|---|---|
| $\Gamma$ | 4/3 |
| $\Sigma$ | $0.0725\ \mathrm{N \cdot m^{-1}}$ |
| M | $1.0016 \cdot 10^{-3}$ Pa • s |
| $\rho_L$ | $1000\ \mathrm{kg \cdot m^{-3}}$ |

The acoustic wave travels at the frequency of $f = 20$ kHz and with an amplitude that is calculated by the following relationship [8, 12]:

$$P_a = \sqrt{2\rho_L c\frac{P}{A_t}} \quad (37)$$

where $P$ is the power of the transducer set to 40 W and $A_t = 0.005\ \mathrm{m^2}$ the area of the tip of the transducer. Thus, the amplitude of the wave is set to be $P_a = 1.53 \cdot 10^5$ Pa.

In terms of the reaction, for p-cresols the Arrhenius constants are $A = 0.1419\ \mathrm{s^{-1}}$ and $E_a = 14.25 \cdot 10^3\ \mathrm{J\ mol^{-1}}$.

It should be noted that equilibrium radius of the single bubble is considered to be $R_0 = 5\ \mu$m and the void fraction is calculated via the following empirical relationship [13]:

$$\beta = N \cdot |p| \quad (38)$$

where $N = 2 \cdot 10^{-9}$.

# RESULTS

The results of the simulation can be divided into two categories: the single-bubble environment, which accounts for the enhancement of the reaction through an increase of the rate constant and wave propagation inside the batch reactor, which reflects the intensity of cavitation phenomena through an increase of the void fraction.

## Single-Bubble Environment

The effect of one wave and two coherent waves on the single bubble have been simulated. Figures 2 and 3 demonstrate the radius changes for each case.

The bubble grows 15 and 50 times its equilibrium size respectively and then it rapidly collapses before the completion of on cycle. The temperature reached by the bubble during the collapse, based on the maximum radius the bubble reaches, is 4780 K for one wave and 13987 K for two waves. Applying a simple conduction model, the area effected by cavitation is 2 times the equilibrium radius and this effect is sustained for 10 periods for both cases.

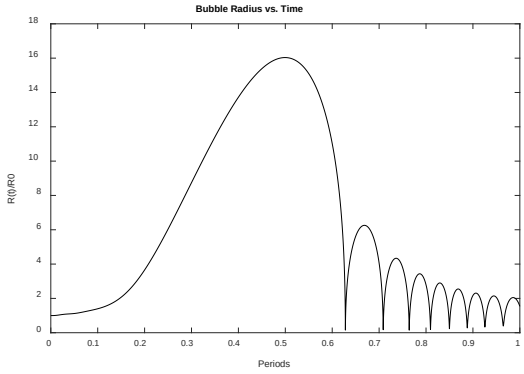

**Figure 2.** Bubble radius as a function of time under one acoustic wave.

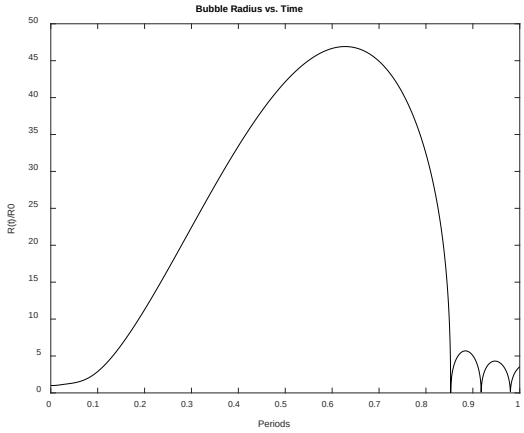

**Figure 3.** Bubble radius as a function of time under two identical acoustic waves

The rate constant in these conditions can be calculated to be $0.2788\ \mathrm{s}^{-1}$ and $0.7733\ \mathrm{s}^{-1}$ respectively, while in bulk conditions the constant is $4.5213 \cdot 10^{-4}\ \mathrm{s}^{-1}$. This accounts for an increase of $615\%$ and $1700\%$ for the rate constant in the cavitation zone compared to the bulk of the liquid.

## One transducer

The first simulation examines a transducer placed at the center of the top of the reactor as shown in Figure 4.

The propagation of the wave in the liquid medium was described by the pressure distribution inside the reactor, while the void fraction demonstrated where cavitation phenomena occur. The YZ cut-plane of the reactor is presented for both parameters in Figures 5 and 6.

The pressure wave appears to have an effect mostly close to the transducer, although small pressure variations exist everywhere inside the reactor. The higher void fraction, in the order of $9 \cdot 10^{-4}$, exists just under the transducer. The mean void fraction was calculated to be $5.32 \cdot 10^{-5}$.

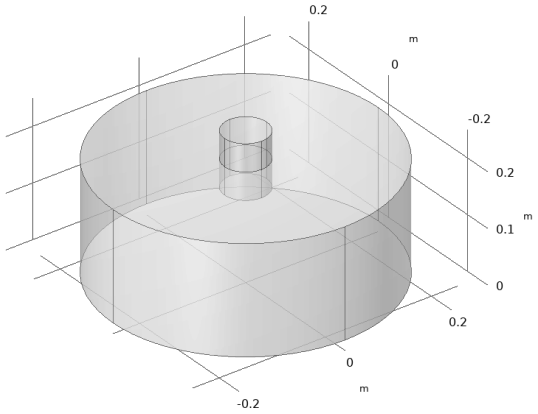

**Figure 4.** Geometry of one transducer at the center of the top of the reactor.

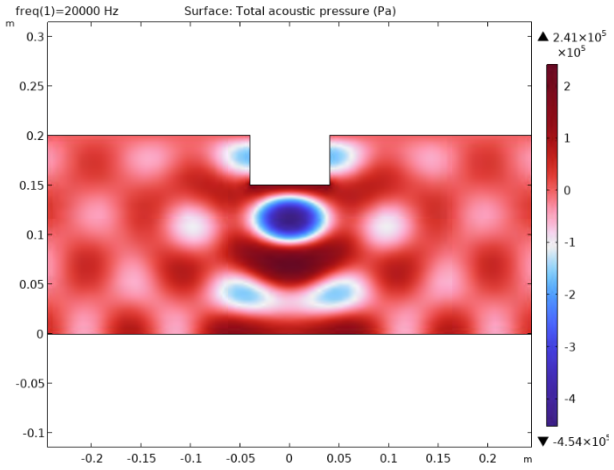

**Figure 5.** Pressure distribution for one transducer.

Given this result and the rate constant for one wave, the effective rate was calculated to be $4.648 \cdot 10^{-4}\ s^{-1}$. This is an increase of $2.8\%$ in the reactions rate. Literature data suggest that the rate is around $4.5 \cdot 10^{-4} s^{-1}$, depending on the exact conditions [14, 15].

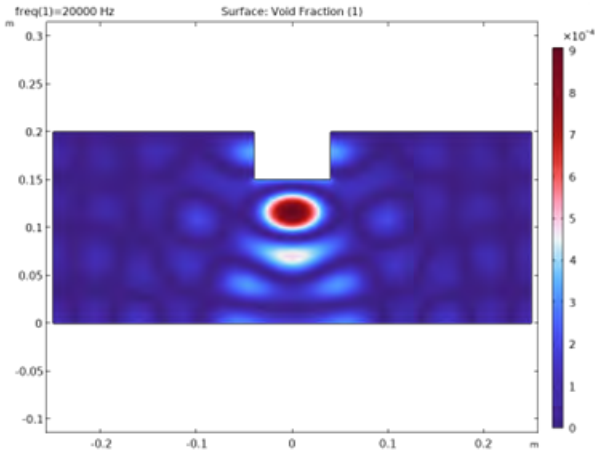

**Figure 6.** Void fraction for one transducer.

## Two transducers

The simplest geometry to simulate the wave propagation from two different transducers is one at the center top of the reactor (as before) and the other at the center bottom of the reactor. Note that for practical reasons the tip of the bottom transducer is placed on the same plane as the bottom of the reactor.

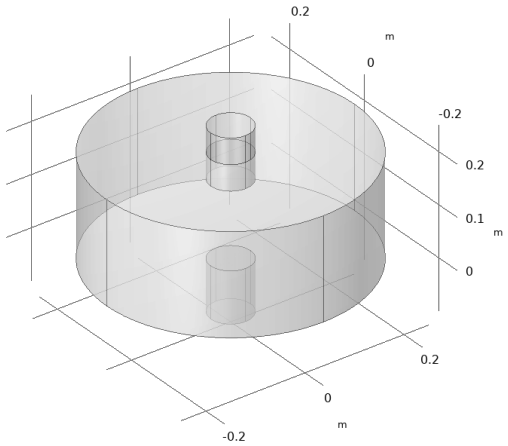

**Figure 7.** Geometry for two transducers.

The same YZ-plane plots for the pressure and void fraction distributions are presented in Figures 8 and 9 respectively. Both figures show little to no changes for the addition of another transducer, just a slightly increased intensity of the variations in the central axis. The mean void fraction was calculated as $4.82 \cdot 10^{-5}$, lower than previously.

Despite that, the two waves introduced into the system affect the single bubble dynamics differently, resulting in more extreme phenomena. Thus, the effective rate was calculated to be $4.873 \cdot 10^{-4} s^{-1}$, representing a $4.8\%$ increase compared to the one transducer simulation.

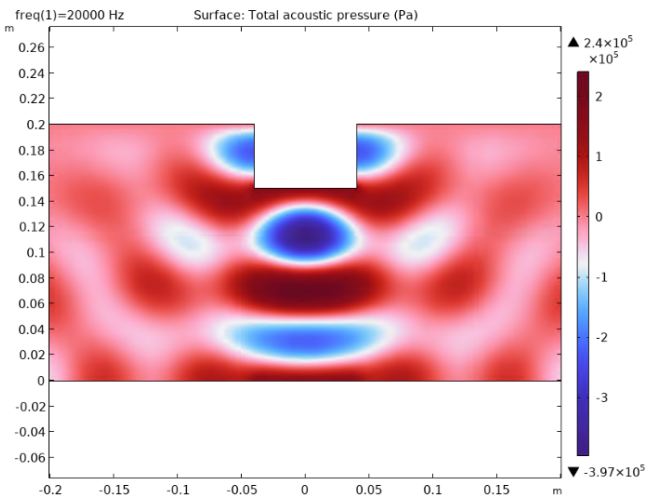

**Figure 8.** Pressure distribution for two transducers

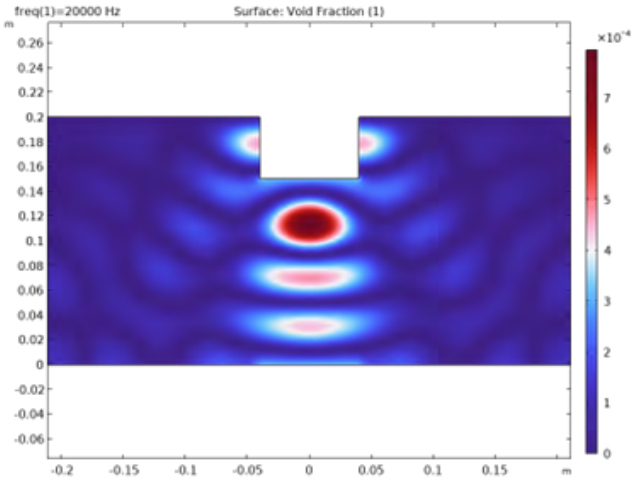

**Figure 9.** Void fraction for two transducers.

## Optimization

To maximize the effective rate we investigated changing the position of the top transducer in all directions and the bottom transducer in x and y directions.

The optimum configuration was found to involve both transducers positioned at the center of the reactor, with the top transducer submerged as deeply as possible. The maximum effective rate was calculated to be $5.640 \cdot 10^{-4} s^{-1}$, which accounts for an increase of 15.7% of the rate calculated in the simple simulation.

In this case, the results were verified by the wave propagation as well. As shown in Figure 10, the pressure distribution changed drastically, when the transducer was well placed. On the central axis, the combination of the two transducers resulted in higher pressure amplitude. Due to more efficient reflection on the walls, the phenomenon was spreading to the rest of the bulk liquid, since pressure variations are observed in all the reactor.

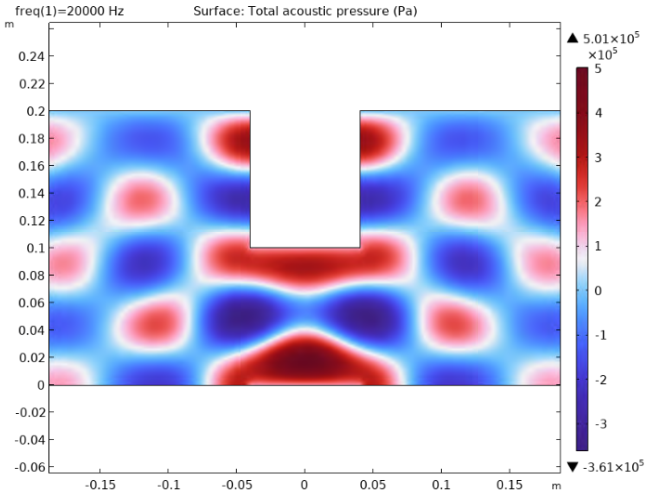

**Figure 10.** Pressure distribution for optimal position for the transducers.

The Void fraction mapping presented in Figure 11 further clarifies the result. Not only the areas with high void fraction were increased between the transducers, but the value of void fraction within these areas was increased as well. The mean void fraction was calculated to be $1.475 \cdot 10^{-4}$, an increase of $206\%$.

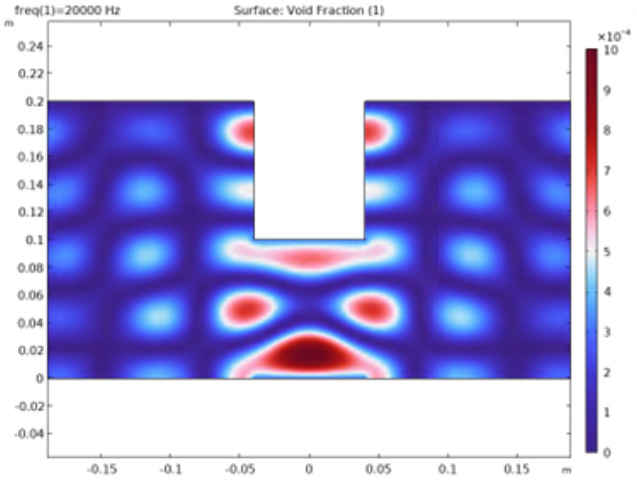

**Figure 11.** Void fraction for optimally positioned transducers.

It should be noted that the void fraction depends on the total volume of the liquid. Submerging the transducer more into the liquid, lowers the liquid volume, resulting in an increase of the void fraction. This plays an important role in the increase and should be expected. Furthermore, the fact that both transducers were optimally placed along the central axis rather than near the walls indicates that, for the present geometry characteristics, the most effective wave propagation occurs at the center, where the reflections constructively reinforce the acoustic field. In this arrangement, the pressure pulsations were symmetrically distributed throughout the reactor volume, ensuring that cavitation activity was present across most of the liquid domain.

## Side transducers

Considering the optimization simulations performed up to this stage, the simulation of the side transducer was omitted, since the behavior of the effective rate was already established. The subsequent step was to determine the optimal placement along the z direction.

The optimal position was found to be in about ¾ the height of the reactor. The mean void fraction and the effective rate of the reaction were calculated to be $8.828 \cdot 10^{-5}$ and $4.746 \cdot 10^{-4}\ s^{-1}$ respectively. This was a slight improvement over only one transducer present.

The intuitive position for the transducer would probably be at half of the height of the reactor for symmetry or as low as possible to enable strong reflection from the walls. However, the optimum position was not even close to these, proving the complexity of wave propagation inside the reactor.

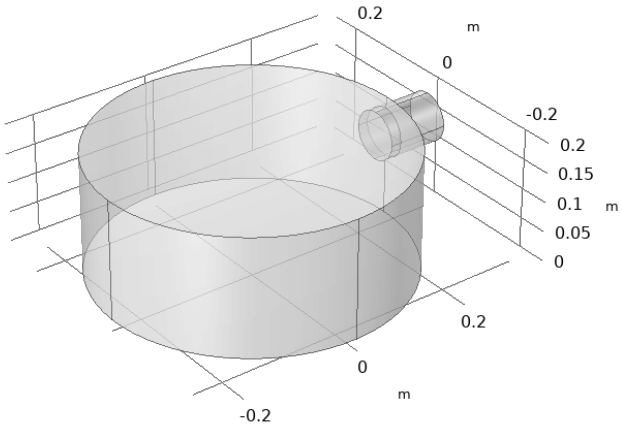

**Figure 12.** Optimal position for one side transducer.

Since the optimal height for one transducer had been calculated, the next optimization was focused on a second side transducer and its relative position to the first one. The optimal position is shown in Figure 13.

The mean void fraction was found to be $1.216 \cdot 10^{-4}$, while the rate of the reaction was $5.440 \cdot 10^{-4} s^{-1}$, which accounted for a $14.6\%$ increase relative to just one transducer.

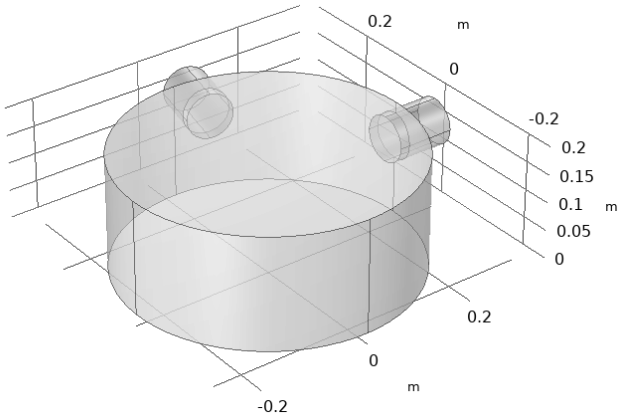

**Figure 13.** Optimal position for two side transducers.

It was expected that the optimum placement for the two side transducers would also be at the opposite sides of the reactor (like the vertical positioning problem solution). However, the optimization results indicates that this is not the case. This outcome can be attributed either to the horizontal orientation of the transducers that change drastically the wave propagation, or the fact that in the opposite-side configuration their separation distance is larger than in the vertical arrangement, increasing the wave damping throughout the liquid.

## CONCLUSION

The present study examined the enhancement of batch reactor performance through the optimal placement of one or more ultrasonic transducers to increase chemical reaction rates. This objective was addressed through an optimization formulation incorporating multiscale modeling, integrating cavitation theory, wave propagation, heat diffusion, and reaction kinetics into a batch reactor model equipped with one or two transducers. Particular emphasis was placed on capturing the effect of transducer placement on reactor performance.

At the single-bubble scale, simulations showed that a bubble exposed to a single ultrasonic wave reached a collapse temperature of ~4800 K, whereas the interaction of two identical waves could increase the collapse temperature to 15, 000 K. This increase in temperature produced a substantial kinetic enhancement, with the reaction rate within the cavitation-affected volume increasing by 600% in the single-wave case and by 1700% in the two-wave case relative to nominal conditions.

At the reactor scale, a configuration with a single transducer submerged from the open top was used to establish baseline conditions. Cavitation activity, quantified by the void fraction, was concentrated beneath the transducer and provided reference values for both the mean void fraction and the effective reaction rate. The introduction of a second transducer increased the effective reaction rate by 5%, despite a slight decrease in the mean void fraction. This result indicates that reactor performance is governed not only by macroscopic wave propagation, but also by microscopic bubble dynamics.

The optimal placement of the two transducers was found to be along the central axis on opposite sides of the reactor, with the upper transducer submerged as deeply as possible. Under these conditions, the effective reaction rate was maximized, reaching a value 16% higher than that of the baseline configuration. Placing a single transducer on the reactor sidewall, had no significant performance enhancement. However, the addition of a second sidewall transducer at an optimized location increased the effective reaction rate by approximately 15% relative to the single-side configuration.

These findings demonstrate that simulation-based optimization can significantly improve the efficiency of sonochemical reactors by guiding the spatial arrangement of transducers. The proposed study highlights the potential of computational approaches for the rational design and scale-up of high-performance ultrasonic systems for chemical engineering applications.

## ABSTRACT

The purification of therapeutic peptides represents a major bottleneck in biopharmaceutical downstream processing due to the structural similarity between target products and closely related impurities. In this study, a shortcut dynamic simulation model of a two-column Multi-Column Countercurrent Solvent Gradient Purification (MCSGP) process is implemented in Aspen Chromatography for peptide separation. Each column is described using a one-dimensional axial dispersion model coupled with mass transfer kinetics and a modulated Langmuir adsorption equilibrium, while time-dependent boundary conditions are applied to represent solvent gradient elution. The model explicitly incorporates internal recycle streams between columns using the cycle organizer approach, capturing the defining operational features of MCSGP. This enables a unified representation of chromatographic transport phenomena, gradient operation, and discrete recycle logic within a single flowsheet-based framework. The novelty lies in treating MCSGP as a hybrid dynamic process rather than a purely chromatographic unit, providing a transferable modelling framework suitable for operability analysis, process comparison, and future optimization of continuous peptide purification systems. Dynamic simulation results for a model mixture of closely eluting peptides demonstrate stable cyclic operation and a substantial improvement in mass recovery compared with conventional batch chromatography under identical transport assumptions. In particular, systematic recycling of intermediate fractions leads to an order-of-magnitude increase in recovered target product.

## 1. INTRODUCTION

Therapeutic peptides represent an increasingly important class of biopharmaceutical products, yet their purification remains one of the most challenging and cost-intensive stages of production. During solid-phase synthesis, numerous closely related impurities are formed, often differing from the target molecule by only a few amino acids [1, 2]. These impurities exhibit very similar physicochemical properties, leading to overlapping retention behaviour during chromatographic separation and making selective purification particularly demanding [3].

Preparative batch chromatography is widely used for peptide purification but typically requires multiple sequential steps and large solvent volumes to achieve the desired purity. This results in long processing times, limited product recovery, and high operational costs. As a consequence, intensified chromatographic processes have gained increasing attention to improve efficiency, sustainability, and scalability in downstream processing [4].

Multi-Column Countercurrent Solvent Gradient Purification (MCSGP) effectively combines the high separation selectivity of gradient elution with the process efficiency offered by countercurrent operation to enhance separation performance. By internally recycling overlapping fractions between columns, MCSGP simultaneously allows for higher product yield and purity levels, while significantly reducing solvent consumption compared to conventional batch chromatography. In the MCSGP process, the chromatographic columns operate cyclically with alternating roles. One column performs gradient elution, during which overlapping fractions containing weak

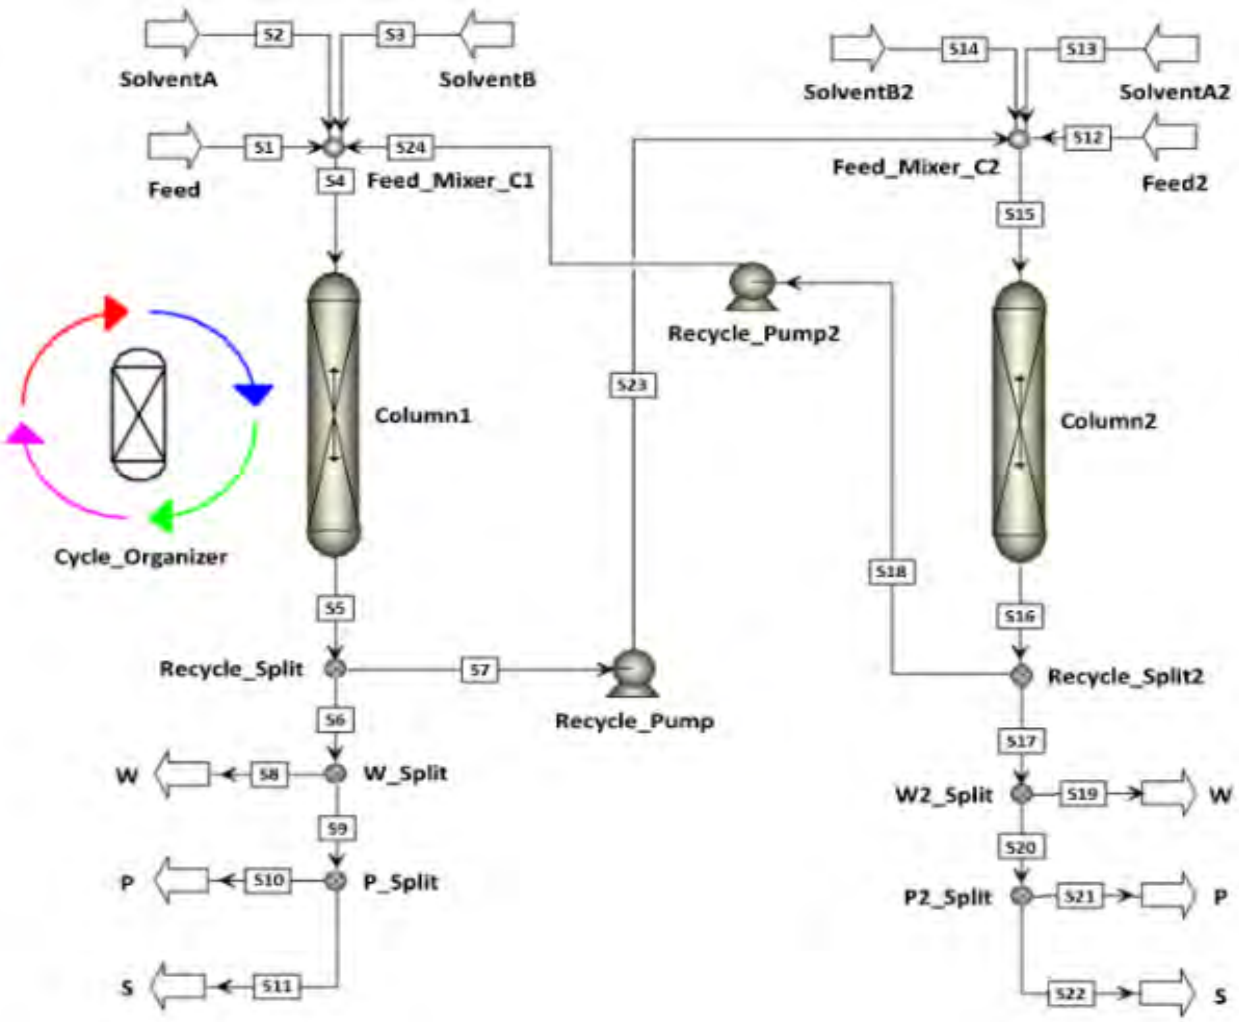

**Figure 1.** Two-column MCSGP process simulation diagram for the continuous separation of peptides developed in Aspen Chromatography.

adsorbed-product and product-strong adsorbed mixtures are internally recycled, while the pure target product fraction is collected. Meanwhile, the second column receives the recycled streams and fresh feed. After regeneration steps, the columns exchange their functions. Following two switches, the system returns to its initial configuration, completing one operating cycle [5–8]. While experimental and modelling studies have demonstrated these advantages, most dynamic MCSGP models for peptides have been developed using in-house numerical solvers, focusing primarily on separation physics rather than process operability [9–11]. From a process systems engineering perspective, MCSGP is inherently a hybrid dynamic process, characterized by continuous transport phenomena, time-dependent solvent gradients, discrete switching events, and internal cycle streams. Capturing these interactions in a transparent and reusable manner is essential for process comparison, operability analysis, and future integration with optimization control strategies.

In this context, the present work develops a dynamic, cycle-resolved simulation for peptide purification within Aspen Chromatography. The objective is not to introduce new separation mechanisms, but to demonstrate that the essential hybrid dynamic features of MCSGP can be represented transparently at the process level, enabling systematic analysis and reuse beyond custom numerical implementations.

## 2. METHODOLOGY

### 2.1. Process representation and simulation strategy

The MCSGP process is represented as a two-column system consisting of identical reversed-phase

chromatographic columns interconnected by internal recycle streams. The overall configuration, shown in Figure 1, reflects the cyclic nature of MCSGP operation, where columns alternate between loading, elution, and regeneration roles.

Each column is modelled using a one-dimensional axial dispersion formulation accounting for convection and axial mixing in the mobile phase. Intraparticle mass transfer resistance is described using the particle mass balance (PMB) kinetic model, capturing pore diffusion and external film resistance. Adsorption equilibrium is represented using a modulated Langmuir isotherm, allowing solvent composition effects during gradient elution to be explicitly incorporated. Dynamic simulations are conducted for a model peptide mixture characterized by closely eluting retention times, representative of realistic purification challenges. The solvent gradient is segmented to reproduce reversed-phase elution conditions commonly employed in peptide purification. Time-dependent boundary conditions are applied to represent both gradient elution and cyclic column switching.

A key methodological aspect of this work is the explicit implementation of column switching, gradient ramps, product withdrawal, and internal recycle streams using the cycle organizer approach in Aspen Chromatography. This avoids custom scripting and enables the MCSGP process to be treated as a hybrid dynamic system within a flowsheet environment, where both continuous dynamics and discrete operational logic are represented consistently.

## 2.2. Mathematical model formulation

The governing equations correspond to a conventional chromatographic transport model extended to include time-dependent boundary conditions and internal recycling. The axial mass balance accounts for accumulation, convection, dispersion, and mass transfer between mobile and stationary phases (Equation 1):

$$\frac{\partial C_i}{\partial t} + \frac{(1-\varepsilon_i)}{\varepsilon_i}\frac{\partial q_i}{\partial t} + \nu\frac{\partial C_i}{\partial z} = \frac{\nu . L}{Pe . \varepsilon_i}\frac{\partial^2 C_i}{\partial z^2} \quad (1)$$

where $C_i$ is the concentration of the compound *i* in the mobile phase, *t* is the time, $\varepsilon_i$ is the inter-particle voidage, $q_i$ is the concentration of the compound *i* in the stationary phase, ν is the superficial velocity of the mobile phase, $z$ is the axial distance through the length of the column, *L* is the column length, and *Pe* is the particle Péclet number.

Intraparticle mass transfer is described using the PMB kinetic model (Equation 2):

$$D_{pi}\left(\frac{\partial C_{pi}}{\partial r}\right) = k_i(C_i - C_{pi}) \quad (2)$$

where $D_p$ is the pore/effective diffusion coefficient, $C_p$ is the macropore concentration, *r* is the particle radius, $k$ is the external film mass transfer coefficient, while local equilibrium between phases is defined by Equation 3:

$$\frac{dq_i}{dt} = \sum_{j=1}^{N}\left(\frac{dq_i}{dc_j}\frac{dc_j}{dt}\right) \quad (3)$$

Adsorption is modelled using a modulated Langmuir isotherm (Equation 4), which captures nonlinear adsorption behaviour and the influence of solvent strength during gradient elution. This formulation has been shown to be suitable for reversed-phase separation of peptides and related biomolecules.

$$q_i = \frac{IP_{1i}\, 10^{IP_{2i} - IP_{3i}\log_{10}(C_m) + IP_{4i}(C_m)}\, C_i}{1 + \sum\left(IP_{1i}\, 10^{IP_{2i} - IP_{3i}\log_{10}(C_m) + IP_{4i}(C_m)}\right) C_i} \quad (4)$$

where *IP* is the isotherm parameter, and $C_m$ is the concentration of the mobile phase.

The numerical solution of the resulting system of differential–algebraic equations is performed in Aspen Chromatography v12 using the fourth-order orthogonal collocation finite element method (OCFE4) with one node per column, combined with an implicit Euler integration scheme suitable for stiff systems.

**Table 1:** Column specifications and mass transfer parameters used for the two-column MCSGP model.

| Parameter | Value/Unit |
|---|---|
| Column length | 10.00 cm |
| Column internal diameter | 1.00 cm |
| Inter-particle voidage | 0.4 $m^3$ void/$m^3$ bed |
| Intra-particle voidage | 0.4 $m^3$ void/$m^3$ bead |
| Particle radius | 60.00 µm |
| Péclet number for dispersion/ACN | 400.00 |
| Péclet number for dispersion / P | 350.00 |
| Péclet number for dispersion / S | 400.00 |
| Péclet number for dispersion / W | 350.00 |
| Diffusion coefficient / ACN | 2.292 x$10^{-3}$ $cm^2$/min |
| Diffusion coefficient / P | 9.167x$10^{-4}$ $cm^2$/min |
| Diffusion coefficient / S | 1.375 x$10^{-3}$ $cm^2$/min |
| Diffusion coefficient / W | 9.167x$10^{-4}$ $cm^2$/min |
| Isotherm parameter 1 / P | 0.10 |
| Isotherm parameter 1 / S | 0.10 |
| Isotherm parameter 1 / W | 0.10 |
| Isotherm parameter 2 / P | 3.00 |
| Isotherm parameter 2 / S | 4.50 |
| Isotherm parameter 2 / W | 1.80 |
| Isotherm parameter 3 / P | 3.00 |
| Isotherm parameter 3 / S | 3.50 |
| Isotherm parameter 3 / W | 2.60 |
| Isotherm parameter 4 / P | 0.0032 |
| Isotherm parameter 4 / S | 0.0032 |
| Isotherm parameter 4 / W | 0.0032 |

## 2.3. Model simulation parameters

The column geometry and mass transfer parameters used in the simulations are summarized in Table 1. Identical parameters are assumed for both columns to isolate the effect of process configuration and operation. Feed

and mobile phase specifications are provided in Table 2, representing a mixture of target peptide (P), a weakly adsorbed impurity (W), and a strongly adsorbed impurity (S).

The solvent gradient strategy employed in the simulations is detailed in Table 3. A sequence of isocratic and linear gradient steps is defined for each column using the cycle organizer. Precisely, post feed loading (step 1) for the first elution of column 2 which receives the overlapped fractions from column 1, the elution of W (step 2), elution of P (step 4), and elution of S (step 6) are achieved during the different established linear ramps. In the meantime, the elution of the overlapping fractions containing the mixture W/P (step 3), and the mixture P/S (step 5) are also completed and internally recycled to column 1. Then, the post-elution time (step 7) allows the complete separation and collection of the strongly adsorbed compound, prior to column equilibration. After two column switches, the system returns to its initial configuration, completing one full MCSGP cycle [12].

Internal recycle streams corresponding to overlapping W/P and P/S fractions are treated as free variables, reflecting their dynamic nature during the process operation.

**Table 2:** Inlet/outlet stream specifications used for the two-column MCSGP model.

| Stream | Value/Unit | Specification |
|---|---|---|
| **Feed** | | |
| Flowrate | 0.20 mL/min | Fixed |
| Concentration (ACN) | 1.50 g/L | Fixed |
| Concentration (P) | 0.05 g/L | Fixed |
| Concentration (S) | 0.01 g/L | Fixed |
| Concentration (W) | 0.015 g/L | Fixed |

## 3. RESULTS AND DISCUSSION

Dynamic simulations are performed for one complete MCSGP cycle with a total duration of approximately 90 minutes, which is sufficient to capture the transition from initial batch-like operation to fully cyclic steady behaviour. Figure 2 shows the outlet concentration profiles of the weakly adsorbed impurity (W), target peptide (P), and strongly adsorbed impurity (S) for both columns. The concentration profiles are reported in absolute concentration units, enabling direct comparison between batch and continuous operation.

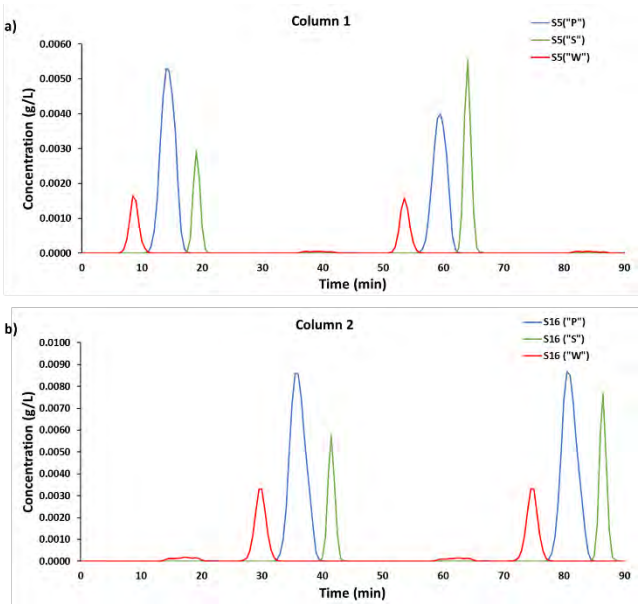

**Figure 2.** Concentration profiles of the MCSGP outlet streams (weakly adsorbed W, red line; target product P, blue line; strongly adsorbed S, green line) obtained after the dynamic simulation of the one cycle for: a) Column 1, and b) Column 2.

Distinct and recurrent elution peaks are observed

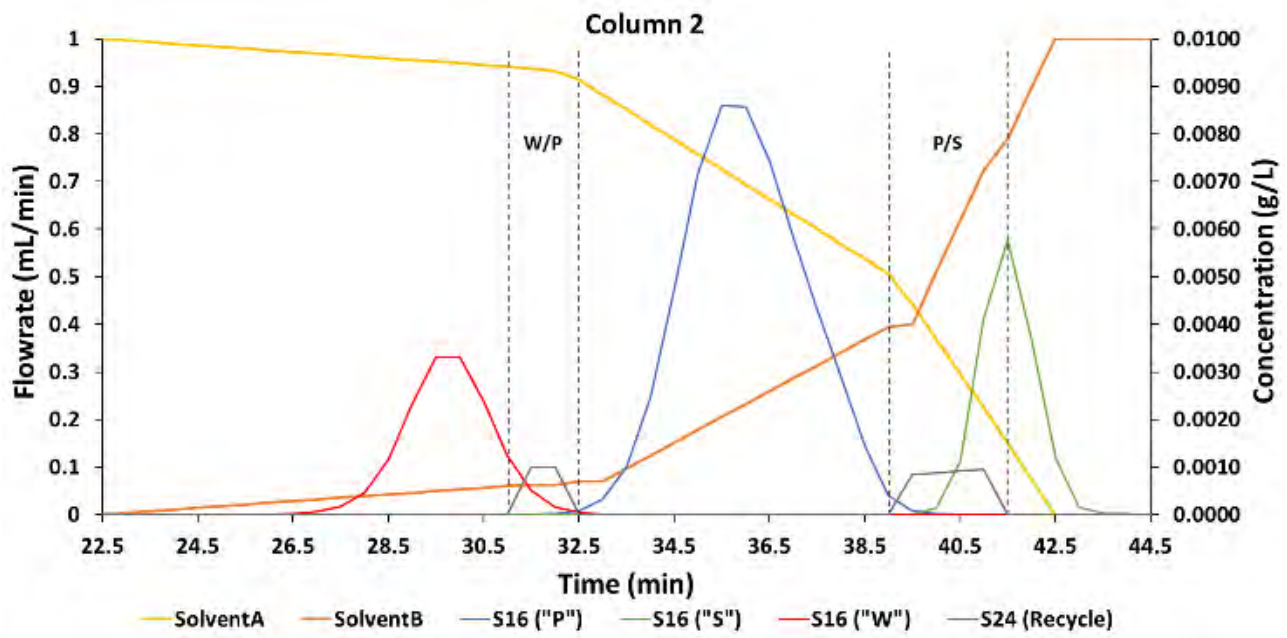

**Figure 3.** Mobile phase flowrates (solvent A, orange line; solvent B, yellow line), recycle flowrates (grey line), and concentration profiles of the outlet streams (weakly adsorbed W, red line; target product P, blue line; strongly adsorbed S, green line) obtained during the first elution of Column 2.

for all components, indicating stable cyclic operation after the initial transient. During the first elution of Column 1, the system operates effectively in batch mode, as no internal recycle streams are yet active. This is reflected in comparatively lower peak concentrations and a single-pass utilization of the injected feed. Once internal recycle streams are activated, subsequent elution exhibits a recurrent and stable pattern, indicating that MCSGP process has reached a cyclic operating regime. In particular, the concentration profiles obtained for Column 2 show noticeably higher peak intensities for the target peptide P, demonstrating the cumulative effect of recycling overlapping W/P and P/S fractions from Column 1.

Figure 2 further shows that peak shapes remain well defined over successive cycles, suggesting that axial dispersion and intraparticle mass transfer resistance are adequately captured by the adopted modelling framework. Limited peak broadening is observed, despite the repeated recycling of intermediate fractions, indicating that the chosen gradient-design and switching strategy preserve separation efficiency while enabling enhanced recovery.

The coupling between solvent gradient elution and component separation is examined in more detail in Figure 3, which reports the mobile phase composition alongside outlet profiles during the first elution of Column 2.

The weakly adsorbed impurity W elutes at low solvent strength during the early gradient segment, while the target peptide elutes at intermediate solvent composition. The strongly adsorbed impurity S is released only at higher solvent strengths during the final gradient steps. Quantitatively, the elution windows of each component correspond closely to the segment gradient ramps defined in Table 3, confirming the cycle organizer approach allows precise synchronization between gradient evolution and recycle timing.

Of particular relevance is the treatment of overlapping fractions. As shown in Figure 3, the elution intervals where W/P and P/S overlap are deliberately short but non-negligible, reflecting realistic separation challenges for closely eluting peptides. Instead of being discarded, these fractions are redirected through internal recycle streams and reintroduced into the opposite column. This process-level mechanism is central to the performance gains observed in MCSGP and cannot be achieved in conventional batch chromatography without additional purification steps.

A quantitative comparison between conventional batch chromatography and two-column MCSGP is presented in Figure 4. Under identical transport and adsorption assumptions, the recovered mass of the target peptide increases from approximately 0.067 g in batch operation to about 0.674 g in MCSGP, corresponding to an order of magnitude improvement in recovery. Similarly, recovery of the strongly adsorbed impurity increases from roughly 0.017 g to 0.598 g, confirming the effectiveness of internal recycling for late-eluting components. The weakly adsorbed fraction shows a more modest increase, from about 0.016 g in batch mode to 0.078 g in MCSGP, consistent with its early elution and

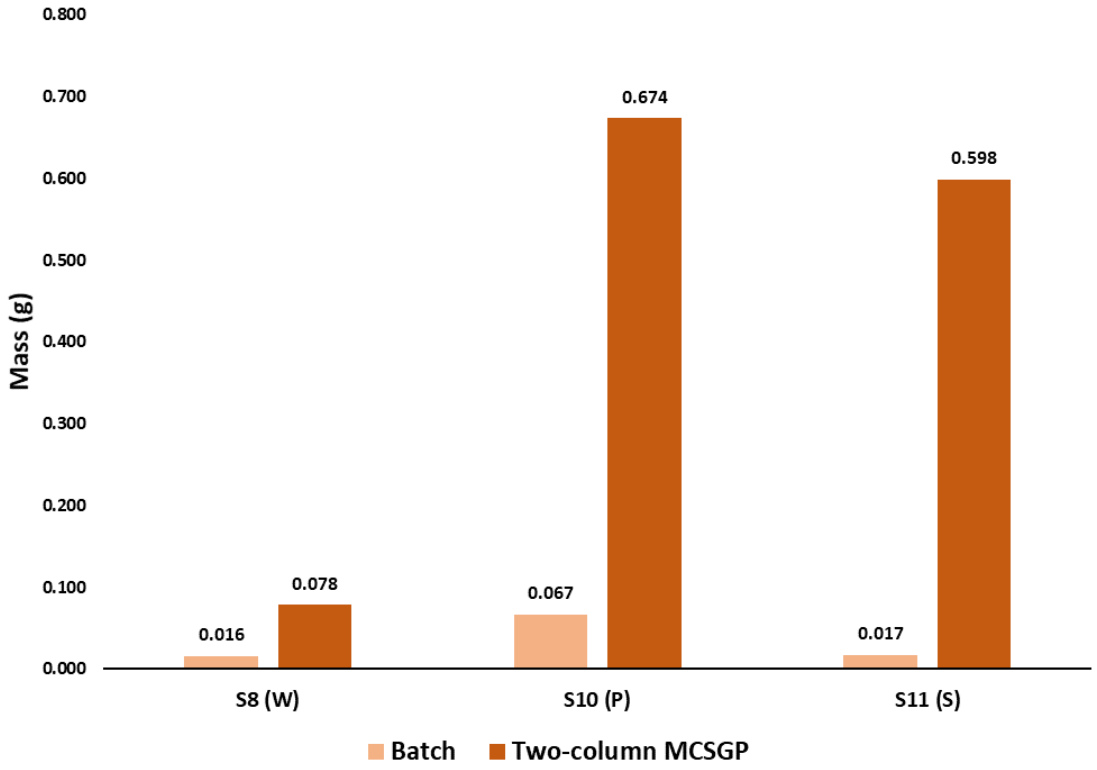

**Figure 4.** Comparative analysis of mass recovery after dynamic peptide separation using conventional batch chromatography and a two-column MCSGP process.

limited overlap.

These quantitative results demonstrate that the performance gains achieved by MCSGP are not due to changes in column design or adsorption parameters, but arise directly from the process configuration and operating strategy. The coordinated interaction between solvent gradient design, recycle timing, and column switching enables the systematic reuse of overlapping fractions that would otherwise be discarded in batch operation.

The observed trends are consistent with previously reported MCSGP modelling studies for peptides and nucleotides [9, 10], particularly with respect to enhanced recovery and selectivity. However, the present work differs in its explicit treatment of MCSGP as a hybrid dynamic process within a commercial simulation environment. By embedding chromatographic transport, gradient elution, and recycle logic in a unified flowsheet-based framework, the model facilitates process-level interpretation and provides a practical basis for future operability, optimization, and control-oriented studies.

## 4. CONCLUSIONS

A dynamic, cycle-resolved simulation model of a two-column MCSGP process for peptide purification has been developed and implemented in Aspen Chromatography. The preliminary results confirm that MCSGP operation substantially improves product recovery compared with conventional batch chromatography through the coordinated application of solvent gradient elution, column switching, and internal recycling of overlapping fractions. Under identical transport and adsorption assumptions, the simulated MCSGP process achieves an order of magnitude increase in recovered target peptide, clearly demonstrating the process-level benefits of continuous operations.

Beyond confirming known separation advantages, the key contribution of this work lies in framing MCSGP as a hybrid dynamic process and demonstrating its essential features can be captured in a transparent and reusable manner within a commercial flowsheet-based simulation environment rather than relying on custom numerical implementations. The proposed model serves as a transferable template for systematic process comparison, operability analysis, and early-stage decision-support in biopharmaceutical downstream processing.

Future work will focus on strengthening the predictive capability and practical relevance of the proposed

framework. This includes validation of the model against experimental peptide purification data, as well as parameter estimation and sensitivity analysis to better quantify uncertainty in mass transfer and adsorption parameters. Extending the model to multi-column configurations and incorporating additional performance indicators, such as solvent consumption, productivity, and robustness to operating disturbances, will further enhance its applicability. Finally, integration of the dynamic MCSGP model with optimization and control strategies represents a promising direction toward digital twin-based design and operation of continuous chromatographic processes.

## ABSTRACT

Low-temperature industrial processes release substantial amounts of waste heat, representing a largely untapped renewable energy resource. This study focuses on the brewery sector, encompassing both beer and whiskey production, along with its integration with manufacturing and city. The brewery industry generates approximately 0.061 kWh of waste heat per liter of beer, while whiskey production releases around 2.2 kWh per liter, with most of this waste heat available at temperatures close to 95 °C. Such low-grade heat is well suited to meet heating demands in manufacturing industries and urban district heating networks, where temperature requirements typically remain below 80 °C. Multiple technological options for meeting process heat requirements and recovering waste heat are evaluated using the OSMOSE energy integration framework. The study assesses the technical performance and economic viability of these options under varying assumptions for electricity prices, natural gas prices, and carbon pricing. Depending on market conditions, overall external utilities consumption reductions ranging from 22% to 63% are achieved. Price of utilities also has an effect on reduction of emission, as it is ranging from 25% to 90%.The results highlight the significant potential for cross-sectoral heat integration between breweries, manufacturing industries, and urban energy systems. A comparison is drawn between a case in which 5 th generation system (case 1) is activated and a case in which 5 th generation is not active (case 2). It was observed in most of the market conditions, case 1 is energetically, environmentally and economically more sustainable compared to case 2. In one of the market condition it was possible for both the cases to be energetically a carbon negative solution as it was economically feasible to capture biogenic $CO_2$. The work helps in validating that strategic waste heat recovery and utilization can substantially enhance energy efficiency, support industrial decarbonization pathways, and improve the resilience of urban energy infrastructures.

**Keywords**: Cross-sectoral Integration, Waste heat utilization, Brewery, Decarbonization, Renewable energy

## INTRODUCTION

In 2023 the energy consumption for all the industrial activities in Europe (majorly EU and UK) was about 2750 TWh/year [1-2]. Meanwhile, the total energy consumption for residential sector is 2650 TWh/year [1-2]. The current work focuses on two industrial sectors: 1) Brewery and Whiskey production and 2) Manufacturing industry and their symbiosis with a typical city. Brewery industry act as source of low-grade heat, which is well suited in meeting the heat demand for manufacturing industry and also, urban district heating networks, where temperature requirements remain typically below 80 °C.

## METHODOLOGY

The section first presents, the brewery and manufacturing process description, along with the considered

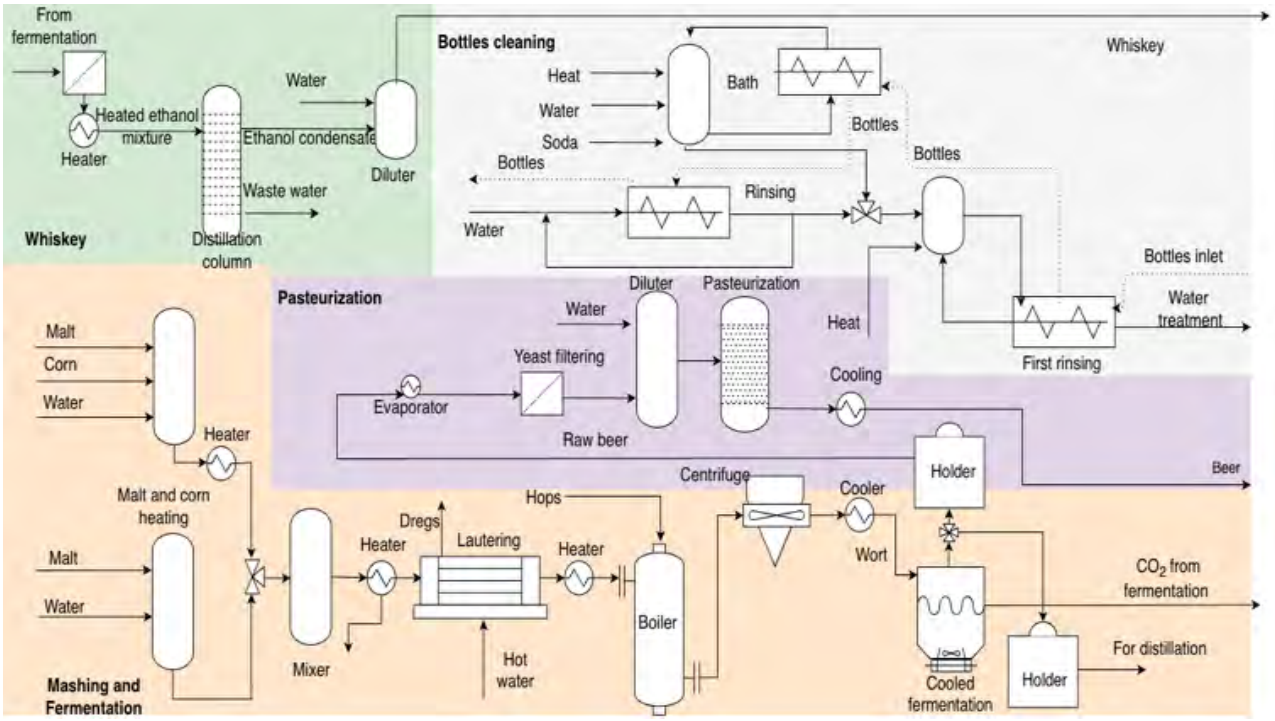

**Figure 1.** Process flowsheet of the beer and whiskey production with cleaning in place of bottles.

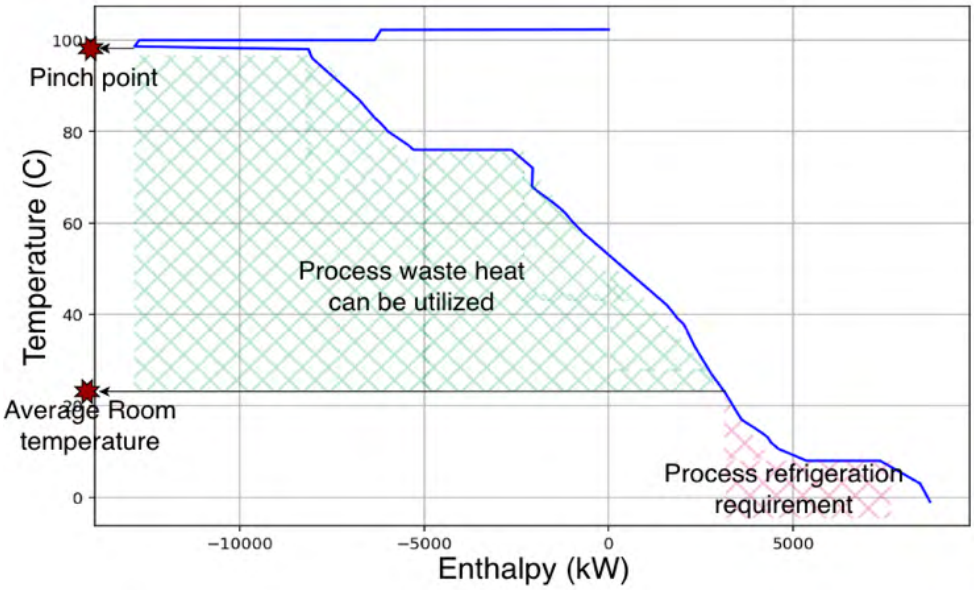

**Figure 2.** Integrated composite curve of the beer and whiskey production. Green shaded region identifies the process waste heat. Red shaded region identifies refrigeration need.

city demands. Next, the cluster analysis is discussed, followed by explaining in brief the various technological options accounted to meet the industrial utility demands. Finally, discussing about the different approaches for waste heat recovery and its subsequent utilization.

## Brewery Industry

The process description is shown in Figure 1. Primary stages in the production of beer and whiskey include malting and fermentation along with pasteurization for beer [3], [4], and distillation for whiskey [5]. The final products are then bottled. In the current analysis the capacity from beer production Is around 49 $m^3/h$, while the capacity of whiskey production is around 2.9 $m^3/h$.

Energy requirement for the processes was

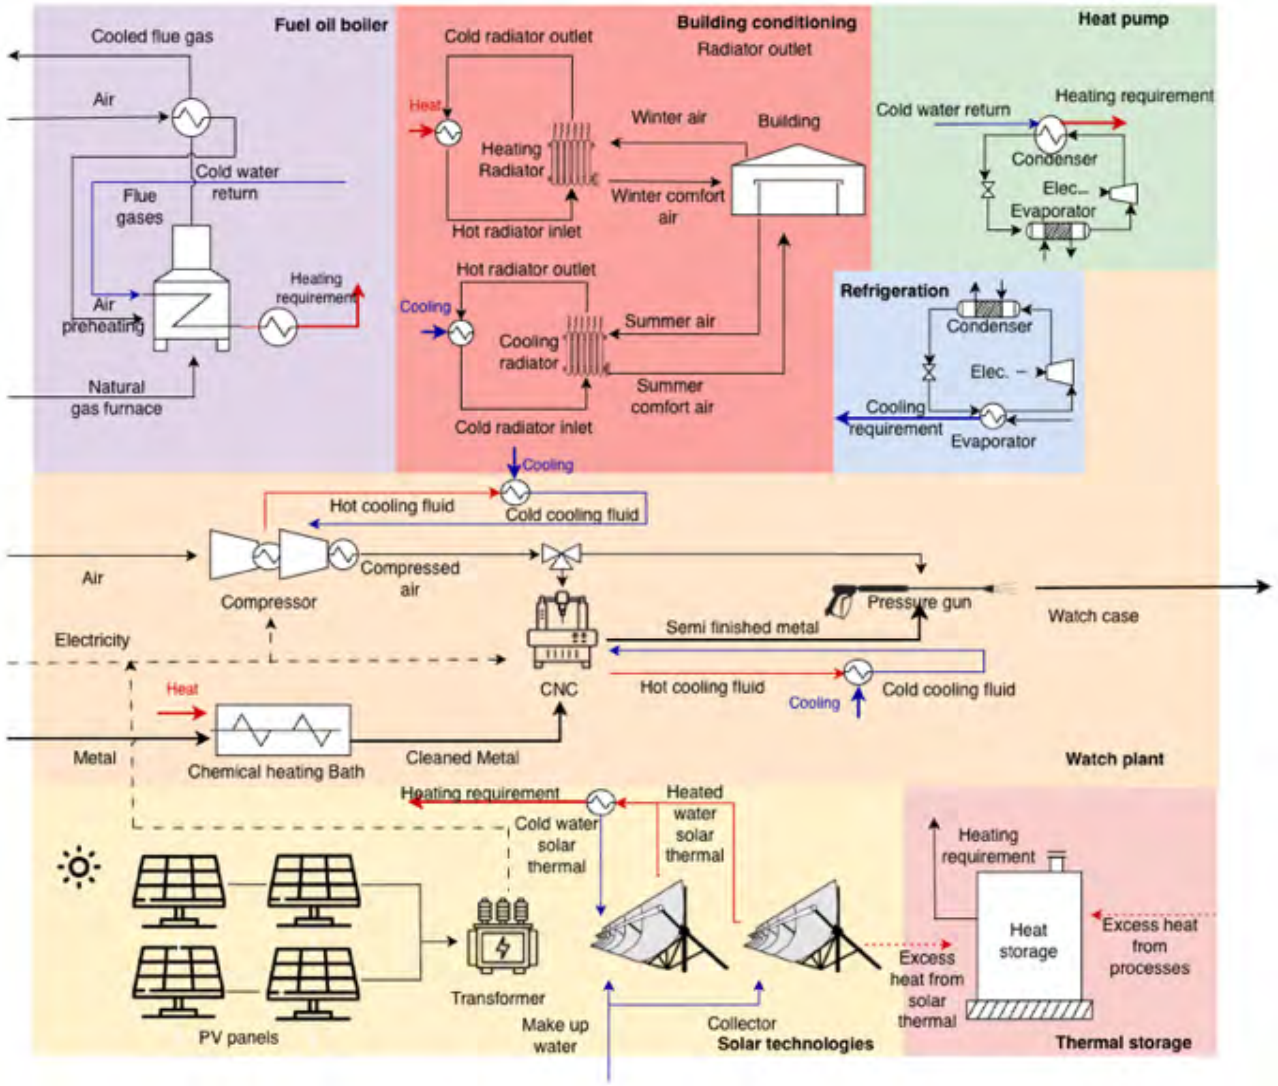

**Figure 3.** Superstructure of manufacturing industry.

simulated using the opensource modelling tool DWSIM. Process integration was performed using OSMOSE [8]. The waste heat available as well as its amounts are shown in Figure 2. Energy requirement remains constant for the whole year as in this analysis the industry is considered to be a largescale industry.

## Manufacturing Industry

The major part of the energy requirement for the manufacturing industry is electricity. Heat is generally required for heating of offices and incoming metal. ([7]). Figure 3 helps in identifying what are the different process involved in machining industry. Energy requirement is varying throughout the year, the variation in energy is depicted in Figure 4.

## City

Energy requirement in city generally corresponds to the energy requirement for residential purpose. The majority of energy consumption is in the form of space heating, water heating, lighting and electrical appliances and cooking.

Energy requirement varies depending upon the season. Variation in energy demand for a city is shown in figure 5.

## Cluster analysis

Accurately capturing temporal variations in industrial demand is essential for system-level energy analysis. However, representing demand at an hourly resolution over an entire year (8, 760 hours) leads to a substantial computational burden. To address this challenge, a K-means clustering algorithm is employed to aggregate hourly demand profiles into 15 representative operating points distributed across the year. A silhouette score of 0.73 indicates good cluster separation, while the elbow

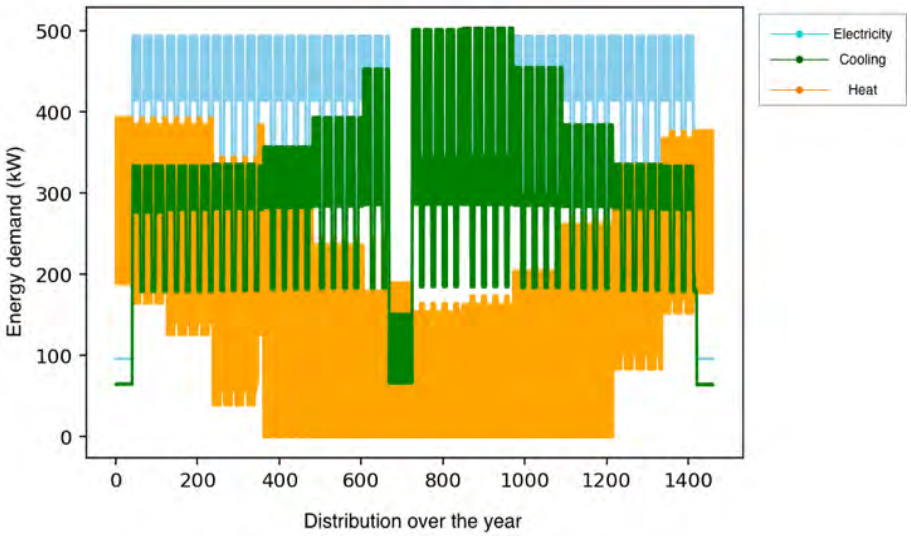

**Figure 4.** Variation in energy demand across the year in manufacturing unit. Each time step represents a typical 6 hours of working.

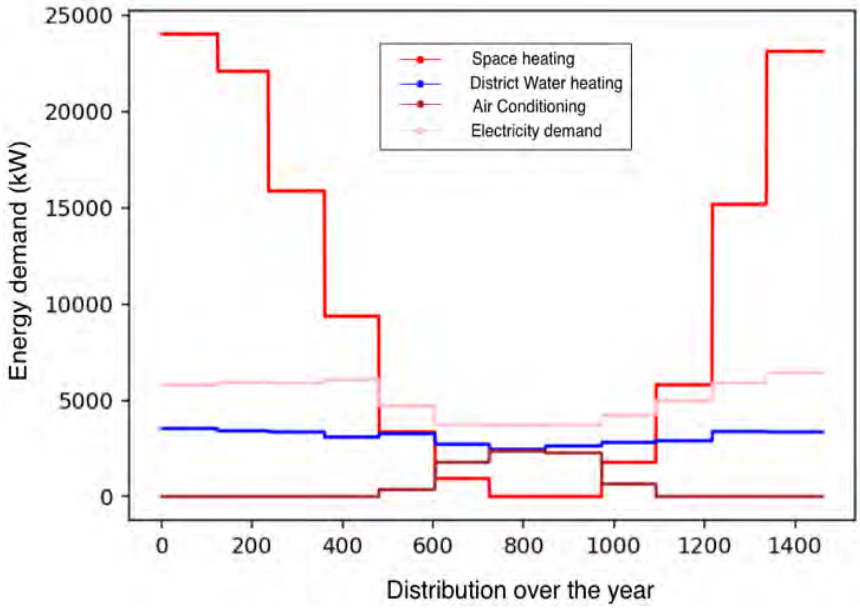

**Figure 5.** Variation in energy demand across the year in a city. In the figure each time step represents a typical 6 hours of working.

method shows that the within-cluster sum of squares (WCSS) approaches a minimum beyond 15 clusters. The resulting representative points preserve both seasonal and operational variability while significantly reducing computational complexity.

## Utilities superstructure

Figure 6 presents the utility supply and waste valorization options available for the brewery industry. A share of the heating and cooling demand can be supplied by heat pumps operating at different temperature levels. The brewery generates by-products such as dregs and releases waste streams including wastewater and biogenic $CO_2$. These streams offer multiple valorization pathways. Dregs can be converted into synthetic natural gas (SNG), which can be used either in gas engines for electricity generation or in furnaces for heat production. Wastewater can be treated to produce sludge, which is subsequently converted into SNG via anaerobic digestion. Biogenic $CO_2$ released during fermentation can be converted into SNG through methanation using hydrogen produced by electrolysis [6].

For the manufacturing (machining) sector, part of

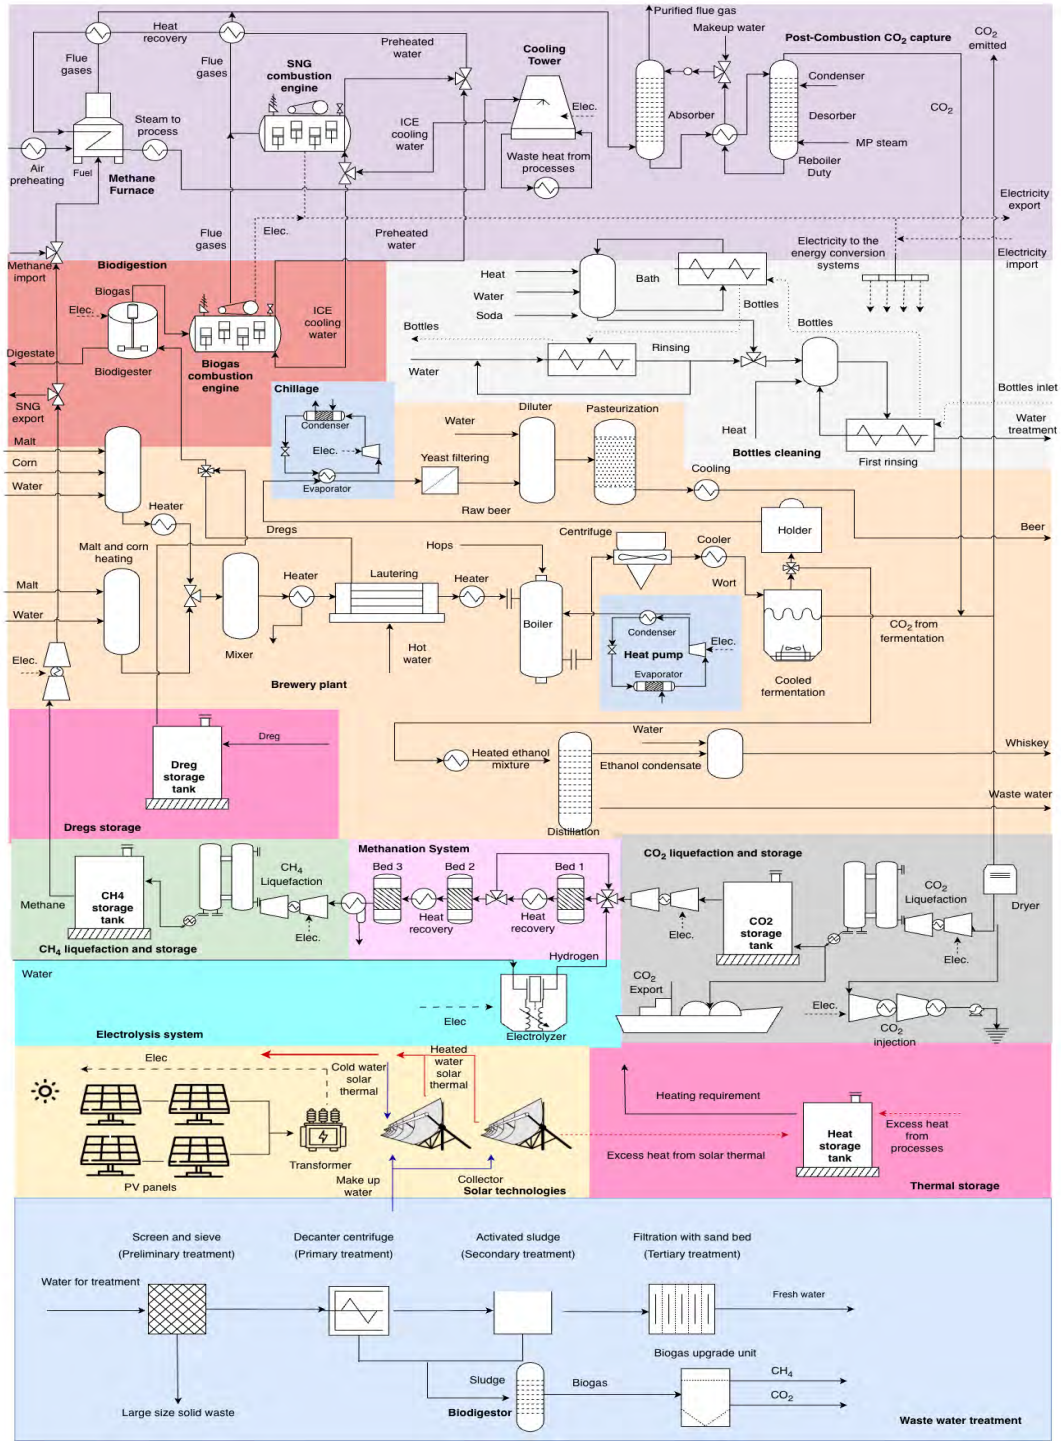

**Figure 6:**Utilities and waste valorization

the heating and cooling demand can similarly be met using heat pumps, while solar thermal energy is considered as an additional option for supplying low-temperature heat. The corresponding utility options are shown in Figure 3 [7].

For the urban sector, heating is supplied through a district heating system in which heat is generated centrally and distributed to residential buildings. Centralized heat supply can be provided by either large-scale heat pumps or NG furnaces, while decentralized NG furnaces can alternatively be replaced by decentralized heat pumps [4].

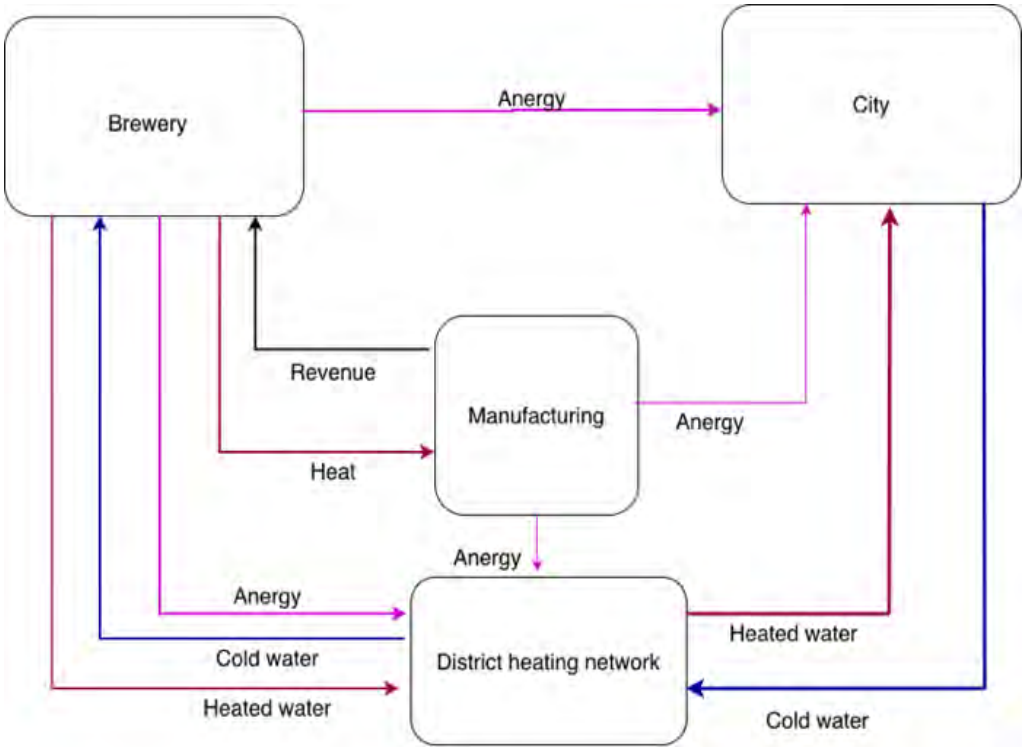

**Figure 7.** 5th generation heat recovery and utiliztaion

## Waste heat recovery.

The brewery industry generates approximately 0.061 kWh of waste heat per liter of beer produced, while whiskey production releases around 2.2 kWh per liter, with most of the waste heat available at temperatures close to 95 °C. For the studied system, this corresponds to a total waste heat potential of approximately 12.76 MW.

Cold outlet from the houses can be heated up to required temperature with the process waste heat released in brewery. In this case some section of district heating network is provided with the help of process waste heat. In brewery and manufacturing industry as depicted in figure. In brewery process as identified from figure 2, there is need of refrigeration system to provide cooling. These refrigeration system act as a source of anergy (low grade heat which cannot be directly used in direct heating). The anergy act as a source of heat for the evaporator section of decentralized or centralized heat pump and provide heating to the house directly or to the district heating network. All these possible options are depicted in figure 7.

## Sensitivity analysis.

Given the multiple utility and waste valorization options shown in Figures 3, 6 and 7, the optimal system configuration is determined using the optimization framework OSMOSE [8]. Technology selection is driven by the chosen objective function. In this study, total cost (TOTEX), defined as the sum of annualized investment and operating costs, is used as the optimization criteria.

Key parameters influencing technology selection include electricity price, natural gas price, and carbon tax level. A sensitivity analysis is therefore performed by varying these parameters to evaluate their impact on system configuration, energy self-reliance, and emissions.

# RESULT

The analysis is carried out for two distinct system configurations. For the System Configauration 1 (SC 1), all three sectors are fully integrated and allowed to exchange mass and energy flows. In System Configuaration 2 (SC 2), brewery, manufacturing sector, and the city operate independently, with no exchange of heat, anergy, or mass flows among them.

For both scenarios, a sensitivity analysis is performed and the results are evaluated based on two criteria: (i) improvements in energy efficiency, (ii) reductions in carbon emissions. In all the comparison, results are evaluated against the base system in which the heating requirement is met with the help of natural gas furnace. The cooling requirement is met with the help of cooling tower and refrigeration system. In all the further discussion this scenario will be considered as base system.

## Self-reliance of system

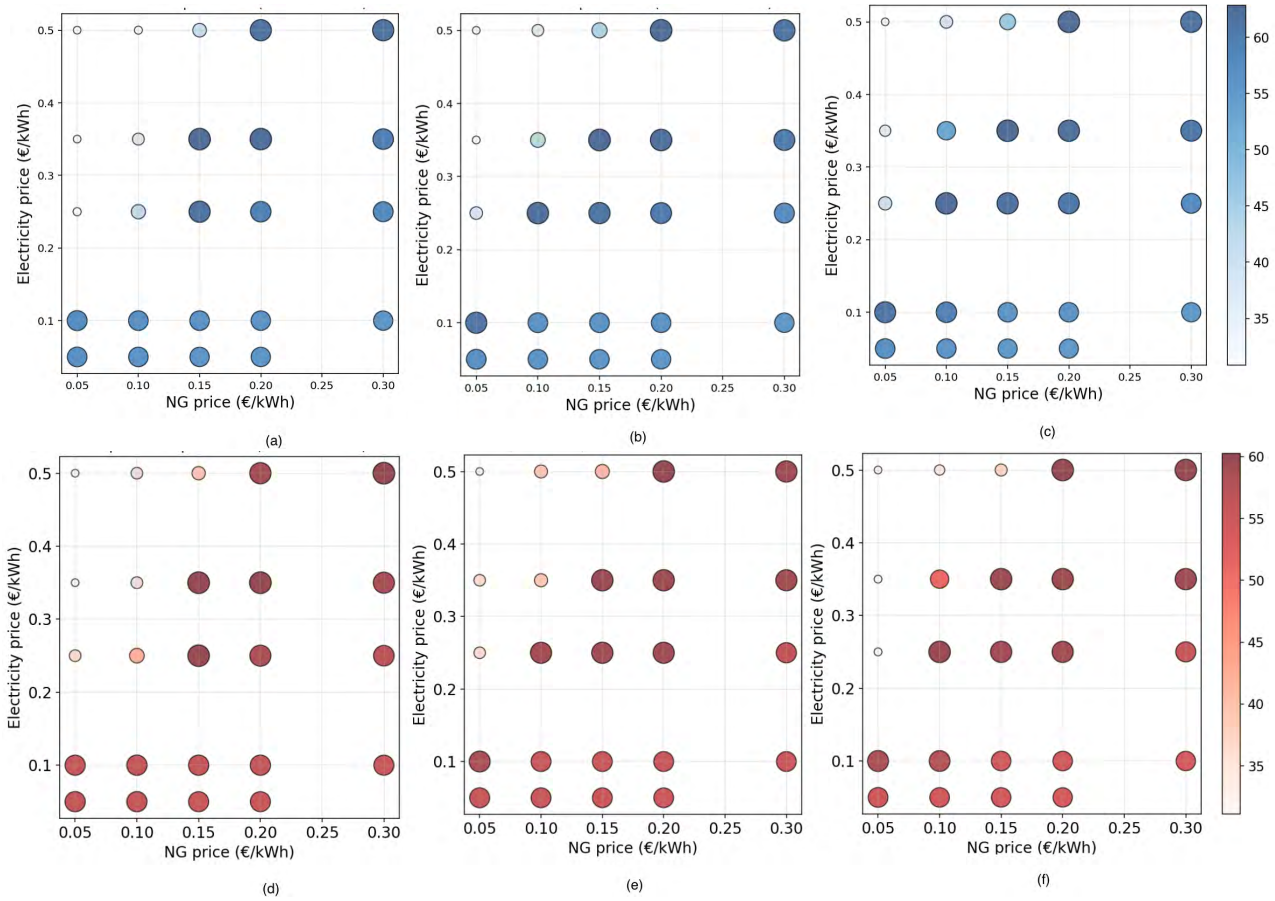

**Figure 8:** Percentage increase in system self-reliance compared to the base system cofiguration, across different electricity prices, natural gas prices, and carbon taxes in both system conifgurations Panels (a), (b), and (c) correspond to the SC1 while panels (d), (e), and (f) correspond to the SC 2. Graph (a) and (d), corresponds to a carbon tax of 0 €/ton, Graph (b) and (e), value of carbon tax is 80 €/ton; and in Graphs (c) and (f), it is 200 €/ton. Darker and larger points indicate solutions that are more energy independent.

In the base system, total natural gas consumption is approximately 216 TWh/year, while total electricity consumption is around 63 TWh/year. In SC 1 and SC 2, consumption of natural gas and electricity varies as a function of electricity price, natural gas price, and carbon tax. Here, energy self-reliance is defined as the reduction in externally purchased electricity and natural gas relative to the base case. Figure 8 illustrates improvements in energy self-reliance by summing purchased electricity and natural gas in each sensitivity case and comparing them to the base scenario.

Across the sensitivity analysis, energy self-reliance improvement has a very wide range of 61–23% for the SC 1, and also 60–25% for SC 2. The reason for the wide range is due to shift of energy vector. As the price of electricity increases, the optimizer chooses to shift from eletrical based utilities to natural gas based utilities. This shift decreases the self sufficieny of the system. The reason is because, heat pumps (electrically driven utility) operate across the system's pinch point and can internally redistribute energy to meet both heating and cooling demands, thereby reducing external energy purchases.

Comparing (Figure 8 (a) and 8(d)) with (Figures 8 (b) and 8(e)) and, (Figure 8(c) and 8 (f)) respectively, increasing ca rbon taxes chooses more energy-independent utilities option. The reason is, electrically driven utilities generally exhibit lower carbon emissions than natural gas-based alternatives. As carbon tax increases, the economic penalty associated with $CO_2$ emissions rises, making low-carbon, electricity-based solutions more attractive despite higher electricity prices. This highlights the role of carbon pricing in incentivizing integrated, low-carbon energy systems, even in contexts with relatively high electricity prices.

**Figure 9.** compares the energy self-reliance of the SC 1 from SC 2, for the value where carbon tax of zero. Overall, the SC 1 exhibits higher self-sufficiency compared to the SC 2, except in scenarios where electricity prices are high and natural gas prices are low. Under these conditions, the SC 1 consumes more natural gas to

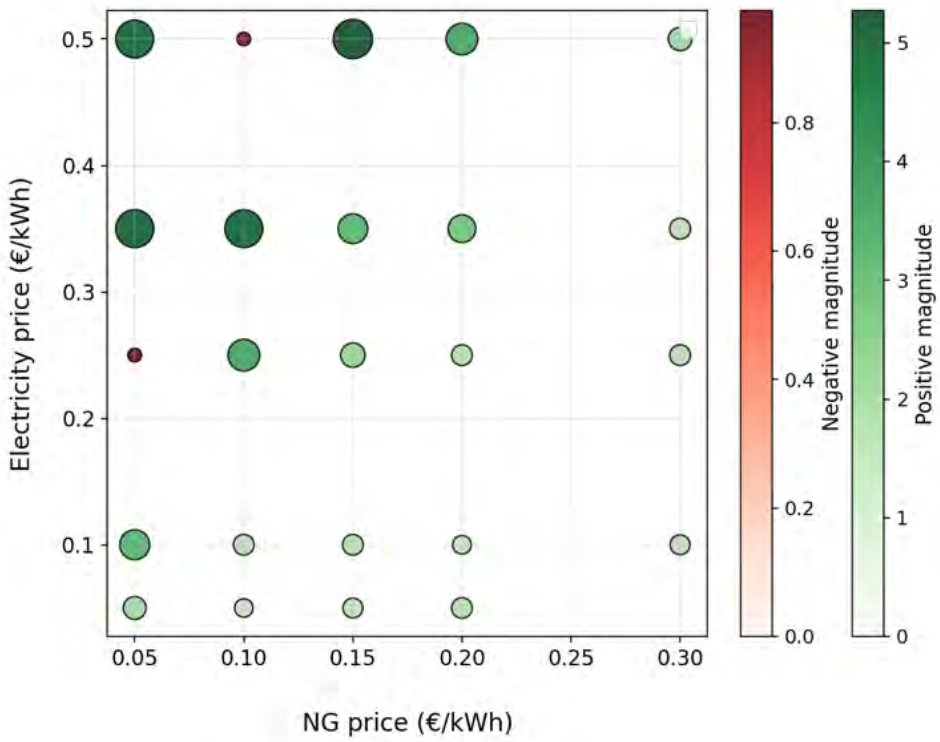

**Figure 9.** Comparing self sufficiency among different system configuartions, across variable electricity and natural gas prices. Green points indicate choices of optmizer where SC 1 results in higher self-sufficiency than the SC 2. Conversely, red point indicate the choices where SC 2 has higher self sufficiency than SC 1. Higher the size and intensity of the color, larger the difference among both the system configuartions.

satisfy energy demand, as the absence of a carbon penalty favors cost-optimal but fossil-intensive solution.

## Environmental analysis

In the base system configuration, the total amount of $CO_2$ released into the atmosphere is approximately 14, 490 kton/year, of which emissions from fermentation account for around 14, 440 kton/year. In the present analysis, only emissions associated with utility choices are considered for comparison. Although fermentation dominates total $CO_2$ emissions, the analysis focuses on utility-related emissions, as these are directly influenced by system configuration and energy price assumptions.

Figure 10 compares the differences in emission reductions among both the system configuration under varying prices of electricity, natural gas, and carbon tax. When the cost of natural gas is higher than or equal to the cost of electricity, SC 1 exhibits slightly lower emissions than the SC 2. However, the difference is relatively small, ranging between 0.2 and 0.3 kton/year. This can be attributed to anergy utilization in the SC 1, which reduces the electricity demand for residential heating. In the same price regime, residential heating in the SC 2 is supplied by decentralized heat pumps operating at higher temperature levels, resulting in lower coefficients of performance (COP) and higher electricity consumption.

When natural gas is cheaper than electricity, SC 2 shows lower emissions than the SC 1 in some cases. The maximum observed difference is approximately 2.2 kton/year, occurring at a carbon tax of 80 €/ton, an electricity price of 0.35 €/kWh, and a natural gas price of 0.05 €/kWh. Under these conditions, the SC 1 consumes more natural gas due to increased availability of waste heat. For system configuration 1, when a heat pump is selected, it upgrades heat below the pinch point to temperatures above the pinch point for use in brewery processes. This reduces the amount of waste heat available for exchange within the proposed heat-exchange network, thereby increasing reliance on natural gas. This also explains the presence of two red points in Figure 10(a) when the carbon tax is zero, since higher natural gas consumption does not incur any economical penalty for the case.

## Scenario analysis

The sensitivity analysis revealed an interesting scenario under specific energy price conditions. When the

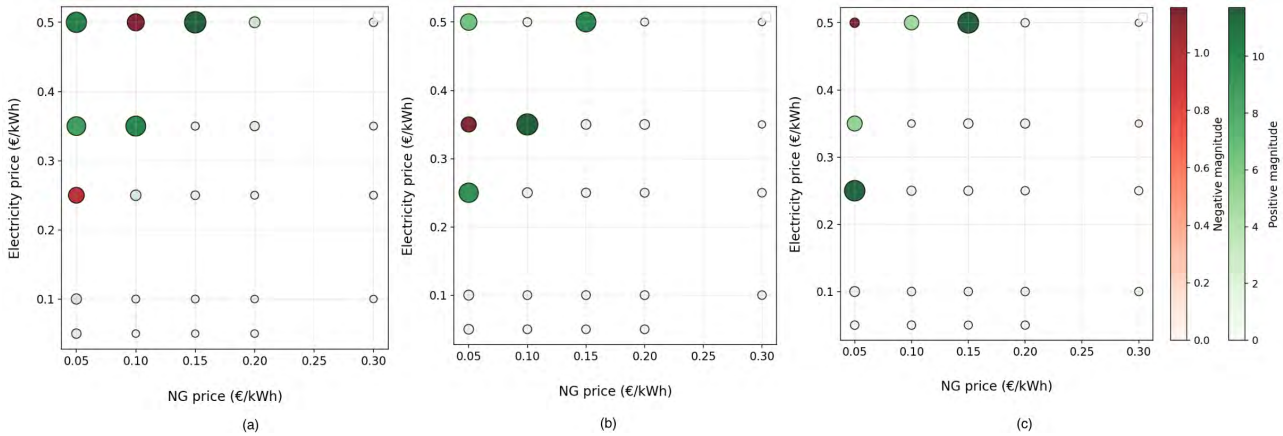

**Figure 10:** Variation in emission reductions across both the system configuration in varible electricity and natural gas prices. Graphs (a), (b), and (c) represent emission reductions for carbon tax values of 0, 80, and 200 €/t$CO_2$, respectively.Green points indicate decisions in which SC 1 results in lower emissions than SC 2. Size of green points reflects the absolute difference in emission reduction between the system configurations. Conversely, red points indicate the decision where SC 2 has lower emissions than the SC 1, with larger red points representing greater differences between the two systems.

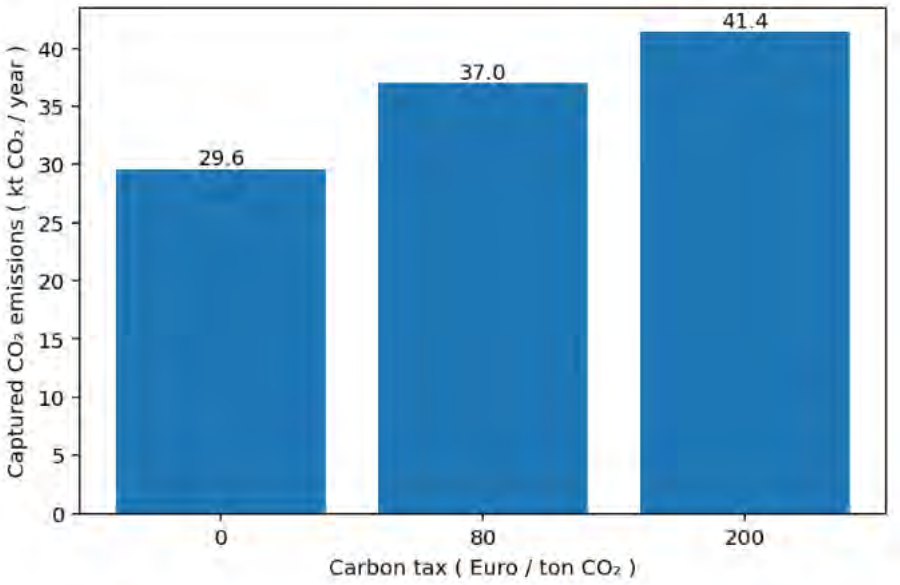

**Figure 11.** Net amount of $CO_2$ captured for SC 1 scenario as a function of carbon tax level.

electricity price is approximately 0.05 €/kWh and the natural gas price is around 0.3 €/kWh, the optimizer captures biogenic $CO_2$ and it is conversted into e-methane via methanation.

The capture and utilization of biogenic carbon enables the brewery system to operate in an energetically carbon-negative mode. In the zero carbon tax scenario (0 €/t$CO_2$), electricity consumption amounts to 691.7 GWh $yr^{-1}$ for the SC 1 and 1, 055 GWh $yr^{-1}$ for the SC 2, while e-methane production reaches 335 GWh $yr^{-1}$ and 520 GWh $yr^{-1}$, respectively. Assuming a grid emission factor of 0.054 kg $CO_2$ $kWh^{-1}$, the $CO_2$ emissions associated with electricity consumption remain lower than the amount of biogenic $CO_2$ captured from fermentation, resulting in net negative emissions in both cases.

In both the system configurations a consistent trend was observed: increasing carbon tax levels leads to more capture of biogenic $CO_2$: increasing the net amount of $CO_2$ catured, thereby enhancing the carbon-negative performance of the system (Figures 11 and 12).

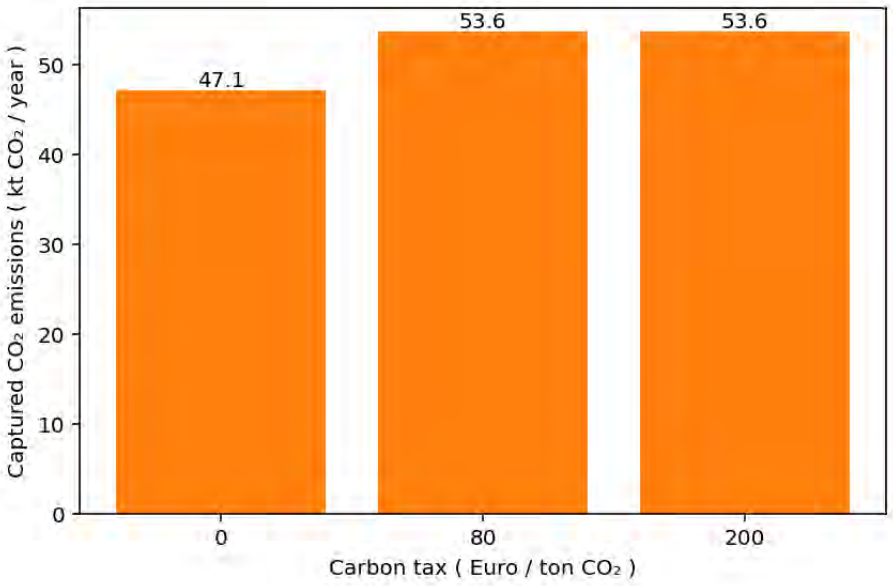

**Figure 12.** Net amount of $CO_2$ captured SC 2 as a function of carbon tax level.

Methanation and electrolysis are exothermic, and the resulting heat generation constrains the maximum $CO_2$ capture through cooling capacity limits. For SC 1, these limits are determined by the combined refrigeration and heat-storage capacities across the brewery, city, and manufacturing sectors enabled by the fifth-generation heat network, whereas in the SC 2 system they are governed by the brewery refrigeration system and cooling tower capacity.

## CONCLUSION

This study demonstrates how integrated industrial–urban energy systems can significantly improve energy self-reliance and environmental performance through coordinated utility selection, waste valorization, and heat recovery. By combining temporal demand clustering with cost-optimal optimization using OSMOSE, the analysis highlights the strong influence of energy prices, carbon taxation, and system integration on technology choices.

The results show that SC 1 generally achieve higher self-sufficiency and lower emissions than SC 2 configurations, particularly under higher carbon tax levels. Notably, under favorable energy price conditions, the system enables the capture and conversion of biogenic $CO_2$ into e-methane, resulting in energetically carbon-negative operation. These findings underline the potential of integrated, low-carbon energy systems and policy instruments such as carbon pricing to support deep industrial decarbonization.

## ABSTRACT

This work presents guidelines for controlling and intensifying mixing in oscillatory opposed-jet mixers, focusing on Confined Impinging Jets (CIJs) as a model system where flow behavior is primarily governed by oscillatory parameters, decoupled from geometric complexity. Computational Fluid Dynamics (CFD) simulations were used to investigate the effects of oscillation amplitude and frequency on mixing. The results show that at high amplitudes, mixing is robust across a broad frequency range, as energy injection is sufficient to promote vortex formation and their propagation to the reactor's outlet. At low amplitudes, mixing is highly sensitive to the oscillation frequency and occurs only near the resonance frequency, the specific frequency at which the flow's response to the applied oscillation is maximized. At low amplitude, lower frequencies fail to inject sufficient energy, while higher frequencies promote flow segregation. Remarkably, effective vortex propagation and mixing were achieved even at very low net Reynolds numbers ($\mathrm{Re}_{\mathrm{net}} = 25$), increasing the residence time from 0.042 s at $\mathrm{Re}_{\mathrm{net}} = 300$ to 0.5 s at $\mathrm{Re}_{\mathrm{net}} = 25$. Two quantitative mixing metrics corroborate the qualitative flow observations and were instrumental in defining practical guidelines for process intensification. These findings provide new insights into how oscillatory forcing can be tuned to control mixing scales, enabling efficient mixing under a wide range of operating conditions, including shear-sensitive processes. The study offers a foundation for the model-based design and optimization of intensified static mixers, linking oscillation parameters, Reynolds number, and residence time to application-specific mixing performance.

**Keywords**: Computational Fluid Dynamics, Fluid Dynamics, Mixing, Process Intensification, Process Design

## INTRODUCTION

Static mixers are characterized by the absence of external moving parts, offering efficient mixing control and low energy consumption, in contrast to mechanically agitated devices. The mixing performance of these devices is strongly dependent on the operating Reynolds number, which should be above a critical threshold, usually $\mathrm{Re}_c > 120$ [1].

Under these specific conditions, the flow evolves from a steady state to a chaotic regime, characterized by the formation of dynamic vortices that enhance heat and mass transfer [2]. Yet, these advantages are restricted to operations above $\mathrm{Re}_c$, and are ineffective when dealing with applications that require long residence times.

Oscillatory flow is an alternative to improve mixing stability in static mixers across a broader Reynolds number range. It consists of imposing an oscillatory flow rate, defined by an oscillation frequency and amplitude.

This concept is already used in Oscillatory Flow Reactors (OFRs), characterized by a baffled tubular reactor with a superimposed oscillatory stream [3], [4]. Mixing in conventional OFRs has mainly evolved from the interplay between geometric design and oscillation conditions, making it difficult to isolate or generalize the influence of oscillation alone. In both OFRs and the more recent O-

NETmix configuration [5], this interdependence arises from the repeated contractions and expansions in the reactors, which modulate the flow field.

Promising alternatives are systems in which oscillation can act as the primary driver of flow dynamics, such as opposed-jet mixers, which allow the development of predictive models that describe flow behaviour as a function of oscillatory parameters alone, decoupled from geometric complexity and net flow rate.

Moreover, opposed jets mixers have been widely implemented in pharmaceutical applications processes, such as the production of lipid nanoparticles for mRNA encapsulation – e.g., mRNA vaccines - [6], where precise control over micromixing scales is critical for product quality. Mixing is achieved by injecting two streams through opposed jets into a confined chamber, where they evolve into larger vortices. These vortices promote the engulfment of the streams, leading to a phenomenon called the inverse energy cascade, typical of 2D turbulent flows, where the energy is injected from smaller scales, approximately with the size of feed flow streams ($\approx d$), growing to feed larger eddies, with roughly the dimension of the reactor diameter or width ($\approx D$) [7]. The dominant mechanism of energy dissipation is the viscous stress field associated with vortices that evolve throughout the reactor, sustained by the inlet jet streams. Previous studies on oscillatory flow in opposed-jet mixers have shown promising results in controlling the 2D turbulent energy spectrum in response to an external stimulus [8].

However, existing numerical studies remain limited: studies on Oscillatory-CIJs (OCIJs) are at an early proof-of-concept stage, lack quantification of mixing, and cover only a small range of oscillation frequencies and Reynolds numbers, constraining model generalization [8].

The present study aims to establish guidelines for implementing oscillatory flow for efficient mixing in chemical reactors, with a demonstrative application to the CIJs case. It also intends to use oscillatory flow to operate at low Reynolds numbers, achieving longer residence times with comparable mixing efficiencies to those in cases with higher Reynolds numbers.

## METHODOLOGY

### Computational Fluid Dynamics (CFD)

The flow was simulated using the CFD package ANSYS/Fluent 2021 R2, considering a 2D model of the CIJs geometry (Figure 1). The geometry consists of a rectangular chamber of width $D$ and length $H$, and two injectors of size $d$, positioned at a distance $h$ from the top wall.

The continuity, Navier-Stokes, and transport of species equations are solved for an isothermal flow and a Newtonian, incompressible fluid,

$$\nabla \cdot \vec{v} = 0 \tag{1}$$

$$\rho\left(\frac{\partial \vec{v}}{\partial t} + \vec{v} \cdot \nabla \vec{v}\right) = -\nabla p + \mu \nabla^2 \vec{v} \tag{2}$$

$$\frac{\partial Y_A}{\partial t} + \nabla \cdot \left(\vec{v} Y_A\right) = D_A \nabla^2 Y_A \tag{3}$$

where $\vec{v}$ is the velocity vector field, $p$ the static pressure, $Y_A$ is fluid A mass fraction, and $D_A = 10^{-9}\ \mathrm{m^2\ s^{-1}}$ is the mass diffusion coefficient of fluid A in fluid B. The working fluid consists of a mixture of two viscous fluids (fluids A and B) both with identical physical properties ($\rho$ = 1000 kg/m$^3$ and $\mu$ = 0.02 Pa·s). Conditions of no gravity were considered in the simulations. These properties were considered to mimic the fluids used in CIJs industrial applications.

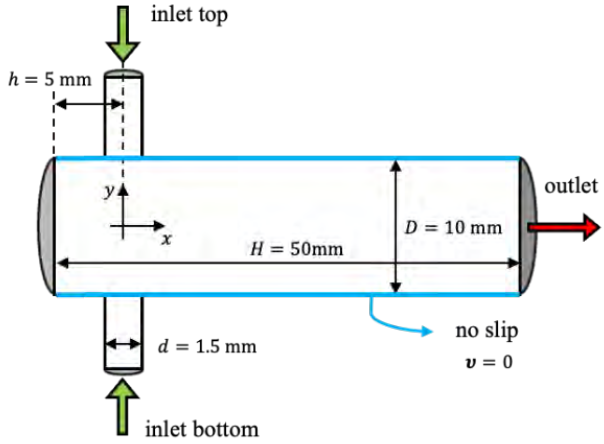

**Figure 1.** 2D CIJs geometry.

The velocities of the liquid stream have two components: (i) a net flow part characterized by a net Reynolds number, and (ii) an oscillatory part described mathematically by a sine wave.

The net Reynolds number is defined at each inlet by

$$\mathrm{Re_{net}} = \frac{\rho d v_{inj}}{\mu} \tag{4}$$

where $\rho$ and $\mu$ are the fluid's density and viscosity, respectively, $d$ is the inlet's width, and $v_{inj}$ is the inlet stream velocity.

The velocity profiles at the inlets are defined by Equation 5 (bottom inlet) and Equation 6 (top inlet)

$$v_{Fluid\,B}(x,t) = \frac{3}{2}\, v_{inj}\left[1 - \frac{4x^2}{d^2}\right]\left[1 + \Psi \sin(2\pi f_o t + \varphi)\right] \tag{5}$$

$$v_{Fluid\,A}(x,t) = \frac{3}{2}\, v_{inj}\left[1 - \frac{4x^2}{d^2}\right]\left[1 + \Psi \sin(2\pi f_o t)\right] \tag{6}$$

where $\Psi = \mathrm{Re_o}/\mathrm{Re_{net}}$ is the amplitude (or velocity ratio), $f_o$ is the oscillatory frequency, and $\varphi$ is the phase-shift between the two inlet streams. In this study, it was considered $\varphi = \pi$, which means that the liquid streams are injected in the confined chamber in out-of-phase.

The average residence time in the reactor can be computed from

$$\tau = \frac{HD}{2v_{inj}d} \quad (7)$$

Simulations employed a pressure-based laminar solver using the Coupled scheme. Discretization utilized Second Order Implicit time integration, Least Squares Cell-Based gradients, PRESTO! for pressure, and Second Order Upwind for momentum.

The CFD mesh considered was validated in previous works [9], consisting of a fine mesh with an element size of $\Delta x$ = 50 $\mu$m.

Although the adopted grid does not resolve the Batchelor scale associated with the high Schmidt number, capturing these micro-scales is unnecessary for this macroscopic study. The mesh has already been validated for hydrodynamics and the resolution of large-scale transport. Furthermore, because this resolution effect is systematic across all simulated cases, the applied metrics remain a strong indicator for comparison of mixing quantification.

The initial solution for the dynamic simulations was a steady-state solution that considered only the net Reynolds number for each tested condition. The reactor was initially filled with fluid A. The simulations ran for 300 000 time-steps, corresponding to 20 times the residence time ($20\tau$), considering a time-step of $\Delta t = 8.3 \times 10^{-6}$ s, with a convergence criterion of $10^{-4}$.

The different conditions tested in the CFD simulations are summarized in Table 1.

**Table 1:** Conditions used for inlet velocity profiles in CFD

| Strategy | $\tau$ (s) | $\mathrm{Re_{net}}$ | $\mathrm{Re_o}$ | $\Psi$ | $f_o$ (Hz) |
|---|---|---|---|---|---|
| No oscillation | 0.25 | 50 | - | - | - |
| | 0.042 | 300 | - | - | - |
| Low amplitude | 0.25 | 50 | 25 | 0.5 | 6 |
| | | | | | 13 |
| | | | | | 80 |
| High amplitude | 0.25 | 50 | 300 | 6 | 6 |
| | | | | | 13 |
| | | | | | 80 |
| Low Reynolds | 0.50 | 25 | 25 | 1 | 6 |

## Mixing of species

Two different approaches were used to quantify mixing and analyse its mechanisms in the CIJs simulations of the binary mixture.

First, the length of the interface between Fluids A and B was computed, which represents the generation of interfacial area in a two-dimensional configuration. The interface can be identified from the simulated flow by extracting an `Iso-Line` corresponding to a fluid's mass fraction of 0.5. The total length of this `Iso-Line`, $s_{interface}$, is then computed.

One of the key characteristics of CIJ reactors is that optimal mixing performance is achieved under chaotic flow conditions, for which the interfacial length grows exponentially along the flow direction [10]. At this regime, mixing can be quantified by the stretching of a material line defining the interface between the two fluids. Consequently, the interface length provides a direct measure of mixing performance: an increase in $s_{interface}$ indicates enhanced stretching and folding, resulting in a larger number of locations where the mass fraction approaches 0.5.

The interfacial area normalized by the inlet's width, $d$, is defined by

$$\alpha = \frac{s_{\mathrm{interface}}}{d} \quad (8)$$

A second metric was computed from the CFD simulations to quantify the species' mixing area. This metric accounts for the fraction of the reactor area in which the fluid's mass fraction lies within a prescribed tolerance of the completely mixed value of 0.5. A tolerance of $\pm$ 20% was adopted, such that regions with mass fraction values between 0.45 and 0.55 are considered mixed. An `Iso-Clip` was applied in CFD-Post to identify these regions, and the mixing area fraction was computed as

$$\beta = \frac{A_{\mathrm{mixed}}}{A_{\mathrm{reactor}}} \quad (9)$$

where the $A_{reactor} = H \times D = 50 \times 10 = 500$ mm$^2$. Together, these metrics provide complementary insights into both mixing performance and the mechanisms underlying it.

The $\alpha$ and $\beta$ values were computed at the last time-step simulated, corresponding to $t = 20\tau$.

# RESULTS AND DISCUSSION

## Non-oscillatory benchmark

Non-oscillatory flow was simulated at Reynolds numbers of Re = 50 and Re = 300, to serve as a benchmark for the oscillatory cases. Figure 2 shows the interface (black line) and mixing area (green) contour map for these two reference cases without oscillation.

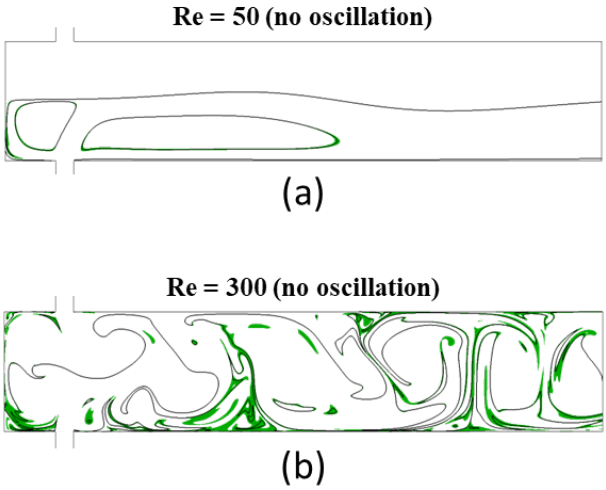

**Figure 2.** Interface line and mixing area contour maps (green) for non-oscillatory flow at: (a) Re = 50 and (b) Re = 300.

The flow regime at Re = 50 is characterized by steady-state flow, in which the two fluids flow parallel to each other in the CIJs chamber [11]. No convective mixing occurs between the two halves of the CIJs chamber, which is shown by the straight interface line formed between the two fluids. The normalized interfacial area achieved a final value of $\alpha$ = 110. This indicates that the interface between fluids A and B increased to 110 times the initial inlet width, $d = 1.5$ mm. The final mixing area is limited to $\beta$ = 2%, meaning that only 2% of the reactor achieved a well-mixed state, defined as having mass fractions between 0.45 and 0.55.

In contrast, at Re = 300, the flow regime is characterized by a self-sustained chaotic flow. The two streams from each jet impact at the center of the chamber, engulfing each other and forming large vortices that propagate throughout the main chamber [11]. The interface line delineates the vortices circular shape, achieving a final value of $\alpha = 312$. The chaotic advection occurring at this regime significantly enhances homogeneity. The well-mixed region expanded to cover a mixing area of $\beta$ = 12 %. These results confirm the strong dependence of the CIJs' mixing performance on the inlet Reynolds number. Operating at Re = 300 produced a threefold increase in interfacial area ($\alpha$) and a sixfold increase in mixing area ($\beta$) compared to the Re = 50 case.

## Oscillatory Flow

Previous work suggests that flow dynamics improve when the oscillation frequency resonates with the frequency of vortex formation [5], [8]. Based on this, a frequency screening was performed at a net Reynolds number of Re = 50 with amplitudes of $\Psi$ = 0.5 and $\Psi$ = 6. The frequencies tested (6 Hz, 13 Hz, and 80 Hz) were specifically chosen to match vortex formation frequencies at Re = 25, 50, and 300. The frequencies of vortex formation ($f_{vortex}$) were computed using the following equation [7], [8]

$$f_{vortex} = \frac{4\mu\,\mathrm{Re}}{\pi\rho\,D^2} \tag{10}$$

Additionally, a lower net Reynolds number, Re = 25, imposing the resonance frequency of 6 Hz and an amplitude $\Psi$ = 1 was also tested.

## Flow dynamics and contour plots

Figures 3 to 5 show the interface (black line) and mixing area (green) for all oscillatory conditions tested.

At low amplitude (Re50_$\Psi$0.5), the hydrodynamic behaviour strongly depends on the frequency used. With an oscillatory Reynolds number of $\mathrm{Re_o}$ = 25, significantly lower than the critical value of $\mathrm{Re_c}$ = 120, the flow regime is dominated by frequency, with amplitude playing a secondary role. This is clearly observed from the interface lines in Figure3b: at $f$ = 13 Hz, with a resonance frequency of Re = 50, there is effective vortex shedding inside the CIJs chamber. Although at $f$ = 6 Hz (Figure 3a), large vortices are formed near the impact point, they tend to lose their shape at the reactor's outlet. At $f$ = 80 Hz (Figure 3c), the oscillation becomes too fast for the low amplitude, resulting in the formation of a waving interface rather than large vortices.

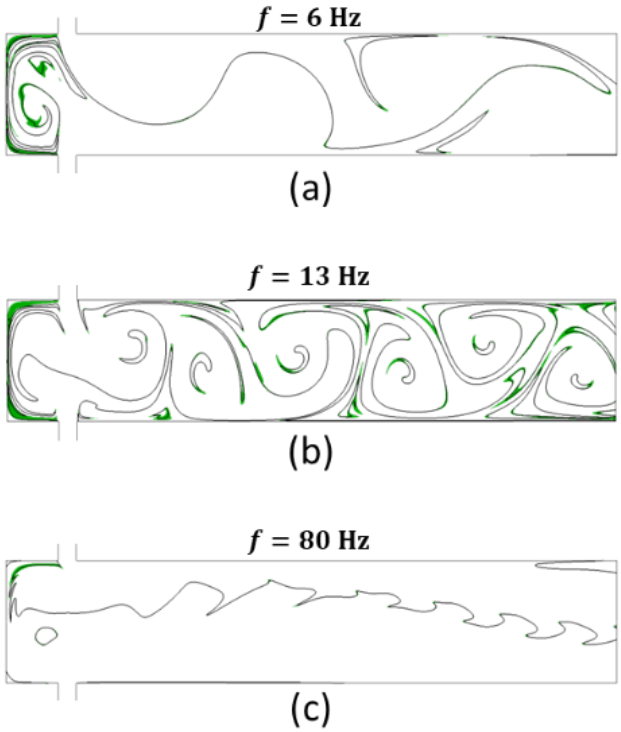

**Figure 3.** Interface line and mixing area contour maps (green) for oscillatory flow with low amplitude ($\Psi = 0.5$) for: (a) $f = 6$ Hz, (b) $f = 13$ Hz and $f = 80$ Hz.

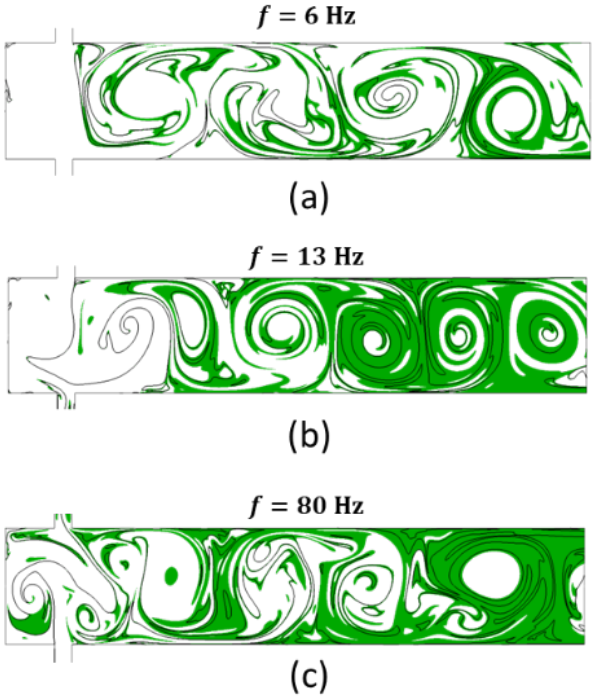

**Figure 4.** Interface line and mixing area contour maps (green) for oscillatory flow with high amplitude ($\Psi = 6$) for: (a) $f = 6$ Hz, (b) $f = 13$ Hz and $f = 80$ Hz.

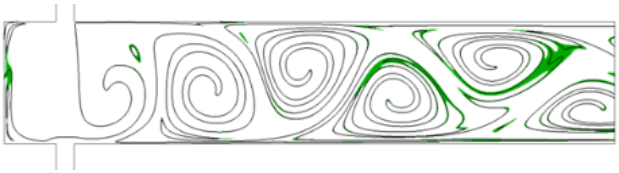

**Figure 5.** Interface line and mixing area contour maps (green) for oscillatory flow with low Reynolds (Re25_Ψ1_$f_o$6Hz).

In contrast, at high amplitude (Re50_Ψ6), the effect of the oscillation is very similar across the three frequencies studied (6 Hz to 80 Hz). Under these conditions, the oscillatory Reynolds achieves $\mathrm{Re_o}$ = 300, which is above the critical Reynolds. At $f_o$ = 6 Hz (Figure 4a), the vortices formed have an elongated, ellipsoidal shape, which becomes more circular and organized when the frequency is increased to $f_o$ = 13 Hz (Figure 4b). The resonance effect leads to the formation of more coherent circular vortices of size $D$ along the entire reactor. In the 80 Hz case (Figure 4c), the vortices degenerate into smaller structures. A progressive increase in the mixing area (green zone) with increasing frequency is observed. A larger mixing area is achieved for $f_o$ = 80 Hz, at high amplitudes.

However, improved control of the mixing scales, defined by the size of the resulting vortex structures, is achieved at low oscillation frequencies, most notably at the resonance frequency of $f_o$ = 13 Hz.

For the low Reynolds condition (Figure 5), a frequency of 6 Hz was applied in the oscillation, matching the frequency of vortex formation at Re = 25. Under these conditions, successive circular vortices develop along the chamber, during which the fluid becomes striated, and lamellar structures are formed. Although the mixing area is smaller than in the high-amplitude cases (Figure 4), the oscillatory Reynolds number is $\mathrm{Re}_o = 25$, which is twelve times lower than the $\mathrm{Re}_o = 300$ used in the high-amplitude case. Consequently, the mixing mechanism is non-chaotic and more closely resembles the striation observed in the low-amplitude cases shown in Figure 3.

In summary, these qualitative observations demonstrate that the mixing phenomenon in oscillatory flow is governed by the interplay between the imposed oscillation frequency and amplitude. The oscillation amplitude acts as the main mechanism for energy injection, providing the necessary momentum to transport vortices from the impact point to the outlet of the chamber.

The energy injection is sufficient to exceed the critical limit when the amplitude considered satisfies $\Psi > \mathrm{Re_c}/\mathrm{Re_{net}}$, a condition that directly drives the oscillatory Reynolds number above the critical value ($\mathrm{Re_o} > \mathrm{Re_c}$). Here, vortex formation becomes widespread and independent of the imposed frequency, even while the net Reynolds number remains below the critical value.

However, when the oscillation frequency is tuned to the natural vortex shedding frequency (defined by $\mathrm{Re_{net}}$), a resonance effect is generated. This resonance allows the instabilities formed at the impingement point to propagate along the length of the reactor, enabling efficient mixing even at low amplitudes.

## Mixing quantification

Figure 6 shows the normalized interfacial area $\alpha$ and mixing area $\beta$ for the low amplitude (orange triangle), high amplitude (black square), and low net Reynolds (yellow circle) conditions.

Both plots, $\alpha$ and $\beta$, confirm a strong frequency dependence in the low-amplitude case (orange). At $f_o$ = 13 Hz, $\alpha$ surpasses the value obtained for the non-oscillatory flow at Re = 300 (green dashed line), while at $f_o$ = 80 Hz, $\alpha$ is below the Re = 50 benchmark (red dashed line). This implies that the combination of low amplitude and high frequency results in a quasi-segregated flow regime, where the two inlet streams barely interact.

Despite the high $\alpha$ at 13 Hz, the mixing area ($\beta$) never exceeds the Re = 300 benchmark. This indicates that low-amplitude oscillatory mixing is driven by laminar stretching and folding rather than the chaotic advection associated with higher Reynolds numbers.

On the other hand, $\alpha$ and $\beta$ are always above the Re = 300 values, when high amplitude is applied (black). This efficient performance indicates that chaotic advection is occurring under these oscillatory conditions.

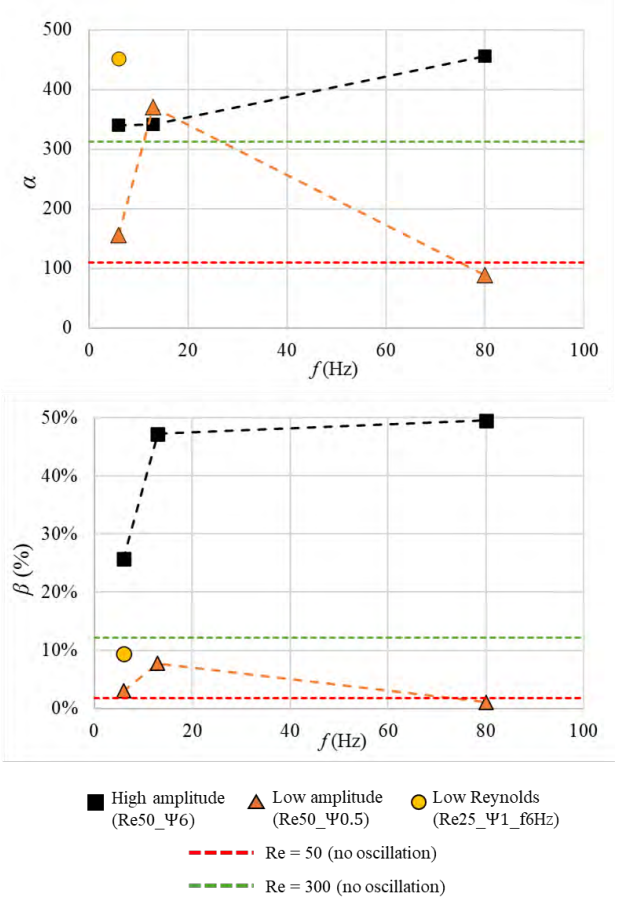

**Figure 6.** Mixing metrics for oscillatory flow in CIJs and non-oscillatory references: (a) normalized interfacial area, and (b) normalized mixing area.

Although the interfacial area values are significantly higher at $f_o$ = 80 Hz, this behavior is not reflected in the normalized mixing area, which shows similar values at $\beta \approx$ 50%, for $f_o$ = 13 Hz and 80 Hz. This means that approximately 50% of the CIJs area is well-mixed, according to the defined criterion.

Finally, for the low net Reynolds condition (yellow), the normalized interfacial area generated is high, and comparable to the high amplitude case with $f_o$ = 80 Hz. This highlights a synergetic effect of frequency and amplitude, since in this case the frequency chosen resonates with both the net Reynolds and the oscillatory Reynolds because $\Psi = 1 \Rightarrow \mathrm{Re_{net}} = \mathrm{Re_o}$. However, as expected, the mixing mechanism is similar to the low amplitude case, laminar stretching and folding, leading to $\beta$ values below the $\mathrm{Re}$ = 300 benchmark.

### Guidelines for oscillatory mixing in CIJs

Based on these results, optimal mixing is obtained by operating at the resonance frequency of the net Reynolds number and using high oscillation amplitudes.

However, the choice of oscillatory conditions strongly depends on the intended application. Operating at low amplitudes, for which the oscillatory Reynolds number $\mathrm{Re_o}$ does not exceed the critical Reynolds threshold, is an advantage for shear-sensitive processes. In this regime, the flow remains at low Reynolds numbers, thereby limiting shear stresses and strong inertial forces. Moreover, at low amplitudes, the flow dynamics are entirely governed by the imposed sinusoidal inlet flow rate, in addition to the associated increase in residence time.

In contrast, high amplitudes are particularly advantageous for processes characterized by low net Reynolds numbers that require fast, efficient mixing, if shear sensitivity is not a limiting factor.

Figure 7 shows a schematic overview of the proposed guidelines for process intensification in oscillatory opposed-jet mixers.

The primary objective of intensifying mixing in these devices is to increase the average residence time without compromising mixing quality. Therefore, the first step is to determine the required average residence time, $\tau$, based on the specific application (e.g., crystallization or cell growth). If Equations 4 and 7 are combined, the net Reynolds number can be computed from the residence time as $\mathrm{Re_{net}} = \frac{\rho H D}{2\mu\tau}$.

It is important to note that this procedure is only valid for $\mathrm{Re_{net}} < \mathrm{Re_c}$. This constraint must therefore be considered when selecting the reactor residence time.

The second step concerns the computation of the oscillatory frequency using Equation 8. Then, the oscillation amplitude should be selected according to the nature of the application: (i) for shear-sensitive processes, a low amplitude is recommended; (ii) for non-shear-sensitive processes, a high amplitude may be employed. The amplitude is classified as low or high depending on whether $\mathrm{Re_o} < \mathrm{Re_c}$ (i.e., $\Psi < \mathrm{Re_c}/\mathrm{Re_{net}}$), or $\mathrm{Re_o} > \mathrm{Re_c}$ (i.e., $\Psi > \mathrm{Re_c}/\mathrm{Re_{net}}$).

Finally, at low oscillation amplitudes, laminar mixing dominates, leading to the formation of an ordered vortex street and predictable fluid striation dictated by the sinusoidal inlet conditions. In contrast, high-amplitude oscillations promote chaotic advection, resulting in a higher degree of fluid homogeneity than in the non-oscillatory chaotic flow regime used as a benchmark.

## CONCLUSIONS

This work represents the first quantification of mixing in oscillatory CIJs using these metrics, interfacial area and mixing area. These metrics were fundamental in defining practical guidelines for process intensification and corroborating the qualitative flow observations. This study also provides new insights into the combined effects of amplitude and frequency and demonstrates effective mixing at net Reynolds numbers way below the critical value.

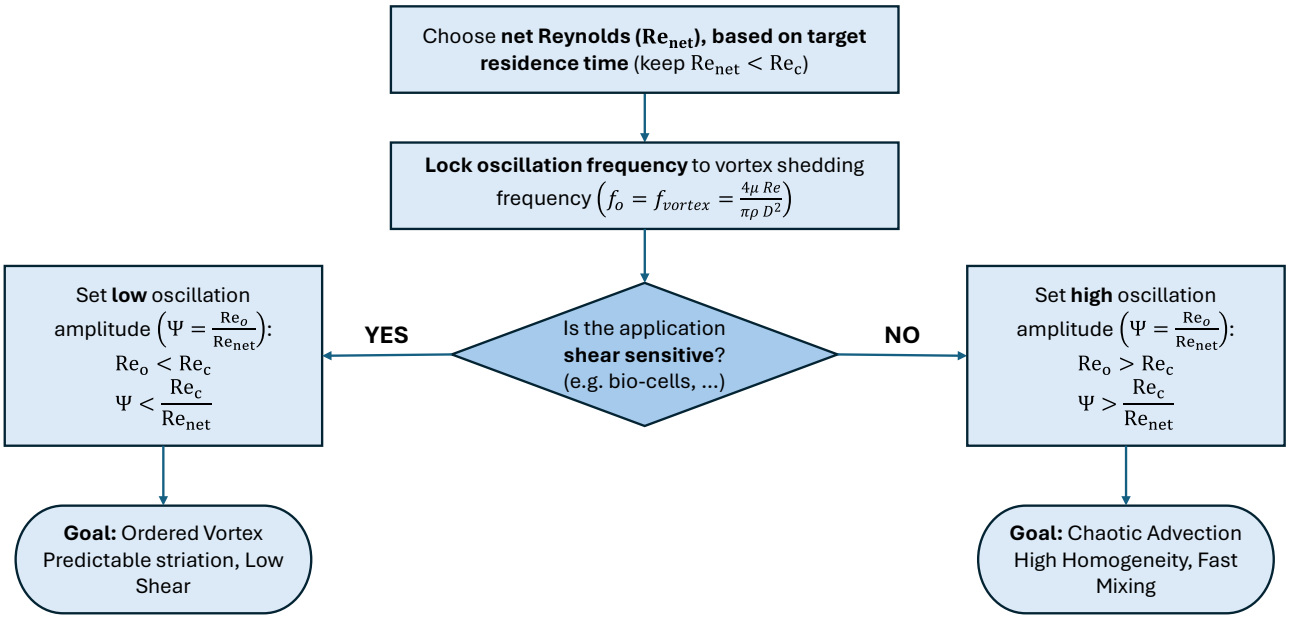

**Figure 7.** Guidelines for mixing in opposed jets mixers

Optimal mixing in oscillatory opposed-jet mixers is achieved at the resonance frequency of the net Reynolds number with high oscillation amplitudes. Nevertheless, the choice of oscillatory conditions depends on the intended application: low amplitudes favor shear-sensitive processes by maintaining laminar mixing, while high amplitudes enhance mixing efficiency and homogeneity in non-shear-sensitive applications.

These findings offer a framework for setting mixing efficiency and dependent product properties from control of the residence time, oscillation frequency, and amplitude based on application requirements, while ensuring operation within the appropriate Reynolds number regime.

## ABSTRACT

Laboratory safety is procedure-dependent: required personal protective equipment (PPE) and permissible actions vary across experiments and across experimental steps, yet most vision-based monitoring remains appearance-driven and often produces generic warnings without reliable procedural context. We propose a multimodal framework for step-aware safety monitoring in laboratory videos. The framework first localizes procedural context through clip-level step prediction and protocol alignment to identify the experiment and current step. Given this context, it retrieves step-specific safety constraints, extracts evidence of step-relevant equipment and interactions using an equipment database, and prompts a video-capable vision-language model (VLM) to generate structured (JSON) monitoring reports supported by retrieved constraints and visual evidence. Experiments on protocol-annotated molecular biology lab videos show that our approach improves the mean score from 0.4352 to 0.6430 and reduces the missing rate from 65.00% to 33.75% relative to a video-only baseline, demonstrating more faithful and step-specific safety judgments.

**Keywords**: Artificial Intelligence, Laboratory Safety Monitoring, Vision-Language Model

## 1. INTRODUCTION

Laboratory research—especially in chemistry and molecular biology—often involves hazardous chemicals, biohazards, pressurized systems, and high-risk instruments. Safe operation therefore requires step-specific compliance: the required personal protective equipment (PPE), permissible actions, and risk controls can change across experiments and even across steps within the same experiment. However, much laboratory safety practice is still evaluated using coarse, self-reported proxies rather than direct, task-level evidence of compliance [1]. Accordingly, modern safety principles emphasize assessing hazards for the specific task and revisiting controls as conditions evolve across steps [2]. This motivates methods that can continuously observe laboratory work and anchor safety judgments in the current procedural context, enabling step-aware checks rather than generic, appearance-driven warnings.

In busy laboratories, day-to-day compliance is difficult to ensure despite training and written protocols. Manual supervision is costly and intermittent, while violations (e.g., missing eye protection, unsafe reagent handling, or incorrect waste practices) may occur abruptly and unpredictably. Computer vision (CV) has therefore been explored for automated inspection—most notably PPE compliance monitoring—because it can, in principle, provide scalable and continuous observation [3, 4]. Yet many existing pipelines remain largely appearance-driven: they often focus on detecting visible PPE items or generic unsafe behaviors, and do not reliably condition judgments on which experiment is being performed and which step is underway. This is a critical limitation because identical motions or object interactions can be compliant in one step but unsafe in another.

A key missing piece is reliable scenario recognition—identifying the ongoing experiment and localizing the current step—so that monitoring can retrieve and apply the correct step-level requirements. Recent procedure-aware video understanding research shows that long activities can be modeled as temporally ordered steps and aligned to protocol text, providing a natural mechanism to connect video observations with procedural context [5-9]. For laboratory environments, ProBio

offers protocol-guided, fine-grained hierarchical annotations for molecular biology experiments, making step-level modeling in realistic lab settings practically feasible [10]. These advances suggest that step localization plus protocol alignment can anchor downstream safety reasoning to the correct procedural context.

In parallel, large vision-language models (VLMs) have advanced toward open-ended multimodal reasoning and instruction following [11, 12], which is attractive for safety monitoring where rules are textual and evidence is visual. However, open-ended generation can produce hallucinated or weakly evidence-supported claims when models lack access to task-specific rules or when evidence is ambiguous [13]. Retrieval-augmented generation (RAG) provides a principled way to inject verifiable external knowledge by conditioning outputs on retrieved documents, improving controllability and evidence linkage [14-16]. For laboratory safety, this suggests combining step-aware retrieval of safety constraints with evidence-supported interpretation of video evidence.

In this work, we propose a procedure-aware laboratory safety monitoring framework that explicitly conditions safety reasoning on the current procedural context. Our key idea is to decouple low-cost procedural localization from higher-cost safety reasoning: we first infer the experiment identity and step context from long, untrimmed videos, and then use step-conditioned retrieval and evidence linkage to produce step-aware, structured safety monitoring reports. Experiments on protocol-annotated molecular biology laboratory videos show that incorporating procedural context substantially improves both faithfulness and coverage compared with a video-only VLM baseline.

Our contributions are threefold:

- **Protocol-aware scenario recognition.** We formulate scenario recognition as clip-level experimental step identification and protocol-based experiment linkage, enabling step-level alignment in long laboratory videos.
- **Evidence-linked multimodal monitoring.** We integrate retrieved step-level constraints and structured equipment evidence with video observations to improve faithfulness and reduce generic warnings and poorly evidence-supported claims.
- **End-to-end video-to-safety framework.** We combine procedure-aware video understanding with VLM-based reasoning to move beyond isolated PPE checks toward context-sensitive, step-specific safety monitoring.

The remainder of this paper is organized as follows. Section 2 presents our methodology, including scenario recognition and the proposed multimodal safety monitoring pipeline. Section 3 reports experimental results and discussion. Finally, Section 4 concludes and outlines limitations and future directions.

## 2. METHODOLOGY

### 2.1 Problem Definition and Framework Overview

We study procedure-aware laboratory safety monitoring, which maps a long laboratory video to step-aware, structured safety issues. As illustrated in **Figure 1**, our framework consists of two stages: (i) scenario recognition, which localizes the procedural context by clip-level experimental step identification and experiment linkage, and (ii) multimodal safety monitoring, which retrieves step-level safety constraints, extracts equipment evidence, and prompts a video-capable VLM to produce structured issues.

Given a laboratory video $V$ that contains a single experiment, we split it into $T$ 1-second clips:

$$V = \{x_t\}_{t=1}^{T} \tag{1}$$

We assume three data sources: a candidate experiment set $E$, where each experiment $e \in E$ has an ordered procedure $P_e = \langle s_1^e, \ldots, s_{L_e}^e \rangle$; a step-level safety analysis report library $R$; and an equipment database $D$ that stores equipment names and visual references.

We predict the experimental step for each clip:

$$\widehat{s_t} = \mathrm{StepID}(x_t) \tag{2}$$

Let $\hat{S} = \langle \widehat{s_1}, \ldots, \widehat{s_T} \rangle$ denote the predicted step sequence. We perform experiment linkage for the full video by aligning $\hat{S}$ with candidate protocols:

$$\hat{e} = \mathrm{argmax}_{e \in E}\ \mathrm{Align}(\hat{S}, P_e) \tag{3}$$

To reduce the number of expensive VLM calls while retaining temporal context, we monitor variable-length segments with a consistent predicted step label. Specifically, we partition the clip sequence into $K$ maximal contiguous segments $\{z_k\}_{k=1}^{K}$, such that all clips within a segment share the same predicted experimental step label:

$$z_k = \{x_t\}_{t=\tau_k}^{\tau_{k+1}-1} \tag{4}$$

$$\widehat{s_t} = \widetilde{s_k} \quad \forall t \in [\tau_k, \tau_{k+1} - 1] \tag{5}$$

Where $\tau_1 = 1, \tau_{K+1} = T + 1$, and $\widetilde{s_k}$ is the shared step label of segment $z_k$. The segment length is therefore adaptive and determined by the duration of the predicted experimental step run, i.e., $W_k = \tau_{k+1} - \tau_k$.

Given $(\hat{e}, \tilde{s}_k)$, we retrieve the corresponding step-level safety analysis report and its equipment list:

$$r_k = \mathrm{Retrieve}(R, \hat{e}, \widetilde{s_k}) \tag{6}$$

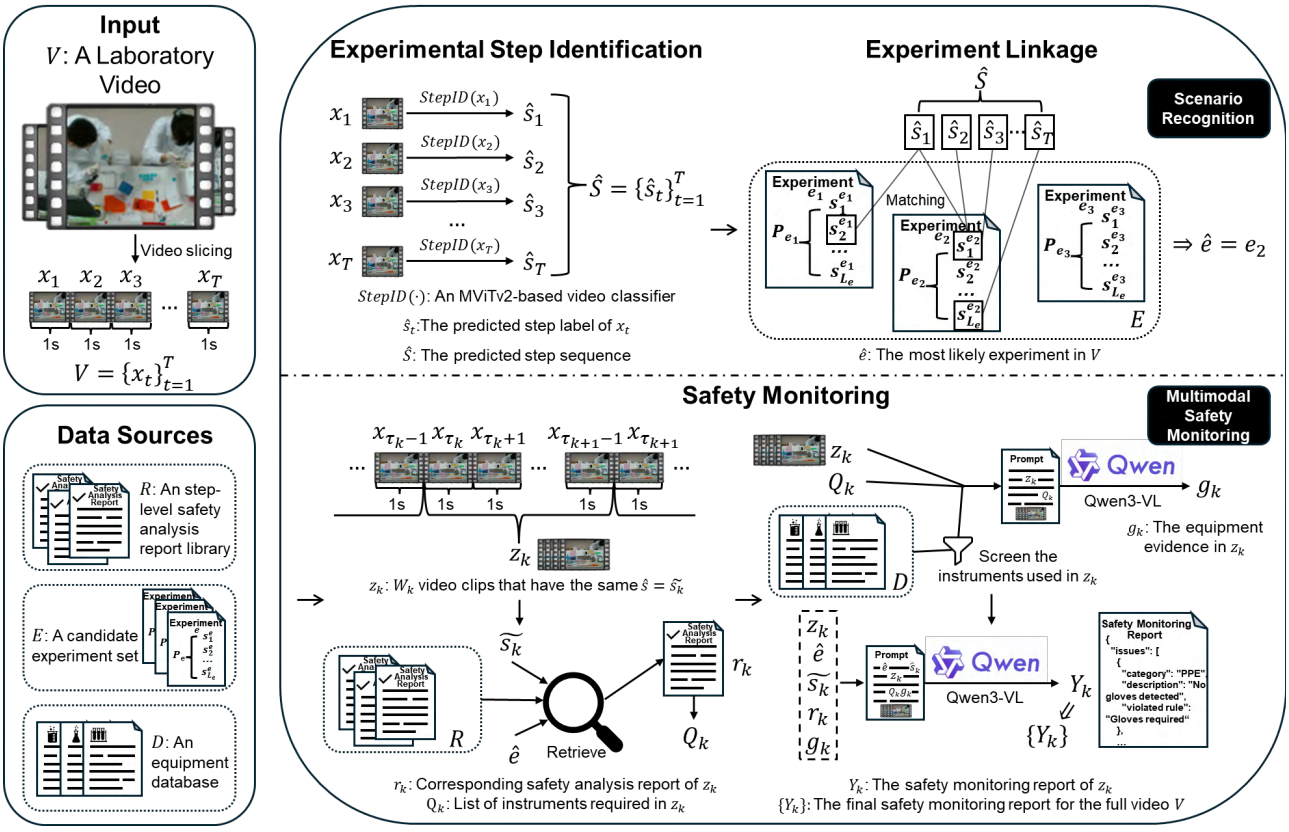

**Figure 1.** Overall framework.

$$Q_k = \text{EquipList}(r_k) \tag{7}$$

We then extract equipment evidence in the segment and prompt the VLM to output structured safety issues:

$$g_k = \text{ExtractEquipEvidence}(z_k, Q_k, D) \tag{8}$$

$$Y_k = \text{Monitor}(z_k, \hat{e}, \widetilde{s_k}, r_k, g_k) \tag{9}$$

Aggregating $\{Y_k\}$ over all segments yields the final safety monitoring report for the full video. This formulation separates dense, low-cost procedural localization from sparser, higher-cost safety reasoning, while ensuring each monitored segment is associated with a single experimental step.

## 2.2 Data Sources

Our framework relies on three complementary data sources to connect procedural text with visual evidence. We first use ProBio molecular biology laboratory recordings with protocol and step annotations to train and evaluate scenario recognition [10]. Each video is split into 1-second clips to produce step predictions over time, and the resulting step sequence is later used for experiment linkage by aligning it to candidate protocols.

Once the experiment and current step are localized, we anchor monitoring in a step-level safety analysis report library that is aligned with experimental procedures. Each entry corresponds to a specific experiment step and summarizes step intent, potential hazards, required PPE, cautions, and forbidden actions. Importantly, the same entry also specifies the equipment involved in that step, providing an explicit, procedure-derived prior for downstream equipment understanding.

To support reliable equipment evidence extraction in video, we further maintain an equipment database that maps equipment names to prompt-ready appearance descriptions and visual references when available. The database covers common laboratory instruments and items such as centrifuges, pipettes, 96-well plates, EP tubes, and frequently handled reagents stored in tubes or vials. Conditioned on the report-provided equipment list, a VLM uses these appearance cues to extract equipment location evidence and human-equipment interaction evidence from the video. This equipment-level evidence is then passed to the final safety monitoring stage to enable more specific and better-supported safety judgments.

## 2.3 Scenario Recognition

To retrieve the correct step-level safety constraints, the system must first localize procedural context in a long, untrimmed video. Scenario recognition provides this context by predicting a step label for each 1-second clip and linking the entire video to an experiment via protocol alignment. These outputs serve as the conditioning signal

for safety monitoring in the next stage.

### 2.3.1 Experimental step identification

Given a laboratory video $V = \{x_t\}_{t=1}^{T}$, we infer the current experimental step using a video classifier. Specifically, the clip-level step prediction is defined in **Eq. (2)**.

We instantiate $StepID(\cdot)$ with an MViTv2-based classifier [17] finetuned on ProBio step annotations [10]. In our implementation, we finetune and evaluate the classifier on step-annotated video segments whose durations range from a few seconds to tens of seconds. Each segment is represented by uniformly sampled frames resized to 224 × 224, and we adopt a fixed train / validation / test split after filtering extremely rare step categories. Step identification is evaluated at the segment level using top-1 accuracy and weighted F1 to account for class imbalance.

Separately, during inference on an untrimmed video $V$, we split it into 1-second clips $\{x_t\}_{t=1}^{T}$ and apply $StepID(x_t)$ to obtain a step sequence $\hat{S} = \langle \hat{s}_1, \ldots, \hat{s}_T \rangle$. For robustness in downstream linkage, we retain the top-3 predicted steps (by posterior probability) in addition to the top-1 label $\hat{s}_t$.

### 2.3.2 Experiment linkage

Given the predicted step sequence $\hat{S} = \langle \hat{s}_1, \ldots, \hat{s}_T \rangle$, we link the long video to the most likely experiment by aligning it to each candidate protocol using **Eq. (3)**.

We implement $Align(\cdot)$ as a soft matching score based on the step posterior from $StepID(\cdot)$. Let $p_t(s)$ be the predicted probability of step $s$ for clip $t$. For each experiment, we accumulate probability mass on protocol steps and average the log score over supported clips:

$$\mathrm{Align}(\hat{S}, P_e) = \frac{1}{|\Omega_e|} \sum_{t \in \Omega_e} log\Big(\sum_{s \in P_e} p_t(s)\Big) \tag{10}$$

$$\Omega_e = \Big\{ t \;\Big|\; \sum_{s \in P_e} p_t(s) > 0 \Big\} \tag{11}$$

In practice, we approximate $p_t(\cdot)$ by retaining only the top-3 predicted steps for each clip and renormalizing their scores to form a sparse distribution, while setting the probabilities of all remaining steps to zero. This reduces noise from low-confidence classes and improves robustness in long, untrimmed videos.

## 2.4 Multimodal Safety Monitoring

After scenario recognition, we perform procedure-aware safety monitoring on multi-second segments $z_k$ that stay within a single predicted step (**Eq. (4)-(5)**). For each segment, we use the linked experiment $\hat{e}$ and step $\widetilde{s_k}$ to retrieve the corresponding step-level safety entry, as defined in **Eq. (6)**, which summarizes step intent, hazards, required PPE, cautions, forbidden actions, and a structured set of monitoring rules (e.g., PPE, required objects, environment constraints, forbidden actions).

To improve evidence support, we extract a step-specific equipment list $Q_k$ from $r_k$ and combine it with the equipment database $D$ to obtain equipment evidence, following **Eq. (7)-(8)**.

We implement $ExtractEquipEvidence(\cdot)$ as a constrained VLM call for evidence extraction rather than safety judgment. Given $z_k$ and the step-specific equipment list $Q_k$ (from $r_k$), we augment each candidate with appearance cues from $D$ and ask the VLM to verify which items are visible and how they are being used. The output $g_k$ is a structured equipment-evidence summary (e.g., present/absent/uncertain with brief visual and interaction cues) that is fed into $Monitor(\cdot)$ to provide stronger evidential support and reduce hallucinations.

Finally, we prompt a video-capable VLM (Qwen3-VL) with (i) the segment $z_k$, (ii) metadata $(\hat{e}, \widetilde{s_k})$, (iii) retrieved constraints $r_k$, and (iv) verified evidence $g_k$, and ask it to produce structured safety issues as defined in **Eq. (9)**. The output is formatted as a list of issues (category, description, violated rule, supporting evidence). Aggregating $\{Y_k\}$ over all segments yields the final video-level safety monitoring report, naturally organized by experimental step.

# 3. RESULTS AND DISCUSSION

## 3.1 Scenario Recognition

Scenario recognition provides the procedural context required for step-level safety retrieval; we therefore evaluate both experimental step identification and protocol-based experiment linkage on long, untrimmed laboratory videos. In this section, we report results for the two components: Experimental step identification and Experiment linkage. Overall, $StepID(\cdot)$ achieves strong step recognition, and protocol alignment yields reliable experiment linkage, especially when videos contain multiple distinct experimental steps.

### 3.1.1 Experimental step identification

We finetune an MViTv2-based classifier (initialized from Kinetics-400 pretraining) to recognize experimental steps in ProBio [10, 17]. After filtering extremely rare step categories (fewer than 5 samples), the final label space contains 77 step classes. The dataset is split into 2, 232 / 1, 116 / 372 samples for training / validation / testing (0.6 / 0.3 / 0.1). As shown in **Table 1**, the best checkpoint is selected by validation accuracy (epoch 36, 0.8952) and achieves 0.8952 top-1 test accuracy and 0.8905 weighted-F1, indicating strong overall performance under class imbalance.

**Figure 2** shows that the confusion matrix is strongly diagonal, with remaining errors concentrated in a few visually similar step pairs. Most frequent confusions occur between near-duplicate primitives with almost identical motions and objects (e.g., different “incubate on ice” targets, and “mix/invert/resuspend” variants), as well as

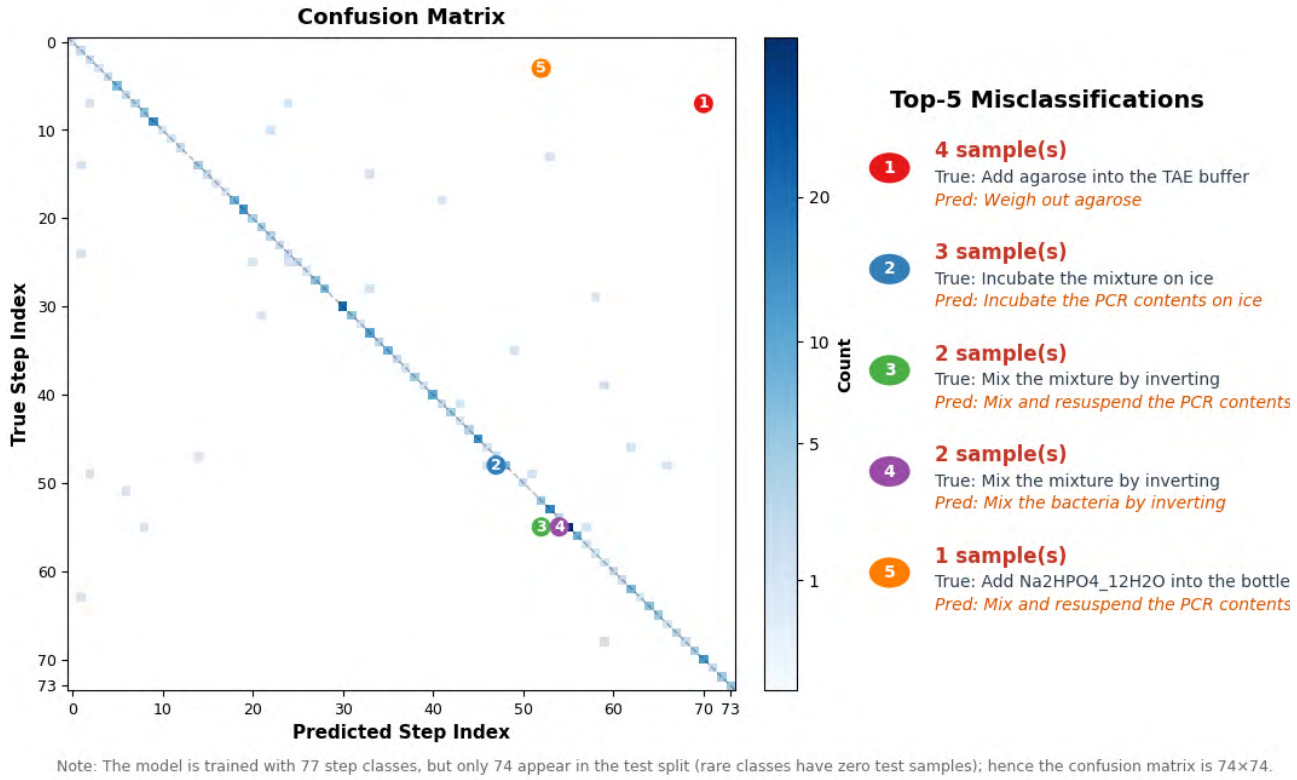

**Figure 2.** Step identification confusion matrix with top misclassifications.

temporally adjacent operations sharing materials (e.g., "weigh agarose" vs. "add agarose into buffer"). The high top-3 test accuracy (0.9731) indicates that misclassifications are typically near-misses rather than gross failures. Accordingly, we propagate the top-3 step hypotheses to the downstream modules to better handle local visual ambiguity during protocol alignment and step-conditioned safety monitoring.

**Table 1:** Experimental step identification performance.

| | Item | Value |
|---|---|---|
| **Model** | Backbone | MViTv2 |
| **Dataset** | Step classes | 77 |
| | Train / Val / Test samples | 2232 / 1116 / 372 |
| **Metrics** | Best Val Acc (epoch) | 0.8952 (36) |
| | Test Top-1 Accuracy | 0.8952 |
| | Test Top-3 Accuracy | 0.9731 |
| | Test Weighted-F1 | 0.8905 |

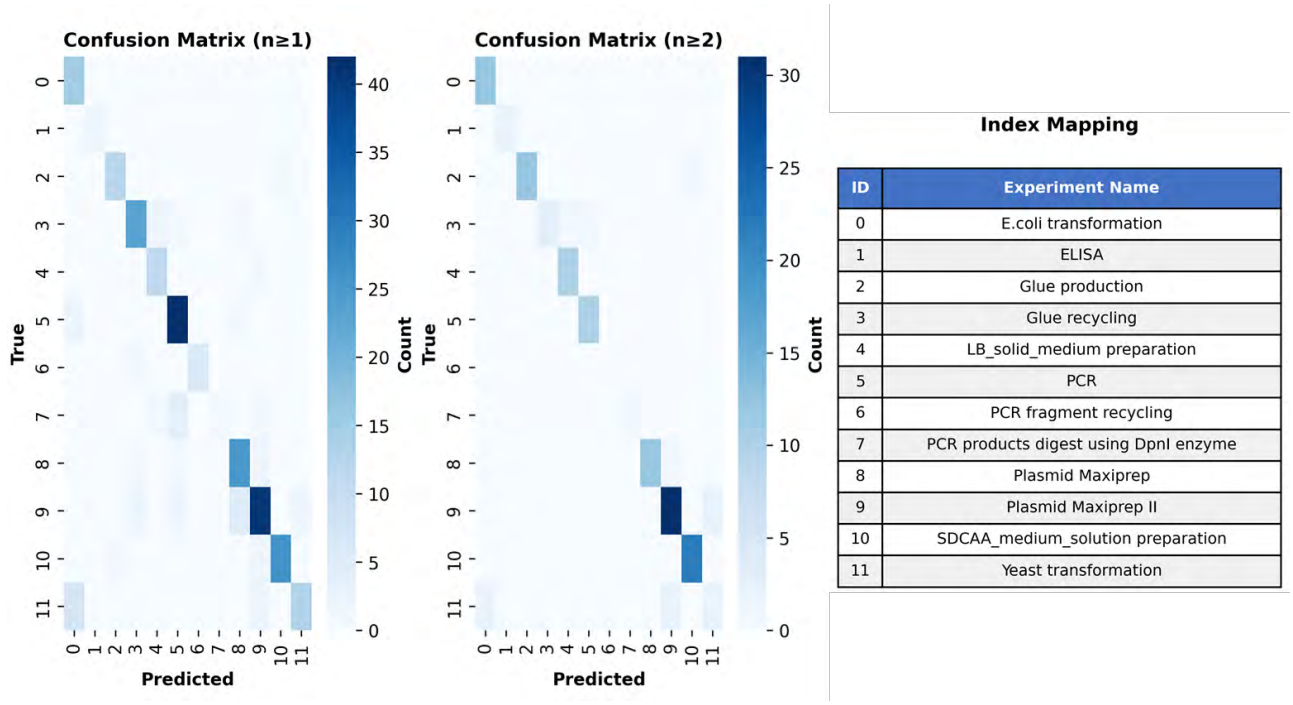
### 3.1.2 Experiment linkage

Using the 1-second step predictions produced by $StepID(\cdot)$, we infer the experiment identity by aligning the predicted step sequence $\hat{S}$ with each candidate protocol $P_e$ via the soft matching score in equation (10)-(11). In practice, we approximate $p_t(\cdot)$ using each clip's top-3 step predictions to improve robustness to locally ambiguous top-1 outputs. We evaluate linkage over 12 experiment classes. Because some videos contain only a few distinct step types (thus providing weak protocol evidence), we report results on subsets defined by the number of unique top-1 step labels $\boldsymbol{n}$ observed across clips. Note that the subset split is computed from the per-clip top-1 labels to count the number of unique predicted steps $\boldsymbol{n}$, whereas the protocol alignment score is still computed by aggregating the top-3 predictions for each clip.

**Table 2.** Experiment linkage performance under different procedural diversity.

| Subset | Videos | Top-1 Acc | Top-3 Acc | Weighted-F1 |
|---|---|---|---|---|
| $n \geq 1$ | 260 | 0.8346 | 0.9654 | 0.8272 |
| $n \geq 2$ | 127 | 0.9213 | 0.9843 | 0.9156 |
| $n \geq 3$ | 14 | 1.0000 | 1.0000 | 1.0000 |

As shown in **Table 2**, linkage accuracy improves monotonically with procedural diversity: when $n$ is small, multiple experiments that share common subroutines can obtain similar alignment scores; when $n$ increases, the



| ID | Experiment Name |
|---|---|
| 0 | E.coli transformation |
| 1 | ELISA |
| 2 | Glue production |
| 3 | Glue recycling |
| 4 | LB_solid_medium preparation |
| 5 | PCR |
| 6 | PCR fragment recycling |
| 7 | PCR products digest using DpnI enzyme |
| 8 | Plasmid Maxiprep |
| 9 | Plasmid Maxiprep II |
| 10 | SDCAA_medium_solution preparation |
| 11 | Yeast transformation |

**Figure 3.** Experiment linkage confusion matrices under different procedural diversity ($n$≥1 vs. $n$≥2).

protocol signature becomes more discriminative and top-1 accuracy rises while top-3 accuracy nearly saturates.

**Figure 3** further illustrates this trend with confusion matrices for $n$≥1 and $n$≥2: the $n$≥2 subset is more diagonal with fewer off-diagonal confusions. The accompanying index mapping links matrix indices to experiment names for inspecting confused pairs.

In practice, ambiguity can often be detected from the margin between the best and second-best alignment scores. When the margin is small, we can defer downstream safety monitoring to a top-k candidate set, consistent with the strong top-3 accuracy of experiment linkage. We leave this ambiguity-aware inference to future work. Further improvements may also come from stronger recognition of protocol-distinctive steps and lightweight temporal smoothing to reduce spurious step switches in $\hat{S}$.

## 3.2 Multimodal Safety Monitoring

After scenario recognition provides the procedural context $(\hat{e}, \widetilde{s_k})$, we perform procedure-aware safety monitoring on each segment $z_k$. The monitoring prompt is constructed by integrating four components: (i) the video segment $z_k$; (ii) experiment and step metadata $(\hat{e}, \widetilde{s_k})$; (iii) the retrieved step-level safety entry $r_k$ (including required PPE, cautions, and forbidden actions); and (iv) structured equipment evidence $g_k$ extracted via a constrained "equipment presence and interaction" call. The final VLM (Qwen3-VL) outputs a strict JSON report with a list of issues (category, description, violated rule, and supporting evidence). We compare against a video-only baseline that prompts the same VLM using only the video segment, without retrieval of step safety entry and without equipment evidence.

### 3.2.1 Quantitative Results

We evaluate $N = 80$ monitored segments. For each monitored segment $z_k$, an expert provides a reference issue set $\mathcal{R}_k = \{I_{k,i}\}_{i=1}^{|\mathcal{R}_k|}$. The model outputs a set of issues $O_k$. The expert aligns model outputs to reference issues at a consistent granularity. For each reference issue $I_{k,i}$, we assign a coverage score $c_{k,i} \in \{1.0,\ 0.5,\ 0.0\}$, where $1.0$ denotes full coverage, $0.5$ partial coverage, and $0.0$ not covered. Any model-reported issue that cannot be aligned to any reference issue is treated as an additional issue. Let $A_k \subseteq O_k$ denote the set of such additional issues. The expert verifies each additional issue against the video and assigns a correctness score $v_{k,j} \in \{1.0,\ 0.5,\ 0.0\}, j = 1, \ldots, |A_k|$, where $1.0$ means verified correct, $0.5$ partially correct/plausible, and $0.0$ incorrect. We compute a single segment score by averaging over reference issues + additional issues:

$$S_k = \frac{\sum_{i=1}^{|\mathcal{R}_k|} c_{k,i} + \sum_{j=1}^{|A_k|} v_{k,j}}{|\mathcal{R}_k| + |A_k|} \tag{12}$$

This penalizes over-generation: adding many incorrect extra issues increases the denominator while contributing little to the numerator. Finally, the **Mean Score** is the average segment score over all monitored

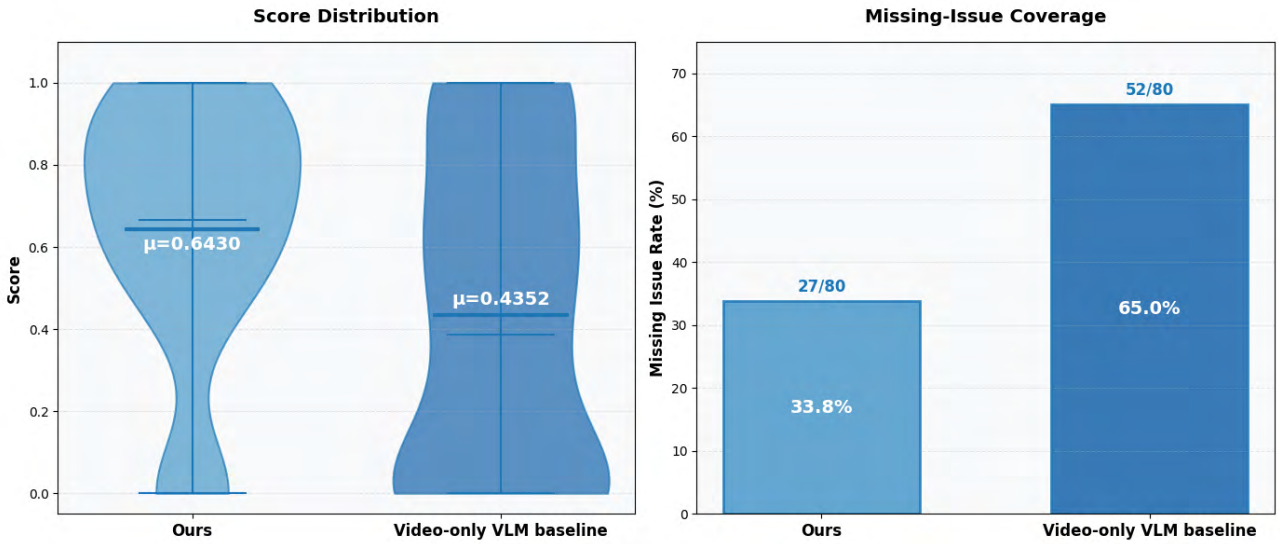


**Figure 4.** Score distribution and missing rate: ours vs. video-only VLM baseline.

segments:

$$MeanScore = \frac{1}{N}\sum_{k=1}^{N} S_k \tag{13}$$

We additionally report a segment-level **Missing Rate**. A segment is marked as missing if the reference issue set $\mathcal{R}_k$ is not fully covered, i.e., there exists at least one reference issue with $c_{k,i} < 1$. Let $m_k \in \{0, 1\}$ denote this missing indicator.

$$m_k = [1 - \min_i c_{k,i}] \tag{14}$$

$$MissingRate = \frac{1}{N}\sum_{k=1}^{N} m_k \tag{15}$$

**Table 3** summarizes the quantitative comparison. Procedure-aware monitoring substantially improves the mean score and reduces the missing rate relative to the video-only baseline.

**Table 3.** Multimodal safety monitoring performance.

| Method | Mean Score ↑ | Missing Rate ↓ |
|---|---|---|
| **Video-only VLM baseline** | 0.4352 | 65.00% |
| **Ours** | 0.6430 | 33.75% |

**Figure 4** visualizes these gains. The left panel shows that our method shifts the per-segment score distribution upward, indicating more valid and better-supported issues across segments. The right panel shows improved coverage: our method reduces missing segments to 27/80 (33.75%), compared with 52/80 (65.0%) for the video-only baseline. Overall, injecting step-specific constraints and providing explicit equipment interaction evidence leads to more evidence-supported, actionable safety judgments while substantially reducing missed violations.

### 3.2.2 Qualitative Analysis

We present a representative case to illustrate how procedural anchoring changes VLM behavior in practice. The example is from Plasmid Maxiprep, step *add_plasmid_into_EP_tube*, using the 0-65s segment of *0802_0_21.mp4*. In this step, the operator pipettes plasmid into EP tubes, and the retrieved step-level safety entry emphasizes PPE compliance and contamination/traceability control (e.g., minimizing open-tube exposure and ensuring proper tube identification before addition).

As shown in **Figure 5**, manual inspection identifies five issues: ① a nearby observer lacks basic PPE (no lab coat or gloves), ② the main operator is missing safety goggles, ③ the EP tubes show no clearly visible labeling before plasmid addition (a traceability risk), ④ EP tubes are left open on the bench during pipetting (increasing contamination/aerosol exposure risk), and ⑤ an experimentalist briefly uses a mobile phone in the laboratory. Our method identifies four issues (①-④). Notably, it goes beyond the most salient PPE cues and also flags step-relevant risks (③-④) that are explicitly emphasized in the retrieved step-level safety entry for this operation, such as contamination control and traceability. In contrast, the video-only VLM baseline identifies three issues, focusing mainly on the more visually obvious PPE-related problems (①-②), and it additionally reports a generic proximity-related concern (standing too close to the work area) that is not part of the manual reference in this example. Both methods miss the phone-use issue ⑤, plausibly because it appears in only a few frames and can be easily overlooked in segment-level monitoring.

| Ours | Manual | Video-only VLM baseline |
|---|---|---|
| The observer (female) is not wearing a lab coat or gloves. | ① An experimentalist is not wearing an experimental suit and is not wearing gloves. | The observer (female) is not wearing a lab coat or gloves, exposing her to potential chemical or biological hazards. |
| The experimenter is not wearing safety goggles. | ② The experimenters are not wearing protective glasses. | The lab technician appears to be wearing gloves but may not be wearing safety goggles, which are essential during pipetting to prevent accidental splashes. |
| Potential cross-contamination risk due to lack of visible labeling on EP tubes before addition of plasmid. | ③ The EP tube does not appear to be marked. | / |
| EP tubes are left open on the bench during pipetting, increasing risk of contamination and aerosol exposure. | ④ During the pipetting process, the EP tube remains open for an extended period of time. | / |
| / | ⑤ An experimentalist takes out a mobile phone in the laboratory. | / |
| / | / | The observer is standing too close to the active work area, potentially causing distraction or contamination risk. |

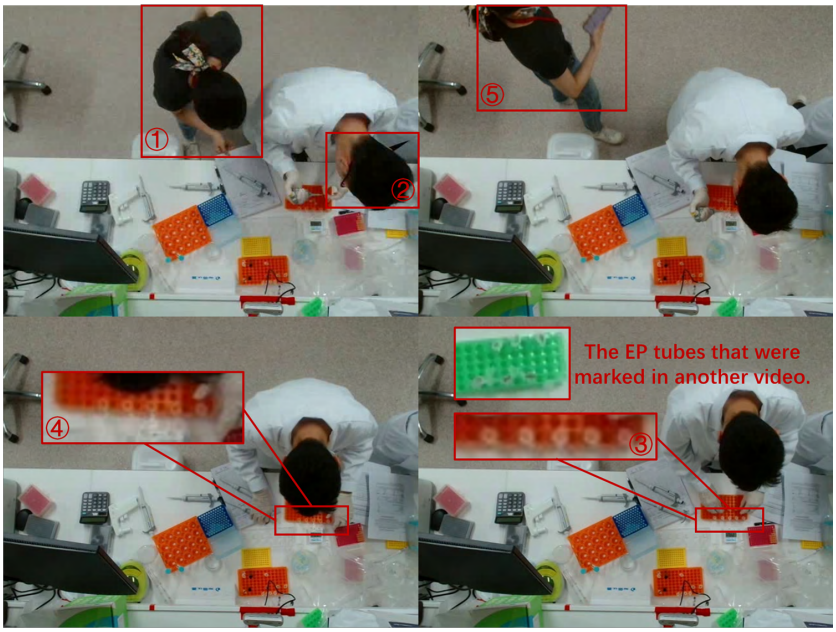

**Figure 5.** Qualitative comparison on plasmid maxiprep. Top: issue lists produced by our method, a manual baseline, and a video-only VLM baseline. Bottom: representative frames with visual evidence; numbered red boxes correspond to the reported issues.

Overall, this case illustrates that procedural anchoring leads to richer and more step-aware safety reports by anchoring generation to step-specific constraints known for the current operation, thereby surfacing context-dependent risks that are less likely to be produced by video-only prompting.

## 4. CONCLUSION

This paper presents a multimodal framework that integrates procedural texts with visual perception for procedure-aware laboratory safety monitoring. Motivated by the experiment- and step-dependent nature of laboratory safety requirements, we decompose the task into two stages: scenario recognition and step-conditioned monitoring. In the first stage, we localize procedural context through clip-level step identification and protocol-based experiment linkage, enabling the system to infer both the most likely experiment and the current step in long, untrimmed laboratory videos. In the second stage, we retrieve the corresponding step-level safety analysis entry, extract a step-specific equipment list, extract equipment presence and interaction evidence via an equipment database, and prompt a video-capable VLM to produce strict JSON-formatted safety issues supported by step-specific constraints and video evidence.

Experiments on a protocol-annotated molecular biology laboratory video dataset show that procedural anchoring improves both faithfulness and coverage. Compared with a video-only VLM baseline, our approach increases the mean score from 0.4352 to 0.6430 and reduces the missing rate from 65.00% to 33.75%. Qualitative results further indicate that conditioning generation on step-level constraints yields richer, more step-aware findings—not only salient PPE violations but also step-dependent risks such as traceability issues and open-tube exposure that the baseline often overlooks.

Despite these gains, several limitations remain. First, fleeting violations that occur in only a few frames can be missed, suggesting the need for finer temporal sensitivity or event-triggered mechanisms. Second, the framework depends on the coverage and quality of the safety report library and the equipment database; incomplete or mismatched entries may reduce retrieval effectiveness and evidence-alignment accuracy. Third, although segment-level processing reduces the number of VLM calls, cost and latency still pose practical challenges for real-world deployment, and privacy considerations must be addressed when monitoring human behavior in laboratory settings.

Future work will focus on robustness and deployment readiness. Promising directions include: (i) stronger temporal modeling and smoothing to reduce spurious step switches and improve detection of fleeting events; (ii) uncertainty-aware retrieval and monitoring that can defer judgment or expand to top-k candidate experiments/steps when linkage margins are small; (iii) scalable approaches to expand and maintain safety-report and equipment knowledge bases, potentially via semi-automated extraction from institutional SOPs and safety documents; and (iv) broader evaluations across more diverse laboratory environments and experiment types.

Overall, our framework provides a practical blueprint for context-sensitive, procedure-aware safety monitoring, moving beyond appearance-driven checks toward step-specific compliance reasoning supported by both text and video evidence.

## ABSTRACT

Mathematical models in process systems engineering (PSE) are widely used to support decision-making in design and operation, but they are mostly limited to deterministic models. For biochemical systems, the biological variability can give rise to stochastic dynamics. This work addresses the question of when to act in such processes, as the stochastic dynamics affect the timing of important events. We consider the case of batch production of malic acid using *Ustilago trichophora*. The goal is to predict when the substrate concentration falls below a predefined threshold. We extend an existing deterministic model of the process to a stochastic differential equation (SDE) formulation by introducing a Monod-like noise term. Simulations of the SDE model reveal a distribution of substrate depletion times and a deviation between the mean of the stochastic trajectory and the deterministic solution due to nonlinear effects. To determine optimal intervention times under uncertainty, we formulate a finite-horizon optimal stopping problem and solve it using the Longstaff–Schwartz algorithm, also known as the Least-Squares Monte Carlo (LSMC). The resulting distribution of optimal stopping times from the LSMC algorithm is shown to closely match the actual first threshold hitting times obtained from *a posteriori* analysis of the stochastic simulations, as confirmed by a two-sample Kolmogorov–Smirnov test. The results demonstrate that optimal stopping provides a framework for decision-making in stochastic biochemical processes, enabling risk-aware operational strategies beyond deterministic optimisation.

**Keywords**: Stochastic differential equations (SDEs), optimal stopping, decision-making under uncertainty

## INTRODUCTION

Biochemical processes play an increasingly important role in the transition toward more sustainable chemical production. By exploiting the metabolic activity of microorganisms, bioprocesses enable the conversion of renewable feedstocks into fuels and platform chemicals that are essential for downstream manufacturing [1]. As these processes move from laboratory to industrial scale, the need for reliable modeling and decision-support tools becomes increasingly critical.

In process systems engineering, mathematical models are routinely used to support design, optimization, and operational decision-making [2]. For biochemical systems, such models are traditionally formulated as ordinary differential equations (ODEs). While such deterministic models are valuable for capturing average system behavior, biological processes are inherently variable due to intracellular heterogeneity, environmental fluctuations, and nonlinear reaction kinetics [3]. As a result, deterministic predictions may fail to adequately represent the range of possible process trajectories, particularly when decisions depend on threshold-based events such as substrate depletion or intervention timing.

Although uncertainty is often addressed in process control frameworks, stochastic effects are rarely incorporated explicitly into optimization and planning problems for biochemical batch processes [2]. Existing studies on biological noise primarily focus on stochastic simulation and analysis [3], while the implications of

stochastic dynamics for decision-making and optimization remain underexplored. In particular, there is a lack of systematic approaches for determining intervention times in stochastic bioprocesses that account for the full distribution of possible system trajectories rather than a single deterministic prediction.

Stochastic decision-making problems have been extensively studied in financial mathematics, where uncertainty is intrinsic to system dynamics [4, 5]. Here, optimal stopping theory provides a framework for determining when to take an action in a stochastic environment, e.g., to maximize an expected reward. The Longstaff–Schwartz algorithm, also known as Least-Squares Monte Carlo (LSMC), enables the solution of optimal stopping problems using simulated trajectories and regression-based approximation of conditional expectations [6].

In this work, we formulate a stochastic model of a biochemical batch reactor using stochastic differential equations (SDEs) and embed this model within an optimal stopping framework. The stochastic formulation explicitly captures process variability through state-dependent noise, while the optimal stopping problem is defined in terms of substrate depletion. The Longstaff–Schwartz algorithm is then applied to learn an optimal intervention time directly from simulated stochastic trajectories.

In this work, we formulate a stochastic model of a batch bioreactor to produce malic acid via *Ustilago trichophora* [7]. We extend an existing ODE model to an SDE formulation to represent the stochastic process. Based on the stochastic model, we analyse an optimal stopping problem using the Longstaff-Schwartz algorithm. The results from the algorithm show that the stochastic system exhibits behaviours that lead to different intervention strategies compared to the deterministic system. The findings of this work highlight the importance of stochastic modelling for decision-making problems.

## STOCHASTIC PROCESS MODEL

This work considers the batch production of the platform chemical malic acid using *U. trichophora* as biomass. For this process, the substrates sucrose, fructose, glucose, and ammonium ($NH_4^+$), as the source of nitrogen, are supplied. During the initial growth phase, sucrose is enzymatically hydrolysed to the monosaccharides glucose and fructose and utilised mainly for biomass formation. As nitrogen becomes depleted, the culture shifts from growth to production. Under these conditions, malic acid is formed as the predominant product. The deterministic ODE model is taken from Maschmeier [7].

$$\frac{d}{dt}\begin{bmatrix} X_a \\ X_i \\ Suc \\ FruGlu \\ N \\ P \end{bmatrix} = \begin{bmatrix} \mu_a \\ \mu_i \\ -q_{split} \\ q_{split} - \frac{\mu_a}{Y_{XS,a}} - \frac{\mu_i}{Y_{XS,i}} - \frac{q_P}{Y_{PS}} \\ -\frac{\mu_a}{Y_{XN}} \\ q_P \end{bmatrix} X_a \tag{1}$$

Here, the specific growth and product formation rates are:

$$\mu_a = \mu_{a,max} \frac{FruGlu}{FruGlu+K_{FG}} \frac{N}{N+K_N} \tag{2}$$

$$\mu_i = \mu_{i,max} \frac{FruGlu}{FruGlu+K_{FG,2}} \frac{K_{IN}}{N+K_{IN}} \left(1 - e^{\frac{X_i/X_a - \phi_X}{\chi_{acc}}}\right) \tag{3}$$

$$q_{split} = q_{split,max} \frac{Suc}{Suc+K_S} \tag{4}$$

$$q_P = q_{P,max} \frac{FruGlu}{FruGlu+K_{PFG}} \frac{K_{IN}}{N+K_{IN}} \frac{K_{IP}}{K_{IP}+\frac{w_N N}{X_a+X_i}} \tag{5}$$

For the definition of the variables in the deterministic model, see Table 1.

**Table 1:** State variables in the model.

| Symbol | Description |
|---|---|
| $X_a$ | Active biomass concentration |
| $X_i$ | Inactive biomass concentration |
| $Suc$ | Sucrose concentration |
| $FruGlu$ | Sum of Fructose and Glucose concentrations |
| $N$ | Nitrogen concentration |
| $P$ | Malic acid concentration |

We extend the deterministic model to describe the stochastic dynamics by adding a differential noise term to the ODE, turning the model equation into an SDE. In general, SDEs have the form

$$dX_t = \mu(X_t)\,dt + \sigma(X_t)\,dB_t, \tag{6}$$

where $\mu(X_t)$ is the drift term, $\sigma(X_t)$ the diffusion term, and $B_t$ the Brownian motion (standard Wiener process) [8]. The deterministic model Eq. 1 serves as the drift term. In the following, we will define the noise term.

In biochemical processes, biomass activities are dependent on the availability of substrates. Therefore, the random fluctuations are modelled to follow the same phenomenon. The biomass activities exhibit minimal fluctuations when the substrate is depleted and reach a saturation point when the substrate is abundant. To capture the substrate dependence, this work proposes modelling the noise term $\sigma_i$ in component *i* using a Monod-like equation. The Monod model is chosen because it relates microbial activities to substrate availability [9]. We note that Eq. 7 does not itself constitute the stochastic noise term. Rather, it defines the substrate-dependent

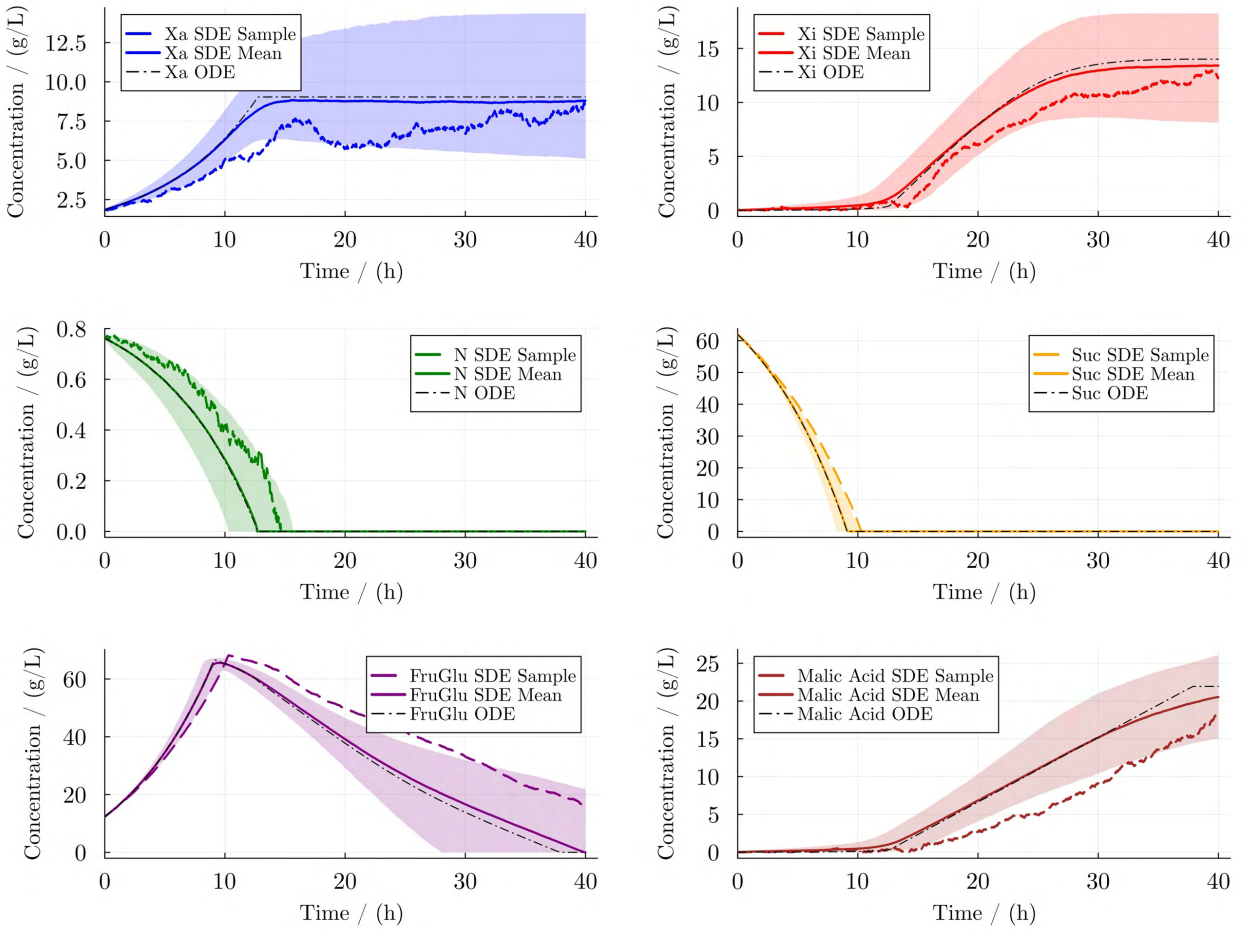

**Figure 1.** Sample stochastic scenario (dashed), deterministic profile (dash-dot), and SDE summary of several simulated scenarios (Set 1) consisting of the averaged concentration profile (solid line) and the 5th to 95th percentile of the scenario distribution (shaded region). From top to bottom, left to right: active biomass, inactive

diffusion coefficient $\sigma_i$, which modulates the stochastic fluctuations in a physically meaningful way. The noise itself enters the SDE through the Wiener increment $dB_t$.

$$\sigma_i = \sigma_{i,max} \frac{S}{K_{\sigma_i}+S} \tag{7}$$

Here, $\sigma_{i,max}$ is the maximum noise intensity and $K_{\sigma_i}$ is the associated half-saturation constant. The variable $S$ represents the substrate, which can be taken up by either $Suc, FruGlu,$ or $N$, depending on which equation the noise term is in. The full noise equation is given in Eq. 8. Each row represents the diffusion coefficient of the corresponding state variable. Thus, together with Equation (1), the mole balance of each species is given as a stochastic differential equation in vector form, with the drift term given by Equation (1) and the diffusion term by Equation (8). The half-saturation constant in the noise term $K_{\sigma_i}$ is set to the value of the reaction kinetics.

This work aims to discuss the optimal stopping algorithm, and no measurements of the variance parameters are available. Instead, the parameter values in the noise terms are selected arbitrarily to be $\sigma_{i,max} = 0.05\ 1/\sqrt{\mathrm{h}}$ for all components. The validation of this proposed noise model and its parameters based on experimental data falls outside the scope of this work and, therefore, can be conducted as a separate study, where other noise models can also be considered.

$$\sigma(X_t) = \begin{bmatrix} \sigma_{X_a,max} \frac{FruGlu}{K_{FG}+FruGlu} \\ \sigma_{X_i,max} \frac{FruGlu}{K_{FG,2}+FruGlu} \\ \sigma_{Suc,max} \frac{Suc}{K_S+Suc} \\ \sigma_{FG,max} \frac{FruGlu}{K_{FG}+FruGlu} \\ \sigma_{N,max} \frac{N}{K_N+N} \\ \sigma_{P,max} \frac{FruGlu}{K_{PFG}+FruGlu} \end{bmatrix} X_a \tag{8}$$

In this work, we simulated two sets of stochastic sample paths, which will be referred to as Sets 1 and 2 in the following. Each set contains five thousand scenarios. Figure 1 shows a sample stochastic scenario from Set 1

and the summary of Set 1 obtained via the Euler-Maruyama scheme. The Euler-Maruyama method is the stochastic extension of Euler's method to numerically solve SDEs [8]. The ensemble summary consists of an averaged profile and the 95% confidence interval at every time point. The initial values are provided in Table 2, and the model parameters in Table 3.

**Table 2:** Initial values

| Variable | Concentration (g/L) |
|---|---|
| $X_a$ | 1.85 |
| $X_i$ | 0 |
| $Suc$ | 61.96 |
| $FruGlu$ | 12.3 |
| $N$ | 0.762 |
| $P$ | 0 |

Figure 1 shows that the average concentration profile of the SDE does not align with the deterministic ODE model (shown in dashed lines) and that the concentrations from the stochastic SDE model are distributed over a range of values. This observation suggests that different results may be obtained when the models are applied to further analysis, such as optimisation or process control. The difference between the stochastic scenarios and the deterministic model can be attributed to the interplay between the model's nonlinearities and the noise. This interplay can be described using Jensen's inequality, which states that the mean of a nonlinear function of a random variable is not equal to the function of the expected value itself [8, 10].

## OPTIMAL STOPPING

Optimal stopping is a problem commonly encountered in derivatives finance, specifically in the context of American Options. An optimal stopping problem poses the question: "When should one exercise an American Option to maximise the payoff?" For more background information on derivatives finance, the reader is referred to [4, 5].

### Least-Squares Monte Carlo

LSMC was originally developed for the valuation of American Options [6]**.** However, the algorithm itself only requires simulated trajectories and a reward function. Thus, the algorithm is model-agnostic, and the method is applicable to problems outside of finance if the underlying model is a stochastic process. This work investigates the application of LSMC to solve an optimal stopping problem, where the underlying stochastic process is the stochastic reactor model.

Consider the SDE given in Eq. 6. The objective of an optimal stopping problem is to determine a time $\tau$ that maximises the expected value of a certain reward function $G_t$. The reward function encodes the performance criterion associated with stopping the process at time $t$.

$$V^* = \sup_{\tau \in [0,T]} \mathbb{E}[G_\tau] \tag{9}$$

**Table 3:** Model parameters

| Symbol | Description | Value | Unit |
|---|---|---|---|
| $\mu_{a,max}$ | Max. growth rate of active biomass | 0.125 | 1/h |
| $\mu_{i,max}$ | Max. growth rate of inactive biomass | 0.125 | 1/h |
| $q_{split,max}$ | Max. split rate | 1.985 | 1/h |
| $q_{P,max}$ | Max. product formation rate | 0.095 | 1/h |
| $K_S$ | Half-saturation constant of sucrose | 0.00321 | g/L |
| $K_{FG}$ | Half-saturation constant of active biomass | 0.147 | g/L |
| $K_{FG,2}$ | Half-saturation constant of inactive biomass | 3.277 | g/L |
| $K_N$ | Half-saturation constant of ammonia | 3.8E-5 | g/L |
| $K_{PFG}$ | Half-saturation constant of product | 0.0175 | g/L |
| $K_{IN}$ | Nitrogen inhibition constant | 0.0147 | g/L |
| $K_{IP}$ | Product inhibition constant | 0.147 | g/L |
| $w_N$ | Internal nitrogen mass fraction | 0.08 | - |
| $\chi_{acc}$ | Acceleration factor | 0.3 | - |
| $\phi_X$ | Max. ratio of inactive to active biomass | 1.56 | - |
| $Y_{XS,a}$ | Yield factor FruGlu to active biomass | 0.531 | - |
| $Y_{XS,i}$ | Yield factor FruGlu to inactive biomass | 0.799 | - |
| $Y_{PS}$ | Yield factor FruGlu to product | 0.508 | - |
| $Y_{XN}$ | Yield factor ammonia to biomass | 9.428 | - |

This formulation constitutes a finite-horizon optimal stopping problem, i.e., the process must be stopped before or at time $T$. Furthermore, the stopping decision must be adapted to the filtration generated by the stochastic process $\{\mathcal{F}_t\}$. In other words, the stopping decision must be made based on the observed process up to time $t$. The first step of the algorithm is to approximate the continuous time horizon on a discrete time grid $\{t_n\}_{n=0}^N$. Here, $G_n$ is the reward from stopping at time $t_n$. The algorithm proceeds with backward induction to determine the optimal stopping time. The backward induction corresponds to the dynamic programming recursion,

Eq. 10, with the terminal condition $S_N = G_N$.

$$S_n = \max\{G_n, \mathbb{E}[S_{n+1}|\mathcal{F}_n]\} \tag{10}$$

At each time step $t_n$, the decision is obtained by comparing the immediate reward $G_n$ with the continuation value, which is defined as the conditional expectation of the future rewards given the current information $\mathbb{E}[S_{n+1}|\mathcal{F}_n]$. The optimal stopping time is thus the earliest time at which stopping is preferable to continuation, i.e., $G_n > \mathbb{E}[S_{n+1}|\mathcal{F}_n]$.

The main component of the LSMC algorithm is to approximate the continuation value, which is essential in the backward induction step. Longstaff and Schwartz proposed approximating the continuation value via simulation and regression [6]. First, a number of sample paths of the stochastic process are generated via Monte Carlo simulation. At each time step, the continuation value is approximated by a regression of realised future rewards onto a set of basis functions $\phi_i$:

$$\mathbb{E}[\, G_{n+1} \mid \mathcal{F}_n \,] \approx \sum_{i=0}^{K} \beta_i \, \phi_i(X_n) \tag{11}$$

Here, the regression coefficients $\beta_i$ are obtained via least-squares minimisation over simulated paths where stopping is admissible. The original method uses the first three weighted Laguerre polynomials. However, numerical tests indicate that the choice of basis polynomials, e.g., unweighted Laguerre, Hermite, Legendre, or Chebyshev, is trivial [6].

## Optimal Stopping of Stochastic Batch Reactor

We now formulate a finite-horizon optimal stopping problem based on the stochastic batch reactor model. The objective is to determine the intervention time at which the substrate concentration approaches a predefined depletion threshold $\epsilon$. We define the reward function to be

$$G_t = -(FruGlu(t) - \epsilon)^2, \tag{12}$$

which is maximised when $FruGlu(t) = \epsilon$. The depletion threshold is defined as 5% of the initial concentration of sucrose, fructose, and glucose $\epsilon = 0.05 \cdot (FruGlu(t_0) + Suc(t_0))$. The optimal stopping problem is given by Eq. 9, and the continuation value approximation is

$$\mathbb{E}[\, G_{n+1} \mid \mathcal{F}_n \,] \approx \sum_{i=0}^{3} \beta_i \, \phi_i(FruGlu(t_n)). \tag{13}$$

In this work, we use the first four unweighted Laguerre polynomials as basis functions:

$$\phi_n(x) = \frac{e^x}{n!}\frac{d^n}{dx^n}(x^n e^{-x}) \text{ for } n \in \{0, 1, 2, 3\}. \tag{14}$$

# RESULTS AND DISCUSSION

The Longstaff-Schwartz algorithm is applied to the formulated optimal stopping problem to obtain a distribution of optimal intervention time. Figure 2 shows the distribution of stopping times obtained from the LSMC algorithm along with a kernel density estimate (KDE) of the distribution. The resulting distribution is unimodal with a mean of 32.91 h and a mode at 33.46 h, which is significantly earlier than the time the deterministic model reaches the depletion threshold, which is at 35.68 h.

To assess whether the LSMC algorithm correctly identifies the relevant stopping point, the distribution of the optimal stopping times is compared to the distribution of the first hitting times. We define the first hitting time as the time when the stochastic path first crosses the depletion threshold, which is obtained from *a posteriori* analysis of the generated stochastic sample paths. The distribution of the first hitting times is shown in Figure 3. We found the average first hitting time to be 32.91 h and the mode of the distribution is 33.47 h, which matches the statistics of the optimal stopping times.

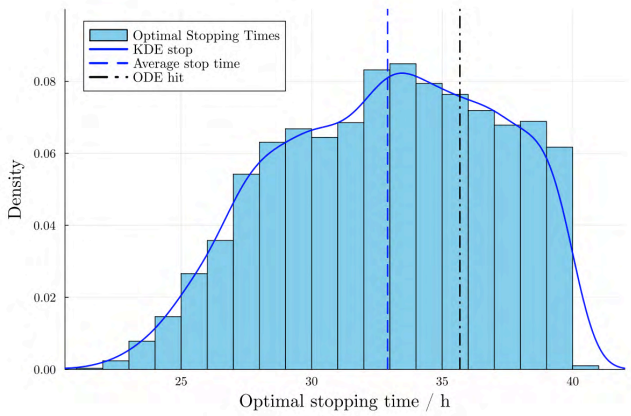

**Figure 2.** Distribution of the optimal stopping times from LSMC and the corresponding KDE.

The similarity between the two distributions is further quantified using a two-sample Kolmogorov-Smirnov test. The test fails to reject the null hypothesis that the two samples are drawn from the same distribution, with a negligible maximum deviation between the empirical cumulative distribution functions obtained from the time distributions, which is shown in Figure 4. This statistical agreement supports the conclusion that the LSMC algorithm yields consistent results.

To assess the robustness of the LSMC method, the analysis was repeated on Simulation Set 2. Set 2 differs in that the generated scenarios now exhibit increased variability and multimodality. However, the average optimal stopping time of 32.96 h differs only slightly from the average time found in the first simulation set (Set 1). This similarity is shown in Figure 5. The Kolmogorov-Smirnov test again indicates statistical similarity between the distributions of the optimal stopping times and the actual first hitting times for Set 2. This finding suggests that the

LSMC algorithm can reliably identify stopping times across different stochastic realisations, considering the nonlinearities of the stochastic process.

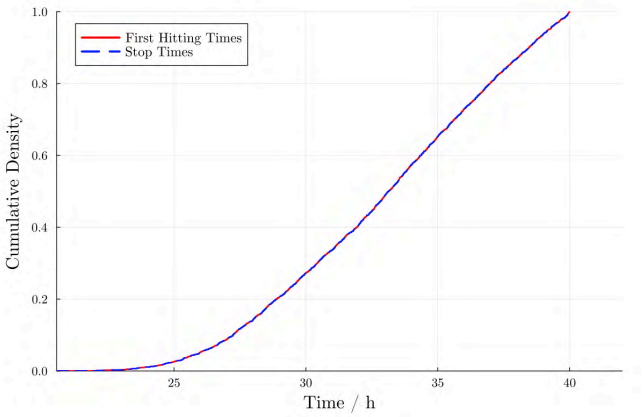

**Figure 4.** Cumulative distribution function (CDF) of the first hitting times and the optimal stopping times

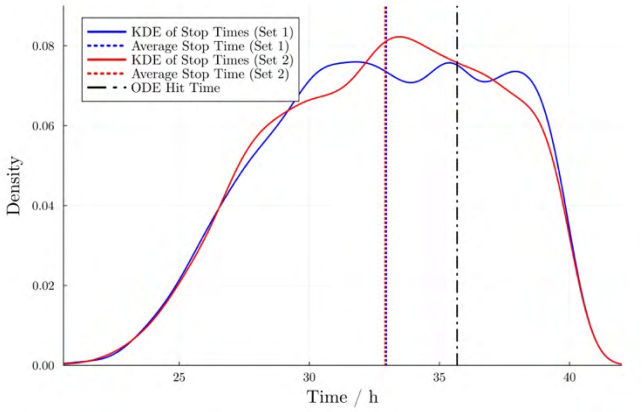

**Figure 5.** Optimal stopping time distributions from Simulation Sets 1 (red) and 2 (blue).

## CONCLUSION

This work demonstrates that stochastic optimal stopping provides a viable and interpretable framework for intervention timing in biochemical batch processes, e.g., by adding new substrate or stopping the production process. By extending a deterministic bioprocess model to a stochastic formulation and coupling it with a regression-based optimal stopping algorithm, the study shows that uncertainty-aware decision-making can lead to systematically earlier interventions than deterministic predictions.

The results demonstrate that stochastic dynamics have a measurable impact on the timing of interventions in biochemical batch processes. Across both simulation sets, the obtained optimal stopping times consistently precede the time the deterministic model reaches the depletion threshold. This shift reflects the influence of stochastic fluctuations on process trajectories and highlights the limitations of deterministic models in decision-making problems under uncertainty.

We have also shown through the close agreement between the optimal stopping time distribution and the distribution of the first-hitting times that the LSMC algorithm accurately captures the stochastic dynamics of the system with little sensitivity across different sets of stochastic realisations. This finding provides empirical validation of the optimal stopping formulation and highlights the broader applicability of methods originating in financial mathematics to process systems engineering problems involving stochastic dynamics. The effectiveness of the optimal stopping framework depends critically on the fidelity of the underlying stochastic model. Future work should therefore prioritise validation and refinement of stochastic models using experimental data, including the exploration of species-specific or correlated stochastic perturbations.

A notable downside of the SDE model in this work is that it allows for physically unrealistic behaviour, e.g., the small increase in nitrogen concentration observed in Figure 1**.** Future work will focus on modelling with alternative stochastic models with an emphasis on physical constraints, specifically mass and energy balances as well as nonequilibrium reactions. Further extensions may include the application of the proposed framework to fed-batch or continuous systems, where real-time measurements enable dynamic intervention strategies. Integrating stochastic optimal stopping with techno-economic analyses also represents a promising direction, allowing intervention decisions to be evaluated directly in terms of operational cost or economic performance. Together, these developments would move stochastic optimal stopping from a methodological concept toward a practical decision-support tool for industrial bioprocess operations.

## ABSTRACT

Digitalization, artificial intelligence, and autonomous experimentation are reshaping chemical process development by enabling data-driven system identification and model-based optimization. Despite these advances, mechanistic models remain a cornerstone for predicting chemical reaction behavior and supporting optimization. However, purely mechanistic models often exhibit limited predictive accuracy when key phenomena affecting kinetics, mass and energy transfer are not fully captured. To address limitations on kinetic modelling, a hybrid modelling framework is proposed in this work that integrates a lumped power-law kinetic model with a Gaussian Process (GP) residual model to predict the reaction rate across the experimental design space while quantifying the uncertainty of the predicted rate. The hybrid model is then coupled with multi-objective Bayesian optimization (MOBO) by employing a weighted-sum approach and an upper confidence bound acquisition function to guide experimental design by simultaneously maximizing reaction rate and minimizing the associated uncertainty on prediction. The approach is tested on a case study related to catalytic methane oxidation in an autonomous microreactor system, where the proposed hybrid model performs comparably to the ground truth model, identifying the same optimal operating conditions when validated against the original experimental data, with an average prediction uncertainty of approximately 2.7%. The results highlight the potential of hybrid modelling and uncertainty-aware optimization for guiding autonomous catalytic experiments in flow systems.

## 1. INTRODUCTION

System identification is reshaping autonomous experimentation by playing a key role in the use of mathematical models and input-output data to describe process behaviour alongside its underlying physics [1]. Identifying mathematical models that adequately represent a process system can be challenging [2], time-consuming and resource-intensive, and constrained by limited budgets, experimental scope, and strict project timelines [3]. Mechanistic models that describe a system can either be (i) simplified (low-fidelity) models, which include only limited mechanistic information and serve as approximate representations of an "assumed" true model or (ii) high-fidelity models that describe the system, capture observable phenomena but require extensive domain knowledge, computational efforts, and detailed satisfactory values of the model parameters.

Mechanistic models (simplified or high-fidelity) can provide valuable physical insights, but their predictive accuracy depends on how completely key phenomena such as kinetics, mass and heat transfer or catalyst deactivation are fully represented in the model [4]. Inaccurate representation of these phenomena in the model leads to a mismatch between the model's prediction and observable reaction rates.

This limitation motivates the development of a systematic hybrid modelling framework [5, 6] that retains the interpretability of mechanistic model while correcting for kinetic mismatch identified from experimental data. The

framework is consistent with recent hybrid Gaussian-process-based multi-objective Bayesian Optimization (MOBO) methods for reaction optimization under uncertainty [7]. This proposed framework offers a new direction in experimental design approaches in that it combines a lumped power-law model (simplified from a Langmuir-Hinshelwood (LH) adsorption mechanism equation) with a GP correction model (which provides data-driven correction for the portions of the reaction behaviour not described by the mechanistic model). The resulting hybrid model was then used in a MOBO procedure to guide optimal experimental design. The overall objective of the design is to identify experimental conditions that: i) maximize reaction rate; and ii) minimize predictive uncertainty in the rate predictions. The framework was demonstrated on a case study related to the catalytic oxidation of methane over $Pd/Al_2O_3$, a system previously investigated in an automated [8] and autonomous microreactor platform [9].

## 2. METHODOLOGY

### 2.1 System Description

The methane oxidation reaction system (see section 2.2 for further details) is modelled as a plug flow reactor (PFR) using differential-algebraic equations (DAEs) describing state variables, inputs, and measured outputs:

$$\mathbf{f}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{u}, \theta, t) = 0 \quad (1) \qquad \mathbf{y} = g(\mathbf{x}, \mathbf{u}, \mathbf{v}) \quad (2)$$

In Eq. (1), and Eq. (2) $\mathbf{x} \in \mathbb{R}^{n_x}, \dot{\mathbf{x}}, \mathbf{u} \in \mathbb{R}^{n_u}, \mathbf{y} \in \mathbb{R}^{n_y}, \theta \in \mathbb{R}^{n_\theta}$, and $t$ denote the vectors for state variables of the system, their time derivative, the manipulated control variables (considered as time-independent inputs in this work), the $N_y$ -dimensional vector of response variables that are measurable, the $N_\theta$ -dimensional vector of model parameters, and time variable, respectively.

### 2.2 Reactor Model for Methane Oxidation

Although the general system formulation in Equation (1) is expressed in terms of time *t*, the PFR model applied here (Eq. 3) is defined with respect to catalyst mass *w* as the independent variable. The physical system had some noisy observation described as $\mathbf{v} \in \mathbb{R}^{n_v}$ which represents random experimental errors in the measured outlet mole fractions where $\mathbb{R}$ denotes the set of real numbers and $n_v$is the dimension of the noise vector.

$$\frac{dx_1}{dw} = \frac{R.u_1}{u_2 P_{avg}} . (-r)\ x_1(0) = u_4$$

$$\frac{dx_2}{dw} = \frac{R.u_1}{u_2 P_{avg}} . (-2r)\ x_2(0) = u_3 . u_4$$

$$\frac{dx_3}{dw} = \frac{R.u_1}{u_2 P_{avg}} . (r) \quad (3)$$

$$\frac{dx_4}{dw} = \frac{R.u_1}{u_2 P_{avg}} . (2r) .$$

In Eq. 3 and following the notation introduced in Eqs. 1-2, the $\mathbf{x}$ vector of state variables $x_1, x_2, x_3$ and $x_4$ represents the mole fractions of methane, oxygen, carbon dioxide and water respectively in the reactor outlet stream, and $R$ $[J\ \mathrm{mol}^{-1}K^{-1}]$ is the universal gas constant, $r$ $[mol\ \mathrm{g}^{-1}min^{-1}]$ represents the reaction rate according to a postulated kinetic model. The set of control variables $\mathbf{u}$ includes the reaction temperature $T[°C]$, flow rate of the feed $[N\mathrm{ml\ min}^{-1}]$, oxygen to methane mole fraction ratio $[\mathrm{mol\ mol}^{-1}]$ and inlet methane mole fraction $[\mathrm{mol\ mol}^{-1}]$ which are respectively denoted as $u_1, u_2, u_3, u_4$ [9]. These controls form the design vector $\boldsymbol{\varphi}$ which is bounded within the experimental design domain as shown in Table 1. The kinetic parameter vector $\theta = [k_0$ and $E_a]$ consists of the pre-exponential factor and activation energy of the Arrhenius rate expression.

**Table 1:** Upper and Lower Bounds on Control Variables Defining the Experimental Design Space

| Control Variables | Range | Units |
|---|---|---|
| Temperature (T) | 250-350 | °C |
| Feed flow rate ($\dot{m}$) | 20-30 | $\mathrm{Nml\ min}^{-1}$ |
| Oxygen to methane mole ratio ($R_{O_2/CH_4}$) | 2-4 | $\mathrm{mol\ mol}^{-1}$ |
| Inlet conc. of methane ($CH_4$) | 0.005-0.025 | $\mathrm{mol\ mol}^{-1}$ |

### 2.3 Hybrid (Power-Law & GP) Framework

A schematic of the proposed hybrid workflow combining the lumped power law model and the GP is shown in Figure 1 and is articulated in the steps below:

1. Lumped Power-law model formulation: a power-law model is a simplified approximation of the LH model for the adsorption of methane. The simplification of the power law model is discussed in Section 2.4.
2. Experiment Execution: the experimental design space (see Table 1) was sampled using Latin Hypercube Sampling (LHS) technique, and physical experiments were conducted in the laboratory generating a set of preliminary experimental data.
3. Parameter Estimation: the lumped power law model parameters were then estimated using the experimental data generated in Step 2. The parameter estimation technique is discussed in Section 2.5
4. Stopping criteria: the process stops when the *t*-test is satisfied for the model parameters or the experimental budget is terminated. If the stopping criteria are not met new experiments from DoE need to be executed.
5. In silico Data Generation from the identified Power-

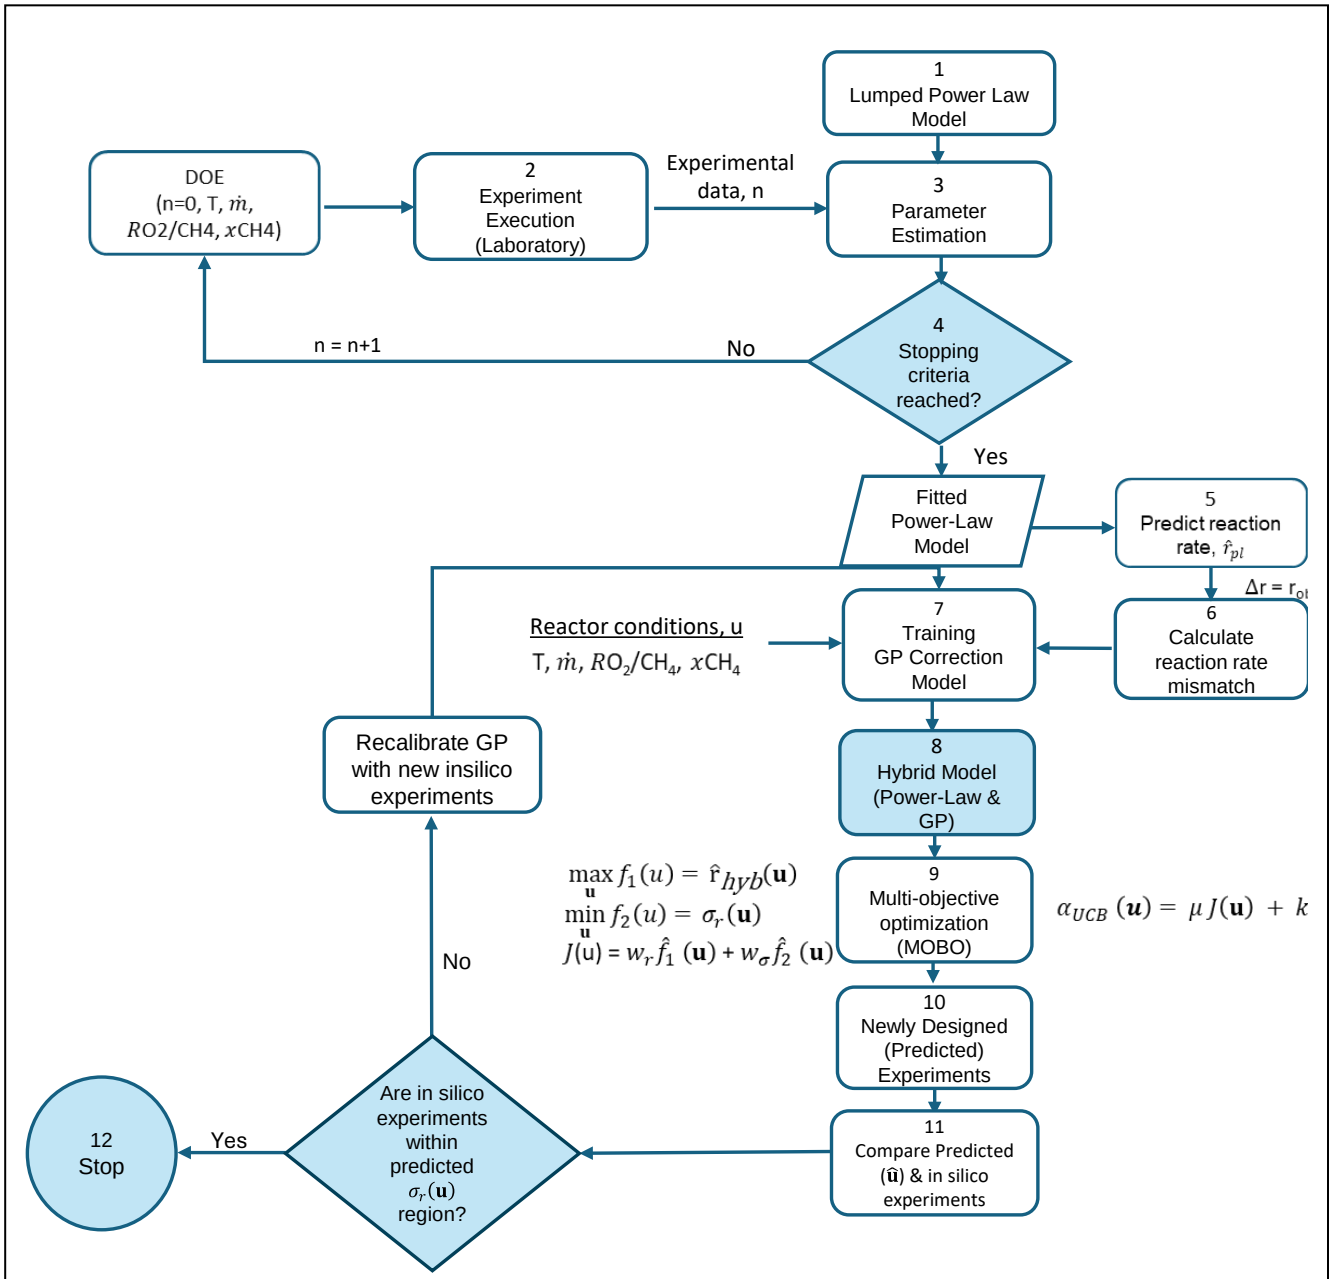

**Figure 1.** Procedural framework for hybrid (Power-Law & GP) model identification and the MOBO workflow.

Law model: after the *t*-test is satisfied, the corresponding parameter values are then applied to the power-law model, and the reactor model is used to simulate the reaction rates at the LHS generated conditions.

6. Calculate Reaction Rate Mismatch: the rates predicted by the model are then compared with the experimentally calculated rates. The rate mismatch calculated across experiments is used to train a GP model at the corresponding input conditions of the experiments.
7. GP Modelling: the GP model is trained using experimental data to learn the relationship between the input conditions and the corresponding system rate mismatch [10]. The dataset includes 30 experiments, with 21 used for training and 9 reserved for testing. The GP is built with a composite kernel function Eq. 4

$$k(\mathbf{u}, \mathbf{u}') = C.RBF(\mathbf{u}, \mathbf{u}') \quad (4)$$

The kernel consists of a constant term ($C$ = 1.0, bounds $10^{-3}$–$10^{3}$) and an *RBF* with length scale 1.0 (bounds $10^{-2}$–$10^{2}$). The hyperparameters of the kernel are optimized during model training by maximizing the log marginal likelihood using gradient-based

optimization technique. In practice, the model automatically tunes its settings during training using a gradient-based method (L-BFGS-B), while respecting predefined bounds.

8. Finalized Hybrid Model: the general form for the reaction rate predicted by the hybrid model is represented in Eq. 5 as:

$$\hat{r}_{\text{hyb}}(\mathbf{u}) = r_{PL}(\mathbf{u};\theta)\exp\left(\boldsymbol{\mu}_{\boldsymbol{GP}}(\mathbf{u})\right) \quad (5)$$

where $r_{PL}(\mathbf{u};\theta)$ is the mechanistic power-law model prediction and $\boldsymbol{\mu}_{\boldsymbol{GP}}(\mathbf{u})$ is the posterior mean of the GP trained on the log-residuals between experimental and mechanistic reaction rates.

9. Multi-objective Bayesian Optimization (MOBO): the multi objectives formulation involve maximizing reaction rate and minimizing uncertainty; this is discussed in details in section 2.6.

10. Newly Designed (Predicted) Experiment: the hybrid-MOBO is then used to design new experiments. These experiments are a pareto sets of optimal experiments (in this case we selected top three (3) experiments) which gives: (i) the predicted reactor conditions ($\hat{\mathbf{u}}$); (ii) the corresponding maximum reaction rate $\hat{r}(\mathbf{u})$; and (iii) minimum uncertainty $\hat{\sigma}_r(\mathbf{u})$ at these conditions.

11. Comparison (Predicted Experiments) With Insilico Experiments: in silico experiments generated using a ground truth model are then compared to the predicted experiments by the hybrid-MOBO framework, where the agreement is evaluated using the GP uncertainty bounds, i.e, the predicted mean (from the ground truth model) reaction rate $\hat{r}_{\text{true}}(\mathbf{u})$ must lie within the confidence region of the hybrid-MOBO. If the insilico results falls inside the uncertainty region, the hybrid model is considered reliable and the workflow terminates. Otherwise, the discrepancy is used to recalibrate the GP correction model, and the optimization-prediction loop is repeated.

12. Stop: the final workflow is terminated when the insilico experimental results consistently fall within the predicted uncertainty bounds of the hybrid-MOBO predictions. i. e., for all newly proposed conditions $\hat{\mathbf{u}}$ from the MOBO step. This indicates that the hybrid power-law-GP model has achieved sufficient predictive accuracy and reliability, and no further model corrections are required.

## 2.4 Lumped Power-Law model formulation

LH mechanism has been proposed as a plausible model by other researchers [8, 11] for catalytic methane oxidation over $Pd/Al_2O_3$. The reaction mechanism occurs with methane and oxygen been adsorbed on the catalyst surface prior to the reaction. The LH rate expression for the system [11] is defined in Eq. 6 as:

$$r_{CH_4} = \frac{k_r K_{CH_4} p_{CH_4} \sqrt{(K_{O_2} p_{O_2})}}{\left(1 + K_{CH_4} p_{CH_4} + \sqrt{(K_{O_2} p_{O_2})}\right)^2} \quad (6)$$

where $k_r$ is the intrinsic surface-reaction rate constant, $K_{CH_4}$ $K_{O_2}$, $p_{CH_4}$ and $p_{O_2}$ are the adsorption equilibrium constants and partial pressures of methane and oxygen respectively. Methane oxidation occurs at low surface coverage with excess oxygen, reflecting adsorption–reaction balance [12, 13].

Under these conditions, $K_{CH_4} p_{CH_4}$ <<< 1, $K_{O_2} p_{O_2}$ >>>1, this approximation reduces the LH rate law to a lumped power-law form defined in Eq. 7 as:

$$r_{CH_4} = k' \; {p_{CH_4}}^a {p_{O_2}}^b \quad (7)$$

where $k'$ is the lumped rate constant and $a$, $b$ are the reaction orders. In the presence of excess oxygen methane adsorption was identified as the rate controlling step [13, 15], thus giving first-order methane and zero-order oxygen dependence; thus, reaction orders were fixed at a = 1 and b = 0, and only $k_o$ and $E_a$ were estimated. The rate constant is expressed in Eq. 8 as:

$$k(T) = exp\left(\log k(T_{ref}) - \frac{E_a}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right) \quad (8)$$

where $k(T)$ is the reaction rate constant at temperature $T$, and $T_{ref}$ = 320 °C and $E_a$ is the activation energy in $kJ/mol$

The resulting lumped power-law model provides a simplified mechanistic representation of the dominant kinetic behaviour derived from the Langmuir–Hinshelwood mechanism under the experimentally relevant conditions. In the proposed hybrid modelling framework, this mechanistic model serves as the baseline predictive model, preserving physically meaningful kinetic parameters such as the activation energy $E_a$and pre-exponential factor $k_0$. The Gaussian Process component is subsequently trained on the residual error between the mechanistic model predictions and the experimental observations, allowing the model to capture discrepancies arising from unmodelled effects such as transport limitations or catalyst heterogeneity while retaining the physical interpretability of the kinetic parameters.

## 2.5 Parameter Estimation

Parameter estimates (indicated as $\hat{\theta}$) were obtained by minimizing the sum of squared residuals between the logarithm of the experimental rates and the logarithm of the model predictions. Assuming an independent Gaussian measurement errors with constant variance ${\sigma^2}_y$, the negative log-likelihood for $N$experiments is expressed in Eq. 9 as:

$$L(\hat{\theta}) = \frac{N}{2}\log(2\pi{\sigma^2}_y) + \frac{1}{2{\sigma^2}_y}\sum_{i=1}^{N}(\log {r_i}^{exp} - \log {r_i}^{model}(\theta))^2 \quad (9)$$

where $r_i^{exp}$ is the observed reaction rate for experiment $i, r_i^{model}(\theta)$ is the power-law model prediction, $N$ is the number of experiments, and $\sigma^2{}_y$ is the constant variance of the measurement noise.

## 2.6 Multi-objective Bayesian Optimization

Bayesian optimization (BO) guided the selection of subsequent experiments using probabilistic predictions from the hybrid power-law–GP model to maximize methane oxidation rate while minimizing uncertainty.

### 2.6.1 Hybrid model predictions

For a given set of experimental conditions $\mathbf{u}$, The hybrid model predicts the methane reaction rate as a posterior distribution $\mathrm{r}(\mathbf{u})$, whose predictive mean is given by $\hat{\mathrm{r}}_{\mathrm{hyb}}(\mathbf{u})$, and expressed in Eq. 10 as:

$$r(\mathbf{u}) \sim N\left(\hat{\mathrm{r}}_{\mathrm{hyb}}(\mathbf{u}), \sigma_r^2(\mathbf{u})\right) \tag{10}$$

where $\sigma_r^2(\mathbf{u})$ is the total prediction uncertainty of the methane reaction rate obtained by combining the GP posterior variance with mechanistic parametric uncertainty propagated through the power-law model under the assumption that all uncertainty contributions are assumed independent, is expressed in Eq. 11 as:

$$\sigma_r(\mathbf{u}) = \sqrt{(\sigma_{mech}^2(\mathbf{u}) + \sigma_{r,GP}^2(\mathbf{u})} \tag{11}$$

where $\sigma_{mech}^2(\mathbf{u})$ is the mechanistic model uncertainty propagated from parameter estimates, and $\sigma_{r,GP}^2(\mathbf{u})$ is the GP-derived predictive uncertainty of methane reaction rate mapped to rate space.

### 2.6.2 Multi objective optimization problem

The resulting multi-objective optimization problem is defined as (i) maximizing the reaction rate of methane; and (ii) minimizing the uncertainty on the predicted rate, and is mathematically formulated in Eq. 12 as:

$$\max_{\mathbf{u}} f_1(u) = \hat{\mathrm{r}}_{\mathrm{hyb}}(\mathbf{u}) \quad \min_{\mathbf{u}} f_2(u) = \sigma_r(\mathbf{u}) \tag{12}$$

To enable practical optimization, the two competing objectives are combined using a weighted sum scalarization shown in Eq 13 as:

$$J(\mathrm{u}) = w_r \hat{f}_1(\mathbf{u}) + w_\sigma \hat{f}_2(\mathbf{u}) \tag{13}$$

where $\hat{f}_1$, and $\hat{f}_2$ denote normalized forms of the rate and uncertainty objectives respectively, and $w_r$ and $w_\sigma$ are non-negative weighting factors satisfying $w_r + w_\sigma = 1$. The weights reflect a user-defined trade-off choice, here prioritizing reaction performance ($w_r$ = 0.6) over uncertainty ($w_\sigma$= 0.4).

### 2.6.3 BO with Upper Confidence Bound (UCB)

The scalarized objective function $J(\mathbf{u})$ defined in Eq. 13 is optimized using BO was implemented in Python using a typed function called “scikit-learn”. The Gaussian process surrogate hyperparameters are learned by maximizing the log marginal likelihood using the L-BFGS-B gradient-based optimizer, while candidate operating conditions are selected by maximizing a UCB acquisition function defined in Eq. 14 (which balances exploitation of conditions with high predicted objective values, and exploration of regions of high uncertainty) over a discretized design space.

$$\alpha_{UCB}(\boldsymbol{u}) = \mu J(\mathbf{u}) + k\sigma J(\mathbf{u}) \tag{14}$$

where $\mu_j(\boldsymbol{u})$ and $\sigma_j(\boldsymbol{u})$ are the predictive mean and standard deviation of the scalarized objective, and $k$ whose value is 0.1 controls the exploration-exploitation trade-off. At each iteration, the next experiment is selected using the expression in Eq. 15:

$$\boldsymbol{u}^* = \underset{\mathbf{u}}{\operatorname{argmax}}\, \alpha_{UCB}(\boldsymbol{u}) \tag{15}$$

UCB was chosen over alternative acquisition function such as Expected Improvement (EI) due to its explicit control of uncertainty-driven exploration, which is particularly suited for autonomous experimentation [14].

Thirty experiments were generated via Latin hypercube sampling, with 21 used for training and 9 for testing. The Mars Van Krevelen (MVK) model reaction rate expression (Eq. 16) was adopted as a “ground truth” model in this study to generate in-silico data in the MOBO step and was experimentally validated in [8] where the authors calibrated the MVK model from flow reactor data.

$$r_{ch4} = \frac{k_1 k_2 P_{CH_4} P_{O_2}}{k_1 P_{O_2} + 2\,k_2 P_{CH_4} + \frac{k_1 k_2}{k_3}(P_{O_2} P_{CH_4})} \tag{16}$$

The MVK model was also adopted to validate the predictive performance of the hybrid model, with the corresponding MVK parameter vector $\theta$ = [5.77, 6.72, 5.87, 9.51, 10.17, 7.98] as reported in [9].

2.7 Reliability Map of the Identified Hybrid Model

To analyse the contribution of each component in the hybrid model, two normalized indices were defined in Eq. 17 based on the hybrid prediction $\hat{y}$, which is taken as the reference (ground truth):

$$\hat{I}_{PL} = \frac{\hat{y}_{PL}}{\hat{y}} \; \hat{I}_{GP} = \frac{\hat{y}_{GP}}{\hat{y}} \tag{17}$$

where $\hat{y}_{PL}$ is the rate prediction from the mechanistic power-law model across the design space, and $\hat{y}_{GP}$ is the GP correction term, and the total hybrid prediction is given by:

$$\hat{y} = \hat{y}_{PL} + \hat{y}_{GP} \tag{18}$$

These indices quantify the relative contribution of each component to the final prediction. Specifically, $\hat{I}_{PL}$ indicates how much of the prediction is explained by the mechanistic model, while $\hat{I}_{GP}$ quantifies the contribution of the data-driven correction.

## 3. RESULTS & DISCUSSION

This section discusses: (i) the predictive performance of the fitted lumped power-law model for observed reaction rate; (ii) the hybrid (power-law–GP) model performance relative to the reference (MVK) model across the design space; and (iii) the reactor operating conditions suggested by the optimization that simultaneously maximize reaction rate and minimize predictive uncertainty.

### 3.1 Performance of the lumped power-law model

As shown in Figure 2, the fitted lumped power-law model captures the general trend of methane oxidation rates across the experimental dataset but exhibits systematic deviations at higher reaction rates.

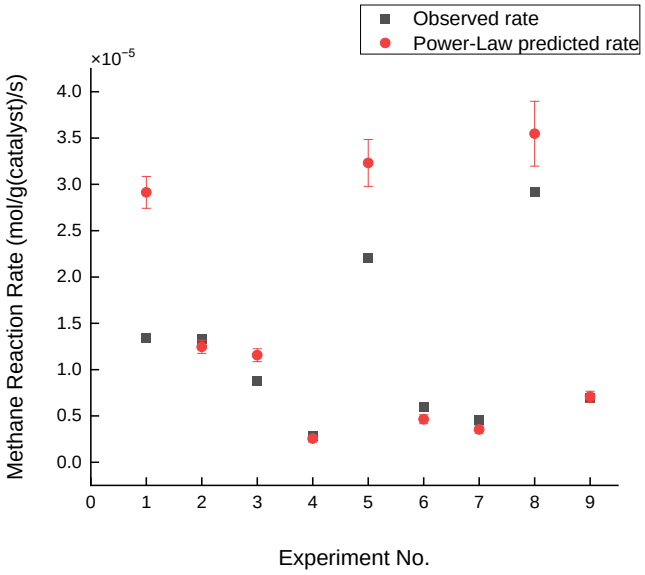

**Figure 2.** Observed methane oxidation reaction rates and Power-Law predictions for the test dataset.

This reflects the breakdown of its simplified kinetic assumptions. Under high reactor rate conditions (i.e. conditions close to the following: $T$ = 350 °C, $\dot{m}$ = 30 $N$ml $min^{-1}$, $RO_2/CH_4$ = 4 mol $mol^{-1}$, $x$CH4 = 0.025 mol $mol^{-1}$) methane oxidation is likely influenced by surface coverage and adsorption saturation effects, which are not captured by the reduced power-law form.

### 3.2 Hybrid Model performance: Power-Law model with Gaussian Process Correction

As shown in Figure 3, the hybrid power-law–GP model reproduces the experimental methane oxidation rates with good accuracy across the test dataset. Predicted rates closely match observed reaction rate values, for example $1.43 \times 10^{-5}$ vs. $1.35 \times 10^{-5}$ mol $g^{-1}$ $s^{-1}$ (Exp.1) and $8.84 \times 10^{-6}$ vs. $8.74 \times 10^{-6}$ mol $g^{-1}$ $s^{-1}$ (Exp.3). At higher temperature (T=342°C, Exp. 8; Table 2), the hybrid model predicts $3.20 \times 10^{-5}$ mol $g^{-1}$ $s^{-1}$, compared to an experimental value of $2.92 \times 10^{-5}$ mol $g^{-1}$ $s^{-1}$, capturing the trend without the systematic overprediction observed for the power-law model. Experiments 1, 3, and 8 were selected as representative cases covering the test dataset operating range (Table 2).

**Table 2**: Selected Experiments from Test Datasets

| Exp | Temp °C | Feed flow $N$ml $min^{-1}$ | $O_2/CH_4$ mol $mol^{-1}$ | $CH_4$ conc mol $mol^{-1}$ |
|---|---|---|---|---|
| 1 | 311 | 23.8 | 3.6 | 0.025 |
| 3 | 290 | 23.5 | 3.2 | 0.021 |
| 8 | 342 | 25.8 | 2.9 | 0.022 |

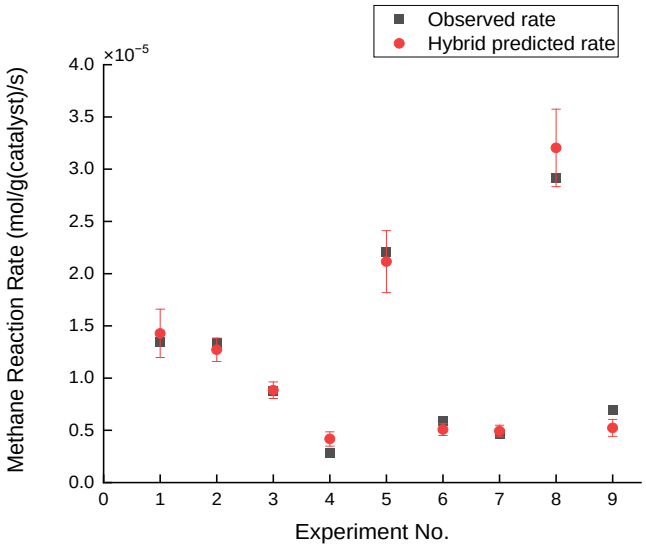

**Figure 3.** Observed methane oxidation reaction rates and hybrid model predictions for the test dataset.

### 3.3 Hybrid Model performance against MVK Prediction

The hybrid model exhibits close agreement with the observed reaction rates across the investigated operating conditions (test dataset), while consistently following the same overall trends as the mechanistic MVK model as observed in Figure 4. At moderate temperature (e.g. Exp. 3, $r_{exp} \approx 8.7 \times 10^{-6}$ mol $g^{-1}$ $s^{-1}$), both the MVK and hybrid predictions are in close agreement with the experimental data, indicating that the MVK formulation adequately captures the dominant reaction pathway in this regime. At higher rates (e.g. Exp. 5 and 8, $r_{exp} \approx (2.2–2.9) \times 10^{-5}$ mol $g^{-1}$ $s^{-1}$), the hybrid model remains well aligned with the measurements, whereas the MVK model slightly underpredicts the observed rates.

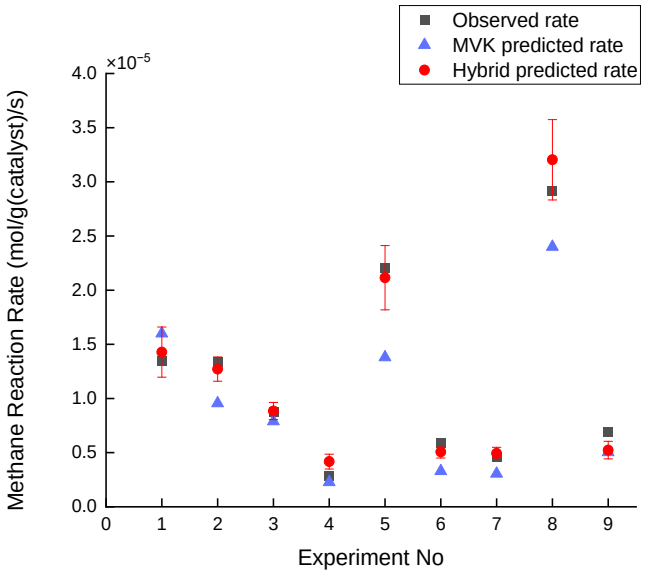

**Figure 4.** Observed MVK, and Hybrid Model Predictions of Methane Oxidation Rates for test dataset.

## 3.4 Experimental Design using Hybrid (Power-law & GP) MOBO

The Hybrid-MOBO strategy identifies the Pareto set which consists of three high-ranking experiments at 350 °C and 30 Nml min$^{-1}$ by balancing predicted reaction rate and uncertainty (Table 3). For $O_2/CH_4$ ratios of 4.0, 3.5, and 3.0, and a constant inlet conc. of methane at 0.005 mol/mol. Hybrid-MOBO predicts reaction rates between 4.71 × 10$^{-5}$ mol g$^{-1}$ s$^{-1}$ and 4.03 × 10$^{-5}$ mol g$^{-1}$ s$^{-1}$.

**Table 3**: Experimental conditions for the top three experimental candidates from MOBO achieving maximum reaction rate and minimum uncertainty.

| Exp | Temp °C | Feed flow $Nml\ min^{-1}$ | $O_2/CH_4$ mol mol$^{-1}$ | $CH_4$ rate (x 10$^{-5}$) mol g$^{-1}$ s$^{-1}$ |
|---|---|---|---|---|
| 1 | 350 | 30 | 4 | 4.7± 2.9 |
| 2 | 350 | 30 | 3.5 | 4.4± 2.6 |
| 3 | 350 | 30 | 3 | 4.0± 2.7 |

When the mechanistic MVK model is evaluated at these same conditions, comparable rates (4.3 × 10$^{-5}$ mol g$^{-1}$ s$^{-1}$ to 4.1 × 10$^{-5}$ mol g$^{-1}$ s$^{-1}$) are obtained, as shown in Figure 5, confirming that the Hybrid-MOBO selected operating conditions align with mechanistic trends while explicitly accounting for predictive uncertainty.

## 3.5 Reliability Maps of the Identified Hybrid Model

Figures 6 and 7 show the spatial distribution of $\hat{I}_{PL}$ and $\hat{I}_{GP}$, respectively, across the design space. The results indicate that the power-law model dominates most of the domain, particularly in the mid-temperature region (~270–320 °C), where $\hat{I}_{PL}$ approaches unity and the GP contribution is minimal. This suggests that the mechanistic model alone adequately captures the system behaviour in this region.

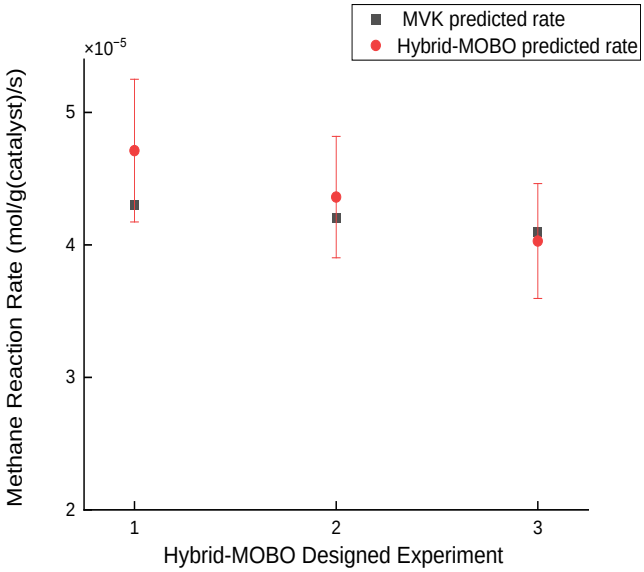

**Figure 5.** Hybrid-MOBO and MVK reaction rate predictions for the top three experiments selected by multi-objective Bayesian optimization.

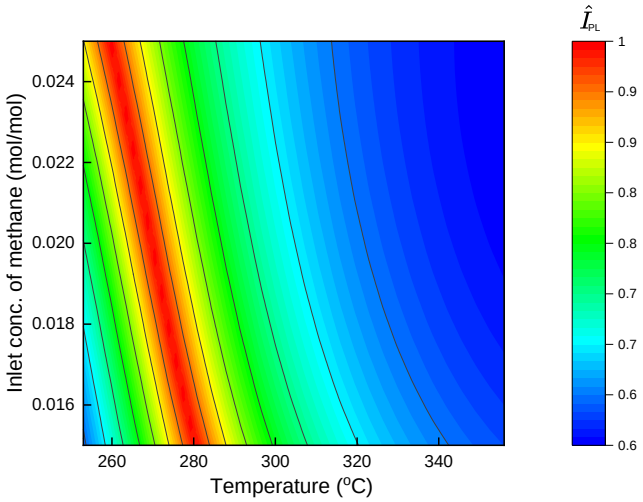

**Figure 6.** Relative local contribution of the mechanistic power-law model across the design space.

At higher temperatures (above ~320 °C), the GP contribution increases (Figure 7), reflecting the need for data-driven corrections to account for deviations from the simplified kinetic model. Overall, these maps highlight regions where the mechanistic model is sufficient and where the GP component becomes essential for accurate predictions.

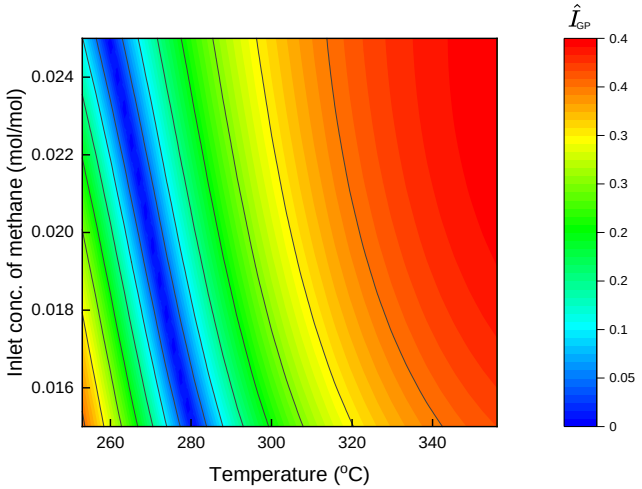

**Figure 7.** Relative local contribution of the GP correction across the design space.

## 4. CONCLUSION

A hybrid modelling MOBO framework was proposed in this work where a lumped power-law kinetic model with a GP residual model was used to improve reaction rate prediction while minimising the uncertainty of the predicted rate. The hybrid MOBO framework identified operating conditions providing high reaction rates with minimum uncertainty. The relative percentage in reaction rate prediction uncertainty of the three top-ranked MOBO designed experiments averaged 2.7% and was in close agreement with the optimal value determined by the MVK ground truth model. Future work will extend the optimization framework to alternative objective functions based on key performance indicators such as cost of operations.

## ACKNOWLEDGEMENTS

The authors are grateful to the Department of Chemical Engineering at University College London (UCL), the Galvanin System Identification Group (GSIG) and the Petroleum Trust Development Fund (PTDF) for their support and sponsorship of the research.

## ABSTRACT

Mathematical models are paramount to the field of reaction engineering, facilitating reaction mechanism discovery, process optimisation, and informed decision making in academic and industrial settings. Nevertheless, the development of precise mechanistic reaction rate models remains experimentally intensive, requires expert knowledge, and is susceptible to the introduction of structural bias. Similarly, the identification of a suitable reaction network that depicts all chemical transformations remains a non-trivial task, with existing techniques often being ill-suited for large and complex systems, hence limiting their scalability and implementation within chemical and biochemical applications. This work develops a two-stage autonomous framework that exploits non-linear sparse optimisation to identify the minimum size global reaction network representative of the system under study, and subsequently proposes and discriminates between interpretable rate equations developed through symbolic regression (SR). The generated SR expressions are constrained to a mechanistically meaningful form through the use of a novel substructure decomposition strategy, largely reducing the search space that must be explored and increasing model interpretability. The framework is evaluated on two case studies; the first, depicting a catalytic methanol synthesis reaction network, and the second, an enzymatic kinetic resolution network. The methodology exhibited high levels of accuracy, scalability, data efficiency, and robust network identification consistent with known physics. Lastly, the potential of augmented intelligence, is discussed as a method to enhance fidelity. Therefore, this work represents a key step toward autonomous process modelling and digitalisation in reaction engineering, providing a foundation for accelerated design and development of chemical and biochemical processes.

**Keywords**: Reaction network identification, Symbolic regression, Interpretable model construction, Model based design of experiments, Augmented intelligence

## INTRODUCTION

The growing global emphasis on sustainability, coupled with mounting economic pressures, has driven the chemical and biochemical industries to seek more efficient processes with reduced waste, energy consumption and raw material costs. A central aspect to enabling the advancement of (bio)chemical processes is the accurate characterisation of reaction mechanisms through reliable modelling techniques, which underpins process optimisation, scale-up, and control.

Conventional modelling practices are typically based on first-principle [1-3] or empirical kinetics such as power-law, Langmuir–Hinshelwood, or Michaelis–Menten expressions [4-7] due to their ability to impart kinetic understanding through their inherent interpretability. However, for complex reaction networks that are less well understood, identifying a representative model is difficult [8], and accounting for all physical phenomena may drive model complexity beyond means which available data can sustain [9]. In order to limit complexity, expert knowledge is exploited, which introduces inductive bias and may reduce model generalisability.

In order to eliminate introducing inductive bias for reaction rate model construction, recent literature has focused on developing efficient automated chemical reaction network (CRN) identification techniques. By formulating the CRN as a mixed-integer linear programming

problem [10, 11], all mass balanced chemical transformations can be found, and rate expressions fitted to experimental data assuming first-order or categorical power law dependencies. However, if the reaction under study is defined by complex kinetics, such as typical within catalytic systems, simple power law dependencies are not sufficient for capturing the underlying physics. Additionally, for reaction networks described by larger numbers of species, the number of mass balanced models that must be evaluated increases exponentially. As a result, existing modelling approaches struggle with accuracy and scalability, particularly for complex systems which are commonplace in industrial and academic research.

To address these challenges, this work introduces a universal data-driven framework for automated reaction network identification and generation of interpretable rate expressions that resemble mechanistic models. We develop a sparse regression based optimisation strategy to effectively identify the underlying reaction network, and evolve an iterative symbolic regression (SR) procedure integrated with model-based design of experiment (MBDoE) to maximise information gain, thus facilitating rapid discovery of mechanistic knowledge for complex reaction systems. The framework was validated on two case studies: (i) a heterogeneous catalytic methanol synthesis reaction network defined by 3 complex Langmuir-Hinshelwood type rate expressions representative of an industrial reaction, and (ii) a larger kinetic resolution network defined by 9 states and 5 net reactions.

We thoroughly investigate how the different attributes of a reaction system influence the identification of characteristic and balanced reaction networks, the achievable model accuracy of any generated SR expressions, and the prospective mechanistic insight that can be gained. Finally, the prospect of augmented intelligence is examined, integrating available domain knowledge with data-driven interpretable modelling in order to accelerate the model development process and promoting the discovery of kinetic knowledge that is physically meaningful. Consequently, this study highlights the potential of the developed framework towards autonomous reaction rate modelling and discovery of process knowledge for chemical and biochemical engineering applications.

## CASE STUDIES

In this work, two in-silico case studies were implemented based on real world scenarios. The first delineates the heterogeneous catalytic hydrogenation of carbon dioxide [12] to methanol and was selected due to the complex nature of the rate expressions that describe the underpinning physics. The second study is an enzyme catalysed kinetic resolution reaction network [13], which was chosen to represent a larger reaction system, hence testing the scalability of the developed framework.

### Methanol Synthesis from $CO_2$ Hydrogenation

The first case study examines the catalytic hydrogenation of $CO_2$ over an unsupported $In_2O_3$ catalyst. Experiments were performed in an isothermal fixed-bed reactor operated under isobaric conditions, with both internal and external mass transfer limitations assumed to be negligible. A comprehensive description of the experimental configuration and the corresponding operating conditions is provided in [12]. Within the operating regions that were investigated, three reversible reactions (R1) were identified that govern the systems behaviour as follows:

$$\begin{aligned} CO_2 + 3H_2 &\rightleftharpoons CH_3OH + H_2O \;\Delta G(25°C) = -0.47kJ\ mol^{-1} \\ CO_2 + H_2 &\rightleftharpoons CO + H_2O \;\; \Delta G(25°C) = 23.4kJ\ mol^{-1} \\ CO_2 + 4H_2 &\rightleftharpoons CH_4 + 2H_2O \;\; \Delta G(25°C) = -130.8kJ\ mol^{-1} \end{aligned} \quad (R1)$$

where the first reaction corresponds to the primary methanol formation pathway via $CO_2$ hydrogenation, and the second and third represent competing side reactions, namely the water–gas shift and methanation reactions. To enable reaction network identification within this in-silico study, four initial experiments were generated, yielding 16 data points across 6 state variables. All generated data was simulated using the literature proposed kinetic model at a temperature of 493 K and weight hourly space velocities (WHSV) ranging from 6000 to 16000 mL $g^{-1}_{cat}$ $h^{-1}$.

The kinetic expressions that describe this system are highly non-linear and have been shown characteristic of standard industrial reactions. Notably, the application of an automated rate model generation technique to a case study high kinetic complexity has not previously been reported in the literature [14]. The ground truth expressions adopted to simulate the in-silico methanol synthesis system are provided in Equation 1.

$$\begin{aligned} r_1 &= \frac{k_1(P_{CO_2}P_{H_2}^3 - \frac{P_{CH_3OH}P_{H_2O}}{K_{eq,1}})}{P_{H_2}^2\left(1 + K_{CO_2}P_{CO_2} + \sqrt{K_{H_2}P_{H_2}}\right)^2} \\ r_2 &= \frac{k_2\left(P_{CO_2}P_{H_2} - \frac{P_{CO}P_{H_2O}}{K_{eq,2}}\right)}{\sqrt{P_{H_2}}\left(1 + K_{CO_2}P_{CO_2} + \sqrt{K_{H_2}P_{H_2}}\right)^2} \\ r_3 &= \frac{k_3\sqrt{P_{CO_2}}\sqrt{P_{H_2}}(1 - \frac{P_{CH_4}P_{H_2O}^2}{K_{eq,3}P_{CO_2}P_{H_2}^4})}{\left(1 + K_{CO_2}P_{CO_2} + \sqrt{K_{H_2}P_{H_2}}\right)^2} \end{aligned} \quad (1)$$

Here, $r_1, r_2$ and $r_3$ refer to the global reaction rates for methanol synthesis via $CO_2$, the water gas shift, and the methanation reaction, respectively. $K_j$ and $P_j$ are the adsorption equilibrium constants and partial pressures of

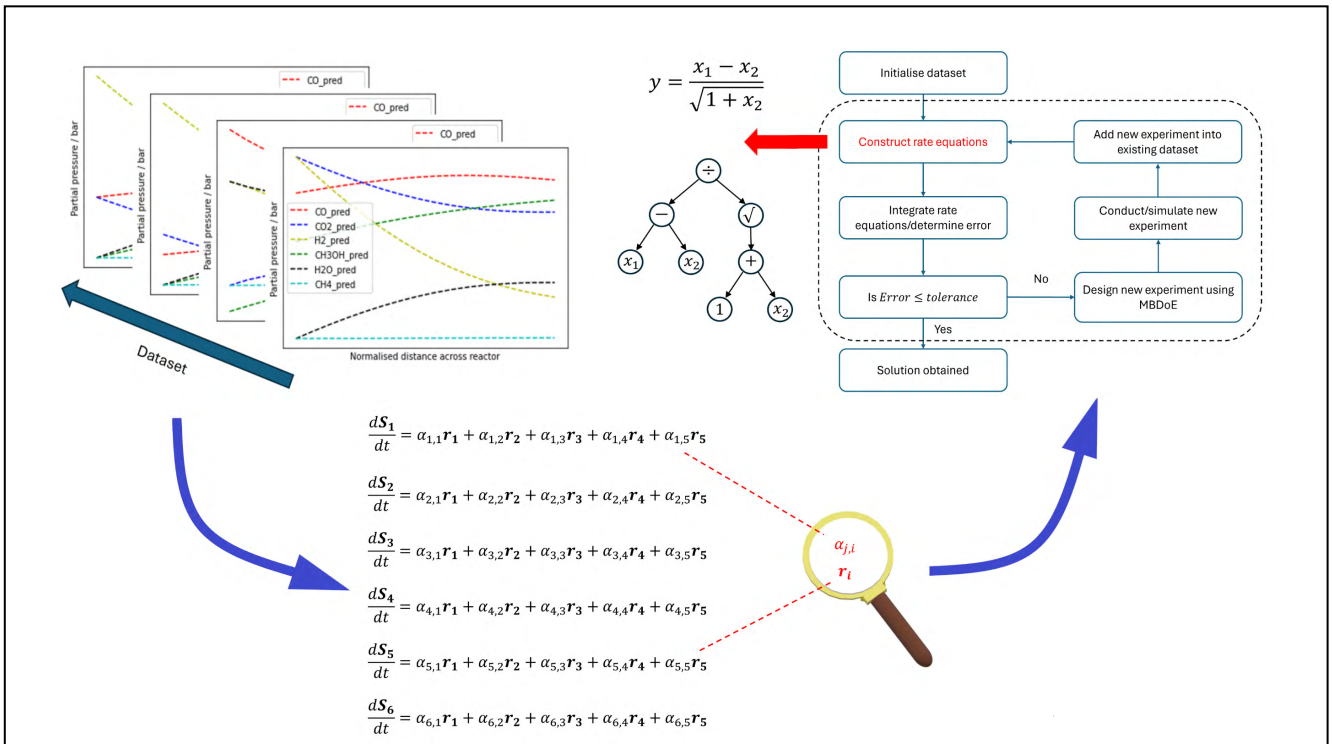

**Figure 1:** Schematic of the general devised framework for the identification of reaction networks and construction of representative rate equations

species $j$. $k_i$ and $K_{eq,i}$ represent the reaction rate constant and equilibrium constant for a given reaction $i$. All values used to parameterise Equation 1 can be found in [12].

## Enzyme Catalysed Kinetic Resolution

The second case study investigates the construction of kinetic models for the kinetic resolution of (+-)-trans-1, 2-cyclohexanediol in supercritical $CO_2$. The reactions take place in a batch reactor containing immobilised enzymes which is operated under isothermal and isobaric conditions. All developed literature rate models were formulated under the assumptions that: all reaction steps are elementary, the concentration of non-activated enzyme remains in excess, the catalysed reactions proceed irreversibly, and perfect mixing is maintained. Additional details surrounding the experimental setup and modelling assumptions can be found in [13].

For the purpose of the present study, the formation of the diacetate product $S_3$ was not ignored in the network to investigate the influence of minor side reactions on the accuracy of the proposed network identification and model generation framework. The reaction network and corresponding rate expressions used as the ground truth for generating the in-silico data are presented in Reaction Network (R2) and Equation (2).

$$VA \rightleftharpoons \mathrm{AE} + AA$$

$$AE + S_1 \rightarrow S_2 \qquad (R2)$$

$$AE + S_2 \rightarrow S_3$$

$$AE + R_1 \rightarrow R_2$$

$$AE + R_2 \rightarrow R_3$$

$$r_1 = k_1 C_{VA} - k_{-1} C_{AE} C_{AA}$$

$$r_2 = k_2 C_{AE} C_{S_1}$$

$$r_3 = k_3 C_{AE} C_{S_2} \qquad (2)$$

$$r_4 = k_4 C_{AE} C_{R_1}$$

$$r_5 = k_5 C_{AE} C_{R_2}$$

Species VA, AE and AA denote vinyl acetate, the active enzyme, and the by-product acetaldehyde, respectively. $S_1$ and $R_1$ correspond to cyclohexanediols, $S_2$ and $R_2$ to the monoacetate products, and $S_3$ and $R_3$ to the diacetate products, with R and S indicating the respective enantiomers. The terms $r_i$ and $k_i$, in Equation 2, are the global reaction rate and rate constant of reaction $i$, while $C_j$ denotes the concentration of species $j$. All parameter values used to parameterise the rate are reported in [13].

Similar to the previous case study, four in-silico experiments were generated, however since there are 9 state variables and 5 overall reactions present, more datapoints are required for network identification; consequently, 21 datapoints were collected per experiment.

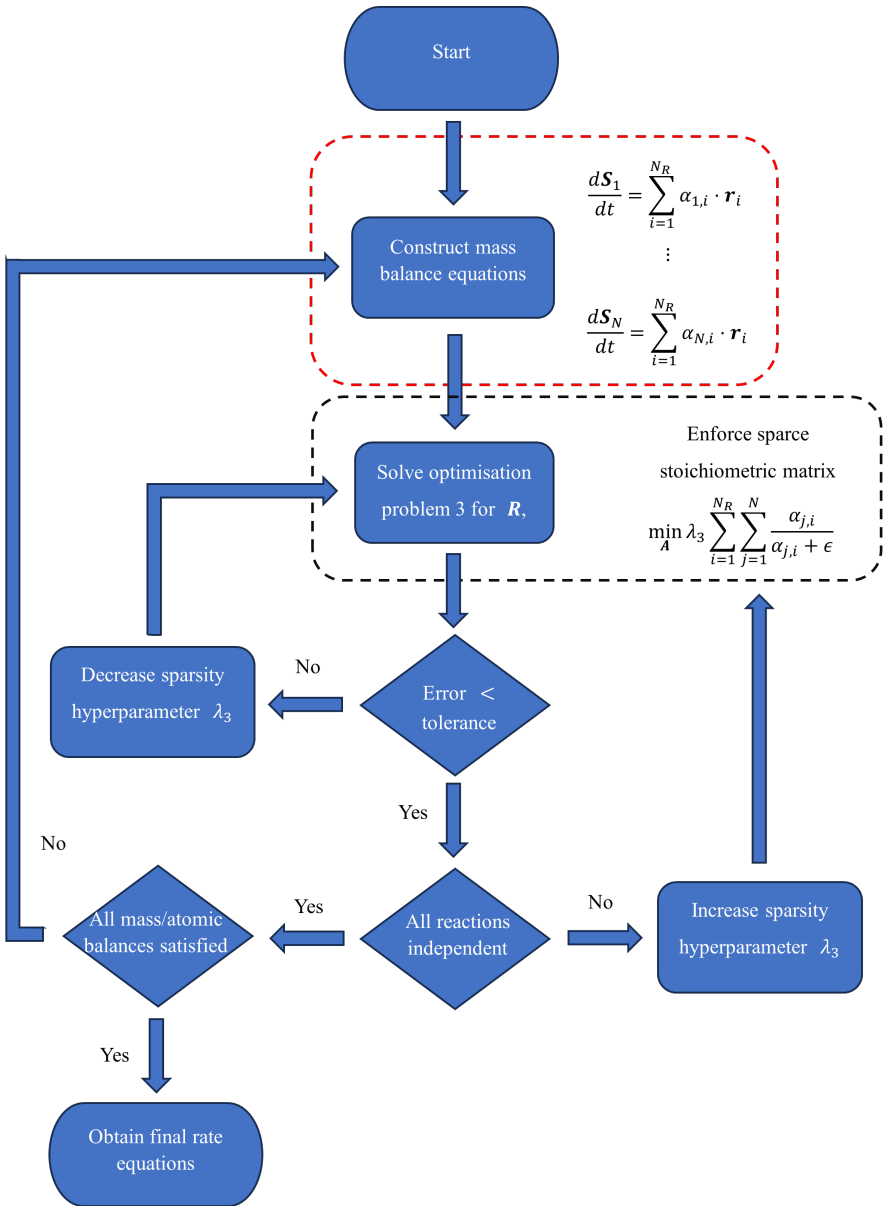

**Figure 2:** Flowchart representation of the methodology for identifying the minimum size global reaction network

## METHODOLOGY

This section will summarise the development of the data-driven framework for autonomous reaction network identification and reaction rate model generation. Explicitly, we will first detail the method used for ascertaining the minimum number of global reactions in addition to the active species involved, then we will show the iterative symbolic regression (SR) strategy employed for the construction and refinement of representative rate equations as illustrated in Figure 1.

To reduce the associated computational expense, we propose a 2-stage workflow. Firstly, we exploit the experimental data to formulate a non-linear programming problem, subject to mass balance constraints, that yields the active reactions, their net reaction rates, $\boldsymbol{R} = \{r_1, r_2 \dots\}$, and the stoichiometric matrix, $\boldsymbol{A}$. Next SR is employed in conjunction with MBDoE in an iterative fashion to produce informative experiments that can facilitate model discrimination and improve the SR results. The iterations continue until no improvements are observed in the pareto front of proposed model candidate or until a threshold criterion is met.

### Reaction Network Identification

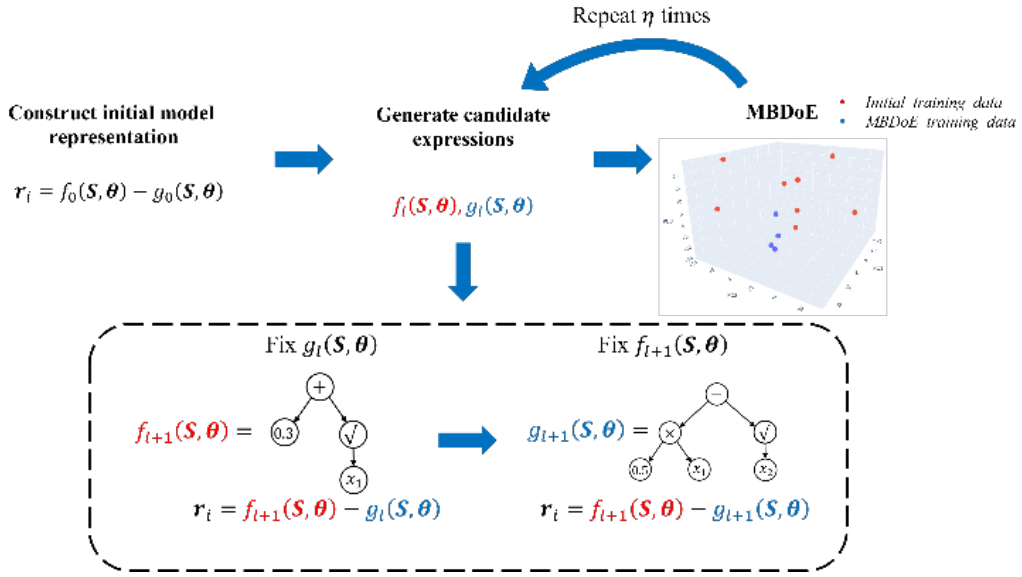

**Figure 3.** Diagram of the iterative approach used for generating rate expressions from data across $\eta$ global iterations of the framework at local iteration, $l$, of tuning the SR model structure.

A chemical reaction network (CRN) is described by a set of characteristics, being the number of global reactions, $N_R$, the total number of active species, $N$, and the stoichiometric matrix, $\boldsymbol{A}$, which captures the interactions among all species within the network. Furthermore, the CRN must adhere to linear algebra constraints such that $N_R \leq N$ [15] because there cannot exist more independent reactions than active species. Using this information, we can derive an optimisation problem of which the solution details the mass balance of species, $\boldsymbol{S}$, as a function of net reactions, $\boldsymbol{R}$, across $N_e$ experiments. The formulation used, given a single experiment $n$, is shown in Equation 3

$$\begin{aligned} \frac{dS_1}{dt} &= \sum_{i=1}^{N_R} \alpha_{1,i} r_i \\ &\vdots \\ \frac{dS_N}{dt} &= \sum_{i=1}^{N_R} \alpha_{N,i} r_i \end{aligned} \tag{3}$$

where $\alpha_{N,i}$ is the stoichiometric coefficient for an individual species within net reaction, $i$.

Once the reaction rates are determined, it is imperative to ensure they are independent from one another. Many techniques exist to this purpose; however, we employ the use of sparse optimisation such that we can simultaneously minimise the total number of identified net reactions and find the corresponding rate profiles. The methodology for this procedure is outlined in Figure 2.

In order to find the minimum dimension reaction network that well fits experimental data, we conduct parameter estimation using the modified least squares objective function in Equation 4, subject to mass and atomic balance constraints.

$$\min_{\boldsymbol{R}(t),\boldsymbol{A}} \sum_{n=1}^{N_e} (\boldsymbol{S}_n - \boldsymbol{S'}_n(\boldsymbol{R}(t),\boldsymbol{A}))^2 + \lambda \sum_{i=1}^{N_R} \sum_{j=1}^{N} \frac{\alpha_{j,i}}{\alpha_{j,i} + \epsilon} \tag{4}$$

Here $\boldsymbol{S}$ and $\boldsymbol{S'}$ are the measured and simulated species concentrations, $\lambda$ is a weighting parameter, and the term $\frac{\alpha_{j,i}}{\alpha_{j,i}+\epsilon}$ encourages model sparsity by minimising the rank of the stoichiometric matrix.

## Reaction Rate Model Generation

Once the global reaction rates have been identified, a SR based approach is implemented to automatically generate representative reaction rate equations directly from the estimated rate profiles, using available literature to exclude terms with no physical relevance to the system under study. We overcome the limitation of SR for complex systems by introducing a substructure decomposition strategy that breaks down the global reaction rates into various terms, each with physical meaning (e.g., forward and reverse reaction rates), as shown in Figure 3.

As illustrated in Figure 3, after the initial candidate expression has been suggested by SR, the individual substructures are then iteratively updated and fine tuned and, once this local iteration completes, MBDoE is performed by maximising the variance between the predictions of the pareto front of SR candidate functions.

# RESULTS AND DISCUSSION

## Results of the Methanol Synthesis Reaction Network

As described in the case study section, the methanol synthesis via $CO_2$ reaction network consists of 6 species in a closed system, meaning that there is a maximum of 5 global reactions. By deriving the problem formulation in Equation 3 and using the sparse optimisation methodology in Figure 2 and Equation 4 to solve the parameter estimation framework, we obtain a set of independent reaction rates, $\boldsymbol{R}$, and stoichiometric coefficients, $\boldsymbol{A}$. Upon rescaling the values of the stoichiometric coefficients to ensure they are all of integer values, we are left with the reduced reaction network in Equation 5

$$\begin{aligned}
\frac{dF_{CO}}{d\tau} &= r_2 \\
\frac{dF_{CO_2}}{d\tau} &= -r_1 - r_2 - r_3 \\
\frac{dF_{H_2}}{d\tau} &= -3r_1 - r_2 - 4r_3 \\
\frac{dF_{CH_3OH}}{d\tau} &= r_1 \\
\frac{dF_{H_2O}}{d\tau} &= r_1 + r_2 + 2r_3 \\
\frac{dF_{CH_4}}{d\tau} &= r_3
\end{aligned} \tag{5}$$

where $F_j$ is the molar flow rate of species $j$ and $\tau$ is the residence time.

When equated to the ground truth in reaction network R1, it can be seen that they are identical. The use of mass and atomic balance constraints allowed for side reactions with minimal influence to be discovered, as is true of the Sabatier reaction, $r_3$, which holds reaction rates 10-100 times less that of $r_1$ and $r_2$.

With the establishment of a valid reaction network, the second stage of the workflow can proceed, enabling the creation of reaction rate models from data. As symbolic regression leverages genetic algorithms to design candidate expressions, it is necessary to introduce approaches to reduce the search space that must be explored to improve solution quality. This can be achieved in several manners, namely the use of structural constraints and imposing restrictions on the list of operators, $\boldsymbol{\varphi} = \{+, -, \times, \div, x_a\}$, and inputs. Within the literature surrounding heterogenous catalysis, it is commonplace to use Langmuir-Hinshelwood type structures to define the kinetics present and, as such, we can enforce SR to abide by the structural form as shown Equation 6.

$$r_i = \frac{f_i(\boldsymbol{S}, \theta) - g_i(\boldsymbol{S}, \theta)}{(1 + h_i(\boldsymbol{S}, \theta))^n} \tag{6}$$

In this manner, the proposed equations will be more interpretable, and we can decompose the LH models based on their definition, where the numerator relates to the thermodynamic driving force and the denominator represents the kinetic resistance. A further advantage stems from stage 1 of the workflow. Since a complete reaction network has been attained, the input features can be curated based on these results, as we have knowledge of which species participate within each reaction, including within the different substructures (forward rate, reverse rate and kinetic inhibition).

Following the iterative SR procedure outlined in Figure 3, 8 further experiments were designed and incorporated into the algorithm, with the best performing models of the final iteration listed in Table 1.

**Table 1:** Top ranked discovered Langmuir-Hinshelwood type equations from the iterative SR procedure in Figure 3. $a_{j,i}$ is a parameter of model $i$.

| Rate | Equation |
|---|---|
| $r_1$ | $\frac{\alpha_{1,1}P_{CO_2}P_{H_2}^2 - \alpha_{1,2}P_{CH_3OH}P_{H_2O}}{P_{H_2}(1 + \alpha_{1,3}P_{CO_2}P_{H_2} + \alpha_{1,4}P_{H_2} + \alpha_{1,5}P_{CO_2} + \alpha_{1,6}P_{CO_2}^2)}$ |
| $r_2$ | $\frac{\alpha_{2,1}P_{CO_2}P_{H_2} - \alpha_{2,2}P_{CO}P_{H_2O}}{(\alpha_{2,3} + \alpha_{2,4}P_{CO_2} + \alpha_{2,5}P_{H_2})(\alpha_{2,6} + \alpha_{2,7}P_{CO_2} + \alpha_{2,8}P_{H_2})}$ |
| $r_3$ | $\frac{\alpha_{3,1}P_{H_2}(1 - \frac{\alpha_{3,2}P_{CH_4}P_{H_2O}^2}{P_{H_3}^3})}{(\alpha_{3,3} + \alpha_{3,4}P_{CO_2} + \alpha_{3,5}P_{H_2})(\alpha_{3,6} + \alpha_{3,7}P_{CO_2} + \alpha_{3,8}P_{H_2})}$ |

From an analysis of Table 1, there exists considerable equivalence to the ground truth structures in Equation 1, indicating that the methodology was capable of learning crucial insight from the data regarding the kinetics. Specifically, the algorithm discerned that, not only do $H_2$ and $CO_2$ individually affect the kinetic resistance, but their interactions also have a substantial contribution. Additionally, in the methanol synthesis ($r_1$) and water gas shift reactions ($r_2$), the influence of $CO_2$ the on the forward rate and $CH_3OH$, CO, and $H_2O$ on the reverse rates were correctly identified as first order. Although, for $r_1$, the order of $P_{H_2}$ was determined to be 2 instead of 3, the dominant impact of $H_2$ in the forward reaction rate was uncovered correctly.

As well as providing deep insight into the kinetics of the reaction, the parameterisation of the models in Table 1 yielded low average fitting percentage errors of 3.3% as shown in Figure 4. In order to assess the predictive capabilities across the entire design space, an experiment was designed to discriminate between the generated SR models and the ground truth. The maximum

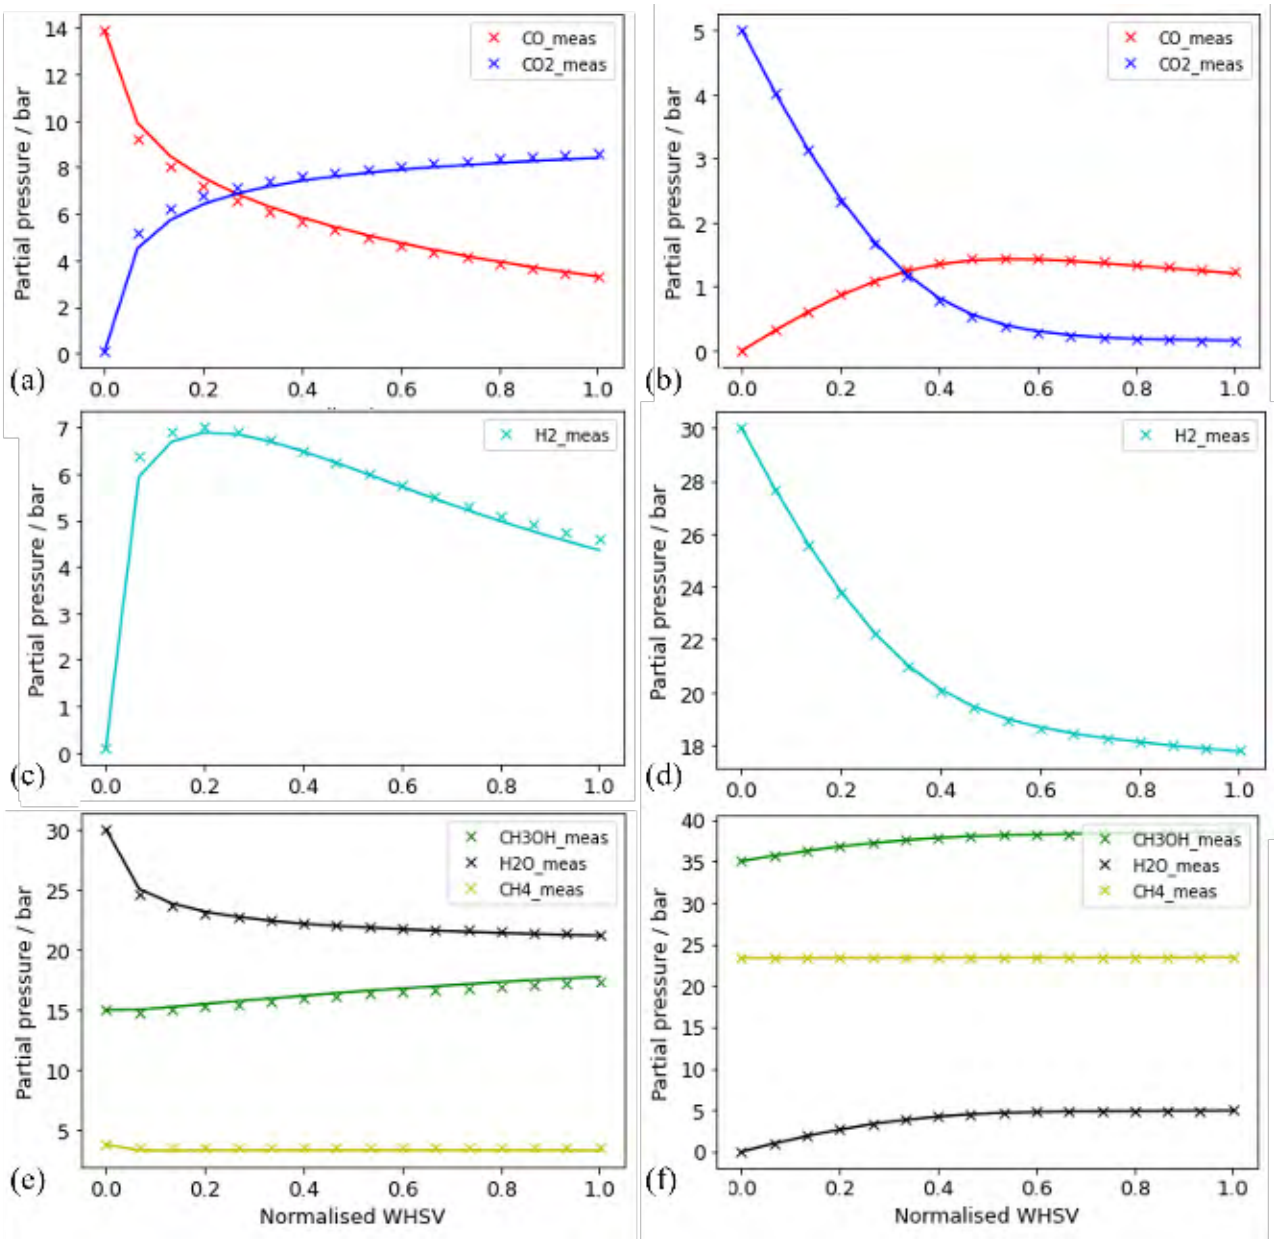

**Figure 4.** Fitting results of the top ranked SR generated models on the MBDoE experiments. (a), (c), and (e) refer to a single experiment and (b), (d), and (f) to another.

average percentage error across the entire operational region was 16.9%, demonstrating that the framework is robust and data efficient, being able to capture highly complex underlying kinetic information with a limited experimental budget.

## Results of the Kinetic Resolution Network

In a similar manner to the methanol synthesis reaction network, we can derive the problem formulation in Equation 3 using 9 active species and therefore a maximum of 8 independent reactions. After solving the problem formulation, it was discovered that only 5 global reactions are required to fit the experimental data, with the final reaction network presented in Equation 7.

$$
\begin{aligned}
r_1&\colon\ VA \rightleftharpoons \mathrm{AE} + AA \\
r_2&\colon\ AE + S_1 \rightarrow S_2 \\
r_3&\colon\ VA + S_2 \rightarrow AA + S_3 \\
r_4&\colon\ AE + R_1 \rightarrow R_2 \\
r_5&\colon\ AE + R_2 \rightarrow R_3
\end{aligned}
\tag{7}
$$

Through comparing the results in Equation 7 to the ground truth (R2), it is possible to observe that all the

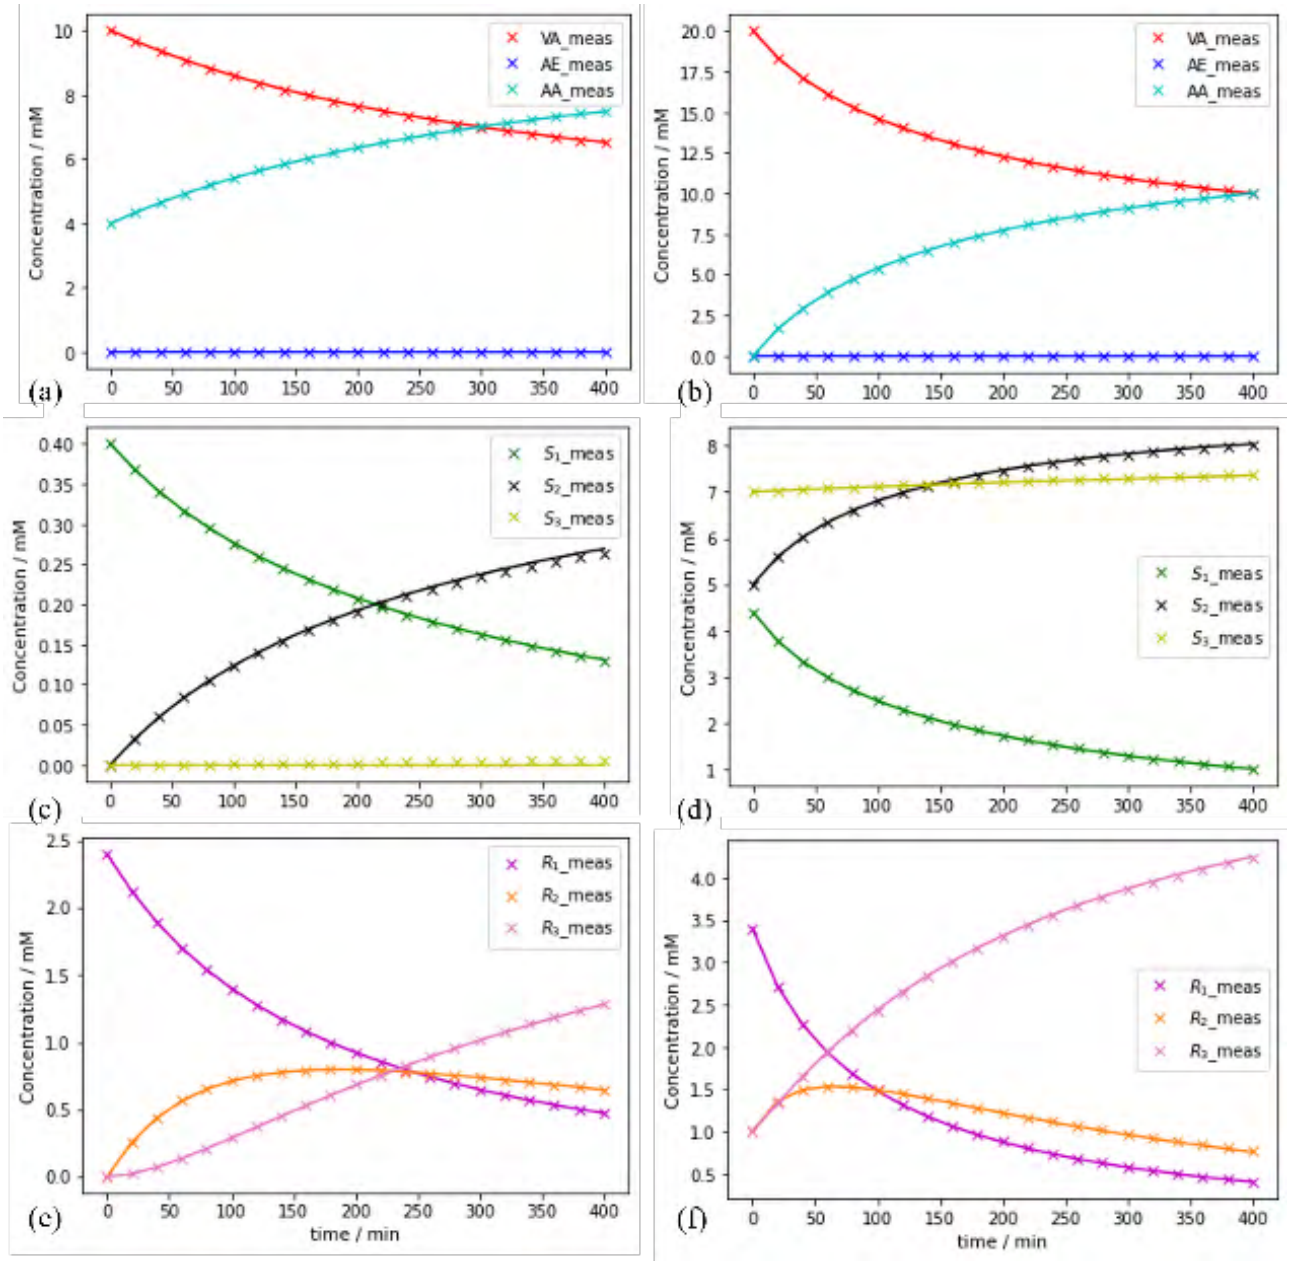

**Figure 5.** Fitting results for the parameterised SR models in Table 2. (a), (c), and (e) refer to a single experiment and (b), (d), and (f) to another.

species that are involved within the reactions as well as their respective stoichiometric coefficients were found with the sole inconsistency being in $r_3$, where $VA$ and $AA$ were included in place of AE. Notably, this is a lumped representation of the $r_1$ and $r_3$ in the ground truth reactions and still satisfies all mass balances. Therefore, the result is physically valid. It is hypothesised that the lumped representation was found due to the high dimensional nature of the optimisation problem requiring over 240 parameters to be solved for. This issue is further complicated by the low relative magnitudes of reaction rates for $r_3$ being 10-1000 times smaller than the reaction rates of all other reactions.

The accurate determination of four global reaction rates provides affirmation of the accuracy and reliability of the developed methodology. Applying the parameterised reaction network in Equation 7 to the initial 4 experiments used for network identification yields minimal percentage errors ($\approx 0\%$), both proving the effectiveness of the strategy, yet also a limitation where recovered reactions may, in actuality, be a lumped representation of the several ground truth reactions.

With the construction of a suitable reaction network, SR can now be applied as dictated in Figure 3. Similar to the previous case study, the literature can be exploited to add suitable constraints to the inputs, operators $\varphi = \{+, -, \times, \div, x_a\}$ and the equations structure. Succeeding the first iteration of running the framework, it was surmised that no further MBDoE was needed due to the correct rate models being recovered immediately for all reactions except $r_3$, as shown in Table 2, with a fitting percentage error of 3.0%.

**Table 2:** Top ranked rate models discovered for the kinetic resolution case study.

| Rate | Equation |
|---|---|
| $r_1$ | $\alpha_{1,1}C_{VA} - \alpha_{1,2}C_{AA}C_{AE}$ |
| $r_2$ | $\alpha_{2,1}C_{S_1}C_{AE}$ |
| $r_3$ | $\alpha_{3,1}C_{S_3}C_{VA}$ |
| $r_4$ | $\alpha_{4,1}C_{R_1}C_{AE}$ |
| $r_5$ | $\alpha_{5,1}C_{R_2}C_{AE}$ |

From Table 2, the interpretability of the generated model structures is apparent, indicating first order dependencies with respect to any species involved, and that all reaction rates possess irreversible behaviour apart from $r_1$. Finally, in both case studies, none of the proposed reaction rate models exhibited complexities beyond that of the ground truth kinetics, providing strong evidence that the framework is capable of yielding highly interpretable and precise representations that describe the underlying reaction networks.

## CONCLUSION

The case studies presented demonstrate that the proposed two-stage framework is capable of accurately recovering underlying reaction networks and automatically constructing interpretable kinetic rate expressions consistent with known physics, operating effectively under a limited experimental budget. Furthermore, the novel iterative application of symbolic regression mitigates the risk overly complex model forms, increasing the practical applicability of SR to real-world reaction systems whilst preserving high levels of interpretability.

Importantly however, the present study is conducted assuming complete observability of all reacting species and noise-free measurements, which are rarely fully satisfied in industrial practice. Future research should therefore assess the robustness of the framework when applied to noisy and sparsely sampled experimental datasets. Nevertheless, when combined with human-in-the-loop guidance, the methodology shows considerable promise for gaining mechanistic insight to support expert analysis. By incorporating augmented intelligence within the workflow, the framework offers a pathway towards accelerated knowledge generation and automated kinetic modelling for complex reaction engineering applications.

## ABSTRACT

Understanding the relationships between operating conditions and product formation pathways in biomass pyrolysis remains challenging due to the complex interactions among temperature, catalytic effects, and feedstock composition. In this work, principal component analysis (PCA) was applied to investigate the combined influence of temperature and catalyst-to-biomass ratio on the pyrolysis of sugarcane bagasse and Salicornia. To preserve mechanistic interpretability, two complementary analyses were performed: one considering only catalytic experiments and a second integrating both thermal and catalytic conditions. Separate PCA were conducted for product yields, gas and liquid compositions, and solid-phase FTIR features. The results reveal that thermal conditions promote severe cracking and solid carbonization, whereas catalytic operation favors secondary pathways associated with controlled dehydration and partial stabilization of liquid products. Distinct patterns between the two feedstocks were also identified, reflecting their intrinsic compositional differences. Based on the multivariate trends identified, a conceptual reaction scheme is proposed to describe the interplay between thermal and catalytic pathways.

**Keywords**: Biomass, Multivariate Statistics, Reaction, Reaction Patterns

## INTRODUCTION

Biomass pyrolysis is a promising thermochemical route to produce biofuels, value-added chemicals, and carbonaceous materials from renewable resources. Lignocellulosic biomass, due to its abundance and carbon-neutral nature, has attracted significant attention as a feedstock for sustainable energy systems. Nevertheless, the intrinsic complexity of biomass and the large number of simultaneous reactions occurring during thermal conversion hinder a detailed understanding of the reaction mechanisms and the control of product distribution [1-2].

From a mechanistic standpoint, biomass pyrolysis is generally described as the superposition of three main primary pathways: char formation, depolymerization, and fragmentation of the macromolecular constituents. These reactions are accompanied by secondary processes such as cracking, recombination, and recondensation of volatile species, which may lead to the formation of low- and high-molecular-weight products as well as secondary char. The relative contribution of these pathways strongly depends on temperature and reactor conditions, resulting in a highly interconnected and nonlinear reaction network [1-2].

The pyrolysis behavior of lignocellulosic biomass is governed by the relative proportions and interactions of cellulose, hemicellulose, and lignin. However, several studies have shown that the pyrolysis of whole biomass cannot be accurately described as a simple superposition of its individual components. Interactions among the main constituents significantly affect product yields and reaction pathways, and their detailed mechanisms remain not fully understood [3].

As an alternative, data-driven methodologies have gained increasing attention for the analysis of complex pyrolysis datasets. Principal Component Analysis (PCA) has been successfully employed to identify dominant patterns, correlate product families, and distinguish between primary and secondary reactions, supporting the proposal of reaction or kinetic schemes without imposing *a priori* assumptions [4].

In this work, an integrated PCA-based approach is

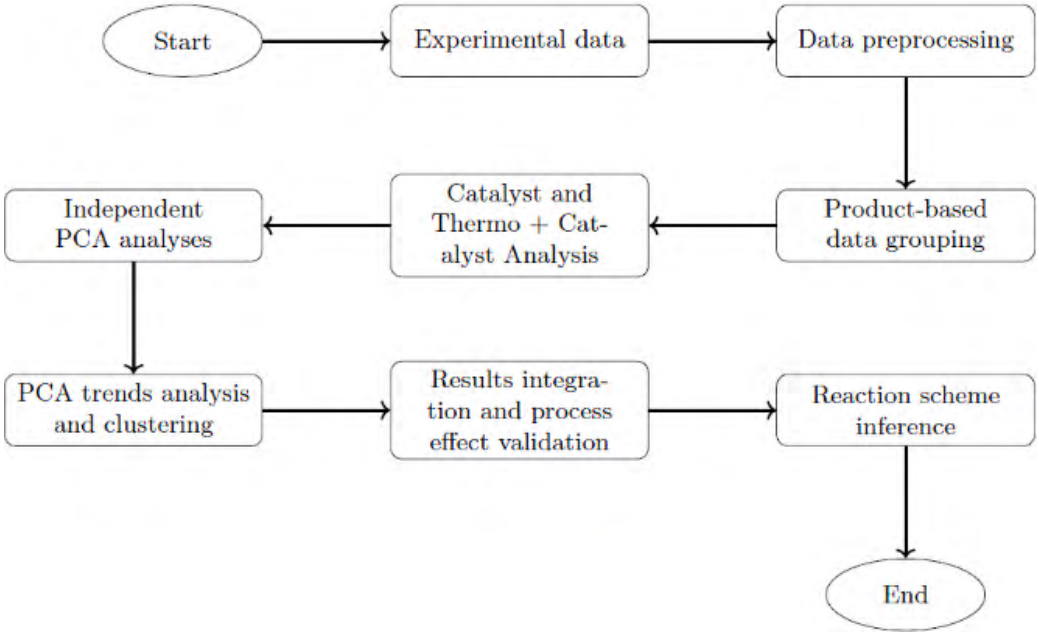

**Figure 1.** Flowchart of PCA methodology.

applied to investigate the catalytic and thermal pyrolysis of lignocellulosic biomass by combining complementary experimental data sets, including global product yields, gas chromatography, and FTIR analysis of solid residues. Independent PCA analyses are performed and subsequently interpreted as a function of temperature and C/B ratio, together with clustering techniques to identify distinct reaction regimes.

## EXPERIMENTAL SETUP

Two biomasses were investigated: sugarcane bagasse and Salicornia sp. Sugarcane bagasse (SCB) was obtained from the Tierra Blanca Sugar Mill (Veracruz, Mexico), while Salicornia (SAA) was collected from cultivated fields in Baja California Sur, Mexico. Both materials were used as feedstock for thermal and catalytic pyrolysis experiments.

Pyrolysis reactions were carried out in a semi-continuous fixed-bed tubular reactor made of titanium, using 1 g of biomass per experiment. Thermal pyrolysis was conducted in the absence of catalyst, whereas catalytic pyrolysis experiments were performed using catalyst-to-biomass (C/B) mass ratios of 1:1, 1:2, and 1:3. For both biomasses, experiments were conducted at reaction temperatures ranging from 400 to 600 °C, while the residence time was kept constant. Nitrogen was continuously fed from the bottom of the reactor to ensure an inert atmosphere.

The experimental setup consisted of a heating furnace, the tubular reactor, a condensation column with a recirculating cooling system, a round-bottom flask for liquid recovery, and a gas collection system. Condensable volatiles were recovered using ethylene glycol as cooling medium at 5 °C, while non-condensable gases were collected in inert multilayer foil sampling bags.

The experimental campaign generated four types of data: (i) overall product yields, (ii) gas-phase composition determined by gas chromatography, (iii) liquid-phase composition analyzed by gas chromatography, and (iv) solid-phase FTIR spectra. Gaseous products were analyzed using a GC-7890B gas chromatograph equipped with a Molecular Sieve 13X column and argon as carrier gas. Liquid products were analyzed using a Clarus 500 gas chromatograph. Solid residues were characterized by FTIR spectroscopy using a PerkinElmer Precisely Spectrum 100 spectrometer.

## METHODOLOGY

The methodology implemented in this work follows a product-based multivariate analysis strategy, as summarized in Fig. 1. The approach integrates experimental data from different product phases with structured data preprocessing and Principal Component Analysis (PCA) to identify dominant trends and infer reaction pathways during biomass pyrolysis.

### Data Preprocessing

All data processing was performed using `Python`, employing standard scientific libraries (`NumPy`, `Pandas`, and `scikit-learn`)[5-7].

Overall product yields, gas-phase compositions, liquid-phase grouped variables, and solid-phase FTIR

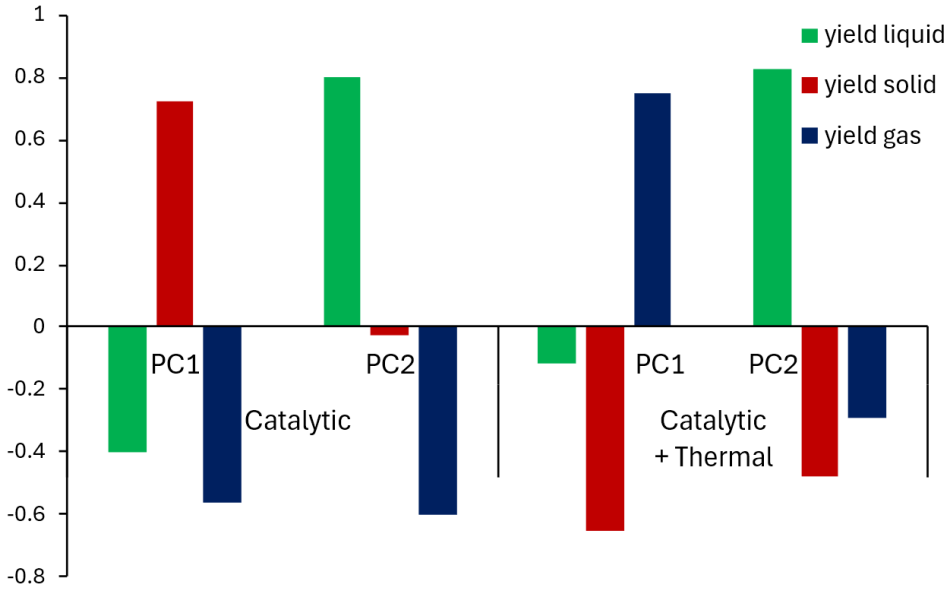

**Figure 2.** Bar plots of yield loadings for each data group.

descriptors were scaled using z-score normalization to ensure comparable variable variance prior to multivariate analysis.

Gas-phase data consisted of the molar fractions of the main species ($CH_4$, $CO_2$, $C_2H_6$, $C_3H_8$, $C_4H_{10}$, $H_2$, and CO), which were directly used as input variables. Liquid-phase chromatographic data were first grouped into chemical families (alcohols, ketones, methylphenols, nitrophenols, and chlorophenols) to reduce dimensionality and improve chemical interpretability.

For solid-phase analysis, FTIR spectra were divided into predefined wavenumber intervals (2700–2350, 2350–2100, 2100–1800, 1800–1500, and 1300–850 $cm^{-1}$). The area under each interval was calculated using numerical integration, providing quantitative descriptors associated with major functional groups in the solid residues.

## Product-based PCA strategy

PCA was applied independently to each product-based dataset using the `scikit-learn` implementation. In all cases, the first two principal components were retained, as they captured the dominant variance and allowed visualization of process trends. To enhance discrimination of reaction regimes, the data were separated into two subsets: catalytic-only and combined thermal–catalytic experiments. Independent PCA models were constructed for each subset, the analysis resulted in a total of eight PCA models: four corresponding to catalytic experiments and four corresponding to the thermal–catalytic dataset.

For each model, the loading patterns of PC1 and PC2 were analyzed to assign physical and chemical meaning to the principal components, while score plots were used to evaluate the evolution of these behaviors as a function of temperature, C/B ratio, and biomass type. Clustering in the score space was further assessed using the `KMeans` algorithm to identify groups exhibiting similar process behavior.

## RESULTS AND DISCUSSION

Table 1 summarizes the explained variance of the first two principal components for yields, gas, liquid, and solid (FTIR) datasets under catalytic and combined catalytic–thermal conditions.

**Table 1:** Explained Variance for each PCA analysis.

| | Explained Variance | | | |
|---|---|---|---|---|
| | Catalytic | | Catalytic + Thermal | |
| | PC1 | PC2 | PC1 | PC2 |
| Yields | 0.639 | 0.361 | 0.523 | 0.477 |
| Gas | 0.331 | 0.237 | 0.331 | 0.237 |
| Liquid | 0.480 | 0.303 | 0.492 | 0.317 |
| Solid FTIR | 0.800 | 0.175 | 0.747 | 0.227 |

For product yields, the catalytic system is predominantly described by PC1, indicating a dominant reaction pathway. When thermal experiments are included, the variance is more evenly distributed between PC1 and PC2, revealing the coexistence of temperature-driven and catalyst-assisted mechanisms.

Gas-phase data display a similar variance

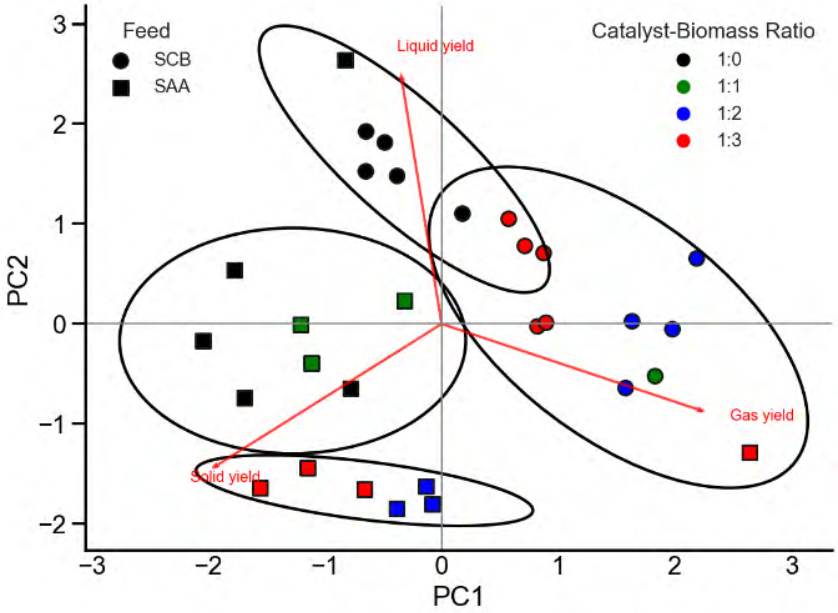

**Figure 3.** Biplot of thermal + catalytic yields scores.

distribution in both cases, suggesting that gas formation is primarily governed by temperature, with limited sensitivity to catalytic effects. In contrast, liquid-phase data show a more balanced contribution of PC1 and PC2, reflecting the superposition of thermal fragmentation and catalytic stabilization pathways. Solid residues characterized by FTIR are largely dominated by PC1 in both scenarios, indicating a robust primary mechanism associated with char formation and structural evolution. The increased contribution of PC2 upon inclusion of thermal experiments suggests secondary temperature-induced modifications without altering the dominant catalytic signature.

## PCA of Product Yields

### Loading Analysis

The loadings bar plots for product yields (see Fig. 2) highlight clear differences between the PCA performed using only catalytic experiments and the one including both catalytic and thermal conditions.

For the catalytic dataset, PC1 accounts for most of the variance and reflects the overall redistribution of products driven by secondary catalytic reactions, separating gas-dominated regimes from those favoring liquids and solids. This indicates that, in the presence of a catalyst, product yields are mainly controlled by the efficiency of catalytic cracking, dehydration, and aromatization pathways.

PC2 captures a secondary contrast associated with the balance between liquid stabilization and solid residue formation, characteristic of intermediate catalytic severities.

When thermal experiments are included, the variance structure becomes more evenly distributed between PC1 and PC2. This redistribution indicates that an additional, non-catalytic source of variability is introduced. In this case, PC1 represents a more general conversion severity axis, combining both catalytic effects and temperature-driven primary decomposition. PC2 gains importance as a discriminator between thermally dominated pathways, characterized by early gas formation and poor liquid stabilization, and catalytically assisted regimes, where yields are redistributed toward upgraded liquids and structured solids.

### Biplot Analysis

Figs. 3 and 4 shows the PCA biplots of product yields for thermo-catalytic and purely catalytic experiments, with samples colored according to the C/B ratio. These biplots allow visualization of the combined effect of reaction regime and catalyst loading on the distribution of products.

For the thermo-catalytic experiments, most SCB samples are in the (+PC1, +PC2) region, while thermal bagasse experiments tend to shift toward the (−PC1, +PC2) quadrant. In contrast, SAA samples predominantly occupy the (−PC1, −PC2) region, with some thermo-catalytic conditions extending toward (−PC1, +PC2). A consistent downward trend along PC2 is observed with increasing C/B ratio for SAA, whereas for SCB the effect of C/B is more pronounced along PC1, with lower PC1 scores associated with lower catalyst loadings.

When considering only catalytic experiments (see

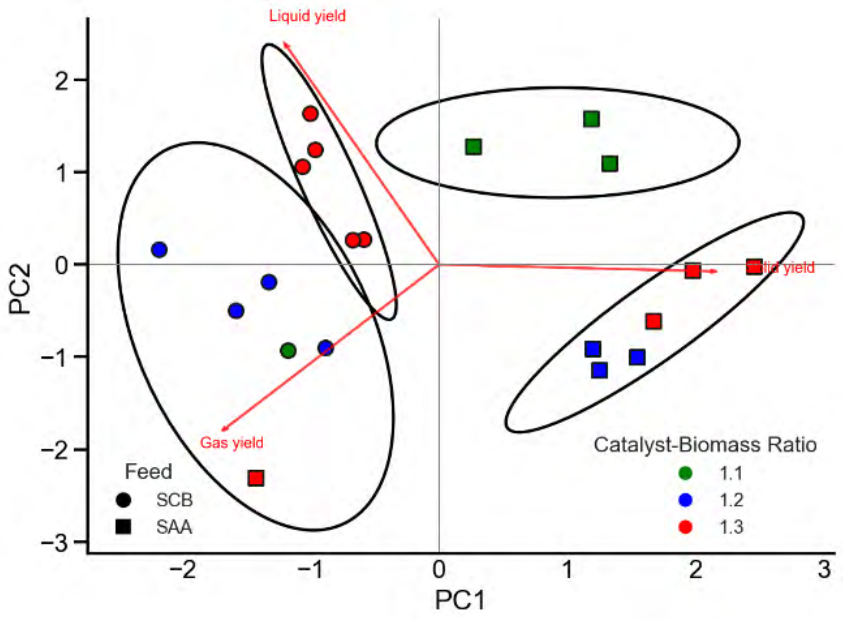

**Figure 4.** Biplot of only catalytic yields scores.

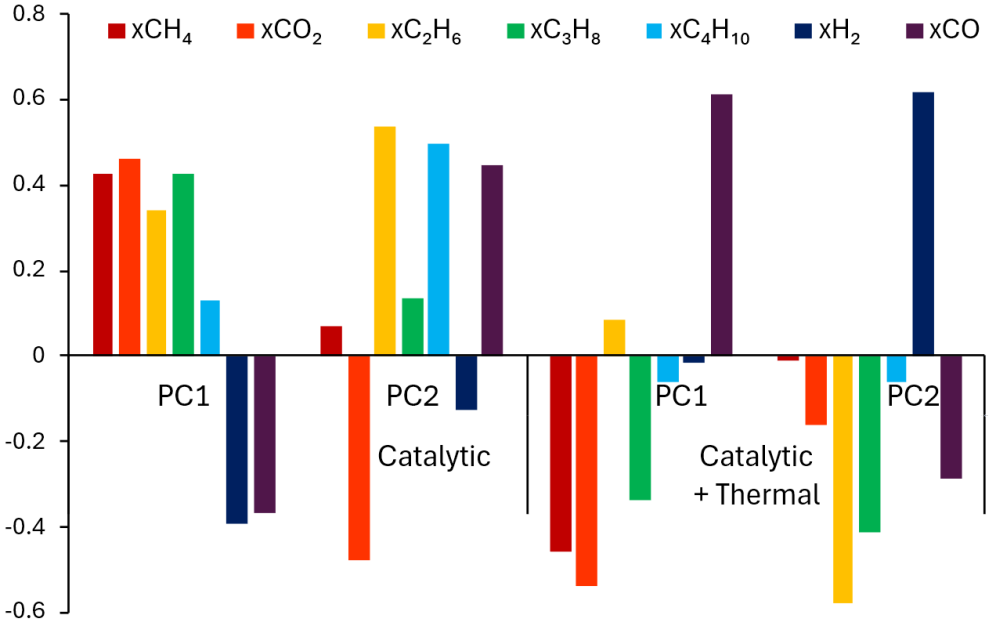

**Figure 5.** Bar plots of gas loadings for each data group.

Fig. 4), the separation between biomasses and catalyst loadings becomes more defined. For SCB, higher C/B ratios are associated with an upward displacement along PC2, indicating a stronger catalytic influence on yield redistribution. In the case of SAA, samples with lower C/B ratios cluster in the (+PC1, +PC2) region, while higher catalyst loadings shift the samples toward (+PC1, −PC2), with a simultaneous increase along PC2 at the highest C/B values.

Overall, these biplots indicate that the C/B ratio governs the main directions of variance in product yields, but its influence depends strongly on both the biomass type and the reaction regime.

## Gas-Phase PCA

### Loadings Analysis

The bar plot of the gas-phase PCA loadings (see Fig. 5) reveals a consistent structure between the catalytic

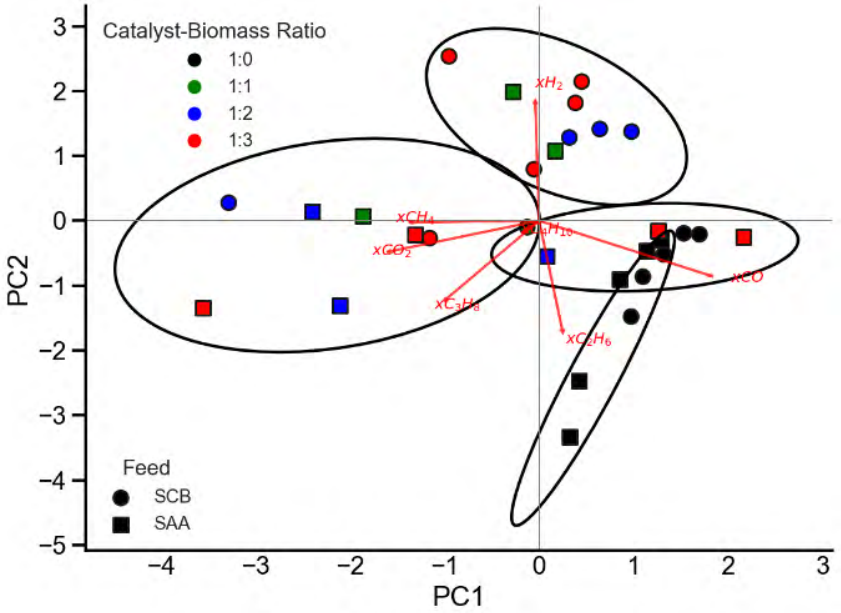

**Figure 6.** Biplot of thermal + catalytic gas scores.

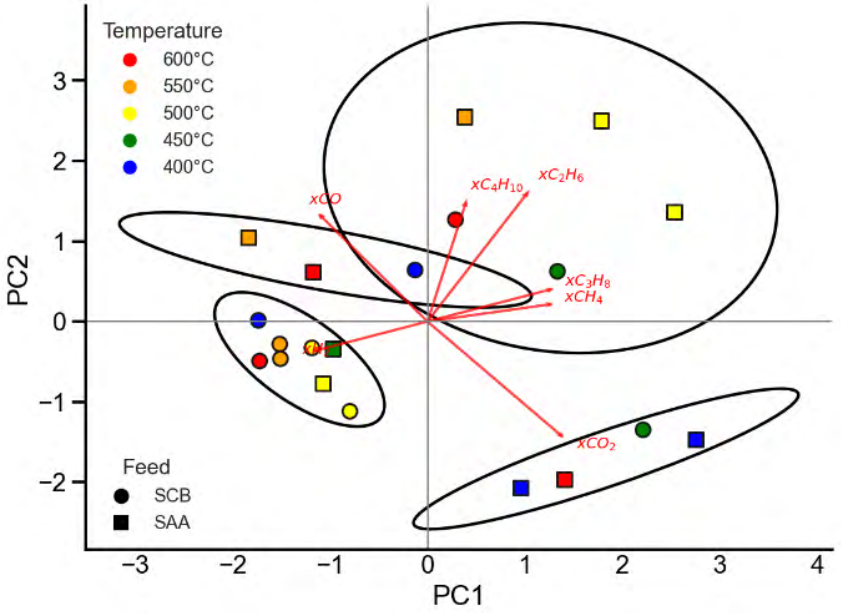

**Figure 7.** Biplot of only catalytic gas scores.

dataset and the combined catalytic–thermal dataset, indicating that the main gas-forming pathways are intrinsically robust and largely governed by fundamental decomposition and reforming reactions.

In both cases, PC1 is dominated by the major permanent gases, reflecting an axis associated with the extent of gasification and secondary cracking severity. Positive PC1 loadings are linked to increased formation of light gases. This confirms that PC1 represents a global severity coordinate.

PC2 shows a more selective contribution, separating gas species associated with primary thermal devolatilization from those arising from secondary catalytic transformations. In the purely catalytic PCA, PC2 captures subtle shifts in gas selectivity driven by catalyst-assisted pathways, whereas in the combined dataset its relative importance increases, highlighting the growing role of temperature-controlled primary gas release.

The similarity of the loadings pattern indicates that gas-phase composition is less sensitive to the coexistence of thermal and catalytic routes. Instead, gas

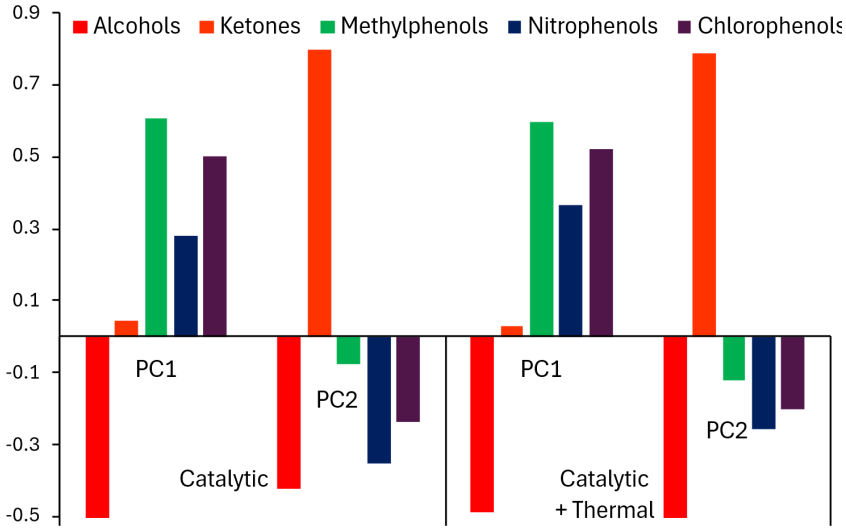

**Figure 8.** Bar plots of liquid loadings in both groups.

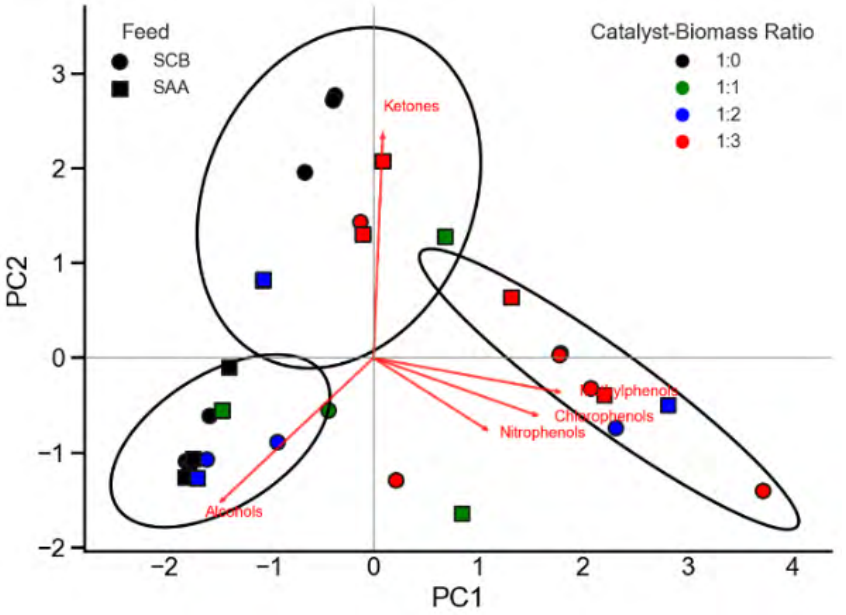

**Figure 9.** Biplot of thermal + catalytic s liquid scores.

formation responds primarily to the overall intensity of bond scission and reforming reactions, where temperature is the dominant driver and catalyst modulating selectivity.

## Biplot Analysis

For the thermo-catalytic dataset, the biplot (see Fig. 6) reveals that thermal experiments are mainly located in the (+PC1, −PC2) region, showing a broader dispersion associated with feedstock type. SCB experiments tend to occupy higher PC2 values, whereas SAA samples are preferentially located at lower PC2 values, indicating distinct gas-phase response patterns between both biomasses under thermal conditions.

In contrast, the catalytic experiments exhibit a clearer organization in terms of the C/B ratio. For SCB, most points are in the (+PC1, +PC2) quadrant, with a systematic upward shift along PC2 as the catalyst loading increases, suggesting an enhanced catalytic contribution to gas-phase transformations. For SAA, although data points remain close to the PC1 axis, an increase in C/B ratio leads to a noticeable displacement toward higher PC1 values, indicating a catalyst-dependent modulation of gas composition.

When considering only catalytic experiments and classifying the data by temperature (see Fig. 7), a strong thermal effect emerges. For SCB, low-temperature experiments cluster in the (+PC1, −PC2) region, while

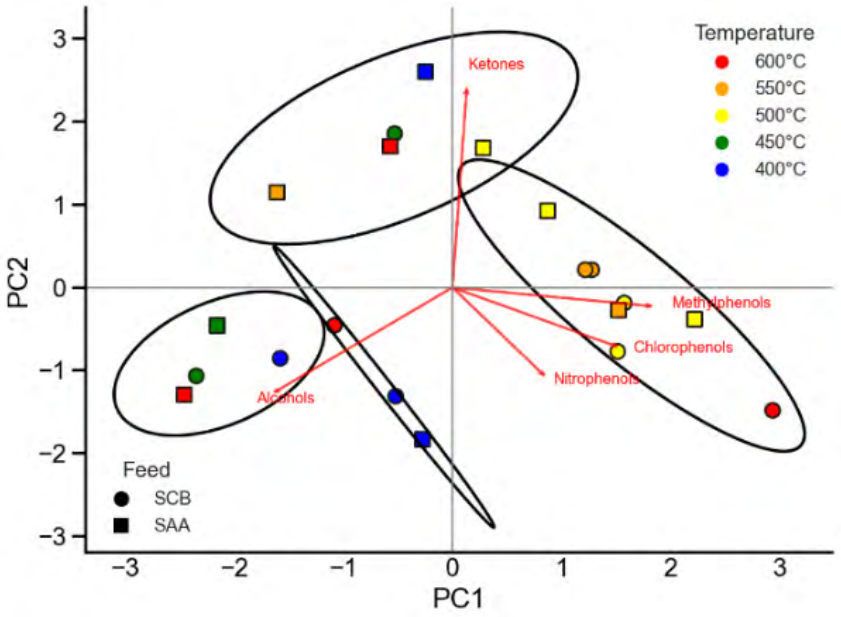

**Figure 10.** Biplot of only catalytic liquid scores.

increasing temperature drives the data upward along PC2 and progressively toward lower PC1 values. This trend suggests a temperature-driven shift in dominant gas-phase pathways. Conversely, SAA exhibits an opposite behavior along PC2: increasing temperature results in a downward displacement, although a consistent shift toward lower PC1 values is also observed, indicating a shared thermal influence on gas evolution despite biomass-specific differences.

## Liquid-Phase PCA

### Loadings Analysis

The loadings bar plot for the liquid-phase PCA (see Fig. 8) captures the dominant chemical differentiation within the bio-oil fraction with respect to the first two principal components.

PC1 is primarily governed by the opposition between alcohols and substituted phenolic compounds, defining an axis associated with the structural origin of liquid products. Negative PC1 loadings are dominated by alcohols, which are characteristic of primary depolymerization products from cellulose and hemicellulose. In contrast, positive PC1 loadings are associated with methyl-, chloro-, and nitrophenols, reflecting lignin-derived compounds and secondary aromatic stabilization pathways. This confirms PC1 as a descriptor of increasing aromaticity and secondary processing severity in the liquid phase.

PC2 is strongly controlled by ketones, which exhibit the largest positive loadings in both PCA configurations. This component represents the prevalence of carbonyl-forming fragmentation routes, typically linked to carbohydrate decomposition. Negative PC2 contributions correspond to alcohols and phenolic species, indicating a shift away from simple fragmentation toward more stabilized or condensed liquid products.

When thermal experiments are incorporated, only minor variations in loading magnitudes are observed, while the overall structure of PC1 and PC2 remains unchanged.

This indicates that the chemical partitioning of liquid products is fundamentally preserved, with temperature primarily affecting the distribution of experiments in score space rather than redefining the underlying liquid-phase reaction pathways.

### Biplot Analysis

For the thermo-catalytic dataset, the biplot (see Fig. 9) shows that thermal experiments are exclusively located in the negative PC1 region, indicating the absence of liquid-phase stabilization associated with positive PC1 scores.

A clear separation by feedstock is observed along PC2: SCB thermal experiments are mainly located at positive PC2 values, aligned with the ketone-related vector, whereas SAA experiments cluster at negative PC2 values, following the alcohol-related direction.

When analyzing the thermo-catalytic data according to the C/B ratio, most experiments with higher catalyst loading for both biomasses shift toward the (+PC1, −PC2) quadrant. This behavior suggests a catalytic-driven transition toward liquid compositions characterized by enhanced dehydration and secondary transformation pathways.

For the catalytic-only dataset (see Fig. 10), the

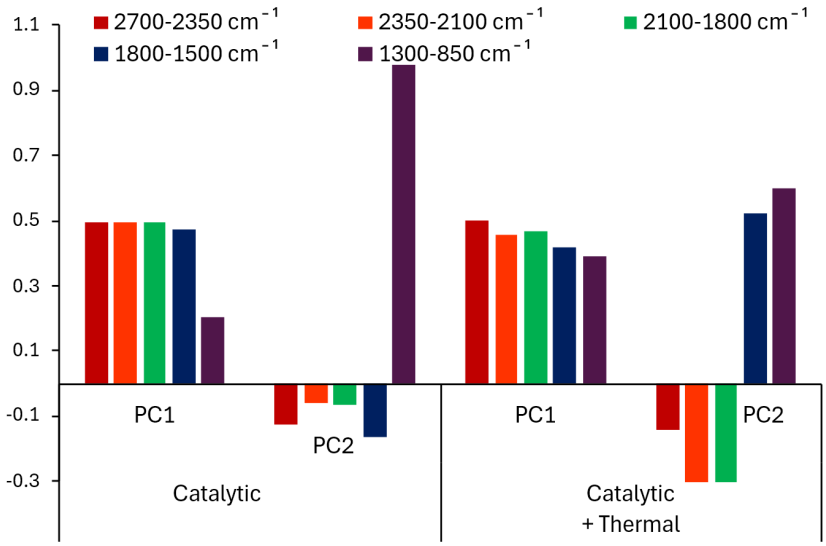

**Figure 11.** Bar plots, solid FTIR loadings in both groups.

temperature-colored biplot highlights a distinct thermal effect. In SCB, increasing temperature promotes a displacement toward positive PC1 values with intermediate PC2 scores, although all bagasse experiments remain in the negative PC2 region. In contrast, SAA exhibits a different high-temperature response: experiments at 600 °C shift toward lower PC1 values, indicating a tendency toward alcohol- and ketone-rich liquid compositions. Despite these differences, both biomasses show a temperature-dependent reorganization of liquid-phase chemistry under catalytic conditions.

## FTIR-Based PCA

### Loadings Analysis

The FTIR-based PCA of solid residues (see Fig. 11) exhibits a highly structured behavior, with the first principal component explaining the majority of the variance in both datasets. This confirms that the chemical evolution of the solid phase is governed by a limited number of dominant transformation pathways rather than by random spectral variations.

PC1 is characterized by uniformly positive loadings across all FTIR spectral regions, indicating that it represents the overall intensity and preservation of functional groups in the solid residue. High PC1 values correspond to solids retaining a broad range of oxygenated and aliphatic functionalities, whereas low PC1 values are associated with extensive devolatilization and carbonization, resulting in weak FTIR signals. The slight reduction in PC1 explained variance upon inclusion of thermal experiments suggests the emergence of additional structural diversity in the solid phase at high temperatures.

PC2 provides chemical discrimination among functional groups, separating spectral regions associated with aliphatic and carbohydrate-related vibrations from those linked to more condensed aromatic structures. Positive PC2 loadings are dominated by low-wavenumber regions (1300–850 $cm^{-1}$ and 1800–1500 $cm^{-1}$), typically attributed to C–O, C–C, and aromatic skeletal vibrations, while negative PC2 contributions are associated with higher-wavenumber regions linked to less condensed structures.

Compared to the catalytic-only PCA, the catalytic–thermal PCA shows a redistribution of PC2 loadings, indicating that temperature enhances structural differentiation within the solid, promoting the coexistence of partially functionalized aromatic char and more condensed carbonaceous domains. Importantly, the interpretation of PC1 as a severity axis and PC2 as a structural-type axis remains robust across both datasets.

### Biplots Analysis

For the thermo-catalytic dataset, the biplot (see Fig. 12) reveals a clear and consistent separation between thermal and catalytic regimes along PC1. All thermal experiments are in the negative PC1 region, whereas catalytic experiments shift toward positive PC1 values, indicating the development of more structured and chemically evolved solid residues under catalytic conditions. Along PC2, feedstock-dependent separation is observed: SCB thermal samples are mainly located at negative PC2 values, while SAA samples cluster toward positive PC2.

Within the catalytic experiments, a systematic trend with C/B ratio is evident. For SAA, increasing catalyst loading induces a displacement along a negative slope, with both PC1 and PC2 values decreasing, suggesting progressive modification of surface functionalities and aromatic structures. In contrast, SCB exhibits a more

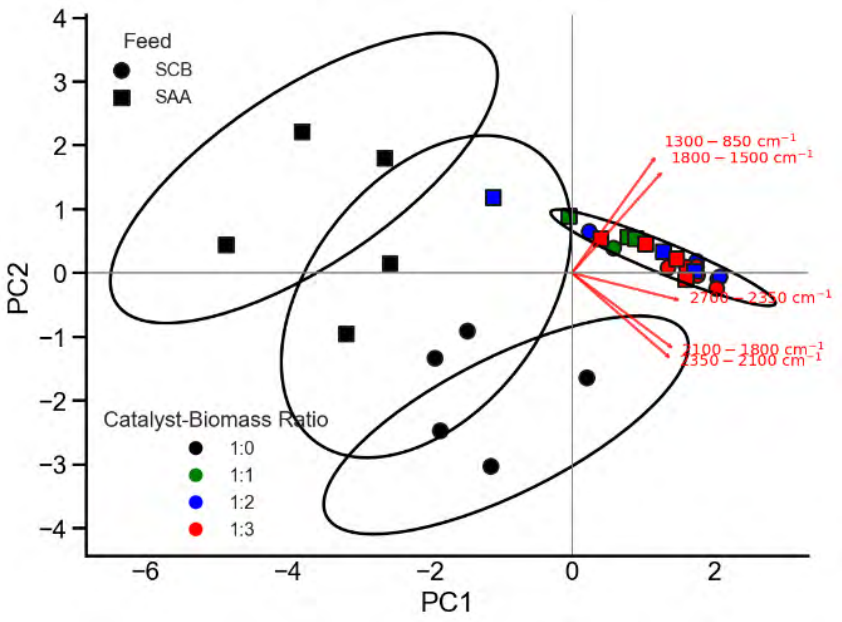

**Figure 12.** Biplot of thermal+catalytic Solid-FTIR scores.

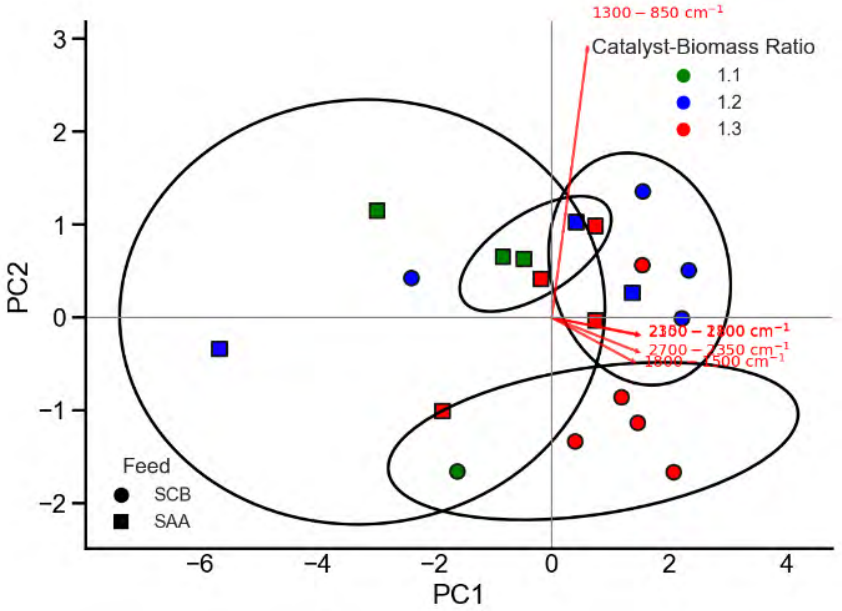

**Figure 13.** Biplot of only catalytic solid-FTIR scores.

pronounced displacement along PC2, with comparatively minor changes along PC1, indicating a different catalytic restructuring pathway of the solid phase.

For the catalytic-only dataset (see Fig. 13), a distinct feedstock-dependent response is observed. In SAA, increasing C/B ratio promotes a shift toward positive PC1 values, consistent with enhanced catalytic control over char aromatization and functional group evolution. Conversely, SCB samples primarily shift downward along PC2, suggesting progressive loss or transformation of specific surface functionalities rather than changes in overall aromaticity.

## Reaction Trends and Proposed Mechanistic Pathways

The integrated interpretation of the PCA results obtained from product yields, gas-phase composition, liquid-phase composition, and solid-phase FTIR provides a

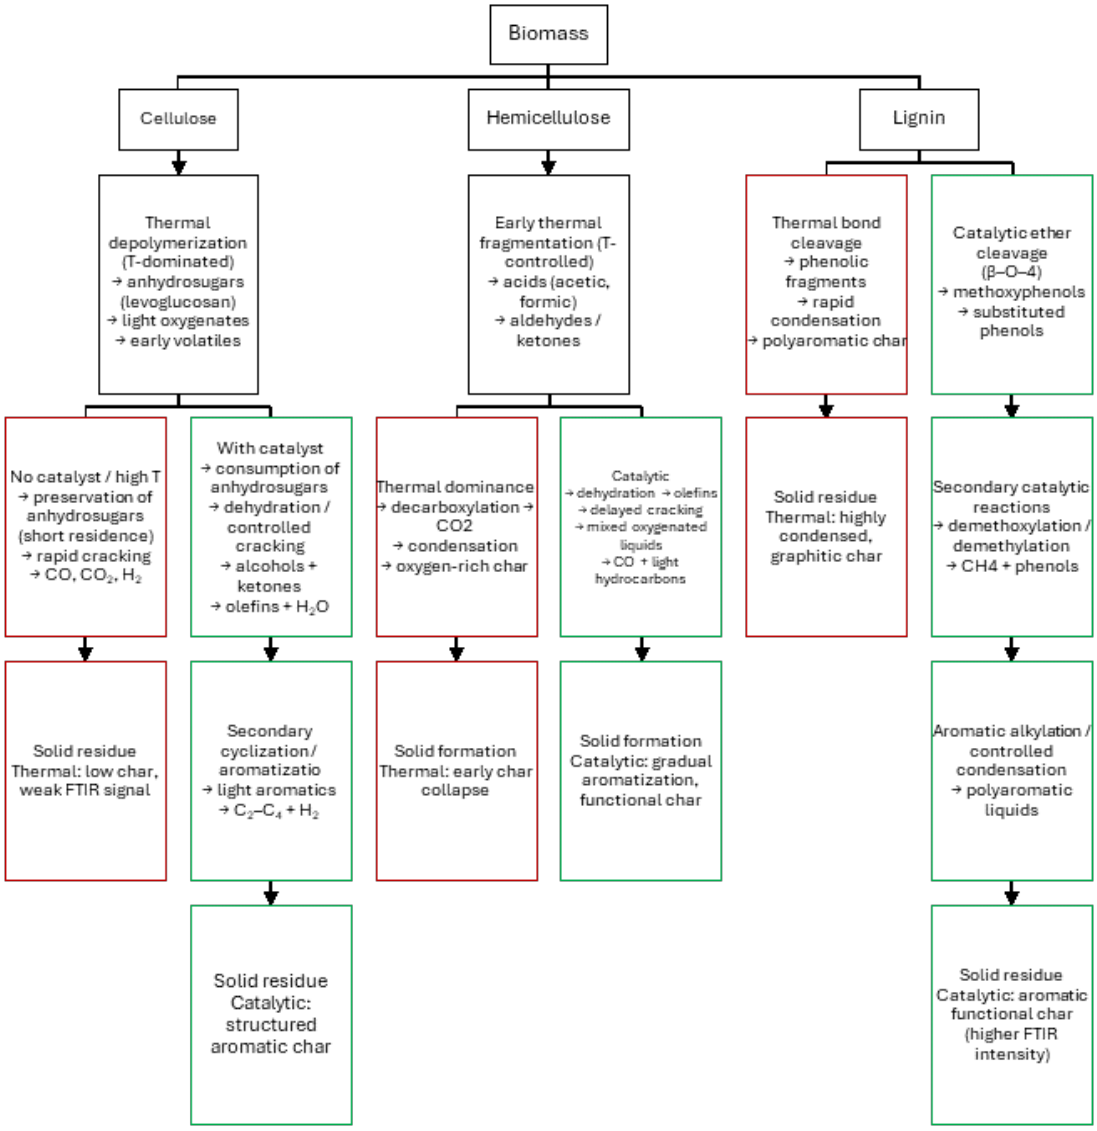

**Figure 14:** Conceptual reaction scheme for biomass pyrolysis highlighting the main transformation pathways of cellulose, hemicellulose, and lignin into gas, liquid, and solid products of temperature-dominated (red boxes) and catalyst-assisted (green boxes) routes.

consistent basis for proposing the reaction pathways summarized in Fig. 14. The multivariate trends indicate that biomass pyrolysis proceeds through the coexistence of temperature-dominated (red boxes) and catalyst-assisted (green boxes) routes, whose relative contributions depend strongly on feedstock composition.

For SCB, thermal effects primarily govern the initial depolymerization of cellulose and hemicellulose, leading to rapid volatilization and gas formation, as reflected by the clustering of thermal experiments in PCA regions associated with negative PC1 or PC2 values in the yields and gas-phase analyses. As depicted in Fig. 14, the presence of catalyst promotes secondary dehydration, cracking, and aromatization reactions, which are evidenced by systematic displacements along PC1 in yields and gas-phase PCA and along PC2 in FTIR. These trends indicate enhanced formation of light hydrocarbons and aromatics, together with the development of a more structured and aromatic solid residue. The C/B ratio therefore modulates reaction severity and solid-phase restructuring rather than fundamentally altering the primary decomposition pathways of bagasse.

In contrast, SAA exhibits a stronger coupling between catalytic effects and reaction selectivity. The biplots for yields, gases, and liquids show clear and systematic shifts with increasing C/B ratio, particularly along

PC2, indicating a catalyst-driven redistribution among oxygenated liquids, permanent gases, and stabilized solids. This behavior is consistent with the reaction scheme in Fig. 14, where catalytic dehydration, decarboxylation, and controlled condensation pathways become increasingly dominant. The FTIR PCA further supports this interpretation, as catalytic experiments display concurrent displacements along PC1 and PC2, reflecting simultaneous changes in aromaticity and surface functionality of the resulting char.

Overall, the PCA trends across all product phases converge toward a unified mechanistic framework, illustrated in Fig. 14, in which temperature controls primary bond cleavage and volatilization, while the catalyst selectively enhances secondary reactions such as dehydration, decarboxylation, aromatization, and controlled condensation. The balance between these pathways is feedstock-dependent, leading to distinct reaction trends and product distributions for SCB and SAA. This figure-assisted mechanistic interpretation captures the essential reaction behavior inferred from the multivariate analysis without requiring an explicit global PCA.

These observations are also consistent with previously reported descriptions of biomass pyrolysis [1, 8].

## CONCLUSIONS

The PCA results demonstrate that separating catalytic and thermal–catalytic datasets is essential to disentangle the dominant reaction regimes during biomass pyrolysis. Temperature primarily governs severe cracking and carbonization pathways, while the catalyst introduces selectivity by promoting secondary reactions and moderating product distribution. The consistent displacement of experimental conditions in the PCA space highlights distinct behaviors for SCB and SAA, linked to their different biochemical compositions. The reaction scheme proposed in this work summarizes these trends and provides a coherent mechanistic framework connecting multivariate patterns with underlying transformation pathways.

## ABSTRACT

In this study, we propose a novel trust-region funnel (TRF) optimisation framework for process systems that integrate external black-box models, such as rigorous models, within equation-oriented (EO) formulations. The framework is applied to optimise a synthetic natural gas production process combining direct air capture and catalytic $CO_2$ conversion using dual-function material (DFM) technology, with the objective of minimising the total annualised cost. The problem is formulated in Pyomo and solved using IPOPT, treating the DFM reactor as an external black-box model. The TRF method achieves substantial improvements compared to published mixed-integer nonlinear programming and direct nonlinear programming approaches, reducing capture cost from 460 USD to 426 USD per tonne of $CO_2$. Key design improvements include reducing the number of DFM units per train by one-third and achieving a 22% reduction in DFM capital costs. These results highlight the TRF framework's ability to overcome numerical challenges and unlock economically superior designs for next-generation carbon capture and utilisation systems.

## INTRODUCTION

Modern challenges in process systems engineering (PSE) increasingly involve multi-scale optimisation problems aimed at rigorously assessing the performance and scalability of emerging technologies, such as carbon capture and utilisation (CCU) systems [1]. These problems are inherently hybrid, combining explicit equation-oriented (EO) glass-box process models with external, implicitly defined components, commonly referred to as black-box models. Black-box components typically originate from rigorous high-fidelity models (e.g., systems of computationally challenging nonlinear algebraic equations or ordinary and partial differential equations) or simulation packages, whose analytical structure is often unavailable or impractical to embed directly within EO formulations. When integrated into EO optimisation frameworks, rigorous high-fidelity models frequently introduce numerical instability and cause convergence issues in traditional nonlinear programming (NLP) solvers, while simulation packages cannot be incorporated as NLPs due to their model form [2].

Achieving convergence to first-order optimality in hybrid glass-box/black-box optimisation problems requires specialised solution strategies that explicitly account for the presence of external models. The classical trust-region filter method is a promising approach for solving such hybrid problems, but it faces significant challenges, including excessive numbers of expensive model evaluations and strong sensitivity to initialisation and algorithmic tuning parameters [3]. To address the limitations of NLP solvers and the trust-region filter method in handling rigorous high-fidelity models, this work proposes a trust-region funnel (TRF) optimisation framework for embedding rigorous external models within nonlinear process flowsheets. The TRF method extends the trust-region filter approach [4] by replacing the filter globalisation strategy with a funnel-based method [5]. This modification improves robustness, preserves convergence guarantees, and reduces reliance on

heuristic parameter tuning, enabling the optimisation of tightly coupled hybrid systems. A key feature of the proposed TRF strategy is its ability to efficiently utilise derivative information whenever available, thereby reducing the computational cost associated with external model evaluations. When analytic derivatives of black-box models are unavailable, the method remains applicable by employing derivative approximation at the cost of additional model evaluations. This flexibility makes the TRF method particularly well-suited for large-scale hybrid optimisation problems involving cyclic operation, implicit system behaviour, or computationally challenging and derivative-free sub-models.

Growing concerns regarding the long-term environmental risks and uncertainties associated with $CO_2$ storage have intensified interest in $CO_2$ utilisation pathways [5]. Among these, catalytic conversion of captured $CO_2$ into synthetic natural gas (SNG) using renewable hydrogen, commonly referred to as power-to-gas (PtG), has emerged as a promising option. This study demonstrates the application of the proposed TRF framework to optimise an integrated SNG production process based on direct air capture (DAC) and catalytic conversion using dual-function material (DFM) technology. The DFM reactor integrates $CO_2$ capture and methanation within a single unit [6]. In addition to the DFM unit, the process flowsheet includes upstream air intake and high-temperature solid oxide electrolyser (SOEL) units, and downstream heat-integration and separation systems.

The resulting problem is characterised by a large number of equality constraints and strong nonlinear coupling across multiple process units, making it computationally challenging for standard NLP solvers. To address these challenges, previous works [6][7] imposed restrictive assumptions, such as fixing key design and operating variables (e.g., adsorption time and DFM mass). While effective for numerical convergence, these restrictions significantly reduce the feasible design space, preventing identification of the true economic optimum.

In this work, we overcome these limitations by introducing additional degrees of freedom, allowing all process variables, including adsorption time and DFM catalyst weight, to vary during the optimisation process. The DFM reactor is treated as an external multi-output black-box component, embedded within an EO formulation, and the resulting hybrid optimisation problem is solved using the proposed TRF method. The results demonstrate that the TRF approach achieves robust and systematic optimisation of process systems that are otherwise difficult to optimise using traditional NLP techniques.

## TRUST-REGION FUNNEL METHOD

The general form of the hybrid optimisation problem considered in this work can be expressed as:

$$\min_{w,z} \; f(w,y,z) \tag{1.1}$$

$$s.t.\; h(w,y,z) = 0 \tag{1.2}$$

$$g(w,y,z) \le 0 \tag{1.3}$$

$$y = t(w) \tag{1.4}$$

where $f$ denotes the objective function, $h$ and $g$ represent equality and inequality constraints, and $t(w)$ is the rigorous (truth) model describing external black-box components. The functions $f, g$ and $h$ are assumed twice continuously differentiable. The variables $w$ correspond to the inputs of the truth model, $y$ are the associated external model outputs, and $z$ denotes the remaining variables.

### Trust-Region Subproblem

Trust-region methods iteratively solve a trust-region subproblem (TRSP) by replacing the truth model with a reduced model (RM). The RM is constructed to be sufficiently accurate within a neighbourhood of the current iterate, satisfying the $\kappa$-fully linear property as defined in [8]. The TRSP at iteration $k$ is formulated as:

$$\min_{w,z} \; f(x) \tag{2.1}$$

$$s.t.\; h(x) = 0 \tag{2.2}$$

$$g(x) \le 0 \tag{2.3}$$

$$y = r_k(w) \tag{2.4}$$

$$\|u - u_k\| \le \Delta_k \tag{2.5}$$

where $x = [w,y,z]^T, r_k(w)$ denotes the RM at iteration $k, u$ is a selected sub-vector from the variable vector $v = [w,z]^T$ that represents independent variables, $u_k$ is the current base point, and $\Delta_k$ is the trust-region radius. The trust-region constraint restricts the step size in $u$ to ensure that the RM provides a sufficiently accurate approximation of the truth model within the trust-region.

### Reduced Model Construction

To enforce local consistency between the reduced and truth models, zero- and first-order correction terms are introduced whenever derivative information from the truth model is available or can be approximated. In this work, the RM is constructed as:

$$r_k(w) = \tilde{r}(w) + \big(t(w_k) - \tilde{r}(w_k)\big) + (\nabla t(w_k) - \nabla \tilde{r}(w_k))^T (w - w_k) \tag{3}$$

where $\tilde{r}(w)$ is a basis (or base surrogate model). In the present case study, $\tilde{r}(w) = 0$, such that the RM corresponds to a first-order Taylor approximation of the truth model about the current base point $w_k$. Although convergence guarantees hold for arbitrary choices of $\tilde{r}(w)$, algorithmic performance improves significantly as the accuracy of the $\tilde{r}(w)$ increases.

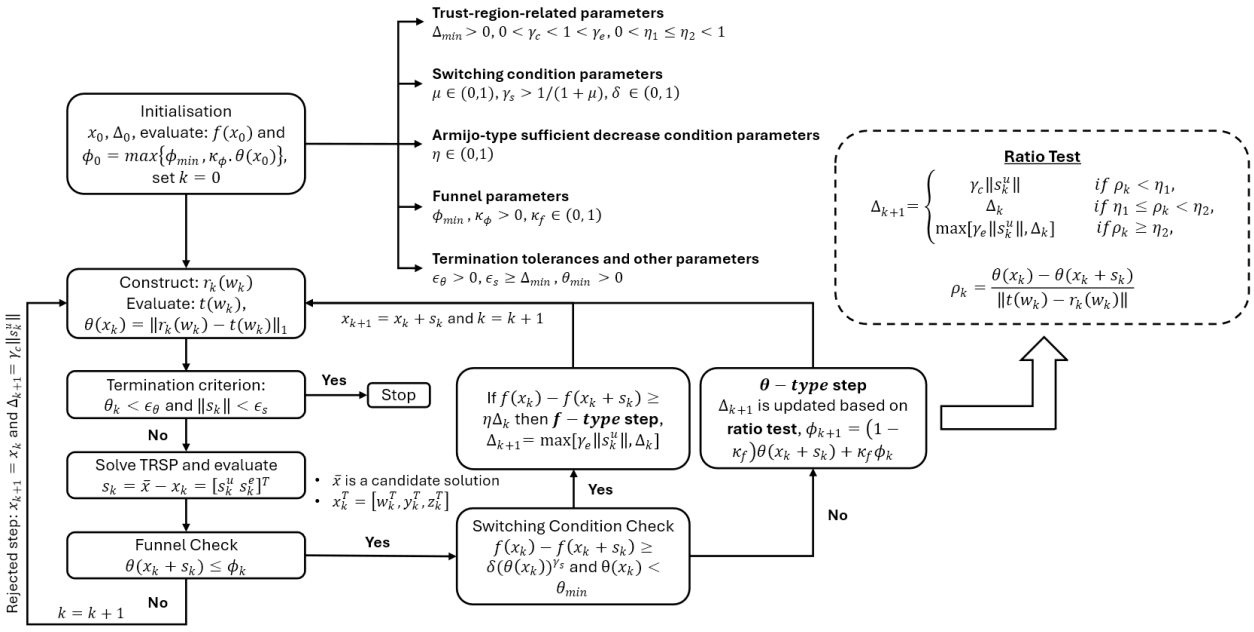

**Figure 1:** Trust-region funnel algorithm.

## Funnel Globalisation Strategy

After solving the TRSP to obtain candidate solutions $w_k^*$ and $z_k^*$, a funnel-based globalisation strategy is applied. The funnel enforces a progressively tightening upper bound $\phi_k$ on the RM approximation error $\theta$, defined as:

$$\theta(w) = \|r(w) - t(w)\|_1. \tag{4}$$

Based on the agreement between predicted and actual reductions in the approximation error, quantified through a ratio test (see Figure 1 for details), and pre-defined funnel acceptance criteria, the trust-region radius is updated, and the candidate iterate is either accepted or rejected.

While the solution of each TRSP primarily targets improvement in the objective function, the funnel systematically drives successive iterates toward feasibility, enabling robust convergence to a locally optimal solution that satisfies first-order optimality conditions [9].

## Algorithm Overview

The TRF algorithm proceeds iteratively as summarised in Figure 1. At initialisation, a base point $x_0$, initial trust-region radius $\Delta_0$, and initial funnel bound $\phi_0 = \max\{\phi_{\min}, \kappa_\phi \cdot \theta(x_0)\}$ are set. At each iteration $k$, the reduced model $r_k(w_k)$ is constructed as per Equation (3) and the truth/rigorous model $t(w_k)$ is evaluated to compute the approximation error $\theta(x_k) = \| r_k(w_k) - t(w_k) \|_1$. If the termination criteria $\theta_k < \varepsilon_\theta$ and $\| s_k \| < \varepsilon_s$ are satisfied, the algorithm stops. Otherwise, the TRSP defined in Equations (2.1)-(2.5) is solved to compute a candidate step $s_k = [s_k^u, s_k^z]^T$, where superscripts $u$ and $z$ denote subvectors of the decision variables and the remaining variables, respectively.

The candidate iterate is then assessed through various sequential checks. First, a funnel check determines whether $\theta(x_k + s_k) \leq \phi_k$. If satisfied, a switching condition is evaluated: if sufficient objective reduction is achieved relative to the approximation error (i.e., switching condition) and trust-region size (i.e., Armijo-type sufficient decrease condition), an $f - type$ step is accepted and the trust-region radius is expanded. Otherwise, a $\theta - type$ step is taken, during which the funnel bound is updated as $\phi_{k+1} = (1 - \kappa_f)\theta(x_k + s_k) + \kappa_f \phi_k$, progressively tightening the feasibility envelope, and the trust-region radius is adjusted via the ratio test (as given in Figure 1). If the funnel check fails, the step is rejected and the trust-region radius is contracted.

This structure shares the switching condition and step-type logic of the classical trust-region filter method, but differs fundamentally in the globalisation strategy. The filter maintains an iteratively updated list of pairs $(f, \theta)$ and requires heuristic tuning of various problem-dependent tuning parameters. By contrast, the funnel can be interpreted as a filter with a single entry, i.e., the funnel width $\phi_k$, updated only during $\theta - type$ iterations and initialised from $\theta(x_0)$ using a problem-independent parameter $\kappa_\phi$. This eliminates the need to maintain non-dominated $(f, \theta)$ pairs or tune sensitive filter parameters, offering a key practical advantage. Importantly, this structural similarity enables convergence guarantees for the TRF method to be derived directly from trust-region filter theory [10].

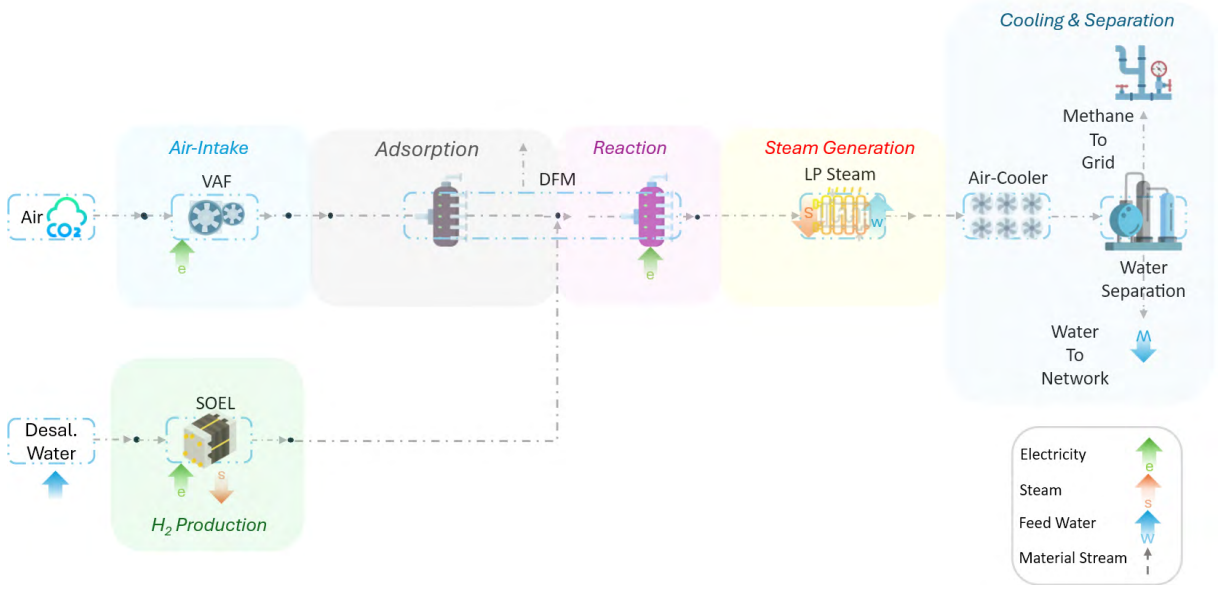

**Figure 2:** DFM DAC-to-SNG process flowsheet.

## Convergence Guarantees

Under standard regularity assumptions, the proposed TRF method guarantees convergence to a first-order optimal point of the original hybrid optimisation problem, even in the presence of inexact or approximated derivative information from the external model [9][4].

# PROCESS MODELLING

The optimisation objective is to minimise the total annualised cost (TAC) of the integrated process flowsheet shown in Figure 2. TAC accounts for capital and operating expenditures, including equipment sizing, material requirements such as water and DFM, and utility costs. The DAC process is assumed to be located within an industrial plant with access to electricity, cooling water, steam, and a boiler feed water network, ensuring the availability of required utilities. The mathematical models for the process units are adapted from [6][7].

## Process Description

As illustrated in Figure 2, ambient air is introduced into the $CO_2$ capture unit via a vane axial fan (VAF) and directed into columns containing large tubes packed with honeycomb-shaped monoliths. These monolithic structures are coated with DFM, which facilitates $CO_2$ adsorption during the adsorption phase as the air stream passes through the monolith channels. The DFM formulation used in this study, $Ni^{(15\%)}Ru^{(1\%)}Na_2O^{(10\%)}/CeO_2$–$\gamma$ $Al_2O_3^{(74\%)}$, is based on published works [11][7]. During this cyclic process, $CO_2$ is captured on the DFM surface, followed by a short nitrogen purge to remove residual gases. Subsequently, a hot hydrogen stream at 350 °C, supplied by SOELs, is introduced to hydrogenate the adsorbed $CO_2$ in situ, producing methane. A final purge completes the cycle before repetition. All electrolysers operate at atmospheric pressure with 100% stoichiometric conversion of desalinated water to $H_2$ and $O_2$, simplifying the model by omitting downstream separation.

The hot gas generated during the cyclic operation is utilised in steam generators to produce low-pressure (LP) steam for export or internal heat integration. After heat recovery, the process stream is trim cooled using an air-cooler and directed to a flash drum for water removal. The resulting gas mixture primarily consists of methane, with residual amounts of water vapour, $CO_2$, and hydrogen. During high-conversion operation, unreacted hydrogen is minimal; however, when excess hydrogen is employed for temperature control or enhanced heat recovery, pressure swing adsorption (PSA) may be used for hydrogen recovery and recycle.

## Reactor Modelling

The DFM reactor is modelled as a multi-output external black-box component within the nonlinear optimisation formulation of the flowsheet. Although the DFM model is equation-based, consisting of a coupled system of nonlinear algebraic equations that describe adsorption, hydrogenation, reactor geometry, energy balances, velocity, and pressure drop, its direct inclusion in the EO flowsheet results in non-convergence of classical NLP solvers, even with near-optimal feasible initialisation.

To ensure numerical tractability while preserving model fidelity, the DFM reactor is externalised as a black-box mapping, which returns product compositions and energy requirements as functions of the operating

conditions. The surrounding process flowsheet is formulated in Pyomo, and the TRSPs are solved using IPOPT.

## RESULTS AND DISCUSSION

The case study considers a techno-economic optimisation of a DAC-DFM flowsheet designed to capture 10, 000 tonnes of $CO_2$ per year, consistent with recently reported industrial-scale benchmarks [6][7]. The proposed TRF framework successfully converged to a first-order stationary point in 38 iterations, as shown in Figure 3, which summarises the solver's performance.

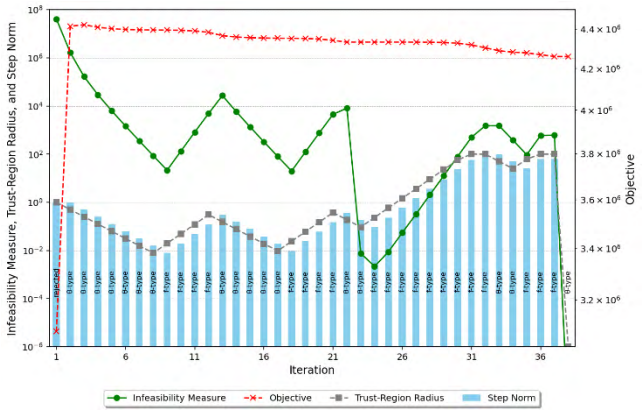

**Figure 3.** Performance metrics for the TRF solver.

### Comparison of Optimisation Approaches

Key process metrics are summarised in Table 1, with an aggregated cost comparison presented in Figure 4. The study evaluates three optimisation approaches.

- The first approach uses a mixed-integer nonlinear programming (MINLP) formulation, where the DFM route, adsorbent mass, and adsorption time were fixed a priori [7].
- The second (direct NLP) optimisation approach converts the published MINLP flowsheet [7] to an NLP formulation while retaining fixed DFM weight and adsorption time to ensure solver convergence.

In the third (TRF-based grey-box) optimisation approach, the DFM reactor is treated as an external multi-output model, allowing both adsorbent weight and adsorption time to vary as decision variables.

As illustrated in Figure 4, the TRF framework achieves reduction in TAC compared to both the published MINLP and direct NLP solutions. While the published and direct NLP cases yield nearly identical results due to their fixed DFM design assumptions, the TRF solution reduces TAC by ~8%, demonstrating the economic benefits of relaxing restrictive design assumptions. The lower TAC is due to lower capital costs, while operational expenditures and revenues are observed to be similar for all optimisation approaches.

The observed improvement primarily stems from the optimisation of the adsorption–reaction unit design. Under the TRF framework, the number of DFM units per train is reduced from 16 to 6, while individual unit size and channel velocity are increased by ~2.9 and ~3.5 times, respectively. Adsorption time is also reduced from 1000 seconds to 626 seconds. These changes lead to a ~6% reduction in adsorbent weight and a corresponding ~23% decrease in DFM capital cost, without compromising capture targets or pressure-drop constraints. Note that the expensive catalyst sites in DFM reactor, particularly Ruthenium, result in significant capital expenditure in all optimisation approaches [7].

These results highlight a fundamentally different trade-off between reactor parallelisation (i.e., monolithic design), adsorption time, and adsorbent weight, systematically identified by the TRF algorithm. Unlike traditional approaches that rely on conservative over-design with multiple small parallel units, the TRF optimiser favours fewer, larger units operating at higher velocities and shorter cycle times. This design strategy reduces both equipment count and adsorbent inventory while maintaining overall process performance.

### Economic and Practical Implications

This study illustrates that the algorithmic structure decisively influences not only whether a solution can be obtained but also its qualitative characteristics. By removing restrictive design and operational assumptions, imposed purely for numerical convenience, TRF method enables a faithful exploration of techno-economic search space and unlocks economically better designs, which is critical for emerging CCU and PtG systems to remain competitive. These systems inherently involve cyclic operation, strong nonlinear coupling, and implicit model formulations.

## CONCLUSION

This study demonstrates the effectiveness of the proposed TRF framework for optimising hybrid glass-box/black-box models in large-scale CCU processes, applied to a SNG production process integrating DAC and catalytic $CO_2$ conversion via DFM technology. The TRF method reduced TAC from 4.6 million USD to 4.26 million USD, achieving an ~8% decrease in the cost per tonne of captured $CO_2$. Key design improvements include reducing the number of DFM units per train (16 to 6), increasing unit size (22 $m^3$ to 63 $m^3$), and decreasing total adsorbent weight (28, 350 kg to 26, 678 kg), resulting in a 22% reduction in DFM capital costs. These results highlight the TRF framework's ability to overcome numerical challenges and deliver economically superior designs compared to traditional NLP/MINLP approaches. Future research will focus on embedding DFM reactor simulations based on partial differential equations within EO flowsheets to explore reactor dynamics and their interactions with the process. Moreover, integrating PSA as a downstream black-box unit can enable hydrogen recovery and recycling for enhanced process efficiency.

## ABSTRACT

Addressing the urgent transition to low-carbon energy systems requires microgrids capable of locally coordinating electricity generation, storage, and flexible consumption. Their efficient integration calls for control strategies that are scalable, privacy-preserving, and robust to uncertainty. To address such a challenging control problem, this work proposes a decentralised Multi-Agent Reinforcement Learning (MARL) approach based on the Cross-Entropy Method (CEM) for the coordination of prosumers, equipped with renewable generation and vehicle-to-grid capabilities. To improve sample efficiency and robustness, the policy is warm-started using Behaviour Cloning (BC) from a classical Proportional-Integral-Derivative (PID) controller, resulting in a hybrid BC–CEM framework. The proposed method is evaluated in a realistic microgrid simulation with stochastic demand and real weather and generation profiles. Results show that BC–CEM accelerates convergence and achieves lower energy costs compared to both PID control and randomly initialized CEM, without sacrificing comfort or mobility requirements. The findings highlight the effectiveness of combining derivative-free optimization with imitation learning in complex MARL tasks, such as energy flexibility coordination.

**Keywords**: Reinforcement Learning, Behavioral Cloning, Derivative-Free Optimization, Machine Learning, Energy Management

## INTRODUCTION

Distributed Energy Resources (DERs) such as rooftop solar panels or batteries empower households to act as prosumers, simultaneously generating and consuming electricity within the energy system. By producing their own electricity from renewable sources close to the point of use, DERs contribute to decarbonisation, improve grid resilience to disturbances, and reduce energy costs for end users [1]. Still, their efficient integration requires advanced control systems, capable of handling the stochastic, high-dimensional, and dynamic nature of these environments.

Although classical mathematical programming techniques provide reliable solutions with optimality guarantees, their applicability in real-life settings is limited, as their centralized formulations may raise privacy concerns, are computationally expensive and require decisions to be computed over the whole planning horizon upfront [2]. The dynamic adaptability of model predictive control (MPC) has motivated its application to DER optimization, but its performance is strongly dependent on the accuracy of the system model and shares computational intractability of classical optimization methods [3].

In this context, Reinforcement Learning (RL) has emerged as a powerful data-driven alternative to traditional control strategies. MARL in particular provides a promising framework for distributed autonomous energy management, as it allows multiple agents to cooperate and facilitates decentralized learning through experience-based optimization [4].

A wide range of approaches have been investigated in the literature. Value-based methods have been proven effective in microgrid coordination [5], but struggle with large continuous action spaces. Policy-based deep RL

algorithms, overcome this limitation and have broadened the applicability of RL to energy management problems [6, 7]. More recently, attention mechanisms have been incorporated into MARL architectures to further improve scalability in complex energy systems [8].

Despite these advances, exiting literature relies mostly on gradient-based optimisation techniques, which typically require extensive exploration and are highly sensitive to hyperparameter tuning. Ji et al. address these challenges by integrating evolutionary strategies in the MARL framework [9], but few studies explore the integration of expert knowledge in this context, despite their success in other control domains [10].

These gaps motivate the proposed hybrid Behaviour Cloning and Cross-Entropy Method (BC–CEM) approach for energy coordination in residential microgrids.

# BACKGROUND

## Reinforcement Learning

RL addresses sequential decision-making problems, modelled as Markov Decision Processes (MDPs), due to its inherent trial-and-error approach. In RL, an agent is defined as a system which takes a specific action based on information about the environment state that results in a transition of the environment to a new state. The goal is to find the policy, i.e., a mapping of states to actions, that maximises the expected cumulative reward over an episode.

In scenarios where multiple entities interact concurrently within a shared environment, agents are typically constrained in their capacity to observe the state of the environment, thereby restricting their ability to make informed decisions, which are based solely on local observations. MARL formalizes such problems as Decentralised Partially Observable MDPs (Dec-POMDPs), enabling each agent to learn autonomously, whilst adapting to other agents' behaviour. Additional challenges include non-stationarity induced by simultaneously learning agents, scalability with increasing agents, and the difficulty of credit assignment when global rewards are used.

Despite the decentralised nature of policy execution, the training process can follow centralized or independent paradigms. In centralized training, agents learn decentralized policies that are assessed by a centralized critic, typically a learned value function, which evaluates agents' actions based on global information about the environment state. Conversely, independent learning treats other agents as part of the environment, with each agent learning to make individual decisions that collectively maximize the global objective.

In energy microgrids, where households must make local control decisions under uncertainty and with limited information sharing, MARL provides a natural solution approach.

## Evolutionary strategies in RL

Evolutionary Strategies (ES) are a class of derivative-free optimization algorithms inspired by biological evolution. Policy parameters are optimized by iteratively sampling a population of policies and recombining the most successful individuals to form the subsequent generation of candidate solutions.

Recent studies have evidenced ES can be competitive with gradient-based RL methods in complex control tasks [9, 10]. Moreover, their advantages are particularly attractive in MARL applications for energy systems given their simple implementation (no backpropagation necessary), resilience to highly stochastic or sparse rewards, and improved credit allocation for long-term horizons or when reliable value estimates are unavailable [11].

# SYSTEM DESCRIPTION

## Environment

The environment considered in this work models a microgrid of prosumers, equipped with photovoltaic panels (PV) and vehicle-to-grid (V2G) technologies, as depicted in **Figure 1**. Though adapted from Charbonnier et al. [5, 7], our implementation differs on action handling and data sampling procedures.

Each prosumer is considered an autonomous agent in a multi-agent framework. The environment operates with hourly time steps $t \in T$ over a 24-hour horizon. PV generation and electricity demands are stochastic, reflecting realistic weather conditions and user behavior. The goal is that each prosumer $p$ learns a cost optimal energy management policy $\pi_\theta$ whilst ensuring comfort and mobility needs.

Only the core equations are reported in this section. For the full mathematical description, the reader is referred to the original formulation [5, 7].

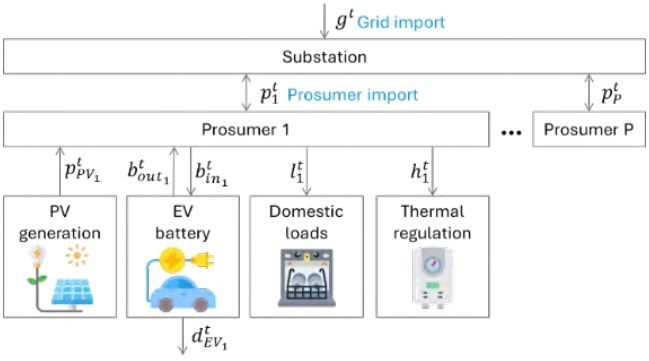

**Figure 1.** Microgrid of prosumers

## Objective

The task is formulated as a multi-objective optimization problem. The primary objective is to minimize total

operational costs $c^t$ according to Eq. 1:

$$c^t = C_g^t(g^t + \epsilon_g^t) + C_d \sum_p max(0, -p_p^t) + C_s \sum_p (b_{in_p}^t + b_{out_p}^t) \quad (1)$$

$C_g^t, C_d$, and $C_s$denote cost coefficients for energy imports, exports, and battery depreciation. Battery charge and discharge flows are represented by $b_{in}$and $b_{out}$, while $p$ and $g$ denote household-level and aggregate energy imports, with $\epsilon_g$ accounting for grid losses.

The maintenance of thermal comfort and sufficient battery levels to ensure mobility are imposed as soft constraints or penalties added to the economic objective.

## Constraints

Home-level constraints determine the energy to be imported and exported, as well as the evolution of the system state. Thus, power, battery state of charge (SoC) and demand balances are enforced in the environment as hard constraints. Energy flows are expressed in kWh and temperatures in °C.

## Power balance

$$p_p^t = l_p^t + h_p^t + {b_{in_p}}^t \eta_{ch} - \eta_{dis} {b_{out_p}}^t - p_{PV_p}^t \quad (2)$$

where $l_p^t$ and $h_p^t$ are domestic and heating loads, $\eta_{ch}, \eta_{dis}$ are battery efficiencies, and $p_{p,t}^{PV}$ is PV generation.

## Battery energy balance

$$E_p^{t+1} = E_p^t + {b_{in_p}}^t - {b_{out_p}}^t - d_{EV_p}^t \quad (3)$$

$$\mu_p^t \underline{E} \le E_p^t \le \mu_p^t \bar{E} \quad (4)$$

with EV demand $d_{EV_p}^t$, battery SoC bounds $\underline{E}$ and $\bar{E}$, and $\mu_p^t$ being a binary variable that equals 1 if EV is plugged and 0 otherwise.

## Battery charge/discharge constraints

$${b_{in_p}}^t \le \mu_p^t \overline{b_{in}} \; ; \; {b_{out_p}}^t \le \mu_p^t \overline{b_{out}} \quad (5)$$

where $\overline{b_{in}}$ and $\overline{b_{out}}$ are maximum charge and discharge rates.

## Thermal model

$$\begin{bmatrix} BMT_p^{t+1} \\ IAT_p^{t+1} \end{bmatrix} = \kappa \left[1, BMT_p^t, IAT_p^t, \phi_p^t, h_p^t\right] \quad (6)$$

where $BMT_p^t$ and $IAT_p^t$ denote building mass and indoor temperatures, $\phi_p^t$ is the solar radiation and $\kappa$ is a coefficient matrix, as defined in [5].

## Consumption flexibility

$$\sum_{t_C \in T} \hat{l}_{p,k,t_C,t_D} f_{p,k,t_C,t_D} = d_{p,k}^{t_D} \quad (7)$$

$$\sum_{t_D \in N_{flex}} \hat{l}_{p,k,t_C,t_D} f_{p,k,t_C,t_D} = l_{p,k}^{t_C} \quad (8)$$

where $\hat{l}_{p,k,t_C,t_D}$ is the fraction of domestic loads $d_{p,k}^{t_D}$ of type $k$ (flexible or fixed) requested at $t_D$ and served at $t_C$. Flexible loads can be delayed up to $n_{flex}$ time steps, and $f_{p,k,t_C,t_D} = 1$ if $t_D \le t_C \le t_D + n_{flex}$.

## Action translation

At each time step, prosumers select three actions:

1. **Battery action** $a_b \in [-1, 1]$ controls actual battery charge $b_{in}$ and discharge $b_{out}$ flows according to Eq. 9, where maximum feasible amounts of charge $\Delta E^+$ and discharge $\Delta E^-$ and are derived from Eq. 3 to 5.

$$\begin{aligned} {b_{in_p}}^t &= a_{b_p}^t \Delta E^+ \; ; \; {b_{out_p}}^t = 0 \quad a_{b_p}^t < 0 \\ {b_{out_p}}^t &= a_{b_p}^t \Delta E^- \; ; \; {b_{in_p}}^t = 0 \quad a_{b_p}^t > 0 \end{aligned} \quad (9)$$

2. **Thermal action** $a_h \in [-1, 1]$ regulates the electricity consumed by a heat pump $h_p^t$ for heating/cooling, relative to its rated power $P_{max}$ and coefficient of performance $COP$.

$$h_p^t = \left| a_{h_p}^t P_{max} \right| / COP \quad (10)$$

3. **Consumption action** $a_c \in [0, 1]$ determines the fraction of deferrable loads $l_{flex}$, within feasible bounds $[\underline{l}_{flex}, \bar{l}_{flex}]$ obtained from Eq. 7 and 8, to be satisfied at each time step $t$.

$$l_{p,flex}^t = \underline{l}_{p,flex}^t + a_{c_p}^t (\bar{l}_{p,flex}^t - \underline{l}_{p,flex}^t) \quad (11)$$

## Policy network

The policy network outputs the mean and standard deviation of Gaussian distributions based on local observations, consisting of a window of $\Delta t$ time steps of battery level, temperature measurements, PV generation and flexible loads, along with temporal features. As outlined in **Figure 2**, observations are normalized before being fed to the network.

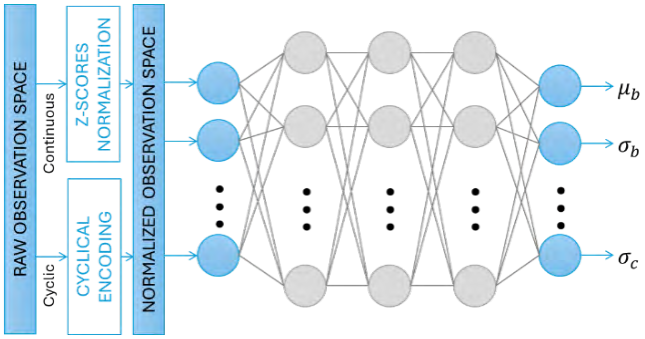

**Figure 2.** Forward pass of the policy network

# METHODOLOGY

Cross-Entropy Method (CEM) is a stochastic, derivative-free optimization algorithm used to train a policy network $\pi_\theta$ by maximising the expected episode return

$J(\theta)$ [12], evaluated running $n_r$ Monte Carlo rollouts:

$$J(\theta) = E_{\tau\sim\pi_\theta}\left[\sum_{t=0}^{T-1} r^t\right] \approx \frac{1}{n_r}\sum_{m=1}^{n_r}\sum_{t=0}^{T-1} r_m^t \quad (12)$$

Each iteration $k$ starts by sampling a random population of $n_c$ candidate parameter vectors $\Theta = \{\theta_i\}_{i=1}^{n_c}$:

$$\theta_i \sim \mathcal{N}\left(\boldsymbol{\mu}_k, \mathrm{diag}\left(\boldsymbol{\sigma}_k^2\right)\right), i = 1, \ldots, n_c \quad (13)$$

These candidates are ranked according to their returns, and the top $(1-\rho)$-quantile is selected as the elite set $\mathcal{E}_\rho$, defined by the return threshold $\gamma$:

$$\mathcal{E}_\rho = \{\theta \in \Theta | J(\theta) \geq \gamma\} \quad (14)$$

The sampling distribution is updated to increase the likelihood of producing the elite following Eq. 15 and 16.

$$\boldsymbol{\mu}_{k+1} = \alpha_\mu \boldsymbol{\mu}_k + (1-\alpha_\mu)\boldsymbol{\mu}_{\mathbf{elite}} \quad (15)$$

$$\boldsymbol{\sigma}_{k+1} = \alpha_\sigma \boldsymbol{\sigma}_k + (1-\alpha_\sigma)\boldsymbol{\sigma}_{\mathbf{elite}} \quad (16)$$

where $\boldsymbol{\mu}_{\mathbf{elite}}$ and $\boldsymbol{\sigma}_{\mathbf{elite}}$ denote the per-parameter mean and standard deviation of the elite set, and $\alpha_\mu, \alpha_\sigma \in [0,1]$ are smoothing factors.

These steps are iterated and eventually yield an improved distribution over the parameter space. The best-performing candidate encountered during optimisation is retained.

While CEM evaluates a population of policies per iteration, its high degree of parallelization and absence of gradient estimation make it computationally attractive for stochastic, non-stationary MARL problems. Notwithstanding, in high-dimensional parameter spaces, vanilla CEM may require extensive exploration and is susceptible to premature convergence to local optima [13], motivating its combination with imitation learning.

Behavior Cloning (BC) is a supervised learning approach where agents learn to mimic expert demonstrations [14]. In this work, a PID controller is rolled out $n_{BC}$ episodes to collect a dataset $\mathcal{D} = \left\{\left(s^{(i)}, a^{(i)}\right)\right\}_{i=1}^{n_{BC}}$. The policy network is then pretrained for a single agent and the optimal weights returned by Eq. 17 are used to initialize the policies of all agents during CEM execution in a favourable region of the parameter space, thus, reducing exploration requirements during CEM phase.

$$\theta_0 \in \underset{\theta}{\mathrm{argmin}} \frac{1}{|\mathcal{D}|}\sum_{(s,a)\in\mathcal{D}} \|\pi_\theta(\boldsymbol{s}) - \boldsymbol{a}\|_2^2 \quad (17)$$

The pseudocode of the BC-CEM strategy is given in **Table 1**. It is worth noting that we opted for an independent learning approach, i.e., CEM is applied per-agent, so that each one learns its own optimal parameter vector $\boldsymbol{\theta}_\mathbf{p}^*$. However, agent returns are computed considering the joint action.

**Table 1:** BC-CEM algorithm

**Input:** $\mathcal{D}$: expert trajectory dataset; $n_c$: number of candidates; $\rho$: elite quantile; $\alpha_\mu, \alpha_\sigma$: mean and standard deviation update smoothing factors; $\sigma_0$: initial standard deviation; $K$: iterations
**Output**: Optimal multi-agent policy parameters $\boldsymbol{\theta}^*$
**Initialization**:
$\boldsymbol{\mu}_0^p \leftarrow$ Eq. 17; $\boldsymbol{\sigma}_0^p \leftarrow \boldsymbol{\sigma}_0$
$J_p^* \leftarrow -\infty$ ; $\boldsymbol{\theta}_p^* \leftarrow \boldsymbol{\mu}_0$
**for** $k$ in $\{1, \ldots, K\}$ **do**
  **for** $p$ in $1, \ldots, n_p$ **do**
    **for** $i$ in $1, \ldots, n_c$ **do**
      $\boldsymbol{\theta}_i^p \leftarrow$ Eq. 13
    **end**
  **end**
  **for** $i$ in $1, \ldots, n_c$ **do**
    $J\left(\left\{\boldsymbol{\theta}_i^p\right\}_{p=1}^P\right) \leftarrow$ Eq. 12
  **end**
  **for** $p$ in $1, \ldots, P$ **do**
    $\mathcal{E}_\rho^p \leftarrow$ Eq. 14
    $\boldsymbol{\mu}_{\mathbf{elite}}^p \leftarrow \frac{1}{|\mathcal{E}_\rho^p|}\sum_{i\,\epsilon\,\mathcal{E}_\rho^p} \boldsymbol{\theta}_i^p$ ; $\boldsymbol{\sigma}_{\mathbf{elite}}^p \leftarrow \sqrt{\frac{\sum_{i\,\epsilon\,\mathcal{E}_\rho^p}\left(\boldsymbol{\theta}_i^p - \boldsymbol{\mu}_{\mathbf{elite}}^p\right)^2}{|\mathcal{E}_\rho^p|}}$
    $\boldsymbol{\mu}_{k+1}^p \leftarrow$ Eq. 15; $\boldsymbol{\sigma}_{k+1}^p \leftarrow$ Eq. 16
    **if** $J\left(\boldsymbol{\mu}_{\mathbf{elite}}^p\right) > J_p^*$ **then**:
      $J_p^* \leftarrow J\left(\boldsymbol{\mu}_{\mathbf{elite}}^p\right)$ ; $\boldsymbol{\theta}_p^* \leftarrow \boldsymbol{\mu}_{\mathbf{elite}}^p$
    **end**
  **end**
**end**

**Table 2:** Hyperparameter set-up for BC-CEM algorithm

| Hyerparameter | Value |
|---|---|
| $n_c$ | 100 |
| $\rho$ | 0.1 |
| $\alpha_\mu$ | 0.7 |
| $\alpha_\sigma$ | 0.5 |
| $\sigma_0$ | 0.01 |
| $n_r$ | 50 |

## RESULTS AND ANALYSIS

### Computational implementation

The training was conducted on a Windows 64-bit computer with an Intel i7-14700K CPU at 3.4 GHz and an NVIDIA GeForce RTX 5080 GPU, requiring 215 minutes (wall-clock) to complete $K = 250$ iterations and coordinate $P = 10$ prosumers. The hyperparameters used to run the training process (**Table 2**) were tuned through Bayesian optimization to maximize performance.

All agents share a common policy architecture, modelled as a three-layer feed-forward network with

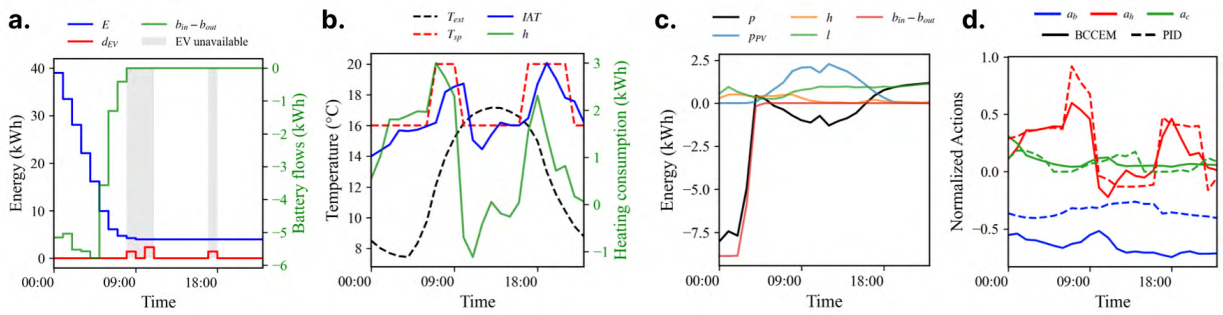

**Figure 3.** Example day representation of energy flows (a), battery SoC evolution (b), temperature evolution (c) and

structure [128, 128, 64] and ELU activations. Inputs concatenate $\Delta t = 3$ time steps of local observation history.Training

**Figure 3** illustrates the evolution of the aggregate episode return $J(\mu_{elite})$ across agents during training, confirming the capacity of CEM to learn effective control policies despite the high stochasticity of the energy system environment.

Plus, it highlights the benefits of BC warm-starts. Agents initialized with expert demonstrations require fewer samples to reach high-performing solutions and consistently achieve higher returns for the same training budget compared to random initialisation.

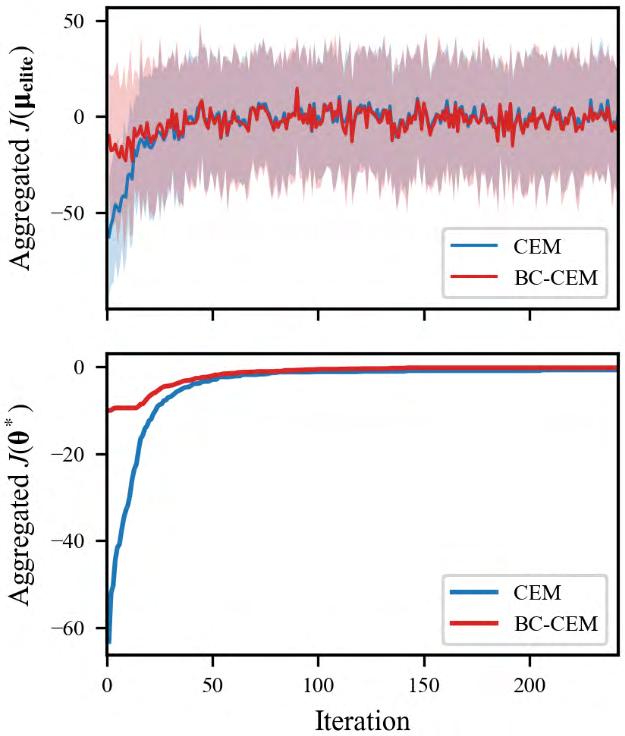

**Figure 4.** Learning curves for CEM and BC-CEM

## Performance assessment

The learned policies are tested on a set of 200 episodes not seen during training, and the distribution of undiscounted episode returns is presented in **Figure 4**.

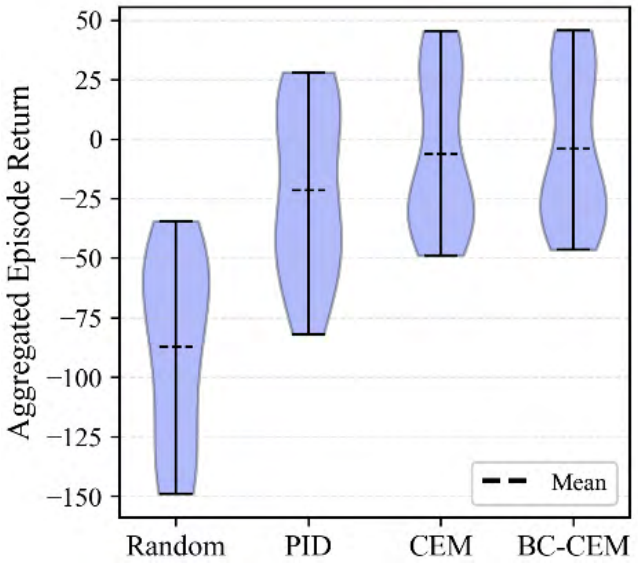

**Figure 5.** Violin plots of episode returns

Our approach outperforms the PID controller, as evidenced by a higher mean return. Quantitative results reported in **Table 3** further corroborate this result. BC–CEM achieves an average cost reduction of 180% relative to the PID baseline, while maintaining comparable levels of mobility feasibility. Although RL policies prioritise economic performance over thermal comfort, deviations remain limited, corresponding to an average hourly temperature mismatch of approximately 0.5 °C per prosumer

**Table 3:** Mean daily results for a 10-prosumer microgrid

| | PID | CEM | BC-CEM |
|---|---|---|---|
| Total daily cost (£) | 17.2 | -12.4 | -13.9 |
| Comfort deviation (°C) | 21.4 | 134 | 133 |
| Battery SoC deficit (kWh) | 1.41 | 1.58 | 1.42 |

Finally, a representative example day is illustrated in **Figure 5a-c**, whereas **Figure 5d** compares the actions suggested by the PID controller with those generated by a BC-CEM agent. While the fine-tuned policies preserve

the smoothness and stability of the PID trajectories, they drive the system towards more cost-optimal behaviour by exploiting flexibility more effectively.

## CONCLUSION

This paper presented a hybrid Behaviour Cloning and Cross-Entropy Method (BC–CEM) approach for decentralised coordination of energy flexibility in residential microgrids. By combining expert demonstrations from classical PID control with derivative-free evolutionary optimisation, this work aggresses training instability under highly stochastic environments and reduces reliance on complex optimization pipelines and hyperparameter tuning. Numerical results in a microgrid environment reflecting realistic consumption patters and leveraging real climate data demonstrate that BC–CEM accelerates convergence and achieves lower operational costs compared to both PID control and vanilla CEM, while maintaining comparable comfort and mobility constraints. These findings highlight the benefits of integrating strong control priors with evolutionary strategies for scalable and robust energy management.

Future work will investigate scalability to larger agent populations, the incorporation of recurrent architectures to better exploit temporal dependencies, the impact of feature engineering on learning performance, the application of constrained reinforcement learning to eliminate residual constraint violations or the use of centralized training with decentralized execution MARL paradigms.

## ABSTRACT

This paper examines the mutually beneficial relationship between biomimetics and modelling and simulation tools, showing how each can enhance the other. Through a literature review and a detailed use case on anaerobic digestion, the study highlights how the complexity, multiscale organisation, and functional richness of biological systems challenge current modelling capabilities. By analysing the contributions of modelling and simulation to product development, such as early performance validation, rapid and low-cost iteration, and multicriteria evaluation, the paper questions whether integrating modelling and simulation tools to biomimetics would bring similar benefits to the design process. Several hypotheses are formulated regarding the potential contributions of modelling and simulation to biomimetics, particularly the improvement of biological system understanding through advanced visualisation and the assessment of functional viability using parametric modelling. Integrating such tools into biomimetics is envisioned as a means to reinforce the existing methodology, support more reliable principle transfer, and facilitate the wider adoption of biomimetics as a problem-solving design approach, ultimately promoting the emergence of biomimetic innovations across diverse applications.

**Keywords**: Biosystems, Modelling and Simulations, Multiscale Modelling, Process Design, Natural Gas

## INTRODUCTION

The integration of modelling and simulation tools into product design and development processes has been widely recognized as a key enabler of reduced time-to-market, increased product complexity, and early validation of performance, safety, and fault tolerance [1]. Simulations allow engineers to rapidly and accurately understand physical behaviours before building physical prototypes, supporting a "learn-before-doing" approach that enhances design efficiency [2]. Beyond accelerating learning, simulation-based approaches enable designers to consider technological, economic, and logistic criteria in parallel, helping identify feasible design alternatives and suitable process plans [3]. Such tools support the design of complex, multidisciplinary systems, facilitate experimentation with technology integration, reduce physical prototyping costs, and promote collaboration among engineering teams [2, 4].

Recent decades have witnessed exponential growth in both numerical computational capabilities and advanced manufacturing technologies. Indeed, the improvements in computing power led to strong progression in the capacity to simulate, model, and forecast intricate systems and processes [5]. Manufacturing technologies have evolved from primarily subtractive processes to include sophisticated additive techniques capable of producing geometries with internal features, gradient materials, and hierarchical structures, previously impossible to fabricate [6]. This convergence of computational and manufacturing capabilities seems to have induced a shift in engineering design, from "what can do" to "what should we do" [7]. In other words, from "what can we feasibly produce given our constraints?" to "what should we create to best meet our objectives?". Technological ceilings have been pushed further, thus opening

the door to design spaces that were previously inaccessible. A next step could be in the remoulding of design approaches from the current top-down approach to a bottom-up one, so true hierarchical structural design of multifunctional materials and products could be achieved. The bottom-up approach is notably observed in nature and living systems. There is a design process, named biomimetics, that is the practice of mimicking biological strategies to fix practical problems in human activities (ISO 18458:2015). Biomimetics offers a compelling framework for the development and improvement of modelling and simulation tools, as biological organisms embody complex, multiscale, and multifunctional systems, difficult to replicate or to model accurately [5, 8].

Drawing on both a literature review and the analysis of a use case on anaerobic digestion, this work aims to highlight the mutually beneficial relationship between modelling and simulation tools and biomimetics. The objective is twofold: first, to explain how biomimetics can drive advancements in modelling and simulation; and second, to explore how these tools, in turn, can enhance the biomimetic design process. To address this objective, the first part outlines the biomimetic approach and summarises its relevance supported by literature for modelling and simulation tools. The second part introduces the anaerobic digestion use case, which examines the relevance in a practical context.

# STATE OF THE ART

## Biomimetics, a branch of design

Biomimetics, or bio-inspired design (BID) is a subset of design sciences, from which it borrows its procedural structure. Two methodological paradigms predominate in BID. The first, known as 'problem-driven', begins with the identification of opportunities and needs. The aim is to search for solutions to a specific technical problem in the living world. The second, known as 'solution-based', starts from an already identified biological mechanism for which potential technical applications are sought [9].

To illustrate this methodological dichotomy, the example of aerodynamic devices at the tips of aeroplane wings (winglets) can be considered. Inspired by the flexible feathers of large birds of prey, these elements significantly reduce the aerodynamic drag of the aircraft, thereby optimising its performance and reducing its energy consumption. This innovation perfectly exemplifies the 'problem-driven' approach, where a specific technical issue has guided research towards an analogous biological solution. Conversely, the mechanism by which burdock seeds attach themselves illustrates the 'solution-based' approach. This plant, commonly found in meadows, uses zoochory as a dispersal strategy, exploiting the passage of animals to passively transport its seeds to new territories. The characteristic hooks on these seeds allow them to adhere effectively to the fur of wildlife, while detaching easily during grooming activities. Georges de Mestral, the inventor of Velcro was inspired by this simple and repeatable hook-and-loop principle to develop a revolutionary fastening system, initially applied to the footwear industry, which has since become a universally adopted product.

These two design pathways are formalised in BID, they answer different stakes, but in themselves are not superior to one another [10].

## Methodological approaches developed

The scientific community has developed various methodological approaches to guide and facilitate the biomimetic process. Zhang identifies three distinct phases in the evolution of these solutions [11]. The first focused on developing generic tools to facilitate the transition between biological and technical fields. The second phase focused on the development of processes and guidelines encompassing the entire biomimetic approach. A third, more contemporary phase focuses on the evolution towards integrated data platforms, with or without the incorporation of artificial intelligence technologies.

The growing interest in integrating advanced digital technologies into biomimetics (digital imaging, parametric design, artificial intelligence…) stems from their ability to facilitate the analysis, emulation, and optimisation of biological structures [12]. The incorporation of these technologies allows iterative feedback loops to be established between the different phases of biomimetic design, simultaneously enriching the design process and the definition of manufacturing requirements [12].

## Biomimetics as a North star

As technological constraints diminish and design possibilities expand, engineering requires guiding principles to direct innovation efforts productively [7]. Biomimetics offers a compelling framework for this purpose.

Biological organisms represent the outcomes of billions of years of evolutionary optimization and adaptability under real-world fluctuating constraints including material availability, energy efficiency, and environmental compatibility [5]. Living systems exhibit remarkable properties achieved through hierarchical structuring, multiscale optimization, and efficient use of available materials [12]. Spider silk, for example, achieves extraordinary tensile strength and toughness through a hierarchical protein structure spanning from the molecular to the fibre scale, with mechanical properties rivalling synthetic high-performance materials despite being produced at ambient temperature and pressure using aqueous processing [13]. This biological example presents both inspiration and technical challenges for engineers. The complexity, multiscale nature, and multifunctionality inherent in biological systems make them difficult to

model accurately with computational tools and challenging to replicate with existing manufacturing processes [8, 14]. However, this difficulty aligns well with the need for ambitious targets that push technological capabilities forward. Biomimetics could thus provide direction for innovation efforts through modelling, simulation and manufacturing, which would stimulate the development of new tools and upgrades [11].

By essence, biomimetics is an interdisciplinary approach. Its integration to modelling and simulation tools would foster the crossing and collaboration of domains, which has been identified as a success factor [15]. Integrating biomimetics to modelling and simulation tools is an opportunity to broaden the problem-solving mindset of engineers [9]. Living principles differ from engineering ones, and so, looking at a problem through a biomimetics lens can sometimes shift perspective and possible solutions on said problem [16].

Another addition to the relevance of biomimetics as a north star for future development in modeling and simulation, is that through biomimetic design, the notions of sustainability, resource efficiency, and environmental compatibility can be accounted for [17]. This is encompassed in the broader term of biomimicry. By essence, a biomimetic product is not intentionally sustainable, but the design process is highly compatible with the inclusion of such factors [18]. This inclusion integrates biomimetic design in the demands set by societal objectives for the environmental transition.

Therefore, biomimetics is an opportunity for the modelling and simulation community to profit from the newly acquired capacities of their tools, and challenge them with the ability to model complex, multiscale, multifunctional systems. Biomimetics also brings an input of interdisciplinarity, and fits well with the consideration of sustainability factors, both essential elements in product design and development.

## MATERIALS AND METHODS

Building on the arguments put forward by the literature in favour of biomimetics for modelling and simulation tools, a use case was set up. The following section presents the materials and methods used in a modelling and simulation-assisted biomimetic approach on the topic of anaerobic digestion (AD).

### Use case presentation

Anaerobic digestion is a biological process in which microorganisms break down organic matter to produce biogas, a renewable energy source [19]. Current digesters offer satisfactory performances, but remain optimisable, as they encounter problems of preferential pathways and dead volume amongst others. On average, 30% of the introduced matter is not recycled in valuable elements [20]. The best digesters (with the strongest yield) are in the living world, in the rumen of bovines. The rumen is a large, pouchlike fermentation chamber, divided into dorsal and ventral sacs by muscular folds. A student project was built around the topic of optimizing the anaerobic digestion process through the development of a biomimetic digester, inspired by the rumen of cows. Students were Master 1 engineering students from UniLaSalle with specialisations raging from geosciences to nutrition, to life-sciences and agronomy. The purpose of the project was to model and run simulations on both the biological model, a rumen, and a biomimetic version of an anaerobic digester, built with the learnings they gathered from the rumen model.

### Use case set up

Students had two weeks to build the models, run the simulations, and come up with a biomimetic digester. Their progression was guided by the design thinking framework. To narrow down the scope of potential upgrades, students were asked to focus on the hydrodynamics, and so mostly worked with Computational Fluid Dynamics (CFD). Modelling was conducted using the Xgenerative design software in the CATIA suite. Simulations were run through Xflow, using the Large Eddy Simulation (LES) approach. The latter was selected for its high accuracy, despite its demand for substantial computational resources. The entry parameter was set to a constant speed, and the exit parameter to atmospheric pressure.

## RESULTS

### Biological model

In the modelling process, students aimed to remain as close as possible to the biological system. The overall shape and architecture were replicated: one big pouch, split into two pockets, dorsal and ventral. Both are visible on the figure below, the dorsal pouch is the top one, and the ventral pouch, the bottom one.

The rumen is submitted to different forces through muscle contraction and movement that aim to move the content of the rumen around (grass and other elements eaten by the animal) so it can be digested by the bacterial mass. These movements also contribute to the physiological regurgitation of nutrition, which can then be chewed and salivated again, an action known as rumination. To model the rumination process, a circulation system was set up, which ensured proper breakdown of solid matter, and prevented congestion in potential dead volumes. Movement is induced through a pump, and reinjection is done by a pipe going from the ventral pouch to the dorsal pouch. The dorsal pouch is where solid matter is broken down and digested. To make sure that the solid matter stayed as long as digested in the dorsal

pouch, and that no amount of it would fall and clog the papillae or the recirculation system in the ventral pouch, a narrow grid was built in. It is only once reduced to particles by the digestate, that former solid matter can fall into the lower pouch.

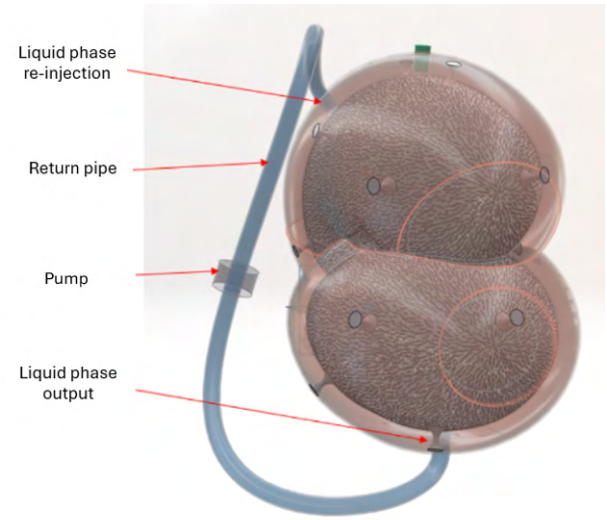

**Figure 1a** Biological model – a rumen

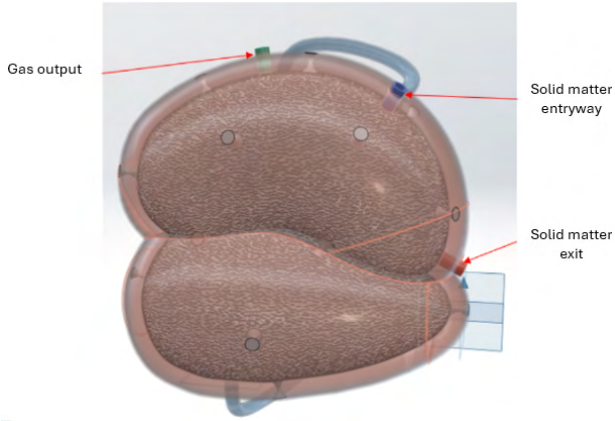

**Figure 1b** Biological model – a rumen

Rumen walls are lined on the inside with shaggy, tongue-like papillae that give it a textured, velvety appearance. Within the mindset of representing all components of the system, to be as reliable as possible in the visual but also functional representation, students integrated inner, smaller-scale structuration into their rendition.

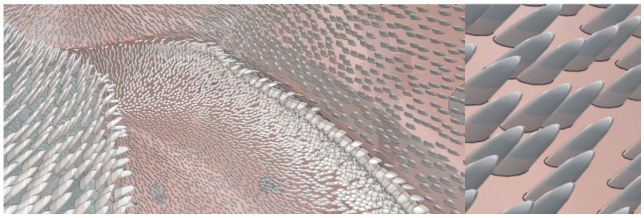

**Figure 2** Inner wall layering in biological model

## Biomimetic model

Anaerobic digestion can follow two main pathways depending on whether the handled feedstock is considered as solid or liquid. Solid-state digestion is built to manage unpumpable, and dry feedstock, where liquid-state digestion handles pumpable, slurry-like feedstock. Students observed CSTR solid and liquid-state digesters as reference systems to design the biomimetic versions. Both are of cylindrical shape, with the addition of a mixer for the liquid-state. Simulations were run to observe matter movement inside of traditional digesters. Below are the simulation results for the solid-state.

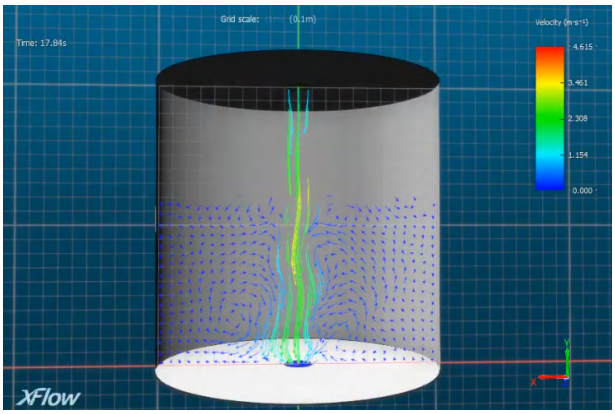

**Figure 3** Solid-state digester fluid dynamic simulation
Color gradient shows fluid velocity in $m.s^{-1}$

Fig. 3 simulates matter movement inside the solid-state digester. The first observation is that there is a definite preferential path to matter movement: a straight line from entry to exit points. The existence of a preferential path in the digester is not a desired effect. Moreover, the path visible here is the most direct one, and carries matter at a high speed (1.15 to 3.40 $m.s^{-1}$) which is not intended. Indeed, the objective is to have sufficient retention time in the digester to allow solid matter exposure with methanogenic bacteria. If the matter tends to go straight from entry to exist, in the fastest way through, retention time is not optimized. Also, if matter follows a preferential path, it means that the matter outside of this path gets stuck, creating dead weight, also an unwanted phenomenon.

Dead volume is the second observation that can be taken from this simulation result. The matter on the left and right of the preferential path moves very little, to not at all. Arrows on the graph do not indicate movement, and if so, only minimal and slow.

As displayed in Fig.4 below, the liquid-state digester also shows subpar fluid dynamics.

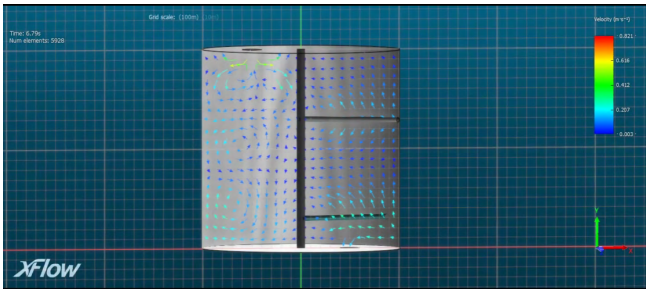

**Figure 4** Liquid-state digester fluid dynamic simulation
Color gradient shows fluid velocity in m.s$^{-1}$

The action of the mixer ensures matter movement around the digester. It appears that matter is pushed around and sped up by the mixer into circle-like pathways. An observation that is worth underlining is that, compared to the solid-state digester, velocity around entry and exit point is not significantly bigger than in the rest of the digester, specifically at the exit point. This leads to wonder if matter is going through. Fig. leaves the question on the recirculation of matter in the digester. In the solid-state digester, the seemingly present issue was of too little retention time, but here, it might be of too big retention time. If feedstock doesn't get though, the bacteria could exhaust the needed molecules for methanogenesis, which would put a halt to production.

Two focus points can be extracted from the analysis of the non-biomimetic digesters: limiting dead volume, and preferential pathways and optimizing retention time.

The goal was then to build a biomimetic digester with improved hydrodynamics to deals with these issues. Students built two different systems for solid-state and liquid-state pathways and ran simulations of internal hydrodynamic flow. For both systems, the shape was designed as rumen-like, with two pockets (dorsal and ventral/upper and lower), and an oval architecture to avoid dead volumes, and allow the entire volume of the digester to be used effectively. Below are the simulation results for the solid-state biomimetic digester.

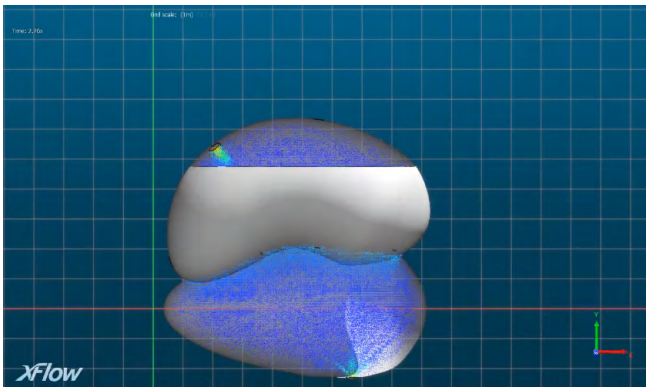

**Figure 5a.** Biomimetic solid-state digester fluid dynamics
Color gradient shows fluid velocity in m.s$^{-1}$

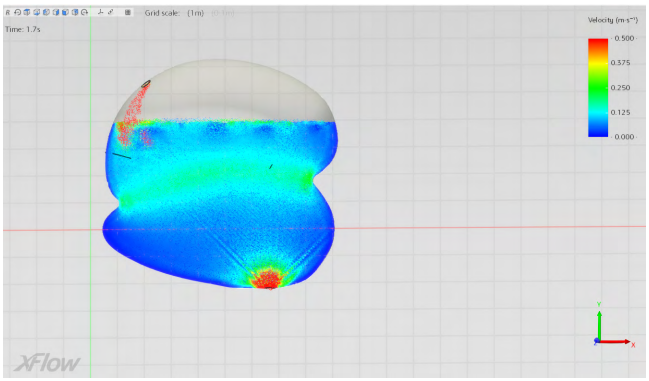

**Figure 5b.** Biomimetic solid-state digester fluid dynamics
Color gradient shows fluid velocity in m.s$^{-1}$

Fluid dynamic simulation in the biomimetic solid-state digester shows varying speed of matter inside of the system. The separation between dorsal and ventral pouches is a "fast-moving" spot with matter circulating around 0, 25 m.s$^{-1}$. It is worth noting that the acceleration occurs through the entire length of the separation and not specifically on one spot. It seems that matter is injected at high speed, slows down in the dorsal pouch, gradually speeds up going through the separating grid, and gradually slows down in the ventral pouch before being pushed out by overflow.

The following results were obtained for the liquid-state biomimetic digester.

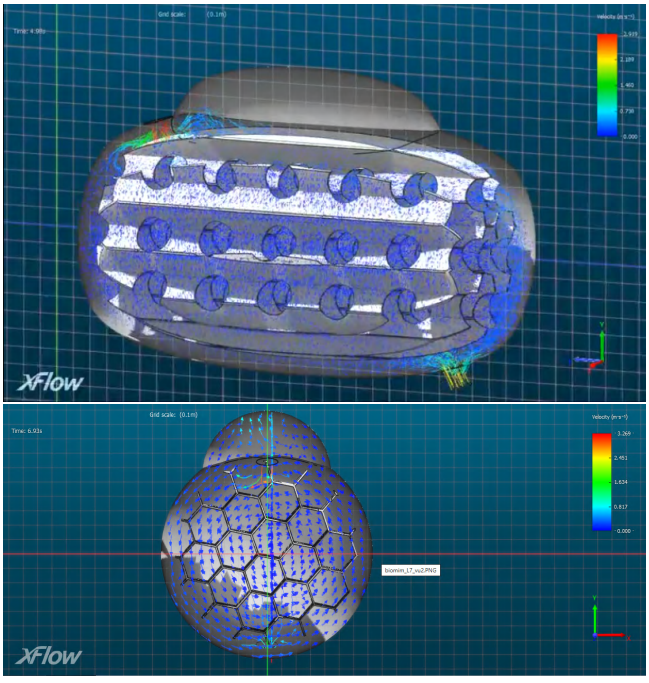

**Figure 6.** Biomimetic liquid-state digester fluid dynamics
Top figure : side view ; Bottom figure : front view
Color gradient shows fluid velocity in m.s$^{-1}$

The main takeaway from these results is that the

redesign of the mixer and the overall shape of the digester are very beneficial to matter movement. Gas production is stored up in the superior pouch, and fluid simulations show the entire volume of matter circulating around all the available space. The light blue strands in Fig. indicate that once matter is introduced in the digester, it does not remain at top or bottom parts but goes through the hive-like mixer. Overall speed is relatively slow (0 to 0, 75 m/s), but movement is homogeneous, which is wished for.

To sum up, a model of a biological system, a rumen, was designed and underwent simulation testing to gather knowledge on its interior fluid dynamics. Fluid dynamics were also observed in non-biomimetic digesters in two pathways for anaerobic digestion: solid-state and liquid state. The analysis highlighted issues of preferential pathways and dead volume in the digester current design. The insights on the inner workings of the rumen, which stands at the top of the yield pyramid for methane production, were used to design biomimetic digesters, with the specific focus of hydrodynamic improvement. Initial simulations of the biomimetic systems show an upgrade in fluid circulation, and so a reduced tendency for preferential pathways and a minimization of dead volume.

Results are still preliminary and superficial and stand more as a qualitative validation of the overall improvement of digesters through a biomimetic approach. Additional data and testing are needed to push the biomimetic systems further. For example, it would be interesting to calculate retention time and biogas production in the biomimetic systems and compare them to the performances of current systems (non-biomimetic digesters). Another opportunity would be to dig deeper on the papillae structures that maximize absorption surface. It was not studied here as only hydrodynamics were of concern, but they remain an addition proposed by the biological system for the technical one and probably play a substantial role.

## DISCUSSION

The central point argued in this paper is that biomimetics and modelling and simulation tools have the potential to work in a mutually reinforcing relationship. Recent works support and put forward arguments showcasing this synergy [5, 8, 14, 21].

On the one hand, the literature and the studied use case support that biomimetics can contribute to the development and improvement of modelling and simulation tools. Following a biomimetic approach indicates the study of biological systems, which are known as complex, multiscale, and multifunctional. This degree of intricate, hierarchal geometry stands on the current edge of the modelling and simulation capacities, despite recent improvements. It is only through these improvements that trying to model biological systems is conceivable, still, not yet easily feasible. The rumen use case discussed previously led to conclusions that support the positioning of biological models on the limit of what tools are currently able to model. Indeed, the design of the rumen pushed the software to its computational limits, specifically, in attempting to replicate the lining of rumen walls with papillae. Due to the sheer scale and number of required features, students were forced to model the papillae at a larger-than-natural scale to achieve convergence. This observation underlines that modelling and simulation tools need to improve in some way to compute and navigate such complexity (ie. multiscale structure). Ability to do so is essential as in biological systems, multiscale structure is often crucial to the performance of a specific function. So, biomimetics can contribute to the development of modelling and simulation tools by challenging them with the innate complexity of biological systems. For example, biology works with both hard and soft components to profit of their respective advantages (resistance, flexibility….), where engineering processes are focused on “hard materials” (steel, concrete…). Modelling biological systems could push the development and expand the versatility of Fluid-Structure Interaction (FSI) capabilities in software. In the presented use case, it would have been more accurate to represent rumen wall deformability and observe the influence of such capacity on fluid dynamics, but it was not feasible.

On the other hand, modelling and simulation tools could also bring beneficial elements to biomimetics.
Their integration to product development has increased product complexity, enabled early validation of performance, as well as quick and cheap iteration loops to test design options, and multicriteria analysis to identify the most suitable design alternative overall (finances, manufacturing capabilities, level of performance…). The biomimetic process would benefit from such additions as it faces struggles, notably related to the disruptiveness of the systems it leads to. This hypothesis opens the door to future work on the validation of mentioned benefits in the case of biomimetic design.

An essential part of the biomimetic process is transferring the principle of the biological function to the chosen field of application. If done poorly, it is likely that the resulting system will not deliver to expected levels. Proper transfer is deeply related to biological system understanding. Visual representations have always been used to describe, and comprehend the way systems, including living ones, function. Modelling and simulation tools lead to advanced visuals, gathering more information of the modelled system with the addition of one dimension (2D to 3D). A double hypothesis stands that through the standard use of modelling and simulation tools in biomimetic design, biological system

understanding would be improved, and resulting biomimetic systems would meet expectations.

In the use case, without modelling and simulation tools, getting to a deep and intricate enough level of understanding of the rumen, and the fluids dynamics it holds, would have been extremely complicated, and vastly more expensive. Using a porthole cow would not have necessarily brought the needed data, on top of being an ethically questionable approach. Perhaps, required data could have been obtained through the ingestion and monitoring of movements, of a traceable sensor by a cow, but it remains a demanding experiment in terms of resources.

Going further than improving the understanding of systems of interest, models and simulations could help figure out the viability frame of biological strategies. As seen in the use case with papillae structures, biology often works at small scales (nano and micro). Being able to assess if the desired function is governed by scale, or other parameters, would be a game-changing ability. In the example, knowing if absorption improvements brought by structures like papillae are only present if said structures are of nano or microscale, is an extremely important fact. Indeed, it indicates that nano or micro texturation would be an essential element to the biomimetic system for it to be functional. Information that signals early-on future manufacturing constraints. A hypothesis is here that models and simulations, specifically parametric models, could assist in the determination of the viability frame of a function, thus informing on its usability by a specific actor, depending on the field of application and manufacturing capacities.

All hypotheses made above must be tested through rigorous experimentation. They stem from the authors reflexion around the relevance of biomimetics and modelling tools together but are not yet verified statements.

## CONCLUSION

The aim of this article was to showcase the mutually beneficial relationship between biomimetics and modeling and simulation tools. The difficulty to model biological systems challenges modelling and simulation tools and stimulates their development and improvement to be able to cope with that level of complexity. Modelling and simulation tools are believed to be relevant to assist in a core step of biomimetics, which is the transfer of the biological function to the chosen field of application. This assistance would stem from the improvement of the understanding of biological systems through informative visuals. Parametric modelling could play a break-through role in determining the viability frame of biological functions, thus advising on biomimetic system feasibility. it is conceivable

Future work could focus on the experimental validation of the hypothesis around modelling and simulation tools for biomimetics, as well as on building the methodological steps needed to standardise the use of such tools in biomimetic design.

The end goal of such work is to facilitate the wider adoption of biomimetics as a problem-solving design approach, ultimately promoting the emergence of biomimetic innovations across diverse applications.

## ACKNOWLEDGEMENTS

The authors wish to express their gratitude to the students of UniLaSalle for their work on the use case.

Acknowledgements to IKOS Consulting and Ceebios for their financial contributions to the PhD work underpinning this research.

# A Comparative Analysis of Sequential Active Learning Approaches: Statistical Design of Experiments versus Bayesian Optimisation

**Daniel V. Batista[a] and Marco S. Reis[a]***

[a] University of Coimbra, CERES, Department of Chemical Engineering, Coimbra, Portugal

## ABSTRACT

As chemical processes become increasingly complex and costs of experimentation increase, understanding the practical effectiveness of Active Learning methodologies is essential. In this regard, an ongoing debate is occurring within the research community about the use of Design of Experiments (DOE) and Bayesian Optimisation (BO). However, this debate is limited by the scarcity of systematic comparative studies. Therefore, this work provides a comparative analysis of two widely adopted data-driven optimisation approaches: DOE and BO. The comparison is conducted across two distinct case studies reflecting different levels of complexity, regarding the quantity and variety of input variables involved. The first case study represents a realistic in silico experimental scenario, with multiple decision variables of different types (continuous, categorical and mixture), and two distinct single-objective optimisation goals, while the second one considers a simpler, well-known benchmark model with just two input continuous variables. Both studies were designed and analysed, while acknowledging the inherent conceptual and operational differences between DOE and BO. The results showed that a sequential DOE strategy, adapted here for optimisation purposes, consistently outperformed classical BO under the tested conditions. Particularly in terms of convergence towards the target response, robustness in identifying the optimal region, and overall experimental budget efficiency. Rather than asserting the superiority of one methodology over the other, this work highlights the need for case-specific adaptation when applying data-driven optimisation strategies in Chemical Engineering. The findings emphasise that theoretical guarantees alone under relatively strict assumptions are insufficient and must be complemented by problem-driven evaluation to support informed decision-making.

**Keywords**: Statistical Design of Experiments (DOE), Bayesian Optimisation (BO), Optimisation, Active Learning (AL) approaches

## INTRODUCTION

Systematic experimentation and mathematical optimisation have played a pivotal role in the advancement of Chemical Engineering Science, as evidenced by the development of new products and processes and their effective transfer and scaling in industrial applications.

Over the years, various optimisation strategies have been developed to address distinct objectives while taking the specific case study into account as much as possible. However, identifying an optimal strategy can be a challenging, time-consuming, and costly endeavour, particularly when the objective function and process model are not explicitly known and must be induced through experimentation.

This situation can prove even more challenging when multiple objectives must be considered and balanced simultaneously (e.g., yield, robustness, cost) and when variables of different types are present (e.g., continuous, multi-level categorical, mixture). Therefore, the primary challenge may lie in establishing an effective data-driven optimisation methodology that can efficiently optimise the systems towards a desired goal, within a reasonable budget of experiments.

Until recently, this activity has been supported by the extensive framework of Statistical Design of

Experiments (DOE) [1-3], widely applied in both research and industry, a methodology that traditionally enables careful planning of experiments followed by a separate optimisation stage. However, a new category of methods has recently attracted considerable interest for its conceptually intuitive formulation, flexibility, and reduced reliance on strong problem-specific assumptions. In particular, Bayesian Optimisation (BO)[4-6] offers a unified approach that incorporates both modelling and optimisation within a single framework.

Furthermore, authors tend to dismiss DOE because it typically relies on a pre-determined sampling pattern, which can hinder adaptation to features that appear during the course of experimentation [7]. Additionally, BO uses spatial correlation, avoiding the matrix singularity problems that can complicate DOE, namely when dealing with mixture variables.

Currently, it is unclear which of the two alternatives is the better choice, and when. The decision-making process can be challenging, particularly due to a lack of comparative evidence on the advantages and disadvantages of each strategy in different practical situations. This ambiguity may hinder engineers and analysts in selecting the most appropriate Active Learning (AL) approach for their specific case, at the cost of being suboptimal in terms of data efficiency and overall experimental costs.

To address such current information bottleneck, we present a comparative analysis of the two approaches (DOE and BO) in two *in silico* scenarios reflecting different application realities, where sequential experimentation is carried out with the goal of optimisation.

# METHODHOLOGY

## Active Learning approaches

In the comparative analysis, two AL approaches were considered (DOE and BO). Regarding DOE, we tested an adaptation of the base methodology that implements a sequential AL approach. This approach initially explores an initial sampling space, followed by sequential exploitation, and it was adapted to each case study scenario, as described in the following sections.

As for BO, the classical methodology was adopted by building a Gaussian process-based probabilistic surrogate model from observed data. This model captures mean predictions and uncertainties, which are fed to the acquisition function, to guide the selection of informative points for sampling, while balancing exploration and exploitation. In this work, we have selected Expected Improvement (EI) for the acquisition function. The model is updated successively, with new points sampled to maximise the acquisition function until the predefined optimisation budget is reached.

Although the statistical foundations underlying DOE and BO are quite different, the study was carefully designed to provide a fair and realistic comparison, minimising potential biases towards either approach. At the same time, the analysis acknowledged the inherent advantages of each method, such as the reduced number of experiments required for starting BO, owing to its sample-efficient nature [5]. Both methodologies were implemented in Python and customised for each case study. For BO, the Ax Python library was used to conduct the study.

## Case studies

The practical comparison was conducted on two distinct case study scenarios, with different levels of complexity regarding the number and typology of input variables involved.

The first case study considers a realistic simulated experimental scenario with two single-optimisation opposing goals (maximisation and minimisation) and several variable types, including continuous, mixture, and multi-categorical variables. The scenario also considers a predetermined experimental budget and target response value.

The second case study represents a typical maximisation problem based on a simple and well-established mathematical function with a known optimum point. In this scenario, the study flexibly covers different options for the initial sample space used for both strategies. For simplicity, contrary to the first case study, only continuous variables are used, and the system is low-dimensional (2 input variables). The scenario also considers various target experimental budgets and a predefined bounded space for analysis.

# CASE STUDY 1: IN SILICO OPTIMISATION OF LNP SYNTHESIS

## Comparison Study

For the first case study, an *in silico* system was adopted, based on a model previously developed from experimental data collected [8]. This model was originally discussed and analysed in earlier work [9] and was adapted for the present study.

The *in silico* system represents the synthesis of lipid nanoparticles (LNPs) by microfluidics and acts as a computational surrogate of a real experimental setting. Due to the high structural complexity of the underlying simulation model, it was treated as unknown for the purposes of this study, effectively constituting a black-box system.

According to the simulation model's specifications, several types of input variables were considered, and their ranges were selected while respecting the feasibility limits of the simulation model, as shown in **Table 1**.

**Table 1:** Input variable ranges and types in simulation model.

| Input Variables | Ranges | Type |
|---|---|---|
| Ionizable Lipid | [0.3;0.6] | Mixture |
| Structural Lipid | [0.185;0.555] | Mixture |
| Helper Lipid | [0.1;0.28] | Mixture |
| PEG Lipid | [0.01;0.045] | Mixture |
| N/P ratio | [6, 14] | Continuous |
| Total Flow Rate | [1, 3] mL/min | Continuous |
| Ionizable Lipid Type | H101 or H102 or H103 | Categorical |

The model also included two response variables: *in vivo* potency and the average size of the LNP. These responses were linked to separate single-objective optimisation goals: potency should be maximised and particle size, minimised. The goals and predefined targets to meet are shown in **Table 2**.

**Table 2:** Response targets and goals.

| Responses | Goal | Target |
|---|---|---|
| Potency (%) | Maximize | 98 % |
| Size (nm) | Minimize | 90 nm |

For the DOE approach, an initial sample space was generated using a D-optimal design strategy for two different model structures with distinct levels of complexity (M2 and M3). Model M2 represents a lower-complexity structure and includes main effects of the mixture components, nonlinear blending terms between pairs of mixture components, and second-order interaction terms among all the remaining input variables. Model M3 extends M2 by incorporating additional Scheffé cubic mixture terms, such as nonlinear blending effects among three mixture components. As the number of model terms increased with model complexity, the required number of experiments also increased. To enable a fair comparison, a minimum initial sample size was imposed for both models, corresponding to 50 experiments, which met the minimum requirements of the more complex model.

Therefore, for the initial DOE sample space, we considered different levels of exploration, using 50, 55, and 60 initial experiments, and a pre-established target budget of 55, 60, and 70 experiments for each case, respectively, during optimisation.

Once the initial sample space was generated, the models were fitted using least-squares estimation. The corresponding optimal input conditions were then determined through an adapted sequential least-squares programming (SLSQP) nonlinear optimisation procedure for categorical variables.

The newly identified optimal input conditions were evaluated using the *in silico* model, after which the existing dataset was appended, and the data-driven model was re-estimated. This sequential process of model fitting and optimisation was repeated iteratively until the predefined experimental budget was exhausted. A schematic representation of this workflow is provided in **Figure 1**.

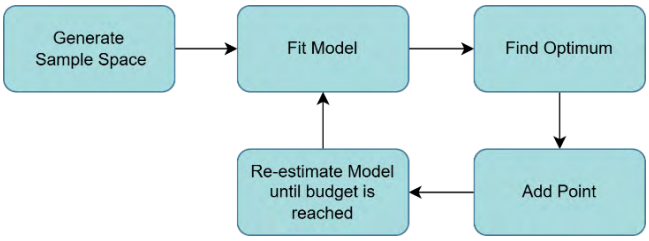

**Figure 1.** DOE framework in Case Study 1.

In the case of Bayesian optimisation, a classical BO framework was adopted, following the previously described reasoning, until the same target budget established for the DOE approach was reached. Given the reduced information requirements of BO, a smaller initial sample space ($N_{init}$)was adopted using a practical rule-of-thumb, based on the number of variables ($N_{var}$), as shown in **Equation (1)**. The sample space was generated using SOBOL sampling, a quasi-random (low-discrepancy) space-filling initialisation method, within the established ranges in **Table 1.**

$$N_{init} = N_{var} + 1 \quad (1)$$

## Results and Discussion

For both active learning approaches, 1, 000 simulation runs per approach were conducted for each scenario to characterize and take into account stochastic variability in the results, while maintaining the same initial sample space across simulations. In addition to the baseline noise level inherent to each simulation model, an alternative scenario with a 20% increase over the original noise level was also investigated. This additional scenario was included to assess the robustness of both approaches under more challenging, noise-dominated conditions.

For each simulation and each AL approach, the best response value achieved (maximum *for* potency or minimum for LNP size) was recorded along with the corresponding experiment location (sequential number of the run where it was obtained).

Additionally, the computational time required to complete each optimisation in DOE and BO were recorded for both responses. The results showed that on a 13th Gen Intel i7-1365U processor, the optimisation time for DOE was approximately between [1.34, 8.90] s for potency and [1.40, 7.32] s for size. In contrast, BO required longer computational time, approximately between [200, 453.70] s and [188.79, 269.53] s for potency and size, respectively.

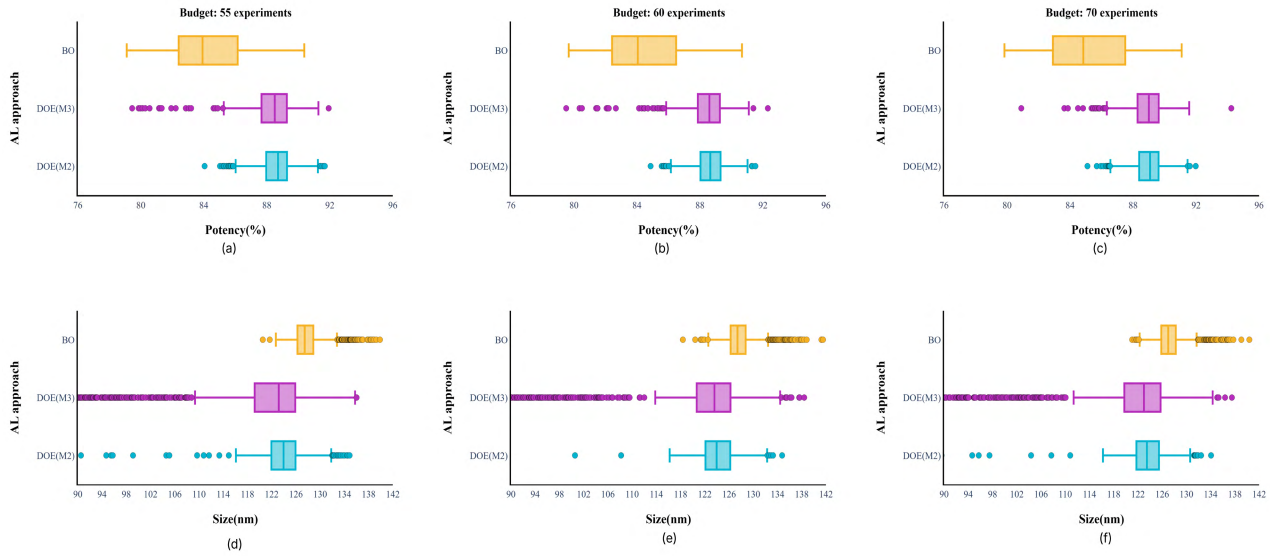

**Figure 2.** Distribution of the responses' best values obtained from 1,000 simulations per AL approach (BO, DOE(M3) and DOE(M2)) at original noise level. (a)-(c) Potency' best values (maximum); (d)-(f) Size's best values (minimum).

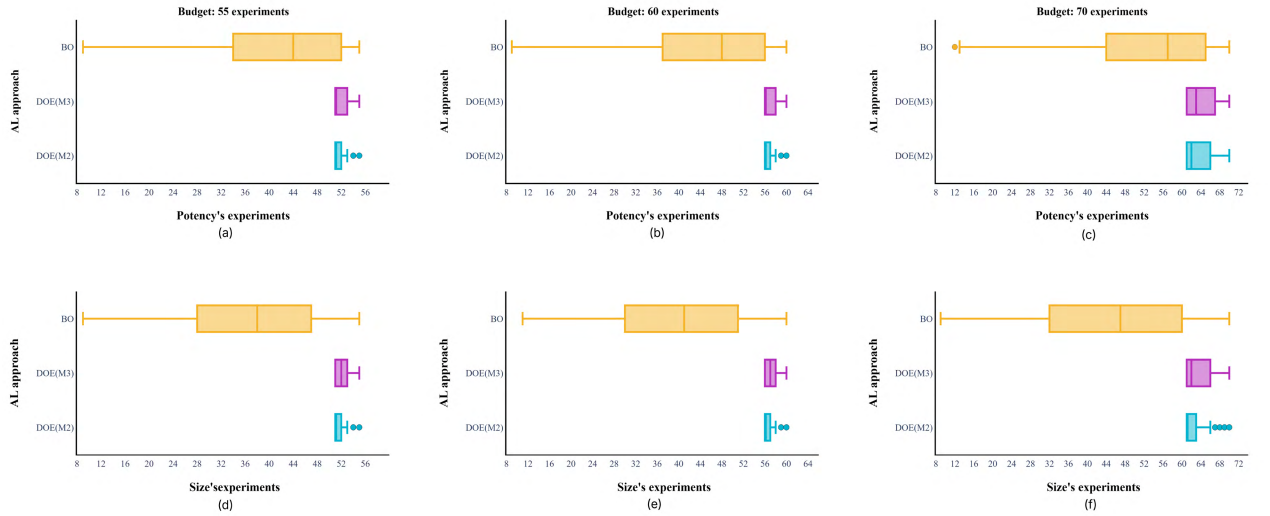

**Figure 3:** Distribution of the location of the experiment's best value, obtained from 1,000 simulations per AL approach (BO, DOE(M3) and DOE(M2)) at original noise level. (a)-(c) Potency; (d)-(f) Size.

The distributions of the optimality outcomes were subsequently visualised using box plots (**Figure 2** and **Figure 3**) to facilitate a comparative assessment of the optimisation performance.

The results in **Figure 2** show that, in both responses, DOE outperformed BO across all established target experiment budgets, as indicated by the spread of box-plot values in each response and by the closeness to target response values (**Table 2**). In particular, for size (**Figure 2 (d-f)**), BO failed to achieve values sufficiently close to the target value (90 nm).

The disparity in performance becomes particularly pronounced when examining the median values depicted in the box plot. These values clearly illustrate a central tendency in DOE that aligns more closely with the target value than BO. Furthermore, in the case of DOE, comparing both DOE strategies, DOE(M2) and DOE(M3), reveals a similar median value, suggesting that, regardless of model complexity, both approaches generally perform similarly in optimisation for this case study.

Lastly, as shown in **Figure 3**, BO exhibits greater variability in pinpointing the optimum location for both

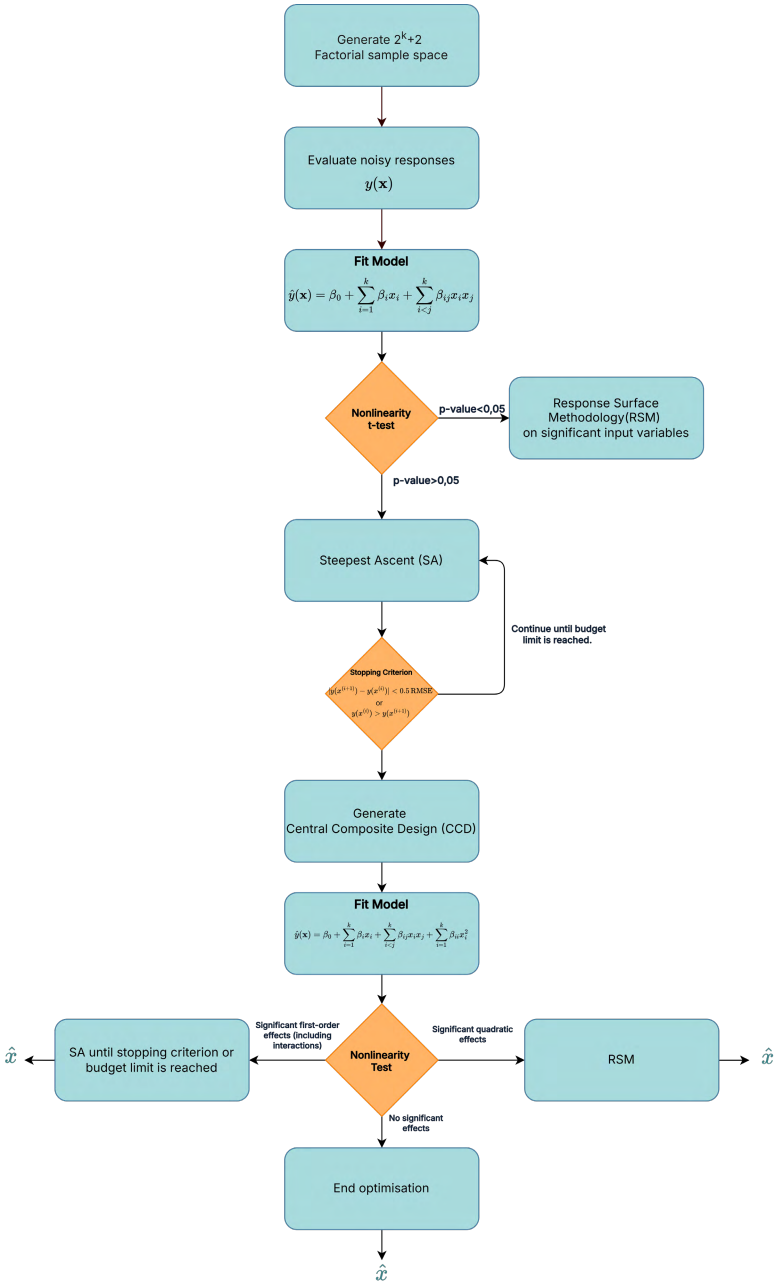

**Figure 4:** DOE framework in Case Study 2.

responses than DOE. This increased variability may be attributed to the exploratory nature of the BO process during the earlier stages of the optimisation phase.

It is important to note that, although not presented in this section, a consistent trend of results was observed regardless of the increased noise level, as shown in the Supplementary Material, **Figure A.1** and **Figure A.2**.

## CASE STUDY 2: MATHEMATICAL BENCHMARK FUNCTION

### Comparison Study

To complement the experimentally driven Case Study 1, this second case study evaluates and benchmarks the performance of active learning approaches in a more controlled benchmark scenario, independent of

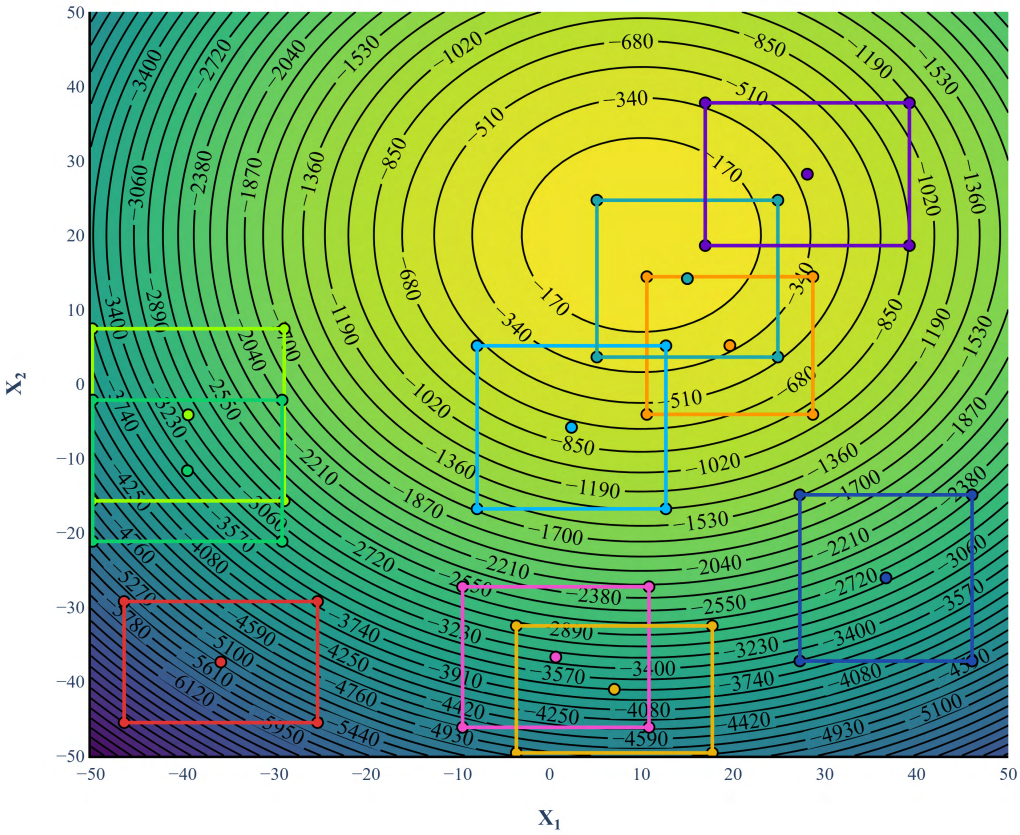

**Figure 5:** Design "Box" factorial sizes from ten simulations distributed across the response surface.

the complexities and uncertainties inherent in experimental systems, where the ground truth is often unavailable or costly to obtain. Therefore, for this case study, we considered a classical maximisation problem based on a well-known two-variable concave function, $f(x)$, shown in **Equation (2)**, which possesses a known global maximum at (10, 20) with an optimum value of 0.

$$f(x) = -(x_1 - 10)^2 - (x_2 - 20)^2 \quad (2)$$

Although the underlying function is known a priori for validation, it is treated as unknown during the optimisation stage for both approaches, with synthetic noise added to the responses to simulate realistic conditions. To reflect stochastic variability, responses were generated from **Equation (2)** with additive Gaussian noise, $y(x) = f(x) + \varepsilon$, where $\varepsilon \sim \mathcal{N}(0, \sigma^2)$. The standard deviation was set as $\sigma = 1.6525$.

Following the methodology from the first case study, the DOE approach was tailored to fit the current problem, namely the different postulated model structure that implies a distinct strategy for its optimisation. However, the sequential active learning principle of exploration followed by exploitation is preserved. The DOE framework was developed in Python, following the workflow shown in **Figure 4.**

The DOE began by generating an initial two-level full factorial design with two replicated central points ($2^k + 2, k = 2$), while adhering to the bounded range for both variables of [-50, 50].

The central point ($x_{\text{centre}}$) was randomly selected from a uniform distribution within this range ($x_{\text{centre}} \sim U(-50, 50)$). The high and low levels of both input variables (X1 and X2) were determined by adding and subtracting, respectively, a predefined distance (l) sampled from a normal distribution, $l \sim N(10, 1)$, thereby allowing for multiple plausible initial sample configurations and design "box" sizes across various simulations (ten in this case study), as shown in **Figure 5**.

Once the initial dataset was established, a least-squares model was fitted to the simulated noisy responses and tested for nonlinearity using a statistical hypothesis test [3]. Sequential optimisation then followed two possible pathways: (i) Response Surface Methodology (RSM) via a central composite design (CCD) on significant inputs if significant nonlinearity was detected, or (ii) Steepest Ascent (SA) starting from the $x_{\text{centre}}$ if no evidence of nonlinearity was observed.

Note that the SA here conducted, considers the

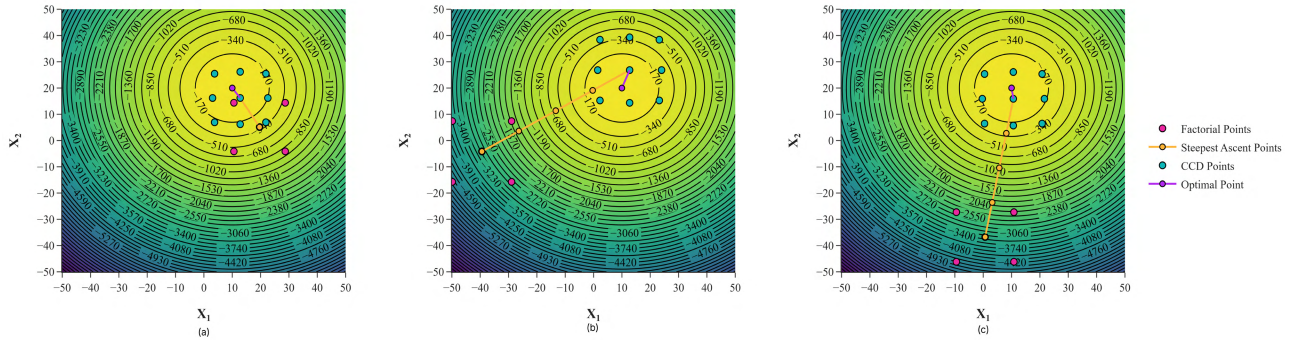

**Figure 6.** DOE optimisation path across the response surface. (a)-(c) First three simulations (Remaining simulations, please consult the Supplementary Material, **Figure B.1**).

fitted model with second-order interactions and recalculates the gradient at each new optimization iteration, as specified by **Equation (3)**.

$$x^{(i+1)} = x^{(i)} + \lambda \frac{\nabla \hat{y}(x^{(i)})}{\left\| \nabla \hat{y}(x^{(i)}) \right\|_2}, \lambda = \sqrt{2} \quad (3)$$

Additionally, the SA process continued until either a set number of experiments (50 in this case) was exhausted, or the stopping criterion was reached. Note that if the stopping criterion was not met, the optimisation could either continue using SA for additional iterations or be terminated.

If the stopping criterion was met during SA, a CCD was generated from the last point, and the model was refitted in the new sample space. Lastly, RSM was applied when significant quadratic effects were identified; otherwise, the SA continued until convergence or the last point in the previous SA was taken as the optimal point.

For the sake of illustration, some results derived from the sequential DOE approach during optimisation are presented in **Figure 6**; for more detailed information please refer to the Supplementary Material, **Figure B.1**.

It is important to note that, as shown in **Figure 6** and **Figure B.1**, all ten simulations during optimisation chose an SA approach, followed by RSM and stopped before reaching the experiment budget of 50.

The total number of experiments conducted was recorded for each simulation, along with the estimated optimal input ($\hat{x}$) and the corresponding noiseless response, $f(\hat{x})$, using Equation (2).

Additionally, across ten simulations, the Euclidean distance from $\hat{x}$ to the true optimal point of $f(x)$, (10, 20) was calculated using the **Equation (4)**.

$$d(\hat{x}) = \sqrt{(\hat{x}_1 - 10)^2 + (\hat{x}_2 - 20)^2} \quad (4)$$

In the case of BO, the classic BO approach was evaluated across three variants to assess the influence of initial knowledge: BO-$N_{min}$, BO-$N_{DOE}$, and BO-$N_{max}$.

For BO-$N_{min}$, a minimal sample space of three points, as defined by **Equation (1)**, was generated using SOBOL across ten independent runs. BO-$N_{DOE}$ was initialised with the same initial sample space knowledge as the DOE approach, consisting of six points, across ten simulations. Lastly, BO-$N_{max}$ employed a SOBOL design of the same size as the DOE initial sample space (six points) across ten independent runs. Note that for BO, a target budget of 50 experiments was used, matching DOE, and a smaller budget of 25 experiments was also considered for comparison.

The optimal point (maximum) at each strategy and simulation was recorded, along with the associated metrics, $d(\hat{x})$ and $f(\hat{x})$.

## Results and Discussion

**Figure 7** presents a summary of results for both AL approach, based on the selected metrics ($d(\hat{x})$ and $f(\hat{x})$). The numerical data are available for consultation in Supplementary Material, **Table B.1**.

The results indicate that, overall, the DOE method, which had lower budget requirements for optimisation, consistently outperformed BO by predicting input values ($\hat{x}$) that were nearer to the true optimal point (10, 20) under noisy conditions, **Figure 7 (a)**.

Additionally, in terms of the optimal value, DOE results were generally closer to the reference optimum value (0), **Figure 7 (b)**.

Although BO employed higher budgets, it did not consistently achieve similar proximity to the optimal values. Nevertheless, it is important to highlight the differences between the BO strategies used, as shown in **Figure 8**.

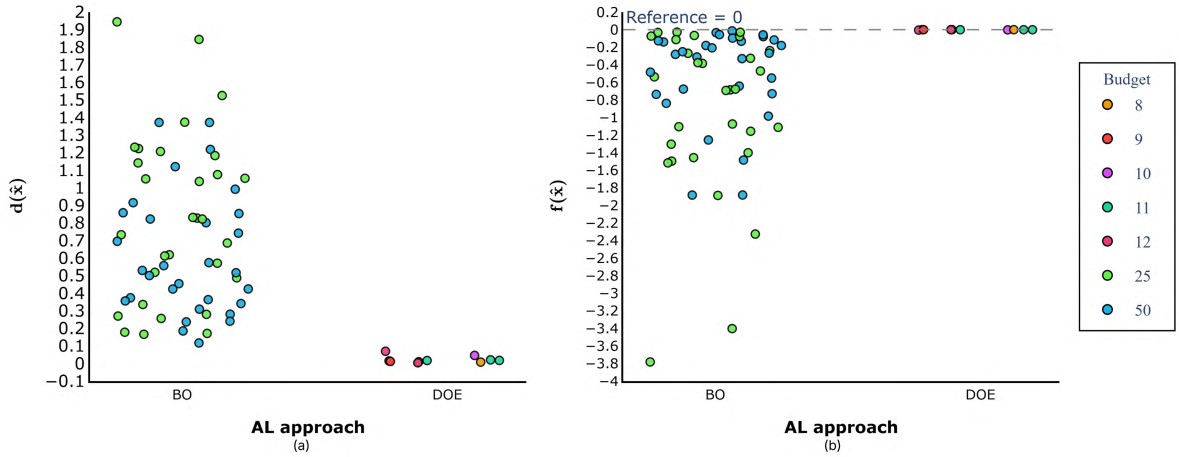

**Figure 7.** Results of $d(\hat{x})$ and $f(\hat{x})$ per the AL approach, coloured by the experiments' budget. (a) $d(\hat{x})$ values; (b) $f(\hat{x})$ values.

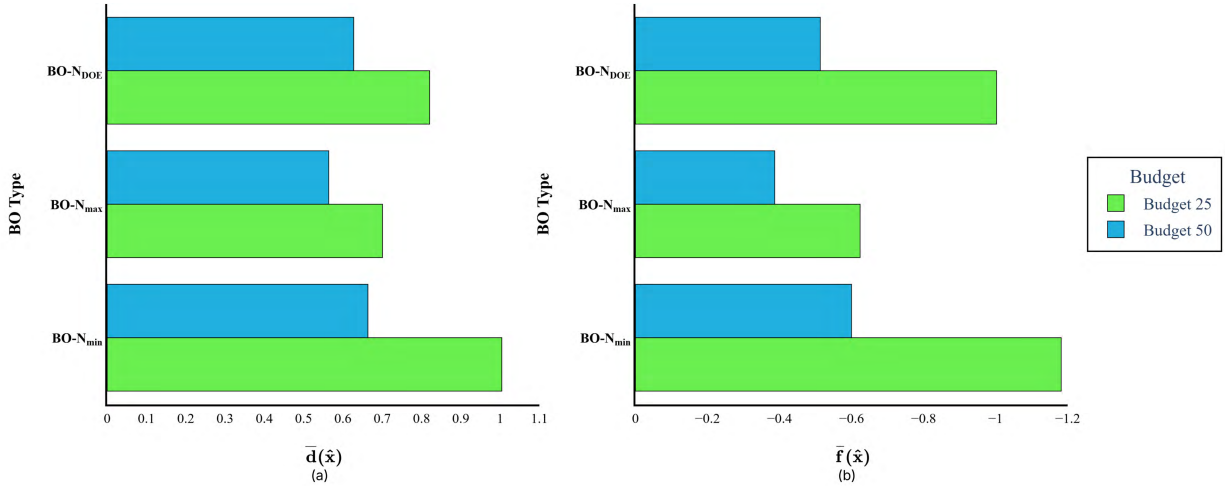

**Figure 8.** Results of average $d(\hat{x})$ and $f(\hat{x})$ per the BO Type, coloured by the two experiments' budget (25 and 50). (a) $\bar{d}(\hat{x})$ values; (b) $\bar{f}(\hat{x})$ values.

According to these findings, in the case of BO for both strategies, a lower experimental budget (25) on average performed worse, as indicated by the metric scores. For both budgets, BO-$N_{min}$ showed the worst performance, whereas BO-$N_{max}$ showed superior average performance, followed by BO-$N_{DOE}$.

These results suggest that, for this scenario, a larger Sobol-generated space (BO-$N_{max}$) may generally enhance the effectiveness of BO optimisation, as opposed to a factorially structured initial design.

Lastly, for this case study, the optimisation times on a 13th Gen Intel i7-1365U processor were recorded once again. For DOE, the optimisation took approximately between [0.22, 0.59] s, whereas BO required between [18.79, 119.96] s.

## CONCLUSIONS

The practical comparison study yielded insights across multiple scenario conditions, ranging from a complex, unknown experimental setting with categorical. continuous and mixture variables to a simpler, well-known system, just composed of continuous variables.

Across these studies, the findings consistently

indicated that an adapted sequential DOE approach consistently outperforms classical BO in several aspects: achieving closer convergence to the target response and the optimal point, decreasing variability in locating the optimum, and requiring a lower experimental budget.

It is important to note that these results do not suggest that BO lacks the potential to excel in other case scenarios. As highlighted by the No Free Lunch theorem, no single algorithm can be expected to outperform all others across every possible problem [10].

As shown here, BO remains promising when carefully tailored, as demonstrated by the size and design space generation discussed in the Case Study 2. Additionally, several aspects remain to be explored in future studies (e.g., the implementation of stopping criteria in BO).

In conclusion, the insights from this analysis indicate that, despite the well-established theoretical foundations of both DOE and BO, focused practical studies remain critical to fully understand their real-world performance and applicability, rather than treating them as competing approaches. Future research will further expand this analysis to tackle the current scarcity in practical comparisons, such as exploring their robustness under model sparsity and evaluating common benchmark optimisation cases (e.g., Hartman6D and Hartman3D).

## ABSTRACT

The bioprocess industry is actively exploring technologies associated with the fourth industrial revolution, with modeling offering considerable potential for process optimization. Nevertheless, model adoption in industry remains limited. This is partly because model development continues to depend heavily on offline sampling, and because relatively few industrial applications convincingly demonstrate their practical value. This study therefore first examines the benefits of online rheology and online biomass measurements for model development and demonstrates, among other aspects, that online biomass significantly improves model fidelity. The second part examines how electricity prices affect process conditions, a key factor in production, and finds that, contrary to common practice, maximizing all operating parameters is not the most cost-effective strategy. Finally, an in-silico framework for model predictive control, applied to a reactor end-fill scenario, demonstrates that oxygen-controlled processes can be dynamically optimized, highlighting the strong potential of bioprocess models for industrial usage.

**Keywords**: Bioprocess Modelling, Cost Analysis, Model Predictive Control

## INTRODUCTION

Fermentation processes are well-established biochemical operations that utilize microorganisms to produce specific compounds, ranging from monoclonal antibodies to chemicals and industrial enzymes [1]. Although individual processes differ substantially, all industrial fermentations rely on a complex interplay between the underlying biological system and its physical reactor environment [2], [3].

Accurate modeling of fermentation processes is considered a crucial step forward in the ongoing optimization, monitoring, control and scaling of such processes [4]. Nevertheless, the application and usage of such mathematical bioprocess models in industry remains limited, largely because the model development is highly resource-intensive and time-consuming [5].

A major contributor to this challenge is the reliance on offline measurements for rheological characterization and cell-weight–based analyses [6].

However, online measurement technologies are constantly emerging within industrial settings, raising the question of to what extent they can support model development and improve model accuracy from an industrial perspective [7].

For instance, rheological offline measurements are laborious and additionally require an estimate of the apparent viscosity based on numerous assumptions. This can be substituted by online measurements of the dynamic viscosity using a vibrational viscometer operating in the upper Newtonian region, in which the fluid behaves shear-independently. Dynamic viscosity is referred to in the following as online viscosity [8]. Additionally, online biomass sensors that quantify viable cells based on permittivity can replace the cumbersome and, under current industrial conditions, error-prone measurements of cell dry weight (CDW) [9], [10], [11].

This work first aims to investigate the extent to which the integration of those two online measurement technologies improves model development and enhances model accuracy for industrial fungal fermentation processes at pilot and production scale.

This is done by comparing three modeling approaches, leading to three different models, developed

using pilot plant data and validated through pilot and large-scale simulations: (i) a mechanistic model based on offline CDW and offline rheology measurements, (ii) a hybrid model combining offline CDW and online viscosity, and (iii) a hybrid model relying on online viable cell concentration and online viscosity. The complexity of the model is addressed in more detail in the "Methodology" section.

Alongside the effort required for development, the usage of models in industry may also be slowed down by a lack of practical examples that clearly demonstrate their benefits [12], [13], [14]. Therefore, the second part of this work presents two model applications tailored to an established dissolved oxygen (DO)-controlled enzyme-production process. First, a cost analysis under varying electricity prices is conducted to provide economic insights into fermentation operations. Second, an in-silico framework for predictive control is implemented to dynamically optimize DO-controlled fermentations, while ensuring a defined reactor fill [15], [16].

This study aims to bridge the gap between existing modeling approaches and their application in industry. This is done by exploring the potential of online measurements for model development, on the one hand, and by presenting model applications specifically tailored to enzyme production processes, on the other hand.

## METHODS AND MODELS

Three bioprocess models are used to discuss and explore the advantages of integrating novel online measurements into model development. All models are designed for the same industrial bioprocess, assuming substrate as the primary limiting factor for cell growth and death. Each model incorporates mass balances for key components, including reactor mass, biomass, substrate, product and dissolved oxygen. Due to confidential reasons, model parameters for each of the models cannot be disclosed.

A pure mechanistic model (model i) exhibits the highest dependency on offline data, requiring both CDW and offline rheology measurements. Essentially the model structure can be seen in Albeak et al., 2012 [6], with the difference being that yields have been linked to the growth rate, rather than being constant as well as the integration of a Monod growth kinetic.

Cell death is not modelled explicitly in model i. This decision reflects the limited precision of CDW measurements, which prevents robust estimation of death kinetics. The linear yields correlation as well as $\mu_{max}$ has been determined experimentally, whereas the remaining parameters were fitted using data from six fermentations covering the relevant operational space. Additionally, enzyme production is modelled based on a constant rate and includes a product inhibition term. The applied $k_La$ correlation is presented in equation 1.

$$k_La = C * \left(\frac{P}{V}\right)^a * v_s^b * \mu_{app}^c \quad (1)$$

The apparent viscosity is described using the Henzler and Otto model in which the power-law parameters are fitted to rheological measurements, as presented in Albeak et al., 2012 [6].

The only distinction between the mechanistic model (model i) and the second model, model ii, is that the apparent viscosity is replaced by online viscosity. In this approach, the $k_La$ correlation, shown in equation 2, includes online viscosity that is predicted by a supervised LGBM machine learning (ML) model, resulting in a sequential hybrid model. The ML model, trained with 27 historical fermentation processes from pilot plant and production, utilizing different fungal strains, predicts the online viscosity based on mechanistic modelled input features, as described in more detail in [17].

$$k_La = C * \left(\frac{P}{V}\right)^a * v_s^b * \mu_{online}^c \quad (2)$$

Therefore, model ii advances model i by increasing the use of online data (i.e. viscosity), while model iii builds upon model ii by integrating additional online measurements (i.e. capacitance), consequently reducing the need for offline sampling. The availability of online viable cell concentration measurements enables model iii to explicitly incorporate cell-growth and cell-death kinetics, both formulated as functions of substrate concentration and dissolved oxygen levels [18].

In addition, model iii integrates an extended ML–based viscosity model from model ii that includes capacitance as an input feature. However, this dataset consists of only two pilot-scale fermentation processes conducted with the same production strain. The restricted size of this dataset reflects the current limited availability of fermentation batches, equipped with online capacitance probes.

Consequently, in contrast to model i and model ii, which model biomass growth with a Monod model, model iii, predicts the viable cell concentration with a Contois-type growth and O'Brien-type death kinetic [19], [20]. As this extension increases the number of kinetic parameters in model iii, a differential evolution algorithm is employed to ensure sufficient exploration of the enlarged parameter space. The optimization applied the '`best1bin`' strategy with a population size of 6 and a maximum of 30 generations as well as a relaxed tolerance of 0.01 to enable early termination when improvement falls below 1% [21].

Due to limitations in the availability of offline and online biomass and rheology measurements, it was not possible to obtain a sufficiently comprehensive data set to calibrate all models on the same dataset, resulting in the use of the two data sets. Model i and ii are calibrated

on six 550L fermentation processes designed to explore the operational space of the system. In contrast, model iii is based on two 550L fermentations with different designs, one targeting three specific growth rates, while the other examines cell behavior under varying $k_L a$ conditions. The presented results are validated on additional fermentation processes at pilot and large scale that were not used for calibrating the models.

## Cost optimization

In-silico cost optimization of a fermentation process using a comprehensive bioprocess model represents a compelling application of modeling for industrial purposes [22].

The first step of a cost optimization involves linking the relevant cost factors, as listed in Table 1, to the simulation. For the purposes of this study, and due to the limited cost information available in the literature, we assumed a fixed baseline operating cost, denoted as fixed overhead costs. These represent expenses that occur regardless of how the fermentation is run. The values are based on internal company data and cannot be disclosed.

Other costs are associated with either the reactor start or end filling, the inherent process operating conditions as well as the fermentation time.

The energy prices in the analysis are based on historical data from the Danish energy market and reflect the minimum, maximum and average price over the last 10 years [23]. The other costs are based on literature values selected to best approximate the present case; however, the availability of detailed information in the literature is rather limited [16], [24], [25].

**Table 1:** Cost factors of a fermentation process

| | | |
|---|---|---|
| **Fixed Costs** | fixed overhead costs | confidential |
| **Variable Costs** | Electricity | 0.8, 1.8, 2.8 [23] [DKK/kwh] |
| | Carbon source | 4.23 [16] [DKK/kg] |
| | Ammonia | 1.94 [16] [DKK/kg] |
| | Media | 0.26 [24] [DKK/kg] |
| | Recovery Cost | 4.49 [25] [DKK/kg] |

In the second step, a realistic manufacturing scenario is embedded within the optimization problem. The problem is formulated as a nonlinear, simulation-based, single-objective constrained optimization problem. The decision variables $\mathbf{x} = [\mathrm{p}, \mathrm{a}, \mathrm{g}, \mathrm{t_f}]^{\mathrm{T}}$, represents pressure, aeration, agitation, and fermentation time. The objective is to minimize the total fermentation cost $\mathrm{C}(\mathbf{x})$, subject to meet a required enzyme production $\mathrm{P}(\mathbf{x}) \geq \mathrm{P_{target}}$ and respecting operational bounds $\mathrm{x_i^{min}} \leq \mathrm{x_i} \leq \mathrm{x_i^{max}}$, represented in the following formulation.

$$\min_{x} C(x),$$

$$s.t.\, P(\boldsymbol{x}) \geq P_{target},$$

$$x_i^{min} \leq x_i \leq x_i^{max}, i \in \{p, a, g, t_f\}$$

A nested root-finding procedure adjusts the initial reactor fill to ensure identical final fill levels across all simulations. Because the model exhibits non-linear, non-convex behavior without analytical gradients, the optimization is solved using a Genetic Algorithm with a population size of 50, up to 25 generations, using tournament selection, two-point crossover (probability 0.5), and Gaussian mutation (probability 0.5). The optimization process is initiated by generating 50 initial points within the design space using Latin Hypercube Sampling (LHS) [26].

## Advanced control for the reactor end fill

Many industrial enzyme production processes have already been extensively optimized, including by adjusting the feed rates to maintain a stable oxygen balance. However, as this normally leads to varying reactor end fills, a subsequent objective might be to reliably hit a defined end fill. Reactor end fills are linked to the total product produced and beyond that enhances manufacturing planning reliability by reducing process deviations. Model predictive control (MPC) is widely regarded as a powerful approach to enable such advanced control [6].

To reduce batch-to-batch variability and achieve this in DO-controlled fungal fermentation, a modular in-silico workflow that combines biased initial planning, real-time parameter adjustment, and constraint-based input optimization, is presented. First, a realistic model-process mismatch is created by distorting a calibrated "source" process model: the dynamic substrate and oxygen yields are influenced by a constant factor that is randomly determined in the range of ±30% of the yield's value. Using this deliberately distorted model, a Brent root-finding optimization is employed to determine the initial reactor fill that would result in the fermentation reaching the predefined final reactor fill. That start fill is applied to the unperturbed source (or truth) model to generate synthetic batch data, representing the realized process.

During the run, the algorithm corrects the distorted model at specified control points by finding correction factors for the dynamic yields, using the available online data of viable cell concentration, oxygen uptake rate (OUR), and feed rate by minimizing a normalized mean-squared error over the time to the checkpoint with Nelder-Mead under conservative tolerances. Normalization guards against misalignment and scale differences and regularization with constraints keeps parameters physically plausible. The corrected model is then rolled forward to forecast the rest of the batch. If the predicted

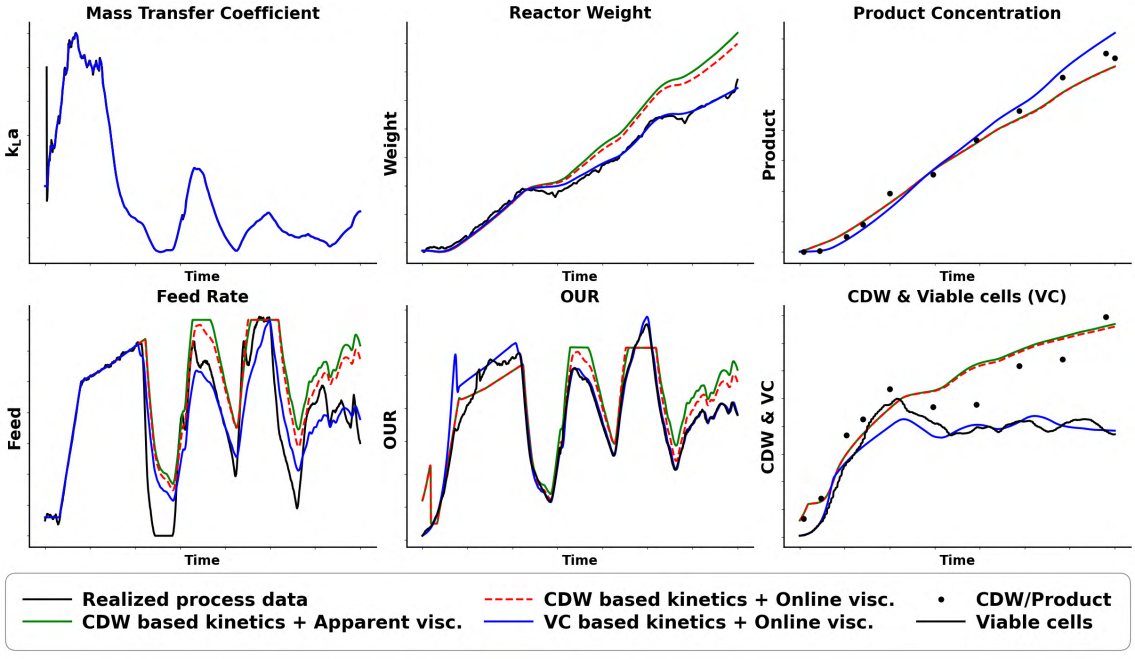

**Figure 2.** Pilot-scale predictions for the three models with realized $k_L a$.

end fill based on the new model deviates from the target beyond a threshold of e.g. ±1%, a bounded L-BFGS-B adjusts the agitator speed and aeration. This approach is possible, as with a DO-controlled process, there is a direct correlation between the OTR and the final reactor fill of a process.

$$Agitation\ and\ Aeration \uparrow \rightarrow OTR \uparrow \rightarrow DO \uparrow \rightarrow feed\ rate \uparrow \rightarrow end\ fill \uparrow$$

By adjusting the agitator speed and aeration under DO-controlled settings, a DO concentration close to the set point as well as a final fill that corresponds to the desired final fill of the process is ensured. This can be achieved by optimizing both the agitation and the

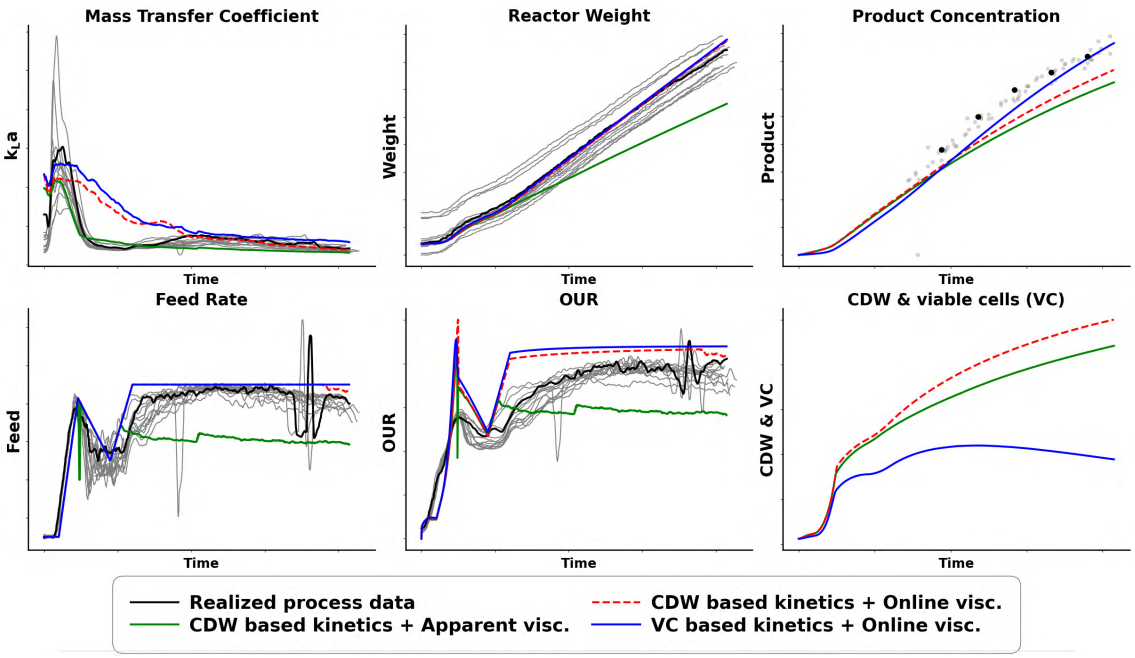

**Figure 3.** Large-scale predictions for the three models.

aeration based on the squared error between the final reactor fill prediction of the corrected model and the target fill using an L-BFGS-B optimization algorithm with moderate tolerances.

After executing this framework at each checkpoint, all actions are logged and saved, as they define the process until the next checkpoint. This fit-predict-control loop repeats to batch completion, maintaining robust DO control while steering the process to the target end fill under initial model inaccuracy. To reduce the computational cost, the framework is only activated at those time points, in which the modelled predictions deviate from the actual realized process data.

# RESULTS

## Model simulation for pilot and large scale

Figure 1 presents the closed-loop simulation results for models i, ii, and iii. The empirical $k_La$ models, each depending on their respective biological and physical sub-models, show reasonable agreement with the measured data throughout most of the fermentation process. Deviations in the predicted $k_La$ values occur primarily during the initial hours and can largely be attributed to viscosity effects. These early-phase differences arise either from the use of different viscosity models or from discrepancies in the biological sub-models implicitly embedded in the $k_La$ estimation.

Because the process is intentionally operated at its maximum feed rate during the initial hours, the early differences in $k_La$ do not translate into additional feed addition. As the predicted $k_La$ converges for the remainder of the fermentation, and because model i and ii share similar underlying biological sub-models, the resulting state predictions overlap for most variables during the closed-loop pilot-scale validation run.

Model iii, which was developed using only two fermentation datasets and viable cell measurements, underestimates the reactor fill compared to the observed data. Further investigation is required to understand the root causes of the discrepancies among the models. One possible diagnostic approach is to rerun the simulations using the realized $k_La$ profile, effectively decoupling the physical mass-transfer model. This allows a focused assessment of the biological sub-models' accuracy, as illustrated in Figure 2.

Figure 2 shows that the biological sub-models in models i and ii systematically result in an overprediction of the reactor mass when the realized $\mathrm{k_La}$ profile is imposed. In contrast the biological sub-model in model iii lead to an accurate prediction of the reactor mass. This indicates that, for models i and ii, inaccuracies in the physical $\mathrm{k_La}$ model and the biological growth model partially cancel each other out, leading to an apparently improved mass prediction in the fully coupled simulation. In contrast, the biological sub-model of model iii seems to be more accurate but does not benefit from this compensatory effect. Therefore, model iii suffers more directly from the limitations of the $\mathrm{k_La}$ model, when it's simulated.

Figure 3 illustrates the performance of the same models at production scale, compared against multiple manufacturing datasets shown in grey, with the black
