## ABSTRACT

Industrial decarbonization has heightened interest in electrifying major chemical processes, but existing planning methods typically assume fixed electricity prices and overlook how industrial power use affects the grid. This work introduces a grid-aware optimization framework that captures two-way interactions between industrial electricity usage and the power flows within the grid. We use the DC Optimal Power Flow (DC-OPF) model to generate Locational Marginal Prices across refinery demand levels and embed a surrogate reflecting the relationship between the power demand and the prices into an operational optimization problem for a partially electrified refinery. The surrogate model is embedded within the optimization problem using disjunctive reformulations and off-the-shelf packages such as OMLT (Optimization and Machine Learning Toolkit). In a case study considering an oil refinery with installed electric boilers, electrolyzers, $H_2$ storage, and post-combustion carbon capture infrastructure, the grid-aware approach lowers operating costs by 7% relative to a price-taker model by anticipating how the refinery's own demand shifts electricity prices. The method is also shown to incorporate the effect of demand uncertainty at other grid nodes by embedding a surrogate model trained using data generated by a chance-constrained DC Optimal Power Flow.

**Keywords**: Energy Systems, Electricity & Electrical Devices, Surrogate Model, Refining, Process Operations

## INTRODUCTION

The chemical industry is undergoing a fundamental transformation toward decarbonization and electrification, driven by the integration of renewable energy and novel low-carbon technologies. Investment and operational planning for this transition are interconnected, as the flexible operation of electrified systems enhances their economic viability. Previous literature typically utilizes multi-period superstructure optimization to determine optimal technology portfolios and operating schedules while satisfying emission targets and physical constraints [1–4, 24]. Stochastic and robust self-scheduling models outperform deterministic approaches by up to 10%, as they effectively hedge against price and renewable production uncertainty [5, 6].

Despite these advances, most optimization studies adopt a price-taker framework, assuming that individual facilities, whether acting on the supply or load side do not influence market prices. By relying on exogenous price profiles, these models overlook the impact of utility-scale loads (100+ MW) on the grid. In U.S. markets, Independent System Operators (ISOs) establish Locational Marginal Prices (LMPs) through a clearing process that dispatches resources optimizing for production cost subject to demand and transmission constraints. When large industrial facilities shift production or deploy storage, they directly alter the demand profile, shifting LMPs and potentially amplifying price volatility. Recent evaluations have shown that these price-taker assumptions in self-scheduling can lead to significant discrepancies when compared to system-scheduling solutions [7–9]. A few recent studies have more explicitly modeled the complex interactions between integrated energy systems (IESs) and the electric grid by embedding market-clearing simulations into facility models [10] or using machine-learning surrogates to capture price formation [11]. Price maker frameworks, on the other hand employ game-theoretic [13–15] or residual demand [12] methods. While previous literature has mostly focused on the supply side, recent work has begun to examine strategies such as demand bidding that have emerged as promising mechanisms for integrating large industrial consumers into power system operations. Tang et al [13] formulate

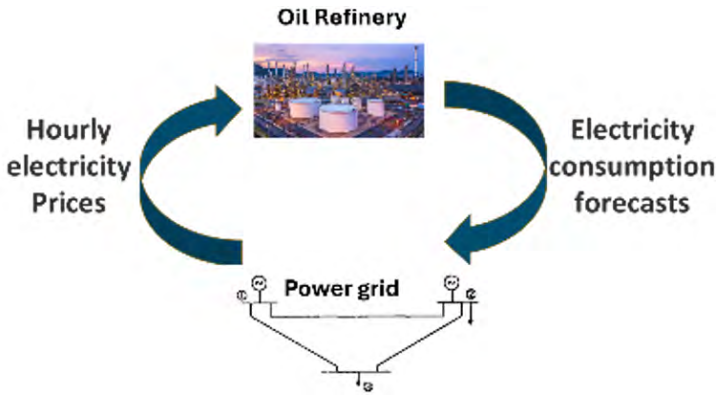

**Figure 1.** Interaction between industries and power grid

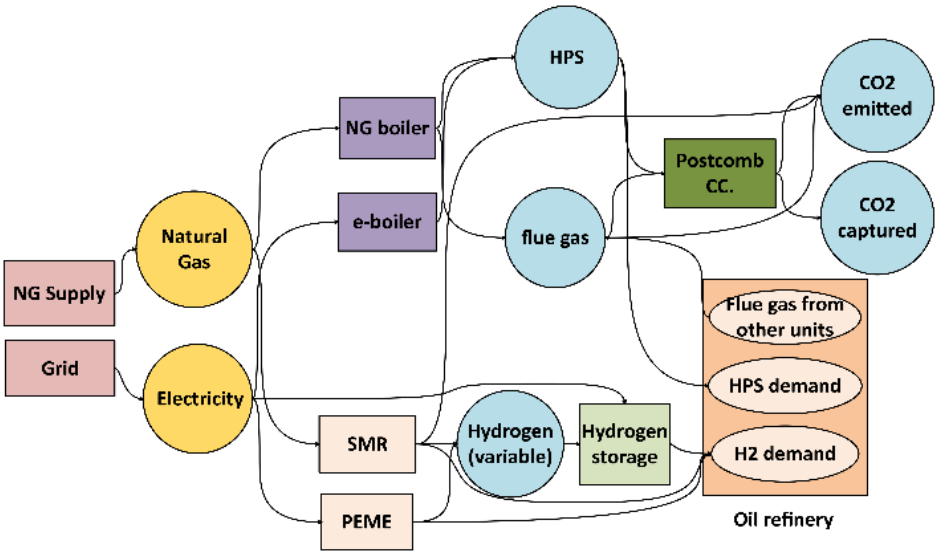

**Figure 2.** Flowsheet for partially electrified refinery

demand bidding within a modified AC optimal power flow framework, interpreting it as negotiation between operators and users. Their case study, implemented using a synthetic model of the Texas ISO, indicates that although the demand bidding framework decreases generation costs, its overall system benefits are restricted by transmission grid limitations and necessitate a level of data sharing not currently standard in the industry. This highlights a critical gap: the need for grid-aware demand-side strategies that allow industrial facilities to internalize grid limitations and price impacts within current data-sharing constraints.

The remainder of this paper is organized as follows. First, we introduce the problem statement. Then we present a multi-period linear program (LP) for operational decision-making in a partially electrified refinery model alongside standard and chance-constrained DC Optimal Power Flow (DCOPF) models to account for uncertainty. We then describe the surrogate modelling strategy capturing LMPs as a function of refinery load, which are embedded into the LP. Finally, we compare a price-taker baseline against these proposed scenarios and state concluding takeaways.

## PROBLEM STATEMENT

Given a partially electrified refinery, where the refinery operator's decision depends on grid electricity prices, which in turn depend on power demand and supply (in the grid network). The public availability of historical load and price data from RTOs [23] allows the refinery to build surrogate models that characterize this relationship, effectively bypassing the need for full access to restricted grid-side data. Our goal is to develop a novel integrated approach that can be used by such refineries to make grid-aware decisions, capturing these price dynamics by embedding the trained surrogate relationship directly into the refinery's operational optimization.

# METHODOLOGY

## Optimization of refinery operations

The flowsheet for the considered partially electrified refinery is shown in Fig 1. The flowsheet is denoted by a resource task network [18-19] with circular nodes depicting the resource nodes and the rectangular nodes showing the task nodes. The steam requirements can be satisfied by a mix of a natural gas (NG) boiler and e-boiler. The $H_2$ requirements are satisfied by the steam methane reformer and proton exchange membrane electrolyzers (PEME). The optimization problem minimizing operational costs for such a refinery is modeled as a multiperiod linear program defined over discrete time periods t ∈ T. Material flows are represented by the $F^{j}_{\mathrm{k,t}}$, where j denotes the technology or subsystem, and k shows the specific inlet or outlet stream.

The emissions from other parts of the refinery, such as the fluid catalytic cracking unit, furnaces, and gas-based units such as the NG boiler and steam methane reformer (SMR), can also be treated by the post-combustion capture unit. All equipment is assumed to operate flexibly within specified operational constraints.

Power outputs are denoted by $P^{o}_{t}$ for an electrically driven device *o*. Storage levels are represented by $L^{s}_{t}$ for each storage technology $s \in S$. These are the decision variables. Installed capacities for units and storage are given by $Q_j$, with minimum-load fractions $\kappa_j$. Conversion efficiencies are denoted by $\gamma^{j}_{k}$, and ramp-up/ramp-down limits by $r^{U}_{j}$ and $r^{D}_{j}$. System demands, such as hydrogen demand $d_{H_2,t}$ and heat/power steam demand $d_{HPS,t}$, must always be met. External energy prices include the natural gas price $\$_{NG}$ and time-varying electricity price $\$_{elec.,t}$. A system-wide $CO_2$ emissions cap is enforced via a $CO2_cap$.

The optimization problem, which minimizes the discounted daily operating cost, is shown in Eq. (1) for steam generation, $H_2$ production, storage, and carbon capture. The hourly operating cost includes the natural gas cost, electricity cost, $CO_2$-capture solvent-related operating costs, and other operating expenses related to the storage systems shown in Eq. (2). The sets used in this formulation are defined in the nomenclature section at the end of this paper.

$$Min: \sum_{t\in T} \frac{OPEX_t}{(1+int)^{\mathrm{yr}}} \tag{1}$$

$$OPEX_t = \Big(\sum_{j\in Out(NG)} F^{j}_{NG,t}\ \$_{NG} + \sum_{j\in Out(grid)} P^{j}_{t} \times \$_{elec.,t}\Big) + \sum_{j\in CC_{units}} \left(\frac{\$_{sol.,j}}{unit_{CO_2capt.}}\right) F^{j}_{CO_2\ capt.,t} + \sum_{s\in S, j\in In(s)} \left(F^{s}_{H_2,t} \times \$OPEX_s\right) \tag{2}$$

Each unit must operate within its maximum installed capacity and above its minimum turn-down, described as a fraction ($\kappa \le 1$) of the installed capacity, as denoted in Eq. (3) and (4). For the $H_2$ storage unit, the state of charge at any given time is lower than the total installed storage capacity, as shown in Eq. (5).

$$\kappa_o Q_o \le P^{o}_{t} \le Q_o\ \forall \mathrm{t}\in \mathrm{T}, \forall \mathrm{o}\in \mathrm{O} \tag{3}$$

$$\kappa_m Q_m \le F^{m}_{k'_m,t} \le Q_m\ \forall \mathrm{t}\in \mathrm{T}, \forall \mathrm{m}\in \mathrm{M} \tag{4}$$

$$L^{s}_{t} \le Q_s\ \forall \mathrm{t}\in \mathrm{T}, \forall \mathrm{s}\in \mathrm{S} \tag{5}$$

Mass balances relating input and output component flows with respect to a key component is denoted by Eq. (6). The energy balances connecting power flows in electrically driven units to the corresponding mass flows of the key component are detailed in Eq. (7). Mass-balance on the $H_2$ storage unit is described in Equation (8) where the state of charge in consecutive time periods is obtained by the net $H_2$ inflow during a particular time. Equation (9) is a mass balance on the resource nodes.

$$F^{m}_{\mathrm{k,t}} = \gamma^{m}_{k} F^{m}_{k'_m,t}\ \forall \mathrm{t}\in \mathrm{T}, \forall \mathrm{m}\in \mathrm{M} \tag{6}$$

$$\gamma^{o} F^{o}_{k'_o,t} = P^{o}_{t} \forall \mathrm{t}\in \mathrm{T}, \forall \mathrm{o}\in \mathrm{O} \tag{7}$$

$$F^{s}_{l,t} - F^{s}_{k,t} = L^{s}_{t+1} - L^{s}_{t}\ \forall \mathrm{t}\in \mathrm{T}, \forall \mathrm{s}\in \mathrm{S} \tag{8}$$

$$\sum_{m\in In(n)} F^{m}_{n,t} = \sum_{p\in Out(n)} F^{p}_{n,t}\ \forall \mathrm{t}\in \mathrm{T}, \forall \mathrm{n}\in \mathrm{N} \tag{9}$$

Equation (10) specifies hourly ramp-up/down limits of the equipment, such as electrolyzers and e-boilers, restricting the feasible space for flexible operations. Operational constraints on the $H_2$ storage nodes limit the maximum charge and discharge rates, as shown in Eqs. (11) and (12).

$$r^{D}_{j} \le |F^{j}_{k'_j,t+1} - F^{j}_{\mathrm{k'_j},t}| \le r^{U}_{j}\ \forall \mathrm{t}\in \mathrm{T}, \forall \mathrm{j}\in \mathrm{J} \tag{10}$$

$$F^{s}_{l_s,t} \le \frac{Q_s}{\tau_{\mathrm{s,c}}}\ \forall \mathrm{t}\in \mathrm{T}, \mathrm{l_s}\in \mathrm{In(s)}, \forall \mathrm{s}\in \mathrm{S} \tag{11}$$

$$F^{s}_{k_s,t} \le \frac{Q_s}{\tau_{\mathrm{s,d}}}\ \forall \mathrm{t}\in \mathrm{T}, \mathrm{k_s}\in \mathrm{Out(s)}, \forall \mathrm{s}\in \mathrm{S} \tag{12}$$

Hydrogen and steam demand from the refinery must always be met as shown in Eqs. (13) and (14). $CO_2$ emissions from low concentration flue gases released by other parts of the refinery, such as the FCC unit and furnaces that do not have any e-based alternatives, are fixed using Eq. (15).

$$\sum_{q\in Q} F^{q}_{H_2,t} \ge d_{\mathrm{H_2},t}\ \forall \mathrm{t}\in \mathrm{T} \tag{13}$$

$$\sum_{h\in H} F^{h}_{HPS,t} \ge d_{HPS,t}\ \forall \mathrm{t}\in \mathrm{T} \tag{14}$$

$$F^{plant}_{flue_gas,t} = F_o \forall \mathrm{t}\in \mathrm{T} \tag{15}$$

The emissions over the time horizon considered are limited by the $CO2_cap$ (Eq. (16)).

$$\sum_{q\in Q}\sum_{t\in T} F^{q}_{CO_2emit.} \le CO_2_cap \tag{16}$$

## DCOPF

This is a linear approximation of the AC Optimal Power Flow problem. Here, the decision variable $P_{G_i}$ represents the power generated by the generator $i$ while the voltage angle at the bus $i$ is given by $\theta_i$. Parameters $P_{D_i}$ denotes the real power demand at the bus $i$. The coefficients $C_i'$ and $C_i$ are the generator cost parameters in the quadratic cost function. The term $B_{ij}$ refers to the line susceptance between buses $i$ and $j$ which is a line property measuring the ease of power flow, and $N_i$ indicates the set of neighboring buses connected to the bus $i$. Parameters $P_{G_i}^{\min}$ and $P_{G_i}^{\max}$ specify the minimum and maximum real power generation limits for the generator $i$, respectively and $P_{ij}^{\max}$ shows the maximum magnitude of power flow through the line connecting buses $i$ and $j$. Eqs. (17)-(20) show the associated quadratic program for the DCOPF problem. Eq. (17) shows the objective function, minimizing the total operating cost of all generators. Each generator's fuel cost is modeled as a quadratic function of its output. Eq. (18) states that the power balance must be satisfied at every bus $i$. According to the DC power flow model, real power flow through a transmission line depends linearly on the line susceptance and on the difference in voltage angles between the two buses it connects. Eq. (19) constraints that each generator must operate within its physical limits, whereas Eq. (20) restricts that the power flows through the lines are within allowed limits.

$$\min_{\{P_G,\theta\}} \varphi = \sum_{i\in G}\left( C_i' P_{G_i}^2 + C_i P_{G_i}\right) \tag{17}$$

$$P_{G_i} - P_{\mathrm{D_i}} = \sum_{\mathrm{j}\in \mathrm{N_i}} B_{ij}\left(\theta_i - \theta_j\right) \forall \mathrm{i} \tag{18}$$

$$P_{G_i}^{min} \le P_{G_i} \le P_{G_i}^{\max} \ \forall \mathrm{i} \in \mathrm{G} \tag{19}$$

$$-P_{ij}^{\max} \le B_{ij}(\theta_i - \theta_j) \le P_{ij}^{\max} \ \forall (\mathrm{i},\mathrm{j}) \in \mathrm{L} \tag{20}$$

The LMP is the electricity price at a specific grid node, representing the cost of delivering an additional unit of power, considering generation costs and transmission constraints as shown in Eq. (21). In practice, this is obtained from the Lagrange multipliers of the corresponding nodal power balance (Eq. (18)).

$$LMP_i = \lambda_i = \frac{\partial \varphi}{\partial P_{D_i}} \ \forall \mathrm{i} \in \mathrm{G} \tag{21}$$

## Chance Constrained DCOPF (CC-DCOPF)

In contrast to the standard deterministic DC-OPF model, this model treats the load as the sum of nominal and uncertain components. Real-time reserve deployment is characterized by generators adjusting their output proportionally to the total demand error, governed by their participation factors, to maintain system balance. This uncertainty is managed using chance constraints, a method widely adopted in the power systems community. Unlike robust optimization, which conservatively targets the absolute worst-case scenario, chance constraints offer a less risk-averse framework by strictly enforcing reliability only up to a specified probability level [20-22]. The chance-constrained DCOPF formulation (shown through Eqs. (22)-(27) accounts for uncertainty in demand for buses. The objective function is augmented to include cost terms not only for scheduled generation but also for reserve deployment, represented by the additional decision variables, $\hat{P}_{G_i}$. While the power balance equations and transmission limits remain consistent with the traditional DCOPF, as shown in Eq. (23) and (25), the generation limits now bound both the base and reserve generation capacities, as shown in Eq. (24). The enhanced formulation introduces a risk-based reserve constraint that requires each generator's reserve contribution to satisfy Eq. (26), where the decision variable $\alpha_{G_i}$ denotes the generator $i$'s participation factor, while the parameters $\sigma$ and $z_{1-\varepsilon}$ capture the magnitude of uncertainty in demand and the risk-taking capacity, respectively [22].

$$\min \sum_{i\in G}\left( C_i' P_{G_i}^2 + C_i P_{\mathrm{G_i}} + C_i' \hat{P}_{\mathrm{G_i}}^2 + C_i \hat{P}_{\mathrm{G_i}} \right) \tag{22}$$

$$P_{G_i} - P_{\mathrm{D_i}} = \sum_{\mathrm{j}\in \mathrm{N_i}} B_{ij}\left(\theta_i - \theta_j\right) \forall \mathrm{i} \tag{23}$$

$$P_{G_i}^{min} \le P_{G_i} + \hat{P}_{G_i} \le P_{G_i}^{\max} \ \forall \mathrm{i} \in \mathrm{G} \tag{24}$$

$$-P_{ij}^{\max} \le B_{ij}(\theta_i - \theta_j) \le P_{ij}^{\max} \ \forall (\mathrm{i},\mathrm{j}) \in \mathrm{L} \tag{25}$$

$$\hat{P}_{G_i} \ge z_{1-\varepsilon}\alpha_{G_i}\sigma \ \forall i \in G \tag{26}$$

$$\sum_{i\in G} \alpha_i = 1 \tag{27}$$

Eq. (26) is derived analytically by integration based on the relation shown in Eq. (28), stating that the probability of the reserve generation capacity being higher than the excess demand is greater than 1- $\varepsilon$. Assuming that the excess demand $\hat{P}_{D_i}$ follows a normal distribution with mean 0 and standard deviation $\sigma_i$, as shown in Eq. (29), the chance constraint is converted into an equivalent deterministic form expressed in terms of the standard normal quantile $\Phi^{-1}(1-\varepsilon)$ which is the same as $z_{1-\varepsilon}$. $\sigma_i$'s are related to $\sigma$ as described in Eq. (30), a normalization condition is introduced in Eq. (27) to ensure complete allocation of reserve responsibilities (participation factor) across the generating fleet. These additions enable the model to incorporate uncertainty-aware scheduling while preserving the structural simplicity of the conventional DCOPF framework.

$$\mathbb{P}\left( \left(\alpha_{G_i}\sum_i \hat{P}_{D_i}\right) - \hat{P}_{\mathrm{G_i}} \le 0 \right) \ge 1 - \varepsilon \ \forall i \in G \tag{28}$$

$$\Rightarrow \ \Phi^{-1}(1-\varepsilon)\alpha_{G_i}\sigma - \hat{P}_{\mathrm{G_i}} \le 0 \ \ \forall i \in G \tag{29}$$

$$\hat{P}_{D_i} \sim N(0,\sigma_i) \qquad \sigma = \left(\sqrt{\sum_i \sigma_i^2}\right) \tag{30}$$

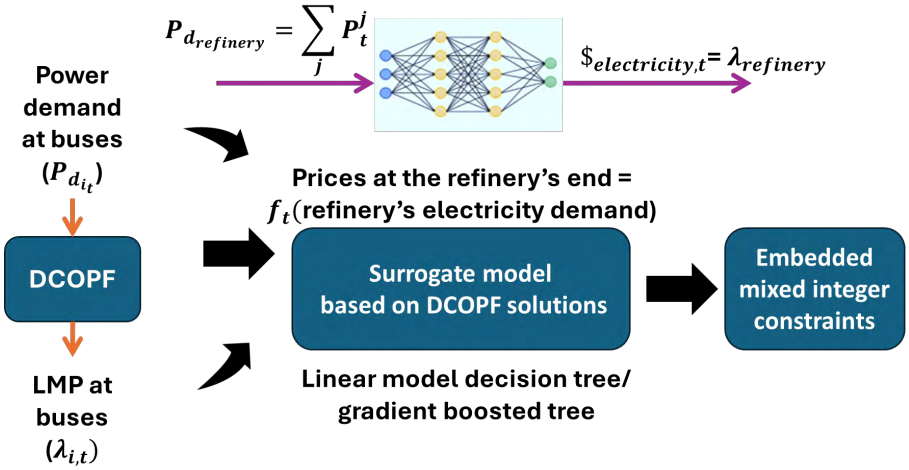

**Figure 3.** Surrogate model training and embedding

## Training the surrogate model

In our framework, we vary the refinery's active-power demand $P_{d_i}$ over a specified range while assuming that the demands at all other nodes are fixed and independent of the refinery's demand. For each time interval in which the non-refinery loads (e.g., residential demand) can be treated as fixed, we solve a series of DCOPF problems to generate training data and fit a separate surrogate model. Since the DCOPF is a quadratic program with linear constraints, its KKT conditions for a given active set constitute a system of linear equations in both the primal and dual variables. This implies that the nodal price is an affine function of the demand within a specific regime. However, as the active constraint set changes, the coefficients of this relationship shift, resulting in a global piecewise linear function. This structure motivates the use of linear-model decision trees and related surrogate models, such as gradient-boosted trees, to capture the varying linear regimes. In this work, we train such models on DCOPF-generated data and embed the resulting relationship into the refinery's operational optimization problem. This could be expressed as the disjunction shown in Eq. (31).

$$\vee \begin{bmatrix} Z_w \\ \underline{P_{w,t}} \le \sum_{j \in Out(Grid)} P_t^j \le \overline{P_{w,t}} \\ \$_{elec,t} = a_{w,t} \sum_{j \in Out(Grid)} P_t^j + b_{w,t} \end{bmatrix} \quad (31)$$

Each disjunct is indexed by $w$, and in every disjunct the refinery's total power demand, $\sum_{j \in Out(Grid)} P_t^j$ is restricted to lie between the lower and upper bounds $\underline{P_{w,t}}$ and $\overline{P_{w,t}}$. Within each disjunct, the electricity price $\$_{elec,t}$ is modeled as a linear function of the total power consumption $\sum_{j \in Out(grid)} P_t^j$, characterized by a slope $a_{w,t}$ and an intercept $b_{w,t}$.

Both the slope and intercept vary over time, as the applicable surrogate model is time-dependent. If we explicitly include equality constraints expressing the total electricity cost, $\$_{elec,t}$, as a function of demand, the objective function (2) still contains non-convex bilinear terms. These terms arise from expressing the total cost as a product of price and power consumption, which significantly increases the computational burden. While off-the-shelf tools like OMLT can automate the embedding of such relationships, a custom reformulation that substitutes the cost function directly into the objective allows for better convergence by avoiding bilinearities. We perform a convex hull reformulation, before substituting the cost term in the objective, Eq. (2). At a given time $t$, exactly one binary variable $y_t^w$ is activated depending on the range in which the total power consumption lies. Depending on this, exactly one auxiliary variable $P_t^w$ and its corresponding quadratic term, $P_t^{w2}$ are nonzero, as shown in Eqs. (34) and (35). The sum of $P_t^w$ over all disjuncts equates to the total consumption across all refinery units. The resulting model obtained by introducing Eqs. (33)-(35) and substituting the term in the RHS of Eq. (32) in the objective function, expressed IN Eq. (2) appropriately, is a Mixed Integer Quadratic Program (MIQP) with a convex relaxation.

$$\$_{elec.,t}\left(\sum_{j \in Out(grid)} P_t^j\right) = \sum_w (b_{w,t} P_t^w + a_{w,t} P_t^{w2}) \; \forall t \in T \quad (32)$$

$$\left(\sum_{j \in Out(grid)} P_t^j\right) = \sum_w P_t^w \; \forall t \in T \quad (33)$$

$$\underline{P_{w,t}} y_t^w \le P_t^w \le \overline{P_{w,t}} y_t^w \; \forall t \in T \quad (34)$$

$$\sum_w y_t^w = 1 \quad (35)$$

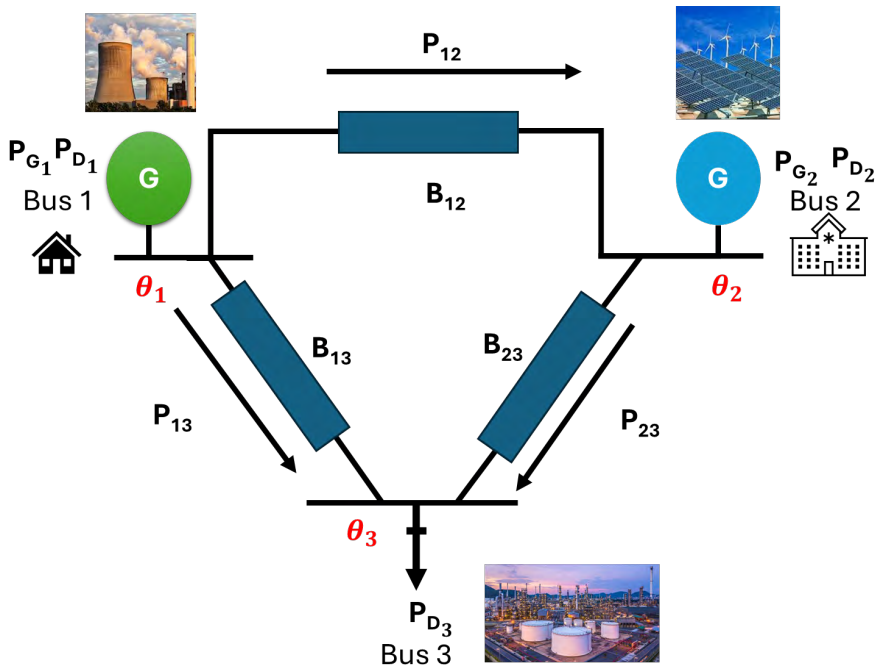

**Figure 4.** Considered Power grid network

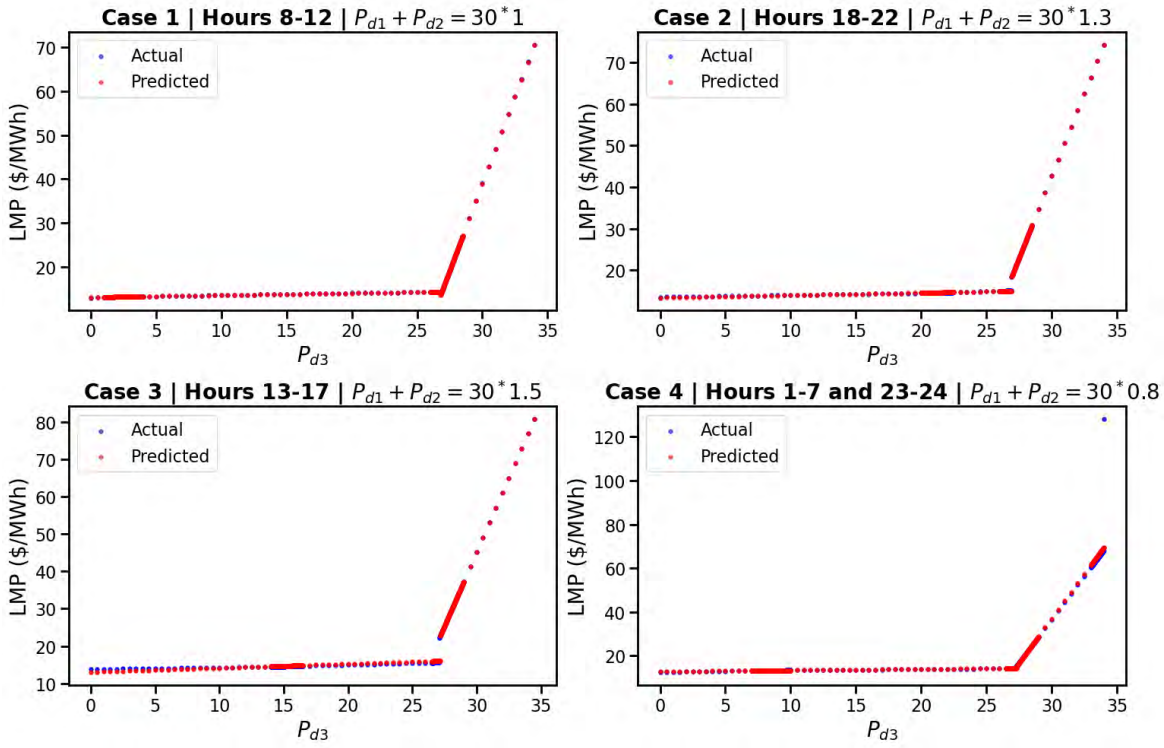

**Figure 5.** Fit for each time segment when demand at the other nodes are fixed using linear model decision trees Chance-constrained DCOPF embedding

## RESULTS

We illustrate the proposed approach on a 3-bus system in which the refinery is at Bus 3. Fig. 4 presents the fits obtained using linear model decision tree surrogates for each time segment, with the

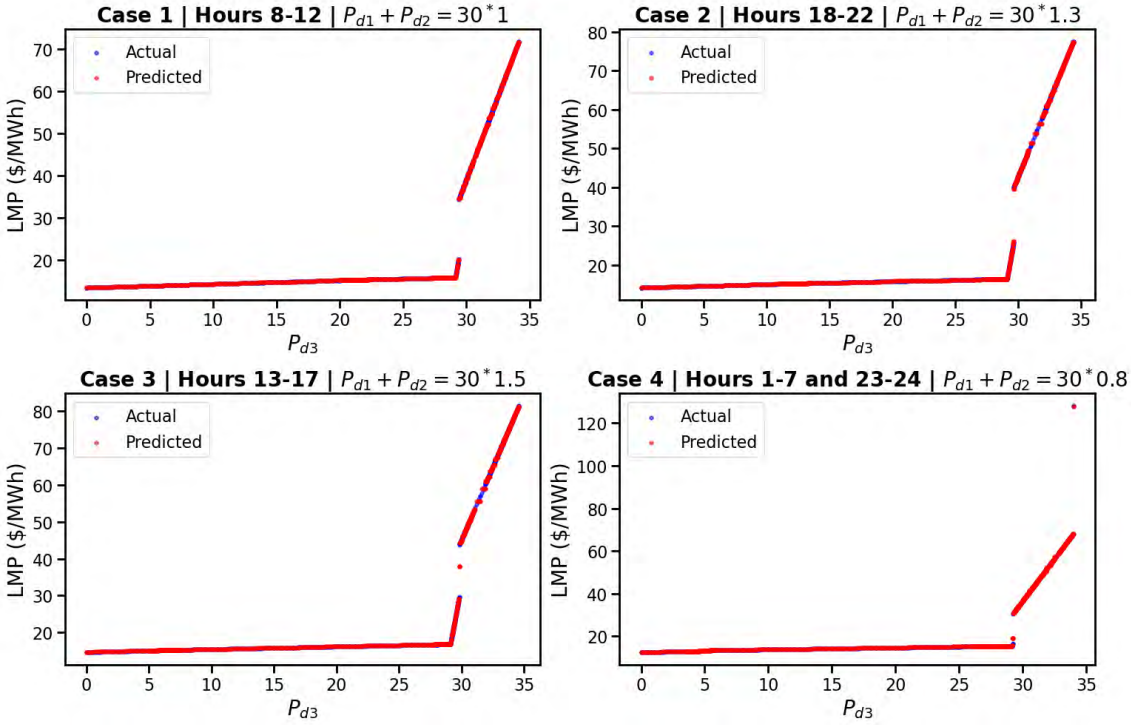

**Figure 6.** Fit obtained for each time segment using GBTs

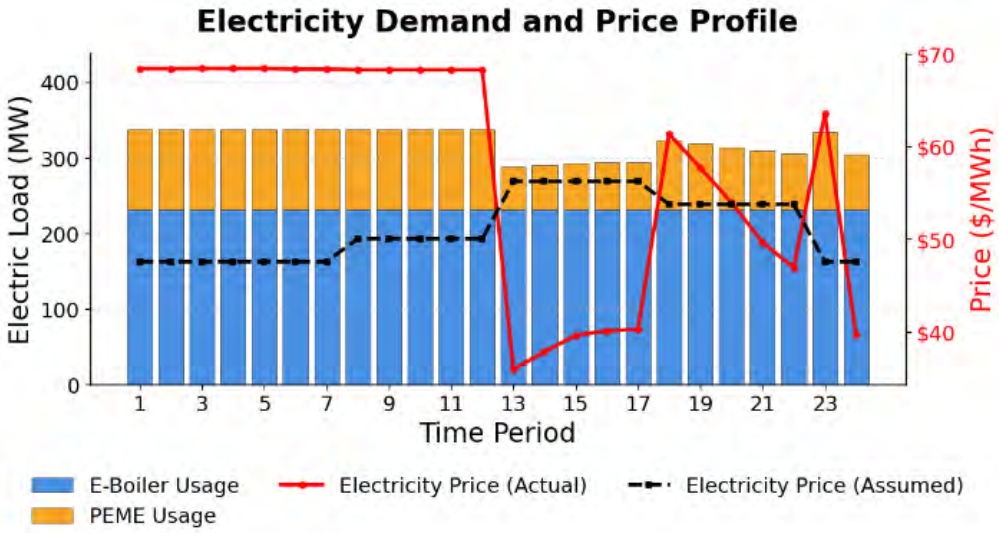

**Figure 7.** Base case electricity usage and prices

corresponding loads at the other buses annotated in the figure (shown in scaled units of 10 MW). Linear model decision trees work by recursively partitioning the data and then fitting a local linear model to each part, so the overall model captures piecewise-linear relationships. To ensure the accuracy of these captured transitions, the surrogate model was trained by sampling more densely around the sharp corners; detailed data regarding both the underlying refinery model and the surrogate fit accuracy shall be published in a forthcoming full-length paper. Since the slopes of all linear functions are positive, the relaxation of the previous formulation is convex. In this setting, we also observe in Fig 5, that the overall piecewise functions can also be represented as a maximum over the constituent linear functions, as shown in Eq. (36). Now, this term in the LHS of Eq. (37) can be substituted by an additional variable $c_t$ in the objective of the refinery optimization problem, as shown in Eq. (2), and the max function can be represented by a series of $W$ inequality functions as shown in Eq. (38). This removes

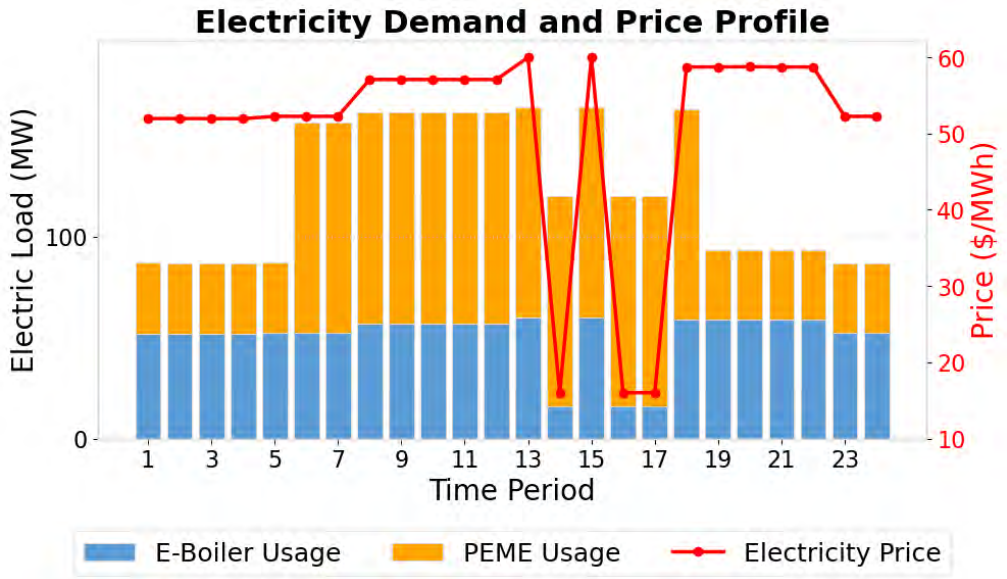

**Figure 8.** Load profile and prices using MIP formulation ranging from 5.9% to 6.7%. (using an embedding built from data generated from DCOPF solutions)

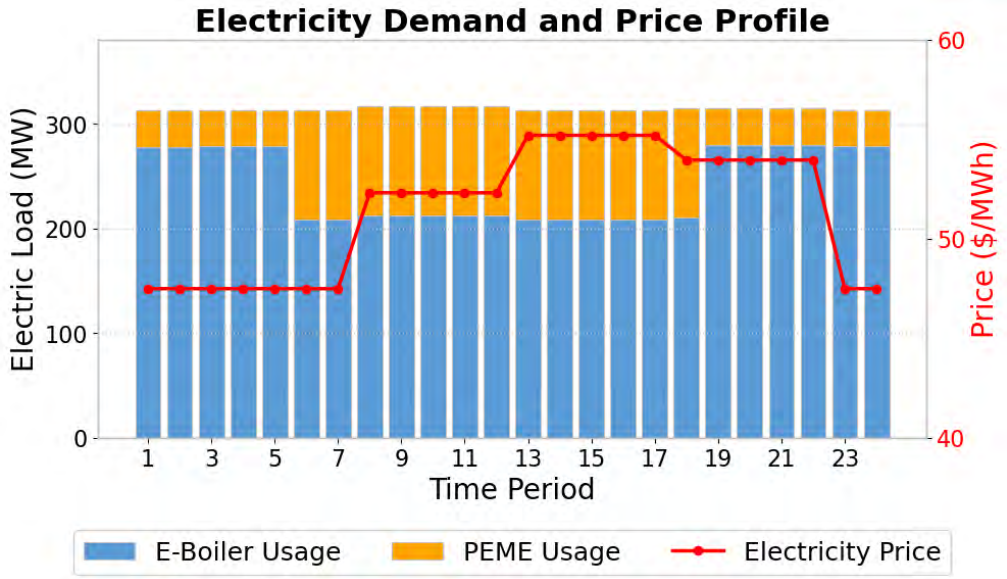

**Figure 9.** Load profile and prices using NLP formulation (using an embedding built from data generated from DCOPF solutions)

the need for additional binary variables and allows the NLP problem to be handled directly by any standard nonlinear solver.

$$\$_{elec.,t}\left(\sum_{j\in Out(Grid)} P_t^j\right) = \max_w a_{w,t}P_t^{w2} + (b_{w,t}P_t^w))\ \forall \mathrm{t} \in \mathrm{T} \quad (36)$$

$$\$_{elec.,t}\left(\sum_{j\in Out(Grid)} P_t^j\right) = c_\mathrm{t}\ \forall t \in T \quad (37)$$

$$c_\mathrm{t} \geq a_{w,t}P_t^{w2} + (b_{w,t}P_t^w)\ \forall w\ \forall \mathrm{t} \in \mathrm{T} \quad (38)$$

In contrast, when using CC DCOPF, expressed using solution Eq (22)-(27), to generate data for surrogate building, the linear model decision trees could not provide satisfactory fits, especially around the sharp corners, irrespective of the denser sampling. On the other hand, gradient-boosted trees provided a better fit. The obtained fit is shown in Fig 6. By varying the hyperparameters, Gradient-boosted trees (GBTs) are used to obtain satisfactory fits on the data. These generate predictions by combining many small decision trees sequentially, where each new tree focuses on correcting the errors of the previous ones. We used OMLT 1.2.2 [17] to generate a mixed Integer formulation.

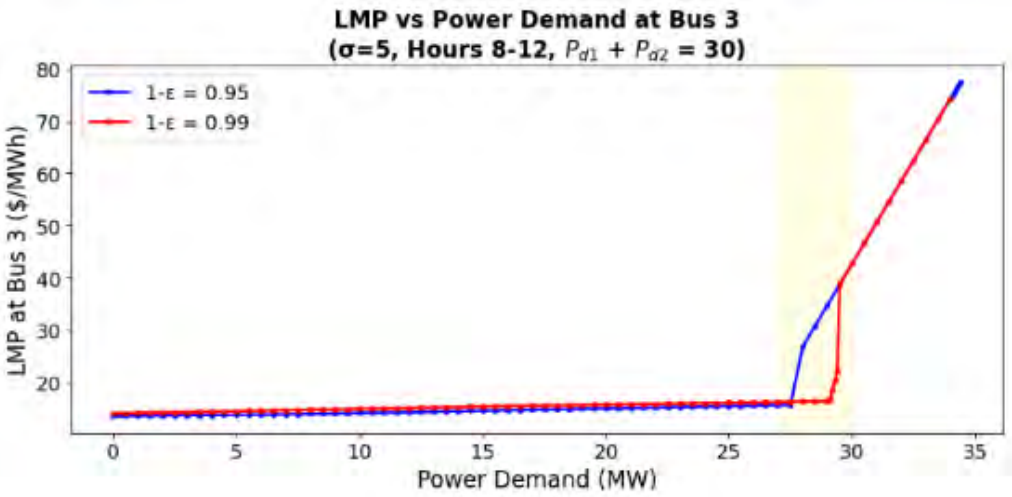

**Figure 10.** Chance constraint generated DCOPF data

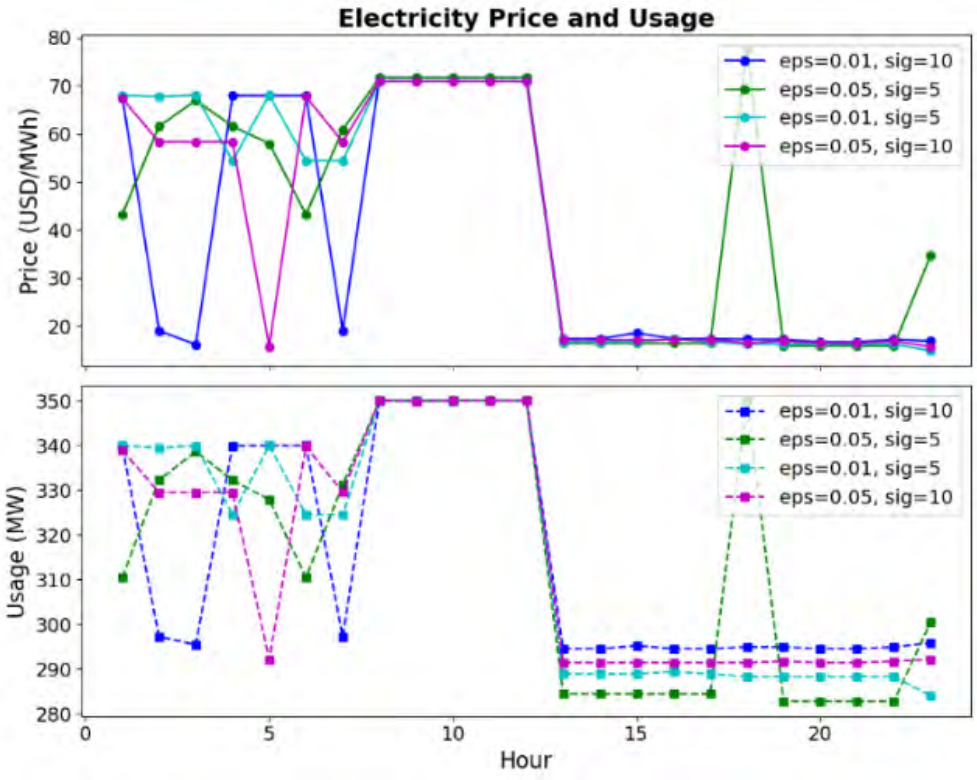

**Figure 11.** Optimal electricity price and Usage with varying hyperparameters within the chance-constrained model

## DCOPF embedding

In the base case, when the price-taker assumption is in place as shown in Fig 7, the model attempts to leverage forecasted periods of low price (assumed price profile shown using the black dotted line) by ramping up production of hydrogen using electrolyzers. However, such actions raise the actual electricity price, which is shown using the solid red line. In this case, with the assumed costs, the optimizer predicted an objective of 0.767 MUSD. But when the demands from the refinery were added to the OPF model, the actual price profiles resulted in a cost of 0.824 MUSD being incurred, a 7.5% increase over the predicted cost. When using the 2 different formulations (MIQP and NLP) consisting of the embedded surrogate model, the objective function value in both these cases was 0.767 MUSD, about 7% lower than the 0.824 MUSD incurred cost in the base case.

The MIQP formulation consists of 1, 082 variables, of which 48 are binaries, and 989 constraints, out of

which 705 are equalities, and was solved using DICOPT 2.0 in 2.2 seconds. The NLP formulation consists of 1, 082 continuous variables and 989 constraints, of which 627 are equalities, and was solved using IPOPT 3.14.17 in 1.5 seconds. However, these two cases produce different load and price profiles that are degenerate solutions of the overall optimization problem (Fig 8 and 9). In particular, the NLP formulation yields a more stable load profile compared to the base case. The degeneracy arises because the model can exploit price variability through the use of hydrogen storage equipment and incorporate a hybrid approach using Proton Exchange Membrane Electrolyzer and Steam Methane Reformer.

A limitation of the previously developed framework is the assumption of perfectly known loads at other nodes and exact grid parameters. Accurately predicting loads at other buses is generally challenging. The resulting formulation obtained by embedding gradient boosted trees trained using optimal solutions to the CC DCOPF is a nonconvex mixed-integer quadratically constrained program (MIQCP) with 28, 360 constraints and 14, 046 variables, of which 3, 508 are binary (and integer). The problem is solved using the Gurobi Optimizer (version 12.0.1) with a time limit of 1, 800 seconds. We illustrate the impact of embedding a chance-constrained DCOPF within the refinery planning model, considering demand uncertainty, under varying risk tolerance ($\epsilon$) and uncertainty levels ($\sigma$). Varying the $\sigma$ and $\epsilon$ values as shown in Table 1, the solution converged with gaps

Lower values of $\epsilon$ and higher $\sigma$ reflect reduced risk-taking capability and higher uncertainty in predictions of load at other nodes, respectively. As shown in Fig 10, while locational marginal prices within each linear segment are slightly higher with reduced $\epsilon$, increased uncertainty causes the upper limit in constraint (24) to become binding at lower demand levels, moving the point of non-smoothness in the LMP–demand curve toward higher power values, as illustrated by the shaded region in Fig. 10. Since the optimal operating region includes the region consisting of this sharp corner, as shown in Fig. 10, higher $\sigma$ values and lower $\epsilon$ values lead to lower overall objective function values due to the lower prices encountered in this region at similar loads (shown in Table 1).

**Table 1.** Objective value with changing hyperparameters

| $\sigma$ | 1-$\epsilon$ | Objective Function (MUSD) |
|---|---|---|
| 5 | 0.95 | 0.7237 |
| 10 | 0.95 | 0.6892 |
| 5 | 0.99 | 0.7046 |
| 10 | 0.99 | 0.6740 |

## CONCLUSIONS

This work presents a framework for incorporating electricity market effects into the operational planning of an electrified oil refinery. These effects are captured by embedding constraints derived from relationships modeled with surrogate models, trained on DCOPF-based data. The surrogate models reflect the impact of refinery load on nodal electricity prices. The piecewise-linear relationship between refinery power demand and prices is approximated with linear model decision trees or gradient-boosted trees. In the illustrative example, the surrogates are embedded within the refinery optimization problem using reformulations of the resulting GDP, namely a MIQCP and an NLP reformulation, or off-the-shelf tools such as OMLT. These demonstrated improved objective values compared to a base case that ignores price feedback from the market, while providing optimal load profiles through coordinated hydrogen storage and hybrid electrolyzer and e-boiler operation. We extend this framework to incorporate uncertainty in load forecasts at other buses by embedding constraints that represent surrogate models trained using optimal solutions obtained from chance-constrained DCOPF. The results show that lower risk-taking capacity and higher uncertainty at the grid operator's end can counterintuitively reduce overall costs at the electrified refinery's end. Despite promising cost-reduction potential, two primary limitations remain for the illustrated framework. The use of a 3-bus system necessitates future testing on larger-scale networks to ensure scalability. Additionally, advancing from DCOPF to ACOPF-based surrogates is essential to capture the reactive power and voltage dynamics necessary for full physical fidelity.

## ABSTRACT

The manufacturing industry is the second largest emitter of $CO_2$, with the cement industry being one of the main contributors (7-8 % of the global emissions). Carbon capture and utilization (CCU) technologies are promising decarbonization solutions for the cement industry, addressing both fossil fuel-related (40 %) and process-derived emissions (60 %). Within a cement plant, producing synthetic natural gas (SNG) from captured $CO_2$ is particularly suitable, as it is sufficient to fully replace solid fuels in the rotary kiln. On the other hand, the use of zero-carbon fuels, such as green ammonia, is also recognized as a promising approach for decarbonization. In this work, a superstructure was developed to explore alternative routes for producing SNG and green ammonia from $CO_2$ and $N_2$ in cement plant flue gas, respectively. The routes were modelled in Aspen Plus® V14, and their economic viability was assessed. Currently, the most promising route, at a cost of 109 €/tonne of flue gas, involves $CO_2$ capture (90% efficiency) and storage, with the N2-rich stream emitted. However, all the routes remain uncompetitive compared with the full emission of the flue gas (22 €/tonne). Routes for green ammonia production from $N_2$ in flue gas were compared with those from atmospheric air but were found to be uncompetitive. Nevertheless, with future developments, the economic feasibility of integrating pathways for synthesizing high-value chemical products into the cement industry is expected to increase.

## INTRODUCTION

Climate change continues to pose a pressing global challenge, driving extensive research and policy initiatives worldwide. The planet's temperature has been exponentially increasing over the past decades, reaching the value of 1.28 °C above the pre-industrial average in 2024 [1]. This translates to a new record high of 37.8 Gt of $CO_2$ emitted [2], which takes responsibility for global warming, as it is the main greenhouse gas (GHG). Relocating electricity and heat consumption to their respective sectors, the industry sector becomes the most impactful one for GHG emissions, accounting for 39% of global $CO_2$ emissions. The cement industry alone is responsible for around 7-8% of GHG emissions, as CO2 is a direct by-product of its production process, which explains the high $CO_2$ content in its flue gas. Carbon capture, utilisation and storage (CCUS) is considered a promising strategy for reducing these emissions. The literature on the treatment of cement plant flue gas focuses primarily on carbon capture and storage technologies [3]. However, studies have reported the possibility of producing high-value chemicals, such as formic acid, dimethyl ether and synthetic natural gas (SNG), despite having obstacles in terms of high energy and raw materials consumption [4]. Among these carbon utilization strategies, the conversion of the captured $CO_2$ into SNG through the Sabatier process, with the addition of green hydrogen and in the presence of metal catalysts, is particularly suitable for the cement industry, as the

produced SNG is enough to fully replace the solid fuels fed into the rotary kiln and precalciner of a cement plant [5].

Since the cement plant flue gas is composed of not only $CO_2$, but also $N_2$ and some minor compounds, the obtention of a high-purity $CH_4$ stream usually requires pre-treatment of the flue gas to remove $NO_x$, $SO_x$, HCl and dust particles and an additional capture unit for $N_2$ separation from $CO_2$ [6]. The best available technologies for pre-treatment include wet scrubbing with hydrated lime and selective catalytic reduction (SCR) for SOx and NOx removal, respectively, while the most mature carbon capture technology is absorption with monoethanolamine (MEA) [7-9].

Traditionally, ammonia ($NH_3$) is synthesized through the Haber-Bosch (H-B) process, which relies on fuel gasification, leading to large $CO_2$ emissions. Power-to-ammonia technologies offer a sustainable alternative, requiring nitrogen ($N_2$), usually obtained from an air separation unit (ASU), and green hydrogen from water electrolysis, which are both highly energy-intensive [10]. Because common cement plant flue gas has a high $N_2$ content, utilizing this component in an ammonia production process offers a promising alternative to bypass the ASU and reduce energy consumption. This way, transforming $N_2$ into $NH_3$, a versatile compound with fertilizer and energy applications, highlights the potential of generating valuable products from the cement plant flue gas.

Despite their potential, CCU and green ammonia production face economic and technical challenges, mainly due to the high cost of green hydrogen. Existing pilot plants study these technologies separately, missing potential synergies between the processes. This work introduces a novel approach by using industrial flue gas as an $N_2$ source, thereby eliminating the need for an ASU.

## METHODS

The flue gas of a cement plant was considered to go through a set of processes defined in a superstructure to capture and either store or convert $CO_2$ into SNG and $N_2$ into ammonia. These processes were modelled using Aspen Plus® v14 and the techno-economic viability of each route of the superstructure was evaluated. The heat exchangers of the processes considered were designed using Aspen Exchanger Design & Rating (EDR)® [11].

### Cement Plant Flue Gas

The typical composition of a cement plant flue gas, which was used as a basis for this work, was retrieved from the work of Schakel et al. [6]. However, only 10 % of the total mass flowrate of the cement plant flue gas was considered, to avoid ammonia market saturation.

### Superstructure

The most mature technologies were integrated to assess the techno-economic feasibility of converting a typical cement plant's flue gas into SNG and green ammonia, reaching the superstructure shown in Fig. 1.

Before feeding the production processes, the flue gas must undergo pre-treatment to remove $NO_x$, $SO_x$, HCl, and dust particles. After this process, four options were considered: the separation of $CO_2$ from $N_2$ with 90 % efficiency ('MEA absorber (90 %)') or with approximately 100 % efficiency ('MEA absorber (~100 %)'), no separation of these components or direct emission of the flue gas. The 'MEA absorber (~100 %)' process was investigated to obtain a $CO_2$-free outlet, which can be sent directly to the H-B process. In the MEA absorption units, the stream is separated into a $CO_2$-rich and a $N_2$-rich stream. The $CO_2$-rich stream can either be sent to the 'Sabatier' unit to generate SNG or to storage, while the $N_2$-rich stream can be valorized into green ammonia in the H-B process or emitted. If the high-purity $N_2$ stream comes from a capturing unit with 90 % efficiency, a methanation step is required beforehand, since the catalysts used for ammonia production are poisoned by oxygen-containing compounds [12]. The 'MEA absorber (~100 %)' option was therefore considered to avoid the need for this additional methanation step. Regarding the option of no $CO_2$/$N_2$ separation, the pre-treated flue gas stream is subjected to methanation for converting the $CO_2$ to methane and sent to the Haber-Bosch process to generate green ammonia. The ammonia is then separated from the methane through distillation. All these routes were compared with the full flue gas emission and with the production of green ammonia through the hydrogenation of atmospheric air. Tab. 1 presents the nomenclature of the different superstructure paths.

**Table 1:** Nomenclature of the superstructure routes. MEA stands for monoethanolamine, and ASU stands for an air separation unit.

| Separation | $CO_2$ stream | $N_2$ stream | Route |
|---|---|---|---|
| MEA absorber (90 %) | Sabatier | Haber-Bosch 1 | $A90^{S}_{HB}$ |
| | | Emit | $A90^{S}_{E}$ |
| | Storage | Haber-Bosch 1 | $A90^{CCS}_{HB}$ |
| | | Emit | $A90^{CCS}_{E}$ |
| MEA absorber (~100 %) | Sabatier | Haber-Bosch 2 | $A100^{S}_{HB}$ |
| | | Emit | $A100^{S}_{E}$ |
| | Storage | Haber-Bosch 2 | $A100^{CCS}_{HB}$ |
| | | Emit | $A100^{CCS}_{E}$ |
| No separation | Sabatier + Haber-Bosch 3 | | $A0^{S}_{HB}$ |
| | Emit | | $E$ |
| ASU | - | Haber-Bosch 2 | $ASU_{HB}$ |

The route nomenclature follows the rule: $X^{i}_{j}$. $X$ represents the separation options of the pre-treated flue gas/air stream, $i$ represents the options of the $CO_2$-rich stream generated after absorption and $j$ represents the

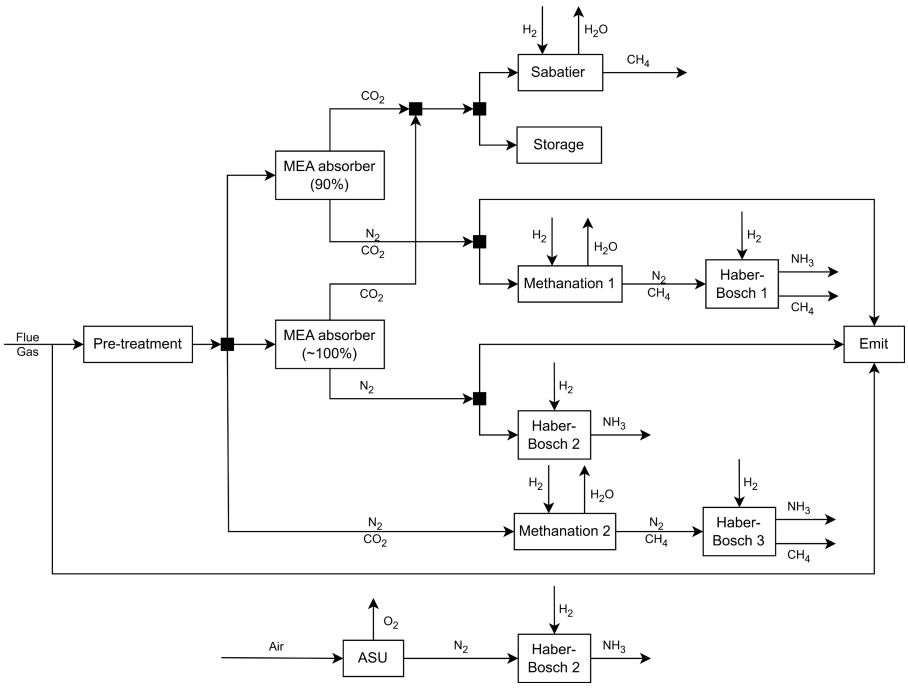

**Figure 1.** Superstructure for synthetic natual gas and green ammonia production from a cement plant flue gas.

options of the $N_2$-rich stream generated after absorption.

## Pre-treatment

The pre-treatment process aims to remove $O_2$, $NO_x$, $SO_2$, HCl, and dust particles from the initial flue gas. For the removal of $SO_2$ and HCl, a 10 %wt. $CaCO_3$ aqueous solution was added to a scrubber, which was simulated in Aspen Plus® V14 by using a *RadFrac* model and implementing the equilibrium reactions described by Duque et al. [13]. The dust particles were also assumed to be removed by the scrubber. On the other hand, rate-controlled reactions were implemented to model the $NO_x$ elimination with $NH_3$ in the SCR using a *RPlug* block, as suggested by Sweeney and Liu [14]. The $O_2$ elimination was modelled using a *RStoic* model, with its reaction with $CH_4$ following the work of Lu et al. [15]. The diameter of the scrubber was calculated by Eq. (1)

$$D_{scrubber} = \sqrt{\frac{4S}{\pi}} = \sqrt{\frac{4Q_{v,gas}}{\pi v_{gas}}} \quad (1)$$

, where $Q_{v,\,gas}$ is the gas volumetric flowrate and $v_{gas}$ is the gas velocity inside the scrubber, which was considered 1 m/s [16]. The scrubber's height (L) was attained using Eq. (2) [16].

$$\frac{L}{D} = 3 \quad (2)$$

Regarding the SCR, a tubular flow reactor must be used, which has a usual residence time ($\tau$) of 0.8 s [17]. This, combined with the gas flowrate going through the reactor, enables the calculation of the volume occupied by the gas ($V_{gas}$). The catalyst volume ($V_{cat}$), which can often be neglected for being considerably smaller than $V_{gas}$, can be calculated using the mass of catalyst inside the reactor ($m_{cat}$) and its density ($\rho_{cat}$), leading to Eq. (3).

$$V_{reactor} = V_{gas} + V_{cat} = Q_{v,gas} \bullet \tau + m_{cat} \bullet \rho_{cat} \quad (3)$$

Applying Eq. (2) to the formula of the volume of a tubular reactor, it is possible to calculate directly the diameter of the reactor ($D$), reaching Eq. (4) [16].

$$D = \sqrt{\frac{4\,V_{reactor}}{\pi L}} \quad (4)$$

Regarding the removal of $O_2$, Lu et al. [15] also suggests a tubular flow reactor, which can be designed using the previous expressions.

## MEA absorption

The goal of the MEA absorption process is to separate $N_2$ from $CO_2$ in the treated flue gas. For this, two MEA absorption systems were simulated: one with 90 % carbon capture efficiency and the other with an almost complete $CO_2$ capture. The two simulations differ only on the reboiler duty needed for stripping the $CO_2$ from the solvent, to regenerate it. An AspenTech example [19] was adapted with the chemistry and reaction models retrieved from the work of Madeddu et al. [9] to build a rate-based model. The main equipment consists of two packed columns, which were simulated as RadFrac models with Sulzer Mellapak 250Y packing: an absorber, where the flue gas enters and contacts with the MEA solvent, which absorbs the $CO_2$, and a stripper, where the $CO_2$-rich solvent is separated from the $CO_2$ and pumped

back into the absorber. The design of both the columns followed the method of Madeddu et al. [9].

### Methanation

The Sabatier process can have two objectives: to solely produce $CH_4$ or to prevent the poisoning of the downstream Haber-Bosch system by converting $CO_2$ into $CH_4$. For the simulation, the reaction of Eq. (5) was implemented with the kinetics retrieved from the study of Koschany et al. [20] with a $NiAl(O)_x$ catalyst.

$$CO_2 + 4H_2 \rightleftarrows CH_4 + 2H_2O \quad (5)$$

Before the reactors, the stream is compressed to 7 bar, not only because the reaction is favoured by higher pressure, but also because the natural gas distribution system operates at this pressure, and the product will be at the required conditions for integration. To achieve this, a three-stage compression system with interstage cooling is implemented. After the stream is compressed and mixed with $H_2$ in a 1:4 mole ratio, it is heated to 290-320 °C and goes through 3-4 Sabatier reactors, simulated by RPlug models, with condensation between each stage. As in the work of Marnate et al. [21], multitubular fixed-bed reactors were chosen for methanation. The dimensions of each tube were fixed at 2 m in height and 1 in. in diameter. Using Eq. (3), the required reactor volume can be calculated, assuming a catalyst density of 2300 kg/m$^3$ [22]. The mass of catalyst was adjusted to maintain the gas flowrate at 120 NL/h/$g_{cat}$ [20]. Dividing the required reactor volume by the volume of each tube yields the required number of tubes.

### Haber-Bosch

The H-B process aims to produce $NH_3$ from $N_2$. An AspenTech example model [19] was adapted, and reaction of Eq. (6) was implemented with the kinetics studied by Tripodi et al. [23] in iron-based catalysts.

$$N_2 + 3H_2 \rightleftarrows 2NH_3 \quad (6)$$

The inlet stream is mixed with $H_2$ at a 1:3 molar ratio and then compressed to 150 bar to favour the reaction [21], using four compression stages with intermediate cooling. The stream is heated to 400-540 °C before entering each reactor, depending on the optimal temperature found. After passing through 3 reactors with intermediate cooling, the product is condensed at -35 °C, and liquid $NH_3$ is separated from the unreacted gases that must be recycled back into the first reactor. The design of the Haber-Bosch reactors involved a sensitivity analysis varying the mass of catalyst and checking its influence on the conversion of each reactor: when the maximum conversion was reached, the value for the mass of catalyst was found. This way, employing Eqs. (3) and (4), it was possible to compute the dimensions of each reactor, using 2900 kg/m$^3$ [24] as $\rho_{cat}$.

## Economic analysis

The cost of each piece of equipment for each other process was primarily estimated using the Aspen Process Economic Analyzer® (APEA) [25]. The equipment costs were then updated to 2025 using the corresponding CEPCI value [26]. The capital expenditure (CAPEX) and the operational expenditure (OPEX) were calculated using the factorial method, as described by Timmerhaus et al. [27]. The CAPEX was annualized using a 0.098 factor, assuming a plant lifespan of 20 years and a discount rate of 7.5%. The OPEX was calculated based on the values in Tab. 2. Adding the OPEX to the annualized capital cost enables the economic analysis of every process and, consequently, every superstructure route.

**Table 2:** Main values for the calculation of the OPEX and of the revenues [28-34].

| Parameter | Value | Unit |
|---|---|---|
| $H_2$ price | 5.1 | €/kg |
| Electricity cost | 0.06 | €/kWh |
| Cooling water | 0.01 | €/m$^3$ |
| Refrigerant | 2.8 | €/GJ |
| Steam | 0.04 | €/kg |
| $NH_3$ value | 521 | €/t |
| $CH_4$ value | 1806 | €/t |
| $O_2$ value | 290 | €/t |
| Storage cost | 30 | €/t |
| Emission cost | 70 | €/t |

Although the Air Separation Unit was not modelled using Aspen Plus® v14, the associated costs were also evaluated. In this case, Eq. (7) [35] was used for the estimation of the equipment cost (EC), being $\dot{m}_{O_2}$ the mass flowrate of $O_2$ entering the system, in tonnes per day.

$$EC\ (M€_{2014}) = 22 \cdot \left(\frac{\dot{m}_{O_2}[t/d]}{432}\right)^{0.6} \quad (7)$$

Electric and steam consumptions of 230 kWh/$t_{O2}$ and 16.2 kWh/$t_{O2}$ were considered, respectively [35]. The value of the mass flowrate of $O_2$ used was calculated considering the mass flowrate of $N_2$ that enters the 'Haber-Bosch 2' process and the mole fractions of $N_2$ (~79 %) and $O_2$ (~21 %) in the air.

Since not all superstructure routes produce the same products, these were assumed to be sold to enable an economic comparison of the routes. In this sense, the revenue was calculated by multiplying the generated flowrate by the respective unitary values. In routes that do not generate any product, such as $A90_E^{CCS}$, $A100_E^S$ or $A0$, no revenue was calculated, but the emissions/storage fees were applied. Adding the costs, and subtracting the revenue, leads to the overall annual cost of each route. This value is then divided by the initial mass flowrate of the cement plant flue gas (42.8 t/h) to assess the cost of treating it per metric tonne.

## RESULTS AND DISCUSSION

The economic results are detailed and discussed in this section for each individual process considered in the superstructure and for each route of the superstructure.

### Pre-treatment

The dimensions of the scrubber, SCR and $O_2$ removal reactor are presented in Tab. 3.

**Table 3:** Design of the main equipment in the pre-treatment section.

| Equipment | Height/Length (m) | Diameter (m) |
|---|---|---|
| Scrubber | 13.0 | 4.3 |
| SCR reactor | 5.8 | 1.9 |
| $O_2$ removal reactor | 2.4 | 0.8 |

After determining the equipment dimensions, the total estimated cost was calculated at approximately 1.56 M€. The simulation enabled the calculation of utility and raw material consumption costs, which totaled 7.9 M€/y, indicating a profit, since steam is generated in this process and can be used in downstream processes.

### MEA absorption

Subsequently to the pre-treatment process, the resulting stream can go through MEA absorption that can either capture 90 % or approximately 100 % of the $CO_2$ present. The dimensions of the absorber and stripper columns are similar for both capturing efficiencies and are presented in Tab. 4.

**Table 4:** Design of the main equipment in the capturing section.

| Equipment | Height (m) | Diameter (m) |
|---|---|---|
| Absorber | 26.9 | 3.4 |
| Stripper | 12.0 | 2.6 |

The equipment costs for both processes were 3.4 M€, while the total expenses for raw materials and utilities were 9.7 M€/y for the 'MEA absorption (90 %)' process and 76.6 M€/y for the 'MEA absorption (~100 %)' process. The large difference in operating costs reflects different steam consumption needs: the last process requires a higher heat duty to regenerate the MEA solvent because it absorbs more $CO_2$.

### Methanation

The Sabatier processes have the objective of solely producing $CH_4$ ('Sabatier') or of eliminating the $CO_2$ content of the stream ('Methanation 1' and 'Methanation 2'), readying the stream for a subsequent H-B process. The design of these processes is presented in Tab. 5.

**Table 5:** Number of tubes ($N_{tubes}$) and mass of catalyst ($m_{catalyst}$) required for each reactor (R) of the Sabatier (S), Methanation 1 (M1) and Methanation 2 (M2) processes.

| | $N_{tubes}$ | | | $m_{catalyst}$ (kg) | | |
|---|---|---|---|---|---|---|
| | S | M1 | M2 | S | M1 | M2 |
| R1 | 1855 | 1346 | 3151 | 240 | 185 | 451 |
| R2 | 665 | 1300 | 1860 | 86 | 162 | 240 |
| R3 | 460 | 1370 | 1768 | 56 | 161 | 215 |
| R4 | - | - | 1867 | - | - | 214 |

The estimated equipment costs are 2.0, 3.7, and 5.2 M€ for the 'Sabatier', 'Methanation 1', and 'Methanation 2' processes, respectively, as they progressively handle higher flow rates and increase the dimensions of the respective equipment. Regarding the consumption of utilities and raw materials, the respective values are 86.2, 10.6, and 96.5 M€/y for the processes. The values differ due to the different needs for green H2 in each process: the inlet stream of the 'Methanation 1' process contains approximately 10 % CO2 relative to the other methanation processes, leading to the lowest green hydrogen consumption and thus the lowest operating costs.

### Haber-Bosch

The design of the reactors of the Haber-Bosch process is presented in Tab. 6.

**Table 6:** Reactor (R) design and mass of catalyst ($m_{catalyst}$) required for each reactor (R) of the Haber-Bosch (HB) processes.

| | Diameter (m) x Length (m) | | | $m_{catalyst}$ (kg) | | |
|---|---|---|---|---|---|---|
| HB | 1 | 2 | 3 | 1 | 2 | 3 |
| R1 | 1.0x3.1 | 1.0x3.0 | 1.4x4.2 | 2 | 2 | 13 |
| R2 | 1.3x3.9 | 1.2x3.7 | 1.8x5.4 | 10 | 9 | 34 |
| R3 | 1.6x4.8 | 1.5x4.6 | 2.6x7.9 | 24 | 21 | 120 |

The estimated equipment costs for producing $NH_3$ through the H-B process are 11.7, 11.6, and 18.5 M€ for the 'Haber-Bosch 1', 'Haber-Bosch 2', and 'Haber-Bosch 3' processes, respectively. The 'Haber-Bosch 3' has the highest equipment costs because it handles the largest amount of inert gas ($CH_4$). This translates into the largest circulating flowrates and, consequently, the largest equipment dimensions.

As for the consumption of utilities and raw materials, all three processes have a value of approximately 211 M€/y, as their green $H_2$ consumption is similar because their respective inlet streams contain equal amounts of $N_2$.

### Air Separation Unit

The estimated equipment cost of the ASU is 17.3 M€, while the estimated annual cost of electricity and steam is 0.9 M€.

## Superstructure

Tab. 7 summarizes the results of the economic assessment for each possible superstructure route, each designated by its respective nomenclature (see Tab. 1).

It is evident that OPEX has a stronger influence on production costs than CAPEX, which is expected, since annualized CAPEX is 1-10% of OPEX. The high OPEX of the processes is mainly related to their high energy and green $H_2$ consumption.

Regarding route revenues, those that include the H-B process to produce green ammonia yielded higher revenues, due to the high $N_2$ content in the flue gas stream, which is converted into green ammonia. However, the routes that consider the emission of the $CO_2$-lean stream after the separation unit ($A90_E^S$, $A90_E^{CCS}$, $A100_E^S$ and $A100_E^{CCS}$), present fewer total costs than the ones that include a H-B system. This means that, despite having the highest revenues, the Haber-Bosch process is currently not economically viable, due to its large equipment costs and high green $H_2$ consumption.

When comparing the routes producing green ammonia from the cement plant flue gas with the benchmark technology to produce green ammonia ($ASU_{HB}$), the latter presents lower total costs, which means that it is currently still uncompetitive to utilize the $N_2$ from the cement plant flue gas instead of using an ASU.

Tab. 7 also reflects the lower costs of the routes including a $CO_2$ capturing unit with 90 % efficiency when compared with the ones comprising ~100 % MEA absorption systems. For example, route $A90_E^{CCS}$ is approximately 70 % less expensive than $A100_E^{CCS}$. This is mainly related to the high medium-pressure (MP) steam consumption required in the MEA absorption unit to capture approximately 100 % of the $CO_2$ emissions.

Among the routes that produce both green ammonia and SNG, route $A100_{HB}^S$ has the highest revenue value due to producing the largest amount of methane and ammonia. However, it also presents the highest total cost, since it not only requires the high green $H_2$ consumption of both the Haber-Bosch and the Sabatier processes, but it also contains the 'MEA absorption (~100 %)' system, which has a high utility demand. Route $A90_{HB}^S$ appears to be a more promising option for producing these two products, since it has lower energy requirements in the CO2-capture unit, leading to significantly lower OPEX. On the other hand, the route $A0$ exhibits the lowest OPEX value of the three, as it does not contain a $CO_2$ capturing unit. For this same reason, it needs to handle the total flue gas flowrate, which requires larger equipment dimensions, therefore it presents the highest CAPEX. The $A0$ route is the one which presents the lowest revenues, due to the need of higher purge flowrates in the process to accommodate the high flowrate of $CH_4$ in the H-B process. The total net cost of treating the flue gas in this route is similar to the $A90_{HB}^S$ route, indicating that the $A90_{HB}^S$ and $A0$ are the most promising routes for the simultaneous production of SNG and green ammonia from a cement plant's flue gas. However, these two routes present total costs approximately 40 times higher than the emission of the cement plant flue gas. This low economic attractiveness of the simultaneous production of e-methane and green ammonia from the cement plant flue gas is mainly related to the high costs of green hydrogen.

Although not producing methane or ammonia, route $A90_E^{CCS}$ is currently the less expensive path to treat the cement plant flue gas. Nonetheless, it is worth noticing the relatively low total cost of path $A90_E^S$, which includes methanation of the $CO_2$-rich outlet of the 'MEA absorption (90 %)' process and emission of the $CO_2$-lean outlet stream, as it presents the second lowest total costs while producing SNG through the Sabatier process. However, under current conditions, no route is economically competitive with the cement plant's total emissions from flue gas. The greatest contributor to the high cost of this route is the cost of green $H_2$, which is expected to decrease in the coming years [36]. By analysing the economic feasibility with the green $H_2$ price evolution, it is possible to conclude that the $A90_E^S$ route becomes the most profitable route when the green $H_2$ price reaches 1.81 €/kg and that its break even $H_2$ price is 1.51 €/kg of $H_2$.

## Conclusions

Given the cement industry's elevated GHG emissions, this work proposes applying SNG and green ammonia production processes to cement plant flue gas. The most mature technologies were investigated and assembled into a superstructure comprising different routes, which were modelled using Aspen Plus®. Firstly, a pre-treatment was employed to remove unwanted components from the flue gas. Then, the possibility of separating $N_2$ from $CO_2$ was studied by applying a MEA absorption system with either 90 % or ~100 % capturing efficiency.

The obtained $N_2$-rich stream could be valorized to $NH_3$ via the Haber-Bosch process or emitted, while the CO2-rich stream could be sent to storage or converted to $CH_4$. Comparing the MEA units studied, as the complete $CO_2$ removal is approached, the system requires higher reboiler duties to strip the $CO_2$ from the solvent due to a substantial increase in MP steam consumption. Thus, the 90 % capture configuration appears to be more energetically and economically advantageous. The ~100% separation unit has the advantage of not requiring a subsequent methanation step to treat the $N^2$-rich stream before it enters the Haber-Bosch process. However, the cost increase of applying a ~100 % separation unit is greater than the cost of adding an extra

**Table 7:** Economic analysis of the superstructure routes.

| Route | $A90^{S}_{HB}$ | $A90^{S}_{E}$ | $A90^{CCS}_{E}$ | $A90^{CCS}_{HB}$ | $A100^{S}_{HB}$ | $A100^{S}_{E}$ | $A100^{CCS}_{E}$ | $A100^{CCS}_{HB}$ | $A0$ | $ASU$ | $E$ |

methanation system.

The routes considering carbon capture with 90 % efficiency, with the emission of the $N_2$-rich stream and either the methanation or storage of the $CO_2$-rich stream are the most economically promising alternatives to treat the flue gas stream, with respective total costs of 263 and 109 €/t of flue gas. However, they are currently uncompetitive due to flue gas emissions (22 €/t).

Nevertheless, it is possible that H2-requiring routes become economically feasible as green hydrogen costs are expected to decline in the coming years. This trend indicates great potential to integrate pathways for synthesizing high-value chemical products into the cement industry, contributing to GHG mitigation and the transition to a more sustainable industrial sector.

## ABSTRACT

Hydrogen is increasingly recognized as a vital energy carrier for a sustainable future. Among the various methods for hydrogen production, alkaline water electrolysis (AWE) stands out as a well-established and commercially viable option. However, their more effective deployment requires more advanced, portable, and scalable designs. This study explores systematic model-based shape optimization of the next generation AWE based on computational fluid dynamic (CFD) aimed to enhance the hydrodynamics and electrochemical performance. Several design geometries and arrangements were proposed including flow baffles to enhance hydrodynamic and facilitate detachment of oxygen and hydrogen bubbles. The findings indicate that the optimal design and location of the baffles improve fluid mixing and enhance bubble detachment, resulting in a more uniform electrolyte distribution and decreased concentration polarization. Several key performance indicators were considered to analyse the performance of proposed designs including gas production rates, polarization curves, and fluid flow velocity profiles. The insights gained from this research offer valuable recommendations for optimizing flow field designs in alkaline water electrolyzers, aiming to enhance efficiency and operational robustness.

**Keywords**: Alkaline water electrolysis, zero-gap cell, CFD, Pyramidal pins, Mesh electrode, Multiphysics model

## INTRODUCTION

Hydrogen is becoming essential in the transition to decarbonized energy systems, influenced by climate targets and energy security [1, 2]. The global demand for hydrogen is expected to increase significantly, shifting from fossil-based “grey hydrogen” to low-carbon “green hydrogen, ” produced through water electrolysis using renewable energy [3]. Hydrogen production via water electrolysis is a key enabling technology for future low-carbon energy systems[4]. There are three primary methods for water electrolysis: alkaline water electrolysis (AWE), proton exchange membrane electrolysis (PEM), and solid oxide electrolysis (SOEC) and among them, alkaline water electrolysis (AWE) is the most established for hydrogen production [1, 3–6]. It offers advantages such as lower material costs, reliance on non-noble catalysts, longer stack lifetimes, and scalability for large deployments, especially in regions abundant in renewable resources [5, 7, 8]. AWE's reliability and adaptability to variable operating conditions are crucial as electrolysis facilities align with fluctuating renewable energy supplies. This adaptability makes AWE an economically viable option for large-scale hydrogen production [9, 10]. As the world moves towards sustainable energy solutions, AWE is positioned to play a significant role in meeting the rising demand for green hydrogen[4].

Alkaline water electrolysis (AWE) faces significant challenges due to complex hydrodynamics, particularly the behavior of gas bubbles at the electrode-electrolyte interface [6, 11, 12]. These bubbles can create localized concentration gradients, increase ohmic losses, and generate thermal hotspots, ultimately diminishing energy efficiency [12]. Factors such as electrode shape, channel geometry, operating conditions, and cell integration strategies influence the distribution of gas and liquid, making the optimization of bubble behavior and internal flow essential for enhancing system performance [7, 9, 11]. Traditional AWE designs often utilize concave-convex spherical (SCC) flow channels to improve mixing; however, these can also lead to stagnant regions and bubble trapping, resulting in non-uniform mass transfer

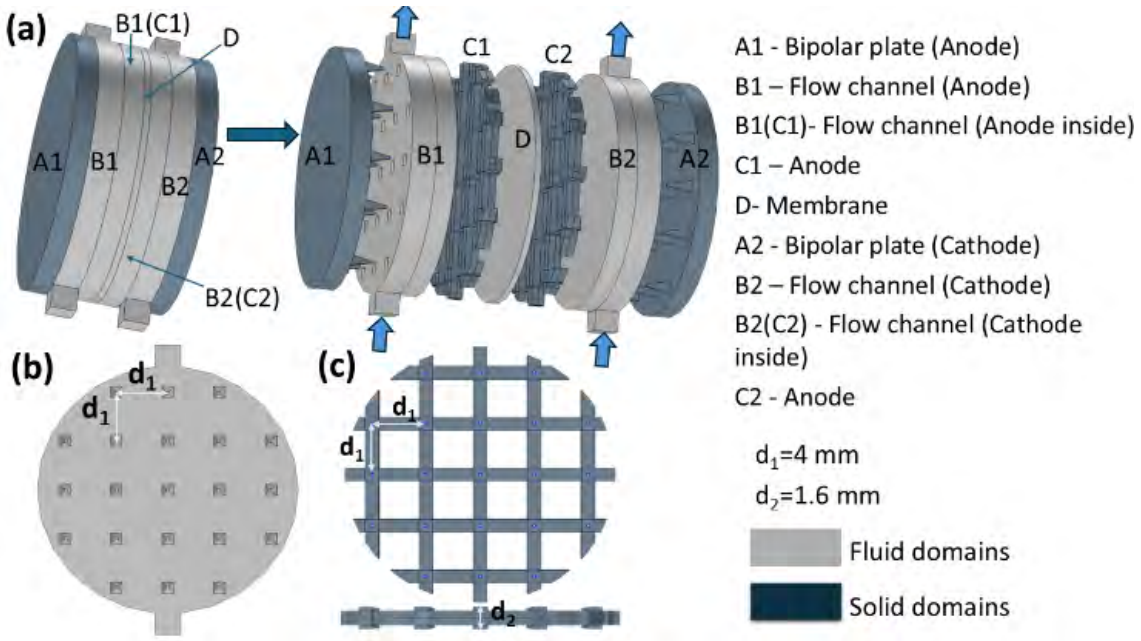

**Figure 1.** Schematics of the alkaline wate electrolyser with individual components, (b) arrangment of the pyramidal pins in the flow channel, and (c) mesh electrode.

[12]. A potential solution involves replacing porous electrodes with mesh-type structures, which may decrease bubble residence time and improve gas release [13]. Nonetheless, the interplay between mesh electrodes, SCC flow fields, and various operational variables have yet to be thoroughly investigated in a cohesive framework.

With increasing computational power, computational fluid dynamics (CFD) methods have gained widespread adoption across multiple disciplines. These methods have been widely implemented to support the optimal design and operation of multiphase systems across multiple scales, from microfluidic devices to mesoscale processes and full industrial-scale systems [14, 15]. Recent CFD applications highlight systematic geometry and shape optimization of small-scale packed-bed reactors with complex internal structures [16]. These methods have opened new opportunities for more effective in silico prototyping, enabling faster design, evaluation, and optimization of next-generation processes and technologies. The proposed CFD-based design framework of zero-gap alkaline electrolyzers allows more robust geometries and configuration through a detailed three-dimensional multiphysics simulation which addresses the limitations of the existing designs. The method incorporates crucial aspects such as heat transfer, gas-liquid transport, and electrochemical kinetics, facilitating a comprehensive assessment of how localized gradients affect system performance. The model evaluates critical parameters including cell voltage, temperature, and inlet flowrate collectively, revealing their interactions and providing insights for optimizing device performance beyond single-parameter analysis. Most importantly, the CFD-based approach reveals more effective alternatives to the traditional porous electrodes such as mesh-type electrodes, enhancing productivity and hydrodynamic performance particularly more effective bubble detachment and transport. The identified optimal designs featuring pyramidal pin structures on the bipolar plates. The method also informed the best trade-offs between mixing and bubble detachment. Ultimately the framework offers essential design insights laying the foundation for enhanced efficiency and durability of industrial green hydrogen production systems.

## METHODOLOGY

A numerical model representing a single cell of an alkaline water electrolyzer is illustrated in **Figure 1**. The computational domain encompasses flow channels, cathode and anode mesh electrodes, bipolar plates, and a porous membrane region that separates the two half-cells. The electrodes are of non-porous made of Nickel metal. Pyramidal pin structures are integrated into the flow channels and attached to the bipolar plates, with sharp edges oriented towards the electrodes to enhance flow distribution and induce local turbulence. The geometric dimensions and physical properties are detailed in **Table 1** and **Table 2**.

**Table 1:** Geometric parameters of the alkaline water electrolyser model.

| Description | Value |
|---|---|
| Cathode and anode radius | 10 mm |
| Cathode thickness | 1.6 mm |
| Anode thickness | 1.6 mm |
| Flow channel radius | 10.1 mm |
| Flow channel thickness | 3.6 mm |
| Bipolar plate radius | 10 mm |
| Bipolar plate thickness | 0.5 mm |
| Membrane radius | 10.1 mm |
| Membrane thickness | 0.5 mm |

**Table 2:** Physical parameters of the alkaline water electrolyser model.

| Parameter | Value |
|---|---|
| Membrane porosity | 0.5 |
| Reference exchange current density (anode) | 100 A/m$^2$ |
| Reference exchange current density (cathode) | 0.1 |
| Transfer coefficient (anode) | 0.5 |
| Transfer coefficient (anode) | 0.5 |
| Inlet electrolyte velocity | 0.01 m/s - 0.2 m/s |
| Outlet pressure | 1 atm |
| Electrolyte conductivity | 40 S/m |
| Bipolar plate conductivity | 4.032e6 S/m |
| Nickel mesh electrode conductivity | 13.8e6 S/m |
| Electrode active surface area | 6.06 cm$^2$ |
| Operating temperature | 80 C |
| Cell voltage | 1.3 V – 2.3 V |
| Electrolyte concentration (KOH) | 3 M |

## Governing equations

The following equations are employed to solve the physics described above:

### Electrochemical model

Alkaline water electrolysis splits water into hydrogen and oxygen using electrochemical reactions at the cathode and anode. An aqueous alkaline solution like KOH serves as the electrolyte, supplying hydroxide ions ($OH^-$) for charge transport, driven by electrical potential.

At cathode (hydrogen evolution reaction – HER):

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (1)$$

At anode (oxygen evolution reaction – OER):

$$4OH^- \rightarrow O_2 + 2H_2O + 4e^- \quad (2)$$

The total cell voltage is calculated by

$$E_{total} = E_{equi} + \eta_{acti} + \eta_{ohmic} \quad (3)$$

The equilibrium cell potential is calculated from the Nernst equation as follows:

$$E_{equi} = E_{0,ref}(T) + \frac{RT}{2F}\ln\left(\frac{p(O_2)^{0.5}p(H_2)}{p(H_2O)}\right) \quad (4)$$

The Butler-Volmer equation describes the relationship between the local current density and activation overpotential as follows:

$$i_{cathode} = a_{HER}i_{0,HER}(1 - s_g)\left[exp\left(\frac{\alpha_c F\eta_{HER}}{RT}\right) - exp\left(\frac{(1-\alpha_c)F\eta_{HER}}{RT}\right)\right] \quad (5)$$

$$i_{anoode} = a_{OER}i_{0,OER}(1 - s_g)\left[exp\left(\frac{\alpha_a F\eta_{OER}}{RT}\right) - exp\left(\frac{(1-\alpha_a)F\eta_{OER}}{RT}\right)\right] \quad (6)$$

The equations for the transport of electrons and ions are given below:

$$\nabla \cdot \boldsymbol{i}_s = \nabla \cdot \left(-\sigma_s^{eff}\nabla\phi_s\right) = S_{\phi,s} \quad (7)$$

$$\nabla \cdot \boldsymbol{i}_l = \nabla \cdot \left(-\sigma_l^{eff}\nabla\phi_l\right) = S_{\phi,l} \quad (8)$$

$$\sigma_l^{eff} = \sigma_l(1 - s_g)^{1.5} \quad (9)$$

The ohmic overpotential resulting from the transport resistances of both electrons and ions is described as follows:

$$\eta_{ohmic} = i\left(\frac{\phi_l}{\sigma_l^{eff}} + \frac{\phi_s}{\sigma_s^{eff}}\right) \quad (10)$$

### Mass transfer model

The Navier-Stokes equations are employed to determine the fluid velocity and pressure within the flow channels of the electrolyzer in the following manner.:

$$\frac{\partial\rho}{\partial t} + \nabla \cdot (\rho\boldsymbol{u}) = 0 \quad (11)$$

$$\rho\frac{\partial\boldsymbol{u}}{\partial t} + \rho(\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = \nabla \cdot \left[-p\boldsymbol{I} + \mu\left(\nabla\boldsymbol{u} + (\nabla\boldsymbol{u})^T\right)\right] + \boldsymbol{F} \quad (12)$$

The phase transport equations have been adopted to describe the distribution of gas-liquid flow as follows:

$$\frac{\partial\rho_i s_i}{\partial t} + \nabla \cdot (\rho_i\boldsymbol{u}_i) = 0 \quad (13)$$

$$\frac{\partial\rho_i s_i}{\partial t} + \nabla \cdot \left[-\rho_i K\frac{K_{ri}}{\mu_i}(\nabla p_i - \rho_i\boldsymbol{g})\right] = Q_i \quad (14)$$

$$Q_{H_2} = \frac{M_{H_2}}{2F}i_v \quad (15)$$

$$Q_{O_2} = \frac{M_{O_2}}{4F}i_v \quad (16)$$

### Heat transfer model

The energy equation has been employed to describe the thermal management inside the electrolyser:

$$(\rho C_p)_{eff}\frac{\partial T}{\partial t} + \rho C_p\boldsymbol{u} \cdot \nabla T + \left(-k_{eff}\nabla T\right) = S_{heat} \quad (17)$$

$$S_{heat} = |i_v||\eta_{acti}| + \frac{i_v^2}{\sigma_s} + \frac{i_v^2}{\sigma_l} \quad (18)$$

The governing equations delineated herein were resolved utilizing CFD through the COMSOL Multiphysics 6.4, employing the finite element method (FEM) [12]. A convergence criterion of relative error less than 0.0001 is applied, using the backward difference formula (BDF) method for time-stepping. This analysis was conducted under specific boundary conditions and underlying assumptions.

### Boundary conditions

The KOH electrolyte solution enters the flow channels of anode and cathode at their inlets with a defined velocity, respectively. The cell voltage is applied on the bipolar plate and other side of the bipolar is made electric ground. The pressure at the outlets of the flow channels is 0 atm. The gravitational forces during the operation are neglected. The $OH^-$ ions are allowed to pass through the porous membrane.

### Assumptions

The flow is assumed to be laminar. There is no crossover of hydrogen and oxygen gases across the membrane. Overpotential losses due to contact resistance inside the electrolyser are assumed to be negligible.

## RESULTS AND DISCUSSION

### Validation

To assess the accuracy of the multi-physics alkaline electrolyzer model, operational parameters from existing literature were employed [12, 17], specifically at 353.15 K and 1 atm, as shown in **Figure 2**. A comparative evaluation of simulation outcomes alongside experimental data [17] and other literature simulations [12] shows a strong correlation within a current density range of 0.1 $\mathrm{A/cm^2}$ to 1.4 $\mathrm{A/cm^2}$. However, at higher current densities, simulated voltages exhibit slight underestimations, likely attributable to the omission of ohmic losses and diffusion voltage effects.

### Effect of pyramidal pins on the velocity distribution

The study analyzed the effect of inlet electrolyte velocity on flow patterns in channels with 10 and 24 pyramidal pins on each side of the electrode, as shown in **Figures 3** and **4**. It has been observed that the flow patterns at velocities from 0.01 m/s to 0.2 m/s demonstrated that the pyramidal pin structures induced changes in the flow field, including local redirection, shear-layer formation, and wake recirculation. These alterations were found to depend significantly on both the inlet velocity and the number of the pins.

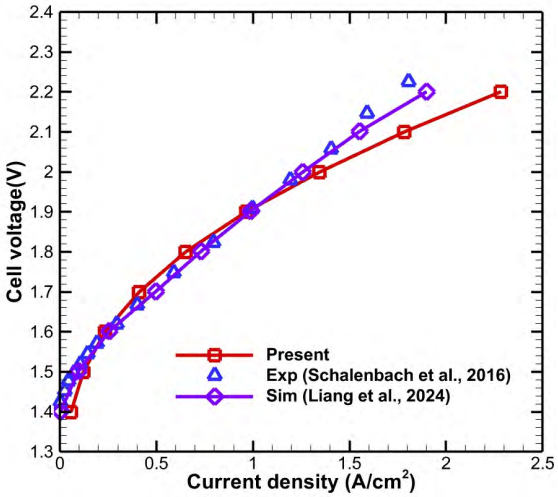

**Figure 2.** Comparison of the present simulation results against the experimental data [17] and other literature simulations [12].

At low velocity of 0.01 m/s, electrolyte motion was dominated by viscous forces. The 10 pins configuration caused minimal axial flow disruption (refer to **Figure 4(a)**), while the 24 pins setup resulted in increased tortuosity and narrower passages (refer to **Figure 4(a)**), leading to longer residence times and persistent recirculation zones, highlighting significant micro-circulation effects typically seen in creeping flow. Increasing inlet velocities of 0.05 m/s and 0.1 m/s intensified inertial effects, enhancing flow separation and wake formation. Higher pyramidal pin number improved hydrodynamic interactions, promoting vortex-dominated flow, which is crucial for enhancing bubble detachment and gas-liquid mass transfer in electrolyzer channels (refer to **Figures 3(b)-(c)** and **4(b)-4(c)**). At 0.2 m/s, strong convection dominated the flow field. In a 10 pins setup, limited recirculation occurred, while a 24 pins configuration enhanced flow complexity and inter-sphere mixing, resulting in maximum velocity uniformity and minimized small eddies with larger wake structures (refer to **Figures 3(d)** and **4(d)**).

### Effect of inlet velocity on the gas volume fraction

The two-phase behavior in the channel arises from the hydrogen evolution reaction at the nickel mesh cathode in alkaline conditions. Gas bubbles form, grow, and detach due to nickel's wettability, leading to localized gas accumulation and high hydrogen volume near the cathode. Inlet electrolyte velocity impacts gas volume fraction distribution, as depicted in **Figures 5** and **6**. At 0.01 m/s, insufficient shear fails to remove bubbles from nickel mesh, increasing residence time and coalescence, leading to higher gas fractions near the cathode, reducing active surface area and hindering reactant replenishment

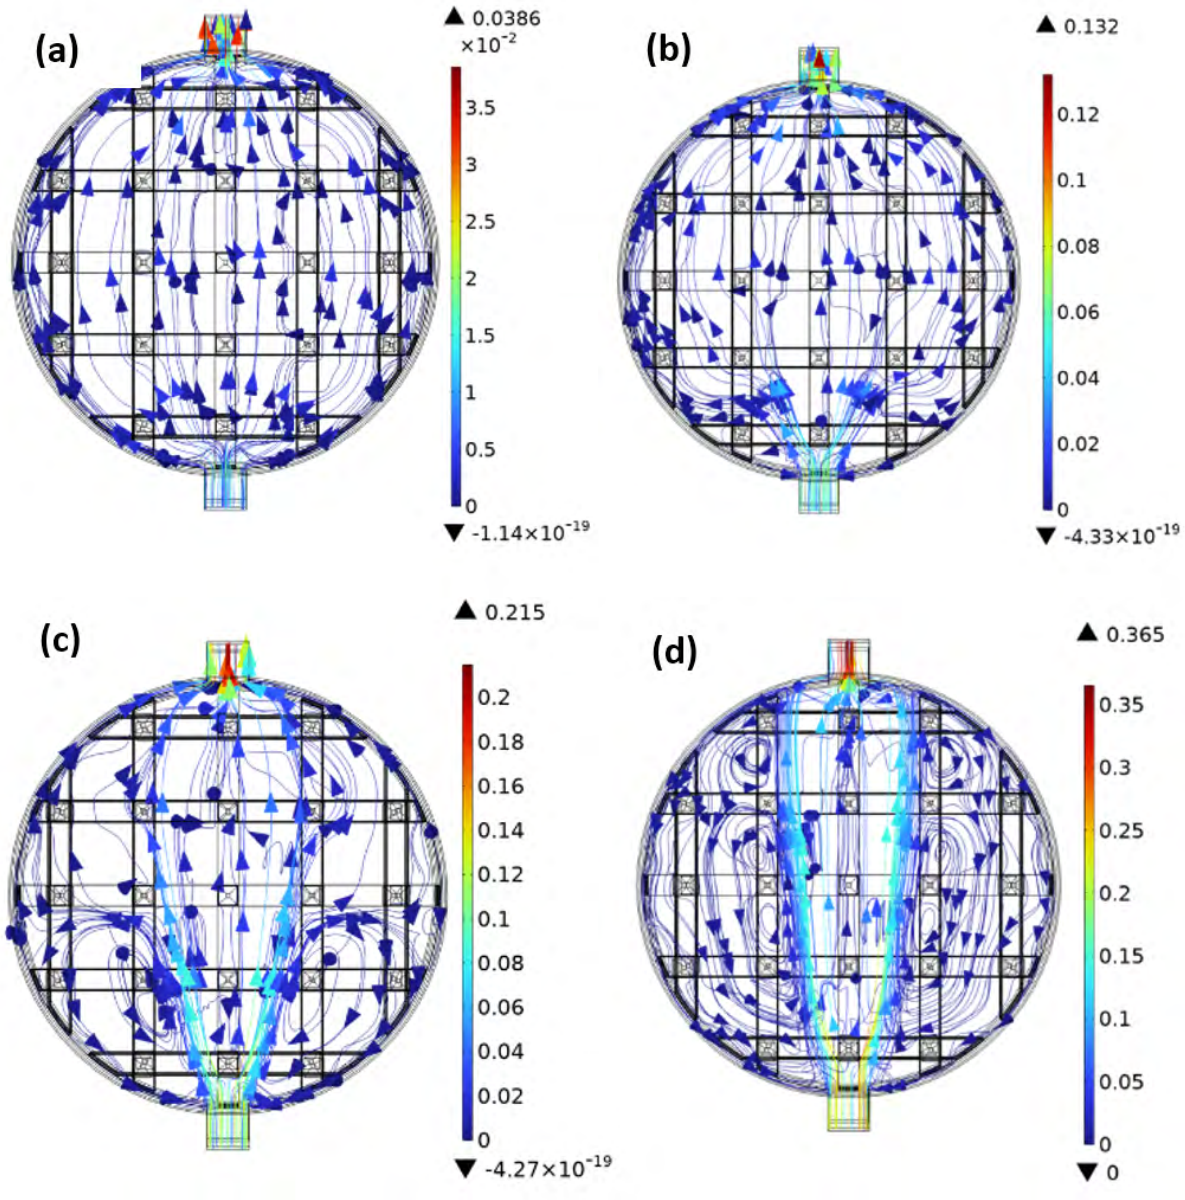

**Figure 3.** Velocity distribution in channels for 24 pyramidal pins, (a) $v_{in} = 0.01\ m/s$, (b) $v_{in} = 0.05\ m/s$, (c) (a) $v_{in} = 0.1\ m/s$, and (a) $v_{in} = 0.2\ m/s$.

(refer to **Figures 5(a)** and **6(a)**). Increasing inlet velocity to 0.05–0.1 m/s improved hydrogen bubble removal by enhancing convective forces, reducing gas volume fraction near the cathode. This facilitated electrolyte access to nickel sites, minimized gas holdup, and maintained efficient gas-evolving cathode performance without raising channel pressure losses (refer to **Figu res 5(b)-(c)** and **6(b)-4(c)**). At 0.2 m/s, the gas volume fraction was minimized, with rapid bubble detachment reducing interaction time with the nickel surface (refer to **Figures 5(d)** and **6(d)**). This inhibited coalescence, promoting effective mass transfer and bubble removal, though it may require higher pumping power for the system.

The study demonstrated minimal differences in gas volume fraction distributions within channels featuring 10 versus 24 pyramidal pins at varying velocities. While heightened pins number improved fluid tortuosity and localized micro-mixing, it did not significantly influence hydrogen bubble retention or removal on nickel mesh, underscoring the inlet velocity's critical impact on hydrogen gas holdup dynamics.

## CONCLUSIONS

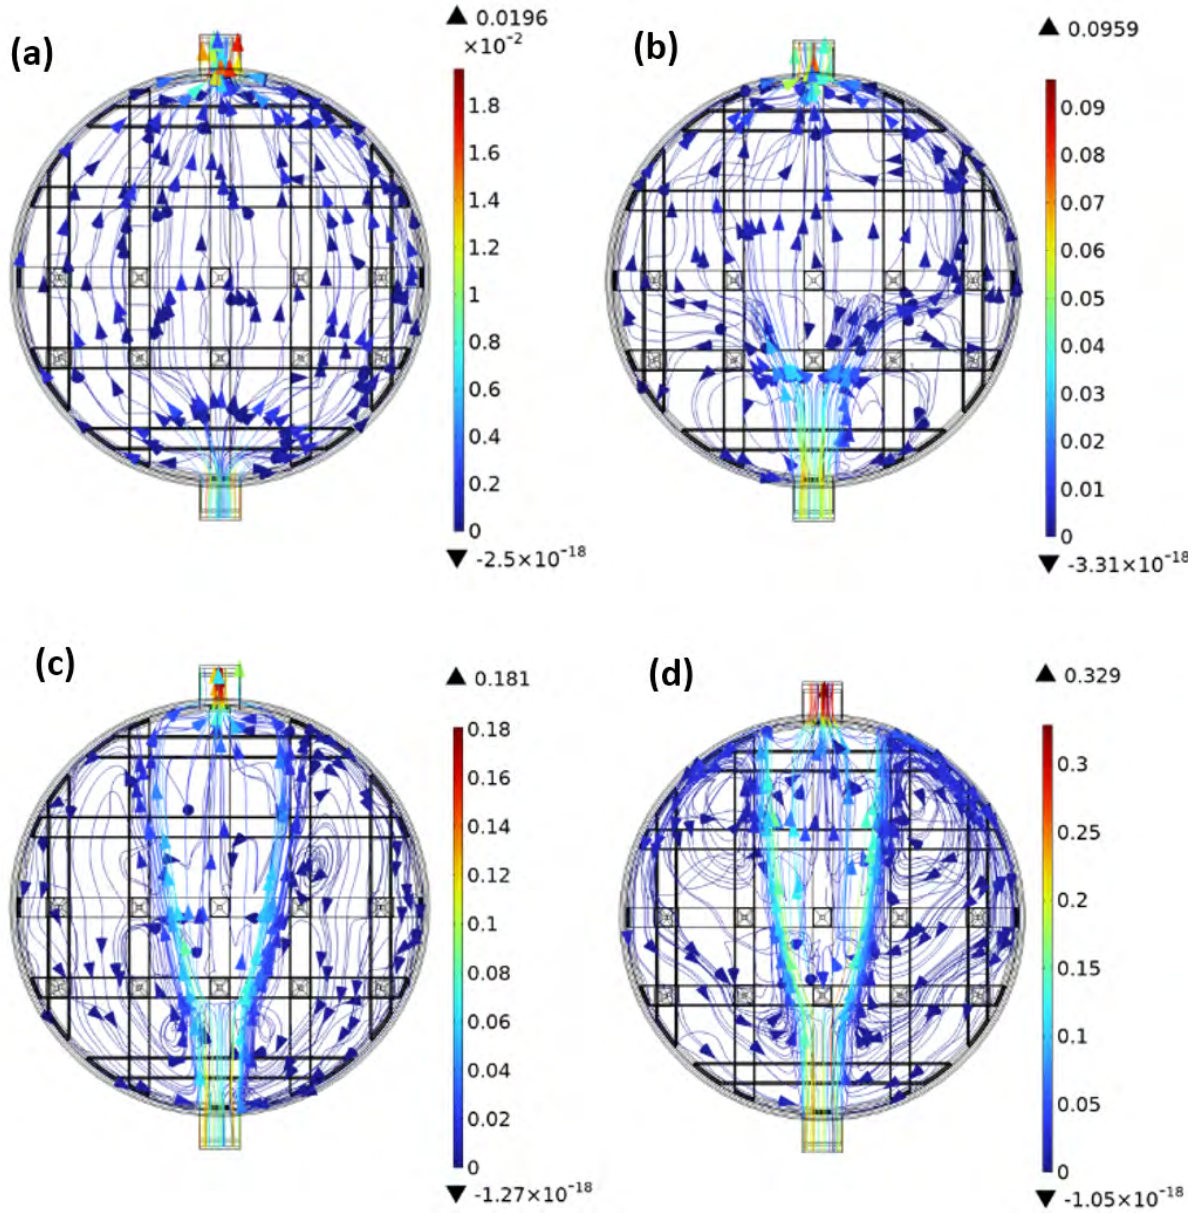

**Figure 4.** Velocity distribution in channels for 10 pyramidal pins, (a) $v_{in} = 0.01\ m/s$, (b) $v_{in} = 0.05\ m/s$, (c) (a) $v_{in} = 0.1\ m/s$, and (a) $v_{in} = 0.2\ m/s$.

A three-dimensional multiphysics model was developed to optimal design of a portable and stackable AWE for hydrogen production exhibiting two-phase flow dynamics and featuring nickel mesh electrodes, augmented by pyramidal pins to enhance flow disturbance and mixing. The simulations, conducted in COMSOL at a voltage of 1.8 V, 3 M KOH and a temperature of 80°C, were rigorously validated for reliability and accuracy. The findings indicated that the inlet elect rolyte velocity plays a pivotal role in hydrogen bubble detachment and gas holdup; specifically, lower velocities resulted in increased gas fractions due to bubble retention, whereas higher velocities facilitated bubble removal. Although increasing the number of pins improved flow tortuosity and micromixing, it did not significantly influence bubble detachment, suggesting that bubble dynamics are predominantly governed by bubble growth kinetics and convective shear forces. These findings imply that enhancing convective flow in proximity to gas-evolving electrodes can mitigate mass transfer limitations and enhance electrolyzer efficiency. Future research should prioritize the optimization of pyramidal pin design to maximize mixing while minimizing pressure drop challenges, advocating for multi-objective optimization to inform the

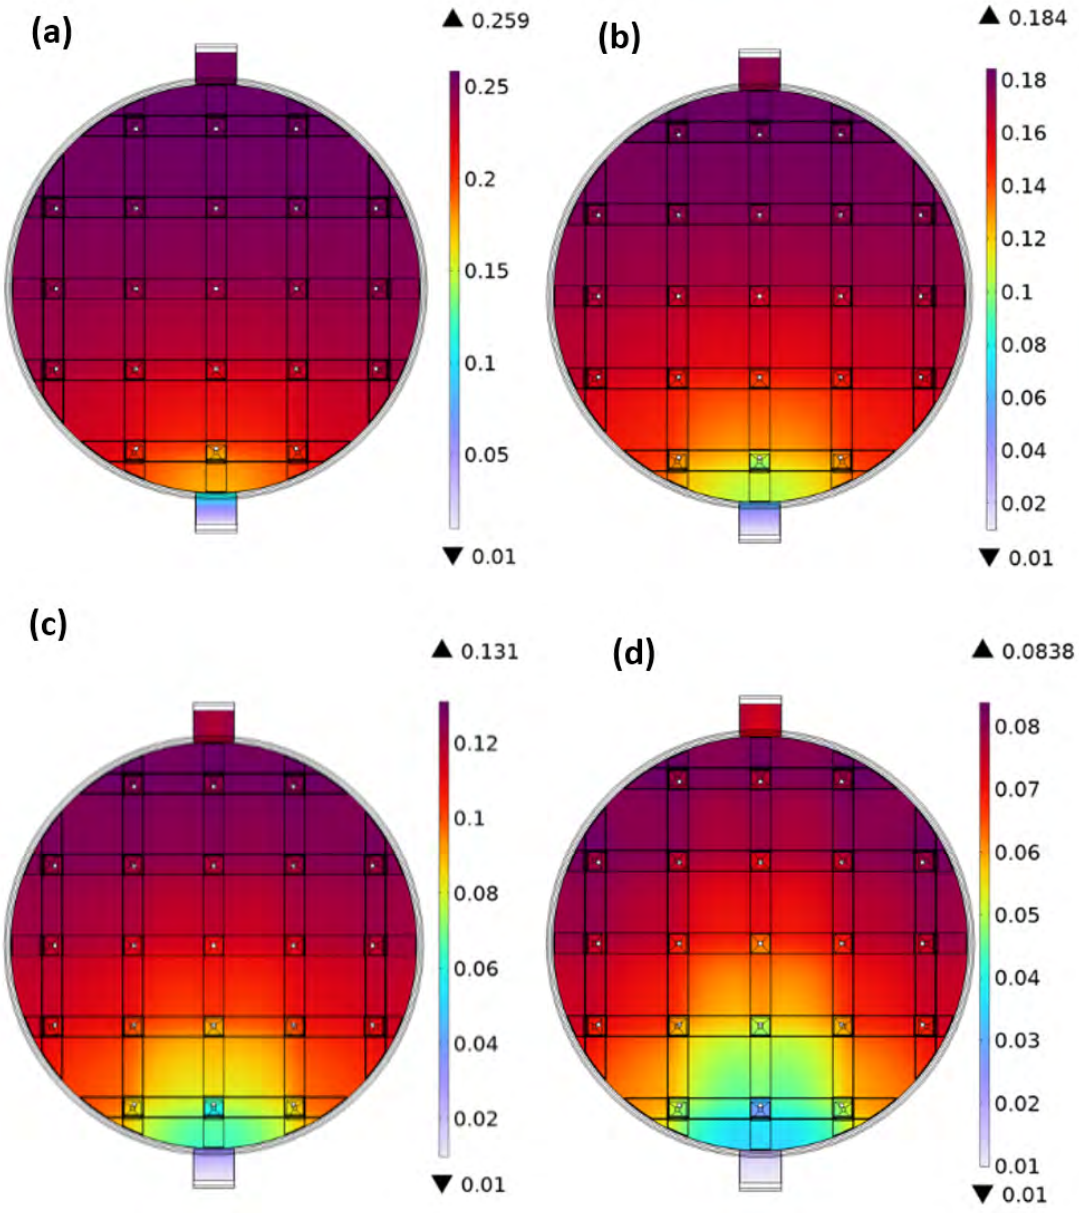

**Figure 5.** Gas volume fraction distribution in flow channels for 24 pyramidal pins, (a) $v_{in} = 0.01\ m/s$, (b) $v_{in} = 0.05\ m/s$, (c) (a) $v_{in} = 0.1\ m/s$, and (a) $v_{in} = 0.2\ m/s$.

development of efficient designs of next-generation alkaline electrolyzers.

## ABSTRACT

Thermal management and heat transfer optimization remain central challenges in next-generation concentrated solar power (CSP) systems employing solid particles for thermal energy storage and heat transfer. Conventional particle receiver concepts, such as fluidized beds and falling particle curtains are constrained by limited particle-wall contact, flow instabilities, and restricted operating temperature. This work presents a combined computational and experimental investigation of a gravity-driven dense-phase moving packed bed receiver featuring a flat conduit geometry and sub-millimeter particles. A multiphase modeling framework is developed and validated against pressure-drop measurements and particle velocity data obtained from dedicated experimental setups. The validated model is subsequently used to quantify dense-flow stability and thermal performance under indirect heating conditions. Results demonstrate stable dense-phase operation with particle volume fractions of approximately 0.6, leading to enhanced particle-wall transfer. Alumina particles achieve wall-to-particle heat transfer coefficients of up to 2.7 $kW \cdot m^{-2} \cdot K^{-1}$, more than twice those obtained with silica sand under comparable conditions. The findings indicate that flat-conduit dense-phase receivers provide a mechanically simple and thermally efficient alternative to conventional particle receiver concepts, supporting high-temperature and more efficient CSP systems.

**Keywords**: Energy Storage, Concentrated Thermal Solar, Computational Fluid Dynamics, Modelling and Simulations

## INTRODUCTION

Concentrated solar power (CSP) technologies play a key role in the transition toward dispatchable renewable electricity and high-temperature industrial heat. In contrast to photovoltaic systems, CSP offers the intrinsic advantage of thermal energy storage, enabling decoupling of energy collection and power generation. While molten salt systems dominate current deployments, their operating temperature is limited by freezing, corrosion, and material compatibility [1].

Solid particles have therefore emerged as a promising alternative heat transfer and storage medium due to their thermal stability and ability to operate at temperatures exceeding 1000 K [2]. In addition, particles can simultaneously serve as heat transfer fluid and storage medium, offering the potential for simplified system layouts and higher energy storage density. These advantages have motivated extensive research into particle-based receiver concepts for next-generation CSP plants.

Several particle-based receiver concepts have been proposed, including fluidized beds, falling particle curtains, and mechanically driven systems [3]. Fluidized beds achieve high heat transfer coefficients but require large gas flow rates, increasing parasitic losses [4]. Falling particle receivers suffer from low residence times and sensitivity to flow instabilities [5]. Mechanically driven receivers can enhance residence time but introduce moving parts that reduce reliability and scalability at high temperatures [6].

Dense-phase, gravity-driven moving packed beds offer an attractive alternative by combining high particle packing density with mechanically simple operation. Heat transfer in such systems is dominated by particle-wall contact rather than gas-solid convection, making them particularly suitable for indirect heating configurations.

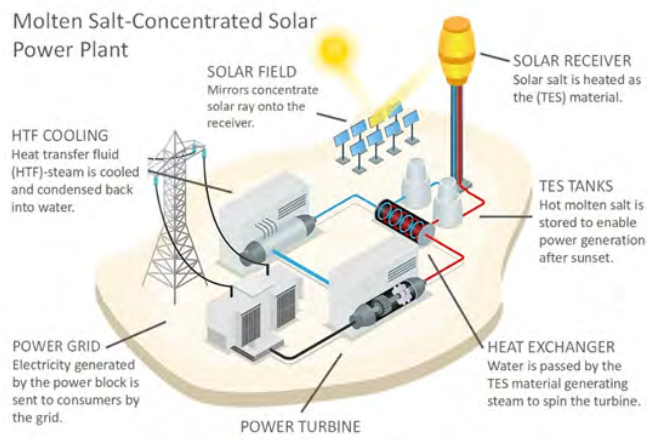

**Figure 1.** Concentrated solar power (CSP) plant.

Figure 1 illustrates the integration of a particle-based receiver within a CSP system with thermal energy storage (TES). Despite their potential advantages, systematic model-based and experimentally validated studies of dense-phase flat-conduit receiver geometries remain limited.

This work addresses this gap by developing and validating a multiphase modeling framework for a flat-conduit dense-phase particle receiver. The study combines computational fluid dynamics (CFD) modeling with targeted experimental validation to quantify dense-phase flow stability and thermal performance, with particular emphasis on the influence of particle material properties. The results provide insight into the design and operation of mechanically simple, high-performance particle receivers for future CSP applications.

## RECEIVER CONCEPT AND OPERATING PRINCIPLE

The investigated receiver consists of a vertical, flat rectangular conduit through which solid particles flow downward under gravity in dense-phase conditions. Heat is supplied indirectly through the receiver wall, representing absorbed solar irradiation transferred to the particles primarily through conduction and contact-based mechanisms. The receiver is intended to operate as part of a particle-based CSP system, where it can be directly coupled to thermal energy storage and high-temperature power conversion units.

As shown schematically in Figure 2, the flat-conduit geometry maximizes particle-wall contact while maintaining a compact and modular design suitable for CSP integration. Unlike fluidized receivers, no external gas flow is required to sustain particle motion. Instead, particles are introduced at the top of the conduit and accelerate under gravity until a balance is reached between gravitational forces, interparticle friction, and wall shear.

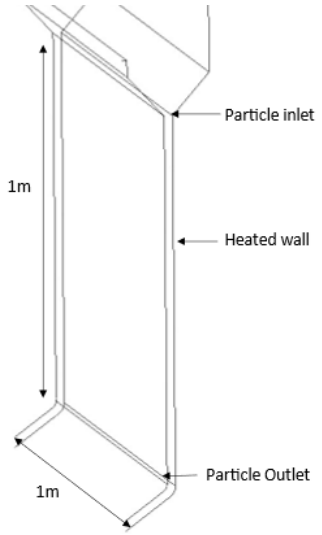

**Figure 2.** Proposed gravity-driven dense-phase solar receiver with indirect heating configuration.

This balance establishes a stable dense-phase flow regime with high and nearly uniform particle volume fractions across the conduit cross-section.

The flat geometry plays a central role in enhancing heat transfer performance. In dense-phase operation, heat transfer is governed primarily by conductive pathways through the particle network and by repeated particle-wall contact, rather than by convective gas-solid interactions. The planar wall surface increases the effective area available for heat exchange compared to cylindrical or free-falling configurations, while the narrow conduit width limits transverse particle motion and suppresses segregation. As a result, particles experience prolonged and repeated contact with the heated wall over the full receiver height, leading to efficient thermal absorption.

The gravity-driven operating principle further contributes to the robustness and simplicity of the receiver concept. Particle motion is established passively, without mechanical conveyance or fluidization, reducing parasitic energy consumption and mechanical complexity. This passive transport mechanism also decouples hydrodynamic stability from thermal operating conditions, enabling independent adjustment of particle residence time and wall temperature. Such flexibility is particularly advantageous for CSP systems operating under variable solar input, where stable flow behavior is required across a wide range of thermal loads.

## MATHEMATICAL FORMULATION

### Governing equations

The multiphase flow is modeled using a Eulerian-Eulerian approach [7], in which the gas phase (subscript *g*) and solid particle phase (subscript *s*) are treated as

interpenetrating continua. This approach is well suited for dense granular flows, where particle-particle interactions dominate and tracking individual particles becomes computationally prohibitive.

The local volume fraction of phase *k* is denoted by $\alpha_k$, its density by $\rho_k$, and its velocity vector by $u_k$.

The continuity equation for each phase k is written as:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \nabla \bullet (\alpha_k \rho_k u_k)$$

Where *t* denotes time and $\nabla \bullet$ is the divergence operator.

The momentum balance for the solid phase is given by:

$$\frac{\partial}{\partial t}(\alpha_s \rho_s u_s) + \nabla \bullet (\alpha_s \rho_s u_s) = -\alpha_s \nabla p + \nabla \bullet \tau_s + \alpha_s \rho_s g + F_{sg}$$

Here, $p$ is the pressure shared by both phases, $\tau_s$ represents the solid-phase stress tensor derived from the kinetic theory of granular flow, $g$ is the gravitational acceleration vector, and $F_{sg}$ denotes the interphase momentum exchange force, modeled using the Syamlal-O'Brien correlation [7].

The energy balance for the solid phase is expressed as:

$$\frac{\partial}{\partial t}(\alpha_s \rho_s h_s) + \nabla \bullet (\alpha_s \rho_s u_s h_s) = \nabla \bullet \left(k_{eff} \nabla T_s\right) + h_{ws} A_{ws} (T_w - T_s)$$

Where $h_s$ is the specific enthalpy of the solid phase, $T_s$ and $T_w$ are the solid and wall temperatures, $k_{eff}$ is the effective thermal conductivity of the packed bed, $h_{ws}$ is the wall-to-particle heat transfer coefficient, and $A_{ws}$ is the specific wall-particle contact area.

Wall-to-particle heat transfer is modeled using the Gunn correlation [8], and the effective thermal conductivity of the packed bed is computed using the Zehner-Bauer-Schlünder formulation [9].

Radiative heat transfer is not included explicitly in the present formulation. This assumption is justified by the moderate temperature range considered and by the objective of isolating conductive and contact-based heat transfer mechanisms in dense-phase operation. While radiation is expected to contribute at higher temperatures, its exclusion allows a clearer assessment of material and hydrodynamic effects and does not affect the comparative analysis between particle materials presented in this study.

The mathematical formulation captures the dominant physical mechanisms governing dense-phase flow and heat transfer in the flat-conduit receiver. By combining granular flow theory with established packed-bed heat transfer correlations, the model provides a physically consistent basis for evaluating receiver performance while remaining computationally tractable for parametric studies.

**Table 1:** Material properties.

| Material | Density ($kg \cdot m^{-3}$) | Specific heat capacity ($J \cdot kg^{-1} \cdot K^{-1}$) |
|---|---|---|
| Air | 1.225 | 1006 |
| Alumina | 3960 | 1250 |
| Silica sand | 2650 | 755 |

All simulations are performed using ANSYS Fluent. Transient simulations are performed to capture dense-phase dynamics. Grid-independence and time-step sensitivity analyses are conducted to ensure numerical stability. Indirect heating is imposed via prescribed wall temperature boundary conditions representative of CSP operation. Table 1 summarizes the thermophysical properties of silica sand and alumina particles used in the simulations. Particles had a size of 500 μm.

## EXPERIMENTAL VALIDATION STRATEGY

The experimental validation strategy is designed to assess the predictive capability of the numerical model under operating conditions representative of gravity-driven dense-phase receiver operation. Rather than attempting full thermal validation at this stage, the focus is placed on validating the hydrodynamic behavior of the particle phase, which is a prerequisite for reliable heat transfer predictions. A transparent flat-conduit receiver prototype is used to obtain particle velocity measurements under controlled operating conditions.

High-speed imaging combined with particle tracking techniques is used to obtain local particle velocities at multiple axial locations along the receiver height. These measurements provide spatially resolved information on particle kinematics, allowing direct comparison with simulated velocity profiles. The experimental setup and measurement planes are shown in Figure 3a.

The validation focuses on particle velocity rather than temperature, as velocity directly governs residence time, particle-wall contact duration, and ultimately heat transfer performance. By ensuring that the model accurately reproduces dense-phase kinematics, confidence is established in its ability to predict thermal behavior when coupled with established heat transfer correlations.

Comparison between experimental and numerical results (Figure 4) shows good agreement, with average relative deviations on the order of 6%. Slight discrepancies are observed near the inlet region, where experimental uncertainties related to particle injection and optical tracking are highest. These deviations do not propagate downstream and do not affect the overall flow regime or residence time distribution.

This validation strategy reflects a deliberate modeling hierarchy. Hydrodynamic validation is performed first to confirm correct representation of dense-phase flow behavior. Thermal predictions are then evaluated numerically using well-established correlations for wall-to-particle heat transfer and effective packed-bed conductivity. This approach avoids conflating hydrodynamic modeling errors with uncertainties associated with high-temperature experimentation and radiative heat transfer.

The experimental validation confirms that the numerical framework captures the key dense-phase flow characteristics relevant to flat-conduit receiver operation. The validated model therefore provides a robust basis for assessing thermal performance and for supporting future experimental campaigns at elevated temperatures.

## RESULTS AND DISCUSSION

### Dense-phase flow characteristics

Simulations of the flat-conduit receiver show stable dense-phase flow with solid volume fractions in the range of 0.62-0.63. As illustrated in Figure 3c, particle velocities remain uniform across the conduit width, with no evidence of channeling or dead zones.

This homogeneous flow structure is a direct consequence of the flat geometry and gravity-driven operation, which promote continuous particle-wall contact and suppress lateral segregation. In contrast to falling particle receivers, where particle dilution and curtain instabilities frequently lead to non-uniform residence times, the dense-phase configuration ensures predictable particle trajectories and well-defined residence times. From a receiver design perspective, this stability is essential for

maintaining consistent thermal performance under fluctuating solar input.

Moreover, the absence of localized regions with reduced solid fraction indicates that heat transfer is not limited by intermittent particle contact, which is a common drawback in dilute-phase systems. These results confirm that the proposed flat-conduit configuration provides a robust hydrodynamic basis for indirect particle heating.

## Thermal performance and material effects

Temperature fields and absorbed thermal power are summarized in Figure 5. For both particle materials, a clear temperature gradient develops between the heated wall and the particle core, indicating wall-dominated heat transfer under dense-phase conditions. However, alumina particles consistently reach higher temperatures throughout the conduit height compared to silica sand.

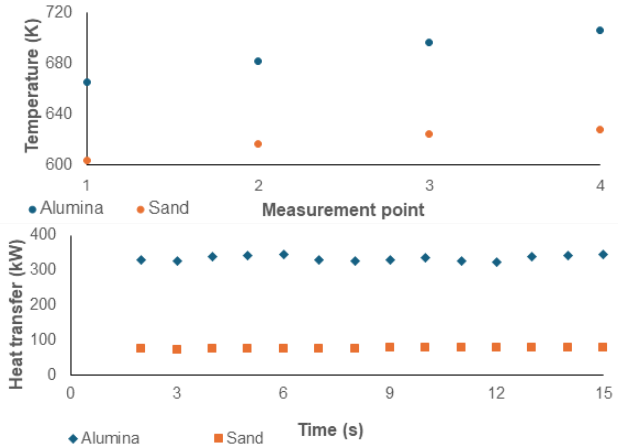

**Figure 5.** a) Particle temperature measurements at $t$ = 15 s; b) Transient heat transfer rate from the receiver wall, comparing sand an alumina.

This behavior can be attributed to the higher density and thermal conductivity of alumina, which enhance both the effective thermal conductivity of the packed bed and the heat capacity flow rate of the solid phase. As a result, alumina particles are able to absorb and transport more thermal energy for a given residence time.

Quantitatively, alumina particles absorb approximately 334 kW of thermal power at a mass flow rate of 11.7 kg·s$^{-1}$, whereas silica sand absorbs about 168 kW at 9.5 kg·s$^{-1}$ under identical conditions. These results demonstrate that material selection alone can nearly double thermal performance in dense-phase receivers.

From a system-level perspective, these results suggest that dense-phase receivers offer significant flexibility in performance tuning through material choice, enabling adaptation to different operating temperature ranges or storage requirements without major design modifications.

## Wall-to-particle heat transfer coefficients

The resulting wall-to-particle transfer coefficients are shown in Figure 6. Alumina achieves peak values of approximately 2.7 kW·m$^{-2}$·K$^{-1}$, while silica sand reaches only 1.2 – 1.4 kW·m$^{-2}$·K$^{-1}$.

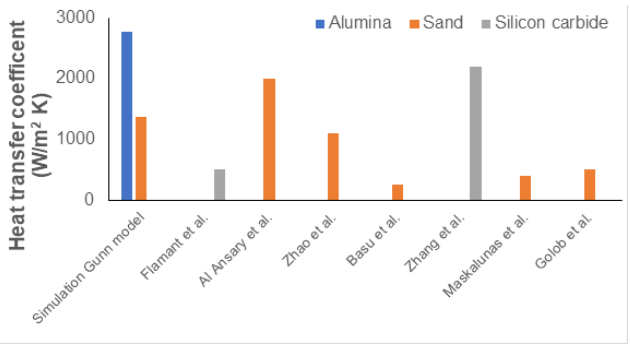

**Figure 6.** Wall-to-solid heat transfer coefficient from the receiver wall to the gas solid phase, comparing experimental results from literature.

These values compare favorably with experimental data reported in the literature for fluidized and falling particle receivers, while avoiding the need for auxiliary fluidization and its associated parasitic losses. The enhanced heat transfer observed in the dense-phase receiver is primarily driven by sustained particle-wall contact and high packing density, rather than by increased gas-solid convection.

The results also indicate diminishing marginal gains in heat transfer at very high packing densities, where increased particle-particle contact resistance can partially offset improvements in wall contact. This highlights the importance of balancing particle size, material properties, and conduit geometry when designing dense-phase receivers to achieve optimal thermal performance.

The heat transfer coefficients achieved in the present configuration demonstrate that dense-phase flat-conduit receivers can compete with, and in some cases outperform, more complex particle receiver concepts while maintaining mechanical simplicity.

# CONCLUSIONS AND OUTLOOK

A flat-conduit dense-phase particle receiver for concentrated solar power applications has been investigated using a combined computational and experimental approach. A multiphase Eulerian-Eulerian model was developed to describe dense-phase hydrodynamics and particle-wall heat transfer and was validated against particle velocity measurements obtained from a transparent receiver prototype. The validation confirms that the model reliably captures gravity-driven dense-phase flow behavior relevant to the proposed receiver concept.

The results show that alumina particles significantly

outperform silica sand, achieving wall-to-particle heat transfer coefficients of up to 2.7 $kW \cdot m^{-2} \cdot K^{-1}$ and nearly doubling the absorbed thermal power under comparable operating conditions. These findings underline the critical role of particle material properties in dense-phase receiver performance and demonstrate that substantial efficiency gains can be achieved through material selection alone.

Beyond quantitative performance metrics, the study highlights the advantages of flat-conduit dense-phase receivers in terms of flow stability, predictability of residence time, and mechanical simplicity. These characteristics make the concept particularly attractive for integration with particle-based thermal energy storage systems and high-temperature CSP architectures.

The present work is subject to certain limitations that define its scope. Thermal predictions are based on conductive and contact-dominated heat transfer mechanisms under indirect heating conditions, and radiative heat transfer effects are not considered explicitly. While this assumption is appropriate for the objectives of the current study and enables a clear assessment of material and hydrodynamic effects, it also motivates further investigation at higher temperatures and under direct solar irradiation

Future work will therefore focus on extending the experimental validation to elevated temperature operation, incorporating radiative heat transfer into the numerical framework, and assessing long-term material behavior under cyclic thermal loading. In addition, scale-up studies and modular receiver integration will be investigated to evaluate system-level performance and economic feasibility. Coupling the validated model with optimization and control methodologies will further support the design of robust dense-phase receivers capable of operating under transient solar conditions.

## ABSTRACT

This work develops a high-spatial resolution multi-stage stochastic programming (MS) model for power grid capacity expansion that co-optimizes generation, transmission, and energy storage system investments under uncertainty. Traditional two-stage stochastic programming (TS) models determine all investments in a single stage, limiting their ability to adapt to changing conditions such as evolving capital costs, policies, or supply chain disruptions. In contrast, the proposed MS formulation introduces sequential decision stages where partial information is revealed over time, allowing for adaptive, scenario-contingent investments. We compare TS and MS formulations using a modified IEEE 24-bus case study to quantify the Value of the Multistage Solution, which measures the economic benefit of allowing investment decisions to adapt over time as uncertainty is progressively resolved. Results show that while MS models are computationally more challenging, they achieve lower expected costs and yield flexible investment strategies that better respond to geopolitical and market uncertainties.

## INTRODUCTION

Electric power systems require long lead times for the development of new infrastructure. Securing regulatory approvals, acquiring land, negotiating fuel supply contracts, and building new generation or transmission assets can take many years to a decade [1]. Planning entities must make critical investment decisions before the full trajectory of technological, policy, and market conditions is known. The challenge lies in acting under uncertainty: delaying commitments until perfect information arrives is untenable, since long construction lead times require proactive expansion to maintain adequate capacity and reliably satisfy electricity demand. This uncertainty is characterized by volatile economic conditions, the rapid growth of energy-intensive data centers, and the increasing penetration of renewable energy sources. Neglecting uncertainty in planning models can lead to stranded assets or a power grid that is vulnerable to blackouts [2].

To inform these long-term investment decisions, planners can rely on capacity expansion planning (CEP) models. CEP models provide optimal investment decisions such as the size, timing, geographic location, and type of technology of new generation, transmission, and storage needed to meet future electricity demand at a minimum capital and operating cost [3]. Traditional formulations often adopt a deterministic approach, in which the expansion of the power grid is planned for a single assumed future where parameters such as fuel prices, capital costs, and electricity demand are treated as known. A wide variety of research papers are available that solve CEP deterministically [4]. However, these plans are likely to fail if implemented, as the realization of these parameters may be different from what the planner initially expected [5].

Stochastic Programming (SP) can hedge against certain outcomes by explicitly embedding multiple future realizations in the decision model. The model will produce plans that remain robust even when reality diverges from any single forecast [6]. Among SP formulations, two-stage stochastic programming (TS) has become the standard approach for power grid expansion planning. Here, first-stage investment decisions are made before

uncertainty is realized, while second-stage recourse decisions adjust operations after uncertainty resolution. This yields a block-angular structure that can be solved using decomposition algorithms such as Progressive Hedging and Benders Decomposition [7, 8].

However, all investment decisions are made upfront in TS formulations, preventing the model, by definition, from adapting to information revealed in later stages. This limitation is critical in contexts where policies evolve over time, potentially leading to premature or suboptimal investments. To overcome this limitation, multi-stage stochastic programming (MS) introduces sequential decision stages that unfold over time. Partial information is revealed at each stage, and nonanticipativity constraints ensure consistency across scenarios that share the same history. This structure captures the dynamic nature of long-term planning, allowing decision-makers to defer and revise investments as uncertainties materialize [9].

In this work, we develop a high-spatial resolution MS stochastic programming model for power grid expansion that co-optimizes generation, transmission, and energy storage system (ESS) investments under geopolitical uncertainty. We then compare the TS and MS formulations to quantify the Value of the Multistage Solution (VMS) [10] on a modified IEEE 24-bus case study. Unlike the Value of the Stochastic Solution (VSS), the VMS does not measure the benefit of modeling uncertainty relative to a deterministic model. Instead, it quantifies the value of adaptability by allowing decisions to adjust over time as uncertainty is revealed. To our knowledge, this is the first study to report this metric in the context of power grid CEP, thus providing the basis for future research on decision-making under uncertainty.

## BACKGROUND

A wide range of multistage stochastic CEP models has been proposed in the literature, each designed to address specific problem statements, system characteristics, and computational trade-offs. These models vary widely in the level of network granularity (regional vs. nodal), the treatment of investment decisions (continuous vs. discrete, with or without lead times), how operations are modeled (with or without unit commitment constraints), and the types of uncertainty (renewable power availability, loads, fuel prices, capital costs).

Liu et al. (2018) developed one of the first multistage, multiscale stochastic CEP models that co-optimizes generation, transmission, and ESS investments [11]. Their formulation is linear and highly aggregated, relying on a pipeline representation of transmission and continuous investment variables. These modeling choices allow the approach to scale well but limit its ability to represent discrete investment decisions, physical power-flow constraints, and delayed asset availability.

Thomé et al. (2019) propose an integrated generation–transmission planning framework that couples a MILP investment module with an SDDP-based multistage operational model [12]. Their formulation includes binary investment variables, power-flow physics, and detailed hydrothermal dispatch. However, the model does not represent construction lead times or ESS, factors that are becoming increasingly important in modern systems.

Hou et al. (2021) develop a multistage stochastic MILP linking long-term planning with hourly unit-commitment operations [13]. Their model co-optimizes generation and transmission expansion, but uses a six-region aggregated network without power-flow physics, continuous generator capacity additions, and no ESS or construction delays. In addition, uncertainty is limited to renewable availability, despite the important role of fuel prices, capital costs, and demand growth in CEP.

Apablaza et al. (2024) introduce a multistage stochastic model that co-optimizes transmission and energy storage investments using a nodal power-flow representation and explicit construction lead times [14]. Uncertainties are considered in fuel prices, load growth, and renewable availability. Because generator capacities are fixed, the model does not consider new generation investments and therefore cannot capture interactions between uncertain long-term conditions and generator siting, sizing, or technology choice.

Hole et al. (2025) present a stochastic planning model for New Zealand's hydro-dominated system that evaluates investments in wind and HVDC capacity using an SDDP-based operational framework [15]. The system is represented through an aggregated 11-node network with major corridors and key reservoirs, which supports large-scale hydrothermal modeling but omits finer spatial detail and storage technologies such as batteries.

These studies illustrate the breadth of modeling assumptions adopted in multistage stochastic CEP. Nonetheless, recent evidence highlights where model fidelity matters: Glista et al. (2025) show that low-spatial-resolution CEP models produce large errors and substantial generation under-investment relative to full-resolution formulations [16], while Watson et al. (2015) demonstrate that unit-commitment constraints have only limited influence on long-term system costs [2]. These insights help guide the modeling priorities of this work.

Our formulation is a nodal multistage stochastic MILP with the DC power flow approximation, discrete investment decisions for thermal generators and transmission lines, continuous sizing for renewable and ESS investments, and explicit construction lead times across stages. This design preserves the spatial accuracy needed for reliable expansion outcomes while avoiding unnecessary operational complexity, enabling the model to capture the spatial and temporal features that shape realistic long-term planning under uncertainty.

## MODEL DEVELOPMENT

In this section, we develop a multi-stage stochastic programming model for power grid capacity expansion planning. We begin by describing the deterministic optimization model and subsequently extend it to MS and TS programs.

### Deterministic program

The model described in this section is a multi-stage extension to the model described in [17]. For brevity, the detailed formulation, as well as notation for sets, parameters, and variables, is shown in the Supplementary Information. We refer to equation numbers in the Supplementary Information for completeness.

The objective function shown in Eq. (1s) minimizes the expected net present value (NPV) of total system costs over a planning horizon, defined as the sum of (i) capital investments in each investment stage for new generators, transmission lines, and ESS and (ii) the probability-weighted operational cost for all representative operating days. The operating component is comprised of fixed operation & maintenance (O&M) costs, variable O&M costs plus fuel expenses for dispatched generation, and a penalty for shortfalls in meeting the Renewable Portfolio Standard (RPS). In addition, each MWh of unserved energy is penalized with the Value of Lost Load (VOLL) – an economic proxy for the outage cost borne by customers. This penalty represents the loss of social welfare from electrical blackouts, and some system operators value it at between 10 and 30 thousand $/MWh in planning models.

Inter-stage linking is enforced through capacity accumulation constraints shown in Eqs. (2s) – (5s), which define installed capacity in each stage as the sum of previously available capacity and new investments, ensuring irreversibility of investment decisions. Consistent with this assumption, power plant retirements are not considered in this model.

Generation dispatch limits, shown in Eqs. (6s) – (8s), constrain power produced by newly built thermal and renewable generators by capacity installed in the previous stage to reflect construction lead times, with renewable output further limited by representative-day availability profiles. Existing generators are bounded by fixed nameplate capacities.

Power flow limits, given in Eqs. (9s) – (11s), bound flows on existing transmission lines by their thermal limits and enforce construction lead times by restricting flows on candidate lines according to capacity installed in the previous stage.

Power flow constraints, given in Eqs. (12s) – (14s), represent power-flow physics using a DC approximation of the AC power-flow equations, also known as the Bθ approximation, in which line flows are modeled as linear functions of phase angle differences. For candidate transmission lines, a disjunction implemented via big-M constraints enforces the DC power-flow relationship only when the line is available; in particular, the formulation links line availability to the prior-stage build decision, consistent with the assumed construction lead time.

ESS constraints, given in Eqs. (15s) – (19s), limit the state of charge by installed energy capacity and bound charging and discharging rates by power conversion capacity. The state of charge evolves according to net charging and discharging decisions, accounting for efficiency losses, with a cyclic condition imposed for each representative day. Unlike generation and transmission investments, ESS capacity is assumed to be immediately available upon installation, and therefore not subject to construction lead-time. This assumption is supported by the short project development timelines of modular battery technologies [18], which are negligible at the temporal resolution of the investment stages considered in this study.

The nodal balance constraint, given in Eq. (20s), equates the transmission inflows and local injections (generation and storage discharge) to transmission outflows and withdrawals (demand and storage charging), with load shed included to maintain feasibility under all operating conditions.

The RPS constraint, given in Eq. (21s), establishes a lower bound on the total power dispatch that must originate from renewable sources. Finally, via Eq. (22s) – (23s), the model establishes a limit on the number of new builds allowed on each bus due to physical space and interconnection capacity.

The formulation shown in the Supplementary Information can be compactly represented as

$$\min \sum_{k=1}^{K} (\alpha_k{}^{\top} u_k + \beta_k{}^{\top} y_k) \tag{1}$$

$$z_k = z_{k-1} + u_k \; \forall \, k = 1, \ldots, K$$

$$B_k y_k \leq b_k + G_k z_{k-1} \; \forall \, k = 2, \ldots, K$$

$$E_k y_k \leq r_k + T_k z_k \; \forall \, k = 1, \ldots, K$$

$$Q_k y_k \leq q_k \; \forall \, k = 1, \ldots, K$$

$$D_k y_k = d_k \; \forall \, k = 1, \ldots, K$$

$$0 \leq u_k \leq \bar{u}_k \; \forall \, k = 1, \ldots, K$$

$$z_0 = \bar{z}$$

where $u_k$ denotes the vector of investment decisions made in stage $k$, with elements representing the number of new thermal generators and candidate lines, as well as the capacity of new renewable generators and ESS. The vector $z_k$ denotes the corresponding cumulative installed capacity available at the beginning of stage $k$, with $z_0$ denoting the initial system capacity prior to any new investments. The vector $y_k$ collects all operational

variables in stage $k$, including generation dispatch, power flows, phase angles, ESS charging and discharging, and slack variables such as unserved energy and RPS non-compliance. The one-stage construction lead time is enforced by applying capacity-dependent operational limits using the lagged state $z_{k-1}$; specifically, the inequality block with matrices $B_k$ and $G_k$ ensures that capacity built in stage $k$ cannot be used for dispatch or candidate line operation until stage $k+1$. This lead time is not enforced for ESS constraints, as shown in the inequality block with matrices $E_k$ and $T_k$. The subsequent equality and inequality constraints represent constraints such as nodal balances, state-of-charge of ESS, and other bounds on the operational variables $y_k$ and stage-wise build limits $u_k$. Finally, the vectors $\alpha_k$ and $\beta_k$ contain investment and operational cost coefficients applied to $u_k$ and $y_k$, respectively.

## Multi-stage stochastic program

To capture the value of sequential decision-making under uncertainty, we now present the MS formulation in which investment decisions are allowed to adapt over time as uncertainty is gradually revealed.

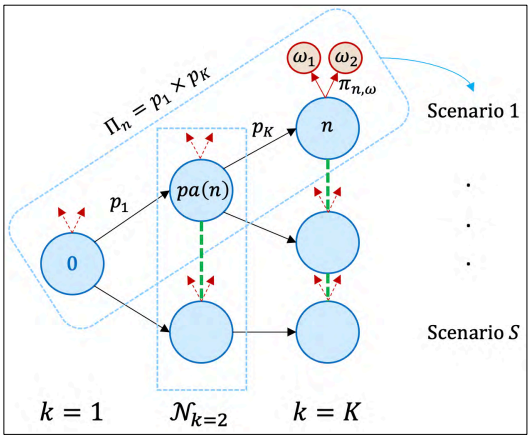

**Figure 1.** The scenario tree used in both MS and TS formulations. The TS model enforces stage-wise non-anticipativity of investment decisions (green dashed line), whereas the MS model allows node-dependent investments.

Uncertainty is represented by a scenario tree, as shown in Figure 1, whose nodes correspond to realizations of higher-level structural uncertainty, such as geopolitical events that affect long-term investment decisions. Let $\mathcal{N}$ denote the set of investment nodes of the scenario tree, with root node $n = 0$, and let $\mathcal{N}_k$ denote the set of investment nodes at stage $k$. Each node $n$ has an associated probability $\Pi_n$, and $pa(n)$ denotes its parent node. Investment decisions $u_n$ are made at each node and are therefore adaptive to the information revealed up to that node; nonanticipativity is enforced implicitly by the tree structure.

Short-term operational uncertainty such as fuel prices and load and renewable power availability profiles is represented through a finite set of operational realizations $\Omega_n$ with associated probabilities $\{\pi_{n,\omega}\}_{\omega\in\Omega_n}$. Operational decisions $y_{n,\omega}$ are variables that adapt to the variability within each node. The scenario tree captures strategic uncertainty that drives investment adaptability, while $\Omega_n$ captures operational variability conditional on each investment node. The formulation is as follows:

$$\min \sum_{n\in\mathcal{N}} \Pi_n \left( \alpha_n{}^{\top} u_n + \sum_{\omega\in\Omega_n} \pi_{n,\omega} \beta_{n,\omega}{}^{\top} y_{n,\omega} \right) \quad (2)$$

$$z_n = z_{pa(n)} + u_n \quad \forall n \in \mathcal{N}$$

$$B_n y_{n,\omega} \le b_{n,\omega} + G_n z_{pa(n)} \; \forall n \in \mathcal{N};\; \omega \in \Omega_n$$

$$E_n y_{n,\omega} \le r_{n,\omega} + T_n z_n \; \forall n \in \mathcal{N};\; \omega \in \Omega_n$$

$$Q_n y_{n,\omega} \le q_{n,\omega} \quad \forall n \in \mathcal{N};\; \omega \in \Omega_n$$

$$D_n y_{n,\omega} = d_{n,\omega} \quad \forall n \in \mathcal{N};\; \omega \in \Omega_n$$

$$0 \le u_n \le \bar{u}_n \qquad \forall n \in \mathcal{N}$$

$$z_0 = \bar{z}$$

## Two-stage stochastic program

The TS model is obtained as a special case of the MS model by restricting investment decisions to be stage-wise non-anticipative. While the strategic scenario tree and the operational recourse structure is identical to that of the MS model, the TS model enforces that all investment decisions taken at the same investment stage are identical across strategic nodes. As a result, investment decisions do not adapt to the realized strategic uncertainty and are selected in a here-and-now fashion. In other words, the TS model does not allow any flexibility in the investment plan with respect to the realized state of the world.

Formally, let $\mathcal{N}_k \subset \mathcal{N}$ denote the set of investment nodes associated with investment stage $k$. The TS model imposes the following stage-wise non-anticipativity constraint:

$$u_n = u_m \qquad \forall n, m \in \mathcal{N}_k;\; k \in K \quad (3)$$

Equivalently, a single stage-level investment decision $u_k$ may be introduced for each stage $k$.

$$u_n = u_k \qquad \forall n \in \mathcal{N}_k \quad (4)$$

Under this restriction, the complete investment plan $\{u_k\}_{k=1}^{K}$ is identical across all strategic scenarios, while operational decisions remain adaptive and are treated as recourse variables conditional on the realized operational uncertainty, such as fuel prices and load and renewable power availability profiles.

**Table 1:** Summary of scenarios considered in this case study.

| Stage ($k$) | Narrative | Parameter materialization | Node | | |
|---|---|---|---|---|---|
| 2 | Policies that favor rapid deployment of low-carbon technologies such as SMR, solar panels, and wind turbines. Reduced demand for fossil-fuel-based generation. | Fuel cost ↓ | 2 | | |
| | A disruption in renewable energy supply chain that shifts policy support toward fossil-fuel-based generation. Increased demand for fossil-fuel-based generation. | Fuel cost ↑↑ | 3 | | |
| | Broad advancements across all generation technologies. Moderately high fossil fuel costs, given no strong shift in generation mix. | Fuel cost ↑<br>Investment costs ↓5% | 4 | | |
| 3 | Moderate demand growth; tamed datacenter growth | Demand ↑ (1.6x) | 5 | 7 | 9 |
| | High demand growth driven by AI datacenter proliferation | Demand ↑↑ (2x) | 6 | 8 | 10 |

## PROBLEM STATEMENT

We study a long-term power grid CEP under uncertainty to determine optimal generation, transmission, and ESS investments, and associated operational decisions, that minimize the expected NPV of total system costs.

The study is conducted on a modified IEEE 24-bus system over an eight-year planning horizon divided into three investment stages. Stage k=1 corresponds to the base year 2025, stage k=2 to 2029, and stage k=3 to 2033. Investment decisions include new open-cycle gas turbines (OCGT), combined-cycle gas turbines (CCGT), coal-fired power plants, small modular reactors (SMR), wind turbines, solar panels, 4h ESS, 2h ESS, and thirty-four candidate transmission lines.

Generators and transmission assets have a construction lead time of one stage, whereas ESS investments are assumed to be immediately available. System operations within each investment stage are represented using two representative days, one winter and one summer, to capture seasonal variability. This simplified choice is intentional, as the study is primarily methodological and designed as a proof of concept to demonstrate the proposed framework and analyze the VMS. In practical planning applications, a larger set of representative days would generally be needed to better capture operational variability. The value of lost load is set to $10, 000/MWh, the RPS is set to 40%, and the discount factor used in the NPV objective is 8%.

Uncertainty in the problem is revealed sequentially and operates at different time scales. The uncertainty structure is chosen to reflect commonly observed drivers of long-term uncertainty in power system expansion studies. At stage k=2, strategic uncertainty is realized in the form of geopolitical events that affect capital and fuel costs. We consider three geopolitical events with equal probabilities. At stage k=3, demand-side uncertainty is realized through load growth trajectories reflecting the expansion of data centers and AI-driven electricity demand. We consider two equiprobable load growth realizations at stage k=3, corresponding to moderate and high demand growth scenarios. A summary is provided in Table 1 and the full scenario tree in Figure 2.

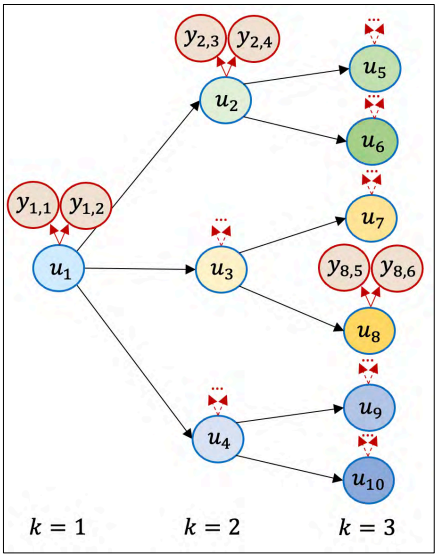

**Figure 2.** Problem-specific scenario tree.

## IMPLEMENTATION

We compare two modeling paradigms. In the TS formulation, the entire investment plan across all stages is

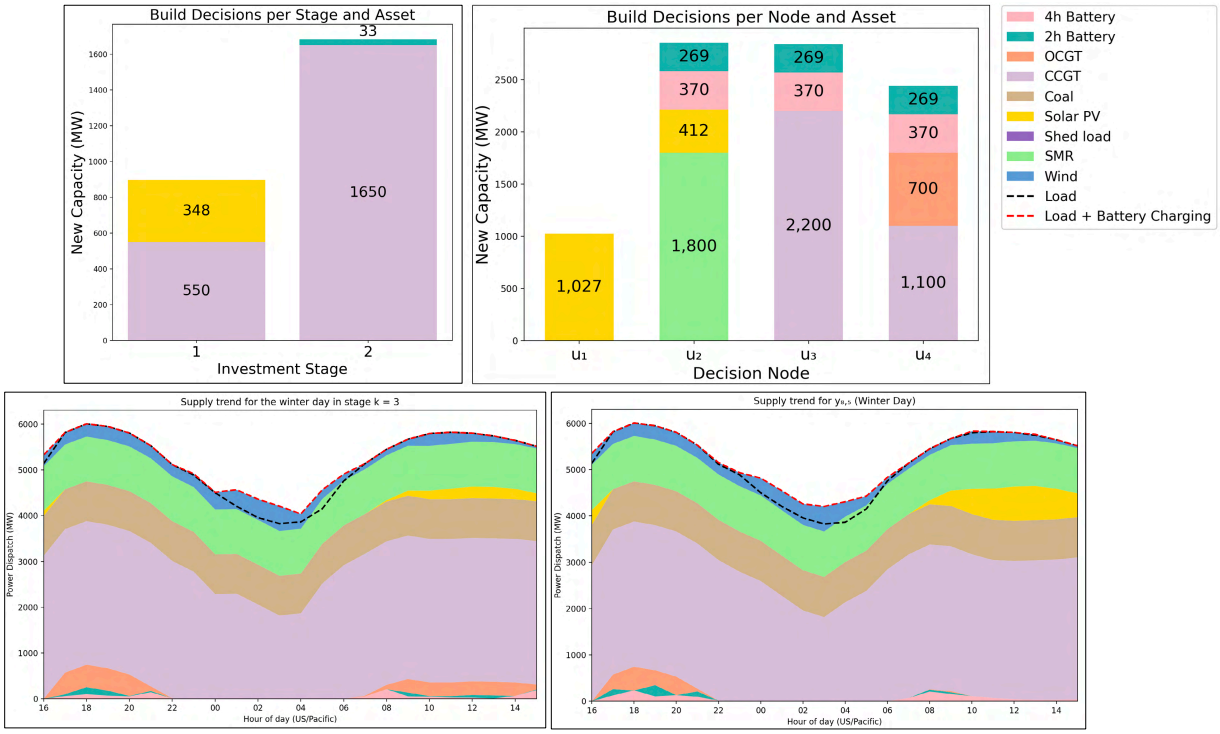

**Figure 3. a) Top left corner**: Investment decisions for the TS formulation; **b) Top right corner**: Investment decisions for the MS formulation; **c) Bottom left corner**: Supply trend for the TS formulation; **d) Bottom right corner**: Supply trend for the MS formulation;

selected prior to the realization of geopolitical events and load growth. In contrast, the MS formulation allows investment decisions to adapt sequentially: investments made at stage k=2 respond to the realized geopolitical event, while investments at stage k=3 further adapt to the realized load growth trajectory.

The formulations were implemented in Pyomo 6.9.5 [19]. The stochastic formulations were constructed using the `mpi-sppy` package [20], which was used to manage nonanticipativity constraints and assemble extensive-form models. The resulting MILP for TS and MS formulations were solved to optimality gaps of ~2% using academic license of Gurobi v12 [21] on an Apple M4 Pro workstation with 48 GB of RAM. In long-term infrastructure planning, optimality gaps on the order of 1 – 3% are commonly considered acceptable, as they are broadly consistent with the uncertainty in input cost data and are sufficient to support investment and policy analysis.

# RESULTS

## Investment decisions

Investment decisions for the TS and MS formulations are shown in Figures 3a and 3b, respectively. For brevity, we omit the expansion decisions for investment stage k=3. We also note that none of the optimal solutions recommend investing in new transmission lines. This outcome is consistent with the findings reported in [17], which show that when generation, transmission, and ESS are co-optimized, ESS often defers the need for new transmission expansions.

In the first stage, we note that the MS model invests in 1027 MW of solar panel capacity and defers 550 MW of early CCGT that the TS model builds, preserving the option to reallocate capital once uncertainty resolves. This difference highlights one advantage of the MS formulation: it acknowledges that future cost shocks will influence the relative attractiveness of thermal vs renewable investments. By waiting, the MS model preserves the option to redirect or delay capital depending on how conditions evolve at later stages.

In the second stage, the MS model selects one of three investment plans that directly reflect the realized geopolitical shock, allowing it to tailor its mix of thermal, renewable, and ESS additions to the actual cost in each branch. Importantly, these decisions correspond to forward-looking investments whose capacity becomes available in the next stage (except for ESS). This flexibility lets the MS model capitalize on low-cost opportunities in some branches while avoiding overly expensive technologies in others. In contrast, the TS model must commit to a single CCGT-heavy plan that applies to all futures, regardless of which shock occurs. Because it cannot adjust to branch-specific cost changes, the TS formulation

might overinvest in thermal capacity and overlook cheaper renewable or ESS options, incurring opportunity costs in branches where a different portfolio would have been more economical.

### Operational decisions

The MS formulation also provides a cheaper operating schedule. For instance, when the disruption in renewable energy supply chain materializes, the dispatch merit order shifts in stage k=3, so CCGT and solar panels serve most hours while the existing OCGT is mostly idle. In contrast, the TS formulation relies more on OCGT, which has elevated fuel costs, given that it did not invest previously on solar panels. This can be seen in Figures 3c and 3d.

### Value of multistage solution

As described in [10], we also denote by $v_{TS}$ and $v_{MS}$ the optimal objective values of the TS and MS formulations, respectively. Thus, the VMS is defined as:

$$\text{VMS} = \frac{v_{TS} - v_{MS}}{v_{MS}} \quad (5)$$

In addition, we can infer that $v_{TS} \geq v_{MS}$, since the MS formulation offers more flexibility in the investment decisions with respect to the set of strategic and operational sets of uncertainty [10]. The objective values obtained for the TS and MS formulations are 393, 857 USD/h and 381, 474 USD/h, respectively. To report costs on standard units, the optimal objective values are normalized by a representative system load, obtained by averaging loads along each root-to-leaf scenario path and then taking expectations over the scenario tree. For the TS and MS formulations we obtain objective values of 0.1179 and 0.1141 USD/kWh.

This reduction in expected electricity prices reflects the value of deferring and adjusting investments in response to realized outcomes. The resulting VMS, defined as the relative improvement of the MS solution over the TS solution, is 3.3%. This result quantifies the economic benefit of modeling investment decisions dynamically and highlights the importance of capturing intertemporal flexibility when planning under long-term uncertainty. For context, retail electricity prices in the United States have been increasing on the order of 2.5 % per year according to EIA data [22], indicating that the modeling difference is economically meaningful.

## CONCLUSIONS

This paper demonstrates the value of multi-stage stochastic programming for long-term power grid capacity expansion planning. By allowing investment decisions to adapt to realized geopolitical events and operational uncertainty, the multi-stage formulation produces more flexible investment paths and improved operational schedules relative to a two-stage stochastic programming model. In the case study, this added flexibility yields a 3.3% reduction in expected electricity costs, highlighting the economic benefit of dynamically adjusting investments rather than committing to a single static plan.

From a practical standpoint, this multi-stage stochastic programming framework is best interpreted as a rolling-horizon planning tool. At each investment stage, planners can redefine the scenario tree based on expert judgment, policy insights, and emerging information about technology costs, fuel markets, and demand growth. In this setting, scenario construction plays a central role and reflects structured expert assessments of plausible future conditions. Although the multi-stage stochastic programming formulation is computationally more demanding than its two-stage counterpart, advances in decomposition methods are expected to support its use in realistic planning contexts.

## DIGITAL SUPPLEMENTARY MATERIAL

The model formulation for the deterministic program can be found in the Living Archive for Process Systems Engineering with LAPSE ID 2026.0017.

## ABSTRACT

Computer-Aided Process Engineering (CAPE) has transformed how we analyze, design, and optimize energy processes. Yet, even advanced models rest on uncertain ground: their reliability depends on how well future operating environments are described—environments that are dynamic, complex, and deeply uncertain. In practice, uncertainty is often reduced to local parameter variations, driven by limited data, computational burden, and overconservative robust formulations. This narrow treatment creates a false sense of confidence: Designs that perform well in theory often fail in real-world operation. In a century marked by economic, climatic, and technological volatility, designing under uncertainty is no longer optional; it is essential.We have developed approaches that place uncertainty at the core of energy process modeling and design. This paper provides an overview of these methods and how uncertainty can be explicitly represented, quantified, and embedded into the design process.We present approaches to characterize uncertainties under data scarcity, including imprecise probabilities to distinguish between aleatory and epistemic uncertainty. To propagate uncertainty through computationally intensive models, we introduce surrogate-assisted techniques that exploit structural sparsity, enabling the analysis of systems with large numbers of uncertain inputs (100+) while mitigating the curse of dimensionality. These methods are integrated into optimization frameworks that target expected performance, robustness, and, for the first time, antifragility—systems that can benefit from variability rather than merely withstand it. We illustrate these approaches across applications ranging from detailed process models to system-level energy analyses, advancing a shift in CAPE toward designs suited for an unpredictable world.

**Keywords**: Uncertainty assessment, Robust design optimization, Process simulation, Antifragility

## INTRODUCTION

Computer-Aided Process Engineering (CAPE) tools, such as Aspen Plus, gPROMS, Thermoflex, and in-house high-fidelity thermodynamic simulators, have become central to process design and operation [1]. Engineers now evaluate complex heat integration networks, power-to-X routes, carbon capture systems, and flexible plants using nonlinear, tightly coupled models that embed thermodynamics, transport phenomena, and equipment constraints. These models can simulate performance with high accuracy, but they remain conditional on

assumptions about their operating environment, such as variations in ambient temperature and humidity, cooling-water temperature, heat-transfer coefficients, fuel composition (carbon, hydrogen, lower-heating value), electricity prices, CAPEX and OPEX of emerging units, policy constraints, market regimes, and evolving sustainability targets. Despite this, uncertainty in many CAPE studies is still mostly handled through deterministic base-case optimization followed by local sensitivity checks or a small scenario sweep [2]. This approach persists for understandable reasons: (i) data about the operating environment is fundamentally incomplete which makes rigorous uncertainty characterization difficult [3], (ii) brute-force Monte Carlo becomes infeasible for expensive nonlinear flowsheets [4], and (iii) worst-case robust formulations often drive designs toward conservatism that is difficult to defend in engineering and economic terms [5]. This narrow treatment of uncertainty can create confidence in designs that are fragile when exposed to operational variability and imperfect foresight.

Over the past decade, we have developed methods that place uncertainty at the center of CAPE modeling and design. This paper documents a probabilistic uncertainty workflow that we use for nonlinear, technology-detailed CAPE models under limited information. We focus on uncertainty characterization under limited data, surrogate-assisted uncertainty propagation that remains tractable for expensive simulations, and robust design optimization that explicitly trades off expected performance and sensitivity to variability. We also present antifragility as a paradigm shift for optimization under uncertainty and ways to address structural uncertainty, where uncertainty is not only about parameter values but also about what the problem formulation should be, for example when stakeholder preferences or acceptability thresholds are uncertain. Finally, we conclude this paper with a discussion and perspectives.

## A FRAMEWORK FOR UNCERTAINTY-AWARE PROCESS DESIGN

In this section, we present a framework for uncertainty-aware process design (Figure 1). It covers methods for characterizing uncertainty, propagating uncertainty and robust design optimization.

### Representing Uncertainty Under Limited Data

Uncertainty characterization translates knowledge about the parameter variation into a mathematical representation that will drive propagation and optimization. In CAPE, researchers repeatedly face the same obstacle [2]: Data about the operating environment is often sparse, inconsistent, or context-specific. For instance, electricity-price projections may exist only as a small set of scenarios, emerging unit costs may be based on few studies with incompatible assumptions, and ambient conditions may only be available at coarse data resolution. In this setting, analysts often default to common distributions such as uniform or normal [3]. In this way, they risk encoding strong assumptions, either by assigning zero probability to tail events or by extrapolating tails from limited central information. In nonlinear flowsheets, these assumptions can change optimized designs because feasibility, active constraints, and operating regimes can switch across the uncertain domain [6].

One way to represent uncertainty uses quantile-anchored parametric distributions by combining data with expert judgment. While frequently available, translating expert judgment into distributional parameters (e.g., mean, variance) is difficult: Even when experts can provide plausible ranges, they struggle to express how probability mass should be distributed within those ranges [7]. Expert sources are usually more consistent when asked for percentile statements [8]. Therefore, a pragmatic way is to elicit expert judgment on quantiles rather than attempt to obtain full distribution parameters directly, such as “a pessimistic value that is likely exceeded in only 5% of the scenarios.” Moreover, if the modeler commits to a distribution type (e.g., a lognormal distribution to represent the future electricity price), two distinct percentiles determine a unique distribution (in the common case of a two-parameter type), so the resulting distribution is fully anchored to explicit expert statements [9]. To illustrate this approach, we elicited two percentiles and distribution types from expert reports and characterized the corresponding distributions for grid electricity price, wind speeds and electricity demand in the assessment of a wind-powered community [8].

A second representation uses imprecise probabilities to treat distributional ambiguity explicitly. The same elicited quantiles may be consistent with a bounded distribution that has hard limits, or with a heavy-tailed distribution that assigns small but decision-relevant probability to extreme outcomes. When this ambiguity affects design choices, a single fitted curve can convey unwarranted certainty. Probability boxes (p-boxes) address this by representing uncertainty as a family of admissible distributions bounded by lower and upper cumulative distribution functions [10]. This representation is particularly useful when epistemic uncertainty dominates, because it treats uncertainty about the distribution itself as part of the model, not as an afterthought. It also supports a separation between aleatory variability, which reflects intrinsic randomness, and epistemic uncertainty, which reflects limited knowledge that could shrink with better information or clearer assumptions.

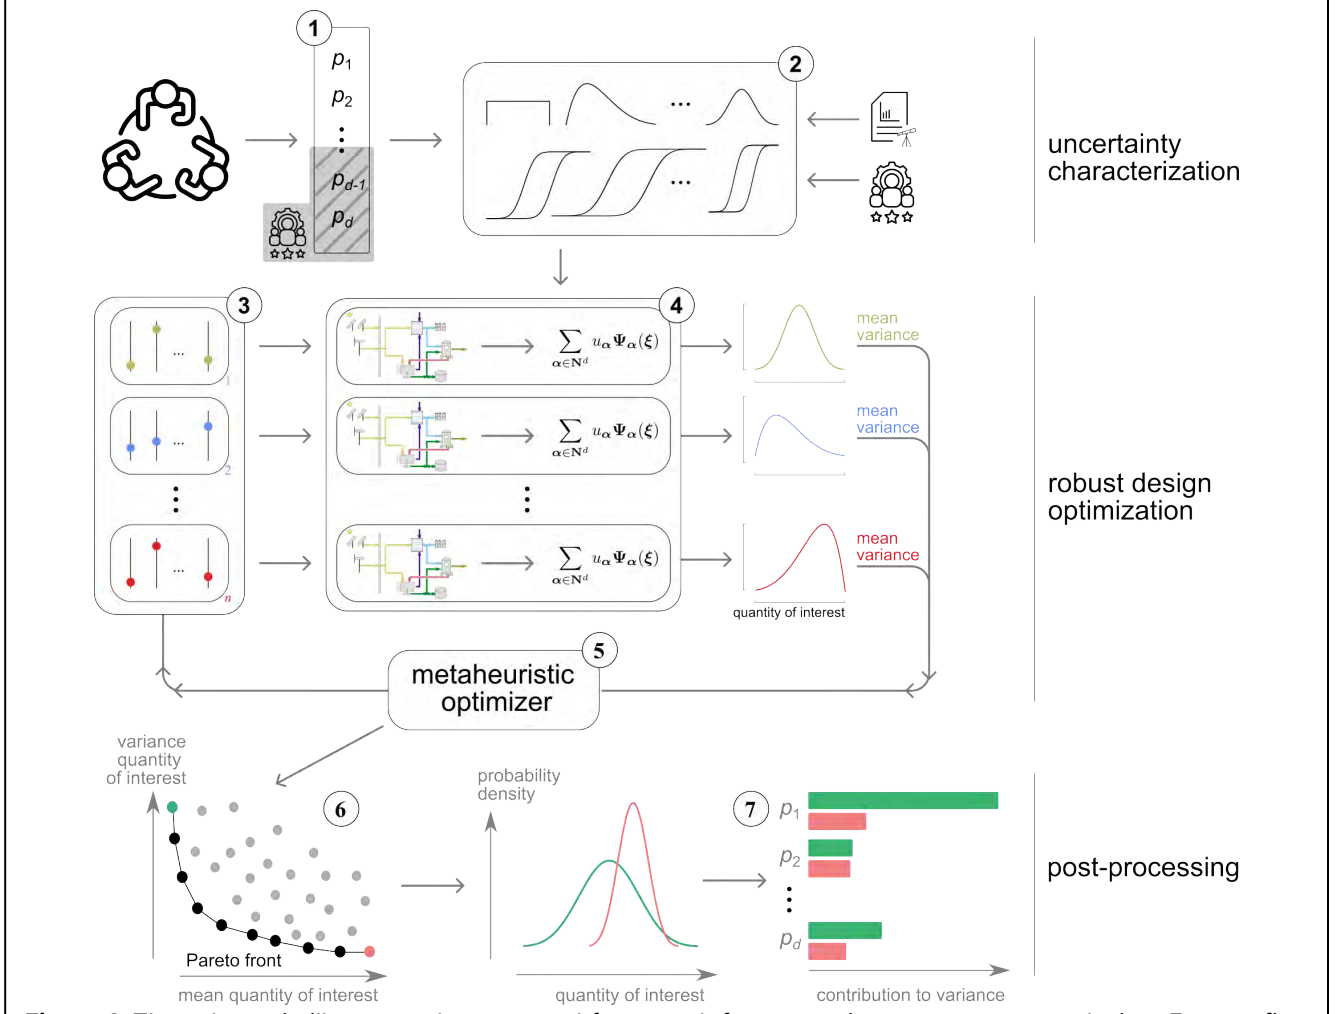

**Figure 1.** The schematic illustrates the proposed framework for uncertainty-aware process design. Experts first identify the parameters to be treated as uncertain (1). An optional expert-based screening may be applied to discard parameters expected to have negligible influence. Uncertainty is then characterized by combining data, projections, and expert judgment, using either precise probabilistic distributions or imprecise formulations when epistemic uncertainty is substantial (2). The optimization workflow then begins. An initial set of candidate designs is generated by exploring the design space, for example using Latin Hypercube Sampling (3). For each candidate design, the process model is evaluated under uncertainty by constructing a surrogate, typically a full or sparse Polynomial Chaos Expansion depending on model complexity and the number of retained uncertain inputs (4). Performance statistics such as the mean and variance, or bounds on these quantities in the imprecise case, are computed analytically from the surrogate and provided to a population-based metaheuristic optimizer as fitness values (5). The optimizer iteratively generates new design populations and updates the design set. After convergence, the resulting Pareto front quantifies the trade-off between expected performance and robustness (6). For selected Pareto-optimal designs, global sensitivity analysis is extracted analytically from the surrogate to identify the uncertain inputs that dominate performance variability and those with negligible influence (7).

We used probability boxes to represent the operating environment of a hybrid renewable energy system comprising a photovoltaic array, batteries, a heat pump, and thermal storage. For electricity and heat demand, aleatory uncertainty represented irreducible variability in future demand, while epistemic uncertainty reflected limited knowledge of occupant behavior and reliance on generic demand profiles. Energy prices were treated analogously, with aleatory uncertainty capturing plausible market evolution and epistemic uncertainty capturing ambiguity in tariffs and supplier choice. We propagated these probability boxes through the system model and used the aleatory component to drive robust design optimization of the levelized cost of exergy, because this

variability cannot be reduced through additional information and can only be mitigated through design choices. In contrast, we used global sensitivity analysis on the epistemic component to identify which uncertain assumptions most affected predicted performance and robustness, thereby indicating where additional information would most effectively reduce decision-relevant uncertainty [11].

In practice, a precise probabilistic formulation is pragmatic, as it is simpler to implement, propagate, and communicate, but it necessarily collapses epistemic uncertainty into a single predictive model. This is often acceptable for parameters such as ambient conditions, standardized fuel properties, or short-term market fluctuations, where uncertainty is largely aleatory or where epistemic uncertainty is small relative to its effect on design decisions. We propose an imprecise representation when epistemic uncertainty is significant, meaning that uncertainty about the parameters or assumptions of the distribution itself is large enough to affect design conclusions. Typical examples include electricity or carbon prices over multi-decadal horizons, CAPEX of emerging technologies, or demand projections driven by poorly specified user behavior. In such cases, explicitly separating aleatory variability, which must be mitigated through design, from epistemic uncertainty, which can be reduced through additional information or specification, avoids masking decision-relevant uncertainty, despite the added conceptual and computational complexity.

## Uncertainty Propagation and Quantification

Once input uncertainties have been characterized, whether through precise or imprecise probabilities, the next step is to propagate that uncertainty through the model to quantify its impact on the outputs of interest. The most straightforward approach is Monte Carlo Simulation (MCS), which samples uncertain inputs from their assigned distributions, evaluates the model for each sample, and estimates output statistics. Although this approach is conceptually simple and asymptotically convergent, it becomes impractical for many CAPE applications. MCS typically requires a large number (~$10^{3\text{-}5}$) of model evaluations to resolve output variability and tail behavior, while high-fidelity CAPE models are computationally expensive (minutes to hours) and often involve many uncertain inputs (>10). As a result, naive Monte Carlo propagation quickly becomes computationally intractable.

An effective alternative is to move to surrogate-assisted Uncertainty Quantification (UQ). The core idea is to replace numerous brute-force evaluations of an expensive simulator with a cheaper approximation that captures the dominant input–output relationships. Among available surrogate approaches, Polynomial Chaos Expansion (PCE) is particularly well suited to UQ because it represents model outputs as an expansion in orthogonal polynomials of the uncertain inputs [12]. Once a PCE surrogate is trained, it can be evaluated orders of magnitude faster (typically milliseconds) than the original model. An additional benefit of PCE is that uncertainty propagation naturally yields statistical moments on the output (mean, variance) and a global sensitivity analysis can be performed at negligible additional cost by exploiting the PCE coefficients. In practice, high Sobol' indices guide where further knowledge is necessary. For example, we applied PCE to the integration of Direct Air Capture (DAC) in a power-to-gas flowsheet to quantify uncertainty in energy efficiency, exergy efficiency and levelized cost under uncertain ambient conditions, sorbent thermodynamics, electricity price, and CAPEX/OPEX. The resulting Sobol' indices identified that electricity price and DAC CAPEX dominated the variance of levelized cost, while thermodynamic model parameters and ambient conditions had a secondary influence on the overall performance [13].

In CAPE applications, the uncertainty space typically includes many input parameters, which makes a full PCE impractical because the number of required expansion coefficients, and thus training simulations, grows combinatorially with both polynomial degree (linked to the nonlinearity of the input-output relation) and the number of uncertain parameters. Dimensionality reduction is therefore unavoidable.

Screening based on expert judgment or coarse sensitivity checks provides a pragmatic first reduction, but it is inherently subjective and can overlook higher-order interactions that only emerge in nonlinear regimes. Multi-fidelity PCE strategies alleviate this by using low-order surrogates to rank influential inputs before constructing higher-order models, but their effectiveness depends on the reliability of these preliminary approximations, which can be poor when responses are highly nonlinear or discontinuous. In a long-term energy-system planning model with many uncertain techno-economic inputs, we used a low-order PCE as a preliminary step to reduce an initial set of uncertain parameters to a smaller set of critical parameters before building the higher-fidelity surrogate and revealed that a small subset of fuel-price and demand-growth assumptions dominated the uncertainty on the system costs [14].

Sparse PCE addresses these limitations by integrating screening directly into surrogate construction, retaining only influential polynomial terms and interactions while discarding the rest, thereby controlling dimensionality without requiring explicit pre-screening or multiple surrogate stages and significantly reducing the number of required training simulations [15]. We used sparse PCE for a Thermoflex®-based retrofit study of a large thermal power plant where 243 uncertain inputs made conventional PCE infeasible, and the resulting Sobol' indices showed that fuel composition, lower heating value, and boiler efficiency parameters dominated variability in

furnace temperature and efficiency, while most auxiliary parameters had negligible influence [16].

PCE can also be applied when input uncertainties are represented through probability boxes. In a parametric p-box setting, uncertainty in the statistical moments, such as the mean and variance, is represented by uniformly distributed variables to reflect bounded epistemic uncertainty. For any specific realization of these parameters, a corresponding formulation of the aleatory uncertainty is defined through the associated conditional distribution. Because this conditional formulation introduces dependence between epistemic and aleatory components, the aleatory variable is rewritten in standardized form, and the physical input is reconstructed by combining this standardized variable with the sampled mean and variance. This reformulation represents the uncertain input through a set of independent variables: one standardized variable capturing aleatory variability and uniform variables capturing epistemic uncertainty in the distribution parameters. A single PCE surrogate constructed on this augmented input space can then be sampled efficiently to compute bounds on the output distribution, yielding the probability box of the model response without resorting to a nested MCS [17]. In a PV–battery–heat-pump system with thermal storage, we represented mixed aleatory variability (demand and weather evolution) and epistemic ambiguity (occupant behavior and cost assumptions) with parametric p-boxes, then used the augmented PCE to propagate output bounds while using the aleatory part for design objectives and the epistemic part for sensitivity-guided information prioritization, showing that aleatory demand variability primarily affected the robustness, while epistemic uncertainty in electricity tariffs and user behavior dominated the epistemic uncertainty on the optimized costs [11].

## Designing for Robustness

Design optimization under uncertainty is where all the pieces come together—and also where computational burden tends to peak. The goal is to identify design decisions (equipment sizes, operating conditions, etc.) that perform well across the range of uncertainties characterized earlier. A specific type of optimization under uncertainty is Robust Design Optimization (RDO), where the mean and variance of the quantities of interest obtained from UQ, such as costs, efficiencies and emissions, define the optimization objectives and constraints.

From a computational perspective, RDO inherits the computational cost of UQ. We therefore build on the surrogate-based propagation strategies introduced in the previous section and embed them within an optimization loop [19]. For a given candidate design, the design variables are held fixed, and the PCE is constructed by sampling the uncertain inputs around that design according to their prescribed probabilistic descriptions. Because the surrogate represents the full input–output map for that design, the statistical moments required for the objectives can be computed analytically from the PCE coefficients. Reliability-type constraints can be acquired in the same way by evaluating, for each design, the probability of violating constraints based on the propagated uncertainty [18]. In a high-fidelity RDO setting considered here, uncertainty propagation is thus performed separately for each candidate design evaluated by the optimizer. While this approach is computationally more demanding than global surrogates spanning both design and uncertainty spaces, it preserves accuracy in the presence of strong nonlinearities in the design space.

The optimization itself is performed using gradient-free, population-based algorithms, which are well suited to the black-box and often nonconvex nature of CAPE problems [20]. In our applications, multi-objective formulations are solved using NSGA-II, with objectives being the mean and variance of the quantity of interest, such as cost, efficiency and emissions. The resulting Pareto front quantifies the trade-off between the expected performance and robustness and provide a structured basis for optimized design selection.

The validity of this approach depends on the reliability of the surrogate models used during optimization. The fidelity is therefore enforced through an automated two-step procedure. First, the design space is explored using a space-filling sampling of the design variables, such as Latin Hypercube Sampling. For this initial set of designs, full PCEs are built for increasing polynomial orders, and the worst-case leave-one-out error over all sampled designs is evaluated. The smallest polynomial order that meets a predefined accuracy threshold is then selected and fixed for the remainder of the optimization. During the RDO iterations, sparse PCEs of this order are constructed for each candidate design, and their accuracy is monitored using leave-one-out error and stabilization of the estimated mean and standard deviation as training samples are added. If a candidate design leads to non-convergent or nonphysical model evaluations for one or more training samples, that design is classified as infeasible and assigned a penalized objective value.

We implemented the full workflow in an open-source framework called RHEIA [21] and applied it to several CAPE applications with distinct process structures and decision variables. In a grid-connected photovoltaic system with battery and hydrogen storage, RDO shifted the preferred designs from photovoltaic-only systems toward battery and hydrogen storage when robustness was valued. For a community-scale system, the robust PV–battery–hydrogen design increased the mean levelized cost of electricity from 269 €/MWh to 363 €/MWh (≈+35%), while reducing its standard deviation from 55.6 €/MWh to 41.9 €/MWh (≈ −25%), explicitly trading expected cost for reduced sensitivity to electricity-price

uncertainty [19]. In a wind-powered power-to-ammonia plant, RDO revealed a clear trade-off between productivity and robustness: the design maximizing mean annual ammonia production achieved 3.2 times higher average output, but its standard deviation of annual production was 2.6 times larger than that of the robust design, indicating substantially higher sensitivity to wind-speed and reactor-temperature uncertainties [22]. Finally, for a renewable-powered hydrogen refueling station and bus fleet, converting 54% of the diesel buses to hydrogen-powered buses reduced the standard deviation of the levelized cost by 36%, reduced the mean carbon intensity by 46%, and reduced its standard deviation by 51%, at the expense of an 11% increase in mean cost [23].

### Limitations

The workflow has three main limitations related to computational cost, input dependency, and accuracy.

First, the computational cost can still be high because the RDO loop requires building, validating, and sampling a surrogate for each candidate design. This nested structure can have computational overhead because of expensive models, large populations, many generations, and higher polynomial orders.

Second, standard PCE construction typically assumes independent uncertain inputs. Many CAPE problems feature correlated drivers (e.g., demand–price coupling, weather covariation, or jointly evolving techno-economic assumptions). Ignoring dependence can misrepresent joint extremes, constraint-violation risk, and sensitivity indices. Accounting for dependence is possible (e.g., via transformations or copula-based modeling), but it introduces additional modeling choices.

Third, PCE accuracy degrades when outputs are non-smooth or discontinuous in the uncertain inputs, which can arise from regime switching, active-constraint changes, phase changes, and feasibility boundaries. In these cases, moment estimates, tail metrics, and Sobol' indices may become unreliable unless more complex surrogate strategies are used (e.g., piecewise surrogates or classification-plus-regression), which reduces the simplicity of the approach.

## EMERGING DIRECTIONS IN UNCERTAINTY-AWARE DESIGN

While RDO provides a principled way to control sensitivity to uncertainty, it implicitly treats uncertainty as a source of risk. As a result, optimization strategies that focus exclusively on robustness tend to penalize all variability symmetrically, which can suppress configurations that would perform better under favorable operating conditions. In addition, RDO primarily addresses uncertainty in model parameters and implicitly assumes that the chosen model structure and objective formulation capture all decision-relevant aspects. In practice, however, factors such as social acceptance and stakeholder preferences may be difficult, if not impossible, to encode, yet they can strongly influence whether an optimized design can be implemented. The following sections therefore examine two complementary extensions: antifragility, which explicitly accounts for asymmetric responses to variability, and approaches that address structural and preference uncertainty by exploring sets of near-optimal alternatives rather than a single solution.

### Antifragility: A Paradigm Shift in Designing Under Uncertainty

Optimization under uncertainty in CAPE has traditionally focused on robustness, that is, identifying designs whose performance is least sensitive to uncertain operating conditions. While effective when uncertainty is well characterized, this paradigm becomes limiting when the magnitude and structure of future techno-economic uncertainty are themselves poorly known. Moreover, robustness treats variability symmetrically: it controls downside risk, but it also suppresses upside opportunity.

An emerging alternative is antifragile design, which shifts the objective from minimizing harm due to uncertainty to exploiting favorable variability—an antifragile system does not merely withstand uncertainty; it benefits from it [24]. We have explored antifragility as an extension of RDO by introducing objectives that reward beneficial variability rather than penalizing variability indiscriminately [8]. One such metric is the Upside Potential Ratio (UPR), which favors designs that achieve substantially better-than-average outcomes while still limiting unacceptable losses. For common performance indicators, encouraging upside variability corresponds to the possibility of higher efficiency, lower cost, or lower emissions than expected under nominal conditions. We also propose using the skewness of the performance distribution as an objective to quantify antifragility. Positive skewness indicates limited downside exposure combined with rare but significant gains, and it captures how a design responds when the actual operating environment is more uncertain than anticipated.

Embedding these objectives within a multi-objective optimization framework yields designs with qualitatively different behavior from conventional robust solutions. In the design of a wind turbine for a community, antifragile optimization led to larger installed capacity than the robust design, deliberately accepting worse median performance and higher variability, but exhibited strongly asymmetric outcomes: when the actual uncertainty exceeded initial assumptions, it delivered substantially lower costs than both the deterministic and robust designs [8]. In a residential heat-pump dimensioning case for a single-family dwelling, antifragile objectives similarly shifted optimal designs away from those minimizing

median cost. Designs with higher antifragility featured larger thermal capacity and storage, which increased cost but limited downside exposure and enabled gains under volatile electricity prices and demand [25].

### Addressing Structural and Preference Uncertainty

Decision-makers are rarely concerned only with the parameters and objectives explicitly modeled. Factors such as social acceptance, siting constraints, permitting risk, or political feasibility are difficult, if not impossible, to encode quantitatively, yet they can strongly influence whether an optimized design can be implemented. As a result, presenting only a single optimized solution, or even a narrow Pareto front, can be misleading. It embeds one particular problem formulation and worldview, while masking structural uncertainty, that is, uncertainty about the appropriate system layout or decision framing.

In the energy modeling literature, Modeling to Generate Alternatives (MGA) is an established response to this problem. MGA has been used primarily in Linear Programming settings to produce sets of near-optimal solutions that are structurally different, allowing decision-makers to choose among alternatives when unmodeled preferences become important [26].

Our work extended MGA concepts to nonlinear multi-objective optimization, generating portfolios of near-optimal designs under preference uncertainty and using these portfolios to reveal which design features are “must-haves” versus genuine degrees of freedom [27]. In practice, this was done by first computing the Pareto-optimal solutions and then solving additional optimization problems that were constrained to remain within a small, predefined degradation of the objective values while forcing variation in configuration choices and key design variables. The resulting set of designs was then analyzed by comparing configurations and parameter ranges across the ensemble. Applied to a Carnot-battery system, this procedure showed that some design choices, such as recuperated subcritical Heat Pump–Organic Rankine Cycle layouts for high-efficiency operation, appeared systematically across all near-optimal solutions and can be considered must-haves. Other choices, including temperature lift, superheating level, and specific operating points, varied widely with little impact on performance, indicating real choices. However, further convergence analysis and benchmarking are needed to assess the effectiveness of the method, and additional development of the post-processing is required to extract clearer and more compelling messages from the large volume of results.

## CONCLUSION

Designing energy and process systems in an increasingly volatile operating environment requires uncertainty to be treated as a core modeling and optimization dimension rather than as a secondary sensitivity check. As operating environments become more volatile and assumptions harder to defend, design methods must explicitly acknowledge limited information, structural ambiguity, and asymmetric responses to variability. In this paper, we presented a coherent workflow for uncertainty-aware CAPE that spans uncertainty characterization under limited information, surrogate-assisted uncertainty propagation for computationally expensive models, and optimization frameworks that explicitly account for variability. Together, these methods advance a shift in CAPE from deterministic optimization toward design strategies that remain credible, informative, and actionable under uncertainty.

## ABSTRACT

Stochastic programming (SP) is a powerful framework for decision-making under uncertainty, but its practical adoption in industry is often hindered by the difficulty in understanding the causal relationships that drive optimal solutions. In the two-stage SP, strategic first-stage decisions are coupled with operational second-stage recourse decisions. When the number of scenarios under consideration is large, understanding the direct link between the uncertainty realization and optimal recourse strategy becomes computationally and cognitively demanding. Common approaches to improve interpretability include trained classification trees or scenario reduction, replacing the large scenario set with a representative subset. This is often achieved through post-hoc clustering (e.g., k-means) based on uncertainty realizations or optimal recourse decisions. While useful, these methods only provide a statistical approximation of the solution space and may fail to reveal the underlying structural properties of the recourse problem that drive optimal first-stage decisions. This work introduces a novel, deterministic approach to explainability using multiparametric programming (mp) within a Benders decomposition framework. We reformulate the recourse subproblem as a multiparametric linear program, generating an explicit map of Critical Regions (CRs), which are polyhedral partitions of the uncertainty space. This allows us to cluster scenarios analytically rather than statistically. We demonstrate this methodology on a supply chain planning under demand uncertainty. Our results show that 100 stochastic scenarios map to exactly six critical region clusters. This mapping allows us to explain optimal capacity planning decisions as a precise trade-off between specific operational modes, providing a fully transparent interpretation of the stochastic solution.

**Keywords**: Stochastic Optimization, Design Under Uncertainty, Supply Chain, Multiparametric Programming

## INTRODUCTION

Optimization under uncertainty is central to Process Systems Engineering (PSE), particularly in applications such as supply chain management, energy systems, and capacity planning. Two-stage stochastic programming (SP) [1] is the standard approach for these problems, distinguishing between "here-and-now" decisions (made before uncertainty reveals itself) and "wait-and-see" recourse decisions (made after the uncertainty is realized).

Despite the mathematical maturity of SP, the resulting solutions often function as "black boxes" for decision-makers [2]. A typical large-scale SP solution provides a single optimal first-stage vector $x^*$ that minimizes expected cost across thousands of scenarios. However, it rarely explains why this specific $x^*$ is robust. For instance, in a capacity expansion problem, a manager might ask: "Why is the optimal capacity for Plant B set to 26 units rather than 30?" The answer lies buried in the complex interactions of thousands of second-stage variables.

Recent developments in Explainable AI [3] have attempted to bridge this gap. In the context of optimization, explainability usually relies on sensitivity analysis, which is inherently local, or post-hoc analysis using machine learning surrogates like classification trees [4].

A common approach to reduce complexity is scenario reduction [5], where a large set of scenarios is clustered into a smaller representative set. This is often achieved through post-hoc clustering [6] techniques (e.g., k-means). Rathi et al. [2] recently proposed

"recourse-based clustering, " where scenarios are grouped not by their input uncertain parameters (e.g., demand), but by the similarity of their optimal recourse decisions ($y^*$). While the method is improved compared to input-based clustering, it remains a statistical approximation, requiring the user to arbitrarily select the number of clusters ($k$), potentially obscuring the exact boundaries where the optimal decision strategy changes.

In this work, we propose a rigorous, analytical alternative to statistical clustering. We leverage the synergy between Benders Decomposition [7] and Multiparametric Programming (mp) [8]. By treating the first-stage variables and uncertainty as parameters in the second-stage subproblem, we can solve the subproblem explicitly [9]. The result is a set of Critical Regions (CRs). Each CR represents a partition of the parameter space where the optimal operating strategy (the set of active constraints) is identical. This allows us to:

- **Derive Explicit Policy Laws:** Within each cluster, the recourse decision is an explicit affine function of the uncertainty.
- **Cluster Scenarios Analytically:** Scenarios are grouped if they fall into the same CR.
- **Quantify Trade-offs:** We can explain first-stage decisions by summing the probability-weighted contributions of specific CRs.

# PRELIMINARIES

## Two-Stage Stochastic Programming

We consider the standard two-stage SP formulation, which can be a Linear Program (LP) or a Mixed Integer Linear Program (MILP):

$$\begin{aligned} &\min_{\mathbf{x}} c^\top \mathbf{x} + \mathbb{E}_\xi[Q(\mathbf{x},\xi)] \\ &\text{s.t. } A\mathbf{x} \le b;\ \mathbf{x} \ge 0 \end{aligned} \tag{1}$$

where $\mathbf{x}$ represents the first-stage decisions (e.g., capacity expansion). The vector $c$ represents the cost coefficients, while $A$ and $b$ define the first-stage constraints. The recourse function $Q(\mathbf{x},\xi)$ is defined as the optimal value of the second-stage problem for a specific uncertainty realization $\xi$:

$$\begin{aligned} Q(\mathbf{x},\xi) = &\min_{\mathbf{y}} q^\top \mathbf{y} \\ &\text{s.t. } W\mathbf{y} \le h(\xi) - T\mathbf{x};\ \mathbf{y} \ge 0 \end{aligned} \tag{2}$$

Here, $\mathbf{y}$ represents operational decisions (e.g., production rates, flows), and $\xi$ captures uncertainties such as demand or prices. The $q$ is the objective coefficient vector, and $W$ (the recourse matrix), $T$ (the technology matrix), and $h$ (right-hand side uncertainty) define the recourse constraints.

## Benders Decomposition

For large-scale problems, the two-stage SP is typically solved using a decomposition approach, such as Benders Decomposition [7], which partitions the problem into a Master problem and a set of sub-problems. The Master problem approximates the recourse cost using cuts [7]:

$$\begin{aligned} &\min_{\mathbf{x},\eta} c^\top \mathbf{x} + \sum_{\omega\in\Omega} p_\omega \eta_\omega \\ &\text{s.t. } \eta_\omega \ge \lambda_\omega^\top (h_\omega - T\mathbf{x})\ \forall \text{ cuts} \end{aligned} \tag{3}$$

Where $p_\omega$ is probability of scenario $\omega$ and $\lambda$ are dual multipliers from the subproblem. Note that we assume relatively complete recourse holds for the problem. While efficient for computation, Benders decomposition does not inherently generate interpretable insights.

## Multiparametric Programming Formulation

In our recent work [9], we reformulate the subproblem using multiparametric programming. In this work, we are exploring this method to gain interpretable insights.

In the recourse problem, the optimal second-stage decision $\mathbf{y}^*$ depends on two vectors: the fixed first-stage decision $\mathbf{x}$ and the random parameter realization $\xi$. We aggregate these into a single parameter vector $\theta = [\mathbf{x},\xi]^\top$ [9]. The recourse problem becomes a multiparametric Linear Program (mp-LP) :

$$\begin{aligned} z(\theta) = &\min_{\mathbf{y}} q^\top \mathbf{y} \\ &\text{s.t. } W\mathbf{y} = F\theta + d;\ \mathbf{y} \ge 0 \end{aligned} \tag{4}$$

The solution to this mp-LP is not a single scalar value, but a set of critical regions. Each region $CR_i$ is a convex polyhedron defined by a set of linear inequalities:

$$CR_i = \{\theta \in \Theta \mid E_i\theta \le f_i\}$$

where $E_i$ and $f_i$ are a matrix and vector (boundary constraints of $CR_i$), respectively, derived from the optimality conditions (active constraints) of the subproblem. The parameter space $\Theta$ is partitioned into non-overlapping polyhedral regions $CR = \cup_i CR_i$. Within each region $CR_i$, the optimal decision variables $y^*$ and the objective function $z$ are explicit piecewise affine functions of $\theta$:

$$\begin{aligned} \mathbf{y}^*(\theta) &= H_i\theta + k_i, \forall\theta \in CR_i \\ z^*(\theta) &= A_i\theta + B_i, \forall\theta \in CR_i \end{aligned} \tag{5}$$

Further details on this multiparametric-based Benders decomposition framework can be found in Brahmbhatt et al. [9]. This structure provides the "white-box" explainability: every scenario $\xi$ maps to a specific $CR_i$, and that region dictates exactly which constraints are binding (e.g., "Demand constraint is active" vs "Capacity constraint is active").

## METHODOLOGY

Our proposed framework integrates mp-programming into the post-optimality analysis of stochastic programming solutions.

**Step 1: Parametric Solution-** We treat the recourse problem as an mp-LP, considering uncertain parameters (e.g., the first stage decision $\mathbf{x}$ and demand $\xi$) as the varying parameters $\theta$. We solve this using an mp algorithm [11]. This generates the set of all possible operational modes (critical regions) the system can experience under the optimal design.

**Step 2: Solve the Full Stochastic Problem-** We solve the original two-stage SP using either the mp Benders method [9] or a monolithic solver to obtain the optimal first-stage solution $\mathbf{x}^*$.

**Step 3: Map Scenarios to Regions: Clustering-** For a given optimal fixed first-stage decision $\mathbf{x}^*$, we project the full set of sampled scenarios $\Omega$ onto the generated critical regions.

$$\text{Cluster}_i = \{\, \omega \in \Omega \mid \xi_\omega \in CR_i \,\}$$

As shown in Figure 1, this mapping is treated as a point location problem. This process simply iterates through the generated regions to find the specific critical region ($CR_i$) where the boundary constraints are satisfied for a given scenario. Here in Figure 1, the demand of 3 different customers is uncertain in the 2nd stage. So, using parametric space for a fixed first-stage decision, we can cluster all demand scenarios in critical region clusters. Unlike k-means, which clusters based on Euclidean distance, this step clusters scenarios based on structural identity. Two scenarios are in the same cluster if and only if they share the exact same active constraints.

**Step 4: Analytical Interpretation-** We explain the optimal $\mathbf{x}^*$ by analyzing the probability mass accumulated in "stress" regions (regions with high penalties or recourse costs) versus "nominal" regions.

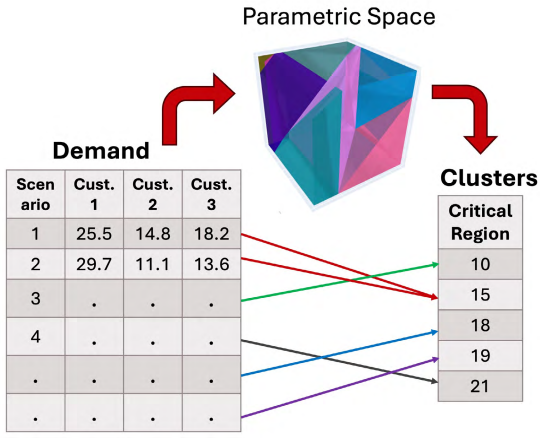

**Figure 1.** Recourse-based clustering of uncertain scenarios using mp critical regions.

## CASE STUDY: SUPPLY CHAIN PLANNING

To demonstrate the efficacy of the proposed multiparametric framework, we utilize a canonical supply chain network design problem adapted from Rathi et al [2]. This problem represents a standard capacity planning challenge where strategic decisions must be made against uncertain customer demands.

### Mathematical Formulation

We consider a network consisting of a set of manufacturing plants $i \in I$ and a set of customers $j \in J$. The problem is formulated as a two-stage stochastic linear program.

**First-Stage Problem:** The decision-maker determines the production quantities $x_i$ for each plant $i$ prior to the realization of uncertain demand. The objective is to minimize the total production cost plus the expected recourse cost. The $C_i^{prod}$ are production costs and $C_i^{max}$ the maximum production capacities of the plants, respectively.

$$\begin{aligned} &\min_x \sum_{i\in I} C_i^{prod} x_i + \mathbb{E}_\xi[Q(x,\xi)] \\ &\text{s.t. } 0 \le x_i \le C_i^{max} \;\forall\, i \in I \end{aligned} \tag{6}$$

**Second-Stage (Recourse) Problem:** Given the first-stage production levels $x$ and a demand realization $\xi$ (where $d_j(\xi)$ is the demand for customer $j$), the recourse problem optimizes transportation flows $y_{ij}$ and external procurement $\bar{y}_j$. External procurement represents a penalty mechanism (e.g., outsourcing or lost sales) used when local production cannot satisfy demand.

$$\begin{aligned} Q(x,\xi) = \min_{y,\bar{y}} &\sum_{i\in I}\sum_{j\in J} C_{ij}^{trans} y_{ij} + \sum_{j\in J} C_j^{ext}\, \bar{y}_j \\ \text{s.t. } &\sum_{j\in J} y_{ij} \le x_i \;\forall i \in I \text{ (Supply Capacity)} \\ &\sum_{i\in I} y_{ij} + \bar{y}_j \ge d_j(\xi) \;\forall j \in J \text{ (Demand Satisfaction)} \\ &y_{ij}, \bar{y}_j \ge 0 \end{aligned} \tag{7}$$

Here, $C_{ij}^{trans}$ is the transportation cost from plant $i$ to customer $j$, and $C_j^{ext}$ is the cost of external procurement, incentivizing satisfying the demand via internal production whenever possible.

### Network Topology and Parameters

We apply this formulation to an instance consisting of two plants ($I = 2$, labeled A and B) and 3 Customers ($J = 3$, labeled 1, 2, and 3) in Figure 2.

**First-Stage Parameters:** The two plants differ in production efficiency. The production costs ($C_A^{prod}, C_B^{prod}$) are \$100/unit and \$150/unit, respectively. The maximum capacity ($C_i^{max}$) is 38.0 units for both plants.

**Second-Stage Parameters:** The unit transportation costs ($C_{ij}^{trans}$) from Plant A to Customers 1, 2, and 3 are \$90, \$67.5, and \$90, respectively. Similarly, the costs from Plant B to Customers 1, 2, and 3 are \$67.5, \$30, and \$67.5, respectively. The external procurement cost ($C^{ext}$) is set at \$500 per unit for each customer. External procurement is set significantly higher than production plus transport to penalize shortages.

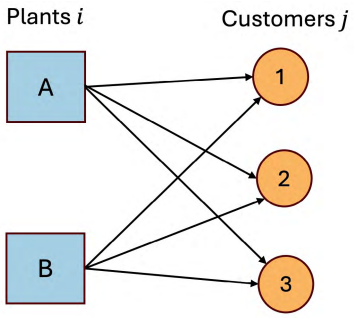

**Figure 2.** The network topology for 2 plants and 3 customers.

**Uncertainty Modeling:** The demand $d_j(\xi)$ for each of the three customers is uncertain. We approximate the uncertainty using a sample average approximation (SAA) approach with $N = 100$ scenarios. The demand for each customer $j$ follows a uniform distribution $\mathrm{U}(10, 30)$.

The resulting problem has 2 first-stage variables, 900 second-stage variables (9 per scenario × 100 scenarios), and 700 constraints. While solvable by standard monolithic solvers, the focus of this study is on analyzing the solution structure using the multiparametric decomposition proposed in [9] and summarized in the previous section.

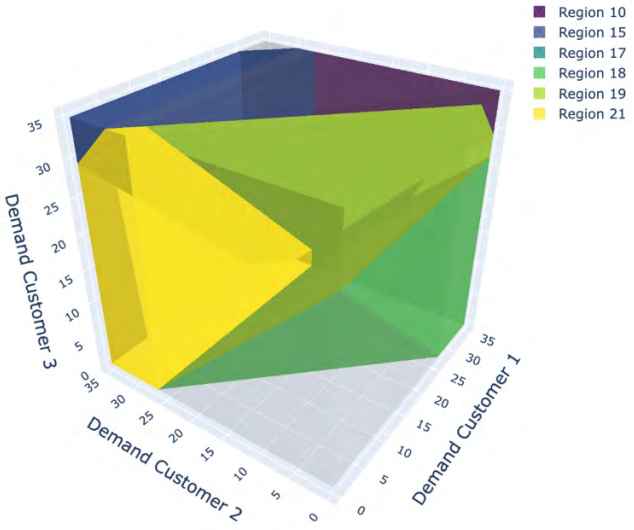

**Figure 3.** Critical regions in demand space given fixed first-stage decisions (each color represents a different critical region).

## RESULTS AND DISCUSSION

The optimal first-stage solution found is Plant A, having a capacity of 38.00 units, and Plant B, having a capacity of 26.41 units, for a total production capacity of 64.41 units.

### Critical Region Clusters Analysis

The multiparametric analysis was implemented in Python using the PPOPT solver [10], and it resulted in 23 critical regions. For the fixed first stage solution ($x^*$), Figure 3 shows the partitioned 3D demand space (Customer 1, 2, 3) with critical regions. Each color in Figure 3 represents a different critical region. While the statistical approach, like k-means, required selecting an arbitrary number of clusters (say k=5 or 6), our analytical approach identified exactly 6 populated critical regions that cover all 100 scenarios. As shown in Figure 1, the proposed clustering method uses the point location problem to find the critical region ID. This is what we call recourse-based clustering, which is shown in Figure 4. Crucially, it demonstrates that while the uncertainty space is continuous, the corresponding optimal recourse strategy is strictly piecewise affine and governed by exactly six distinct critical regions, each defined by a unique set of active constraints in the recourse (sub-problem) decision space.

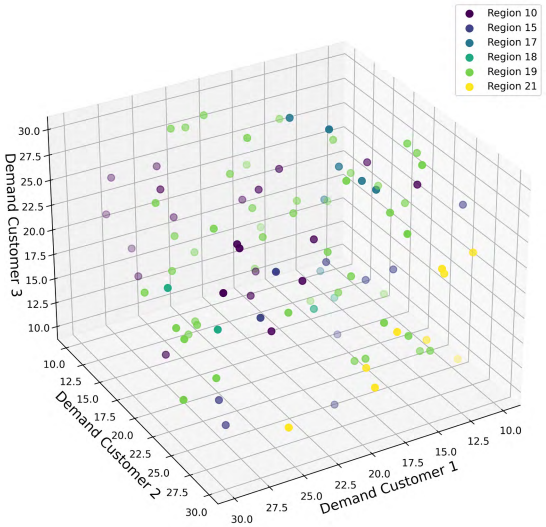

**Figure 4.** 3D Visualization of the 100 demand scenarios mapped to 6 Critical Regions. The recourse clustering is defined by polyhedral boundaries (active constraints) rather than simple distance.

A comparison of our recourse-based clustering with scenario realization-based clustering is presented in Figure 5, which shows the 100 scenarios clustered using the k-means clustering method, indicating that scenarios of the same type were grouped together within the same

cluster ID. But based on recourse-based clustering using mp critical region, we can say that scenarios that are similar in their uncertainty realizations may not lead to the same optimal recourse decisions. Figure 6 shows the clusters of recourse decision for all 100 scenarios based on the mp critical regions. Within the same critical region clusters, the scenarios have the same recourse decisions.

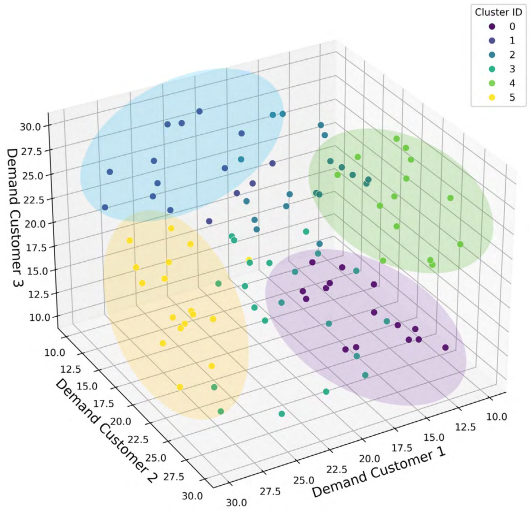

**Figure 5.** 3D Visualization of the 100 demand scenarios mapped to 6 clusters using k-means clustering.

## Operational Modes (Clusters)

Figure 7 shows the average recourse decisions over different critical region clusters. The size of the square shows the production level, which is fixed for all scenarios. The size of the circle shows the average demand in each critical region cluster. As we can see Region 19 (Probability: 0.49) is the "Nominal Operation" mode. It contains nearly half of all scenarios. In this region, total demand is moderate, and the production from A and B is sufficient. No external procurement is required. Region 21 (Probability: 0.09): A transition region where demand is slightly higher, shifting transportation routes, but still manageable without external purchase. Regions 10 & 15 (Probability: 0.21 & 0.10): These are "Failure/Recourse" modes. In these regions, high simultaneous demand on the customer's side exceeds the available inventory (64.41 units). The system hits the active constraint $\sum y \leq x$, forcing the variable $\bar{y}$ (external procurement) to become non-zero. The average amount of this outside procurement is explicitly indicated by the red numbers next to the customer nodes in Figure 7. The probability here is calculated by the number of scenarios that got clustered in each specific region over the total scenarios.

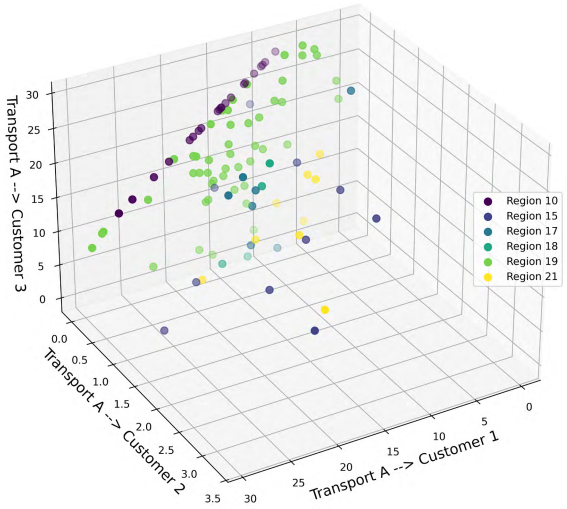

**Figure 6.** The recourse decisions of all 100 scenarios got clustered in 6 mp clusters. The 3 axes represent the transportation of the product from Plant A to customers 1, 2, and 3, respectively.

## Explaining the Capacity Decision

The central explainability question for this SP solution is: Why is the optimal production at Plant B set to 26.41 units instead of its maximum 38.0 units? A human planner might argue: "We are hitting penalty costs in Regions 10 and 15 (31% of the time). Why not increase production at Plant B to avoid this?" Our mp based framework allows us to answer this with a precise cost-benefit calculation. As shown in Figure 8, for the higher demand for all customer cases (Regions 10 and 15), we have very high second-stage costs. But these 2 clusters (Region 10 and 15) have an overall low probability; they make a very low contribution to the overall second-stage cost. Current external procurement cost contribution from Regions 10 and 15 is approximately $2220 (weighted by probability). While increasing Plant B capacity and transportation of product to customers to cover these scenarios would cost roughly $3319 in additional first-stage investment.

It is mathematically cheaper to accept the "failure" (external procurement) in 31% of scenarios falling into Regions 10/15 than to pay for the capacity to cover them. This transforms the result from a simple number into a clear economic decision. The model intentionally incurs penalties in these specific high-demand regions rather than over-investing in capacity.

While the analysis above explains why we do not increase capacity to meet peak demand in Regions 10 and 15, a symmetrical question arises: Why is the optimal capacity for Plant B set to 26.41 units and not lower? The multiparametric framework allows us to answer this by analyzing the "nominal" operating modes, specifically Region 19 and Region 21. These regions have a combined probability of 0.58 and average demands (over all customers) of 56.51 and 60.10 units, respectively. Currently,

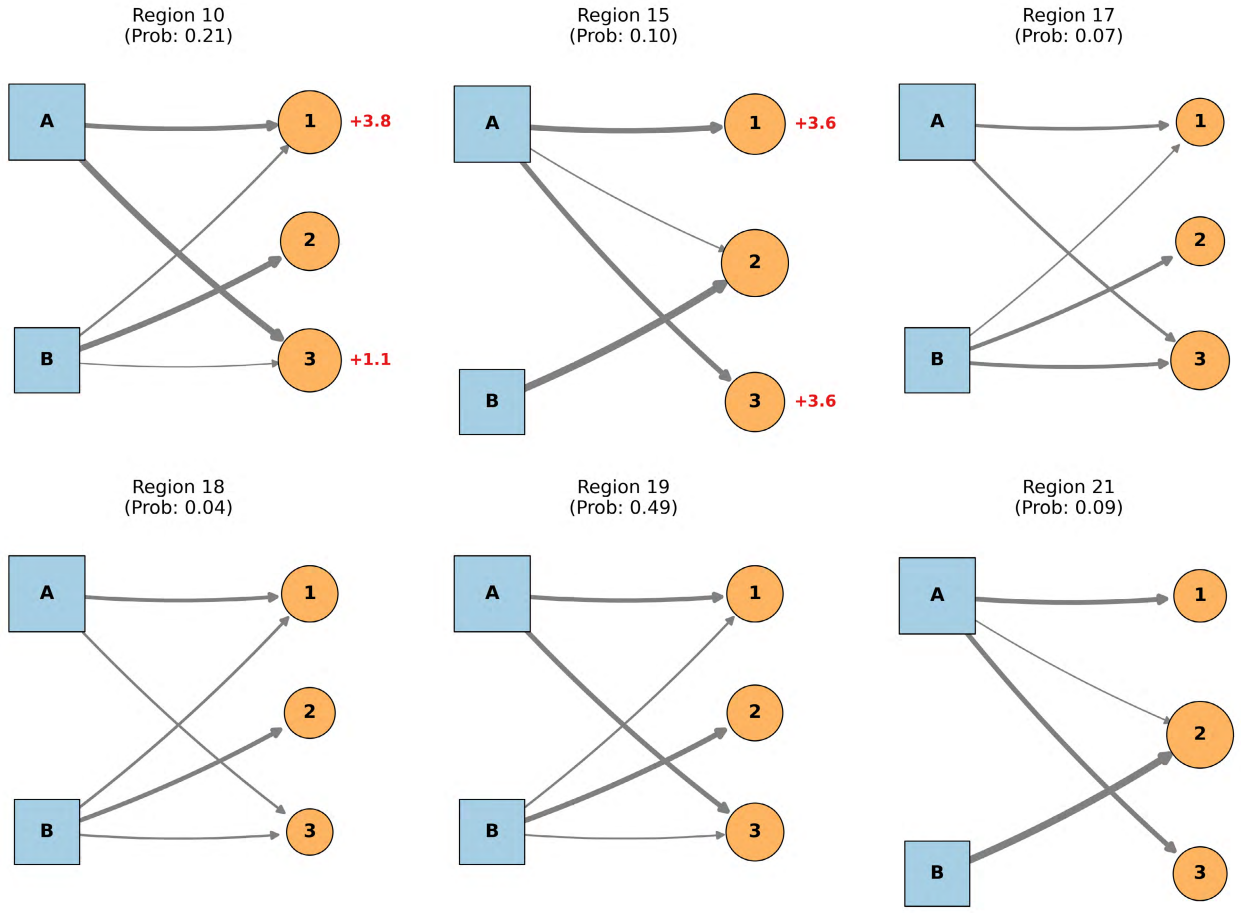

**Figure 7.** Visualization of recourse decisions averaged across the six Critical Region clusters. The square nodes represent manufacturing plants, where the size corresponds to the fixed production capacity. The circular nodes represent customers, with their size proportional to the average demand within that specific cluster. The red numbers adjacent to customer nodes indicate the specific quantity of external procurement required to satisfy

the total system capacity of 64.41 units is sufficient to satisfy these demands without external procurement. However, if we were to further reduce Plant B's capacity, we would force external procurement in these highly probable regions. Reducing capacity by one unit saves the guaranteed investment cost but incurs an expected penalty of $445.0 in additional external procurement costs across these clusters. This far exceeds the marginal cost of $182.32 to produce and transport that unit internally from Plant B. Thus, the optimal capacity of 26.41 units represents the precise equilibrium where the marginal savings of capacity reduction are outweighed by the expected penalties in the dominant operating regions.

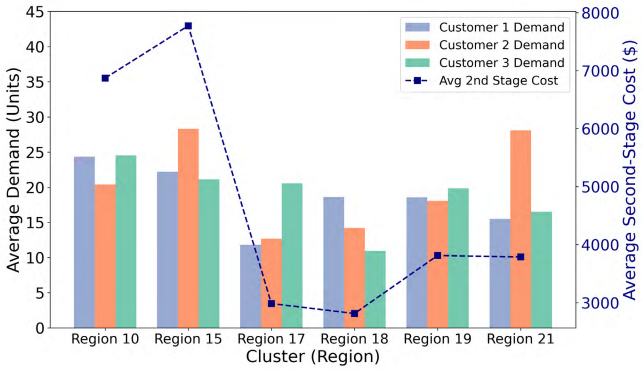

**Figure 8.** Average demand and average second-stage cost in different clusters.

## CONCLUSION

We presented a methodology for enhancing the interpretability of stochastic programming solutions using multiparametric programming inspired by Rathi et al. [2].

By using the Benders subproblem to generate explicit critical regions, we achieve an objective, model-driven clustering of scenarios. Notably, while the presented case study demonstrated an LP formulation, this framework is fully applicable to problems involving Mixed-Integer Linear Programming (MILP) first-stage decisions.

Applied to a supply chain case study, this method successfully reduced 100 scenarios into 6 logical operating modes. It allowed us to explain the optimal first-stage production levels by rigorously quantifying the trade-off between guaranteed production costs and the expected recourse costs associated with specific critical regions. While this approach is effective, a key limitation is its scalability with respect to problem size. Specifically, as the number of uncertain parameters increases, the multiparametric solution becomes computationally intensive because the total number of critical regions grows combinatorially. Future work will focus on alternative mp algorithms, which generate only the relevant Critical Regions encountered by the Benders cuts, rather than exploring the entire parameter space, enabling scalability to larger networks.

## ABSTRACT

Although rare, unexpected events such as financial crises, geopolitical conflicts, and pandemics have reshaped reality in recent years. Despite their strong potential to affect the energy transition, such events are still largely overlooked in energy planning studies. Ignoring them can lead to poorly informed decisions that may jeopardize the transition. Identifying early-stage decisions that remain robust under unexpected events is therefore essential. To address this challenge, EnergyScope Pathway, a whole-energy system model with limited foresight, is applied to Belgium. To increase the likelihood of a successful transition, the Modeling to Generate Alternatives approach is used to diversify early-stage decisions in 2035. These alternatives are allowed to be up to 10% more expensive than the cost-optimal solution. However, the large number of alternative designs is difficult to navigate for decision makers. To address this, a decision-support framework based on the Multi-Armed Bandit framework is used to identify early-stage decisions that are most robust to future unexpected events. In this step, the remaining transition phases are optimized under unexpected events sampled within predefined impact ranges. The results show that, under normal conditions, there is a high degree of flexibility in the decision space for the 2030–2035 phase, with many technologies or resources that can be entirely omitted. However, robust early-stage decisions rely on a diverse energy generation portfolio, with a stronger emphasis on wind deployment, early mobility shifts toward battery electric vehicles, and the import of e-fuels. These insights can help decision makers steer the energy transition toward a robust path from the beginning. While Belgium is used as a case study, this framework is transferable to other contexts.

## 1. INTRODUCTION

The need for an energy transition has become increasingly urgent due to the impacts of climate change on the economy, food security, and human health [1]. To guide this transition, energy system modeling has emerged as a key tool for shaping policies and investment decisions. Despite the large number of studies on this topic, progress in the energy transition has been hindered by hesitation and inaction, largely driven by the many uncertainties surrounding energy projects [2]. Many existing energy planning studies ignore uncertainty altogether [3], making their solutions highly sensitive to inaccuracies in future conditions and ultimately prone to failure. A striking example is the collapse of General Electric's thermal power business, which lost approximately $193 billion between 2016 and 2018 due to incorrect assumptions favoring gas over renewables [4]. In the rare cases where uncertainty is considered, most models rely on local sensitivity analysis or probability-based approaches [5]. While useful, these methods fail to capture deeper and more complex forms of uncertainty, particularly those that are rare in nature but have significant consequences: unexpected events. These are largely mispredicted or unpredicted occurrences that deviate strongly from expectations and persist long enough to

influence strategic decisions [6]. Such events have already affected the energy sector in the past and are likely to do so again [7, 8]. They may arise from technological breakthroughs, supply-chain disruptions, global pandemics, geopolitical conflicts, or societal and political shifts. The COVID-19 pandemic, for instance, reshaped the global energy sector by altering fuel demand, accelerating the deployment of renewables, and highlighting vulnerabilities in global supply chains [9].

Despite their importance, unexpected events are poorly represented in energy planning tools [6]. Their low probability and the scarcity of data needed to characterize them make them difficult to incorporate into standard uncertainty analysis methods.

This paper addresses these challenges by proposing a novel framework to identify early-stage energy transition decisions that perform well under unexpected events.

The whole-energy, regional energy model EnergyScope Pathway [10] is applied to Belgium using a multistage formulation with limited foresight, ensuring that events occurring in later stages are not anticipated from the beginning but instead arise as surprises. The model optimizes the energy transition by minimizing costs, subject to constraints that ensure a carbon-neutral Belgium by 2050. The decision space is then expanded using the Modeling to Generate Alternatives (MGA) approach [11], which is applied to the early transition phase from 2030 to 2035 to generate a diverse set of near-optimal early-stage decisions. These decisions, such as not importing e-fuels or not relying on nuclear energy, increase the likelihood of a successful transition by providing more diverse starting conditions. Afterwards, these decisions are evaluated under unexpected events occurring in the remaining stages of the transition, from 2035 to 2050. Finally, a decision-making framework based on the Multi-Armed Bandit (MAB) algorithm [12] is used to identify the most robust early-stage decisions in 2035. Although the Belgian energy transition is used as a case study, the proposed framework is highly transferable and can be applied to other contexts, both within the energy sector and in other planning applications.

In this paper, we first present the EnergyScope Pathway model, the MGA approach, the generation of unexpected events, and the MAB approach (Section 2). The results section (Section 3) begins by illustrating the diversity of the near-optimal space, followed by the selection of representative early-stage decisions. The robust early-stage decisions are then identified using the MAB approach. Section 4 concludes the paper by summarizing the main takeaways.

# 2. METHODS

## 2.1 EnergyScope Pathway

The energy model used in this work is EnergyScope Pathway [10], a regional, whole-energy system model applied to the Belgian case. It covers most energy sectors, including electricity, heating, transport, and non-energy demand. It includes six demand categories and 112 technologies covering energy supply, storage and conversion, as well as import and export interactions with neighbouring countries. The model is formulated as a linear multistage optimization problem, with the objective of minimizing the total transition cost. In the pathway (multistage) formulation, the energy transition is divided into multiple phases, each with its own parameters and variables. The results of one phase are passed to the next as initial conditions, allowing the model to capture the evolution of investment decisions over time. The model can be used either with an hourly resolution, using a typical days approach [13], or with a monthly resolution, where each month is represented by a single time point. While the monthly formulation offers faster solution times, it is less detailed, as renewable intermittency and hourly demand variations are not explicitly captured. As a result, some technologies, such as storage technologies, are not included.

EnergyScope Pathway supports both perfect foresight and myopic foresight formulations. In the perfect foresight case, the entire transition is optimized in a single run, assuming full knowledge of future conditions, and decisions for all phases are optimized simultaneously. A global $CO_2$ emissions budget is imposed, allowing any decarbonization pathway as long as the final emissions target is met by the end of the transition. In the myopic foresight formulation, each phase of the transition is optimized on its own, sequentially, without knowledge of future conditions. Since each phase is optimized separately, a global $CO_2$ emissions constraint cannot be applied. Instead, a specific $CO_2$ emissions constraint is imposed for each one. These constraints follow an exponential decay formulation [14]:

$$e(t) = e_0(1 + (r + m)t)e^{-mt} \quad (1)$$

where $e_0$ 124 MtCO2/yr ) is the initial emission level, $r$ is the initial slope parameter (set to zero), and $m$ is the decay parameter. The parameter $m$ is calibrated such that the trapezoidal approximation of emissions, evaluated in five-year steps between 2020 and 2050, matches the cumulative emissions budget 1.5 GtCO2 [15]. The resulting emissions levels at each five-year node are then used as constraints in the myopic optimization. In this work, the monthly and myopic options are chosen.

Additional details on the model can be found in [6, 10].

## 2.2 Early stage decisions

EnergyScope Pathway optimizes the energy transition by minimizing costs, delivering a single cost-optimal solution. While informative, this approach is not enough,

as it lacks the diversity of solutions required for decision makers with their different preferences. Moreover, relying on a single solution is risky, as it may not perform well under structural uncertainties, particularly high-impact ones such as unexpected events. For instance, under normal conditions, a maximum deployment level may be assumed for a given technology. The cost-optimal pathway will then size its PV deployment to this maximum in the early stages of the transition. Under unexpected events, however, this maximum deployment could be reduced by half, leaving the optimal solution unable to cope with such situation. To address this limitation, we rely on the Modeling to Generate Alternatives (MGA) [11] approach to explore the near-optimal space of early-stage decisions for the transition phase 2030–2035. MGA allows a small increase (slack) in cost in exchange for greater solution diversity. In this work, a 10% slack (cost increase) is allowed during the 2030–2035 phase relative to the cost of that phase, and all solutions satisfying this condition are identified as near-optimal. As a result, by 2035, rather than a single optimal energy system, a set of diverse energy systems with near-equivalent economic performance is identified. Considering such alternative solutions can lead to better performance when unexpected events occur. These alternatives may include, for example, energy systems with lower reliance on PV, reduced fossil fuels imports to accelerate early decarbonization, or higher e-fuels imports during the initial transition stages. These choices, among many others, provide policymakers with a broader decision space, rather than locking decisions into a single pathway. The focus on the 2030–2035 period is motivated by the need to provide actionable guidance for decisions that need to be taken today or in the near future, helping to place the energy transition on the right track from the beginning.

Another key element in defining the MGA problem is the choice of the MGA variables. These variables are allowed to vary within the feasible space to explore the near-optimal solutions. Ideally, the MGA variables would include all investment decisions. However, due to computational limitations, only a limited number of variables can be considered. In this work, the selected MGA variables are: battery electric vehicles (BEV) [Mpkm/h], nuclear capacity [GW], PV capacity [GW], wind capacity (the sum of onshore and offshore wind) [GW], e-fuels imports (the sum of imported renewable methanol, ammonia, and hydrogen) [GWh], and fossil resource imports (the sum of imported coal, diesel, and gas) [GWh]. These variables correspond to the strategic decisions that governments and policymakers can directly influence.

Using the MGA approach, the near-optimal space is defined as:

$$W = \{ x \in X \mid f(x) \leq f(x^{\wedge} *)(1 + \varepsilon) \} \quad (2)$$

where $X$ is the feasible solution space, $\varepsilon$ is the slack parameter, $f(x)$ denotes the objective function, and $x^*$ is the optimal solution. In this study, $f(x)$ corresponds to the cumulative cost of the transition up to 2035, and $\varepsilon$ is set to 10%. As a result, all solutions that are at most 10% more expensive than the minimum-cost solution are accepted. The exploration of the near-optimal space follows the Modeling All Alternatives (MAA) approach developed by Pedersen et al. [16]. This method maps the entire near-optimal space by defining its convex hull, which is the smallest polyhedron containing all near-optimal solutions. Since the original problem formulation is linear, the near-optimal space is guaranteed to form a polyhedron. The method starts with an initial set of near-optimal solutions, from which a first convex hull is constructed using the Quickhull algorithm. In the next iteration, new near-optimal points are generated to increase the volume of the convex hull. Once the convex hull is fully defined, it is then sampled since all points within it are valid near-optimal solutions. After generating a large set of near-optimal solutions, using all of them as early-stage decisions becomes computationally expensive. Therefore, a representative subset is selected using the k-means clustering approach, which groups solutions with similar characteristics. The centroid of each cluster is chosen as a representative solution, and the number of clusters is determined using the elbow method [17].

## 2.3 Unexpected events

Following the work of Coppitters et al. [6], six categories of unexpected events are identified. The first category concerns the availability of imported resources, including electrofuels, biofuels, and electricity. The second category is resistance to change, which includes PV and wind deployment, low-temperature heating renovations, and private mobility changes. The third category relates to exchange-rate deterioration, and the fourth to increases in energy demand. The fifth category concerns unicorn technologies, including small modular reactors (SMR), carbon capture and storage (CCS), geothermal power, ammonia-fired combined cycle gas turbines (CCGT), and ammonia cracking. The final category is the nuclear phase-out. For the first four categories, each subcategory is characterized by four parameters, each corresponding to a specific year of impact: 2035, 2040, 2045, and 2050. Each parameter can take one of six values: 0, 20, 40, 60, 80, or 100, where 0 indicates no impact and 100 represents full impact in the corresponding year. For the fifth category, each subcategory is characterized by a single parameter indicating when the technology becomes available: 2040, 2045, 2050, or after that. Similarly, the nuclear phase-out is represented by a single parameter indicating when the phase-out occurs: 2035, 2040, 2045, 2050, or after that.

From this parameter space, 1000 unexpected-event scenarios are sampled using Sobol sampling to ensure

uniform coverage of the space. For further details on the selection, parametrization, and generation of unexpected events, the reader is referred to [6].

## 2.4 Multi-armed bandit

After generating a set of early-stage decisions for the year 2035 using MGA (Subsection 2.2), the objective is to identify the most robust ones of these decisions under the unexpected events defined in Subsection 2.3. Policymakers can take one of these decisions in the near future. However, evaluating all possible combinations of early-stage decisions and unexpected event scenarios is computationally expensive, even for simplified models such as the monthly model used in this work. To address this computational challenge, a reinforcement learning approach based on the Multi-Armed Bandit (MAB) algorithm is used [12].

The MAB problem can be illustrated by a gambler playing slot machines with multiple arms, each returning random rewards. At each time step, the gambler pulls an arm and gets a reward. Based on the history of rewards, the MAB algorithm suggests which arm to pull next in order to maximize the expected reward. In the context of this work, each early-stage decision for the year 2035 represents an arm, and the reward corresponds to the final outcome of the energy transition. Each time a specific early-stage decision is selected, the energy system in 2035 is fixed according to the decision, and the remainder of the transition is optimized under a randomly selected unexpected event scenario drawn from the 1000 generated scenarios. This is where the uncertainty in the reward arises. By balancing exploration and exploitation, the MAB approach identifies the most robust early-stage decisions without the need to evaluate all possible scenario–decision combinations.

In this MAB problem, the Upper Confidence Bound (UCB) policy [12] is used. The policy defines the logic behind the selection of the next arm at each time step. Let $K$ denote the number of arms. At each time step $t$, an arm $a_t \in \{1, \dots, K\}$ is pulled, resulting in a random reward $r_t$. The UCB policy defines an objective that combines exploitation, through the use of empirical mean of the previous rewards, and exploration, through an explicit uncertainty term that accounts for how often each arm has been pulled. This objective is maximized to select the next arm $a_{t+1}$ to pull.

The reward is typically defined within the interval [0, 1]. For that, the reward in this work is defined as follows:

$$r_t = \begin{cases} \frac{C_{\text{optimal}}}{C_{\text{scenario}}}, & \text{if the CO_2 target is met by 2050} \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

where $C_{\text{optimal}}$ is the minimum (optimal) cost, under normal conditions and $C_{\text{scenario}}$ is the cost of the scenario defined by the combination of an unexpected event scenario and the selected early-stage decision.

A summary of the methodology is illustrated in Figure 1.

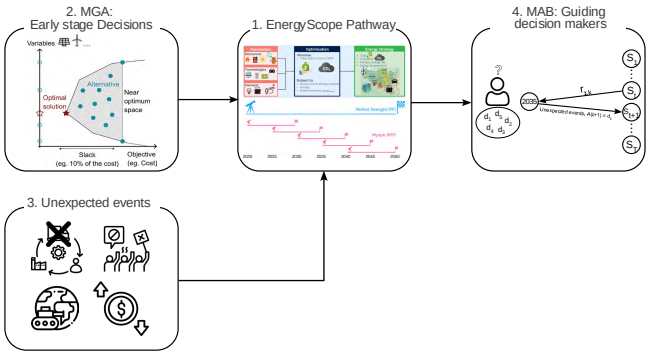

**Figure 1:** The methodology starts by setting up the energy transition model (1). Then, a set of alternative early-stage decisions for the year 2035 is generated (2), along with a set of unexpected-event scenarios (3). A MAB approach (4) is used to test the early-stage decisions against these unexpected events and identify the most robust ones.

# 3. RESULTS

## 3.1 Near-optimal space

The optimal early-stage decision, as well as the near-optimal decisions for the year 2035, are presented in Figure 2. The figure shows the probability mass functions (PMFs) of the near-optimal space together with the optimal values, indicated by red stars, for the MGA variables: BEV, nuclear capacity, PV capacity, wind capacity, e-fuels imports, and fossil resource imports.

The optimal solution is characterized by high nuclear and wind deployment, and fossil resource imports, medium level of integration for BEV and low PV deployment and e-fuels imports, as seen in the range of the near-optimal space. The near-optimal alternatives themselves span a wide range of values, indicating a high degree of flexibility and the existence of solutions that are structurally very different from the optimal one. For instance, most variables can reach zero or near-zero values, meaning that their corresponding technologies or resources can be entirely omitted (for example, some near-optimal systems have no wind deployment or almost no fossil fuels imports) while remaining at most 10% more expensive than the optimal system by 2035. However, the near-optimal solutions are not evenly distributed across this wide range. Looking at the PMFs of wind, PV, and nuclear capacity, distributions are skewed toward higher values, suggesting that higher deployment levels are more frequently favored among near-optimal solutions. This tendency does not always coincide with the optimal value, as seen for PV capacity. In contrast, the BEV PMF is normally distributed around the optimal value, indicating that the optimal BEV level is the most

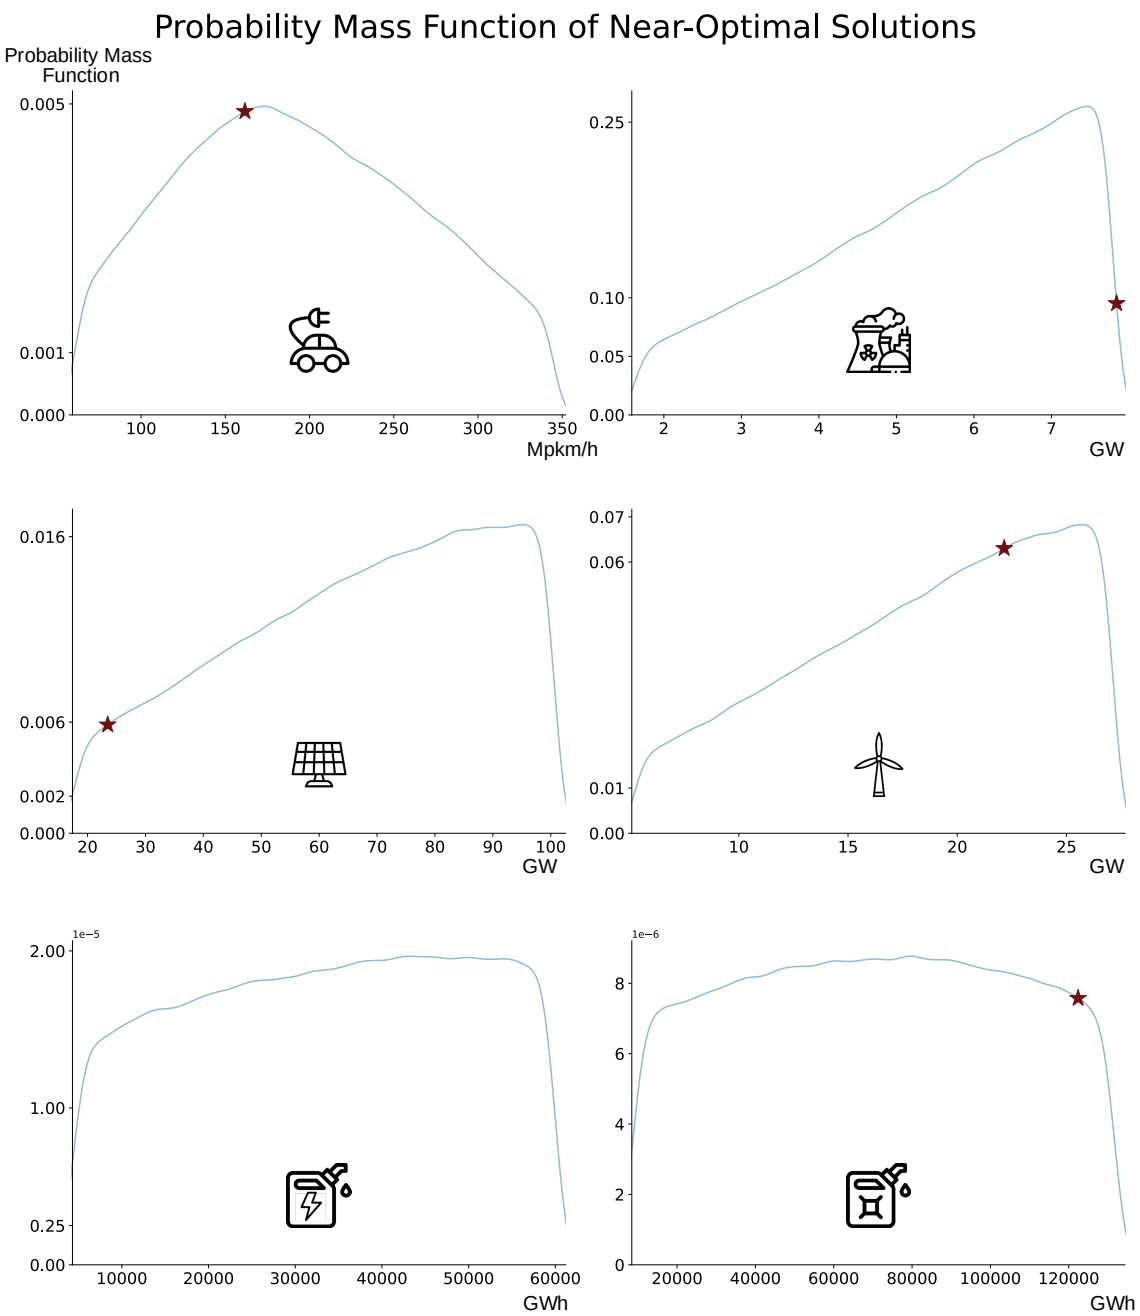

**Figure 2.** The probability mass function plots of the near-optimal space show a wide variety of feasible solutions. Despite this large space, solutions are not evenly distributed across the full range of values. PV, wind, and nuclear deployment exhibit strong skewness toward higher values. BEV is normally distributed around its optimal value (indicated by the red star), whereas fuels imports are more uniformly distributed across the near-optimal space.

favored option. Finally, for fuels imports, both distributions are close to uniform, with a slight skew toward higher values for e-fuels imports, indicating that near-optimal solutions are evenly spread across these dimensions of the decision space. At this stage, it should be kept in mind that this flexibility concerns only early-stage decisions specific to the year 2035 of the transition.

## 3.2 Early stage decisions selection

The MAA method generates thousands of near-optimal early-stage decisions for the year 2035. However, retaining the full set of solutions to study their robustness would be computationally expensive, as discussed in Section 2.2. To address this, the near-optimal space is reduced using representative solutions, selected as the

centroids of clusters obtained through k-means clustering. The elbow method suggested dividing the space into 5 to 10 clusters: for better interpretability, the space was finally clustered into 5 clusters.

Figure 3 illustrates the resulting heatmap of early-stage decisions. All MGA variables are normalized to the [0, 1] interval, where a value of 0 represents the absence of the technology, while 1 corresponds to its maximum level. The optimal solution is shown in the first row, followed by the five cluster centroids that characterize the near-optimal solution space. Across all early-stage decisions, high deployment of wind, solar, and nuclear technologies is a consistent feature, with at least two of these technologies reaching high levels in every case. BEV integration is generally moderate, with two exceptions: a low level in decision 2 and a slightly higher level in decision 5. Fossil fuels imports are similar across decisions, with mostly mid-level imports and higher imports in the optimal solution. In contrast, e-fuels imports are generally moderate, except in the optimal solution, where they are comparatively low.

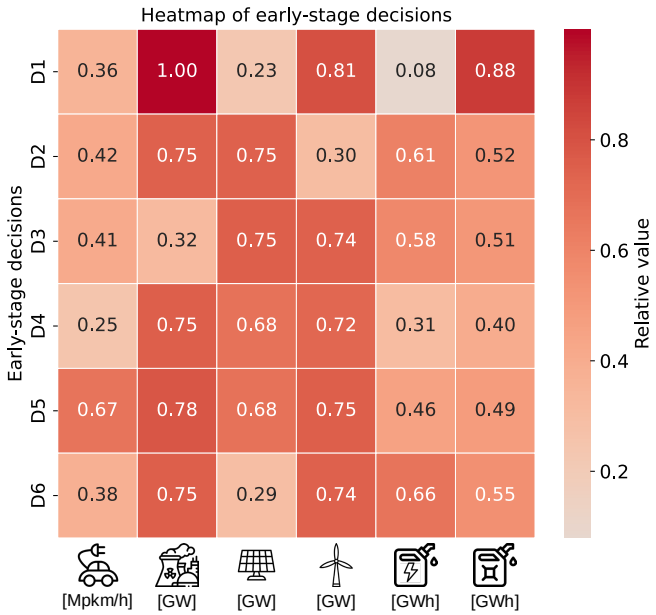

**Figure 3.** Heatmap of relative MGA variable values ([0, 1]) for the optimal solution and the five cluster centroids representing the near-optimal space. The figure shows consistent high deployment of wind, solar, and nuclear technologies across early-stage decisions, while BEV integration remains mostly moderate. Fossil fuels imports are present in all cases, with higher levels in the optimal solution, whereas e-fuels imports are generally moderate and lower in the optimal case.

The near-optimal early-stage decisions (decisions 2 to 6 in Figure 3) are then evaluated under normal conditions, without unexpected events. In 2035, the energy system is fixed according to each of these early-stage decisions, and the remainder of the transition is optimized under a cost-minimization objective. All of the decisions lead to a successful transition, in the sense that the 2050 $CO_2$ target is met in all cases. However, the associated total transition costs (all of the transition, up until 2050) differ. As shown in Figure 4, all decisions result in higher total costs than the total optimal solution (red dashed line). Nevertheless, total costs remain within the 10% slack of the total optimal solution (grey dashed line): below 110% of the minimum total transition cost. In terms of specific values, decisions 2, 3, and 4 have similar total costs, around 960 b€. Decision 5 leads to the highest total cost (≈ 968 b€), while decision 6 leads to the lowest total cost (≈ 943 b€).

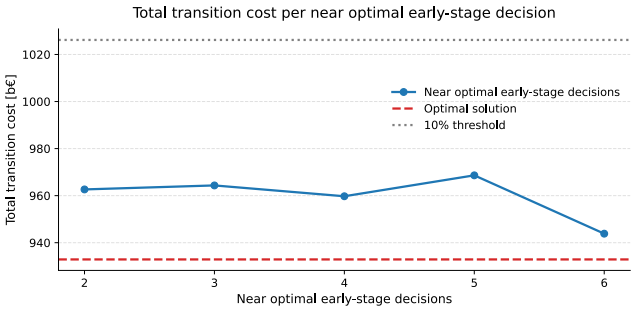

**Figure 4.** Total transition costs associated with the near-optimal early-stage decisions, compared to the optimal solution (red dashed line), under normal conditions. All near-optimal decisions result in higher total costs than the optimal case, while remaining below 110% of the minimum total transition cost (grey dashed line). Decision 2, 3 and 4 have similar costs, while decision 5 has the highest cost and decision 6 has the lowest cost.

## 3.3 Robust early stage decisions

The multi-armed bandit (MAB) method is used to identify the most robust early-stage decisions. The algorithm is run for 1000 time steps. At each step, a decision is selected (pulled) based on the UCB policy, and a random unexpected events scenario is applied starting from 2035. Figure 5 shows the cumulative number of pulls for each decision over time. Decision 6 clearly stands out, as it is selected most often, followed by decisions 3 and 5. In contrast, decisions 1 (the optimal decision for the 2030-2035 phase), 4, and 2 are selected least frequently. Similar conclusions can be drawn from the evolution of the average reward per decision, shown in Figure 6. Decision 6 reaches the highest average reward (≈ 0.49) (Eq. 3), followed by decisions 3 and 5 with average rewards of about 0.41. The weakest performing decisions are decisions 1, 4, and 2, with average rewards of approximately 0.35, 0.28, and 0.20, respectively.

One important observation is that all early-stage decisions share a common feature: they all have a mixed energy generation portfolio. However, what separates

well-performing decisions from poorly performing ones is the specific combination of technologies and resources that is chosen. When comparing decisions 2 and 3, both share similar characteristics, but decision 2 relies more on nuclear power, while decision 3 relies more on wind power. The better performance of decision 3 suggests that wind deployment provides greater robustness under uncertainty than relying mainly on nuclear power. Nuclear capacity can be entirely phased out during the transition, meaning that all previously installed nuclear capacity may eventually be dismantled. In contrast, even under resistance to further wind deployment, wind capacity installed earlier in the transition continues to be used.

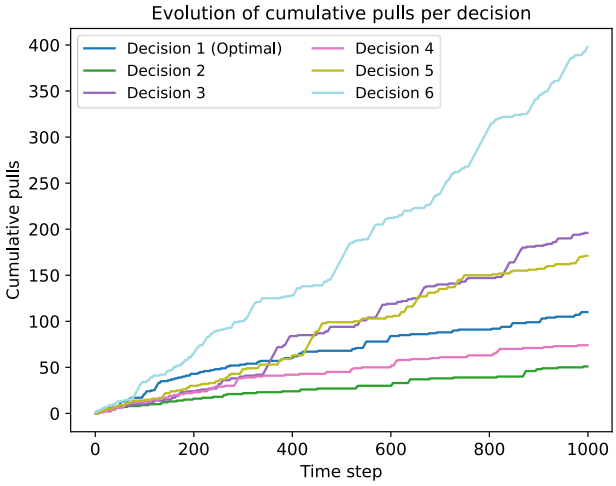

**Figure 5.** Cumulative number of pulls per decision over time. Decision 6 is selected most often, indicating the highest robustness, followed by decisions 5 and 3. Decisions 1, 4, and 2 are selected least frequently.

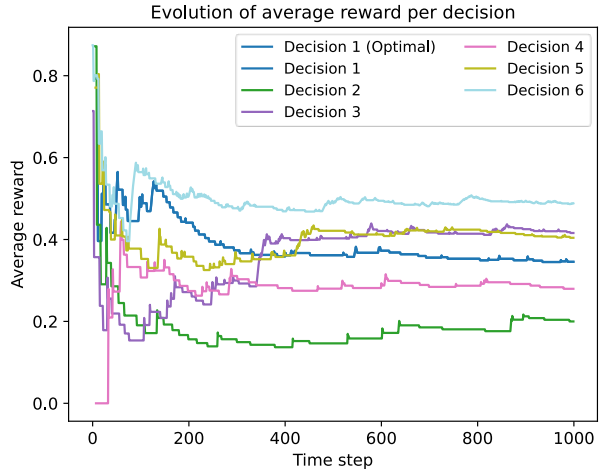

**Figure 6.** Evolution of the average reward per decision over time. Similar to the previous figure, decision 6 performs best, achieving the highest average reward over most time steps, followed by decisions 5 and 3. Decisions 1, 4, and 2 have the lowest final average rewards.

A similar pattern appears when comparing decisions 4 and 5. Although both have a diverse generation mix, decision 5 performs better because it includes higher BEV integration and higher e-fuels imports. This shows that having a mixed generation portfolio alone is not sufficient: early changes in mobility and use of e-fuels also play an important role.

Finally, decisions 1 and 6 also share some similarities, as both invest in the same technologies and resources, with the main difference being that decision 1 does not invest in e-fuels. Despite this similarity, their performance differs significantly. Decision 1 invests very heavily in a few technologies, with almost full nuclear and wind deployment and high fossil fuels imports. Decision 6 also invests strongly in nuclear, wind, and fossil fuels, but at more moderate levels, and additionally relies on e-fuels imports. This more balanced approach leads to better performance under uncertainty.

Overall, the results show that a diverse energy mix and strong wind deployment are essential, but they are not enough by themselves. Robust early-stage decisions also require early investment in e-fuels and mobility changes toward BEVs.

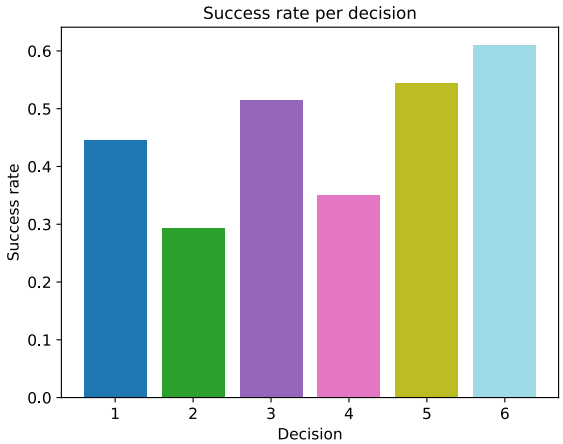

**Figure 7.** Success rate of each early-stage decision, defined as the ratio of successful trials meeting the 2050 $CO_2$ target to the total number of times each decision is selected. Decision 6 shows the highest success rate, followed by decisions 5, 3, 1, 4, and 2.

Digging deeper into the analysis of the results, the success rate is computed for each decision. The success rate is defined as the ratio of successful trials that meet the 2050 $CO_2$ target to the total number of times each decision is selected (Figure 7). In addition, the average total transition cost of the successful trials is calculated (Figure 8).

Consistent with previous results, decision 6 achieves the highest success rate at 61%, followed by decision 5 at 54%, decision 3 at 51%, decision 1 at 44%,

decision 4 at 35%, and decision 2 at 29%. When looking at the average total transition costs, decision 3 has the lowest cost at 1156 b€, followed by decision 6 at 1166 b€, decision 4 at 1172 b€, decision 1 at 1202 b€, decision 5 at 1255 b€, and decision 2 at 1372 b€. An important observation is that although decision 4 has one of the lowest average costs, it lacks robustness compared to decision 5, which has a higher average cost but performs better in terms of robustness. The same pattern appears when comparing decision 5 with decisions 1 and 3. Even though decisions 1 and 3 have lower average costs, they are less robust. This confirms that selecting the least costly option is not always the best strategy. Choosing alternatives that may be more expensive but ensure a robust transition leads to better outcomes.

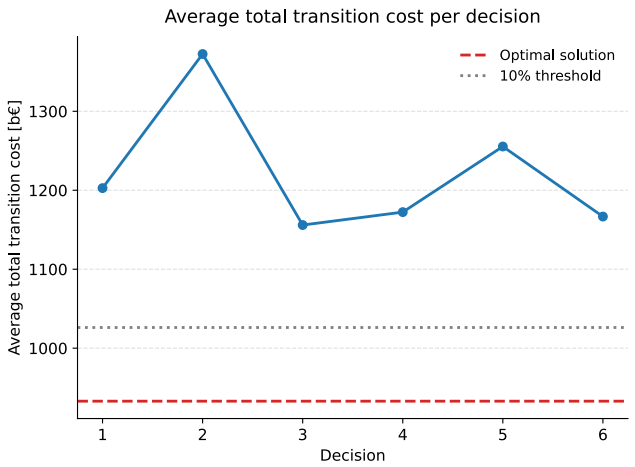

**Figure 8.** Average total transition cost of the successful trials for each early-stage decision. Although decision 3 exhibits the lowest average cost, it does not rank among the most robust options. Decision 6 combines relatively low costs with high robustness, while decision 5 shows higher average costs but stronger robustness compared to decisions 1, 3, and 4. This highlights that lower costs do not necessarily imply better robustness.

## 4 CONCLUSION

In this work, we explored the near-optimal space of early-stage decisions for the energy transition, focusing on the year 2035, and identified the most robust decisions under a broad range of unexpected events. To do so, we proposed a new decision-making framework that combines Modeling to Generate Alternatives (MGA) with a Multi-Armed Bandit (MAB) approach. This framework addresses the limitations of relying on a single cost-optimal pathway, which may perform poorly when unexpected events occur. In addition, the proposed approach reduces the computational effort required to identify robust early-stage transition strategies. Using the MGA approach on BEV adoption, nuclear, PV, and wind deployment, as well as e-fuels imports and fossil fuels imports, the near-optimal space reveals a wide range of solutions that differ structurally while remaining close in cost. For the period 2030–2035, almost any technology or resource among the MGA variables can be entirely omitted without exceeding 110% of the minimum cost for that phase. However, near-optimal solutions are not evenly distributed across the solution space: solar, wind, and nuclear deployment are skewed toward high levels, BEV adoption is centered around the optimal value, and e-fuels and fossil fuels imports are more uniformly distributed. After selecting five representative early-stage decisions from the large near-optimal space using k-means clustering, the MAB analysis shows that robust early-stage decisions are characterized by diverse energy generation portfolios, with a strong emphasis on wind deployment. In addition, early mobility changes toward BEVs and the use of e-fuels imports play an important role in improving robustness. These insights can support decision makers facing highly uncertain and unpredictable futures by highlighting actions that can be taken today to place the energy transition on a more robust path from the start.

Future work will define early-stage decisions as sets of alternatives rather than single solutions (entire clusters instead of centroids). This would better reflect real-world decision-making, where policies often guide the system toward general directions rather than fixed technology levels.

## ABSTRACT

Resilience is becoming a top priority across industrial sectors, with increasing pressures to assess it systematically. In this work, we present an optimization-based framework for proactive design and planning under uncertainty of multi-product manufacturing networks, and testing of the reactive strategies available to withstand unforeseen disruptions. Specifically, the design problem is formulated as a two-stage stochastic optimization, integrating multi-period planning and scheduling, aimed towards mitigation against uncertainty. Designs are then fixed and tested through simulated outcomes from *out-of-sample* uncertainty distributions, with feasibility of operation monitored through the time-to-recover post disruption. Infeasibility triggers a scenario-update procedure via $K$-means clustering, whereby critical uncertainty information based on simulated outcomes is integrated in the proactive planning step, including low-probability high-impact scenarios. Modular and non-modular designs are compared to quantify the value of recourse actions with respect to responsiveness to disruptions. Results highlight that adaptable modular designs enable shorter recovery times combined with lower cost commitments. Overall, the framework underpins the development of tools for the anticipation and mitigation of disruptive events and systematic re-design based on continuously updated uncertainty information.

## INTRODUCTION

As disruptions become the new normal in manufacturing networks operation and management, there emerges a need to develop tools to test and quantify system resilience. In this context, process systems engineering opens opportunities to systematically design process systems under known uncertainty, operate them and test the capacity to withstand emerging unknown disruptive events. Following a disruptive event, data-driven methods offer the opportunity to learn and adapt process system design, integrating feedback from acquired knowledge regarding uncertainty[1].

Proactive strategies to improve resilience involve posing the design problem with respect to expected outcomes of uncertainty. For instance, a stochastic optimization problem is solved based on an approximation of fitted historical data of known demands which correspond to current available uncertainty information. This approach is well established across applications, including chemical supply chains, energy systems and pharmaceuticals [2, 3, 4].

During operation, design decisions are fixed and degrees of freedoms to withstand unforeseen scenarios and disruptive events depend on recourse actions available and the timescale of deployment of such measures. In this reactive planning step, available actions may range from adaptation of schedules to set up of additional capacity. To this end, processes with embedded modularity may allow flexibility to use repurpose and reconfigure equipment trains. Furthermore, modules can also correspond to parallel equipment lines which can be set up to rapidly scale-out/up capacity.

From a modelling perspective, simulation approaches such as rolling horizon [5] in this space are aimed at quantifying the reactive capabilities of a network/process design. In other words, reactive planning can be framed as a simulation of design performance as an *out-*

*of-sample* test of the first-stage decisions obtained based on the sampled uncertainty in the proactive planning step. Through simulation, significant deviations in target metrics can be monitored, such as service levels and time to recover. Acquired knowledge on system response can be then systematically incorporated in the overall design decisions through a learning step, iteratively re-solving the proactive problem and adjusting design-level decisions. To this end, there emerge opportunities to develop holistic methodological frameworks for the integration of feedback emerging from the reactive-planning part in the proactive layer to obtain better resilience-aware plans/design. This helps quantify resilience as the capacity to both *anticipate* and *respond* to uncertainty.

This study aims to provide a methodological iterative framework for doing so, illustrated on a pharmaceutical manufacturing network case, although transferable to any other batch manufacturing application, undergoing disruptions causing parameter fluctuations. In this work, modular versus non-modular manufacturing equipment cases are systematically compared to quantify the value of recourse capacity installation with respect to cost and adaptability to unforeseen uncertainty.

# METHODS

## Problem Statement

A capacity planning problem is considered, aimed at minimizing total network-level and scheduling costs. The objective is to evaluate candidate design alternatives based on the ability to anticipate uncertainty and respond under minimal cost and time delay. In this work, a pharmaceutical case study is considered, based on the multi-product manufacturing network shown in Figure 1a and manufacturing-level equipment network shown in Figure 1b. The problem considers:

- A set $T$ of time periods $t$ (daily);
- A subset $TT$ of time periods $ts$ (bi-monthly);
- A set $S$ of states $s$,
- A subset $S^p$ of product states $s$,
- A set $I$ of tasks $i$,
- A set $J$ of equipment $j$,
- A set $A$ of scales $a$,
- A set $U$ of parallel modules $u$,
- A set $\Omega$ of demand scenarios $d$.
- A set $M$ of manufacturing facilities $m$
- A set $K$ of storage nodes $k$
- A set $L$ of demand zones $l$

In this work, multipurpose manufacturing is modelled. Additionally, parallel units can be installed for each equipment. Two alternatives are modelled, namely *modular* manufacturing, under the assumption that equipment can be installed with a time delay, and a *non-modular* option where equipment is installed once and cannot be scaled out in response to variability and disruptions. This effectively corresponds to comparing design with capacity-level recourse actions to fixed designs. The aim of the optimization is to determine the following decisions:

1. Investment in equipment in facilities ($F_{jm}$),
2. Scale and parallel units ($K_{jamu,ts,d}, Y_{jamu,ts,d}$)
3. Task allocation to equipment ($W_{ijamutd}$)
4. State inventories in manufacturing ($S_{std}$)
5. Transport flows ($Q_{sjk,ts,d}, Q_{skl,ts,d}$)
6. Sales to meet demands ($Sales_{s,ts,d}$).

Decision 1 is scenario-independent and made at a *first stage*, prior to uncertainty realization. In the modular case, Decisions 2-6 are scenario-dependent and related to operations of the manufacturing network. Hence, these can be defined as *second-stage* decisions, adaptive to scenario realizations. In the non-modular case, Decision 2 is instead a first stage scenario-independent decision.

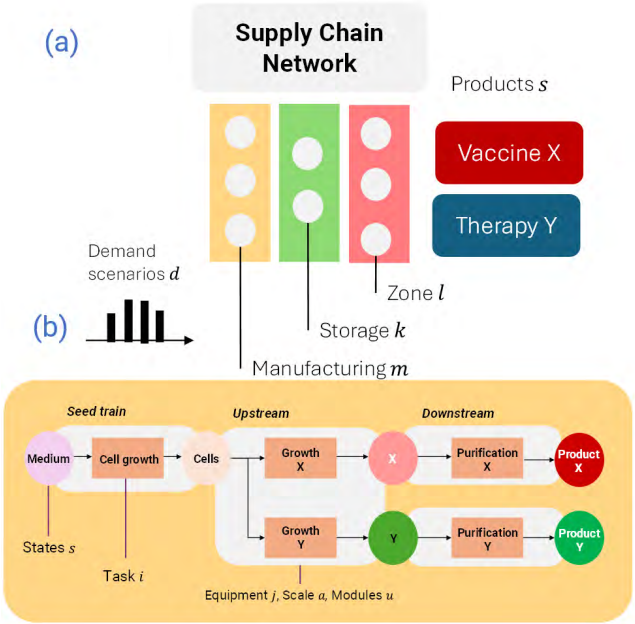

**Figure 1.** Optimization superstructure at (a) network level, (b) manufacturing process level, integrated supply chain network design and states-task network scheduling.

**Algorithm 1:** Framework Pseudo Code

Inputs:

- Initial scenario set $\Omega$ with probabilities $\phi$
- Stress test sample size $N_{stress}$
- Time-to-recover threshold $\tau_{TTR}$
- Initialize violation set $\Omega^{obs} \leftarrow \varnothing$

Initialize: $\epsilon \leftarrow 0$

while $\epsilon < 10$ do

Solve stochastic optimization problem $(\Omega^{\epsilon}, \phi^{\epsilon})$

Obtain first-stage variables $\alpha^{\epsilon}$, second-stage variables $\beta^{\epsilon}$

Fix first-stage variables $\alpha^{\epsilon}$

Generate out-of-sample scenarios $\Omega^{stress}, |\Omega^{stress}| = N_{stress}$

**for** each sample $d = 1$ to $N_{stress}$ **do**

Solve deterministic optimization problem

Evaluate time to recover $TTR_{pd}$ for all products $p$

Compute $\widehat{TTR_d} = \max_p TTR_{pd}$

**if** $\widehat{TTR_d} \geq \tau_{TTR}$ **then**

Let $\Omega^{obs} \leftarrow \{D_1, \ldots, D_n\}$ for both products and $N = d$

Partition samples by regime into subsets $\Omega^{obs,r}$

Count regime occurrences $N_r = card(\Omega^{obs,r})$

Compute empirical regime probabilities $\pi_r = \frac{N_r}{N}$

Solve $K$-means $K_r := \min(K, N_r)$ for each regime $r$

Assign scenario realizations: $D_d^X := \mu_\kappa^{X,r}, D_d^Y := \mu_\kappa^{Y,r}$ for each $(k, r)$

Compute scenario probabilities $\phi_d := \pi_r p_\kappa^r$

Update scenario tree $(\Omega^{\epsilon+1}, \phi^{\epsilon+1}) \leftarrow \{(D_d^X, D_d^Y, \phi_d)\}_{d=1}^{\Delta}$ with $\Delta = \sum_r K_r$

break

end if

end for

$\epsilon \leftarrow \epsilon + 1$

end while

**Outputs:** First-stage design vector $\alpha^*$

## Framework implementation

The workflow for the proactive, reactive planning and scenario updating problem is presented in Algorithm 1. First, a scenario-tree is postulated based on available uncertainty information and a stochastic optimization is solved (Step 3-6).

Iteratively, the obtained design is simulated for samples that are obtained from an unseen distribution, with the aim of testing design feasibility (Step 8-10). If $\widehat{TTR_d}$ is larger than a set threshold $\tau_{TTR}$, the violation is deemed critical, hence the scenario tree is updated (Step 12-19), and the stochastic proactive problem resolved to obtain a new design. Ultimately, the iterative procedure terminates when a first-stage decision vector $\alpha^*$ is optimal with respect to the postulated scenario tree $\Omega^{\epsilon}$ and feasible with respect to all disruptive scenarios $\Omega^{\text{Stress}}$.

## Process and demand data

Techno-economic models of manufacturing technologies of interest are developed using the flow sheeting software SuperPro Designer (Intelligen)[5]. Nominal capital, labor and variable cost and process tasks lengths ($p_i$) are presented in the SI document, for process volumetric scales $a = \{1000, 2000\}$. With respect to demand data, the optimization considers:

$$D_d^Y \sim \mathcal{U}(1000, 2000)\ \forall d = d1, \ldots, d5 \quad (1)$$

$$D_d^X \sim \mathcal{U}(10^6, 2 \times 10^6)\ \forall d = d1, \ldots, d5 \quad (2)$$

Whereby the demand samples are generated by sampling a uniform distribution which represents the knowledge based on historical data of demand patterns. Hence, $D_d^X$ and $D_d^Y$ correspond to samples for demand of product $X$ and $Y$ respectively. These correspond to the initialized scenario tree, with probabilities $\phi_d = \frac{1}{card(D)}$.

## Manufacturing level formulation

The scheduling level is formulated as states-task network[6], modifying some constraints to account for scale-dependent ($a$) and parallel units ($u$).

Resource balance constraints model the relation between consumption and production ($B_{ijmautd}$) and storage ($S_{smtd}$) of each resource as follows, for every state $s$, time period $t$, facility $m$, equipment $j$, scale $a$ and scenario $d$:

$$S_{smtd} = S_{s,t}^0 + S_{sm,t-1,d} + \sum_i \bar{\rho}_{is} \sum_{j,u,a} B_{ijmau,t-p_{is}d} - \sum_i \rho_{is} \sum_{j,u,a} B_{ijmautd}$$

$$\forall s, m, t, d \quad (3)$$

Here, it is worth noting that all $\bar{\rho}_{is}$ and $\rho_{is}$ are equal to 1, due to each task modelled as a single state input/output entity (Figure 1b) (SI document).

The amount of material states processed in

equipment $j$, scale $a$ and unit $u$ through task $i$ and time $t$ in scenario $d$ ($B_{ijmautd}$) is bounded by processing constraints, which also are tied to task allocation, via the binary of task-equipment allocation ($W_{ijmautd}$).

$$V_{ija}^{min} W_{ijmautd} \leq B_{ijmautd} \leq W_{ijmautd} V_{ija}^{max} \; \forall i, j, m, a, u, t, d \quad (2)$$

It is worth noting that each of these operational variables is scenario dependent $d$ and made network-node dependent $m$, scale dependent $a$ and unit $u$ dependent through the respective indices.

Furthermore, task allocation is constrained by the following equation, which models the logic of equipment occupancy for equipment $j$ at scale $a$ and in unit $u$ once a task is allocated, for the length of its duration $p_i$.

$$\sum_i \sum_{t'=t}^{t-p_i+1} W_{ijmautd} \leq 1 \; \forall i, j, m, a, u, t, d \quad (4)$$

Resource storage constraints model the bound on inventory for each state, with a capacity limit ($C_s$):

$$0 \leq S_{smtd} \leq C_s \; \forall s, m, t, d \quad (5)$$

Task allocation occurs only within installed equipment, which is modelled through the following constraint:

$$W_{ijmautd} \leq Y_{jmau,t_s(t),d} \; \forall i, j, m, a, u, t, d \quad (6)$$

Where $t_s(t) = \max\{t' \in T^m : t' \leq t\}$, hence corresponds to the month period $ts$ that encompasses day $t$.

Equipment installation occurs only within installed facilities suited to produce equipment $j$ at scale $a$ ($F_{jma}$):

$$Y_{jmau,ts,d} \leq F_{jm} \; \forall i, j, m, a, u, ts \in TT, d \quad (7)$$

In the modular case modules can be additionally installed through investment decisions and available after a lead time of 60 days :

$$Y_{jmau,ts,d} = Y_{jmau,ts,d} + K_{jmau,ts-60,sd} \; \forall i, j, m, a, u, ts \in TT, d \quad (8)$$

In the non-modular case, no new investment is possible and availability is carried forward:

$$Y_{jmau,ts,d} = Y_{jmau,ts,d} \; \forall i, j, m, a, u, ts \in TT, d \quad (9)$$

Additionally, line installation is not scenario dependent, but rather an investment made as a first-stage decision, hence fixed across scenarios via the following set of additional constraints:

$$Y_{jmau,ts,d1} = Y_{jmau,ts,d'|d' \neq d1} \; \forall i, j, m, a, u, ts, d' \quad (10)$$

## Network level formulation

At supply chain level, inventory balance constraints model the shipment from manufacturing facilities to storage facilities. For the states that are only produced ($s^P$):

$$S_{smtd} = S_{s,t}^0 + S_{sm,t-1,d} + \sum_i \bar{\rho}_{is} \sum_{j,u,a} B_{ijmau,t-p_{is}d} - \sum_k Q_{smk,ts,d} \; \forall s^P, m, t, d \quad (11)$$

Where, the outbound flow of manufacturing is considered as a consumption term ($Q_{smk,ts,d}$). Shipments to storage facilities $k$ feed into the following equation which models the storage at each facility:

$$\sum_m Q_{smk,ts,d} = \sum_l Q_{skl,ts,d} \; \forall s \in S^P, k, ts \in TT, d \quad (12)$$

In this work, product inventory is not considered and these flow variables are matched only at time periods within the set $TT$, thus forcing shipments to only occur at time periods $ts$.

Transport flows from each storage facility feed into demand zones, where demand is fulfilled. Hence:

$$\sum_k Q_{skl,ts,d} = S_{sl,ts,d} \; \forall s \in S^P, l, ts \in TT, d \quad (13)$$

The following sales-demand constraint ensures the amount of doses sold for both product states, at each demand zone l and time period t within the mid term horizon is greater than the demand in each scenario:

$$Sales_{sl,ts,d} \delta_s \geq D_{sl,ts,td} \; \forall s \in S^p, l, ts \in TT, d \quad (14)$$

The demand in each demand zone is calculated based on the total demand sampled, previously computed:

$$D_{sl,ts,d} = \frac{D_d^s}{card(l)} \forall s \in S^p, l, ts \in TT, d \quad (15)$$

## Objective function

The total cost of the supply chain is calculated as a function of the capital, labor, variable manufacturing costs and logistics costs:

$$\min Expected\ COST = \sum_{jm} c_j^{FAC} F_{jm} + [\sum_{ijtaumd} \phi_d c_{jai}^{MOD}(Y_{jmautd}) + \sum_{ijtaumd} \phi_d c_{jai}^{LAB}(W_{ijtaumd}) \sum_{ijtaumd} \phi_d c_{jai}^{VAR}(B_{ijtaumd}) + \sum_{std} \phi_d c_s^{STOR}(S_{std})] + \sum_{sltd} \phi_d c^P(\eta_{sltd}) + \sum_{smktd} c^T \lambda_{mk} Q_{smktd} + \sum_{skltd} c^T \lambda_{kl} Q_{skltd} \quad (16)$$

Where the expected cost is sum of scenario-independent investment and scenario-dependent weighted average sum over the operational, transport, storage decisions and, in the modular case, capacity expansion. Here, $c_{ja}^{FAC}, c_{jai}^{MOD}, c_{jai}^{LAB}, c_{jai}^{VAR}, c_s^{STOR}, c^P, c^T$ correspond to the capital, facilities dependent, labor, variable, storage and penalty cost coefficients respectively.

## Optimization-based Simulation

The first-stage decisions are fixed and the violation of the sales demand constraint is monitored and penalized. Hence Equation 14 is modified as follows:

$$Sales_{sl,ts,d} \delta_s + \eta_{sl,ts,d} \geq D_{sl,ts,d} \; \forall s, l, ts \in TT, d = d1 \in \Omega^{Stress} \quad (17)$$

The time to recover $TTR$ is the minimum time required to restore service after a disruption, corresponding to the

last time period and the first time period undergoing disruption:

$$TTR_{sd} = \max\{ts \in TT, |\sum_l \eta_{sl,ts,d} > 0\} - \min\{ts \in TT, |\sum_l \eta_{sl,ts,d} > 0\}\ \forall s, d = d1 \in \Omega^{Stress} \quad (18)$$

In the simulation step, the objective function (Equation 16) is modified with the addition of a penalty term calculated as function of the shortage of therapies.

$$\begin{aligned} \min Expected\ COST\ &= \sum_{jm} c_j^{FAC} F_{jm} \\ &+ [\sum_{ij,ts,aumd} \phi_d\, c_{jai}^{MOD}(Y_{jmau,ts,d}) + \sum_{ijtaumd} \phi_d\, c_{jai}^{LAB}(W_{ijtaumd}) \\ &+ \sum_{ijtaumd} \phi_d\, c_{jai}^{VAR}(B_{ijtaumd}) + \sum_{std} \phi_d\, c_s^{STOR}(S_{std})] \\ &+ \sum_{sl,ts,d} \phi_d\, c^P(\eta_{sl,ts,d}) + \sum_{smk,ts,d} c^T \lambda_{mk}(Q_{smk,ts,d}) \\ &+ \sum_{skl,ts,d} c^T \lambda_{kl}(Q_{skl,ts,d}) \quad (19) \end{aligned}$$

Upon simulation of reactive planning, the scenario set is reduced to $\{d1\}$, with demand levels assigned iteratively to out-of-samples generated in $\Omega^{stress}$. Hence, demands are generated from out-of-sample distributions:

$$D_d^Y \sim \mathcal{U}(1000, 3000)\ \forall d = d1 \quad (20)$$

Whereby the bounds of the monthly demands for Product Y are modified (Figure 2a).

Additionally, the disruptive regime for Product X is generated based on conditional probability theory, considering a bimodal distribution of demands, where the modes are defined by the sample regime $R_d$ (Figure 2b):

$$R_d \sim Bernoulli(p_{Disruption}), p_{Disruption} = 0.04\ \forall d = d1 \quad (21)$$

$$D_d^X = \begin{cases} Z_d^{disruption}, if\ R_d = 1 \\ Z_d^{Normal}, if\ R_d = 0 \end{cases} \quad (22)$$

Where:

$$Z_d^{disruption} \sim \mathcal{N}(\mu_{disruption}, \sigma^2_{disruption}),$$

$$\mu_{disruption} = 8 \times 10^7, \sigma^2_{disruption} = 2 \times 10^7 \quad (23)$$

$$Z_d^{Normal} \sim \mathcal{N}(\mu_{Normal}, \sigma^2_{Normal})$$

$$\mu_{Normal} = 7 \times 10^6, \sigma^2_{disruption} = 1 \times 10^6 \quad (24)$$

## Scenario tree update

The scenario tree update mimics the concept of learning from the demand observed throughout the time horizon. $K$-means clustering allows systematic grouping collected data in set of $K$ clusters, selected equal to the number of scenarios to build the tree for stochastic optimization and cluster heights used to scale scenario probabilities, whilst also accounting for regime information that enable partition of the samples and construction of regime-specific clusters. Here, $\Omega^{Obs} = \{(D_d^X, D_d^Y, r_d)\}_{d=1}^N$ is the set of demand samples $d$ observed up to iteration $\epsilon$ with a recorded corresponding regime. The samples belonging to each regime can be defined as the subsets:

$$\Omega^{Obs,r} = \{(D_d^{X,r}, D_d^{Y,r}) : r_d = r\} \quad (25)$$

The number of occurrences of regime $r$ is defined as:

$$N_r = \text{card}(\Omega^{Obs,r}) \quad (26)$$

Hence, the empirical probability of regime $r$ is the ratio of samples when the regime $N_r$ realizes and the total $N$:

$$\pi_r = \frac{N_r}{N} \quad (23)$$

For each regime, $K$-means clustering is performed by solving:

$$\min_{\mu_\kappa^r} \sum_{\kappa=1}^{K_r} \sum_{d \in C_\kappa^r} \left\| \begin{pmatrix} D_d^X \\ D_d^Y \end{pmatrix} - \mu_\kappa^r \right\|^2 \quad (27)$$

Where the $C_\kappa^r$ is the set of samples $d$ assigned to cluster $\kappa$ under regime $r$ and $\mu_\kappa^r$ is the centroid of cluster $\kappa$ under regime $r$, corresponding to the vector $\begin{pmatrix} \mu_\kappa^{X,r} \\ \mu_\kappa^{Y,r} \end{pmatrix}$ with respect to each product X and Y. The number of clusters per regime is therefore defined as:

$$K_r := \min(K, N_r) \quad (28)$$

Through Equation 28, if a new regime is discovered, $N_r$ new leaves of the scenario tree are added if $N_r$ is below that of the target number $K$ of clusters, which in this work equals 3. Otherwise, $K$-means yields $K$ scenarios for the each detected regime. The resulting scenario tree probabilities would be adjusted by regime-specific probabilities which are also computed based on collected data during the reactive stage. Therefore, once solved, $K$-means yields the new scenario realizations, which are reassigned as equal to the identified cluster centroids $\mu_r^k$. Each cluster $(k, r)$ defines a scenario $d$.

$$D_d^X := \mu_\kappa^{X,r} = \frac{1}{|C_\kappa^r|} \sum_{d \in C_\kappa^r} D_d^{X,r}$$

$$D_d^Y := \mu_\kappa^{Y,r} = \frac{1}{|C_\kappa^r|} \sum_{d \in C_\kappa^r} D_d^{Y,r} \quad (29)$$

New scenario probabilities can be derived from the empirical regime probabilities and the probabilities $p_k^r$ of cluster $k$ for each regime $r$ are calculated as the number of samples that fall under cluster $C_k^r$ and the occurrence of regime $r$:

$$p_\kappa^r = \frac{card(C_\kappa^r)}{N_r} \quad (30)$$

Hence, overall scenario probabilities are obtained as:

$$\phi_d := \phi_\kappa^r = \pi_r p_\kappa^r \quad (31)$$

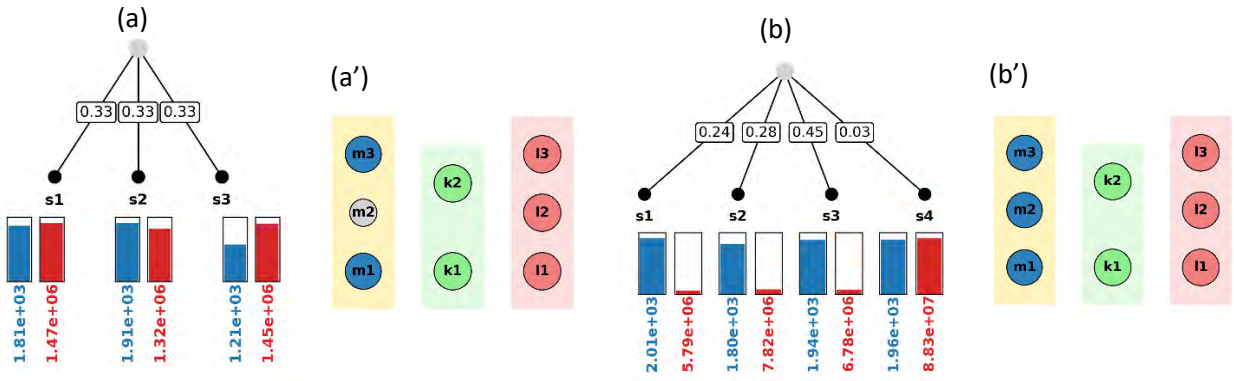

**Figure 2.** Inputs and first-stage outputs of iterative workflow (a) scenario tree for Iteration 1 (initialization, $\Omega = \Omega^1, \phi = \phi^1$), (a') network-level optimized design for iteration 1, (b) updated scenario tree for iteration 2 (K-means generated, $\Omega = \Omega^2, \phi = \phi^2$), (b') network-level optimized design for iteration 2.

## COMPUTATIONAL STATISTICS

The framework is built in Python 3.11 implementing the PYOMO package. The MILP is solved with GUROBI v11 on a Intel(R) Core(TM) i7-10700 CPU @2.90 GHz machine with 64.0 GB RAM. Table 1 presents the computational time for the modular and the non-modular case. It is worth noting that both result in the same number of variables and different computational times across iterations, as the non-modular case is solely obtained by fixing binaries of equipment activation across scenarios (Equation 10), rather than reformulating the problem.

**Table 1:** Computational Statistics

| Iteration | Metric | Modular | Non-modular |
|---|---|---|---|
| 1 | *CPUs* | 236.1 | 170.11 |
| | *Continuous* | 522 | 522 |
| | *Integer* | 62,061 | 62,061 |
| | *Constraints* | 62,595 | 62,595 |
| 2 | *CPUs* | 690.78 | 443.14 |
| | *Continuous* | 696 | 696 |
| | *Integer* | 82,701 | 82,701 |
| | *Constraints* | 83,409 | 83,409 |

Statistics are reported for the proactive solution stage, The reactive stage was found to lead to computational times of $< 1s$, with CPUs reduced due to the fixing of the design degrees of freedom, speeding up convergence.

## RESULTS & DISCUSSION

The proposed framework provides a platform to test design feasibility and adaptation capacity to unforeseen uncertainty. Figure 2a presents the initializing scenario tree, which corresponds to equiprobable scenarios sampled from the distributions presented in Equation 1-2. This results in first-stage network-level decisions which are equivalent in the modular and non-modular case (Figure 2a'), corresponding to two facilities installed, namely $m1$ and $m3$, minimizing transport cost and distance travelled, and fulfilling the expected demands. It is worth noting that first-stage equipment-level decisions for the modular and non-modular decisions differ and this is displayed in Figure 3a and Figure 3b, at time period $t = 0$, with different equipment lines installed in terms of scale and parallel units. This is due to the fact the modular equipment allows for ad-hoc installation of capacity as second-stage decisions, whilst the non-modular case considers that the installed equipment is fixed and should fulfill the postulated demand scenarios.

Fixing these case-specific first-stage decisions, stress testing allows the quantification of the adaptive capability of each alternative. In Figure 4a-a' the outcomes of stress testing are highlighted with respect to each product. For each demand realization highlighted in black, modular and non-modular options yield a feasible solution, whereby feasible corresponds to a network that ensures supply given the installed equipment capacity (non-modular case) or through installation of additional units. This is done minimizing cost and time to recover, and, if feasible, the time to recover is below the threshold of $\tau_{TTR} = 120\ days$. Instead, samples highlighted in red are those that trigger this infeasibility, corresponding to a $1900$ doses of Y and critically, a 10-fold increase in demand for X, which in this case study corresponds to low-probability, high impact occurrence of a pandemic.

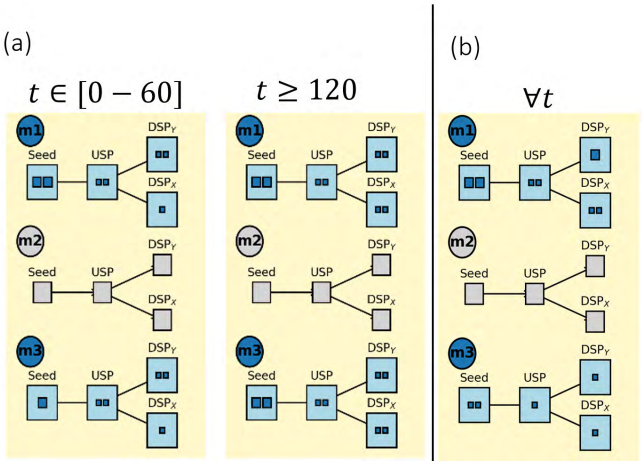

**Figure 3.** Equipment-level decisions: (a) modular case, (b) nonmodular case fixed equipment structures. Line activated (■), facility inactive (■). Number of lines $u$ and scale $a$ is illustrated for each process equipment type $j$.

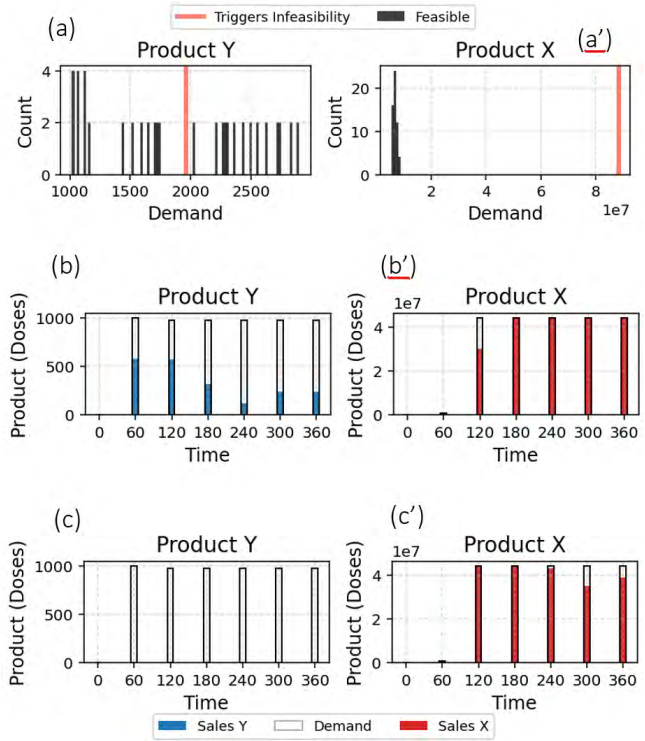

**Figure 4.** Infeasibility detection: (a) demand for Y, (a') demand for X, (b-b') time to recover in modular case, (c-c') time to recover in non-modular case.

As can be seen in Figure 4b-b', in the modular case, the disruption occurrence causes a $\widehat{TTR_d}$ with respect to product X of approximately $300\,days$ and a minimized $\widehat{TTR_d}$ of $60\,days$ with respect to X. Shortages are even more significant in the non-modular case, with delays of shortages of 120 days on the X side (Figure 4c') and unfulfilled demands on the Y side (Figure 4c).

The response capabilities of the network are seen in Figure 3a and b, where the adaptation of the second-stage decisions is displayed for $t > 60\,days$. In the modular case (Figure 3a), a scale-out of seed capacity and additional DSPx lines to cater for the increased X demand. This leads to the service levels seen in Figure 3b' for X, which are attainable without compromising on capacity for the manufacturing of Y. This then leads to a $\widehat{TTR_d}$ which still does not satisfy the feasibility check; however, it is less significant than in the fixed non-modular case. Figure 3b illustrates instead a fixed structure that is not scenario dependent on the entirety of the time horizon, hence the only degrees of freedoms to respond to disruptions become the adjustments of the operational planning decisions. This leads to more significant shortages and longer $\widehat{TTR_d}$ times in the non-modular case.

Additionally, Figure 2b highlights how post-infeasibility, $K$-means clustering generates a new scenario tree, systematically incorporating 1 new leaf, which corresponds to the detected 1 low-probability $(0.03)$ high impact $(8.37e8\,doses)$ scenario representing the *disruption* regime, and adjusted probabilities based on the realized demands for the *normal condition* regime. Solving the stochastic optimization again leads to adjusted first-stage decisions, which also embed the activation of facility $m2$ (Figure 2b')

Based on the updated design, the simulated stress test is repeated, resulting in feasibility for all samples within $\Omega^{Stress}$, for both the modular and non-modular case. Then, it becomes worth comparing the costs of optimality and feasibility. In Figure 5a, the costs for the modular case is displayed, with iteration 1 resulting in costs of $8.3M\ USD/y$ for facility capital-investment related decisions. The CapEx of the module investment ($90M\ USD/y$), the variable ($11M\ USD/y$) and labor costs ($6M\ USD/y$) are second-stage because dependent on operation and scenario realization and therefore not-committed a priori. Instead, in the non-modular case, the equipment is installed and fixed, hence the total displayed CapEx of $12.8M\ USD/y + 131.9M\ USD/y$ is a cost-commitment taken prior to scenario realization and larger, as expected to cater for all demand occurrences, including increased demands with additional capacity.

Stress testing in Iteration 1, highlights that in both the modular and non-modular case the expected cost can increase, due to realization of larger demands not captured in the scenario tree. Specifically, the outlier on the modular case corresponds to the sample displayed in Figure 4b-b', where increased production levels to minimize shortages lead to higher costs. At Iteration 2 the expected optimal costs in both cases result higher based on an updated scenarios that capture the observed samples in the previous iteration, until infeasibility was detected. Added cost results from idle equipment in $m2$, catering for disruptions and increased demand resulting from it; expected modular costs remain lower.

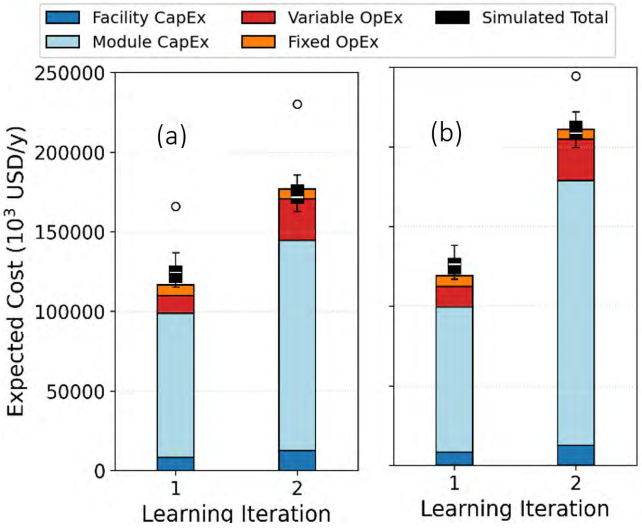

**Figure 5.** Expected and simulated costs for (a) modular, (b) non modular case over iterations

It emerges that flexibility of rapid scale-out allows minimization of cost commitments and better adaptability to disruption scenarios. Hence, the presented comparison between modular and non-modular equipment is fundamentally a theoretical comparison on benefit of recourse actions in ensuring cost-effective anticipation and response to disruptive events that impact the system.

Based on the results presented, there emerge avenues of development of the optimization-based assessment platform. First, the reactive planning part solves a deterministic optimization problem which assumes perfect foresight of the disruption realizing at time $t = 60$. Hence the $TTR$ is computed optimistically, based on deterministic disruption anticipation and mitigation. Nevertheless, solving this part through a rolling horizon optimization would correspond to a more-realistic response characterization as part of the feasibility test. Second, expected cost was primarily used as performance indicator when comparing the two manufacturing alternatives. Sustainability metrics for capacity establishment and operation could be integrated in the optimization constraints: the former would account for footprint of facility establishment, multiplied by the selection of binary installment variables (e.g. $Y_{jmau,ts,d}$) and the latter accounting for footprint scaling production levels (e.g. $B_{ijtaumd}$) and resource use (e.g. heat and electricity).

Overall, the proposed tool enables process design resilience assessment prior to deployment at scale and during operation. On the one hand, the modelling platform could support comparative assessments, as shown in this study, to identify good design candidates that perform cost-effectively in response disruptions. On the other hand, the tool could be deployed as a back-end simulator, with testing for a continuously updated set of disruptive events and anticipation of re-design priorities prior to disruptions striking in real life scenarios.

## CONCLUSIONS

Resilience is becoming a growing priority across industrial sectors, with pressures to design systems that are adaptive to evolving uncertainty from diverse sources. In this work, we develop a framework for proactive design under a priori postulated uncertainty and testing for adaptation to unforeseen uncertainty through simulation. This is achieved through an *out-of-sample* optimization-based simulation from distributions that describe occurrences of disruptive events impacting demand scale for the products. To update uncertainty information when significant service loss due to disruptions emerge, scenario clustering techniques are leveraged to allow updating of the scenario tree, updating uncertainty information worth integrating in the design steps.

The capabilities of the framework are shown comparing examples of modular and non-modular manufacturing equipment designs, highlighting the value of recourse capacity expansion which the former option offers, alongside to initial lower cost commitments. Overall, the tool enables comparative analyses towards the establishment of more resilient designs centered around continuous improvement via systematic uncertainty-related data, making it a valuable tool in real-time simulation of future disruptions through anticipation, mitigation and adaptation of process/network design.

## ABSTRACT

Wine consumers are increasingly health- and environmentally conscious. At the same time, white wine and rosé drinkers favour freshness and varietal aromas, which requires low-temperature regimes that extend fermentation time and increase energy demand. Additionally, global warming accelerates grape ripening which increases alcohol level in wine. To reduce cost and alcohol levels while maintaining quality, predictive tools that forecast how fermentation conditions impact fermentation time, and primary and secondary metabolite concentrations, can provide practical benefits to wineries by expediting oenological decisions-making and in turn reducing energy demand. Additionally, literature highlights static models in smart manufacturing suffer from performance degradation with data drift. In light of this, we successfully developed and evaluated pipelines for the automated design and training of three ML methods - support vector regression, random forest and artificial neural networks – to predict fermentation outcomes from ten initial features. The dataset employed captures the fermentation of nine commercially available *Saccharomyces cerevisiae* strains, each performed in triplicate, across two synthetic media and four temperature regimes, sampled at nine time points. The targets we focused on included time to complete fermentation, Ethanol, Acetate, given its undesired spoilage effects and ten secondary metabolite concentrations, given their synergistic impact on aroma. We were able to recommend effective pipelines for each task and identified our feature set contained adequate predictive signal for ethanol, acetate and fermentation duration predictions, but inadequate for the multi-output regression of secondary metabolite concentrations, which exhibited target heterogeneity. Ultimately, embedding these pipelines into optimisation frameworks, offers an actionable route to tailoring wine characteristics to evolving consumer preference, while reducing energy demand.

**Keywords**: alcoholic fermentation, machine learning, artificial neural network, support vector regression, random forest regression, fermentation time, efficacy, secondary metabolite concentration

## INTRODUCTION

In 2024 the International Organization of Vine and Wine attributed the six-decade low wine consumption, 214.2 million hectolitres, to high average prices and emerging consumer trends [1]. These trends include prioritizing health, sustainability, and preferring low-alcohol beverages. The wine industry therefore requires solutions to produce environmentally friendly, low-alcoholic and high-quality wines, whilst reducing cost.

This is a particularly significant challenge in white-wine and rosé production as consumers prefer freshness and varietal aromas [2]. This requires low-temperature fermentation as it fosters the development and preservation of volatile compounds [3]. However, low-temperature isothermal programs (12-19 °C) can extend the duration of fermentation and increase the risk of sluggish and stuck fermentations. Given that alcoholic fermentation is exothermic, the process requires wineries to actively cool fermentation vats. This cooling accounts for between 45% and 90% of the total energy consumption in manufacturing. In the case of white wine and rosé, where fermentation is prolonged, the process becomes environmentally unfriendly and costly [4]. To address this challenge Minebois et al. investigated a non-isothermal temperature regime on 9 commercially available *Saccharomyces cerevisiae* strains across two synthetic grape must (SGM) compositions. The non-isothermal

temperature regime, henceforth referred to as the time-varying temperature regime (TVAR), began fermentation at 23°C, to leverage *S. cerevisiae's* higher optimal growth temperature, and upon entry into the stationary phase of fermentation switched to 15°C [2]. The two SGM compositions contained 210 g $L^{-1}$ and 250 g $L^{-1}$ total sugars (glucose and fructose in racemic quantities) and hence-forth will be referred to as MS210 and MS250, respectively. Additionally, the TVAR was compared to three isothermal regimes (12°C, 18°C, 25°C). The published dataset captures the complex interaction between temperature, strain, and fermentation media.

Initial fermentation conditions strongly influence the final composition and therefore quality of wine. These conditions affect the concentrations of primary metabolites such as ethanol, acetate, and glucose, as well as the concentrations of secondary metabolites that define the wines aroma profile. Glucose contributes to sweetness and elevated acetate levels can produce vinegary notes [2]. Therefore, predictive tools that forecast the impact of fermentation conditions on fermentation time, and, primary and secondary metabolite concentrations can accelerate oenological decision-making, whilst ensuring quality and reducing both costs and energy demand. Considering this, we looked to employ three machine learning (ML) methods – support vector regression (SVR), random forest (RF), artificial neural networks (ANN) – to forecast these outcomes, given their proven ability to map complex interactions [5]. However, in recognition that literature adopts static ML models, often with arbitrarily selected architectures and hyperparameters, where performance degrades with data shifts [6]. We therefore developed and evaluated pipelines an actionable workflow for the automated design and training of these methods.

Consumers have become increasingly conscious of adverse health effects and roadside safety, and, as climate change increases alcohol level in wines by accelerating grape ripening, research on reducing alcohol content in wine has intensified [7]. Subsequently, the primary metabolites we chose to predict were ethanol and acetate, considering that bacteria from grapes have been found to oxidize ethanol to acetic acid, a volatile acid that causes wine spoilage [8]. We chose to predict secondary metabolite concentrations for their synergistic effects on wine's aroma profile, a key component of wine quality.

## Machine Learning Methods

In our investigation we explored supervised learning methods which aim to find parameters, $\theta$, that minimize the average loss over a finite training set of input-output pairs $\{(x_i, y_i)\}_{i=1}^{N}$. Where, $x_i$ encodes strain identity, synthetic must strength (MS210 or MS20), temperature regime and initial metabolites, and $y_i$ denotes our predicted targets.

### Support Vector Machines (SVM)

Support Vector Machines (SVM) are large-margin classifiers that separate labeled data by maximizing the margin between classes [9]. For linear SVM, the decision function is $f(x) = \omega^{\top} x + b$, where $\omega$ is the weight vector and $b$ is the bias. The parameters $(\omega, b)$, are obtained by solving the soft-margin optimization problem. SVR extends this principle to continuous targets by introducing Vapnik's $\varepsilon$-insensitive loss, where an $\varepsilon$-tube is fitted around the regression function [9]. Deviations larger than $\varepsilon$ incur a penalty and the optimization problem becomes,

$$min_{\omega,\xi,\xi^*} \frac{1}{2}\|\omega\|^2 + C\sum_{i=1}^{N}(\xi_i + \xi_i^*) \quad (1)$$

s.t. the constraints (Eq. 2, 3, 4),

$$y_i - f(x_i) \leq \varepsilon + \xi_i^* \quad (2)$$

$$f(x_i) - y_i \leq \varepsilon + \xi_i^* \quad (3)$$

$$\xi_i, \xi_i^* \geq 0 \quad (4)$$

where the slack variables, $\xi_i$ and $\xi_i^*$, measure how far sample $i$ lies outside the $\varepsilon$-tube, $C$ adds a linear penalty to those violations and $y_i$ is the true target value. To capture nonlinearity, SVMs employ the kernel trick, replacing the inner product $\omega^{\top} x$ with a kernel function $K(x, x')$ that behaves like an inner product in some (potentially higher) feature space. A common choice is the radial basis function (RBF) kernel, $K(x, x') = e^{\left(-\gamma\|x - x'\|^2\right)}$, where $\gamma$ is a scaling parameter that controls the width of the Gaussian kernel function.

### Random Forest (RF)

Random Forest (RF) is an ensemble learning method that combines many decision trees using bootstrap aggregation (bagging). Each tree is fit to a bootstrap sample of the training data, and at every split the algorithm considers only a random subset of the input features. This randomization reduces correlation and tends to improve generalization [10]. For regression, the forest prediction for an input vector $x$ is the average of individual tree predictions,

$$\hat{y}(x) = \frac{1}{T}\sum_{t=1}^{T} f_t(x) \quad (5)$$

where $T$ is the number of trees in the forest and $f_t(x)$ is the prediction of $t$-th tree trained on its own bootstrap sample. Within each tree, splits are chosen to minimize the mean squared error (MSE) of the target values in the child nodes and a cost complexity pruning parameter, $\alpha$, can be added to penalize larger trees.

### Artificial and Recurrent Neural Networks (ANN)

An Artificial Neural Network (ANN) is a parametric

function approximator that learns the mapping $f_\theta$: $\mathbb{R}^d \rightarrow \mathbb{R}^m$, where $d$ and $m$ are the number of input and output dimensions, respectively. Given an input vector $x \in \mathbb{R}^d$ and parameters $\theta = \{\omega, b\}$, each neuron computes a weighted sum $f(x) = \omega^\top x + b$, to which a non-linear activation function is applied, this mathematically replicates a biological neuron [10]. Each neuron then passes the processed signal forward as its output and multiple neurons constructs a layer. If we denote $k$ as a discrete training step, the output of a single neuron can be written as,

$$y(k) = F\left(\sum_{i=0}^{m} w_i\,(k) \bullet x_i\,(k) + b\right) \tag{6}$$

where $F\,(\bullet)$ is the activation function, $x_i\,(k)$ is the $i$-th input component and $y(k)$ is the output [11]. A common activation function that applies a nonlinear transform is the rectified linear unit function (ReLU), which is applied component-wise,

$$ReLU(z) = \begin{cases} z, z > 0 \\ 0, z \leq 0 \end{cases} \tag{7}$$

where z is the pre-activation function within Eq.6 [8]. A Feed-forward ANN (FFANN) is one in which information flows strictly in one direction from the input layer to the output layer. A common FFANN is a multilayer perceptron (MLP) where all layers are fully connected (dense) [11]. An MLP with two or more hidden layers is referred to as a deep neural network and can learn hierarchical feature representations.

When training, a backpropagation algorithm was employed to minimize the mean squared error between predicted and observed targets, Eq. 8 [12]. Backpropagation applies the chain rule to efficiently compute the gradient of the loss with respect to each weight and bias, Eq. 9. Weights are then updated with the Adam optimizer, an adaptive variant of stochastic gradient descent that uses exponentially decaying, bias-corrected first and second order moment loss gradient estimates, eq. 11.

$$\mathcal{L}(\theta) = \frac{1}{m} \sum_{j=1}^{m} \left(y_j - \hat{y}_j\right)^2 \tag{8}$$

$$\frac{\partial \mathcal{L}}{\partial \omega_{kj}} = \frac{\partial \mathcal{L}}{\partial \sum_i \omega_{kj} a_j + b_k} \bullet \frac{\partial \sum_i \omega_{kj} a_j + b_k}{\partial \omega_{kj}} \tag{9}$$

$$\omega_{kj}{}^{(t+1)} = \omega_{kj}{}^{(t)} - \eta \frac{\hat{m}_{t,kj}}{\sqrt{\hat{v}_{t,kj}} + \epsilon} \tag{10}$$

where $\mathcal{L}(\theta)$ is the MSE loss-function, $y_j$ is the true target value, $\hat{y}_j$ is the models prediction, $a_j$ is the activation output of neuron $j, \frac{\partial \mathcal{L}}{\partial \omega_{kj}}$ is the loss gradient with respect to weight $\omega_{kj}(k), t$ is the current training step, $\hat{m}_{t,kj}$ and $\hat{v}_{t,kj}$ are the bias corrected first and second order moments and $\eta$ is the learning rate.

## METHODOLOGY

Minebois et al.'s dataset contains samples of biomass, primary metabolites, amino-nitrogen species, and volatile compounds at nine time points ($T_0$- $T_8$), where $T_8$ marks the completion of fermentation. Data was collected for nine commercially available *S. cerevisiae* strains across two synthetic must strengths (MS210, MS250), and four temperature regimes. As mentioned above, this included a time-varying temperature regime (TVAR) that switches from 23°C to 15°C at one-third completion of fermentation and 3 isothermal regimes ($12°C, 18°C, 23°C$). We developed supervised ML pipelines to predict fermentation outcomes at $T_8$ from the initial measurements at $T_0$.

A compact set of ten variables were identified using literature and spearman's correlations including: strain, temperature regime, MS, cell counts, ethanol, glycerol, organic acids, and $NH_4Cl$. Categorical features were one-hot encoded, and numerical features were median-imputed and standardized [13]. For the SVR and ANN pipelines, numerical features were also converted to orthogonal components via PCA to reduce collinearity and dimensionality (95% of variance retained). In contrast, PCA was *not* applied to the RF pipeline because tree-based ensembles are inherently robust to collinearity, and this could discard predictive low-variance signals. The models were evaluated on several train-test splits (80:20%, 70:30%, 60:40%, 50:50%) to mimic data limitations and distributional shifts using a grouped splitting method, ensuring that each *Strain-MS-Temperature-regime* combination was contained entirely within either the training or testing set to prevent information leakage.

For the SVR and RF, hyperparameters were tuned on the training set using an exhaustive grid search method with a 5-fold grouped cross-validation (CV) technique. The hyperparameters were selected using a mean MAE fitness across folds. The selected model was refit on the full training set and evaluated on the unseen test set. For the ANN, we replaced the grid search with a genetic algorithm (GA) as a more efficient search of both the architecture and hyperparameter space. The 5-fold grouped CV prevented leakage by keeping all samples from the same combination within a single fold and allowed us to gauge how well the model generalizes to unseen conditions.

Pipeline recommendations were primarily based on mean CV MAE (predictive accuracy) and CV MAE range (robustness) across splits, with the test set used to check for overfitting, and quantified through CV-Test MAE difference (Generalization behaviour). Additionally, deeper analysis was performed on the models out-of-fold (OOF) CV predictions at the 80:20 split, where models were least-data limited.

Results were performed in triplicate, so predictions were averaged within each Strain-MS-Temperature-regime combination. Minebois et al. implicitly define time $T_8$ as the point at which $CO_2$ evolution has effectively

ceased and the cumulative weight-loss curve reaches a plateau.

As mentioned, the primary metabolite regressed included concentration ($g\ L^{-1}$ ) of ethanol and acetic acid. The targets were predicted using separate models to optimize hyperparameters. The secondary metabolite regression included concentrations ($mg\ L^{-1}$) of ethyl acetate, isobutyl alcohol, isoamyl acetate, isoamyl alcohol, ethyl hexanoate, ethyl octanoate, phenylethyl acetate, phenyl ethanol, octanoic acid, and decanoic acid. Given the time constraints we choose predict all secondary metabolite concentrations in one pipeline. However, *scikit learns* SVR function does not natively support multi-output regression, therefore, we employed a wrapper that fits one model per target. Additionally, because some targets were right skewed (e.g. Fig. 1) the pipelines assessed if applying a logarithm transform to the targets improves predictive accuracy.

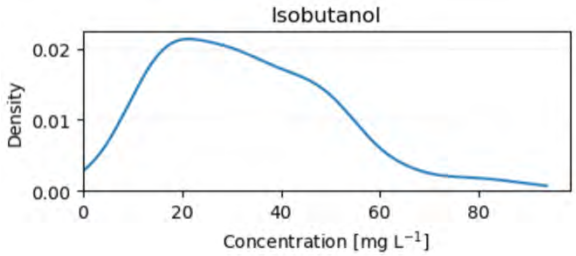

**Figure 1:** Kernel density estimate of Isobutanol concentrations.

## RESULTS AND DISCUSSION

Across train-test splits, the Random Forest pipeline achieved the lowest mean cross-validated (CV) MAE (38.57h) and was the most robust to data partitioning (CV MAE range = 4.09h), outperforming the ANN (CV MAE = 40.59h, CV MAE range = 9.94h) and SVR (CV MAE = 42.5h, CV MAE range = 8.11h) pipelines. Generalization behaviour (CV-Test MAE gap) was also the most stable (-0.30h) indicating that the RF model performances transferred most consistently to the held-out test sets. Although larger training sets typically improve generalization, the RF pipeline achieved its lowest CV MAE at the 50:50 split (36.04h). This likely reflects split-composition effects in a small, heterogeneous, group-split dataset, where the presence/absence of harder regimes can dominate the CV error. Accordingly, we place stronger emphasis on 80:20 pipeline performance, as the split is the least data-limited and best reflects achievable performance given the feature set. The model at the 80:20 split achieved competitive CV metrics with strong test set performance (CV MAE = 39.65 h, test MAE = 32.68 h, both $R^2$ = 0.91). The model's configuration used 800 trees of unrestricted depth, that sampled 100% of feature at each split, with mild regularisation through minimum leaf size (4) and cost-complexity pruning ($\alpha = 1 \times 10^{-4}$), and chose to log transform targets. The 80:20 RF model, built in mean decrease in impurity (MDI) identified temperature (0.659) as the most important feature, consistent with the temperature-dependent yeast metabolism reported in literature [14].

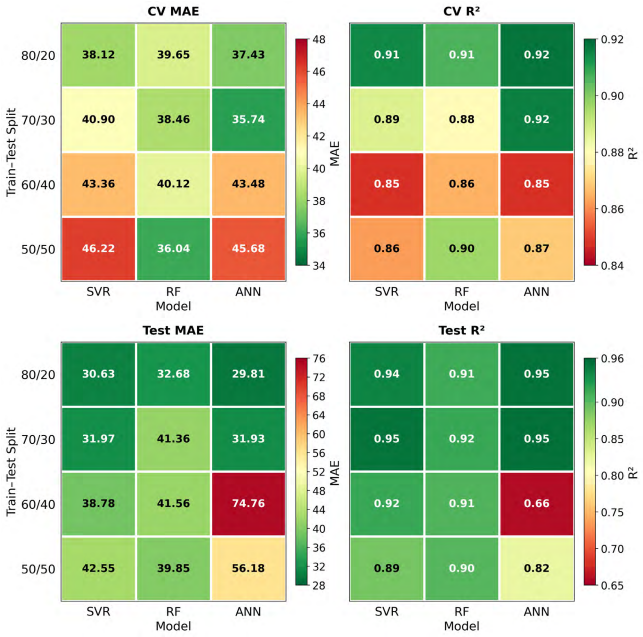

**Figure 2:** Cross-validated (CV) and test, MAE and $R^2$ scores for time to complete fermentation (hours) predictions across train-test splits and model pipelines.

Given the ANN's strong performance at higher splits (≥70:30), analysis of out-of-fold CV predictions relative errors (RE) and absolute relative errors (ARE) of both the RF and ANN is appropriate. Models at the 80:20 split were slightly positively biased, with RF achieving a closer to zero mean bias (RE = 0.63% vs +1.76%). RF was also more accurate than the ANN (mean ARE = 7.63% vs 8.60%), with an equivalent standard deviation (SD) (ANN: 0.104, RF: 0.101). Additionally, RF exhibited a heavier tail than the ANN (max. RE = +27.70% vs +22.04%, min. RE = -21.55% vs -18.99%), with a larger strain level bias. The RF model was found to be less biased to isothermal temperate regimes (12℃, 18℃, 25℃) and more biased under TVAR than the ANN (RE: +1.30% vs +1.10%), with the ANN being markedly more biased at 25℃ (RE = +3.98% vs -0.12%). RF exhibited a smaller MS level bias, with the ANN being notably more sensitive to MS210 (RE: +3.18% vs +0.78%), but both displayed poor predictive accuracy at MS210 compared to MS250 (MS210 vs MS250 mean ARE, **ANN: 9.38%** vs 7.95%, RF 9.50% vs **6.07%)**.

This supports recommending RF as the default pipeline, it was most robust to reduced training data and achieved the lowest mean error across splits. The 80:20 RF model was more accurate than the ANN overall, but

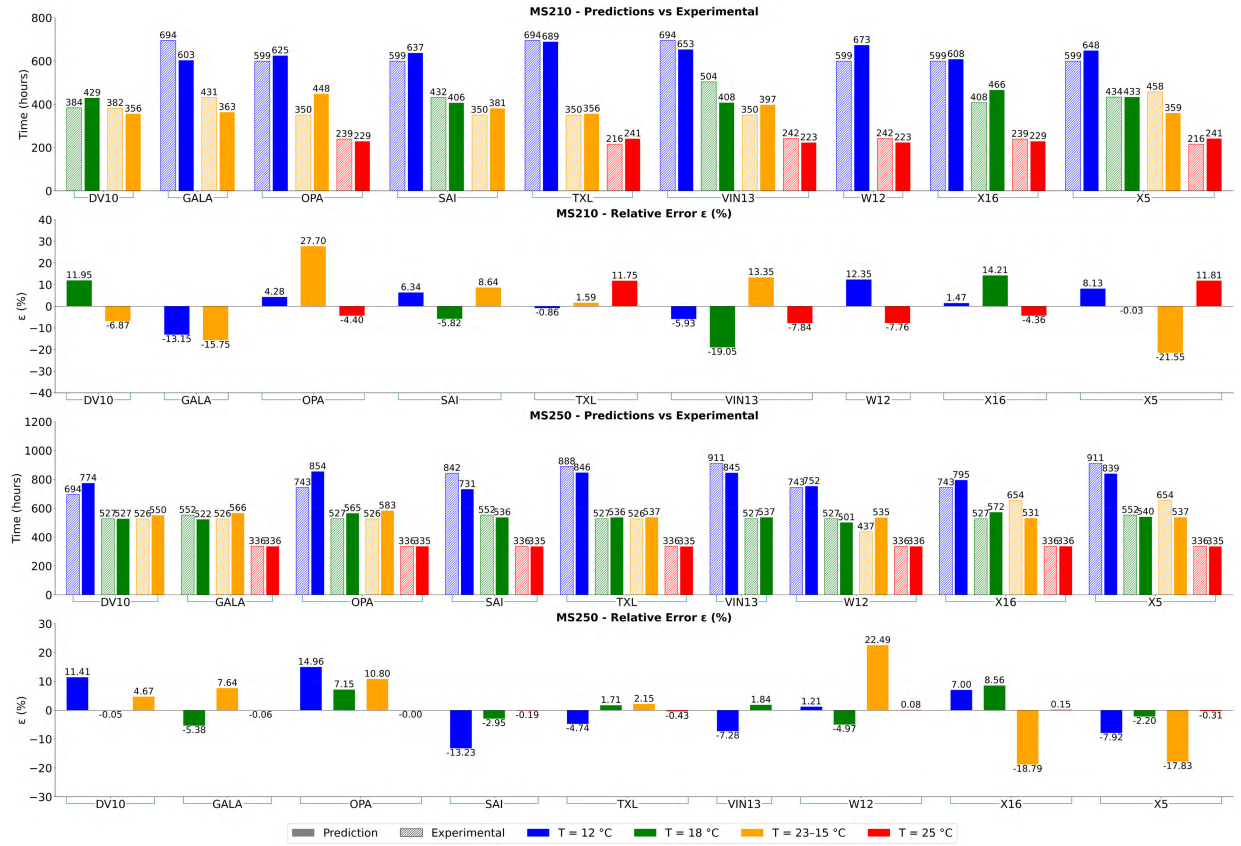

**Figure 3.** Random Forests 80:20 split out-of-fold cross-validation fermentation duration predictions relative

exhibited less stable tail behaviour. A key limitation is that Minebois et al. does not define an explicit quantitative stopping rule for complete fermentation, so time-to-completion may contain irreducible noise, regardless, the pipeline successfully predicted fermentation duration.

For the ethanol content (%) regression, across train-test splits ethanol was shown to be a learnable relationship on all three pipelines, but performance and stability varied. Over the splits, RF achieved the lowest mean CV MAE (0.563 %), outperforming both the ANN (0.566%) and SVR (0.605 %). However, SVR was the most robust across the train-test splits (smallest CV MAE range = 0.0319%) and exhibited the best generalisation behaviour (smallest CV-Test MAE gap: - 0.0799%).

Figure 3 shows RF achieved lower CV errors compared to SVR, across all splits, with RF being most competitive at the lower splits (≤60:40). The ANN marginally outperformed RF at the high splits (≥70:30) but was less robust overall. The best performing RF model occurred at the 50:50 split, again reflecting impact of the absence of difficult regimes in small, heterogeneous, group-split datasets. At 80:20 split the RF configuration employed 100 trees of restricted depth (max_depth = 10), considered 30% of feature set at each split, and applied regularisation through minimal cost-complexity pruning ($\alpha = 1 \times 10^{-2}$), and chose to log transform targets. The RF model at the 80:20 split's MDI identified must strength (0.695) as the most important feature, consistent with the fermentation's primary reaction. The 80:20 ANN exhibited competitive performance in Figure 3, with a four hidden-layer funnel configuration ($[48, 24, 12, 12]$), moderate drop-out rate ($0.163$), weak L2 regularisation ($\lambda = 3.36 \times 10^{-5}$) and a relatively high learning rate ($\eta = 3.64 \times 10^{-3}$), with the targets log transformed.

Analysis of out-of-fold CV predictions RE and ARE of both the RF and ANN at the 80:20 split shows that the ANN exhibited a slightly more negative mean bias (RE = $-0.37\%$ vs $-0.06\%$), with the RF achieving a greater average predictive accuracy (mean ARE: RF = 3.07%, ANN = 3.56%). RF achieved a slightly tighter error distribution (SD = 0.0429 vs 0.0459), but both models exhibited stronger positive tails (max. RE: RF = +16.24%, ANN = +17.01%, min. RE: RF = -8.67%, ANN = -6.96%). At the temperature level, both models were unbiased under 12°C and TVAR, unpredicted at 18°C and overpredicted at 25°C, with the ANN exhibiting markedly larger under-predictions than RF at 18°C (RE = -1.86% vs -0.94%). However, RF was more accurate in absolute terms at every temperature regime. Strain level biases were small on both models (RE $\sim \pm 2\%$), but on harder to predict strains (OPA, X16) RF was consistently more accurate (lower mean ARE). Finally, both models were less

accurate at MS210 (mean ARE: ANN = 4.45%, RF = 4.00%) than at MS250 (mean ARE: ANN = 2.82%, RF = 2.28%), with RF being more accurate at both must strengths, with negligible MS level bias.

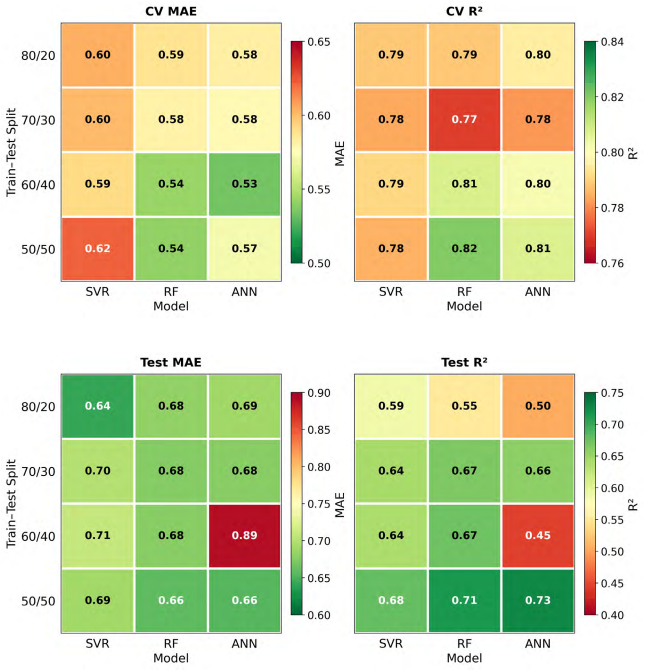

**Figure 4:** CV and test, MAE and $R^2$ scores for ethanol (%) predictions across train-test splits and model pipelines

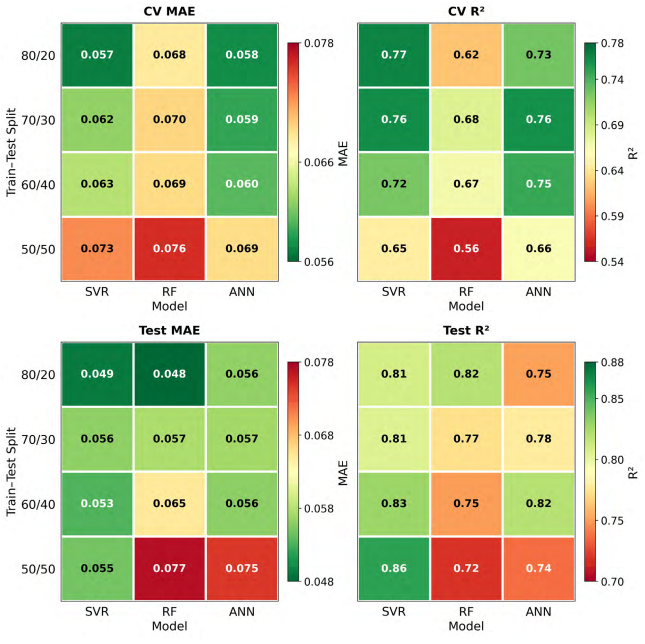

**Figure 5:** CV and test MAE and $R^2$ scores for acetate conc. ($gL^{-1}$) predictions across train-test splits and model pipelines.

Overall, the evidence supports recommending RF as the default pipeline because, although, SVR was the most robust to reduced training data, RF achieved the lowest mean error across splits and under the least data limited regime (80:20), RF achieved greater predictive accuracy, a tighter error distribution, and a smaller temperature and must strength dependency. However, the ANN produced fewer outlier (beyond $IQR \times 1.5$) predictions. A methodological refinement is to model ethanol yield (final – initial) instead of predicting final ethanol with initial ethanol included as a feature, which conflates baseline ethanol with yield.

For the acetate concentration task, across splits the ANN pipeline achieved the lowest mean CV MAE (0.0615 $gL^{-1}$) and the smallest CV-Test MAE gap (0.0007 $gL^{-1}$), therefore indicating stable generalization. The RF pipeline was the most robust to splits (smallest CV MAE range: 0.0075 $gL^{-1}$), however, achieves the worst predictive accuracy (mean CV MAE: 0.0708 $gL^{-1}$) and explained variance. The SVR pipeline achieved a close second in predictive accuracy across splits (mean CV MAE: 0.0638 $gL^{-1}$), whilst being the least robust (CV MAE range: 0.0155 $gL^{-1}$) and exhibiting the largest CV-Test MAE gap (0.0105 $gL^{-1}$), such that generalization was much stronger, indicating training **sampling noise** (test set was easier).

The SVR configuration at the 80:20 split used an **RBF kernel** with **C=100, $\epsilon$=0.05$, $\gamma$=0.003**, and **no target transformation. This corresponds to a smooth nonlinear mapping with relatively strong penalization of training errors. The ANN at the 80:20 split used** a **shallow network** with one hidden layer ([5])**, a** low dropout rate (0.09), moderate L2 regularisation ($\lambda = 2.3 \times 10^{-3}$) and a relatively high learning rate ($\eta = 5.02 \times 10^{-3}$), with a log-transformed target.

Analysis on the 80:20 CV out-of-fold predictions indicate SVR was more positively biased than the ANN (RE = +1.25% vs +0.22%), but both achieved negative median RE (SVR −0.63%, ANN −1.52%), therefore on typical cases the models underpredicted, especially the ANN. The mean ARE highlights that the SVR was more accurate (mean ARE: 7.80% vs 9.15%) than the ANN, and given a typical condition is 52% more accurate (median ARE: 5.42% vs 8.22%). Additionally, the SVR's error distribution was tighter (SD = 0.0999 vs 0.1189). The ANN shows greater strain level bias than SVR, with SVR achieving a greater predictive accuracy for five of the nine strains (OPA, TXL, VIN13, X16, X5). The ANN exhibited particularly weak performance on X16. Both models were less accurate at **MS250** than **MS210**, with higher mean absolute relative error (ANN: 9.73% vs 8.46%, SVR: 8.39% vs 7.09%). Across MS, SVR was more accurate with a small positive bias and the ANN's bias changed sign, **overpredicting** at MS210 (mean RE = +2.56%) and **underpredicting** at MS250 (mean RE = −1.75%).

Finally, the evidence supports recommending the ANN pipeline when mean predictive accuracy, with moderate robustness across splits is preferred. However, the

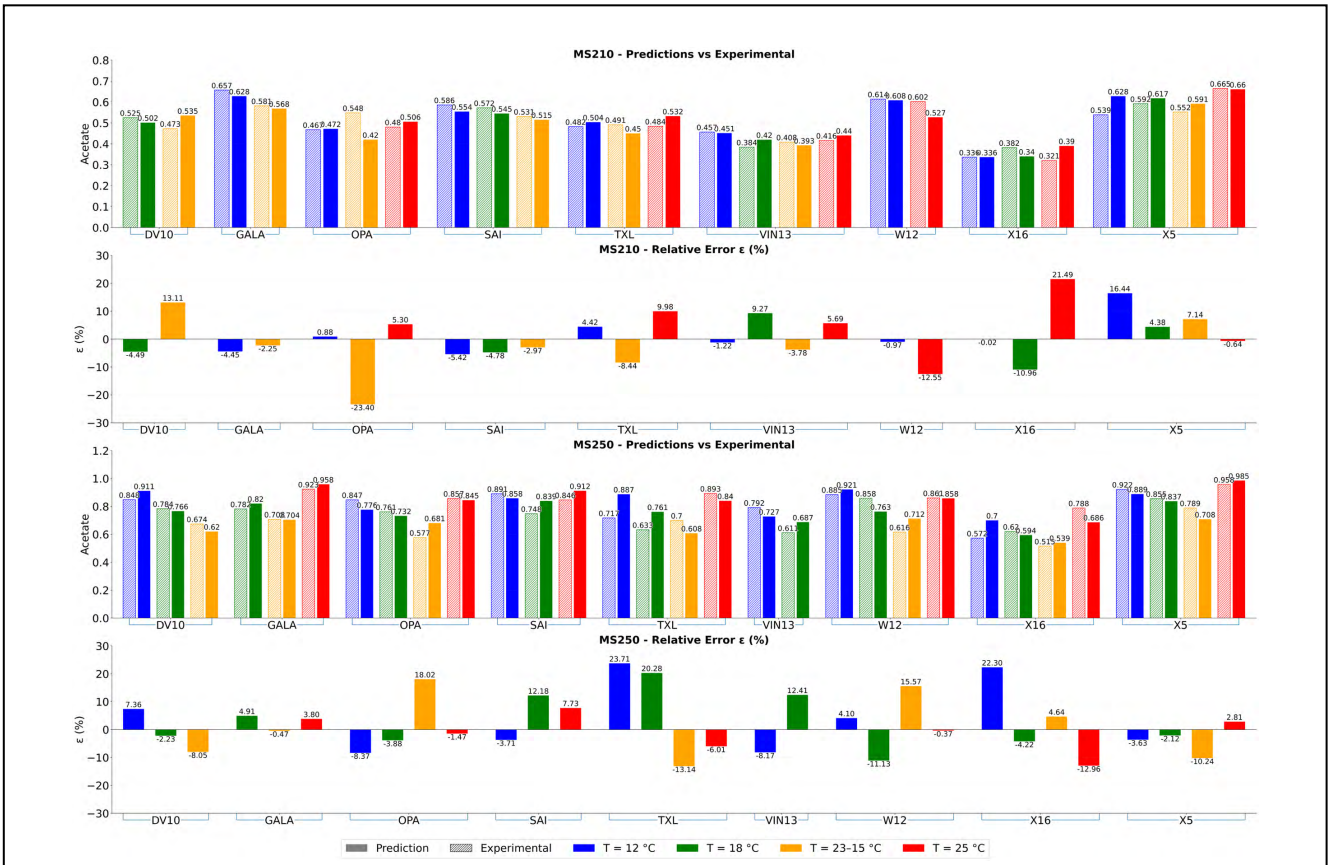

**Figure 6.** Support vector regression 80:20 split out-of-fold cross-validation acetate concentration ($mgL^{-1}$) predictions relative errors.

ANN's least data limited model (80:20) exhibited a wider error distribution and lower absolute predictive accuracy, with instability on the X16 strain, stronger MS dependence, and higher errors at **12°C and 25°C. Therefore, if predictive accuracy under non-data limited regimes is preferred, the SVR pipeline is recommended for its lower mean ARE, tighter error distribution and smaller MS and temperature dependence.**

For the secondary metabolite task, across the train test splits, SVR was both the most accurate and robust pipeline. On every split it achieved the lowest mean CV MAE across the 10 targets (4.97 $mgL^{-1}$) and highest mean CV $R^2$ (0.22 $mgL^{-1}$). However, the ANN pipeline achieved the smallest mean CV-test MAE gap (-0.05 $mgL^{-1}$), indicating the most stable generalization. Regardless SVR was the most competitive on the held-out test set.

Across the splits, the pipeline selected the same SVR configuration, an RBF kernel, $C = 100, \epsilon = 0.1$ and $\gamma = 0.001$, with a log-transform of the target variable, aside from at the 70:30 split, where the pipeline reduced $\epsilon$ (0.05). When coupled with the almost identical model configurations, the monotonic improvement of mean CV MAE and $R^2$ as training fraction increased is consistent with gradual loss of predictive signal under reduced sample size, rather than model instability.

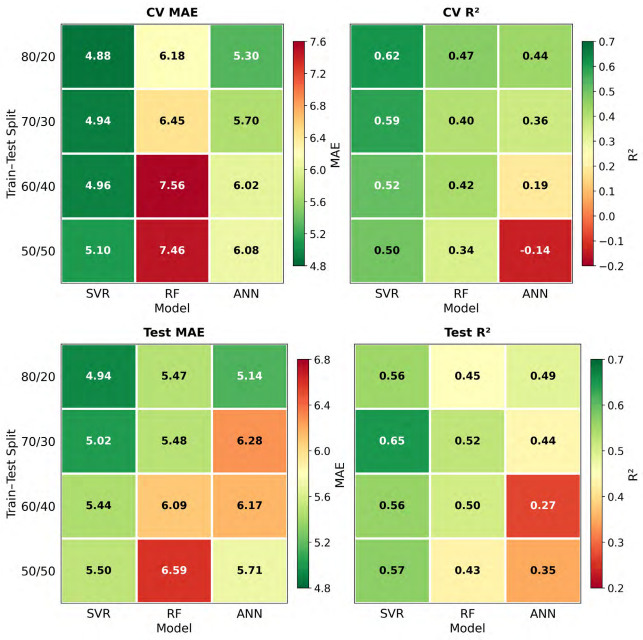

**Figure 7:** Mean CV and test, MAE and $R^2$ scores across secondary metabolite ($mgL^{-1}$) predictions from different train-test splits and model pipelines.

Although the mean results across the target show that the RF pipeline was most accurate and robust to train-test splits, the per target analysis at the 80:20 split reveals large target heterogeneity (Table 1). Specifically higher alcohols and their related esters (**PhenEtoh, Isobutanol, IsoamylAlcohol, PhenEthAcetate, IsoamylAcetate**) exhibit high learnability, whereas several medium-chain fatty acids and ethyl esters (OctanoicAcid, EthylHexanoate, DecanoicAcid, EthAcetate, EthOctanoate) remained difficult to learn.

**Table 1:** Per-target out-fold CV performance of SVR at the 80:20 train–test split, reported as normalized MAE (nMAE) and $R^2$.

| Target | nMAE | $R^2$ |
|---|---|---|
| PhenEtoh | 0.144 | 0.886 |
| Isobutanol | 0.151 | 0.835 |
| PhenEthAcetate | 0.224 | 0.834 |
| IsoamylAlcohol | 0.115 | 0.814 |
| IsoamylAcetate | 0.286 | 0.759 |
| OctanoicAcid | 0.138 | 0.598 |
| EthylHexanoate | 0.237 | 0.444 |
| DecanoicAcid | 0.278 | 0.436 |
| EthAcetate | 0.133 | 0.343 |
| EthOctanoate | 0.271 | 0.206 |

The target learnability trend could be partially explained through feature set selection as medium-chain fatty acids and related ethyl esters depend on absent features like lipid/fatty-acid availability, thus limiting predictability.

Of the targets that exhibit high explained variance ($R^2$) PhenEthAcetate has an elevated nMAE which indicates predictions capture variance with poor practical accuracy. This can be caused through systematic bias and is common in targets with a small range, like PhenEthAcetate, where even modest absolute errors are large fraction of the data's range.

Analysing PhenEtoh, Isobutanol and IsoamylAlcohol out-offold CV predictions for their high learnability and low nMAE, we find that the three targets exhibit near-unbiased central behavior (median RE = -0.08-0.71%), but regime dependent heavy tails. For example, all targets performed relatively poorly on 12**°C** (larger positive bias, higher MARE, and outlier clustering). In terms of absolute accuracy and stability, the model performed best on IsoamylAlcohol (mean ARE = 11.05%, SD = 0.162, max. RE = +66.42%), while Isobutanol and PhenEtoh are less accurate on average (mean ARE = 16.07% and 16.32%) and with longer tails, especially Isobutanol which exhibited the largest upside tail risk (max RE = +157.58%). The mean ARE was higher at MS210 for IsoamylAlcohol and PhenEtoh regression, whereas Isobutanol regression showed a higher mean ARE at MS250. Additionally, the **SAI strain is repeatedly the most difficult to predict across the three targets,** indicating a strain specific failure.

The heterogeneous predictability across the ten metabolites indicates that a single, fixed model configuration is unlikely to be optimal for all targets. This reinforces concerns in the literature that applying static model (non-case specific) configurations limits industrial practicality.

Given the time constraints, we used a task-agnostic feature set and fitted one pipeline across all 10 targets. As a result, the chosen model configurations were likely a compromise that limited target instability on the least learnable targets, rather than refining configurations for highly learnable targets. We would therefore recommend future work expands the feature set to fatty acids/lipids, and include additional assimilable nitrogen sources (Lysine, Proline, Ornithine) and either, fit a pipeline per target or pipelines to groups of targets (higher alcohols, acetate esters, ethyl esters, medium-chain fatty acids).

## CONCLUSION

This study successfully demonstrated that machine learning pipelines can map controllable fermentation conditions to fermentation kinetics and endpoint metabolite concentrations in *S. cerevisiae. Moving away from static ML models and motivated by industry constraints, we* developed pipelines that designed and trained three different ML models (SVR, RF, ANN), across four tasks (time to complete fermentation, and ethanol, acetate, and ten secondary metabolite concentrations). We evaluated the pipelines ability to cope with limited data and distributional shifts through evaluation on multiple train–test splits. We employed a *GroupKFold* splitting strategy to prevent information leakage and used five-fold cross-validation to improve generalization performance. Primary assessment criteria included mean MAE, CV MAE range, competitive $R^2$, and held-out tests were used to assess generalisation stability.

A compact ten variable feature set of operationally accessible predictors was identified: strain, temperature regime, must strength, biomass counts, early metabolites, and a key nitrogen source. This feature set was highly predictive for time, ethanol, and acetate tasks, supporting practical deployment, however, secondary metabolite predictions would likely benefit from additional predictors and per-target pipeline fits.

Performance was task-dependent, for **time-to-completion,** the RF pipeline is recommended as it

achieved the lowest mean CV error and highest robustness to split variation, although the ANN pipeline was competitive when sufficient training data was available (≥70:30). For **ethanol,** again the RF pipeline is the primary recommendation, as it achieved the lowest mean CV MAE with stable generalisation and the RF at the 80:20 split compared to the ANN achievd nearer-zero bias, with weaker temperature and must-strength dependence. For **acetate,** if robustness to split variations with competitive mean accuracy is the priority, the ANN is recommended. However, at the least data limited regime (80:20) the ANN exhibited lower accuracy and a wider error distribution than SVR, with stronger temperature and MS dependence. Therefore, if accuracy under high data availability is the priority, SVR is preferred due to lower mean ARE at the 80:20 split, a tighter error distribution and weaker MS/temperature dependence. For **secondary metabolites,** the per-target SVR models was both most accurate and most robust pipeline, highlighting the value of fitting separate models for targets with heterogeneous signal strength. Higher alcohols and associated acetate esters were highly learnable ($R^2$ ≥0.75), whereas several ethyl esters and medium-chain fatty acids remained weakly predicted, consistent with missing predictors such as lipids/fatty-acids.

Key methodological refinements for future work include, defining a quantitative fermentation endpoint, calculating and predicting ethanol yield (final–initial) to isolate production, adopting task-specific feature selection, expanding the secondary-metabolite feature space (Lysine, Proline, Ornithine, lipids/fatty acids), and increasing the GA search budget. Finally, we believe the recommended pipelines could be embedded in an optimisation framework to support industry and, to our knowledge, the present work was the first to train an machine learning models on a time-varying temperature regime in wine manufacturing.

## ABSTRACT

Ensuring reliable operations of modern power systems under uncertainty remains a key challenge, particularly due to the non-convex nature of Alternating Current (AC) power flow equations and the presence of high-impact disturbances from load and renewable generation fluctuations. In this work, we address the robust AC Optimal Power Flow (AC OPF) problem by developing a robust spatial branch-and-bound (RsBB) algorithm. Robustness is achieved by identifying worst-case uncertainty realizations and iteratively incorporating robust cuts to eliminate constraint violations. To accelerate convergence and tighten bounds, Optimization-Based Bound Tightening (OBBT) and Feasibility-Based Bound Tightening (FBBT) techniques are integrated into the framework. The proposed method yields global robust solutions with certified optimality gaps below 0.01% across standard PGLib test cases.

**Keywords**: Nonconvex Robust Optimization, AC OPF, Cutting planes, Bound Tightening, Uncertainty, Global Optimization

## INTRODUCTION

The AC optimal power flow (ACOPF) problem is a fundamental tool in power-system operations, computing minimum cost dispatch subject to power balance equations and network limits (e.g., voltage and thermal constraints) [1]. In practice, ACOPF is often solved deterministically using forecasts of demand and renewable injections. With the growing penetration of wind and solar, forecast errors can be substantial, so a deterministic operating point may violate constraints in real time (e.g., line overloads or voltage excursions) [2, 3]. Such violations jeopardize security and reliability and may push the system outside its secure operating limits. This motivates robust OPF formulations that remain feasible for all realizations of uncertainty within a prescribed set [4].

Existing OPF methods address uncertainty mainly via: (i) stochastic programming, which optimizes over sampled scenarios but can become computationally prohibitive as the number of scenarios grows, and is sensitive to scenario-generation and reduction errors [5, 6]; (ii) chance-constrained and distributionally robust chance-constrained models, which provide probabilistic security but typically rely on DC approximations or convex relaxations to gain tractability, thereby sacrificing exact AC feasibility and certifiable global optimality for the original nonconvex AC OPF [7, 8]; and (iii) robust optimization, which enforces feasibility for all uncertainty realizations, but in AC settings is still predominantly relaxation-based (SOCP/SDP/DC or convex restrictions), leading to conservatism and again losing guarantees of global optimality and exact AC feasibility [9-11].

Despite this progress, to the best of our knowledge there is still no method that simultaneously guarantees (a) robust feasibility for all values in a continuous uncertainty set and (b) certifiable global optimality for the full nonconvex ACOPF. Prior approaches either relax the AC physics or robustness to obtain tractability, or provide only scenario-based or probabilistic guarantees that do not cover the entire uncertainty set. This gap motivates the development of global-optimization framework tailored to robust ACOPF.

Such framework draws on several complementary lines of work. In semi-infinite global optimization, restriction and outer-approximation ideas provide a principled way to enforce constraints over continuous parameter domains [12]. In nonlinear robust optimization, generalized cutting-set procedures similarly generate many worst-case scenarios to certify feasibility over uncertainty sets [13]. On the algorithmic side, global solvers rely on systematic strengthening methods, including convex underestimators for trigonometric nonlinearities

[14] and optimality-based domain reduction to contract variable bounds during the search [15]. Complementing these methodological advances, recent power-system studies demonstrate that tailored global/MINLP strategies can be made effective at scale, e.g., for security-constrained unit commitment [16]. Together with broader developments in global optimization for MINLP [17], these ingredients provide the foundation for our robust spatial branch-and-cut approach for certifiable global robust ACOPF.

In this paper, we build on our previous work [18] and present a framework to globally solve the robust ACOPF via bound tightening and robust spatial branch-and-cut. The main contributions are as follows:

- BT–RsBB for global robust ACOPF: a robust spatial branch-and-cut scheme that iteratively refines convex relaxations while branching over the nonconvex region, converging to a globally robust optimal solution.
- Integrated bound tightening: a combination of optimization-based bound tightening (OBBT) and feasibility-based bound tightening (FBBT), where FBBT is applied within OBBT iterations to strengthen relaxations and shrink the search space at low overhead.
- Efficient trigonometric relaxations: an improved relaxation strategy that leverages precomputed sine-envelope parameters to rapidly generate tight linear relaxations of trigonometric constraints during the search.
- Parallel cut generation: concurrent generation of multiple cutting planes at nodes with uncertainty violations, improving node relaxations and accelerating pruning of robust-infeasible regions.

The remainder of the paper is organized as follows. Section **II** presents the ACOPF formulation and the relaxations used in the global algorithm. Section **III** details the robust spatial branch-and-cut procedure, including infeasibility testing, branching, cut generation, and bound tightening. Section **IV** reports numerical results and comparisons. Section **V** concludes.

# PROBLEM FORMULATION

## Deterministic AC-OPF (Polar Formulation)

We consider the standard AC optimal power flow (ACOPF) in polar coordinates, where each bus $k \in \mathcal{B}$ has voltage magnitude $V_k$and phase angle $\theta_k$, and each generator $i \in \mathcal{G}$ controls real and reactive outputs $(P_i^g, Q_i^g)$. Let $(P_{km}, Q_{km})$ denote the sending-end real/reactive line flows on branch $(k,m) \in \mathcal{L}$ , with line parameters $(G_{km}, B_{km}, B_{km}^c)$[19]. The deterministic ACOPF minimizes a quadratic generation cost subject to (i) nodal real/reactive power balance (eq. 1b – 1c), (ii) voltage and generator operating limits (eq. 1d – 1f), (iii) nonlinear AC power-flow relations in polar form (eq. 1g), (iv) angle-difference bounds (eq. 1h), and (v) apparent-power (thermal) limits (eq. 1i). For compactness, we refer the interested read for the full formulation in [19-22], and succinctly present the problem below:

$$\min \quad \sum_{i\in\mathcal{G}} \left(c_{2i}(P_i^g)^2 + c_{1i}P_i^g + c_{0i}\right) \tag{1a}$$

$$\text{s.t.} \quad \sum_{i\in\mathcal{G}(k)} P_i^g - P_k^d - G_s V_k^2 = \sum_{km\in\mathcal{L}^+(k)} P_{km} + \sum_{km\in\mathcal{L}^-(k)} P_{mk}, \forall k \in \mathcal{B} \tag{1b}$$

$$\sum_{i\in\mathcal{G}(k)} Q_i^g - Q_k^d + B_s V_k^2 = \sum_{km\in\mathcal{L}^+(k)} Q_{km} + \sum_{km\in\mathcal{L}^-(k)} Q_{mk}, \forall k \in \mathcal{B} \tag{1c}$$

$$\underline{V}_k \le |V_k| \le \bar{V}_k, \forall k \in \mathcal{B} \tag{1d}$$

$$\underline{P}_i \le P_i^g \le \bar{P}_i, \forall i \in \mathcal{G} \tag{1e}$$

$$\underline{Q}_i \le Q_i^g \le \bar{Q}_i, \forall i \in \mathcal{G} \tag{1f}$$

$$c_{km} = V_k V_m cos(\theta_k - \theta_m), \forall (k,m) \in \mathcal{L} \tag{1g.1}$$

$$s_{km} = V_k V_m sin(\theta_k - \theta_m), \forall (k,m) \in \mathcal{L}$$

$$P_{km} = G_{km} V_k^2 - G_{km} c_{km} - B_{km} s_{km}, \forall (k,m) \in \mathcal{L} \tag{1g.2}$$

$$Q_{km} = -(B_{km} + B_{km}^c) V_k^2 - G_{km} s_{km} + B_{km} c_{km}, \forall (k,m) \in \mathcal{L} \tag{1g.3}$$

$$P_{mk} = G_{km} V_m^2 - G_{km} c_{km} + B_{km} s_{km}, \forall (k,m) \in \mathcal{L} \tag{1g.4}$$

$$Q_{mk} = -(B_{km} + B_{km}^c) V_m^2 + G_{km} s_{km} + B_{km} c_{km}, \forall (k,m) \in \mathcal{L} \tag{1g.5}$$

$$\theta_k - \theta_m \in [\underline{\theta}_{km}, \bar{\theta}_{km}], \forall (k,m) \in \mathcal{L} \tag{1h}$$

$$P_{km}^2 + Q_{km}^2 \le (\bar{S}_{km})^2, \forall (k,m) \in \mathcal{L} \tag{1i.1}$$

$$P_{mk}^2 + Q_{mk}^2 \le (\bar{S}_{km})^2, \forall (k,m) \in \mathcal{L} \tag{1i.2}$$

Note that, a reference angle constraint $\theta_{\text{ref}} = 0$ is imposed to ensure uniqueness of the polar representation [23].

## Convex Relaxations for Global Optimization

We employ convex relaxations to provide valid lower

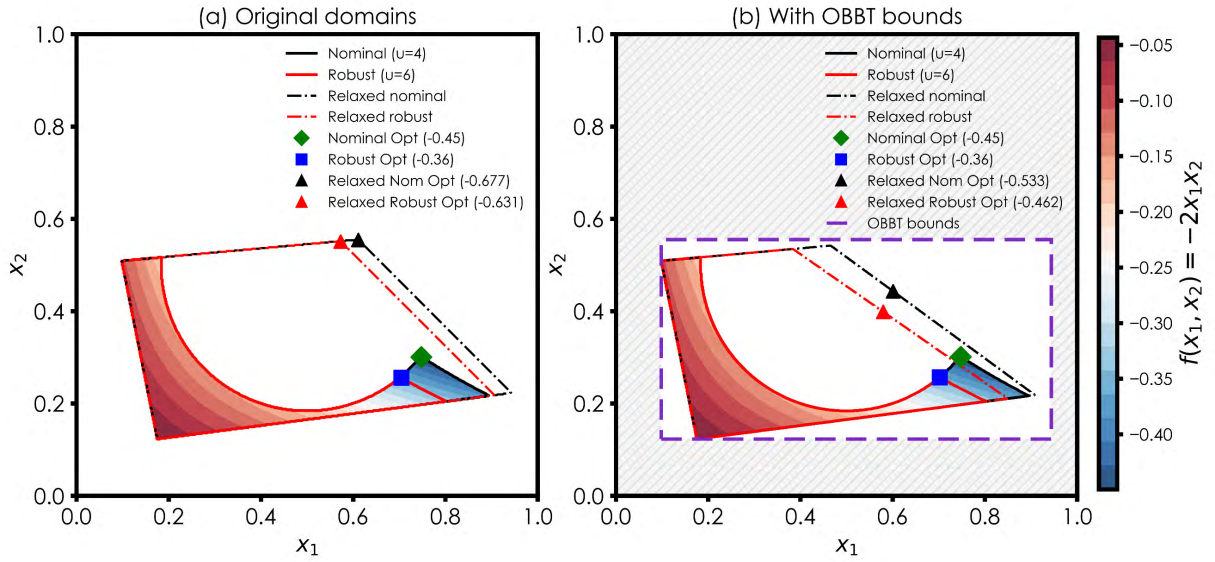

**Figure 1.** Illustration of the relationship between robust optimization and bound tightening: (a) original domains showing the nominal and robust feasible regions; (b) reduced domains after bound tightening, where the shaded region indicates the eliminated search space.

bounds within branch-and-bound. We adopt a quadratic-convex (QC) relaxation of the polar ACOPF [20, 22, 24]. The key idea is to lift the nonconvex bilinear and trigonometric terms and replace them with convex envelopes. In particular, we introduce lifted variables:

$$V_{km} \approx V_k V_m, V_{kk} \approx V_k^2, \cos_{km} \approx \cos(\theta_{km}) \tag{2}$$

$$\sin_{km} \approx \sin(\theta_{km}), \theta_{km} := \theta_k - \theta_m \tag{3}$$

We further define $\beta_{km}$ and $\gamma_{km}$ to represent the lifted products $V_{km}\cos_{km}$ and $V_{km}\sin_{km}$, respectively. Each lifted relation is relaxed using: (i) McCormick envelopes for bilinear products, (ii) convex quadratic envelopes for $V_k^2$, and (iii) convex/concave envelopes for $\sin(\cdot)$ and $\cos(\cdot)$ over the phase angle difference interval $\theta_{km} \in [\theta_{km}^l, \theta_{km}^u]$. Collectively, these constraints define a relaxation set $\mathcal{E}_{\mathrm{MC/QC}}(V^l, V^u, \theta^l, \theta^u)$. To further tighten the QC relaxation, we include a standard second-order cone (SOC) constraint

$$\beta_{km}^2 + \gamma_{km}^2 \le V_{kk} V_{mm}, (k,m) \in \mathcal{L} \tag{4}$$

which couples the lifted terms and strengthens the QC bound.

## Improved Trigonometric Relaxation

The tightness of the QC relaxation is often dominated by the quality of the envelopes related to the trigonometric functions present. Instead of a single generic sine envelope, we use a tighter piecewise outer approximation of $\sin(\theta)$ over $[\theta_{km}^l, \theta_{km}^u]$ that adapts to the interval sign pattern. Let the secant and tangent (supporting) lines be:

$$f^{\sec}(\theta^l, \theta^u) := \left(\frac{\sin(\theta^u) - \sin(\theta^l)}{\theta^u - \theta^l}\right)(\theta - \theta^l) + \sin(\theta^l) \tag{5}$$

$$f^{\tan}(t) := \sin(t) + \cos(t)(\theta - t) \tag{6}$$

If the interval does not cross zero, the global convexity/concavity of $\sin(\cdot)$ yields a strong two-sided envelope. If $\theta_{km}^l < 0 < \theta_{km}^u$, we combine a secant with a small set of tangent supports (e.g., at an endpoint and a midpoint on each active side) to obtain a strictly tighter polyhedral outer approximation:

$$\begin{aligned} \sin_{km} &\le f^{\sec}(\theta_{km}^l, \theta_{km}^u), \\ \sin_{km} &\ge \max\{ f^{\tan}(t) : t \in T_{km} \} \end{aligned} \tag{7}$$

(or the symmetric variant with reversed inequalities, depending on the interval regime). For efficiency within RsBB, the tangent locations $T_{km}$ and any regime-dependent transition parameters are precomputed and stored; during branching and bounds tightening, only the active constraints for the detected region are enforced, while interval bounds are updated via mutable parameters. This construction yields tighter node relaxations and accelerates convergence by reducing feasible domains and strengthening lower bounds.

# ROBUST OPTIMIZATION METHODOLOGY

We consider the original nonconvex robust optimization problem

**Table 1**: Quality and runtime results of robust ACOPF (optimality gaps are expressed in %). Results are obtained under a 1% perturbation. Times are CPU seconds. For BT–RsBB, the reported time is shown as the summation of bound-tightening time and subsequent RsBB time. IR denotes the improved relaxation and RR denotes the reference relaxation.

$$\min_{x\in\mathcal{X}} f(x) \ \text{s.t.}\, g(x,u)\le 0, \forall u\in\mathcal{U}, \tag{8}$$

where $x$ denotes the decision variables, $\mathcal{X}$ is a bounded feasible region, $u$ is an uncertain parameter lying in a prescribed uncertainty set $\mathcal{U}$, and $g(\cdot,\cdot)$ collects the uncertain constraints. Since global solution of (8) is challenging for nonconvex models, we adopt the robust spatial branch-and-bound (RsBB) framework in [25], which provides finite convergence to a globally robust optimal solution under standard regularity assumptions (boundedness, continuity, and tractability of the inner maximization).

## RsBB Framework: Master Problems and Infeasibility Test

At each spatial branch-and-bound node, RsBB maintains: (i) a nonconvex master problem that enforces robustness over a current finite subset of uncertainty realizations, and (ii) a convex relaxation that yields valid lower bounds. Specifically, for a cutting-set $\hat{\mathcal{U}}\subseteq\mathcal{U}$, the node master is

$$(P_{\text{nonc}})\ \min_{x\in\mathcal{X}} f(x) \ \text{s.t.}\, g(x,u)\le 0, \forall u\in\hat{\mathcal{U}}, \tag{9}$$

whose robust-feasible solutions provide incumbents (upper bounds). Next, we solve a convex relaxation

$$(P_{\text{conv}})\ \min_{x\in\mathcal{X}} f_{\text{conv}}(x) \ \text{s.t.}\, g_{\text{conv}}(x,u)\le 0, \forall u\in\hat{\mathcal{U}}, \tag{10}$$

where $f_{\text{conv}}$ and $g_{\text{conv}}$ are convex relaxations of $f$ and $g$. The optimal value of $P_{\text{conv}}$ is a valid node lower bound, and the global lower bound is the minimum across open nodes, as in standard spatial B&B [25].

Robust feasibility of a candidate $x^*$ from $P_{\text{nonc}}$ is checked by an infeasibility test (inner maximization)

$$(P_{\text{it}})\ \max_{u\in\mathcal{U}} g(x^*,u), \tag{11}$$

which returns a worst-case realization $u^*$. If $g(x^*,u^*)>\varepsilon_{\text{it}}$, then $x^*$ is not robustly feasible and the violating scenario $u^*$ is added to $\hat{\mathcal{U}}$ (equivalently, we append the cut $g(x,u^*)\le 0$ to both $P_{\text{nonc}}$ and $P_{\text{conv}}$ at the node). This cutting-set loop is repeated until no violation is found (within $\varepsilon_{\text{it}}$), after which the resulting $x^*$ is robust-feasible over $\mathcal{U}$ up to tolerance. The outer spatial branching loop guarantees global optimality by maintaining valid bounds and partitioning variable domains; full algorithmic details and convergence arguments follow [25].

## Uncertainty in AC OPF

In this work, uncertainty enters through bus

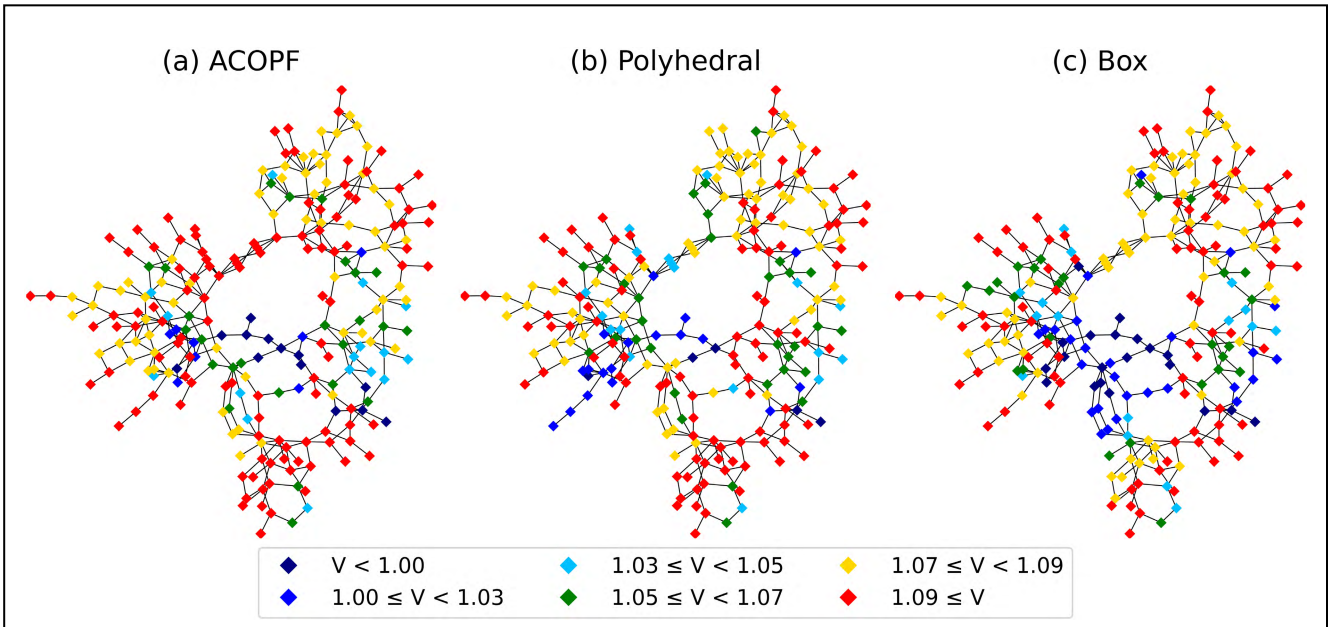

**Figure 2.** Voltage magnitude profiles for case240_pserc: (a) nominal ACOPF solution without uncertainty, (b) robust ACOPF under polyhedral uncertainty, and (c) robust ACOPF under box uncertainty, obtained by BT–RsBB with the improved relaxation. Bus colors indicate voltage bins (p.u).

demands. Let $(P^d_{k,\text{nom}}, Q^d_{k,\text{nom}})$ be nominal loads and define

$$\tilde{P}^d_k = (1+\xi_k)P^d_{k,\text{nom}},\ \tilde{Q}^d_k = (1+\xi_k)Q^d_{k,\text{nom}}, \xi \in \mathcal{U}. \qquad (9)$$

We consider standard convex uncertainty sets, either a box $\mathcal{U}_{\text{box}} = \{\xi : |\xi_k| \le \Psi_k, \forall k\}$, or a budgeted polyhedral set $\mathcal{U}_{\text{poly}} = \{\xi : |\xi_k| \le \Psi_k, \forall k, \sum_{k\in\mathcal{B}} |\xi_k| \le \Gamma\}$. Robustness is enforced by replacing the (deterministic) active/reactive power-balance equalities in (1) with robust constraints $\forall \xi \in \mathcal{U}$, and update violated constraints via $P_{it}$ as described above. In our implementation, the inner maximization is solved using the current candidate operating point $(P^{g*}, Q^{g*}, V^*, \theta^*, \dots)$, and any violating realization $\xi^*$ generates a cut corresponding to the power-balance constraint at $\xi^*$.

## Bounds Tightening

To accelerate RsBB on the nonconvex AC OPF, we apply bound tightening to strengthen relaxations without materially increasing model size. As shown in Figure. 1, tightening contracts the variable domains and removes portions of the search space that cannot contain feasible solutions, thereby improve relaxation strength and reduce the need for branching. We use:

- **Feasibility-based bound tightening (FBBT):** inexpensive constraint propagation applied to the relaxation to remove infeasible portions of variable domains.
- **Optimization-based bound tightening (OBBT):** stronger tightening obtained by solving auxiliary minimization/maximization subproblems over the current convex relaxation to contract selected variable bounds (here, primarily $V_k$ and $\theta_{km}$).

FBBT is applied as preprocessing and after OBBT to propagate improvements through the constraint set. The resulting tighter bounds improve the quality of QC relaxations, reduce branching, and speed up convergence of the robust global algorithm.

# NUMERICAL RESULTS

We evaluate the proposed robust ACOPF framework on benchmark networks and study three factors: (i) the effect of uncertainty set choice (nominal vs. box vs. polyhedral), (ii) the impact of bound tightening (RsBB vs. BT–RsBB), and (iii) the benefit of the improved trigonometric relaxation relative to a reference sine relaxation.

## Test Cases and Computational Setting

Experiments are conducted on 17 test cases from PGLib-OPF [26] with fewer than 500 buses. Active and reactive demands are perturbed by $\xi_k \in [-0.01, 0.01]$ (1% level). We consider box $\mathcal{U}_{box} = \{\xi : |\xi_k| \le \Psi_k, \forall k\}$ and polyhedral set $\mathcal{U}_{\text{poly}} = \{\xi : |\xi_k| \le \Psi_k, \forall k, \sum_{k\in\mathcal{B}} |\xi_k| \le \Gamma\}$, and also report the deterministic nominal case. All models are implemented in Pyomo 6.9.2 (Python 3.10.18). Nonconvex NLP sub-problems are solved with IPOPT (tolerance $10^{-8}$). The infeasibility test uses $\varepsilon_{\text{it}} = 10^{-4}$, and RsBB termination/fathoming uses a global relative tolerance $\varepsilon = 10^{-4}$. Bound tightening uses a hybrid FBBT + OBBT procedure with $\varepsilon_{\text{bt}} = 10^{-2}$ and at most 10 iterations; OBBT subproblems are run in parallel on 16 cores. Each RsBB

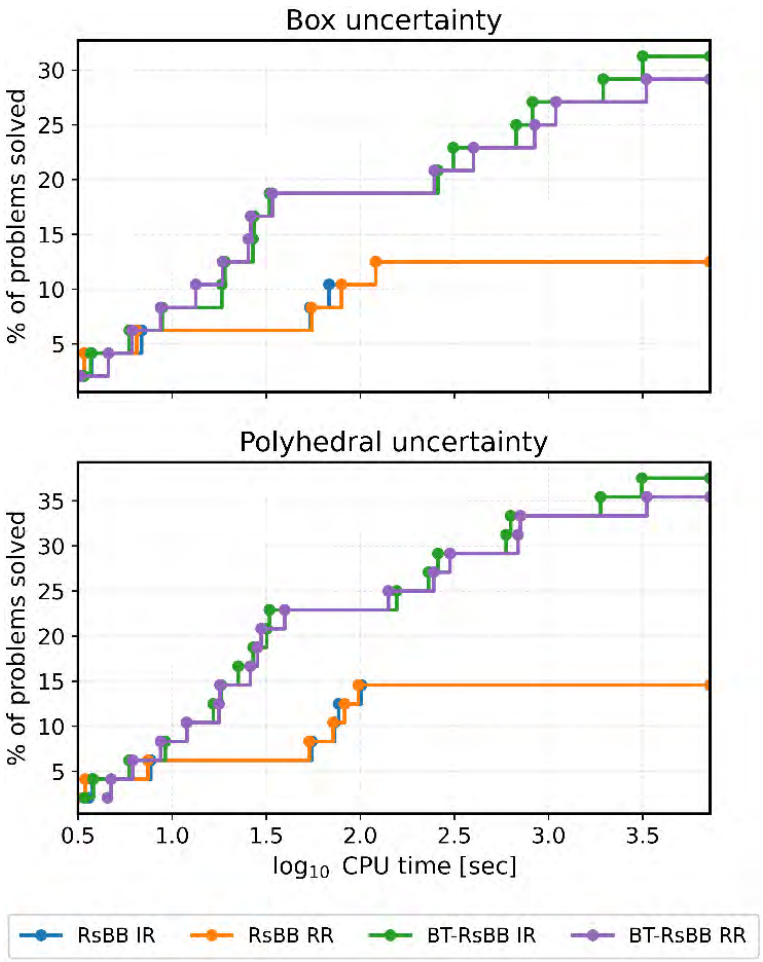

**Figure 3.** Percentage of instances certified within a given CPU time (log-scale) under a 2h time limit (7200 s). Curves compare RsBB vs. BT–RsBB with the improved relaxation (IR) and the reference relaxation (RR).

run has a 2 h time limit. Experiments are executed on a Windows workstation (Intel Core Ultra 7, 32GB).

## Robust Operating Points and Computational Tractability

**Table 1** reports robust AC OPF benchmark results under a $1\%$ demand perturbation ($\xi = 0.01$) for both box and polyhedral uncertainty sets. For each test case, we compare RsBB against BT–RsBB (with FBBT+OBBT), and we also compare the improved relaxation (IR) with the reference relaxation (RR). Reported gaps are relative robust optimality gaps (in %), and times are CPU seconds (stopped at the 2h limit).

Overall, BT–RsBB consistently yields smaller gaps and/or more solved instances within the time limit than pure RsBB, confirming that bound tightening strengthens the relaxations and reduces the required branching effort. Across both uncertainty sets, IR tends to achieve smaller final gaps than RR for comparable runtimes, or reaches similar gaps faster, indicating that tighter trigonometric envelopes improve lower bounds and accelerate convergence. Finally, polyhedral uncertainty is generally easier than box uncertainty, since the budgeted structure is less conservative and typically produces weaker worst-case violations, leading to a smaller and faster global search.

**Figure 2** illustrates the voltage magnitude profile for case240_pserc under: (a) nominal ACOPF, (b) polyhedral robustness, and (c) box robustness (BT–RsBB with the improved relaxation). Compared with the nominal dispatch, robust solutions reshape the voltage profile to preserve feasibility under demand deviations. The box robust solution is visibly more conservative than the polyhedral one, consistent with the fact that $\mathcal{U}_{\text{box}}$ allows simultaneous worst-case deviations at all buses, while $\mathcal{U}_{\text{poly}}$ limits the deviation via a budget $\Gamma$.

**Figure 3** reports empirical solve-rate curves (fraction of instances certified globally optimal within a given CPU time, log-scale) for RsBB and BT–RsBB under both uncertainty sets, using either the improved relaxation (IR)

or the reference relaxation (RR).

Three trends are consistent across the benchmark suite:

- **Bound tightening is the main accelerator.** BT–RsBB solves substantially more instances than baseline RsBB within the 2 h limit. Tightened bounds shrink the search space and strengthen node relaxations, leading to fewer branch-and-bound nodes and faster gap closure.
- I**mproved trigonometric relaxation provides additional speedups.** IR yields systematically faster convergence than RR, reflecting tighter lower bounds and reduced relaxation error in the lifted sine/cosine constraints. The effect is moderate on the log-time plot but corresponds to noticeable reductions in wall-clock time on solved cases.
- **Polyhedral uncertainty is less conservative and easier computationally than box uncertainty.** Under Upoly, more instances are certified within the time limit. The budget constraint limits extremal scenarios, typically requiring fewer robust cuts and producing smaller search trees than the harsher Ubox setting. Overall, the numerical results indicate that combining RsBB with hybrid bound tightening is critical for scalability on robust ACOPF, while tighter trigonometric envelopes further improve performance. The choice of uncertainty set strongly affects both conservatism and computational difficulty, with box uncertainty being the most demanding.

## CONCLUSION

In this paper, we developed an enhanced BT–RsBB framework to compute globally robust optimal solutions for nonconvex ACOPF under uncertainty. Building on the RsBB methodology, we improve practical efficiency via (i) parallel robust-cut generation in the infeasibility test, (ii) a hybrid bound-tightening module combining FBBT and OBBT, and (iii) a tighter trigonometric relaxation based on a precomputed mapping that strengthens node relaxations without substantially increasing model size.

We evaluate the method on 48 PGLib-OPF benchmark networks under three operating conditions (TYP, API, SAD) with both box and budgeted polyhedral uncertainty sets. The results show that BT–RsBB consistently outperforms baseline RsBB: bound tightening significantly contracts variable domains, strengthens relaxations, and accelerates robust gap closure, yielding more certified solutions within a two-hour limit. The improved sine relaxation further reduces runtimes by tightening lower bounds and decreasing the number of explored nodes.

The study also reveals strong sensitivity to operating conditions and uncertainty set geometry. Box uncertainty is systematically more conservative—and typically harder—than polyhedral uncertainty because it permits simultaneous worst-case deviations at all buses. Overall, our results provide a rigorous global benchmark for robust ACOPF with certified bounds and transparent convergence behaviour. Future work will target scalability through adaptive bound tightening, stronger branching and range-reduction strategies, and learning-based acceleration for cut selection, node selection, and relaxation refinement.

## ABSTRACT

Mathematical models are increasingly used in pharmaceutical process development within quality-by-design (QbD) frameworks to reduce experimental effort and enable rational process design. However, model validation is still often based on deterministic performance indicators, which do not explicitly account for experimental variability, measurement noise, and model uncertainty. This work proposes an uncertainty-aware framework for model validation in pharmaceutical processes that quantifies predictive reliability in probabilistic terms, consistent with regulatory concepts. The framework explicitly integrates uncertainty in operating conditions, measurements, and model parameters, and evaluates model performance based on the probability that prediction satisfy predefined acceptance criteria rather than on single-point accuracy indicators. An in-silico case study of crystallization was performed to demonstrate the approach, where synthetic experimental data with controlled uncertainty were generated. This enables systematic assessment of the effect of data quality, data quantity, and methods of uncertainty analysis on model validity results. Overall, the proposed framework provides a structured and robust approach for uncertainty-aware, regulatory-aligned model validation in pharmaceutical process development.

**Keywords**: Process Design, Design Under Uncertainty, Industry 4.0, Jacobian, Modelling and Simulations

## INTRODCUTION

The increasing use of mechanistic, data-driven, and hybrid models in pharmaceutical process development reflects a broader shift toward model-based decision-making within quality-by-design (QbD) frameworks. Process models are increasingly used for process scale-up and design space exploration, contributing to significant reductions in experimental effort while enabling deeper process understanding [1]. From a regulatory perspective, however, model credibility and suitability must be systematically assessed in order to support risk-informed decision-making [2].

Since uncertainty plays a central role in process development, many process systems engineering studies have focused on uncertainty analysis and stochastic simulation. For example, Geremia et al. presented robust design spaces that capture the effects of process uncertainties on drug product quality [3], and Pessina et al. proposed a Bayesian framework for parametric uncertainty quantification in nonlinear protein crystallization models [4]. These studies primarily emphasize prediction of expected variability in product quality, rather than model credibility assessment.

Despite these advances, model validation in practice is still often based on deterministic goodness-of-fit metrics such as the coefficient of determination or the root mean square error. While these metrics quantify agreement between model predictions and experimental data, they do not explicitly account for experimental variability, measurement uncertainty, or uncertainty in model structure and parameters. Although Barhate et al. assessed the robustness of estimated parameters in crystallization by comparing parametric uncertainty with measurement uncertainty [5], model robustness and reliability remain difficult to quantify in a generalized manner. This gap limits the ability to perform risk-informed, context-dependent assessment of model credibility.

In this work, we present an uncertainty-aware model validation framework for pharmaceutical process development. An in-silico case study of cooling crystallization was used to demonstrate the approach, where

synthetic experimental datasets with controlled operational and measurement uncertainty were generated using a population balance model (PBM). By considering scenarios with different uncertainty levels and different amounts of experimental data, multiple validation criteria and model uncertainty quantification approaches were compared to assess the influence of data quality, data quantity, and uncertainty treatment on validation outcomes. The objective is to provide a structured and transparent methodology for uncertainty-aware, regulatory-aligned model validation in pharmaceutical process development.

## PROPOSED METHODOLOGY

### In-silico experimental data generation

Two sources of experimental variability were considered in the in-silico experiments. The first source is "operational variability" ($\varepsilon_{\mathrm{ope}}$), which represents deviations between nominal setpoints and actual process conditions. The second source is "measurement variability" ($\varepsilon_{\mathrm{meas}}$), which combines sampling effects and measurement errors. In this in-silico study, the function $f_{\mathrm{GT}}$ is treated as a ground-truth process model. The true response $\boldsymbol{y}_{\mathrm{true}}$ is defined as the noise-free outputs of $f_{\mathrm{GT}}$, whereas the observed response $\boldsymbol{Y}_{\mathrm{meas}}$ denotes a synthetic observable generated from this model with imposed variability.

The true values and the observed values are defined as :

$$\boldsymbol{y}_{\mathrm{true}} = f_{\mathrm{GT}}(\boldsymbol{x}, \theta) \tag{1}$$

$$\boldsymbol{Y}_{\mathrm{obs}} = f_{\mathrm{GT}}\left(\boldsymbol{x} + \varepsilon_{\mathrm{ope}}\boldsymbol{x}, \theta\right) + \varepsilon_{\mathrm{meas}} \tag{2}$$

where $\boldsymbol{x}$ and $\theta$ denote nominal operating conditions and model parameters, respectively.

### Uncertainty-conscious predictions

After parameter estimation yielding $\hat{\theta}$ of the predictive model $f_{\mathrm{pred}}$, quality attributes can be predicted with uncertainty. Here, uncertainty is categorized into "parametric uncertainty" ($\varepsilon_{\theta}$) and "experimental variability" ($\varepsilon_{\mathrm{exp}}$). Model predictions are denoted by the parametric predicted values $\boldsymbol{Y}_{\mathrm{pred,par}}$ and the full predicted values $\boldsymbol{Y}_{\mathrm{pred,full}}$, corresponding to parametric uncertainty only and combined parametric and experimental uncertainty, respectively.

$$\boldsymbol{Y}_{\mathrm{pred,par}} = f_{\mathrm{pred}}\left(\boldsymbol{x}, \hat{\theta} + \varepsilon_{\theta}\right) \tag{3}$$

$$\boldsymbol{Y}_{\mathrm{pred,full}} = f_{\mathrm{pred}}\left(\boldsymbol{x}, \hat{\theta} + \varepsilon_{\theta}\right) + \varepsilon_{\mathrm{exp}} \tag{4}$$

### Parametric uncertainty quantification

As summarized in the literature [6, 7], several approaches exist to quantify parametric uncertainty, which differ in terms of their assumptions, computational cost, and the extent to which they explore the parameter space. These approaches can be categorized into derivative-based methods and sampling-based methods.

Derivate-based methods approximate uncertainty locally around the estimated parameter vector $\hat{\theta}$. The Jacobian-based approach is the most common and relies on a first-order linearization of the residual function, which may lead to underestimation of uncertainty for strongly nonlinear models. The Hessian-based approach incorporates second-order curvature information of the objective function. For derivate-based methods, accurate parameter estimation is critical, as the covariance is computed locally around $\hat{\theta}$.

In contrast, sampling-based approaches aim to characterize uncertainty more globally by repeatedly refitting the model to resampled datasets (e.g., bootstrap) or by sampling from a parameter distribution consistent with the data (e.g., Markov Chain Monte Carlo). These methods are generally more robust to nonlinearity and multimodality [4] but are computationally expensive. In this study, Jacobian- and Hessian-based covariance approximations were employed due to their computational efficiency within the proposed validation framework.

### Regulatory-aligned model validation metrics

#### Threshold-based validation approach

US Food and Drug Administration (FDA) has proposed a "threshold-based" acceptance criterion for medical-device submissions to assess whether a model produces results that are sufficiently reliable from a safety standpoint [8]. This approach validates the closeness between simulation and experimental results relative to a safety threshold $y_{\mathrm{th}}$. The comparison error $E$ and the proximity $\Omega$ are computed for attribute $i$ as:

$$E^{(i)} = \left|Y^{(i)}_{\mathrm{pred,par}} - Y^{(i)}_{\mathrm{obs}}\right| \tag{5}$$

$$\Omega^{(i)} = \left|y^{(i)}_{\mathrm{th}} - Y^{(i)}_{\mathrm{pred,par}}\right| \tag{6}$$

where a probability distribution of $Y^{(i)}_{\mathrm{obs}}$ is generated based on experimental data $y^{(i)}_{\mathrm{obs}}$ and $\varepsilon^{(i)}_{\mathrm{exp}}$. The model is considered validated if i) $\mathbb{E}[E] < \mathbb{E}[\Omega]$ and ii) the confidence intervals (CIs) of $E$ and $\Omega$ do not overlap.

For general model validation, the safety threshold can be extended to acceptable prediction errors relative to experimental data. Using a predefined tolerance $\varepsilon^{(i)}_{\mathrm{th}}$, the threshold $y^{(i)}_{\mathrm{th}}$ is defined as $\left(1 \pm \varepsilon^{(i)}_{\mathrm{th}}\right) \bullet y^{(i)}_{\mathrm{obs}}$. Since this yields two-sided thresholds, the proximity is extended to $\Omega_{\mathrm{lower}}$ and $\Omega_{\mathrm{upper}}$.

#### Model reliability assessment

Alternatively, model reliability under uncertainty is assessed as illustrated in Figure 1. A reliable model

**Table 1:** In-silico DoE used for parameter estimation and validation.

| Purpose | Seed fraction [%] | Cooling rate [K s$^{-1}$] | Seed size [μm] | # of experiments |
|---|---|---|---|---|
| Parameter estimation | {0, 1.0} | {0.002, 0.008} | 60 (if seeded) | 4 |
| Experimental variability | 0.5 | 0.004 | 60 | 3 |
| Interpolating validation | {0.25, 0.75} | {0.003, 0.006} | 60 | 4 |
| Extrapolating validation | {0.5, 1.5} | {0.001, 0.0015, 0.004, 0.010} | {50, 60, 70} | 6 |

should exhibit a small deviation between $\boldsymbol{y}_{\text{true}}$ and $\mathbb{E}[\boldsymbol{Y}_{\text{pred,par}}]$ and a small statistical distance between the distributions of $\boldsymbol{Y}_{\text{obs}}$ and $\boldsymbol{Y}_{\text{pred,full}}$. Since neither $\boldsymbol{y}_{\text{true}}$ nor distributions of $\boldsymbol{Y}_{\text{obs}}$ is known in practice, reliability metrics are introduced to estimate model confidence.

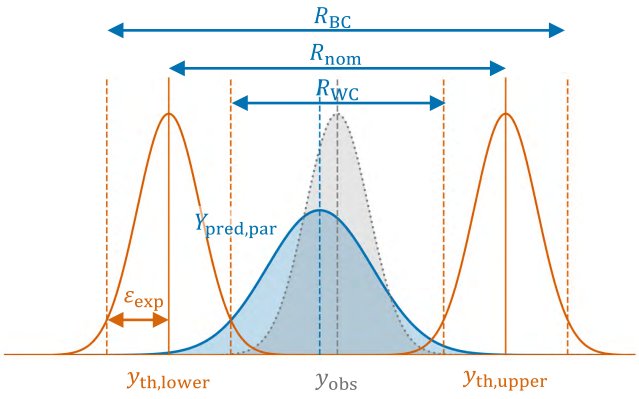

**Figure 1.** Concept of reliability scores based on (a) $\boldsymbol{Y}_{\text{pred,par}}$ and (b) $\boldsymbol{Y}_{\text{pred,full}}$.

First, predictions with parametric uncertainty $Y^{(i)}_{\text{pred,par}}$ are compared against thresholds (Figure 1(a)). The nominal reliability score $R_{\text{nom}}$ is defined as:

$$R^{(i)}_{\text{nom}} = \mathbb{P}\left(y^{(i)}_{\text{th,lower}} \le Y^{(i)}_{\text{pred,par}} \le y^{(i)}_{\text{th,upper}}\right) \quad (7)$$

To incorporate experimental variability, worst-case $R_{\text{WC}}$ and best-case reliability scores $R_{\text{BC}}$ are defined as:

$$R^{(i)}_{\text{WC}} = \mathbb{P}\left(y^{(i)}_{\text{th,lower}} + \varepsilon^{(i)}_{\text{exp}} \le Y^{(i)}_{\text{pred,par}} \le y^{(i)}_{\text{th,upper}} - \varepsilon^{(i)}_{\text{exp}}\right) \quad (8)$$

$$R^{(i)}_{\text{BC}} = \mathbb{P}\left(y^{(i)}_{\text{th,lower}} - \varepsilon^{(i)}_{\text{exp}} \le Y^{(i)}_{\text{pred,par}} \le y^{(i)}_{\text{th,upper}} + \varepsilon^{(i)}_{\text{exp}}\right) \quad (9)$$

While $R_{\text{WC}}$ cannot be high when experimental variability is large, $R_{\text{BC}}$ should be sufficiently high; otherwise $\boldsymbol{Y}_{\text{pred,par}}$ deviates substantially from $\boldsymbol{y}_{\text{true}}$ or parametric uncertainty is excessive.

An alternative reliability score $R_{\text{unc}}$ is described based on $\boldsymbol{Y}_{\text{pred,full}}$ (Figure 1(b)) as:

$$R^{(i)}_{\text{unc}} = \mathbb{P}\left(y^{(i)}_{\text{th,lower}} \le Y^{(i)}_{\text{pred,full}} \le y^{(i)}_{\text{th,upper}}\right) \quad (10)$$

## CASE STUDY DESCRIPTION

To demonstrate the proposed validation framework, a case study was conducted using cooling crystallization of paracetamol. Both the experimental conditions and the true values of model parameters were defined based on literature data [9].

### Model description

A one-dimensional population balance model (PBM) was used for synthetic experimental data generation, parameter estimation, and model validation. In this case study, the same PBM formulation was employed as both $f_{\text{GT}}$ and $f_{\text{pred}}$. The number density of crystals of size $L$, denoted by $n(L)$, was described by considering crystal growth, primary nucleation, and secondary nucleation:

$$\frac{\partial n(L)}{\partial t} + \frac{\partial [Gn(L)]}{\partial t} = \left[B_{\text{p}} + B_{\text{s}}\right] \cdot \delta(L - L_{\text{n}}) \quad (12)$$

where $\delta$ is a Dirac delta function and $L_{\text{n}}$ is the nuclei size.

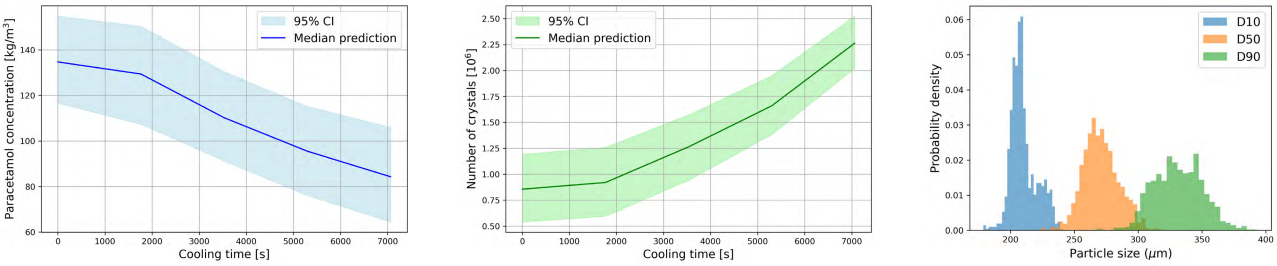
The growth rate $G$, the primary nucleation rate $B_{\text{p}}$, and the secondary nucleation rate $B_{\text{s}}$ are defined as:

$$G = k_{\text{g}}\sigma^{g}\exp\left(-\frac{E_{\text{A}}}{RT_{\text{K}}}\right) \quad (13)$$

$$B_{\text{p}} = k_{\text{p}}\sigma^{p} \quad (14)$$

$$B_{\text{s}} = k_{\text{s}}\sigma^{s}A_{\text{c}} \quad (15)$$

where $\sigma$ is the relative supersaturation, $R$ is the gas constant, $T_{\text{K}}$ is the temperature, $A_{\text{c}}$ is the specific surface area of crystals. The seven model parameters



(a) (b) (c)

**Figure 2.** In-silico experimental data wih uncertainty at the centerpoint. (a) paracetamol concentration profile with 95% CIs, (b) crystal number profile with CIs, (c) probability densities of $D_{10}$, $D_{50}$, and $D_{90}$ of the final products.

$k_g, g, E_A, k_p, p, k_s$, and $s$ were estimated. All computational work was performed using PharmaPy, an open-source tool for the digital pharmaceutical process design [10].

## In-silico design of experiments (DoE)

Table 1 summarizes the in-silico DoE used to generate synthetic experimental data, using the ground truth model. Two-level full factorial experiments in seed fraction and cooling rate were performed for parameter estimation, with three additional repeated runs at the center point to assess experimental variability. Two sets of validation runs were designed: four interpolating conditions and six extrapolating conditions. In the extrapolating conditions, seed size was also varied as an additional factor. Variability terms $\varepsilon_{ope}^{(fra)}, \varepsilon_{ope}^{(cl)}$, and $\varepsilon_{ope}^{(size)}$ were assigned to seed fraction, cooling rate, and seed size, respectively.

During the in-silico experiments, both the paracetamol concentration and the total number of crystals were recorded at five normalized time points corresponding to 0, 0.25, 0.5, 0.75, and 1 times the total cooling duration, with measurement variabilities $\varepsilon_{meas}^{(conc)}$ and $\varepsilon_{meas}^{(num)}$. After completion of each experiment, product size quantiles $D_{10}, D_{50}$, and $D_{90}$ were also generated, with associated measurement variabilities $\varepsilon_{meas}^{(D10)}, \varepsilon_{meas}^{(D50)}$, and $\varepsilon_{meas}^{(D90)}$.

# CASE STUDY RESULTS

The generated measured values $\boldsymbol{Y}_{obs}$ at the center point of the operating conditions are shown in Figure 2. Normal distributions were assumed for all variability terms. The standard deviations of operating variabilities were set to 5% for $\varepsilon_{ope}^{(fra)}, \varepsilon_{ope}^{(cl)}$, and $\varepsilon_{ope}^{(size)}$, while the standard deviations of measurements variabilities were defined as $\sigma\left(\varepsilon_{meas}^{(conc)}, \varepsilon_{meas}^{(num)}, \varepsilon_{meas}^{(D10)}, \varepsilon_{meas}^{(D50)}, \varepsilon_{meas}^{(D90)}\right)$ = (10 kg m$^{-3}$, $10^5$, 3 μm, 5 μm, 8 μm).

## Parametric uncertainty results

Parameter estimation was performed by minimizing a weighted least-squares objective function constructed from all available in-silico observations. To account for differences in magnitude and measurement reliability among these quantities, the weighting factors were defined based on the inverse of the experimental variability observed from the three repeated center-point runs.

**Table 2:** Estimated model parameters and 95% CIs using Jacobian and Hessian matrices.

| Parameter | Estimated value | CI (Jacobian) | CI (Hessian) |
|---|---|---|---|
| $k_g$ [$10^4$m s$^{-1}$] | 2.92 | [2.91, 2.92] | [2.71, 3.13] |
| $g$ [-] | 1.24 | [1.24, 1.24] | [0.98, 1.50] |
| $E_A$ [kJ mol$^{-1}$] | 63.2 | [63.1, 63.4] | [62.6, 63.8] |
| $k_p$ [$10^5$m$^{-3}$ s$^{-1}$] | 4.84 | [4.83, 4.85] | [3.56, 6.12] |
| $p$ [-] | 2.61 | [2.60, 2.61] | [2.25, 2.97] |
| $k_s$ [$10^4$m$^{-2}$ s$^{-1}$] | 10.2 | [10.2, 10.2] | [10.0, 10.4] |
| $s$ [-] | 1.86 | [1.86, 1.86] | [1.61, 2.11] |

After parameter estimation, covariance matrices were computed using both the Jacobian and Hessian approximations. The resulting 95% CIs are summarized in Table 2. The Jacobian-based approach produced very narrow CIs, all within 0.5% of the estimated values. In contrast, the Hessian-based approach yielded substantially wider CIs, ranging from 0.9 and 26.5% of the estimated values, reflecting the nonlinear sensitivity of the model parameters.

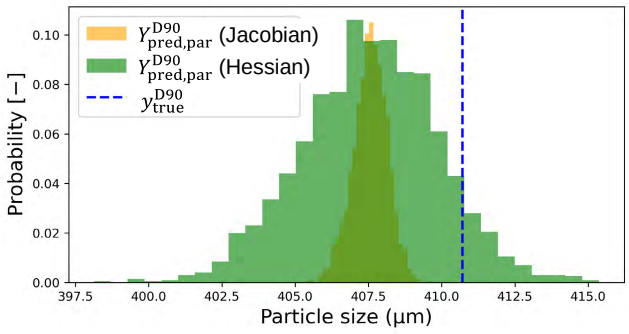
## In-silico validation experiments

At the validation conditions summarized in Table 1, both $\boldsymbol{y}_{true}$ and $\boldsymbol{Y}_{obs}$ were generated. Among the quality attributes, $D_{90}$ was selected as the most critical attribute, and a relative tolerance of $\varepsilon_{th}^{(D90)}$=15% was applied.

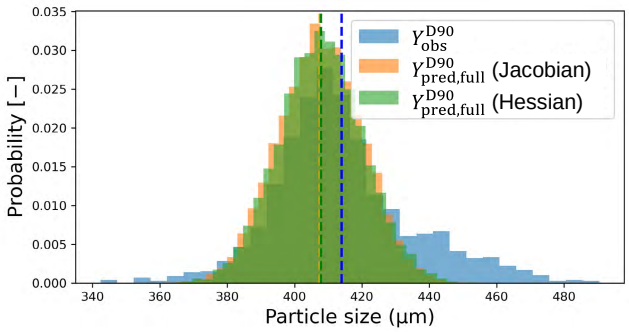
Figure 3(a) shows the probability density functions of $Y_{pred,par}^{(D90)}$ for one representative validation condition. The expected value $\mathbb{E}\left(Y_{pred,par}^{(D90)}\right)$ was very close to $y_{true}^{(D90)}$, with a relative error of 0.8%. However, the Jacobian-based $Y_{pred,par}^{(D90)}$ did not cover $y_{true}^{(D90)}$, whereas $y_{true}^{(D90)}$ fell within the support of the Hessian-based $Y_{pred,par}^{(D90)}$. Similar

trends were observed in eight out of ten validation runs, indicating that the Jacobian approximation systematically underestimates parametric uncertainty.

The probability density functions of $Y_{\text{pred,full}}^{(\text{D90})}$, shown in Figure 3(b), were very similar for the Jacobian- and the Hessian-based approaches. This occurs because experimental variability dominates over parametric uncertainty for this attribute. Compared to $Y_{\text{pred,full}}^{(\text{D90})}$, the distribution of $Y_{\text{obs}}^{(\text{D90})}$ exhibited a broader distribution with weak bimodality. This discrepancy is attributed to underestimation of experimental variability and to the assumption of normally distributed noise.



(a)



(b)

**Figure 3.** Probability density distributions of $D_{90}$ at a validation run: (a) $y_{\text{true}}$ and $\boldsymbol{Y}_{\text{pred,par}}$; (b) $\boldsymbol{Y}_{\text{obs}}$ and $\boldsymbol{Y}_{\text{pred,full}}$.

## Validation metrics

For validation, it was assumed that only a single experimental observation $y_{\text{obs}}^{(\text{D90})}$, sampled from $Y_{\text{obs}}^{(\text{D90})}$, is available per validation condition, reflecting typical experimental practice. This observation was compared against the Hessian-based $Y_{\text{pred,par}}^{(\text{D90})}$ using the proposed validation metrics.

To assess the effect of experimental replication, three independent in-silico observations were generated per validation condition and their mean was used for validation, with the effective experimental variability $\varepsilon_{\text{exp}}$ estimated separately for each condition rather than from center-point repeats.

Using the threshold-based approach, six out of ten validation conditions satisfied the validation criteria. Most failures were associated with large uncertainty in the comparison error $E^{(\text{D90})}$, which was primarily driven by experimental variability. When the mean of three repeated measurements was used for each condition, the number of validated conditions decreased to five, indicating that the validation outcome changed only marginally with replication in this dataset.

Table 3 summarizes the results of different validation metrics, including conventional deterministic metrics: the coefficient of determination ($R^2$), root mean square error ($RMSE$), and mean absolute percentage error ($MAPE$). Both deterministic and uncertainty-aware metrics changed with the number of samples; however, the interpretation may differ. The deterministic metrics are directly affected by experimental variability, meaning that validation conclusions based on unrepeated experiments can be strongly influenced by random experimental noise, making rational decision-making challenging.

**Table 3:** Summary of different validation metrics using a single sample and the mean of three repeated runs per condition.

| Metrics | Single sample | Three samples |
|---|---|---|
| $R^2$ [-] | 0.9066 | 0.9616 |
| $RMSE$ [µm] | 19.75 | 13.35 |
| $MAPE$ [%] | 5.65 | 3.98 |
| $\mathbb{E}\left(R_{\text{nom}}^{(\text{D90})}\right)$ [%] | 91.54 | 100 |
| $\mathbb{E}\left(R_{\text{WC}}^{(\text{D90})}\right)$ [%] | 61.04 | 81.14 |
| $\mathbb{E}\left(R_{\text{BC}}^{(\text{D90})}\right)$ [%] | 100 | 100 |
| $\mathbb{E}\left(R_{\text{unc}}^{(\text{D90})}\right)$ [%] | 91.29 | 98.38 |

In contrast, the proposed validation metrics could provide additional diagnostic insight into both model validity and data quality. The best-case reliability $R_{\text{BC}}^{(\text{D90})}$ remained at 100% across all cases, which is important because it avoids rejecting model validity solely due to large experimental variability. The worst-case reliability $R_{\text{WC}}^{(\text{D90})}$ was relatively low when only a single observation per condition was available. This indicates that there remains a non-negligible risk that the model could be incorrect, because a single noisy observation cannot reliably distinguish model mismatch from experimental scatter. When the mean of three repeated measurements was used, $R_{\text{WC}}^{(\text{D90})}$ increased, reducing the risk of an incorrect model conclusion. In this case, $R_{\text{WC}}^{(\text{D90})}$ acts as a conservative indicator of the remaining model risk under uncertainty.

Overall, these results highlight how uncertainty-aware validation metrics can improve interpretability of

model credibility and provide a structured way to assess the impact of experimental variability and replication on validation outcomes.

## CONCLUSIONS

This work presented an uncertainty-aware framework for model validation in pharmaceutical process development from a regulatory perspective. By distinguishing between parametric uncertainty and experimental variability, the framework enables probabilistic rather than purely deterministic validation. The proposed reliability-based metrics extend traditional goodness-of-fit measures by quantifying the likelihood that predictions satisfy predefined acceptance criteria under uncertainty. An in-silico crystallization case study demonstrated how uncertainty quantification methods, experimental design, and replication influence validation outcomes. The results highlight limitations of local linear uncertainty approximations and the need to account for experimental variability when interpreting validation results.

Future work will focus on broader application of the framework across pharmaceutical unit operations, such as reactions and wet milling, as well as its application to real experimental datasets. Further development will also address systematic treatment of structural model uncertainty and improved characterization of experimental variability, including non-Gaussian noise and correlated disturbances. Ultimately, extending the framework toward integrated consideration of model, parameter, and experimental uncertainties can support transparent, risk-informed, and regulatorily aligned use of process models throughout pharmaceutical development and scale-up.

## ABSTRACT

Traditional centralised manufacturing offers efficient economies and broad market reach but faces increasing limitations with the rise of complex products requiring rapid localised delivery and greater supply chain resilience. The logistics demands of hospital-compounded therapies expose vulnerabilities in existing infrastructure, accentuating the need for rigorous evaluation of alternative paradigms. This study investigates the comparative performance of centralised and decentralised pharmaceutical manufacturing models, applying an agent-based simulation framework designed for specialised or time-sensitive drug product orders. The work implements an agent-based simulation to model both centralised and decentralised scenarios using key structural, resource, and demand parameters identified within the supply chain ecosystem. Comparison criteria include labour requirements, sustainability (as measured by environmental emissions and operational efficiency), and end-to-end supply chain lead times, informed by the geospatial distribution of manufacturers, hospitals, and clinics. The centralised case considers a single facility supplying major hospitals and several clinics from a designated hub, while the decentralised case models multiple smaller production sites supplying care centres more directly. Demand frequency, emergency inventory buffers, personnel allocations, and practical constraints are explicitly built into the simulation inputs. Preliminary simulation results reveal trade-offs between manufacturing paradigms across multiple performance dimensions. The decentralised model shows potential advantages in reducing supply chain lead times and improving responsiveness to localised demand surges, while the centralised model demonstrates efficiency gains in resource utilisation under steady-state conditions. The framework enables quantitative comparison of throughput, cost implications, delivery timeliness, and system resilience under varied operational scenarios. These findings will inform strategic design decisions for patient-centric and resilient pharmaceutical supply chains, facilitating adoption of flexible models capable of meeting modern healthcare delivery needs within the medicines manufacturing and supply ecosystem.

## INTRODUCTION

Pharmaceutical supply chains are increasingly exposed to operational fragility, as demonstrated by recent global disruptions that have propagated rapidly through tightly coupled and inventory-lean networks. These failures highlight a structural dependence on centralised manufacturing architectures, where long replenishment paths and limited buffering capacity amplify the risk of shortages. [1-6].

Although decentralised and point-of-care manufacturing models are frequently proposed as a means of improving responsiveness and reducing logistical delays, existing literature provides limited quantitative

comparison of these paradigms under realistic demand and operational conditions. In particular, there is no systematic, simulation-based evaluation of how centralised and decentralised architectures differ in inventory behaviour, coverage performance, responsiveness, and environmental impact across multiple supply-chain echelons [7-9].

An increasingly prominent part of this discussion concerns the shift from batch based centralised production to decentralised or point of care (POC) manufacturing models, enabled by advanced processing technologies. Decentralised pharmaceutical manufacturing has attracted growing attention due to its potential to reduce transport delays, shorten replenishment lead times, and enable agile response to localised demand surges. Analyses across cell and gene therapy, monoclonal antibody production, and specialised medicines have highlighted those decentralised architectures, when underpinned by modern technologies, may achieve superior responsiveness and greater operational flexibility relative to traditional centralised paradigms [6, 10, 11].

This study addresses this gap by developing a multi-tier agent-based simulation of a representative pharmaceutical supply chain in Scotland. Two contrasting manufacturing configurations, a single large centralised plant and a set of smaller decentralised plants, are evaluated under identical downstream network structures. The model enables direct comparison of echelon-specific performance across inventory, service coverage, responsiveness, and emissions. The results provide an evidence-based assessment of trade-offs between efficiency, resilience, and sustainability across alternative manufacturing paradigms [6, 7, 9, 11].

# METHODOLOGY

## Pharmaceutical manufacturing paradigm Assessment

The pharmaceutical supply chain examined in this study (Figure 1) consists of four primary tiers: manufacturers, hospitals, clinics, and end consumers. The flow of products and information follows a demand-driven structure, where downstream demand signals propagate upstream to guide production and replenishment decisions. This pharmaceutical supply chain problem characterized by its structural configuration, connectivity among actors, and the policies and rules of engagement governing material and information flows, can be formulated as below:

Given

- Structure and connectivity between nodes, determining flow paths and network robustness.
- Policies and rules of engagement governing ordering, replenishment, and allocation.
- Emission rate associated with manufacturing activities.
- Demand variation arising from end consumers.

## Evaluate

- Holding inventory as a cost indicator.
- Inventory coverage ratio showcasing the responsiveness of the system to meet demand reliably
- Emission levels as a measure of environmental impact generated by manufacturing segment

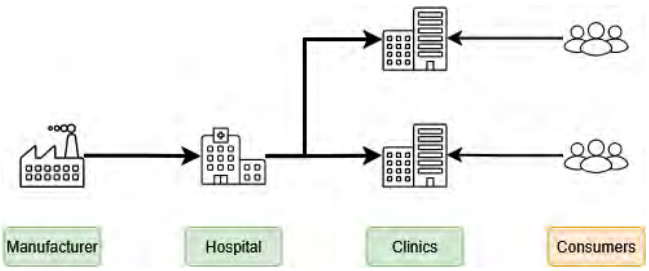

**Figure 1.** Conceptual model of the pharmaceutical supply chain.

## Multi-Scale Agent-Based Model

The model, illustrated in Figure 2, is built on a foundational agent structure that is shared across all supply-chain entities (Figure 2-Top left). The application-level system built in the AnyLogic software (ver. 8.7.9), involves four primary agent types: manufacturer, distributor, health centre, and consumer, each instantiated from the same base agent template. As shown in Figure 2 (Top right), every agent in the logistic chain contains three core state variables: backlog, inventory, and a demand forecast, following system dynamic formulations reported in prior studies [12, 13]. Downstream demand is estimated using a first-order exponential smoothing process, and this forecast directly determines the agent's next order quantity. A set of behavioural parameters governs how each agent manages its inventory and backlog dynamics, shaping responsiveness and replenishment behaviour.

Interaction among agents occurs through order placement and shipment receipt, implemented via message-passing mechanisms that accommodate diverse ordering frequencies across tiers. Each agent type follows its own inventory policy, reflecting its position in the supply chain and influencing ordering decisions. To capture the logistics layer, the model incorporates explicit shipping and fleet components that represent transportation processes, queueing, and shipment delays, enabling a realistic depiction of material flows throughout the network.

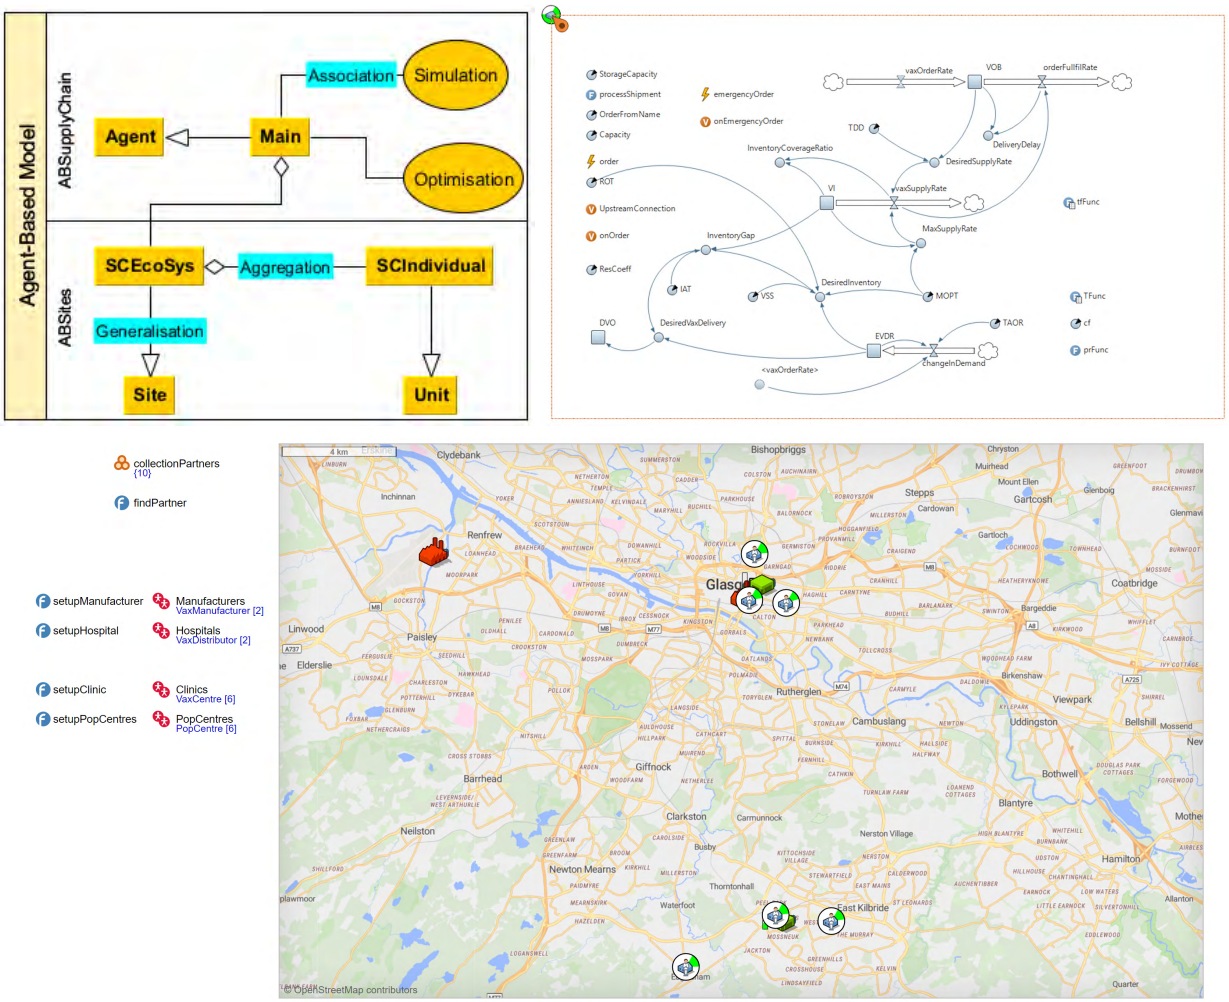

**Figure 2.** (Top left) The foundational representation of agent-based model (Top right) Dynamic agent behaviour representation (Bottom) Simulation model for Greater Glasgow pharmaceutical supply chain.

To represent the geographical distribution of supply chain entities, the model incorporates Geographic Information System (GIS) capabilities available within AnyLogic. These tools allow the spatial layout of manufacturers, distributors, and health centres to be embedded directly into the simulation environment, ensuring that distances, travel paths, and regional clustering are reflected in the system's behaviour. By linking agent locations to real or stylised geographic coordinates, the model captures spatial dependencies that influence shipment times, fleet utilisation, and overall logistics performance. This spatial layer complements the behavioural and structural components of the base model, enabling a more realistic depiction of how geography shapes SC dynamics.

The model uses a compact set of input data describing demand behaviour, operational policies, manufacturing capabilities, logistics characteristics, and sustainability factors. Demand inputs define the average and variable requirements of hospitals and clinics; operational inputs specify ordering rules, replenishment timings, and transport delays; manufacturing inputs capture production rates and process characteristics for both centralised and decentralised plants; and sustainability inputs include the emission factors associated with each manufacturing technology. Together, these inputs provide a consistent basis for comparing the two manufacturing paradigms under equivalent conditions.

## Case study

The case study focuses on a pharmaceutical supply chain located in Scotland, modelled using two alternative manufacturing paradigms: a centralised configuration with a single large production plant, and a decentralised configuration with two smaller plants. In both scenarios, the downstream structure remains identical, consisting of two hospitals, six health centres, and six consumer centres. The overall supply-chain layout follows the structure

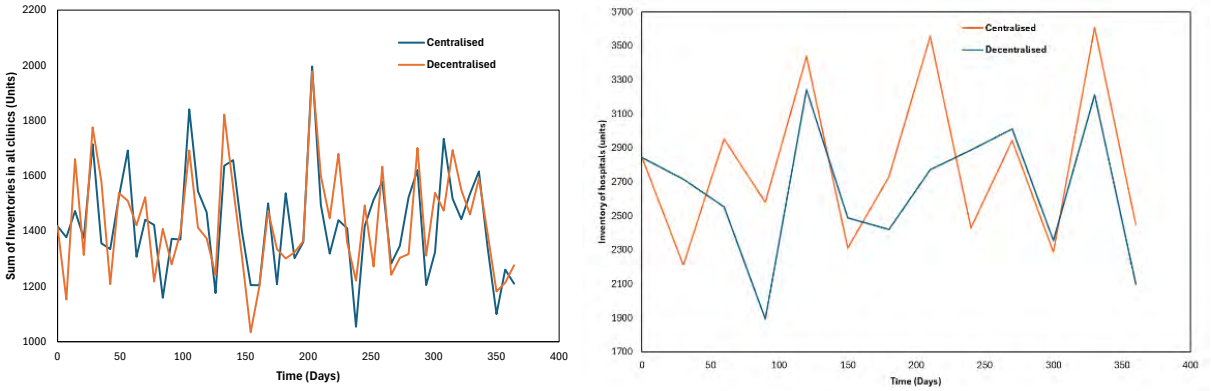

**Figure 3:** (left) Sum of inventory units in all clinics, and (right) Inventory of hospitals (Glasgow Royal Infirmary and Haimyres) in centralised and decentralised cases.

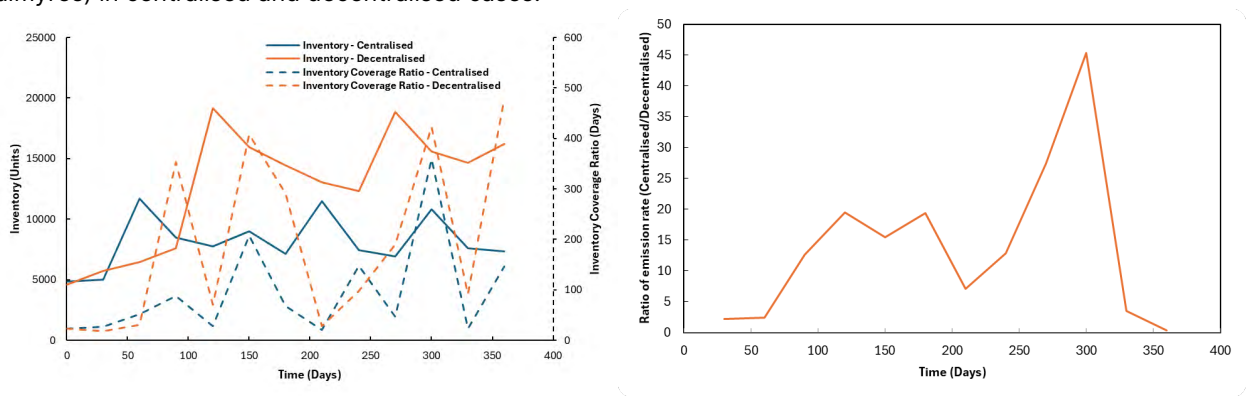

**Figure 4:** (left) Inventory units and inventory coverage ratio in centralised and decentralised cases, and (right) Ratio of emission rate of centralised over decentralised manufacturing cases.

reported in du Plessis, van Vuuren [14]. Under the centralised paradigm, hospitals place orders directly with the large plant, whereas in the decentralised paradigm each hospital orders from its corresponding small plant. Operational and logistical parameters for all tiers, as well as demand-variation characteristics, are taken from du Plessis, van Vuuren [14], ensuring behavioural realism. Emission parameters for manufacturing activities are also drawn from Hindiyeh, Altalafha [15] to capture sustainability impacts accurately. All agent locations in the model reflect their actual geographic coordinates, enabling spatially realistic routing, travel distances, and logistics performance within the Scottish context.

## RESULTS AND DISCUSSION

The simulation outcomes reveal a structured set of performance differences between the centralised and decentralised pharmaceutical manufacturing paradigms. Performance differences emerge because clinics, hospitals, and manufacturers operate under distinct replenishment cycles, buffering rules, and demand-propagation dynamics. These structural differences cause each echelon to respond uniquely to changes in manufacturing configuration, leading to divergent inventory and coverage behaviours across the network. The analysis therefore demands a tiered interpretation rather than a monolithic comparison.

## CLINIC LEVEL PERFORMANCE

Figure 3-Left shows the sum of all inventories at the clinic level in the centralised and decentralised cases. At the outermost tier (the six clinics) the two manufacturing architectures display no substantive divergence in overall inventory behaviour or service attainment. Although the decentralised system occasionally offers marginally tighter control of coverage during transient spikes, the broader simulation horizon demonstrates that clinics ultimately experience comparable stock levels and service stability under both paradigms. This is consistent with the observation that clinic level performance is heavily buffered by upstream nodes in the centralised case, while in the decentralised case it is moderated by shorter replenishment paths rather than by increased local inventory. Although decentralised manufacturing shortens physical

delivery distances, clinic-level performance remains comparable across both scenarios because clinics are heavily buffered by upstream inventory. In the centralised case, hospitals carry larger safety stocks to compensate for longer replenishment paths, while in the decentralised case shorter delivery routes offset lower upstream inventory. These opposing mechanisms result in similar clinic-level stability despite architectural differences.

## Hospital Level Inventory

A more differentiated behaviour emerges at the hospital tier, where the simulation tracks the aggregated inventory of Glasgow Royal Infirmary and Hairmyres Hospital. The results show that the centralised scenario consistently yields slightly higher combined hospital inventories (Figure 3 - Right). While the magnitude of this increase is modest, its operational implications are not. Hospitals, as high cost stockholding environments, are disproportionately affected by incremental increases in buffer requirements. The elevated stock levels observed under the centralised architecture arise from the longer replenishment lead times from a single remote hub, compelling hospitals to hold additional safety stock. In contrast, under the decentralised configuration, more responsive resupply from CMAC and NMIS enables hospitals to operate with leaner inventory profiles, thereby reducing their holding cost burden.

## Manufacturing Level Inventory

Figure 4-Left shows the inventory and coverage ratio over time for the manufacturers in the centralised (MMIC) and decentralised (CMAC + NMIS) cases. It can be seen that for the majority of the period considered, the decentralised case sees a higher total inventory (and therefore coverage ratio) maintained. This reflects the potential for greater fluctuations in order size in the decentralised case as a result of interactions between the larger number of participants. In the centralised case, the manufacturer is required to meet the demand of each hospital and so maintains an inventory sufficient to fulfil this requirement. In the decentralised case, each manufacturer could receive orders from either hospital, and does not know the orders placed to the order manufacturer. As a result, larger inventories are maintained as a means of ensuring resilience against downstream demand shocks. This effect is representative of a fundamental supply chain principle: the loss of risk pooling when production is divided across multiple smaller facilities. Each decentralised site must individually buffer against local variability, leading to a structurally heavier stock profile. The centralised facility, by contrast, benefits from statistically aggregated demand and can therefore operate more efficiently with lower safety stock requirements. Accordingly, while decentralisation may offer logistical and resilience benefits (as discussed below), it does so at the cost of increased working capital and reduced inventory efficiency at the manufacturing tier.

## Coverage Ratios and Responsiveness

Despite its higher manufacturing inventory, the decentralised system exhibits stronger inventory coverage ratios, particularly during demand intensification periods. This reflects the inherent advantage of shorter physical and operational distances between production and consumption nodes. In practice, the decentralised units can respond more promptly to emergent demand fluctuations, thereby mitigating the risk of stockouts despite their smaller individual production capacity. This does not, however, translate into dramatically superior outcomes at the clinic tier (as previously noted), because the centralised system compensates through largescale throughput capability. Nevertheless, the decentralised architecture clearly delivers greater temporal responsiveness, and this confers a form of operational resilience that is particularly relevant for time sensitive or specialist pharmaceutical products.

## Sustainability Metrics

Figure 4-Right shows the ratio of emissions in the centralised and decentralised cases. It can be seen that for the majority of the period considered, the centralised emissions are significantly greater than for the decentralised case. This is a result of the improved technologies used, but the variation in this ratio over time also shows a story of changing production rates. Spikes in the emissions ratios correspond to instances where centralised manufacturing increases in response to a low coverage ratio (see Figure 4-Left) whilst dips correspond to the inverse case with increased decentralised manufacturing.

This behaviour mirrors the technological assumptions embedded in the model: MMIC represents a traditional batch-based facility with correspondingly high emissions intensive cycles, whereas CMAC and NMIS operate small manufacturing processes with materially lower per unit emissions. The data confirms that even when emissions from both decentralised sites are combined, total environmental impact remains substantially below the centralised equivalent. This establishes that decentralisation provides a robust and widening sustainability advantage, conditional on the adoption of advanced continuous technologies rather than scaled-down legacy batch operations.

Beyond emissions, the manufacturing tier labour burden could also be compared across centralised and decentralised architectures, since site level carbon footprints can be translated into indicative fulltime equivalent (FTE) requirements using established energy and process intensity correlations. This linkage provides an

additional operational lens, suggesting that lower emission continuous manufacturing sites may also exhibit reduced labour intensity relative to traditional batch-based facilities of equivalent throughput.

### Synthesis and Implications

The findings reveal that the comparative merits of centralised and decentralised manufacturing are multidimensional and echelon specific. The centralised architecture optimises inventory efficiency, while the decentralised architecture optimises responsiveness and sustainability. For strategic planning, this implies that pharmaceutical supply chains must prioritise between cost efficiency, resilience, and environmental performance, recognising that these objectives are not simultaneously maximised by any single configuration.

The results show that centralised manufacturing benefits from statistical risk pooling, which reduces total manufacturer-level inventory and stabilises upstream stock levels. This efficiency, however, comes at the cost of longer replenishment paths that require hospitals to maintain higher safety stocks and accept slower response during demand surges.

Decentralised manufacturing exhibits the opposite behaviour. Shorter transport distances and geographically distributed production enable faster recovery from demand spikes, as reflected by higher coverage ratios during high-demand periods. This responsiveness is complemented by significantly lower emissions due to continuous manufacturing technologies used at decentralised sites.

These patterns confirm that no single architecture is universally optimal. Centralisation minimises inventory, decentralisation maximises responsiveness and sustainability, and each performance dimension emerges from structural features of the network rather than parameter tuning alone.

## CONCLUSIONS

This study demonstrates that the comparative performance of centralised and decentralised pharmaceutical manufacturing is echelon dependent rather than monolithic. At the periphery of the network (the clinics) both architectures converge to broadly similar service outcomes, indicating that geographical proximity alone does not yield decisive gains in routine delivery performance. At the hospital tier, the centralised configuration imposes a modest but persistent inventory uplift relative to the decentralised case, implying a higher holding cost burden in an inherently expensive stockkeeping environment. The effect is operationally material despite its limited magnitude and is consistent with longer replenishment paths from a single remote hub. At the manufacturing tier, the trade-off reverses. Decentralisation raises total upstream inventory, particularly pronounced at individual sites, reflecting the expected loss of risk pooling when capacity is fragmented across multiple smaller facilities. This escalates working capital requirements even as it improves responsiveness.

Critically, decentralisation delivers stronger inventory coverage ratios and greater temporal responsiveness during demand intensification, strengthening resilience against localised shortages. However, this advantage does not translate into a dramatic superiority at the clinic level, because the centralised system offsets through high throughput.

The environmental signal is unambiguous. The ratio of emissions intensity (centralised/decentralised) remains above unity throughout and increases as the simulation progresses, establishing a clear and widening sustainability advantage for decentralised production, conditional on the adoption of modern continuous processes rather than scaled down legacy batch operations.

There is no single dominant architecture. Centralisation minimises aggregate inventory via pooling, while decentralisation optimises responsiveness and sustainability. Strategic design must therefore be explicit about priorities: cost efficiency (inventory), resilience (coverage and surge handling), or environmental performance. A balanced network strategy may combine a limited number of advanced, decentralised nodes to secure responsiveness and carbon performance, while retaining selected centralised capabilities to preserve pooling efficiency, were economically critical.

The results should be interpreted within the bounds of the modelled demand cycles and behavioural rules. Extending the analysis to alternative demand regimes, richer disruption scenarios, and technology pathways would further illuminate design envelopes where hybrid architectures outperform either extreme. Incorporating explicit costings for transport, quality systems, and regulatory overheads across sites would allow a fuller economic assessment to complement the inventory, coverage, and emissions metrics reported here.

## ABSTRACT

The objective of this work is to investigate strategies for the calibration of crystallization models aimed at predicting particle size distributions (PSDs) of active pharmaceutical ingredients (APIs) when using industrial datasets, which are limited in terms of number or information for the modeling exercise. In this work, the calibration task relies on two kinds of measurements, commonly performed in industrial crystallization practice: offline measurements of PSDs and API solute concentration carried out only at the beginning and at the end of experiments, and online measurements of chord length distributions (CLDs). Particularly, a strategy is proposed to use CLDs data from focused beam reflectance measurement (FBRM) probes as proxies of the PSD, which is the main key performance indicator for the model exercise. Industrial data concerning a seeded batch cooling recrystallization of an API in an organic solvent are used as a case study. The PharmaPy process simulator is used for parameter estimation and process simulation. Results demonstrate that, with proper data processing and feature extraction, all parameters can be estimated with sufficient precision. The model performance is satisfactory for most of the batch duration, even though some shortcomings highlight possible limitations in the data and/or in the model itself. From the industrial perspective, results pave the way for a quantitative usage of FBRM probes to enhance process understanding and to guide process development and scale-up.

**Keywords**: Pharmaceuticals, Crystallization, Population Balances, Modelling, Parameter estimation

## INTRODUCTION

Crystallization is a key step in the downstream manufacturing of active pharmaceutical ingredients (APIs), since it is responsible for the isolation of the target compound as a stable solid phase. It has a huge impact on the final product's critical quality attributes (CQAs), which are mainly related to purity and size distribution of the obtained particles [1]. Models can be employed to predict such CQAs based on system properties and operating conditions, allowing for simulation, optimization and scale-up of crystallization unit operations. In this way, the application of model-based approaches can represent an answer to the increasing demand in research efficiency and quality assurance in pharmaceutical process design and setup [2].

A variety of phenomena can influence the evolution of crystal size distribution (CSD) during a crystallization process: nucleation and growth are typically the main ones, but also breakage and agglomeration of particles can occur. Whether each of these phenomena is triggered, and the mechanism according to which it may develop, depend on many different factors, e.g. the way and the rate at which the driving force is generated, the operation history, the equipment geometry and mixing, etc.

Population balance models (PBMs), combined with momentum, mass and energy balances, may allow for a comprehensive description of the crystallization process [3]. They are founded on the knowledge of the physics of the system, preserving interpretability and demanding less information to be calibrated with respect to data-driven alternatives. Moreover, they are more suitable to use such information, typically retrievable from

laboratory scale, to represent crystallizers at the industrial scale. For this reason, they are a very common and powerful tool for crystallization modelling [4].

Still, the calibration of PBMs is a non-trivial task, and often relies on multiple experiments characterized by different operating conditions, with measurements of particle size distribution (PSD) and concentration that allow to track the evolution of CQAs during the process [5, 6]. Performing such measurements can be difficult and time consuming, especially when it comes to PSD, due to the complexity either in treating samples for offline measurements or in getting the desired data for PBM calibration from online probes, such as FBRM or in process microscopy. However, industrial contexts are usually characterized by tight constraints on time and budget, and therefore the minimization of resources required for experimental campaigns is paramount. Therefore, developing calibration methods for PBMs that require fewer data points is important when available instrumentation, experimental setups, and sample sizes are limited.

For instance, exploiting measurements of crystals' chord length distributions (CLDs) is deemed as an interesting solution to maximize the extraction of information for PBMs calibration, even if in industrial practice they are typically used as qualitative indicators only [7]; in fact, they are often available and can be continuously recorded by process analytical technology (PAT) tools installed inline. However, CLDs are inherently different from CSDs, and then system-specific transformations should be applied in order to be able to use those quantities for parameter estimation [8]. In this work a more general strategy is proposed, based on the assumption that the CLDs collected by focused beam reflectance measurement (FBRM) probes can be compared to CSDs obtained as model outputs through their derivatives. Thus, trends in CLD data are combined with concentration and PSD data gathered only for the initial and final conditions of each batch, in order to calibrate PBMs with good predictive capability for industrial purposes.

## MATERIALS AND METHODS

The proposed approach is presented in this section, starting from the definition of the batch cooling crystallization model. After that, the strategy for model calibration with limited datasets is illustrated, together with criteria for the assessment of fitting quality. Finally, the application to the industrial case study concerning API crystallization are commented on.

### Model structure

Mechanistic models are chosen over data-driven models, since their calibration needs less data, they are interpretable and they are typically more suitable for scale-up problems. In particular, population balance models are a staple in the field, since they allow to describe the evolution of distributed properties, like particle sizes. Hence, the following formulation of the population balance equation (Equation 1) is derived from the general form for the case of a simple batch cooling crystallization in which mixing can be assumed ideal, volume of the slurry can be considered constant, 3D particles are characterized by a single equivalent dimension, and there are no significant dissolution, breakage or agglomeration phenomena:

$$\frac{\partial n(t,L)}{\partial t} + G \bullet \frac{\partial n(t,L)}{\partial L} = B \bullet \delta \bullet (L - L_0) \quad (1)$$

Here, $n$ represents the CSD, depending on time $t$ and the internal coordinate $L$, $B$ and $G$ represent the nucleation and growth kinetic terms, respectively, $\delta$ is the Kronecker's delta and $L_0$ is the minimum value of the internal coordinate $L$, namely the minimum characteristic size of a particle. As typically done [4], the terms for nucleation ($B$) and growth ($G$) kinetics are defined as Arrhenius-like laws based on the relative supersaturation.

$$B = B_s = e^{ln(k_{bs})} \bullet \mu_3^j \bullet S(T)^{bs} \quad (2)$$

$$G = e^{ln(k_g)} \bullet S(T)^g \quad (3)$$

$$S = \frac{c_{tgt} - c_{sat}(T)}{c_{sat}(T)} \quad (4)$$

$$c_{sat} = A + \frac{B}{T} + C \bullet ln(T) \quad (5)$$

This latter is denoted with $S$ (Equation 4) and, in turn, depends on the difference between the concentration of the target compound in the liquid ($c_{tgt}$) and its solubility ($c_{sat}$, Equation 5), which varies with the temperature ($T$). If the crystallization is seeded, it is reasonable to take into account the effect of the total volume of particles already present in the system ($\mu_3$) on the generation of new crystals, and thus to formulate $B$ as a secondary nucleation term ($B_s$, Equation 2).

$K_{bs}, j, bs, k_g$ and $g$ are kinetic parameters specific to each crystallization process, while $A, B$ and $C$ are coefficients of the Apelblat equation, used to describe the solubility curve. In addition, the model includes the equation for the mass balance, based on concentrations, coupled with an equation to track the evolution of liquid volume:

$$\frac{dc_i}{dt} = -\frac{\rho_{crys} \bullet k_v \bullet (3G \bullet \mu_2 + B \bullet V_{liq} \bullet L_0^3)}{V_{liq}} \bullet \left(\delta - \frac{c_i}{\rho_{liq}}\right) \quad (6)$$

$$\frac{dV_{liq}}{dt} = -\frac{\rho_{crys} \bullet k_v \bullet (3G \bullet \mu_2 + B \bullet V_{liq} \bullet L_0^3)}{\rho_{liq}} \quad (7)$$

where, $c_i$ is the concentration of the compound $i$, $V_{liq}$ is the liquid volume, $k_v$ and $\mu_2$ are the shape factor and the total surface area of the crystals, while $\rho_{cryst}$ and $\rho_{liq}$ are the densities of the crystals and of the liquid, respectively. The energy balance is not considered, instead, since temperature is assumed to be perfectly controlled

and to follow a known temperature profile. The standard method of moments (SMOM) is used to discretize the partial differential equations, obtaining a closed form of the set of equations to be solved [3].

## Model calibration

In order to estimate the model parameters, pre-processing of available datasets is required. In this way, the model calibration strategy is refined by excluding possible outliers in the data and by selecting which model responses or features should be considered. Total counts and particles' population weighted mean diameter are chosen as core quantities for the calibration method, together with initial and final API concentration. In particular, derivatives over time of such core quantities are employed, based on the assumption that they are comparable for CLDs and CSDs. In this way, trends of FBRM measurements can be used in a quantitative manner, combined with the few samples that are available for the other types of measurements. Average size allows to solve potential consistency issues between the information provided by CLD trends and that provided by initial and final PSD measurement, so that the maximum amount of information can be exploited. The objective function ($OBJ$) to be minimized is defined as a weighted mean square error (WMSE) that compares model responses and experimental data:

$$\begin{aligned} OBJ = & \frac{w_0}{N_{CLD}} \sum_i^{N_e} \sum_j^{N_{CLD}} \left(\mu_{0,m,ij}{}' - \mu_{0,CLD,ij}{}'\right)^2 \\ & + \frac{w_1}{N_{CLD}} \sum_i^{N_e} \sum_j^{N_{CLD}} \left( \left(\frac{\mu_{1,m,ij}}{\mu_{0,m,ij}}\right)' - \left(\frac{\mu_{1,CLD,ij}}{\mu_{0,CLD,ij}}\right)' \right)^2 \\ & + \frac{w_2}{N_{PSD}} \sum_i^{N_e} \sum_j^{N_{PSD}} \left( \left(\frac{\mu_{1,m,ij}}{\mu_{0,m,ij}}\right) - \left(\frac{\mu_{1,PSD,ij}}{\mu_{0,PSD,ij}}\right) \right)^2 \\ & + \frac{w_3}{N_c} \sum_i^{N_e} \sum_j^{N_c} \left(c_{m,ij} - c_{ij}\right)^2 \end{aligned} \quad (8)$$

Here, $w$ coefficients indicate the weights attributed to each of the terms in the summation, $N_e$ indicates the number of experiments, $N_{CLD}, N_{PSD}$ and $N_c$ indicate the number of samples available for each type of measurement, $c$ indicates concentrations and $\mu_0$ and $\mu_1$ indicate moments of size distributions. Subscripts of moments refer to the kind of size distribution (PSD or CLD) and the applied pre-treatments that are used to perform the calculations. All the quantities reported with the subscript $m$, instead, correspond to model outputs. It is important to highlight that the first two terms involve derivatives over time of total counts and particles' mean diameter, respectively, instead of their absolute values.

The SciPy implementation of adaptive Nelder-Mead algorithm is used for parameter estimation; multiple starts from different initial conditions reduce the possibility to incur local minima. Note that, for the same reason, terms in Equations 2 and 3 are formulated by employing dimensionless transformations of all parameters, and logarithmic versions of the pre-exponentials. The precision of the parameters' estimates is evaluated by means of a t-test, according to Equation 9.

$$t_{\theta,i} = \frac{\hat{\theta}_i}{\sqrt{\nu_{\theta,ii}}} > t_{ref}(1 - \alpha/2, N_{sp} - N_\theta) \quad (9)$$

Each parameter estimate $\hat{\theta}_i$ is considered statistically meaningful only if the related t-value $t_{\theta_i}$ exceeds a specific reference value $t_{ref}$. This latter is identified as the percentile with $\alpha$ confidence of a standardized t-distribution, characterized by a number of degrees of freedom which is obtained as the difference between the number of samples $N_{sp}$ and $N_\theta$. Parameter uncertainties are computed based on the diagonal terms of the variance-covariance matrix $\nu_{\theta,ii}$, which in turn is retrieved from the local sensitivities of responses with respect to parameters, thanks to common assumptions of local linearity [10].

## Case study

Model and methods implementations are built around tools and functionalities provided by the PharmaPy library, which serves as core process simulator [11]. Procedures are tested on real data collected in industrial laboratories for a seeded batch cooling recrystallization of an API in an organic solvent. The experimental campaign includes five experiments: three runs are distinguished only by different temperature profiles, while the other two are characterized by either different batch size or seed quantity. Indirect estimates of initial and final concentration are available for all the experiments, together with measurements of the seed and final product PSDs obtained by laser diffraction on the dried product. In addition, the evolution of the CLDs is tracked online by FBRM probes during the entire batches. Furthermore, for all the experiments, some data points are removed from the calibration set mainly due to probe fouling and cleaning, or to the unwanted recording of the addition of seed material.

# RESULTS

In this section, results that were achieved by applying the presented methodology to the industrial case study are discussed. The model was calibrated on the data gathered during the experimental campaign described in the previous paragraph.

Table 1 shows the estimates of the kinetic parameters. It can be noticed that their values are outside the typical ranges [4]. In particular, the exponent in the growth term is higher than the exponent in the nucleation term, implying that the growth phenomenon is faster and requires higher levels of supersaturation to be triggered, with respect to nucleation. Even though this is not commonly verified in crystallization systems, it is actually coherent with the behavior of the available experimental

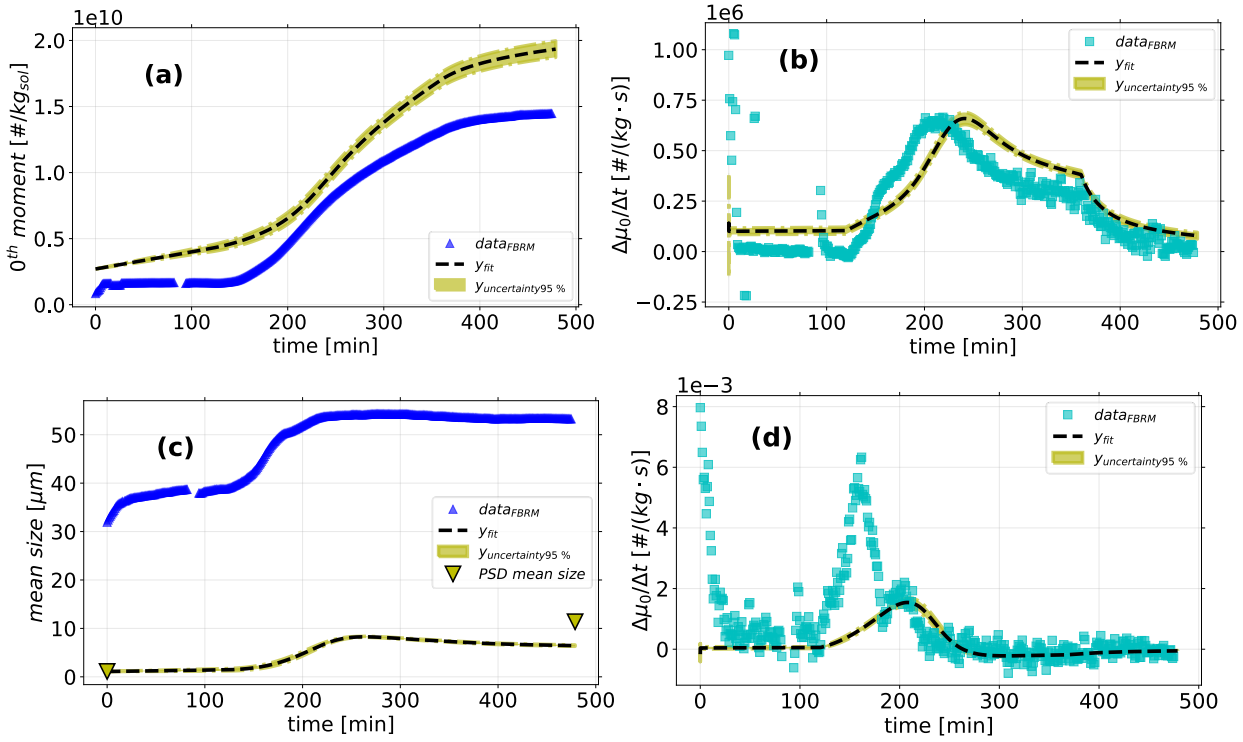

**Figure 1:** Fitting results for the first experiment of the campaign. Each graph shows: the quantity derived from chord length distribution data ($data_{FBRM}$, dots), the curve of model output, or feature, obtained from simulation with estimated values of kinetic parameters ($y_{fit}$, dashed line), 95 % confidence bounds ($y_{uncertainty,95\ \%}$, yellow area). **a)** total counts. **b)** Derivative of total counts. **c)** Average size, with initial and final point values computed from laser diffraction measurements (*PSD mean size*, yellow triangles). **d)** Derivative of average size.

data gathered by the FBRM probes.

**Table 1:** Estimated values of the kinetic parameters with the respective units, 95 % confidence intervals (95 % CI) and t-values. $t_{ref}$ indicates the reference threshold value for the t-test.

| Parameter | Units | $\hat{\theta}$ | 95% CI | *t*-value |
|---|---|---|---|---|
| $log\ (k_{bs})$ | $\frac{\#}{kg \bullet s}$ | 21.79 | 0.13 | 333.72 |
| $b_s$ | - | 0.54 | 0.09 | 11.37 |
| $j_s$ | - | 0.57 | 0.06 | 17.96 |
| $log(k_g)$ | $\frac{\mu m}{s}$ | -5.92 | 0.07 | 165.57 |
| $g$ | - | 1.61 | 0.18 | 17.18 |
| | | | | $\lvert t_{ref} \rvert = 1.96$ |

Moreover, computed uncertainties are relatively low, as proven by the very high t-values that easily overcome the threshold reference value for all the parameters; for this reason, all of them can be considered as statistically significant. This is a non-obvious finding because population balance models, and especially Arrhenius-like kinetic equations, often suffer from strong correlation among parameters, which undermines parametric precision. In this case, the large number of available samples allows decreasing the uncertainty on the estimates, and it represents one of the main advantages of exploiting data from online probes.

Fitting results for the first experiment of the campaign are represented in Figure 1. Each blue dot in Figure 1.a represents the total number of particles (or $0^{th}$ moment) calculated from the CLD measured by the FBRM probe at a specific time point. The same holds for blue dots in Figure 1.c, except that they refer to population weighted mean size. In both cases, the dashed lines represent the corresponding curves obtained from model outputs after simulating with the estimated values of kinetic parameters. Furthermore, 95 % confidence bounds of the outputs are calculated by following a Monte Carlo approach, and are reported as yellow areas. In the case of average size (c), the initial and final values derived from the laser diffraction measurements are also included (yellow triangles). Figures 1.b and 1.d show the derivatives of what is displayed in 1.a and 1.c, respectively.

From the profiles it can be seen that the main trends in the experimental data are fitted by the model, in particular for the total counts. However, the increase in average size in the first half of the batch is not captured,

and this leads also to a slight underestimation in the prediction of the end-point value. In general, even by testing slightly different calibration setups, one part of the process is always less accurately described, highlighting the limitations in the available measurement techniques and, possibly, in the structure of the model itself. Offsets in the plots of the non-differentiated quantities are expected, since the model was trained on the derivatives of CLD data, but used information from the laser diffraction measurements as initial conditions.

The outcomes are deemed satisfactory, and demonstrate that FBRM measurements can be used as complementary information to more reliable data about the starting point of the process and product properties. The proposed strategy can be very valuable from the industrial perspective, especially for early-stage process development, where resources are limited and maximizing information from scarce data can be a key advantage.

## CONCLUSIONS

First-principles models based on population balances are powerful tools that can enhance the understanding and aid the development of crystallization processes for API production. Identifying a proper structure and achieving an accurate calibration for PBMs can be a challenging task, particularly in an industrial environment, where thorough experimental campaigns may not be affordable, and advanced instrumentation and setup may not be available. Thus, being able to exploit in a quantitative manner trends in data that are usually interpreted as qualitative indications of process evolution, like CLDs measured by FBRM probes, can be crucial. The results of this work demonstrate the potential of strategies built around the usage of such CLD data, in combination with a minimum amount of offline measurements and with proper data processing, feature extraction and numerical routines. In fact, statistically precise estimations for kinetic parameters of basic PBMs formulations that include nucleation and growth mechanisms are obtained, together with good prediction capabilities for early-stage process development purposes. Future work will be focused on assessing the impact that measurement availability can have on model performances, which will be evaluated both in calibration and in validation. Similar approaches will be applied on different datasets and by varying the amount and type of data used for parameter estimation, with the aim of finding an optimum trade-off between model quality and experimental effort.

## ABSTRACT

Crystallisation is a promising and scalable alternative to chromatography for biologics purification. However biologics such as proteins and peptides often crystallise only in narrow operating windows, limiting process flexibility. Template-induced crystallisation can lower supersaturation requirements and expand feasible operating ranges, yet the template dependence of nucleation and growth kinetics remains difficult to parametrise mechanistically. To address this, we develop and experimentally validate uncertainty-aware hybrid models for lysozyme crystallisation on hydroxyl- and carboxyl-functionalised silica templates. A mechanistic population-balance model is coupled to a data-driven regressor that maps operating conditions and template variables to effective nucleation and growth rates. We compare a neural network baseline against a structured neural power-law surrogate, which embeds a supersaturation-dependent power-law form. Both hybrid models are trained in-the-loop via differentiable simulation, and variational inference is used to obtain posterior parameter distributions and calibrated predictive uncertainty. Across cross-validation and off-grid tests at previously unseen combinations of temperature and template loading, the hybrid models accurately reproduce solute concentration dynamics and capture key particle-size trends, while the neural power-law surrogate provides improved robustness and faster uncertainty quantification. These results support hybrid, uncertainty-aware PBMs as practical tools for prediction, design-space exploration, and comparison of template-enabled protein crystallisation processes.

**Keywords**: Crystallisation, Hybrid Models, Uncertainty-aware

## INTRODUCTION

Crystallisation is emerging as a viable downstream alternative to chromatography for the purification and formulation of biologics-based therapeutics. As demand for protein- and peptide-based drugs continues to increase, improvements in upstream productivity have shifted the bottleneck to the purification train where conventional chromatographic steps are capital- and material-intensive and can be challenging to scale. In contrast, crystallisation produces a highly pure, easily filterable solid form of the active pharmaceutical ingredient with favourable stability, storage and handling characteristics, and is inherently well suited to scale-up and continuous processing [1]. Yet despite its extensive use for small-molecule APIs, translating crystallisation into a robust, industrially relevant unit operation for macromolecules remains difficult, and largely empirical due to the complexity of protein crystallisation, resulting in poor control of the process and its' quality attributes [2].

To overcome such limitations and widen the conditions at which crystallisation occurs, template-assisted crystallisation has attracted growing interest. In templated systems, a finely dispersed solid phase, such as a porous or nanostructured material with tailored surface chemistry, is introduced into the solution to promote nucleation. Experimental studies have shown that varying template loading, pore structure and surface

functionalisation can lower the supersaturation required for nucleation, shift metastable zone boundaries and improve control over crystal size and habit for both small molecules and biologics [3–6]. In the context of protein crystallisation, such templates offer a route to mitigate the harsh supersaturation conditions and long induction times often required to obtain crystals, and introduce the possibility of designing more flexible, template-enabled crystallisation processes for biologics. However, these benefits come at the cost of additional complexity: the nucleation behaviour now depends on a richer set of process and material descriptors, including template loading, surface charge, chemistry, pore architecture, and their coupling with solution conditions such as pH, buffer and precipitant concentration.

Mechanistic population balance models (PBMs) provide a powerful tool to describe crystallisation, combining mass and energy balances with kinetic expressions for nucleation, growth, aggregation and breakage. They can be used to rationalise experimental trends, perform *in-silico* process development, and support scale-up and control of both small-molecule and protein crystallisers [7]. In conventional applications, nucleation and growth rates are described with a relatively small number of parameters using, for example, classical nucleation theory and empirical power-law kinetics. These expressions, while still imperfect, are often sufficient to capture the behaviour of unseeded or seeded cooling and anti-solvent crystallisations under well-characterised conditions. For template-induced systems, the effective nucleation mechanism involves a combination of adsorption, confinement, local changes in supersaturation and potentially intermediate dense-liquid or amorphous phases, all strongly modulated by template morphology and surface chemistry [4]. The unique, condition-dependent nature of protein crystallization means that static kinetic expressions can lack the flexibility to describe different templated systems. Since a unified framework for these interactions has yet to be established, there is no assurance that a model structure identified for one process will hold for another. This lack of transferability necessitates a more robust modeling approach that can internalize these dependencies without requiring a complete mechanistic rebuild for every new template loading or chemistry.

The core challenge is therefore the explicit parametrisation of the kinetics in terms of experimentally tunable template variables. For each new combination of template material, surface functionalisation and loading, one would, in principle, need to postulate a new kinetic expression, re-estimate kinetic parameters and re-assess identifiability and uncertainty. In practice, the scarcity and noise of protein crystallisation data, the stiffness and non-linearity of PBMs, and the lack of a clear mechanistic consensus on template-induced nucleation make this programme difficult to sustain. Mismatch between the assumed kinetic law and the true, template-dependent behaviour can yield models that appear to fit calibration data but fail to generalise to new template loadings or process conditions, undermining their usefulness for process design and risk assessment.

## HYBRID MODELLING

Hybrid modelling offers an attractive route to overcome the obstacles of repeated parametrisation and uncertainty quantification for each unique template chemistry and loading. In a hybrid formulation, a data-driven regressor is embedded directly within the mechanistic PBM to predict effective kinetic rates from the current process state and operating variables, while the population balance and mass balance equations continue to enforce conservation and encode the underlying physics. Rather than writing down an explicit expression for the nucleation rate as a function of supersaturation and template loading, we instead learn this relationship from data using a flexible model class. This architecture is particularly appealing for template-induced protein crystallisation, where relevant inputs naturally include both solution variables (e.g., temperature, current protein concentration) and template descriptors (e.g., loading). The model can possibly be augmented with further process variables (buffer and precipitant conditions, average pore diameter, zeta potential, surface functional group) which might be difficult to integrate in an explicit kinetic expression. By learning a mapping from this input space to effective nucleation and growth rates, hybrid models can internalise complex, template-specific effects without sacrificing the interpretability and extrapolation structure provided by the mechanistic balances. Nielsen et al. successfully applied this methodology to model a crystallisation process, and noted that while hybrid models have higher data requirements than purely mechanistic models, they are effective in cases where there is high-frequency measurements from PAT and incomplete knowledge, such that a mechanistic model could not have been properly formulated [8]. McKay et al. applied a parallel hybrid methodology for the control of a fed batch crystalliser, notably with high data availability and a large number of generated batches from a reference in-silico model. In this case, the data-driven regressor is successfully used to correct the mispredictions of a mechanistic model, formulated with kinetic parameters with 5% deviation from the reference parameters used to generate the original data [9]. In both cases, training data for the data driven regressor had to be carefully collected with simulations of the reference model to train the data-driven counterpart. It would therefore be advantageous to be able to train the whole hybrid model ‘in-the-loop’, without lengthy data generation tasks.

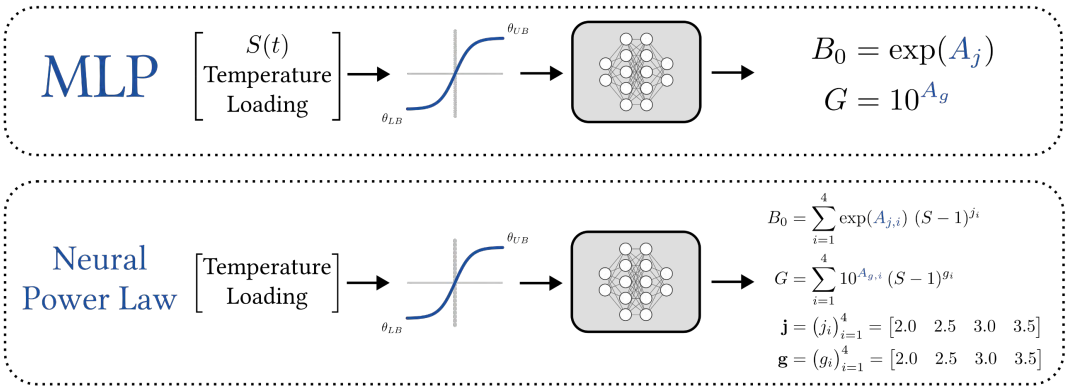

**Figure 1.** Structure of the two proposed regressors to be embedded in the mechanistic model.

## VARIATIONAL INFERENCE

For hybrid models to be actionable in process development, point predictions are insufficient. Protein crystallisation experiments are inherently noisy, and the kinetic identification problem must account for both irreducible experimental noise (aleatoric) and limited confidence in regressed neural network parameters (epistemic). Uncertainty-aware formulations that quantify the posterior variability in kinetic surrogates, and propagate it through the PBM, are essential for assessing confidence in predicted trajectories and prioritizing future experiments. Traditional Bayesian techniques, such as Markov Chain Monte Carlo, are often computationally prohibitive for the high parameter counts typical of neural networks. Variational Inference (VI) offers a scalable alternative by reframing the inference problem as an optimization task [10]. The true but intractable posterior distribution of network weights $p(\omega|D)$ is approximated with a simpler, variational distribution $q_\theta(\omega)$ such as a multivariate Gaussian. The parameters $\theta$ are then optimized to minimize the Kullback–Leibler (KL) divergence from the true posterior, which is equivalent to maximizing the Evidence Lower Bound (ELBO).

$$\text{ELBO} = \boldsymbol{E}_{q_\theta(\omega)}[\log p(\omega|D)] - \text{KL}(q_\theta||p(\omega)) \quad (1)$$

The first term encourages the model to fit the experimental concentration and crystal size data, while the second acts as a Bayesian regularizer. By sampling from the optimized $q_\theta(\omega)$ during the ODE integration, we can propagate weight uncertainty through the population balance equations to generate predictive intervals for the entire process trajectory.

In this work, we address these challenges by developing and experimentally validating uncertainty-aware hybrid PBMs for lysozyme crystallisation in the presence of porous silica nanoparticle templates with different surface functionalisations. We consider two hybrid architectures in which a multi-layer perceptron neural network learns effective nucleation and growth rates as functions of process and template variables, while a mechanistic population balance model governs the evolution of the crystal size distribution and solute concentration. The data-driven components are trained in-the-loop via auto-differentiable programming, and variational inference is used to recover posterior distributions over the hybrid model parameters and corresponding predictive uncertainty. By validating these models on unseen template loadings and comparing their accuracy and calibration across distinct template chemistries, we aim to demonstrate that hybrid, uncertainty-aware formulations can bridge the gap between rich, template-enabled experimental design spaces and mechanistically grounded, in-silico process models for protein crystallisation.

## METHODOLOGY

### Experimental Methodology

This architecture is applied to experimental datasets of template-induced lysozyme crystallisation. Lysozyme was crystallised in a 0.1 M sodium acetate buffer (pH = 4.2) containing 50mg/ml NaCl. Experiments are conducted in both template-free solutions and in the presence of irregularly shaped, porous silica nanoparticles functionalised with carboxyl and or hydroxyl surface groups. For each tested condition, three independent replicates are performed. Crystallisations are carried out at three temperatures (17, and 21°C) and three nanoparticle loadings (1, 5 and 10 mg/ml) and 2 template chemistries (Hydroxyl and Carboxyl functionalised). Validation experiments were carried out at intermediate loading and temperatures (19°C, 7.5 mg/ml), to assess the interpolative ability of the hybrid models. Two initial protein concentrations are tested per temperature–loading combination. Reactions were conducted in 20 ml volumes

under constant stirring at 75 rpm. Protein concentration was monitored every 30 minutes using a UV Nanodrop spectrophotometer. Upon batch termination, the slurry is filtered, dried, and the crystal size distribution is measured using a laser-diffraction particle size analyser.

## In-Silico Methodology

Eq 1 shows the population balance with negligible aggregation and breakage, while Eq2 describes the mass balance. To solve this hyperbolic PDE, a method of moments transformation is used to recover the moments of the crystal size distribution. Rather than defining explicit equation for nucleation and growth, neural networks are embedded in the mechanistic model framework. By implementing the model in an auto-differentiable language such as JAX, Pytorch or Julia, the neural networks can be trained by minimising a parameter estimation loss function and a gradient-based optimiser. In both regressors sigmoid input and output transformations are implemented to the predicted rates remain in feasible ranges that won't make the ODE simulation unstable when the network is first initialised. They also serve to improve the gradient conditioning and smoothness.

$$\frac{\partial n}{\partial t} + \frac{\partial (Gn)}{\partial L} = B_0 \delta(L - L_{min}) \tag{2}$$

$$\frac{dc}{dt} = -3\rho_c k_v \int_0^\infty GnL^2 \, dL \tag{3}$$

$$d_{43} = \frac{\mu_4}{\mu_3} \tag{4}$$

Figure 1 shows the two proposed data driven kinetic regressors. The MLP regressor takes the supersaturation at each ODE call, and the temperature and loading as inputs. Those are passed to a sigmoid function, scaled on global lower and upper bounds (Table 1). The sigmoid-transformed inputs pass through a neural network, which outputs a nucleation and growth coefficient which are finally passed to exponential functions for a physically-feasible scaling. The Neural Polynomial, is also proposed as an alternative architecture. In this architecture the neural network only takes temperature and loading as input, and outputs coefficients of a sum of power law expressions for nucleation and growth. Training of both regressors is done in a 2-stage approach to improve the conditioning of the regressors, in which the hybrid models are first trained on 50% of the initial timepoints before including the whole dataset. Both neural networks have 1 layer, 150 neurons, and were trained with the following schedule: Phase 1 LR = $8 \times 10^{-4}$, Steps = 40; Phase 2 LR = $2 \times 10^{-3}$, Steps = 200. Variational inference is performed with 5000 steps and LR = $1 \times 10^{-3}$. The prior distribution is centred around the weights of the trained hybrid model regressor, with 10% standard deviation.

**Table 1.** Bounds for sigmoid transformations

| Name | Lower Bound | Upper Bound |
|---|---|---|
| Temperature [°C] | 13 | 27 |
| Template Loading [mg/ml] | 0 | 30 |
| Solute conc. [mg/ml] | 0 | 25 |
| A_j [-] | -15 | 30 |
| A_g [-] | -15 | -5 |

# RESULTS AND DISCUSSION

## Hold-one-out Validation

Hold-one-out (HOO) validation was performed using the training experiments, where each experiment is left out in turn and predicted using a model trained on the remaining experiments. As a result, some of the validation cases are extrapolating with respect to the initial conditions (and occasionally the transient state trajectory), while others are more interpolative. However, each validation experiment still shares the same discrete temperature and template loading values with at least some of the training experiments. In other words, across the HOO benchmark the model is never forced to extrapolate temperature or loading; the “hard” extrapolation is primarily in the initial condition and the resulting early-time dynamics.

It is important to note that HOO is an inherently biased validation procedure in data-scarce settings [11] as leaving out any single experiment can change the empirical mean and variance of the training set. This means HOO effectively introduces a fair amount of extrapolation into the evaluation, which is notoriously challenging for any regressor embedded in a stiff mechanistic simulator, but it also makes the benchmark quite strict. In practice, this is useful here because generalisation is often presented as a key advantage of mechanistic PBMs, and HOO provides a direct stress test of whether the hybrid formulation can retain that behaviour under limited data.

**Table 2.** Hold-one-out validation mean absolute error for hydroxyl and carboxyl systems, MLP and Neural P-L models.

| Model | Conc. MAE [mg/ml] | PS MAE [micron] |
|---|---|---|
| | *Hydroxyl System* | |
| MLP | 1.402 | 4.089 |
| Neural P-L | 1.439 | 4.078 |
| | *Carboxyl System* | |
| MLP | 1.876 | 5.506 |
| Neural P-L | 1.468 | 3.558 |

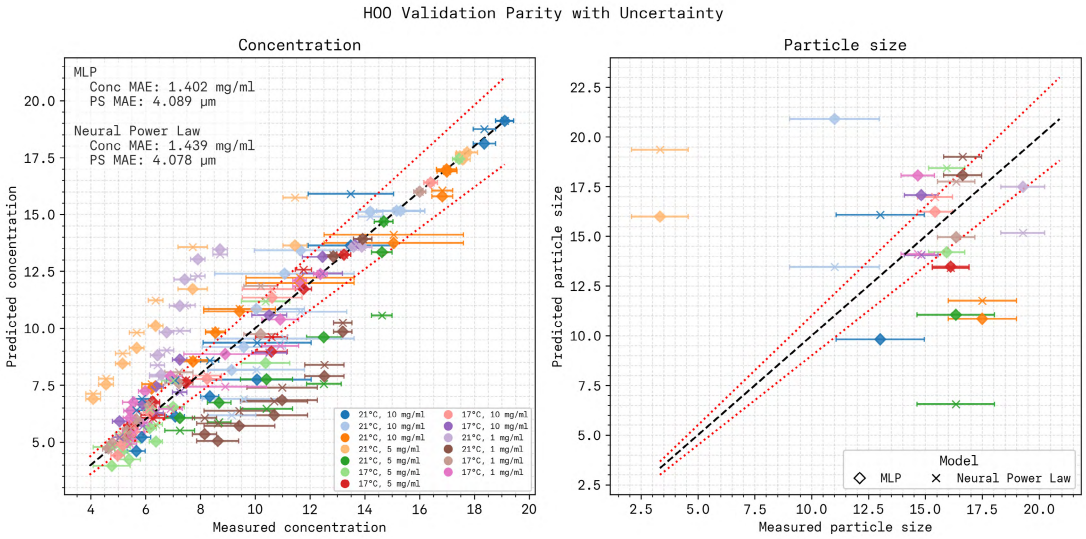

**Figure 2:** Hold-one-out Validation parity plot for the Hydroxyl template system.

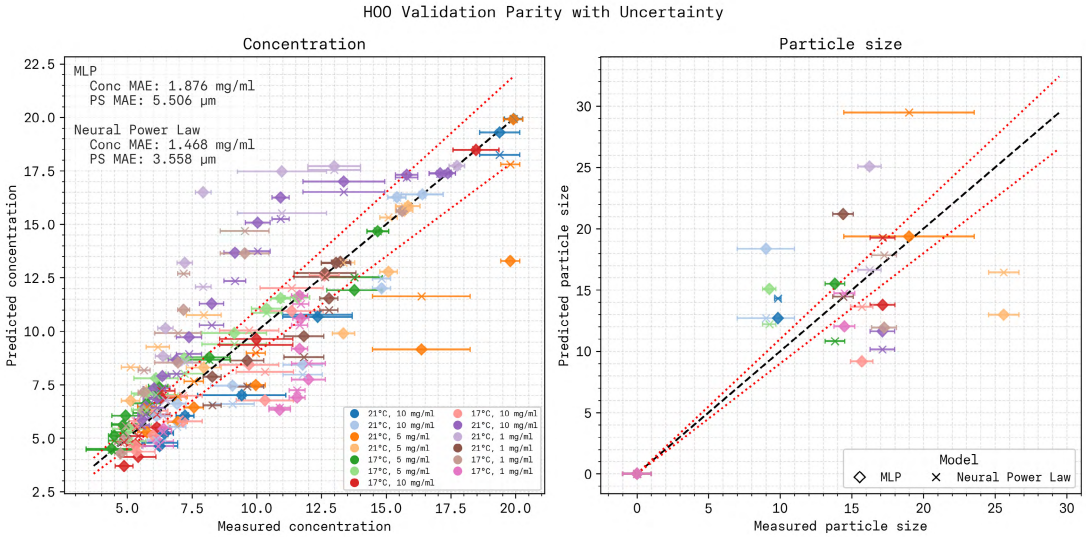

**Figure 3:** Hold-one-out Validation parity plot for the Carboxyl template system.

The HOO parity plots are shown in Figure 2 (hydroxyl- template) and Figure 3 (carboxyl- template), and error metrics are reported in Table 2. Across both datasets (hydroxyl- and carboxyl- functionalised templates) and both hybrid architectures, we observe consistent trends. First, the overall performance in the HOO benchmark is similar between the two models. Both regressors typically recover the main features of the concentration trajectories and the end-point particle size metric with comparable mean absolute errors. In both hydroxyl and carboxyl datasets, most experiments are predicted reasonably well, but there are 2–3 validation experiments where the prediction is noticeably poorer. This pattern suggests that a small subset of experiments sit in a more difficult region of the design space (e.g., sharper nucleation, stronger nonlinearity, or less informative measurements), and these become “failure modes” for both hybrid parametrisations.

Second, even though the two regressor setups are structurally different, the predicted validation trajectories are often very similar, especially for concentration. This is quite striking: despite one model predicting rates directly as a function of state (via the MLP) and the other enforcing a more structured supersaturation dependence (via the neural power-law surrogate), both end up producing closely aligned concentration dynamics across most left-out cases. One plausible interpretation is that, within the range of operating conditions covered by the training grid, both models are converging to essentially the same effective kinetic relationship. The neural power-law explicitly constrains the supersaturation dependence to a sum of power laws, while the MLP may be

learning a function that is effectively equivalent over the observed supersaturation range. In that sense, the two architectures may be different parametrisations of the same learned dynamics, rather than fundamentally different learned behaviours.

In contrast, particle size predictions are generally less accurate than concentration predictions in the HOO benchmark, as reflected by higher relative errors. This is not unexpected given the experimental data structure: each experiment contributes a full concentration time series (multiple points) but only a single average particle size value is available at batch termination. The loss therefore contains substantially more information about concentration than about size, and the hybrid model is asked to infer size dynamics largely through the mechanistic coupling rather than through direct dense measurements. This imbalance renders the particle size objective harder to learn and easier to over/under-shoot, particularly for the more challenging left-out experiments. For carboxyl templates specifically, the neural power-law surrogate tends to yield slightly better particle size errors, which suggests that the additional structural bias in the kinetics help stabilise the size predictions when size data are sparse.

**Table 3**: training and variational inference times for the 2 models.

| Model | Avg. HOO training time [s] | Variational Inference time [s] |
|---|---|---|
| MLP | 62 ± 8.5 | 1498 |
| Neural P-L | 51 ± 12 | 910 |

By calling the network only once per simulation, rather than once per ODE call, the computational graph is simplified leading to improved memory usage and faster training. Secondly, this simplifies the kinetic identification problem by removing the time dependence of the inference and training problem. The hybrid model training and uncertainty quantification runtimes are reported in Table 3. The neural power-law regressor also delivers a ~40% speed-up under the same variational inference settings, which is consistent with its reduced computational graph (the regressor being called once per simulation rather than at every ODE evaluation), and is a relevant advantage when scaling these methods to larger experimental grids, or more complex (like multidimensional) models.

Overall, the HOO results indicate that both hybrid PBMs learn the core crystallisation dynamics reasonably well, with concentration being the easier and more consistently captured output. The remaining gaps, most clearly in particle size and in a small number of difficult experiments, are likely dominated by the combination of sparse size supervision and the intrinsic ambiguity of mapping limited measurements to effective nucleation/growth kinetics in template-induced systems.

## Off-grid Validation

**Table 4**: Off-grid validation mean absolute error for hydroxyl and carboxyl systems, MLP and Neural P-L models.

| Model | Conc. MAE [mg/ml] | PS MAE [micron] |
|---|---|---|
| | *Hydroxyl System* | |
| MLP | 1.56 | 2.48 |
| Neural P-L | 0.75 | 1.5 |
| | *Carboxyl System* | |
| MLP | 0.73 | 0.26 |
| Neural P-L | 0.64 | 3.24 |

Next, we examine the interpolative validation experiments, with predictions shown in Figure 4 (hydroxyl-template) and Figure 5 (carboxyl- template), and error metrics are reported in Table 4. These validation runs were carried out at 19 °C and 7.5 mg/ml template loading, i.e. conditions chosen halfway between the training temperatures and loadings. Unlike the HOO benchmark, where each validation experiment still shared the same discrete temperature and loading values with some of the training data, these validation conditions are unique and are not present anywhere in the training set. This means the models are genuinely required to interpolate jointly in temperature and template loading, rather than only interpolating in initial condition or trajectory shape.

Across both template chemistries, the two hybrid architectures recover the overall dynamics, but with consistent biases. In both systems, the MLP tends to underpredict the concentration during the batch. The resulting trajectories often follow the correct qualitative shape, but are shifted downward relative to the measurements, suggesting that the learned effective kinetics lead to overly fast depletion (or equivalently an overestimation of net crystallisation rate) at the interpolated condition. By comparison, the neural power-law surrogate is generally closer to the measured concentration trajectories, and for the hydroxyl templates (Figure 4), it gives an almost perfect fit over the entire horizon.

For the carboxyl template system (Figure 5), the two models produce broadly similar concentration trajectories, and the concentration MAE is comparable between them despite the MLP underprediction. The difference is more visible in the particle size metric: the neural power-law surrogate slightly underpredicts the particle size, while the MLP predicts particle size more accurately, in some cases essentially matching the measurement within experimental error bounds. This is consistent with the trade-off observed in other parts of the evaluation: the more flexible direct-rate MLP can sharpen the size prediction when it lands in the right region of rate space,

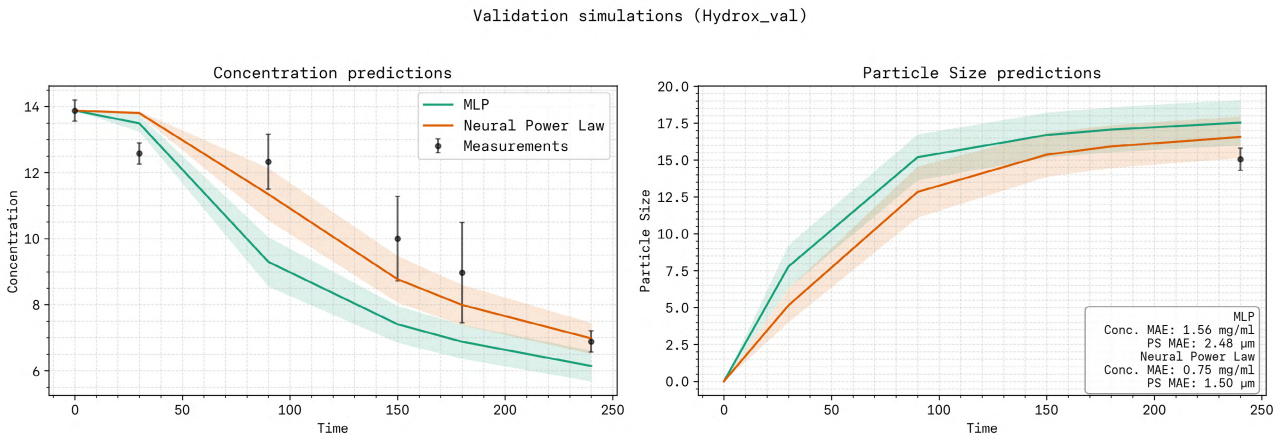

**Figure 4.** Off-grid validation prediction plots for the Hydroxyl template system at T = 19°C, Loading = 7.5 mg/ml

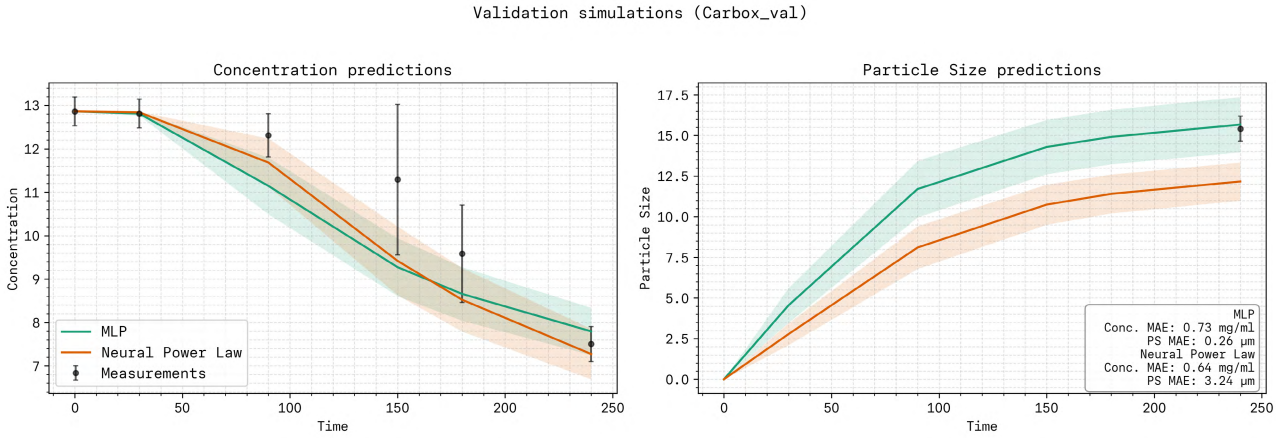

**Figure 5.** Off-grid validation prediction plots for the Carboxyl template system at T = 19°C, Loading = 7.5 mg/ml

whereas the more structured surrogate can prioritise capturing the concentration evolution, sometimes at the cost of a small bias in the final size metric.

For hydroxyl templates, the separation between the models is clearer. The neural power-law surrogate matches the validation concentration trajectory extremely well, while the MLP again underpredicts concentration across the batch. For particle size, both models slightly overpredict, but the neural power-law surrogate has the better overall outcome when considering both the mean prediction and the uncertainty intervals. Importantly, even where the point predictions differ, both models' confidence intervals appear reasonably calibrated: the predictive bands are typically consistent with the observed experimental scatter and remain within the reported measurement error. This is particularly relevant here because the validation condition is unseen, so interval calibration is a stronger test than simply matching a single mean trajectory.

Taken together, the interpolative validation suggests that both hybrid PBMs can generalise to new temperature–loading conditions without re-fitting, but the two kinetic surrogates exhibit distinct failure modes. The MLP appears prone to a systematic concentration underprediction at the interpolated condition, while the neural power-law surrogate is more robust in concentration interpolation and tends to produce more conservative uncertainty. Meanwhile, the MLP can provide sharper particle size predictions when the learned kinetics align well with the true size dynamics at that condition. This highlights that model choice should not rely purely about average error: for template-enabled process design, the preferable surrogate will depend on whether the primary objective is accurate concentration trajectory prediction (e.g. yield/endpoint concentration targets) or more accurate particle size outcomes (e.g. downstream filtration and formulation constraints), and on whether conservative uncertainty quantification is preferred for risk-aware decision making.

Beyond the specific comparison of the two architectures, the results presented here raise several broader open questions for hybrid PBM development. First, the data requirements of these models remain to be systematically assessed. The experimental grid used in this work is deliberately compact, and while both regressors demonstrate reasonable generalisation, it is not yet clear

how much additional experimental coverage would be needed to meaningfully improve the learned kinetics, nor at what point diminishing returns set in. Closely related is the question of data quality: in protein crystallisation, measurements are subject to heteroscedastic noise, batch-to-batch variability, and limited temporal resolution, all of which propagate through the training loss. The extent to which measurement quality, as opposed to sheer quantity, limits the fidelity of the trained regressor is an important practical consideration that is not addressed here. Finally, the hybrid models as presented remain black-box at the kinetic level: the learned regressors capture effective nucleation and growth rates, but these rates are not readily interpretable or transferable in the way that a compact, explicit kinetic expression would be. Distilling the trained surrogate into a human-readable form, for example via symbolic regression on the learned regressor outputs, would allow practitioners to extract mechanistic insight from the flexible model, compare it against established kinetic forms, and stress-test the resulting expression outside the data-supported region. These open questions, data sufficiency, data quality, training robustness, and interpretability, represent natural directions for further development of hybrid PBMs for template-induced crystallisation.

## CONCLUSIONS

This work proposes a workflow for the development and experimental validation of uncertainty-aware hybrid population balance models for template-induced protein crystallisation.

Across the hold-one-out benchmark, the two hybrid architectures present very similar effective dynamics, despite making different modelling choices about how kinetics are captured. Improving the HOO performance likely requires either more experimental coverage, since both regressors still have capacity and will generally benefit from additional temperature–loading combinations and denser particle-size information, or strategies that effectively densify the dataset without simply overfitting. One plausible direction is data augmentation through mechanistic fits on subsets of experiments to generate richer trajectories; however, this must be approached carefully, because any model–data mismatch in the mechanistic fits would be inherited by the augmented dataset and may ultimately degrade calibration.

The off-grid validation is arguably the more demanding test: here the models interpolate in temperature and loading, rather than relying on having seen the same discrete operating values during training. Under this stress test, the Neural Power Law structure with its explicit decoupling of supersaturation dependence, tends to deliver more robust concentration predictions and more conservative uncertainty, while the MLP can produce sharper particle-size predictions. Overall, these results support the central conclusion of this study: uncertainty-aware hybrid PBMs can learn useful, template-dependent kinetic relationships even under severe data scarcity and measurement sparsity and can generalise to unseen operating conditions without re-training.

Several directions for future work emerge from these findings. The data requirements of hybrid PBMs, both in terms of quantity and quality, remain to be characterised more rigorously: understanding the minimum experimental coverage needed to train a reliable regressor, and quantifying how measurement noise and temporal resolution affect the learned kinetics, would provide actionable guidance for experimental planning. There remains also an opportunity to explore interpretability further. A key advantage of purely mechanistic PBMs is that the kinetic relationships are compact and human-readable; hybrid models trade some of that transparency for flexibility. One natural next step is therefore to treat the trained kinetic surrogate as a discovery tool and distil it into an explicit functional form, for example by applying symbolic regression to the learned regressor heads, so that the final outcome is both accurate in the data-supported region and easier to communicate, compare, and stress-test for process design.

## ABSTRACT

Mathematical models play a central role in biopharmaceutical manufacturing, especially within the Quality by Design framework. For these models to be effectively used in optimization tasks, they must be both reliable and capable of delivering results in an affordable computational time. This work proposes a strategy to model aggregate formation during viral inactivation in the context of monoclonal antibody downstream processing. These units often display mixing-sensitive behavior because aggregation kinetics is controlled by local pH, whose spatial heterogeneities arise from titrant addition at a defined feed point. To address this challenge, compartment models (CMs) are employed. This modeling approach captures spatial inhomogeneities within the unit by leveraging flow-exchange information derived from a single steady-state Computational Fluid Dynamics (CFD) simulation involving only the solution of mass, momentum and turbulence equations. Results obtained by comparing compartment models with both perfectly mixed models and full CFD simulations including aggregation kinetics demonstrate that CMs can reproduce the CFD results with good approximation, while reducing computational time by orders of magnitude.

**Keywords**: Compartment Models, Computational Fluid Dynamics, Monoclonal Antibodies, Downstream Bioprocessing

## INTRODUCTION

Mathematical modeling has become a cornerstone in the modernization of pharmaceutical manufacturing, enabling process optimization, quality-by-design strategies, and the development of digital twins [1]. To effectively serve this role, models must ensure robustness and reproducibility under real manufacturing conditions, especially because this level of reliability is increasingly required by regulatory frameworks.

Beyond supporting unit-operation design, mathematical models are equally essential at the system level, where they allow the integrated optimization of process configurations, resource allocation, and operational strategies.

Achieving this goal calls for an accurate description of the relevant phenomena across multiple scales, from process-level behavior down to local fluid dynamics [2]. This aspect is particularly critical in unit operations where fluid flow and mixing have a decisive impact on process outcomes.

In the context of biopharmaceutical manufacturing for monoclonal antibodies (mAb) production, one of the most critical operations where mixing plays a central role is the viral inactivation step. This step takes place in the downstream section of the process, during which purification and product quality refinement are carried out. This operation is designed to ensure product safety by lowering the solution pH through the addition of an acidic titrant and holding this condition for a minimum amount of time, thereby inactivating acid-labile viruses. However, low pH conditions simultaneously trigger aggregation kinetics for certain monoclonal antibodies [3]. Aggregation is a key risk, as it may impact product quality and reduce yield, and its kinetics depend strongly on the local pH distribution within the vessel. Therefore, spatial heterogeneities in mixing directly translate into variations in aggregation rates, linking hydrodynamics with critical

quality attributes, especially for proteins that are prone to low-pH aggregation.

A model of the unit in which the viral inactivation step is performed must therefore be able to capture the influence of imperfect mixing on both pH distribution and aggregation kinetics in order to provide reliable and accurate predictions. Additionally, the application of a unit model inside process-level optimization tasks requires the capability of this model to provide predictions within a significantly reduced computational time. This combination of physical fidelity and computational efficiency is essential to enable model-based decision-making in biopharmaceutical development and manufacturing.

Due to their simplicity and fast computational times, models that assume perfectly mixed conditions inside the vessel are commonly used in process-level optimization tasks. However, these models fail to represent the effect of fluid dynamics on the aggregation kinetics, leading to an underestimation of aggregation risks and potentially misleading performance predictions. On the other hand, when a detailed hydrodynamic description is required, computational fluid dynamics (CFD) models that solve both the flow behavior and the transport of species are generally employed. While this kind of approach can be highly accurate, it requires substantially higher computational time and resources, which limits its applicability for system-level optimization and for extensive exploration of complex physical phenomena [4].

To overcome the challenge of developing hydrodynamics-oriented yet time-efficient models, a multi-scale approach should be adopted for the modeling of the vessel. One promising way to implement such a multi-scale strategy is through compartment models (CMs). In this modeling approach, the vessel is discretized into a network of interconnected compartments, each assumed to be ideally mixed [5]. The exchange of mass between compartments is not modeled directly by solving the full fluid-flow equations, but is instead derived from a single CFD simulation that solves only the flow and turbulence equations [6]. This makes it possible to capture the large-scale hydrodynamics at a reduced computational cost, while retaining spatial heterogeneities and flow non-idealities within the equipment. Compartment models therefore provide a powerful intermediate between overly simplified ideal-mixing assumptions and the full resolution of CFD simulations [7][8][9]. This makes them particularly useful for describing the pH distribution inside the unit and, in turn, its effect on aggregation kinetics at a significantly reduced computational cost.

This work aims to examine the applicability of compartment modeling to the viral inactivation step in mAb production processes, with the goal of developing a model that incorporates local pH gradients to improve predictive accuracy compared to perfectly mixed models, while providing results in a substantially shorter time than a full CFD simulation. Such a model can be readily used for process-level optimization or for evaluating alternative operating conditions that do not affect the underlying fluid dynamics.

## MODELING WORKFLOW

The modeling workflow adopted in this study is described in this section.

The development of the compartment model follows a sequential procedure. First, a CFD simulation resolving only the fluid flow (momentum, continuity, and turbulence equations) is performed. The process geometry is then discretized into compartments, after which the mass-flow exchanges between compartments are computed from the CFD results. Finally, the corresponding material balances are solved. The following sections detail each step of this workflow.

### Fluid flow only CFD simulation

A steady-state CFD simulation resolving the fluid flow (momentum, continuity, and turbulence equations) serves as the starting point for the development of the compartment model.

Two different vessel geometries representative of equipment used during industrial viral inactivation at different scales are here considered. Comparing these two configurations allows to investigate how vessel geometry and characteristic scales influence mixing patterns, pH distribution, and consequently aggregation behavior.

The first geometry, referred to as the *R&D scale* vessel, consists of a cylindrical unbaffled tank with a conical bottom and a maximum working volume of 200 L, operated here with 90L of liquid. The nominal impeller speed is set to 230 RPM. The second geometry, referred to as the *Clinical scale* vessel, features a square cross-sectional area and a maximum working volume of 1000 L, and it is operated with 550L of liquid. The nominal impeller speed is set to 180 RPM.

An unstructured polyhedral mesh was selected for the simulations of both geometries. The meshes were generated using Ansys® Fluent, release 25.1 watertight geometry meshing workflow. The resulting meshes comprise 377348 computational cells for the *R&D scale* vessel and 1261684 cells for the *Clinical scale* one. CFD simulations were run using Ansys® Fluent, release 25.1.

The fluid inside the vessel comes the prior purification step. It contains the product, process impurities, and buffer components. The density is 1007 kg/m$^3$, while the viscosity is $10^{-3}$ Pa·s.

To model turbulence, the SST k-ω model is selected, retaining the default parameters. To model the impeller rotation, the Multiple Reference Frame approach is used; the rotating reference frame is shown in Figure 1 for the *R&D scale* vessel and in Figure 2 for the *Clinical*

*scale* one.

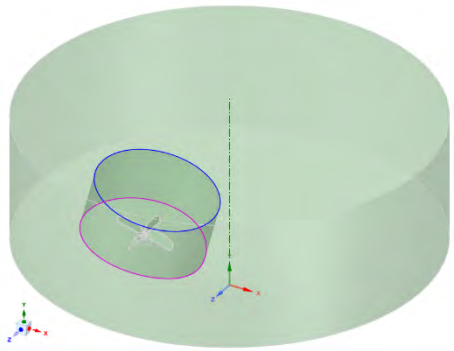

**Figure 1.** 3D geometry of the *R&D scale* vessel.

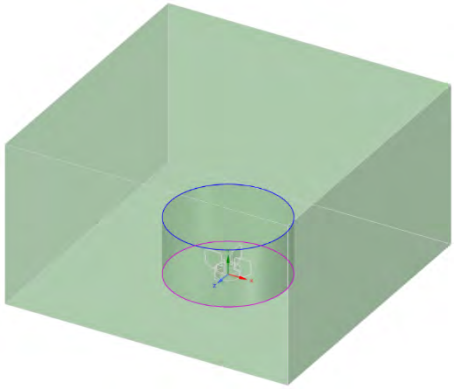

**Figure 2.** 3D geometry of the *Clinical scale* vessel.

The simulations are performed under steady-state conditions and the resulting fluid-flow behavior was validated against experimental operating data from the vessel, using blend time as the metric for comparison.

Key information required to build the compartment model (e.g. cell centroid coordinates, volume, velocity components, data concerning neighbouring cells) are exported in text files using User Defined Functions.

## Compartment model

Starting from the results of the steady-state CFD simulation describing the detailed fluid flow behavior, the compartment model is built through a sequence of steps: first, the geometry is divided into compartments; next, the fluxes between compartments are computed; and finally, the material balances within each compartment are solved. All implementations were carried out in a Python 3.13 environment.

### Compartmentalization

The compartmentalization procedure is the preliminary step in constructing the compartment model. Its purpose is to divide the system geometry into compartments, each representing a volume in which the perfectly mixed assumption is applied. Adjacent compartments are then allowed to exchange mass with one another.

In this study, a basic compartmentalization procedure is employed. More complex approaches, e.g. accounting for the flow patterns inside the tank, can be found in the literature [10][11][12].

The selected compartmentalization procedure consists of defining the number of compartments to be generated along the different coordinate axes. In this way, the system is compartmentalized so that all compartments have approximately the same volume. Due to the distinct geometries of the two vessels, a cylindrical coordinate system (r, θ, y) was used for the *R&D scale* tank whereas a cartesian coordinate system (x, y, z) was adopted for the *Clinical scale* tank. An example of compartment division with 4 compartments along each coordinate is visualized in Figure 3 using cylindrical coordinates for the *R&D scale* vessel, in Figure 4 using cartesian coordinates for the *Clinical scale* one.

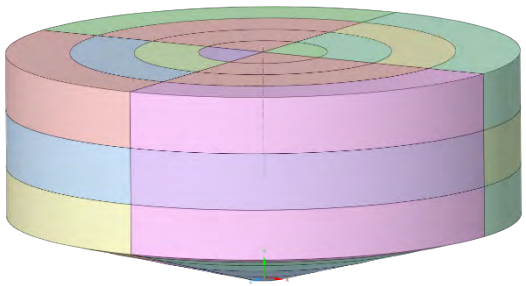

**Figure 3.** Example of compartmentalization with four compartments along the different coordinates for the *R&D scale* vessel using cylindrical coordinates.

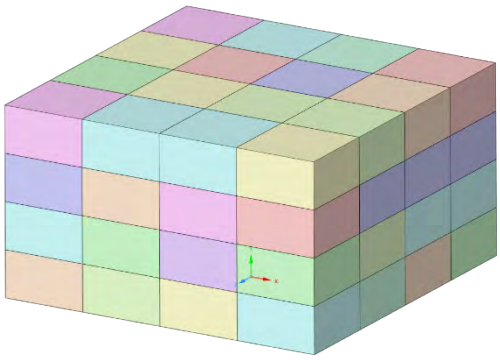

**Figure 4.** Example of compartmentalization with four compartments along the different coordinates for the *Clinical scale* tank using cartesian coordinates.

After this subdivision, the CFD mesh cells are grouped based on whether their centroids fall within the coordinate bounds of each compartment [13]. Consequently, at the end of this step, a mapping is obtained that associates each CFD mesh cell with its corresponding compartment.

### Fluxes computation

To compute the material exchanges between compartments, the face flux data exported from the CFD

simulation are used. For each mesh face *k*, the CFD solver provides a flux value $f_k$.

Faces that connect cells belonging to two different compartments are identified by examining the compartments associated with their neighboring CFD cells. Let compartment *i* contain the set of CFD mesh cells $\mathcal{C}_i$, and compartment j the set $\mathcal{C}_j$. A face *k* contributes to the exchange between compartments *i* and *j* if it connects a cell $c_a \in \mathcal{C}_i$ and a cell $c_b \in \mathcal{C}_j$. Based on this identification, the set of faces contributing to the flux from compartment *i* to compartment *j* can be defined as:

$$\mathcal{F}_{i\to j} = \{k \mid k \text{ connects a cell in } \mathcal{C}_i \text{ to a cell in } \mathcal{C}_j\} \quad (1)$$

A schematic illustrating how cells and faces are assigned to each set is shown in Figure 5.

The total flux from compartment *i* to compartment *j* is then computed as the sum of the corresponding face fluxes:

$$F_{i\to j} = \sum_{k\in\mathcal{F}_{i\to j}} f_k \quad (2)$$

Consequently, the overall outgoing and incoming fluxes for compartment *i* are defined as:

$$F_i^{out} = \sum_{j=1}^{N} F_{i\to j} \quad (3)$$

$$F_i^{in} = \sum_{j=1}^{N} F_{j\to i} \quad (4)$$

where *N* is the total number of compartments.

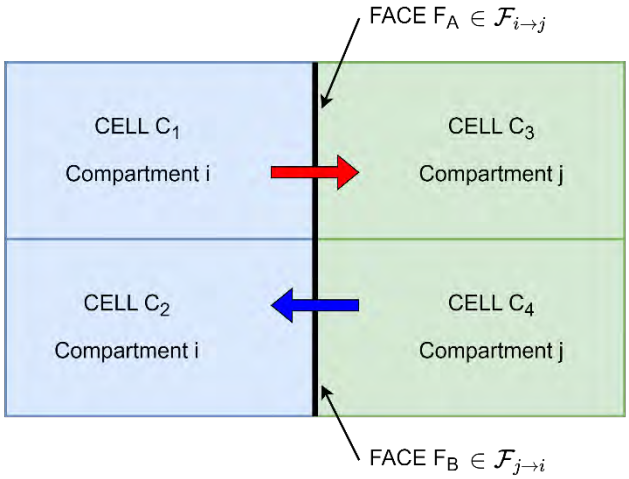

**Figure 5.** Schematics of assignments of cells and faces. $C_1, C_2 \in \mathcal{C}_i, C_3, C_4 \in \mathcal{C}_j$. Face $F_A$ divides cells $C_1 \in \mathcal{C}_i$ and $C_3 \in \mathcal{C}_j$, and is assigned to set $\mathcal{F}_{i\to j}$ since mass flux is from $C_1$ to $C_3$; face $F_B$ divides cells $C_2 \in \mathcal{C}_i$ and $C_4 \in \mathcal{C}_j$, and is assigned to set $\mathcal{F}_{j\to i}$ since mass flux is from $C_4$ to $C_2$.

### Material balances

The compartment model then solves a system of ordinary differential equations, composed of one equation per species in each compartment. The mass balances are expressed as follows:

$$\frac{dM_{i,c}}{dt} = \sum_{k=1}^{N}(F_{k\to c} * w_{k,i}) - w_{c,i} * F_{c,outgoing} + R \quad (5)$$

where $M_{i,c}$ is the mass of species *i* in compartment *c*, *N* is the total number of compartments, $w_{c,i}$ is the mass fraction of species *i* in compartment *c*, *R* represents reaction or source terms for species *i* in compartment *c*.

The resulting system of material balances is solved using the *solve_ivp* function from the *scipy* library, with the BDF method selected as the numerical solver.

The solution returns the mass profiles of each species within all compartments as a function of time. To enable comparison across different models, the total mass of each species in the tank is then computed at every timestep by summing its mass over all compartments.

All simulation results will be compared to that of a perfectly mixed tank.

## CASE STUDY

Some monoclonal antibodies are prone to aggregation under low-pH conditions. A simplified kinetic expression describing this behavior was derived from the work of Arosio et al. (2011) [3]. The simplified aggregation mechanism can be represented as:

$$M + M \xrightarrow{k_{aggr}} A \quad (6)$$

The kinetic constant $k_{aggr}$ is assumed to depend on pH according to the following relationship:

$$k_{aggr} = \left(k^0_{aggr}\right) \cdot \exp\left(-\beta(pH - 3.334)\right) \quad (7)$$

where $k^0_{aggr}$ and $\beta$ are model parameters estimated from experimental data. Their numerical values are reported in Table 1.

**Table 1:** Aggregation kinetics model parameters.

| Parameter | Value |
|---|---|
| $k^0_{aggr}$ | 4.518 [m³/(kg h)] |
| β | 8.468 [-] |

The reaction rate can therefore be expressed on a mass basis as:

$$R = k_{aggr} \cdot [M]^2 \quad (8)$$

where *[M]* is the mass concentration of the mAb.

All kinetic expressions were formulated on a mass basis to simplify their implementation in the CFD simulations, since no information on the molecular weight of the mAb was available.

To incorporate the aggregation kinetics into both the CFD simulations and the compartment models, three species must be considered: the monoclonal antibody, referred to as the monomer; the product formed through aggregation, referred to as the aggregate; and the

oxonium ion, which is included to represent the pH distribution inside the tank through its definition:

$$pH = -\log_{10}[H_3O^+] \quad (9)$$

where $[H_3O^+]$ is the molar concentration of oxonium ion expressed in mol/L. Since the total fluid density is assumed to remain constant, an additional species, referred to as the solvent, is considered implicitly. Its mass is not obtained by solving a dedicated balance equation; instead, it is computed at each time step as the difference between the total fluid mass and the sum of the masses of all explicitly modeled species.

The viral inactivation process operates in fed-batch mode, as a titrant is continuously added to the vessel to reduce the pH to the desired target value. In principle, this would result in a time-varying liquid volume inside the tank. However, to simplify the set up of the simulations, the process was modeled under the assumption of constant volume.

In the CFD simulations, the reaction rate is implemented as a source term for monomer or aggregate in all fluid zones using Equation (5). The continuity, momentum, and turbulence equations were not solved during this stage, and the flow variables were fixed to the values obtained from the initial steady-state simulation.

All simulations were carried out in transient mode. The simulations were initialized using typical values reported in experimental studies of aggregation kinetics for pH, monomer concentration, and aggregate concentration. These initial conditions were assumed to be homogeneous throughout the vessel volume. The process was simulated until the pH reached the final target value, corresponding to a decrease of 1.55 relative to the initial condition.

## RESULTS

This section presents the main results obtained in assessing the performance of the compartment models, comparing them against both the perfectly mixed models and the CFD simulations. The CFD results are taken as the most representative approximation of real process behavior, as no experimental data were available for direct validation.

For the compartment model, different numbers of compartments were investigated in order to evaluate how the degree of geometric discretization influences the model predictions. The number of compartments selected along each coordinate is reported in Table 2. At the finest discretization level, the total number of compartments differs between the *R&D scale* and *Clinical scale* vessels due to the conical bottom of the *R&D scale* tank, which results in some compartments containing no CFD mesh cells and therefore being excluded from the model.

**Table 2:** Different degrees of compartmentalization considered.

| Number of compartments | | | Tot. comp. |
|---|---|---|---|
| x/r | y | z/θ | |
| 2 | 2 | 2 | 8 |
| 4 | 4 | 4 | 64 |
| 8 | 4 | 8 | 256 |
| 12 | 8 | 12 | 1152 (Clin.)<br>1068 (R&D) |

Two scenarios were considered in the performance assessment. In the first scenario, a slow titrant addition was modeled: the amount of titrant required to reach the target pH was fed over a 30 minutes interval. The simulation was then run for a total of 35 minutes to allow both the addition to be completed and the pH to homogenize throughout the tank. In the second scenario, the titrant was added over a 0.5 seconds interval, representing an almost instantaneous addition. In this case, the simulations were performed over a 35 seconds time window to ensure that mixing and pH homogenization could be observed across the entire vessel. The second scenario, characterized by a fast titrant addition, was included because it is expected to generate stronger local inhomogeneities within the tank. This, in turn, is anticipated to amplify the differences in the predictions obtained from the different modeling approaches.

### Scenario 1: Slow titrant addition

The time profiles of the total monomer mass inside the vessel, normalized with respect to the initial value, as predicted by the different models for the first scenario, are shown in Figure 6 for the *R&D scale* vessel and in Figure 7 for the *Clinical scale* one.

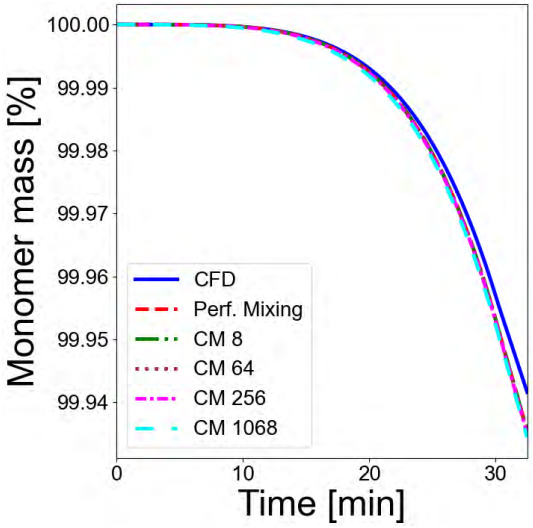

**Figure 6.** Scenario 1: total monomer mass profiles for the R&D scale vessel.

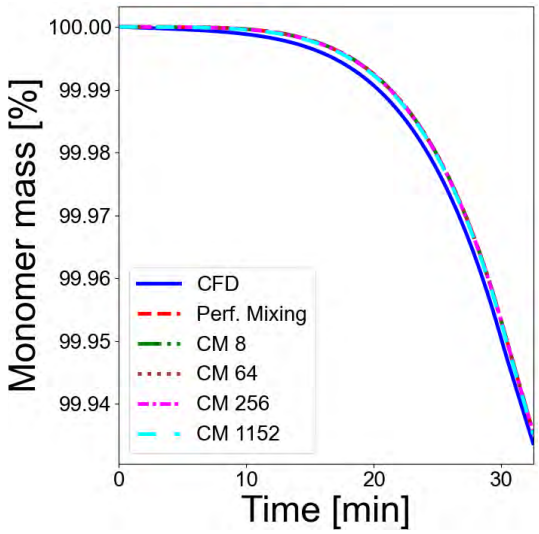

**Figure 7.** Scenario 1: total monomer mass profiles for the *Clinical scale* vessel.

The profiles obtained with the perfectly mixed model and the compartment models are nearly identical and closely match the CFD results, with discrepancies below 0.01%. This means that for scenario 1 both vessels behave as perfectly mixed systems. Consequently, in this scenario, both CFD and compartment models do not provide a strategic advantage with respect to the perfectly mixed model in predicting the unit behavior.

## Scenario 2: Fast titrant addition

The time profiles of the total monomer mass inside the vessel, normalized with respect to the initial value, as predicted by the different models for the second scenario, are shown in Figure 8 for the *R&D scale* vessel and in Figure 9 for the *Clinical scale* one.

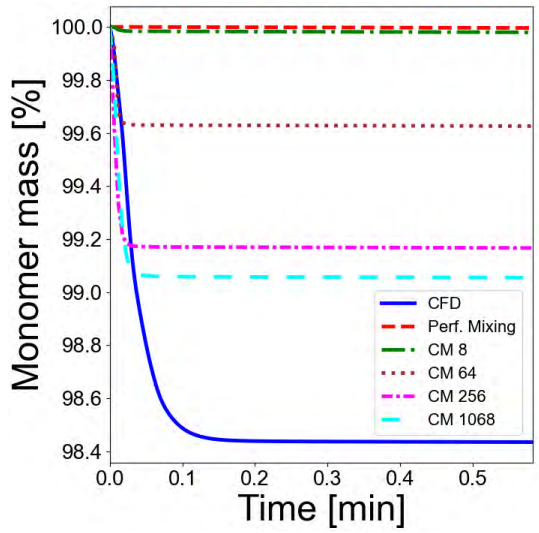

**Figure 8.** Scenario 2: total monomer mass profiles for the *R&D scale* vessel.

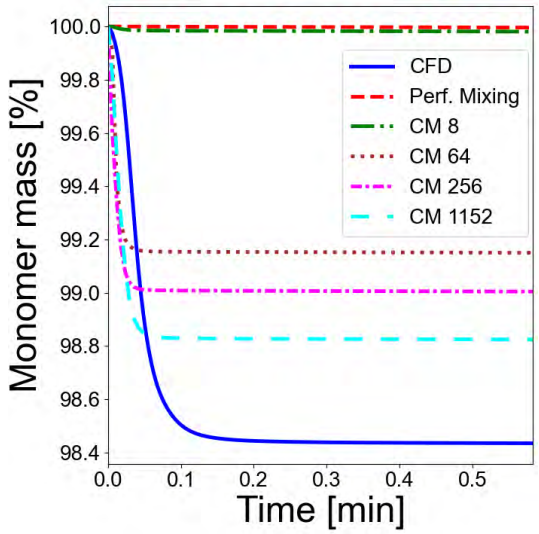

**Figure 9.** Scenario 2: total monomer mass profiles for the *Clinical scale* vessel.

As expected, this second scenario in which the titrant is added almost instantaneously inside the tank leads to the formation of pronounced localized pH inhomogeneities within the tank. These local variations are inherently captured by the CFD simulations but are not represented by the perfectly mixed model, which assumes instantaneous homogenization throughout the vessel. As a consequence, in this second scenario the CFD simulation predicts a pronounced initial aggregation that is not captured by the perfectly mixed approach. The compartment models, on the other hand, are able to reproduce this early aggregation behavior with increasing accuracy, as their predictions progressively approach the CFD results when a finer level of compartment discretization is employed.

Table 3 reports the computational times for both the R&D scale and the Clinical scale vessels.

**Table 3:** Computational times for the model solution under the fast titrant addition scenario.

| Model | Computational time | |
|---|---|---|
| | R&D scale | Clinical scale |
| CFD | 16.75 [h] | 75 [h] |
| Perf. Mixed | 0.05 [s] | 0.05 [s] |
| CM 8 | 0.05 [s] | 0.05 [s] |
| CM 64 | 0.13 [s] | 0.16 [s] |
| CM 256 | 1.17 [s] | 1.51 [s] |
| CM 1068 or 1152 | 39.40 [s] | 56.30 [s] |

A substantial reduction in computational cost can be observed: while the CFD simulations required days, the compartment models provided the predictions in less than a minute at the highest level of discretization, and in less than two seconds for the coarser discretizations. The reported computational times do not include the

duration of the preliminary steps required for model preparation, as these must be performed only once before the model can be repeatedly solved. The preliminary steady-state CFD simulations, required for both the CFD runs and the compartment models with kinetics included, took approximately 4 hours for the R&D-scale vessel and 8 hours for the clinical-scale vessel. The compartmentalization step took approximately 5 seconds, independent of the discretization level and the vessel scale.

## CONCLUSIONS

This study explored the integration of fluid-flow information obtained from CFD simulations into modeling frameworks that require significantly lower computational effort. The proposed procedure was applied to a viral inactivation process within the context of downstream biopharmaceutical manufacturing.

The results demonstrated that compartment models are able to provide predictions that are closer to the CFD results than those obtained with perfectly mixed models, while requiring substantially less computational time. This makes these models suitable for system-level optimization studies and, more generally, for scenarios in which multiple simulations are needed.

These models also offer the capability to rapidly evaluate different process operating conditions, provided that such variations do not affect the underlying fluid-flow behavior.

Opportunities for further improvement lie primarily in the compartmentalization procedure, where more advanced techniques could enhance both model performance and reliability.

## ABSTRACT

Continuous pharmaceutical manufacturing (CM) offers improved quality assurance, operational agility, and supply resilience, yet process development remains dominated by expensive trial-and-error experimentation and high-dimensional space exploration. Motivated by ICH Q13, we develop a generative inverse-design framework that maps target product quality to feasible process recipes for an integrated twin-screw wet granulation and segmented fluidized-bed drying line. The framework integrates three components: (i) a Conditional Variational Autoencoder (CVAE) generator that proposes process parameter sets conditioned on desired Critical Quality Attributes (CQAs), (ii) a Gaussian Process (GP) surrogate validator that screens candidates for manufacturing feasibility, and (iii) SHapley Additive exPlanations (SHAP) to interpret the generated designs. Training data were produced from a validated gPROMS digital twin of the Diamond Pilot Plant (DiPP) ConsiGma-25 line, covering liquid -to-solid ratio, drying temperature, drying time and air flowrate, with CQAs including granule moisture content, average particle size and porosity. The trained CVAE generated ~50, 000 candidate recipes and learned constrained feasible regions of the design space. Across seven operating scenarios, generated recipes achieved low deviations from targets. For a target-center case, deviations were 2.0% (moisture), 0.4% (particle size) and 0.5% (porosity). Edge cases remained acceptable, with the largest deviation observed for moisture in a high-moisture scenario (8.8%). SHAP analysis highlighted drying time and liquid-to-solid ratio as the dominant drivers of moisture, while liquid-to-solid ratio governed particle size and porosity. Overall, the approach enables rapid, explainable exploration of CM design spaces, reducing experimental burden and supporting QbD-aligned development for integrated continuous processes.

Keywords: Design space, Generative Artificial Intelligence, Pharmaceutical manufacturing, Inverse Design, Quality by Digital Design, Conditional Variational Autoencoder

## INTRODUCTION

Continuous manufacturing (CM) is increasingly adopted in the pharmaceutical sector to improve product quality, manufacturing agility and supply resilience. Unlike traditional batch processing, CM operates closer to a steady state and can enable tighter coupling between process analytical technology, advanced process control and real-time release testing. This evolution is supported by the broader shift toward digital applications (online/real-time, model-based decision support and control) and by the growing role of AI across the pharmaceutical lifecycle [1-4]

Regulatory agencies have actively encouraged CM adoption; in particular, ICH Q13 consolidates scientific and regulatory considerations for CM development, implementation, operation and lifecycle management, and emphasizes systematic approaches to define and maintain a state of control [5] Within the Quality-by-Design (QbD) paradigm (e.g., ICH Q8), the central engineering task is to connect Critical Process Parameters (CPPs) to Critical Quality Attributes (CQAs) and to identify a design space (DS) that guarantee product quality [6]

Despite these advantages, CM process development and scale-up remain resource intensive. Integrated drug-product flowsheets frequently involve several unit operations. As a result, CPP-CQA relationships are highly nonlinear and can exhibit strong cross-unit interactions.

A representative example is the integrated twin-screw wet granulation and segmented fluidized-bed drying line used in continuous tableting: granulation conditions govern nucleation, growth and consolidation through liquid bridge formation and shear, while drying conditions determine moisture removal and influence granule structure and porosity [7]. Because these mechanisms interact across units, traditional design-of-experiments (DoE) campaigns can become prohibitively expensive, requiring many experiments (or high-fidelity simulations) to explore multidimensional spaces and capture cross-unit effects.

Inverse design reframes this workflow by treating product specifications as the starting point. Instead of asking "what CQAs result from these CPPs?", the inverse problem asks "which CPPs can achieve a target set of CQAs?". This aligns naturally with QbD because target CQAs and acceptable ranges define the desired product profile, and the process recipe should be selected from within a feasible and validated design space. However, inverse design in CM is challenging: several distinct CPP combinations can yield similar CQAs (a one-to-many mapping), feasible regions can be non-convex, and manufacturing constraints (equipment limits, residence-time windows, safe operating envelopes) are difficult to encode explicitly.

Deep generative models offer an alternative route to solve inverse problems. Variational autoencoders (VAEs) learn probabilistic latent representations enabling stable training and sampling of new candidates through latent-space exploration [8].Conditional variants (CVAEs) extend VAEs by learning conditional distributions given labels or targets, providing direct controllability for inverse design [9]. In materials discovery, deep generative models have been widely explored to accelerate inverse design by encoding structure-property relationships into latent spaces that can be navigated to propose candidates with targeted characteristics [10]. In pharmaceutical sciences, generative models have achieved notable success in drug discovery and are now being explored for digital formulation optimization[11-12]. Related work in particle engineering has shown that CVAEs can generate particle geometries to match target sphericity and packing fraction, illustrating the suitability of conditional generation for constrained inverse tasks [13]

Despite this progress, the application of generative inverse design to integrated, industrial-style CM unit-operation networks remain limited. Existing CM studies often focus on data augmentation. For example, Ma et al. combined GAN-based data augmentation with surrogate models and multi-objective optimization for an integrated synthesis-crystallization case study [14]. In GMP-relevant CM, however, robustness, feasibility screening and interpretability are essential: candidate recipes must remain within validated operating envelopes and the rationale for recipe selection should be explainable to support process understanding and lifecycle management.

In this work, we propose a three-component framework tailored to CM inverse design. First, a CVAE acts as a generator that learns the conditional distribution of CPP recipes given target CQAs, enabling controllable, one-to-many generation. Second, an independent Gaussian Process (GP) surrogate acts as a validator to screen generated candidates for feasibility and to quantify predictive uncertainty; this reduces the risk of selecting recipes that exploit model artefacts or extrapolate beyond the validated region. Third, we apply SHapley Additive exPlanations (SHAP) [15] to the surrogate validator (GP model) that maps CPPs to CQAs. The resulting feature attributions explain how changes in CPPs drive the validator's predicted CQAs and can be used to interpret candidate CPP sets generated by the CVAE.

We demonstrate the framework using a validated gPROMS flowsheet model representative of the Diamond Pilot Plant (DiPP) ConsiGma-25 continuous tableting line, integrating twin-screw wet granulation with segmented fluidized-bed drying [7-16] .The case study covers four CPPs (liquid-to-solid ratio, drying temperature, drying time and air flowrate) and three CQAs (granule moisture content, average particle size and porosity). Results show that the CVAE can generate large sets of candidate recipes that cluster around desired CQAs while maintaining operational diversity, and that feasibility and interpretability layers provide robust screening and actionable process insight. Together, these capabilities support data-efficient CM development aligned with ICH Q13 and QbD principles.

## METHODOLOGY

Figure 1 summarizes the Conditional Variational Autoencoder (CVAE) architecture adopted for inverse design. The encoder maps process parameters together with target CQAs into a low-dimensional latent representation, and the decoder reconstructs process parameters conditioned on the target CQAs. Sampling in latent space enables generation of multiple diverse recipes for the same target product profile.

### Data generation and preprocessing

Training data were generated using a validated gPROMS FormulatedProducts flowsheet model of the integrated twin-screw wet granulation and segmented fluidized-bed drying line [7-16]. A space-filling Sobol sequence was used to sample the CPP design space efficiently and to avoid clustering typical of purely random sampling [17]. A dataset of 300 formulations was used with 210 for training and 90 for validation. The same dataset was used to train the GP and CVAE models. Training on the same data as the CVAE ensures consistency in the

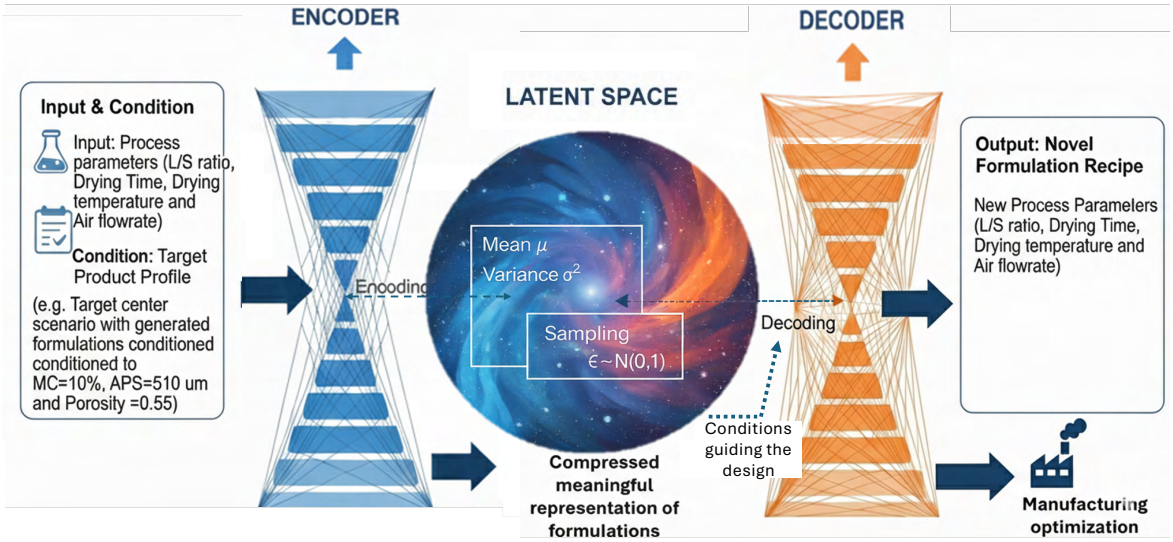

**Figure 1.** Conditional Variational Autoencoder (CVAE) architecture adapted for inverse design.

modeling framework and leverages the full available training information for robust surrogate predictions. For the GP model, the validation dataset was used to evaluate the GP's generalization performance on unseen data.

Inputs and outputs were standardized prior to training; CQAs were scaled to facilitate conditioning and multi-output learning.

## CVAE generator for inverse design

We formulate inverse design as learning the conditional distribution $p(\boldsymbol{u}|\boldsymbol{y})$, where $\boldsymbol{u}$ denotes CPPs and $\boldsymbol{y}$ denotes target CQAs. The CVAE is trained by minimizing a composite loss function (Eq. 1) consisting of an MSE reconstruction term and a Kullback-Leibler divergence regularizer [8], [9]

$$L_{CVAE}(\theta,\ \varphi;\ x,\ y) = L_{recon}(x,\ \hat{x}) + \beta(D_{KL}(q_{\varphi}(z \mid x,\ y) \mid\mid p(z))) \quad (1)$$

Where:

- $\boldsymbol{x}$: vector of critical process parameters (CPPs), scaled to the range [0, 1].
- $\hat{\boldsymbol{x}}$: reconstructed vector of critical process parameters (CPPs).
- $L_{recon}\ (\boldsymbol{x},\hat{\boldsymbol{x}})$: reconstruction loss that enforces similarity between the original CPPs and the reconstructed CPPs. In this work, the mean squared error (MSE) is used.
- $\boldsymbol{y}$: vector of conditioning critical quality attributes (CQAs), representing the desired product quality targets.
- $q_{\varphi}(\mathbf{z} \mid \mathbf{x}, \mathbf{y})$: approximate posterior distribution learned by the encoder network. It is assumed to follow a multivariate Gaussian distribution with diagonal covariance
- p(**z**): prior distribution over the latent variables, defined as a standard normal distribution N(0, 1).
- β: weighting coefficient controlling the trade-off between reconstruction accuracy and latent space smoothness/continuity of the latent space.

## Latent space and regularisation

The CVAE introduces a low-dimensional latent variable $z$ that captures the unobserved factors and one-to-many variability in feasible CPP recipes that can produce the same target CQAs. This is important for inverse design because multiple CPP combinations can satisfy a single product specification; sampling different $z$ values allows the model to generate diverse candidate recipes for the same $y$, rather than collapsing to one deterministic solution.

To make latent-space sampling meaningful, the latent distribution must be well-structured. The Kullback–Leibler (KL) divergence term regularises the encoder's approximate posterior $q\varphi(z|x,\ y)$ toward a simple prior $p(z)=N(0,\ 1)$. This discourages the encoder from memorising training samples (overfitting) and helps avoid irregular latent regions ("holes") where sampling would decode to unrealistic CPPs. As a result, the decoder can reliably generate feasible recipes by sampling $z\sim p(z)$ and conditioning on the desired CQAs $y$.

A key practical requirement in CM is recipe diversity under constraints. By sampling the latent space, the CVAE generates a distribution of recipes rather than a single optimum. This flexibility can support operational preferences, robustness to disturbances and equipment

limitations while still meeting target CQAs.

### GP validator for feasibility assessment

To screen AI-generated recipes, we train a Gaussian Process (GP) surrogate model that predicts CQAs from CPPs and provides predictive uncertainty. Candidate recipes are accepted when predicted CQAs fall within specification windows and uncertainty remains below a threshold. This validator step reduces the risk of selecting recipes outside the validated region and provides an additional safety layer for GMP-relevant deployment.

### Explainability with SHAP

To support interpretability, we apply SHapley Additive exPlanations (SHAP) to the surrogate validator (GP) used to predict CQAs from CPPs. SHAP decomposes each predicted CQA into additive contributions from individual CPPs, providing global trends (feature importance across the design space) and local explanations for specific CPP candidates. In the continuous manufacturing context, this supports "Quality by explainability" [18] by identifying which CPPs most strongly drive each predicted CQA and therefore should be prioritized for monitoring and control.

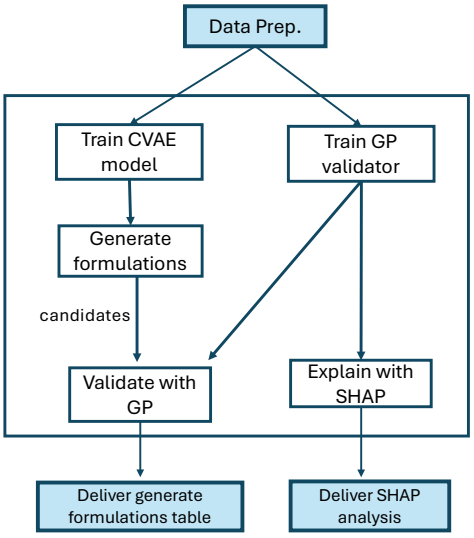

**Figure 2.** Generative inverse design workflow: CVAE generation.

## CASE STUDY: INTEGRATED WET GRANULATION AND DRYING

The case study considers an integrated twin-screw granulator coupled with a segmented fluidized-bed dryer from the ConsiGma-25 continuous tableting line at the Diamond Pilot Plant (DiPP) [7]. The process model, implemented in gPROMS, captures nonlinearities and cross-unit couplings relevant to granule formation and moisture removal.

Four CPPs are considered: liquid-to-solid ratio (L/S), drying temperature (Tem), drying time (DT) and air flowrate (AF). Three CQAs are targeted: granule moisture content (MC), average particle size (APS) and porosity (Poro).

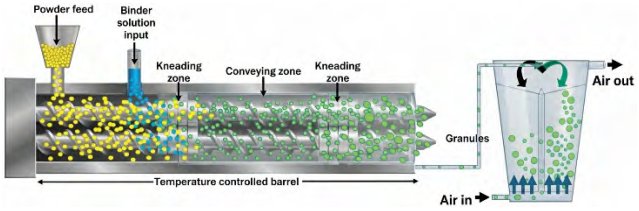

**Figure 3.** Integrated twin-screw wet granulator and segmented fluidized-bed dryer (ConsiGma-25 line, DiPP).

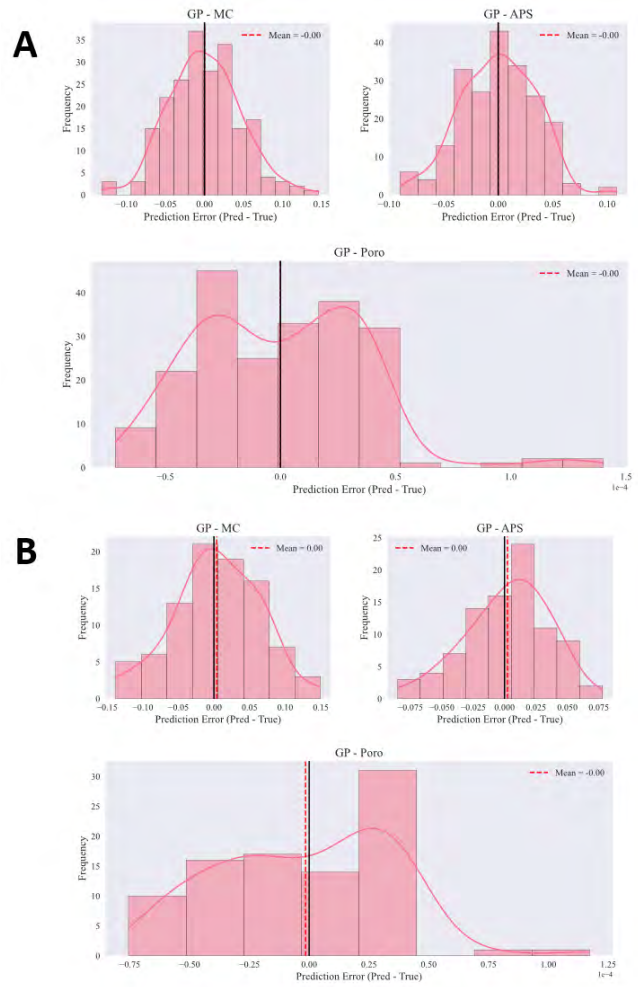

**Figure 4.** Prediction error distribution for the Gaussian Process validator. A. Training B. Validation

The inverse design task is to generate CPP recipes that meet specified targets (e.g., MC≈10%, APS≈510 µm, Poro≈0.55) while remaining operable for the integrated process.

## RESULTS AND DISCUSSION

### Validator accuracy

The GP validator achieved high accuracy on training and validation data, with prediction errors tightly centered around zero for all CQAs (Fig. 4).

### Explainability and process insight

SHAP analysis (Fig. 5) indicates that drying time (DT) and liquid-to-solid ratio (L/S) exert the strongest influence on moisture content, consistent with heat and mass transfer fundamentals in drying.

In contrast, APS and porosity are primarily governed by L/S, aligning with granulation theory where liquid availability controls nucleation, coalescence and consolidation. These explanations help translate data-driven recipes into actionable engineering understanding and support monitoring and control strategies centered on the most influential CPPs.

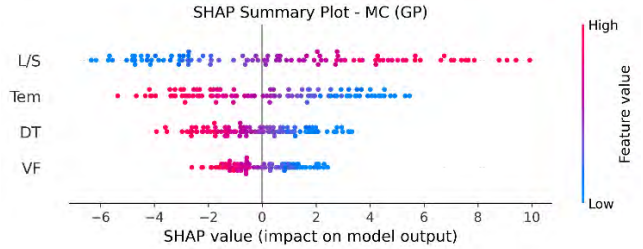

**Figure 5.** SHAP summary plot highlighting dominant CPP drivers for the CQAs.

### Design-space coverage and conditional generation

The trained CVAE generated approximately 50, 000 candidate recipes. Figure 6A shows that generated recipes explore the broader CPP design space while clustering into feasible regions that correspond to target formulations. The generator naturally produced multiple distinct CPP combinations that meet the same target CQAs, illustrating the one-to-many nature of the inverse design

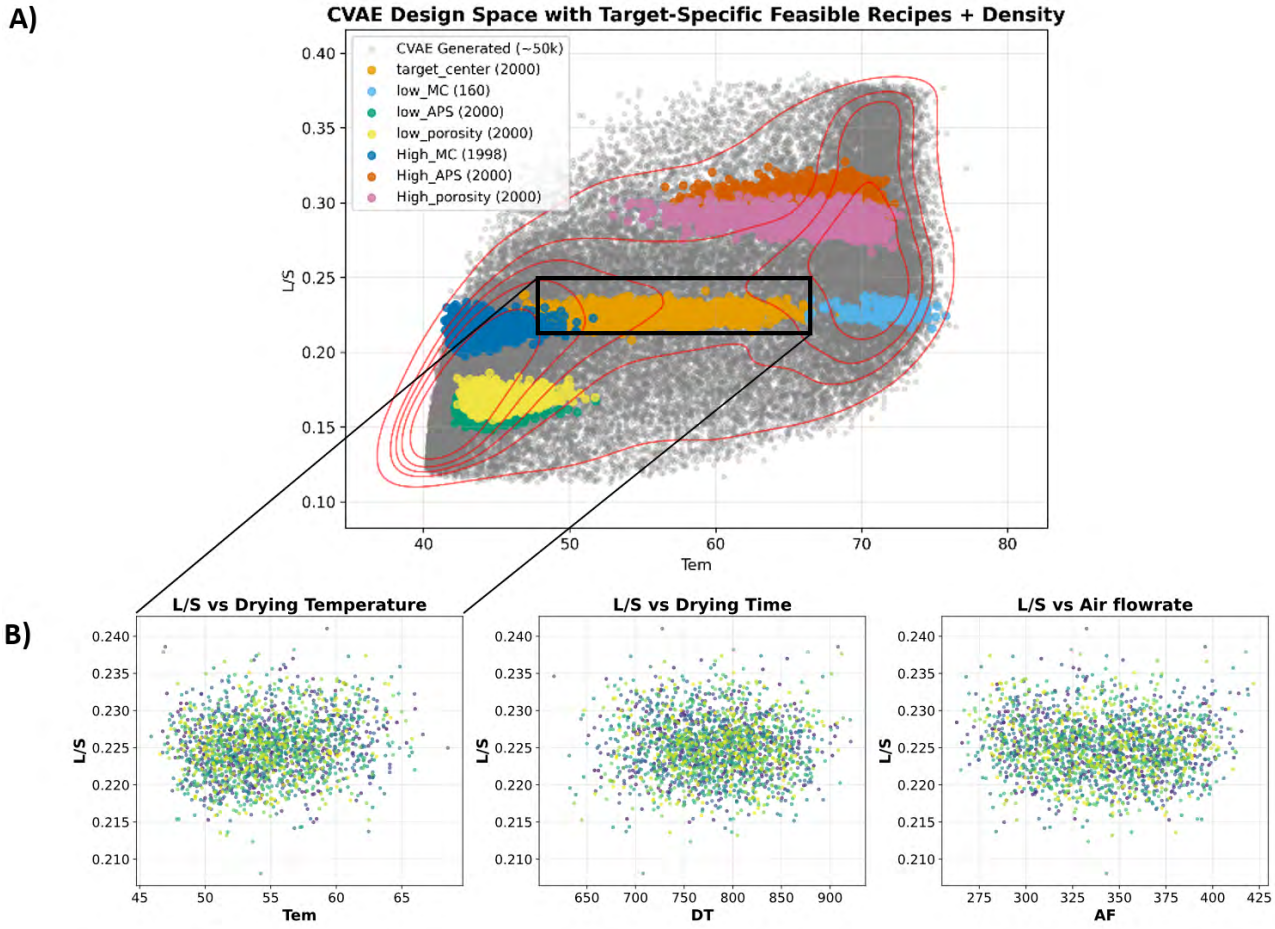

**Figure 6.** A. CVAE design-space exploration with clustered target formulation regions (colored) within the broader feasible set (grey). B. Close-up of Target center scenario with generated formulations conditioned to MC=10%, APS=510 um and Porosity =0.55.

mapping.

This inverse-design workflow complements established DS determination and uncertainty-aware DS methodologies by providing a generative mechanism to propose diverse CPP candidates that can then be validated within a DS framework [19-23]

Figure 6B illustrates example generated recipes conditioned on a representative target profile (MC=10%, APS=510 µm, Poro=0.55). Recipes remain diverse in CPP space while producing similar CQAs after feasibility screening, enabling operational flexibility.

## Robustness across operating scenarios

Robustness was tested across seven operating scenarios that probe challenging specification demands (including low/high moisture, low/high APS, and low/high porosity).

Figure 7 summarizes percentage deviations from targets across scenarios. The target-center scenario achieved deviations of 2.0% (MC), 0.4% (APS) and 0.5% (Poro). The low-moisture scenario also performed well (3.1%, 0.3%, 0.7%).

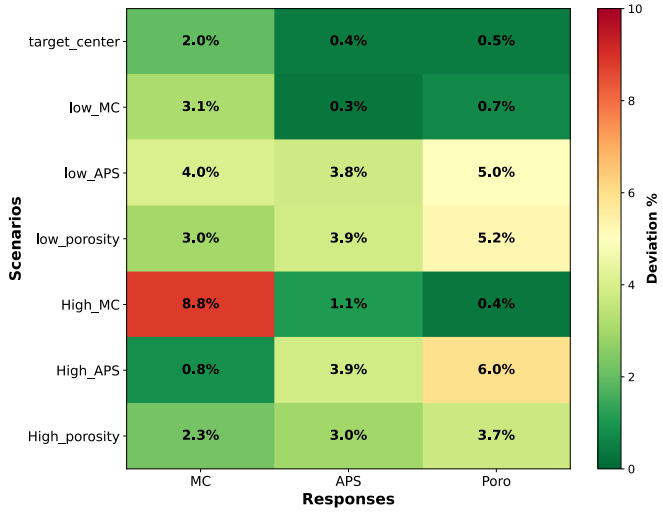

**Figure 6.** Deviation study for generated recipes across seven operating scenarios.

The most challenging case was high moisture content, where MC deviation increased to 8.8% while APS and porosity remained close to targets (1.1% and 0.4%). Overall, results indicate that the CVAE can learn constrained feasible regions and produce recipes that satisfy tight specifications across a range of industrially relevant conditions.

## CONCLUSIONS AND FUTURE WORK

We presented a generative inverse-design framework for integrated continuous pharmaceutical manufacturing that combines a CVAE generator, a GP feasibility validator and SHAP-based explainability. Using a realistic wet granulation-drying case study, the framework generated large sets of candidate recipes (~50k) and achieved low deviations from targets across seven scenarios (best-case: target-center: 2.0% MC, 0.4% APS, 0.5% porosity; worst-case: 8.8% MC in the high-moisture scenario). Explainability analysis provided physically consistent insights, highlighting drying time and liquid-to-solid ratio as key levers for moisture control and L/S as the dominant driver for particle size and porosity.

Future work will focus on hybrid generative architectures, as well as experimental validation of selected recipes on pilot-scale equipment.

## ABSTRACT

Accurate calibration of spectroscopic measurements is essential for reliable real-time monitoring and control of crystallization processes. In this work, calibration strategies for Attenuated Total Reflectance Fourier Transform Infrared (ATR-FTIR) spectroscopy were systematically evaluated for concentration monitoring in batch cooling crystallization of paracetamol in ethanol. Linear regression (LR), Partial Least Squares Regression (PLSR), Principal Component Regression (PCR), and symbolic regression (SR) were compared using both peak-based features and full spectral representations. Peak-based models provided a transparent baseline, with peak-area-based models consistently outperforming peak-height-based models. For LR, incorporating multiple absorption bands reduced the mean squared error (MSE) by nearly one order of magnitude compared to single-peak models. Using the same peak-based inputs, SR further improved performance, reducing prediction bias at high concentrations and yielding higher coefficients of determination ($R^2$ > 0.99) compared to LR. A substantial improvement was achieved when full spectral information was used. Among all evaluated approaches, SR with unprocessed spectra yielded the best overall performance, achieving an $R^2$ of 0.996 and an MSE of $1.4 \times 10^{-6}$ on the validation dataset. This model also demonstrated strong generalization on an independent solubility test dataset, closely reproducing the reference solubility curve over the full temperature range with minimal deviation. In contrast, PCR and PLSR models showed increased sensitivity to preprocessing choices and exhibited larger errors on the test dataset. SR provided an accurate, robust, and interpretable calibration framework for ATR-FTIR, with reduced reliance on spectral preprocessing and potential for real-time process analytical technology and control applications.

**Keywords**: PAT, Preprocessing, Process monitoring, PLSR, Crystallization

## INTRODUCTION

Crystallization is a key separation and purification unit operation in the pharmaceutical and fine chemicals industries, where stringent quality requirements demand tight control over product attributes such as purity, crystal size distribution (CSD), polymorphic form, and morphology [1]. In batch cooling crystallization, these attributes are influenced by the temporal evolution of supersaturation, which governs nucleation and crystal growth kinetics. Poor supersaturation control can lead to excessive primary or secondary nucleation, agglomeration, fouling, and batch-to-batch variability, ultimately compromising product quality and process robustness [2]. As a result, real-time monitoring and control of crystallization processes have been a long-standing focus of research in process systems engineering and control [3].

The introduction of process analytical technology (PAT) frameworks has significantly advanced the monitoring and understanding of crystallization systems [4].

PAT tools enable real-time or near-real-time access to critical process information, supporting data-driven decision-making and advanced control strategies [5]. Commonly applied PAT techniques in crystallization include attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy, Raman spectroscopy, focused beam reflectance measurement (FBRM), particle vision and measurement (PVM), and ultrasonic spectroscopy [6]. Spectroscopic techniques such as ATR-FTIR and Raman are primarily used for monitoring solute concentration and supersaturation, whereas chord length distribution (CLD) measurements from FBRM and image-based measurements from PVM provide indirect information related to particle size and shape. The complementary use of multiple PAT tools has enabled more comprehensive characterization of crystallization dynamics and facilitated the development of model-based monitoring and control frameworks [7].

Among these techniques, ATR-FTIR spectroscopy has become one of the most widely adopted PAT tools for concentration measurement in crystallization processes [8]. Its popularity stems from its non-invasive operation, fast sampling rates, robustness in slurry environments, and compatibility with laboratory and pilot-scale crystallizers. However, ATR-FTIR does not provide direct concentration measurements; instead, it generates spectra that must be translated into quantitative concentration estimates through calibration models [7]. The reliability of any ATR-FTIR-based monitoring or control strategy therefore depends fundamentally on the accuracy, robustness, and generalization capability of the calibration model [4, 6].

Early ATR-FTIR calibration approaches were predominantly based on linear regression (LR) models using selected peak heights or peak areas, often combined with baseline correction and explicit temperature compensation [9]. While these methods are straightforward to implement and interpret, they rely heavily on expert-driven feature selection and may fail to capture nonlinearities arising from temperature effects, solute–solvent interactions, and spectral overlap. To address these limitations, multivariate statistical techniques such as partial least squares regression (PLSR) have become the standard approach to develop ATR-FTIR calibration models [6]. PLSR enables dimensionality reduction while maximizing covariance between spectral data and concentration and has been successfully applied in a wide range of crystallization studies [10, 11].

Despite their widespread use, conventional calibration approaches exhibit several limitations. Linear models can be overly restrictive, while PLSR models are often sensitive to data preprocessing choices, including spectral filtering, scatter correction, and wavelength range selection [12]. Furthermore, latent-variable models such as PLSR may suffer from reduced interpretability, as the physical meaning of latent components is not always clear. These challenges become particularly pronounced when calibration models are expected to operate across varying temperatures, solvent compositions, or process conditions, motivating the exploration of more flexible and robust modeling strategies [4, 6].

In recent years, machine learning techniques have been increasingly investigated as alternatives or complements to classical calibration methods in spectroscopic PAT applications [13]. Approaches such as support vector regression, Gaussian process regression, and artificial neural networks (ANNs) have demonstrated improved predictive performance in some cases, particularly when nonlinear effects are significant [6]. However, many of these methods function as black-box models, limiting their interpretability and complicating their deployment in regulated industrial environments [4]. Moreover, their computational complexity and reliance on large, representative datasets can pose challenges for real-time implementation and long-term maintenance.

Within this context, symbolic regression (SR) has emerged as a promising interpretable machine learning approach for process modeling and calibration [7]. SR aims to identify explicit mathematical expressions that relate input variables to outputs, without assuming a predefined model structure [14]. By balancing model accuracy and complexity, SR can uncover nonlinear relationships while producing closed-form equations that are transparent and amenable to physical interpretation [15]. These characteristics make SR particularly attractive for PAT-enabled crystallization systems, where interpretability, robustness, and ease of deployment are critical.

Although SR has been successfully applied to a variety of chemical engineering problems, including model correction, system identification, and control-oriented modeling [14-16], its application to ATR-FTIR calibration for crystallization monitoring remains limited in the open literature [7]. Most existing studies continue to rely on LR or latent-variable methods, despite growing interest in interpretable scientific machine learning frameworks [4, 6]. This gap highlights the need for a systematic evaluation of SR as a calibration methodology and a direct comparison with established approaches under consistent experimental conditions.

In this work, ATR-FTIR calibration models were developed for paracetamol–ethanol systems using SR and benchmarked against conventional LR, PLSR, and and principal component regression (PCR) models. As presented in Figure 1, different input representations were investigated, including peak-based features, temperature, and principal components derived from limited spectral ranges. The influence of common preprocessing strategies was assessed, and the resulting models were evaluated in terms of predictive accuracy, robustness, and generalization capability. The main objective was to

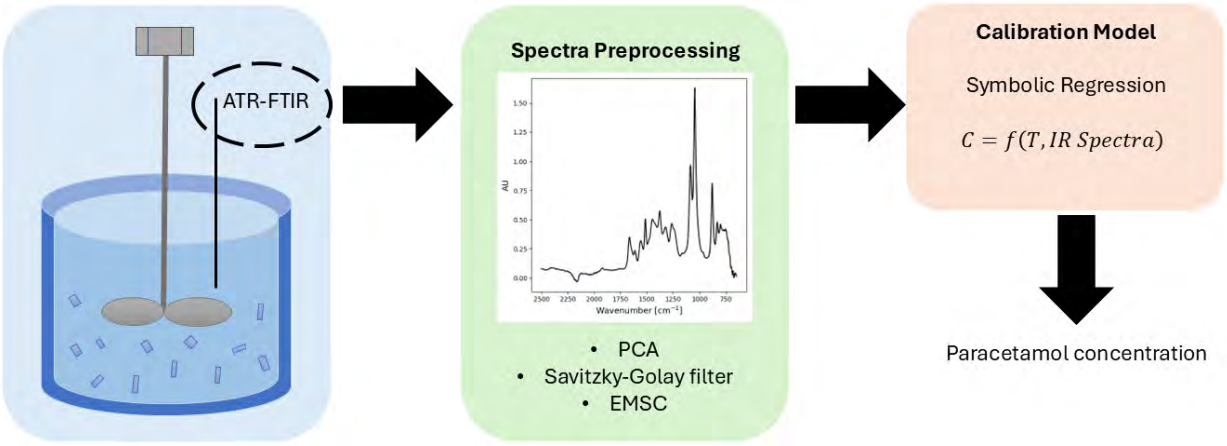

**Figure 1.** Symbolic regression approach proposed to develop ATR-FTIR calibration models.

assess the suitability of SR as a practical and interpretable alternative for ATR-FTIR calibration in crystallization monitoring and control applications.

## DATA ACQUISITION

The experimental dataset used in this work was obtained from the batch crystallization study reported in Lima et al. [7]. In that work, paracetamol–ethanol mixtures were prepared gravimetrically and monitored in situ using ATR-FTIR spectroscopy, with complementary PAT tools (FBRM and temperature sensing) available in the same setup. Infrared spectra were acquired using a ReactIR system over 648–2500 $cm^{-1}$ at a sampling rate of one spectrum per minute.

For calibration-model development, the dataset comprises 107 ATR-FTIR spectra paired with reference concentrations covering 0 to 0.5 g paracetamol/g ethanol and temperatures spanning from 10 to 70 °C. The data originate from four calibration experiments designed to systematically vary composition and temperature, including dilution sequences where ethanol was added to a fully dissolved paracetamol–ethanol solution and stepwise addition of paracetamol into ethanol. Across these experiments, spectra for a given concentration level were acquired at multiple temperatures, ensuring that the calibration models capture the coupled influence of concentration and temperature on spectral response. This dataset was randomly divided into calibration and validation subsets, with 70 % of the samples used for model training and the remaining 30 % reserved for validation.

In addition to the calibration and validation datasets, an independent test dataset was used to evaluate model generalization. This test set corresponds to an equilibrium solubility experiment reported in Lima et al. [7], where a paracetamol–ethanol mixture was held at 10 °C for 3 h to ensure equilibrium and then heated at 0.1 K/min up to 55 °C. The resulting equilibrium concentrations were compared against the solubility model reported by Griffin et al. [17], providing an external check that model-predicted concentrations reproduce physically meaningful temperature–solubility trends beyond the calibration split.

## SPECTRAL PREPROCESSING AND FEATURE CONSTRUCTION

Preprocessing approaches were systematically tested to quantify how common chemometric treatments and feature representations affect calibration accuracy and robustness. The starting point was a peak-based calibration strategy derived from chemically meaningful absorption bands of paracetamol in the ATR-FTIR spectra. Both peak height and peak area were evaluated as inputs. Prior to peak extraction, baseline subtraction was applied to reduce offsets and slow drifts in the spectra. Peak areas and peak heights were then computed over the following wavenumber intervals: 1584-1532 $cm^{-1}$, 1532-1492 $cm^{-1}$, and 1292-1184 $cm^{-1}$.

Beyond the peak-based representation, full-spectrum representations were also investigated to evaluate whether multivariate inputs improve performance relative to hand-crafted features. In addition to the full spectral range, a reduced window between 600 and 1800 $cm^{-1}$ was considered, as it concentrates the most informative absorbance features for paracetamol while excluding regions more affected by noise or solvent interference. For noise attenuation, Savitzky–Golay filtering was tested using SciPy [18]. To compensate for baseline shifts and multiplicative scattering effects, extended multiplicative signal correction (EMSC) was evaluated using the chemometrics Python package [19], both alone and combined with smoothing. When spectral vectors (full or reduced) were used as model inputs, dimensionality reduction via principal component analysis (PCA) was performed using scikit-learn [20], and the resulting

components were used as regressors together with temperature.

All preprocessing variants were applied consistently across training, validation, and test datasets, and preprocessing parameters were kept fixed across modeling approaches to avoid information leakage and ensure that observed performance differences reflect the calibration models rather than data handling choices.

## CALIBRATION MODEL DEVELOPMENT

Four calibration strategies were investigated to calculate the paracetamol mole fraction and compared in this work: LR, PLSR, PCR, and SR. LR models were constructed using peak-based spectral features obtained after baseline subtraction. Both peak heights and peak areas were considered as explanatory variables, together with temperature to account for its influence on spectral response and solubility. Model parameters were estimated using ordinary least squares as implemented in scikit-learn [20]. These linear models were directly compared to SR models using the same peak-area and peak-height inputs, enabling an explicit assessment of whether SR provides benefit over the conventional peak-based calibration strategy.

PLSR and PCR models were developed using spectral information in combination with temperature, using implementations available in scikit-learn [20]. Depending on the preprocessing strategy, either full-spectrum data or reduced spectral windows were used as inputs. For PCR, PCA was first applied to the spectral matrix, and a fixed number of principal components were retained as regressors in a linear model together with temperature. For PLSR, latent variables were extracted by maximizing covariance between spectral inputs and concentration. In both PCR and PLSR, the number of retained components/latent variables was selected a priori by inspecting the cumulative explained variance of the spectral decomposition and the stability of prediction performance on the held-out validation split, and then fixing a single value used consistently across all subsequent comparisons.

SR was employed as an interpretable machine learning approach to develop nonlinear calibration models without assuming a predefined functional form. SR models were developed using the PySR framework [21], which searches for explicit mathematical expressions relating spectral inputs and temperature to solute concentration. Different input representations were explored, including peak-based features (peak height/area) and principal components derived from full or reduced spectra. Model complexity was controlled by limiting expression depth and length to promote models suitable for real-time monitoring and control applications.

Across all calibration strategies, model performance was evaluated using identical data splits and performance metrics, ensuring a consistent and fair comparison between linear, latent-variable, and symbolic approaches.

## RESULTS AND DISCUSSION

### Peak-based Calibration Models

Initially, calibration models based on manually selected spectral features were investigated. Peak-based models were constructed using both peak height and peak area extracted from characteristic paracetamol absorption bands after baseline subtraction. The models were initially developed using a single absorption band and subsequently extended by including additional chemically relevant peaks, specifically the 1292–1184 $cm^{-1}$, 1532–1492 $cm^{-1}$, and 1584–1532 $cm^{-1}$ regions. These models represent the conventional approach adopted in ATR-FTIR calibration and provide a benchmark against which multivariate and symbolic regression models can be assessed. The SR models were trained with 200 iterations and a population size of 20.

**Table 1:** Performance of the LR and SR models to calculate the paracetamol mole fraction for the validation set, considering temperature and peak areas or heights as inputs

| Peak Area | | | |
|---|---|---|---|
| **Model** | **Number of Inputs** | **$R^2$** | **MSE** |
| LR | 2 | 0.982 | $1.40 \times 10^{-5}$ |
| LR | 3 | 0.984 | $1.31 \times 10^{-5}$ |
| LR | 4 | 0.990 | $7.74 \times 10^{-6}$ |
| SR | 2 | 0.985 | $1.21 \times 10^{-5}$ |
| SR | 3 | 0.991 | $7.16 \times 10^{-6}$ |
| SR | 4 | 0.994 | $4.41 \times 10^{-6}$ |
| **Peak Height** | | | |
| **Model** | **Number of Inputs** | **$R^2$** | **MSE** |
| LR | 2 | 0.986 | $1.08 \times 10^{-5}$ |
| LR | 3 | 0.986 | $1.14 \times 10^{-5}$ |
| LR | 4 | 0.993 | $5.75 \times 10^{-6}$ |
| SR | 2 | 0.976 | $3.49 \times 10^{-3}$ |
| SR | 3 | 0.992 | $5.97 \times 10^{-6}$ |
| SR | 4 | 0.997 | $2.37 \times 10^{-6}$ |

Table 1 summarizes the performance of the LR and SR models developed using peak-based spectral features and temperature as inputs. For both peak height and peak area representations, increasing the number of peaks used as inputs leads to a systematic improvement in model accuracy, as reflected by increasing $R^2$ values and decreasing mean squared error (MSE). This trend is observed consistently for both LR and SR models and indicates that incorporating multiple chemically relevant

absorption bands provides complementary information, reducing sensitivity to noise and local spectral distortions associated with individual peaks.

For LR models, the improvement with additional peaks is particularly evident when moving from two to four inputs, where the MSE decreases significantly for both peak height and peak area representations. This reflects the limited expressive capability of linear models, which rely on sufficiently rich input information to approximate the underlying concentration–temperature relationship. Eq. 1 shows the resulting LR formulation, where the predicted concentration is expressed as a weighted linear combination of peak intensities and temperature. While this structure is transparent and easy to interpret, it cannot explicitly represent nonlinear interactions between spectral features and temperature.

$$X_{para} = -0.000191T + 0.271\,h_{1256} + 0.356h_{1512} - 0.559h_{1560} + 0.0447 \quad (1)$$

On the other hand, the SR model, given in Eq. 2, introduces nonlinear combinations of peak intensities and temperature through higher-order and multiplicative terms. These nonlinear structures allow the model to capture temperature-dependent changes in spectral response and interactions between absorption bands that are not accessible to linear regression. As a result, SR achieves lower MSE and higher $R^2$ values than LR for the same set of peak-based inputs, particularly when three or four peaks are included. The model described in Eq. 2 was obtained using the three peak heights as inputs, but only the most relevant inputs stay in the equation in symbolic regression.

$$X_{para} = h_{1512}[\,(0.714 + 0.430h_{1512})^4 - 0.00553h_{1560}T] \quad (2)$$

Figure 2 presents the parity plots for LR and SR models using four peak heights and temperature as inputs. Both models show good agreement between predicted and reference concentrations. However, the SR model exhibited reduced bias at higher concentrations and improved clustering around the parity line. This behavior was consistent with the nonlinear structure of Eq. 2, which enables better extrapolation toward the solubility limit compared to the linear formulation in Eq. 1.

Despite these improvements, peak-based models remain fundamentally limited by the reduced information content of manually selected spectral features. Although SR partially mitigates this limitation through nonlinear functional forms, the performance gains remain modest when compared to multivariate models based on full or reduced spectral representations. Nevertheless, the peak-based analysis establishes a clear and interpretable baseline, demonstrating that SR can extract additional predictive value from low-dimensional inputs while preserving model transparency and suitability for real-time implementation.

## Spectra-based Calibration Models

To overcome the limitations associated with manually selected peak-based features, calibration models based on spectral representations were subsequently investigated. In this approach, the ATR-FTIR spectra were used directly as model inputs together with temperature, allowing the calibration models to exploit distributed spectral information related to both concentration and temperature effects. The comparative performance of the spectra-based calibration models is summarized in Table 2 for the validation set, while representative parity plots for the validation dataset are shown in Fig. 3.

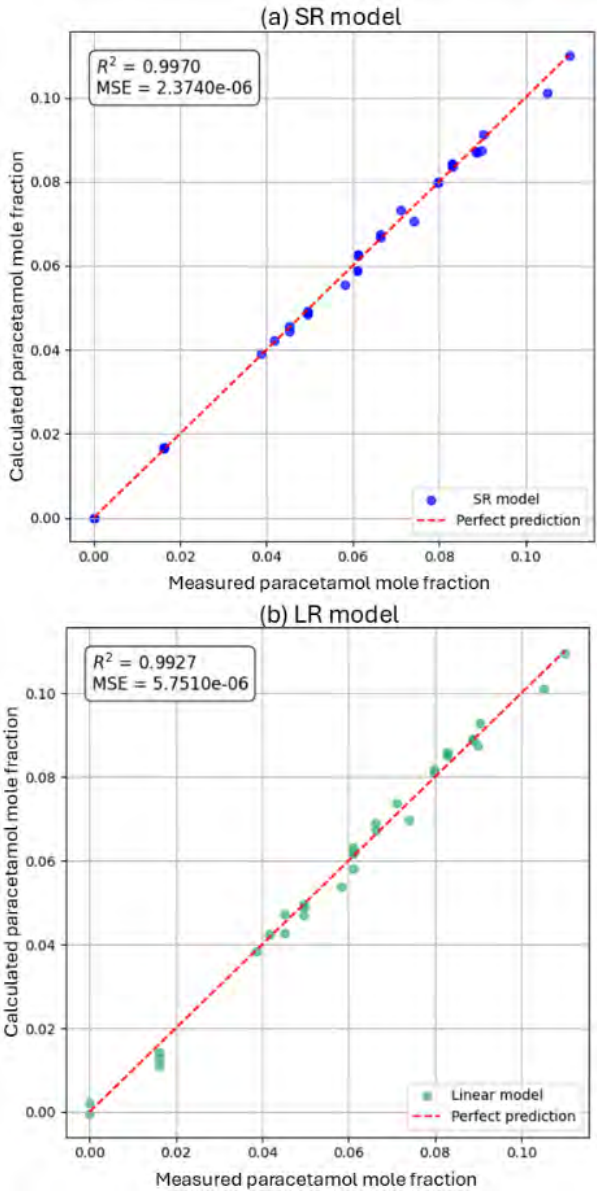

**Figure 2.** Comparison between the predicted and measured values of the paracetamol mole fraction for the validation set, considering SR and LR models using four peak heights and temperature as input.

**Table 2:** Performance of spectra-based calibration models considering different preprocessing strategies for the validation set

| | Metric | Full spectra | | | Trimmed spectra | | |
|---|---|---|---|---|---|---|---|
| | | SR | PLSR | PCR | SR | PLSR | PCR |
| No preprocessing | $R^2$ | 0.996 | 0.974 | 0.971 | 0.992 | 0.974 | 0.9708 |
| | MSE | $1.40\times10^{-6}$ | $9.83\times10^{-6}$ | $1.12\times10^{-5}$ | $3.18\times10^{-6}$ | $9.83\times10^{-6}$ | $1.12\times10^{-5}$ |
| SG filter | $R^2$ | 0.997 | 0.998 | 0.997 | 0.998 | 0.998 | 0.997 |
| | MSE | $1.15\times10^{-6}$ | $8.48\times10^{-7}$ | $1.03\times10^{-6}$ | $8.06\times10^{-7}$ | $9.60\times10^{-7}$ | $1.20\times10^{-6}$ |
| EMSC | $R^2$ | 0.994 | 0.994 | 0.992 | 0.992 | 0.994 | 0.992 |
| | MSE | $2.31\times10^{-6}$ | $2.32\times10^{-6}$ | $2.91\times10^{-6}$ | $3.10\times10^{-6}$ | $2.32\times10^{-6}$ | $2.91\times10^{-6}$ |
| EMSC + SG filter | $R^2$ | 0.995 | 0.997 | 0.996 | 0.992 | 0.992 | 0.996 |
| | MSE | $1.83\times10^{-6}$ | $1.03\times10^{-6}$ | $1.62\times10^{-6}$ | $3.11\times10^{-6}$ | $2.91\times10^{-6}$ | $1.48\times10^{-6}$ |

The influence of spectral preprocessing was systematically evaluated using common chemometric approaches, including Savitzky–Golay (SG) filtering, EMSC, and spectral range reduction. As presented in Table 2, these preprocessing steps noticeably affect linear and latent-variable models, but have a limited impact on SR. Notably, the best overall performance was obtained with SR trained on the full, unprocessed spectra, indicating that SR can internally construct nonlinear combinations of spectral features that effectively account for baseline variations, noise, and temperature-dependent distortions without requiring explicit preprocessing. In several cases, applying preprocessing led to negligible improvements or slight degradations, reinforcing that extensive preprocessing is not necessary for the SR workflow in this dataset.

As shown in Table 2, spectra-based models consistently outperformed peak-based strategies across all modeling approaches. This improvement is particularly pronounced for SR, which achieves the lowest prediction errors and highest coefficients of determination. The parity plots in Fig. 3 presents the improved agreement between predicted and measured concentrations when full spectral information is used, with reduced scatter and minimal systematic bias across the calibration and validation datasets.

The calibration model obtained by SR using the raw spectra and temperature as inputs is described in Eq. 3. $\hat{h}_i$ is the absorbance intensity at wavenumber $i$ $cm^{-1}$. All SR models were trained with 200 iterations and a population size of 20.

$$X_{para} = \hat{h}_{1656}(1.148 - \hat{h}_{1056}) + 2.425(\hat{h}_{2128}^2 - 0.00419) \quad (3)$$

Eq. 3 highlights the ability of SR to identify compact and interpretable nonlinear relationships directly from raw spectral inputs. The model combines contributions from multiple spectral regions through both linear and nonlinear terms, capturing interactions that are not explicitly represented in linear or latent-variable models.

The generalization capability of the spectra-based models was further assessed using an independent test dataset, corresponding to equilibrium solubility measurements. The performance on this test dataset is shown in Fig. 4, in which model predictions are compared against reference solubility model as a function of temperature from Griffin et al. [17]. The SR model trained on the full, unprocessed spectra shows close agreement with the reference solubility behavior over the investigated temperature range, with only minor deviations near the solubility limit. The performance of the SR model confirms the extrapolation capability beyond the calibration split and demonstrates that the model preserves physically meaningful concentration–temperature trends under equilibrium conditions.

PCR and PLSR models exhibited more dependence on preprocessing choices. Although dimensionality reduction and scatter correction can improve calibration and validation metrics, increased deviation from the reference solubility trend was observed on the test dataset, as shown in Fig. 4, indicating reduced robustness when

extrapolating toward equilibrium conditions. Overall, the spectra-based analysis demonstrates that combining full ATR-FTIR spectra with SR yielded the most accurate and robust calibration strategy investigated in this study, and that its accurate performance on the independent solubility test dataset supports its suitability for reliable spectroscopic monitoring and control of crystallization processes.

## CONCLUSION

This study evaluated different calibration strategies for ATR-FTIR-based concentration monitoring, comparing conventional peak-based models with spectra-based approaches using LR, latent-variable methods, and SR. Peak-based models provided a transparent baseline, with improved performance when multiple absorption bands and peak areas were used. SR consistently outperformed LR for the same peak-based inputs by capturing nonlinear interactions between spectral features and temperature, although performance remained limited by the reduced information content of manually selected peaks.

The use of full spectral information led to a substantial improvement in calibration accuracy and robustness. Among all approaches, SR applied directly to the unprocessed spectra yielded the best performance and demonstrated generalization on an independent solubility test dataset. The ability of SR to deliver compact, interpretable models without extensive preprocessing highlights its potential as a practical and robust calibration methodology for real-time spectroscopic monitoring and control of crystallization processes.

## ABSTRACT

Oligonucleotides are short, sequence-defined nucleic acid chains with major therapeutic and diagnostic potential. Their industrial production is currently dominated by solid-phase oligonucleotide synthesis (SPOS), which suffers from mass-transfer limitations, limited scalability, lack of real-time process monitoring, and high process mass intensity. Membrane-enhanced liquid-phase oligonucleotide synthesis (LPOS) has emerged as a scalable alternative, in which oligonucleotide chains are grown on soluble anchors and organic solvent nanofiltration is used (OSN) to remove excess reagents and by-products between each reaction steps. However, diafiltration also introduces a risk of large cumulative product loss over multiple addition cycles, which requires fine-tuning of design and operational strategies in practice. This paper presents the results of a comparative assessment of two LPOS variants with either a single- or dual-stage diafiltration against a state-of-the-art SPOS, within a unified dynamic modelling framework. A recent mechanistic kinetic model of SPOS is transferred to LPOS, including a description of OSN diafiltration dynamics and internal recycles. A feasibility analysis is conducted to identify operating regimes under which LPOS outperforms SPOS in terms of selected yield and impurity performance indicators and to expose the underlying trade-offs. Overall, the results establish LPOS with dual-stage diafiltration as a promising configuration towards more flexible and sustainable oligonucleotide manufacturing.

## INTRODUCTION

Oligonucleotides are short sequence strands of DNA or RNA that are central in modern biotechnology and medicine [1]. Their high selectivity and specificity allow targeted modulation of gene expression, underpinning applications ranging from antisense and RNA interference therapies to gene editing, molecular diagnostics, and polymerase chain reaction [2]. The growing clinical success of oligonucleotide-based drugs, together with increasing demand for personalised and precision medicine, has intensified the need for efficient, scalable and sustainable manufacturing routes.

Industrial oligonucleotide production is currently dominated by solid-phase oligonucleotide synthesis (SPOS), typically based on phosphoramidite chemistry [3]. In SPOS, nucleotide monomers are sequentially added to a growing chain immobilised on an insoluble resin, with each cycle comprising detritylation, coupling, oxidation, and capping steps [1]. Excess reagents and by-products are removed through repeated washing steps. However, SPOS suffers from mass-transfer limitations due to heterogeneous reaction conditions, which requires large excess of costly reagents and extensive solvent use and leads to high process mass intensity (PMI) [3]. In addition, SPOS scalability is constrained by resin handling and the lack of real-time monitoring hinders advanced process control strategies.

Liquid-phase oligonucleotide synthesis (LPOS) has emerged as a promising alternative to overcome these limitations [4-6]. In LPOS, the oligonucleotide chain is grown on a soluble multibranched support (homostar), allowing reactions to proceed under homogeneous

conditions. Unreacted reagents and by-products are removed between the reaction steps using organic solvent nanofiltration (OSN), while retaining the supported oligonucleotide due to the large size of the homostar complex. This configuration improves mass transfer, facilitates inline monitoring, and provides greater operational flexibility compared with SPOS. However, even small loss of supported oligonucleotides through the membrane during each cycle can significantly reduce the product yield after multiple cycles of addition. Multi-stage membrane configurations with intermediate recycle offer a strategy to enhance product recovery, but recycling of intermediate streams between diafiltration stages can also increase impurity retention. Careful process design and fine-tuned operational strategies thus become essential for LPOS to outperform SPOS.

Through this paper, we apply a consistent dynamic modelling framework to quantify and compare the performance of LPOS against SPOS. We adapt a recent mechanistic kinetic model of SPOS [7] to predict LPOS performance in both single- and dual-stage diafiltration configurations. We conduct a feasibility analysis to characterize operating regions in which LPOS outperforms SPOS in terms of product yield and impurities. These results provide clear insight into the conditions under which membrane-enhanced LPOS can provide a scalable and more sustainable route for oligonucleotide manufacture.

## METHODOLOGY

### Description of SPOS and LPOS Processes

Since SPOS is the industrial benchmark for oligonucleotide manufacture, it is used as the reference for comparison in this work. In SPOS, oligonucleotides are assembled via sequential phosphoramidite chemistry on an insoluble polymeric support, typically a functionalised polystyrene resin. The growing chain remains covalently bound to the solid phase throughout the synthesis, while reagents and by-products are convectively transported through the resin bed with the solvent [7]. Each synthesis cycle comprises four main steps: detritylation, coupling, oxidation (or thiolation), and capping [7]. Detritylation removes the 5′-dimethoxytrityl (DMT) protecting group, generating a reactive hydroxyl site. During coupling, an activated phosphoramidite monomer reacts with the deprotected chain, followed by oxidation of the internucleotide linkage. Unreacted hydroxyl groups are finally capped to prevent further chain extension, thereby limiting impurity formation. Excess reagents and by-products are removed through repeated washing steps between the reactions.

In LPOS by contrast, the oligonucleotide chains are grown onto a soluble multibranched support (homostar), enabling all reactions to occur under homogeneous conditions [4-6]. The reactor is coupled to an OSN unit for removing small molecules—including acids, activators, unreacted monomers, and by-products—while retaining the large homostar-supported oligonucleotides. Chain extension proceeds similarly to SPOS through repeated cycles of detritylation, coupling, and quenching, except that each reaction step is now followed by a constant volume diafiltration stage, during which fresh solvent is added at the same rate as permeate removal. In addition to eliminating diffusion limitations and facilitating inline monitoring of the liquid phase, LPOS therefore decouples the reaction times for both deprotection and coupling steps from the purification steps [4-6].

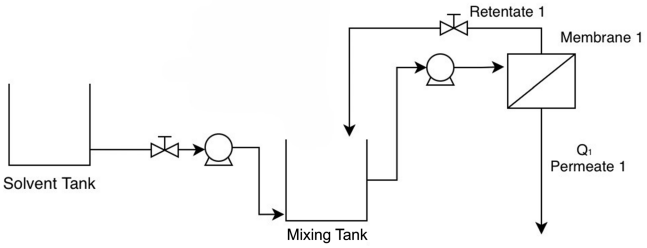

**Figure 1.** LPOS-1S process layout with single-stage OSN diafiltration (adapted from Kim et al. [5]).

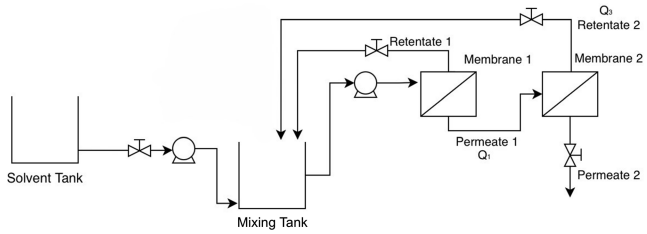

**Figure 2.** LPOS-2S process layout with dual-stage OSN diafiltration (adapted from Kim et al. [5]).

Although it is effective at removing small molecules, insufficient rejection of the supported oligonucleotide by the OSN membrane can incur large product loss over multiple cycles of addition [8]. To mitigate this loss, a LPOS configuration with dual-stage diafiltration (LPOS-2S, Figure 2) is investigated alongside single-stage diafiltration (LPOS-1S, Figure 1). In this configuration, the retentate from the first OSN unit is fed to a second OSN unit, and the retentate streams from both stages are returned to the reactor. The addition of a second stage improves the retention of supported oligonucleotides and increases product yield across multiple cycles [5, 6], but it also increases the residence time—and therefore the residual concentration—of other solutes that may interfere with subsequent coupling steps. The two-stage configuration therefore introduces a key trade-off between enhanced product recovery and increased impurity retention.

In this work, a unified dynamic modelling framework is used to describe the LPOS-1S and LPOS-2S process variants and enable their comparison with SPOS in terms of yield and impurity in a systematic feasibility analysis.

## LPS transferred model

The mechanistic kinetic model of SPOS proposed by Pfister et al. [7]. is here transferred to LPOS. The key structural modification is the removal of resin-related transport phenomena. The SPOS model distinguishes concentrations between the bulk liquid and resin pores, relying on solid-phase balances and corresponding mass-transfer terms. In the LPOS model by contrast, all the solutes are in a well-mixed liquid phase. Intraparticle diffusion, pore–bulk gradients, and resin-phase balances are therefore neglected, and reaction rates are written directly in terms of bulk concentrations.

For a target sequence comprising $N$ building blocks, the LPOS process is represented as a sequence of $N$ repeated synthesis cycles. Within cycle $n = 1, \dots, N$, anchored oligonucleotides are described by their protected and deprotected states, denoted as $OP_k$ and $OD_k$, respectively, and indexed by the chain length $k$. Small molecules include the acid catalyst used for deprotection and the building block added during coupling. The model is formulated as a multistage dynamic system, with state discontinuities at stage transitions describing pulse additions of reagents.

At the start of the synthesis, each homostar branch carries an unextended anchored chain, such that

$$OP_0(0) = HS \bullet NB \tag{1}$$

where $HS$ (mol m$^{-3}$) denotes the homostar concentration, and $NB$ (-) the number of branches per support. The total concentration of anchored oligonucleotides is given by

$$OT(t) = \sum_{k=0}^{N} \left( OP_k(t) + OD_k(t) \right) \tag{2}$$

## Deprotection

In [7], detritylation is described as a reversible acid-catalysed reaction, reflecting possible re-attachment of the trityl group under resin-bound conditions. In practice, detritylation is operated far from equilibrium and the deprotection step can thus be modeled as an apparent irreversible reaction [4]. The balance equations describing the conversion of protected chains of lengths $k = 0, \dots, n-1$ into deprotected chains during cycle $n$ are given by

$$\dot{OD}_k(t) = -\dot{OP}_k(t) = k_D OP_k(t) DCA(t) \tag{3}$$

where $k_D$ (m$^3$ mol$^{-1}$ s$^{-1}$) is the deprotection kinetic constant, and $DCA$ (mol m$^{-3}$) denotes the acid catalyst concentration. The latter is introduced at the start $t_{D,n}$ of each deprotection stage as a pulse addition,

$$DCA\left(t_{D,n}^{-}\right) + DCA^{\text{in}} \tag{4}$$

## Coupling

The coupling reaction follows standard phosphoramidite chemistry, with two LPOS-specific simplifications. First, the chain-length-dependent reduction in coupling reactivity included in the SPOS model to account for steric hindrance within the resin is omitted, as such effects are not observed under homogeneous liquid-phase conditions. Second, no capping step is included since homogeneous mixing and tighter control over reaction times in LPOS allow incomplete coupling to be minimised without deliberate chain termination. During the coupling stage of cycle $n$, deprotected anchored chains react with the $n$-th building block $BB_n$ to form protected chains of length $k+1$,

$$OD_k + BB_n \rightarrow OP_{k+1}$$

The corresponding balance equations are:

$$\dot{OP}_{k+1}(t) = -\dot{OD}_k(t) = k_C BB_n(t) OD_k(t) \tag{5}$$

where $k_C$ (m$^3$ mol$^{-1}$ s$^{-1}$) denotes the coupling kinetic constant. The building block is introduced at the start $t_{C,n}$ of each coupling stage via a pulse addition,

$$BB_n\left(t_{C,n}^{+}\right) = BB_n\left(t_{C,n}^{-}\right) + BB^{\text{in}} \tag{6}$$

The auxiliary reactions (e.g. oxidation or quenching) are assumed to occur on much faster timescales than the coupling and diafiltration and are therefore not included in the dynamic model.

## Single-Stage Diafiltration

After each reaction step, excess reagents and by-products are removed using OSN membrane technology [6]. Constant-volume diafiltration is used, where solvent is added at the same rate as permeate removal. Under perfect mixing conditions, the concentrations of solute $X \in \{OP_k, OD_k, BB_n, DCA\}$ in the retentate is described by the following balance equation

$$\dot{X}(t) = -\frac{Q_1}{V_1}(1 - r_X) X(t) \tag{7}$$

where $V_1$ (m$^3$ s$^{-1}$) denotes the retentate volume of the membrane unit, $r_X$ (-) the observed membrane rejection of species $X$, and the permeate flow rate $Q_1$ (m$^3$) is defined as

$$Q_1 = AK\Delta p_1 \tag{8}$$

with $A$ (m$^2$) the membrane area, $K$ the membrane permeability (m s$^{-1}$ bar$^{-1}$), and $\Delta p_1$ (bar) the transmembrane pressure difference.

## Dual-Stage Diafiltration

The dual-stage diafiltration is described by the following coupled balance equations

$$\dot{X}_1(t) = \frac{1}{V_1}\left[-Q_1 X_1 (1 - r_X) + (Q_1 - Q_2) X_2\right] \tag{9}$$

$$\dot{X}_2(t) = \frac{1}{V_2}\left[Q_1 X_1 (1 - r_X) - Q_2 X_2 (1 - r_X) - (Q_1 - Q_2) X_2\right] \tag{10}$$

where $V_1$ and $V_2$ ($m^3$) denote the retentate volumes of the first and second stages, respectively, $X_1(t)$ and $X_2(t)$ (mol $m^{-3}$) the corresponding concentrations of each solute $X \in \{OP_k, OD_k, BB_n, DCA\}$, and the same membrane in terms of the rejection parameter $r_X$ is assumed in both stages. In addition to the permeate flowrate from the first stage given by Eqn. (8), the permeate flowrate from the second stage is such that

$$Q_2 = (1-\rho)Q_1 \tag{11}$$

where the recycle ratio $\rho$ is treated as an independent operating variable. The solute concentrations in the second-stage retentate are initially set to $X_2(0) = 0$. Then, at the end of each diafiltration stage, the retentates from both stages are recombined to set the initial condition of the subsequent reaction step [6].

## Process Performance Indicators

The process performance is quantified in terms of three metrics:

- The overall yield, $Y$, is defined as the ratio of correctly assembled, fully protected oligonucleotides after $N$ synthesis cycles to the theoretical maximum amount supported on the homostar:

$$Y = \frac{OP_N(t_{F2,N})}{HS \cdot NB} \tag{12}$$

  where $t_{F2,n}$ corresponds to the end of the final diafiltration step.

- The product purity, $P$, measures the fraction of correctly sequenced oligonucleotides relative to the total amount of anchored material present at the end if the synthesis:

$$P = \frac{OP_N(t_{F2,N})}{OT(t_{F2,N})} \tag{13}$$

  Achieving a high product purity is essential, as sequence impurities directly compromise therapeutic effectiveness. Moreover, sequence errors and desired products exhibit very similar physicochemical properties, which makes downstream separation particularly challenging. As a result, impurities need to be minimised within the synthesis process itself.

- The maximal residual building block ratio, $R$, is defined as the largest ratio between the total concentration of remaining building blocks and the total anchored material, following each coupling step:

$$R = \max_{n=1,\ldots,N} \left[ \frac{\sum_{k=1}^{n} BB_k(t_{C,n})}{OT(t_{C,N})} \right] \tag{14}$$

A low $R$ value prevents the accumulation of unreacted building blocks during each cycle and thus limits the risk of unwanted side reactions in subsequent cycles, as per standard operational strategies in iterative oligonucleotide synthesis.

Overall, good process performance should seek to maximise the overall yield $Y$ and product purity $P$, while simultaneously minimising the maximal residual building block ratio $R$.

## Computational Aspects

We conducted feasibility analysis using the Python module NSFeas, interfaced from the C++ library MAGNUS (v4.0, https://github.com/omega-icl/magnus), which implements a nested sampling algorithm [9]. The method maintains a population of live points of given size that it steers towards the feasible operating domain through adaptive sampling. Each sample is labelled based on the extent to which their performance indicators $Y, P$ and $R$ violate the respective target thresholds, and those having the highest violation are replaced with newly drawn samples with lower violation and stored as dead points for subsequent reconstruction of the feasible domain. The algorithm is interrupted as soon as the live points all belong to the feasible domain.

Simulation of the dynamic LPOS model with either single- or dual-stage diafiltration was implemented using the Python module ODESLV, interfaced from the C++ library CRONOS (v4.0, https://github.com/omega-icl/cronos). Expression trees for the model equations and all the necessary derivatives are constructed using the library MC++ (v4.0, https://github.com/omega-icl/mcpp). ODESLV calls the solver CVODES of the library SUNDIALS (v7.1.1) [10] for numerical ODE integration, with relative and absolute tolerances set to $10^{-7}$.

**Table 1:** Design and model parameter values used in this work. *Equivalent amounts are relative to the initial anchored oligonucleotides $OT(0) = HS \cdot NB$.

| Parameter | Nominal value |
|---|---|
| $N$ | 20 cycles |
| $HS$ | 5.0 mol $m^{-3}$ |
| $NB$ | 4 |
| $k_D$ | 0.65 $m^3$ $mol^{-1}$ $s^{-1}$ |
| $k_C$ | 1.5 × $10^{-4}$ $m^3$ $mol^{-1}$ $s^{-1}$ |
| $BB^{in}$ | 1.5 eq* |
| $DCA^{in}$ | 9.0 eq* |
| $A$ | 8.5 × $10^{-2}$ $m^2$ |
| $V_1$ | 9 × $10^{-4}$ $m^3$ |
| $\Delta p_1$ | 8.9 bar |
| $K$ | 5.6 × $10^{-7}$ $m^3$ $s^{-1}$ $bar^{-1}$ |
| $r_{BB}$ | 0.40 |
| $r_{DCA}$ | 0.33 |

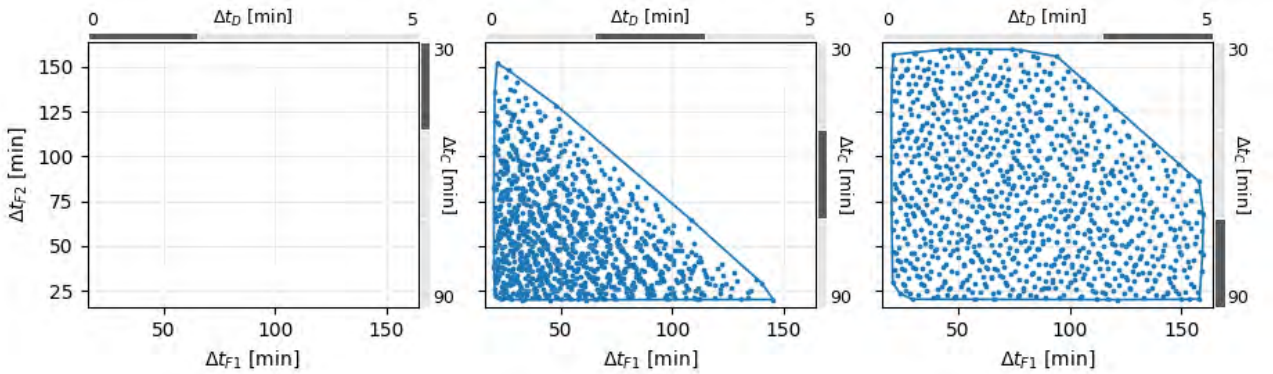

**Figure 3:** Feasible operating region of LPOS with single-stage diafiltration in terms of the yield constraint $Y \geq 0.86$.

## RESULTS

We present the results of a case study for $N = 20$ synthesis cycles, using the parameter values in Table 1. The kinetic parameter values and reagent concentrations are adapted from Pfister et al. [7], and the LPOS-specific values are taken from [6, 8]. Unless otherwise noted, a homostar rejection of 99.90% is assumed for the OSN membrane. Due to the absence of diafiltration steps and neglecting any detachment of oligonucleotides from the resin support, the yield and purity of SPOS were both estimated at 86%, consistent with the specifications of the experimental system reported in Pfister *et al.* [7, 11], while the residual building block content trapped within the resin pores was estimated at 2%. These threshold values are used in the ensuing feasibility analysis of LPOS with OSN diafiltration.

A key advantage of LPOS over SPOS lies in the ability of exerting tighter control over the reaction steps, enabling higher product purity. Figure 3 compares the feasible operating regions of LPOS with single-stage diafiltration for the benchmark purity constraint $P \geq 0.86$ (blue points & line) as well as a tighter purity $P \geq 0.95$ (orange points & line). Projection onto the subspace $(\Delta t_C, \Delta t_D)$ of reaction times reveals that both regions are lower bounded by a convex combination of minimal deprotection and coupling times, as incomplete reactions directly reduce the formation of the desired product. Overall, this first comparison also shows that LPOS can achieve purities well above the SPOS purity benchmark of 86%.

Figure 4 shows the feasible operating region of LPOS with single-stage diafiltration for the benchmark yield constraint $Y \geq 0.86$. The four-dimensional feasible region is represented on a trellis chart, with the diafiltration times $\Delta t_{F1}$ and $\Delta t_{F2}$ on inner axes, and the deprotection and coupling times $\Delta t_D$ and $\Delta t_C$ indicated by grey-shaded ranges on outer axes. Since longer diafiltration steps (inner axes) result in greater loss of anchored oligonucleotides through the membrane, the feasible region is upper bounded by a maximal combined diafiltration duration, $\Delta t_{F1} + \Delta t_{F2} \leq 250\,\text{min}$. This maximal duration is seen to increase for longer deprotection and coupling times (outer axes), as bringing the reactions closer to completion during each addition cycle also increases the overall product yield.

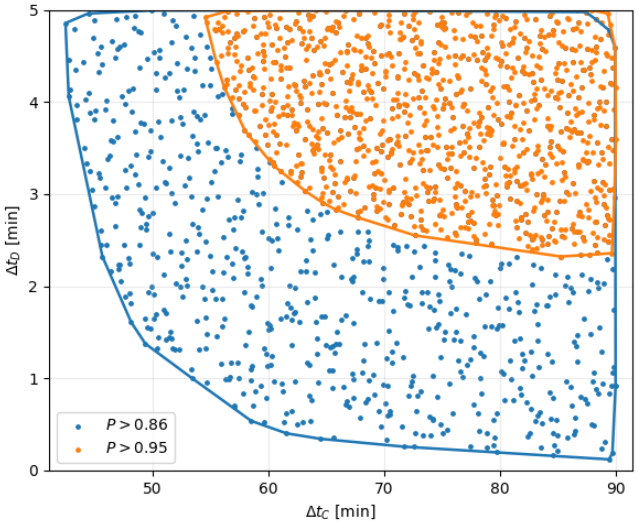

**Figure 4.** Feasible operating region of LPOS with single-stage diafiltration for two purity constraints $P \geq 0.86$ and $P \geq 0.95$.

Figure 5 shows a projection of the feasible region for the residue constraint $R \leq 0.02$ onto the subspace $(\Delta t_{F1}, \Delta t_{F2})$ of diafiltration times. In contrast to the yield constraint in Figure 4, this region is now lower bounded by a minimal diafiltration duration, $\Delta t_{F1} + \Delta t_{F2} \geq 215\,\text{min}$, as short diafiltration times can leave large amount of residual building blocks in the solvent. The feasible region of $R \leq 0.02$ is also less sensitive to the durations of the reaction steps: with 1.5 equivalents of building block added at each coupling step, even complete conversion of anchored oligonucleotides leaves a residual excess of 0.5 equivalents, so that the removal of residual building

blocks is primarily governed by the diafiltration times rather than the reaction times. In practice, the improved reaction control afforded by LPOS compared to SPOS greatly reduces the need for operating with large excess of reagents.

Taken together, Figures 4 & 5 highlight the opposing effect that the combined diafiltration duration $\Delta t_{F1} + \Delta t_{F2}$ has on the feasibility constraints $Y \geq 0.86$ and $R \leq 0.02$. Fine-tuning is thus critical if LPOS is to outperform SPOS simultaneously in terms of yield and purity. This trade-off is captured in Figure 6 by the projection of the combined feasible region for $Y \geq 0.86, P \geq 0.86$ and $R \leq 0.02$ onto the subspace $(\Delta t_{F1}, \Delta t_{F2})$ of diafiltration times.

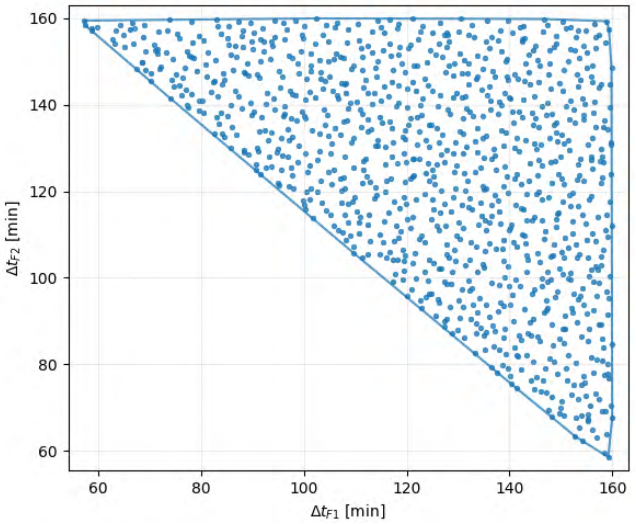

**Figure 5.** Feasible operating region of LPOS with single-stage diafiltration in terms of the maximal residual building block constraint.

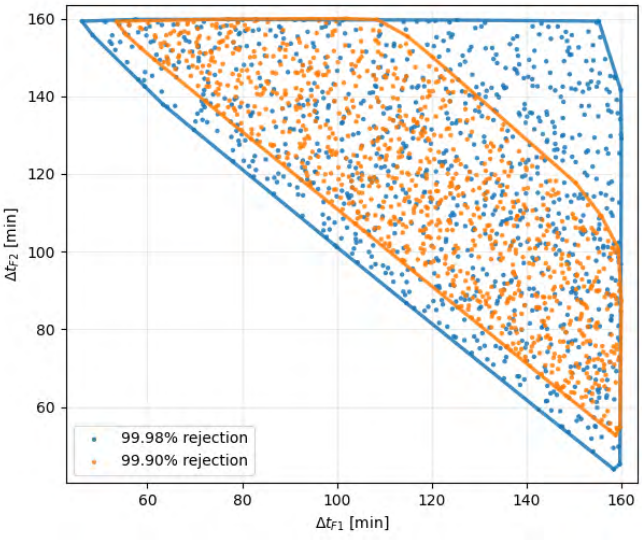

**Figure 6.** Feasible operating region of LPOS with single-stage diafiltration for the combined constraints $Y \geq 0.86, P \geq 0.86, R \leq 0.02$, comparison for two homostar rejection values of 99.90% and 99.98%.

For high homostar rejection values of 99.98% (blue points and lines, Figure 6), extending the combined diafiltration time, e.g. beyond 300 min in each cycle, does not result in appreciable product loss. But for lower rejection values of 99.90% (orange points and lines), the feasible region is clearly bracketed between a minimal and maximal combined diafiltration duration, e.g. between 210–270 min. Although homostar rejection in OSN membranes nowadays exceed 99.95% [4], this comparison demonstrates the strong interplay between the membrane selection and operational strategy on LPOS performance.

In principle, the implementation of dual-stage diafiltration can provide additional operational flexibility in LPOS, as it enhances product retention, while still allowing low residual building block levels. To establish this potential, the feasible operating regions on Figure 7 are computed for the tighter combined constraints $Y \geq 0.95, P \geq 0.95, R \leq 0.01$, considering homostar rejections of 99.90% and 99.25% by the OSN membrane (assumed identical in both stages). Notably, no feasible operating region exists for single-stage diafiltration under these combined constraints. Recall that dual-stage diafiltration introduces two extra operational parameters: the retentate volume $V_2$ of the second membrane stage (set to $V_2$= 5x10$^{-5}$ m$^3$ on Figure 7), and the recycle ratio $\rho$. The extent of these feasible regions, here projected onto the subspace $(\Delta t_{F1} + \Delta t_{F2}, \rho)$, establishes that the performance of LPOS with dual-stage diafiltration can significantly exceed that of SPOS, even with relaxed membrane specifications.

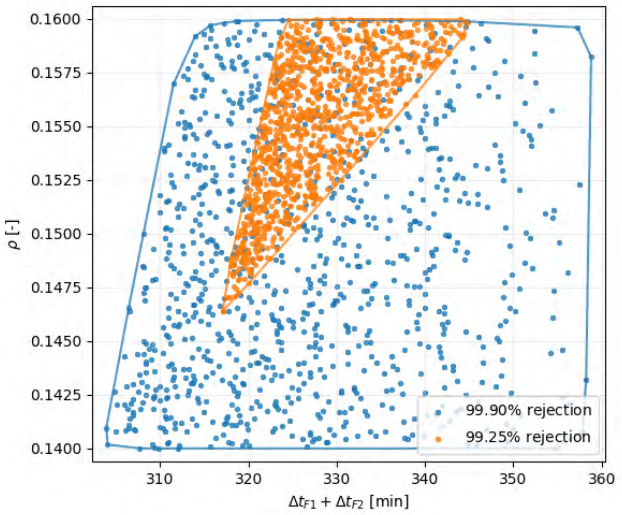

**Figure 7.** Feasible operating region of LPOS with dual-stage diafiltration for the tighter constraints $Y \geq 0.95, P \geq 0.95, R \leq 0.01$, comparison of two homostar rejection values 99.90% and 99.25% with a second-stage diafiltration volume $V_2$= 5x10$^{-5}$ m$^3$.

The boundary of the feasible region on Figure 7 shows a clear interplay between the recycle ratio and the combined diafiltration time when the OSN membrane's rejection of homostar is low (orange points and line). In this case, the maximal diafiltration times (right boundary of projected feasible region) coincide with higher recycle ratios in order to avoid excessive loss of homostar-supported oligonucleotides through the membrane; whereas the minimal diafiltration times (left boundary of project feasible region) is driven by the stringent constraint $R \leq 0.01$, which is also contingent on the extents of the chemical reactions. The span of the feasible operating region (blue points and line) expands significantly as the membrane's rejection of homostar-supported oligonucleotides increases. Clearly, a higher rejection reduces the loss of oligonucleotides for a given recycle ratio, leading to higher building block consumption and in turn allowing for shorter diafiltration durations to achieve sufficient building block removal.

## DISCUSSION

The comparison on Figure 6 establishes the potential of LPOS to outperform SPOS even with a single-stage diafiltration. However, the analysis also confirms that this configuration is highly sensitive to the diafiltration duration settings in an interplay with the OSN membrane's rejection properties. Diafiltration introduces a fundamental trade-off: longer diafiltration times improve the removal of unreacted building blocks, but they also increase the overall loss of product through the membrane; whereas shorter diafiltration times preserve the product yield, but they limit the washout of excess reagents. As a result, the feasible operating region of LPOS with single-stage diafiltration can be quite narrow and its high sensitivity to membrane selection requires careful tuning to balance excessive product loss with sufficient removal of unreacted reagents.

The deployment of dual-stage diafiltration with LPOS shows great promises for mitigating these challenges. The second stage increases effective product retention and provides additional flexibility through the recycle ratio and second-stage volume, allowing high yield and purity to be achieved while maintaining low residual building block levels. Consequently, LPOS with dual-stage diafiltration is predicted to significantly outperform nominal SPOS performance over a wide range of operating conditions, even for OSN membranes with low homostar rejection by today's standards. The dynamic model developed through this work predicts that the product yield and purity with LPOS could even reach values as high as 99.5%.

## CONCLUSIONS

We conducted a model-based feasibility analysis to compare the performance of LPOS with both single- and dual-stage diafiltration against state-of-the-art SPOS. We transferred a mechanistic model of SPOS to LPOS by including OSN diafiltration dynamics and defined consistent performance indicators and threshold. While LPOS with single-stage diafiltration can outperform SPOS, its performance is highly sensitive to diafiltration times and membrane rejection properties. With dual-stage diafiltration, LPOS provides greater flexibility and can achieve higher product yield and purity, making it a promising alternative. Future work will expand the analysis to account for uncertainty in the kinetic and membrane parameters and enable probabilistic characterisation of the feasible operating space, and will seek to validate the model-based predictions experimentally.

## ABSTRACT

Identifying cost-optimal yet environmentally friendly crystallisation processes in the production of small molecule pharmaceuticals is a highly complex task, since multiple solvent systems often exist which could be used to purify a given drug to a similar standard. It is, however, rarely possible to test each of these solvent systems within a laboratory setting, since this would be time-consuming and incur large material costs. It has, therefore, been suggested that process modelling tools should be used to screen different crystallisation processes available to produce a new drug prior to studying them experimentally – essentially allowing a shortlist of promising process candidates to be created. Indeed, it has been shown by several authors that this sort of work can be conducted without any need to establish the crystallisation kinetics associated with each drug-and-solvent combination considered: the reason being that crystallisation processes may be defined as simple solid-liquid equilibria (SLE) problems using thermodynamic models alone. Considering this, the present work has used SLE modelling to assess the cost and environmental impact of different solvent systems available for the crystallisation of pregabalin – an anticonvulsant and anxiolytic drug used to treat epilepsy, anxiety and neuropathic pain. Moreover, it has used entirely data-led approaches to achieve this: leveraging established costing methodologies and green metrics (i.e., Scope 1 and 2 $CO_2$e emissions) to assess their economic viability and carbon footprint. This modelling framework can be used to identify viable crystallisation strategies for other small molecules.

**Keywords**: Pregabalin, technoeconomic analysis, crystallisation, environmental impact analysis, solvent selection.

## 1. INTRODUCTION

In 2024, pregabalin – a generic anticonvulsant drug and anxiolytic agent commonly used to treat epilepsy, anxiety and neuropathic pain [1-3] – had a global market of 1.8 billion USD, and it is expected that this market will continue to grow at a compound annual growth rate (CAGR) of 5.1 % between 2025 and 2034 [4]. Consequently, this work aims to identify technoeconomically optimal – and environmentally benign – manufacturing routes that can be used for its production. To achieve this, it has used in-silico technoeconomic analyses and environmental impact assessments to establish which solvents (of those commonly used in the crystallisation of small molecule pharmaceuticals) and process conditions allow cost-effective – yet green – pregabalin manufacturing.

## 2. PROCESS MODELLING STRATEGY

Designing crystallisation processes for pharmaceuticals can be an arduous process, since often several solvent systems will exist which could be used to perform the purification required by a given process – each of which will hold unique crystallisation kinetics. Recent studies [5, 6] have shown that promising crystallisation setups can be identified for new processes entirely in silico, without the need to establish kinetics (thereby greatly reducing the number of experiments required during process design). Thermodynamic modelling alone [5-7] can be used to achieve this by simply ranking each system based on their expected trends in process costs as API solubility varies under different operating conditions.

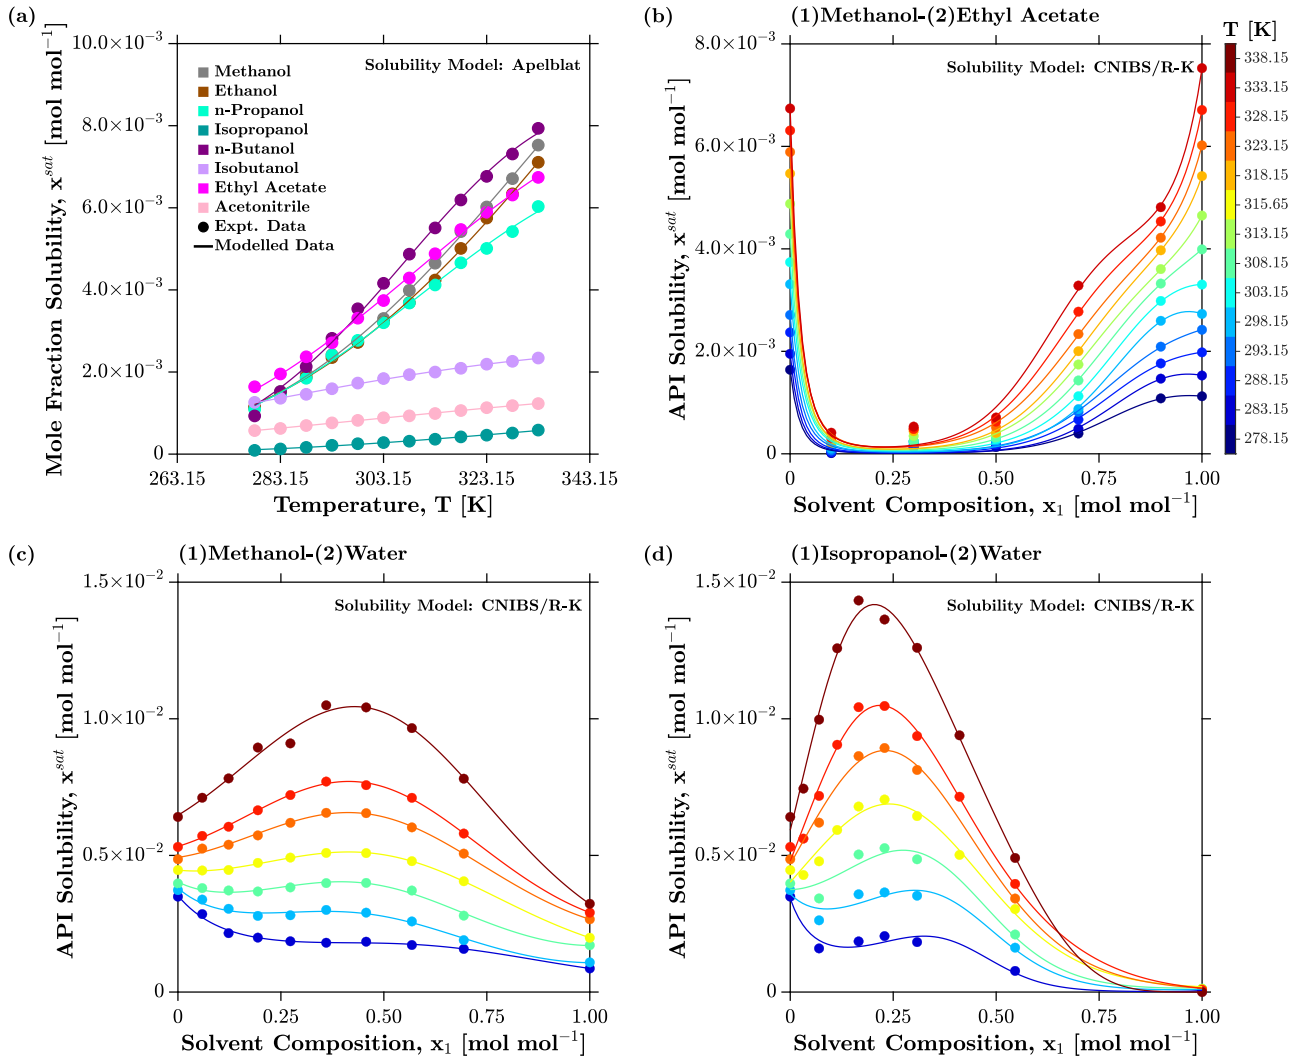

**Figure 1.** Pregabalin solubility in (a) pure and (b-d) mixed solvents [8-9].

This paper uses the modified Apelblat equation (Eq. 1) to model the temperature dependent solubility of pregabalin in pure solvents (methanol, ethanol, n-propanol, isopropanol, n-butanol, isobutanol, ethyl acetate, acetonitrile), whilst it has used the Combined Nearly Ideal Binary Solvent/Redlich-Kister (CNIBS/R-K) model (Eq. 2) to study its solubility in solvent mixtures (i.e., (1) methanol-(2) ethyl acetate, (1) methanol-(2) water, (1) isopropanol-(2) water) with varying molar compositions [8, 9] (Fig. 1).

$$\ln x^{sat} = A + \frac{B}{T} + C\ ln(T) \tag{1}$$

$$\ln x^{sat} = B_0 + B_1 x_1 + B_2 x_1^2 + B_3 x_1^3 + B_4 x_1^4 \tag{2}$$

Material balances can be computed for all processes, assuming that they will produce 100 metric tonnes of pregabalin over an annual operating time of 6000 h ($m_{annual}$) – thus allowing solid-liquid equilibrium (SLE) principles (Eqs. 3-6) to be used to determine the mass of pregabalin that would be (theoretically) produced per each batch ($m_{BC}$) in each crystallisation process proposed under various different operating conditions (i.e., solvent mixture composition, $T_0$ and $T_f$) [5, 7].

$$n_{prod,0} = x_{prod,0}^{sat} n_{S_T,0} \tag{3}$$

$$n_{prod} = x_{prod}^{sat} n_{S_T} \tag{4}$$

$$n_{prod}^{cryst} = n_{prod}^{0} - n_{prod} \tag{5}$$

$$m_{prod}^{cryst} = M_{prod} n_{prod}^{cryst} \tag{6}$$

It is important to note, however, that it has been assumed in this work that all process mixtures considered are well-mixed, fully suspended, and have uniform temperature and concentration profiles. Moreover, it has been assumed that each crystallisation process takes 12 hours ($t_{cryst}$) – since the thermodynamic models used

herein (Eqs. 1-2) have no time element – whilst the clean-in-place requirements of any equipment has been set to 30 minutes ($t_{CIP}$) [7, 10, 11].

This framework may be used to model both pure and mixed solvent systems; however, when dealing with mixed solvent systems, it is important to note that the total amount of solvent in each system must also obey the relationships expressed in Eqs. 7-14. In other words, the total amount of solvent present in the initial and final states of each system will be the sum of any solvents and antisolvents present (Eqs. 7-8) – noting that the composition of the initial and final states will be different if an antisolvent is added throughout the crystallisation process (Eqs. 9-12). Hence, the solute-free compositions of each solvent system must be held between 0 and 1 in each state (Eq. 13), whilst also summing to 1 (Eq. 14).

$$n_{S_T,0} = n_{S_1,0} + n_{S_2,0} \tag{7}$$

$$n_{S_T} = n_{S_1} + n_{S_2} \tag{8}$$

$$n_{S_1} = n_{S_1,0} + n_{S_1,+} \tag{9}$$

$$n_{S_2} = n_{S_2,0} + n_{S_2,+} \tag{10}$$

$$n_{S_1}^{+} \geq 0 \tag{11}$$

$$n_{S_2}^{+} \geq 0 \tag{12}$$

$$0 \leq \{x_1, x_2\} \leq 1 \tag{13}$$

$$x_1 + x_2 = 1 \tag{14}$$

Eqs. 15-16 should be used to determine the size of any equipment required by each process – noting that only standard sizes of crystalliser (i.e., 5000, 10000, 20000 L) which have a 70 v/v % fill capacity may be used. Moreover, parallel production lines ($N_{PT}$) should be permitted whenever a single production line proves incapable of meeting throughput requirements for a specific process. It is important to note, however, that – since other unit operations (e.g., reactions, filtrations and liquid-liquid extractions) are likely to precede crystallisation steps in production processes – this work has also stipulated that each production line designed may only complete one batch cycle per day to prevent unrealistic manufacturing processes (i.e., those which require unreasonably large numbers of batches per day) from being developed. Eqs. 17-18 are used to determine the cycle time ($t_{BC}$) and heating requirements of each process, whilst Eq. 19 are used to compute theoretical product recovery.

$$V_{sys} = V_{liq} + V_{cryst} \tag{15}$$

$$m_{annual} = m_{BC} N_{BC} N_{PT} \tag{16}$$

$$t_{BC} = t_{cryst} + t_{CIP} \tag{17}$$

$$Q \approx \bar{C}_{P_{S_T}} \bar{n}_{S_T} \Delta T \tag{18}$$

$$r_{API} = 100 \left( \frac{n_{prod,0} - n_{prod}}{n_{prod,0}} \right) \tag{19}$$

Physical properties required to implement this model (e.g., the molecular weights, melting points and boiling points of pregabalin and any solvents) have been taken from the literature wherever possible [8, 9, 12]. Thus, established temperature dependent correlations have been used to assess the density and specific heat capacities of each solvent [13]. However, it should be noted that the initial temperature of each process should always be greater than or equal to its final temperature (Eq. 20), whilst respecting the limits specified in Eq. 21 ($T_{OS,1} = 5\ K; T_{OS,2} = 10\ K$) at all times, so as to make sure that: (i) crystallisation occurs, whilst (ii) the freezing and/or evaporation of any solvent does not [5, 6]. Likewise, it has been stipulated that (in order to avoid high shear forces during mixing) at least 4 mL of solvent should be used per gram of API being processed in each system [3].

$$T_0 \geq T_f \tag{20}$$

$$\max \left\{ \begin{matrix} T_{SM}^{\min} \\ T_{mp} + T_{os_1} \\ T_{phys}^{\min} \end{matrix} \right\} \leq \{T_0, T_f\} \leq \min \left\{ \begin{matrix} T_{SM}^{\max} \\ T_{bp} - T_{os_2} \\ T_{phys}^{\max} \end{matrix} \right\} \tag{21}$$

Each of the mathematical terms presented in Eqs. 1-21 are defined as described by the following statements. Term $x^{sat}$ denotes the mole fraction (mol mol$^{-1}$) of API in a given solvent system when saturated, whilst terms $x_{prod,0}^{sat}$ and $x_{prod}^{sat}$ denote the fraction of drug product dissolved in a system during the initial and final states of a crystallisation process (mol mol$^{-1}$). Terms $x_1$ and $x_2$ then denote the solute-free mole fraction of solvents 1 and 2 in each solvent mixture (mol mol$^{-1}$). $A$ (–), $B$ (K) and $C$ (–) are correlation coefficients in the Apelblat equation, whilst $B_0, B_1, B_2, B_3$ and $B_4$ are CNIBS/R-K coefficients (–). Term $T$ then denotes the temperature of each system, such that $T_0$ and $T_f$ may be used to denote their initial and final temperatures. Meanwhile, terms $T_{bp}$ and $T_{mp}$ have been used to represent the boiling and melting point temperatures of each system. Terms $T_{SM}^{min}, T_{SM}^{max}, T_{phys}^{min}, T_{phys}^{max}$ then symbolise the minimum and maximum temperatures of the solubility (i.e., Apelblat, CNIBS/R-K) and physical property models used herein – leaving $T_{os_1}$ and $T_{os_2}$ to represent the temperature offsets applied to each system to prevent freezing and boiling, respectively. Term $\Delta T$ then represents the temperature difference between the initial and final states of a system. Meanwhile, terms $n_{S_T}$ and $n_{S_T,0}$ denote the total moles of solvent used in the initial and final states of each process (mol); $n_{S_1,0}, n_{S_1}, n_{S_2,0}$ and $n_{S_2}$represent the initial and final amounts of any solvents and antisolvents in a system (mol); $n_{S_1,+}$ and $n_{S_2,+}$ signify the amount of solvent or antisolvent added to each

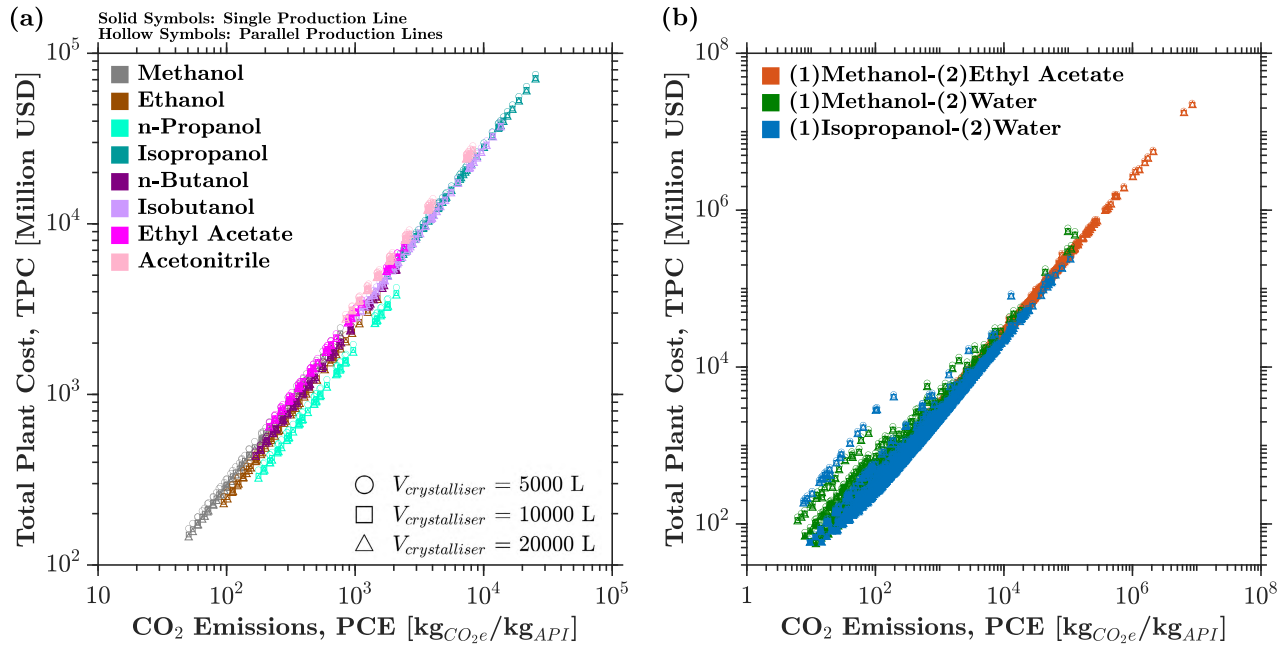

**Figure 2.** Relationship observed between the total cost and (scope 1 and 2) carbon emissions of each process.

system between the initial and final states (mol); $n_{prod,0}$ and $n_{prod}$ give the amount of API product dissolved in this each system in each state (mol); and $n_{prod}^{cryst}$ represents the amount of API crystallised during each process (mol). Meanwhile, $\bar{n}_{S_T}$ represents the average moles of solvent associated with a given system over its batch operating time. $N_{BC}$ then denotes the annual number of batch cycles required by each production line. Symbols $m_{prod}^{cryst}$ (kg) and $M_{prod}$ (g mol$^{-1}$) then describe the mass and molar mass of the API product. Term $V_{sys}$ then symbolises the total volume of a batch in a given process, whilst $V_{liq}$ and $V_{cryst}$ denote its liquid (mother-liquor) and crystal components (L). $Q$ (kJ) then represents the heating requirements of each process, whilst $r_{API}$ (%) gives the API recovery of each system. $\bar{C}_{P_{S_T}}$ (J mol$^{-1}$ K$^{-1}$) then represents the average specific heat capacity of a system over its batch operating time.

## 3. CARBON EMISSIONS ANALYSIS

Carbon emission factors ($PCE$) have been used to assess the environmental impact of each process (Eq. 22) [7, 10] – assuming that any $NO_x$ and $SO_x$ generated by each process can be entirely abated by on-site scrubbing and catalytic conversion units. To allow this, it has been assumed that any waste will be incinerated and experience complete combustion, with every 1 kWh of electricity used producing 0.20705 kg of $CO_2e$ [14].

$$PCE = \frac{m_{total\ CO_2e}}{m_{total\ prod}} \quad (22)$$

Terms $m_{total\ prod}$ and $m_{total\ CO_2e}$ in Eq. 22 denote total API production and $CO_2e$ emissions (kg).

## 4. TECHNOECONOMIC ASSESSMENT

The cost of each process has been evaluated using an established costing methodology where: (i) capital costs ($CapEx$) are taken as the sum of any fixed ($FCC$) and working ($WCC$) capital costs (Eq. 23); whilst (ii) operating costs ($OpEx$) are set equal to the sum of any fixed ($FCOP$) and variable ($VCOP$) costs of production (Eq. 24).

$$CapEx = FCC + WCC \quad (23)$$

$$OpEx = FCOP + VCOP \quad (24)$$

Thus, the total cost of each process ($TPC$) has been calculated via Eq. 25 – assuming a plant lifetime ($t_{LTP}$) of 20 years and an annual discount rate ($I_{dr}$) of 5.5 % [10, 15].

$$TPC = CapEx + \sum_{n=1}^{t_{LTP}} \frac{OpEx}{(1+I_{dr})^n} \quad (25)$$

Within this, the $FCC$ costs for each process have been estimated by taking the sum of any inside battery limits, outside battery limits, engineering and contingency costs – ultimately allowing any $WCC$ costs to be calculated as 15 % of the $FCC$. Meanwhile, $VCOP$ costs have been calculated by assessing the raw material, waste disposal, and utility requirements of each process.

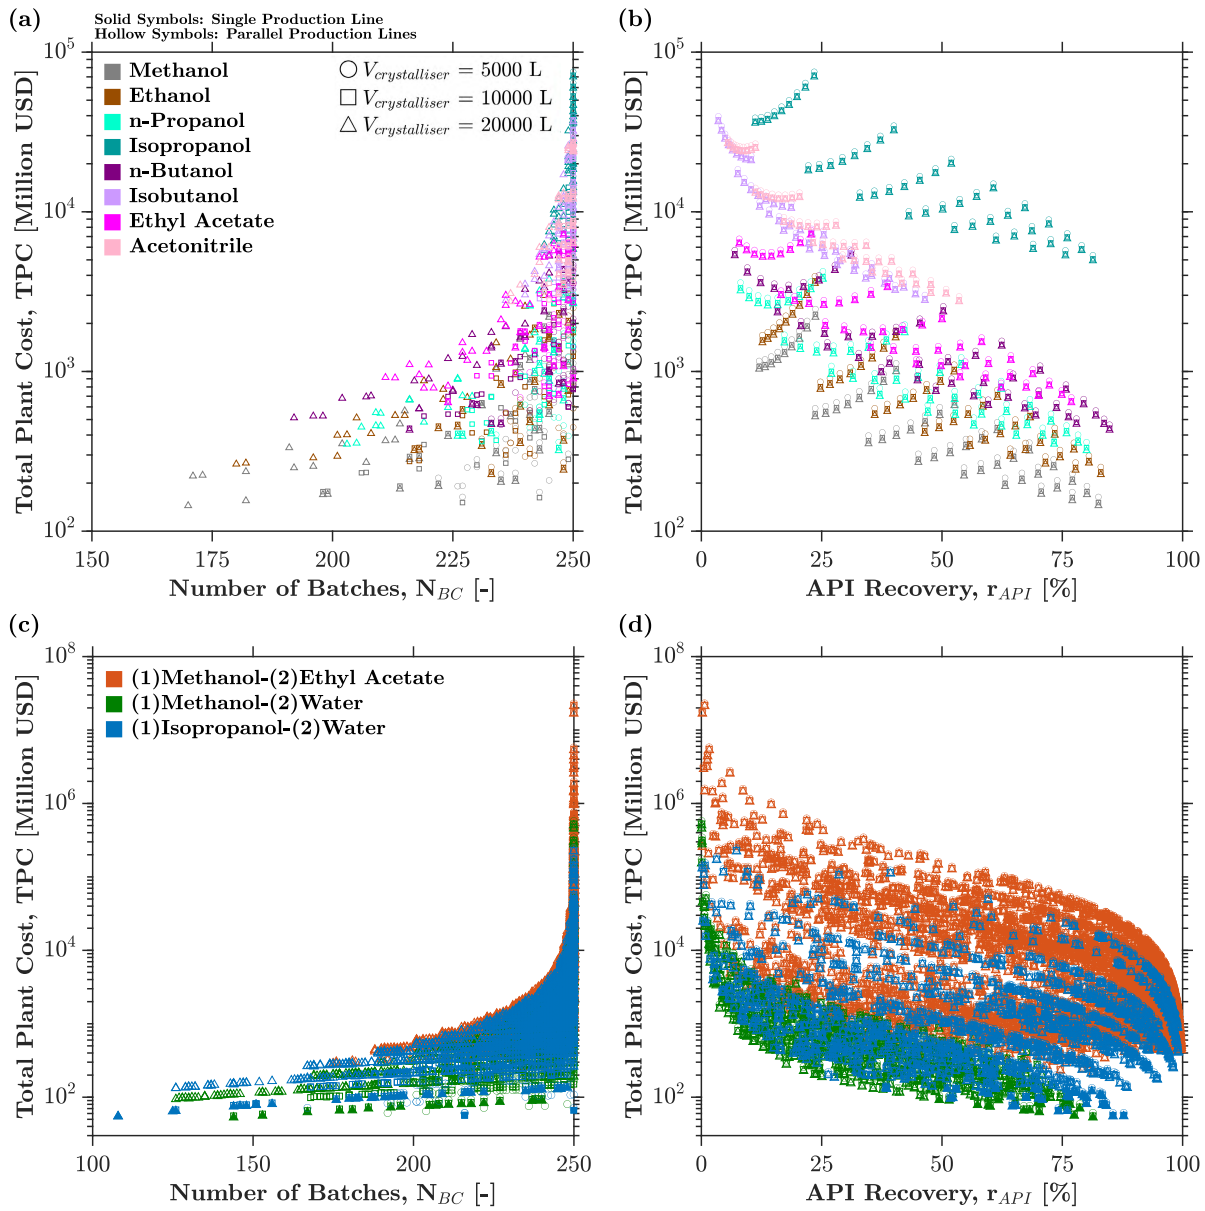

**Figure 3.** Impact of solvent system and crystalliser volume on the batch processing requirements (left), API recovery (right), and process costs associated with the production of pregabalin when using (a, b) pure and (c, d) mixed solvent systems to bring about its crystallisation under varying process conditions ($x_{1,0}$, $x_{1,f}$ $T_0$, $T_f$).

Any *FCOP* costs have then been evaluated by assessing any supervision and management, labour, and maintenance costs incurred alongside any costs arising from property taxes, rental payments, insurance premiums and direct salary overheads.

Considering this, an energy efficiency of 40 % has been assumed for any electrical equipment designed in his work. Meanwhile, any raw materials required by each process have been priced using: (i) average vendor prices published by market research firms (e.g., the IMARC group [16]); and (ii) national import and export reports across major markets. Whereas waste disposal costs have been calculated in line with recommendations made by the World Health Organization (1999) [12] and Jolliffe and Gerogiorgis (2017) [11].

## 5. DISCUSSION OF RESULTS

The modelling framework developed in Sections 2-4 has been used to map the design space associated with each crystallisation process considered herein. From this, it has been shown that for each solvent system: (i) the

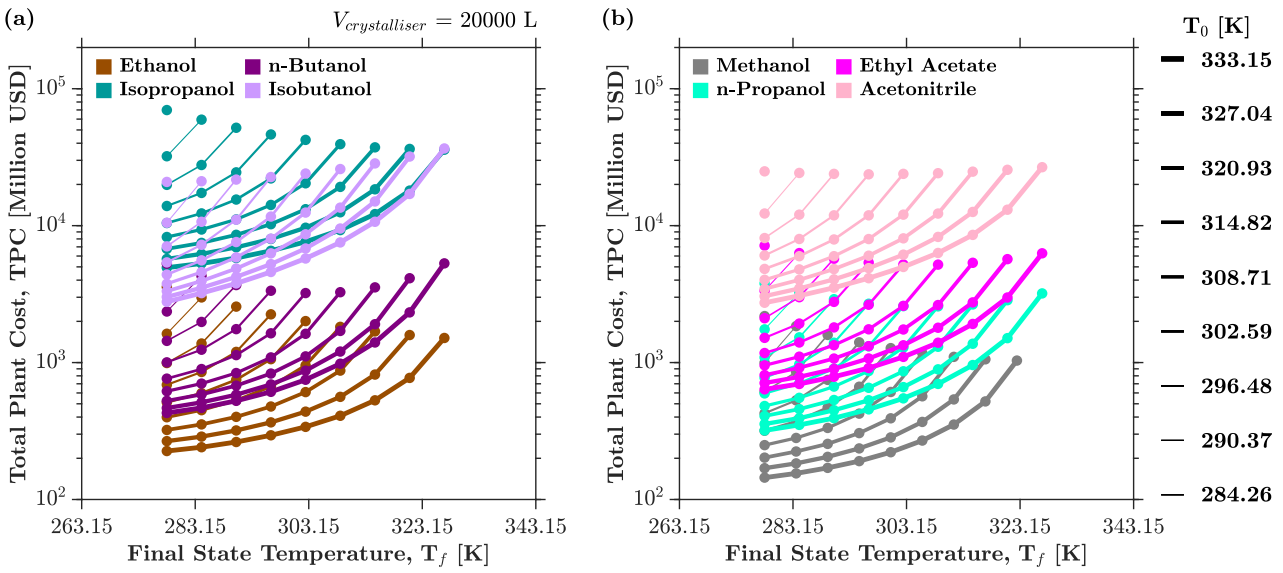

**Figure 4.** Impact of $T_0$ and $T_f$ on the total cost of each pure solvent system.

cost of crystallisation is proportional to its expected carbon emissions, and (ii) its total costs drop when larger crystallisers are used (Fig. 2). Hence, crystalliser volume should be maximised (i.e., set to 20000 L) to simultaneously minimise process costs and environmental impact. Fig. 3 has been used to highlight this concept by demonstrating that increasing crystalliser volume: (i) reduces process costs, and (ii) simplifies manufacturing strategy (i.e., the number of parallel production lines required by a process, and the number of batches that these lines must produce to meet throughput targets). It is, therefore, clear that maximising crystalliser volume leads to cheaper, faster, and simpler pregabalin production.

Upon fixing the crystalliser volume for each solvent system at 20000 L, relationships between process temperature ($T_0, T_f$) and process cost can be determined for each of the pure solvent systems (Fig. 4). Meanwhile, the impact of any changes in process temperature ($T_0, T_f$) and the initial ($x_{1,0}$ and $x_{2,0}$) and final ($x_{1,f}, x_{2,f}$) compositions of the mixed solvent systems can be established (Figs. 5-6). In this regard, identical trends can be seen for each of the pure solvent systems whereby maximising their initial temperature whilst minimising their final temperature minimises costs (Table 1) – with methanol offering the most cost-effective process overall on account of its high API solubility (Fig. 1) and low purchase cost [16]. However, much more complicated trends exist when dealing with the mixed solvent systems – specifically because their cost depends strongly upon their initial and final solvent compositions (Fig. 5). For example, looking at the (1) methanol-(2) ethyl acetate system in Fig 5, it can be concluded that maximising its initial temperature whilst using an initial solvent composition ($x_{1,0}$) of either 0.0 or 1.0 mol mol$^{-1}$ will yield reduced process costs regardless of the final temperature used. On the other hand, when looking at the (1) methanol-(2) water system, it can be seen that (again, regardless of the final temperature used) employing an initial solvent composition ($x_{1,0}$) of 0.30 mol mol$^{-1}$ whilst maximising its initial temperature gives lower costs. Meanwhile, the (1) isopropanol-(2) water system benefits from maximising the initial temperature and using an initial solvent composition ($x_{1,0}$) of 0.10 mol mol$^{-1}$. Interestingly, however, it can be seen that, for all three systems, setting the initial and final solvent compositions equal to one another generally reduces costs. To illustrate this point, Fig. 6 has been used to examine the impact of changing the final temperature and solvent composition on each system more closely. From this, it can be seen that minimising the final temperature of each mixed solvent system minimises costs (just as seen for the pure solvent systems), whilst maintaining a constant solvent composition throughout the process also reduces costs. This is because introducing fresh antisolvent to each system raises operating costs whilst often only marginally reducing API solubility.

Considering this, optimal process conditions for each of the pure and mixed solvent systems could be identified as shown in Table 1. Hence, it could be deduced that the mixed solvent systems containing (1) methanol-(2) water and (1) isopropanol-(2) water will likely offer the lowest process costs, whilst methanol is expected to be the best performing pure solvent. However, as can be seen rom Table 1, the two mixed solvent systems greatly outperform methanol in terms of their overall cost and carbon emissions. Interestingly, however, the (1) methanol-(2) water system is expected to offer lower manufacturing costs but higher emissions than the (1) isopropanol-(2) water system. In fact, upon

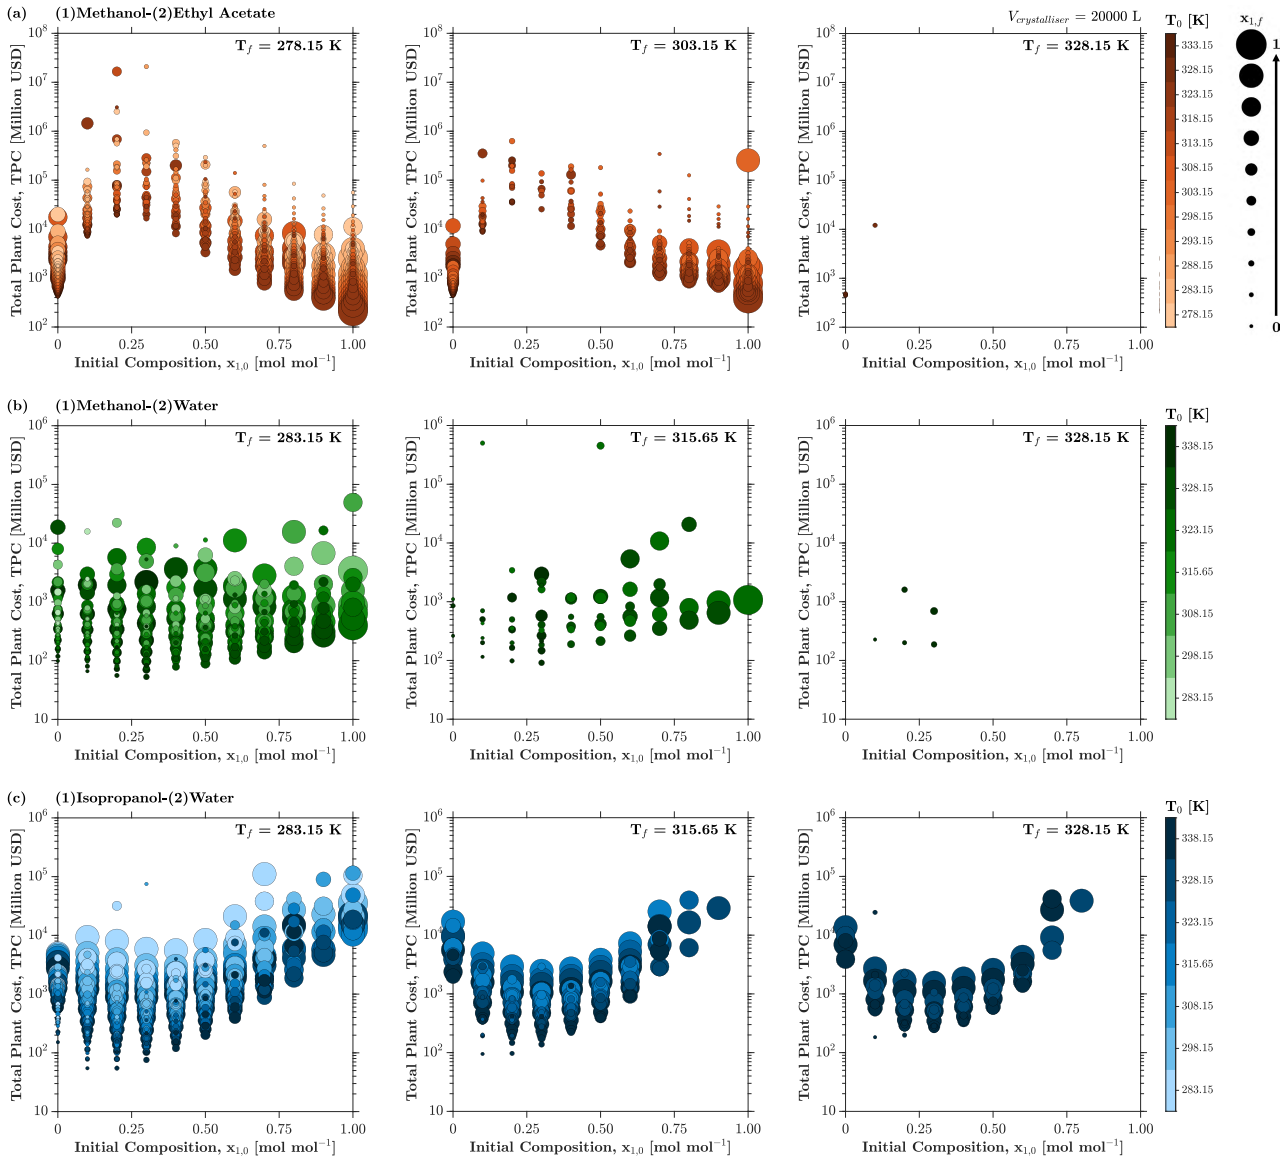

**Figure 5.** Impact of solvent composition ($x_{1,0}$ and $x_{1,f}$) and operating temperature ($T_0$ and $T_f$) on the total cost of each mixed solvent system.

closer inspection of the results in Table 1, it can be seen that the (1) methanol-(2) water system will only offer a saving of 3.21 % when compared with the (1) isopropanol-(2) water system, yet will emit 25.13 % more $CO_2$e. Thus, the (1) isopropanol-(2) water system should be selected as the best performing system.

It is important to note, however, that these results have been gathered using thermodynamic principles alone, and do not consider the crystallisation kinetics of each system as a consequence. Hence, they should only be used as a guide to rank promising systems before conducting experimental trials – thereby streamlining experimental campaigns.

## 6. CONCLUSIONS

This study has demonstrated that pharmaceutical crystallisation processes can be visualised in silico using thermodynamics principles alone for pure and mixed solvent systems. Further to this, it has shown how this approach can be used to identify promising process configurations (and operating conditions) when presented with a wide range of potential manufacturing routes for a new drug. Indeed, it has then used this framework to identify cost-optimal and environmentally friendly manufacturing routes for pregabalin production by carefully considering a wide range of process conditions ($x_{1,0}, x_{1,f}$ $T_0, T_f$) and solvent systems (i.e., 9 pure solvents, 3 mixed solvents): ranking each of these routes from best to worst based on their expected emissions and total manufacturing costs. This ultimately resulted in a mixed solvent system (i.e., (1)

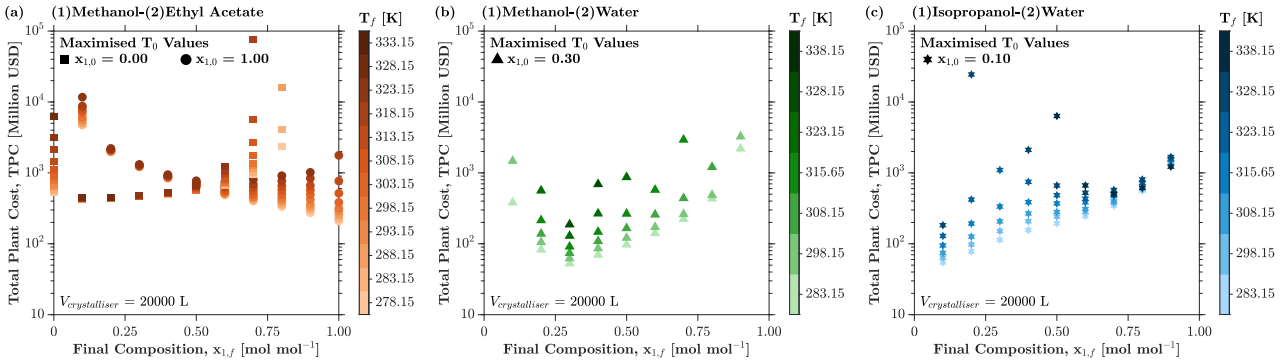

**Figure 6.** Impact of $x_{i,f}$ and $T_f$ on process cost for each mixed solvent system, using maximised $T_0$ and optimised $x_{i,0}$.

**Table 1:** Cost-optimal process conditions for each crystallisation process ($V_{crystalliser}$ = 20000 L).

| Isobutanol | 333.15 | 278.15 | – | – | 1029.57 | 2784.17 |
| Isopropanol | 333.15 | 278.15 | – | – | 1785.30 | 4935.44 |

isopropanol-(2) water) being selected as the most promising process available (c.f. Table 1).

More importantly, however, this work has served to demonstrate how the enhanced solubility trends often seen for solvent mixtures (Fig. 1) do not promise that antisolvent crystallisation will yield cost-optimal results. In fact, it shows that adding an antisolvent to a system could increase its process costs quicker than it decreases an API's solubility, ultimately causing the volume of solvent available for the API to dissolve into to increase faster than API recovery. As such, it is clear that new crystallisation processes should be studied in-silico (using models such as those proposed herein) prior to conducting experimental trials if one wishes to streamline their experimental campaigns by reducing their search space.

## ABSTRACT

Computer-aided molecular design (CAMD) is an efficient product design method that is gradually attracting attention at present. It mainly uses data mining technology to extract information from the existing chemical molecular data and use this information to generate potential excellent molecules. However, the key that CAMD can truly provide accurate and reliable results lies in the efficient utilization of chemical data. In this paper, a series of chemical data analysis methods based on molecular similarity are proposed to enhance the data utilization efficiency of CAMD, which mainly includes 3 applications: adaptive modeling, reliability assessment and advanced data preprocessing including molecular recommendation, data consistency test and data augmentation. We propose specific methodology for each application, and use multiple cases to verify the effect. The results show that molecular similarity can help to improve the accuracy of property prediction at the data level, provide quantification for property prediction reliability, recommend potential excellent molecules with similar structures, locate data mistakes and perform reliable data augmentation, finally enhancing the data utilization efficiency of CAMD.

**Keywords**: Molecular design, Similarity, Reliability quantification, Data preprocessing, Property prediction

## 1. INTRODUCTION

The rapid development of industry has put forward higher requirements for efficient chemical product design. Due to the time-consuming, labor-intensive and easy to miss the potential excellent molecules in the traditional expert-based product molecular design, and the rapid development of modern computer technology, computer-aided molecular design (CAMD) has gradually attracted attention. CAMD mainly includes two parts: property prediction and molecular structure optimization. In these two parts, many researchers have achieved a lot of outcomes. In property prediction, a variety of models has been proposed to improve the prediction accuracy, such as group contribution models [1], machine learning-based models [2]and neural network-based models [3]. In molecular structure optimization, researchers have proposed numerous applications for different products such as fragrance [4], solvent [5] and refrigerant [6].

The core of the above advances in CAMD is to extract the characteristics of molecules and analyze the relationships between molecules. On the other hand, molecular similarity is an indicator used to measure the correlation between molecules, so it can play an important role in the data analysis of CAMD. The calculation of molecular similarity mainly includes two parts: molecular fingerprint and similarity measure method. Molecular fingerprint is used to convert molecular structure into mathematical description such as vector, and then the similarity measure method is used to quantify the molecular similarity. Different molecular fingerprints and similarity formulas adapt to different scenarios. Since the similarity of molecular structures often leads to the similarity of properties, there are many applications of chemical data analysis based on molecular similarity, such as database searching and virtual screening, including drug discovery for anti-cancer agents [7], COVID-19 therapeutics [8], and constrained optimization of drug like molecules [9].

Although some progress has been made in CAMD and molecular similarity, the current application of molecular similarity mainly focuses on the retrieval of known datasets. There are still many unexplored uses of

molecular similarity for CAMD that need to design potential novel molecules. Therefore, this paper proposes 3 main applications of molecular similarity to enhance CAMD: (i) adaptive modeling, (ii) reliability assessment, and (iii) advanced data preprocessing.

## 2. SIGNIFICANCE OF MOLECULAR SIMILARITY IN CAMD

In the molecular structure chemical space, closer molecules tend to present similar properties or follow similar rules, so these similar molecules can provide more valuable information to each other, that is, molecular similarity can be used as a measure of the value of information between two molecules. This provides a basis for molecular similarity to enhance data analysis in CAMD.

Since group contribution (GC) method provides the important advantages of simplicity, quick property predictions without requiring substantial computational resources, and being convenient to be integrated into optimization formulation, this paper uses the GC method [10] to describe the molecular structure, that is, the molecular structure $M$ can be expressed as follows:

$$M = [n_1, n_2, n_3, \cdots \cdots, n_{220}] \quad (1)$$

The molecular structure $M$ can be represented as a 220-dimensional vector, and each element $n_i$ of this vector represents the number of the $i^{th}$ group contained in $M$. The GC method can also achieve compatibility with the existing CAMD method. In order to more accurately measure information value between molecules, this paper uses the molecular similarity coefficient (MSC) proposed by Xu et al. [11] in this paper. Here, the value of MSC ranges from [0, 1], where closer to 1 means two molecules are more similar, and closer to 0 means less similar. An MSC value of 1 indicates that the two molecules are exactly the same, and an MSC value of 0 indicates that two molecules do not have any common groups, namely, cannot provide any valuable information between each other. This MSC integrates molecular chemical characteristics and can effectively deal with issues such as molecular type and molecular size, so as to more accurately measure the value of information that molecules can provide to each other, which is the most critical property of molecular similarity for the data analysis applications proposed in this paper. Next, we discuss the application of molecular similarity: adaptive modeling, reliability assessment, and enhanced data preprocessing in detail.

## 3. THE APPLICATION OF MOLECULAR SIMILARITY IN CAMD

### 3.1. Adaptive modeling

The first application of molecular similarity to CAMD data analysis is adaptive modeling. The main modeling work in CAMD is the molecular property prediction model. The basic flowchart of this adaptive modeling method for property prediction is shown in Figure 1.

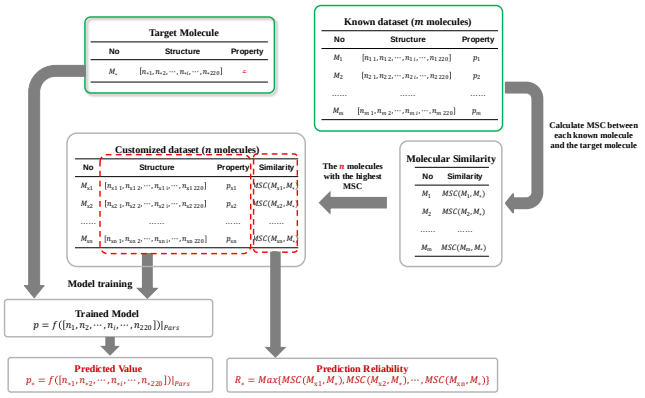

**Figure 1.** Adaptive property modeling method

As can be seen in Figure 1, for a target molecule $M_*$, the $MSC$ between it and all the $m$ molecules $(M_1, M_2, \ldots\ldots, M_m)$ in the known dataset are calculated, those are, $MSC(M_1, M_*), MSC(M_2, M_*)$, ....., $MSC(M_m, M_*)$. Then the $n$ molecules with the highest $MSC$ to $M$ are screened out as the customized training set of $M$, those are $MSC(M_{x1}, M_*), MSC(M_{x2}, M_*)$ , ....., $MSC(M_{xn}, M_*)$ , which are used for the model training and the property prediction of $M$, that is $p_*$.

General machine learning methods will directly use all available known molecular dataset to train the model, so as to obtain a property prediction model with fixed parameters, which is then used to predict the properties of all molecules. However, this approach lacks targeted utilization of dataset. The ultimate goal of the property prediction model is to predict the properties of new molecules individually. In this process, we are most concerned about whether the property prediction of each molecule is accurate. Moreover, when all the known molecular data are used for training, the molecules dissimilar to the target molecule will also be used, and the influence of these molecules on the model will affect the property prediction accuracy for the target molecule. Therefore, it necessitates a more targeted method to predict the property of a single target molecule, that is, adaptive modeling.

The basic idea of adaptive modeling method is that when predicting the properties of a target molecule, we can first construct a customized training dataset for the target molecule according to the similarity between the target molecule and the known molecules, and use the customized training dataset to train the model and predict the properties of the target molecule. Through this method, we can use the information most relevant and valuable to the target molecule for modeling. Different target molecules will adaptively customize their own

training dataset, so as to improve the accuracy of property prediction from the data level. This prediction accuracy improvement has been proved by Xu et al. 's research through a variety of property datasets, and the detailed tests can refer to their work [11].

## 3.2. Reliability Assessment

Another application of molecular similarity lies in reliability assessment. In CAMD, the molecular evaluation is often performed based on the predicted properties. However, the property prediction error is inevitable and it will directly affect the judgment of the molecular performance and even lead to a large difference between the predicted property of the designed molecule and its experimental verification value, losing the guiding significance for experiment. In addition, the property prediction error can only be obtained after experimental verification, which means that high costs have been paid. Therefore, it is important to assess the prediction reliability before experimental verification. To this end, this paper proposes a novel application of molecular similarity in reliability assessment.

The basic idea of this method is to quantitatively evaluate the property prediction reliability of a target molecule according to its information correlation with its training information. The flowsheet is also shown in Figure 1. In section 3.1, we have introduced customizing the training data set according to molecular similarity. Here, we can still employ this concept. Since these customized training data can provide the most valuable information for the target molecule, we can use the comprehensive relevance of this information to design a reliability quantification index for the target molecule. If the comprehensive similarity between the customized training dataset and the target molecule is large, the more information value these training molecules can provide for the target molecule, and the more reliable the property prediction of the target molecule will be. Conversely, if the training molecules customized by similarity are still molecules very different from the target molecule, the information value of these molecules for the target molecule will be very low, and the unreliability of the prediction accuracy will be higher. Here, we choose the maximal MSC of the customized training molecules as the comprehensive similarity, which is used to characterize the comprehensive information value of the customized training data, that is, the reliability index of the target molecular prediction, which is defined as R. As shown in Figure 1, for a target molecule $M_*$, its R is calculated according to Eq. (2),

$$R_* = Max\{MSC(M_{x1}, M_*), MSC(M_{x2}, M_*), \cdots, MSC(M_{xn}, M_*)\} \quad (2)$$

The value range of R is also [0, 1], the closer R is to 1, the more reliable the prediction is, and the closer R is to 0, the less reliable the prediction is. If a molecule has an R of 1, it is a molecule already existing in the known dataset.

Then, we need to verify if R can indeed be used as a quantitative indicator of prediction reliability. In this regard, Xu et al. have verified the performance of the reliability index R in quantification of prediction reliability through tests in a variety of property datasets. Specific testing details can be referred to their work [11].

## 3.3. Advanced data preprocessing

Another application of molecular similarity lies in enhancing data preprocessing. This paper introduces 3 applications of molecular similarity in data preprocessing, which are molecular recommendation, data consistency test and data augmentation.

### 3.3.1. Molecular Recommendation

In molecular design, the recommendation of potential excellent molecules is very meaningful, which can help to narrow the search scope of molecular chemical space, and give priority to the performance evaluation of some molecules, so as to find excellent molecules more efficiently. In the process of molecular design, we often have known molecules with excellent properties at hand. Since molecules with similar structures often show similar properties, we can use these known excellent molecules as reference molecules, and then recommend potential excellent molecules based on molecular similarity. Specifically, molecular recommendation can be divided into single reference molecule-based and multiple reference molecules-based, as shown in Figure 2. Then they are introduced separately as follows.

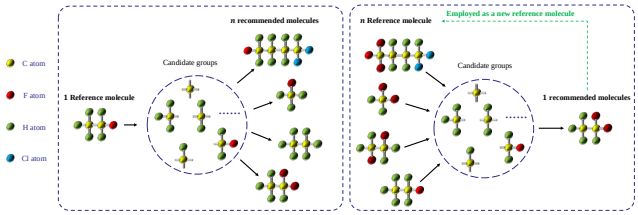

**Figure 2.** The flowsheet of molecular recommendation

From the figure, in the process of molecule generation through the candidate groups, we can generate molecules similar to the reference molecule by adding the similarity constraint between the generated molecule and the reference molecule. In addition, molecular recommendation in CAMD cannot be limited to screening molecules from known molecular dataset, and it is necessary to break through this limitation to achieve the recommendation of potential novel molecular structures. Therefore, the proposed molecular recommendation method is based on the concept of optimization, that is, generating the optimal potential recommended molecular structure that best satisfies the constraints. The specific molecular

**Table 1:** The recommended molecules using a single reference molecule

| No | $CH_3$ | $CH_2$ | CH | C | COOH | MSC | Name | Application |
|---|---|---|---|---|---|---|---|---|
| | 2 | 14 | 1 | 0 | 1 | 1.00 | Isooctadecanoic acid [a] | Cosmetics, emollient |
| 1 | 2 | 15 | 1 | 0 | 1 | 0.94 | | |
| 2 | 2 | 13 | 1 | 0 | 1 | 0.93 | | |
| 3 | 2 | 16 | 1 | 0 | 1 | 0.88 | 2-octyldodecanoic acid [b] | Emulsifier, Lubricant |
| 4 | 2 | 12 | 1 | 0 | 1 | 0.87 | 2-Hexyldecanoic acid [c] | Emulsifier, Lubricant |
| 5 | 2 | 17 | 1 | 0 | 1 | 0.83 | | |
| 6 | 2 | 11 | 1 | 0 | 1 | 0.80 | | |
| 7 | 2 | 18 | 1 | 0 | 1 | 0.79 | | |
| 8 | 2 | 19 | 1 | 0 | 1 | 0.75 | | |

d. https://www.thegoodscentscompany.com/data/rw1446781.html#tosafiu

recommendation optimization model is as follows:

Objective:

$$\text{Max: } Obj_{dummy} = 1 \tag{3}$$

Subject to:

$$M = [n_1, n_2, n_3, \cdots \cdots, n_{220}] \tag{4}$$

$$\sum(\upsilon_j - 2)n_j + 2q = 0 \tag{5}$$

$$\sum_{i \neq j} n_i \geq (\upsilon_j - 2)n_j + 2 \; j = 1, 2, 3, \cdots, 220 \tag{6}$$

$$ng_{lower} \leq \sum n_j \leq ng_{upper} \tag{7}$$

$$nf_{lower} \leq \sum n_j - n_{CH3} - n_{CH2} - n_{CH} - n_C \leq nf_{upper} \tag{8}$$

$$Mw_{lower} \leq \sum(Mw \times n_j) \leq Mw_{upper} \tag{9}$$

$$n_{lower} \leq n_j \leq n_{upper} \tag{10}$$

$$MSC(M, M_{reference}) \geq 0.7 \tag{11}$$

Here, $\upsilon_j$ and $n_j$ refer to the valency and number of the j[th] group. Eqs. (5)-(10) are structural constraints about the octet rule and size related boundary. Eq. (5) indicates that the sum of the number of free electrons of all groups constituting a molecule is -2q. q is a constant, q=1 for acyclic molecules, q=0 for monocyclic molecules, and q=-1 for bicyclic molecules. Eq. (6) states that the total number of free electrons across all instances of the j[th] group must not exceed that of all other groups, ensuring a neutral molecule with a total charge of zero. Eq. (7) limits the total number of groups in the molecule to be between $ng_{lower}$ and $ng_{upper}$. Eq. (8) limits the total number of functional groups in the molecule to be between $nf_{lower}$ and $nf_{upper}$. Eq. (9) ensures that the molecular weight falls within the range of $Mw_{lower}$ and $Mw_{upper}$. Eq. (10) limits the number of the j[th] group to be between $n_{lower}$ and $n_{upper}$. The constraint shown in Eq. (11) limits that only molecules whose similarity to the reference molecule is larger than 0.7 can be recommended. Finally, we define a dummy objective function shown in Eq. (3) to generate all the feasible solutions. Consequently, the molecular recommendation model can be solved through NIP solver and output all feasible molecules.

Then we show a case. This case is about emollient molecule recommendation. In order to design new emollient molecules, we need to recommend some potential molecules which have a high probability of having excellent performance to be emollient. Besides, we already have some known emollient molecules. Therefor, in this case, we just use a known excellent emollient molecule as a reference to recommend some potential emollient molecules through the proposed method. The reference molecule employed here is Isooctadecanoic acid. The recommended molecules are shown in Table 1:

From the table, we can see that the MSC between these molecules and Isooctadecanoic acid remains above 0.7, and we find that among the 10 recommended molecules, molecules 3 (2-octyldodecanoic acid), molecule 4 (2-Hexyldecanoic acid), and molecule 9 (2-hexyloctanoic acid) are also excellent emollient molecules, which proves that the proposed molecular recommendation method can effectively generate molecular with similar excellent performance to the reference molecule.

However, the single reference molecule-based recommendation has a shortcoming, that is, the structural

diversity of the recommended molecules is relatively limited. For example, in the above cases, the generated molecules are all homologs of the target molecule. Therefore, we need to use multiple structurally diverse reference molecules, so as to achieve more diverse molecular recommendation. The corresponding molecular recommendation optimization model is shown below:

Objective:

$$\text{Max: } \sum_i MSC(M, M_{reference_i}) \tag{12}$$

Subject to:

$$M = [n_1, n_2, n_3, \cdots \cdots, n_{220}] \tag{13}$$

$$\sum(v_j - 2)n_j + 2q = 0 \tag{14}$$

$$\sum_{i \neq j} n_i \geq (v_j - 2)n_j + 2 \; j = 1, 2, 3, \cdots, 220 \tag{15}$$

$$ng_{lower} \leq \sum n_j \leq ng_{upper} \tag{16}$$

$$nf_{lower} \leq \sum n_j - n_{CH3} - n_{CH2} - n_{CH} - n_C \leq nf_{upper} \tag{17}$$

$$Mw_{lower} \leq \sum(Mw \times n_j) \leq Mw_{upper} \tag{18}$$

$$n_{lower} \leq n_j \leq n_{upper} \tag{19}$$

$$MSC(M, M_{reference_i}) < 1 \; for \; \forall i \tag{20}$$

The model uses the sum of MSC between the generated molecule and all reference molecules as the objective function to generate the recommended molecule with the highest comprehensive similarity with all reference molecules, as shown in Eq. (12). At the same time, the constraint shown in Eq. (20) requires that the generated molecule is different from all reference molecules. Eqs. (13-19) are the same with Eqs. (4-10).

Then we show another case. This case is about the design of environmentally friendly refrigerants. Here, we employ several known environmentally friendly refrigerants as reference molecules to recommend some potential molecules which has high possibility of having excellent environmental-related properties such as low GWP and ODP. The reference molecules are shown in Table 2.

**Table 2:** List of reference refrigerants

| No | SMILES |
|---|---|
| 1 | FCF |
| 2 | FC(F)F |
| 3 | FCC(F)(F)F |
| 4 | FC(F)C |
| 5 | FC(F)C(F)(F)F |
| 6 | C=C(F)C(F)(F)F |
| 7 | FC=CC(F)(F)F |
| 8 | CCC |
| 9 | CC(C)C |
| 10 | FC(F)C(F)(F)C |
| 11 | FCC(F)F |

Through the solving of the molecular recommendation model, we can generate a molecule with the highest comprehensive similarity to these reference molecules. After that, we can continue to insert the recommended molecule into the reference molecule list and use this updated reference molecule list to recommend a new molecule again. 10 rounds of molecular recommendation are repeated according to the above steps, thus generating 10 recommended molecules as shown in Table 3.

**Table 3:** The recommended molecules using multiple reference molecules

| No | SMILES | ASHRAE Name | Environmental Impact |
|---|---|---|---|
| 1 | C(F)(F)(F)F | R14 | GWP=7390, ODP=0 |
| 2 | FC(F)C(F)(F)C(F)(F)F | | |
| 3 | FC(F)(F)C(F)(F)F | R116 | GWP=12200, ODP=0 |
| 4 | FC(F)C(F)(F)F | R125 | GWP=3500, ODP=0 |
| 5 | C=C(F)C(F)F | | |
| 6 | FC=CC(F)F | | |
| 7 | FCC(F)(F)F | R134a | GWP=1430, ODP=0 |
| 8 | FCC(F)F | | |
| 9 | FCC(F)(F)C(F)F | R245ca | GWP=693, ODP=0 |
| 10 | FCCC(F)(F)C(F)F | | |

As we can see from the table, these molecules maintain structural similarity with all the reference molecules but also have difference. In addition, we found that among the 10 recommended molecules, molecules 1 (refrigerant R14), 3 (refrigerant R116), and 4 (refrigerant R125) have an ODP of 0, but they have a higher GWP. Molecules 7 (refrigerant R134a) and molecule 9 (refrigerant R245ca) have 0 ODP and low GWP. Therefore, this case can show that the proposed molecular recommendation method can effectively generate excellent molecules with similar performance to multiple reference molecules.

### 3.3.2. Data Consistency Test

Another application of molecular similarity in data preprocessing is data consistency test. The correctness of data is the basis of data analysis, and effective data mistake localization is of great significance. Here, we propose a molecular similarity-based method for data mistake localization, namely data consistency test. As we have mentioned above, using the most similar molecules to as the training set can provide the most valuable information for the target molecule, thereby improving the accuracy of property prediction and quantifying prediction reliability. Then, if the reliability index R of the target

molecule is high, the prediction accuracy should have high possibility to be high. However, if we find that the prediction error for the target molecule is very large in this situation, we have reason to suspect that the data of the target molecule and its customized training molecules may have mistakes. For example, when using the critical temperature (Tc) dataset to conduct the adaptive modeling for molecules in test dataset, we found that the prediction reliability R of a molecule $CH_3(CH_2)_{16}COOH$ in the test set was 0.9437, but the prediction error was 10.55% after comparing its predicted value with the real data record in the original dataset. Using the above analysis, we exported the property data of $CH_3(CH_2)_{16}COOH$ and its customized training molecule in Table 4.

**Table 4:** The customized training dataset of $CH_3(CH_2)_{16}COOH$

| No | MSC | Tc (real)/K | $CH_3$ | $CH_2$ | COOH |
|---|---|---|---|---|---|
| $CH_3(CH_2)_{16}COOH$ | 1.00 | 799 | 1 | 16 | 1 |
| Molecule 1 | 0.94 | 474.2 | 1 | 17 | 1 |
| Molecule 2 | 0.94 | 590 | 1 | 15 | 1 |
| Molecule 3 | 0.89 | 809 | 1 | 18 | 1 |
| Molecule 4 | 0.88 | 785 | 1 | 14 | 1 |
| Molecule 5 | 0.82 | 693 | 1 | 13 | 1 |
| Molecule 6 | 0.76 | 568 | 1 | 12 | 1 |
| Molecule 7 | 0.70 | 591.15 | 1 | 11 | 1 |
| Molecule 8 | 0.64 | 618 | 1 | 10 | 1 |
| Molecule 9 | 0.58 | 654 | 1 | 9 | 1 |
| Molecule 10 | 0.52 | 456.86 | 1 | 8 | 1 |

As can be seen, these molecules belong to the homologue, the only difference being the number of carbon atoms. According to the law of chemistry, there is a monotonic trend in Tc and the number of carbon atoms of these molecules. Therefore, we plotted Tc versus the number of carbon atoms for these molecules in Figure 3 (a). It can be seen that there is no monotonic law, indicating that the property data of these molecules are highly likely to be erroneous. Therefore, we checked these data through ICAS software [12], and eventually, we did find some data mistakes, and the corrected data are shown in Table 5.

**Table 5:** The customized training dataset of $CH_3(CH_2)_{16}COOH$ (corrected)

| No | MSC | Tc (real)/K | $CH_3$ | $CH_2$ | COOH |
|---|---|---|---|---|---|
| $CH_3(CH_2)_{16}COOH$ | 1.00 | 799 | 1 | 16 | 1 |
| Molecule 1 | 0.94 | 812[a] | 1 | 17 | 1 |
| Molecule 2 | 0.94 | 793[a] | 1 | 15 | 1 |
| Molecule 3 | 0.89 | 821[a] | 1 | 18 | 1 |
| Molecule 4 | 0.88 | 785 | 1 | 14 | 1 |
| Molecule 5 | 0.82 | 775[a] | 1 | 13 | 1 |
| Molecule 6 | 0.76 | 765[a] | 1 | 12 | 1 |
| Molecule 7 | 0.70 | 754[a] | 1 | 11 | 1 |
| Molecule 8 | 0.64 | 734[a] | 1 | 10 | 1 |
| Molecule 9 | 0.58 | 732[a] | 1 | 9 | 1 |
| Molecule 10 | 0.52 | 722.1[a] | 1 | 8 | 1 |

a: checked in ICAS (Integrated Computer Aided System).

Similarly, we plot the corrected Tc versus carbon atoms as shown in Figure 3 (b).

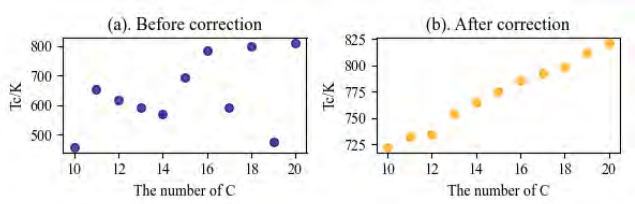

**Figure 3.** The data of Tc with the number of C

As we can see, there is a monotonic trend between Tc and the number of carbon atoms now. Furthermore, we use the corrected data to predict Tc of $CH_3(CH_2)_{16}COOH$, and find that the prediction error is 0.42% now, which indicates that the data have been corrected.

Based on the above case, we propose the data consistency test method. Its flowsheet is shown in Figure 4.

The basic idea of this method is to score the inconsistency of each molecule by analyzing the degree of inconsistency between each molecule and other molecules in the known dataset, and sort all molecular data according to the inconsistency score. The molecule with a higher inconsistency score has a higher probability of having data mistakes, and the more recommended to users for verification. The most critical step in the above flowsheet is how to analyze the inconsistency score for each molecular data. So, we propose a data inconsistency evaluation method based on molecular similarity, as shown in Figure 5.

First of all, we take out a molecule $M_i$ from the known dataset. Using other known molecules as candidate training data, the training molecules of $M_i$ are customized based on molecular similarity, and the property prediction and reliability assessment are carried out. The prediction value is compared with the property data of $M_i$ to calculate the prediction error. Next, we set up an inconsistency scoring mechanism. Initially, all the molecules have an inconsistency score of 0. When molecule $M_i$ satisfies the inconsistency condition, that is, when the prediction reliability of $M_i$ is greater than 0.9 but the prediction error is greater than 5% or the prediction reliability is greater than 0.7 but the prediction error is greater than 10%, the inconsistency score of $M_i$ and all molecules in its customized training dataset is increased by 1. According to the above method, each molecule in the known dataset is evaluated for inconsistency. Finally, the molecules with the highest inconsistency are recommended for verification of data mistake.

Next, we show a case. The case was to conduct data consistency test for a critical volume (Vc) dataset and screen out the potential data mistakes from this dataset. A part of the dataset is shown in Table 6.

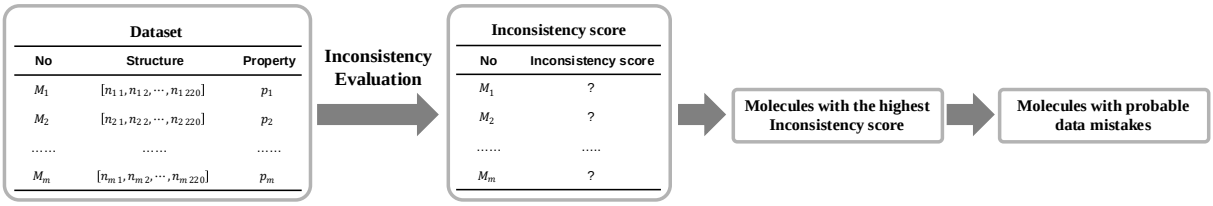

**Figure 4.** The workflow of Data Consistency Test

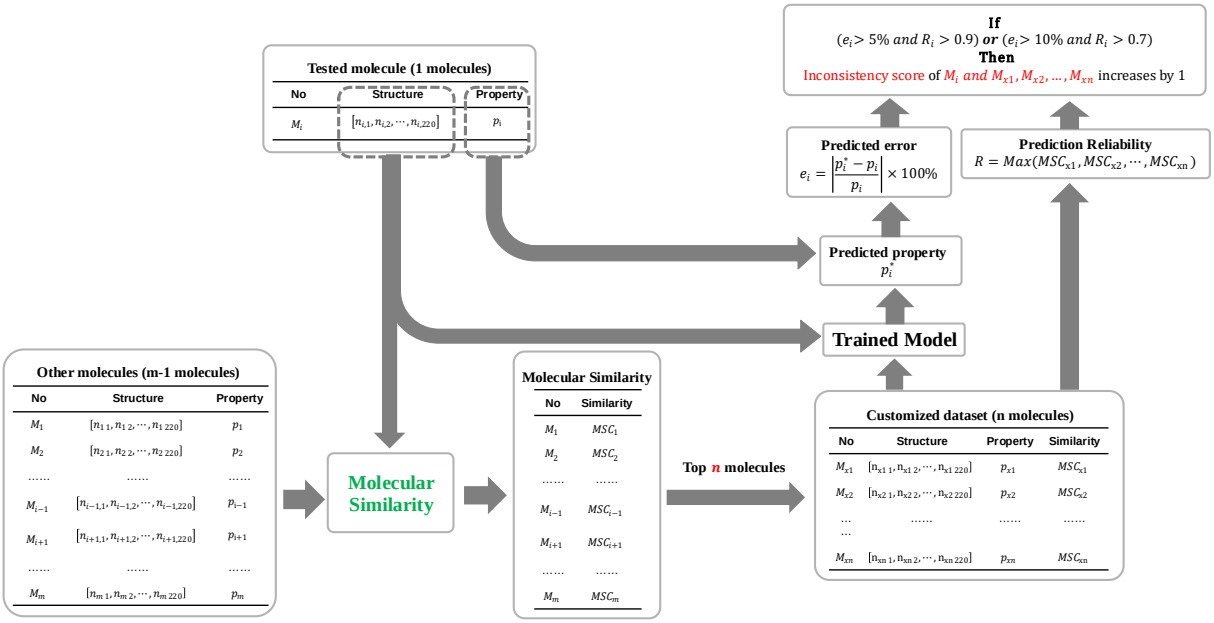

**Figure 5.** The algorithm of inconsistency evaluation

**Table 6:** A Part of the dataset of critical volumes (Vc)

| No | SMILES | Vc/(mL/mol) |
|---|---|---|
| 1 | C=CCCCCCCCCCC | 684 |
| 2 | C=COCC | 263 |
| 3 | O=N(=O)c1ccccc1C | 441 |
| 4 | FC(F)C | 179 |
| 5 | CCCCOC(=O)C(=C)C | 481 |
| ... | ... | ... |

After conducting the proposed data consistency test in this dataset, the inconsistency evaluation results can be obtained, shown in Table 7.

**Table 7:** The result of Data Consistency Test

| SMILES | Vc(mL/mol) | Inconsistency score |
|---|---|---|
| CCCCCCCCCCCCCCC(=O)O | 1059 | 4 |
| CCCCCCCCCCCCCCCC(=O)O | 1130 | 4 |
| CCCCCCCCCCCCCCCCCCC(=O)O | 1346 | 3 |
| CCCCCCCCCCCCCCCCC(=O)O | 1251 | 3 |
| CCCCCCCCCCCCCCCCCC(=O)O | 1070 | 3 |
| CCCCCCCCCCCCCCCCCCCC(=O)O | 1485 | 2 |
| CCCCCCCCCCCCCC(=O)O | 1002 | 2 |
| CCCCCCCCCCCCC(=O)O | 811 | 1 |
| CCCCCCCCCCC(=O)O | 705 | 1 |
| CCCCCCCCCC(=O)O | 653 | 1 |
| C=CCCCCCCCCC | 684 | 0 |
| C=COCC | 263 | 0 |
| ..... | ..... | ..... |

From this result, we can see that there is a total of 10 molecules with an inconsistency score greater than 0, and these molecules are the molecules that need to be paid attention to. Next, we try to correct the property data of them and the result is shown in Table 8.

**Table 8:** The result of data correction

| SMILES | Vc/(mL/mol) | Correct Vc(mL/mol) |
|---|---|---|
| CCCCCCCCCCCCCCC(=O)O | 1059 | 917 |
| CCCCCCCCCCCCCCCC(=O)O | 1130 | 969 |
| CCCCCCCCCCCCCCCCCCC(=O)O | 1346 | 1130 |
| CCCCCCCCCCCCCCCCC(=O)O | 1251 | 1020 |
| CCCCCCCCCCCCCCCCCC(=O)O | 1070 | 1070 |
| CCCCCCCCCCCCCCCCCCCC(=O)O | 1485 | Missing |
| CCCCCCCCCCCCCC(=O)O | 1002 | 864 |
| CCCCCCCCCCCCC(=O)O | 811 | 811 |
| CCCCCCCCCCC(=O)O | 705 | 705 |
| CCCCCCCCCC(=O)O | 653 | 653 |

It can be seen that there are mistakes in the property data for a total of 5 molecules out of the 10 most inconsistent molecules. In addition, the corrected property data of CCCCCCCCCCCCCCCCCCCCCCC(=O)O is missing, which will be introduced in the next application again. This result demonstrates the effectiveness of the proposed data consistency test method. Additionally,

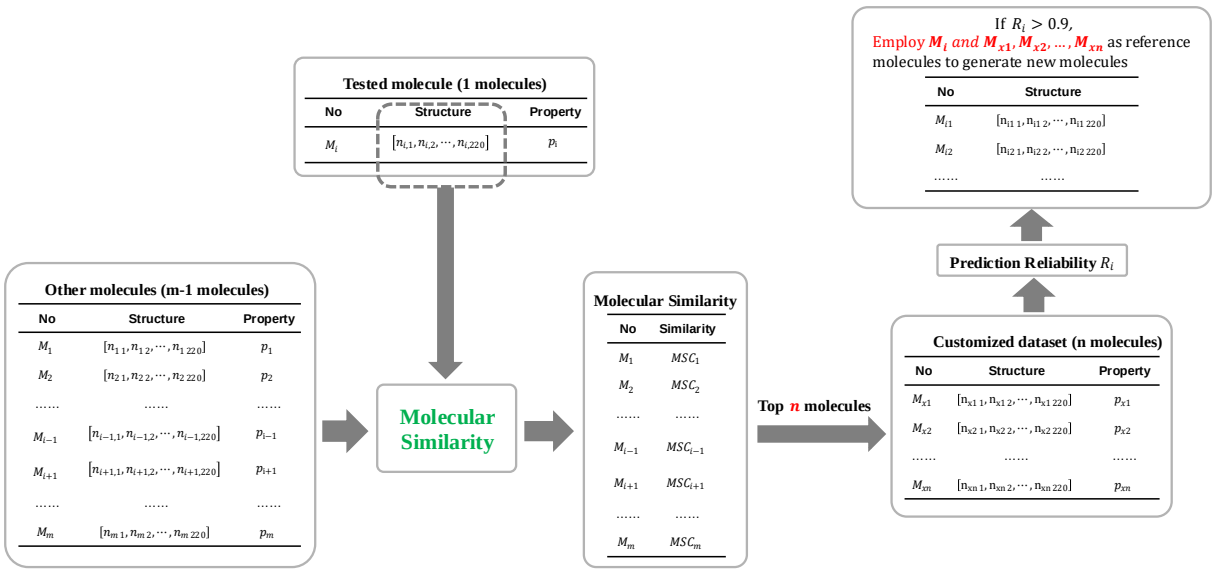

**Figure 6.** The flowsheet of data augmentation

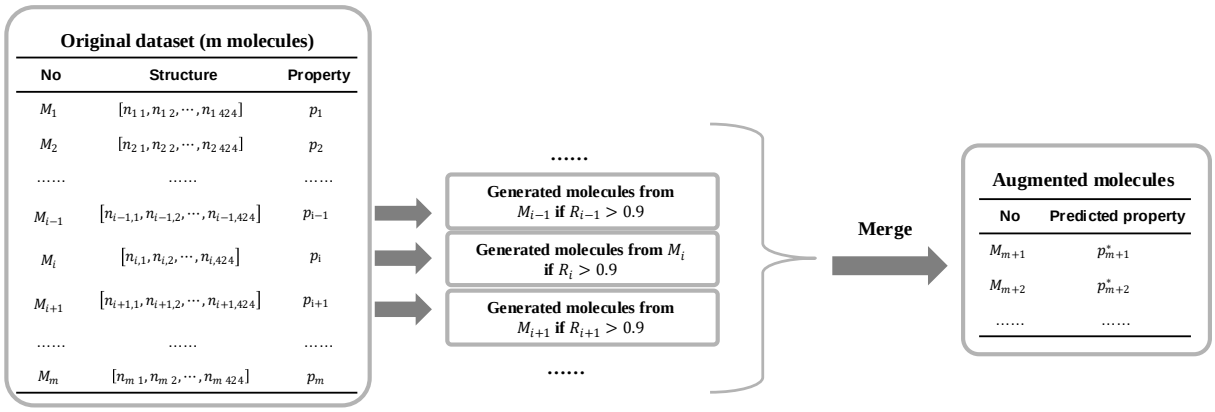

**Figure 7.** The merge of augmented molecules

this method essentially provides a quantitative assessment of the probability that the data has mistakes. It does not mean that the data with high inconsistency must have mistakes or the data with low inconsistency must not have mistakes. In addition, we only evaluated and counted the inconsistency of molecules with high prediction reliability. This is because when the actual prediction error of molecules with high prediction reliability is large, we have higher confidence to conclude that the data have mistakes. For molecules with low prediction reliability, their training molecules can provide low information value itself, even if the data is correct, the prediction error may still be high, so there is no great confidence to evaluate the data based on the large prediction error.

### 3.3.3. Data Augmentation

Data augmentation is a very important data enhancement method in chemical data analysis. For the augmentation of chemical molecular dataset, we need to generate some augmented molecules with high prediction reliability, so that these molecules can be insert in the original molecules reliably. According to the reliability assessment method introduced above, if a target molecule can collect customized training molecules with high similarity to it from the known dataset, then its property prediction reliability will be significantly high. Therefore, we can use this conclusion in turn to generate molecules with high comprehensive similarity to the known molecules, and then use the adaptive modeling method to predict the properties of them. Their prediction reliability will be very high, so, we can then use these generated molecules and their predicted properties as augmentations to the original dataset. This is the basic idea of the proposed data augmentation method.

First, we present a case. This case is about the augmentation of missing data. In the case of data consistency test, after the data correction, there is still a molecule CCCCCCCCCCCCCCCCCCCCCC(=O)O in the

dataset whose real property data is missing. However, when we use other known molecules as candidate training dataset for adaptive modeling and reliability assessment of CCCCCCCCCCCCCCCCCCCCCCC(=O)O, we can obtain a predicted Vc of 1232 mL/mol for it with a prediction reliability of 0.9 which is very high. Therefore, we can try to directly use this prediction value as an augmentation for its missing property data. To see if this method is feasible, we performed the data consistency test on the dataset. The results are shown in Table 9.

**Table 9:** The data consistency test result for the dataset after the data augmentation

| SMILES | Vc(mL/mol) | Inconsistency score |
|---|---|---|
| C=CCCCCCCCCCC | 684 | 0 |
| C=COCC | 263 | 0 |
| O=N(=O)c1ccccc1C | 441 | 0 |
| FC(F)C | 179 | 0 |
| CCCCOC(=O)C(=C)C | 481 | 0 |
| OCCCCCCCCCC | 600 | 0 |
| Clc1ccc(Cl)cc1 | 351 | 0 |
| CC=Cc1ccccc1 | 407 | 0 |
| CCC(Cl)C | 305 | 0 |
| CCCCN(CCCC)CCCC | 735 | 0 |
| ..... | ..... | ..... |

It can be seen that the inconsistency scores of all the molecular data are 0, which shows the consistency of the dataset and the feasibility of the above augmentation method for missing data.

Based on the results of the above case and the basic idea, we propose the data augmentation flowsheet shown in Figure 6. For a known molecular dataset, we first take out one of the molecules $M_i$, and use other known molecules except $M_i$ as candidate training dataset to conduct reliability assessment. If the reliability of $M_i$ is high, for example greater than 0.9, then the similarity between $M_i$and its customized training molecules will be high. Then, we can use $M_i$ and its customized training molecules as reference molecules to perform molecular recommendation introduced above. For example, we generate 10 recommended molecules, which will have high similarity with these reference molecules. Through the above method, we can try to generate augmented molecules from each known molecule. Next, we merge all the augmented molecules as shown in Figure 7. Firstly, the duplicated augmented molecules are removed, and then the adaptive modeling and reliability assessment are carried out for them. We then remove augmented molecules with reliability of 1, since they are already present in the original known dataset rather than new molecules. Finally, we selected the augmented molecules with reliability index greater than 0.9 as the final augmented molecules, and added them to the original molecular dataset to complete the data augmentation.

Next, we show another case. This case uses the Vc dataset after data correction and missing data augmentation described above. In this way, the original dataset can be clean and correct. Then we use the proposed data

**Table 10:** The augmented molecules

| No | SMILES | Predicted Vc(mL/mol) | R | Real Vc(mL/m |
|---|---|---|---|---|
| 1 | CCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCC | 2147.06 | 0.97 | |
| 2 | CCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCC | 2032.88 | 0.97 | |
| 3 | CCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCC | 1918.69 | 0.97 | |
| 4 | CCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCC | 1804.50 | 0.97 | |
| 5 | CCCCCCCCCCCCCCCCCCCCCCCCCCCCCC | 1690.32 | 0.97 | |
| 6 | CCCCCCCCCCCCCCCCCCCCCCCCCCCC | 1576.13 | 0.96 | |
| 7 | CCCCCCCCCCCCCCCCCCCCCCC(=O)O | 1284.53 | 0.95 | |
| 8 | OCCCCCCCCCCCCCCCCCCCCC | 1171.85 | 0.95 | |
| 9 | CCCCCCCCCCCCCCCCCCCCC(=O)O | 1179.25 | 0.95 | |
| 10 | OCCCCCCCCCCCCCCCCCCC | 1067.81 | 0.95 | 1070 |
| 11 | C=CCCCCCCCCCCCCCCCCCC | 1221.02 | 0.95 | |
| 12 | CCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCC | 2204.16 | 0.95 | |
| 13 | C=CCCCCCCCCCCCCCCCC | 1104.87 | 0.94 | 1100 |
| 14 | OCCCCCCCCCCCCCCCCC | 964.37 | 0.94 | 960 |
| 15 | CCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCC | 1975.78 | 0.94 | |
| 16 | C=CCCCCCCCCCCCCCCC | 988.73 | 0.94 | 992 |
| 17 | OCCCCCCCCCCCCCCCC | 859.73 | 0.93 | 854 |
| 18 | OCCCCCCCCCCCCCC | 755.08 | 0.93 | 749 |
| 19 | CCCCCCCCCCCCC(=O)O | 760.97 | 0.92 | 758 |
| 20 | CCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCCC | 2261.25 | 0.92 | |
| 21 | CCCCCCCCCCCCCCCCCCCCCCCC(=O)O | 1337.17 | 0.91 | |
| 22 | OCCCCCCCCCCCCCCCCCCCCCC | 1221.73 | 0.91 | |

augmentation method to expand this dataset. Finally, we can obtain the augmented molecules shown in Table 10. From this result, we can see that a total of 22 augmented molecules was generated, and their prediction reliability is very high. Then, we tried to verify their predicted property and finally obtained some of the real property values, as shown in the table. We can see that the prediction errors of the verified augmented molecules are all less than 1%, and the average error is 0.47%, which indicates that the proposed data augmentation method can indeed generate augmented molecules with reliable property information, so as to form reliable and accurate information enhancement to the original dataset.

## 4. CONCLUSION

This paper presents several applications of molecular similarity in data analysis for CAMD, including adaptive modeling, reliability assessment, and data preprocessing. Of course, none of these applications are isolated; they can be used in conjunction with each other. For example, the molecules generated by data augmentation cannot guarantee the correctness completely. In this case, the data consistency test can be used to further remove the incorrect data. Besides, adaptive modeling and reliability assessment have high requirements for the correctness of data. Therefore, the data consistency test method can be used to screen data mistakes for them. Finally, the molecular recommendation method can generate potential excellent molecules, and the adaptive modeling and reliability assessment can generate accurate property prediction and reliability index for them. Using these two indices can screen out molecules with both excellent performance and high reliability, thereby improving the reliability and accuracy of CAMD. In addition, the specific algorithm framework of each application introduced in this paper is not fixed. They can be adjusted and expanded according to the specific molecular fingerprint, similarity formulas and application scenario, which are also worthy of improvement in the future. In summary, this paper presents multiple applications of molecular similarity to enhance the efficiency of data utilization, laying the foundation for more efficient, accurate and reliable chemical data analysis and molecular design.

## ABSTRACT

This work presents Pareto Front Guided Sampling (PFGS), a model-guided Design of Experiments (DoE) strategy for bioprocess development that makes the exploration–exploitation trade-off explicit and integrates human expertise into experiment selection. Starting from an initial experimental design, PFGS fits a probabilistic surrogate and then proposes new experiments by solving a multi-objective design problem that simultaneously rewards (i) high predicted performance (posterior mean) and (ii) high information gain (posterior uncertainty). Rather than collapsing this trade-off into a single acquisition value, PFGS generates a Pareto set of candidate experiments, that reflect different balances between improvement-seeking and learning. To prevent wasted runs, an automated screening step is performed to remove candidates in (i) low predicted-mean regions unlikely to yield near-optimal performance and (ii) low-uncertainty regions already well explained by the surrogate, concentrating effort on promising yet under-explored areas and encouraging coverage of multiple near-optimal basins. For industrial application, PFGS was extended to batch selection by choosing a diverse subset of Pareto candidates to support parallel experimentation without substantial loss in sample efficiency, and a termination rule to stop experimentation once user-defined accuracy thresholds are met. PFGS is benchmarked against Latin Hypercube Sampling (LHS) and Bayesian Optimisation (BO) on two representative problems: (i) a bioprocess case study with shallow performance gradients, where naive exploitation is unreliable and non-adaptive designs are inefficient, and (ii) a multi-modal landscape, where methods that focus on a single basin can miss alternative optima. Across these settings, PFGS allocates experimental resources more effectively than non-adaptive baselines and, in the multi-modal case, uniquely identifies and characterises all stationary regions while maintaining strong overall performance. By combining Pareto-transparent decision support, automated filtering, batch practicality, and principled stopping, PFGS provides an interpretable and resource-efficient DoE methodology for biopharmaceutical process optimisation.

## INTRODUCTION

The biopharmaceutical industry faces mounting pressure to optimize processes due to elevated development costs, stringent regulatory requirements, and the inherent complexity of bioprocesses. Digital tools, including hybrid modeling and advanced statistical methodologies, have become essential for reducing development timelines and ensuring consistent product quality. Design of experiments has emerged as a critical methodology for systematically identifying and optimizing the critical factors that influence bioprocess outcomes, thereby enabling researchers to efficiently navigate complex experimental domains [1].

Classical approaches, such as Full Factorial Design (FFD), remain widely utilized in the pharmaceutical

industry owing to their simplicity and effectiveness in systematically mapping investigation spaces [2]. However, these methodologies prove insufficient for the demands of modern biopharmaceutical development, which increasingly necessitate rapid iterative refinement and stringent cost management [1]. Classical DoE methods typically necessitate a large number of experiments, which introduces substantial costs and extended timelines. Furthermore, conventional DoE frameworks, including FFD, are fundamentally limited in their capacity to model highly nonlinear processes, as they are restricted to approximating response functions using first- or second-order polynomial equations. Although LHS provides improved coverage for complex response surfaces, it similarly lacks adaptive and iterative refinement capabilities.

In contrast, model-based DoE approaches based on BO are becoming increasingly relevant because they (i) accommodate model uncertainty as actionable information for decision-making, and (ii) enable iterative experimental design optimization through systematic incorporation of knowledge from preceding experiments [1]. Methods such as Batch Bayesian Optimization (BBO) facilitate simultaneous optimization of multiple parallel experiments. Despite their considerable potential, these approaches remain underutilized in industrial settings, primarily due to challenges associated with integrating complex algorithms into established workflows [3]. Moreover, these methods are primarily designed for optimization rather than comprehensive mapping of the optimal region, which is essential for developing robust models capable of generalizing across diverse operational conditions.

## Problem Statement

This work addresses the development of a comprehensive Design of Experiments framework designed to efficiently guide experimentation in bioprocesses. The overarching objectives are:

- to optimize an objective function (e.g., maximize product concentration),
- to systematically explore the investigation space such that the underlying, often nonlinear, process behavior can be accurately modeled with minimal experimental burden, and
- to accommodate practical constraints inherent to industrial operations (e.g., parallel experimentation or discretization).
- to provide transparent, human-interactable results that facilitate domain expert engagement and enable systematic incorporation of prior knowledge into the experimental design process.

The primary goal is to efficiently acquire process knowledge in regions of the investigation space near optima. This necessitates balancing between exploitation of known promising regions and exploration of uncertain or under-sampled areas, while simultaneously accounting for process nonlinearity and operational constraints of real-world systems. Furthermore, the practical requirements for adherence to experimental timelines and parallelization of resources motivate the development of algorithms capable of proposing multiple diverse, high-performing experimental candidates concurrently.

A fundamental challenge lies in the inherent trade-off between exploitation and exploration. Optimization-focused sampling strategies tend to concentrate proposed experiments in regions of high performance, potentially overlooking broader system dynamics and behavior. Additionally, designs proposed by such algorithms like BO are often not easily human-interpretable and often feel random and unfounded. Conversely, space-filling design approaches enhance model generalizability but may allocate resources inefficiently to regions of limited practical interest. This inefficiency is further compounded by the curse of dimensionality, whereby the investigation space expands exponentially with increasing numbers of input factors, rendering uniform sampling impractical. Effective DoE must therefore balance these competing objectives, emphasizing relevant design subspaces while maintaining sufficient global representativeness.

Industrial applications impose additional constraints that must be addressed: input variables may exhibit discretization due to measurement limitations, categorical factors introduce discontinuities, and operational feasibility considerations and Critical Quality Attributes (CQAs) substantially constrain the accessible design space. Consequently, any newly proposed DoE framework must integrate three fundamental aims: (i) identifying high-performing regions within a multi-dimensional investigation space, (ii) ensuring sufficient coverage to reliably capture process behaviour, and (iii) adhering to practical constraints, like batch operating modes, typical of industrial bioprocessing.

In summary, there is a critical need for integrated methodologies that efficiently balance exploration, exploitation, and practical operational considerations to accelerate biopharmaceutical process development under constraints of cost and regulatory complexity. Importantly, such advancement does not necessarily require the development of novel or more sophisticated acquisition functions for BO. Rather, existing algorithms should be adapted to enhance human-machine interaction and facilitate the systematic incorporation of domain expertise, thereby improving user accessibility and comprehensibility. This emphasis on human-centered design is essential, as human decision-making remains a predominant factor in contemporary process development

workflows.

## METHODS

### Classical Design of Experiment Techniques

**Full Factorial Design** is a statistical experimental methodology in which each factor is evaluated at $n$ discrete levels, and all possible combinations of factor levels are systematically evaluated within the investigation space (an example is presented in Figure 1 to inform model development. This approach enables investigation of both the effects of each variable. However, the experimental complexity of FFD increases exponentially with the number of factors, rendering this method impractical in high-dimensional investigation spaces [4]. Despite this limitation, Fractional Factorial Design, a subset of FFD utilizing a reduced set of the experimental runs that only mildly mitigates the problem of the number of experiments, remains widely utilized in pharmaceutical research applications. Its continued adoption is attributable to its simplicity and experimental efficiency. Furthermore, the results obtained from factorial designs can be directly interpreted by researchers without requiring the development of a formal predictive model [2].

One of the most widely employed Monte Carlo-based sampling techniques for systematic space exploration is Latin Hypercube Sampling. Applied across diverse scientific and engineering disciplines, LHS is extensively utilized for uncertainty quantification and reliability analysis [5]. The foundational methodology, stratified sampling, partitions the investigation space into distinct strata, which are weighted according to their respective conditional probabilities. In LHS, each dimension is subdivided into $n_s$ mutually non-overlapping subspaces. From these subspaces, random pairings are performed across dimensions such that each value from each dimension is selected exactly once without replacement, yielding $n_s$ experimental designs of dimensionality $h_d$. A representative example of a LHS in two dimensions is illustrated in **Figure 1.** LHS and its variants are generally preferred for their computational efficiency and demonstrated capacity to capture nonlinear behavior across the investigation space with a minimal number of experiments.

### Bayesian Optimization

Bayesian optimization is employed for the optimization of computationally expensive, black-box functions, such as in materials design applications [6]. BO utilizes a probabilistic surrogate model, typically a Gaussian process (GP) regressor, to approximate the objective function and to systematically guide the selection of promising candidate points [7]. The method balances exploration (sampling regions of maximum uncertainty) and exploitation (optimizing the objective function) through the implementation of acquisition functions [6], which are subsequently maximized using standard optimization algorithms. A widely employed acquisition function is the Upper Confidence Bound (UCB), which manages the exploration-exploitation trade-off by adopting an optimistic perspective regarding uncertainty. UCB is computed according to:

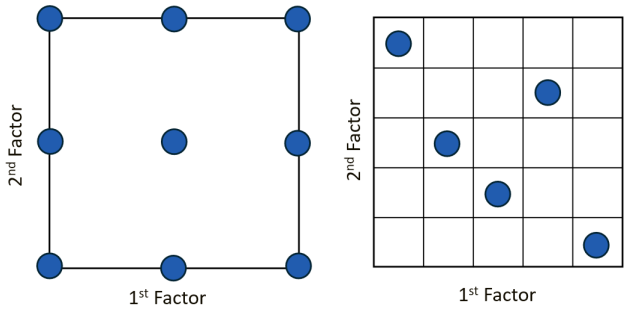

**Figure 1** Example of a 3-level FFD (left) and a LHS (right) in two dimensions.

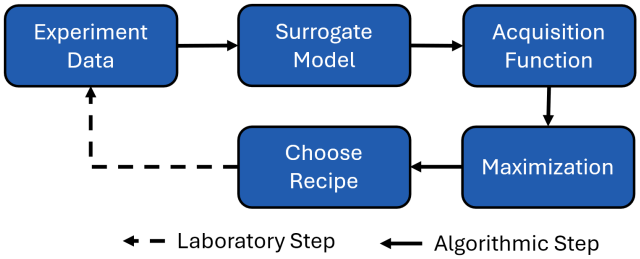

**Figure 2** Overview of BO framework. BO uses the experimental data to train a surrogate model, from which an acquisition function is derived. This function is then maximized to find the most promising recipe.

$$\mathrm{UCB}(\boldsymbol{x}) = \mu(\mathbf{x}) + \beta * \sigma(\mathbf{x});\ \beta > 0 \qquad (1)$$

where $\mu$ and $\sigma$ represent the mean and standard deviation of the surrogate model at point $\boldsymbol{x}$, respectively, while $\beta$ is a hyperparameter that controls the exploration versus exploitation balance [8]. Alternatively, more sophisticated acquisition functions include Expected Improvement and Probability of Improvement. A representative workflow for BO is illustrated in **Figure 2**.

### Batch Bayesian Optimization

The simultaneous sampling of multiple experimental designs using a BO approach is referred to as BBO [9]. BBO extends the principles of standard BO by enabling the concurrent evaluation of multiple candidate points in parallel, rather than sequentially. This parallelization offers substantial advantages in scenarios where multiple experiments or simulations can be conducted simultaneously, such as in distributed computing environments or laboratory settings equipped with multiple testing units. The primary challenge in BBO is that the acquisition function must be modified between successive point

selections to prevent redundant sampling of the same design point [9].

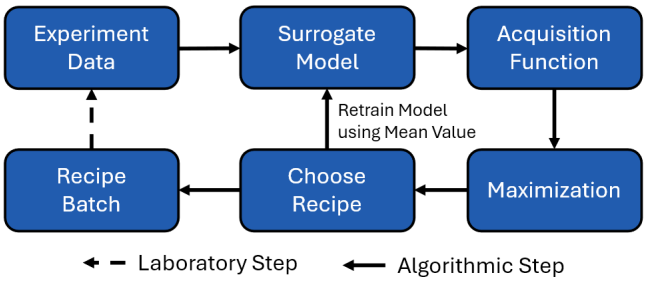

**Figure 3** Overview of BBO. In q-point BO experimental data is used to generate a surrogate model from which an acquisition function is then maximised. The mean of the optimal point $\boldsymbol{x}$ is then added to the experimental batch and the surrogate model is retrained. This iterative procedure is performed until $q$ points are sampled.

In classical BO the maximum of the acquisition function is identified and an experiment at the corresponding point $\mathbf{x}$ is conducted to obtain the true response $\mathrm{y}$. This result is subsequently used to retrain the surrogate model. In q-point BO, a BBO method, no experiment is performed after the first BO iteration. The retraining procedure is performed by employing the mean prediction of the surrogate model $\mu(\boldsymbol{x})$ as a surrogate true value. After iterating this procedure $n_q$ times, where $n_q$ represents the batch size, all $n_q$ experiments are executed in parallel, and the surrogate model is retrained with the empirically obtained values [9]. This approach is called BBO with Kriging Believer. The procedural flow of this algorithm is visualized in **Figure 3**.

## Pareto Front Guided Sampling

In this work, a novel DoE methodology termed Pareto Front Guided Sampling was developed. The fundamental principle underlying PFGS is the generation of a Pareto front that explicitly addresses the exploration-exploitation trade-off. The methodology proceeds as follows: the surrogate model is initially trained on available experimental data. Subsequently, a Pareto front is generated to identify candidate points representing optimal compromises between competing objectives, like exploration (posterior mean) and exploitation (posterior uncertainty). An initial experimental design is selected from this Pareto front, and additional candidate designs are systematically identified based on the maximum Euclidean distance between candidate parameter vectors within the normalized, predefined investigation space. Once a sufficient number of candidate designs has been identified, the corresponding experiments are executed in a controlled laboratory setting, and the surrogate model is updated with the empirically obtained results. A comprehensive schematic representation of the PFGS algorithm is presented in **Figure 4**.

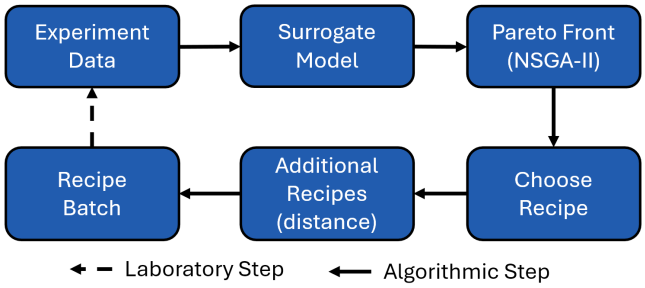

**Figure 4** Overview of PFGS framework. The PFGS algorithm uses experiments to train the surrogate model from which a Pareto front is generated. The recipes are selected and experiments performed.

## Pareto Front Generation

The Pareto front is generated by simultaneously optimizing the mean prediction of the surrogate model (representing exploitation) and the corresponding standard deviation (representing exploration) using a Multi Objective Optimization (MOO) Algorithm. The resulting Pareto front is subsequently refined through the elimination of candidate points from two distinct regions, as illustrated in **Figure 5**. First, candidate points characterized by low mean prediction are systematically removed, as these regions are of limited interest for identifying optimal process conditions. Second, candidate points located in regions of low standard deviation are removed. This elimination strategy serves two purposes. On the one hand it mitigates the influence of process measurement noise by focusing on dominant trends. On the other hand it ensures that the resulting sampling points are appropriately distributed throughout the investigation space, leveraging the property that standard deviation increases with distance from previously sampled experimental designs.

## Recipe Selection

To determine the next experimental design in the batch, a candidate point must be selected from the remaining Pareto front (white region in **Figure 5**). In principle, all remaining points on the Pareto front are equally suitable for sampling. However, the specific selection depends on user preferences and objectives. The selection of the first recipe employs the utopia point as a reference. The utopia point is defined as the hypothetical point simultaneously maximizing both the mean prediction and standard deviation. Ideally, this utopia point (green) would be directly sampled; however, since it does not exist in the investigation space, the geometrically nearest point is selected using the Euclidean distance calculated in the normalized parameter space. For subsequent selections within the batch setting, the remaining candidate designs are sequentially identified from the Pareto front by maximizing the Euclidean distance (in the input space)

to previously selected experimental designs and executed experiments.

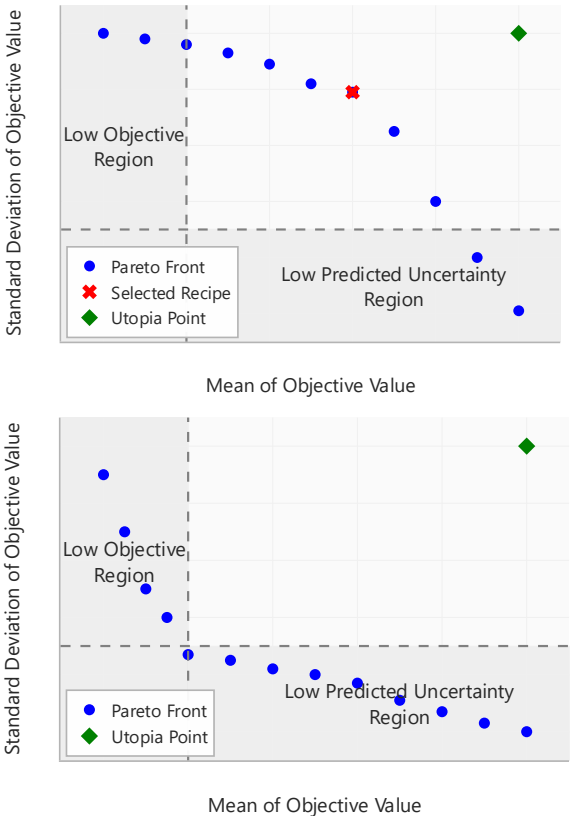

**Figure 5** (top) The generated Pareto front using the model's mean and standard deviation. The gray areas are not sampled due to the low objective values or low uncertainty. (bottom) The Pareto front shown in blue is moving towards lower standard deviations as the model's knowledge is improving, resulting in the case that no point of the Pareto front is selected.

## Stopping Criteria

The algorithmic structure enables termination of experimental design generation when the surrogate model achieves a specified level of accuracy within the target region of interest. **Figure 5** illustrates the Pareto front at an early sampling stage, where numerous candidate points occupy the white region from which the algorithm draws samples. However, as iterations progress and the model improves through successive refinement, the Pareto front gradually shifts toward regions of lower standard deviation. Eventually, no candidate points remain within the white sampling region.

This termination condition can occur at two distinct stages of the algorithm. First, termination may occur during batch selection, where insufficient candidate points remain in the sampling region to complete the full batch. For example, if five experimental designs were requested but only three viable candidates remain in the white region, the algorithm terminates early, resulting in an adapted (reduced) batch size. This indicates that continued sampling of the investigation space is not justified for the current model state. To obtain the remaining designs, either the elimination barrier that constrains sampling to high-performing regions must be relaxed, or a higher accuracy threshold must be set. Alternatively, the three available designs can be executed, and sampling can resume in the subsequent iteration. Second, termination may occur when no candidate points remain in the white sampling region at the initiation of an iteration. In this case, the algorithm ceases entirely, indicating that the surrogate model has achieved a sufficient level of training for the specified objectives.

## Case Study

To demonstrate the efficacy of the proposed PFGS algorithm, two case studies of varying complexity were selected. To facilitate interpretability and explainability, the dimensionality was intentionally constrained to two input parameters (pH and temperature) and one output parameter (product concentration) across both case studies. The studies should represent simplified practical objectives for bioprocesses. In both cases no noise was added to the data.

### Bioprocess

The first case study is based on a simplified Chinese Hamster Ovary (CHO) cell bioprocess model described in [10] that models a product concentration by varying pH and temperature. A visualization of the process response surface is presented in **Figure 6**. This case study presents the challenge of a relatively shallow gradient across most of the investigation space, which consequently renders optimization computationally challenging.

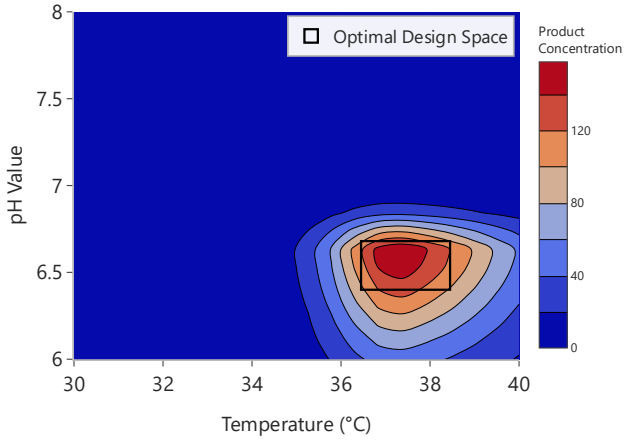

**Figure 6** The optimization landscape of the bioprocess optimization problem.

### Adapted Himmelblau Function

A second case study was developed using the well-established Himmelblau function [11]. The function was adapted to a maximization problem with an investigation space equivalent to that employed in the first case study. This case study presents the distinct challenge of systematically identifying and characterizing multiple local maxima. From a practical perspective, the global maximum (located in the upper left region) may be characterized by excessively constrained input variable ranges, rendering implementation infeasible in an industrial context. Conversely, the broader local maxima positioned in the right region of **Figure 7** offer more favorable practical operating conditions.

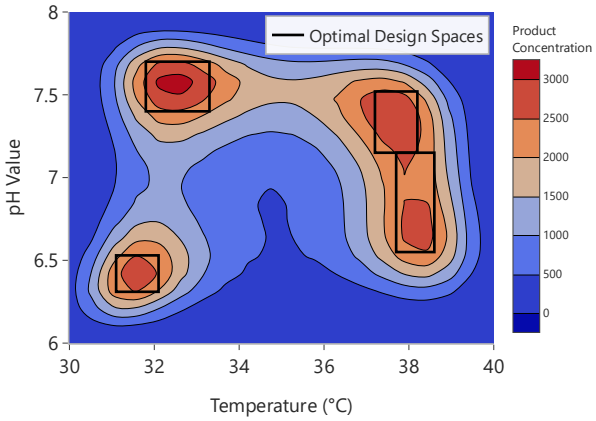

**Figure 7** The adapted Himmelblau function to the optimization capabilities of the algoritms when multiple optima are present.

## Experimental Setup

To evaluate the algorithm's performance, the optimal design regions are identified and delineated by black boxes. These regions are then used to generate test datasets by systematic sampling from the ground truth function. The resulting test datasets are presented in **Figure 8**.

Three distinct algorithms were compared in this study: LHS, BO, and the proposed PFGS. For both BO and PFGS, batch implementations were additionally evaluated. An initial sampling phase was conducted using LHS for all approaches, and a GP was trained on the resulting experimental data. Following initialization, the Relative Root Mean Squared Error (RRMSE) shown in **Equation 2** was calculated using the two previously defined test datasets.

$$RRMSE = \frac{\sqrt{mean((y_{predicted} - y_{test})^2)}}{std(y_{test})} \quad (2)$$

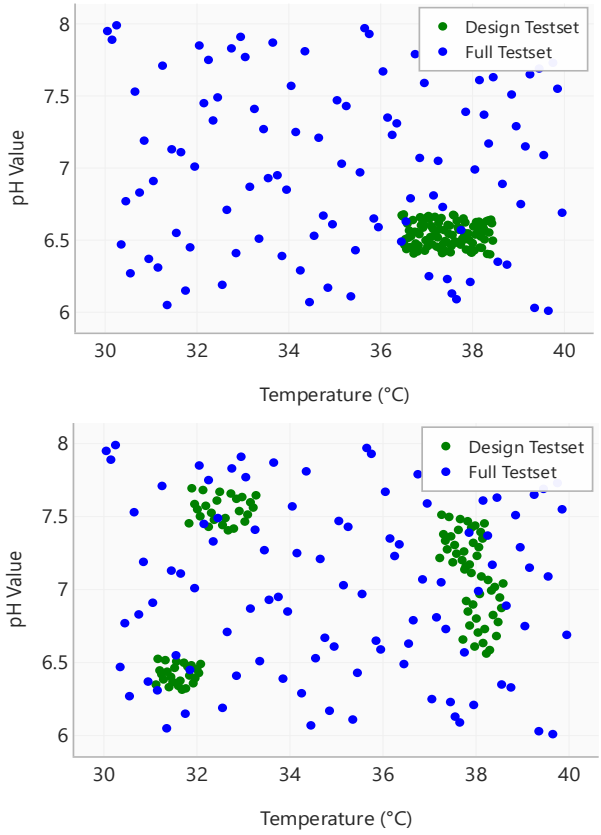

**Figure 8** The test set for the classical Bioprocess (top) and the adapted Himmelblau function (bottom). The blue points correspond to the full dataset and the green ones to the design dataset.

$y_{predicted}$: test set values predicted with GP

$y_{test}$: true test set values

Subsequently, experimental designs were generated according to the respective algorithmic approaches, a GP was trained and the RRMSE was recalculated after each sample or batch of samples using the testset in order to track model improvement.

## Implementation

In this study the data was sampled using LHS sampling implementation of the pyDOE2 package [12]. For all algorithms a GP was trained using botorch [13]. The MOO of the PFGS was performed using the NSGA-II algorithm [14] of the pymoo package [15], and BBO was used in the Kriging Believer setting with and UCB acquisition function with $\beta = 1.96$ and maximized using particle swarm optimization [16] with the pyswarm package [17]. The code is available online on the Autonomous Industrial Systems Laboratory GitHub Page.

# RESULT & DISCUSSION

Results were generated using the same five random

seeds initializations across the five independent runs for each algorithm. All plots display the mean RRMSE calculated from the five replicate runs and the 95% confidence interval. However, for the PFGS algorithm in the first case study, the stopping criterion was occasionally satisfied prior to completion of all five runs, resulting in mean RRMSE values calculated from fewer than five independent replicates. For automated boundary selection in PFGS, threshold values constraining the objective function and uncertainty metrics must be specified. In the first case study, a minimum objective value of 20 and a standard deviation threshold of 10 were established. For the adapted Himmelblau function, minimum objective and standard deviation thresholds of 1500 and 1000, respectively, were employed. These threshold values were derived from the initial Pareto front. However, in a human-in-the-loop setting, these parameters could be iteratively adjusted during each sampling iteration. For reproducibility and standardization purposes, such manual adjustments were not implemented in this study.

## Bioprocess

The first bioprocess case study (**Figure 9**) clearly demonstrates that algorithmic guidance is essential for efficient identification of the optimal region within the investigation space. LHS exhibited the poorest performance, which is attributable to the relatively small region of practical interest compared to the total investigation space size. Consequently, LHS allocated experimental resources inefficiently to regions of negligible interest.

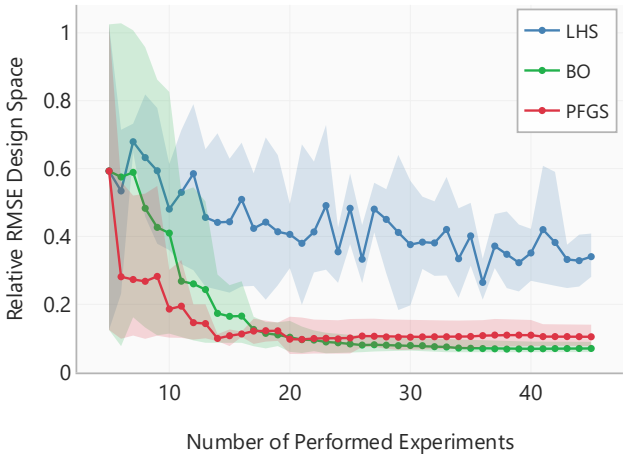

**Figure 9** Bioprocess case study: Performance on the Design space test set of LHS, BO and PFGS with one experiment taken at each iteration.

**Figure 10** presents the results for the batch optimization setting, where five parallel experiments were conducted simultaneously in each iteration. Both PFGS and BBO demonstrated comparable performance trajectories. When these batch results are compared to the sequential sampling approach (one experiment per iteration, shown in **Figure 9**), a modest decline in model performance is observed upon transition to the batch setting. This performance reduction is a well-established phenomenon in batch optimization, arising from the delayed model updating schedule; the surrogate model is updated only after completion of all five experiments within each batch, rather than after each experiment.

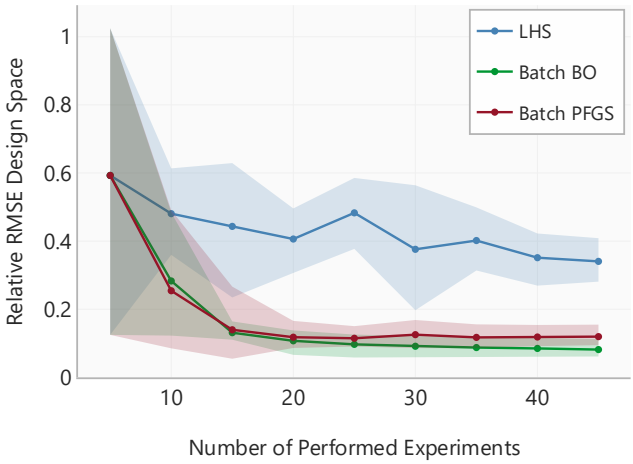

**Figure 10** Performance on the Design space test set of LHS, Batch BO and Batch PFGS with five experiments taken at each iteration.

## Adapted Himmelblau Function

This case study presents a more complex landscape characterized by three local optima and one global optimum. BBO encounters limitations in this setting, as it is fundamentally designed to identify a single maximum rather than to comprehensively map regions of interest. This limitation is evident in **Figure 11**, where the BO algorithm has a high RRMSE. As shown in **Figure 12** BO converges to a single optimum and focuses subsequent sampling efforts on local exploitation rather than exploring the different optima like PFGS. LHS demonstrated substantially improved performance in this case compared to the first example, attributable to the distributed spatial arrangement of the optima across the investigation space. However in needs to be mentioned that LHS is not suited in a practical setting due to its noniterative nature. Finally, PFGS allocates experimental resources more efficiently and does not wastefully concentrate sampling in subregions of negligible interest. It demonstrated comparable performance to LHS while possessing the distinct advantage of identifying and systematically sampling all four optima.

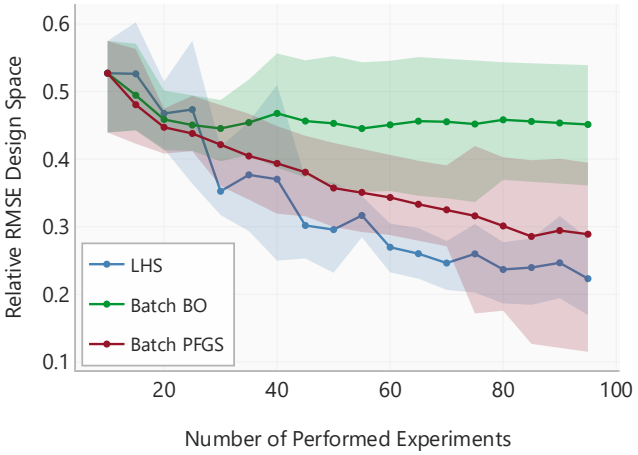

**Figure 11** Himmelblau Case Study: Performance on the Design space test set of LHS, BBO and PFGS with one experiment taken at each iteration.

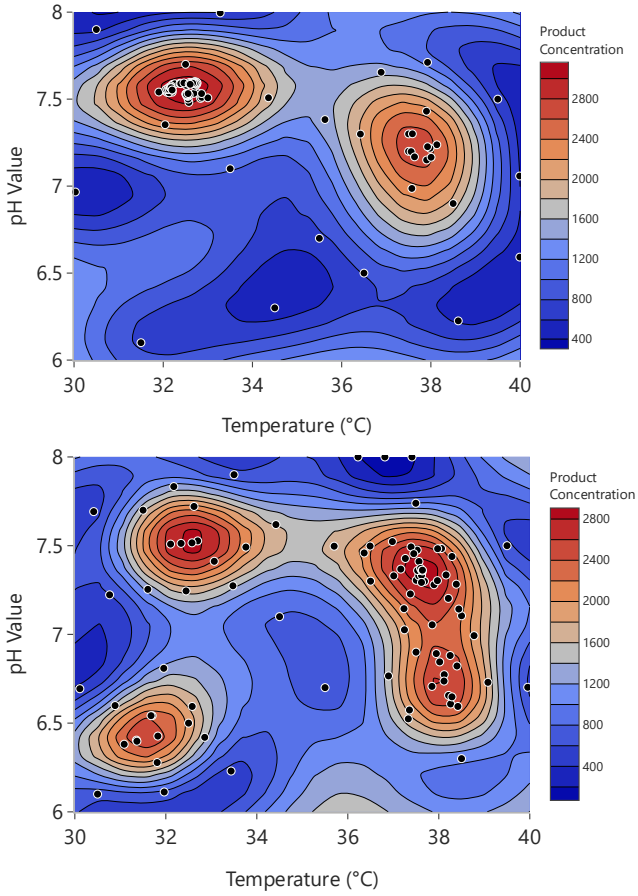

**Figure 12** The location of sampled points (95 total) in the investigation space for one seed of Batch BO (top) and Batch PFGS (bottom). Additionaly a contour plot of the trained GP on those samples is visible.

The performance across the entire investigation space is illustrated in **Figure 13**. Both optimization-focused algorithms demonstrate comparatively poor performance in regions of low objective values. This outcome reflects the inherent trade-off previously described wherein improved accuracy in high-performing regions is achieved at the cost of reduced sampling coverage in regions of low objective values. However, this sampling bias is not problematic from a practical standpoint, since in industrial applications, experimental resources devoted to regions of limited practical interest represent an inefficient allocation.

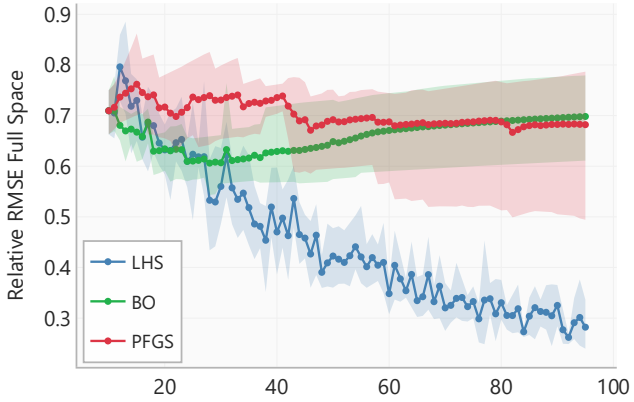

**Figure 13** The performance of the algorithms on the full space (blue points in **Figure 8** (bottom) for the Himmelblau case study).

## CONCLUSION

This work presents Pareto Front Guided Sampling, a novel DoE methodology that systematically addresses the fundamental trade-off between exploitation and exploration in nonlinear bioprocess optimization. The proposed algorithm generates a Pareto front representing simultaneous optimization of the surrogate model's predictive accuracy (mean prediction) and uncertainty quantification (standard deviation), enabling intelligent selection of experimental designs that balance the identification of high-performing with consideration of undersampled regions.

In the first bioprocess case study, characterized by shallow gradients across the investigation space and one optima, PFGS showed similar performance to BO, efficiently allocating experimental resources to regions of practical interest. However, the ability of PFGS to better distribute experiments might still lead to increased performance relative to BO, particularly in high-dimensional settings or under substantial process noise; these aspects were not investigated in this study and remain directions for future work. In the second case study with multiple local and global optima, PFGS outperformed BO and was able to uniquely identify and systematically sampling all stationary points, a capability unavailable to classical BO approaches optimized for single-point convergence. Furthermore, the batch implementation of PFGS

maintains performance while accommodating the practical requirement for parallel experimentation, a critical consideration in industrial bioprocessing workflows. It is crucial to emphasize that PFGS does not outperform classical BO strategies in a strict sense. Rather, within bioprocessing contexts, broader coverage of the optima landscape is often desirable, as it facilitates identification of optimal design spaces. In this framework, the uncertainty threshold effectively biases the acquisition toward increased exploration.

The algorithmic framework incorporates automatic termination criteria, enabling the method to cease experimentation once the surrogate model achieves specified accuracy thresholds within regions of interest. This feature substantially reduces experimental burden and development costs while respecting practical constraints inherent to industrial bioprocesses, including parameter discretization, categorical factors, and critical quality attributes.

## OUTLOOK

Future extensions of this work will incorporate constrained optimization and multi-objective formulations to address more complex bioprocess scenarios requiring simultaneous optimization of multiple competing performance criteria. Additionally, multi-fidelity optimization strategies leveraging experimental data from distinct reactor types and scales are envisioned, enabling more efficient knowledge transfer across different bioprocessing modalities. In this study, the analysis was constrained to two-dimensional investigation spaces to facilitate the interpretability and validation of the PFGS methodology. However, future investigations should systematically evaluate algorithm performance in high-dimensional investigation spaces representative of realistic bioprocess scenarios with numerous controllable parameters.

## ACKNOWLEDGEMENTS

This research was conducted during a Master's thesis research at ETH Zurich in collaboration with DataHow AG and was subsequently further developed during doctoral studies at Imperial College London. This work was supported by financial contributions from DataHow AG and the Department of Chemical Engineering Scholarship from Imperial College London.

## ABSTRACT

Managing cellular resources, especially transcription and translation machinery, constitutes a significant constraint in the effective synthesis of useful bio-compounds from synthetic gene circuits. Although light-based optogenetic control approaches provide precise temporal and spatial control that can balance growth and production. The increased complexity adds on to the competition for cellular resources such as ribosomes and RNA polymerases. The optimization of regulatory elements in bioengineering is a vital task, as the selection of promoters and ribosome binding sites (RBS) directly affects transcriptional initiation rates and translation efficiency, hence influencing resource allocation. The vast number of potential parameter combinations requires systematic approaches to narrow the design space and determine which bioparts most significantly influence system performance. Furthermore, it is crucial to ascertain the uncertainty regarding which bioparts exert the most significant influence on the performance of engineered gene expression. In this study, we conduct an exploratory analysis by combining two established global gene expression models with two optogenetic TCS regulation models within a 2×2 framework. The first resource model (McBride & Del Vecchio, 2021) illustrates resource competition via coupled transcription-translation dynamics, but the second model (Santos-Navarro, 2021) identifies translation as the primary resource-limiting factor. We illustrate the utility of Sobol Global Sensitivity Analysis (GSA) to evaluate which model parameters (bioparts) influence target gene expression in the CcaS/CcaR optogenetic system regulating GFP expression. The findings indicate that the formulation of resource competition, rather than regulatory complexity, fundamentally dictates the rankings of parameter sensitivity. The sensitivity ranking explicitly indicates which design parameters require tight control and which may be relaxed, resulting in a significant reduction in design space.

**Keywords**: Optogenetic Control, Resource Competition, Global Sensitivity Analysis

## INTRODUCTION

Optogenetic systems have gained traction in bioprocess engineering as compelling alternatives to chemical inducers, largely because they avoid contamination issues and simplify downstream processing [2, 12, 13]. The CcaS/CcaR two-component system derived from Synechocystis sp. PCC 6803 represents a prime example—it offers reversible, light-responsive regulation while imposing less metabolic load than conventional IPTG or arabinose-based approaches [2, 5]. Yet designing optogenetic bioprocesses presents an inherent difficulty: competition for cellular resources between engineered circuits and endogenous pathways intensifies considerably under industrial settings characterized by dense cultures and prolonged production timescales [3, 4]. Synthetic gene circuits applied for bioproduction must contend with resource depletion dynamics that can substantially shift system performance across extended production windows.

Two distinct modelling approaches have been established to capture the resource competition dynamics in gene expression. The McBride & Del Vecchio method tackles competition at the gene level, incorporating constraints of both RNA polymerase and ribosome availability via coupled demand parameters [6]. The Santos-Navarro RRS (Ribosome-Recruitment-Strength) model focuses exclusively on ribosomal competition, positing that

translation is the primary limitation in gene expression [11]. Analyzing these differing assumptions on cellular resource allocation provides a chance to investigate how model architecture and mechanistic intricacies affect design recommendations.

Sobol-based sensitivity approaches offer a flexible and computationally efficient means to assess parameter influence on elaborate bioprocess systems [1, 10]. Sensitivity analysis identifies parameters that consistently influence system thereby supporting robust design decisions, especially in synthetic gene circuits where experimental validation for all tunable parts is laborious. In this work, we establish a 2×2 sensitivity framework comparing both resource competition models coupled with optogenetic TCS (Two-Component System) regulation at varying levels of mechanistic detail, as outlined in Table 1. Using the CcaS/CcaR system regulating GFP production in E. coli as our case study, we examine how structural uncertainty in model assumptions propagates to parameter importance rankings and derive practical guidelines for gene circuit optimization.

**Table 1.** Model framework combinations used in the 2×2 sensitivity analysis. Each configuration pairs a resource competition model (columns) with a TCS (Two Component System) regulatory description (rows) at varying mechanistic details.

| | | Resource Competition Models | |
|---|---|---|---|
| | | McBride & DelVecchio | Santos-Navarro RRS |
| TCS Models | Simple TCS | Model 1: McBride + Simple TCS | Model 3: RRS + Simple TCS |
| | Detailed TCS | Model 2: McBride+ Detailed TCS | Model 4: RRS + Detailed TCS |

# METHODS

## Resource Competition Models

### McBride & Del Vecchio Model

The McBride model represents resource competition through gene-level demand weights that account for both RNA polymerase and ribosome [6]. For gene $i$, the resource demand weight is calculated as:

$$w_i = D_i \times \frac{k_{tx,i}}{k_{tx,ref}} \times \left(1 + \frac{k_{tl,i}}{k_{tl,ref}} \times \frac{P_{tot}}{R_{tot} \cdot \delta}\right)$$

where $D_i$ is the gene copy number, $k_{tx,i}$ and $k_{tl,i}$ are transcription and translation rates, $P_{tot}$ and $R_{tot}$ are total RNA polymerase and ribosome counts, and $\delta$ is the mRNA degradation rate. The resource availability factor is then computed as:

$$\rho_{McBride} = \frac{1}{1 + \sum_j w_j \cdot F_j}$$

where $F_j$ represents the regulatory state (constitutive: $F_j = 1$; regulated: $F_j =$ Hill function).

### Santos-Navarro RRS Model

The Santos-Navarro model focuses on mRNA-level ribosome competition through effective RBS strength parameters [11]. The effective ribosome sequestration strength for gene $i$ is:

$$K_{C0,i} = K_{C0,ref} \times \frac{\mathrm{TIR}i}{\mathrm{TIR}ref}$$

where $K_{C0,ref} = 0.04\ molecule^{-1}$ for ribosomal genes and $K_{C0,ref} = 0.1\ molecule^{-1}$ for non-ribosomal genes, with $\mathrm{TIR}_{ref} = 6030$ representing the RBS strengths of non-ribosomal genes providing calibration scaling [6, 9, 11]. The resource availability factor becomes:

$$\rho_{RRS} = \frac{1}{1+\sum_j K_{C0,j} \times m_j}$$

where $m_j$ is the mRNA concentration of gene $j$ .

## Tw-Component System Models

### Simplified TCS Model

The simplified model assumes rapid equilibration of the CcaS photocycle, with light-dependent active fraction $y$:

$$\frac{d[\mathrm{CcaR}]}{dt} = k_{tl,CcaR} \cdot m_{CcaR} \cdot \rho - k_{phos,eff} \cdot [\mathrm{CcaR}] + k_{dephos} \cdot [\mathrm{CcaR\text{-}P}] - \gamma \cdot [\mathrm{CcaR}]$$

$$\frac{d[\mathrm{CcaR\text{-}P}]}{dt} = k_{phos,eff} \cdot [\mathrm{CcaR}] - k_{dephos} \cdot [\mathrm{CcaR\text{-}P}] - \gamma \cdot [\mathrm{CcaR\text{-}P}]$$

where $k_{phos,eff} = k_{phos} \times y \times [\mathrm{CcaS}_{tot}]$ and the regulatory function is $F_{GFP} = \frac{[\mathrm{CcaR\text{-}P}]^n}{K_d^n + [\mathrm{CcaR\text{-}P}]^n}$ .

### Detailed TCS Model

The detailed model explicitly tracks CcaS photocycle dynamics:

$$\frac{d[\mathrm{CcaS}_g]}{dt} = JCcaS - k_1[\mathrm{CcaS}_g] + (k_2 + k_{dr})[\mathrm{CcaS}_a] + k_{phos}[\mathrm{CcaS}_a][\mathrm{CcaR}] - \gamma[\mathrm{CcaS}_g]$$

$$\frac{d[\mathrm{CcaS}_a]}{dt} = k_1[\mathrm{CcaS}_g] - (k_2 + k_{dr})[\mathrm{CcaS}_a] - k_{phos}[\mathrm{CcaS}_a][\mathrm{CcaR}] - \gamma[\mathrm{CcaS}_a]$$

where $JCcaS = k_{tl,CcaS} \cdot m_{CcaS} \cdot \rho$ represents CcaS protein synthesis rate while $CcaS_g$ and $CcaS_a$ represent ground and active state respectively, with photoconversion rates $k_1$ and $k_2$ determined by wavelength and intensity [7].

## Gene Expression Dynamics

**Table 2:** Parameters used in the Simulations.

| Parameter Type | Parameter Symbol | Description |
|---|---|---|
| Common Parameters | AU_CcaS | CcaS promoter strength |
| | AU_CcaR | CcaR promoter strength |
| | AU_GFP_max | GFP promoter strength (activated) |
| | AU_GFP_basal | GFP promoter strength (basal) |
| | TIR_CcaS | CcaS RBS strength |
| | TIR_CcaR | CcaR RBS strength |
| | TIR_GFP | GFP RBS strength |
| | $\gamma$ | Protein degradation rate |
| | $\delta$ | mRNA degradation rate |
| | $D_{CcaS}$ | CcaS gene copy number |
| | $D_{CcaR}$ | CcaR gene copy number |
| | $D_{GFP}$ | GFP gene copy number |
| TCS Parameters | $K_d$ | Activation threshold (half-maximal CcaR-P) |
| | $n_{hill}$ | Hill coefficient (cooperativity) |
| | $k_{phos}$ | Phosphorylation rate |
| | $k_{dephos}$ | Dephosphorylation rate |
| | $k_{dr}$ | Dark reversion rate (detailed TCS only) |
| | $k_1$ | Light activation rate (detailed TCS only) |
| | $k_2$ | Light deactivation rate (detailed TCS only) |

For all models, mRNA dynamics follow:

$$\frac{dm_i}{dt} = k_{tx,i,eff} \cdot D_i - \delta \cdot m_i$$

where $k_{tx,i,eff} = k_{tx,i,basal} + (k_{tx,i,max} - k_{tx,i,basal}) \times F_i$ for regulated genes and where $k_{tx,i,max}$ directly correlates to promoter strength (AU_gene). Target protein dynamics are governed by:

$$\frac{d[\mathrm{GFP}]}{dt} = k_{tl,GFP} \cdot m_{GFP} \cdot \rho - \gamma \cdot [\mathrm{GFP}]$$

where $\mathrm{X_i}$ is protein concentration of gene $i$ and $k_{tl,i}$ is translation rate for gene $i$ and directly corresponds to RBS strength of the gene (TIR_gene).

## Sobol Global Sensitivity Analysis

Global sensitivity analysis provides a systematic framework for quantifying parameter importance in complex systems with multiple uncertain inputs [10]. Let $Y$ be the system output (steady-state GFP concentration) that depends on a set of uncertain parameters $\boldsymbol{X} = \{X_1, X_2, \dots, X_k\}$. The Sobol method decomposes the total output variance into contributions from individual parameters and their interactions: $\mathrm{Var}(Y) = \sum_i V_i + \sum_{i<j} V_{ij} + \sum_{i<j<l} V_{ijl} + \cdots + V_{1,2,\dots,k}$ where $V_i$ represents the variance contribution from parameter $X_i$alone, $V_{ij}$from the interaction between parameters $X_i$ and $X_j$, and so forth. First-order sensitivity indices quantify the main effect of each parameter:

$$S_i = \frac{V_i}{\mathrm{Var}(Y)} = \frac{\mathrm{Var}[E(Y|X_i)]}{\mathrm{Var}(Y)}$$

Total-order sensitivity indices capture all effects involving parameter $X_i$, including interactions:

$$S_{T_i} = 1 - \frac{\mathrm{Var}[E(Y|X_{\sim i})]}{\mathrm{Var}(Y)}$$

where $X_{\sim i}$ denotes all parameters except $X_i$. Sensitivity indices are computed using Saltelli's sampling scheme with N=256 base samples, resulting in $N \times (2k + 2)$ toal model evaluations where $k$ is the number of parameters. All simulations were performed to $t = 500$ minutes to ensure steady state was reached. The analysis was implemented using the SALib Python library. The main parameters used in the simulations are listed in Table 2.

# RESULTS AND DISCUSSION

## McBride Resource Competition Models

In this analysis, we consider the McBride resource competition model integrated with both simplified and detailed TCS descriptions. The TCS parameter values were drawn from published characterizations of the CcaS/CcaR system [7], resource competition parameters from [6], [11], and promoter and RBS strengths were computed using the Salis Lab RBS Calculator [9].

Steady-state GFP expression was assessed at constant green light and served as the output metric for sensitivity analysis. Figure 1 illustrates the variations in the sensitivity profiles between the simplified and detailed TCS implementations. In Model 1 (McBride + Simple TCS),

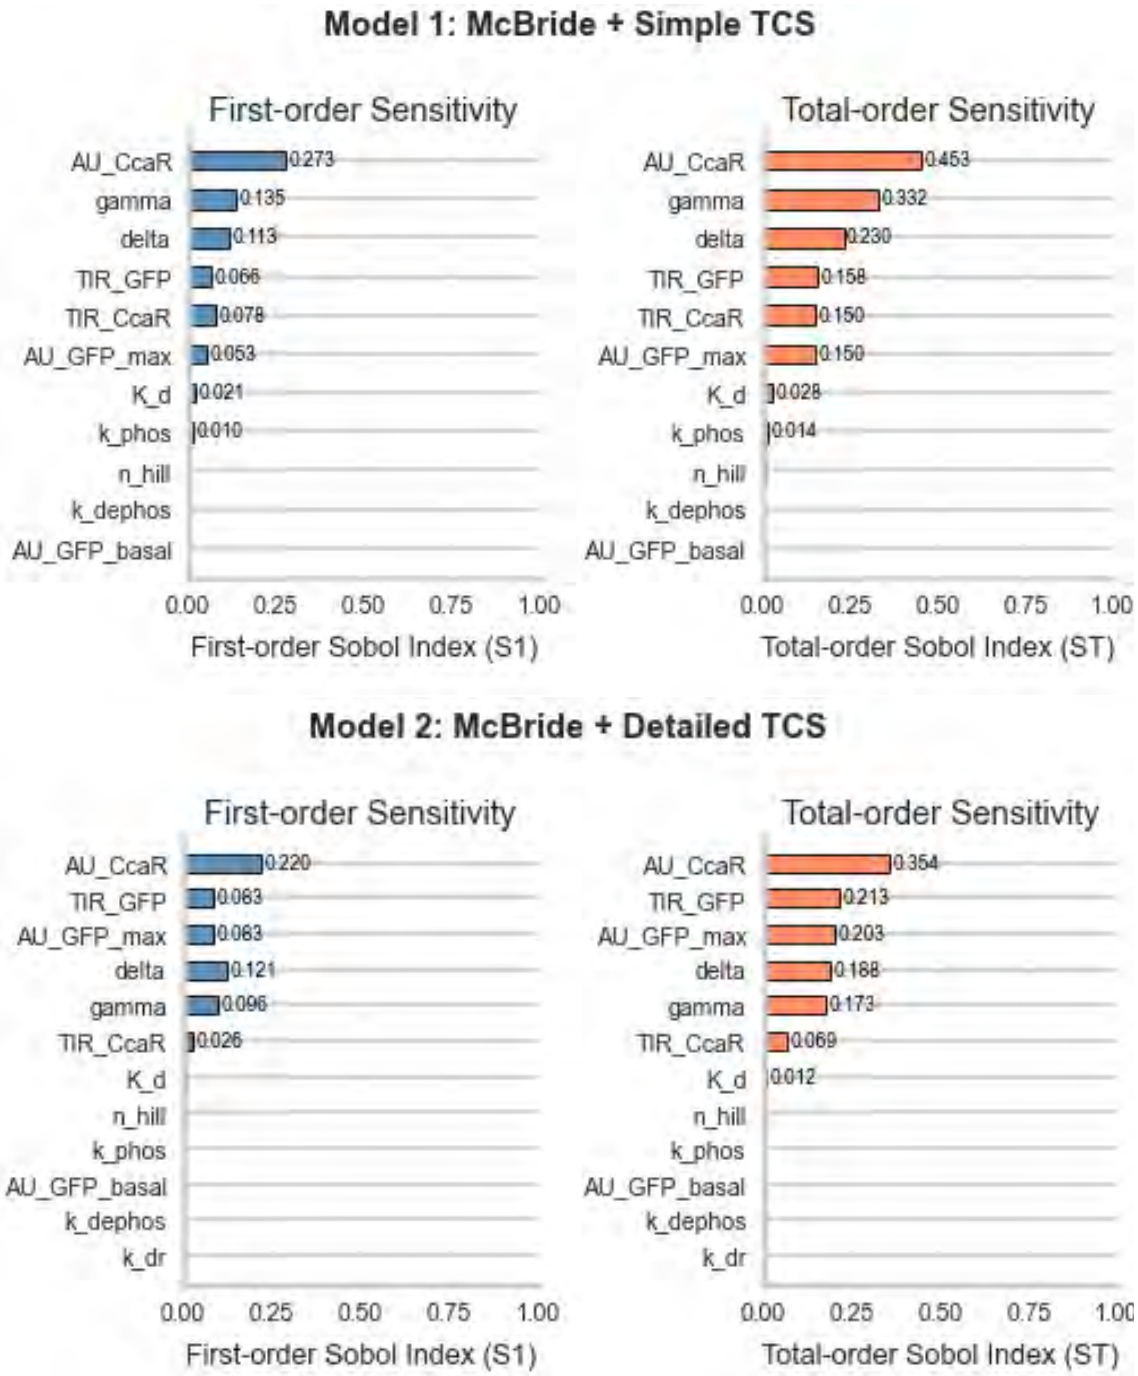

**Figure 1.** Global sensitivity analysis of McBride models showing first-order indices ($S_1$, blue bars) and total-order indices (ST, orange bars) for Model 1: McBride + Simple TCS (on top) and Model 2: McBride + Detailed TCS (bottom). CcaR promoter strength (AU_CcaR) dominates sensitivity in both models, with detailed TCS implementation showing increased sensitivity to target gene parameters (TIR_GFP, AU_GFP_max).
Santos-Navarro RRS Model

the CcaR promoter strength (AU_CcaR) exhibits the highest sensitivity index at ST = 0.45, followed by protein degradation (γ, ST = 0.33) and mRNA degradation (δ, ST = 0.23). Target gene parameters demonstrate a moderate effect, with TIR_GFP and TIR_CcaR presenting ST values in the range of 0.15–0.16. This pattern indicates that transcriptional regulation through CcaR availability primarily controls system output while degradation kinetics contribute secondarily.

In Model 2 (McBride + Detailed TCS), AU_CcaR

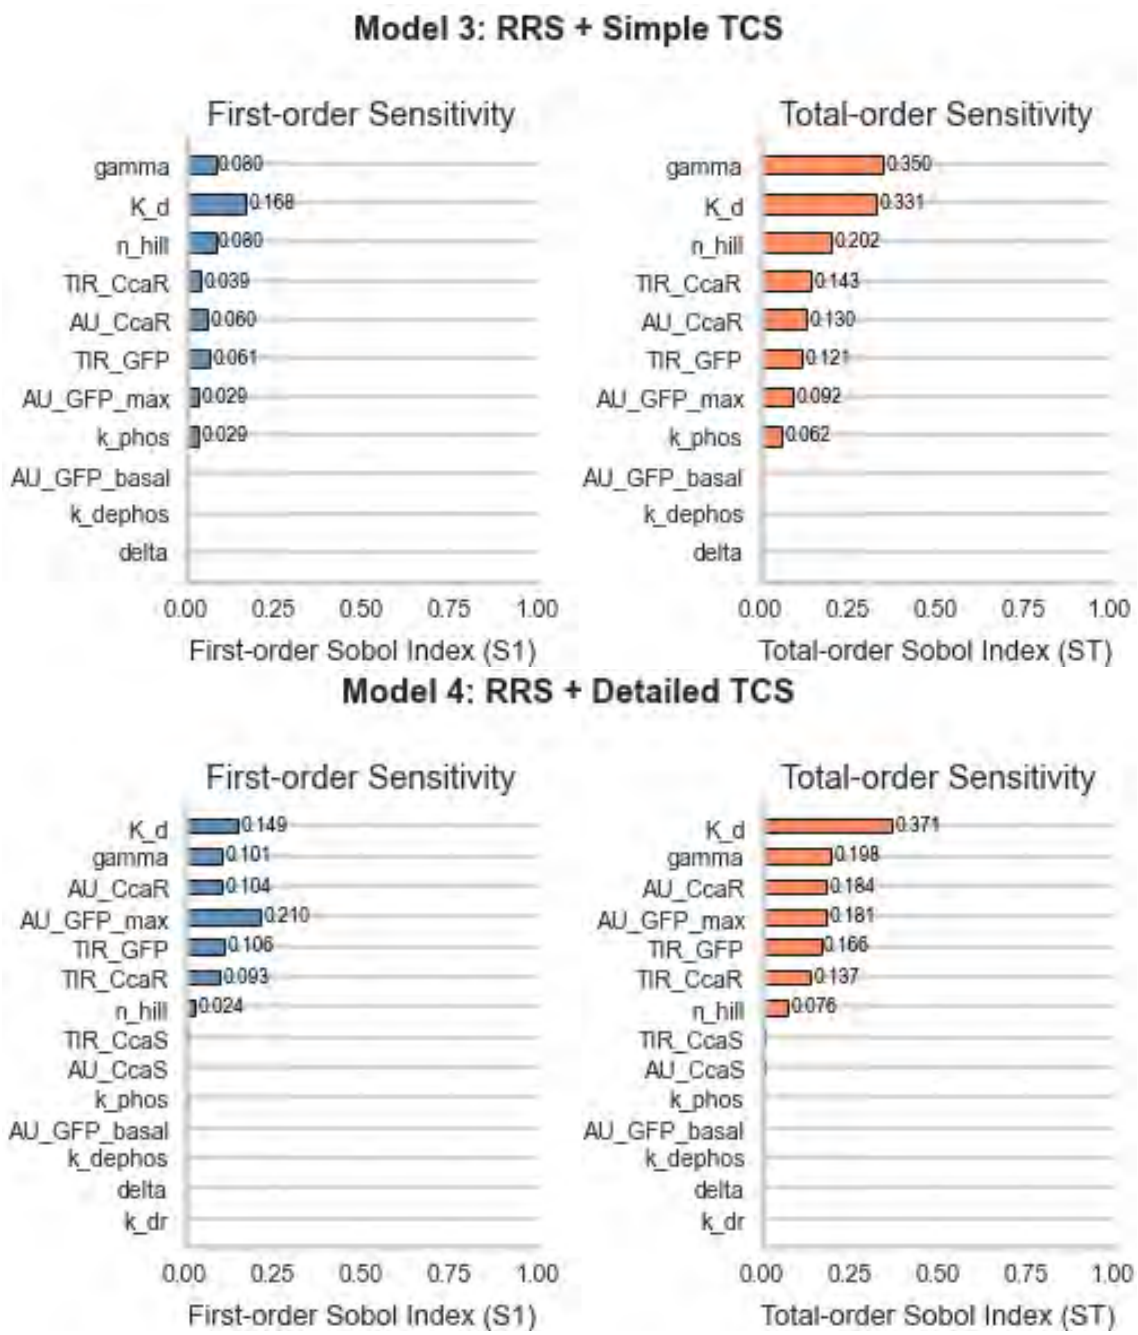

**Figure 2.** Sobol sensitivity analysis of Santos-Navarro RRS resource competition models. Global sensitivity analysis showing first-order indices ($S_1$, blue bars) and total-order indices (ST, orange bars) for Model 3: RRS + Simple TCS (on top) and Model 4: RRS + Detailed TCS (bottom). TCS activation threshold ($K_d$) emerges as the dominant parameter in both RRS formulations.

remains as the most sensitive parameter (ST = 0.35), albeit with a reduced extent. A notable shift in the sensitivity indices emerges as target gene parameters become more significant, with TIR_GFP as the second most influential parameter (ST = 0.21), followed by AU_GFP_max (ST = 0.19). Degradation parameters (δ, γ) exhibit a decline in relative importance. This shift suggests that explicit photocycle dynamics redirects sensitivity toward downstream expression elements while maintaining transcriptional dominance.

The Santos-Navarro resource competition models reveal a distinct sensitivity landscape compared to McBride models, despite same parameter set, as shown in Figure 2. For Model 3 (RRS + Simple TCS), protein

degradation (γ) emerges as the dominant parameter with ST = 0.39, while the TCS activation threshold ($K_d$) exhibits substantial influence (ST = 0.33). The Hill coefficient ($n_{hill}$) gains notable importance (ST = 0.20), reflecting heightened sensitivity to cooperative binding dynamics. TCS regulatory parameters (TIR_CcaR, AU_CcaR) show moderate sensitivity (ST = 0.13–0.14), while target gene parameters (TIR_GFP, AU_GFP_max) display reduced influence compared to McBride models.

In Model 4 (RRS + Detailed TCS), $K_d$ becomes the most influential parameter (ST = 0.37), representing a shift toward signal transduction-dominated sensitivity. Protein degradation (γ) maintains high sensitivity (ST = 0.20), followed by balanced contributions from AU_CcaR (ST = 0.18), AU_GFP_max (ST = 0.18), and TIR_GFP (ST = 0.17). TIR_CcaR also retains moderate importance (ST = 0.14). Notably, mRNA degradation (δ) becomes negligible in both RRS models (ST < 0.05), contrasting sharply with its importance in McBride models. This reflects the RRS framework's emphasis on translational resource competition, where mRNA steady-state levels exert reduced influence on system dynamics.

## CONCLUSION

We put forward a sensitivity-driven approach for studying light-controlled gene expression systems, through a comparative sensitivity-based evaluation of resource competition models. The approach described above systematically identifies essential design parameters and quantifies the impact of model structural assumptions for optimising synthetic gene circuits. Notably, certain parameters demonstrate model-invariant behaviour: CcaS expression (AU_CcaS, TIR_CcaS), basal GFP levels (AU_GFP_basal), and photocycle kinetics ($k_{dephos}$) consistently exhibit negligible sensitivity (ST < 0.05), indicating these are not rate-limiting under either framework.

From a practical standpoint, this approach enables substantial design space reduction as parameters with ST < 0.1, comprising approximately 40–50% of each model, can be fixed at nominal values, thereby directing experimental effort toward high-impact parameter targets while minimizing combinatorial burden.

Though experimental validation of model predictions to confirm both simulated system behavior and sensitivity rankings remains to be seen. The framework's modularity readily allows for adaptation to other bacterial species and various genetic circuit architectures. Integration with automated strain engineering platforms [8] represents a particularly promising direction for accelerating sensitivity-informed optimization of bioproduction systems.

# Genome to Production: A Multiscale Model for Bioprocess Design

**Rajiv Kailasanathan[ab], Mohammad Reza Boskabadi[a], Abhishek Sivaram[a], Seyed Soheil Mansouri[a]***

[a] Department of Chemical and Biochemical Engineering, Technical University of Denmark, Kongens Lyngby, Denmark

## ABSTRACT

Bioprocesses are inherently multiscale, spanning intracellular metabolism to production-scale reactors. Simulation models that integrate these scales offer potential strategies to study the effect of changing metabolic states and enable efficient integration of biological knowledge gathered from lab-scale experiments. In this study, we demonstrate the potential of such simulation model towards the production of mevalonate, an important pharmaceutical drug compound produced through fermentation of a fungal species *Aspergillus terreus*. We integrate a genome-scale metabolic model of the organism with a plant-wide simulation model for the bioprocess that encompasses several upstream and downstream unit operations. Through this integration, we identify potential targets for metabolic engineering towards increased product flux and simultaneously estimate the associated oxygen requirements. This framework serves as a foundation for developing digital twins of bioprocesses that bridges strain engineering with process design and operations.

**Keywords**: Simulation, Biosystems, Fermentation, Optimization, Multiscale Modelling, Metabolic models

## INTRODUCTION

Bioprocesses are multiscale phenomena, where organic reactions catalysed by enzymes ($10^{-9}$ m) occur within cells ($10^{-6}$ m) that exist in complex chemical environments inside fermenters ($10^{0}$–$10^{4}$ $m^3$). Digital models of bioprocesses typically approximate this complexity using parameterized kinetics (e.g.: Michaelis-Menten, Hill) without detailed descriptions of intracellular metabolism. The basis of modern industrial biotechnology is formed on the ability to engineer intracellular metabolism, resulting in development of strains with metabolic capabilities distinct from wild-type. Genome-scale metabolic networks (GEMs) provide this intracellular resolution, allowing us to study the characteristics of altered metabolic states. Strain design based on computational tools are at the forefront of modern systems biology research.

Modern bioprocess development follows the Design-Build-Test-Learn (DBTL) cycle at both strain and process levels. These cycles are interdependent: a strain optimised under idealised conditions may underperform in production-scale fermenters, while processes designed around wild-type kinetics may fail to exploit engineered hosts. Currently, these cycles occur independently. Metabolic engineers use genome-scale models under steady-state assumptions, while process engineers develop dynamic simulations from empirical data. Neither captures the feedback between intracellular metabolism and process operating constraints.

An integrated framework embedding GEMs within dynamic process models closes this gap. Candidate strains can be evaluated in silico under realistic conditions before costly experiments, while operating strategies can be tailored to host-specific metabolic capabilities. Such integration supports early techno-economic assessment by propagating flux predictions through to process metrics—titres, yields, productivities—and identifies which metabolic states satisfy process objectives under realistic operating conditions.

In this study, we demonstrate integration of a plant-wide simulation model with a genome-scale metabolic model of *Aspergillus terreus* for mevalonate production. Through this framework, we investigate intracellular flux distributions under process conditions, determine metabolic reorganisation required for high production, and predict oxygen requirements inaccessible from empirical

models alone. This framework demonstrates a step toward bioprocess digital twins, where mechanistic metabolic models inform process design and enable the DBTL cycle to operate across scales.

## METHODS

The proposed approach is implemented on the KTB1 simulator, which is a MATLAB/Simulink benchmark for continuous biomanufacturing that couples an upstream CSTR bioreactor with realistic downstream operations (cell removal/clarification, filtration, buffer tanks, and chromatography)[1]. The KTB1 simulator considers a regulatory controller, considering noise and delay for sensors and actuators. This simulator provides physics-based unit models, instrumentation hooks, and disturbances to study end-to-end monitoring, control, and soft-sensor design in an integrated upstream–downstream setting. The bioreactor module is constructed from a kinetic model of *Aspergillus terreus* that characterizes the yield of mevalonate from lactose and adenine[2]. A genome-scale metabolic model of *Aspergillus terreus* (iJLi454)[3] is used to provide the intracellular resolution into the process. The model comprises 1451 reactions and 1160 metabolites, and the metabolic pathways required to produce the product precursor, mevalonate, are already present in the model.

### Metabolic regimes for high product productivity

A key question is whether the current metabolic state fully exploits the cell's biosynthetic capacity, or whether alternate flux distributions could achieve higher yields under identical process constraints. To investigate the metabolic flux redistribution required to achieve high mevalonate production, flux sampling was performed on the GEM under two scenarios: (1) mevalonate production constrained to 13% of the theoretical maximum, representing the current CSTR operating point predicted by empirical kinetics, and (2) mevalonate production constrained to 90% of the theoretical maximum, representing a high-production target. Both scenarios were subject to identical constraints on biomass formation rate ($\mu$ = 0.00149 $h^{-1}$), lactose uptake (0.00906 mmol/gDW/h), and adenine uptake (0.00106 mmol/gDW/h), derived from the KTB-1 model at steady state. Constraints were applied with ±5% tolerance to ensure numerical feasibility.

Flux sampling was performed using the OptGP algorithm[4] implemented in COBRApy, which employs a hit-and-run approach to uniformly sample the feasible solution space. For each scenario, 5000 flux distributions were collected with a thinning parameter of 500 steps between samples to minimise autocorrelation. Sampling was parallelised across 8 processes.

Flux distributions for 47 reactions spanning glycolysis, pentose phosphate pathway (PPP), TCA cycle, glyoxylate shunt, and anaplerotic pathways were compared between scenarios. Statistical significance was assessed using the Mann-Whitney U test with Bonferroni correction for multiple comparisons. Reactions were considered significantly altered if the adjusted p-value was less than 0.05.

### Oxygen requirements for continuous operation of the bioprocess

The oxygen requirement of the process is not considered by the KTB-1 system, and the kinetic model assumes that the reactor is supplied with enough oxygen to sustain its metabolism. In this study, we use the genome-scale reconstruction to estimate the oxygen requirement for the continuous operation of the process. The steady-state specific rates from KTB-1 simulator were used to constrain flux bounds in the genome-scale metabolic model (GEM). Three fluxes were constrained based on CSTR predictions: lactose uptake, adenine uptake (nitrogen source), and biomass formation rate. Specific rates from the CSTR model (g/gDW/h) were converted to GEM-compatible units (mmol/gDW/h) using molecular weights of 342.3 g/mol for lactose, 70 g N/mol for adenine (based on nitrogen content), and 148.16 g/mol for mevalonate. Constraints were applied with a ±1% tolerance to account for numerical precision.

Flux variability analysis (FVA) [5] was performed on oxygen uptake and mevalonate production reactions to determine the feasible flux ranges under CSTR constraints. Subsequently, a Pareto analysis [6] was conducted by systematically varying the oxygen uptake constraint across its feasible range and maximising mevalonate production at each level, generating the oxygen–mevalonate trade-off frontier. All simulations were performed using COBRA Toolbox in MATLAB, and COBRApy with the GLPK solver [7].

## RESULTS

### Metabolic flux redistributions at high product production

Specific reaction rates of lactose uptake, adenine uptake, mevalonate production, and the specific biomass production rate were extracted from KTB-1 simulator. After constraining the genome-scale metabolic model iJL1454 with the extracted rates, the model was optimized for maximum mevalonate production, and the resultant rate was compared with current specific productivity of the process. It was found that the current process operates at 13% of the maximum flux predicted by the model. This suggests that either the current operating conditions do not fully exploit the metabolic capacity for mevalonate synthesis, or that regulatory constraints not captured by the stoichiometric model limit production

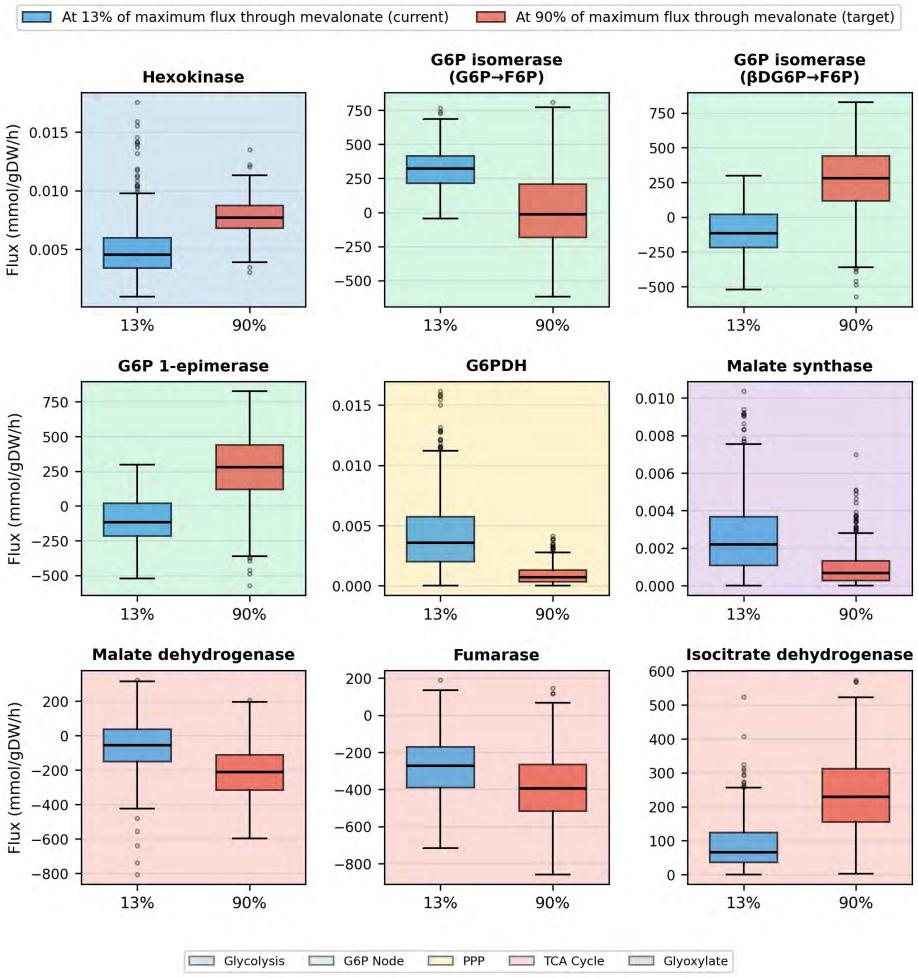

**Figure 1.** Box-plots of the distributions of reactions in the central carbon metabolism at the current efficiency (13%) and at 90% of the theoretical maximum of mevalonate production flux. The glucose-6-phosphate node shows metabolic reorganization, where the canonical enzyme is seen to be likely decreased in magnitude, while the other isoforms simultaneously show large changes in their distributions.

in vivo. This provides scope for metabolic engineering strategies that can increase the specific flux through the mevalonate production pathway.

To compare the systemic characteristics in the metabolism of a high-yielding strain, two models were constructed: In one, the flux through the mevalonate pathway was constrained to the current value (13% of theoretical maximum), and in another, the flux was constrained to 90% of the maximum.

Flux sampling confirmed that both the 13% and 90% mevalonate scenarios were feasible under the conditions specified by the KTB-1 simulator, with biomass flux tightly controlled (0.00142 ± 0.000003 $h^{-1}$ in both cases). Comparison of flux distributions revealed significant changes in several reactions in the central carbon metabolism, indicating widespread metabolic reorganisation when shifting from low to high mevalonate production (Figure 1).

At the pathway level, the citric acid cycle showed the largest average flux change, followed by glycolysis. Anaplerotic reactions and glyoxylate shunt showed relatively minor variations, indicating that these pathways do not influence the high productivity strain. The flux through the upper glycolysis (hexokinase) is increased in the higher-yielding strain. However, at the glucose-6-phosphate (G6P) node, flux through the canonical isomerase (G6P to fructose-6-phosphate) decreased, while alternate isomerases (G6P 1-epimerase and β-G6P) increased their activity. At lower glycolysis (G6PDH) the flux is seen to have decreased.

In the mitochondria, the largest changes were observed in malate dehydrogenase, fumarase, and isocitrate dehydrogenase, indicating an altered TCA cycle that has reorganized to meet the energetic and co-factor demands of the product. These findings demonstrate the value of model-driven metabolic engineering.

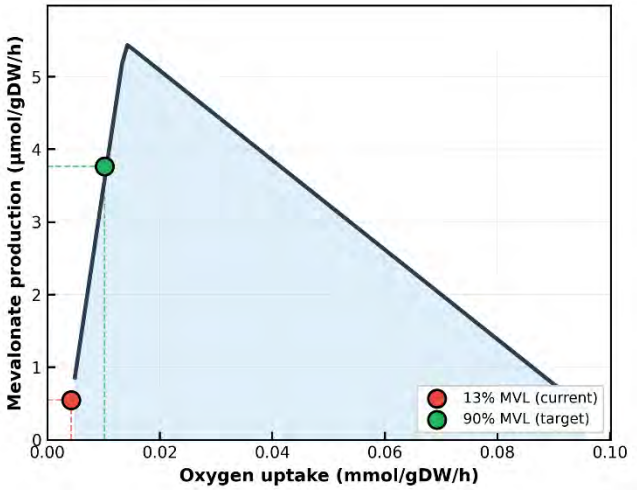

**Figure 2.** Pareto front showing the trade-off between oxygen uptake and mevalonate production under CSTR-derived constraints on lactose uptake, adenine uptake, and biomass formation. The solid line represents the maximum achievable mevalonate flux at each oxygen uptake level determined by FBA. The shaded region indicates the feasible operating space. Red circle marks the current operating point (13% of theoretical maximum mevalonate); green circle marks the target operating point (90% of maximum). Dashed lines indicate the minimum oxygen uptake required to sustain each production level.

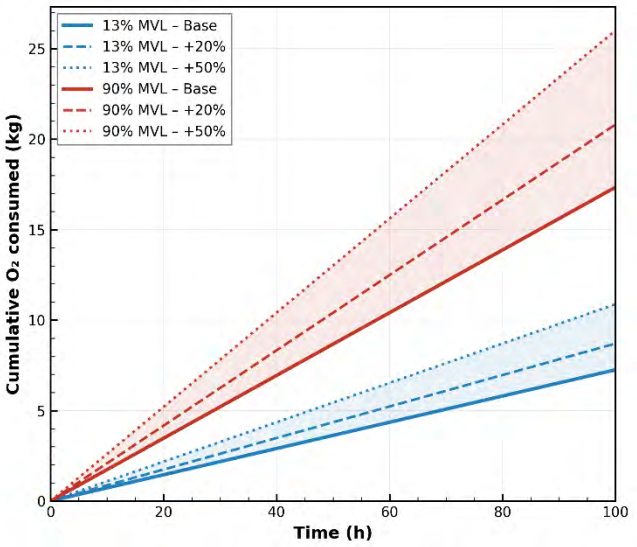

**Figure 3.** Sensitivity analysis on the cumulative oxygen requirements over 100 hours of steady state operations at the current productivity and at 90% of the theoretical maximum.

## Oxygen demand – mevalonate production trade-offs

The GEM analysis confirmed that the steady-state operating point (growth rate = 0.00149 $h^{-1}$, lactose uptake = 0.00906 mmol/gDW/h, adenine = 0.00106 mmol/gDW/h) is metabolically feasible. Under these constraints, FVA revealed that the oxygen uptake rate can range from 0.0071 to 0.0964 mmol/gDW/h, while meeting the metabolic demands for product production.

The Pareto analysis identified a trade-off between oxygen efficiency and mevalonate productivity. Maximum mevalonate production (0.0054 mmol/g_DW/h) required an oxygen uptake of 0.0145 mmol/g_DW/h, approximately thrice the minimum oxygen requirement (Table 1). The minimum oxygen operating point yielded only 9% of the maximum achievable mevalonate flux, indicating that oxygen availability strongly influences product formation capacity. The Pareto front is visualized in Figure 2.

**Table 1:** Key operating points identified from the pareto front.

| Operational mode | Oxygen uptake (mmol/gDW/hr) | Mevalonate flux (max) (µmol/gDW/hr) |
|---|---|---|
| Maximum mevalonate | 0.0145 | 5.4 |
| Minimum oxygen | 0.0049 | 0.485 |

As seen from the Pareto analysis, any strategies undertaken to increase the product productivity under the current conditions would also be associated with increased oxygen demand. Through steady state simulations of the KTB-1 model, we visualize the cumulative oxygen demands over 100 hours of steady state operation while operating at 13% of the theoretical maximum product flux (current) as well as at 90% of the maximum. In both cases, the minimum oxygen consumption was computed by minimizing the flux through oxygen uptake while tightly constraining the fluxes through biomass, lactose uptake, and mevalonate production. In addition, a sensitivity analysis on the metabolic respiration efficiency was performed by assuming that the cells require 20% and 50% more oxygen than the minimum requirement. These results are visualized in Figure 3.

The results suggest that the minimum volumetric oxygen demand increase by 139% when the product flux increases from 13% of the theoretical maximum to 90% of the maximum. When the cells are metabolically inefficient, and they consume 50% more oxygen than the minimum, the difference in the cumulative oxygen demand over 100 hours of system operation correspond to an increased requirement of around 473.15 mols (15.1 kg) of oxygen.

# DISCUSSION

The integrated framework provides quantitative predictions that are inaccessible from either model in isolation. The KTB-1 model tracks extracellular concentrations and predicts product titres, but lacks crucial information about oxygen demand, which is a critical parameter for reactor design and operating costs. By constraining the GEM with CSTR-derived specific rates, we determined that achieving 90% of the theoretical maximum mevalonate production requires 139% increase in the minimum oxygen demand compared to the current operation. Through the integrated framework, we can gather information essential for sizing aeration equipment and estimating utility costs during early-stage process development.

The flux sampling analysis further identified specific metabolic engineering targets. The substantial flux reorganization at the glucose-6-phosphate node and the shift in malate dehydrogenase activity between compartments suggest that cofactor balancing and carbon routing are key bottlenecks limiting mevalonate production. These predictions can guide the DBTL cycle by prioritizing genetic interventions. The current results suggest that modifying G6P isomerase expression or engineering redox shuttle capacity are potential metabolic engineering strategies that can improve the yield of the process.

From a techno-economic perspective, the framework enables the comparison of strain candidates not only on theoretical maximum yields, but on their associated oxygen costs and process requirements. A strain achieving high titers, but demanding excessive aeration, may prove uneconomical at scale. A multi-scale integration as demonstrated here could allow us to study such trade-offs *insilico,* before committing to expensive experimental campaigns.

## CONCLUSIONS

This study demonstrates that integrating genome-scale metabolic models with dynamic process simulations provides mechanistic insight into bioprocess operation that neither approach offers alone. By bridging intracellular metabolism with reactor-scale mass balances, the framework enables prediction of oxygen requirements, identification of metabolic bottlenecks, and quantitative comparison of strain candidates under process-relevant conditions. These capabilities support rational decision-making in both strain and process engineering, allowing the DBTL cycle to operate across scales. As bioprocess development increasingly relies on engineered strains with non-native pathways, such integrations will become necessary as empirical correlations from wild-type strains may be insufficient. This work represents a step toward comprehensive digital twins for industrial biotechnology, where mechanistic models inform experiment design, accelerate scale-up, and reduce the cost and the risk of bringing new bioproducts to market.

## ABSTRACT

Recombinant protein production in *Escherichia coli* is a widely used system in industry for biopharmaceuticals, enzymes or other proteins. For protein expression, lactose poses as a more favorable and cost-effective induction agent over the common IPTG trigger. It imposes less stress on the cells and is fully metabolizable by the strain used. Therefore, lactose serves as an additional substrate source and adds a degree of freedom through tunable induction levels. To harness this opportunity, a physiological bioprocess model was created, describing the growth and production dynamics of this 2-feed system. Green fluorescent protein is expressed as a model protein in a fed-batch process using glucose as the main substrate and lactose as the digestible inducer. A suitable production kinetic is chosen by fitting a number of models to a collected dataset. The resulting model is used to highlight opportunities for improved process design and control of a 2-stage fed-batch process. It emphasizes the benefit of model-based methods to directly optimize for productivity over traditional design of experiment approaches.

## INTRODUCTION

*Escherichia coli* (*E. coli*) is one of the most extensively used host systems to produce recombinant proteins. The product palette ranges from biopharmaceuticals over industrial enzymes to functional proteins for emerging food applications [1]. The organism offers a manifold of advantages such as fast growth, cheap substrate sources or broad availability of biotechnological tools [2, 3].

The common procedure in triggering the production of recombinant proteins utilizes the T7 promoter system. Naturally, it is activated by the presence of lactose in the media, while in industry the analogue chemical isopropyl β-d-1-thiogalactopyranosid (IPTG) is used. It is non-digestible by the cells and serves as a one-shot addition that induces a strong transcription of the encoded protein [4]. This triggers high levels of productivity but also elevated stress on the cells, giving rise to the formation of misfolded protein aggregations called inclusion bodies [5]. Using lactose as an digestible inducer allows for tunable induction, which provides an opportunity for improved process design. Previous studies have shown the positive impact of manipulating physiological parameters such as the specific uptake rates of glucose and lactose for improving productivity and inclusion body content [6]. Nevertheless, the used strains lacked the ability of metabolizing galactose, the first metabolic product of digesting lactose. This leads to metabolite accumulation, blocking further digestion of the inducer and even re-induction after the depletion of lactose, also called “Lazarus effect” [7]. To enable a fully controllable induction process, this study employed a strain that retains the full galactose metabolism.

Commonly, fed-batch processes are designed in two phases. After an initial batch-phase, a fed-batch regime is started with the aim to grow the biomass in the reactor. Microbial cells act as a catalyst for the production, therefore a higher concentration is favorable for increased output. In the last phase, the induction agent is added, and the cells are triggered to produce the encoded protein. The feeding rates and substrate levels in the reactor need to be efficiently controlled, as a surplus can lead to repression or byproduct accumulation [8].

The tunable induction system provides an opportunity to optimize the protein expression dynamically

throughout the changing process conditions of a cultivation. Capturing the intrinsic connections in a model lays the foundation for improved process design and advanced control strategies to ensure higher productivity over extended periods or move towards continuous operation [9].

For this purpose, the interaction of the two substrates onto cell growth and product expression needs to be studied. Previous works focused on describing the effects of two available sugars on the respective uptake rates and their interaction through classical design of experiment [6, 7]. This work expanded this approach to create a novel model, which describes the productivity as a function of the two independent substrate additions. Several experiments were carried out to retrieve data for the characterization and modelling of the presented strain's ability to produce green fluorescent protein (GFP) when using separate glucose and lactose feeds. The parameterized model was then utilized to dynamically optimize the two feed-rates for a 2-stage fed-batch process to improve production processes for different design objectives.

## MATERIAL & METHODS

This contribution suggests a physiological growth and productivity model for a microbial process focusing on the impact of separate glucose and lactose feeds. The data was obtained through lab-scale cultivations in a glass stirred-tank bioreactor system (Biostream International, The Netherlands) with a maximum working volume of $2\,L$. In total 5 experiments were conducted and used for parameter estimation and validation. The modelling steps were implemented through custom Python scripts and followed the iterative workflow for the setup of mechanistic models by Daume et al. [10].

### Cultivation conditions

The cultivation uses DeLisa minimal media [11] consisting of 13.3 g/L $KH_2PO_4$, 4 g/L $(NH_4)_2HPO_4$, 1.7 g/L citric acid, 1.2 g/L $MgSO_4{\cdot}7H_2O$, 0.1 g/L Fe(III) citrate, 8.4 mg/L EDTA, 1.3 mg/L $Zn(CH_3COO)_2{\cdot}2H_2O$, 4.5 mg/L thiamine HCl, 50 mg/L kanamycin, and 5 mL/L of a trace element solution. The trace element solution contained 2.5 mg/L $CoCl_2{\cdot}6H_2O$, 15 mg/L $MnCl_2{\cdot}4H_2O$, 1.5 mg/L $CuCl_2{\cdot}4H_2O$, 3 mg/L $H_3BO_3$, and 2.5 mg/L $Na_2MoO_4{\cdot}2H_2O$.

### Strain

The *Escherichia coli* strain HMS174 (DE3) was used with a pET28a(+) plasmid incorporated to produce His-tagged green fluorescent protein (GFP) after induction. Production was triggered through the lac-operon by the presence of lactose. The cell line retained all enzymes of the Leloir pathway, enabling it to metabolize the inducer as well as all its primary metabolites, such as galactose.

### Cultivation procedure

The cultivations were carried out in several steps. First, a cryogenic vial containing the cells was transferred from the cell bank to a shake flask containing 50 mL Luria-Bertain (LB) medium and incubated in a shaking cabinet (Infors HT Multitron, Switzerland) at 37 °C and 270 rpm. After 5-8 h 1 mL of the grown culture was transferred to 100 mL of DeLisa minimal media in a 500 mL shake flask and further incubated overnight.

On the next day the preculture media was transferred to the bioreactor system containing DeLisa media to form a total of 1 L batch volume to start the main cultivation. The bioreactor system used feedback control to maintain the temperature at 37 °C and the pH at 6.75 through the addition of 12.5 w-% ammonia. The dissolved oxygen level was kept above 30 % through a split-range PID controller acting on the stirring speed and the sparger airflow.

The reactor cultivations consisted of a batch phase, lasting until the initial substrate was depleted. Afterwards a fed-batch phase followed through the separate addition of a 300 g/L glucose feed and a 100 g/L lactose feed with peristaltic pumps. The feed-rates were implemented as feed-forward control to match certain specific uptake rates $q$ for each experiment, resulting in exponential feeding. The added amounts of substrate were monitored through balances, and the recorded signal was used to correct the actual additions for the data analysis.

The rates investigated are listed in Tab. 1, where the different setpoints were maintained for several hours before switching to the next ones. The selected setpoint combinations resulted in 13 unique cultivation conditions. 9 conditions of 3 experiments were used to parameterize the proposed model structures and 2 experiments using 4 different setpoint combinations for validation and model selection.

**Table 1:** Specific uptake rate setpoints for parameterization (P) and validation (V) cultivation experiments.

| Experiment | | Type | Setpoint in g/g/h | | |
|---|---|---|---|---|---|
| | | | 1 | 2 | 3 |
| 1 | $q_{S,Gluc}$ | P | | 0.15 | |
| | $q_{I,Lac}$ | | 0 | 0.075 | 0.15 |
| 2 | $q_{S,Gluc}$ | P | 0.325 | 0.125 | |
| | $q_{I,Lac}$ | | 0 | 0.0375 | 0.25 |
| 3 | $q_{S,Gluc}$ | P | 0.325 | 0.375 | |
| | $q_{I,Lac}$ | | 0 | 0.0375 | 0.25 |
| 4 | $q_{S,Gluc}$ | V | 0.375 | 0.15 | 0.075 |
| | $q_{I,Lac}$ | | | 0.225 | |
| 5 | $q_{S,Gluc}$ | V | | 0.1125 | |
| | $q_{I,Lac}$ | | | 0.225 | |

### Sample analysis

An autosampler (Biolab A/S, Denmark) collected cultivation samples automatically every 1-2 h, which were immediately cooled to 4 °C and stored for analysis.

Biomass concentration was determined in duplicates through dry cell weight (DCW) analysis. 1.8 mL of sample were centrifuged for 5 min at 10, 000 rcf, decanted and subsequently washed with 1 mL of 0.9 % (w/v) NaCl solution. The initial supernatant was frozen and the cell pellet was dried at 105 °C for >72 h.

The supernatant sample was analyzed for its metabolites content. The glucose concentration was obtained through an enzymatic assay (Megazyme International Ireland Ltd., Ireland). The absorbance changes of a standard curve and the diluted cultivation samples in triplicates were measured with a 96-well microplate reader (Tecan, Switzerland). Lactose, galactose, acetate and ethanol concentration were obtained through high-performance liquid chromatography (HPLC) using the Aminex HPX-87H column (Bio-Rad, USA).

GFP concentrations were obtained in triplicates from diluted cultivation samples with a microplate reader (Tecan, Switzerland), using black flat-bottom 96-well plates. The samples were excited at 485±10 nm and the emissions at 530±10 nm were measured. The resulting fluorescence measurements were converted from RFU to ng GFP/well using a standard curve prepared with the GFP quantification kit (Abcam, Cambridge, UK).

## Process model

The *E. coli* process was modeled as a state-space model. The chosen state vector to describe the dynamics was $x = [V_R, c_X, c_S, c_I, c_P]^T$, consisting of the reactor volume $V_R$ in $L$, the concentrations for biomass $c_X$, the main substrate glucose $c_S$, the inducing agent lactose $c_I$ in $g/L$, as well as the product concentration $c_P$ in $mg/L$.

$$\frac{d}{dt}\begin{bmatrix} V_R \\ c_X \\ c_S \\ c_I \\ c_P \end{bmatrix} = \begin{bmatrix} F_{in,S} + F_{in,I} - F_{out} \\ \left(\mu - \frac{F_{in,S}+F_{in,I}}{V_R}\right) \bullet c_X \\ c_{S,in} \bullet \frac{F_{in,S}}{V_R} - q_S \bullet c_X - c_S \bullet \frac{F_{in,S}+F_{in,I}}{V_R} \\ c_{I,in} \bullet \frac{F_{in,I}}{V_R} - q_I \bullet c_X - c_I \bullet \frac{F_{in,S}+F_{in,I}}{V_R} \\ q_P \bullet c_X - c_P \bullet \frac{F_{in,S}+F_{in,I}}{V_R} \end{bmatrix} \quad (1)$$

The state update vector $dx/dt$ in eq. (1) contains the mass balance of the system together with the biological kinetics of microbial growth and product expression. The glucose consumption $q_S$ was modeled as a Monod kinetic on the glucose concentration in eq. (2). The specific lactose uptake rate $q_I$ was setup as a Monod kinetic on the lactose concentration, but with an additional inhibition term related to the specific glucose uptake rate, see eq. (3). This followed the assumption that glucose is the more bioavailable substrate source and the cells prefer it over the disaccharide lactose, similar to Wurm et al. [12].

$$q_S = q_{S,max} \bullet \frac{c_S}{c_S + K_S} \quad (2)$$

$$q_I = q_{I,max} \bullet \frac{c_I}{c_I + K_I} \bullet \frac{K_{IS}}{q_S + K_{IS}} \quad (3)$$

The specific growth rate $\mu$ was set up as a combination of the conversion rates of the two available substrate sources minus the maintenance rate $q_m$. The collective substrate conversion rate was then multiplied with a lumped biomass yield in eq. (4).

$$\mu = (q_S + q_I - q_m) \bullet Y_{X/S} \quad (4)$$

The formulation of the specific product formation rate $q_P$ was found by testing different common kinetic expressions for bioprocesses, listed in Tab. 2. The general structure considered the influence of the two substrates, glucose and lactose influencing a maximum productivity $q_{P,max}$, following eq. (5).

$$q_P = q_{P,max} \bullet \mathrm{f}(c_S \; or \; q_S) \bullet \mathrm{f}(c_I \; or \; q_I) \quad (5)$$

## Model identification and parameterization

The model was parameterized in two main steps. First the growth model was fitted to the process data without the product formation dynamics. The measured values for DCW, glucose and lactose concentration were used to minimize the normalized root mean squared error (NRMSE) to the simulation values.

In a second step the tuned growth model was extended with different models for the specific product formation $q_P$, based on Schügerl and Bellgardt et al. [13]. The model structures listed in Table 2 were tuned to fit the offline GFP measurements and the resulting NRMSE values for the product concentration were used to identify the best model formulation.

## Process optimization

The final parameterized model was used to design an optimized cultivation process. The cultivation layout consisted of an initial batch followed by an exponential fed-batch phase by adding glucose with the setpoint $q_{S,grow}$. The objective of this phase was to increase the biomass content, therefore the setpoint was fixed with the maximum substrate uptake rate. After a certain time $t_{ind}$ the process focus was switched to production where glucose and lactose were added with the new setpoints of $q_{S,ind}$ and $q_{I,ind}$ respectively. These 3 parameters defining the induction phase were tuned to optimize the process for 3 different objectives, by maximizing the performance indicators listed in Tab. 3. The process was designed to start with $V_{R,0} = 1\,L, c_{X,0} = 0.1\,g/L$ and $c_{S,0} = 8\,g/L$. The feeding was stopped after $100\,g$ of combined substrate was added and fully consumed. With the parameterized biomass/substrate yield $Y_{X/S}$ the expected final biomass was ~$31.5\,g/L$.

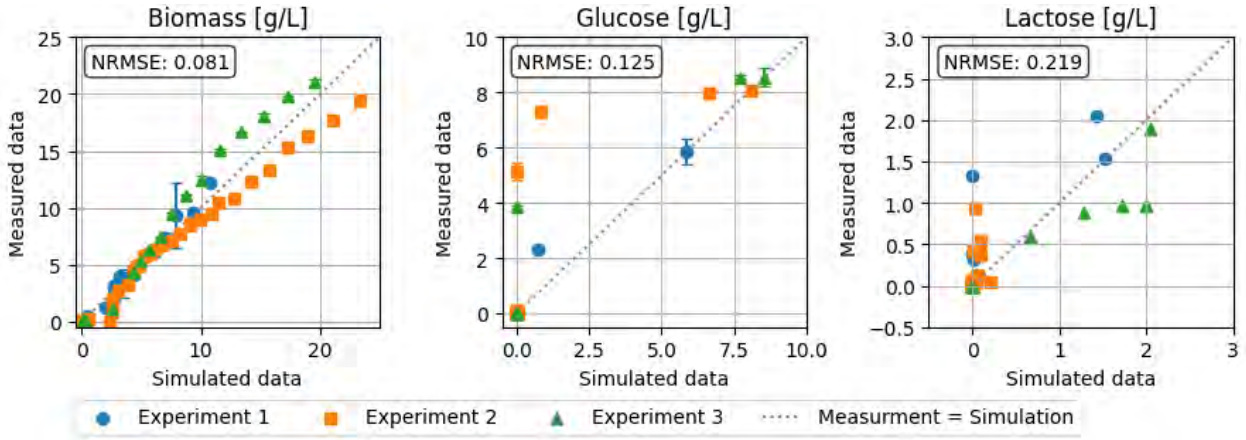

**Figure 1.** Comparison of growth model fit with NRMSE values for each variable of the parameterization datasets.

**Table 2:** Potential productivity models

| Model | Equation |
|---|---|
| P1 | $q_P = q_{P,max} \bullet \frac{q_I}{q_I + K_{PI}}$ |
| P2 | $q_P = q_{P,max} \bullet \frac{c_I}{c_I + K_{PI}}$ |
| P3 | $q_P = q_{P,max} \bullet \frac{{q_I}^{k_{PN}}}{{q_I}^{k_{PN}} + {K_{PI}}^{k_{PN}}}$ |
| P4 | $q_P = q_{P,max} \bullet \frac{{c_I}^{k_{PN}}}{{c_I}^{k_{PN}} + {c_{PI}}^{k_{PN}}}$ |
| P5 | $q_P = q_{P,max} \bullet \frac{q_I}{q_I + K_{PI}} \bullet \frac{K_{PS}}{q_S + K_{PS}}$ |
| P6 | $q_P = q_{P,max} \bullet \frac{q_I}{q_I + K_{PI}} \bullet \frac{{K_{PS}}^{k_{PN}}}{{q_S}^{k_{PN}} + {K_{PS}}^{k_{PN}}}$ |
| P7 | $q_P = q_{P,max} \bullet \frac{q_I}{q_I + K_{PI}} \bullet \frac{q_S}{q_S + K_{PS}}$ |
| P8 | $q_P = q_{P,max} \bullet (\frac{q_I}{q_I + K_{PI}} + \alpha \bullet \frac{q_S}{q_S + K_{PS}})$ |
| P9 | $q_P = q_{P,max} \bullet \frac{q_I}{q_I + K_{PI}} \bullet (1 + \beta \bullet \frac{q_S}{q_S + K_{PS}})$ |
| P10 | $q_P = q_{P,max} \bullet \frac{q_I}{q_I + K_{PI}} \bullet \left(1 + \beta \bullet \frac{q_S}{q_S + K_{PS}}\right) + q_{P,\mathrm{base}}$ |
| P11 | $q_P = q_{P,max} \bullet \frac{q_I}{q_I + K_{PI}} \bullet \frac{q_S}{q_S + K_{PS}} + q_{P,\mathrm{base}}$ |
| P12 | $q_P = q_{P,max} \bullet \frac{c_I}{c_I + K_{PI}} \bullet \frac{K_{PS}}{c_S + K_{PS}}$ |

**Table 3:** Investigated process objectives

| Objective | Symbol | Equation |
|---|---|---|
| Total product | $P$ | $c_{P,end} \bullet V_{R,end}$ |
| Product concentration | $c_P$ | $c_{P,end}$ |
| Space-time yield | $STY$ | $c_{P,end}/t_{end}$ |

## RESULTS & DISCUSSION

The model building process was separated into a procedure for the growth dynamics on the two separate substrate feeds and the selection of a fitting productivity kinetic. The final model structure was then used for a process optimization simulation study.

### Growth model parameterization

The described growth model was parameterized by minimizing the NRMSE between model and offline samples for DCW, glucose and lactose concentration, using all available datasets. The resulting parameter values are listed in Tab. 4.

**Table 4:** Fitted growth model parameters.

| Parameter | Symbol | Value | Unit |
|---|---|---|---|
| Max specific glucose uptake rate | $q_{S,max}$ | 2.350 | g/g/h |
| Monod constant glucose | $K_S$ | 0.014 | g/L |
| Max specific lactose uptake rate | $q_{I,max}$ | 0.456 | g/L |
| Monod constant lactose | $K_I$ | 0.005 | g/L |
| Monod constant lactose-glucose inhibition | $K_{IS}$ | 0.270 | g/L |
| Specific maintenance coefficient | $q_m$ | 0 | g/g/h |
| Biomass/substrate yield | $Y_{X/S}$ | 0.296 | g/g |

The performance of the model is visualized in Fig. 1 through a simulated vs measured plot for the 3 variables. The data showed a satisfying fit for all variables, where the biomass was described the best with a remaining NRMSE of 0.081. The glucose concentration showed a similarly low level of 0.125, the deviations stemmed mostly from a slower growth dynamic in the batch phase of the measured data in Experiment 2. The lactose model showed the highest remaining error of 0.219. Overall, the model fit was deemed as satisfactory in face of the low amount of experimental data.

### Production model parameterization

The production model was obtained by testing

different kinetic formulations, listed in Tab. 2. Their performance to describe the productivity was evaluated through the NRMSE and the conditional number, using experiment 1-3 for parameterization and 4-5 as validation sets. Fig. 2 depicts the NRMSE values for the parameterization and validation datasets for each model formulation.

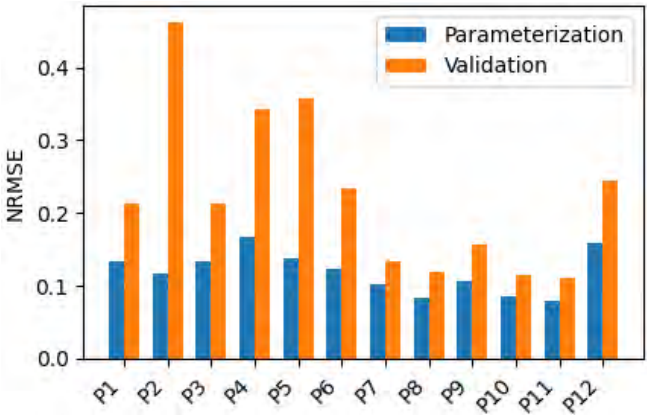

**Figure 2.** Productivity model NRMSE values for parameterization and validation datsets.

The chosen productivity kinetic for the final model was P11, with the parameter values given in Tab. 5. It showed the overall lowest remaining error of the validation dataset compared to the other options with 0.111. The selected model structure in eq. 6 consisted of a positive Monod type influence for both substrate uptake rates $q_S$ and $q_I$., with an additional constant base expression rate $q_{P,base}$.

$$q_P = q_{P,max} \cdot \frac{q_I}{q_I + K_{PI}} \cdot \frac{q_S}{q_S + K_{PS}} + q_{P,base} \quad (6)$$

**Table 5:** Fitted growth model parameters.

| Parameter | Symbol | Value | Unit |
|---|---|---|---|
| Max specific GFP productivity | $q_{P,max}$ | 2.017 | mg/g/h |
| Monod constant glucose-product | $K_{PS}$ | 0.361 | g/g/h |
| Monod constant lactose-product | $K_{PI}$ | 0.147 | g/g/h |
| Base specific GFP productivity | $q_{P,base}$ | 0.06 | mg/g/h |

The inclusion of a base product expression rate hints at a certain leakiness of the expression system. This means that the microbes showed GFP expression without an induction trigger present. Further, the model fit concluded that both substrate uptake rates have a positive influence on productivity. Nevertheless, the growth model included an inhibition term in the lactose uptake related to high glucose uptakes, limiting the double enhancing effect of high substrate feed-rates. This influence of glucose and lactose uptake rates onto the modeled specific product expression rate values are shown in Fig. 3.

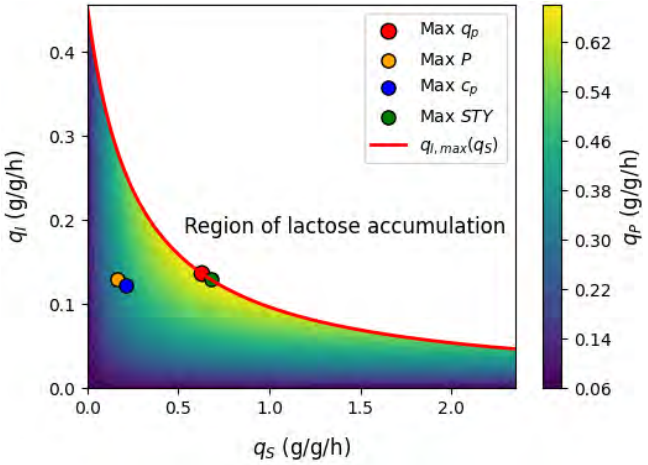

**Figure 3.** Contour plot of the parameterized productivity $q_P$ as a function of the substrate uptake rates $q_S$ and $q_I$, including the optimal setpoints for different objectives.

## Process optimization – Simulation study

The model structure suggested that the combination of moderate glucose and lactose uptake rates results in the highest specific productivity. Nevertheless, the biomass concentration is the catalyst in translating the specific rates to absolute product amounts in the reactor. Since high substrate feed-rates favor biomass formation, a non-trivial optimization problem is presented.

A global optimization algorithm was applied to optimize the induction phase and different optimal feeding strategies for each of the 3 objectives listed in Tab. 3 were found. All simulations were limited to add a maximum of 100 g of combined substrate to the process. The optimal specific substrate uptake rates are marked in the contour plot in Fig. 3 and the resulting objective values for each process are compared in Tab. 6.

**Table 6:** Performance values of optimized processes.

| Objective function | $P_{end}$ [mg] | $c_{P,end}$ [mg/L] | STY [mg/L/h] |
|---|---|---|---|
| max($P_{end}$) | 121.18 | 74.41 | 2.17 |
| max($c_{P,end}$) | 119.43 | 75.77 | 2.49 |
| max(STY) | 82.51 | 57.30 | 3.70 |

The resulting profiles in Fig. 4 show that the optimal feeding strategies are dependent on the objective. The highest absolute product content was achieved with lower setpoints for the two specific substrate uptake rates. With a focus on higher space-time-yield a faster feeding regime was proposed. All the processes included

only a short initial growth phase, where solely the glucose feeding was active at the maximum substrate uptake rate to build more initial biomass. Therefore, higher objective values in all categories were achieved when both feeds were active simultaneously for the fed-batch phase.

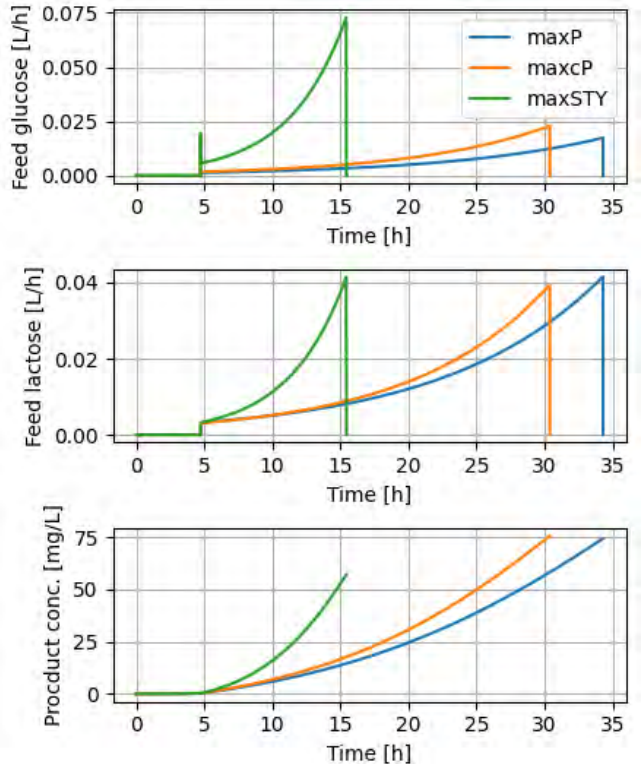

**Figure 4.** Optimized feeding strategies and product concentration for three different process objectives for the 2-feed process.

## CONCLUSION

A novel physiological model is presented for growth and productivity of an *E. coli* process which uses two independent feed sources, glucose as main substrate and lactose as digestible inducer and opens the possibility of tunable induction. The experimental data of 5 lab-scale processes was used to identify and parameterize a suitable model structure. The results showed that both substrate uptake rates were enhancing the product formation, which is in line with the observations of Wurm et al. [6, 12] where low glucose uptake resulted in lower productivity. The lactose uptake on the other hand was repressed by increased glucose uptake rates, which created a non-trivial optimization problem.

By optimizing the individual feed-rates for a simulated 2-stage fed-batch process, the dynamic model suggested moderate substrate and inducer uptake rates result in the highest productivity. Different objective functions were investigated and showed that for a high space-time yield setpoints close to the maximum specific product formation rate were favorable, while for high titers a slower feeding regime is preferred.

This contribution established a physiological bioprocess model for recombinant protein production in *E. coli* with tunable induction through separate glucose and lactose feeds. The resulting model presents an opportunity for improved process design and advanced process control such as described in Ulonska et al. [9] and shows potential for enabling continuous operation modes.

## ABSTRACT

The volumetric gas-liquid mass transfer coefficient ($k_La$) is a key performance parameter in stirred tank reactors and is commonly determined through extensive experiments across the operational space. This work presents an automatic, closed-loop framework for $k_La$ determination based on model-based design of experiments (MBDoE), in which agitation and aeration inputs are adapted in real time.During each experiment, dissolved oxygen data is collected and used to estimate the parameters of a Van't Riet $k_La$ relation. The parameter uncertainty is quantified using the covariance matrix, and the experiments are iteratively selected based on D-optimality or E-optimality MBDoE, until a threshold of $RSE_i < 0.15$ is reached for all parameters. The MBDoE approach is evaluated through repeated runs and compared against random designs, full factorial (FF) design, and a full grid design.The results demonstrate that the closed-loop MBDoE framework can significantly reduce the number of experiments required to characterize $k_La$ while maintaining accurate predictions of gas-liquid mass transfer over the design space. D-optimal MBDoE converges in fewer than four experiments on average, while E-optimal MBDoE converges in less than six experiments on average, translating into approximately a 60% reduction of the number of experiments as compared to a full factorial DoE design.

**Keywords**: Optimization, Modelling, Numerical Methods, Model-based design of experiments, Gas-liquid mass transfer, Stirred tank reactors

## INTRODUCTION

### $k_La$ identification as an experiment design problem

The volumetric gas-liquid mass transfer coefficient ($k_La$) is a key performance parameter of stirred tank reactors and its determination can be vital to avoid oxygen limitations and to optimize bioprocesses. In practice, the $k_La$ can be affected by several different factors such as tank geometry, operational conditions and properties of the mixture/fluid/medium [1]. Consequently, $k_La$ is typically determined experimentally by running multiple experiments under different combinations of operational inputs, followed by fitting an empirical correlation to the experimental data [2].

Fundamentally, this is an experimental design problem. Each experiment results in different excitation profiles of the operational inputs and consequently in different information content. Therefore, each experiment provides different information about the underlying $k_La$ model. Because experiments in stirred tanks can be time-consuming and resource-intensive, reducing the number of experiments required to obtain a reliable $k_La$ estimate is important for rapid bioreactor characterization and process development.

### Limitations of classical design strategies

Classical $k_La$ characterization strategies rely on predefined experimental designs, such as full factorial designs and stepwise variation of the input variables [3]. Although these approaches can give a good coverage of the design space, they do not exploit the information gained during the experiments, *i.e.*, later experiments are not adapted based on what has already been learned, which can lead to redundancy.

Model-based design of experiments (MBDoE) defines a structured way to iteratively select the input trajectories of the experiments that maximize information about the system. Along the experiments there is a

constant and iterative retrofitting of the prototype model with new data, which ensures minimal experimental redundancy and inclusion of information gathered throughout the process [4]. Thus, a closed-loop approach is established, in which experimental conditions are adapted in real time based on continuously updated parameter estimates and uncertainty information.

### Contributions of this work

In this work, we present an automatic, closed-loop framework for $k_La$ determination in stirred tank reactors using MBDoE. The system iteratively performs experiments in which agitation and aeration are varied, the experiment is run, the data of the dissolved oxygen trajectory is collected in real time, the parameters of the Van't Riet $k_La$ correlation [5] are estimated, and the next most informative experiment to perform is computed.

The methodology is evaluated on a stirred-tank $k_La$ case study, using D-optimal and E-optimal MBDoE strategies and it is compared against random designs, full factorial DoE designs, and a grid of 100 experiments with uniform stepwise variation of the two inputs covering the full design space (referred to as full-grid). The performance is assessed in terms of the number of experiments required to reach a target level of parameter uncertainty, as well as the accuracy of the resulting $k_La$ predictions across the design space.

## MATERIALS AND METHODS

### Experimental system

The experiments were conducted in a lab-scale Biostream glass stirred tank reactor, equipped with a top mounted Rushton impeller, a dissolved oxygen (DO) probe, mass flow controller for air and nitrogen supply, and a Biostream tower. The tower is connected to the Lucullus software (Securecell, Urdorf, Switzerland), thus facilitating data acquisition and remote control. A Rest API connection is used to communicate between the software and python scripts, thus allowing for a full closed-loop automated system.

The reactor was operated in a gas-liquid system using 2L of water without biological consumption, so that oxygen transfer is governed exclusively by physical mass transfer.

The agitation speed and the gas flow rate were used as the manipulated variables. For each experiment, the DO concentration was recorded continuously, from which the experimental $k_La$ corresponding to the operational inputs was calculated. This was computed by performing a dynamic oxygen balance model (Eq. 1) and using nonlinear regression techniques.

$$\frac{dC}{dt} = k_L a\,(C^* - C) \tag{1}$$

Where $C$ represents the DO concentration at time $t$ and $C^*$ is the DO concentration at saturation.

The experiments are performed using the gassing-out method [5], where nitrogen gas is sparged through the liquid to strip it of DO before a $k_La$ experiment.

The design space is restricted to air flow [0.4 : 4.0] L/min and stirrer speed [100 : 1000] rpm.

### $k_La$ model, parameter estimation and uncertainty

The volumetric mass transfer coefficient is described using a Van't Riet correlation [5], which relates $k_La$ to the power input $P$ (directly related to agitation speed) and superficial gas velocity $v_g$ (directly related to aeration rate), and reactor geometry, where $V_R$ is the reactor volume (Eq. 2).

$$k_L a = K\left(\frac{P}{V_R}\right)^{\alpha} v_g^{\beta} \tag{2}$$

For each experiment, the model parameters ($K, \alpha, \beta$) were estimated by minimizing the normalized root-mean-square error (NRMSE) between the measured and simulated $k_La$.

Parameter uncertainty was quantified by relative standard errors (RSE), computed based on the covariance matrix ($Cov$) of local sensitivities. The local sensitivity matrix ($S$) is computed based on central differences with a relative step of 1%. Standard errors (SE) are computed to quantify the spread of the estimate around its value and scaled by the parameter value (Eq. 3 – 4).

$$SE_i = \sqrt{Cov(\hat{\theta})_{ii}} \tag{3}$$

$$RSE_i = \left|\frac{SE_i}{\hat{\theta}_i}\right| \tag{4}$$

### Closed-loop MBDoE workflow

The $k_La$ identification was performed using an iterative, closed-loop MBDoE framework (Figure 1). Each run started from a predefined initial experiment, defined at the centre of the design space. After each experiment, the collected DO data were used to re-estimate the model parameters. Based on the calibrated model, sensitivities and uncertainties are computed with respect to each of the parameters. The updated model is then used to solve the MBDoE optimization problem and suggest the next most informative experiment. For this, a genetic algorithm is used, by sampling, *in silico* and across the design space, new experiments to perform. The objective is to maximize the expected information gain of the next experiment. The resulting inputs are then applied to the reactor, generating a new DO time series, and the procedure is repeated. The iteration can be terminated when all the model parameters are below a threshold of parameter uncertainties or a threshold of the maximum allowed number of experiments performed has been reached.

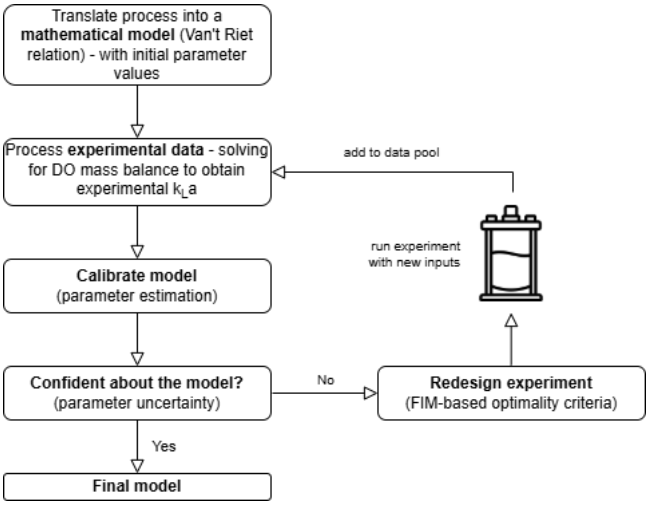

**Figure 1.** Closed-loop MBDoE worflow for the $k_La$ model.

## Design strategies

The information content given by the closed-loop MBDoE framework was quantified using two different optimality criteria: D-optimality and E-optimality. D-optimality or determinant optimality, aims to maximize the determinant of the Fisher Information Matrix (FIM), thereby minimizing the overall parameter uncertainty. E-optimality or eigenvalue optimality, aims to maximize the smallest eigenvalue of FIM, thus targeting a balanced identifiability across all parameters.

$$\Phi_{D-opt} = \det(\mathrm{FIM}) \tag{5}$$

$$\Phi_{E-opt} = \lambda_{min}(\mathrm{FIM}) \tag{6}$$

To benchmark the performance of the MBDoE framework, other alternative designs were evaluated, such as random uniform design, full factorial (FF) design and full grid design.

All design methods were evaluated using the same benchmark $RSE_i < 0.15$. For each method that does not rely on pre-setting the operational inputs, 10 independent runs were performed, so to account for stochastic effects. The FF DoE were performed in triplicates.

All final parameter estimates were evaluated against a full grid reference by computing the NRMSE of the predicted $k_La$ surface over the design space.

# RESULTS AND DISCUSSION

## Number of experiments to converge

The primary performance metric evaluated was the number of experiments required to satisfy the stopping criterion $RSE_i < 0.15$ for all model parameters. Figure 2 summarizes the mean and standard deviation of the required number of experiments over 10 independent runs for each design strategy.

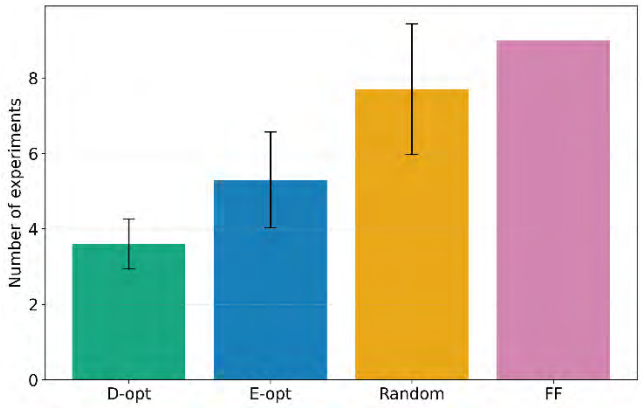

**Figure 2.** Number of experiments required to reach $RSE_i < 0.15$ for all parameters.

Both closed-loop MBDoE strategies substantially reduced the number of experiments necessary to reach the target precision as compared to the benchmark designs. In particular, the D-optimal MBDoE method converged in significantly fewer experiments with a mean of 3.60 ± 0.66 number of experiments. The E-optimal MBDoE strategy required 5.30 ± 1.27 experiments on average, while the random strategy required 7.70 ± 1.73 experiments to reach the same parameter uncertainty threshold. The full factorial design required 9 experiments by construction, while the full grid consisted of 100 experiments.

These results show a substantial reduction in experimental effort when using a closed-loop MBDoE design. D-optimal MBDoE reduced the number of experiments by 60% and 47% respectively, compared to a full factorial design and a random strategy. The relatively small standard deviation of the D-optimal MBDoE further indicates robustness to stochastic variation between runs.

## Parameter uncertainty collapse

Figure 3 shows the evolution of the RSE of the parameters $K, \alpha, \beta$ of the Van't Riet relation as a function of the experiment number, averaged over 10 independent runs.

For the D-optimal and E-optimal MBDoE strategies, the parameter uncertainties decrease rapidly during the first few experiments. Random designs reduce uncertainty more slowly and with larger variability, reflecting the lack of adaptation to the collected data thus far.

These results show how real-time recalibration of parameter estimates pushes the MBDoE framework to select highly informative agitation and aeration inputs.

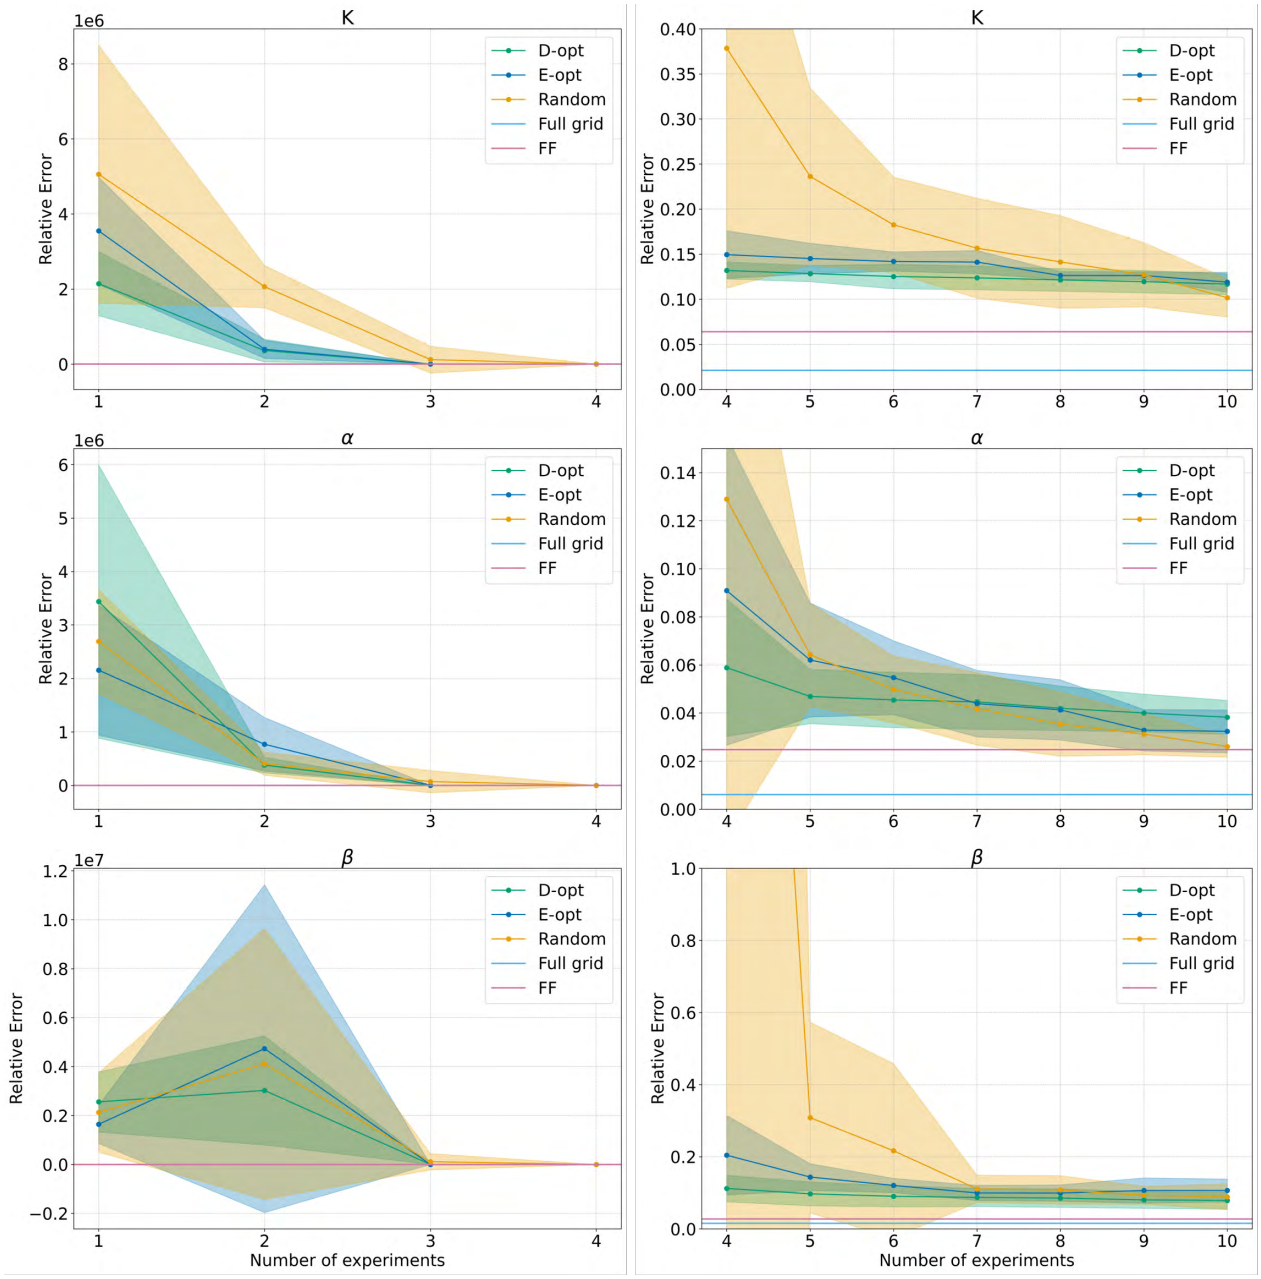

**Figure 3.** Evolution of the parameters RSE along the experiments for 10 independent runs.

## $k_La$ surface accuracy

Although the closed-loop algorithm terminates based on parameter uncertainty, the practical objective of the $k_La$ characterization is an accurate prediction of this coefficient over the operational space. In order to assess this, we compare the $k_La$ surfaces that were obtained by the different designs when they reached convergence.

For each design strategy, the final parameter estimates were averaged across the ten independent runs. This parameter set is the one used in the model (Eq. 2) to compute the $k_La$ surface over the operational space of agitation and aeration. The resulting $k_La$ surfaces are compared pointwise to the reference $k_La$ surfaces by NRMSE (Figure 4).

The $k_La$ surface references used are (a) the model fit to the full grid design of 100 experiments and (b) the model fit to the full factorial (FF) dataset. When compared against the full factorial reference, the D-optimal MBDoE strategy achieved the lowest deviation, with an NMRSE of 0.020. The E-optimal MBDoE and random strategies showed larger discrepancies, with NRMSE values of 0.092 and 0.122, respectively. This shows that the

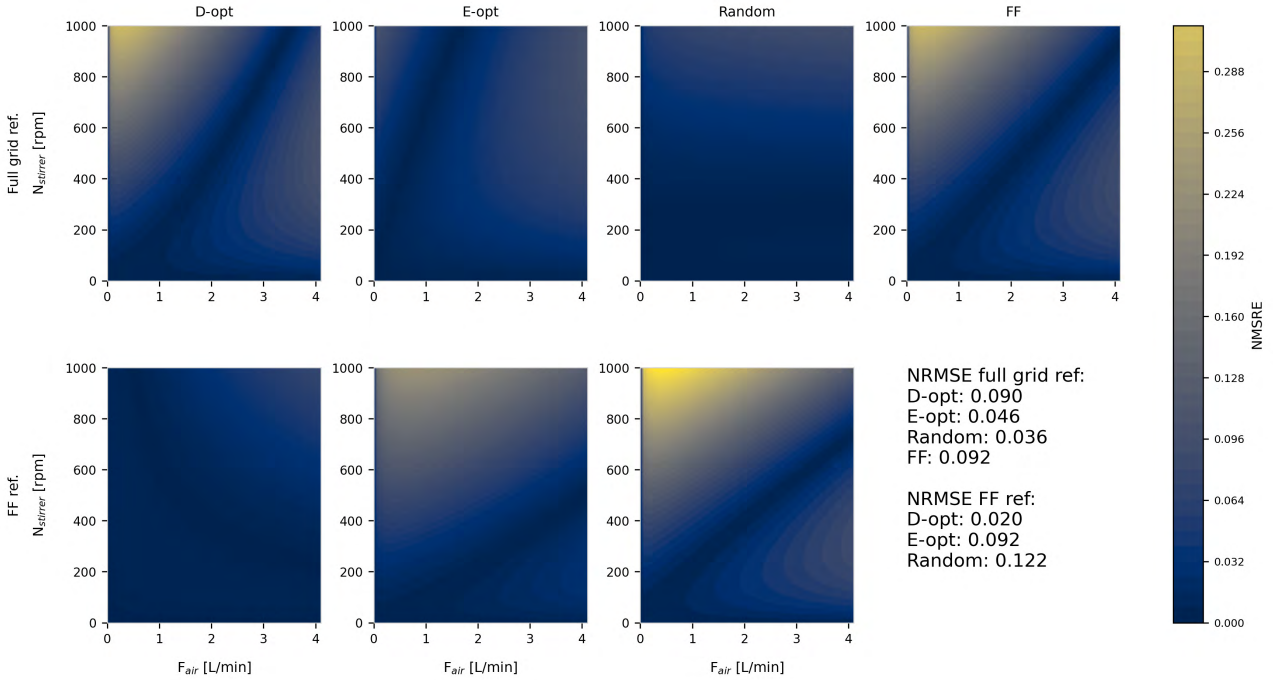

**Figure 4.** NRMSE of the predicted $k_La$ surfaces in reference to the full grid design (upper row) and full factorial design (lower row). The aggregated NRMSE per design and per reference are listed on the bottom right.

closed-loop MBDoE approach achieves a similar $k_La$ surface as the one learned by the FF dataset using substantially fewer experiments – 3.60 ± 0.66 as opposed to 9.

However, when comparing to the full grid reference, all design strategies show similar NRMSE ranges, although neither FF nor a MBDoE approach resulted in a better accuracy. Because different methods converge to different parameter estimates, these results further suggest that multiple parameter sets can produce identical $k_La$ predictions across the design space.

## Identifiability and model sloppiness

The differences observed between the two reference comparisons highlight a fundamental limitation of the Van't Riet model parametrization used in this study. Although this model provides an empirical description of $k_La$ which is widely accepted, its parameters are structurally non-identifiable (over the explored design space)[2, 6].

This consequently results in the situation that distinct parameter vectors obtained by fitting the Van't Riet model to different experimental datasets, can generate very similar $k_La$ surfaces. In such cases, low parameter uncertainty does not necessarily imply a better model. The accuracy of the predicted $k_La$ surface can provide a more meaningful measure of the model quality.

Nevertheless, it is important to note that, in practical applications, the true parameter values are not known a priori and thus the objective of MBDoE is not to identify a unique "true" parameter set, but to obtain a model that can predict the $k_La$ behaviour reliably with minimal experimental burden. Hence, the here proposed closed-loop MBDoE framework remains effective.

These results further indicate that the MBDoE stopping-criterion is better interpreted as an indication of prediction confidence rather than an indication of convergence to unique parameter vectors for a Van't Riet relation.

## CONCLUSIONS

This work presented an automatic, closed-loop MBDoE framework for $k_La$ determination in stirred tank reactors. By iteratively recalibrating the parameter estimates and uncertainty information from time-series data of dissolved oxygen, this approach autonomously selects agitation and aeration inputs that maximize information gain.

The results demonstrated that closed-loop MBDoE can substantially reduce the number of experiments necessary to reach a confidence threshold as compared to other design strategies, namely full factorial DoE, full grid over the operational space, and random inputs selection. In particular, a D-optimal MBDoE approach achieves the set uncertainty threshold of $RSE_i < 0.15$ with a 60% reduction in the required number of experiments as compared to a full factorial design.

Furthermore, comparison of the predicted $k_La$ surfaces against full factorial and full grid designs showed

that, although the parameter values obtained differ between design strategies, the resulting $k_La$ predictions over the design space are often comparable. This reflects the lack of identifiability of the Van't Riet relation and further suggests that the uncertainty-based stopping criterion indicates mostly a convergence of predictive behaviour rather than convergence to unique model parameters values.

Future and ongoing work shall extend the proposed framework to include additional operational variables, such as temperature, pressure, ionic strength, and viscosity, all important factors to gas-liquid mass transfer [1].

The methodology here suggested provides a foundation for autonomous reactor characterization, in particular for situations where experimental efficiency is of the most importance.

## ABSTRACT

The decarbonization of pharmaceutical manufacturing is critical for achieving the industry's net-zero targets, and electrochemistry is emerging as a promising green technology that could play a key role in this transition. This work evaluates a continuous-flow electrochemical route for ibuprofen synthesis through electrochemical carboxylation of 1-chloro-(4-isobutylphenyl) ethane as a low-carbon alternative that can be directly coupled with renewable electricity. Experimental studies have demonstrated the selective formation of ibuprofen using a silver cathode in the ionic liquid N-methyl-N-propylpiperidinium bis(trifluoromethanesulfonyl)imide (PP13 TFSI). While the reaction mechanism is based on laboratory-scale, batch experiments, this study develops a conceptual design and scale-up methodology for the continuous route to provide an evaluation of the industrial feasibility of this electrochemical pathway through a rigorous plant-wide simulation in AVEVA® Process Simulation. Global sensitivity analysis is employed to identify key operating variables and evaluate their impact on reactor and process performance, energy consumption, and ionic liquid recovery. These insights provide a robust foundation for informed decision-making in process intensification, demonstrating the technical viability and scalability of continuous flow electrosynthesis as a sustainable alternative to conventional API manufacturing.

**Keywords**: Process Design, Simulation, Renewable and Sustainable Energy, Pharmaceutical Manufacturing

## INTRODUCTION

As the pharmaceutical industry is a significant contributor to global emissions, increasing the focus on decarbonizing active pharmaceutical ingredient (API) manufacturing is crucial to achieving global net-zero goals. For this purpose, renewable energy sources should be utilized, and electrosynthesis is one of the green alternatives that offers an electrified synthetic pathway to replace carbon-intensive routes.

However, the feasibility and economic viability of achieving high throughput from electrosynthesis for the pharmaceutical industry remain underexplored. While batch reactors are frequently used for exploration in research due to their simple setup, flexibility, and predictability, they have significant limitations for industrial production. Flow reactors provide improved mass transfer, enhanced safety, and greater control over reaction parameters, ensuring the reproducibility required for pharmaceutical standards. Additionally, they are easier to scale up by using modular stacked-cell configurations. Considering the advantages, the transition from batch to continuous flow reactors is needed to achieve a successful scale-up, and the reliable implementation of this transition depends on the conscious design of the electrochemical flow reactor [1].

This work proposes a conceptual design for a greener, continuous electrochemical alternative to the established Hoechst process [2] for ibuprofen synthesis, which was evaluated in our previous work [3]. Mena et al. [4] demonstrated that using a silver cathode and ionic liquid (IL) allow for selective ibuprofen synthesis from electrochemical carboxylation of 1-chloro-(4-isobutylphenyl) ethane in a divided cell by suppressing side reactions without sacrificial metals. It is demonstrated that using dried ionic liquid, N-Methyl-N-propylpiperidinium

bis(tri-fluoromethanesulfonyl) imide (PP13 TFSI), overcomes significant drawbacks found using other electrolytes, such as imidazolium-based ionic liquids or organic solvents like dimethylformamide (DMF). The main advantage of using PP13 TFSI is the decreased electrochemical reduction potential which improves the energy efficiency of the process [4]. Even though the ionic liquids are more expensive than the conventional electrolytes, their recovery and recyclability capability, along with other advantages, show the potential of industrial scale-up using flow chemistry.

This study presents a rigorous plant-wide simulation of this greener, electrochemical route using AVEVA® Process Simulation. By translating laboratory cyclic voltammetry (CV) data into a modular, scalable filter-press reactor model and expanding the experimental separation logic into a full-scale downstream separation and purification stages, this work provides a methodology for early-stage conceptual design and scale-up analysis.

A global sensitivity analysis is performed to assess the impact of key operating parameters on the performance of the process. This analysis identifies the feasible operating ranges and quantifies the trade-offs between space-time yield, overall process yield, specific energy consumption, and electrolyte recovery efficiency. By identifying the operational limits and quantifying key performance indicators (KPIs), this study provides a comprehensive evaluation of the scalability of the process, offering a robust foundation for transitioning from laboratory-scale electrosynthesis to industrial production.

## METHODOLOGY

The process flowsheet, illustrated in Figure 1, is developed in AVEVA® Process Simulation using mass and energy balances to model and simulate the steady-state performance of the individual unit operations.

### Reactor Modelling & Scaling Up

To achieve industrial-scale throughput, we follow the technical specifications of the commercial filter-press reactor, Electro Prod Cell, marketed by Electrocell AB, which supports up to 16 $m^2$ of projected electrode area per module by using multiple electrodes, with a single electrode area of 0.4 $m^2$ [5]. To achieve higher yields, we assume that we have three reactors in series reaching a total projected electrode area of 48 $m^2$, each including modular 40 stacked cells having the highest possible area of Electro Prod Cell.

Each reactor is modeled as a steady-state Plug Flow Reactor unit in AVEVA® with uniform mass transfer characteristics. The reactor is modeled using a divided cell configuration, where the cathodic and anodic compartments are separated by a membrane to prevent product crossover and undesired secondary reactions. While the physical system consists of both compartments, we specifically model the cathodic compartment and its associated electrochemical kinetics in this study, as the electrochemical carboxylation of the organic chloride occurs at the silver cathode. The total active electrode area ($A_e$) and the total catholyte channel volume ($V$) are calculated as:

$$A_e = LW\sigma_{active}N_{cells} \quad (1)$$

$$V = LWd_sN_{cells} \quad (2)$$

where $L$ and $W$ represent the length and width of each cathode electrode, both set to 0.633 m to support for the maximum allowable area based on Electro Prod Cell specifications, and $d_s$ represents the cathode-to-membrane spacing, which is set to minimum allowable distance 0.001 m, $\sigma_{active}$ accounts for the effective surface area in contact with the electrolyte, set to 1.

In alignment with the experiments conducted by Mena et al. [4], it is assumed that carbon dioxide ($CO_2$) is pre-dissolved into the electrolyte until reached saturation before entering the reactor. This assumption allows for the treatment of electrolysis as a single-phase liquid process, simplifying the process by eliminating the complexities associated with gas bubble formation within the narrow electrolyte channels.

To optimize the industrial operation, the cells in one reactor module are configured in parallel for fluid flow and in series for electrical connectivity. The parallel fluid arrangement ensures that the total pressure drop across the stack is minimized while keeping uniform residence time and reactant distribution across all 40 cells per module. On the other hand, electrical connectivity is configured in series to ensure a uniform current across all cells, allowing the stack to operate at an optimized voltage under galvanostatic control.

### Electrochemical Kinetics & Parameter Estimation

The electrochemical carboxylation follows an electrochemical-chemical-electrochemical (ECE) mechanism as summarized in Figure 2.

$$\textit{Step } 1: \quad R - Cl + e^- \rightarrow [R - Cl]^{\bullet -}$$

$$\textit{Step } 2: \quad [R - Cl]^{\bullet -} \rightarrow R^{\bullet} + Cl^-$$

$$\textit{Side Reaction}: \quad R^{\bullet} + H \rightarrow R - H$$

$$\textit{Step } 4: \quad R^{\bullet} + CO_2 + e^- \rightarrow R - COO^-$$

$$\textit{Step } 5: \quad R - COO^- + HCl \rightarrow R - COOH + Cl^-$$

**Figure 2:** Reaction Mechanism for Electrochemical Carboxylation of Organic Chlorides

The initial electron reduction produces a radical

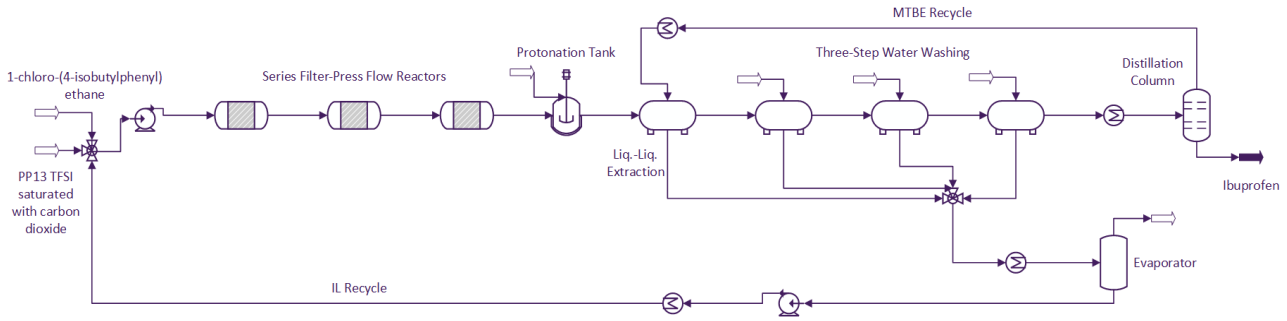

**Figure 1.** Ibuprofen Synthesis via Electrochemical Carboxylation Process Flowsheet.

anion, which undergoes rapid, irreversible C-Cl bond cleavage. The resulting intermediate can either form ibuprofen anion or a side-product, isobutyl ethyl benzene (IBEB). Following the second electron transfer, the resulting carboxylate anion is protonated to yield the neutral ibuprofen molecule.

The half-cell kinetic parameters are estimated using the established engineering correlations, based on data provided from Mena et al. [4]. The rate equation is derived from Faraday's Law and adapted for plug flow behavior [6].

$$\frac{dC_j}{d\tau} = \upsilon_j \eta \frac{C_j k_{eff}}{1+\frac{k_{eff}}{k_m}} \frac{A_e}{V} \tag{3}$$

Where $C_j$ is the concentration of the compound j, $\tau$ is the residence time in the reactor, $\upsilon_j$ is the stoichiometric coefficient for the compound j, $\eta$ is the Faradaic efficiency, $k_{eff}$ is the effective electrochemical rate constant and $k_m$ is the mass transfer coefficient.

The formation rates for ibuprofen and IBEB are determined by multiplying the absolute consumption rate by a selectivity ratio $(S_R)$ of 0.9 and $(1 - S_R)$, respectively. This ensures a closed mass balance where 90% of the converted reactant is directed toward the target API, ibuprofen.

Because the chemical step is extremely fast and lacks a return peak in cyclic voltammetry, the reaction can be modeled using a single effective rate constant. This simplifies the multi-step sequence into a single rate-determining approximation suitable for plant-wide simulation in AVEVA®. The effective kinetic rate constant $(k_0)$ is estimated using the Tafel approximation of the Butler-Volmer equation.

$$k_{eff} = k_0 \exp\left(\frac{-\alpha_c n F (E_{op,c} - E_{eq,c})}{RT}\right) \tag{4}$$

Where $\alpha_c$ is the cathodic charge transfer coefficient, $n$ is the number of electrons required, $F$ is the Faraday's constant, $E_{op}$ is the cathodic operating potential, $E_{eq}$ is the standard equilibrium potential, $R$ is the universal gas constant, and $T$ is the reaction temperature, which is 25 °C.

To estimate the standard cathodic rate constant for irreversible reactions, the Klingler-Kochi equation [7] is used, and the charge transfer coefficient $(\alpha_c)$ and cathodic peak potential $(E_{p,c})$ values are taken from the cyclic voltammetry (CV) results provided by Mena et al. [4] for the silver cathode and PP13 TFSI ionic liquid as 0.37, and -1.66 V, respectively.

$$k_{0,c} = \sqrt{\frac{D\alpha_c n F \upsilon_{scan}}{RT}} exp\left(\frac{\alpha_c n F (E_{p,c} - E_{0,c})}{RT} + 0.78\right) \tag{5}$$

Where $D$ is the diffusion coefficient and $\upsilon_{scan}$ is the scan rate used for the CV experiment, which is 0.5 V/s.

The mass transfer coefficient is determined by the fluid dynamics inside the filter-press cell, and we assume that we have turbulent promoters to enhance the mass transfer.

$$k_m = \frac{ShD}{d_H} \tag{6}$$

Where the Sherwood number $(Sh)$ is a function of the Reynolds number $(Re)$ and Schmidt number $(Sc)$.

We assume that the process operates under stage-wise galvanostatic conditions, where a constant current is maintained across the 40-cell stack. To estimate the required operating potential for the n$^{th}$ reactor unit for galvanostatic operation, the following equation is used.

$$E_{op,c,n} = E_{eq,c} - \frac{RT}{\alpha_c nF} \ln\left(\frac{i_n k_{m,c}}{k_{0,c}(i_{lim,n} - i_n)}\right) \tag{7}$$

Where $i_n$ is the applied current density, calculated as a fixed ratio of the limiting current density and the limiting current density $(i_{lim,n})$ is calculated by $nFC_b k_{m,c}$ for each reactor unit due to mass-transport limitations.

The total specific cathodic energy consumption per unit mass of product is determined by summing the power requirements of the three individual reactor modules. Each module's voltage $(V_{stack.n})$ is calculated by adding the activation overpotentials and ohmic losses $(V_{ohmic,n})$ of its 40 stacked cells.

$$Specific\ Energy\ Consumption = \frac{\sum_{n=1}^{3}(V_{stack,n} I_n)}{\dot{m}_{ibuprofen}} \tag{8}$$

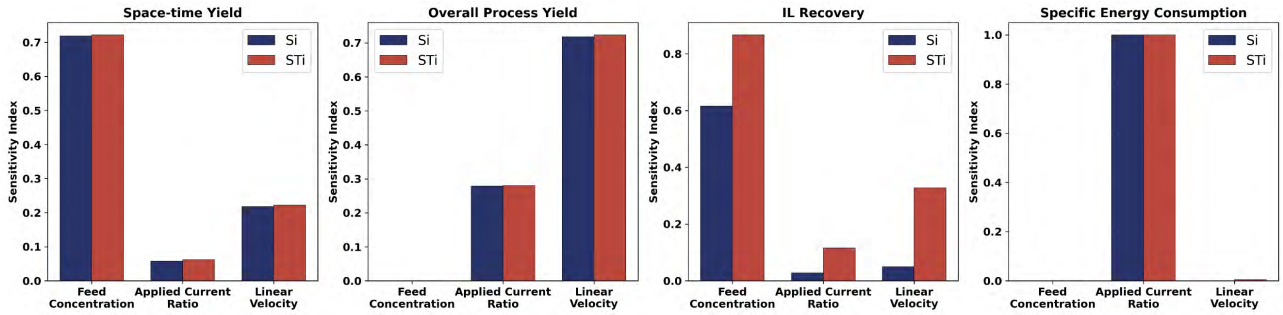

**Figure 3.** Global Sensitivity Analysis Results.

$$V_{stack,n} = 40(|E_{op,c,n}| + V_{ohmic,n}) \quad (9)$$

$$V_{ohmic,n} = i_n\left(\frac{d_s}{\kappa}\right) \quad (10)$$

Where $\kappa$ is the electrolyte conductivity.

## Downstream Processes

To model phase equilibria, the NRTL (Non-Random Two-Liquid) property method is utilized for components with established experimental binary parameters. To accurately capture the non-ideal behavior of the ionic liquid and its interactions with organic solutes, the Modified UNIFAC (Dortmund) Group Contribution Method is used to estimate the required thermodynamic parameters. For vapor-liquid equilibrium calculations, the vapor phase is modeled using the Ideal Gas Law, as the system operates at pressures where gas-phase non-ideality is negligible. These enable a rigorous calculation of activity coefficients and phase equilibria during both the reaction and downstream stages.

The reactor effluent enters a Liquid-Liquid Extraction (LLE) unit, where methyl tert-butyl ether (MTBE) is used to separate the ibuprofen from the ionic liquid. In this model, the recovery efficiency for ibuprofen is set at a fixed design specification of 90% for the LLE unit and 92% for the subsequent washing stages to simulate a standardized quality for downstream processes. Under these constraints, initial separation yields a recovery of approximately 30% of the ionic liquid. To enhance this, the ibuprofen-rich stream undergoes a 3-step deionized water wash. Finally, the multi-stage separation achieves a total recovery of the ionic liquid of approximately 70%.

This downstream configuration scales up the laboratory logic established by Mena et al. [4], where ether extraction and a single water wash achieved approximately 80% ionic liquid recovery in a laboratory scale, batch setting.

To ensure the ionic liquid is suitable for recycling and reuse as the electrolyte, an evaporator is used to dry the recovered ionic liquid by removing residual water and ether. Simultaneously, the ibuprofen-rich stream is sent to a distillation column where MTBE is recovered for recycling, and the final ibuprofen product is purified to pharmaceutical standards.

## SENSITIVITY ANALYSIS RESULTS AND DISCUSSION

The global sensitivity analysis is conducted using the Sobol variance-based method to estimate first-order sensitivity indices ($S_i$), which quantify the individual contribution of each parameter to the output variance, excluding interaction effects, and total-order sensitivity indices ($S_{Ti}$), which quantify the total contribution of each parameter, including all interactions with other parameters [8]. The analysis is performed using a quasi-Monte Carlo (QMC) Sobol sequence sampling [9] and the Saltelli design [10] with a base sample size of 2048, resulting in 10240 simulation runs to construct the required matrices for the three input variables. The indices are then calculated using the Jansen estimator [11].

For this study, the reactor dimensions are kept constant based on the industrial specifications of the Electro Prod Cell. The sensitivity analysis focuses on operational variables, specifically the feed concentration, applied current ratio, and electrolyte linear velocity, to evaluate the process performance.

The feed concentration consisting of 1-chloro-(4-isobutylphenyl) ethane dissolved in $CO_2$-saturated ionic liquid (PP13 TFSI) is assumed to be varied between 0.2 and 0.3 kmol/m$^3$. This range is chosen to balance the need for high industrial throughput with the solubility limits and viscosity constraints of the ionic liquid. To evaluate the reactor's performance near its physical limits, the applied current density is defined as a fraction of the limiting current density. The ratio is assumed to be varied between 0.7 and 0.9. This range is selected to investigate the mass-transfer controlled regime, which is of particular interest for industrial scale-up. The linear velocity is assumed to be varied between 0.02 and 0.03 m/s, comparably lower since we use ionic liquids that are highly viscous.

To provide a comprehensive evaluation, four key

performance indicators (KPIs) are selected: space-time yield (STY), which provides a measurement for reactor productivity; overall process yield, which assesses both the upstream and downstream efficiency; specific cathodic energy consumption, which quantifies the electrical energy requirements; and ionic liquid recovery to evaluate the economic viability and sustainability. The results from the global sensitivity analysis are presented in Figure 3.

Results reveal that the space-time yield is dominated by the feed concentration, while the feed concentration has a negligible impact on the overall process yield. This behavior is caused by the first-order kinetics of electrochemical synthesis. The rate of reaction scales linearly with bulk concentration; therefore, increasing feed concentration directly increases the amount of product produced per volume per unit time. However, because conversion and yield are fractional metrics, they remain unchanged. Additionally, because the downstream recovery ratios for ibuprofen are fixed, the overall process yield also remains unchanged. This suggests that the process can achieve higher throughputs by increasing concentration without sacrificing the chemical efficiency of the reactor, considering the solubility limits of the ionic liquid.

While both electrolyte linear velocity and applied current ratio theoretically influence the reaction rate, the Sobol analysis unveils a higher impact of the linear velocity on the overall process yield compared to the applied current ratio. Lowering the velocity increases the residence time, which proves to be the dominant factor in ensuring sufficient duration for the electrochemical conversion.

Even though there is a trade-off since lowering the velocity also decreases the space-time yield, the results guides for a strategic pathway for optimization. Because feed concentration has a more dominant effect on space-time yield than velocity does, by increasing feed concentration, the plant can offset the productivity losses occurred from lowering the velocity. This strategy can allow us to achieve high chemical efficiency and high industrial throughput, reaching the target production without the loss of performance associated with increased residence time.

In contrast to the other input variables, the ionic liquid recovery showed high parameter interactions, with higher total-order indices compared to first-order indices. As the feed concentration increases, the mass of ibuprofen in the effluent also increases. To maintain the fixed recovery specifications, the process scales the consumption of MTBE and water. As more solvent flows through the system, it physically carries away more of the ionic liquid, either as tiny droplets or by slightly dissolving it. This creates a direct trade-off: as production capacity increases, the efficiency of the ionic liquid recycling decreases.

Finally, the Sobol analysis reveals that the specific energy consumption is exclusively governed by the applied current ratio, with a total-order index of approximately 1.0. While the feed concentration and electrolyte linear velocity both fundamentally influence the limiting current density, their impact on the energy intensity is neutralized. Consequently, the only variable that can change the cost per kilogram is the applied current ratio.

As the applied current ratio increases, the cell operates closer to its mass-transfer limit, in this region the specific energy consumption behaves asymptotically, as the cell voltage increases significantly without a matching proportional increase in mass yield. This result proves that the energy cost is decoupled from production throughput; we can increase the plant's capacity by raising the feed concentration without observing an increase in the electricity cost per unit of product.

## CONCLUSION AND FUTURE WORK

This work presents a rigorous modeling and simulation framework for the design and scale-up of continuous electrochemical flow reactors, applied to an electrosynthesis route for ibuprofen production. A modular filter-press reactor is selected to reflect industrial electrochemical practice and is modeled using a plug flow reactor, as the electrolyte flows through narrow channels with plug-flow-like behavior and uniform mass transfer characteristics along the electrode surface. For the smooth transition from laboratory-scale data to industrially relevant design parameters, we use governing equations to define electrochemical kinetics, mass-transfer limitations, hydrodynamics, and reactor geometry. The simulation of the process flowsheet demonstrates the technical feasibility and scalability of continuous electrochemical carboxylation for ibuprofen synthesis.

Global sensitivity analysis is used as a guidance tool to explore the simulated process and identify the operating variables that most strongly govern productivity, efficiency, energy intensity, and electrolyte recovery. The results reveal clear trade-offs between throughput, residence time, energy efficiency, and ionic liquid losses that are inherent to the scale-up of electrochemical flow reactors. Importantly, the analysis shows that production capacity can be increased through feed concentration without penalizing specific energy consumption, while electrolyte recovery emerges as a critical bottleneck at higher throughputs.

Beyond demonstrating process feasibility, this study highlights that rigorous reactor and downstream processes modeling combined with the global sensitivity analysis is a necessary early-stage step for scale-up and decision making toward economically viable electrochemical API manufacturing. By identifying the key

operating variables with dominant effects and feasible operating windows, the proposed framework provides a robust foundation for reliable techno-economic and sustainability analysis.

Future work will extend the current framework to include full-cell kinetics, incorporating anodic reactions, additional voltage losses through membrane resistance, and anodic potential. Based on the results from the global sensitivity analysis, the optimization will be performed, and techno-economic and life cycle analysis will be conducted comparing the green pathway with the current manufacturing pathway for the ibuprofen synthesis.

## ABSTRACT

Real-time monitoring of bioprocesses is hindered by sparse, heterogeneous measurements of key biological states, such as biomass, substrate, and product concentrations. Extended Kalman Filter (EKF)–based soft sensors offer a physics-grounded solution but are sensitive to limited observability, sensor bias, and process-model mismatch—conditions common in industrial fermentations. This work proposes a Levelized Hybrid Estimation Architecture (LHEA) that systematically enhances physics-based state estimation through increasing robustness and adaptivity while preserving model transparency and regulatory interpretability. The approach is evaluated using the KTB1 benchmark simulation model for continuous lovastatin production under an industrially realistic, cost-constrained sensor configuration combining dissolved oxygen, biomass proxy, volume measurements, and sparse HPLC product assays. Three estimator levels are investigated: (L1) a baseline EKF, (L2) a bias-augmented EKF for sensor-drift robustness, and (L3) a hybrid EKF with physics-constrained residual learning driven by sparse assays. Results show that L1 provides stable state reconstruction under nominal conditions but is sensitive to bias and model mismatch. L2 effectively isolates measurement bias, while L3 adapts to evolving process kinetics and achieves the lowest estimation errors under mismatch. These findings demonstrate that a structured, levelized integration of machine learning can significantly enhance soft-sensor reliability without sacrificing interpretability, providing a practical pathway toward robust digital twins.

**Keywords**: Biosystems, Process Monitoring, Hybrid Modelling, Soft Sensor

## INTRODUCTION

Real-time monitoring and optimization of biomanufacturing processes remains an open challenge due to the limited availability of reliable online sensors for critical variables such as biomass, substrates, and product concentrations [1]. While measurements such as dissolved oxygen, pH, and flow rates are typically available at high frequency, key quality attributes and performance indicators are often accessible only through infrequent and costly offline assays [2]. In continuous biomanufacturing, long operating horizons, tight quality constraints, and economic pressures further exacerbate these challenges. As a result, soft sensors must operate under sparse, asynchronous, and noisy measurements, where sensor drift, calibration errors, and process disturbances can significantly degrade estimation performance.

Model-based state estimation methods, particularly Extended Kalman Filters (EKFs), have been widely applied to infer unmeasured states in bioprocesses using first-principles dynamic models [3], [4]. When accurate models and informative measurements are available, EKFs can provide effective real-time monitoring of biological systems. However, in realistic biomanufacturing environments, model mismatch arising from uncertain kinetics, unmodelled physiological shifts, and slowly varying parameters is unavoidable. Combined with sensor drift and measurement bias, these effects can lead to filter inconsistency, biased estimates, or even divergence in the estimation [5], [6]. Addressing robustness to both model mismatch and measurement imperfections, therefore, remains a central challenge in the development of

reliable soft sensors for bioprocess monitoring.

Machine-learning (ML)–based soft sensors have attracted increasing attention due to their ability to capture complex nonlinear relationships directly from process data [7]. Despite their predictive power, purely data-driven approaches raise concerns related to interpretability, extrapolation beyond training data, sensitivity to operating conditions, and regulatory acceptance [8]. In regulated biomanufacturing contexts, particularly biopharmaceuticals, the lack of explicit physical structure makes it difficult to guarantee mass-balance consistency, diagnose estimation failures, or ensure reliable performance during process regime changes. These limitations motivate hybrid approaches that combine the transparency and structure of first-principles models with the adaptability of data-driven learning [9].

This study presents a *levelized hybrid Extended Kalman Filter–Machine Learning (EKF–ML) approach* for robust soft sensing in bioprocesses, where robustness refers to the preservation of estimator stability and acceptable estimation accuracy in the presence of sensor drift, measurement sparsity, and structural mismatch between assumed and true process kinetics. The methodology is evaluated using the KTB1 MATLAB/Simulink benchmark, a realistic simulator for continuous biomanufacturing that couples an upstream CSTR bioreactor with downstream operations and incorporates sensor noise, delays, and regulatory control [10]. The main contributions of this work are fourfold:

(i) the development of a *robust soft-sensing model* that enhances state estimation accuracy and reliability under realistic measurement limitations;

(ii) the introduction of a *levelized estimation structure*, enabling systematic investigation of increasing model–data hybridization and facilitating future methodological extensions;

(iii) a *comprehensive case study* demonstrating the practical value of the approach under nominal operation, sensor bias, and process-regime changes; and

(iv) the release of an *open-source implementation* to support transparency, reproducibility, and further research in hybrid soft-sensor design (https://github.com/Boskabadi/LHEA).

## METHODOLOGY: LEVELIZED HYBRID ESTIMATION ARCHITECTURE (LHEA)

### We consider a nonlinear bioprocess described by a first-principles mass-balance model:

$$\dot{x}(t) = f(x(t), u(t)), \tag{1}$$

where $x(t) \in \mathbb{R}^{n_x}_{\geq 0}$ denotes the process states (e.g., volume, biomass, substrates, product, dissolved oxygen), $u(t) \in \mathbb{R}^{n_x}_{\geq 0}$ represents known non-negative manipulated inputs (e.g., feed flow rates and compositions), and $t \in \mathbb{R}_{\geq 0}$is time. The nonlinear function $f(\cdot)$represents the reactor mass-balance equations derived from conservation laws and kinetic expressions, and is assumed to be continuously differentiable with respect to $x$within the physically admissible operating region. Only a subset of states is measured online at heterogeneous sampling rates, while key quality attributes (e.g., product concentration) are available through sparse laboratory assays, e.g. at the end of the batch. State estimation is performed using an Extended Kalman Filter (EKF) as a baseline estimator. The novelty of this work lies not in the EKF formulation itself, but in a systematic, levelized extension of the estimator to address practical challenges in bioprocess monitoring, i.e. weak observability, sensor drift, and model mismatch.

### Level 1 (L1): Physics-based soft sensor

Level 1 implements a standard physics-based EKF using the mechanistic model and available multi-rate measurements. The process dynamics are given by

$$\dot{x(t)} = f(x(t), u(t)), \tag{2}$$

$$y_k = h_k(x) + v_k, \tag{3}$$

where $h_k(\cdot)$represents the subset of sensors available at the time $t_k$, and $v_k$ is measurement noise. In the multi-rate implementation, each measurement channel is incorporated only when its corresponding sampling time is reached, so the EKF evolves continuously by model prediction between measurement arrivals and applies discrete corrections at the sensor and assay instants. For numerical robustness, the covariance update is implemented using the Joseph form [11], with covariance symmetrization after propagation and update. L1 serves as a baseline physics-consistent soft sensor, providing real-time state estimates under nominal conditions but remaining sensitive to sensor bias and model mismatch.

### Level 2 (L2): Bias-robust estimation via state augmentation

Level 2 extends the EKF by explicitly estimating slowly varying sensor biases. This is achieved by augmenting the state vector as:

$$x_a = \begin{bmatrix} x \\ b \end{bmatrix}, \tag{4}$$

where $b$ represents unknown measurement bias terms associated with selected sensors (e.g., volume or dissolved oxygen probes). The bias dynamics are modeled as a random walk,

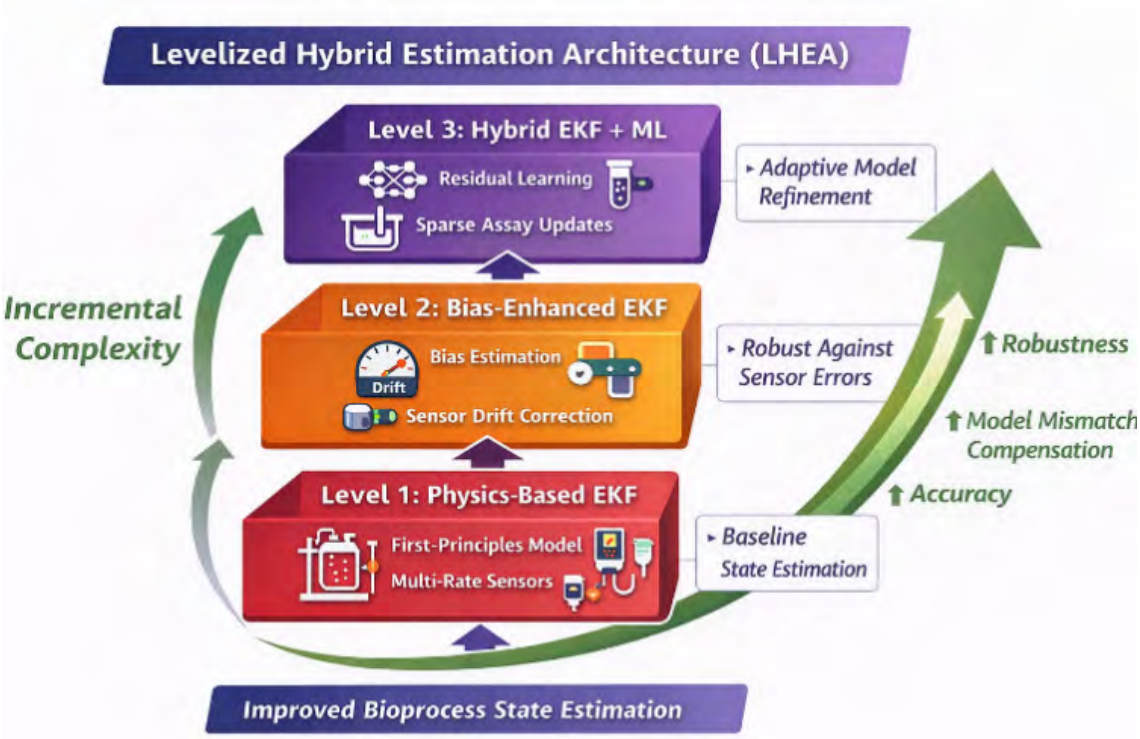

**Figure 1.** Conceptual illustration of the proposed Levelized Hybrid Estimation Architecture (LHEA). The framework progresses from a physics-based EKF (L1, red), to a bias-robust augmented EKF (L2, orange), and finally to a hybrid EKF–ML estimator (L3, purple). Sparse and multi-rate measurements are incorporated at all levels.

$$\dot{b}(t) = w_b(t), \tag{5}$$

reflecting slow drift due to fouling, calibration loss, or aging. Measurements affected by bias are written as

$$y_k = h(x_k) + b + v_k. \tag{6}$$

Importantly, neither the presence, magnitude, nor onset of bias is assumed to be known a priori. Only the possibility of bias in specific measurement channels is assumed based on engineering knowledge. The EKF jointly estimates process states and bias terms using innovation statistics, allowing sensor drift to be absorbed without corrupting the underlying state estimates. At this level, the process model remains unchanged, and no data-driven components are introduced.

## Level 3 (L3): Physics-constrained hybrid EKF–ML

Even with bias handling, first-principles models inevitably exhibit a mismatch due to uncertain kinetics, physiological adaptation, or operating-regime changes. Level 3 introduces a physics-constrained residual learning mechanism within the EKF to compensate for such a mismatch while preserving interpretability. The process model is augmented as

$$\dot{x}(t) = f\big(x(t), u(t)\big) + r_\theta\big(\phi(x(t))\big), \tag{7}$$

where $r_\theta(\cdot)$ is a learned residual correction and $\phi(x)$ is a low-dimensional, interpretable feature vector (e.g., biomass and dissolved oxygen). The residual is restricted to selected dynamics (e.g., product formation) and is bounded to ensure physical plausibility, meaning that it (i) does not violate mass-balance structure, (ii) preserves state positivity, and (iii) remains bounded within a small fraction of the nominal kinetic rates. These constraints prevent violations of positivity, mass conservation, or known stoichiometric relationships.

The residual parameters $\theta$ are updated online only when sparse laboratory assays become available (e.g., HPLC product measurements every 24 h), using a lightweight adaptive law (e.g., normalized gradient or RLS-type update), triggered only when sparse, high-fidelity laboratory assays become available. Learning therefore, occurs within the same run, without offline retraining. The feasibility of this adaptation is ensured by (i) fast online measurements that constrain the state trajectory, (ii) sparse but informative assays that anchor slow dynamics, and (iii) the low dimensionality of the residual parameterization. The preceding observability analysis confirms that inclusion of sparse product measurements renders the system observable over the estimation horizon,

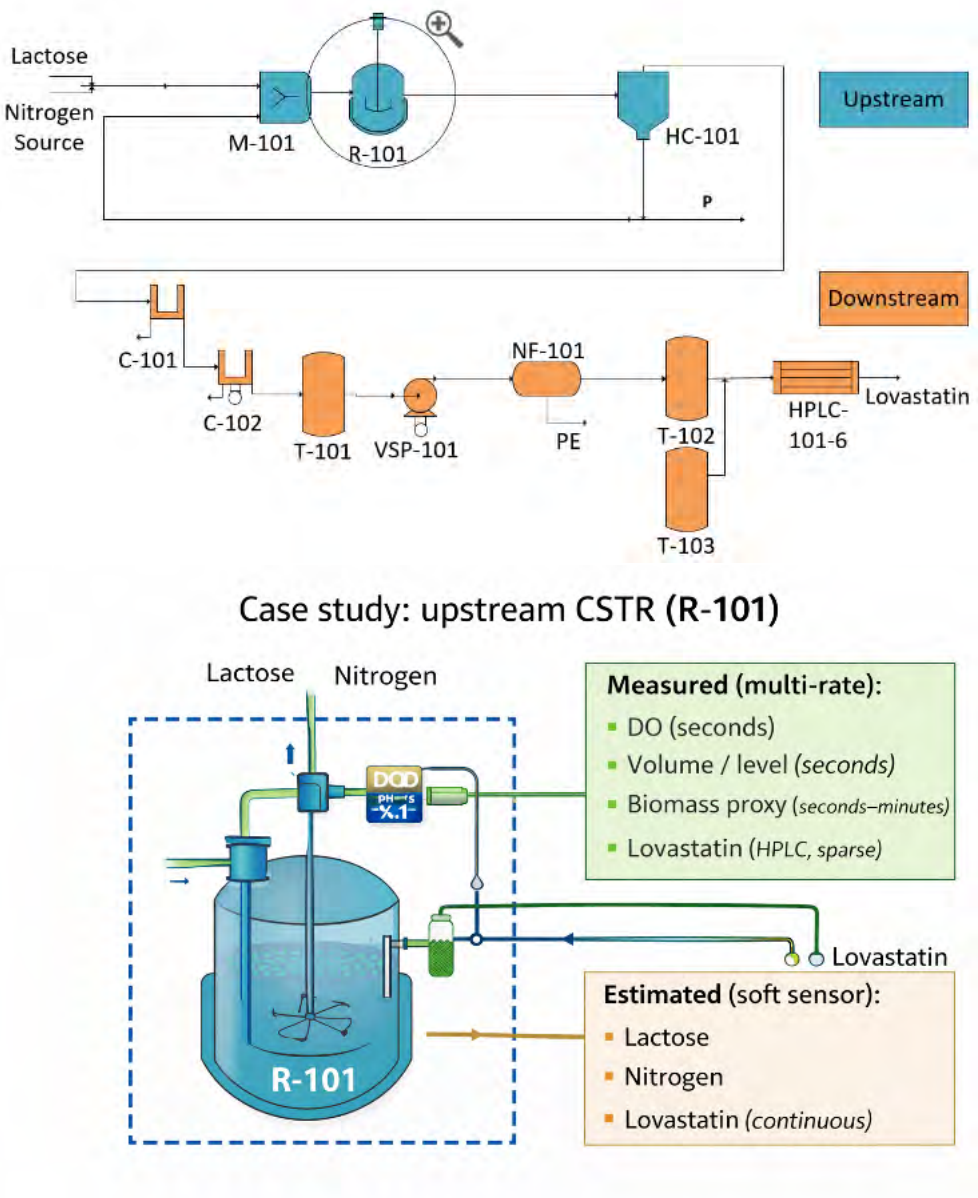

**Figure 2.** (a) Overall process flow diagram (PFD) of the KTB1 continuous biomanufacturing benchmark, including upstream fermentation and downstream separation units for lovastatin production. (b) Zoomed-in schematic of the CSTR reactor (R-101) highlighting available online sensors, sparse laboratory assays, and the hybrid EKF-based soft-sensor role for real-time state estimation.

enabling meaningful online learning.

In addition, slowly varying kinetic effects can be represented through a scalar scaling parameter:

$$q_{\text{eff}}(t) = q_{\text{nom}}\, q_{\text{scale}}(t), \tag{8}$$

which is updated using assay information and constrained within physically meaningful bounds.

Figure 1 summarizes the proposed *Levelized Hybrid Estimation Architecture (LHEA)* and illustrates how estimation capability is progressively enhanced through structured hybridization. Starting from a purely physics-based estimator (L1), each subsequent level introduces additional mechanisms to address practical limitations encountered in bioprocess monitoring, including sensor bias, model mismatch, and sparse measurements. The color coding highlights the incremental nature of the

framework: L1 (red) provides baseline real-time state reconstruction using first-principles models; L2 (orange) augments the estimator with bias states to improve robustness against sensor drift without altering the underlying process model; and L3 (purple) incorporates physics-constrained, sparsely trained machine-learning residuals to compensate for unmodelled kinetics or slowly varying parameters. Multi-rate and sparse measurements (green) are consistently integrated across all levels, reflecting realistic PAT availability. As illustrated by the upward trend in the figure, each level systematically increases estimation robustness, tolerance to model mismatch, and predictive accuracy while preserving physical interpretability.

## CASE STUDY: CONTINUOUS LOVASTATIN PRODUCTION IN THE KTB1 SIMULATOR

### Process Description

This study uses the KTB1 simulation platform, implemented in MATLAB/Simulink, as a representative case study for continuous biomanufacturing (Figure 2 a). KTB1 models the continuous production of the Activate Pharmaceutical Ingredient (API) lovastatin and includes realistic upstream and downstream unit operations. The upstream section consists of a mixer, a continuous stirred-tank bioreactor (CSTR), pumps, and a hydrocyclone, while the downstream section includes centrifuges, buffer tanks, a variable-speed pump, nanofiltration, and HPLC columns for product isolation. The simulator is able to account for sensor noise, actuator delays, and regulatory control, making it a suitable benchmark for evaluating advanced monitoring and soft-sensing strategies under industrially relevant conditions [10].

The focus of this work is the upstream CSTR reactor (R-101), where lovastatin is produced by *Aspergillus terreus*. Continuous monitoring of key states inside the reactor—particularly substrate and product concentrations—is essential for maintaining process stability, ensuring consistent product quality, optimizing yield, and enabling early fault detection. However, continuous monitoring in bioprocesses remains challenging, and this difficulty is especially pronounced for secondary metabolites such as lovastatin [12].

Continuous monitoring of lovastatin inside the reactor is challenging due to several practical limitations. Online sensors are affected by noise, drift, and delays, which can significantly degrade estimation performance during long continuous runs. Moreover, lovastatin is produced at low concentrations in dilute fermentation broths, resulting in weak analytical signals. Direct in-line quantification remains limited, and product measurements typically rely on sparse at-line or offline HPLC assays. In addition, slow biological kinetics and strong upstream–downstream coupling in continuous operation amplify the impact of measurement delays, making adequate feedback control difficult.

The dynamic CSTR model in KTB1 explicitly represents six key reactor states: biomass concentration, nitrogen (adenine), lactose (substrate), lovastatin (product), dissolved oxygen, and liquid volume/level. Table 1 summarizes these states, their symbols and units, typical measurement availability, preferred sensing technologies, and representative sampling cadences reported in the literature. While dissolved oxygen and volume/level are routinely available at fast sampling rates, substrate and product concentrations are typically measured only sparsely or inferred via soft sensors.

**Table 1.** Reactor states considered in the CSTR model, including symbols, units, measurability, typical sensing technologies, and realistic sampling cadences.

| State | Symbol & unit | Preferred sensors & cadence | Key refs |
|---|---|---|---|
| Biomass | C_X (g/L) | Capacitance (5–15 s); OD/Turbidity (1–5 s) | [13] |
| Nitrogen | C_N (g/L) | HPLC-UV 260 nm (10–30 min); UV/Vis or Raman + PLS (30–120 s) | [14] |
| Lactose | C_LAC (g/L) | HPLC/enzymatic (5–30 min); Raman/NIR + PLS (30–120 s) | [15] |
| Lovastatin | C_MEV (g/L) | HPLC (30–120 min); LC-MS for intermediates; Raman soft-sensor (1–3 min) | [16] |
| Dissolved oxygen | C_DO (g/L) | Optical DO probe (1–5 s); polarographic (legacy) | [17] |
| Liquid volume/level | V (L) | Level sensor 1–5 s + geometry | [17] |

### Observability Analysis and Sensor Scenarios

To systematically assess how realistic sensor configurations affect state reconstruction, a multi-rate observability analysis was performed on the CSTR model. Nine sensor scenarios were defined, reflecting progressively richer combinations of online, at-line, and sparse measurements commonly encountered in industrial practice. These scenarios are summarized in Table 2.

**Table 2.** Sensor configuration scenarios used for the observability analysis, showing included measurements, and sampling cadences

| Scenario | Sensors included | Sampling cadence |
|---|---|---|
| 1 | DO | 5 s |
| 2 | DO, Volume/Level | DO: 5 s, Level: 5 s |
| 3 | DO, Biomass proxy (capacitance) | DO: 5 s, Biomass: 10 s |
| 4 | DO, Biomass proxy, Volume/Level | DO: 5 s, Biomass: 10 s, Level: 5 s |
| 5 | DO, Lactose (Raman) | DO: 5 s, Lactose: 60 s |
| 6 | DO, Biomass proxy, Lactose | DO: 5 s, Biomass: 10 s, Lactose: 60 s |
| 7 | DO, Biomass proxy, Lactose, Volume/Level | DO: 5 s, Biomass: 10 s, Lactose: 60 s, Level: 5 s |
| 8 | Scenario 7 + Product (MEV, HPLC) | DO: 5 s, Biomass: 10 s, Lactose: 60 s, Level: 5 s, MEV: 30 min |
| 9 | Scenario 4 + Product (MEV, HPLC) | DO: 5 s, Biomass: 10 s, Level: 5 s, MEV: 24 h |

The observability rank for each scenario was evaluated over a 24-hour horizon using a base integration step of 1 s. The results are summarized graphically in Figure 3. As shown, DO-only sensing (Scenario 1) yields limited observability (rank 4), as oxygen dynamics alone are insufficient to uniquely reconstruct all material balances. Adding either volume/level measurements (Scenario 2) or a biomass proxy (Scenario 3) increases the observability rank to 5, demonstrating the importance of dilution effects and growth-related information. However, neither configuration alone achieves full state observability.

Scenario 4, which combines DO, biomass proxy, and volume/level measurements at realistic online cadences, consistently achieves an observability rank of 5 out of 6. This indicates that all states except the product concentration are practically observable, a result that aligns well with industrial experience: product formation dynamics are only weakly coupled to fast online sensors. The inclusion of substrate measurements (Scenarios 5–7) does not fundamentally improve observability unless combined with complementary sensors, highlighting that additional measurements must contribute independent dynamic information to be effective.

Full observability (rank 6) is achieved only in Scenarios 8 and 9, where sparse product (lovastatin) measurements are included, because the product state cannot be uniquely inferred from fast online measurements alone. Occasional product assays provide independent information that anchors the slow product dynamics and closes the observability gap when fused with faster measurements. Notably, Figure 3 shows that even very slow product assays—on the order of tens of minutes to several hours—are sufficient to close the observability gap when fused with faster online measurements over an extended horizon. Based on these results, Scenario 9 was selected as the primary sensor configuration for the subsequent estimation studies. This scenario reflects a cost-constrained yet industrially realistic sensing setup and serves as a stringent test case for the proposed levelized hybrid estimation architecture.

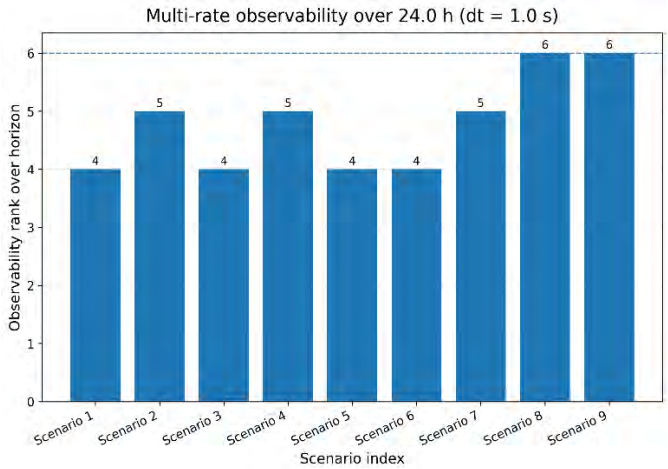

**Figure 3.** Multi-rate observability rank of the CSTR reactor states over a 24 h horizon for different sensor configurations (Scenarios 1–9). The dashed line indicates full observability (rank 6). Scenarios 8 and 9 have full observability.

## RESULTS AND DISCUSSION

Considering the observability analysis in Figure 3, prior experience with similar industrial fermentations, and economic constraints associated with advanced sensing, *Scenario 9* was selected for subsequent estimation studies. This scenario combines volume/level measurement, a capacitance-based biomass proxy, dissolved oxygen, and sparse HPLC product assays, representing an industrially realistic and cost-constrained sensor configuration.

### EXP1. Nominal estimation performance

Figure 4 compares the lovastatin concentration estimates obtained under nominal operating conditions. The normal reactor trajectory, shown as the blue line, remains nearly constant at approximately 1.2 g/L over the operating horizon. The Level 1 estimate, based solely on the first-principles model together with the available online measurements and sparse 24 h product assays, remains numerically stable and exhibits small discrete corrections at the assay instants. These update events confirm that the baseline EKF does assimilate the sparse

laboratory measurements; however, between assay times, a mild downward drift is still observed, indicating sensitivity to residual process-model mismatch. The Level 2 bias-augmented EKF estimate follows the Level 1 trajectory closely and shows the same assay-driven corrections, with only marginal deviation from Level 1 under nominal conditions. This behavior indicates that, in the absence of systematic measurement bias, the additional bias states remain weakly excited and therefore provide limited improvement in estimation accuracy**.** In contrast, the Level 3 hybrid estimator (dashed red), in which the physics-based EKF is augmented with residual learning driven by sparse HPLC product assays, remains tightly bound around the normal reactor trajectory, with small corrective adjustments occurring at assay times. These results demonstrate that, under nominal conditions, even when all estimators receive the sparse assays, the primary performance improvement arises from adaptive compensation of process-model mismatch rather than sensor bias handling.

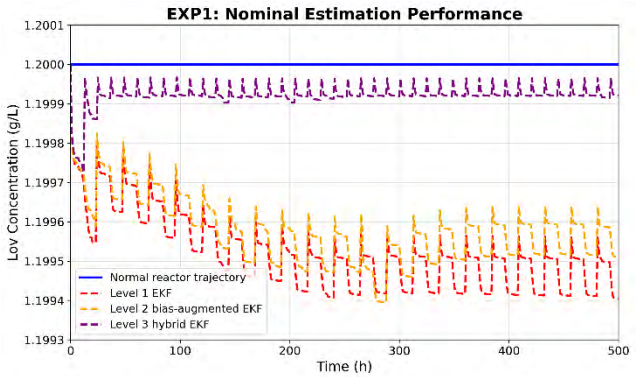

**Figure 4.** Lovastatin concentration estimates under nominal operation. The blue curve represents the true lovastatin concentration. Level 1 (EKF), Level 2 (bias-augmented EKF), and Level 3 hybrid are overlaid for direct comparison

## EXP2. Robustness to measurement bias

Figure 5 evaluates estimator robustness to sensor bias by introducing a step change only in the measured reactor volume (5000 → 5050 L at t = 50 h), while the true process remains unchanged. The normal reactor trajectory, shown as the blue line, remains consistent with the nominal operating case. The Level 1 estimate (dashed red) directly follows the biased volume signal; once the bias is introduced, its lovastatin estimate progressively deviates upward from the normal reactor trajectory, indicating that the standard EKF propagates the biased measurement through the process model and mass balances. The Level 2 bias-augmented EKF estimate (dashed orange) effectively absorbs the artificial measurement shift through its bias states, maintaining a lovastatin estimate consistent with the nominal case. The Level 3 estimator (dashed purple) exhibits similar stability under this scenario, as no kinetic mismatch is present. These results demonstrate that the primary contribution of Level 2 is robustness to sensor bias and drift rather than improved nominal accuracy.

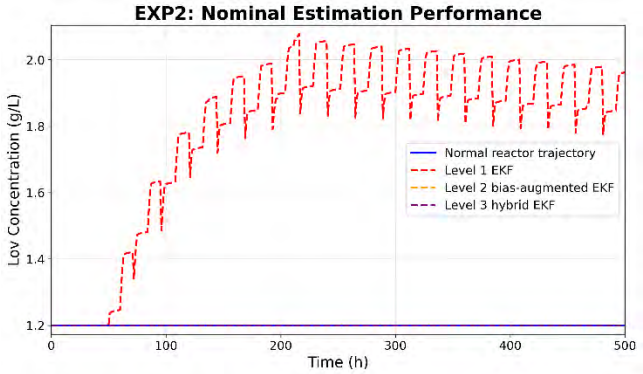

**Figure 5.** Lovastatin concentration estimates under a measurement bias scenario. The normal reactor trajectory (blue) is shown together with Level 1 EKF (dashed red), Level 2 bias-augmented EKF (dashed orange), and Level 3 hybrid EKF (dashed purple).

## EXP3. Adaptation to process-model mismatch

Figure 6 examines estimator performance under a true process-model mismatch, introduced by increasing the intrinsic product formation rate $q_{\max,\mathrm{MEV}}$by 20% at $t =$ 50h. The resulting reactor lovastatin concentration, shown as the blue line, exhibits a gradual but persistent deviation from the nominal trajectory due to the altered kinetics. Under this mismatch, the Level 1 estimate (dashed red) and the Level 2 bias-augmented EKF estimate (dashed orange) are repeatedly corrected by the sparse assay updates; however, both remain limited by the fixed process model and therefore do not fully recover the transient lovastatin evolution. In contrast, the Level 3 estimator (dashed purple) tracks the changes in the trajectory much more closely by combining physics-based prediction with a bounded residual correction learned from the assay information. Notably, the Level 3 estimate is not simply a sample-and-hold reconstruction: it evolves between assay times and provides a smoother and more accurate transient estimate than a zero-order-hold (ZOH) baseline. The ZOH baseline yielded an RMSE of $3.24 \times 10^{-4}$g/L and an MAE of $2.10 \times 10^{-4}$g/L, whereas Level 3 achieved lower errors, corresponding to a 41.3% reduction in RMSE and a 38.0% reduction in MAE relative to ZOH. These results demonstrate that residual learning provides a capability fundamentally distinct from bias handling, enabling accurate estimation under evolving bioprocess kinetics.

Table 3 summarizes the quantitative estimation performance of the three estimator levels across the three

evaluation scenarios: nominal operation, measurement bias, and kinetic mismatch. Under nominal conditions, all estimators achieve low prediction errors, with Level 1 and Level 2 showing comparable RMSE and MAE values, reflecting the adequacy of the baseline physics-based EKF when model assumptions hold. When a measurement bias is introduced, the error metrics of Level 1 increase substantially, whereas Level 2 maintains nearly unchanged performance due to its explicit bias-state formulation.

Under kinetic parameter uncertainty or change, Level 3 provided the lowest estimation error, while Levels 1 and 2 remain more strongly affected by the structural model discrepancy. Overall, the results confirm that each estimator level contributes a distinct and complementary capability: baseline state reconstruction (L1), robustness to sensor bias (L2), and adaptation to process-model mismatch (L3), supporting the proposed levelized estimation strategy.

**Table 3.** Quantitative comparison of lovastatin concentration estimation accuracy (RMSE, MAE) for Level 1–3 estimators under nominal operation, measurement bias, and kinetic mismatch scenarios.

| Level | Index | EXP1 | EXP2 | EXP3 |
|---|---|---|---|---|
| Level 1 | RSME | 0.00049 | 0.64920 | 0.00121 |
| | MAE | 0.00048 | 0.59454 | 0.00099 |
| Level 2 | RSME | 0.00043 | 0.00043 | 0.00102 |
| | MAE | 0.00042 | 0.00042 | 0.00082 |
| Level 3 | RSME | 8.5e-5 | 8.3e-5 | 0.00019 |
| | MAE | 7.9e-5 | 7.9e-5 | 0.00013 |

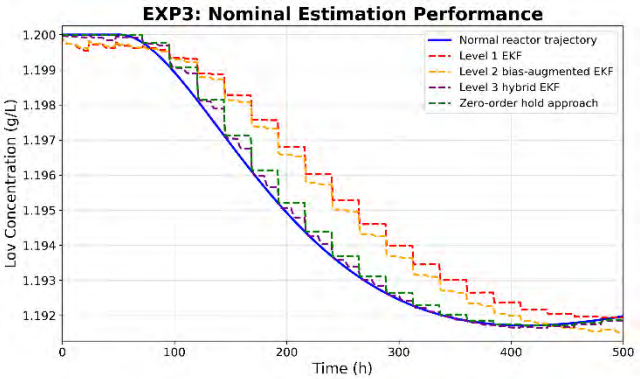

**Figure 6.** Lovastatin concentration under a true process–model mismatch. The reactor trajectory (blue) is shown together with Level 1 EKF (dashed red), Level 2 bias-augmented EKF (dashed orange), Level 3 hybrid EKF (dashed purple), and zero-order hold baseline (dashed green).

## Perspective and Future Work

This work demonstrates the first three layers of the proposed Levelized Hybrid Estimation Architecture (LHEA), showing how physics-based EKF estimation can be systematically enhanced to improve robustness and accuracy under realistic sensing constraints. While this study focuses on state reconstruction, bias robustness, and physics-constrained residual learning, several extensions remain for future work. These include learned measurement models that convert auxiliary PAT signals (e.g., Raman or capacitance) into soft measurements, innovation-adaptive noise tuning for automated robustness, and physics-regularized surrogate models for operation under severe regime changes. Integrating the levelized estimators with closed-loop control and validating the framework on experimental or pilot-scale data are also important next steps. Together, these directions complete the envisioned framework and position LHEA as a scalable, interpretable pathway for incorporating machine learning into high-reliability soft sensing for continuous biomanufacturing

## ABSTRACT

Roller compaction is widely used in pharmaceutical manufacturing to improve powder flowability and enable robust tablet production. Although often treated as producing a homogeneous granule population, ribbons may undergo splitting during compaction, generating structurally distinct granules that affect downstream tableting. This study investigates the impact of ribbon splitting on tablet critical quality attributes (CQAs) for 10% and 20% acetaminophen (APAP) formulations. Reduced-order models (ROMs) proposed by Bachawala et al. [1] were applied to predict tablet density, elastic recovery, tensile strength, and tablet weight under split and non-split conditions. Although ribbon splitting alters the granule size distribution (GSD) and ribbon density, tablet CQAs such as tensile strength, elastic recovery, and tablet density are accurately predicted by the existing ROM framework, provided that GSD and ribbon density are known. In contrast, tablet weight predictions deteriorate when split and non-split data are combined, reflecting the sensitivity of die filling to granule packing changes induced by splitting. Separating the datasets improves weight prediction for non-split granules, while split granules remain challenging to model. A multitask Gaussian Process regression model is further used to analyze splitting as a process disturbance, highlighting the need for extended or data-driven approaches to accurately predict tablet weight under split conditions.

**Keywords**: Ribbon splitting, Roller compaction, Tableting, Granule Size Distribution, Reduced Order Models

## INTRODUCTION

Roller compaction followed by milling is widely used in pharmaceutical manufacturing to enhance powder flowability and ensure robust tablet production, where powders are first consolidated into ribbons and then milled into granules. Although often treated as producing a single homogeneous ribbon/granule population, several studies have shown that ribbons exhibit spatial heterogeneity in solid fraction and stress state and may undergo distinct failure modes, such as longitudinal or transverse splitting upon exiting the rolls, leading to materially different structures entering downstream processes such as tableting [2], [3], [4], [5], [6].

In particular, Shahab et al. [6] demonstrated that ribbon splitting originates during the roller compaction stage as the ribbon exits the rolls. They attributed this behavior to non-uniform stress and density distributions across the ribbon thickness, coupled with differential elastic recovery, which generate tensile stresses exceeding the fracture strength of the compacted material. As a result, two physically distinct ribbon states may be produced under otherwise similar operating conditions: intact (non-split) ribbons and ribbons that undergo longitudinal splitting. These structural differences are subsequently inherited by the granules formed during milling, leading to variations in granule morphology and packing characteristics [7], [8], [9]. While Shahab et al. identified

and characterized split and non-split ribbons based on their fracture behavior at the roll exit during roller compaction, prior studies have not assessed whether ribbon splitting itself selectively influences tablet properties such as tablet weight, tablet density, or tensile strength.

Bachawala et al. [1] developed a reduced-order mechanistic framework linking granule size distribution, packing fraction, ribbon density, and compaction behavior to predict tablet critical quality attributes (CQAs), including density, tensile strength, and weight, demonstrating strong predictive capability across process conditions. However, the model assumes that ribbons are fully characterized by density and size distribution, without explicitly accounting for ribbon formation pathways or splitting behavior.

From a manufacturing standpoint, this assumption may be limiting, as ribbon splitting modifies the internal structure and effective packing of granules, potentially influencing die filling and mass deposition during tableting. As a result, some tablet properties may be sensitive to splitting, while others may remain unaffected.

The objective of this work is to examine the extent to which ribbon splitting influences tablet properties, specifically tablet weight, tablet density, and tensile strength, in order to identify which critical quality attributes are sensitive to splitting phenomena. Furthermore, building on the reduced-order modeling framework proposed by Bachawala et al. [1], this study evaluates the applicability and robustness of the existing models under split and non-split ribbon conditions, and assesses whether additional data-driven approaches, such as machine learning, are required to accurately predict tablet properties in cases where the reduced-order models are insufficient.

# MATERIALS AND METHODS

## Preparation and Characterization of Granules

Granules were produced using an Alexanderwerk WP120 roller compactor from two formulations: (i) 90% w/w microcrystalline cellulose (MCC; Avicel PH-102, International N&H USA, Inc.) with 10% w/w acetaminophen (APAP; Grade 0048, Mallinckrodt Pharmaceuticals), and (ii) 80% w/w Avicel PH-102 with 20% w/w APAP. Powder blends (3 kg) were prepared in a 5-L tote blender and pre-mixed for 30 min, then fed by a Coperion Ktron feeder into a Gericke GCM-250 continuous blender operating at 150 rpm before conveyance to the roller compactor. No lubricants or glidants were added.

The experimental campaign followed Shahab et al. [6], where roll gap, roll pressure, and roll speed were varied while screw feed speed was adjusted to achieve target set points. A three-level Box–Behnken design of experiments was employed to reduce experimental runs while enabling robust analysis [2], [3]. Thirty-two granule batches (sixteen per formulation) were produced by varying hydraulic pressure (30–90 bar), roll gap (1.4–2.4 mm), and roll speed (3.5–5.5 rpm). Ribbons were milled using the integrated two-stage hammer mill with 2.5 and 1.25 mm screens. Ribbon density was measured using a GeoPyc 1360 pycnometer, while granule samples collected at the compactor outlet were analyzed for GSD using a Canty SolidSizer and used for tablet production on a rotary tablet press. The measured GSD was modeled using a bimodal Weibull distribution.

$$P(x) = \alpha\left[\frac{k_1}{\lambda_1}\left(\frac{x}{\lambda_1}\right)^{k_1-1} e^{-\left(\frac{x}{\lambda_1}\right)^{k_1}}\right] + (1-\alpha)\left[\frac{k_2}{\lambda_2}\left(\frac{x}{\lambda_2}\right)^{k_2-1} e^{-\left(\frac{x}{\lambda_2}\right)^{k_2}}\right] \quad (1)$$

where $\alpha$ denotes the fraction of the small mode and $(\lambda_1, k_1)$ and $(\lambda_2, k_2)$ are the scale and shape parameters of the small and large modes, respectively. The mean granule size is then calculated as a weighted average of the mean sizes of each mode ( $\mu_{GSD} = \alpha\mu_1 + (1-\alpha)\mu_2$ ) with $\mu_1 = \lambda_1\Gamma(1+1/k_1)$, $\mu_2 = \lambda_2\Gamma(1+1/k_2)$, and $\Gamma(\cdot)$ denotes the gamma function.

## Preparation and Characterization of Tablets

Granules were tableted on a Natoli NP-400 rotary press using doubly convex D-type tooling, producing thirty two tablet batches. The dosing position and precompression thickness were fixed at 9 mm and 6 mm, respectively, with a feeder speed of 35 rpm. The main compression thickness was varied between 2.5 and 3.5 mm, while the turret speed was adjusted from 15 to 20 rpm. After manufacturing, tablets were stored in Ziploc bags for 24 h to allow elastic relaxation and were then tested using a SOTAX AT4 tablet tester to measure tablet weight, tensile strength, tablet density, and elastic recovery following the work of [1]. The tablet volumes at different compaction stages [10] are determined from tablet geometry following [1], where $t^{fill}$, $t^{in\text{-}die}$, and $t^{tablet}$ represent the fill depth, in-die thickness, and final tablet thickness, respectively, and $h$ is the punch cup depth. Using the tablet weight and true density, the in-die and final tablet relative densities are then calculated. Tablet tensile strength is obtained from the measured crushing force $F$ using Pitt's model as recommended by Razavi et al. [11], with the full expression available in the cited literature [1]. It is worth mentioning that many of these quantities are not available online during manufacturing, motivating the need for predictive reduced-order models to estimate Critical Material Attributes (CMAs) and CQAs for process monitoring and control.

## Tableting Reduced-Order Models

Mechanistic and semi-mechanistic reduced-order models (ROMs) provide a practical balance between physical interpretability and computational simplicity, enabling their use in process design, optimization, and control of pharmaceutical tableting [12], [13]. The ROM

framework describes die filling, compaction, unloading, and ejection using physically based equations that link material and process variables to tablet CQAs [1]. The ROM framework was employed by Bachawala et al. [1], [14] to establish a quantitative link between dry granulation and the downstream tableting process. The mathematical expressions for die-filling efficacy coefficient $(\eta)$, the elastic recovery $(\epsilon_\rho)$, the tablet density $(\rho^{tablet})$, and the Leunberger's tablet tensile strength $(\sigma_t)$ are listed below:

$$\eta = \frac{W}{\rho_b V^{fill}} \tag{2}$$

$$\epsilon_\rho = \epsilon_0 \left( \frac{\rho^{in-die} - \rho_{c,\epsilon}}{1 - \rho_{c,\epsilon}} \right)^n \tag{3}$$

$$\rho^{tablet} = \rho^{in-die}(1 - \epsilon_\rho) \tag{4}$$

$$\sigma_t = \sigma_0 \left[ 1 - \left( \frac{1 - \rho^{tablet}}{1 - \rho_{c,\sigma_t}} \right) e^{(\rho^{tablet} - \rho_{c,\sigma_t})} \right] \tag{5}$$

Here, $\rho_b$ is the bulk density of the powder blend. The parameter $\epsilon_0$ represents the elastic recovery at full compaction (zero porosity), $\rho_{c,\epsilon}$ is the minimum in-die relative density at which elastic recovery begins, and $n$ accounts for the nonlinearity of this behavior. Tablet tensile strength $\sigma_t$ depends on the tablet relative density after elastic recovery $\rho_{tablet}$, the maximum tensile strength at full densification $\sigma_0$, and the critical relative density $\rho_{c,\sigma_t}$ required for forming a mechanically stable tablet.

## Model Selection and Parameter Estimation

Bachawala et al. [1] developed a reduced-order modeling (ROM) framework that propagates dry granulation attributes—ribbon density and granule size distribution—into tableting ROMs using normalized rational functions, with model selection guided by the Akaike Information Criterion (AIC). In this work, the same framework is adopted to evaluate the applicability and robustness of these ROMs under split and non-split ribbon conditions, with emphasis on predicting tablet weight, density, and tensile strength. Upstream CMAs and critical process parameters (CPPs) are coupled to the tableting ROM parameters through nonlinear mappings of normalized variables, $X = \left((x - lb)/(ub - x)\right)^{r_X}$, where $lb$ and $ub$ are variable bounds and $r_X$ accounts for nonlinear effects. Each ROM parameter $f$ is expressed as a bivariate rational function,

$$f(X, Y) = \frac{p_1 XY + p_2 X + p_3 Y + p_4}{q_1 XY + q_2 X + q_3 Y + 1} \tag{6}$$

with parameter set $\theta = p_1, p_2, p_3, p_4, q_1, q_2, q_3, r_X, r_Y$ estimated from experimental data. Model complexity is controlled by progressively simplifying the rational function to form a library of candidate models, with selection based on:

$$AIC = n \ln \frac{SSE}{n} + 2Np \tag{7}$$

where $n$ is the number of data points, $SSE$ the sum of squared errors, and $N_p$ the number of parameters. The lower the AIC values, the better the model. The optimal model structure $m$ and its parameters $\theta$ are given by:

$$m, \theta = \arg\min_{m \in F} \left[ n \ln \left( \frac{1}{n} \min_{\theta^m \in D_m} \left( \sum_{i=1}^{n} \left( M^i(\theta^m) - E^i \right)^2 \right) \right) \right] + 2N_p^m \tag{8}$$

Here, $M^i(\theta^m)$ denotes the model prediction, $E^i$ the experimental value, $n$ the number of data points, $N_p^m$ the number of parameters, and $D_m$ the feasible parameter space. Parameter estimation is carried out using MATLAB's genetic algorithm, followed by `fmincon` and `GlobalSearch`, to reduce sensitivity to initial guesses and improve convergence to the global optimum.

Although the 10% APAP formulation matches that of Bachawala et al. [1], parameters are re-estimated here because a different MCC 102 manufacturer was used, and all ribbon density and GSD data were measured experimentally, rather than predicted by machine learning models as in Huang et al. [15]. Moreover, the tablets produced in this study exhibit higher densities compared to those reported in the authors' work.

## Machine Learning framework

Gaussian Process (GP) regression is a Bayesian nonparametric method for modeling nonlinear input–output relationships with uncertainty quantification. A GP defines a prior over latent functions $f(x) \sim GP\big(m(x), k(x, x')\big)$, where $m(x)$ is the mean function and $k(x, x')$ the covariance kernel, and observations are modeled as $y = f(x) + \varepsilon$, with $\varepsilon \sim \mathcal{N}(0, \sigma^2)$. Given training data, posterior predictions yield analytical expressions for both predictive means and variances, with hyperparameters learned by maximizing the marginal likelihood.

To jointly model correlated tablet properties, multitask Gaussian Process regression (MT-GPR) was implemented using the Intrinsic Coregionalization Model (ICM), where the joint covariance between outputs $t$ and $t'$at inputs $x$ and $x'$ is defined as $K\big((x, t), (x', t')\big) = k_{data}(x, x') \cdot B_{t,t'}$, where $k_{\text{data}}$ captures input-space similarity, while $B$ is a low-rank coregionalization matrix that encodes inter-task correlations, enabling information sharing across outputs while preserving task-specific variability. The input kernel was specified as an additive combination of a linear kernel and a Matérn kernel with automatic relevance determination to capture both global trends and smooth nonlinear effects. Task-specific observation noise was modeled using a multitask Gaussian likelihood with weakly informative priors, with continuous inputs standardized prior to training and binary indicators left unscaled. This multitask formulation enables coherent joint inference and uncertainty propagation across tablet properties, which is essential for analyzing process disturbances affecting multiple CQAs simultaneously.

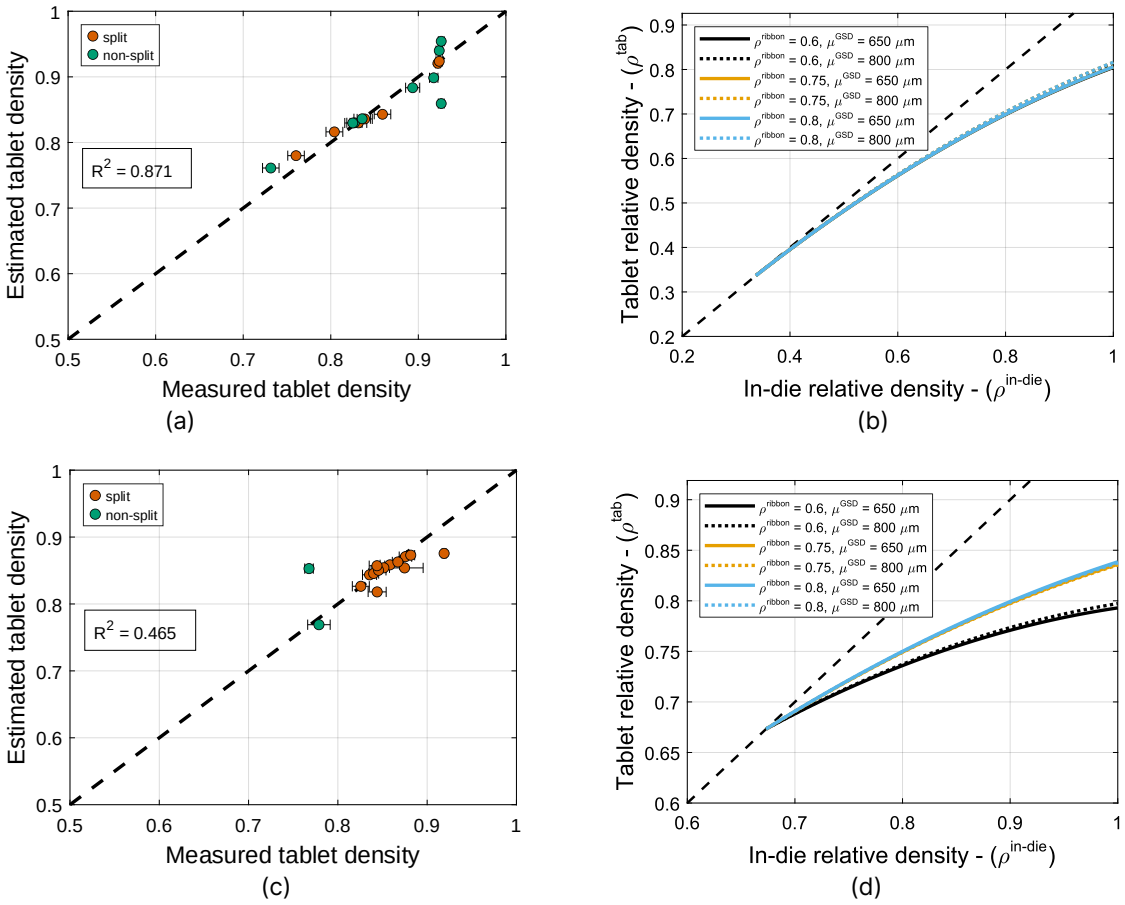

**Figure 1:** The top row corresponds to the 10% APAP formulation and the bottom row to the 20% APAP formulation, (a), (c) goodness of the tablet density prediction, and (b), (d) prediction of the tablet density model.

## RESULTS AND DISCUSSION

### Impact of Splitting on Granule Size Distribution and Ribbon Density

Ribbon splitting during roller compaction produces structurally weakened ribbons with internal cracks, resulting in reduced effective ribbon density. These defects promote enhanced fragmentation during milling, shifting the granule size distribution toward finer particles and increasing fines content. In contrast, non-split ribbons retain higher structural integrity and generate coarser, more stable granule populations. Similar relationships between ribbon failure modes, granule size outcomes, and ribbon mechanical integrity have been reported in prior studies on roller compaction and ribbon fracture behavior [6].

### Rational Function-Based Approach for Integrating Dry Granulation with Tableting

In this section, the framework of the previous section is used to integrate dry granulation with tableting as demonstrated by Bachawala et al [1]. The ROMs for tablet weight, tablet density, elastic recovery, and tablet tensile strength are presented sequentially. The best-performing models proposed by Bachawala et al. [1] have been adopted for parameter estimation and analysis of the results.

### Elastic recovery and tablet density

Ribbon relative density $\rho^{ribbon}$ and mean granule size $\mu^{GSD}$ are selected as the two upstream CMAs governing the coupling between unit operations. Their normalized forms are defined as:

$$X = \left(\frac{\rho^{ribbon}-\rho_{c,rib}}{1-\rho^{ribbon}}\right)^{r_X}, \qquad Y = \left(\frac{\mu^{GSD}}{D/6-\mu^{GSD}}\right)^{r_Y} \tag{9}$$

### The ROM parameters for the elastic recovery model (equation (3)) are expressed as

$$\epsilon_0 = \frac{p_1XY+p_2X+p_4}{q_1XY+q_2X+1}, \qquad \rho_{c,\epsilon} = p_4 \tag{10}$$

For the best model, $r_X = r_Y = 1$ in Equation (9). Parameters were estimated simultaneously for split and non-split data as described previously.

Figure 1 summarizes the results for both formulations. The tablet density model yields $R^2 = 0.87$ for 10% APAP (Figure 1(a)) and a lower $R^2 = 0.46$ for 20% APAP (Figure 1(c)), attributed to the limited range of measured densities, which could be improved by expanding the experimental space. The relationship between tablet density and in-die density is shown in Figures 1(b) and 1(d).

Ribbon splitting reduces effective ribbon density and shifts the GSD toward finer particles. Since ribbon density and granule size are included as model inputs, the ROMs of Bachawala et al. capture trends accurately for both split and non-split conditions for 10% APAP formulations.

In Equation (3), the fitted exponent $n$ is 1.20 for the 10% APAP formulation and 1.003 for the 20% APAP formulation. For Equation (10), the estimated parameters for 10% APAP are $p_1 = 4.39, p_2 = 4.72, p_4 = 0.201, q_1 = 28.64$, and $q_2 = 18.64$, while for 20% APAP they are $p_1 = 2.44, p_2 = 5.67, p_4 = 0.423, q_1 = 14.45$, and $q_2 = 37.19$. In Equation (10), $\rho_{c,\epsilon} = p_4$ is estimated as 0.336 for 10% APAP and 0.673 for 20% APAP.

## Tablet tensile strength

Nordström et al [16] showed that tablet tensile strength depends on the coupled effects of particle size ratio and the fraction of large particles rather than mean granule size, whereas most earlier studies focused on monodisperse or narrowly sieved granules, reporting either stronger tablets for smaller granules [17] or no significant effect of granule size on tensile strength [18]. Hence, Bachawala et al. expanded the model library to include dependence on ribbon density $\rho^{ribbon}$ and packing fraction $\phi$ through the normalized variables

$$X = \left(\frac{\rho^{ribbon} - \rho_{c,rib}}{1 - \rho^{ribbon}}\right)^{r_X}, Z = \left(\frac{\phi - \phi_{min}}{\phi_{max} - \phi}\right)^{r_Z} \quad (12)$$

The ROM parameters for the tensile strength model (equation (5)) are expressed as

$$\sigma_0 = \frac{p_1XZ + p_2X + p_3Z + p_4}{q_1XZ + q_2X + q_3Z + 1}, \qquad \rho_{c,\sigma_t} = \frac{p_1XZ + p_2X + p_3Z + p_4}{q_1XZ + q_2X + q_3Z + 1} \quad (13)$$

Parameter estimation results are reported in Table 1, with predictions shown in Figure 2 and 3 for both 10% and 20% formulations. The ROMs exhibit excellent predictive performance for both formulations ($R^2 \approx 0.99$). Although ribbon splitting modifies the GSD and consequently influences the packing fraction, this effect is inherently accounted for in the tensile strength model through the inclusion of packing fraction as an input, enabling the ROMs to accurately capture the experimental trends.

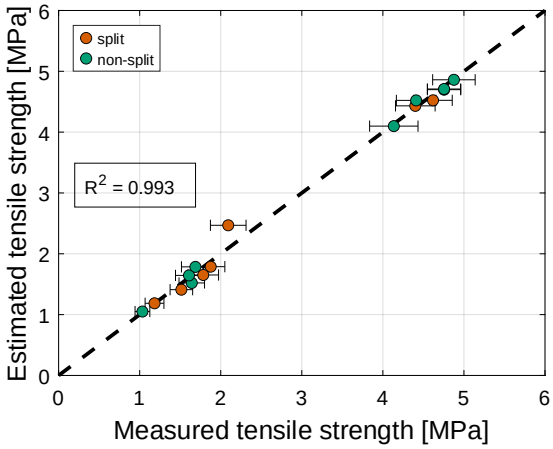

**Figure 2**: Goodness of the tensile strength prediction for 10% APAP.

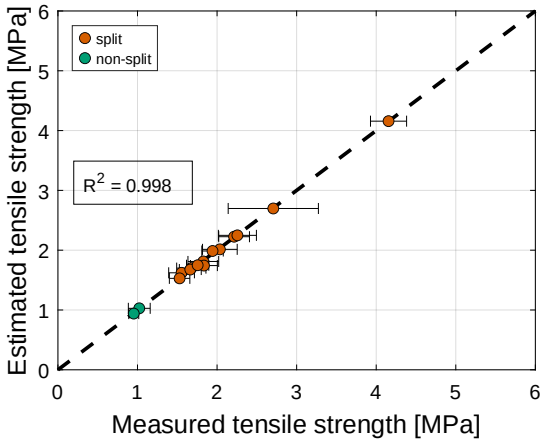

**Figure 3**: Goodness of the tensile strength prediction for 20% APAP.

**Table 1**: Estimated parameters for the tensile strength models are listed below.

| Equations | Parameters 10% APAP | Parameters 20% APAP |
|---|---|---|
| Equation 12 | $r_X = 3.21$<br>$r_Z = 0.05$ | $r_X = 9.98$<br>$r_Z = 5.72$ |
| Equation 13<br>$\sigma_0$ | $p_1 = 215.07$ MPa<br>$p_2 = 71.86$ MPa<br>$p_3 = 59.51$ MPa<br>$p_4 = 0.08$ MPa<br>$q_1 = 0.04$<br>$q_2 = 15.66$<br>$q_3 = 5.34$ | $p_1 = 1.28$ MPa<br>$p_2 = 345.79$ MPa<br>$p_3 = 0.34$ MPa<br>$p_4 = 422.84$ MPa<br>$q_1 = 6.54e-04$<br>$q_2 = 145.89$<br>$q_3 = 0.09$ |

## Tablet weight

For tablet weight, coupling is introduced through the packing fraction $\phi$, determined from:

$$W = \eta\rho_b V^{fill} = \phi(X,Y)\rho_{true}\rho_{ribbon}V_{fill} \quad (14)$$

The packing fraction is modeled using a simplified rational function:

$$\phi(X,Y) = p_4 \frac{q_2X+1}{q_1XY+q_2X+1} \quad (15)$$

with $X = (1-\alpha)*(1-{\mu_1}^3/{\mu_2}^3)$ and $Y = \alpha$.

Here, $\mu_1/\mu_2$ is the size ratio of the bimodal distribution. This formulation is motivated by the analytical expression proposed by Brouwers and co-workers for the packing fraction of bimodal hard spheres, which relates packing efficiency to the size ratio and composition of the mixture [19], [20].

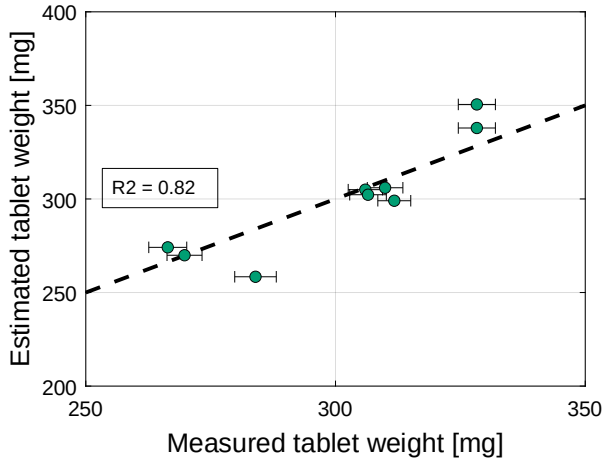

**Figure 3:** For 10% APAP, goodness of the tablet weight prediction for non-split data.

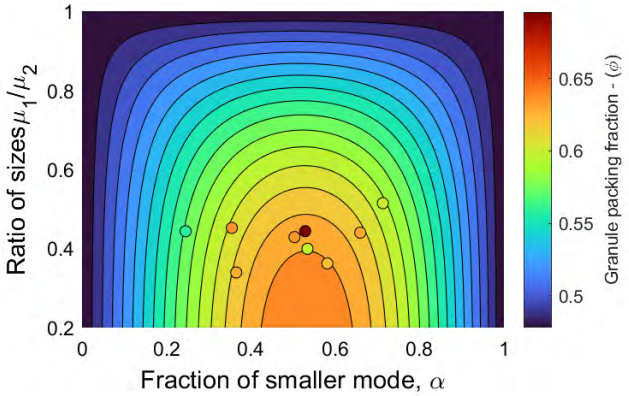

**Figure 4:** Predictions of the packing fraction model for 10% APAP (non-split data).

Parameter estimation was performed using combined split and non-split data, and the tablet weight model showed limited accuracy with $R^2 \approx 0.6$. Although the tablet weight model depends on packing fraction ϕ and ribbon density ρ, ribbon splitting alters granule shape, surface roughness, porosity, and cohesion, which modify die filling dynamics and effective fill efficiency in ways not fully captured by these two inputs, leading to lower accuracy in weight prediction [14], [21], [22].

The datasets were therefore separated, and parameters were estimated independently for split and non-split granules. For the non-split 10% APAP formulation, tablet weight prediction improves markedly ($R^2$ = 0.82, Figure 3), and the contour plot (Figure 4) reproduces the trend reported by Bachawala et al, with a maximum packing fraction at α ≈ 0.7 and increasing packing fraction with decreasing $\mu_1/\mu_2$ for 0.6 < α < 0.9. By contrast, predictions for split granules show lower accuracy ($R^2$ = 0.552) and are not shown here, indicating that the current tablet weight model does not adequately capture split behavior and may require modification or alternative approaches such as machine learning. For the 20% APAP formulation, limited non-split data prevented separation, resulting in lower prediction accuracy ($R^2$ = 0.616, Figure 5) as the model is dominated by split conditions.

The estimated parameters (Equation (15)) for the 10% APAP formulation are $p_4 = 0.48, q_1 = -1.23$, and $q_2 = 0.32$. For the 20% APAP formulation, the corresponding parameters are $p_4 = 0.63, q_1 = -0.10$, and $q_2 = 999.99$. The value of $\rho_{c,rib}$ was kept constant at 0.566, and the values of $\phi_{min}$ and $\phi_{max}$ were set to 0.367 and 0.75, respectively.

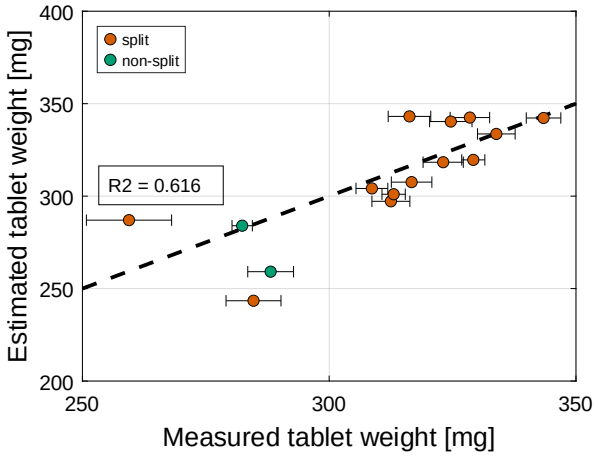

**Figure 5**. Goodness of prediction for tablet weight (both split and non-split data included) for 20% APAP.

## Impact of Splitting on Tablet Properties

To quantify the impact of splitting on tablet properties, a multitask Gaussian Process Regression (MT-GPR) model was implemented to simultaneously predict four CQAs: tablet weight (W), elastic recovery (ER), relative density (RD), and tensile strength (TS). The multitask

formulation exploits correlations among outputs, improving robustness relative to independent single-output models. The covariance kernel was defined as an additive combination of linear and Matérn ($\nu = 2.5$) kernels, $K(x, x') = K_{\text{Linear}} + K_{\text{Matérn}}$, enabling the capture of both linear trends and smooth nonlinear dependencies in process variables (e.g., roll gap, pressure, and speed). Automatic relevance determination (ARD) was employed to weight input contributions. The model was implemented in GPyTorch using a multitask Gaussian likelihood, and hyperparameters were optimized by maximizing the exact marginal log-likelihood with the Adam optimizer (learning rate 0.03, 2000 iterations). All continuous inputs and outputs were standardized prior to training to ensure numerical stability and interpretability.

**Table 2**: The predictive performance of the MT-GPR model and independent GP models.

| Model | RMSE | MAE | NLPD | Coverage (90%) |
|---|---|---|---|---|
| Multitask GP | **0.41** | **0.37** | 4.4 | **0.91** |
| Ind. GPs | 0.58 | 0.39 | **1.21** | 0.77 |

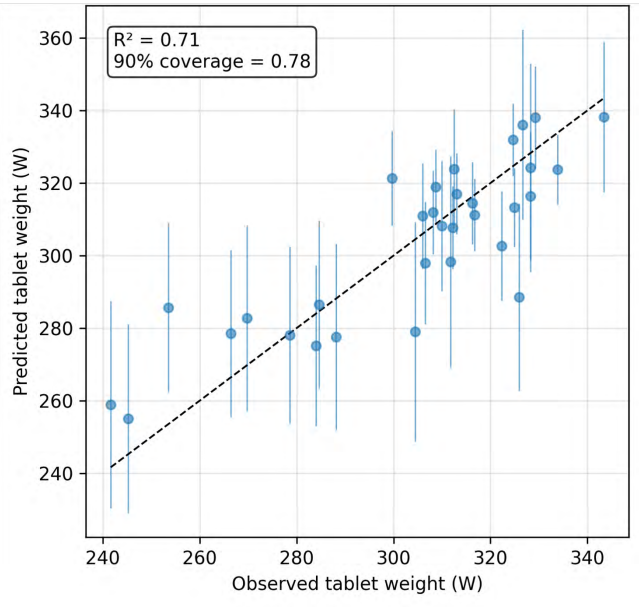

**Figure 6.** Goodness of prediction for tablet weight.

The predictive performance of the MT-GPR model was evaluated against independent GP models using leave-one-out cross-validation (Table 2), with RMSE, MAE, negative log predictive density (NLPD), and 90% predictive interval coverage as metrics. For tablet weight, the goodness of MT-GPR prediction is shown in Figure 6. The MT-GPR achieved lower overall RMSE and MAE, indicating improved average accuracy, and demonstrated superior uncertainty calibration through improved predictive interval coverage. While independent GPs achieved lower RMSE for tablet weight (0.591), the multitask model provided substantially improved accuracy for elastic recovery (0.027) and relative density (0.027), reflecting the inherent trade-off in multitask learning whereby information sharing benefits noisier outputs at the cost of modest degradation for dominant responses. MT-GPR yields coherent joint predictions, and consistent uncertainty estimates across all tablet properties, which are not guaranteed with independent models, making it better suited for multivariate, uncertainty-aware analysis of coupled process disturbances such as ribbon splitting.

To quantify splitting effects, a binary split indicator was included, and a counterfactual impact analysis was performed by predicting tablet properties across the experimental design under forced control (Split = 0) and failure (Split = 1) scenarios. The resulting differences (Figure 7) represent the predicted change in tablet properties due to splitting. Splitting emerges as a significant process disturbance, primarily reducing tablet weight (−3.16 mg ± 6.43) and tensile strength (−0.49 MPa ± 0.8). The large variability indicates strong interactions between splitting and roll conditions, localizing quality risk within specific regions of the design space. Splitting is associated with over-compaction or high elastic recovery in the nip region, producing structurally compromised, work-hardened ribbons that generate finer, bimodal GSDs during milling. Elevated fines degrade hopper flow and die filling consistency, reducing tablet weight and increasing variability, while reduced deformability and bonding area lead to lower tensile strength.

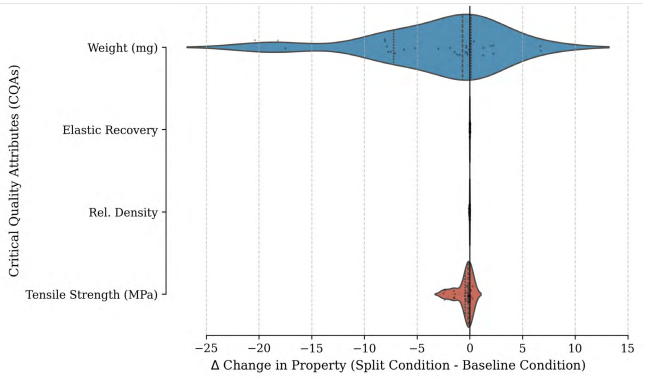

**Figure 7.** Impact of splitting on tablet properties using counterfactual impact analysis.

## CONCLUSION

Ribbon splitting was investigated as a process disturbance in dry granulation and its impact on downstream tablet CQAs was quantified using reduced-order and machine-learning models. Although ribbon splitting alters the granule size distribution (GSD) and ribbon density, tablet CQAs such as tensile strength, elastic recovery, and tablet density are accurately predicted by the

existing ROM framework, provided that GSD and ribbon density are known. In contrast, tablet weight is strongly affected by splitting due to changes in granule packing and die filling. Separating split and non-split data improves weight prediction for non-split ribbons, but split granules remain challenging to model mechanistically. These findings highlight the need for extended or data-driven approaches to ensure robust tablet weight prediction under splitting conditions.

## ACKNOWLEDGEMENTS

This work was supported by the National Science Foundation grant No. 2140452, titled “Right First Time Manufacturing of Pharmaceuticals (RIFTMaP)”. The authors gratefully acknowledge Natoli Engineering Company for providing the Natoli NP-400 tablet press and Alexanderwerk (Germany) for supplying the WP120 roller compactor used in this study.

## ABSTRACT

In pharmaceutical process engineering, accurate prediction of tablet properties is crucial for ensuring product quality, optimizing manufacturing efficiency, and advancing sustainable production practices. This study presents a physics-informed neural network (PINN) framework for predicting the physical properties of pharmaceutical tablets from near-infrared (NIR) spectra. The PINN framework integrates revised Kubelka-Munk theory and physical constraints to ensure physically consistent predictions while requiring less training data than conventional artificial neural networks. Tablets were manufactured using acetaminophen and microcrystalline cellulose formulations with varying compositions and compression settings. The PINN framework successfully predicts critical quality attributes, including tensile strength, porosity, and density. It offers a data-efficient, interpretable solution for pharmaceutical tablet quality control.

**Keywords:** Physics-Informed Neural Networks, Machine Learning, Industry 4.0, Near Infrared Spectroscopy, Pharmaceutical Tablets.

## INTRODUCTION

Tablet quality attributes including size, hardness, tensile strength, porosity and density are critical for ensuring mechanical integrity, dissolution performance and bioavailability in pharmaceutical manufacturing [1,2]. The US Food and Drug Administration (FDA) requires rigorous monitoring of these properties as critical quality. However, different tablet compression machines, operating conditions and formulation compositions can introduce substantial quality variations. Traditional tablet testing methods are time consuming and destructive and only provides limited inspection into the sampled tablets.

Near-infrared (NIR) spectroscopy enables rapid, non-destructive and continuous analysis of tablets, which is suitable for process monitoring [3, 4]. Current NIR calibration methods employ chemometric techniques such as partial least squares regression (PLSR) or machine learning models like artificial neural networks (ANNs). However, in predicting physical properties, PLS models often struggles with accuracy, and ANNs requires substantial training datasets and offer limited model interpretability [5, 6].

The NIR reflectance of tablets is fundamentally governed by light scattering and absorption in porous media. The revised Kubelka-Munk theory (RKM), developed by Yang and Kruse, describes scattering-induced photon path variation (SIPV) to the original Kubelka-Munk theory. By introducing the SIPV factor μ, the RKM theory accounts for changes in the effective light path length in highly scattering samples [7]. This provides a physics-based framework for relating spectral features to tablet microstructure. Physics-informed neural networks (PINNs) integrate physical laws into the training process of neural networks, which can improve data efficiency and prediction consistency [8].

In this study, we present a PINN model that incorporates RKM equations to predict tablet properties based on NIR spectra. The model learns the intrinsic absorption and scattering coefficients, as well as the SIPV factor, while predicting tablet critical quality attributes. We compare the performance of the PINN-RKM model with conventional ANN model and evaluate the data requirements for both approaches. The results show that integrating physical constraints reduces the need for training data while maintaining prediction accuracy.

# METHODS

## Experiments

A powder formulation was prepared for the tablet production: 80% microcrystalline cellulose (Avicel PH-102, IFF, USA) and 20% acetaminophen (Mallinckrodt Pharmaceuticals). The powders were blended for 30 minutes in a five-liter tote blender and then processed through an Alexanderwerk WP120 roller compactor to produce granules. Ten granulation sets were produced for each formulation with varying roller compaction settings (roller speed, hydraulic pressure, and roll gap), while three granulation sets were further used to evaluate the proposed models.

Tablets were manufactured using a Natoli NP-400 tablet press with D-type tooling (D = 7.94 mm, h = 0.3302 mm) at a constant turret speed of 20 rpm, feed-frame speed of 35 rpm and precompression thickness of 6mm. Three main compression thickness settings (3.0, 3.5, and 4.5 mm) were used for each granule set.

## Data Acquisition

For each tableting condition, 20 tablets were sampled and measured sequentially. Each tablet was measured three times. Near-infrared (NIR) reflectance spectra (1100–2100 nm) were acquired at-line with the probe in direct contact with the tablet surfaces. External referencing was performed before each dataset using a certified 99% reflectance Spectralon standard. An example of raw tablet spectra is shown in Figure 1. After the NIR measurement, the tablets were characterized using an AT4 tablet tester to determine their weight, hardness, diameter, and thickness. Tensile strength was calculated from the hardness measurements using the method described in Bachawala et al [].

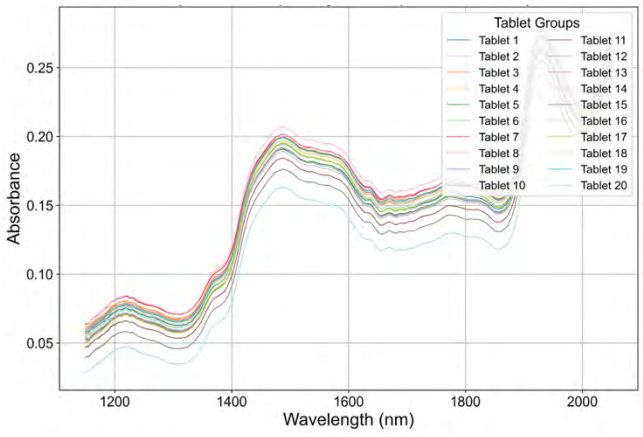

**Figure 1.** Raw NIR spectra from one tableting conditon.

## Model Architecture

The revised Kubelka-Munk (RKM) theory describes effective absorption and scattering coefficients by $K = \mu * \alpha * a$ and $S = \frac{1}{2} * \mu * \alpha * s$, where a and s are the intrinsic absorption and scattering coefficients. $\alpha$ is the diffuse light factor, and $\mu = \sqrt{s/a}$ is the SIPV factor that characterizes the effective photon path length. The reflectance for an infinitely thick sample is $R_\infty = 1 + \left(\frac{K}{S}\right) - \sqrt{(K/S)^2 + 2(K/S)}$. This theory links NIR reflectance to tablet physical properties through the intrinsic optical coefficients.

The RKM theory describes light propagation in pharmaceutical tablets more accurately than the original Kubelka-Munk theory because it explicitly accounts for path variation. When photons scatter through an opaque and heterogeneous media, they do not follow straight paths. Instead, photons go through multiple scattering events, leading to path length distributions that deviate from the classical two-flux assumptions in original KM theory. The SIPV factor $\mu$ captures this phenomenon. When scattering dominates ($s > a$), photons travel longer effective distances ($\mu > 1$). This makes the RKM theory ideal for PINN implementations because it provides a mechanistic link between measurable NIR spectra and the underlying tablet microstructure. Therefore, the PINN can learn physically consistent representations of tablet properties rather than purely empirical correlations.

The PINN-RKM architecture we developed consists of multiple sub-networks that simultaneously predict tablet physical properties and optical coefficients from NIR spectra. Physics parameter networks predict porosity, density, and tablet thickness. A composition network estimates component fractions at absorption bands identified through SHapley Additive Explanations (SHAP) analysis of wavelength importance, which revealed key bands around 1150, 1450, 1730, 1940, and 2050 nm corresponding to characteristic chemical bonds in the formulation. Optical coefficient networks predict wavelength-dependent intrinsic coefficients a and s, which are then used to calculate the SIPV factor. A property prediction network maps the predicted physics parameters to target tablet properties.

The total loss function integrates data-driven and physics-informed terms: $\mathcal{L}_{total} = \mathcal{L}_{porperty} + w_1 * \mathcal{L}_{spectrum} + w_2 * \mathcal{L}_{physics} + w_1 * \mathcal{L}_{bounds}$, where $\mathcal{L}_{porperty}$ is the mean squared error between predicted and measured tablet properties, $\mathcal{L}_{spectrum}$ quantifies reconstruction error between measured and RKM predicted reflectance spectra, $\mathcal{L}_{physics}$ penalizes violations of physical constraints, and $\mathcal{L}_{bounds}$ enforces physically reasonable parameter ranges. Physical constraints include the porosity-density relationship, SIPV factor, and parameter bounds for porosity, density, intrinsic absorption coefficient, intrinsic scattering coefficient, thickness and light penetration depth. The constraint weights were empirically tuned to balance prediction accuracy and physical consistency.

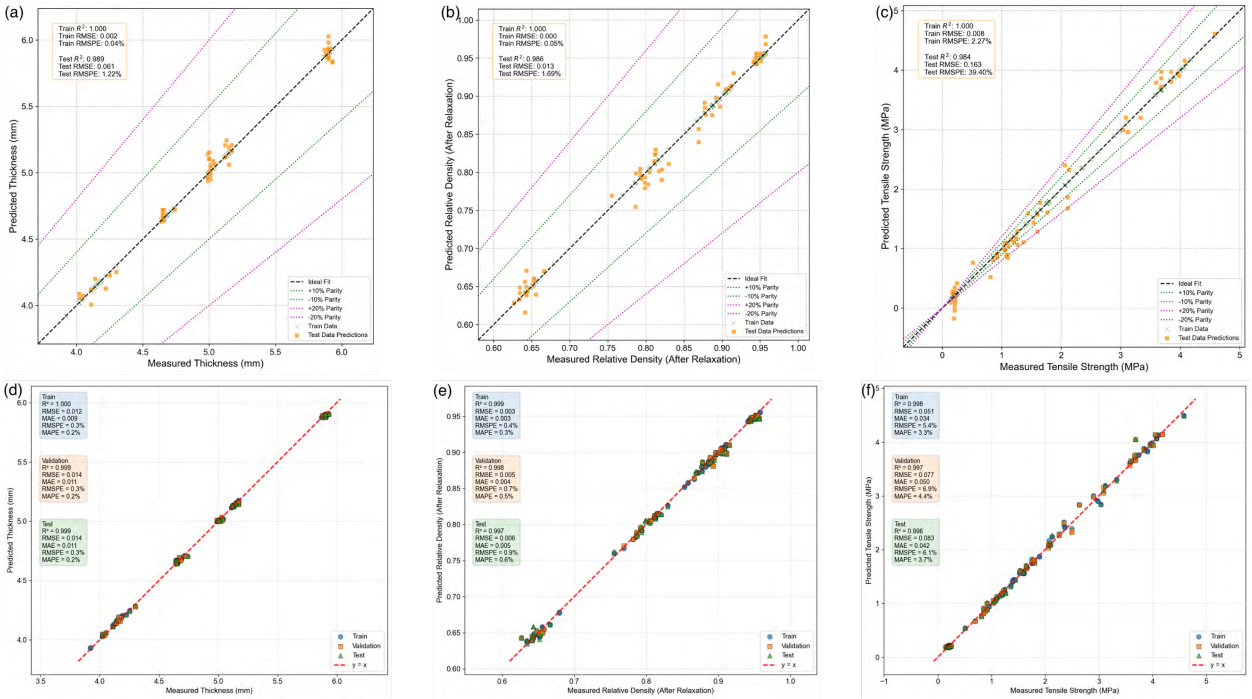

**Figure 2.** Parity plots of the ANN models (a) tensile strength (b) relative density (c) thickness, and PINN-RKM models (d) tensile strength (e) ) relative density (f) thickness.

The network was implemented in PyTorch and trained using the Adam optimizer with learning rate 5×10-4 for 1500 epochs with early stopping (patience = 300 epochs). Data were split 70/30 for training and testing, with standard scaling applied to both NIR spectra and tablet properties. The PINN performance was evaluated against a conventional feedforward ANN with identical network capacity.

## RESULTS AND DISCUSSION

Table 1 compares the performance of the proposed a PINN-RKM model with that of a standard ANN in predicting three critical tablet properties from near-infrared (NIR) spectra. The PINN-RKM model demonstrated higher predictive accuracy for all three tablet properties compared to the standard ANN approach. As shown in Figure 2, both models achieved high $R^2$ values, indicating strong correlations between predictions and reference values. However, the PINN-RKM model has substantially lower prediction errors. PINN-RKM model was able to achieve an improvement in tensile strength predictions, where it reduced the root mean square error (RMSE) by 49% (from 0.163 to 0.083) compared to the standard ANN model. For relative density and thickness predictions, the PINN-RKM model achieved reductions in RMSE of 54% and 77%, respectively. This demonstrates its consistent superiority across properties with different physical characteristics and measurement scales.

**Table 1:** Modeling results.

| Model | Test$R^2$ | RMSE | RMSPE(%) |
|---|---|---|---|
| Tensile Strength | | | |
| PINN-RKM | 0.996 | 0.083 | 6.1 |
| ANN | 0.984 | 0.163 | 39.4 |
| Relative Density | | | |
| PINN-RKM | 0.997 | 0.006 | 0.9 |
| ANN | 0.986 | 0.013 | 1.69 |
| | | | |
| Thickness | | | |
| PINN-RKM | 0.999 | 0.014 | 0.3 |
| ANN | 0.989 | 0.061 | 1.22 |

Beyond improved accuracy, the PINN-RKM framework provides physically interpretable parameters that offer mechanistic insights into tablet microstructure and light-matter interactions. Figure 3 illustrates the wide range of physical properties and the correlations between the properties and the tablet tensile strength.

As shown in Figure 3, the tablet porosity ranged from 0.06 to 0.21 with a mean of 0.12, while the density distribution peaked at a mean of 1.2. These variations directly influenced the SIPV factor, which showed a mean value of 2.18. A clear positive correlation was observed between porosity and the SIPV factor. As porosity increases, the increased number of air-solid interfaces

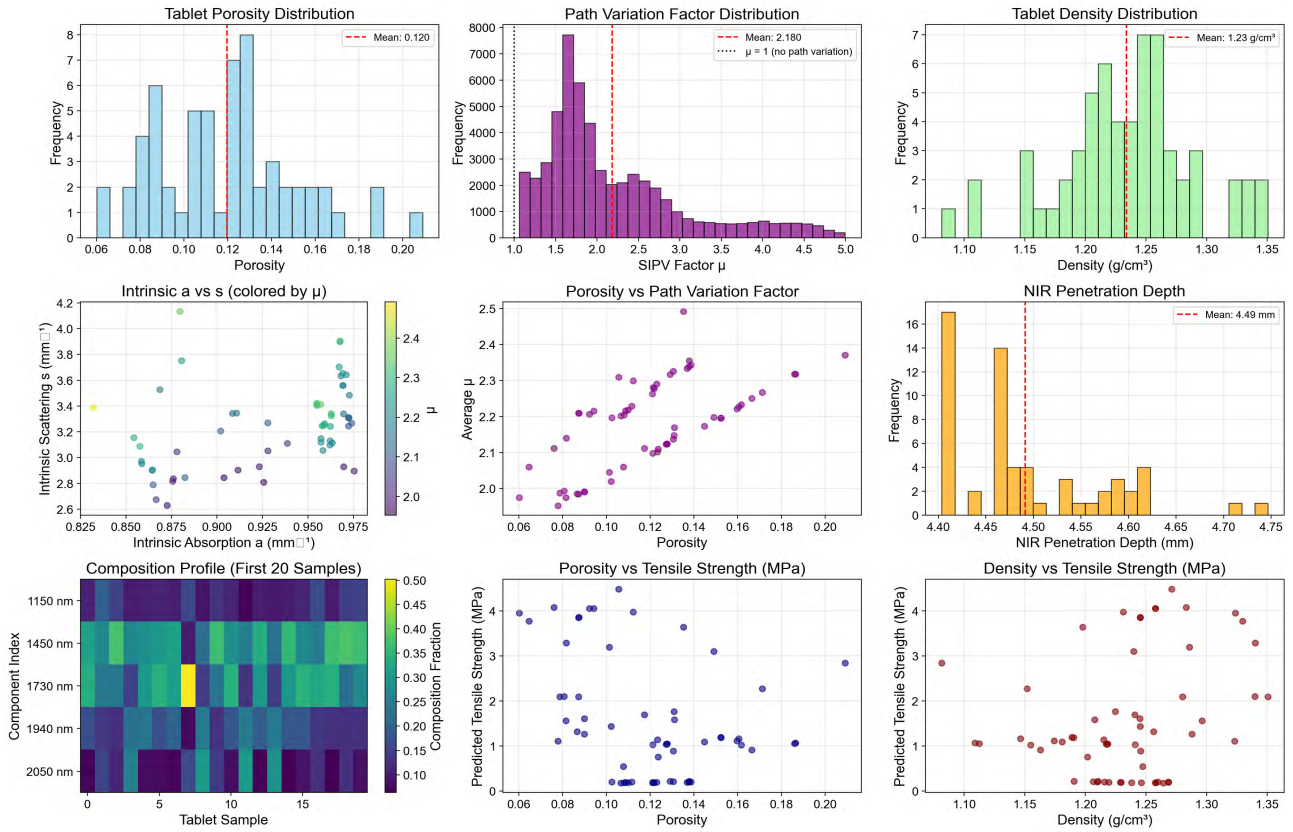

**Figure 3.** PINN-RKM model mechanistic interpretations.

within the tablet enhances light scattering, thereby extending the total photon pathlength. Furthermore, the NIR penetration depth aligns with the tablet thickness settings, suggesting that the NIR spectra effectively sampled the internal bulk properties of the tablets. However, previous research indicates that the NIR penetration depth in pharmaceutical compacts typically does not exceed 3 mm. Although our model results indicate effective sampling up to the maximum experimental thickness, this discrepancy highlights the need for further study to confirm the accuracy of depth predictions.

## CONCLUSION

This research introduces a novel Physics-Informed Neural Network (PINN) architecture integrated with Revised Kubelka-Munk (RKM) theory for the non-destructive characterization of pharmaceutical tablets. By including fundamental light-propagation physics into the deep neural networks, the model successfully transitioned from a traditional empirical correlation to a robust, physics-aware predictive framework. The PINN-RKM model demonstrated superior predictive performance across all evaluated Critical Quality Attributes (CQAs). Specifically, the framework achieved an R2 of 0.999 for thickness and 0.998 for tensile strength, significantly outperforming conventional artificial neural. In summary, the integration of RKM physics provides a significant advancement. This method not only enhances predictive accuracy but also offers a high degree of model interpretability, providing a solid solution for process monitoring and quality assurance in pharmaceutical manufacturing.

## ABSTRACT

Probabilistic design spaces enable pharmaceutical manufacturers to balance regulatory compliance and operational efficiency. In this context, the "edge-of-failure" separating compliant from non-compliant operation is not a fixed line, but an uncertain region driven by model parameter uncertainty. Traditional methods typically map this probability of failure across the whole design space, which is a computationally expensive task. We propose a more direct approach, reformulating the problem using quantile functions to search for a deterministic boundary at a desired confidence level. These functions are approximated via Gaussian process surrogates using a novel adaptive sampling strategy. An industrial peptide acylation case study identifies the probabilistic design space using 13 experiments versus 18 from a traditional DoE; a 28% reduction. The framework quantifies trade-offs between operational robustness and yield optima.

**Keywords**: Probabilistic design space, Adaptive sampling, Pharmaceutical manufacturing, Surrogate modeling

## INTRODUCTION

In pharmaceutical manufacturing, a design space (DS) is *"the multidimensional combination and interaction of material attributes and process parameters that have been demonstrated to provide assurance of quality"* [1]. Once approved, a DS allows manufacturers to adjust process settings within its bounds without additional regulatory submissions, enabling operational flexibility [2]. A DS can be expressed mathematically as

$$\{\mathbf{x} \in \mathcal{K} \mid \forall \ell \in \{1, \dots, L\}, g_\ell(\mathbf{x}, f(\mathbf{x}, \theta)) \leq 0\}, \quad (1)$$

where $\mathcal{K} \subseteq \mathbb{R}^P$ is the knowledge space, and the process model $\mathbf{y} = f(\mathbf{x}, \theta)$ predicts CQAs $\mathbf{y} \in \mathbb{R}^Q$ with fixed model parameters $\theta \in \mathbb{R}^R$. Each constraint $g_\ell$ represents a CQA specification limit or a process constraint.

Ignoring model parameter uncertainty yields a deterministic design space (DDS), as in Eq. (1). In practice, parameter uncertainty can reduce or reshape the DS, motivating methods to define a probabilistic design space (PDS). In this context, the model parameters follow a conditional density $p(\theta \mid \mathbf{x})$, which can be inferred via first-order Taylor series approximation [3] or Bayesian parameter estimation [4]. Under model parameter uncertainty, the constraints in Eq. (1) become probabilistic

$$\{\mathbf{x} \in \mathcal{K} \mid \forall \ell \in \{1, \dots, L\}, \mathbb{P}(g_\ell(\mathbf{x}, f(\mathbf{x}, \boldsymbol{\Theta})) \leq 0) \geq C\}, \quad (2)$$

where $\boldsymbol{\Theta}$ is a random variable with density $p(\theta \mid \mathbf{x}), C$ is a reliability level, and

$$\mathbb{P}(g_\ell(\mathbf{x}, f(\mathbf{x}, \boldsymbol{\Theta})) \leq 0) = \int_{\{\theta \mid g_\ell(\mathbf{x}, f(\mathbf{x}, \theta)) \leq 0\}} p(\theta \mid \mathbf{x}) \, \mathrm{d}\theta. \quad (3)$$

The central challenge in PDS identification is the computational cost of evaluating Eq. (3). The objective of this paper is to propose a method that bypasses this cost by reformulating Eq. (2) as a deterministic problem.

### Sampling-based approaches to PDS identification

Wet-lab experimentation is a costly and time-consuming task in pharmaceutical development. Therefore, the literature favors model-based methods for mapping the DS [5]. Knowledge-driven models are often preferred over purely empirical ones as they embed physical principles, require less calibration data, and extrapolate more reliably beyond the training domain [6].

Standard PDS identification typically employs a Monte Carlo framework [7]. The knowledge space $\mathcal{K}$ is discretized, and the model $f(\mathbf{x}, \boldsymbol{\theta})$ is evaluated by drawing samples of $\boldsymbol{\theta}$ at each discrete point $\mathbf{x}$. The feasibility probability in Eq. (3) is estimated as the fraction of simulations satisfying all CQA constraints. The PDS is then defined as the set of inputs $\mathbf{x}$ where this probability meets the reliability level $C$.

While robust and widely applicable, this approach carries a computational cost proportional to the product of grid points and parameter samples, which often proves prohibitive for complex models or large knowledge spaces. To combat this, dimension reduction techniques like partial least squares (PLS) are used to project high-dimensional inputs into a tractable latent space prior to PDS mapping [19]. Computational overhead can also be managed through targeted exploration; nested sampling [8], for instance, accelerates convergence by iteratively discarding low-probability points in favor of candidates near the target threshold $C$. Furthermore, adaptive surrogate-driven sampling [9] can reduce simulation requirements by learning a surrogate of the feasibility probability and direct new evaluations to the most informative regions (e.g., near the feasibility boundary [10]). Common surrogates include Gaussian process (GP) regression [11] to drive acquisition via uncertainty estimates, or artificial neural networks (ANNs) [12], which have recently been deployed to approximate expensive mechanistic models under material uncertainty [20]. Alternative approaches replace the inner sampling over $\boldsymbol{\theta}$ by a fast optimizer inspired by flexibility analysis [13], though it tends to yield more conservative PDS estimates.

After identifying the PDS, a common next step is to inscribe the largest axis-aligned (hyper)rectangle within it - the *acceptable operating region* (AOR) - as this facilitates simple communication about process flexibility to regulatory authorities. However, a fundamental limitation persists across the aforementioned methods: they rely on grid discretization to generate probability maps. If explicit analytical expressions for the boundary constraints existed, AOR identification could be formulated directly as a volume-maximizing problem, akin to flexibility index calculations [13]. Because current sampling-based approaches lack these explicit expressions, AOR identification typically demands complex post-processing via computational geometry [5]. This highlights a critical gap: *the need for a methodology that generates explicit boundary constraints to streamline AOR identification and reveal flexibility-limiting boundary points.*

### Quantile-based PDS formulation

To provide practitioners with explicit boundaries, we propose a new formulation of the PDS, inspired by methods from reliability-based design optimization [14, 17]. We utilize the quantile function, which is defined as

$$Q_\ell^{(C)}(\mathbf{x}) = \inf\{q \in \mathbb{R} \mid \mathbb{P}(g_\ell(\mathbf{x}, f(\mathbf{x}, \boldsymbol{\Theta})) \leq q) \geq C\}, \quad (4)$$

for each $\ell = 1, \ldots, L$. Effectively, $Q_\ell^{(C)}$ acts as the inverse of Eq. (3). Leveraging the properties of $Q_\ell^{(C)}$, we can recast the probabilistic constraints in Eq. (2) into

$$\mathbb{P}(g_\ell(\mathbf{x}, f(\mathbf{x}, \boldsymbol{\Theta})) \leq 0) \geq C \;\Leftrightarrow\; Q_\ell^{(C)}(\mathbf{x}) \leq 0, \quad (5)$$

for all $0 < C \leq 1$. Using Eq. (5), PDS identification turns into a deterministic problem, where the zero-level set $\{\mathbf{x} \mid Q_\ell^{(C)}(\mathbf{x}) = 0\}$ explicitly defines the "edge-of-failure" boundary at a fixed reliability level $C$. Unlike raw probabilities, the quantile constraint provides a clearer, more useful signal for targeted experimentation: its sign indicates feasibility, and its magnitude measures the distance to the boundary.

The challenge lies in learning a surrogate for these quantiles based on data from a small DoE. This work addresses three practical questions:

**(i)** **Surrogate construction:** *How do we build quantile surrogates that account for input and model uncertainty?* We employ GP surrogates trained with a novel three-phase adaptive sampling scheme: (1) sample along the PDS boundary, (2) target intersection points between the boundary and the AOR to identify binding constraints, and (3) sample near KPI optima to balance performance with robustness.

**(ii)** **Experiment selection**: *Which experiments most effectively reduce uncertainty?* We target the intersection of the AOR and the feasibility boundary to pinpoint edge-of-failure zones.

**(iii)** **Stopping criteria:** *How many experiments are required?* We monitor the convergence of the size of the AOR to determine a minimum viable dataset.

The remainder of this paper details the methodology, applies it to an industrial API case study, and validates the results against traditional approaches.

## METHODOLOGY

This paper introduces a novel methodology to identify PDSs using quantile surrogates, as summarized in Fig. 1. The core innovation is to replace expensive Monte Carlo simulations with a surrogate model that predicts the quantiles of the CQA constraints to account for both process and model uncertainty. To use the methodology, we assume the following two requirements are met:

**(a)** **Process model:** A mechanistic model $f$ exists, mapping process parameters $\mathbf{x}$ and model parameters $\boldsymbol{\theta}$ to the relevant CQAs.

**(b)** **Uncertainty characterization**: We assume a small initial DoE has already been performed. This data

is used to fit the model $f$ and will result in a conditional probability density $p(\boldsymbol{\theta} \mid \mathbf{x})$ that quantifies the uncertainty in the model parameters.

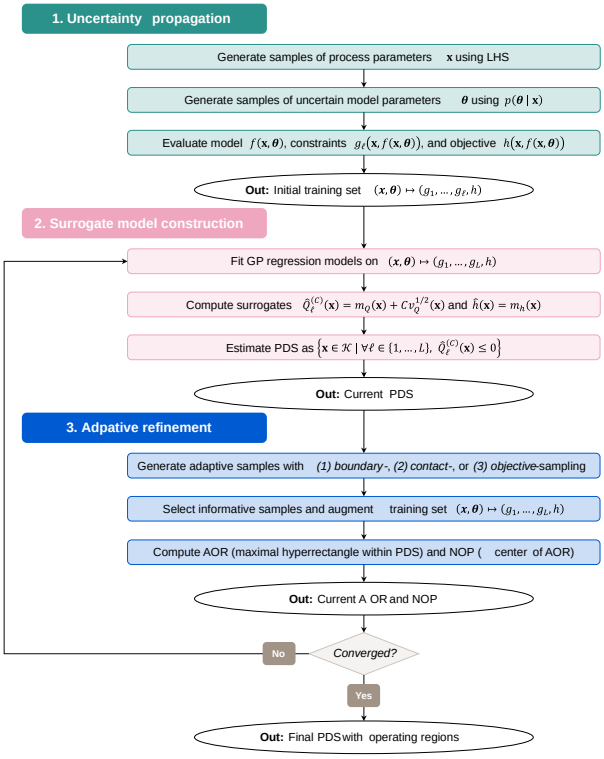

**Figure 1.** PDS identification methodology.

## Step 1: Uncertainty propagation

The first step generates an initial training set to capture how parameter uncertainty propagates to the constraints $g_\ell$, as well as to the objective function $h$, which describes process KPIs like yield or capacity. To obtain analytical expressions of uncertainty, we require Gaussian model parameters. Since this may not be true in general, we assume a transformation $T$ (e.g., Box-Cox) exists such that the transformed model parameters $\mathbf{Z} \coloneqq T(\boldsymbol{\Theta})$ are distributed as $\mathbf{Z} \sim \mathcal{N}(\boldsymbol{\mu}(\mathbf{x}), \boldsymbol{\Sigma})$. This leads to analytical results for the model uncertainty and avoids expensive Monte Carlo sampling in subsequent steps [16].

We generate an initial training set $\mathcal{D}_0$ by sampling $I_0$ process parameter points using Latin hypercube sampling (LHS) for uniform coverage. At each process point, we draw $J_0$ model parameter realizations from the conditional density. In practice, we typically find that $I_0 \in [5, 15]$ and $J_0 \in [1, 10]$ are sufficient. The model $f$ is evaluated at these points to compute the constraints and objective. The surrogate fits to the output $w_{ij}$, which is defined according to the function being modeled:

$$w_{ij} = \begin{cases} g_\ell(\mathbf{x}_i, T^{-1}(\mathbf{z}_{ij})), & \text{constraint model l,} \\ h(\mathbf{x}_i, T^{-1}(\mathbf{z}_{ij})), & \text{objective model.} \end{cases} \tag{6}$$

This yields an initial training set of input-output pairs $\mathcal{D}_0 = \{(\mathbf{v}_{ij}, w_{ij})\}_{1 \le i \le I_0, 1 \le j \le J_0}$, where the input vector $\mathbf{v}_{ij} \coloneqq [\mathbf{x}_i;\ \mathbf{z}_{ij}]$ concatenates both the deterministic process settings and the transformed model parameters.

## Step 2: Surrogate model construction

Given the initial training set $\mathcal{D}_0$, we employ GP regression to model the constraint functions $g_\ell$ and objective $h$. GP regression is preferred for its strength in uncertainty quantification [11]. The GP assumes a zero-mean prior and a squared exponential (SE) kernel function with automatic relevance determination (ARD) [15]. This allows the model to learn unique length-scales for each input dimension, effectively identifying the importance of each process and model parameter.

**Analytical moment matching:** Standard GP prediction assumes deterministic inputs. However, our inputs include uncertain model parameters $\mathbf{Z}$. While mapping a Gaussian input through a nonlinear GP generally yields a non-Gaussian predictive distribution, we approximate the resulting distribution with a Gaussian using moment matching [16]. As a result, we can derive closed-form expressions for the mean $\tilde{m}_w(\mathbf{x}^*)$ and variance $\tilde{s}_w(\mathbf{x}^*)$

$$\begin{aligned} \tilde{m}_w(\mathbf{x}^*) &\coloneqq \boldsymbol{\beta}^\top \mathbf{q}(\mathbf{x}^*), \\ \tilde{s}_w(\mathbf{x}^*) &\coloneqq \alpha^2 - \operatorname{tr}\Big((\mathbf{K} + \sigma_\varepsilon^2 \mathbf{I})^{-1} \mathbf{Q}(\mathbf{x}^*)\Big) \\ &\quad + \boldsymbol{\beta}^\top \mathbf{Q}(\mathbf{x}^*) \boldsymbol{\beta} - \tilde{m}_w^2(\mathbf{x}^*). \end{aligned} \tag{7}$$

We refer the reader to [16] for the definitions of $\boldsymbol{\beta}, \mathbf{q}$ and $\mathbf{Q}$ and the full derivation of Eq. (7). The other parameters include the signal variance $\alpha^2$ of the SE kernel and the observation noise $\sigma_\varepsilon^2$. The covariance matrix $\mathbf{K}$ is computed by evaluating the SE kernel across all input pairs.

**Quantile surrogate construction:** Using these analytical moments, we construct the $C$-level quantile surrogate. For a required reliability level $C$ (e.g., 95%), the surrogate is defined as the upper confidence bound of the predictive distribution

$$\hat{Q}_\ell^{(C)}(\mathbf{x}) = \tilde{m}_w(\mathbf{x}) + \Phi^{-1}(C) \sqrt{\tilde{s}_w(\mathbf{x})}, \tag{8}$$

where $\Phi^{-1}$ is the quantile function of the Gaussian distribution. The PDS can then be directly approximated as

$$\big\{\mathbf{x} \in \mathcal{K} \mid \forall \ell \in \{1, \dots, L\}, \hat{Q}_\ell^{(C)}(\mathbf{x}) \le 0\big\}, \tag{9}$$

thereby accounting for both input and model uncertainty. Unlike Eq. (8), the objective surrogate is expressed as $\hat{h}(\mathbf{x}) = \tilde{m}_w(\mathbf{x})$, as it approximates only the expected value rather than a quantile. At this stage, all surrogates are built on $\mathcal{D}_0$, and the next step is to refine them near AOR-critical regions and the process optimum.

## Step 3: Adaptive refinement

Surrogates based on space-filling designs often lack accuracy at the specific boundaries that define

feasibility. We define a three-phase adaptive sampling strategy to combat this. At each iteration, the algorithm selects a new design point $\mathbf{x}^*$ and parameter realization $\mathbf{z}^*$ to evaluate, refits the surrogates, and updates the PDS.

- **Phase 1: Boundary-guided sampling:** Early iterations focus on sharpening the PDS boundaries. We search for process settings where the constraints are closest to their critical values (the zero-level set). This amounts to minimizing the worst-case constraint violation, i.e.., $\max_{\ell} |\hat{Q}_{\ell}^{(C)}(\mathbf{x})|$. To enable gradient-guided optimization, we build a smooth proxy of the worst-case constraint violation, given by

$$r(\mathbf{x}) = \frac{1}{\eta} \log\Big(\sum_{\ell=1}^{L} \exp\big(\eta\, \hat{Q}_{\ell}^{(C)}(\mathbf{x})\big)\Big), \tag{10}$$

  where $\eta > 0$ is a sharpness parameter. As $\eta \to \infty, r(\mathbf{x})$ approaches $\max_{\ell} \hat{Q}_{\ell}^{(C)}(\mathbf{x})$. We optimize

$$\mathbf{x}^* = \operatorname*{argmin}_{\mathbf{x}\in\mathcal{K}} r^2(\mathbf{x}), \tag{11}$$

  to target regions where $r(\mathbf{x}) \approx 0$, which correspond to the zero-level set of the worst-case constraint.
- **Phase 2: Contact-guided sampling**: Once the quantile boundary is defined, we focus on the AOR - the largest hyperrectangle inscribed within the PDS. The accuracy of the AOR depends on the so-called *contact points*, which we define as the points where the rectangle intersects the PDS boundary. We first solve an optimization problem to maximize the AOR volume. We then sample the edge points of this hyperrectangle that are predicted to lie on the quantile boundary. This refines the "edge-of-failure" regions that ultimately limit the size of the operating window.
- **Phase 3: Objective-guided sampling**: Finally, the strategy aims at optimizing process performance. We maximize the objective surrogate subject to the quantile constraints. This ensures the PDS is accurate in the region of optimal operation, verifying that the identified optimum is truly robust to uncertainty.

**The Next Iteration:** Once the best process point $\mathbf{x}^*$ is identified (from any of the three phases), we must select which parameter realization $\mathbf{z}^*$ to simulate. Simply sampling the mean is insufficient. Instead, we draw candidates from the parameter distribution $\mathcal{N}(\boldsymbol{\mu}(\mathbf{x}^*), \boldsymbol{\Sigma})$ and select the one that minimizes the *boundary uncertainty*. Mathematically, we identify active constraint $\ell^* \in \{1, \dots, L\}$ (defined as the one nearest to $\mathbf{x}^*$) and compute

$$\mathbf{z}^* = \operatorname*{argmin}_{\mathbf{z}} \frac{|m_{\ell^*}([\mathbf{x}^*;\mathbf{z}])|}{\sqrt{s_{\ell^*}([\mathbf{x}^*;\mathbf{z}])}}, \tag{12}$$

where $m_{\ell^*}$ and $s_{\ell^*}$ are the GP posterior mean and variance for constraint $\ell^*$ [15]. This criterion selects parameters where the constraint prediction is near the boundary (small $|m_{\ell^*}|$) yet highly uncertain and poorly informed (large $s_{\ell^*}$) [17]. If multiple parameter samples are desired (as in Step 1), we select those close to the minimum.

The new simulation is added to the training set

$$\mathcal{D}_i \leftarrow \mathcal{D}_{i-1} \cup \begin{cases} \{\mathbf{v}^*, g_{\ell}(\mathbf{x}^*, T^{-1}(\mathbf{z}^*))\}, & \textit{constraint } l, \\ \{\mathbf{v}^*, h(\mathbf{x}^*, T^{-1}(\mathbf{z}^*))\}, & \textit{objective.} \end{cases} \tag{13}$$

and all surrogates are refitted. Convergence is assessed differently for each phase: An error-based stopping criterion (ESC) is used for boundary sampling (see [18] for details), AOR size stability is used for contact sampling, and optimizer convergence is used for the objective phase. When one phase converges, we either advance to the next or analyze the final PDS. If not, we can add more digital samples or update with new experimental data.

## CASE STUDY

In this paper, we consider an acylation reaction step, which is a critical synthetic step in the production of a long-acting peptide-based API. The process attaches a hydrophobic side chain to the peptide intermediate to form the final API. Several competing reactions must be balanced to achieve high product purity and yield while minimizing the formation of impurities.

### Reaction scheme and knowledge-driven model

The mechanistic model comprises seven coupled ordinary differential equations tracking the concentrations of the species: $\mathrm{SM}$ (starting material), $\mathrm{P}$ (desired product), $\mathrm{A}$ (impurity from undesired acylation), $\mathrm{HI}$ (hydrophobic impurities from di-acylation), $\mathrm{HSC}$ (hydrolyzed side chain reagent), $\mathrm{SC}$ (side chain reagent), and $\mathrm{P}^*$ (degraded product). The reaction scheme is:

$\mathrm{SM} + \mathrm{SC} \xrightarrow{k_1} \mathrm{P}$ (desired acylation at primary site)

$\mathrm{SM} + \mathrm{SC} \xrightarrow{k_2} \mathrm{A}$ (undesired acylation at secondary site)

$\mathrm{P} + \mathrm{SC} \xrightarrow{k_2} \mathrm{HI}$ (di-acylation at secondary site)

$\mathrm{A} + \mathrm{SC} \xrightarrow{k_1} \mathrm{HI}$ (di-acylation at primary site)

$\mathrm{SC} \xrightarrow{k_3} \mathrm{HSC}$ (hydrolysis of side chain reagent)

$\mathrm{P} \xrightarrow{k_4} \mathrm{P}^*$ (product degradation)

We assume that reactions at the same site happen at identical rates regardless of the other site's state, so only two acylation rates are required. We also assume that both rates depend on pH and temperature, $k_i = k_i(\mathrm{pH}, T)$ for $i = 1, 2$. The hydrolysis and degradation rates follow $k_i = k_i(T)10^{\mathrm{pH}-14}$ for $i = 3, 4$, reflecting their hydroxide-catalyzed mechanisms. All rate parameters are log-transformed and estimated using least-squares regression on the 18 available LHS experiments

$$
\begin{aligned}
\log\big(k_1(\mathrm{pH},T)\big) &= \beta_{1,1} + \beta_{1,2}/T + \beta_{1,3}\mathrm{pH} + \beta_{1,4}\mathrm{pH}^2 + \varepsilon_1,\\
\log\big(k_2(\mathrm{pH},T)\big) &= \beta_{2,1} + \beta_{2,2}/T + \beta_{2,3}\mathrm{pH} + \beta_{2,4}\mathrm{pH}^2 + \varepsilon_2,\\
\log\big(k_3(T)\big) &= \beta_{3,1} + \beta_{3,2}/T + \varepsilon_3,\\
\log\big(k_4(T)\big) &= \beta_{4,1} + \beta_{4,2}/T + \varepsilon_4,
\end{aligned}
\tag{14}
$$

where the $\beta$s denote regression coefficients, and the $\varepsilon$s are zero-mean Gaussian errors. The $1/T$ term captures Arrhenius temperature dependence, and log-transformation ensures approximate Gaussianity (as required by Step 1 of the methodology), with means parameterized by $\mathrm{pH}$ and $T$. As an example, take $\mathrm{pH} = 11.5, T = 2.50°\mathrm{C}$. Then $\log([k_1,k_2,k_3,k_4]^\top) \sim \mathcal{N}(\boldsymbol{\mu}(11.5,2.50),\boldsymbol{\Sigma})$ with

$$
\begin{aligned}
\boldsymbol{\mu}(11.5,2.50) &= [-4.26,-8.11,1.11,-0.950]^\top,\\
\boldsymbol{\Sigma} &= 10^{-3}\,\mathrm{diag}(5.96,0.856,915,269).
\end{aligned}
\tag{15}
$$

For brevity (and model confidentiality), we do not report the full distributions across all $(\mathrm{pH},T)$. By construction, the rates are modeled as independent random variables (no covariance entries in $\boldsymbol{\Sigma}$).

## RESULTS AND DISCUSSION

We demonstrate the methodology on the peptide acylation case study. Based on the reaction scheme, a standard kinetic model was formulated as a system of ordinary differential equations. With this, Requirement (a) of the methodology (**process model**) is fulfilled. Furthermore, the fitted rate parameters in Eq. (14) follow a Gaussian distribution, thereby meeting Requirement (b) (**uncertainty characterization**).

### Design space characterization

We characterize the PDS by two CQAs - hydrophobic impurities $\leq 2\%$ (constraint 1) and purity $\geq 70\%$ (constraint 2) over $\mathrm{pH} \in [10.5, 12.5]$ and $T \in [-3, 10]°\mathrm{C}$. We set $\mathbf{x} \coloneqq [\mathrm{pH}, T]^\top$ and $\mathbf{z} \coloneqq \log([k_1,k_2,k_3,k_4]^\top)$ and calibrate with 13 experiments (this choice is justified later). The reliability level is set at $C = 0.975$. For each sample of $\mathbf{x}$, we draw five $\mathbf{Z} \sim \mathcal{N}(\boldsymbol{\mu}(\mathbf{x}),\boldsymbol{\Sigma})$. The surrogate is initialized with 10 LHS points in $\mathbf{x}$, then refined adaptively.

Fig. 2 shows the PDS evolution at 15/30/40 iterations using the three-phase sampling strategy. At iteration 15 (Fig. 2**(a)**), boundary-guided samples (black ×) cluster on $\hat{Q}_1^{(C)} = 0$ and $\hat{Q}_2^{(C)} = 0$ (solid lines), quickly capturing the quantile boundary. Separation from the mean contours (dashed lines) reflect model uncertainty.

By iteration 30 (Fig. 2**(b)**), the AOR (black □) is identified, and contact-focused samples (orange ×) intersect the contours. The PDS geometry changes only slightly, with the mean purity contour shifting toward the quantile, indicating reduced uncertainty; the AOR's upper-left corner remains unsampled because it is unconstrained. The nominal operating point (NOP) lies around $\mathrm{pH} \approx 11.8$ and $T \approx 1.6°\mathrm{C}$ (black ★).

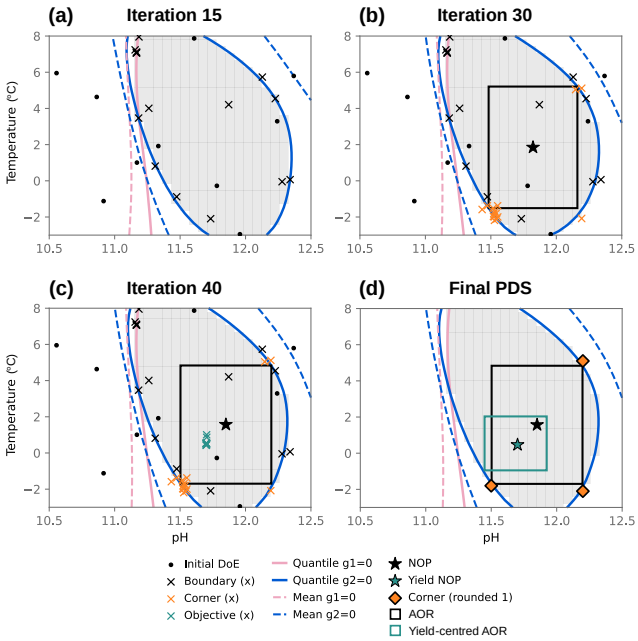

**Figure 2.** Snapshots of the PDS identification scheme.

At iteration 40 (Fig. 2**(c)**), we introduce a yield objective. Objective-guided samples (green ×) cluster near $\mathrm{pH} \approx 11.7$ and $T \approx 0.5°\mathrm{C}$, producing a yield-centered NOP (green ★). The AOR has shifted slightly to the right, possibly reflecting selection among equally sized rectangles.

The resulting PDS (Fig. 2**(d)**) shows two sets of NOPs and AORs: the yield-centered AOR (green □) has area $\approx 1.8$ versus $\approx 4.6$ for the maximal-flexibility AOR (black □), quantifying the robustness–performance trade-off. Maximizing yield narrows the window and raises violation risk, yet the flexibility-oriented AOR still contains the yield optimum, enabling optimal operation within robust ranges. Three edge-of-failure points (orange ♦) are found as local averages of the corner-point clusters. Using these as suggestions for follow-up experiments will most efficiently sharpen the boundary between feasible and infeasible operation.

### Convergence analysis and experimental strategy

Fig. 3 shows convergence of the three-phase adaptive sampling. The error-based stopping criterion (ESC) in Fig. 3**(a)** converges within ~10 boundary-guided iterations: the purity error ($e_2$) drops from ~18% to ~7.5% and remains below 10%, while the impurity constraint ($e_1$) is reliably identified within five iterations. We extend to 15 iterations to confirm stability of the estimates.

The NOP stabilizes after 15 iterations of contact-guided sampling (30 iterations in total). Another 10 iterations of objective-guided sampling shows that the NOP remains locked at $\mathrm{pH} \approx 11.8$ and $T \approx 1.6°\mathrm{C}$ (Fig. 3**(b)**). Overall, we ran 40 iterations (five parameter draws each)

plus 10 LHS burn in runs, totaling 210 evaluations of $f$.

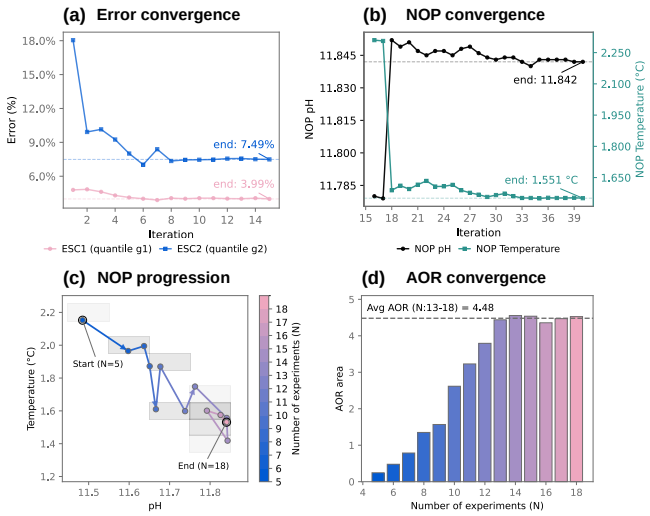

**Figure 3.** Convergence analysis.

Fig. 3**(c)** uses the edge-of-failure points (orange ♦) to guide laboratory experimentation. We start with $N = 5$ experiments (the minimum to estimate Eq. (14)) and iteratively add new experiments by choosing $(pH, \mathrm{T})$ settings near these points. As $N$ increases, the NOP converges; a color gradient shows experiment order, and the gray background partitions points into bins by rounding them to one decimal place; darker shading indicates a higher concentration of points. By $N = 10$, the NOP is near its final location, with most runs at $pH \approx 11.8$ and $T \approx 1.6$°C.

Fig. 3**(d)** confirms that 13 experiments suffice to estimate the PDS: tracking the AOR area for $N \in [5, 18]$ shows stabilization at $N = 13$, with an average area of $\sim 4.48$; additional runs will not expand the feasible region.

### Validation and practical considerations

We validated the PDS against a DDS derived from standard Monte Carlo [7]. Rather than sampling across an uncertain parameter space, we fix the log-transformed rates at their expected values $\boldsymbol{\mu}(\mathbf{x})$ and compute $\max(g_1, g_2)$ on a $250 \times 250$ grid (totaling 62500 evaluations of $f$). We report that the PDS mean boundary closely aligns with the DDS boundary, while the PDS quantile boundary is strictly enclosed by the DDS, ensuring a conservative buffer against parameter uncertainty.

**Implementation alongside traditional workflows:** Traditional (large factorial) DoEs lack adaptivity and expend runs in infeasible or low-information regions; our approach concentrates experiments at feasibility boundaries to most effectively reduce uncertainty and define the operating window.

In process development, a small confirmation study is often included between process characterization and validation to address residual gaps; the proposed methodology in this paper can guide this stage. Furthermore, it naturally accommodates incremental updates with new data from scale-up and commercial manufacturing, making it well-suited for lifecycle management.

**Batch-wise experimentation:** As shown in Fig. 3, targeting edge-of-failure points reduced experiments from 18 to 13; an important saving given costly intermediates/reagents and reaction times of up to 17 hours. In practice, single-run experimentation is often infeasible, as samples are sent for analysis at central facilities. This can delay results for hours or days. Batch-sequential design can address this by bundling the experiments, with adaptive refinement between batches.

**Model extensions:** CQA data may exhibit significant analytical variation. To account for this uncertainty, implementing stochastic differential equations (rather than ordinary differential equations) could provide a more robust analysis by explicitly modeling measurement noise alongside process dynamics.

## CONCLUSION

We present a quantile-based, adaptive methodology for probabilistic design space identification that efficiently characterizes feasible operating regions under parameter uncertainty; it yields explicit boundary constraints, identifies edge-of-failure points for targeted experimentation, and provides convergence criteria for reliable characterization.

Applied to industrial API manufacturing, the methodology identified the probabilistic design space in 13 rather than 18 experiments (28% reduction), saving costly intermediates and time. It also computed the largest inscribed operating window at the most flexible point (AOR area ≈ 4.5) and at the yield optimum (AOR area ≈ 1.8), capturing the robustness–performance trade-off.

Future extensions include: (i) strategies for cases where the process optimum lies on the feasibility boundary (vanishing flexibility); and (ii) multi objective formulations using convex combinations of yield, capacity, and unit cost to map trade-offs and define operating windows spanning multiple modes. A mode-switching policy could alternate between these optima as conditions change, enabling real-time optimization while maintaining compliance. In summary, quantile-based design space identification provides a fast route to process characterization that balances product quality and process efficiency.

## ABSTRACT

The formulation of oral solid dosage forms can have a significant impact on drug bioavailability, particularly for poorly soluble drugs. However, traditional formulation development relies heavily on extensive experimental testing, which limits its efficiency and effectiveness in oral drug product design. In this study, we present an integrated framework to support rational formulation design and exploration of optimal dosage regimens. This framework combines population balance-based tablet disintegration and dissolution modeling with physiologically based pharmacokinetic (PBPK) modeling to link critical material attributes (CMAs) with the pharmacokinetic response. The anti-coagulant drug rivaroxaban is selected as a model compound for calibration and deployment of the framework, enabling systematic investigation of the effects of crystal size distribution (CSD) and tablet porosity on in vivo performance. The results demonstrate that CSD has a pronounced impact on in pharmacokinetics, whereas tablet porosity exhibits a smaller but non-negligible effect. Furthermore, optimization is implemented to identify the optimal dose amount under a given formulation for producing the desired pharmacokinetic profile for average patient group, demonstrating the potential of this framework for the digital design of both drug efficacy and treatment strategies.

**Keywords**: PBM, PBPK, Optimal Dose regimen

## 1. INTRODUCTION

The performance of oral solid dosage forms can be critically influenced by formulation attributes such as particle size distribution (PSD) of active pharmaceutical ingredient (API), solubility, excipient type, and porosity of dosage form. These properties collectively governed dissolution behavior and, in turn, oral drug absorption. Although formulation effects on dissolution have been widely studied, formulation development still relies largely on traditional trial-and-error experimentation, resulting in substantial resource demand [1]. The challenge arises from the complex, combined effects of CMAs, and the gap between *in vitro* dissolution and in *vivo* performance [2].

Model-informed formulation development has therefore emerged as an important strategy in order to bridge formulation properties and *in vitro* dissolution with *in vivo* performance. By integrating experimental data with computational approaches, this method provides us an effective tool for understanding properties impact. *In vitro-in vivo* correlation (IVIVC) is one of the most widely used approaches. It involves establishing empirical or semi-empirical relationships between dissolution profiles and absorption kinetics, which is inferred from plasma drug concentration data [3]. Although IVIVC can be useful in certain formulation development contexts, it depends on great amounts of paired in vitro and in vivo data to build robust correlation. It is also typically specific to a given drug, and offers limited mechanistic interpretability.

To address the limitations of IVIVC, hybrid approaches that combine dissolution modeling or IVIVC concepts with physiologically based pharmacokinetic (PBPK) modeling have been introduced. PBPK modeling is a mechanistic modeling approach that predicts drug concentration-time profiles. It is based on mass balance equations defined over structured compartments, which incorporate relevant physiological process and drug-specific physicochemical parameters. Several studies

have integrated PSD–dependent dissolution model with PBPK model. For example, Stefan et al. coupled a Noyes–Whitney–based dissolution model with a PBPK framework to study PSD effects on cilostazol absorption [4]. Pepin et al. incorporated the API PSD into the commercial PBPK software, and demonstrated its application for regulatory support [5]. Although these studies successfully link PSD to in *vivo* performance, there is still a lack of systematic frameworks that can evaluate the combined effect of multiple CMAs on pharmacokinetic response.

This work aims to present a framework that integrates predictive modeling with optimization methods to support both formulation design and the development of dose regimen. A PBM-based dissolution model coupled with a PBPK model is developed. Using this combined model, a preliminary investigation is conducted to evaluate the influence of CSD and tablet porosity on plasma drug concentration for rivaroxaban. Additionally, the dose is optimized to achieve a target pharmacokinetic profile.

## 2. PROPOSED METHODOLOGY

### 2.1 The digital design framework

A framework is proposed for the integrated digital design of pharmaceutical formulations and dosing regimen, as illustrated in Figure 1. Within this digital design framework, a hybrid model is developed to predict systemic pharmacokinetics from formulation properties, while optimization approaches can be applied to explore optimal formulation design variables and dosing strategies, either independently or simultaneously.

The hybrid model is developed using a two-stage, sequential integrated strategy. In the first stage, a PBM-based tablet disintegration and dissolution model is independently employed to simulate the dissolution behavior of an immediate-release tablet. This model accounts for the impact of CMAs, including tablet porosity and API PSD. Parameters set a priori represent stomach-specific physiological conditions such as solubility, while adaptive parameters are calibrated using in vitro dissolution data under gastric-relevant conditions. Upon completion of tablet disintegration, the outputs from the first stage, including the dissolved API concentration and PSD, are used as initial conditions for the second stage.

In the second stage, the PBM-based dissolution model is embedded within a PBPK framework to describe the dissolution of remaining API particles in the gastrointestinal (GI) lumens. The PBM models predicts time-dependent dissolved API concentrations which act as state variables governing the absorption rate in the PBPK model. The PBPK model accounts for patient physiology and whole-body absorption, distribution, metabolism, and excretion (ADME). Physiological parameters are obtained from literature or databases, while a subset of adaptive parameters is calibrated using in vivo clinical plasma concentration data.

This two-stage strategy is based on the assumptions that (i) tablet disintegration predominantly occurs in the stomach, and (ii) GI transit after the disintegration is complete. These assumptions are based on the consideration that disintegration occurs rapidly relative to gastrointestinal transit and absorption timescale, thereby, treated as a fast initial process.

### 2.2 Stage I: The PBM-based tablet dissolution and disintegration model

The PBM-based tablet disintegration and dissolution model, adopted from a previous study [6], describes the temporal evolution of crystal populations in different status. It is formulated using two population balance equations (PBEs): one for the number density of bound crystals within the tablet, $n_{CB}(t,L)$, and one for released crystals $n_{CR}(t,L)$, both as functions of time $t$ and particle size $L$:

$$\frac{\partial n_{CB}(t,L)}{\partial t} = -S_1(t) n_{CB}(t,L) \tag{1}$$

$$\frac{\partial n_{CR}(t,L)}{\partial t} = -\frac{\partial (n_{CR}(t,L) D_c(t))}{\partial L} + S_1(t) n_{CB}(t,L) \tag{2}$$

Here, $S_1(t)$ denotes the tablet disintegration rate, which is described using the Washburn equation. In Eq. (3), $\theta$ represents the contact angle, $\gamma$ is surface tension, and $\delta$ denotes to viscosity of liquid. The effective pore length, $L_{eff}$, is estimated from cubit root of its total pore volume. Tablet porosity ($\varepsilon$) is correlated with effective capillary radius ($r_e$) through empirical relationship.

$$S_1(t) = \frac{1}{L_{eff}} \sqrt{\frac{r_e(\varepsilon)\gamma \cos\theta}{2\delta}} \cdot \frac{1}{2\sqrt{t}} \tag{3}$$

$D_c(t)$ represents the Noyes-Whitney based dissolution ra, in which $k_c$ is the dissolution rate constant, $C_{API}$ is the concentration of API, and $C_s$ is solubility:

$$D_c(t) = -k_c\left(1 - \frac{C_{API}}{C_s}\right) \tag{4}$$

The concentration of API dissolved in liquid can be calculated as follows:

$$\frac{dC_{API}}{dt} = -3\rho_c k_v \int_0^\infty L^2 n_{CR}(t,L) D_c(t)\, dL \tag{5}$$

where $k_v$ corresponds to crystal shape factor and $\rho_c$ represents crystal density.

### 2.3 Stage II: The coupled PBM-PBPK model

The PBPK model represents the human body using multiple anatomically relevant compartments, including: brain, lung, adrenal, thyroid, heart, liver, pancreas, spleen, kidney, skin, fat, skeleton, and the gastrointestinal (GI) tract, which are interconnected through blood flow or gastrointestinal transit. The bronchial is grouped

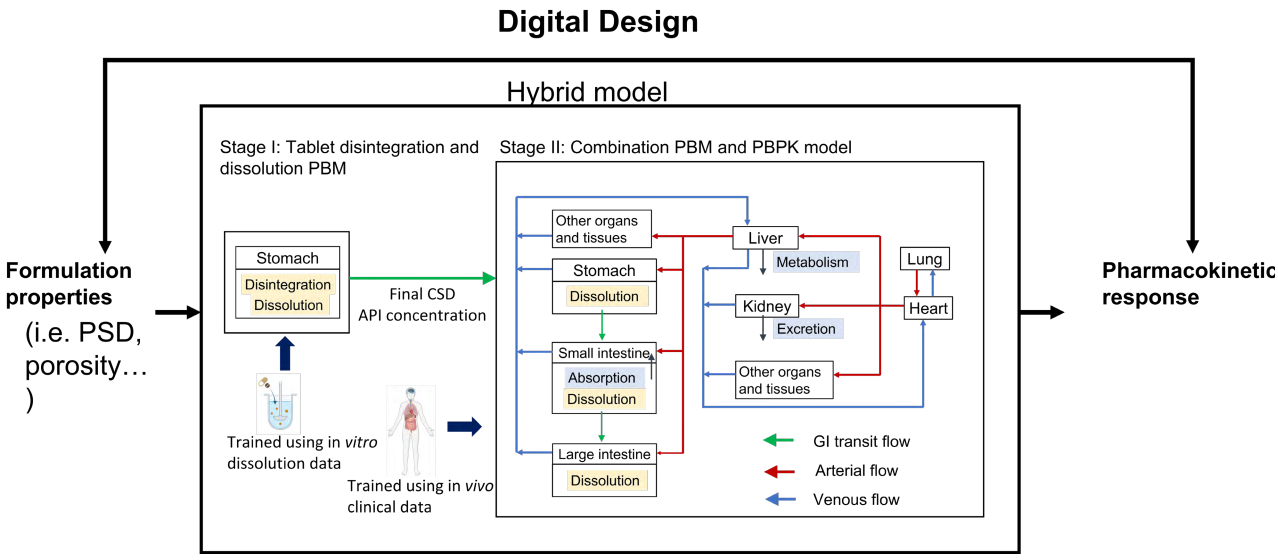

**Figure 1.** Digital design framework enabling the integrated optimization of drug formulation and dosing regimen design.

within the lung compartment; coronary and heart are unified due to their similar composition. The remaining organs and tissues such as bladder, gonads are lumped into a single compartment because of the low perfusion index (i.e. their minimal blood flow).

Each compartment is divided into three components: plasma, blood cell, and tissue sub-compartments. Drug exchange within a compartment occurs between plasma and blood cells and between plasma and tissue. Under the assumption that GI dissolution and absorption is the rate determining step, intra-compartment drug distribution is assumed to reach rapid equilibrium, thus characterized using partition coefficient $K_{eq}^{B}$ (blood cell-to-plasma) and $K_{eq}^{T}$ (tissue-to-plasma). Only the unbound fraction of drug can across cell membranes freely, thereby participating in the process of intra-compartment transport, metabolism and excretion. Consequently, the unbound plasma drug concentration in compartment $i$, $C_{u,i}(t)$, is selected as the primary state variable in the PBPK model. The corresponding total plasma drug concentration can be calculated from $C_{u,i}(t)$ using Eq. (6), where $f_u$ is the constant unbound fraction.

$$C_{u,i}(t) = f_u C_i(t) \tag{6}$$

Based on mass-balance principles, the temporal evolution of the unbound plasma drugs in compartment $i$ is governed by convective blood flow transport and can be expressed as:

$$\frac{dC_{u,i}(t)}{dt} = F_{in,i}C_{u,i+1}\varphi_{i+1} - F_{out,i}C_{u,i}\varphi_i \tag{7}$$

Here, $F_{in,i}$ and $F_{out,i}$ denote the volume arterial inflow and venous outflow rates of blood. The weighting factor $\varphi_i$ is a function of plasma, blood, and tissue volumes as well as the partition coefficients, and is used to calibrate the unbound plasma drug concentration to effective concentration associated blood flow, ensuring consistency in mass-balance calculations.

Three compartments are considered to represent the physiological structure of the GI tract: the stomach, small intestine, and large intestine. Within each compartment, a luminal sub-compartment is introduced to describe intraluminal particle transport, dissolution, and drug absorption. The GI compartments are interconnected through GI transit and systemic blood flow (Figure 2). A single luminal component is used for stomach and large intestine. However, small intestine lumen is subdivided into three segments — duodenum, jejunum, and ileum — to capture regional differences in luminal conditions, including surface area and absorption capacity. Within each luminal segment, a PBE is employed to describe the evolution of API particle size distribution influence by dissolution ($D_c(t)$) and transit flow.

$$\frac{\partial(n_j V_{L,j})}{\partial t} = f_{j-1}n_{j-1-}f_j n_{j-}\frac{\partial(n_j D_c V_{L,j})}{\partial L} \tag{8}$$

where $n_j$ denotes the API number density in $j^{th}$ lumen, $f_j$ and $V_{L,j}$ represents the luminal transit volume flow rate and the liquid volume, respectively.

The luminal liquid phase is assumed to consist primarily of solvent. The luminal liquid volumes of the small and large intestines are assumed to be constant due to bal-anced inflow and outflow. In contrast, the luminal volume of stomach is time-dependent variable because it lacks the upstream gastrointestinal supply. The PBE is coupled with a solute mass balance to describe the mass

of dissolved API ($m_{API,j}$) in each luminal compartment. This accounts for contributions from dissolution and luminal transit. It is noted that for the small intestine lumens, additional drug absorption terms are incorporated to represent systemic uptake:

$$\frac{dm_{API,j}}{dt} = f_{j-1}\frac{m_{API,j-1}}{V_{L,j-1}} - f_j\frac{m_{API,j}}{V_{L,j}} - \int_0^{\infty} k_c\rho_c L^2 n_j D_c V_{L,j}\, dL - P_1 - P_2 \quad (9)$$

Drug absorption is governed by two primary mechanisms: passive and active transport. Passive transport ($P_1$) is modeled as a permeability-limited flux driven by the concentration gradient across the intestinal membrane. The Passive transport rate is modeled by Fick's law equation, in which permeability ($K$) is considered. Active transport ($P_2$) process is mediated by membrane transporters and is modeled using Michaelis–Menten kinetics, where the kinetics is controlled by maximum transport velocity ($V_{max}$) and protein-drug affinity ($K_m$).

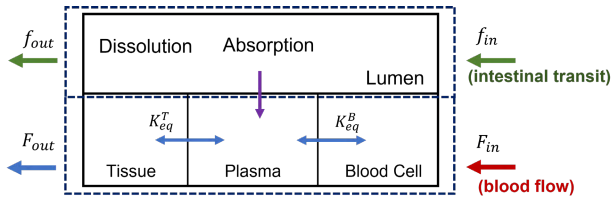

**Figure 2.** Small intestine compartment scheme.

Drug metabolism and excretion are modeled within the liver and kidney compartments, respectively. Since the hepatic metabolism is also an enzyme-mediated bioprocess, it is described using Michaelis–Menten equation. The excretion is considered in the kidney compartment by using the total renal clearance.

### 2.4 Dose regimen optimization formulation

For this study, the optimization problem is expressed as a non-linear constrained design problem. The objective function is to minimize the integral of the squared deviation between the predicted plasma concentration profile and a desired target concentration. The proper definition can be seen in following equations:

$$\min_x J(x,z,t) \quad (10)$$

$$s.t.\frac{dz}{dt} = f(x,z,t)\; t \in [0,T] \quad (11)$$

$$x_{lb} \le x \le x_{ub}$$

$$g_i(x,z,t) \le 0$$

Eq. (11) represents the combined PBM-PBPK model as a differential-algebraic equation (DAE) system. The decision variable $x$ denotes the dose amount, where $x_{lb}$ and $x_{ub}$ represent the lower and upper bounds, respectively. The treatment horizon $T$ is defined and considered fixed. In this case, the dosing interval is set to a constant value. The constraint equation $g_i$ represent the toxicity limit. This optimization problem is solved using PyNomad.

## 3. RESULTS AND DISCUSSION

Within this proposed framework, rivaroxaban, an anticoagulant, is selected as the model drugs. Rivaroxaban is classified as Biopharmaceutics Classification System (BCS) class II drug. BCS class II drugs have low solubility and high permeability, for which dissolution is considered to be the rate-determining step for absorption. The PBM-based tablet disintegration and dissolution model is first calibrated using published in vitro dissolution profiles (Figure 3) [7]. These two dissolution profiles were obtained from dissolution tests of commercial rivaroxaban tablet (Xarelto) in fasted-state simulated gastric fluid (FaSSGF) and intestinal fluid (FaSSIF). The parameters that set a *prior* are summarized in Table 1. The parameters of Washburn equation (Eq. (3)) were obtained from literatures [8].

For the input CMAs parameters, the CSD is assumed to follow a Gaussian distribution with a mean size reported in the literature [7], and the tablet porosity is assumed to be 0.85. The two fitted parameters, including dissolution rate constant and effective capillary radius constant, are shown in Table 2. The fitted results (Figure 3) show good agreement between the PBM model predictions and dissolution profiles.

**Table 1:** Parameters of the disintegration and dissolution PBM set to literature values

| Parameter | Description | Value |
|---|---|---|
| $C_{sg}$ | Solubility in FaSSGF | 0.011mg/mL |
| $C_{si}$ | Solubility in FaSSIF | 0.0121mg/mL |
| $\rho_c$ | Crystal density | 1491 kg/m$^3$ |
| $\gamma$ | Surface tension | 0.00723 N/m |
| $\delta$ | Liquid viscosity | 0.001Pa s |
| $\theta$ | Contact angle | 88.2° |

**Table 2:** Estimated parameter for the disintegration and dissolution PBM

| Parameter | Description | Value |
|---|---|---|
| $k_d$ | Dissolution rate constant | 0.039 μm/s |
| $r_e$ | Effective capillary radius | 1509 μm |

The corresponding average plasma drug concentration data were obtained from 40 patients under fasted conditions following a single 15-mg dose of rivaroxaban [7]. For PBPK model, the body characteristic parameters were calculated based on an average standard adult BMI value. Cardiac output and tissue mass were taken from published data [9] and rescaled to the reference BMI using allometric relationships.

Blood flow in each compartment is assigned

proportionally to tissue volume while ensuring the total flow matched cardiac output. For drug-specific parameters, tissue-to-plasma partition coefficients (K_eq^T) are predicted using the Rodgers and Rowland model [10], with the compound type set to neutral. The blood-to-plasma partition coefficients (K_eq^B) are set to be 0.8, following previous report [11]. The unbound fraction (f_u) is set as 0.1 [12].

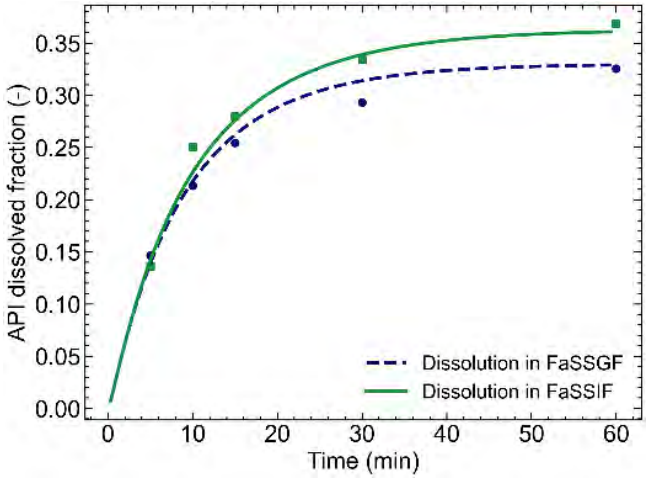

**Figure 3.** Fitted dissolution profiles under different physiological conditions.

For physiological processes, absorption is assumed to occur solely via passive transport. Given the high permeability of rivaroxaban, passive transport is expected dominate the absorption process. The permeability $(K)$ is set as an adaptive parameter. Hepatic metabolism is modeled using Michaelis-Menten equation, with $K_m$ fixed based on reported value for CYP3A4, which is one of the main enzymes responsible for rivaroxaban metabolism in liver [13]. To prevent overfitting, renal clearance for kidney excretion is also assigned based on literature [12]. The overall estimated model parameters are summarized in Table 3.

**Table 3:** Estimated parameter of PBPK

| Parameter | Description | Value |
|---|---|---|
| $V_{max}$ | Maximum velocity | 39.5 μg $min^{-1}$ $mL^{-1}$ |
| $K_1$ | Permeability 1 | 0.032 $min^{-1}$ |
| $K_2$ | Permeability 2 | 0.084 $min^{-1}$ |
| $f_i$ | Flow rate constant | 0.002 $min^{-1}$ |

The fitted results (Figure 4) demonstrate that the mean predicted plasma drug concentration profile of rivaroxaban from PBM-PBPK model showed good agreement with the observed data. The predicted area under the curve from the time of administration up to 48 hours ($AUC_{0-48h}$) is 1667 h μg/L and the ($AUC_{0-48h}$) for observed data is 1710 h μg/L. The plasma drug concentration increases initially due to dissolution and absorption, reaching a maximum around 2 hr after administration. It then gradually decreases as the metabolism and excretion dominate drug elimination.

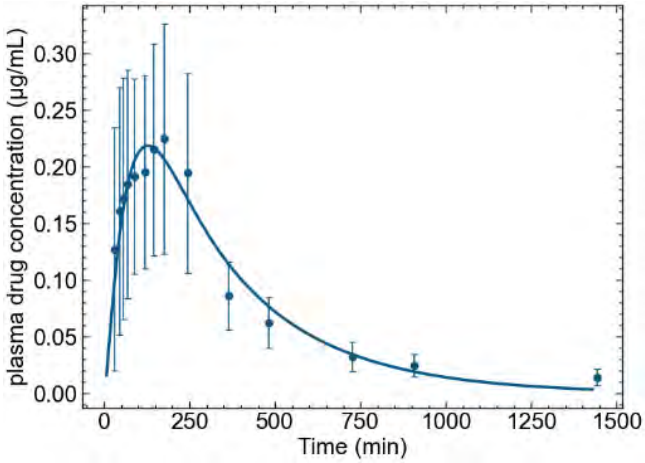

**Figure 4.** Fitted plasma drug concentration profile.

CSD is considered one of the most impactful tablet properties on dissolution [6], an increase in mean size reduces the dissolution due to the smaller available surface area. This slower dissolution decreases the drug concentration in the intestinal lumen, which in turn lowers the absorption rate. As a result, larger crystal sizes lead to lower maximum plasma concentration and a longer time to reach that maximum (Figure 5(a)). In contrast, tablet porosity primarily influences drug release through disintegration rate. The higher tablet porosity (smaller relative density) results in increased maximum plasma concentration, suggest the impact of initial concentration.

The calibrated model is further employed in the optimization problem. Figure 6 demonstrates the optimal dose regimen, in which the optimal single dose is 20.6 mg adminitered at a dose interval of 4 h over a 24 hr treatment period. In this study, the optimization problem is considered to focus only on the dose amount; however, within the proposed framework, it is possible to consider both the dose regimen and formulation properties. On one hand, the optimal dose regimen can be investigated under a fixed formulation design. On the other hand, a multi-objective optimization problem can be formulated to investigate the minimization of both cost (i.e., the amount of drug) and dosing regimen by considering both dose amount, dosing interval, and formulation properties as decision variables. The therapeutic window can be considered as a constraint not only for the maximum limit but also for the lower limit after the first dose.

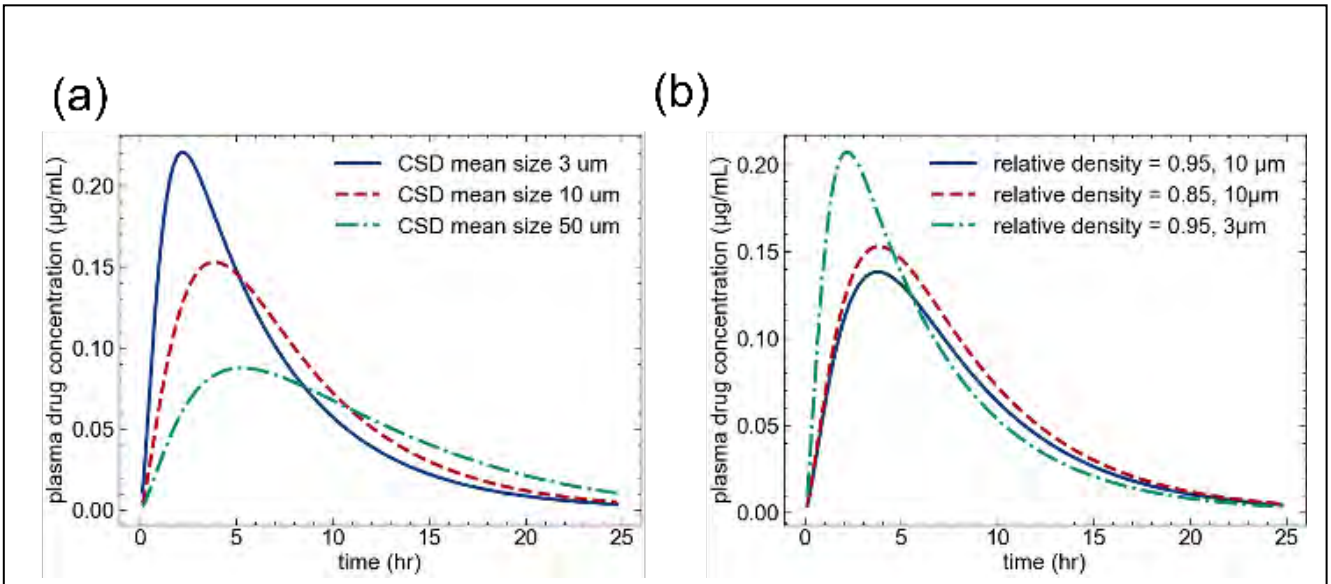

**Figure 5.** Impacts of (a) CSD and (b) tablet porosity on plasma drug concentrations.

## 4. CONCLUSION

This work presented an integrated PBM–PBPK digital design framework for rational formulation development and dosing strategy optimization of oral solid dosage forms. By mechanistically linking critical material attributes, including crystal size distribution and tablet porosity, to systemic pharmacokinetics, the framework enables quantitative assessment of formulation–performance relationships beyond traditional approaches. Application to rivaroxaban demonstrated that crystal size distribution has a dominant impact on plasma exposure. Furthermore, optimization of dose amount illustrated the framework's capability to support model-informed dosing decisions, highlighting its potential for data-efficient formulation and regimen design.

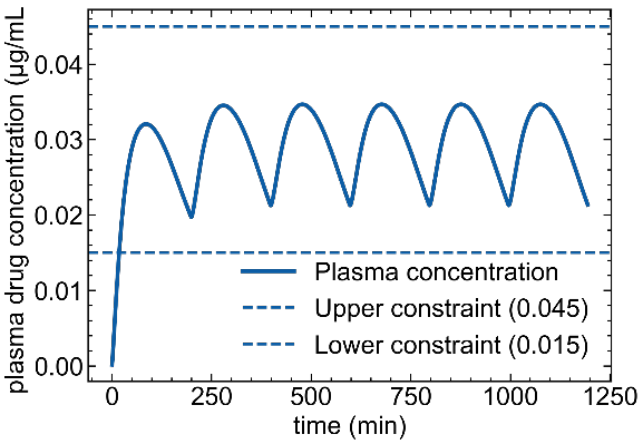

**Figure 6.** Dose regimen under the optimal dose amount

## ABSTRACT

Single-cell protein (SCP) fermentation efficiently converts carbohydrates into high-protein food products but typically relies on purified glucose. Better understanding of SCP growth on mixed sugar substrates could allow for use of lower-cost, less processed sugars and waste-derived feedstocks. Glucose–fructose mixtures are particularly relevant, as these are the main sugars in sucrose hydrolysates and are also common in many food and beverage waste streams. In this study, the growth of *Fusarium venenatum* on glucose–fructose mixtures was investigated experimentally and modelled using a lagged dual-substrate Monod framework incorporating inhibition of fructose growth by glucose. Batch fermentations were conducted at a fixed total sugar concentration (15 g/L) with four different initial substrate compositions. Model parameters were estimated using both single-experiment and multi-experiment fitting strategies using differential evolution and wild bootstrap uncertainty analysis. A shared parameter set reproduced biomass growth and substrate depletion across all conditions with only a modest increase in prediction error relative to individual fits. Bootstrap analysis revealed substantial correlation among uptake and inhibition parameters, while yield coefficients were well constrained. These results demonstrate that mixed-sugar growth of *F. venenatum* can be described using a unified kinetic model, supporting the feasibility of transitioning from glucose-only to mixed-substrate SCP fermentation.

## BACKGROUND

Single-cell protein (SCP) fermentation provides an efficient route for converting carbohydrate into high-protein food products and has the potential to reduce land use, greenhouse gas emissions, and resource intensity relative to conventional animal-based protein production [1]. Among SCP microorganisms, filamentous fungi such as *Fusarium venenatum* are of particular industrial interest because their mycelial morphology imparts a fibrous, meat-like texture desirable in food applications [2]. Industrial SCP processes commonly rely on refined carbohydrate feedstocks, most commonly glucose [3]. However, the use of single, purified substrates increases upstream processing requirements and cost and limits the flexibility of fermentation systems to utilise heterogeneous, low-cost and waste-derived carbon sources [4].

There are many potential feedstocks that are composed of mixtures of sugars rather than a single monosaccharide. Glucose–fructose mixtures are especially relevant, because sucrose hydrolysates and many sugar-rich food and beverage waste streams, including fruit-processing and soft-drink manufacturing waste streams are rich in these monosaccharides [5]. When glucose and fructose are both present, there will be an interaction between their metabolisms. Quantifying this interaction is essential for constructing accurate growth models and therefore, for the rational design of fermentation strategies based on mixed-sugar feedstocks.

In this work, we estimate the parameters of a dual-substrate growth model describing the growth of *F. venenatum* on glucose–fructose mixtures. By explicitly characterising mixed-substrate kinetics, this study provides a basis for assessing the feasibility of transitioning from glucose-based operation to mixed-sugar fermentation and so supports the development of more flexible, sustainable and economically robust SCP production

processes. This will help to inform industrial process design and operation, helping to derisk the transition to dual substrate fermentation, from existing glucose-based processes.

# METHODOLOGY

## Experimental Methodology

50 ml of fermentation media, as defined in Table 2, was transferred into a 250 ml baffled flask. Total sugar concentration was fixed at 15 g/L. Four different initial substrate compositions were investigated: 15 g/L glucose, 10 g/L glucose + 5 g/L fructose, 5 g/L glucose + 10 g/L fructose, and 15 g/L fructose. This was then inoculated with *F. venenatum* A3/5 spores to give an initial spore concentration of 10, 000/ml in each flask. Spores were generated by inoculating a 30g/l glucose/low-nitrogen RHM media with a plate culture provided by Quorn Foods, incubating this broth in a shaker-incubator at 28°C for 4 days, and then straining to remove fungal filaments.

To ensure sufficient oxygen transfer to the fermentation broth, oxygen and compressed air were blended to give a headspace oxygen concentration of 200% of the oxygen concentration of air (~42% oxygen by volume). This enriched air was humidified before it entered the fermentation flask to prevent evaporation losses. The oxygen flow rate was ~0.2 LPM and the air flow rate was ~0.5 LPM, for a total flow rate of ~0.7 LPM, or ~0.2 LPM /flask. This is substantially in excess of metabolic requirements, meaning that the headspace gas composition should remain unchanged during the fermentation. The flasks were vented to maintain atmospheric pressure throughout the fermentation.

PreSens SFR vario readers (PreSens, Germany) were used to measure biomass concentration, pH, and broth dissolved oxygen concentration during the fermentation runs. The biomass concentration measure is based on the reflectance of the fermentation broth, while pH and dissolved oxygen are determined based on pre-calibrated optical sensor spots. Biomass and pH concentration were recalibrated after each experiment using the start and end points. At the endpoint, to determine the biomass concentration, the fermentation broth from each flask was vacuum filtered through a pre-dried, pre-weighed fine fibre-glass filter. It was then rinsed with deionised water and then dried to constant mass in a 65 °C oven, before the filter was reweighed using a precision balance.

Each experiment was conducted in triplicate. During each run, 300 µL samples were collected from the flasks at regular intervals, with sampling concentrated in the exponential growth phase, for substrate analysis by high-performance liquid chromatography (HPLC). The HPLC parameters are given in Table 3. Before the fermentation experiments, the linear relationship between peak area and substrate concentration was confirmed, and calibration curves for glucose and fructose were established over the full concentration ranges observed. The fermentation was allowed to continue until HPLC analysis showed the sugar substrates had been fully depleted.

Oxygen uptake rate (OUR) was calculated according to Equation 1, where $kLa$ is the volumetric mass transfer coefficient, $C_{O_2}$ is the measured dissolved oxygen concentration in the fermentation broth, and $C^*_{O_2}$ is the equilibrium dissolved oxygen concentration based on Henry's Law. $kLa$ was determined using the gassing-out method, in which dissolved oxygen was first reduced to near zero by nitrogen sparging and then monitored during re-aeration using a PreSens DO sensor.

$$OUR = kLa * (C^*_{O_2} - C_{O_2}) \quad (1)$$

Biomass growth rate was estimated by applying a Savitzky–Golay differentiating filter [6] to the biomass concentration time series, in order to reduce the effect of noise in the biomass concentration measurement. The specific growth rate was estimated by linear regression of $ln(X)$ against time within a centred sliding window, where $X$ is the biomass concentration, with the local slope taken as the instantaneous growth rate.

**Table 1:** Experimental Parameters

| Parameter | Value |
|---|---|
| Broth Volume | 50 ml |
| Shaker Orbit | 20 mm |
| Shaker Rotational Speed | 220 RPM |
| Incubation Temperature | 28 °C |
| Headspace Oxygen Concentration | 200 % air saturation |
| Volumetric Mass Transfer Coefficient ($kLa$) | 96 /h |

**Table 2:** Fermentation Media Components

| Media Component | Amount per Flask (ml) |
|---|---|
| Rank Hovis McDougal Media (RHM) [7] with 30 g/l $KH_2PO_4$ | 46 |
| Polypropylene Glycol (5% w/w) Solution | 0.5 |
| Tween-80 (1% w/w) Solution | 0.5 |
| Glucose (25% w/v) | 3-x |
| Fructose (25% w/v) | x |
| $x \in \{0, 1, 2, 3\}$ | |

**Table 3:** HPLC Parameters

| Parameter | Value |
|---|---|
| Column | Bio-Rad Aminex HPX-87H |
| Detector | Shimadzu RID-20A |
| Mobile Phase | 0.001 M $H_2SO_4$ |
| Run Time | 35 min |
| Column Temperature | 30°C |
| Flow Rate | 0.4 mL/min |
| Injection Volume | 5 mL |

## Computational Methodology

Biomass growth was modelled using a lagged dual-substrate Monod [8] framework, with glucose assumed to be the preferred substrate. Accordingly, the model includes inhibition of fructose utilisation by glucose, but no inhibition of glucose utilisation by fructose. During the lag phase of duration $\lambda$, biomass growth and substrate consumption were assumed to be negligible, such that $\dot{X} = \dot{S}_1 = \dot{S}_2 = 0$. After the end of the lag phase, the system dynamics are given by:

$$\dot{X} = (\mu_1 + \mu_2) X \quad (2)$$

$$\dot{S}_1 = \frac{-\mu_1}{Y_1} X \quad (3)$$

$$\dot{S}_2 = \frac{-\mu_2}{Y_2} X \quad (4)$$

with specific growth rates:

$$\mu_1 = \mu_{max,1} \frac{S_1}{S_1 + K_{S1}} \quad (5)$$

$$\mu_2 = \mu_{max,2} \frac{S_2}{S_2 + K_{S2}} \frac{1}{1 + \frac{S_1}{K_I}} \quad (6)$$

Here, $X$ denotes biomass concentration, $S_1$and $S_2$ are the concentrations of glucose and fructose, respectively, $\mu_{\max,1}$ and $\mu_{\max,2}$ are the maximum specific growth rates, $K_{S1}$and $K_{S2}$are the Monod half-saturation constants, $K_I$ is the glucose inhibition constant for fructose growth and $Y_1$and $Y_2$ are yield coefficients. A step-function lag phase, as described in [9], was included to account for delayed onset of growth. The $\frac{1}{1+\frac{S_1}{K_I}}$ term models catabolite repression of fructose by glucose, as in [10]. Note that $K_I$ is the minimum glucose concentration sufficient to halve the fructose-related specific growth rate, $\mu_2$. Therefore, smaller values of $K_I$ indicate stronger inhibition.

Model parameters were estimated using two fitting strategies: (i) individual fits to each experiment, and (ii) a combined multi-experiment fit. In the multi-experiment fit, seven kinetic parameters ($\mu_{\max,1}, \mu_{\max,2}, K_{S1}, K_{S2}, K_I, Y_1$, and $Y_2$) were constrained to be identical across all four experiments, while the lag time and initial biomass concentration were estimated separately for each experiment, giving a total of 15 fitted parameters. The values obtained from this shared-parameter fit were subsequently compared with those obtained from the single-experiment fits to assess the consistency and robustness of the kinetic estimates.

Parameter estimation was performed by minimising a weighted sum of squared errors across biomass and substrate measurements from triplicate flasks. To account for the higher sampling frequency of biomass measurements relative to substrate measurements, substrate residuals were weighted by $w_S = \frac{n_X}{n_S}$, where $n_X$ is the number of biomass measurements and $n_S$ is the total number of substrate measurements. This weighting equalises the aggregate contribution of the substrate data to that of the biomass data.

Equation 7 defines the single-flask error, with $i \in \{1, \dots, 4\}$ indexing the initial substrate condition, $f \in \{1, 2, 3\}$ the flask replicate, $k$ the biomass observation time index, and $j$ the substrate observation time index. The error for each initial substrate condition was then $E_{\mathrm{i}} = \sum_{f=1}^{3} E_i$. This is used as the objective function for the single experiment fit. For the multi-experiment fit, the objective function was $E_{\mathrm{tot}} = \sum_{i=1}^{4} E_i$.

$$E_{i,f} = \sum_{k=0}^{n_x-1} \left( X_{i,f}^{pred}[k] - X_{i,f}^{obs}[k] \right)^2 + \sum_{j=0}^{n_s-1} w_s \left( S_{i,f,1}^{pred}[j] - S_{i,f,1}^{obs}[j] \right)^2 + \sum_{j=0}^{n_s-1} \mathrm{w_s} \left( S_{i,f,2}^{pred}[j] - S_{i,f,2}^{obs}[j] \right)^2 \quad (7)$$

**Table 4:** Kinetic Parameter Bounds

| Parameter | Lower Bound | Upper Bound | Type | Unit |
|---|---|---|---|---|
| $\mu_{max,1}$ | 0.01 | 0.6 | Global for shared fit | /h |
| $\mu_{max,2}$ | 0.01 | 0.6 | | /h |
| $K_{S1}$ | 0.001 | 5.0 | | g/L |
| $K_{S2}$ | 0.001 | 5.0 | | g/L |
| $K_I$ | 0.001 | 5.0 | | g/L |
| $Y_1$ | 0.01 | 1.0 | | g/g |
| $Y_2$ | 0.01 | 1.0 | | g/g |
| $\lambda$ | 0 | 60.0 | Experiment specific | h |
| $X_0$ | 0 | 0.5 | | g/L |

Optimisation was performed using differential evolution as implemented in SciPy [11], using the best1bin strategy, a population size of 50, mutation dithering over [0.5, 1.0], and a crossover probability of 0.7, followed by local polishing with L-BFGS-B. The bounds used for each parameter are set out in Table 4.

Confidence intervals for the parameter estimates were constructed using the wild bootstrap method [12], which does not require the assumption of homoscedastic residuals. Per-observation residuals were first computed from the fitted model on the original data. For each of 50 bootstrap replicates, a synthetic response dataset $y_n^*$was generated by adding randomly signed residuals to the model fitted values. Specifically, if $\hat{y}_n$ denotes the predicted value at observation $n$ and $\hat{e}_n = y_n - \hat{y}_n$the corresponding residual, then the bootstrap data were constructed as $y_n^* = \hat{y}_n + w_n\hat{e}_n$, where $w_n \in \{-1, +1\}$ is a Rademacher random variable taking each value with equal probability. This procedure preserves the magnitude and structure of the original residuals while randomly reversing their sign, thereby maintaining the mean trend and accommodating heteroscedastic error behaviour. Each synthetic dataset was then re-fitted using the same differential evolution procedure, and the distribution of the resulting parameter estimates across all replicates was used to construct 95% bootstrap confidence intervals.

# RESULTS & DISCUSSION

## Experimental Results & Discussion

The experimental results in Figure 2 show good repeatability within an experiment, particularly for the substrate and biomass concentrations, as well as pH. There are greater differences between replicates for oxygen concentration, oxygen uptake rate (OUR), biomass growth rate and specific growth rate. With respect to biomass growth rate and specific growth rate (SGR), part of this is probably due to noise in the biomass concentration readings. However, despite this, many of the results are as would be expected: the peak OUR and SGR are highest for the pure glucose substrate, and monotonically reduce as the initial glucose concentration is reduced in favour of fructose. The SGR results suggest, in contrast to the lag model, which assumes that SGR is maximum at the very start of the exponential growth phase, that there is a gradual ramp up in SGR, until the falling substrate concentrations begin to reduce SGR again.

The length of the lag phase doesn't follow the expected pattern, with a shorter lag phase for the fructose-glucose mixture than for the pure glucose. This is believed to be driven by differences in the age and viability of the inoculation conidia.

The HPLC results show some anomalies, with the substrate concentrations not always monotonically decreasing with time. This could be due to heterogeneity in the fermentation broth, or HPLC-related factors such as peak overlap with other broth components, baseline drift, or small variations in sample preparation and integration that introduce apparent fluctuations in the measured concentrations.

## Computational Results & Discussion

The MAE for the multi-experiment fit was larger than that of the single-experiment fits, as expected due to the reduced number of free parameters. However, despite the single-experiments fit providing many more degrees of freedom, since the single-experiment fits allow independent estimation of kinetic parameters for each dataset, whereas the multi-experiment fit enforces a shared parameter set, the difference in the magnitude of the MAE between the two is slight, at c. 30% higher total MAE for the multi-experiment fit compared to the single experiment fit. MAE for the multi-experiment is still below 0.5 g/l.This suggests that the model is flexible enough to describe growth rates with various initial glucose and fructose concentration, without requiring re-estimation of kinetic parameters for each initial condition. From a process modelling perspective, this supports the use of a globally parameterised model for predictive simulations and control design.

Figure 4 shows that there is considerable variation in the single experiment parameter estimates, suggesting weak identifiability from individual datasets, particularly as some of the parameters estimated based on single experiments seem to be outside the plausible range. For example, the $Y_2$ estimate from the Glu 10 g/l + Fru 5 g/l is nearly 1. The parameters estimated on data from all four experiments are more reliable. However, the $K_{S,1}$estimate would be expected to be smaller than the $K_{S,2}$estimate, as glucose is the favoured substrate.

Comparison of the median $\mu_{\max,1}$and $\mu_{\max,2}$ estimates (Figures 4 and 6) with the observed specific growth rates under pure glucose and pure fructose

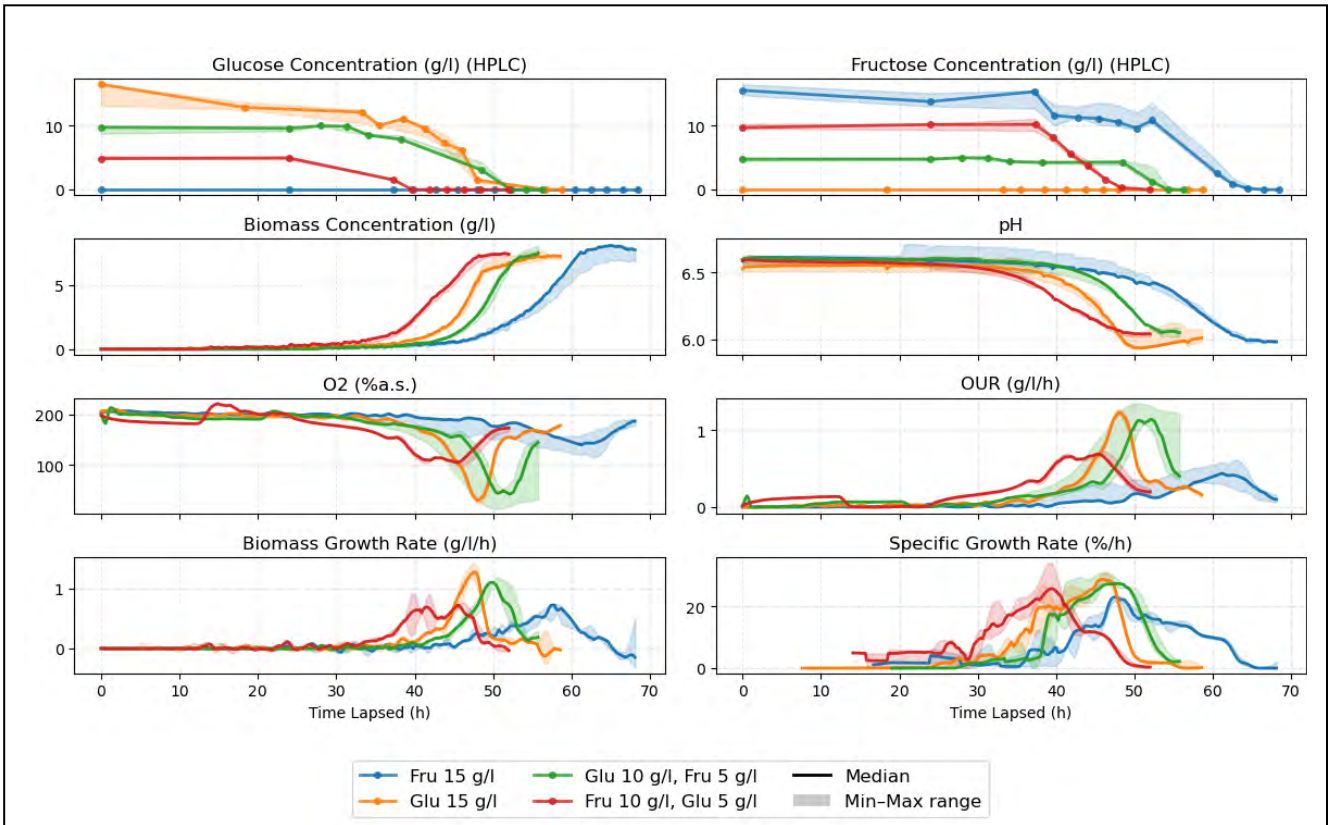

**Figure 2.** Experimental results for glucose-fructose mixed-substrate batch fermentations. Substrate and biomass concentrations, as well as pH and $O_2$, were directly measured. OUR, biomass growth rate and specific growth rate were calculated based on the measurements as explained in the Methodology.

conditions (Figure 2) shows that the peak specific growth rates exceed the corresponding estimates. This reflects the modelling assumption of a step change in growth rate at the end of the lag phase, which is not supported by the data. Instead, the specific growth rate increases gradually to a maximum, leading to underestimation of the true peak growth rate by $\mu_{\max,1}$and $\mu_{\max,2}$.

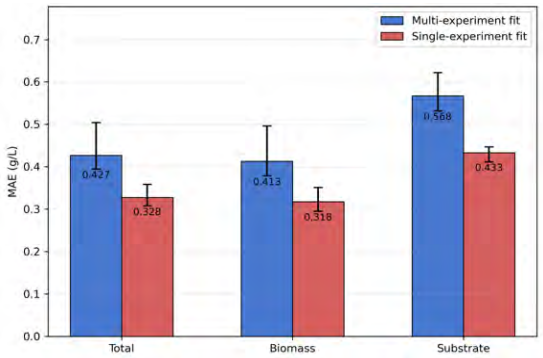

**Figure 3.** Mean absolute error (MAE) of multi-experiment and single-experiment model fits evaluated against observed biomass and substrate concentrations. Bar heights represent the median MAE across 20 wild bootstrap replicates and error bars denote the 95% confidence interval.

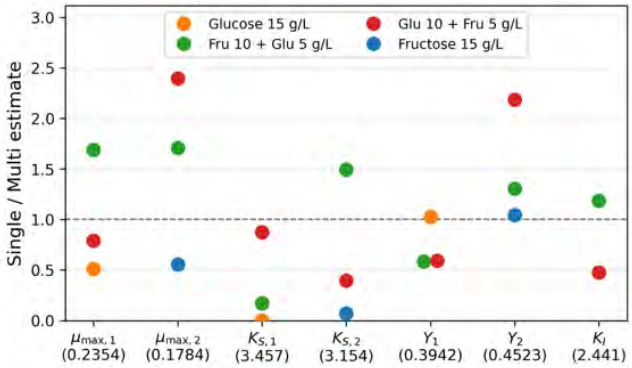

**Figure 4.** Single-experiment parameter estimates (median of 20 bootstrap replicates) for each experimental condition, normalised by the corresponding multi-experiment estimate (median of bootstrap replicates). A value of unity indicates agreement between the two fitting approaches.

Importantly, the multi-experiment model reproduces the qualitative and quantitative features of the growth and substrate depletion dynamics across all 4 experiments (Figure 5), capturing the timing and shape of the exponential growth phase and the coupled consumption of glucose and fructose. Deviations between the

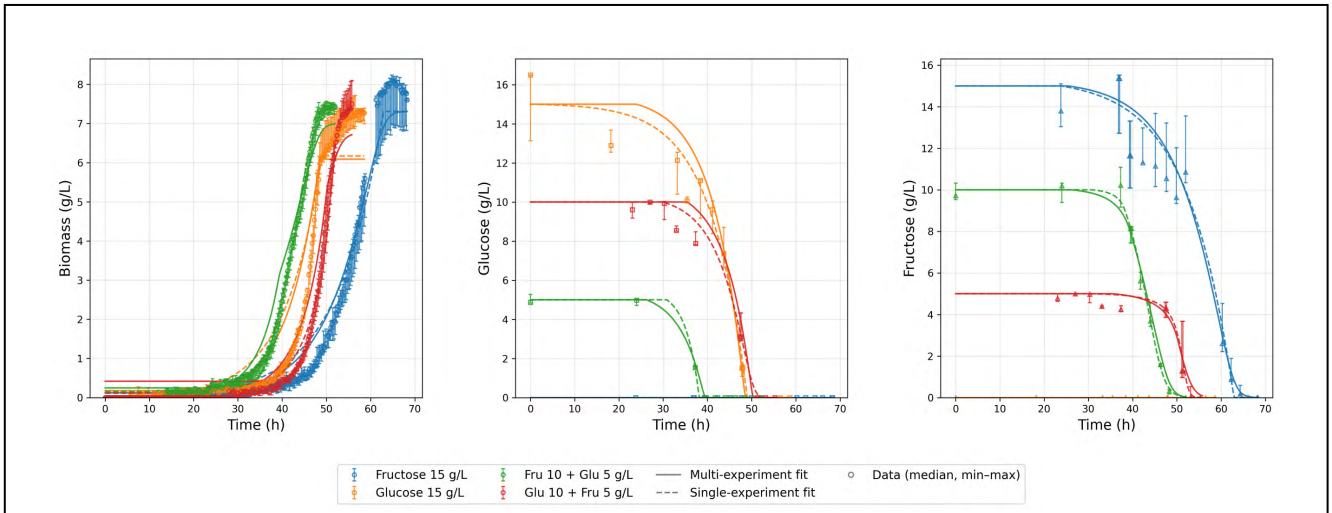

**Figure 5.** Comparison of single-experiment and multi-experiment model fits against original experimental data for a lagged dual-substrate Monod kinetic model, for batch fermentation across 4 different initial substrate conditions.

model predictions from the shared parameters and the experiment-specific parameters are generally small.

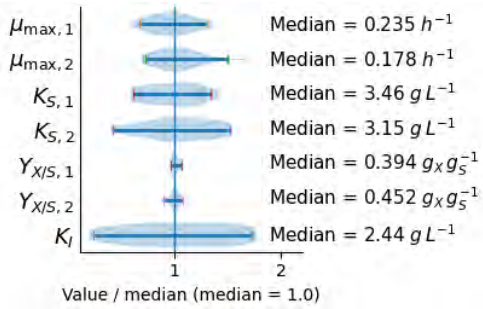

**Figure 6.** Median value and 95% confidence intervals for glucose-fructose dual substrate growth parameters based on wild bootstap method with 20 replicates.

The bootstrap results show considerable residual uncertainty in many of the parameter estimates. With the exception of the two yield coefficients, the redundancy in the model and the limited amount of substrate concentration data make it difficult to disentangle the effects of $\mu_{\max,1}$ and $K_{S,1}$ in the case of glucose growth, and $\mu_{\max,2}$, $K_{S,2}$ and $K_I$ in the case of fructose growth. This can be seen in the Spearman Correlation Heatmap, which shows strong positive correlation between $\mu_{\max,1}$ and $K_{S,1}$, as well as $\mu_{\max,2}$ and $K_{S,2}$, and strong negative correlation between $K_I$ and both $\mu_{\max,2}$ and $K_{S,2}$. As a result, the observed fructose uptake can be equivalently explained by a reduced $\mu_{\max,2}$, a high effective $K_{S,2}$, or strong glucose inhibition (low $K_I$), limiting mechanistic interpretability of the fitted parameters.

## CONCLUSION

This study investigated the growth of *F. venenatum* on glucose–fructose mixtures and quantified the associated kinetics using a lagged dual-substrate Monod model with glucose inhibition of fructose utilisation. Although noise in derived rates and minor non-monotonicity in HPLC measurements introduced uncertainty, the overall trends were reproducible across replicates and aligned with expected physiological behaviour. Notably, the specific growth rate exhibited a gradual increase during early exponential growth rather than an instantaneous maximum, indicating that a strict step-change assumption at the end of the lag phase may be an oversimplification of the underlying dynamics.

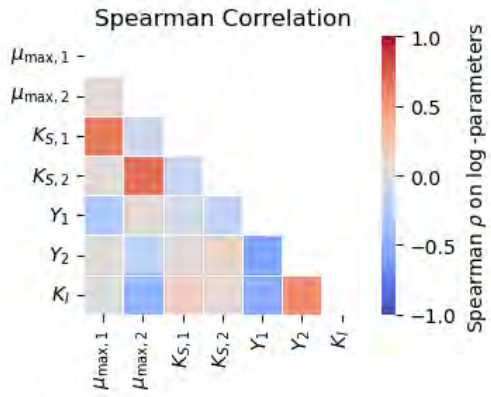

**Figure 7.** Heatmap of pairwise Spearman rank correlation coefficients between kinetic parameter estimates across wild bootstrap replicates, indicating the degree of parameter interdependence in the fitted model.

Parameter estimation using both single-experiment and multi-experiment fitting demonstrated that a common set of kinetic parameters can describe growth across a range of initial substrate compositions with only a modest loss of accuracy relative to individually fitted models. This supports the suitability of a unified dual-

substrate framework for representing mixed-sugar growth in *F. venenatum*. Wild bootstrap analysis revealed substantial uncertainty and correlation among several kinetic parameters, particularly those governing fructose uptake and inhibition, reflecting structural redundancy in the model and limited resolution in the available substrate data. By contrast, yield coefficients were comparatively well identified, suggesting that overall carbon conversion efficiency is more robustly constrained than individual uptake kinetics.

Together, these results provide quantitative evidence that glucose–fructose mixtures can be modelled within a mechanistic kinetic framework and that mixed-substrate operation can be described without re-parameterising the model for each feed composition.

This contributes to the development of predictive tools for SCP fermentations using heterogeneous sugar streams and supports the feasibility of transitioning from glucose-only processes to mixed-sugar feedstocks.

## FUTURE WORK

Future work will investigate the applicability of this model to continuous fermentation of *F. venenatum* on glucose-fructose mixtures. This is a more industrially relevant mode of operation, and will help to address the key question of whether significant simultaneous co-utilisation of glucose and fructose can be realised in industrially relevant conditions.

## ACKNOWLEDGEMENTS

The authors gratefully acknowledge funding from Quorn and the BBSRC, under project reference 2725958. Additionally, the authors would like to thank Mark Taylor (Quorn Foods) for technical advice, and material support, such as access to the *F. venenatum* A3/5 strain.

## ABSTRACT

Decisions taken throughout a bioprocess lifecycle are often guided by heuristic knowledge that is difficult to summarize and sort, scattered across heterogeneous tools and documents, and partly retained as tacit expert mental models alongside fragmented computational models. This fragmentation remains a central barrier to reproducibility, transparent provenance, and systematic reuse of prior learning across comparable development projects. In this paper, it is argued that a key missing link toward Bioprocessing 5.0 is the digitalization of FAIR knowledge through a Cognitive Digital Thread that couples semantic knowledge graphs with AI methods to connect experimental data, protocols, workflows, and decision rationale with mathematical models and digital twins in a machine-actionable and auditable manner. A digitalization roadmap is outlined as a sequence of capability stages—from local device and data integration, to reproducible workflow execution and metadata capture, to semantic knowledge digitalization and explainable reasoning, to secure cross-institutional exchange of FAIR data and knowledge (optionally anchored via permissioned blockchain and smart contracts for authorship, versioning, and IP provenance), and finally to human-in-the-loop collaborative environments for model-informed bioprocess design and control. The result is a layered conceptual architecture that clarifies required functions and dependencies and provides a practical framework for implementing cognitive decision support across the bioprocess lifecycle.

**Keywords**: Bioprocess development, Industry 5.0, Cognitive Digital Thread, Information Management, Supply Chain, Blockchain, Knowledge Graphs

## INTRODUCTION

Industry 4.0 introduced powerful technologies with connectivity, automation, digital twins (DTw) [1, 2], and data-driven control, that raised expectations for more robust, scalable, and faster bioprocess development by reducing uncertainty across scales and development stages through continuously linking evidence, models, and decisions. However, while physical and digital integration of systems has significantly advanced, expectations have largely fallen short in practice. While device integration, automation and data acquisition have improved, the inherent complexity of biological systems, limited and heterogeneous datasets, and missing semantic structure are currently the bottleneck in the development of bioprocesses. Experimental workflows in bioprocess engineering still rely heavily on manual steps, which are often not captured, resulting in experimental knowledge that is incompletely documented, metadata fragmented across institutional data silos, and critical decisions that are rarely traceable across development stages. The absence of semantic connectivity between devices, data streams, experimental workflows, and computational models across laboratories and IT systems means that data are exchanged without shared meaning [4], which undermines the reproducibility, robustness, scalability, and cross-institutional collaboration [3]. This results in experiments that cannot be reproduced, which imposes substantial hidden costs in research and development, as experiments must be repeated, process knowledge must be re-established during scale-up and technology transfer, and previously generated insights are lost due to insufficient data contextualization. Beyond waste of resources, these inefficiencies increase the risk of failure during development, delay time-to-market, and limit systematic learning

across projects and institutions. These limitations expose a fundamental mismatch between technology-centric Industry 4.0 concepts and the knowledge-intensive nature of bioprocess engineering, motivating a shift towards the human-centric Industry 5.0 paradigm [5, 6]. In this context, the concept of the Cognitive Digital Thread (CDTh) can be understood as a qualitative extension beyond Industry 4.0: a human-centric digital infrastructure that links data, models, decisions, and expertise across the bioprocess lifecycle, addresses semantic fragmentation, and establishes the foundations for reproducibility and provenance in experimentation and throughout the complete developmental pipeline. This contextualization turns datasets gathered at different experimentation scales into a reproducible development path by preserving their context from experimental planning through execution context, and up to analysis. Taken from system engineering, the digital thread in bioprocess engineering materializes as a cognitive cyber-physical system, in which physical experimentation, computational models, and human decision-making are tightly coupled through continuous digital feedback. Finally, to foster collaborative research and knowledge transfer across institutions, the system must be extended with a blockchain-enabled infrastructures [7, 8] in which smart contracts ensure transparent and verifiable provenance of intellectual property, authorship, and contributions.

## From Digital Thread to Cognitive Digital Thread

A Digital Thread (DTh) is a structured and persistent information framework that links data, models, and decisions across the full lifecycle of a system, product, or process so that information remains traceable, interpretable, and reusable over time. The concept emerged in the early 2010s, most prominently in aerospace and defense [9], where long lifecycles, safety critical requirements, and fragmented engineering workflows created a need for end-to-end accountability and configuration control. In these settings, the core use case was to reduce information loss between lifecycle phases, enable traceability from requirements to implementation and maintenance, support compliance and auditability, and eliminate redundant data entry and manual translation across tools. Closely aligned with Model Based Systems Engineering and Product Lifecycle Management, Digital Thread approaches have since been applied beyond aerospace, where complex product structures and strict quality requirements similarly benefit from lifecycle wide traceability [10].

A Cognitive Digital Thread (CDTh) [11] extends this continuity beyond connectivity by making domain knowledge and human decision making first class, machine actionable elements of the thread to reinforce contextual understanding and provenance. This cognitive dimension arises from combining semantic representations such as KGs with semantic web technologies [4], interoperable lifecycle linking mechanisms, and AI supported reasoning and learning, so that the system can store artifacts and contextualize them, relate them, and reactivate them for decision support. In bioprocess engineering this is particularly valuable because biological variability, small and heterogeneous datasets, and pervasive manual steps often lead to poorly captured context, fragmented metadata, and persistent data silos, which hamper reproducibility and limit technology transfer. A CDTh addresses these bottlenecks by explicitly linking experimental conditions, workflow intent, model assumptions, digital objects, and experimental or computational outcomes into an evolving knowledge base. By this, the CDTh supports reproducible workflows, interoperable models/DTs, and traceable decision provenance across scales and organizations. DTs, for example, fit naturally within the structure of the CDTh [1, 2] as lifecycle specific virtual representations of physical processes, while the CDTh provides the overarching “information flow” that connects multiple twins with experimental evidence and design rationale. In collaborative settings, the CDTh can be complemented by permissioned blockchain infrastructures to anchor provenance and governance for shared digital objects (models, designs, datasets, etc.) enabling knowledge exchange across institutional boundaries while preserving authorship and accountability is mandatory for trust [7, 8].

Enabling technologies for semantic digitalization in a DTh include FAIR-by-design data practices with persistent identifiers, rich metadata, and controlled vocabularies captured at execution time, as well as metadata standards and ontologies that provide structured terminology for process descriptions, experimental context, and model lineage. Workflow and device integration are required to automate the capture of run context and intent, while provenance mechanisms such as audit trails and versioned artifacts preserve who generated which data, when, with which methods, models, and assumptions. Together, these components operationalize the reproducibility loop of bioprocess development, where experiments, models, and decisions continuously inform each other through explicit, machine-readable context.

It is worth noting the difference between a DTh and a digital twin (DTw). The latter is an adaptive representation of the system based on information artifacts or models that continuously resembles the structure, state, and behavior of a natural, engineered, or social system. For accuracy, this representation must be dynamically updated with data from its physical twin counterpart to guarantee its predictive capability for real-time decision-making in monitoring, optimization and control tasks. The bidirectional interaction between the virtual and the physical twins is central to the concept of DTw [1].

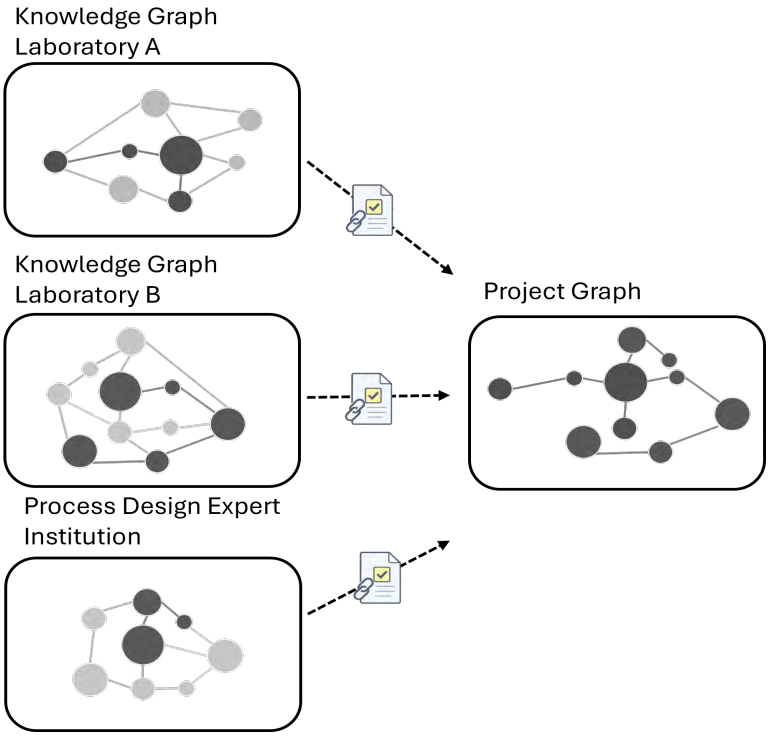

**Figure 1.** Federated knowledge integration across multiple local knowledge graphs. Selected nodes and relations from each local graph are curated and merged into a shared project graph that serves as the project's single source of truth. Access control, versioning, and provenance of the contributed graph fragments are governed by smart contracts.

## Blockchain enabled IP provenance

Blockchain technology is a distributed digital ledger that is jointly maintained by multiple participants in a network. Instead of relying on a single central authority, the decentralized ledger is updated through a consensus process, and each new record is cryptographically linked to previous records. This structure makes the ledger tamper-proof, since altering past entries would require changing the entire chain consistently across the network. In collaborative research settings where trust is paramount, blockchain technology is therefore primarily useful as a shared, auditable record of contributions, IP ownership and transfer transactions, and full traceability of decision making [7, 8].

A blockchain-enabled CDTh can enable trusted data and knowledge exchange between research institutions and companies of different sizes by providing a provenance layer while keeping sensitive assets protected under local control. High volume experimental datasets, models, process designs and protocol packages remain off chain in controlled repositories such as institutional storage, encrypted object stores, or secure data spaces. The blockchain stores on chain only compact, verifiable evidence, descriptive metadata, including cryptographic hashes, timestamps, identifiers, and signed metadata that describe authorship, ownership, version, and intended usage context. Smart contracts provide the governance logic for automated collaboration by recording transfers as auditable events and by encoding usage conditions, such as attribution requirements and rules for version supersession, while retrieval of off-chain artifacts is mediated through secure authorization mechanisms [7, 8].

To exchange knowledge related digital objects in collaborative bioprocess engineering, such as a DTw of a bioreactor or a scale up ready process model package, IP NFTs can build on this infrastructure by representing each object as a uniquely identifiable digital asset on a consortium blockchain. The token acts as a persistent reference to the dataset and its contextual metadata, while transfer events record who created the asset, who shared it, and when a specific version was exchanged, enabling traceability of dataset lineage and authorship across institutional boundaries [7, 8]. Smart contracts can register new versions over time and trigger transparent update events that reference evolving off chain states, which is particularly relevant for DTw that are refined as new experimental results and model updates become available [1, 2].

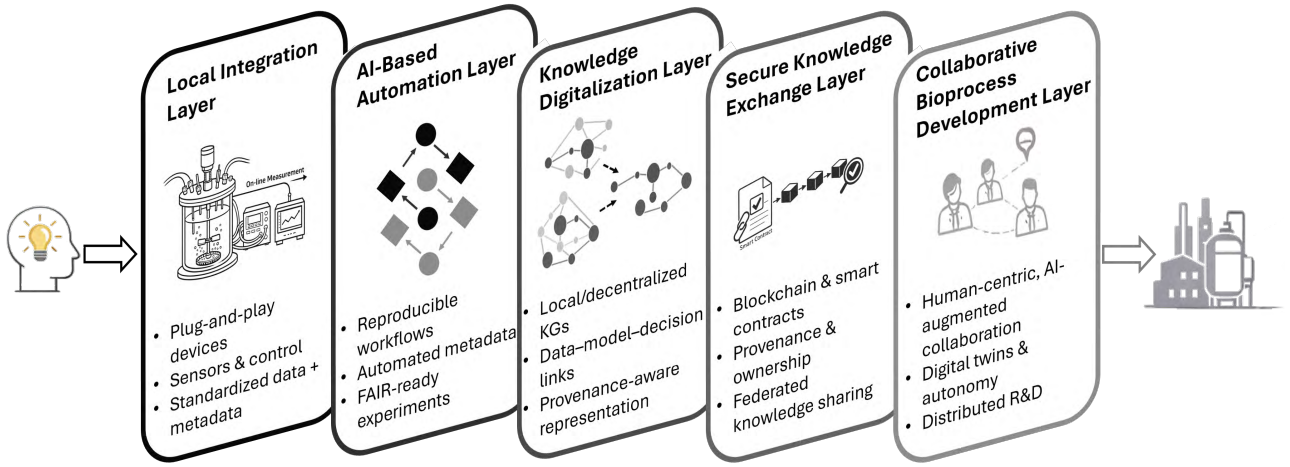

**Figure 2. Five-layer architecture of a Cognitive Digital Thread for bioprocess engineering.** Including (1) Local Integration (device connectivity, standardized data capture), (2) AI-Based Automation (reproducible workflows, automated metadata generation), (3) Knowledge Digitalization (local/decentralized knowledge graphs linking data–models–decisions with provenance awareness), (4) Secure Knowledge Exchange (governance of provenance, ownership, and access via blockchain and smart contracts), and (5) Collaborative Bioprocess Development (human-centric, AI-augmented collaboration). Together, the architecture enables a coherent digital pathway from scientific hypotheses to efficient biotechnological production.

## From Silos and Lakes to Semantic Graphs

Digitalization in bioprocess engineering still operates in a fragmented landscape: experimental evidence is distributed across instruments, vendor-specific software, ELN and LIMS entries, spreadsheets, locally maintained scripts, and experimental inputs computed by several control and optimization algorithms [3]. These data silos constrain reuse and comparison of experiments, hinder systematic learning across projects, and complicate technology transfer because critical context and decision rationale remain scattered or implicit. Data lakes can centralize heterogeneous files and time series streams, yet they often lack sufficiently rich, standardized, and machine-actionable metadata, which limits interpretability for both domain experts and AI pipelines. In response, the trajectory toward semantic graphs treats contextualization as the primary design goal: Knowledge Graphs (KG) represent entities such as runs, strains, media, equipment, sampling events, analytics, models, and decisions as linked objects with explicit relationships and time-dependent context [4, 12]. This graph-based structure supports reproducibility as reconstruction, because the experimental and computational conditions that produced a result become queryable and transferable across scales and institutions [12].

At the project or facility level, CDThs can connect run-specific artifacts such as ELN records, instrument logs, bioreactor control data, Manufacturing Execution System events, and analytical Quality Control results into a continuous trace. When captured through standardized pipelines and FAIR-aligned metadata, each cultivation run, for example, is automatically linked to its design parameters, execution context, and outcomes. Aggregating multiple project-level threads into a KG then enables cross-project insight through context-rich queries, for example by retrieving: i) all experiments that used a given cell line, media formulation, ii) reactor configuration, iii) identifying recurring quality deviations across studies. In this way, the KG becomes a semantic layer that connects current and future projects while preserving traceability back to the original sources.

A natural extension of local KGs is the concept of a shared KG (Figure 1) that supports collaboration across laboratories, companies, and research institutions by linking knowledge products rather than merely exchanging raw data [3]. In this setting, partners contribute selected, contextualized graph fragments such as model versions, curated metadata, protocol templates, or decision rationales into a shared semantic layer that acts as an authoritative, lifecycle-spanning reference for a joint development effort. In practice, the shared graph becomes the project graph and serves as the single source of truth for all jointly relevant artifacts, while local graphs remain the source for private or institution-specific knowledge. To support IP-sensitive collaboration, the shared graph should include explicit nodes that capture IP-related metadata (e.g., ownership, licensing scope, usage constraints, attribution requirements) linked to the contributed knowledge fragments. A permissioned blockchain infrastructure can complement this approach by enabling targeted sharing through smart contracts,

which record immutable provenance of contributions and govern which specific knowledge artifacts are released, under which conditions, and to whom [7, 8]. This allows collaborators to retrieve precisely scoped information without granting access to an entire local knowledge base, preserving sovereignty while still enabling traceable reuse and attribution. Importantly, a shared KG does not require a single global uniform ontology across all participants. Interoperability can be achieved when shared artifacts are sufficiently contextualized and machine-readable, using persistent identifiers, explicit relationships, and semantic mappings that preserve meaning across heterogeneous ontologies, so that the intent and interpretation of the exchanged knowledge remain clear even when internal conceptual models differ [4].

This shift from siloed records and weakly annotated repositories toward semantically grounded local and shared graphs provides the informational substrate for a Cognitive Digital Thread, because cognition in bioprocess engineering depends on linking data to intent, assumptions, and decision provenance, and on enabling humans and AI systems to retrieve, compare, and reuse knowledge rather than isolated datasets.

## CDTH IN A 5 LAYER ARCHITECTURE

To translate the previously outlined CDTh vision into a technically and organizationally implementable concept for bioprocess engineering, an architectural structure is required [10]. We propose a Five Layer Architecture (Figure 2) that describes how a CDTh can be constructed as a stepwise transformation from heterogeneous laboratory and production connectivity into a distributed, trustworthy, and human-centered decision environment. Its central premise is that cognition does not emerge from data availability or automation alone, but from the combination of reliable data acquisition, explicit contextualization, semantically grounded knowledge representation, governed collaboration, and human-in-the-loop decision processes. To operationalize these requirements, the CDTh is decomposed into a coherent dependency chain of modular capabilities.

### Layer 1: Local Integration Layer as the foundation for interoperability and data integrity

The Local Integration Layer ensures plug-and-play compatibility of laboratory instruments, sensors, and control systems. It enables seamless data acquisition and device interoperability while capturing high-frequency process data and operational metadata in standardized formats. In bioprocess research environments, this is particularly challenging due to extreme heterogeneity across device vendors, device generations, communication protocols, and update capabilities. Legacy equipment is often difficult to integrate because older hardware cannot support modern interface standards. Even when connectivity is technically possible, heterogeneity in exported data products remains a critical issue. As of today, there is no general standard for communication between laboratory devices in biotechnology.

In addition, semantic inconsistencies in units, abbreviations, and references can cause misinterpretation even when data transport is syntactically correct. These issues tend to be more pronounced in academic laboratories than in industrial facilities, as research environments are often organically grown and frequently reconfigured to accommodate changing project needs.

For Layer 1 to support FAIR compliance, operational metadata must be captured systematically. This includes standardized instrument and method metadata, measurement context and uncertainty, and consistent time references. Robust identifiers for runs, workflows, and responsible agents are required to ensure machine readability and unambiguous linkage of records across the Digital Thread.

### Layer 2: AI Based Automation Layer as reproducible experimental execution

Layer 2 provides reproducible experimental workflows and automated metadata capture to support FAIR compliance, but its function goes beyond documentation [12]. It turns experimental execution into a knowledge-generating process by explicitly linking experimental intent, model-based decision support, and reproducible workflows. As a result, experimental data are consistently accompanied by structured contextual information required for interpretation, comparability, and downstream reasoning.

A prerequisite for this layer is machine-readable data and context. Without a consistent semantic foundation, AI-enabled automation can execute tasks, but it cannot support trustworthy cognitive decisions or maintain verifiable control.

Layer 2 therefore requires machine-controllable experimentation through programmable devices, liquid handling systems, robotic assistants, or integrated laboratory infrastructures that connect cultivation with analytics via automated sampling and transport. A workflow management software (WMS) or workflow execution system can operationalize this requirement by orchestrating end-to-end experimental runs across devices via APIs, enforcing workflow templates and parameter sets, and automatically capturing execution logs and deviations as structured metadata. Reproducibility depends on minimizing manual interventions or capturing them explicitly in standardized form. Formal intent capture enables decision provenance, improves comparability across experiments, and supports explainable AI.

An essential element of this layer is the

reproducibility of AI workflows. Reproducibility in this context requires the reconstruction of objectives, decision rules, model versions, and decision outcomes under the same operational context. Semantic mechanisms must therefore provide explicit descriptions of objectives, context, and assumptions, while organizational mechanisms include workflow templates, parameter sets, and audit trails that act as metadata scaffolding to reduce manual burden while ensuring comparability and reproducibility.

Explainable AI is a core requirement, because AI components must provide transparent, human-understandable rationales for predictions and recommendations so that scientists and engineers can validate or challenge them. This supports human-in-the-loop oversight, improves failure analysis, strengthens governance of AI-assisted automation, and supports more robust transfer learning across development projects [13].

This layer is also relevant for rule-based systems, model predictive control, multi-agent systems, workflow engines, and orchestration tools that interface with Layer 1 via device APIs. Human-in-the-loop operation remains essential for safety, exception handling, and oversight of unintended system behavior [14].

## Layer 3: Knowledge Digitalization Layer as the semantic backbone and the first truly cognitive layer

Layer 3 establishes local and decentralized KGs that represent entities such as process runs, organisms, materials, measured attributes, models, and decisions as nodes, with edges encoding relationships, context, and temporal dependencies [12]. By linking data, models, and decisions to underlying metadata, and assumptions, the graph makes experimental outcomes interpretable beyond isolated datasets and enables decision provenance across development steps. Within a CDTh, Layer 3 forms the semantic backbone that transforms bioprocess data into reproducible, explainable, and transferable knowledge.

A critical requirement is that KGs must be dynamic [1]. Bioprocess knowledge evolves continuously as new experiments are executed, model structures are updated, and assumptions are revised. Dynamic graphs support event-driven updates, time-dependent states, and evolving validity of models and decisions, so that the knowledge state relevant to a specific result can be reconstructed and compared against later revisions. Typical use cases include representing experimental trajectories, decision paths with their constraints, and explicit model version histories linked to the evidence that motivated updates [11].

Layer 3 also provides the interface between human reasoning and AI systems. It supports explainable AI by providing structured context, enables domain-specific querying by making relationships between evidence, models, and decisions explicit. This reduces redundancy by allowing teams to locate and reuse previously generated knowledge that would otherwise remain trapped across repositories, and it supports hypothesis generation by exposing patterns across runs, organisms, and operating regimes.

Semantic querying across projects enables comparability and transfer learning, for example by retrieving analogous processes or comparable organisms via structured relationships. Importantly, federation does not imply centralized control or raw data sharing. Instead, it relies on selective exchange of contextualized graph fragments and explicit semantic alignment where knowledge is shared, while local sovereignty and access control remain intact.

## Layer 4: Secure Knowledge Exchange Layer as an optional trust and governance layer

In collaborations with limited institutional trust, intellectual property sensitivity, or strict audit requirements, Layer 4 adds a permissioned blockchain and smart contracts to provide verifiable provenance, attribution, and enforceable governance for shared knowledge artifacts across organizational boundaries. The purpose of this layer is not to store knowledge itself, but to make the terms and history of knowledge exchange tamper-evident and auditable.

When required, the core architectural principle of this layer is the separation of trust from knowledge. KGs store content, semantics, and context, while Layer 4 provides registries, signatures, governance and verification mechanisms. This preserves local sovereignty over sensitive assets while enabling traceable reuse in joint projects [7, 8].

A particularly important function of this layer is KG versioning. Because KGs are dynamic, context-dependent, and decision-relevant, it is critical to identify which knowledge state was valid at the time of a decision, which model version supported an experiment, and which assumptions were later revised [11].

Smart contracts operationalize these requirements by acting as version registries and trust anchors. They identify registered graph states or exchanged artifacts via cryptographic hashes and immutable metadata (timestamps, authorship, project scope), while keeping large datasets and models off-chain in controlled repositories. Smart contracts can further encode and enforce access rights and usage policies such as automatic attribution recording, purpose limitation, and rules for version supersession, thereby supporting reproducibility, accountability, and explainable reasoning despite ongoing knowledge evolution.

By making usage conditions explicit and enforceable, Layer 4 complements social trust with machine-

verifiable traceability and supports collective intelligence without forcing loss of control.

### Layer 5: Collaborative Bioprocess Development Layer as the socio technical locus of system cognition

Finally, layer 5 integrates perception, contextualization, goal orientation, learning, and human interaction into actionable decision processes, making cognition operational. Lower layers provide the prerequisites as structured data and metadata (Layer 1), reproducible and standardized workflows (Layer 2), explicit knowledge representation (Layer 3), and governed collaboration where required (Layer 4). Layer 5 combines these elements into a shared decision space that supports human-centered, AI-augmented collaboration across distributed laboratories while preserving accountability and reproducibility.

At this level, the CDTh connects automated experimentation systems, DTw environments, simulation workflows, and expert reasoning interfaces across laboratories and sites. Cross-laboratory orchestration is enabled by standardized workflows from Layer 2, federated KGs from Layer 3, and trust mechanisms from Layer 4, allowing joint objectives and information flows to be aligned without enforcing central control over local assets.

A defining feature of Layer 5 is the human-in-the-loop operation. AI systems contribute recommendations, alternatives, and uncertainty estimates, while humans retain decision authority and responsibility. Cognition emerges as co-cognition rather than full autonomy. Humans validate model assumptions, interpret results, and override system decisions. Layer 5 operationalizes intentionality by enabling objectives to be formulated, revised, and prioritized, and by making trade-offs explicit. It supports context-sensitive decision-making across organizational boundaries by combining distributed knowledge with local expertise and by accounting for uncertainty and knowledge gaps. Learning across time is enabled by making prior project experience retrievable and by embedding decisions in versioned knowledge contexts.

Because Layer 5 is the primary user-facing locus of the CDTh, it must also reduce cognitive burden rather than amplify it. Role-specific views, prioritization, and consistent templates are required to build digital dexterity and avoid transformation fatigue, ensuring that transparency and traceability translate into faster, more robust decisions instead of information overload.

## CONCLUDING REMARKS

In this review, we positioned Bioprocessing 5.0 as a human-centered, knowledge-driven, and collaborative development strategy that responds to the unmet promises of Industry 4.0 in bioprocess engineering [5, 6]. We conclude that this vision will not be fully realized without a CDTh that unifies data, knowledge, and decision provenance across the bioprocess lifecycle [11]. The CDTh enables end-to-end traceability of decisions by explicitly linking data, experimental context, models, and human intent, and it supports reproducible experimental and computational workflows through machine-actionable, audit-ready execution traces. Its semantic backbone, implemented through KGs, enables interoperable models that can be transferred, compared, and reused across projects and scales, while explainable AI is essential to make algorithmic recommendations transparent and thereby trustworthy for scientific validation and regulatory adoption [4, 12, 13]. To extend these capabilities beyond organizational boundaries, blockchain-based mechanisms can serve as a trust anchor for collaboration, where smart contracts provide verifiable provenance of intellectual property, authorship, and contributions without requiring the sharing of raw data [7, 8]. With the combined use of FAIR-aligned data platforms, semantic KGs, explainable AI, and collaborative software agents embedded in human-in-the-loop decision environments, the field can transcend current limitations in reproducibility, scalability, and knowledge transfer [14]. Taken together, this review provides a framework for future trends in bioprocess digitalization and charts a path toward an Industry 5.0 paradigm that blends human creativity with machine precision in collaborative bioprocess development [5, 6].

## ABSTRACT

Recent advances in computer-aided retrosynthesis (CAR), flow chemistry, and continuous manufacturing collectively offer new opportunities to enable environmentally sustainable development and manufacturing practices across the pharmaceutical development and manufacturing value chain. However, the implementation of these methods and technologies remains scattered and fragmented, preventing full realization of their potential to address one of the most urgent needs in the pharmaceutical and related sectors. This work introduces a holistic digital framework for the design and optimization of an end-to-end manufacturing process for paracetamol (acetaminophen). The framework integrates Green-by-Design synthetic and purification routes of the active pharmaceutical ingredient (API) aims to deliver cost efficiency and robust quality, safety, and environmental sustainability assurance. The approach integrates AI-driven CAR with plant wide modelling, Techno-Economic Analysis (TEA), and prospective cradle-to-gate prospective Life Cycle Assessment (LCA) to evaluate designs options and greener, chemically feasible, and more selective synthetic pathways. An end-to-end mathematical model is implemented in gPROMS Formulated Products® to optimize operating and design parameters and generate inventory data for TEA/LCA. The framework also embeds Quality by Digital Design (QbDD) to identify CPPs and CMAs that influence CQAs, enabling definition of a robust design space. Finally, a multicriteria decision-aiding approach is implemented to determine the best trade-offs among yield, productivity, resource efficiency, cost, and environmental performance, providing a transferable Safe-and-Sustainable-by-Design (SSbD) methodology for developing greener and more resilient pharmaceutical manufacturing systems.

## INTRODUCTION

Pharmaceutical manufacturing is among the most solvent- and utility-intensive industries and is frequently characterized by very high waste-to-product ratios. The development and manufacturing of pharmaceutical products is a long complex and fragmented journey, characterized by early-stage discovery and clinical trials, followed by process development, scale-up and optimization, regulatory validation, and commercial manufacturing. Reducing the environmental footprint of pharmaceutical manufacturing require the development of changes that cut across synthesis, separations, and solvent recovery. Early LCA work on API manufacture highlighted that solvents could dominate material usage and that solvent production and waste management can drive a large share of life-cycle emissions, making solvent choice/recycle central to greener manufacturing [1-4]. More recent investigations confirm that, across pharmaceutical LCAs, energy consumption and synthetic and purification processes are frequently the key contributors to the overall environmental impacts, while noting persistent limitations in inventory transparency and system boundary consistency [5, 6].

Advances in computer-aided retrosynthesis (CAR) have

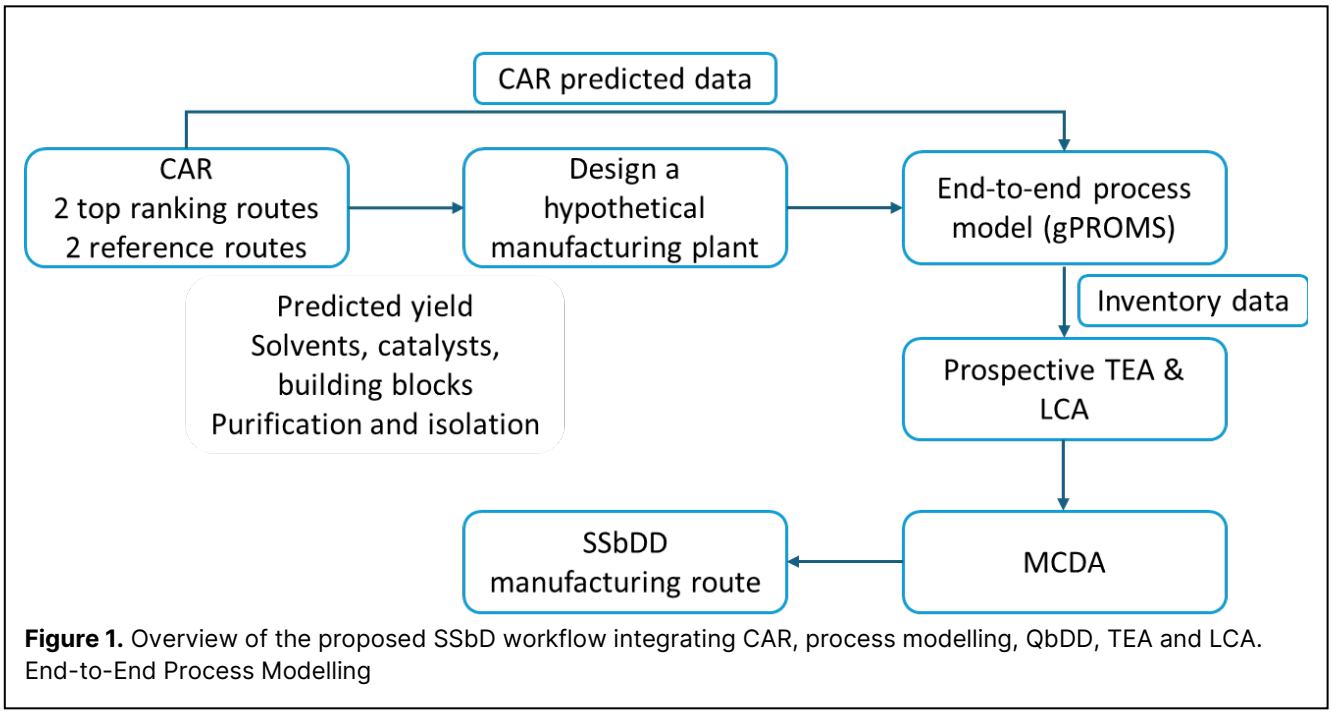

**Figure 1.** Overview of the proposed SSbD workflow integrating CAR, process modelling, QbDD, TEA and LCA. End-to-End Process Modelling

enabled rapid generation of feasible and Green-by-Design synthetic routes and systematic route comparison, moving beyond expert-based and trial-and-error based synthetic route design [5-6]. On the manufacturing side, continuous flow and telescoped processing have demonstrated clear potential to improve safety and footprint by enabling tighter control, improved heat/mass transfer, and avoidance of isolating unstable intermediates; for paracetamol specifically, multistep continuous-flow synthesis and automated optimization studies illustrate both feasibility and the value of algorithmic design-space exploration [7]. Renewables-oriented thinking is also gaining traction in pharmaceutical manufacturing, with recent work explicitly proposing and evaluating renewable routes using green chemistry analysis [8]. However, current practice still largely treats synthetic route design, process development, and sustainability/techno-economics (LCA/TEA) as separate activities, limiting the ability to steer route selection using end-to-end sustainability and robustness metrics early in development.

The emergence of digital frameworks such as Quality by Digital Design (QbDD) is transforming the pharmaceutical manufacturing landscape, placing model-based and data-driven methods at unprecedented levels of importance and integration. [16]

This work aims to address the critical gaps highlighted above by developing and validating an integrated SSbD digital framework that couples: (i) CAR-assisted Green-by-Design synthetic route generation and ranking, (ii) end-to-end synthesis and purification process modelling, and (iii) integrated prospective TEA and cradle-to-gate LCA, while embedding QbDD concepts to ensure built-in quality and safety assurance. The proposed approach aims to connect design space definition with sustainability performance. By linking CAR decisions to process simulation outputs and inventory generation, the framework enables multi-objective optimization over yield, resource efficiency, cost, and environmental impacts, supporting early, data- driven selection of greener and more robust paracetamol manufacturing solutions. Paracetamol (acetaminophen), a high-volume essential medicine, is selected to validate the proposed framework. Its substantial environmental footprint linked to large-scale production makes it a suitable case study for demonstrating the value of the holistic methodology.

## METHODOLOGY

The proposed end-to-end SSbD workflow is captured by the flow diagram shown in figure 1. Paracetamol, the top-selling over-the-counter pharmaceutical with a global market volume of nearly 275 tonnes and a value of USD 876.48 million in 2024, is used to demonstrate the proposed framework. The proposed end-to-end manufacturing interstates process of Paracetamol involves aromatic functionalization and acetamidation chemistry, with well-known trade-offs between selectivity, solvent usage, and purification effort. Multiple synthesis concepts are therefore feasible, making paracetamol particularly suitable for route screening and comparative sustainability analysis. Candidate synthesis routes are structured into four route families as shown in Table 1:

(i) Route A: CAR (SYNTHIA) baseline / conventional-like route (used as an internal benchmark)
(ii) Route B: CAR (SYNTHIA) SSbD-preferred route

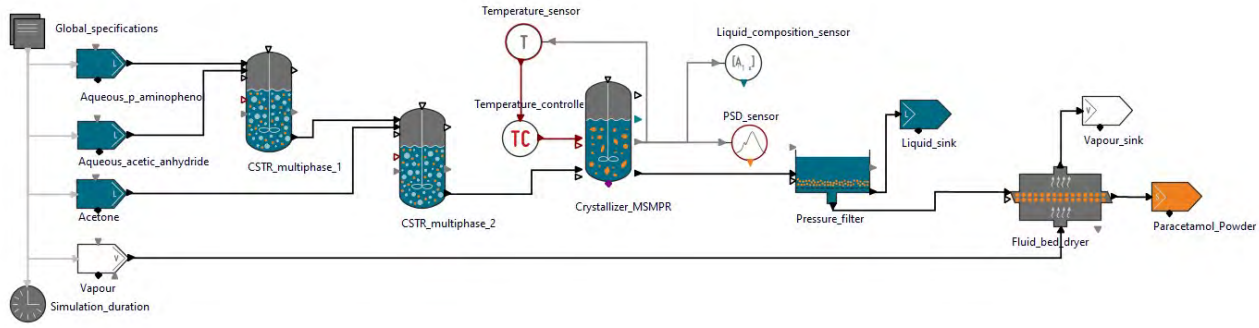

**Figure 2** End-to-end flow diagram of paracetamol manufacture

(screened for lower expected separation burden and improved operability)
(iii) Route C: Renewable phenol-based route [10]
(iv) Route D: Bio-waste-derived concept (β-pinene-based continuous route) [13]

**Table 1:** Selected synthesis routes for paracetamol

| Routes | # Steps | Yield | Solvents |
|---|---|---|---|
| A | 2 | 88% | Acetic anhydride |
| B | 2 | 92% | Acetic acid |
| C | 3 | 85% | Ammonium acetate |
| D | 4 | 90% | Methanol |

These routes form the basis for CAR-based screening and subsequent process modelling within a common superstructure. CAR is used as the entry point of the workflow to generate feasible retrosynthetic pathways for paracetamol using SYNTHIA®, with pathway exports supporting transparent route documentation [8, 9]. In contrast to conventional retrosynthesis, route evaluation is extended beyond chemical feasibility to include sustainability-relevant attributes. Each candidate route is assigned a composite screening score based on normalized indicators representing step count, feedstock origin, reagent/solvent hazard proxies, telescoping potential, a selectivity-related impurity risk proxy, and compatibility with continuous processing. The highest-ranked routes are retained for detailed process modelling, ensuring direct propagation of early-stage design decisions into downstream simulation, TEA and LCA.

The selected total paracetamol synthetic routes are integrated to an end-to-end manufacturing superstructure developed in gPROMS Formulated Products® as shown in figure 2. The superstructure comprises raw material, solvent, catalyst feed streams, reaction, quenching and conditioning, API isolation, crystallization, solid–liquid separation, drying, formulation and solvent recovery where feasible. Route-specific differences are represented through variations in reaction sequence, solvent systems, operating conditions, and separation difficulty. Reaction selectivity is captured using impurity load proxies, which directly affect yield losses and solvent demand in purification. This abstraction enables quality-sustainability coupling while remaining suitable for early-stage design studies. The model generates consistent mass and energy balances for all unit operations, producing inventory-quality data for the prospective TEA and LCA.

## Quality by Digital Design

To deliver built-in quality assurance for safety, a QbDD approach is embedded within the modelling framework to systematically identify relationships between CPPs, CMAs, and CQAs for paracetamol manufacture. CQAs considered at the API stage include product purity, levels of impurities, and residual solvent content. Candidate CPPs and CMAs include reaction temperatures, residence times, solvent choice, crystallization conditions, and solvent recycling ratios. Sensitivity analyses are used to quantify their influence on CQAs, yield, and resource consumption. Variations that degrade quality typically increase solvent usage and energy demand, thereby linking quality robustness directly to sustainability performance.

## Integrated Techno-Economic Analysis and Life Cycle Assessment

Prospective TEA and LCA are addressed based on the inventory data extracted from the gPROMS simulations. The TEA captures the capital and operating expenditures, with particular emphasis on solvent consumption, recovery efficiency, and energy demand.

A cradle-to-gate life cycle assessment (LCA) is performed to quantify the environmental impacts of each manufacturing alternative associated with shortlisted total synthetic routes. The proposed LCA is consistent with the ISO 14040/44 standards, covering four key steps: goal and scope definition, inventory analysis, impact

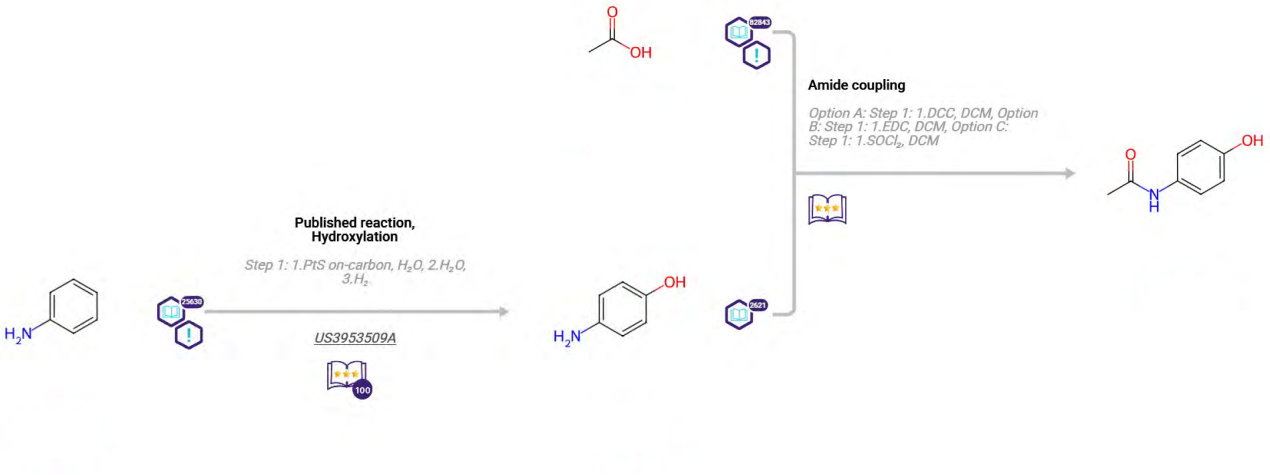

**Figure 3.** Route B from SYNTHIA® retrosynthesis

assessment, and interpretation. Environmental impacts were assessed across multiple categories, including global warming potential, energy use, and waste generation.

### Goal and Scope

Perform the LCA for all case model simulations with the functional unit of 1 kg paracetamol products.

### Life cycle inventory

Based on the process simulation outputs, detailed inventory data were gathered for each route. This data encompasses material usage, energy consumption, waste generation, and emissions at each processing stage.

### Impact assessment

The impact assessment is based on the method ReCiPe 2016 available in SimaPro with the Ecoinvent 3 environmental footprint database. The ReCiPe 2016 captures three endpoint categories (human health, ecosystems, and resources) and seventeen midpoint categories. These different categories provide a comprehensive basis to compare the different design options.

### Interpretation of results

Finally, the results obtained from the previous steps are interpreted and the environmental hotspots are identified.

The overall LCA was structured with a cradle-to-gate system boundary for API manufacture. The boundary includes raw material production (reagents, solvents and auxiliaries), on-site utilities (electricity/steam and cooling), and treatment of process waste streams associated with synthesis, purification, and solvent recoveryAPI production: The environmental impacts associated with the synthesis of the API, including raw material extraction, energy use, solvent recovery and waste generation during API production.

### Multicriteria Decision-Making

A multicriteria decision aiding approach is implemented to identify the best compromises between environmental impacts, economic performance, yield, and robustness of CQAs. Integrating this approach to SSbD delivers a recommended paracetamol synthesis route together with a robust operating and design space that satisfies quality constraints while minimizing economic and environmental burdens.

## RESULTS AND DISCUSSION

### CAR route screening and selection

CAR was applied using SYNTHIA® Retrosynthesis to generate feasible synthetic paracetamol pathways along with transparent route documentation. Route A represents a SYNTHIA-generated baseline pathway selected primarily based on the feasibility criteria (short step count and readily available starting materials), while Route B represents a SYNTHIA-generated SSbD-preferred pathway selected using additional screening for lower expected separation burden (telescoping potential and reduced impurity risk proxy) and improved operability. Additionally, these routes are benchmarked against two published synthetic routes namely: Route C (renewables-based routes) [10] and Route D (bio-waste β-pinene concept) [13]. These four routes were each translated into an integrated synthesis–purification superstructure for consistent simulation, inventory generation, and TEA/LCA based comparison.

- Route A (CAR baseline): SYNTHIA® retrosynthesis

**Table 2:** KPIs for different routes

| Route | Fresh solvent use (kg/kg API) | Energy use (MJ/kg API) | GWP (kg CO2-eq/kg API) | Production cost (Dollars/kg API) |
|---|---|---|---|---|
| Route A | 25 | 120 | 18 | 3 |
| Route B | 15 | 85 | 11 | 2.55 |
| Route C | 18 | 95 | 13 | 2.85 |
| Route D | 14 | 80 | 10 | 2.7 |

route (2 steps) selected as a feasibility/benchmark-like pathway; expected higher purification burden and solvent demand due to conservative isolations.

- Route B (CAR SSbD): SYNTHIA® retrosynthesis route (3 steps) down-selected through sustainability-based screening (telescoping potential and reduced impurity-risk proxy); expected reduced separation burden and lower solvent/energy intensity as shown in Figure 3.

## End-to-end process-based performance

The integrated process model provides consistent comparison of synthesis + purification under a common functional unit (kg API). In the current dataset, overall yields range from 85–92%, indicating that route choice affects not only productivity but also purification recovery efficiency:

- Route A (CAR baseline): 88%
- Route B (CAR SSbD): 92%
- Route C (renewables literature): 85%
- Route D (β-pinene literature): 90%

The higher yield exhibited by Route B indicates that either the route exhibits enhanced selectivity or /and reduced losses during isolation. Conversely, Route C (renewables-based) shows relatively lower yield which may be due to the nature of renewable feed stocks. While yield strongly correlated to the process economics, it should not be treated as an isolated objective in SSbD, as a route with marginally lower yield can still be preferred if it substantially reduces solvent intensity and utilities, because solvent/utility hotspots often dominate cradle-to-gate impacts and cost. Hence, the SSbD decision requires multi-criteria decision aiding to address the conflicting or competing nature of these objectives. Other KPIs including solvent intensity, energy intensity, environmental intensity and economic intensity are as shown in Table 2.

### Solvent intensity

Solvent intensity is an emergent property of selectivity/impurity formation, crystallization efficiency, and recycle strategy. Routes that reduce impurity load reduce the number/volume of wash and recrystallization steps and therefore reduce both solvent purchase and solvent recovery duty. As a direct indicator of separation burden and a major driver for both OpEx and environmental impacts (solvent production + waste handling + recovery duties). The four routes show strong differentiation as outline below:

- Route A: 25 kg solvent/kg API
- Route B: 15 kg solvent/kg API (40% reduction vs A)
- Route C: 18 kg solvent/kg API (28% reduction vs A)
- Route D: 14 kg solvent/kg API (44% reduction vs A)

These reductions provide critical insight: the best-performing routes (B and D) are those that are expected to require less intensive recrystallization/washing and/or have more effective recycle structures. For CAR, this is where Route B demonstrates tangible value, CAR selection can target reaction sequences and solvent sets that reduce downstream separation intensity.

### Energy intensity

Energy intensity (MJ/kg API) integrates heating/cooling duties for reaction temperature control, crystallization cooling, solvent recovery, and drying. The four routes in the dataset show as below:

- Route A: 120 MJ/kg API
- Route B: 85 MJ/kg API (29% reduction vs A)
- Route C: 95 MJ/kg API (21% reduction vs A)
- Route D: 80 MJ/kg API (33% reduction vs A)

The close alignment between solvent reductions and energy reductions is expected because solvent recovery and drying duties often scale with solvent throughput. Hence, reducing solvent makeup yields a compounding benefit: lower fresh solvent demand reduces recovery loads, which reduces utility demands and associated emissions. In SSbD optimization, solvent intensity is not only a material KPI; it is also a strong proxy for energy intensity and therefore for climate impacts. This justifies (i) using solvent-related screens already at

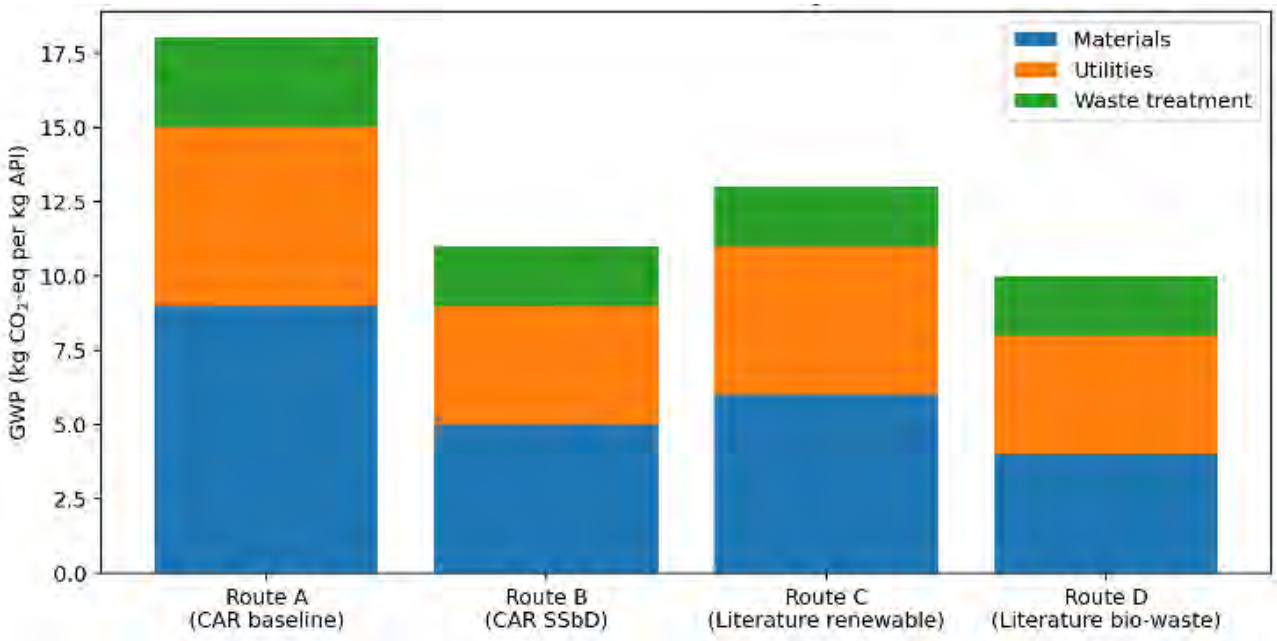

**Figure 4.** GWP hotspot breakdown

the CAR stage and (ii) prioritizing route selections compatible with solvent recycle/recovery strategies.

## Environmental intensity

With the predicted inventories as inputs, the hotspot breakdown can be analysed by converting gPROMS outputs (fresh reactants/solvents, steam/electricity/cooling, waste flows) into LCI flows and multiplying by characterization factors (ReCiPe 2016) to obtain the contribution scores. This decomposition is particularly important for CAR-derived Route B: if Route B reduces GWP primarily via utilities, it suggests the improvement arises from reduced recovery duty; if it reduces GWP primarily via materials, it suggests the route reduces fresh solvent/reagent demand. For climate change impacts, the draft cradle-to-gate GWP comparison shows a clear route dependence as below:

- Route A: 18 kg $CO_2$-eq/kg API
- Route B: 11 kg $CO_2$-eq/kg API (~39% reduction vs A)
- Route C: 13 kg $CO_2$-eq/kg API (~28% reduction vs A)
- Route D: 10 kg $CO_2$-eq/kg API (~44% reduction vs A

To move beyond ranking and support actionable SSbD decisions, hotspot interpretation is essential. Another effective reporting structure decomposes total GWP into materials, utilities, and waste treatment contributions as shown in Figure 4: The baseline CAR Route A exhibits the highest total GWP, driven primarily by the materials contribution, consistent with higher fresh input requirements (notably solvent and reagent supply chains) and the propagation of separation intensity into upstream burdens. In contrast, the CAR Route B (SSbD-preferred) achieves a lower total GWP, with reductions observed in both materials and utilities components, indicating that improvements are not solely attributable to energy efficiency but also to reduced fresh material demand (e.g., solvent makeup) and associated recovery duties.

Among the literature comparators, Route D (bio-waste derived concept) shows the lowest total GWP in this breakdown, reflecting reduced contributions from both materials and utilities relative to the baseline. Route C (renewables-based concept) displays intermediate performance, suggesting that feedstock substitution alone may not guarantee minimum impacts unless coupled with process designs that reduce solvent throughput and utility demand. Overall, the environmental intensity indicates that end-to-end impacts are governed by coupled effects of solvent/material intensity and utility demand, supporting the SSbD rationale for combining CAR route selection with process modelling and integrated TEA/LCA.

## Techno-economic comparison

Techno-economic analysis (TEA) was applied to quantify the manufacturing cost implications of route selection under a consistent cradle-to-gate system boundary (API synthesis + purification) and a common

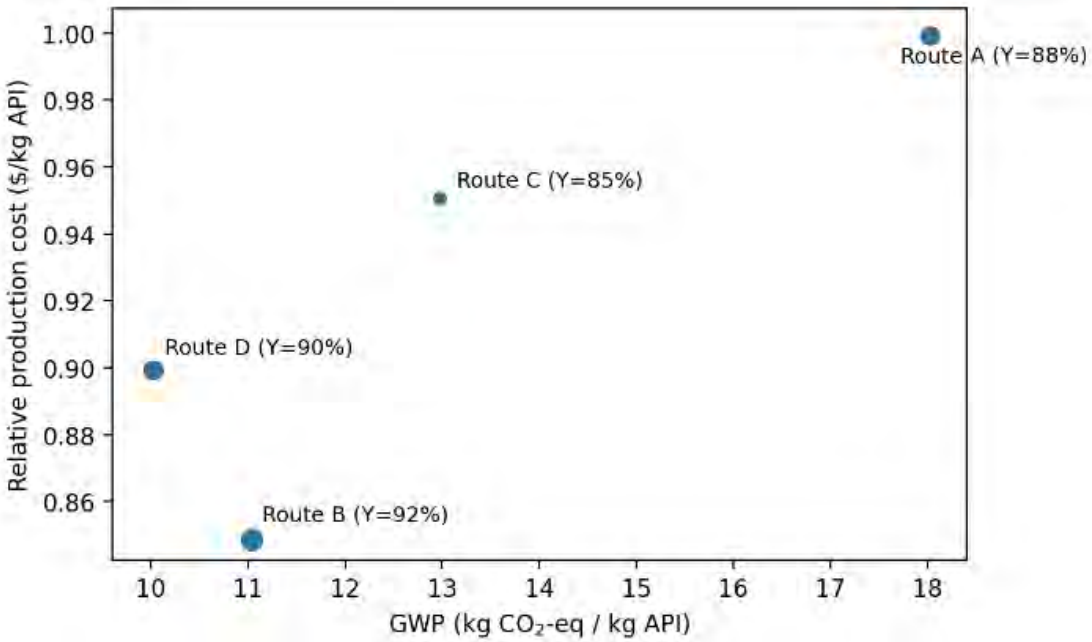

**Figure 5.** Comparison of the different scenarios in the KPI space.

functional unit (cost per kg paracetamol API). To avoid over-interpretation at conceptual stage, results are reported on a relative cost basis normalised to Route A (CAR baseline) (= 1.00). The comparative TEA indicates that route selection yields meaningful cost differences, with the ranking:

- Route A (CAR baseline): 1.00
- Route B (CAR SSbD): 0.85
- Route C (literature renewable): 0.95
- Route D (literature bio-waste): 0.90

The dominant cost drivers are consistent with the process-level KPIs reported in previous sections. Specifically, solvent management (fresh solvent purchase, solvent recovery, and solvent losses to waste streams) and utilities (steam/electricity for heating, cooling, and drying) are the primary contributors to operating expenditure (OpEx), while recovery and drying capacity influence capital expenditure (CaPEx) proxies. In this context, Route A exhibits the highest relative cost due to its elevated fresh solvent makeup and energy intensity, which increase both (i) recurring material and utility costs and (ii) equipment sizing requirements for solvent recovery and drying.

In contrast, the CAR Route B shows the lowest cost in the current assessment, consistent with (i) reduced solvent intensity (40% lower than Route A) and (ii) reduced energy demand (≈29% lower than Route A), which together decrease solvent purchasing, recovery duty, and drying load. Importantly, Route B also shows the highest yield), improving effective throughput per unit feed and lowering cost per kg API. These results support the SSbD premise that CAR-guided route selection can deliver economically favourable alternatives when the screening explicitly targets reduced separation burden and improved end-to-end efficiency.

The two literature comparators provide additional context for route selection. Route D (bio-waste derived) is economically competitive (0.90) while exhibiting the lowest GWP, indicating that sustainability-oriented route concepts can remain cost-viable when solvent and utility demands are constrained. Route C (renewables-based) shows intermediate cost performance (0.95), suggesting that feedstock substitution alone may not ensure minimum manufacturing cost unless accompanied by downstream separation designs that minimise solvent throughput and recovery duty.

## Multi-criteria decision aiding

Figure 5 shows the conflicting nature of the multicriteria decision problem associated with the proposed SSbD using 2 critical KPIs: the relative production cost and cradle-to-gate GWP, with each point annotated by overall yield.

In this assessment, Route A occupies the unfavourable region with the highest cost (normalized to 1.00) and highest climate impact (18 kg $CO_2$-eq/kg API) and is therefore dominated by multiple alternatives. In contrast, Route B is positioned in a strongly favourable region, combining the lowest relative cost (0.85) with a substantially reduced GWP (11 kg $CO_2$-eq/kg API) and the highest

yield (92%). The location of Route B indicates that CAR-informed route selection can produce pathways that improve both economic and environmental performance simultaneously, consistent with the SSbD hypothesis that reductions in separation intensity (solvent and recovery duty) deliver compounding benefits across TEA and LCA.

Among the published reference synthetic routes, Route D exhibits the lowest GWP (10 kg $CO_2$-eq/kg API) while maintaining competitive cost (0.90) and high yield (90%), placing it close to the lower-left region of the MCDA space. Route C remains intermediate in both cost and environmental performance. Importantly, Figure 6 indicates a non-trivial trade-off between Route B and Route D: Route B offers the lowest cost and highest yield, whereas Route D offers the lowest climate impact. This provides a clear SSbD decision interpretation: selection depends on the weighting of economic vs environmental objectives and on robustness considerations. In practice, such a MCDA representation is preferable to single-metric ranking because it transparently communicates which improvements are achievable without sacrifice and where genuine trade-offs remain.

While Figure 5 provides a two-objective SSbD decision surface (cost vs climate impact), route selection for pharmaceutical manufacture typically requires consideration of multiple performance dimensions simultaneously, including yield, solvent intensity, and utility demand. Figure 6 therefore provides a normalized, multi-metric summary across five key indicators (Yield, Solvent, Energy, GWP, and Cost), with values normalized such that 1 indicates best performance among the compared routes. This representation supports rapid identification of "balanced" candidates and clarifies whether a route's apparent advantage is narrow (e.g., only cost) or systemic (across multiple indicators).

The radar plot indicates that Route A performs worst (near-zero normalized scores) in solvent intensity, energy demand, GWP, and cost, confirming that it serves primarily as a baseline reference rather than an optimal SSbD choice. Route B exhibits consistently high normalized scores across all indicators, reflecting a comparatively balanced pathway that is simultaneously high-yield and low in both operating burden (solvent/energy) and system-level metrics (cost/GWP). Route D shows particularly strong normalized performance in solvent and energy intensity and in GWP, with somewhat weaker (but still competitive) cost performance relative to Route B. Route C shows intermediate performance and highlights that renewable feedstock concepts may require additional process intensification or separation optimization to reach best-in-class end-to-end metrics.

From a QbDD perspective, Figure 6 can be interpreted as evidence that routes with reduced separation intensity (lower solvent and energy) are inherently favourable not only for LCA and TEA but also for quality robustness. In practice, reduced purification demand generally increases robustness margins because fewer or less severe isolation steps reduce sensitivity to upstream variability (e.g., selectivity fluctuations propagating into impurity burden). Within the proposed SSbD framework, this motivates a coupled optimization strategy in which CPPs/CMAs (e.g., reagent stoichiometry, temperature, crystallization endpoint, recycle ratio) are tuned to satisfy CQA constraints while simultaneously minimizing solvent and energy penalties. Therefore, multi-metric results such as Figure 6 provide a compact screening tool to identify routes that are likely to admit a robust design space under QbDD constraints, rather than merely optimizing nominal performance. A preliminary QbDD screening for Route B indicates a constrained operating window in which near-stoichiometric acetic acid usage and high 4-aminophenol purity jointly maximize yield, highlighting the coupling between input material quality (CMA) and stoichiometric control (CPP) in determining CQA performance as shown in Figure 7.

## CONCLUSIONS

This work presented an integrated SSbD framework for paracetamol manufacturing that couples CAR with model-based end-to-end process design, TEA, and prospective LCA, while embedding Quality by Digital Design (QbDD) principles to support robust decision-making. The case study compared four alternative route candidates: two CAR/SYNTHIA®-derived routes (Route A as a baseline, conventional-like pathway and Route B as an SSbD-preferred alternative) and two literature comparators (renewables-based and bio-waste derived concepts).

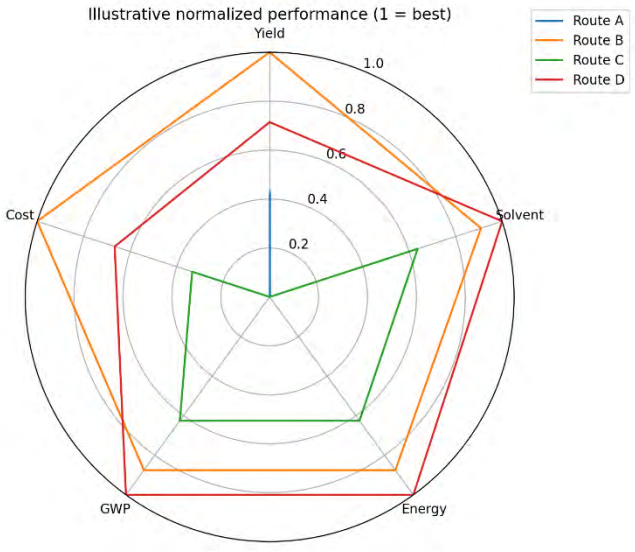

**Figure 6.** Normalized multi-criteria performance comparison (1 = best) for yield, solvent intensity, energy intensity, GWP, and relative production cost.

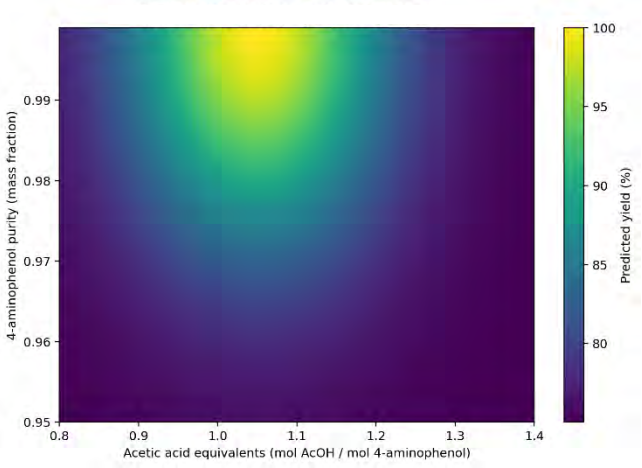

**Figure 7.** Design space analysis for route B.

Across the evaluated KPIs, route choice was shown to strongly influence end-to-end performance through coupled effects on separation intensity, solvent makeup, and utility demand. The results indicate that Route A is dominated by the alternative candidates, while Route B (CAR SSbD route) and Route D (bio-waste literature route) occupy the preferred region of the cost–impact trade-off space. Hotspot analysis further indicates that reductions in environmental burden are primarily achieved by lowering materials-related contributions (notably solvent/reagent supply chains) and utilities-related contributions (solvent recovery and drying duties), reinforcing the importance of solvent management as a central SSbD lever. Multi-criteria comparison provided a transparent basis for decision-making by revealing where improvements can be achieved simultaneously and where genuine trade-offs remain between cost, climate impact, and yield.

It is important to note that the mapping between reaction-level impurity proxies and downstream separation intensity in the present framework represents a comparative screening abstraction rather than a strictly linear mechanistic relationship. In pharmaceutical crystallization systems, minor variations in specific impurity concentrations can significantly alter nucleation kinetics, crystal habit, polymorphic outcome, and filterability. Consequently, the current modelling approach should be interpreted as an early-stage digital screening tool intended to prioritize candidate routes. Experimental validation, including crystallization studies and solid-state characterization, remains essential to confirm separation behaviour and product quality attributes prior to scale-up.

Overall, the study demonstrates that integrating CAR route generation with process simulation and prospective TEA/LCA enables earlier, more quantitative screening of "Greener-by-Design" options than conventional sequential development workflows. Future work will explore more placeholders with SYNTHIA-exported route descriptors and gPROMS-derived inventories and will extend the framework by explicitly quantifying robustness under uncertainty (CPP/CMA variability) to link QbDD design space definition with sustainability and economic outcomes.

## ABSTRACT

Magnetic Inductive Swing Adsorption (MISA) is a carbon dioxide capture process similar to Temperature Swing Adsorption that uses direct electromagnetic heating instead of classic heating systems for the regeneration step of the process. However, the lack of validated dynamic models hinders process optimization. This work introduces an open-source MISA model in the IDAES framework, incorporating Specific Absorption Rate (SAR) physics (SAR $\propto B^2$) to capture electromagnetic heating. Binary Sips isotherm parameters for $Fe_3O_4$@HKUST-1 were fitted to experimental data, achieving high statistical agreement (R2 > 0.996, RMSE < 0.022 mol/kg). Comprehensive validation was performed against adsorption isotherms, dynamic breakthrough curves, and desorption profiles. The model predicts breakthrough time with only 9% error and saturation time with 6% error. Crucially, the coupled thermal transport and SAR heating model capture temperature evolution during desorption within 5% error across all field strengths. Although the use of Linear Driving Force kinetics introduces minor systematic overprediction, the model successfully bridges the gap between laboratory feasibility and industrial design. This validated tool enables the first systematic investigation of cycle configurations, providing a platform for techno-economic comparisons and scale-up of energy-efficient magnetic carbon capture.

## 1. INTRODUCTION

Mitigating anthropogenic carbon dioxide emissions remains critical for achieving global climate targets, with post-combustion carbon dioxide ($CO_2$) capture representing a key near-term strategy for industrial decarbonization [1]. Traditional Temperature Swing Adsorption (TSA) processes regenerate solid adsorbents through external heating, but suffer from fundamental limitations; poor thermal conductivity creates temperature gradients, slow heat penetration extends cycle times, and thermal resistances cause energy losses often exceeding 3-4 GJ/tonne $CO_2$ [2].

Magnetic Inductive Swing Adsorption (MISA) addresses these limitations through direct volumetric heating of magnetic nanoparticles embedded in adsorbent materials [2]. When exposed to alternating magnetic fields, $Fe_3O_4$ nanoparticles generate heat through hysteresis and relaxation mechanisms, bypassing thermal resistances inherent in conventional TSA. Bellusci *et al.* [2] demonstrated that $Fe_3O_4$@HKUST-1 composites achieve 95% $CO_2$ recovery in about 2.5 minutes, almost four times faster than Temperature Swing Adsorption (TSA) [2].

Despite experimental demonstrations of MISA feasibility, validated dynamic models for process design remain lacking. Existing fixed-bed models in process simulation frameworks do not include electromagnetic heating capabilities, and proprietary models are not publicly available. This absence of validated open-source tools represents a barrier to systematic exploration of MISA cycle configurations and scale-up necessary for industrial implementation.

This work presents a new, validated open-source MISA model using the Institute for the Design of Advanced Energy Systems (IDAES) framework [3]. The model extends the standard `FixedBed1D` class with Specific Absorption Rate (SAR) physics for electromagnetic heating. Binary Sips isotherm parameters were fitted to experimental data [2, 4] using Python Adsorption Parameter Estimation Package (pyAPEP) [5], achieving $R^2$ >

0.996 for both $CO_2$ and Nitrogen ($N_2$). Comprehensive validation was performed against three independent datasets: adsorption isotherms (273-403 K), dynamic breakthrough curves (15-50% $CO_2$), and magnetic desorption profiles (11.1-12.6 mT). The validated implementation enables systematic investigation of cycle design and optimization, providing the computational foundation for techno-economic analysis and scale-up studies.

## 2. MATERIALS AND METHODS

### 2.1 Adsorbent Material and Isotherms

The adsorbent material used in this study is a $Fe_3O_4$@HKUST-1 magnetic composite developed by Bellusci *et al.* [2]. This material consists of the metal organic framework (MOF) HKUST-1 ($Cu_3(BTC)_2$) impregnated with 17 wt% magnetite ($Fe_3O_4$) nanoparticles. The magnetic nanoparticles enable direct heating of the solid phase through electromagnetic induction, while MOF provides high $CO_2$ adsorption capacity.

The adsorption equilibrium for both $CO_2$ and $N_2$ was modeled using the Sips isotherm, which combines Langmuir and Freundlich characteristics:

$$q_{(eq,i)(T,P_i)} = \frac{n_{\infty,i}(b_i(T)\,P_i)^{c_i}}{1+(b_i(T)\,P_i)^{c_i}} \quad (1)$$

where $q_{(eq,i)}$is the adsorbed amount of component $i$ (mol/kg), $n_{\infty,i}$ is saturation capacity, $b_i(T)$ is the affinity parameter as a function of $T, c_i$ is the heterogeneity parameter, and $P_i$ is the partial pressure. The affinity parameter exhibits temperature dependence according to:

$$b_i(T) = b_{ref,i}\exp\left[\frac{\Delta H_{b,i}}{R}\left(\frac{1}{T_{ref}}-\frac{1}{T}\right)\right] \quad (2)$$

where $\Delta H_{b,i}$ is the isosteric heat of adsorption and $T_{ref}$ = 298 K.

Experimental adsorption isotherms for both $CO_2$ and $N_2$ were obtained from Bellusci *et al.* [2, 4] by manual extraction of gas uptake (mol/kg) versus pressure (kPa) data across multiple temperatures (273-403 K for $CO_2$, 273-308 K for $N_2$) using a plot digitation tool. The extracted dataset served as the training set for parameter estimation.

The binary Sips isotherm parameters were determined through nonlinear regression using pyAPEP [5], which performs global nonlinear regression to simultaneously optimize all parameters.

Figure 1 demonstrates excellent agreement between the fitted model and experimental data. The fitted parameters (Table 1) reveal the expected selectivity: $CO_2$ exhibits significantly higher saturation capacity. The heats of adsorption ($\Delta H_b$ = 23.5 kJ/mol for $CO_2$, 15.3 kJ/mol for $N_2$) are physically reasonable for physisorption and correctly predict decreased loading with increasing temperature and is close to the experimental value of 23 kJ/mol for $CO_2$ [2]. The validated isotherm provides the thermodynamic foundation for all subsequent dynamic simulations.

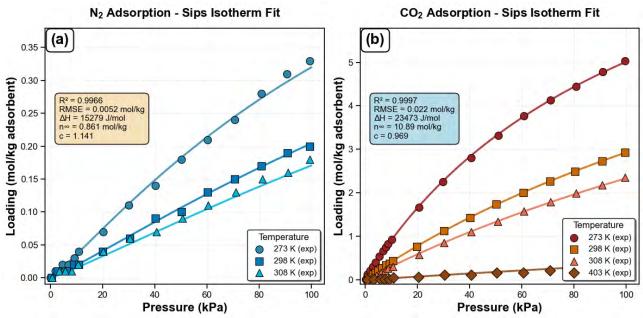

**Figure 1.** Validation of Sips isotherm model against experimental adsorption data from Bellusci et al. [2, 4]. (a) $N_2$ adsorption (273-308 K, $R^2$=0.9970). (b) $CO_2$ adsorption (273-403 K, $R^2$=0.9997). Lines: model predictions; symbols: experimental measurements.

Table 1 presents the fitted parameters along with statistical measures of goodness-of-fit. The high $R^2$ values (>0.996) and low RMSE values indicate excellent agreement with data across the measured temperature and pressure ranges (298 – 403K, 0.01-100 kPa). Details are available in the supplementary material.

**Table 1.** Sips Isotherm Parameters found

| Parameter | $CO_2$ | $N_2$ | Unit |
|---|---|---|---|
| $n_\infty$ | 10.89 | 0.926 | $mol/kg$ |
| $b_{ref}$(298K) | 4.24 × $10^{-6}$ | 1.57 × $10^{-6}$ | $Pa^{-1}$ |
| $c$ | 0.969 | 1.128 | – |
| $\Delta H_b$ | 23, 473 | 15, 184 | $J/mol$ |
| $R^2$ | 0.9997 | 0.997 | – |
| $RMSE$ | 0.022 | 0.0049 | $mol/kg$ |

### 2.2 Mathematical Model

#### 2.2.1 System Description and Assumptions

The Magnetic Inductive Swing Induction process is modeled as a one-dimensional fixed bed adsorber operated in transient mode. The model captures the coupled dynamics of gas flow, heat transfer, and adsorption/desorption in a cylindrical packed bed containing $Fe_3O_4$@HKUST-1 composite adsorbent. The key modeling assumptions are:

- **One-dimensional plug flow:** Radial concentration and temperature gradients are negligible compared to axial variations
- **Dynamic operation:** Transient behavior captured through time-dependent terms
- **Two-phase system** with local thermal non-equilibrium between gas and solid phases

- **Ideal gas behavior:** Gas mixture obeys the ideal gas law
- **Uniform bed properties:** Bed porosity and particle size throughout the bed
- **Linear driving force (LDF) kinetics:** Adsorption rate proportional to difference between equilibrium and actual loading
- **Negligible axial dispersion:** Convective transport dominates over diffusive/dispersive transport in the gas phase
- **Local pressure equilibrium:** Pressure within particle pores instantly equilibrates with the bulk gas pressure

### 2.2.2 Conservation Equations -Standard Framework

We implemented the model in IDAES using the `FixedBed1D` class, which generates standard conservation equations [6]. The governing equations include:

Gas phase material balance for each component $i$ ($CO_2$, $N_2$):

$$A_b \cdot \varepsilon_b \cdot \frac{\partial(\rho_{mol} \cdot y_i)}{\partial t} = -\frac{\partial(F_{mol,i})}{\partial x} - A_s \cdot \rho_p \cdot r_{ads,i} \quad (3)$$

Gas phase energy balance:

$$A_b \cdot \varepsilon_b \cdot \frac{\partial(\rho_{mol} \cdot h_{mol,g})}{\partial t} = -\frac{\partial H_g}{\partial x} - \frac{6h_{gs}}{d_p} \cdot A_s \cdot (T_g - T_s) \quad (4)$$

Momentum Balance (Ergun Equation):

$$-\frac{dP_g}{dx} = \frac{150\mu_i(1-\varepsilon_b)^2 u}{\varepsilon_b{}^3 d_p^2} + \frac{1.75\rho_g(1-\varepsilon_b)u^2}{\varepsilon_b{}^3 d_p} \quad (5)$$

Solid Phase material balance for adsorbed component $i$:

$$A_s \cdot \rho_p \cdot \frac{\partial(q_i)}{\partial t} = A_s \cdot \rho_p \cdot r_{ads,i} \quad (6)$$

where geometric parameters include bed porosity $\varepsilon_b$[-], bed cross-sectional area $A_b$ $[m^2]$, solid cross-sectional area $A_s = (1-\varepsilon_b)\,A_b$ $[m^2]$, and particle diameter $d_p[m]$. Gas phase variables include molar density $\rho_{mol}$ $[mol/m^3]$, mass density $\rho_g$ $[kg/m^3]$, species mole fraction $y_i$ [-], superficial velocity $u$ $[m/s]$, temperature $T_g$ [K], absolute pressure $P_g$ $[Pa]$, viscosity $\mu_g$ $[Pa \cdot s]$, and specific enthalpy $h_{mol,g}$ $[J/mol]$. Enthalpy flow rate $H_g = u \cdot A_b \cdot \rho_{mol} \cdot h_{mol,g}$ $[W]$ and species molar flow rate $F_{mol,i} = u \cdot A_b \cdot \rho_{mol} \cdot y_i$ $[mol/s]$. Solid phase variables include particle density $\rho_p$ $[kg/m^3]$ adsorbed loading $q_i$ $[mol/kg]$, temperature $T_s$ $[K]$, and adsorption rate $r_{ads}, i$ $[mol/(kg \cdot s)]$. The gas-solid heat transfer coefficient is $h_{gs}$ $[W/(m^2 \cdot K)]$.

Bed porosity (void fraction) is calculated using the following relation [7]:

$$\varepsilon_b = 0.38 + 0.073\left[1 - \frac{\left(\frac{d_b}{d_p} - 2\right)^2}{\left(\frac{d_b}{d_p}\right)^2}\right] \quad (7)$$

where $d_b$ is bed diameter and $d_p$ is the particle diameter.

### 2.2.3 Inductive Heating Model

The key innovation extends the standard IDAES `FixedBed1D` model with inductive heating capability. When an alternating magnetic field is applied, the $Fe_3O_4$ nanoparticles within the composite generate heat through magnetic losses (hysteresis and relaxation mechanisms). This enables direct volumetric heating of the solid phase, bypassing the thermal resistances inherent in conventional TSA.

#### Specific Absorption Rate (SAR)

The heating power is characterised by the Specific Power Loss (SPL) or Specific Absorption Rate (SAR), which represents the power dissipated per unit mass of material. Based on magnetic relaxation theory[8, 9], SAR exhibits a quadratic dependence on the applied magnetic field amplitude:

$$L(B) = L_{ref}\left(\frac{B}{B_{ref}}\right)^2 \quad (8)$$

$B$ is the applied magnetic field amplitude (mT), $B_{ref}$ = 12.6 mT is the reference field amplitude, $L$ is the SAR as a function of $B$, and $L_{ref}$ = 1.6 W/g is the experimentally measured SAR of the $Fe_3O_4$@HKUST-1 composite at the reference field amplitude [2]. This quadratic scaling captures the fundamental physics of magnetic power dissipation in the superparamagnetic regime.

#### Modified Solid Energy balance

$$A_s \cdot \rho_p \cdot c_{p,s} \cdot \frac{\partial T_s}{\partial t} = \frac{6h_{gs}}{d_p} \cdot A_s \cdot (T_g - T_s) - A_s \cdot \rho_p \sum_i [\Delta H_{ads,i} \cdot r_{ads,i}] + Q_{ind} \cdot A_s - Q_{wall} \quad (9)$$

where $Q_{ind}$ $[W/m^3]$ is the volumetric inductive heating rate defined in Eq. (10), $\Delta H_{ads,i}$ $[J/mol]$ is the heat of adsorption for species $i$ (negative for exothermic adsorption), and $Q_{wall}$ $[W/m]$ is the heat loss to ambient defined in Eq. (11)

$$Q_{ind} = L(B) \cdot \rho_p \quad (10)$$

$$Q_{wall} = h_{wall} \cdot \pi \cdot d_b \cdot (T_s - T_{ambient}) \quad (11)$$

where $h_{wall}$ is the wall heat transfer coefficient and $T_{ambient}$ = 298 K is ambient temperature.

This formulation has three key advantages for MISA modeling:

- **Direct solid heating:** Energy is deposited directly in the solid phase, eliminating gas-to-solid heat transfer resistance
- **Controllable heating:** SAR is proportional to $B^2$,

allowing precise control via magnetic field amplitude

- **Rapid thermal response:** Inductive heating timescale (seconds) is much faster than conductive heating (minutes) in conventional TSA

When $B$ = 0 (adsorption phase), $Q_{ind}$ = 0 and the model reduces to the standard fixed-bed model but with wall heat loss. This enables modeling of complete MISA cycles where the magnetic field is switched on only during the desorption step.

### 2.2.4 Constitutive Relations

The model is completed with the following constitutive relations:

**Adsorption equilibrium:** Binary Sips isotherm (Section 2.1)

**Adsorption kinetics:** Linear Driving Force (LDF) model:

$$r_{ads,i} = k_i(q_{eq,i} - q_i) \qquad (12)$$

where $k_i$ is the mass transfer coefficient, $q_{eq,i}$ is the equilibrium loading from the Sips isotherm, and $q_i$is the average solid-phase loading concentration of component $i$ within the adsorbent particle at a given time. The mass transfer coefficient ($k_{CO_2}$ = $0.15\ s^{-1}$) was determined by fitting experimental breakthrough curve data. The $N_2$ coefficient ($k_{N_2}$ = $0.20\ s^{-1}$) was set higher than $CO_2$, consistent with $N_2$'s weaker adsorption (lower heat of adsorption) and minimal contribution to overall bed dynamics due to its low saturation capacity (0.93 mol/kg vs. 10.89 mol/kg for $CO_2$).

**Gas phase thermodynamics:** Ideal gas equation of state. Pure component properties are calculated from temperature-dependent correlations: heat capacity from NIST Shomate equations [10], and while viscosity and thermal conductivity use temperature-dependent power law correlations [11]. Mixture heat capacity is calculated as mole-fraction weighted average of component values. Mixture viscosity and thermal conductivity are calculated using Wilke mixing rules [12].

**Heat transfer:** The gas-solid heat transfer coefficient ($h_{gs}$) is calculated from particle-scale Nusselt number correlations as described in the IDAES documentation [6].

## 2.3 Numerical Implementation

The mathematical model was implemented using IDAES framework built on the Pyomo optimization modeling environment [13]. IDAES provides standardized property package interfaces, robust initialization strategies for DAE systems, and integration with state-of-the-art solvers. The IDAES `ControlVolume1D` and `FixedBed1D` classes automatically generate standard conservation equations (material, energy, momentum), while custom constraints were implemented for inductive heating and wall heat loss.

**Table 2**. Model Parameters

| Parameter | Value | Units |
|---|---|---|
| **Column Geometry** | | |
| Length (L) | 1.5 | $cm$ |
| Diameter (D) | 1.0 | $cm$ |
| Bed porosity ($\varepsilon_b$) | 0.39 | – |
| **Adsorbent Properties** | | |
| Particle diameter ($d_p$) | 0.5 | $mm$ |
| Particle density ($\rho_p$) | 1170 | $kg/m^3$ |
| Solid heat capacity ($C_{p,s}$) | 1070 | $J/(kg \cdot K)$ |
| **Operating Conditions - Adsorption** | | |
| Feed temperature ($T_{in}$) | 303 | $K$ |
| Feed pressure ($P_{in}$) | 1.3 | $bar$ |
| $CO_2$ concentration | 15 | $mol\%$ |
| Molar flow rate | $3.33 \times 10^{-5}$ | $mol/s$ |
| Magnetic field (B) | 0 | $mT$ |
| **Operating Conditions - Desorption** | | |
| Feed temperature ($T_{in}$) | 303 | $K$ |
| $CO_2$ concentration | 15 | $mol\%$ |
| Molar flow rate | $3.33 \times 10^{-5}$ | $mol/s$ |
| Magnetic field (B) | 11.1 - 12.6 | $mT$ |
| **Inductive Heating Parameters** | | |
| SAR at 12.6 mT ($L_{ref}$) | 1.6 | $W/g$ |
| Frequency ($f$) | 190 | $kHz$ |
| $Fe_3O_4$ content | 17 | $wt\%$ |
| **Heat Transfer** | | |
| Wall heat transfer Coeff. ($h_{wall}$)[a] | 20 | $W/(m^2 \cdot K)$ |
| Ambient temperature ($T_{amb}$) | 298 | $K$ |

[a] Values chosen to be in line with the literature [2, 16]

The reactor length domain (0 ≤ x ≤ L) was discretized using the backward finite difference method:

$$\frac{\partial \psi}{\partial x|_i} \approx \frac{\psi_i - \psi_{i-1}}{\Delta x} \qquad (13)$$

This discretization converts the PDEs into a DAE system in time. The backward difference scheme ensures numerical stability for convection-dominated flows and preserves causality in the flow direction.

A two-phase solution strategy was employed.

**Phase 1 (Initialization):** The model was initialized using hierarchical block triangularization with IPOPT [14]. State variables were temporarily fixed and constraints progressively activated in this order: thermophysical

properties, hydrodynamics, mass balances, energy balances.

**Phase 2 (Dynamic Integration):** The spatially discretized DAE system was integrated forward in time using the PETSc library [15] with backward Euler method:

$$\frac{\partial \psi}{\partial t}|_{n+1} \approx \frac{\psi_{n+1} - \psi_n}{\Delta t} \quad (14)$$

where $\Delta t$ is the time step (adaptive). Backward Euler provides stability for stiff systems, essential for capturing fast thermal transients during inductive heating.

Table 2 summarizes the operating conditions, bed geometry, and material properties used in all simulations.

## 2.4 Cycle Configuration

A simple MISA process operates as a three-step cyclic process: adsorption, inductive desorption, cooling.

**Step 1 – Adsorption:** The regenerated bed, initially equilibrated with pure $N_2$ at 303 K, is exposed to the adsorption operation condition given in Table 2. $CO_2$ selectively adsorbs onto the $Fe_3O_4$@HKUST-1 composite until the bed approaches saturation, typically occurring at 135-145 seconds under the conditions in Table 2.

**Step 2 - Magnetic Desorption:** Upon completion of adsorption, the magnetic field is activated ($B$ = 11.1-12.6 mT, $f$ = 190 kHz) while maintaining the same feed flow. Electromagnetic energy is directly absorbed by the $Fe_3O_4$ nanoparticles, causing rapid localized heating of the solid adsorbent. This direct solid-phase heating mechanism bypasses the thermal resistances inherent in conventional TSA, where heat must be conducted through the reactor walls and gas phase. The bed temperature rises rapidly from 303 K to approximately 440 K (167°C), driving $CO_2$ desorption. At $B$ = 12.6 mT ($L$ = 1.6 W/g), approximately 95% of adsorbed $CO_2$ is recovered within 2.11 minutes—a 4-fold reduction compared to conventional TSA [2].

**Step 3 - Cooling:** The magnetic field is deactivated, and the bed is cooled by continuing gas flow (pure $N_2$) until thermal equilibrium is restored at 303 K. Cold $N_2$ (convection) and wall heat loss ($h_{wall}$) to ambient contribute to cooling. Once cooled, the system begins the next adsorption cycle.

This cycle configuration serves as the basis for the validation studies in Section 3.

# 3 MODEL VALIDATION AND DISCUSSION

The model demonstrated two independent tests: dynamic breakthrough behavior, magnetic desorption performance. This demonstration approach ensures the model accurately and captures both thermodynamic equilibrium and transport-limited dynamic behavior under both adsorption and desorption conditions.

## 3.1 Breakthrough Validation

Dynamic breakthrough simulations were performed to validate the coupled mass transfer and equilibrium behavior of the model under transient conditions. The breakthrough experiments reported were replicated numerically using the operating conditions in Table 2. A step change in feed composition from pure $N_2$ to a binary mixture (15% $CO_2$, 85% $N_2$) was introduced at $t$ = 0 to a freshly regenerated bed initially at 303 K. The outlet $CO_2$ concentration was monitored until bed saturation.

### 3.2.1 Detailed Validation at 15% $CO_2$

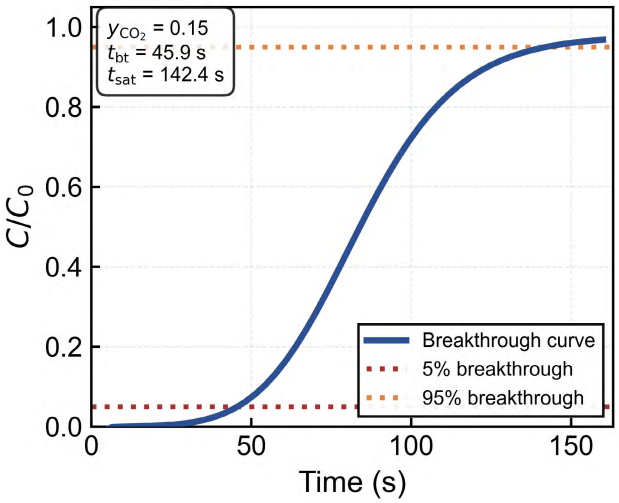

**Figure 2.** Solid line: model prediction. Orange dashed lines indicate the model's calculated 5% breakthrough (t = 45.9 s) and 95% saturation (t = 142.4 s) times. These are compared against the experimental benchmark values of 42 s and 138 s, respectively, as reported in the text of [2].

Figure 2 shows the high-resolution breakthrough curve validation for the 15% $CO_2$ feed case over a 0–160 second timeframe. Breakthrough curves express outlet concentration normalized by inlet ($C/C_0$). Time domain was discretized into 50 points.

Comparison with experimental data demonstrates strong agreement. The model achieves 9% error in breakthrough time and 6% error in saturation time relative to experimental values from [2]. This close agreement validates both the Sips equilibrium isotherm parameters (Table 1) and the LDF mass transfer coefficients, confirming that the model accurately captures the coupled thermodynamic and adsorptive behavior of the system.

The slight overprediction of breakthrough times may be attributed to factors like: i) the LDF approximation assumes a uniform concentration driving force within particles, while actual intraparticle profiles may be more complex [17] ii) bed channeling or radial flow maldistribution in the experimental setup, which are not captured by the 1D model [18].

### 3.2.2 Effect of Feed $CO_2$ Concentration

To further demonstrate the model's predictive capability across a wider operating range, breakthrough simulations were performed at three different $CO_2$ feed concentrations: 15%, 30%, and 50% (balance $N_2$). Figure 3 shows the simulated breakthrough curves over a 0–15 minute timeframe for all three cases. As expected, increasing $CO_2$ concentration results in earlier breakthrough and faster approach to saturation due to the higher driving force for adsorption and the more rapid consumption of available adsorption sites.

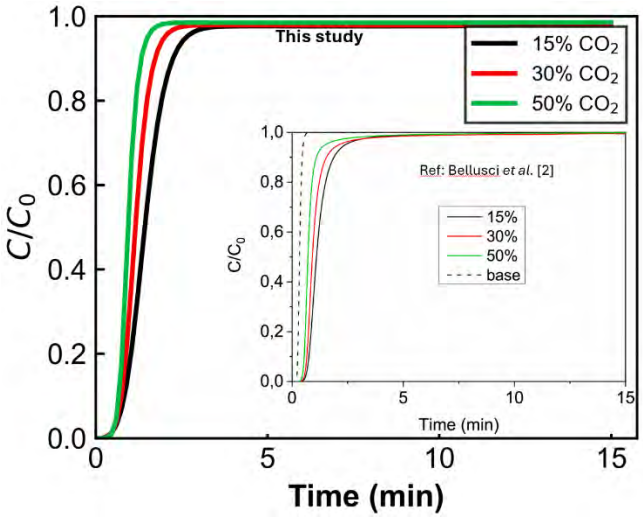

**Figure 3.** Breakthrough behavior at varying $CO_2$ feed concentrations (15%, 30%, 50%).

High-resolution experimental data for quantitative validation at 30% and 50% $CO_2$ were not available in [2]. However, the model captures the expected theoretical behavior: increasing the $CO_2$ feed concentration from 15% to 50% reduces the saturation time by a factor of 1.6. This response is consistent with the competitive adsorption physics described by the binary Sips isotherm, where higher partial pressures drive faster saturation.

## 3.2 Desorption Validation

Desorption simulations were performed to demonstrate the inductive heating capability and thermal coupling in the model. The desorption experiments were also replicated numerically by first saturating the bed with 15% $CO_2$ at 303 K, then activating the magnetic field while maintaining the same feed flow rate and composition. Three different magnetic field intensities were tested: $B$ = 11.1, 11.8, and 12.6 mT at $f$ = 190 kHz.

### 3.2.1 $CO_2$ Desorption Profiles

Figure 4 presents the simulated outlet $CO_2$ concentration profiles. Following bed saturation, the magnetic field is activated at t=0, and the outlet concentration is monitored. The peak outlet concentration reaches 28.3 vol% at 12.6 mT, demonstrating near-complete regeneration.

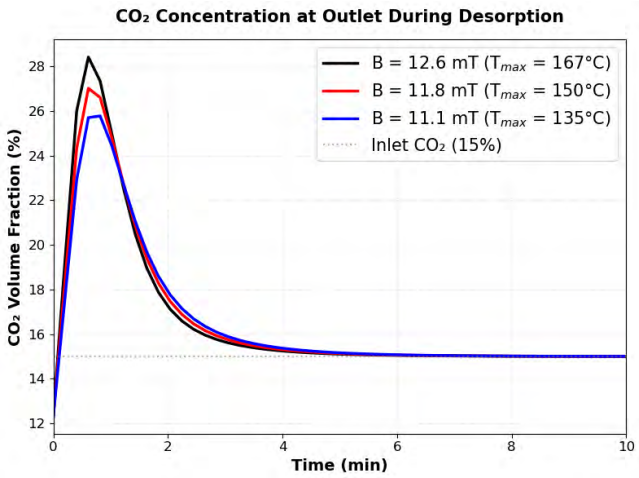

**Figure 4.** $CO_2$ desorption curve at different applied magnetic fields with maximum temperature attained at each magnetic field.

These results demonstrate the quadratic $B^2$ scaling relationship in the SAR model (Equation 8), consistent with Rosensweig's theory [8]. To substantiate the model's accuracy, Table 3 compares the results with experimental data from Bellusci et al. [2]. The model achieves high quantitative accuracy, predicting peak desorption magnitudes with <6% error across all field strengths. While the simulation predicts a slightly broader desorption profile due to continuum mass-transfer assumptions, the peak magnitude and total regeneration times show strong agreement with experimental values. We note that the experimental values shown in Table 3 are not precise because they were digitally determined from a low-resolution figure, so peak error is only valid to one significant figure.

**Table 3**. Quantitative comparison of simulated desorption against experimental data [2].

| Field | Peak $CO_2$ (vol%) | Peak Error | Time to Peak (min) |
|---|---|---|---|
| mT | Exp./Sim. | (%) | Exp./Sim. |
| 12.6 | 29.0/28.3 | 2 | 0.50/0.65 |
| 11.8 | 26.5/27.0 | 2 | 0.48/0.65 |
| 11.1 | 24.5/25.8 | 5 | 0.49/0.65 |

### 3.2.2 Temperature Evolution

Figure 5 shows the simulated bed temperature profiles during magnetic desorption for the same three field strengths. The temperature evolution directly reflects the electromagnetic heating rate determined by the SAR value. At $B$ = 12.6 mT, the bed temperature rises rapidly from 303 K to a peak of approximately 440 K (167°C). At the lower field strengths, the peak temperatures are

proportionally lower: ~423 K (150°C) at $B$ = 11.8 mT and ~408 K (135°C) at $B$ = 11.1 mT.

Table 4 provides a quantitative comparison of the predicted peak temperatures against experimental measurements. The model produces close match to experimental data, with errors under 5% for all three field strengths. At the highest field strength ($B$ = 12.6 mT), the model predicts 440 K (167°C) versus the experimental value of 448 K (175°C), representing a 4.5% error. This close agreement validates both the SAR heating model (Equation 8) and the thermal energy balance (Equation 9), confirming that the model accurately captures the coupled heat generation, accumulation, and loss mechanisms.

**Table 4.** Temperature and Regeneration Validation

| $B$ (mT) | $T_{max}$ Exp. | $T_{max}$ Model | Error (%) |
|---|---|---|---|
| 12.6 | 448 K (175°C) | 440 K (167°C) | 4.5 |
| 11.8 | 428 K (155°C) | 423 K (150°C) | 3.2 |
| 11.1 | 403 K (130°C) | 408 K (135°C) | 3.8 |

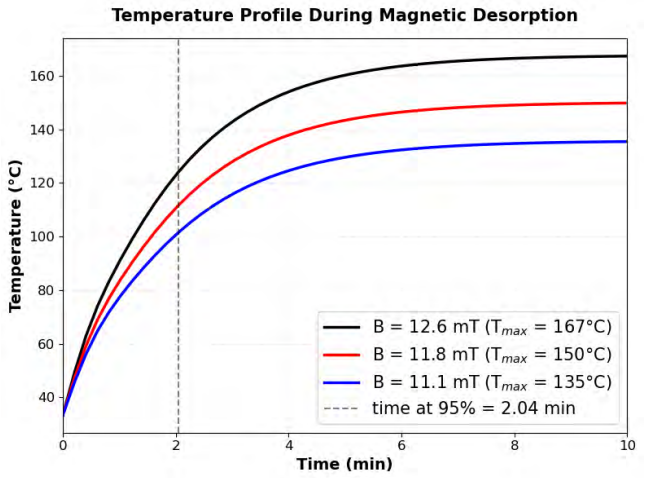

**Figure 5.** Temperature evolution at different $B$ values and 95% regeneration time.

The slight underprediction of peak temperatures may be attributed to: (*i*) radial temperature gradients not captured by the 1D axial model - the thermocouple may measure local radial hot spots near the wall or center that differ from the radially-averaged temperature predicted by the 1D formulation [18], (*ii*) uncertainty in the solid heat capacity ($Cp,s = 1070\,J/(kg \cdot K)$), which was assumed constant but varies with temperature, and (*iii*) heat losses through the reactor wall ($h_{wall}$ = 20 $W/(m^2 \cdot K)$), which may be overestimated, leading to lower predicted peak temperatures.

Despite these minor discrepancies, the strong correlation between predicted and experimental temperatures across three different field strengths confirms that the model correctly captures the physics of electromagnetic heating and thermal transport in the MISA system. The validated thermal model enables confident prediction of energy requirements and regeneration performance under various operating conditions.

### 3.3 Model Limitations and Applicability

While the model accurately captures thermodynamic limits, two approximations introduce kinetic deviations. First, the LDF approximation ($k_i$= 0.15 $s^{-1}$) simplifies intra-particle transport, resulting in a broader desorption profile and slower post-peak decay compared to the sharp experimental release [18]. Second, the continuum heating assumption causes a minor onset lag (~0.15 min), as volume-averaged temperatures respond slower than instantaneous local "hot spots." Despite these broadening effects, the model's thermodynamic accuracy (<6% peak error) and robust regeneration time predictions validate its utility for cycle optimization and scale-up.

## 4 CONCLUSION AND FUTURE WORK

This work presents the first validated open-source IDAES model for Magnetic Inductive Swing Adsorption, extending the standard `FixedBed1D` framework with electromagnetic heating capability via Specific Absorption Rate physics. Multi-level validation against experimental data confirms the model accurately captures coupled thermodynamic-kinetic-thermal behavior across different conditions for $CO_2$ capture (273-440 K, 15-50% $CO_2$, 11.1-12.6 mT), with breakthrough predictions within 9%, temperature predictions within 5%, and isotherm fits exceeding $R^2$ = 0.996. The validated quadratic $L \propto B^2$ scaling confirms MISA achieves four-fold faster regeneration than conventional TSA.

While the LDF kinetic approximation introduces ~10% systematic error in breakthrough times and validation remains limited to laboratory scale, the model provides a robust foundation for cycle optimization and techno-economic analysis. Future work will leverage this platform to identify optimal cycle configurations through multi-objective optimization, compare MISA economics against conventional TSA/PSA technologies, and guide scale-up to pilot demonstration.

The open-source implementation enables model extensions and facilitates MISA advancement from laboratory demonstrations toward industrial deployment for energy-efficient $CO_2$ capture.

## ABSTRACT

In the field of biochemical process design, the accurate modeling of microbial growth is essential for the development and optimization of biological reactors used in the production of high-value compounds. Achieving this objective requires a detailed understanding of how environmental factors—such as pH and nutrient availability—influence microbial dynamics across the four distinct growth phases: lag, exponential, stationary, and death. Traditionally, reactor design relies heavily on the Monod model, which provides a simplified representation of microbial growth, focusing primarily on the exponential phase under constant operating conditions (1). However, this model presents substantial limitations when applied to dynamic environments where key parameters vary over time. To overcome these constraints, the present study proposes a data-driven modeling approach using a multilayer perceptron (MLP) artificial neural network for the prediction of microbial growth trajectories under varying pH conditions and substrate compositions. The yeast strain *Candida guilliermondii* was selected as the model microorganism due to its industrial relevance. Experimental growth data were collected through optical density measurements using a Multiskan™ FC Microplate Photometer (Thermo Scientific), covering a pH range from 6.0 to 8.5 and two substrate scenarios: pure xylose, and a 1:2 glucose–xylose mixture. The experimental data were used to train the MLP neural network, which generated predictive models capable of estimating growth behavior under the specified input conditions. This modeling approach enables the simulation of microbial growth curves at any given time point within the defined parameter space, providing a more flexible and comprehensive tool compared to classical models. The results of this study demonstrate that the proposed MLP-based model is a powerful computational tool for both the design and real-time control of bioprocesses. The integration of these tools into predictive control strategies is a key aspect of the bioprocess research. The model's versatility and its ability to predict microbial behavior make it a very important tool for bioreactor control.

**Keywords**: Artificial Intelligence, Modelling and Simulations, Machine Learning, Optimization, Biomass, microbial growth

## INTRODUCTION

The design and operation of biological reactors critically depend on an accurate representation of microbial growth kinetics. These kinetics directly determine reactor productivity, stability, and control perfor-

mance. Among the most widely adopted kinetic formulations, the Monod model remains a foundational tool due to its simplicity and interpretability. Nevertheless, its validity is constrained to dilute systems, constant environmental conditions, and predominantly the exponential growth phase. Consequently, significant uncertainty arises when Monod-based models are employed for predicting microbial behavior under dynamic conditions, particularly during the lag and stationary phases.

In recent years, surrogate modeling techniques based on artificial intelligence and machine learning have emerged as promising alternatives for representing complex biological phenomena. Neural network–based models are capable of learning nonlinear relationships directly from experimental data without requiring explicit mechanistic assumptions. This makes them particularly suitable for systems involving multiple substrates, inhibitory effects, high substrate concentrations, and environmental variability.

Previous studies have explored surrogate models for microbial and microalgal growth under limited and mostly static conditions. For instance, Lee et al. (2015) reviewed kinetic models for microalgae cultivation, while Akkermans and Van Impe (2018) investigated the effect of pH inhibition using mechanistic approaches. More recent works have applied data-driven techniques to microbial systems; however, these efforts typically focus on one or two growth phases or assume fixed operating conditions. Notably, Murrieta-Dueñas et al. (2022) proposed a neural network approach to describe exponential growth under dynamic conditions, yet a comprehensive representation of the full growth trajectory remains largely unexplored.

To the best of the authors' knowledge, no previous study has demonstrated the prediction of multiple microbial growth phases under simultaneously varying pH and substrate conditions using a single surrogate model. Therefore, this work aims to fill this gap by developing an MLP-based surrogate model capable of predicting the complete microbial growth trajectory of *Candida guilliermondii* under dynamic environmental conditions.

# METHODOLOGY

Figure 1 illustrates the overall methodology adopted in this study, which consists of two main stages: (i) experimental data acquisition and (ii) surrogate model development.

## Experimental Design

Microbial growth experiments were conducted under controlled laboratory conditions to generate high-resolution kinetic data. The experimental matrix included pH values ranging from 6.5 to 8.5 and two substrate formulations: pure xylose and a glucose–xylose mixture (1:2). Cultivations were performed over a 24-hour period to capture the lag, exponential, and stationary growth phases. Optical density measurements were collected every 15 minutes in triplicate to ensure reproducibility and statistical robustness.

## Surrogate Model Development

The second stage involved the construction of a surrogate model using a multilayer perceptron neural network. The MLP was trained to approximate the nonlinear mapping between the input variables—time and pH—and the output variable, optical density (absorbance). Different network architectures were evaluated by varying the number of neurons and activation functions. Model performance was assessed using standard statistical metrics, including AIC, MSE, RMSE, and the coefficient of determination ($R^2$).

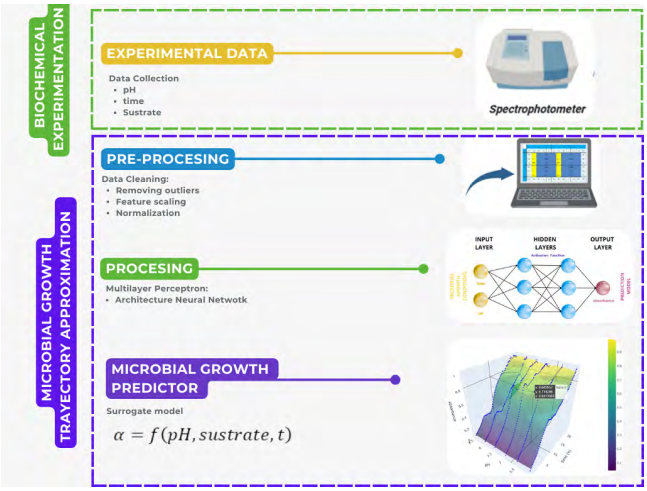

**Figure 1.** Methodology of Microbial growth trajectory approximation.

## Biochemical Experimentation

Microbial growth is conventionally described through four distinct phases: lag, exponential, stationary, and death. The lag phase corresponds to the period immediately following inoculation, during which microorganisms adapt to the new environmental conditions and activate the metabolic pathways required for growth. Once adaptation is complete, the system enters the exponential phase, characterized by rapid cell division and substrate consumption at an approximately constant specific growth rate. As nutrients become depleted and inhibitory metabolites accumulate, the system transitions into the stationary phase, where cell growth and death rates are approximately balanced. Finally, the death phase is marked by a progressive decline in viable biomass, resulting in a significant reduction or cessation of microbial growth. These phases constitute a generalized kinetic framework that applies to a wide range of microorganisms, including bacteria,

fungi, yeasts, and microalgae.

In this study, the kinetic behavior of the yeast *Candida guilliermondii* was selected as the model system. This microorganism is widely distributed in natural environments and can be readily isolated from fruits and berries with high sugar content. In addition, it is commonly found as part of the native microflora of human skin and mucous membranes. Beyond its ecological prevalence, C. guilliermondii is of considerable biotechnological interest due to its ability to act as a biological control agent and its well-documented capacity to bioconvert xylose into xylitol, a high-value polyol with applications in the food and pharmaceutical industries. This metabolic capability relies on the efficient production of enzymes and cellular energy required for pentose assimilation.

Under optimal conditions, C. guilliermondii exhibits maximal growth at approximately pH 7 and a temperature of 28 °C. However, industrial bioprocesses often operate under suboptimal or fluctuating environmental conditions. For this reason, the present work explores a broader pH range, from 6.5 to 8.5, in order to capture the adaptive kinetic response of the microorganism. These controlled pH variations enable the observation of different growth regimes over a 24-hour cultivation period, thereby generating a comprehensive dataset that spans multiple growth phases.

Given the relevance of C. guilliermondii in xylose bioconversion, two substrate formulations were evaluated: a culture medium containing xylose as the sole carbon source and a mixed-substrate medium consisting of a glucose–xylose blend at a 1:2 ratio. The inclusion of glucose aims to assess its influence on reducing the lag phase and accelerating the onset of exponential growth, a strategy commonly employed to enhance process productivity in mixed-sugar fermentations.

All experiments were conducted in triplicate to ensure reproducibility and statistical reliability. Experimental analyses were performed at the Microbial Interaction Laboratory of the National Technological Institute of Mexico, Irapuato campus. Microbial growth was monitored via optical density measurements at 600 nm, which served as a proxy for biomass concentration. Measurements were recorded every 15 minutes over a 24-hour period at a constant temperature of 28 °C using a Thermo Scientific Multiskan™ FC Microplate Photometer. Cultivations were carried out in multiwell plates, allowing for high-throughput data acquisition and consistent experimental conditions across all runs.

## Microbial Growth Trajectory Approximation

The second stage of the proposed methodology focuses on learning the underlying data patterns from the experimentally obtained microbial growth kinetics of C. guilliermondii. To this end, a data-driven surrogate model based on machine learning was developed using a multilayer perceptron (MLP) neural network. The well-established capabilities of modern artificial intelligence techniques, particularly neural networks, provide an efficient and flexible framework for predicting microbial growth under previously unobserved combinations of operating conditions.

The MLP architecture employed in this study consists of three main components: (i) an input layer, (ii) one or more hidden layers, and (iii) an output layer. Input signals are propagated forward through the network, where each neuron applies a nonlinear transformation to a weighted linear combination of its inputs. The final output of the network is a scalar value representing the predicted absorbance. In this work, the MLP is used as a nonlinear function approximator and predictive model to estimate the absorbance $\alpha$ as a function of time $t$ and the pH of the culture medium.

From a theoretical standpoint, a multilayer perceptron is a universal approximator of continuous nonlinear functions, which makes it particularly suitable for modeling complex biological and biochemical processes. Formally, the MLP implements the functional mapping described by Equation (1), where the output is expressed as a composition of nonlinear activation functions parameterized by a set of weights and biases.

This modeling approach allows the MLP to implicitly capture phase transitions and nonlinear growth dynamics without explicitly segmenting the growth curve, thereby offering a significant advantage over classical kinetic models when dealing with dynamic and non-ideal operating conditions.

From a formal perspective, the MLP implements the function described by Equation 1.

$$y = f(x, \omega) \qquad \text{Eq. (1)}$$

Where $f$ is a composition of nonlinear functions parameterized by weights and biases, ω.

The experimental setup is as follows: The number of neurons in the hidden layer was varied to determine the optimal topological architecture for our artificial neural network. Three activation functions—Sigmoid, ReLu, and Tanh—were analyzed. We implemented the Adam optimizer to automatically adjust the learning rate of each parameter, allowing for faster and more stable convergence. The number of neurons is as follows: 2, 4, 6, 8, and 10. We used a dataset of 540 feature vectors. We use the widely tested least squares function as the fitness function during the training stage. We validate our model using standard growth factors. We trained the machine learning model using three pH values (6.5, 7.5, 8, and 8.5) and substrate formulations in the culture medium (xylose at 100% and glucose-xylose at a ratio of 1:2). Our model predicts absorbance values for any combination of pH between 6.5 and 8.5, substrate (xy-

lose or glucose-xylose), and timestamp (hours) between 0 and 24.

## RESULTS

In this work, a machine-learning–based framework was developed for the estimation and prediction of microbial growth kinetics, as schematically illustrated in Fig. 6. The proposed framework comprises two main stages: model training and model testing. During the training stage, experimentally obtained kinetic data are used to fit the parameters of the neural network and to quantify the training error, expressed in terms of the mean squared error (MSE train ). This stage results in the construction of the HC-MLP predictor model, which encapsulates the learned nonlinear relationship between the input variables and the microbial growth response.

To rigorously assess the generalization capability of the trained model, the testing stage employs an independent replicate of the experimental kinetic data that was not used during training. The prediction error obtained at this stage, quantified as MSE test, provides an unbiased evaluation of the model's predictive performance. Based on the results of the testing stage, the final surrogate model is obtained. This surrogate model generates a continuous response surface that represents the MLP approximation of the output variable—optical density (absorbance)—as a function of the input variables, time (t) and pH, for culture media containing xylose as the carbon source.

A case study was conducted to evaluate the predictive capability of the proposed MLP framework. The objective of this analysis was to assess the model's ability to accurately predict microbial growth for arbitrary combinations of pH and time within the studied domain. Specifically, the model was used to estimate absorbance values over a time horizon ranging from 0 to 24 h and pH values between 6.5 and 8.5, assuming xylose as the sole substrate. To identify the optimal network topology, the number of neurons in the hidden layer was systematically varied, allowing for an evaluation of the trade-off between model complexity and predictive accuracy.

To select the most appropriate neural network architecture, several complementary performance metrics were employed, including the Akaike information criterion (AIC), mean squared error (MSE), root mean squared error (RMSE), and the coefficient of determination ($R^2$). The AIC was used as the primary criterion for model selection, as it simultaneously accounts for goodness of fit and model parsimony by penalizing excessive complexity. Lower AIC values indicate a more favorable balance between predictive accuracy and information loss. The MSE quantifies the average squared deviation between predicted and observed values and was primarily used to compare model performance during the training phase. The RMSE, expressed in the same units as the experimental measurements, provides an intuitive measure of prediction error and was used for both validation and testing stages. Finally, the coefficient of determination ($R^2$) evaluates the proportion of variance in the experimental data explained by the model, with values approaching unity indicating excellent agreement between predictions and observations.

Table 1 summarizes the values of all performance metrics for the several MLP architectures evaluated in this study. Each metric is reported for the training, validation, and testing stages, providing a comprehensive basis for selecting the optimal neural network configuration.

As evidenced by the results summarized in Table 1, configuration 2 exhibits the most robust and consistent performance across all selected evaluation metrics. This configuration yields the lowest Akaike information criterion (AIC) value during the training phase (–1825.33), indicating an optimal trade-off between model fidelity and structural complexity. Comparable AIC behavior is observed in the validation and testing phases, which

further suggests that the selected architecture generalizes well beyond the training dataset.

In terms of predictive accuracy, configuration 2 achieves one of the lowest mean squared error (MSE) values, equal to 0.005842, demonstrating a high-quality fit to the experimental data. A similar trend is observed for the root mean squared error (RMSE), with values of 0.074527 and 0.069864 obtained for the validation and testing stages, respectively. These low RMSE values, expressed in the same units as the measured absorbance, confirm the model's ability to accurately reproduce microbial growth dynamics across the studied domain. Furthermore, the coefficient of determination ($R^2$) for this configuration approaches unity in all stages, indicating that the surrogate model explains nearly all of the variance observed in the experimental measurements.

Taken together, these results indicate that configuration 2 provides the most favorable balance between predictive performance, model parsimony, and computational efficiency. Consequently, the optimal MLP architecture corresponds to a network with two hidden layers comprising six neurons each, which minimizes the risk of overfitting while maintaining high predictive capability.

Figure 2 illustrates the three-dimensional response surface generated by the surrogate model corresponding to configuration 2 of the multilayer perceptron neural network. In this representation, the experimental data points are shown as blue markers, while the continuous surface depicts the MLP-based approximation of the microbial growth trajectory within the defined data domain. The smoothness and continuity of the predicted surface, together with its close agreement with the experimental observations, demonstrate the model's ability to capture the underlying nonlinear kinetics of *Candida guilliermondii* growth as a function of time and pH.

As illustrated in Figure 2, red neuronal perception can effectively predict the four phases of microbial growth: lag, exponential, stationary, and death. This observation is consistent across the pH range analyzed in the experimental setting (6.5–8.5). The resulting model is able to predict the trajectory of microbial kinetics from a point within the experimental data space. This trajectory can be verified by the gray line shown as an example in Figure 2. This trajectory can be verified at any point in the analyzed space and yields the corresponding coordinate values. Therefore, if we are aware of this condition, we can predict the microorganism's growth phase and implement the appropriate control measures to ensure the highest possible yield of the biological reaction.

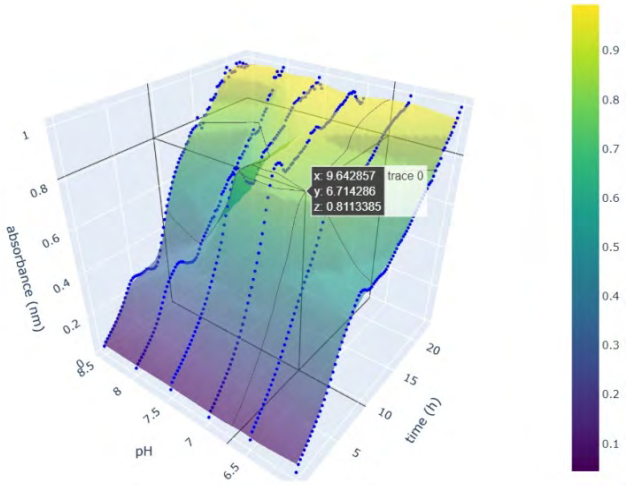

**Figure 2.** Best surrogate model of configuration 2, for predicted microbial growth kinetics trajectory of *Candida guillermondii*.

## CONCLUSIONS

This study presents a robust data-driven framework for modeling microbial growth kinetics under dynamic environmental conditions using a multilayer perceptron neural network. Unlike classical kinetic models, the proposed surrogate model successfully captures nonlinear microbial behavior across multiple growth phases without relying on restrictive mechanistic assumptions.

The results demonstrate that the MLP-based model provides accurate predictions of microbial growth trajectories for *Candida guilliermondii* under varying pH and substrate conditions. This approach significantly enhances the flexibility and predictive capability of kinetic modeling tools, making it particularly suitable for applications in bioreactor design, optimization, and real-time control.

From an engineering perspective, the developed surrogate model enables rapid scenario analysis and supports the automation of experimental workflows, thereby reducing experimental costs and development time. Future work will focus on extending the model to include additional environmental variables, such as temperature and substrate inhibition, as well as integrating the surrogate model into advanced process control and digital twin frameworks for industrial bioprocesses.

## ABSTRACT

This work presents the dynamic optimization of glucose feed in cell cultivation considering the balance between productivity and impurity generation. We first developed a mechanistic model considering cell growth promotion by glucose and cell growth inhibition by osmolarity for a newly developed, high-productivity CHO-MK cell line. For model development, fed-batch cultivation experiments were conducted at a 250 mL scale under three different glucose feeding profiles. Results from a single-objective dynamic optimization, using the glucose feed profile as a design variable, were compared to those from multi-objective problem settings with varying weights assigned to productivity and final impurity concentrations. Simulation results suggested different glucose feed profiles depending on the priority given to the mAb and impurities, where the main difference was in the generated viable cell density profiles. Productivity-focused profiles employed a low–high–intermediate feeding strategy, in which the total glucose feed over the cultivation period was set to a balanced level, with an initially low rate, followed by a gradual increase, and a later decrease. Profiles focusing on impurity reduction adopted a feeding strategy that maintained a high glucose feed throughout the cultivation period. This work demonstrated the power of mechanistic-model-based process design and is expected to encourage further model-based process design in biopharmaceutical manufacturing.

## INTRODUCTION

Monoclonal antibody (mAb) drugs are effective for the treatment of serious diseases, leading to rapid expansion of the mAb market and the development of new technologies, including host cell lines such as the newly developed high-productivity CHO-MK cell line [1]. In the cultivation step, cells grow and produce mAb while consuming nutrients such as glucose. Impurities such as host cell protein (HCP) are released from viable and dead cells, whereas impurities such as charge variants are acidic or basic modifications of the mAb. These impurities need to be removed during the succeeding purification step, which is costly, making it crucial to maximize mAb yield while minimizing impurity concentrations during cultivation. To achieve this objective, feed rate of glucose, which serves as a primary nutrient for cells, has been reported to play an important role. Insufficient glucose supply can lead to its depletion as cell density increases, whereas excessive supply can result in high osmolarity, both of which negatively affects cell growth [2].

Design of the cultivation step should carefully consider dynamic changes and cell phases (such as stationary and exponential growth phases) by accordingly adjusting process parameters. Several studies have proposed experimental approaches for controlling glucose feed rates, in which feeding strategies were adjusted in response to changes in measurable physical parameters (such as glucose concentrations [3] and oxygen uptake rates [4]). Although these experimental approaches can

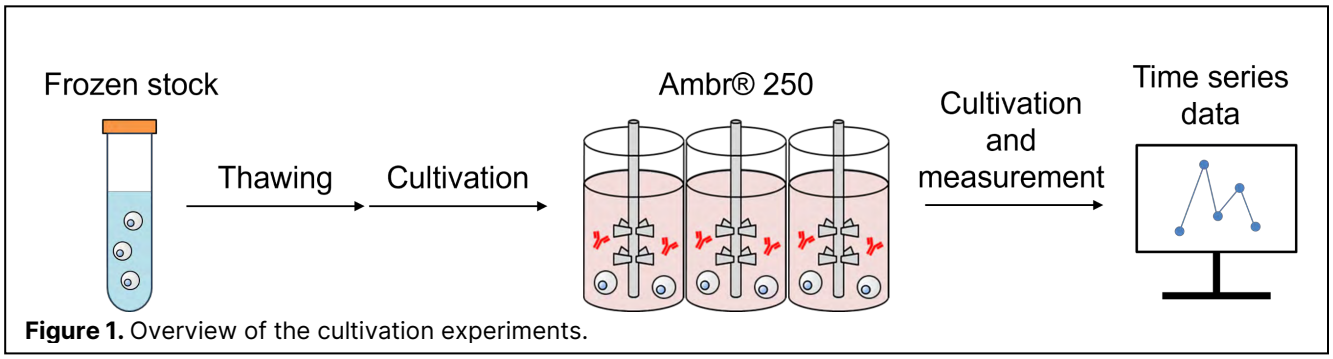

**Figure 1.** Overview of the cultivation experiments.

be useful, they are often limited in exploration range due to the reliance on empirically determined setpoints. As an alternative, mathematical models offer a powerful means to efficiently explore combinations of process parameters. In fed-batch cultivation, variables such as glucose feed rates [5], and in perfusion cultivation, bleed rates [6], have been employed as design variables to maximize the final mAb product concentration. While some studies considered the balance between productivity and impurity concentrations such as aggregates through multi-objective optimization [7], generally the consideration of quality attributes in these works remain limited.

This work presents dynamic optimization of glucose feed in cell cultivation considering the balance between mAb productivity and the generation of multiple impurities. We first developed a mechanistic model that considers cell growth promotion by glucose and cell growth inhibition by osmolarity for a newly developed, high-productivity CHO-MK cell line. For model development, fed-batch cultivation experiments were conducted at a 250 mL scale under three different glucose feeding profiles. The developed model was then applied to dynamic optimization with the glucose feed profile as a design variable. Single-objective optimization aimed at maximizing mAb productivity and multi-objective optimization considering impurities were compared. The results suggested different glucose feed profiles depending on the relative priority of mAb and impurities, with the main differences observed in the generated viable cell density profiles.

# METHODS

## Experimental methods

Figure 1 represents an overview of the experimental methods. To obtain experimental data for modeling, cultivation experiments were conducted using a newly developed CHO-MK cell line [1] was used. Cells were extracted from a frozen stock, thawed, and cultured in flasks for one week to increase cell density. Subsequently, cultivation was carried out with Ambr® 250 at a 250 mL scale. Initial solution volume ($V_0$ [L]) was set to 0.17 in all experiments. Three fed-batch cultivation experiments, each lasting one week, were conducted at a 250 mL scale using Ambr® 250 under different glucose feed rate conditions ($F_{\mathrm{in,glc}}$ [$V_0$ g day$^{-1}$]: 6, 11, and 15), hereafter referred to as Experiments (A), (B), and (C), respectively. The values of $F_{\mathrm{in,glc}}$ were set within the range of 6–15 $V_0$ g day$^{-1}$ commonly used by cultivation experts. In the experiments, medium feed rate ($F_{\mathrm{in}} = 8$, 10 % $V_0$ day$^{-1}$), feed start time ($t_{\mathrm{in}} = 48$ h), glucose feed start time ($t_{\mathrm{in,glc}} = 48$ h), agitation rate ($\omega = 1$, 200 rpm), and dissolved oxygen ($DO = 20$ %) were set as specified. In addition to viable cell density, the concentrations of multiple components (e.g., mAb, impurities, and metabolites) were measured offline once or twice per day Table 1 shows the values of $F_{\mathrm{in,glc}}$ in the three experiments.

**Table 1:** Values of $F_{\mathrm{in,glc}}$ in Experiments (A)–(C).

| Experiments | (A) | (B) | (C) |
|---|---|---|---|
| $F_{\mathrm{in,glc}}$ [$V_0$ g day$^{-1}$] | 6 | 11 | 15 |

## Model development

### Mechanistic model equations

A mechanistic model was developed as shown by Eqs. (1)–(6) in Table 2, where $V$ [L], $X_{\mathrm{v}}$ [cells L$^{-1}$], $X_{\mathrm{d}}$ [cells L$^{-1}$], [GLC] [mmol L$^{-1}$], [mAb] [g L$^{-1}$], [Main] [g L$^{-1}$], [Acid] [g L$^{-1}$], [HCP] [g L$^{-1}$], $Osm$ [mOsm kg$^{-1}$] are the solution volume, viable, and dead cell densities, glucose, mAb, main/acidic/basic charge variant, and HCP concentrations, as well as osmolarity. $\mu$ [h$^{-1}$] and $\mu_{\mathrm{d}}$ [h$^{-1}$] represent specific cell growth and death rates, respectively. $\mu_{\max}$ [h$^{-1}$] is the maximum value of $\mu$ described by the Monod type equations. $q_{\mathrm{p,a}}$ [g$^{-1}$ cell] and $q_{\mathrm{p,b}}$ [g cell$^{-1}$ h$^{-1}$] are the growth-dependent and growth-independent constants for mAb production, respectively. $k_{i,\mathrm{lysis}}$ [h$^{-1}$] is the rate constant of the dead cell lyses and the HCP dissolution, where $i$ includes dead cell and HCP. $k_{\mathrm{acid}}$ [h$^{-1}$] is the rate constant for acidic charge variant formation. $Y_{\mathrm{hcp}/X_{\mathrm{v}},X_{\mathrm{d}}}$ [g cell$^{-1}$] is the mass of HCP released from a viable cell and a lysed dead cell. $f_{\mathrm{osm}}$ [–] is the growth inhibition term due to osmolarity, taking a value in the range of 0–1. $K_{\mathrm{osm}}$ [mOsm kg$^{-1}$] represents the minimum osmolarity of the

subject to

$$\boldsymbol{x} = \left(F_{in,glc}\big|_{48 \leq t < 72}, F_{in,glc}\big|_{72 \leq t < 96}, F_{in,glc}\big|_{96 \leq t < 120}, F_{in,glc}\big|_{120 \leq t < 144}, F_{in,glc}\big|_{144 \leq t}\right)$$
$$F_{in,glc} \in \{6,7,\ldots,14,15\}$$

$$\alpha + \beta + \gamma = 1 \qquad t\ [h] \leq 168 \qquad F_{in}\ [\%\ V_0\ day^{-1}] = 8$$

solution. $Osm_{lim}$ [mOsm kg$^{-1}$] is the osmolarity value which represents osmolarity levels with zero growth levels. In this work, osmolarity was considered to depend on the number of dissolved particles per unit weight of solution, based on a previous study [8]. It was expressed as a linear function of the viable and dead cell densities and the glucose concentration which are described in the model.

## Model fitting and validation

Model fitting and cross-validation were performed using cultivation data from Experiments (A)–(C). Model parameters were estimated for two cases: one case in which Experiments (A) was used as the validation batch in Case 1, and one case in which all three experiments were used for training (Case 2). The system of ordinary differential equations was solved using the Python package solve_ivp with a time step of 0.001 h. Parameter estimation was performed using the Nelder-Mead optimization method to maximize the sum of coefficients of determination ($R^2$) between the calculated and measured values of all system components. Parameter uncertainty was analyzed by computing standard errors via inversion of the Hessian matrix, using the Python package lmfit.

## Multi-objective dynamic optimization

By using the developed mechanistic model, a design problem was defined as shown in Eq. (7) in Table 3 for performing optimization by adjusting the glucose feed rate $F_{in,glc}$ every 24 h starting from the initiation of feeding (48 h after the start of cultivation). In the optimization, both single-objective optimization to maximize mAb productivity and multi-objective optimization considering impurities were conducted. Glucose feed rates on days 2–6 were determined. The values of $F_{in,glc}$ were set in the range of 6 to 15 $V_0$ g day$^{-1}$ with an increment of 1 $V_0$ g day$^{-1}$ (a total of 10 values) to ensure that the exploration remained within the applicable range of the model. As a result, a total of $10^5$ (100, 000) profiles were explored, with the total glucose feed over the entire cultivation period ranging from 30 to 75 $V_0$ g. The simulation was performed from $t$ = 2 h, which corresponds to the starting time of data measurements in the cultivation experiments, until t = 168 h. The measured values $t$ = 2 h were used as initial conditions. The update frequency of $F_{in,glc}$ (i.e., every 24 h) was determined based on expert recommendations. The feed start time ($t$ = 48 h) was set to the same value

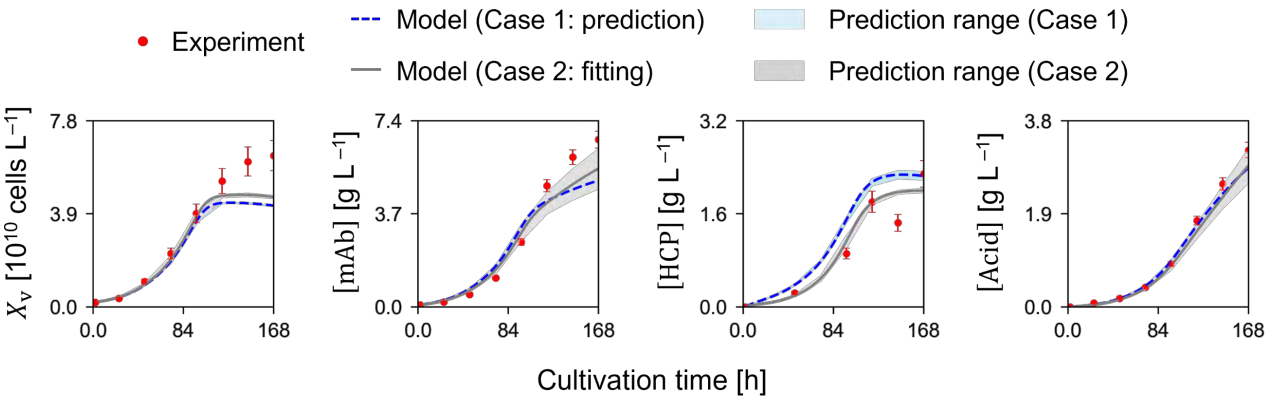

**Figure 2.** A part of the fitting and validation results for Experiment (A).

**Table 4:** Average values of $R^2$ and NRMSE across all modeled components for the validation batch in Case 1 and for all training batches in Case 2.

| Case (Validation batch) | 1 (A) | 2 (All data used for training) |
|---|---|---|
| $R^2$ | 0.84 | 0.95 |
| NRMSE | 0.13 | 0.13 |

as that used in the model training experiments (Experiments (A)–(C)). $[\mathrm{mAb}]_{\max}, [\mathrm{mAb}]_{\min}, [\mathrm{Acid}]_{\max}, [\mathrm{Acid}]_{\min}, [\mathrm{HCP}]_{\max}$, and $[\mathrm{HCP}]_{\min}$ represent the maximum and minimum calculated values of $[\mathrm{mAb}], [\mathrm{Acid}]$, and $[\mathrm{HCP}]$, respectively, at the end of cultivation ($t$ = 168 h) among the 100, 000 profiles considered. $\alpha, \beta$, and $\gamma$ are the weighting values for the normalized values of each component in the objective function, and the sum is always equal to 1. $\alpha, \beta$, and $\gamma$ represent the priorities of mAb productivity and the burden of acidic variants and HCP in the purification process, respectively. To assess the impact of the chosen three weighting factors, two scenarios where $(\alpha, \beta, \gamma)$ = (1, 0, 0) and (0.4, 0.3, 0.3) were investigated as Scenarios (i) and (ii), respectively. In Scenario (i), the weighting of $\alpha$ was set to 1, aiming for single-objective optimization considering only mAb productivity. In contrast, in Scenario (ii), multi-objective optimization was performed.

# RESULTS AND DISCUSSION

## Modeling results

Model fitting and validation were performed for the two cases (Cases 1 and 2), each using different experimental data as training sets. Figure 2 shows the fitting and validation results of the mechanistic model for Experiment (A) as an example of the obtained results. In each figure, the results for Cases 1 and 2 are represented in blue and gray, respectively. Calculated results for the training and validation data are shown as solid and dashed lines, respectively. The shaded prediction range represents the interval between the minimum and maximum predicted profiles, calculated using the estimated parameter values and their standard errors under the assumption that the parameters follow a normal distribution. Table 4 summarizes the $R^2$ and normalized root mean square error (NRMSE) values averaged over all components for the validation batch in Case 1 and for the three experimental datasets in Case 2. High predictive accuracy was confirmed in the cross-validation of Case 1, with an $R^2$ value of 0.84. The model parameters estimated in Cases 1 and 2 took similar values, demonstrating the robustness of the model. In the subsequent simulations, the parameter values estimated in Case 2 were used, where all three experimental datasets were used for training.

## Multi-objective dynamic optimization

The mechanistic model was applied to find the solution to the single-objective (Scenario (i)) and multi-objective (Scenarios (ii)) design problems (Eq. (7)) shown in Table 3. The glucose feed profiles that maximized the objective function in Scenario (i) and Scenario (ii) were $(F_{\mathrm{in,glc}}|_{48\le t<72}, F_{\mathrm{in,glc}}|_{72\le t<96}, F_{\mathrm{in,glc}}|_{96\le t<120}, F_{\mathrm{in,glc}}|_{120\le t<144}$, and $F_{\mathrm{in,glc}}|_{144\le t})$ = (6, 13, 15, 15, 11) and (15, 15, 15, 15, 15), respectively. Figure 3 shows a part of the simulation results based on the optimized profile in each scenario, where

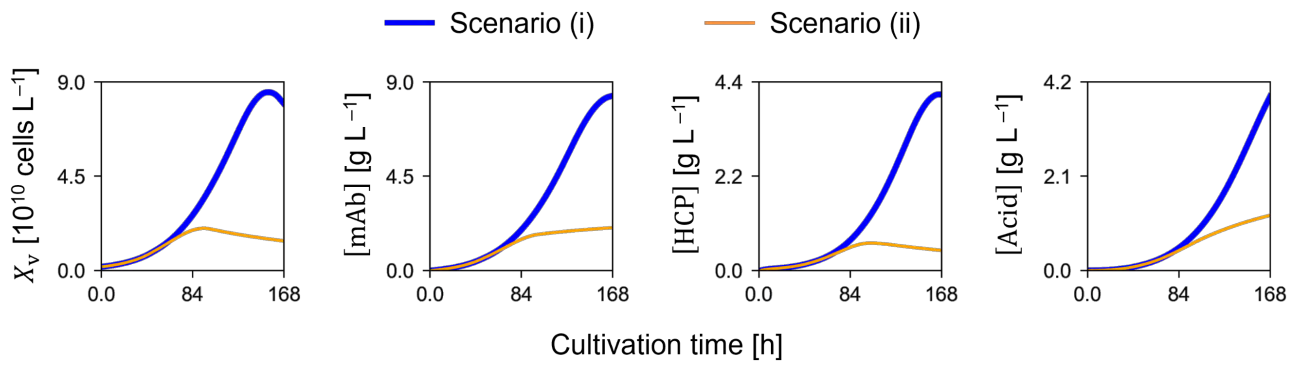

**Figure 3.** Simulation results based on the optimized profile in the two scenarios.

different glucose profiles and simulation outcomes were observed. In the two scenarios, based on the combination of weighting values, glucose feed profiles were appropriately set to adjust viable cell density, which would directly affect mAb and impurity concentrations, for achieving a suitable balance between nutrient availability and osmolarity. The following points were considered as the factors that led to the selection of the optimized profile in the two scenarios.

### <Scenario (i)>

In the optimized profile, the total glucose feed over the entire cultivation period, which was explored within the range of 30–75 $V_0$ g, was found to take a value of 60 $V_0$ g. This value is considered to reflect a balance aimed at avoiding both glucose depletion due to excessively low feeding and increased osmolarity due to excessively high feeding. The optimized profile exhibited a low-high-intermediate feeding strategy: the feed rate was kept low (6 $V_0$ g day$^{-1}$) during the early stage of cultivation ($t$ = 48–72 h), then gradually increased ($t$ = 72–96 h: 13 $V_0$ g day$^{-1}$; $t$ = 96–144 h: 15 $V_0$ g day$^{-1}$), and subsequently reduced toward the late stage of cultivation ($t$ = 144–168 h) to 11 $V_0$ g day$^{-1}$. In this low–high–intermediate strategy, glucose feed rates were kept low during the early stage of cultivation to avoid an increase in osmolarity. Subsequently, during the mid-to-late stage when cells grow exponentially, the feed rates were increased, implying that a sufficient amount of glucose was supplied.

### <Scenario (ii)>

In the optimized profile, the total glucose feed was 75 $V_0$ g with glucose feed rates maintained at high levels throughout the cultivation period. This outcome can be explained as follows: high values of $F_{\mathrm{in,glc}}$ lead to growth inhibition due to elevated osmolarity, resulting in a decrease in viable cell density as well as a concomitant decrease in dead cell density. Since mAb and HCP originate from viable and dead cells, and acidic variants originate from mAb, the reduction in viable cell density is considered to contribute to the decrease in impurity concentrations observed in the simulation results.

## CONCLUSIONS AND OUTLOOK

This work presented dynamic optimization of glucose feed in cell cultivation considering the balance between productivity and impurity concentrations. A mechanistic model was developed to describe concentration profiles of mAb as well as multiple impurities, considering cell growth promotion by glucose and cell growth inhibition due to osmolarity for a newly developed, high-productivity CHO-MK cell line. The developed model enabled the optimization of glucose feed profiles to maximize mAb yield, as well as multi-objective optimization considering multiple impurities. The simulation results indicated that distinct glucose feed profiles were obtained depending on whether priority was placed on mAb production or impurity reduction, with the primary difference reflected in the resulting viable cell density profiles. In the productivity-focused profile, the total glucose feed over the entire cultivation period was set to a balanced level (60 $V_0$ g) within the explored range of 30–75 $V_0$ g, and a low–high–intermediate feeding strategy was adopted. In contrast, the impurity-focused profile employed a strategy that maintained the maximum glucose feed within the explored range (15 $V_0$ g day$^{-1}$) throughout the cultivation period. This work demonstrated the power of mechanistic-model-based process design in biopharmaceutical manufacturing. The future work includes experimental validation of the proposed low-high-intermediate feeding strategy.

## DIGITAL SUPPLEMENTARY MATERIAL

The raw experimental data used for Figure 2 are available as Table S1 in LAPSE:2026.0040.

## ACKNOWLEDGEMENTS

This work was supported by the Japan Agency for Medical Research and Development (AMED) under Grant Number JP21ae0121015 and by JST SPRING under Grant Number JPMJSP2108, and Leadership Development Program for Ph.D., the University of Tokyo. The authors would like to thank Dr. Takayuki Horiuchi for providing general support for this work.

## ABSTRACT

In this work, artificial neural networks are used to represent advanced oxidation processes, such as electrochemical oxidation, electro-Fenton, and photoelectro-Fenton, for the degradation of two dyes. The effect of treatment time, initial dye concentration, and current density on the degradation percentage is studied. Additionally, a network is developed to include discrete variables, such as treatment type and dye type, as input features, enabling it to predict the system's performance across different technologies and pollutants. Operating conditions are optimized using the universal ANN as a surrogate model and the adaptive differential evolution algorithm to maximize dye removal efficiency. According to the results, after optimizing the architecture of the artificial neural networks using Bayesian optimization, deviations of 3.9% or less are obtained for purple RL removal predictions, while for Green A, deviations of 8% or less are obtained. These models may serve as a basis for more robust representations in the future, including the effects of electrochemical device size, among other relevant variables.

**Keywords**: artificial neural networks, dye removal, electrochemical processes

## INTRODUCTION

Water is a highly important resource for humankind, fundamental for the development of life on the planet. Unfortunately, water scarcity has increased over the last few years in several countries [1, 2], underscoring the urgent need for strategies to reduce the water footprint of human activities. Among the actions to reduce such a footprint, the treatment and reuse of industrial wastewater have gained importance, as they reduce the need for fresh water in industrial processes [3]. These actions are highly relevant, as approximately 25-30% of the total wastewater discharged into water channels comes from the industrial sector [4, 5].

In particular, the textile industry discharges large volumes of polluted water, including dyes and other chemicals that must be removed to prevent damage to aquatic plants and animals [6]. Another industry with a high contribution of dyes to wastewater is the tannery industry, due to the materials used to color leather in the post-tanning stage [7]. Electrochemical advanced oxidation processes, such as electrochemical oxidation (EO), electro-Fenton (EF), and photoelectro-Fenton (PEF), have proven to be highly efficient technologies for degrading dyes from wastewater [8]. Electrochemical oxidation involves the direct oxidation of the pollutant at the anode surface, mediated by hydroxyl radicals [9]. On the other hand, the EF and PEF processes use the Fenton reaction to generate hydroxyl radicals from hydrogen peroxide. In the electro-Fenton approach, H2O2 is generated internally by electrical power [10], whereas the PEF approach involves exposing the solution to ultraviolet light [11].

Rigorous mathematical models have been reported to represent the performance of electrochemical advanced oxidation technologies. Cañizares et al. [12] visualized the system as three interconnected stirred-tank reactors, one where a chemical reaction occurred, the

other two corresponding to the cathodic and anodic reaction zones. Similarly, Chen et al. [13] presented a model that accounted for mass transfer due to electromigration, surface adsorption and desorption, and oxidation at the anode. Unfortunately, the available models have diverse limitations stemming from the assumptions they make. Since kinetic models require information on reaction stoichiometry and kinetic parameters, it is necessary to understand how each type of pollutant reacts. Moreover, it is necessary to estimate the mass transfer coefficients for the pollutant under analysis. Additionally, using actual wastewater introduces additional complexity in obtaining the parameters required to solve the mathematical model and obtain reliable information about the system. As an alternative to overcome such limitations, the use of artificial intelligence-based models has been proposed in recent years to represent the interactions among variables in systems whose mechanistic models are complex or inaccurate. Among the artificial intelligence tools used to represent the relationships between variables in a given system, artificial neural networks (ANNs) are powerful and widely used in recent years for a variety of applications. ANNs mimic the learning capacities of the human brain to analyze and process data. By this approach, patterns in complex systems can be identified by providing sufficient data, and it is theoretically capable of approximating any nonlinear functionality [14]. Thus, these techniques can be adequate for representing the relationships among the relevant variables associated with electrochemical advanced oxidation processes.

## CASE STUDY

The removal of two dyes commonly used in the tannery industry (Green A and Purple RL) was investigated using three electrochemical advanced oxidation processes: EO, EF, and PEF. For each experiment, 100 mL of dye solution at initial concentrations of 30, 50, and 80 ppm was treated. The electroactive area was 2 $cm^2$, using a Dimensionally Stable Anode–Boron Doped Diamond (DSA–BDD) anode (electroactive area 2 $cm^2$) and a Pt cathode, with $Na_2SO_4$ as the supporting electrolyte. The pH was adjusted to 3.0 and maintained, and three current densities were applied: 25, 35, and 50 mA $cm^{-2}$. All experiments were conducted over 60 minutes, with samples collected every 10 minutes (Figure 1). The percentage of pollutant removal was determined as the response variable by UV–Vis spectrometry. The full set of variables used to develop the ANN models and their values are summarized in Table 1.

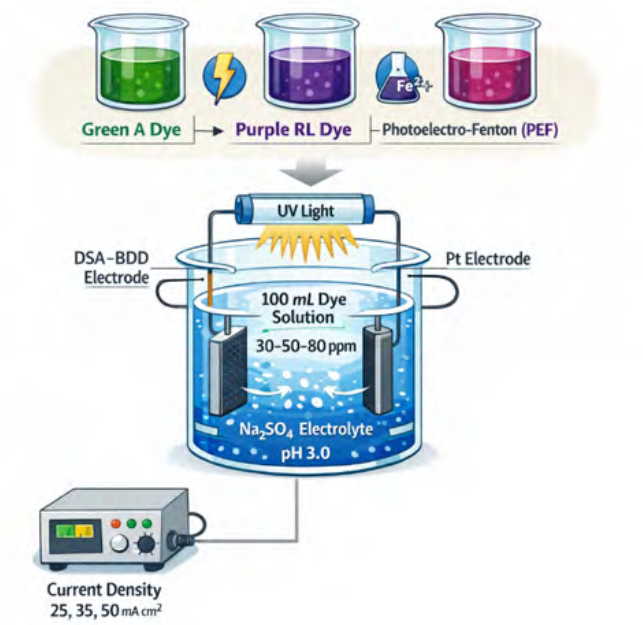

**Figure 1.** Schematic of the EO, EF, and PEF system for removing Green A and Purple RL dyes, showing the DSA–BDD anode and Pt cathode, $Na_2SO_4$ electrolyte at pH 3.0, current densities (25–50 mA $cm^{-2}$), UV light for PEF, and UV–Vis monitoring of dye removal.

**Table 1:** Variables used in the ANN models.

| Variable | Description | Values |
|---|---|---|
| D | Dye type (1 = Green A, 2 = Purple RL) | 1, 2 |
| P | Electrochemical process | 1, 2, 3 |
| C | Initial dye concentration (ppm) | 30, 50, 80 |
| I | Current density (mA cm^-2) | 25, 35, 50 |
| t | Treatment time (min) | 0, 10, 20, 30, 40, 50, 60 |
| Removal (%) | Dye removal efficiency | 0-100 |

## METHODOLOGY

A total of 378 experimental data points were obtained (63 points for each Dye-Process combination). The input variables selected for the ANN models were dye concentration, current density, and treatment time. For the ANN models developed at the colorant level, the type of electrochemical process was additionally included as an input variable, encoded numerically as EF = 1, EO = 2, and PEF = 3.

The experimental dataset was randomly split into training and test sets at 80–20%. Prior to training, all continuous input variables were standardized using a StandardScaler to ensure comparable magnitudes and to

improve training stability. The output variable (% removal) was kept on its original physical scale.

## Artificial neural network modeling

Two ANN modeling strategies were adopted in this work. First, individual ANN models were developed for each dye–process combination, yielding 6 neural networks in total. These models were used exclusively for predictive purposes, enabling the assessment of removal behavior under fixed electrochemical conditions without optimization. The optimal architecture for each ANN was determined using Bayesian optimization (Table 2).

All networks were trained by backpropagation, and the training optimizer (Adam or stochastic gradient descent, SGD) was selected as part of the Bayesian optimization search space.

Second, a single universal ANN model was developed by integrating both dyes and all electrochemical processes into one predictive framework. In this model, the dye type and the electrochemical process were included as discrete input variables, while dye concentration, current density, and treatment time were experimentally defined at discrete levels but treated as continuous variables within the ANN and optimization framework. A repair mechanism was applied during optimization to ensure that all evaluated solutions corresponded to experimentally feasible operating conditions. The universal ANN was optimized and used as a surrogate model for process optimization.

**Table 2:** Search space for Bayesian optimization of ANN architectures.

| Variables | Values |
|---|---|
| Number of layers | [1 - 4] |
| Number of neurons | [1 - 16] |
| Activation function | [ReLU, ELU, Leaky ReLU] |
| Optimizer | [Adam, SGD] |

## Physical consistency and output constraints

Although the ANN output layer employed a linear activation function to avoid saturation and preserve sensitivity near optimal conditions, no explicit output constraint was enforced during training. Consequently, the model may sometimes predict removal efficiencies that exceed the physically feasible range, especially when extrapolating outside of the experimental domain. To ensure physical consistency, predictions were clipped post-processing to the range 0–100% during the optimization stage.

It is important to note that this clipping operation does not improve the predictive performance of the ANN nor correct any model deficiencies. Instead, it introduces a limitation in the interpretation of predictions: while clipped values prevent unphysical results, they mask potential overestimation in regions where the model extrapolates beyond the available data. Therefore, clipped predictions should be viewed as upper-bound estimates rather than definitive predictions, and experimental validation remains essential to confirm the actual removal efficiencies under the predicted conditions. In the future, further model refinements could address this limitation and improve accuracy, potentially eliminating the need for post-processing clipping.

## Optimization of operating conditions

The universal ANN model was used as a surrogate objective function to determine the operating conditions that maximize dye removal efficiency. The optimization was performed using the adaptive differential evolution algorithm (JADE). JADE was used for operating-condition optimization with the following parameters: population size of 20, 50 generations, mutation factor (default value), and crossover rate (default value). The convergence criterion was based on a threshold for improvement in the fitness value.

The optimization was conducted independently for each dye, with the dye identifier fixed prior to execution. The decision variables included the electrochemical process, initial dye concentration, current density, and treatment time. Discrete variables were handled through a repair mechanism, which involved rounding the values to the nearest experimentally feasible levels. This repair mechanism ensured that all candidate solutions corresponded to experimentally feasible conditions.

## Model validation and interpretation

The predictive performance of the ANN models was evaluated using the test dataset through quantitative error metrics, including the Mean Absolute Error (MAE) and standard deviation of the predicted removal efficiencies. Given the limited dataset size, no cross-validation or random splits were performed during this analysis. Although, the performance metrics consistently demonstrated a reliable model prediction across the dataset. The standard deviation was We chose ordinal encoding as a practical approach to represent the process and dye types while avoiding a large increase in feature dimensionality. One-hot encoding could potentially be more appropriate for certain models, but we believe the ordinal encoding sufficiently captured the relationships between the variables without overcomplicating the model. We will explore alternative encoding strategies, such as one-hot encoding, in future work to better understand its impact on the model performance and accuracy calculated from the residuals, defined as the difference between experimental and predicted removal efficiencies for all test samples.

Parity plots were also generated to compare experimental and predicted removal efficiencies. For the optimization results, the ANN-derived optimal conditions

**Table 3:** Optimal ANN architectures and predictive performance for individual dye–process models.

| Dye | Process | Hidden layers | Neurons per layer | Activation function | Optimizer | Standard deviation of prediction error (%) (test set) |
|---|---|---|---|---|---|---|

| Green A | EO | 2 | 14-9 | Leaky ReLU | Adam | 7.963 |
| Green A | PEF | 4 | 14-12-1-6 | ELU | Adam | 2.040 |
| Purple RL | EF | 1 | 6 | ELU | SGD | 3.832 |
| Purple RL | EO | 3 | 13-12-8 | ELU | Adam | 3.733 |
| Purple RL | PEF | 2 | 16-12 | ELU | Adam | 6.635 |

**Table 4:** Optimal architecture and performance metrics of universal ANN model.

| Dye | Hidden layers | Neurons per layer | Activation function | Optimizer | Standard deviation of prediction error (%) (test set) |
|---|---|---|---|---|---|
| Scope Both Dyes | 4 | 10-16-13-9 | Leaky ReLU | SGD | 3.977 |

**Table 5:** Optimal operating conditions predicted by the universal ANN models and corresponding experimental validation.

| Dye | Pro-cess | Concentration (ppm) | Current density (mA cm^-2) | Time (min) | ANN-predicted re-moval (%) | Experimental re-moval (%) |
|---|---|---|---|---|---|---|
| Green A | PEF | 30 | 50 | 60 | 100.0 | 95.0 |
| Purple RL | PEF | 30 | 50 | 50 | 100.0 | 100.0 |

were experimentally validated, and any discrepancy between predicted and observed removal efficiencies was attributed to model interpolation and extrapolation effects inherent to data-driven approaches.

# RESULTS

## Performance of individual ANN models.

Six individual ANN models were developed for each dye–process combination. These models were not used for operating-condition optimization and were used solely to evaluate the predictive capability of the ANN approach under fixed electrochemical conditions.

The optimal architectures of the individual ANN models, obtained via Bayesian optimization, are summarized in Table 3. The low standard deviations across all models indicate satisfactory predictive performance.

Parity plot comparing experimental and predicted removal efficiencies for Green A (PEF process) is presented in Figure 2, showing good agreement across the evaluated operating range.

## Universal ANN model

A single universal ANN model integrating both dyes and all electrochemical processes was developed and optimized. The optimal architecture and performance metrics of the universal ANN model are reported in Table 4.

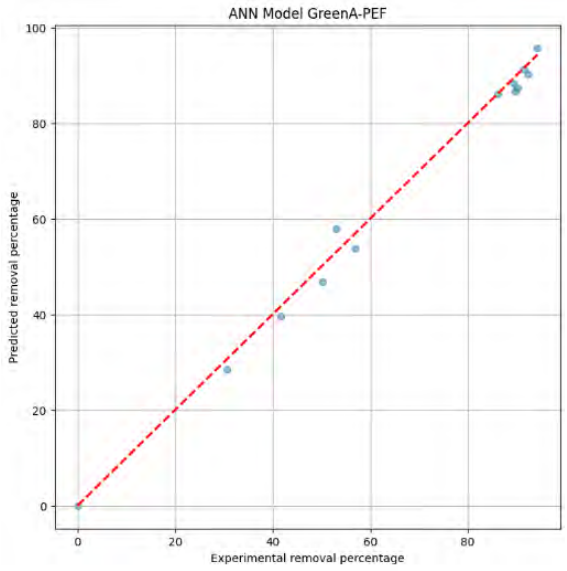

**Figure 2.** Parity plot for individual ANN models.

Despite the increased complexity of modeling multiple dyes and processes, the universal ANN demonstrated strong predictive capability, as evidenced by the parity plot shown in Figure 3.

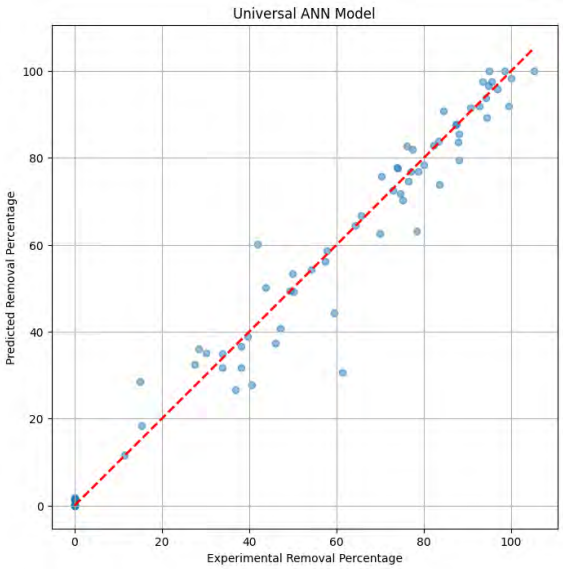

**Figure 3.** Parity plot for Universal ANN model.

## Optimization of operating conditions

The optimized universal ANN model was employed to determine the operating conditions that maximize dye removal efficiency. The optimization was performed independently for each dye by fixing the dye identifier and maximizing the ANN-predicted removal efficiency with respect to the operating variables.

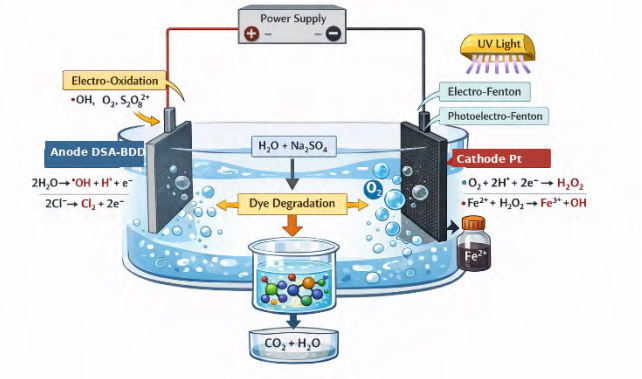

**Figure 4:** Electrochemical system for dye degradation showing EO, EF, and PEF pathways, with •OH generation at the DSA–BDD anode, $H_2O_2$ production and Fenton reactions at the Pt cathode, and UV-assisted $Fe^{2+}$ regeneration leading to dye mineralization.

Table 5 summarizes the optimal operating conditions predicted by the ANN-based optimization framework, along with the corresponding predicted removal efficiencies. Experimental validation confirmed that the optimized conditions yielded high removal efficiencies, though slightly lower than the ANN-predicted theoretical maxima.

Overall, Figure 4 shows how the combination of EO, EF, and PEF processes sustains the continuous generation of highly reactive species in the system.

The formation of •OH radicals at the anode and through the Fenton reaction at the cathode, together with the photochemical regeneration of $Fe^{2+}$ under UV irradiation, maintains a strongly oxidizing environment that accounts for the progressive degradation of the dyes. This behavior highlights the importance of the synergy between electrochemical and photochemical pathways in driving the transformation of contaminants into increasingly simpler products.

## CONCLUSIONS

Artificial neural networks-based models have been developed to represent the performance of three electrochemical advanced oxidation techniques in the degradation of dyes. Both the individual and the universal models predict accurately the performance of the processes, with deviations lower than 10%. This indicates that these models can properly predict the complex performance of the electrochemical advanced oxidation techniques, opening further research areas for more detailed analysis.

## ABSTRACT

Reliable kinetic models are essential for the design, optimisation and operation of methanol synthesis reactors in power-to-X applications. However, parameter estimation is frequently performed without prior assessment of parametric identifiability or the information content of experimental conditions, often resulting in poorly constrained parameters and inefficient experimental campaigns. This study introduces a systematic, pre-calibration, information-driven framework for identifiability analysis and experimental design. The framework integrates local sensitivity analysis, structural and practical identifiability metrics and a Sequential Information-Driven Experimental Selection (SIDeS) strategy to guide experiment selection prior to parameter estimation. The methodology is applied to four literature kinetic models for methanol synthesis, spanning varying levels of mechanistic detail. A Sobol-sampled design space is first screened for feasibility and local information content, followed by cumulative Fisher information analysis. Results demonstrate that conventional screening campaigns provide limited gains in parameter precision, whereas SIDeS identify compact experimental sequences that significantly improve practical identifiability within a constrained experimental budget. Cross-model comparison reveals that increased mechanistic description does not necessarily translate to improved identifiability under fixed experimental resources. The proposed framework supports informed model selection, reduces unnecessary calibration effort, and provides actionable design-of-experiments recommendations for methanol synthesis systems.

**Keywords**: Methanol Synthesis, Kinetic Modelling, Identifiability Analysis, Fisher Information Matrix, Design of Experiments

## 1. INTRODUCTION

Methanol is a versatile chemical used as a fuel, hydrogen carrier, and precursor to a wide range of industrial products. Its synthesis from captured $CO_2$ and green hydrogen represents a key component of emerging power-to-X technologies aimed at reducing carbon emissions. Accurate kinetic models are central to the design, optimisation, and simulation of methanol synthesis reactors, yet predictive modelling remains challenging due to the complex reaction network and variability across catalysts and operating conditions [1].

The literature reports several kinetic expressions and mechanistic formulations developed under different assumptions, datasets, and catalyst systems [1, 2, 3, 4]. As a result, reported parameter values exhibit significant variability, reflecting differences in operating windows, data quality, and estimation methodologies. Historically, parameter estimation has relied on nonlinear regression of reactor-specific datasets, with limited assessment of model transferability. Moreover, calibration is typically performed without prior evaluation of structural or practical parameter identifiability, i.e. whether model parameters can be uniquely inferred from the available measurements under the given experimental condition, nor of the information content of the underlying experimental conditions [5]. This limits confidence in estimated parameters and hampers the design of informative

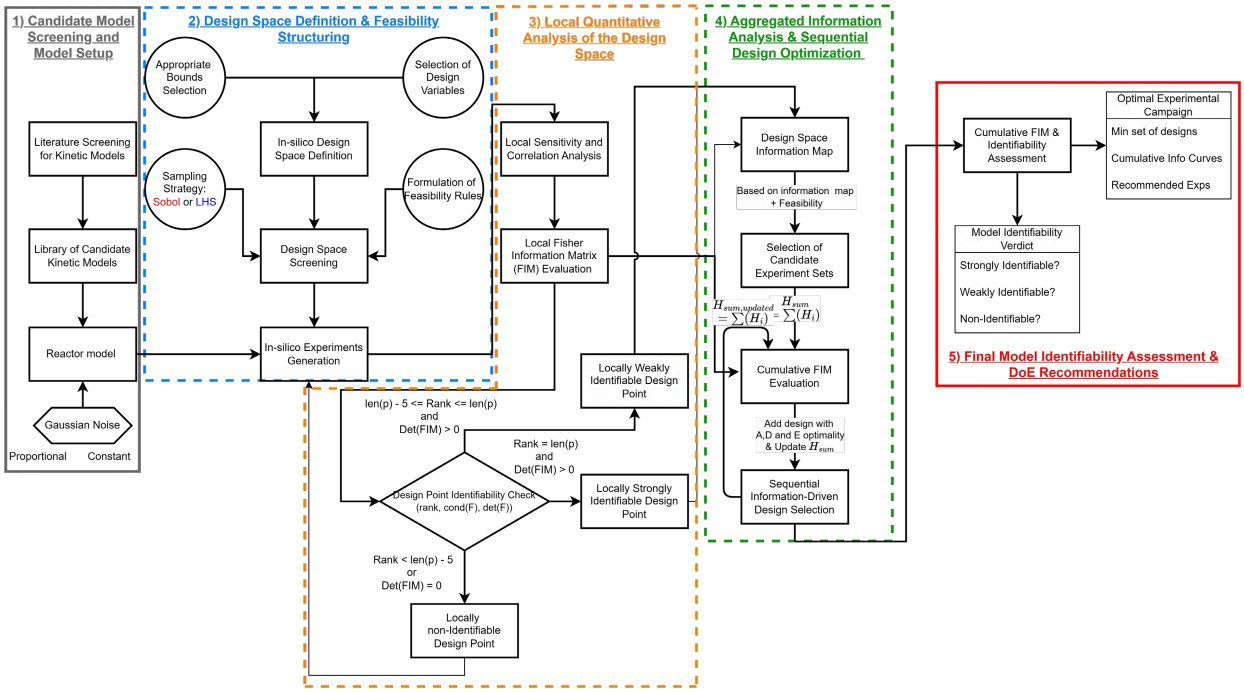

**Figure 1.** Overview of the proposed pre-calibration identifiability and sequential design framework. The workflow comprises: (1) model setup and candidate screening, (2) design space definition and feasibility constraints, (3) local sensitivity-based information analysis, (4) cumulative FIM-based SIDeS design selection, and (5) final identifiability assessment and DoE recommendations.

experiments.

Model-based design of experiment (MBDoE) techniques has been widely applied to improve parameter precision and guide experiment selection for kinetic models using Fisher-information-based criteria. Early contributions focused on optimal experiment design for parameter estimation in reaction systems, while more recent studies have explored identifiability analysis and information-driven experiment selection strategies for reactor models and catalytic systems. For example, De Luca et al. (2016) [8] investigated experiment redesign strategies for improving parameter estimation, while Deussen et al. (2022) [9] analysed identifiability issues in kinetic model calibration workflows. More recent work by Friso and Galvanin (2024) [10] further explored advanced MBDoE methodologies for reaction engineering applications. However, these approaches are typically applied during or after calibration, whereas the present work focuses on pre-calibration screening of kinetic models and operating conditions, aiming to identify informative experimental regions before parameter estimation is performed.

This study introduces a systematic, pre-calibration, information-driven framework integrating local sensitivity analysis, structural identifiability, practical identifiability under assumed noise, and a sequential information-driven experimental selection (SIDeS) strategy [6, 7]. The framework is applied to four literature kinetic models of methanol synthesis, ranging from the classical Graaf et al. model [1] and Vanden Bussche and Froment (VBF) ([2] to more recent models proposed by Slotboom [3] and Seidel [4]. The aim is to characterise the identifiability properties of each model, identify informative regions of the design space, and provide experiment design recommendations prior to calibration, thereby supporting model selection and reducing unnecessary calibration effort.

Section 2 describes the proposed methodology. Section 3 presents the identifiability and information analysis results and discusses the SIDeS-based design recommendations. Section 5 summarises the main conclusions.

## 2. METHODOLOGY

This section outlines the proposed pre-calibration, information-driven framework, beginning with the definition of candidate kinetic models and the reactor representation (Section 2.1), followed by information and identifiability analyses across the design space (Section 2.2 – 2.5), and finally the application of SIDeS to reach a final identifiability decision and experiment-selection recommendations. An overview of the workflow is provided in Figure 1, which organises the methodology into five consecutive stages, that are detailed in the following

sections.

## 2.1. Candidate Models and Reactor Representations

### 2.1.1 Reactor model

A one-dimensional pseudo-homogenous packed-bed reactor model was used to simulate species and temperature profiles under non-isothermal conditions. The model incorporates a non-isothermal energy balance with axial thermal dispersion. Radial dispersion, catalyst deactivation, and external or internal mass-transfer limitations were neglected as standard simplifying assumptions [11].

Non-ideal gas behaviour was modelled using the Soave-Redlich-Kwong (SRK) equation of state [11]. Component fugacity's were defined as the product of partial pressure and SRK-derived fugacity coefficients, while equilibrium constants were evaluated using the correlations of Graaf and Winkelman [12]. These thermodynamic relationships were applied consistently across all kinetic models to ensure a uniform physical basis for comparison and identifiability analysis.

### 2.1.2 Candidate kinetic models

Four literature kinetic models were examined: the classical dual-site LHHW formulation of Graaf et al. [1], the single-site Vanden Bussche–Froment (VBF) model which omits direct CO hydrogenation [2], the three-site 10-parameter refit of Slotboom et al. [3], and the $CO_2$-oriented mechanistic model of Seidel et al [4]. These models span different mechanistic assumptions and levels of parameterisation, ranging from detailed adsorption structures to reduced-order kinetic expressions, providing a representative basis for identifiability screening.

Kinetic and adsorption parameters appearing explicitly in the rate expressions were treated as uncertain parameters. Outlet molar flowrates of $CH_3OH$, $CO_2$, CO, $H_2$ and $H_2O$, together with the outlet temperature and pressure, were used as model observables for computing local sensitivities and Fisher information metrics. Identifiability analysis was performed solely on model-predicted responses without the need of experimental data (a priori identifiability). A concise comparison of the four kinetic models is provided in Table 1.

**Table 1:** Summary of the kinetic models considered in this study, including parameter counts and key mechanistic characteristics.

| Model | No of Params | Type |
|---|---|---|
| Graaf et al. | 12 | Type 1, Dual-site LHHW |
| VBF | 9 | Type 2, Single-site |
| Slotboom | 10 | Type 2, 3-site mechanism |
| Seidal et al. | 14 | Type 1, 3-site mechanism |

All four kinetic models were evaluated under identical reactor and thermodynamic assumptions to ensure that differences in identifiability arise solely from the kinetic formulations.

## 2.2. Design Space Definition and Feasibility Filter

A multidimensional design space was constructed by incorporating key operating variables relevant to methanol synthesis, including reactor inlet temperature, inlet pressure, gas hourly space velocity (GHSV), and inlet composition expressed via the stoichiometric number (SN). Additionally, bounds were selected to reflect industrially relevant operating windows [3, 10], and a low-discrepancy Sobol method [13] was used to generate uniformly distributed inlet candidate design points. Each candidate point corresponds to a complete inlet-condition vector, which is used to generate in-silico reactor outputs for subsequent sensitivity and information analysis.

Static feasibility constraints were imposed prior to simulation, including SN > 2 to ensure hydrogen-rich operation [3], adherence to sum-to-one constraints for inlet compositions and temperature and pressure limits consistent with industrial practice [3, 14]. Each feasible candidate was then evaluated using the full reactor model, and points resulting in solver failure, negative concentrations or thermodynamic inconsistencies under the SRK EOS were discarded. This two-stage feasibility filter ensured that the resulting design set was both physically meaningful and operationally realistic.

The final feasible design space forms the basis for local sensitivity analysis and the subsequent sequential design optimisation in SIDeS.

## 2.3. Local Sensitivity Analysis and Structural Identifiability

Local parameter sensitivities were computed to quantify response of model outputs to perturbations in each kinetic parameter. For a given design point and nominal parameter vector $\theta$, the sensitivity matrix is defined by the following [15]:

$$S_{ij} = \frac{\partial y_i}{\partial \theta_j} \tag{1}$$

Where $y_i$ denotes a simulated model response. In this study, the response vector $\boldsymbol{y}$ comprises steady-state outlet measurements, namely the outlet molar fractions of the species together with outlet temperature and pressure. Sensitivities were computed using a forward finite difference method, with the resulting matrix forming the basis of the information-based identifiability analysis.

Structural identifiability is assessed using the noise-free standard Fisher Information Matrix (FIM):

$$H_\theta = S^T S \quad (2)$$

The rank and conditioning of the FIM provides information on parameter identifiability. A full-rank FIM and non-singular (non-zero determinant) indicates all parameters are linearly independent and locally identifiable at the given point, whereas rank deficiency reveals structurally unidentifiable or redundant parameter combinations. Additionally, the trace of the FIM is used as a scalar metric of the overall information content, which in this case reflects the aggregate magnitude of the kinetic parameter sensitivities. Furthermore, eigen-analysis of the FIM was deployed to examine the null-space directions associated with weakly identifiable parameters. On this basis, operating points were classified as i) strongly identifiable when the FIM was full-rank and well-conditioned; ii) weakly identifiable when near-singular behaviour or pronounced null-space directions were present; and iii) non-identifiable when the determinant approached zero or the rank was deficient [6, 7].

## 2.4. Practical Identifiability

Practical identifiability quantifies parameter uncertainty in the presence of measurement noise. All practical uncertainty calculations were performed around nominal parameter values obtained from the literature for each kinetic model. Two noise structures were considered: a constant Gaussian noise model and a proportional Gaussian noise model, each defining the corresponding diagonal weighting matrix $\boldsymbol{\Sigma}_y$ used in the weighted FIM. An additive noise model was assumed for temperature ($\sigma_T = 1\,\mathrm{K}$), whereas composition measurements $y_i$ were described by Gaussian noise with standard relative deviation of $\sigma_{y_i} = 2\%$. For a given design point, the weighted FIM is defined by [15, 9]:

$$H_\theta = S^T \Sigma_y S \quad (3)$$

Parameter uncertainties were obtained from the variance-covariance matrix $\boldsymbol{V}_\theta$, which is computed from FIM as follows:

$$V_\theta = {H_\theta}^{-1} \quad (4)$$

Where the diagonal entries $V_{\theta,ij}$ represent the variances of the kinetic parameters.

Practical identifiability was assessed using the relative standard error (RSE%):

$$\mathrm{RSE_j} = \frac{\sqrt{V_{\theta,jj}}}{\theta_j} \times 100\% \quad (5)$$

Each RSE has a corresponding *t*-statistic in the form:

$$\mathrm{t_j} = \frac{\theta_j}{\sqrt{V_{\theta,jj}}} \quad (6)$$

Low RSE values and large $|\,t_j\,|$ indicate practically identifiable parameters, whereas large uncertainties imply weak or non-identifiability. For each parameter, practical identifiability was further assessed by comparing the computed t-statistic to the corresponding critical value at a 95% and 99% confidence level. The effective degrees of freedom were taken as the number of in-silico experiments accumulated at that stage of the cumulative FIM evaluation [9, 10, 15].

## 2.5. Cumulative Information Metrics

When multiple experiments are considered, the total information available for parameter estimation is represented by the cumulative FIM, which is defined as:

$$H_{\theta,\mathrm{cum}} = \sum_{k=1}^{N_{\mathrm{exp}}} H_\theta^{(k)} \quad (7)$$

Where $\boldsymbol{H}_\theta^{(k)}$ denotes the weighted FIM for the kth design point. The cumulative variance-covariance is obtained from:

$$V_{\theta,\mathrm{cum}} = H_{\theta,\mathrm{cum}}^{-1} \quad (8)$$

This allows the evaluation of cumulative RSE% and t-statistics as additional experiments are incorporated. The trace of $\boldsymbol{H}_{\theta,\mathrm{cum}}$ is used as a scalar measure of overall information content to visualize information gain across experiment sequences. This cumulative information is the underpinning principle behind the SIDeS strategy described in section 2.6 below [13].

## 2.6. SIDeS Design Strategy

The Sequential Information-Driven Experimental Selection (SIDeS) procedure was used to construct an experiment sequence that maximises parameter identifiability while minimising the number of required experiments. SIDeS operate on the feasible design space defined in Section 2.2, in which each candidate point has an associated local FIM and information metric.

The algorithm begins with no prior experiments. The first experiment is selected as the design point with the highest local information content, based on the chosen scalar objective. In this work, the scalar objective was defined as the reduction in the worst-case parameter RSE, favouring experiments that most improve the least identifiable parameter.

The cumulative FIM is then initialised using this first experiment, and subsequent experiments are added in a "greedy" manner. At each iteration, every remaining feasible design point is evaluated in terms of its marginal information contribution, defined as the improvement in the selected identifiability objective when its FIM contribution is added to the current cumulative FIM, given by Eq. (9). In this study, identifiability objectives are evaluated through practical identifiability metrics derived from the inverse cumulative FIM, namely the parameter %RSE (Eq. 5) and their associated t-statistics (Eq. 6). This

criterion accounts for both the magnitude and direction of the parameter sensitivities, ensuring that additional experiments provide complementary, non-redundant information rather than reinforcing already saturated directions.

After selecting the kth design, the cumulative FIM is updated as follows:

$$H_{\theta,\mathrm{cum}}{}^{(n+1)} = H_{\theta,\mathrm{cum}}{}^{(n)} + H_{\theta}{}^{(k)} \tag{9}$$

Here, $n$ denotes the iteration index of the sequential design procedure, such that $\boldsymbol{H}_{\theta,\mathrm{cum}}^{(n)}$ represents the cumulative FIM after $n$ experiments have been selected.

The procedure terminates when either the maximum number of design steps (the experiment budget) is reached or when the user-defined identifiability criterion is satisfied, such as achieving a specified structural rank or meeting practical identifiability thresholds for the parameters of interest.

All simulations were implemented in Python using the SciPy scientific computing ecosystem and executed on a workstation equipped with an Intel i7 processor and 32 GB RAM.

# 3. RESULTS AND DISCUSSION

## 3.1 Case Study and Design Space

The case study focuses on the Graaf et al. kinetic model, which remains one of the most widely adopted reference formulations for methanol synthesis in the literature, integrated in a non-isothermal packed-bed reactor model with axial dispersion.

For the purposes of identifiability analysis, the uncertain kinetic and adsorption parameters of the Graaf model are collected into a parameter vector expressed as

$$\theta_k = [k_{0,CO}, Ea_{CO}, k_{0,CO_2}, Ea_{CO_2}, k_{0,RWGS}, Ea_{RWGS},$$

$$\Delta S^{o}_{ads,CO}, \Delta H^{o}_{ads,CO}, \Delta S^{o}_{ads,CO_2}, \Delta H^{o}_{ads,CO_2}, \frac{A_{K_{H_2O}}}{K_{H_2}^{0.5}}, \frac{B_{K_{H_2O}}}{K_{H_2}^{0.5}}]$$

Where the elements correspond to kinetic and adsorption-related parameters appearing in the Graaf rate expressions. These parameters constitute the target of the subsequent identifiability and experimental design analyses.

A Sobol low-discrepancy sampling scheme was employed to generate 50 candidate design vectors, each defined by inlet composition, inlet temperature, inlet pressure, and gas hourly space velocity (GHSV). These vectors constitute a discrete set of in-silico candidate experiments used to probe the design space prior to any experimental execution.

The local information content of each candidate design is quantified using the trace of the FIM, which is widely employed as a scalar measure of parameter sensitivity magnitude [14]. While the trace provides a convenient aggregate metric, it does not account for directional information or parameter correlations. Directional diagnostics, such as eigenvalue-based criteria, are therefore considered in later stages of the framework.

Figure 2 illustrates the candidate design space (three of eight design variables shown for visual clarity), with each point coloured by its local FIM trace value. The Sobol sampling strategy yields a well-distributed coverage of the admissible design space. Despite this uniform geometric coverage, the associated information content exhibits substantial variability, with only a limited subset of designs providing comparatively high local information.

Executing all candidate experiments without regard to their information content would be highly cost-inefficient and representative of unstructured screening experimental practice. This observation motivates the need for information-driven experiment selection strategies that explicitly account for both model structure and parameter sensitivities. The application of the Sequential Information-Driven Experimental Selection (SIDeS) framework is therefore investigated in the following sections.

## 3.2 Identifiability Analysis from screening experiments

This section presents the identifiability analysis of the Graaf et al. kinetic model from screening experiments, conducted prior to the application of the SIDeS framework. Identifiability is assessed assuming all candidate experiments are performed without optimisation or reordering, following the original Sobol-generated order. Herein, a preliminary identifiability analysis on Sobol generated screening experiments is presented to provide a diagnostic reference against which the benefits of the information-driven experiment selection can be assessed later.

As shown in Figure 2, local information content and single-experiment identifiability vary substantially across the candidate design space. While certain operating conditions exhibit comparatively high Fisher information trace values, most individual experiments remain locally weak or non-identifiable when assessed in isolation. These single-experiment identifiability results are presented for diagnostic purposes only, but, in practice, reliable parameter identification requires the aggregation of information across multiple experiments.

Having established the limitations of single-experiment identifiability, the cumulative effect of aggregating experimental information is now examined. Cumulative identifiability is assessed using practical metrics that quantify parameter precision under the assumed noise model. In the following, relative standard errors (%RSE) are used to evaluate how parameter uncertainty evolves

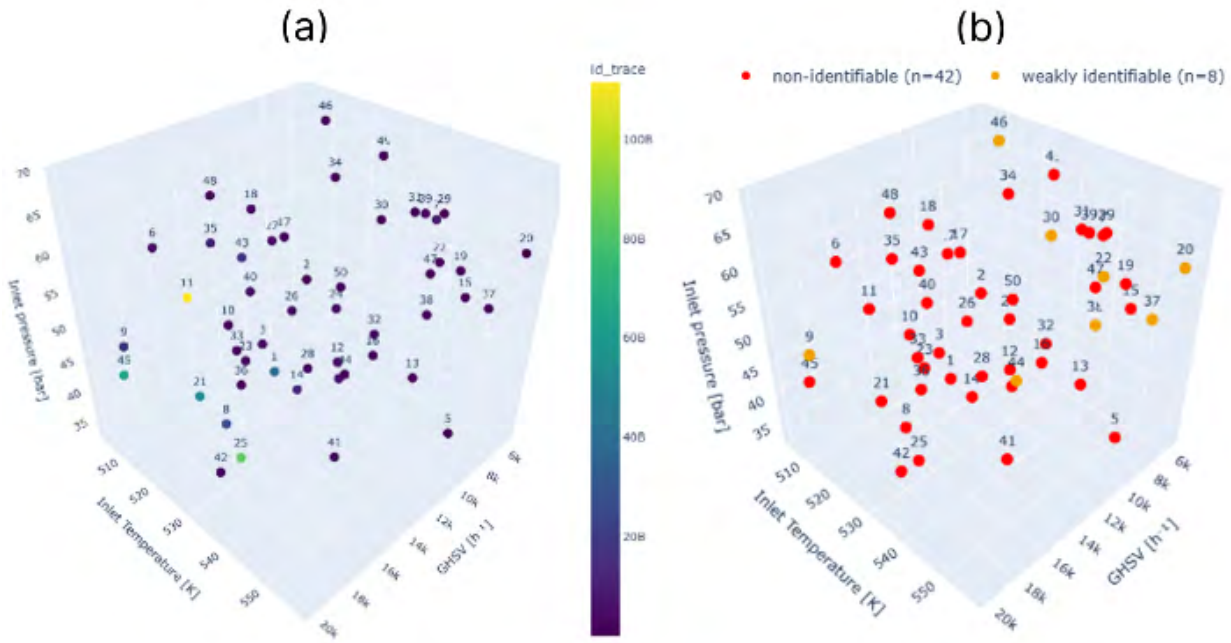

**Figure 2.** Candidate design space generated using Sobol sampling. **a):** Points coloured by the local Fisher information trace, indicating the magnitude of parameter sensitivities ats each individual design. **b):** The same design space coloured by local identifiability verdicts based on single-experiment Fisher information analysis. Each point corresponds to a feasible in-silico experiment and is labelled by its design identifier.

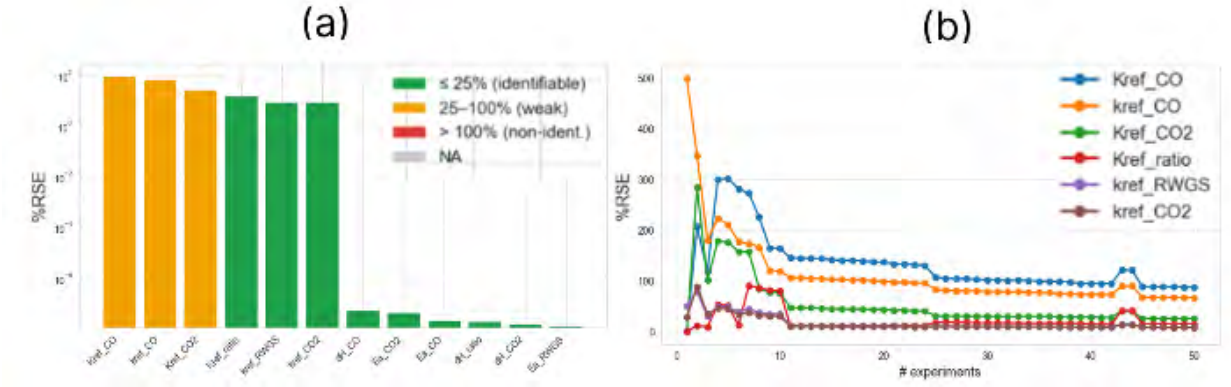

**Figure 3.** a) Evolution of cumulative parameter relative standard error (%RSE) as a function of number of experiments b) Final cumulative % RSE for each kinetic parameter after all candidate experiments are added.

as experiments are progressively added without optimal design, providing insight into the effectiveness of screening experiments. The cumulative evolution of parameter uncertainty across screening experiments is illustrated in Figure 3.

Figure 3.a illustrates the evolution of cumulative parameter %RSE as a function of the number of experiments. While uncertainty decreases as additional experiments are incorporated, convergence is slow, and highly non-uniform across the parameters. Importantly, most of the uncertainty reduction is achieved within the first approximately 10 screening experiments, beyond which further additions yield diminishing returns.

The final cumulative identifiability status after the full set of screening experiments is summarised in figure 3.b. Although some parameters achieve acceptable precision, others remain weakly identifiable according to the chosen %RSE thresholds. This result highlights that increasing the number of experiments alone is insufficient in guaranteeing practical identifiability, and that the distribution of experimental information across parameters is highly uneven.

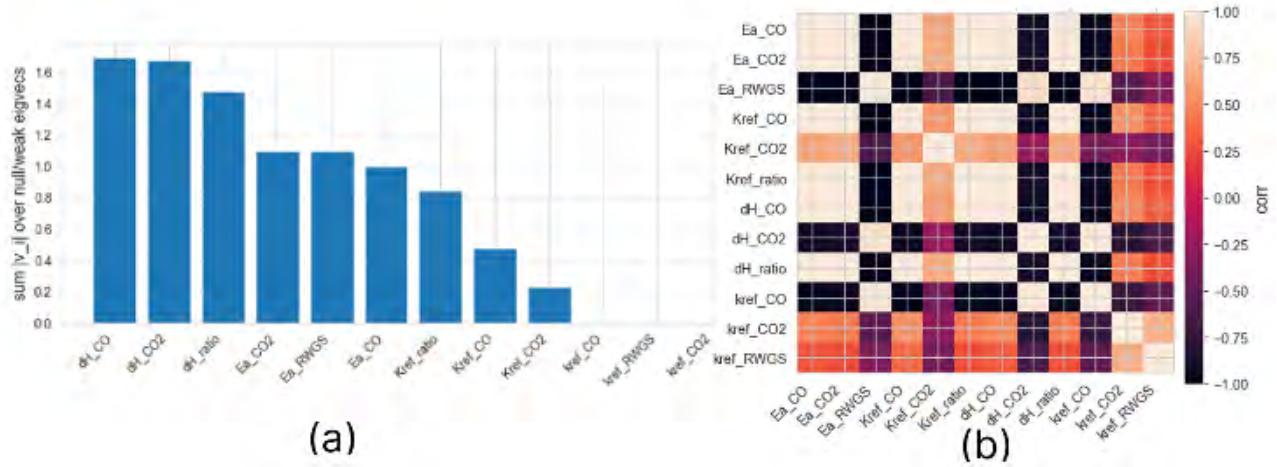

**Figure 4.** a) cumulative null-space loadings, indicating contribution of each parameter to weakly excited eigen-directions of FIM. b) Cumulative parameter correlation matrix after 50 experiments

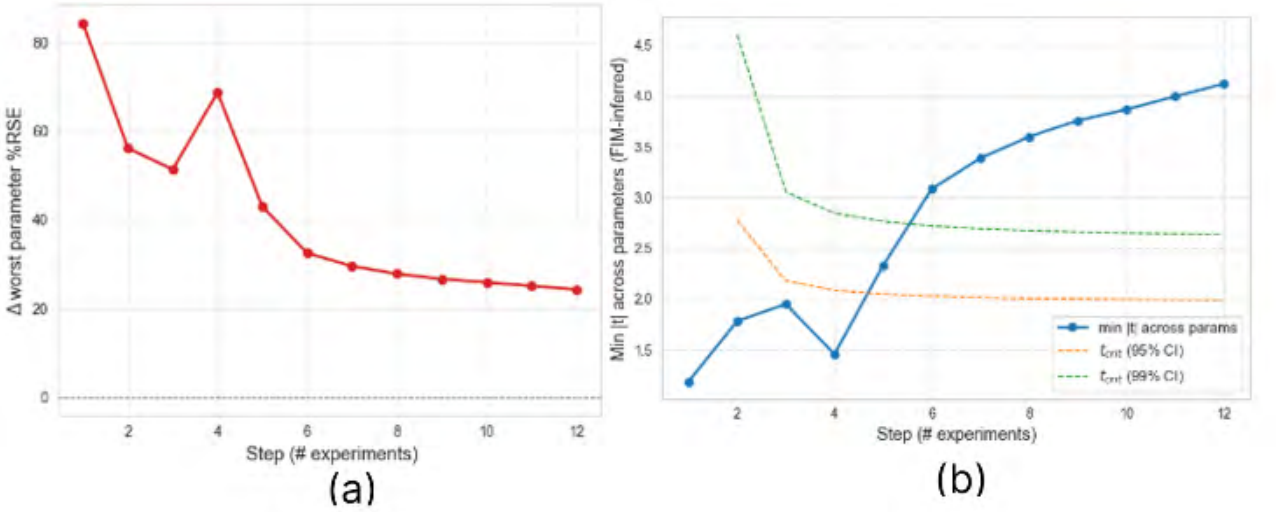

**Figure 5.** a) Evolution of the worst parameter %SE as a function of SIDeS iteration b) Convergence of minimum absolute t-statistic across parameters, with critical values of 95% and 99% shown for reference.

To further interpret the observed limited increment in parameter precision, null-space loadings and cumulative parameter correlations of the FIM are examined in Figure 4.a and 4.b, respectively. Strong and persistent correlations are observed between several kinetic parameters, indicating that specific parameter combinations remain poorly distinguishable even as additional experiments are added. Similarly, null-space analysis reveals dominant weakly excited directions associated with the corresponding parameters. This confirms that unstructured experimental screening fails to systematically resolve structural collinearity and weakly informed parameter subspaces.

Together, these results demonstrate that uniform coverage of feasible design space does not translate into uniform information gain across parameters. Screening Experiments without SIDeS leads to inefficient use of experimental effort, motivating the need for an information-driven experiment selection strategy capable of explicitly targeting weakly excited parameter directions. This motivation is at the cornerstone of the application of the SIDeS framework, which is examined next.

## 3.3 SIDeS Results

The SIDeS framework was applied to the same candidate design used in Section 3.2 to ensure a fair comparison against screening experiments. A maximum experimental budget of 12 experiments was imposed. The experimental selection objective was defined as the minimisation of the worst-case parameter %RSE at each iteration. Experiments were then selected sequentially using a greedy strategy without repetition, with FIM cumulatively updated after each addition. The SIDeS algorithm executed successfully, reaching full identifiability for all

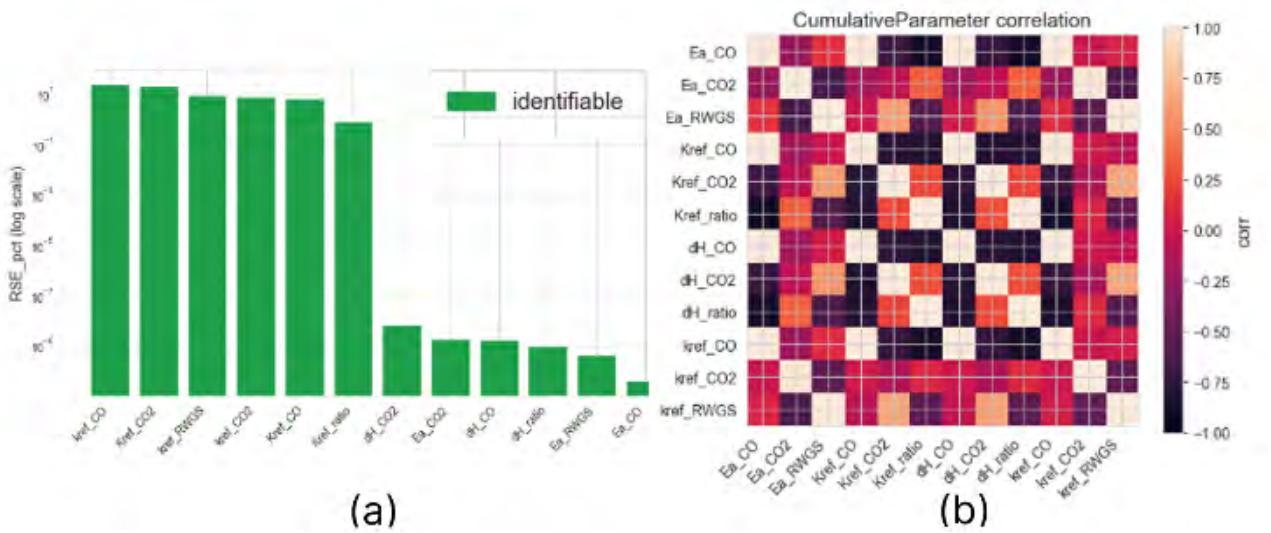

**Figure 6.** a) Final parameter %RSE after SIDeS campaign. b) Cumulative parameter correlation matrix after SIDeS campaign.

**Table 2:** Cross-model identifiability and SIDeS outcomes.

| Kinetic Model | # Params | # Active Sites | Baseline Identifiability | SIDeS steps to full Iden | Worst %RSE (Final) | Dominant Design Bias | Residual Correlation |
|---|---|---|---|---|---|---|---|
| **Graaf** | 12 | 2 | Weakly Iden | 12 | 24% | High Temp, | Moderate |
| **VBF** | 9 | 1 | Weekly Iden | 8 | 18% | high GSV | Low |
| **Slotboom** | 10 | 3 | Weekly Iden | >12 | 35% | High P, mid T | Moder- |
| **Seidel** | 14 | 3 | Non Iden | >12 | >100% | Broad pattern | ate/high |
| | | | | | | No clear bias | Very high |

models after reaching the pre-selected budget of 12. The chosen sequence of experiments based on candidate design ID was [41, 16, 36, 11, 45, 39, 25, 37, 50, 8, 7, 1].

Figure 5.a shows the evolution of the worst-case parameter %RSE as experiments are sequentially selected by the SIDeS. A rapid reduction appears in uncertainty during the initial iterations (up to step 6). This is followed by diminishing improvements as the experimental budget increases. This behaviour reflects an initial exploration phase, in which dominant information directions are rapidly resolved, followed by refinement phase where additional experiments yield progressively smaller marginal gains. This is complimented by the evolution of minimum absolute t-statistic across parameters shown in Figure 5.b. The t-statistics are computed from FIM-inferred standard errors under the assumed Gaussian noise model and provide an additional screening metric for practical identifiability. As experiments are added, the minimum $|t|$ increases and exceeds the critical values associated with common confidence levels of 95% and 99%. This indicates that all parameters become statistically distinguishable from zero within the local linear approximation.

Figure 6.b presents the cumulative parameter correlation matrix after SIDeS. Compared to correlation structure obtained from screening experiments, the strong parameter couplings are significantly reduced, particularly among adsorption and kinetic pre-exponential terms. This structural improvement confirms that SIDeS actively select experiments that resolve poorly identifiable parameter directions and does not just reduce overall uncertainty. This leads to a more informative and balanced parameter estimation problem.

The final parameter uncertainties obtained from the SIDeS-selected experimental campaign are summarised in Figure 6.a. In contrast to the experimental screening of all 50 candidate experiments presented in Section 3.2, SIDeS achieve practical identifiability for all kinetic parameters using only 12 experiments.

These result highlights the inefficiency of uninformed experimental accumulation and demonstrates the effectiveness of information-driven design in extracting parameter-relevant information, leading to substantially reduced experimental effort.

Furthermore, Examination of the SIDeS-selected

experimental sequence reveals clear qualitative trends in the regions of the design space identified as most informative for the Graaf et al. model. Within the admissible operating window, the algorithm exhibits a pronounced tendency to prioritise experiments at elevated inlet temperatures, often in combination with moderate-to-high pressures and higher space velocities. These conditions enhance sensitivity contrasts in Arrhenius and adsorption terms, thereby improving distinguishability among kinetic parameters. Importantly, the selected experiments are not confined to a single local optimum; instead, SIDeS distribute experiments across complementary regions of the design space, progressively exciting parameter directions that remain weakly informed at earlier stages. This behaviour reflects the algorithm's emphasis on directional information gain rather than purely scalar sensitivity magnitude. Importantly, these trends are specific to the Graaf model and the explored design space and are reported as qualitative insights rather than prescriptive operating guidelines.

### 3.4 Cross-model Comparison

This section compares the identifiability characteristics and information requirements of the four candidate kinetic models considered, under identical reactor, thermodynamics and design-space assumptions.

Table 2 summarises the cross-model identifiability outcomes obtained. Although all kinetic models describe the same methanol synthesis systems, substantial differences are observed in baseline identifiability, achievable parameter precision, and experimental information requirements. These results emphasize the strong dependence of practical identifiability on not only the experimental design bounds, but also the kinetic model structure. As such, the comparison thus provides a systematic basis for assessing the trade-off between mechanistic detail and experimental feasibility prior to model calibration.

Looking at Table 2, a clear inverse relationship is observed between model complexity and identifiability. The Graaf and VBF models, which contain fewer parameters and simpler active-site assumptions, exhibit weak baseline identifiability, but can be rendered fully practically identifiable using the SIDeS framework within modest experimental budgets. In contrast, the Slotboom and Seidel models, which introduce additional parameters and multi-site reaction mechanisms, display significantly poorer identifiability characteristics.

The Seidel model, comprising the largest parameter set, remains non-identifiable even after 12 optimally selected experiments, with worst-case %RSE exceeding 100%. This observation is accompanied by persistently high residual parameter correlations, indicating fundamental redundancy within the kinetic formulation. The variation in the budget required to achieve identifiability for the four kinetic models, including cases where identifiability was not attained, indicate that even information-driven experiment selection cannot fully compensate for intrinsic structural complexity. Within the investigated design space and experimental budget, the results suggest that increasing mechanistic detail does not necessarily yield improved practical identifiability and may be associated with higher information requirements.

Furthermore, analysis of the selected experiments reveals distinct model-dependent biases in the informative regions of the design space. The Graaf model consistently favours high temperature and high GHSV conditions, whereas VBF model priorities higher pressure combined with moderate inlet temperatures. In contrast, the Slotboom and Seidel models do not exhibit a favouritism to any region of the design space. Particularly for Seidel, where the absence of design bias suggests no single operating regime sufficiently resolves its parameter interdependencies.

From a practical perspective, these results demonstrate that model choice should be guided not only by mechanistic completeness but also by identifiability and experimental tractability. Models such as Graaf et al. and VBF offer a favourable balance between descriptive capability and calibrability, whereas more complex formulations may require significantly large or specialised experimental campaigns to achieve reliable parameter estimates. The proposed framework therefore enables informed kinetic model selection prior to experimental execution. Therefore, the risk of under-determined calibration and wasted experimental effort is reduced.

## CONCLUSION

This work presented an information-driven framework for pre-calibration identifiability assessment and experimental screening in methanol synthesis kinetics. By combining local sensitivity analysis, Fisher information–based metrics and the Sequential Information-Driven Experimental Selection (SIDeS) strategy, the framework enables systematic screening of kinetic models and operating regions prior to parameter estimation. Application to four literature kinetic models showed that unstructured screening experiments yield diminishing gains in parameter precision, whereas SIDeS identify compact experimental campaigns that substantially improve practical identifiability within a fixed budget. Cross-model comparison further indicated that increased mechanistic description does not necessarily lead to improved identifiability under constrained experimental resources. The proposed framework is intended as a precursor to full model-based design of experiments (MBDoE), providing an informed starting point for optimal experimental campaign design in power-to-methanol applications.

## ABSTRACT

Geologic hydrogen has emerged as a promising low-carbon energy vector, but its sustainable recovery requires effective stimulation and production strategies. This study presents an integrated process-modeling framework for evaluating hydrogen extraction from hydraulically stimulated reservoirs. The framework combines fracture propagation, damage evolution, Darcy-scale multiphase flow, permeability–aperture dynamics, and a dual-porosity dual-permeability (DPDP) representation to simulate hydrogen production in fractured source rock systems. In addition to production dynamics, the framework tracks operational water and energy inputs and incorporates a simplified reaction-extent formulation to represent hydrogen generation under data-limited conditions. The model was benchmarked against published shale gas production results to evaluate its ability to reproduce fracture-controlled production behavior and was subsequently applied to a representative multi-well hydrogen development scenario. Simulation results indicate that hydrogen production is strongly fracture-dominated, with fracture pathways accounting for more than 98% of total modeled output. Under the simulated conditions, the system produced approximately 1.13 million kg of hydrogen, with an estimated operational energy intensity of 3.4 MJ/kg $H_2$ and water consumption of 0.02 $m^3$/kg $H_2$. These values represent model-based estimates within the defined operational system boundary and illustrate the potential performance indicators that the framework can generate. Per-well analysis reveals variability in water and energy efficiency across the multi-well system, highlighting the importance of fracture design and reservoir characterization. The simulations also indicate that matrix contributions to total recovery are limited under the assumed conditions, suggesting potential benefits from strategies that enhance matrix reactivity or transport processes. Overall, the framework provides an integrated approach for exploring hydrogen production dynamics together with associated resource requirements. As field and experimental data for geologic hydrogen systems become available, the framework can be further refined through improved parameterization, sensitivity analysis, and calibration to support future technical, environmental, and economic assessments.

## INTRODUCTION

The intensifying global energy crisis, propelled by geopolitical instability and the objectives of the 2015 Paris Agreement to restrict warming to below 2 °C and achieve net-zero emissions by 2050, highlights the pressing necessity for a swift transition to reliable, sustainable energy sources [1]. A significant issue in this shift is the identification of carbon-free, economically feasible, and sustainable energy sources [2].

Hydrogen has emerged as a cornerstone of the global energy transition, offering a versatile, low-carbon energy vector capable of decarbonizing hard-to-abate sectors [3, 4]. While manufactured hydrogen from electrolysis or reforming dominates current discourse, these pathways remain constrained by high costs, scalability challenges, and significant energy or carbon footprints [5]. In contrast, geologic hydrogen naturally generated in the subsurface through processes such as serpentinization, radiolysis, and iron oxidation has recently attracted

attention as a potentially abundant and low-emission alternative [6]. The accidental discovery and subsequent exploitation of native hydrogen in Bourakébougou, Mali, demonstrated the feasibility of harnessing subsurface hydrogen resources, catalyzing global interest in both natural accumulations and engineered stimulation approaches [6–8].

Recent research has introduced the concept of stimulated geologic hydrogen production, sometimes termed "orange hydrogen, " which seeks to actively engineer subsurface conditions to accelerate hydrogen-generating reactions in iron-rich ultramafic rocks [9, 10]. Techniques such as hydraulic fracturing, thermal treatment, chemical stimulation, and electrical reservoir stimulation have been proposed to enhance permeability, reactive surface area, and geochemical kinetics [11]. Numerical modeling studies indicate that stimulation can increase hydrogen yields by several orders of magnitude compared to unstimulated systems, with fracture networks and damage zones playing a decisive role in enabling efficient hydrogen migration and recovery [11, 12]. However, despite promising laboratory and pilot-scale results, critical uncertainties remain regarding the efficiency, sustainability, and resource requirements of such systems [13].

A key challenge lies in balancing water and energy inputs with hydrogen outputs. Stimulated systems require a continuous water supply to sustain serpentinization, while compression and fracturing impose significant energy costs [14]. Recent circularity studies suggest that integrating waste heat recovery and water recycling can reduce operational burdens, yet quantitative assessments of water–energy–hydrogen balances at the reservoir scale remain scarce. Moreover, while fracture-dominated pathways have been shown to account for the majority of production [15], the contribution of the rock matrix is often minimal, and this raises questions about how stimulation design and reservoir characterization can be optimized.

Against this backdrop, this study introduces an integrated process-modeling framework for evaluating geologic hydrogen recovery in hydraulically stimulated reservoirs. The framework combines fracture propagation, damage evolution, Darcy-scale multiphase flow, permeability–aperture dynamics, and a dual-porosity dual-permeability (DPDP) representation to simulate hydrogen production from fractured source rock systems.

Existing fractured-reservoir models primarily focus on fluid flow and production forecasting, while reactive transport models emphasize geochemical reactions and species transport in porous media. These approaches are typically applied independently and are not specifically designed to evaluate the coupled production dynamics and resource requirements associated with geologic hydrogen extraction.

The framework developed in this study integrates fracture-controlled flow behavior with a simplified representation of hydrogen-generating reactions and explicit accounting of water and energy inputs. This system-level integration enables quantitative evaluation of water–energy–hydrogen trade-offs in hydraulically stimulated reservoirs. It provides a basis for exploring operational constraints and efficiency considerations in geologic hydrogen development.

By linking subsurface production dynamics with resource-use metrics, the framework provides a tool for estimating production performance, evaluating resource consumption requirements, and informing future optimization of stimulation strategies. In the absence of field-scale geologic hydrogen datasets, the framework is intended as a first-order modeling approach that can be refined as new experimental and field observations become available.

The objectives of this study are therefore to (i) develop the integrated modeling framework, (ii) demonstrate its application to hydraulically fractured hydrogen systems, and (iii) evaluate production performance together with associated water and energy requirements.

## FRAMEWORK DEVELOPMENT

This study develops an integrated process modelling framework to quantify hydrogen generation, transport, and recovery in hydraulically stimulated geologic hydrogen systems. The approach couples (i) fracture propagation and damage evolution, (ii) dual-porosity dual-permeability (DPDP) fluid flow, (iii) multiphase reactive transport, (iv) permeability-aperture evolution, and (v) thermal feedback from serpentinization reactions.

### Governing Equations

In order to simulate the generation and transport of geologic hydrogen in the source rock, mass and energy conservation were solved.

$$\rho C_p \frac{\partial T}{\partial t} + \nabla \cdot \left(\rho_f C_{p,f} \vec{v} T - k \nabla T\right) = q_{rad} + \Delta H_r R_H \quad (1)$$

Where $\rho$ is the rock density, $C_p$ is the rock's specific heat capacity, $\rho_f$ is the fluid density, $C_{p,f}$ is the fluid specific heat capacity, $\vec{v}$ is the fluid velocity (m/s), T is the temperature, k is the thermal conductivity, $q_{rad}$ is the radiogenic heat generation, $\Delta H_r$ is the heat from serpentinization ($J/mol$) and $R_H$ is the generation rate from serpentinization (mol/m$^3$.s).

$$\frac{\partial C_H}{\partial t} + \nabla \cdot \left(-D_H \nabla C_H + \vec{v} C_H\right) = R_H - R_{microbial} - R_{leak} \quad (2)$$

Where $D_H$ is hydrogen diffusivity, $C_H$ is hydrogen concentration (mol/m$^3$), $R_{microbial}$ is the microbial

hydrogen consumption, and $R_{leak}$ is the loss due to leakage through fractures or faults.

$$R_H = \frac{\varepsilon_{max}}{b} \bullet \frac{exp\left(\frac{-t-t_{1/2}}{b}\right)}{(1+exp\left(\frac{-t-t_{1/2}}{b}\right))^2} \quad (3)$$

$$\varepsilon(t) = \frac{\varepsilon_{max}}{1+exp(\frac{-t-t_{1/2}}{b})} \quad (4)$$

Where $\varepsilon_{max}$ is the maximum reaction extent(%), t is the time in days, $t_{1/2}$ is the time to reach half-reaction extent (days), b is the rate constant in days, and $\varepsilon(t)$ is the reaction extent.

The fracture propagation with damage evolution and the aperture evolution are accounted for using equations (5)-(7).

$$\frac{dD}{dt} = A_d \bullet (\sigma - \sigma_{crit})_+^n \quad (5)$$

Where D is the damage variable, $A_d$ is the rate constant for damage growth, $\sigma$ is the applied stress, and $\sigma_{crit}$ is the threshold for damage initiation.

$$k(D) = k_o \bullet (1 + \alpha_k D) \quad (6)$$

$$a(D) = a_o \bullet (\beta D) \quad (7)$$

Where a(D) is the evolving fracture aperture and $\alpha_k$ and $\beta$ are sensitivity coefficients.

Mass transfer between the fracture and the fracture and matrix is accounted for using the dual permeability model.

$$Q_{f\to m} = \alpha \bullet (P_f - P_m) \quad (8)$$

Where $Q_{f\to m}$ is the flowrate between fracture and matrix ($m^3/s$), $\alpha$ is the transfer coefficient ($s^{-1}$), and $P_f, P_m$ is the pressures in fractures and matrix.

The temperature feedback and fluid temperature change in the fractures is accounted for using equations (9) and (10), respectively.

$$Q_{rxn} = \Delta H_r R_H \to T^{n+1} = T^n + \frac{\Delta t}{\rho_r C p_r} Q_{rxn} \quad (9)$$

$$T_{out} = T_g - (T_g - T_{in}) \bullet exp(\frac{-h_c A}{\dot{m} C_{p,f}}) \quad (10)$$

Where $T_{out}$ is the outlet fluid temperature, $T_g$ is the rock matrix temperature, $\dot{m}$ is the fluid mass flowrate (kg/s), A is the contact area ($m^2$), and $h_c$ is the convective heat transfer coefficient.

## Numerical Implementation

The governing equations describing fluid flow, hydrogen transport, and reaction extent were solved numerically using a finite-difference discretization on a structured grid. The spatial domain representing the reservoir and fracture system was discretized into grid blocks that capture both matrix and fracture regions within the dual-porosity dual-permeability framework. Grid resolution was selected to resolve fracture–matrix interactions while maintaining computational efficiency adequately.

Time integration was performed using an implicit time-stepping scheme to ensure numerical stability for the coupled flow, transport, and reaction processes over the simulation period. The time step size was adjusted to capture the early-time production dynamics and longer-term stabilization behavior observed in the system.

All simulations were conducted over a 365-day production period using the parameter set described in Table 1. The computational implementation was developed in a numerical simulation environment capable of solving coupled nonlinear equations representing subsurface flow and reaction processes. Simulation runtimes for the scenarios presented in this study were on the order of minutes on a standard workstation, indicating that the framework is computationally efficient for scenario analysis and preliminary system evaluation.

**Table 1:** Parameters used in this study

| Parameter | Value |
|---|---|
| Number of wells | 5 |
| Initial reservoir pressure | 50 MPa |
| Reservoir thickness | 50 m |
| Rock density | 3300 kg/m³ |
| Rock heat capacity | 870 J/kg·K |
| Rock thermal conductivity | 3.45 W/m·K |
| Matrix porosity | 0.02 |
| Matrix permeability | 5 × $10^{-12}$ mD |
| Hydrogen viscosity | 8.90 × $10^{-6}$ Pa·s |
| Enthalpy of reaction | –520 J/mol |
| Matrix diffusivity | 5 × $10^{-8}$ m²/s |
| Fracture diffusivity | 1 × $10^{-5}$ m²/s |
| Reaction extent | 0.30 |
| Half-life | 60 days |
| Hydrogen heat capacity | 14, 300 J/kg·K |
| Hydrogen density | 80 kg/m³ |

# FRAMEWORK VALIDATION

To evaluate the proposed framework, published shale gas production results were used as a reference dataset for benchmarking. Since direct field-scale data for geologic hydrogen are not yet available, shale gas was selected due to its analogous subsurface extraction processes and reliance on hydraulic fracturing. Parameters from Zhao et al. [16], who developed a variable-fidelity radial basis function (VFRBF) surrogate-assisted model for multi-objective fracture stage placement optimisation, were incorporated into the framework to generate simulated production curves. This allowed the framework outputs to be compared against a well- characterised set of published results. The resulting

cumulative production curves for a single well are shown in Figure 1, illustrating the temporal evolution of gas production predicted by the framework. Quantitative performance metrics further confirm the close alignment, with $R^2$ =0.9928, RMSE=0.2689, and MAE=0.2108. These values indicate that the framework reproduces single-well production dynamics with high fidelity, explaining more than 99% of the variance in the surrogate data while maintaining average errors below 0.3 million $m^3$.

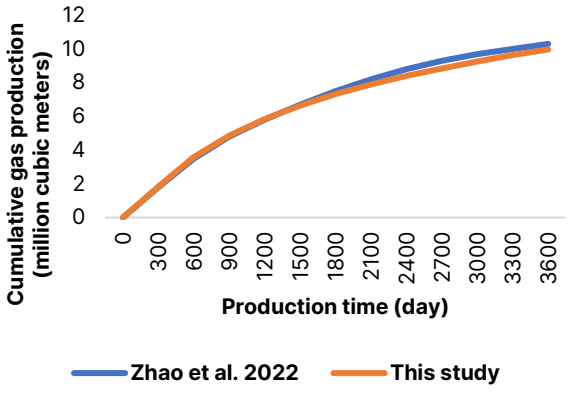

**Figure 1.** Cumulative production curves for a single well comparing Zhao et al. [16] and this study. The framework demonstrates strong agreement with the VFRBF model, supported by performance metrics: $R^2$ = 0.9928, RMSE = 0.2689, and MAE = 0.2108.

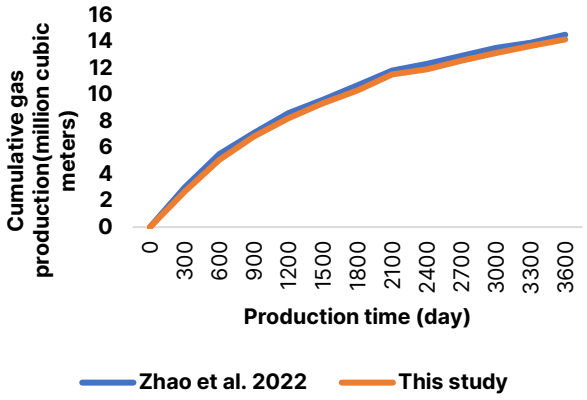

**Figure 2.** Cumulative production curves for multiple wells comparing Zhao et al. [16] and this study. The outputs from this framework show close alignment with the VFRBF model, validated by performance metrics: $R^2$ = 0.9940, RMSE = 0.3333, MAE = 0.3154.

The cumulative production curves produced by the framework show strong agreement with the results reported by Zhao et al. [16], suggesting that the framework can reliably capture the dynamics of resource extraction and production decline in hydraulically fractured reservoirs. A multi-well comparison is presented in Figure 2, highlighting consistent trends and close alignment between the aggregated outputs and the results reported by Zhao et al. over the production period. Statistical validation supports this observation, with $R^2$ =0.9940, RMSE=0.3333, and MAE=0.3154. These metrics show that the framework explains over 99% of the observed variance at the multi-well scale, with deviations representing less than 2% of total cumulative production.

It should be noted that this comparison primarily evaluates the framework's ability to reproduce production decline behavior in hydraulically fractured reservoirs. The benchmarking exercise, therefore, tests the production forecasting component of the framework but does not constitute direct validation of the coupled reactive transport processes, thermal feedback mechanisms, hydrogen generation kinetics, or the water–energy accounting components included in the model. Because field-scale datasets for geologic hydrogen systems are not yet available, validation of these processes remains limited. The present comparison should therefore be interpreted as a model-to-model benchmarking exercise focused on production dynamics, providing an initial consistency check rather than a comprehensive validation of all coupled processes.

While shale gas differs from hydrogen-bearing formations in geochemical properties, the observed alignment supports the framework's validity as a first-order estimation tool. This validation establishes confidence in the framework's applicability and provides a foundation for future refinement once empirical data on geologic hydrogen become available.

## FRAMEWORK APPLICATION

Following benchmarking with shale gas data, the framework was applied to geologic hydrogen extraction scenarios to demonstrate its utility in estimating resource usage under realistic subsurface conditions. The application considered hydrogen generation from source rock formations, parameterized with representative geologic and operational inputs. In this case, a multi-well development consisting of five hydraulically fractured wells was assumed, reflecting typical field-scale deployment strategies in unconventional reservoirs. Table 1 shows the parameters used in this study.

The framework integrated source rock properties, fracture design parameters, and well spacing to simulate cumulative hydrogen production and associated resource requirements. The multi-well configuration allowed assessment of inter-well interactions and aggregate production behavior, providing insight into scalability and efficiency. Results indicated that the framework successfully captures the production dynamics across the five-well system, generating a cumulative production curve that highlights both individual well contributions and overall field performance. This application

demonstrates the framework's adaptability to geologic hydrogen contexts and establishes a basis for future refinement once empirical hydrogen production data become available.

The reaction extent formulation used in this study is intended as a phenomenological representation of hydrogen generation from subsurface water–rock interactions. Because field-scale kinetic data for geologic hydrogen systems remain limited, the model employs simplified parameters that capture the dominant temporal behavior of reaction-driven resource generation.

In this formulation, the half-life parameter represents an effective kinetic timescale governing the rate at which reactive minerals contribute to hydrogen generation under reservoir conditions. The maximum reaction extent parameter represents the fraction of the reactive mineral inventory that can realistically participate in hydrogen-producing reactions, accounting for constraints such as mineral accessibility, transport limitations, and thermodynamic equilibrium.

These parameters should therefore be interpreted as effective model parameters rather than direct measurements of intrinsic reaction kinetics. Their values were selected to represent plausible reaction timescales reported in studies of water–rock reactions and hydrogen-generating geochemical systems. Because uncertainties remain in these processes, the present formulation is intended as a first-order approximation suitable for framework development. Future work will include systematic sensitivity analysis and calibration as experimental and field data for geologic hydrogen systems become available.

The simulation results reveal a stark contrast between hydrogen production from the matrix and fracture domains. As shown in Figure 3, the fracture system dominates hydrogen output, with production rates rapidly rising to approximately 4000 kg/day within the first 100 days and remaining stable through 365 days. In contrast, matrix production remains negligible throughout the simulation period, indicating a limited contribution to the overall yield. This disparity underscores the critical role of fracture-enhanced transport and reactivity in enabling scalable hydrogen recovery from source rocks. The results demonstrate the framework's sensitivity to diffusivity and permeability parameters and highlight the importance of fracture network design in optimizing hydrogen extraction efficiency.

Figure 4 illustrates the temporal evolution of hydrogen output and water utilization efficiency over a 365-day simulation period. Hydrogen production rate increases steadily during the initial 180 days, reaching a plateau at approximately 4000 kg/day, consistent with fracture-dominated flow behavior observed in earlier results. Simultaneously, water efficiency, defined as kilograms of hydrogen produced per cubic meter of water used, rises gradually and reaches about 57 kg $H_2/m^3$ by day 365. This trend reflects improving resource utilization over time, as the system becomes more productive without proportional increases in water input.

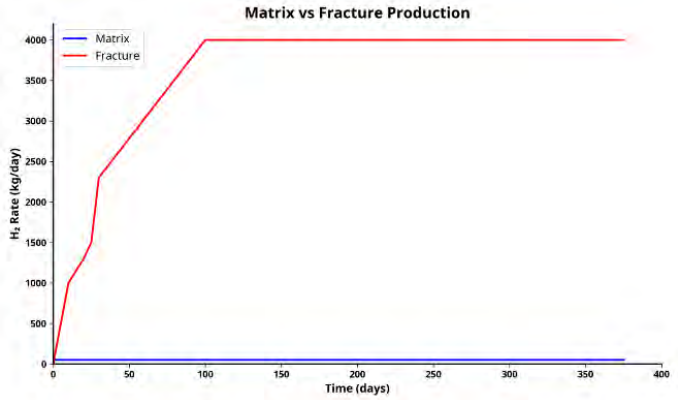

**Figure 3.** Hydrogen production rate over time from matrix and fracture domains

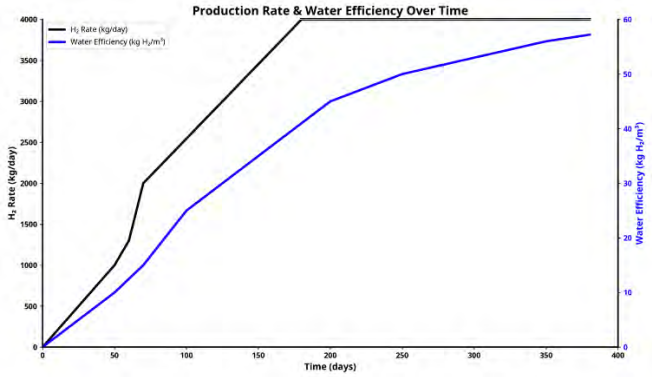

**Figure 4.** Hydrogen production rate and water efficiency over time

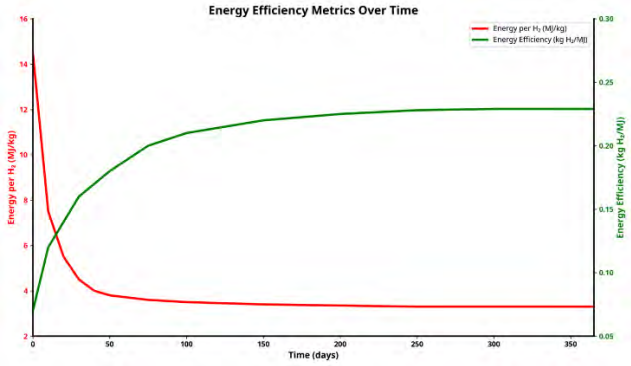

**Figure 5.** Energy efficiency metrics over time during hydrogen extraction

The energy and water estimates reported in this analysis are defined within a well-field operational system boundary. The accounting includes the primary operational energy inputs associated with subsurface hydrogen extraction, specifically hydraulic fracturing operations, fluid pumping during production, and gas compression required for surface handling of the produced

gas stream. Upstream processes such as drilling equipment manufacturing, infrastructure construction, and downstream processes, including hydrogen purification, storage, or long-distance transport, are not included. Consequently, the reported energy and water metrics represent direct operational requirements rather than a full life-cycle assessment. When comparisons are made with conventional hydrogen production pathways, they should therefore be interpreted as contextual benchmarks rather than strict life-cycle comparisons.

The co-evolution of these metrics highlights the framework's ability to capture both production dynamics and sustainability indicators. The plateau in hydrogen rate suggests stable fracture performance, while the continued rise in water efficiency implies that early water investment yields increasingly favorable returns. These insights are critical for evaluating the viability of geologic hydrogen extraction, especially in water-constrained environments. The results reinforce the importance of fracture design and operational timing in optimizing both output and efficiency.

Figure 5 provides insight into the evolving energy performance of the hydrogen extraction system. Over the 365-day simulation, the energy required per kilogram of hydrogen decreases steadily from around 16 MJ/kg to approximately 4 MJ/kg, indicating improved thermodynamic efficiency as the system stabilizes. Concurrently, the energy efficiency, expressed as kilograms of hydrogen produced per megajoule of input energy, increases and plateaus near 0.25 kg $H_2$/MJ. This inverse relationship reflects the system's optimization over time, where less energy is needed to sustain high hydrogen output. These trends underscore the framework's ability to capture not only production dynamics but also energy sustainability, offering a valuable metric for evaluating the long-term viability of geologic hydrogen operations.

The key performance indicators over the 365-day simulation period provide a comprehensive snapshot of the system's overall efficiency and sustainability. Total hydrogen production reached 1, 132, 287 kg, demonstrating the scalability of the multi-well fracture-based extraction approach. Water consumption averaged 0.02 $m^3$ per kilogram of hydrogen, translating to an overall water efficiency of 57 kg $H_2/m^3$. This aligns with the trends observed in the water efficiency graph, confirming that the system maintains high productivity with minimal water input.

Energy consumption averaged 3.40 MJ per kilogram of hydrogen, yielding an overall energy efficiency of 0.29 kg $H_2$/MJ. These values reflect the system's ability to optimize energy use over time, as previously shown in the declining energy-per-kilogram and rising energy efficiency metrics. Together, these indicators validate the framework's capacity to simulate not only production dynamics but also resource efficiency, offering a robust foundation for evaluating geologic hydrogen extraction under realistic operational constraints.

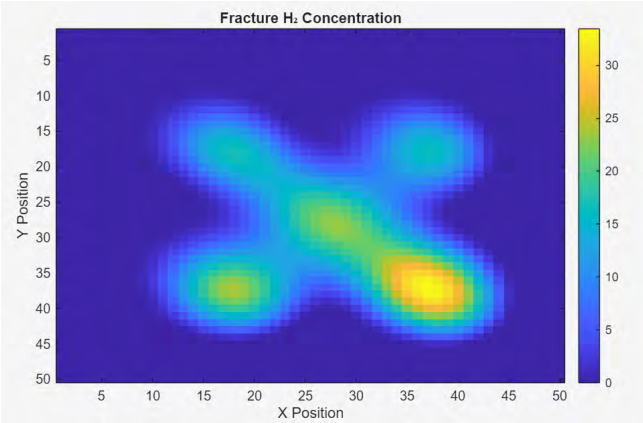

**Figure 6.** Fracture $H_2$ concentration distribution

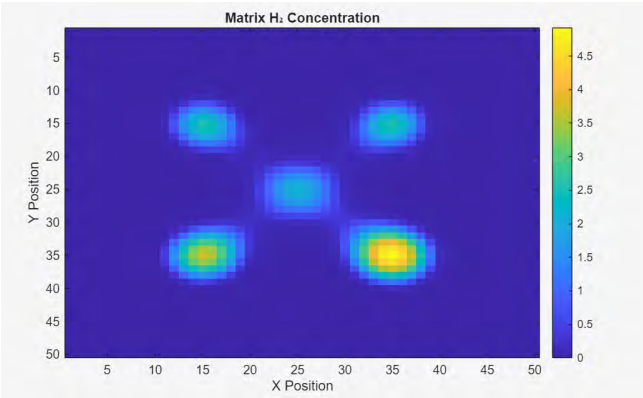

**Figure 7.** Matrix $H_2$ concentration distribution

The fracture hydrogen concentration distribution shown in Figure 6 demonstrates the dominant role of fracture networks in controlling recovery efficiency. Concentrations along the fracture plane are relatively uniform and continuous, reflecting the high permeability and aperture evolution captured in the dual-porosity dual-permeability (DPDP) framework. This behavior confirms that fracture-dominated pathways serve as the primary conduits for hydrogen transport, accounting for the vast majority of cumulative production. The spatial spread of hydrogen within the fracture system highlights how fracture propagation and connectivity enable rapid mobilization of hydrogen, minimizing diffusion limitations and ensuring efficient recovery at low water and energy costs.

By contrast, the matrix hydrogen concentration distribution in Figure 7 reveals a different behavior. Concentrations are localized and attenuated, with values significantly lower than those observed in fractures. The patchy distribution reflects the limited contribution of the matrix to overall recovery, a consequence of lower permeability and slower diffusion processes. This observation aligns with the model's prediction that the matrix

contributes minimally to total recovery, underscoring the need for enhancement strategies such as chemical stimulation to increase reactivity or thermal stimulation to accelerate diffusion and desorption. The figure also highlights the heterogeneity of reservoir performance, where matrix zones act more as secondary storage rather than primary flow pathways.

Taken together, the two figures validate the DPDP representation by illustrating the duality of reservoir behavior: fractures act as high-efficiency flow channels. At the same time, the matrix functions as a low-efficiency reservoir. This duality explains the efficiency trade-offs identified in the system-wide benchmarks, where fracture-driven recovery achieves specific energy consumption of 3.4 MJ/kg $H_2$ and specific water consumption of 0.02 $m^3$/kg $H_2$, an order of magnitude lower than conventional hydrogen production methods. At the same time, the limited matrix contribution points to opportunities for optimization through stimulation design and reservoir characterization. These results emphasize that while fracture systems provide the cornerstone of geologic hydrogen recovery, unlocking the potential of the matrix remains a critical frontier for future research and development.

## CONCLUSION

This study presents an integrated modeling framework for estimating resource usage associated with geologic hydrogen extraction via hydraulic fracturing. By adapting published shale gas production results for benchmarking and applying the framework to a multi-well hydrogen development scenario, the model demonstrates its capability to simulate fracture-controlled production dynamics and associated resource utilization under representative subsurface conditions. The results highlight the dominant role of fracture networks in controlling hydrogen recovery and illustrate how production behavior, water use, and energy inputs evolve during reservoir operation.

A key component of the framework is the phenomenological reaction-extent formulation used to represent hydrogen-generating reactions. Although simplified relative to detailed geochemical models, this approach provides a practical means of exploring hydrogen generation and production efficiency in the absence of well-constrained field-scale kinetic data. Under the simulated multi-well scenario, the framework produced indicative performance metrics including cumulative hydrogen production of approximately 1.13 million kg, a water utilization efficiency of about 57 kg $H_2/m^3$, and an operational energy intensity of roughly 3.40 MJ/kg $H_2$, corresponding to an energy efficiency of 0.29 kg $H_2$/MJ. These values represent model-based estimates under the assumed conditions and illustrate the type of system-level performance indicators that the framework can generate.

The framework is intended as an exploratory tool for assessing production dynamics and resource requirements under data-limited conditions rather than as a fully validated predictive model. The benchmarking exercise against published shale gas results primarily evaluates the framework's ability to reproduce production decline behavior, while other components, including reactive transport processes and hydrogen generation kinetics, remain subject to uncertainty due to the limited availability of field-scale geologic hydrogen datasets.

Despite these limitations, the framework demonstrates how fracture-controlled production behavior, simplified reaction modeling, and resource accounting can be integrated within a single modeling structure. This integration provides a basis for evaluating water–energy–hydrogen trade-offs and exploring operational scenarios relevant to geologic hydrogen development. As experimental and field data become available, the framework can be refined through improved parameterization, sensitivity analysis, and calibration to support more detailed technical, environmental, and economic assessments of geologic hydrogen extraction.

## ABSTRACT

The objective of the present work is to optimize the simulation of an electrodialysis reactor for the desalination and regeneration of multi-ionic wastewater with high salt contents and conductivities, within the framework in the Sustainable Development Goal 6 (clean water and sanitation) and remarking the Electrodialysis (ED) as a highly energy-efficient and sustainable technology. The mathematical modelling has been carried out by using a semiempirical model that involves an algebraic system of differential equations, including mass and charge balances (taking into account the ions present in the wastewater: $Na^+$, $Ca^{2+}$, $Mg^{2+}$, $Cl^-$, $SO_4^{2-}$, and $HCO_3^-$), and the total electrodialysis stack voltage considering ohmic drops (in the dilute and concentrate compartments), the potential of membrane in each cell pair, and the electrode potentials. In the simulation process, different theoretical and experimental parameters are necessary such as number of cells, membrane working areas, efficiency, diffusion coefficients, molar conductivity at infinite dilution, etc.The experimental parameters have been obtained initially with a specially designed batch reactor printed with 3D technology, to imitate the hydrodynamics and the behavior of the industrial final reactor used. Additionally, to increase the accuracy of the simulation results, same parameters such as the resistance of the membranes ($r_m$), the transport numbers and the mass transfer coefficient ($k_m$) can be optimized by using a metaheuristic derivative-free optimizer, specifically a proprietary version of Particle Swarm Optimization (PSO) implemented in MatLab®.The results obtained yield a satisfactory reproduction of the observed experimental behavior, analyzing the evolution over time of the intensity, conductivity, and concentration of the concentrated and diluted currents, respectively. In addition, the evolution of the different contributions of the stack voltage and the membrane resistances are shown, in order to confirm the coherence of the results obtained.

## INTRODUCTION

Wastewater Treatment Plants (WWTP) constantly receive water from industrial process that can present salinity levels from 1 wt % up to values similar to seawater (3.5 wt %) [1], including also domestic uses such as detergents or water softening processes [2], or waste derived from constructions and transportation activities [3]. This problem also occurs in coastal areas due to marine intrusion. On the other hand, waste water with high salinity degree released into the environment may cause damage by contaminating soils, surfaces, groundwater, or any water body with which they come into contact [4] There is evidence that it affects ecosystem processes by altering the decomposition of organic matter, biomass production, and reducing biodiversity [5].

Thus, in order to reuse any treated water as regenerated water for instance in urban cleaning tasks, garden watering, agricultural uses, etc., regulations must be followed to mitigate their impact. According to the FAO

(Food and Agriculture Organization), for conductivities higher than 3 mS/cm water must be under several restrictions and controls, between 0.7 and 3 mS/cm those restrictions are lower, and with electrical conductivities under 0.7 mS/cm there are any restriction [6].

In this context, electrodialysis (ED) appears as a very energy efficient and sustainable wastewater desalination treatment for those type of salinized water compared to other processes [7, 8]. Additionally, ED process is driven by an electric field and neutral species present in wastewater that may be associated with beneficial elements for plants, such as urea or organic nitrogen, are almost not altered by the process [9, 10, 11].

The ED process is conducted in a membrane stack (electrodialysis reactor) where two kind of exchange membranes: N+1 cation exchange membranes (CEM) and N anion exchange membranes (AEM) are alternatively located generating a series of N+1 compartment between two different consecutives membranes. A potential difference is applied across the membrane stack using two electrodes placed at the sides of it. The feed solution flows through the membranes, generating a dilute channel and a concentrate channel as a result of ion migration. The cathode is negatively charged, so cations migrate toward it by passing through the CEMs, but they cannot pass through the AEMs. Likewise, the positively charged anode attracts anions, which migrate toward it under the same selective transport mechanism [12].

To scale up an ED process without the need to perform many experimental tests at each stage of the scaling procedure, it is absolutely necessary to have a mathematical model to simulate the main characteristics of the process.

However, electrochemical processes are particularly complex to model due to their multiscale and multiphysics nature. In such processes, phenomena of different origins coexist, requiring the simultaneous consideration of thermodynamic and kinetic aspects together with the distribution of electric potential and ionic transport in the solution [13, 14]. In this sense, there are ED mathematical models capable of predicting the desalination rate and the current density [15] depending on the water composition, as well as the electrical energy consumption of the process [16].

In the case of the model presented by Ortiz et al. [16], parameters such as membrane resistance (Rm) and the potential difference between electrodes are introduced and assumed to be constant. The potential difference depends on the overpotential (μ), which also depends on the current density (j), the exchange current density (j0), and the Tafel slope (b). All of these parameters, including membrane resistance, vary depending on the type of electrolyte, its concentration and the hydrodynamics of the reactor. Treating these parameters as constants leads to a loss of accuracy in the results, for that, it is needed to determinate these parameters under specific operating conditions of each reactor or experiment.

Thus, this work presents a new modified and optimized version of the model developed by Ortiz [16, 17] further extended to a multi-ionic wastewater system. As case study, a Wastewater Treatment Plant in Santa Pola (Spanish east cost) has been selected where, even with effective tertiary treatment, the final water has conductivities between 4 and 7 mS/cm that hinder its reuse for purposes such as irrigation. Although the regulations considered these waters have high conductivity, for a desalination process they are relative low salinities.

## MATHEMATICAL MODEL

The proposed model is structured into two blocks: one that defines mass transfer through mass balances equations, and another that is responsible for providing all the electrical data via the calculation of the total potential.

### Mass balance

It is necessary to know the ionic composition of the solution, both in the reactor (concentrated and diluted compartments) and in the concentrated and diluted product tanks. To this end, the corresponding mass balances over the time are established. Assuming that the electrodialysis reactor and the reservoirs or tanks follow a perfectly mixed reactor model and that the compartments are equivalent, the following mass balances can be established for each cation (*i*) present in the concentrate and dilute compartments of the electrodialyzer, respectively:

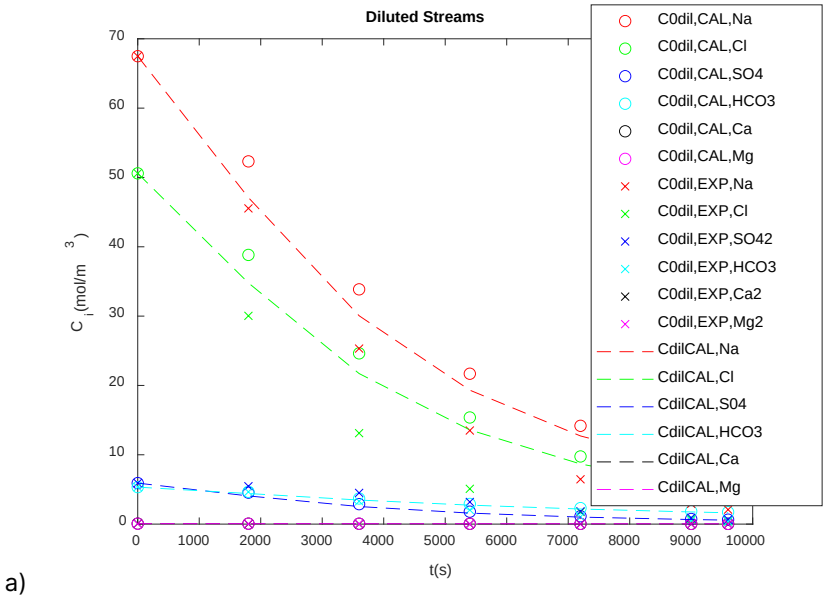
$$NV_k \frac{dC_{conc,i}}{dt} = Q_{conc}C^0_{conc,i} - Q_{conc}C_{conc,i} + \\ +NA(J_i^{cat} - J_i^{an}) \quad (1)$$

$$NV_k \frac{dC_{dil,i}}{dt} = Q_{dil}C^0_{dil,i} - Q_{dil}C_{dil,i} - NA(J_i^{cat} - J_i^{an}) \quad (2)$$

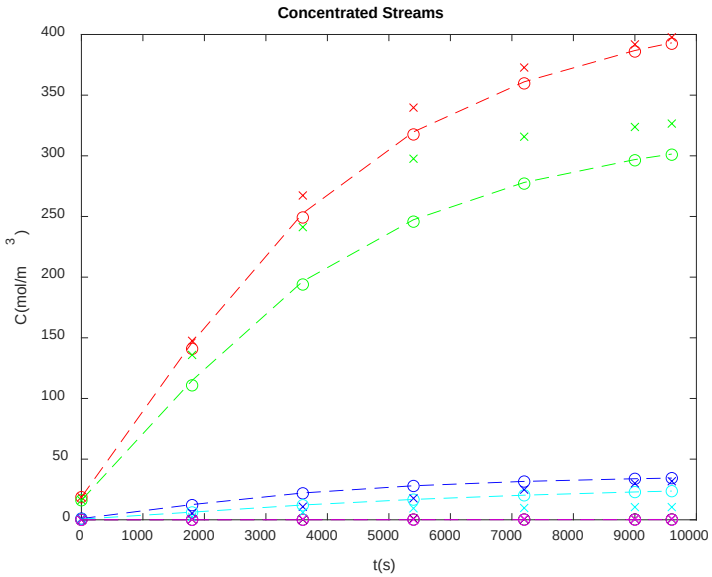
where $N$ is the number of cells, $V_k$ is the volume of the compartments ($m^3$), $t$ is time (s), $C^0_{dil,\,i}$ and $C^0_{conc,\,i}$ are the initial concentrations or inlet concentrations of the ion $i$ in the dilute and concentrate compartments, respectively, and $C_{dil,\,i}$ and $C_{conc,\,i}$ are the corresponding outlet concentrations ($mol/m^3$). $Q_{dil}$ and $Q_{conc}$ are the flow rates of the dilute and concentrate compartments ($m^3/s$), A is the electrode area ($m^2$), and $J_{cat,\,i}$ and $J_{an,\,i}$ are the fluxes of cations and anions of species $i$ through the cation-exchange and anion-exchange membranes, respectively ($mol/m^2$).

For anions, the expression would be equivalent, but with the opposite sign for the ionic fluxes:

$$NV_k \frac{dC_{conc,i}}{dt} = Q_{conc}C^0_{conc,i} - Q_{conc}C_{conc,i} +$$



a)



b)

**Figure 1.** Composition profiles obtained for a sample with a initial conductivity of 6 mS/cm.

$$+NA(J_i^{an} - J_i^{cat}) \quad (3)$$

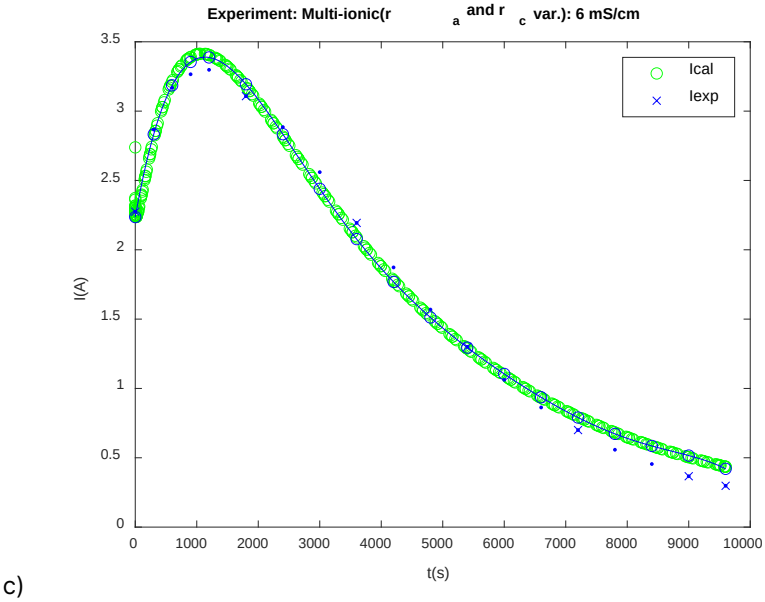
$$NV_k \frac{dC_{dil,i}}{dt} = Q_{dil}C^0_{dil,i} - Q_{dil}C_{dil,i} - NA(J_i^{an} - J_i^{cat}) \quad (4)$$

The ionic fluxes for ions i are given by the sum of the migration and diffusion components:

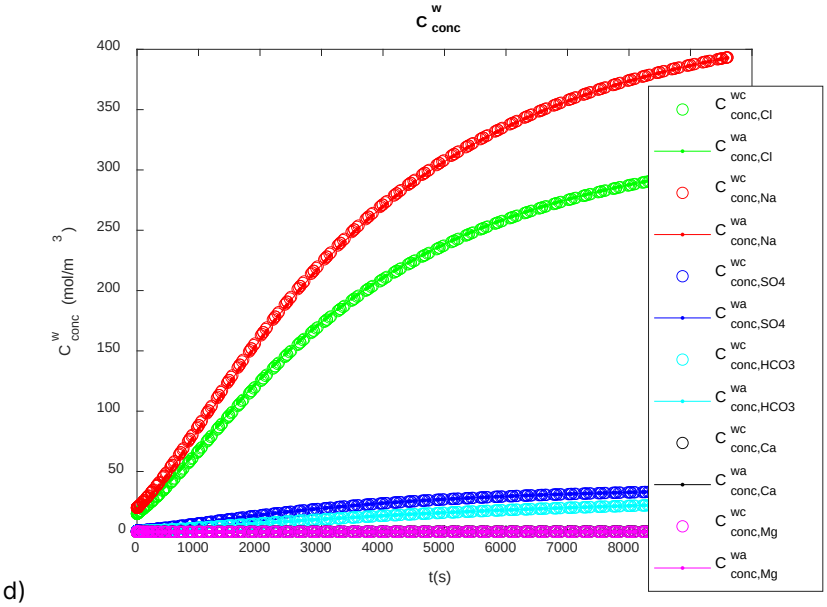
$$J_i^{cat} = \sum J_{i,mig}^{cat} + \sum J_{i,dif}^{cat} = \frac{\phi t_i^{cat}}{z_i F} j - D_i^{cat} \frac{C^{w,cat}_{conc,i} - C^{w,cat}_{dil,i}}{l_m^{cat}} \quad (5)$$

$$J_i^{an} = \sum J_{i,mig}^{an} + \sum J_{i,dif}^{an} = \frac{\phi t_i^{an}}{z_i F} j - D_i^{an} \frac{C^{w,an}_{conc,i} - C^{w,an}_{dil,i}}{l_m^{an}} \quad (6)$$

where $\phi$ is the experimental current efficiency, $t^{cat}_i$ and $t^{an}_i$ are the transport numbers of ion $i$ in the cation-exchange and anion-exchange membranes, respectively, $z_i$ is the ionic charge, $F$ is Faraday's constant (C/mol), $j$ is the current density (A/m$^2$), $D^{cat}_i$ and $D^{an}_i$ are the diffusion coefficients of ion $i$ in the cation-exchange and anion-exchange membranes, respectively (m$^2$/s), $C^{w,\,cat}_{conc,\,i}$ and $C^{w,\,cat}_{dil,\,i}$ are the concentrations of ion $i$ at the surface of the cation-exchange membrane for the concentrate and dilute compartments, respectively (mol/m$^3$), $C^{w,\,an}_{conc,\,i}$ and $C^{w,\,an}_{dil,\,i}$ are the analogous concentrations for the anion-exchange membrane, and $l^{cat}_m$ and $l^{an}_m$ are the thicknesses of the cation-exchange and anion-exchange membranes (m). This expression is equivalent for cations and anions, the only difference lies in the values of the corresponding parameters.



c)



d)

**Figure 1(cont.).** Intensity, membrane compositionc and potential profiles obtained for a sample with an initial conductivity of 6 mS/cm.

The corresponding concentrations in the membranes can be calculated as follows:

$$C_{dil,i}^{wa} = C_{dil,i} - \frac{\phi j}{|z_i|Fk_m}\left(t_{i,contra\text{ or }co}^{ma} t_{contra\text{ or }co}^{a} - t_i^{dil}\right) \quad (7)$$

$$C_{conc,i}^{wa} = C_{conc,i} + \frac{\phi j}{|z_i|Fk_m}\left(t_{i,contra\text{ or }co}^{ma} t_{contra\text{ or }co}^{a} - t_i^{conc}\right) \quad (8)$$

$$C_{dil,i}^{wc} = C_{dil,i} - \frac{\phi j}{|z_i|Fk_m}\left(t_{i,contra\text{ or }co}^{mc} t_{contra\text{ or }co}^{c} - t_i^{dil}\right) \quad (9)$$

$$C_{conc,i}^{wc} = C_{conc,i} + \frac{\phi j}{|z_i|Fk_m}\left(t_{i,contra\text{ or }co}^{mc} t_{contra\text{ or }co}^{c} - t_i^{conc}\right) \quad (10)$$

where the value of the transport numbers $t^{c\text{ or }a}{}_{contra}$ is 0.999, with $t^{c\text{ or }a}{}_{co}$ = 1-$t^{c\text{ or }a}{}_{contra}$.

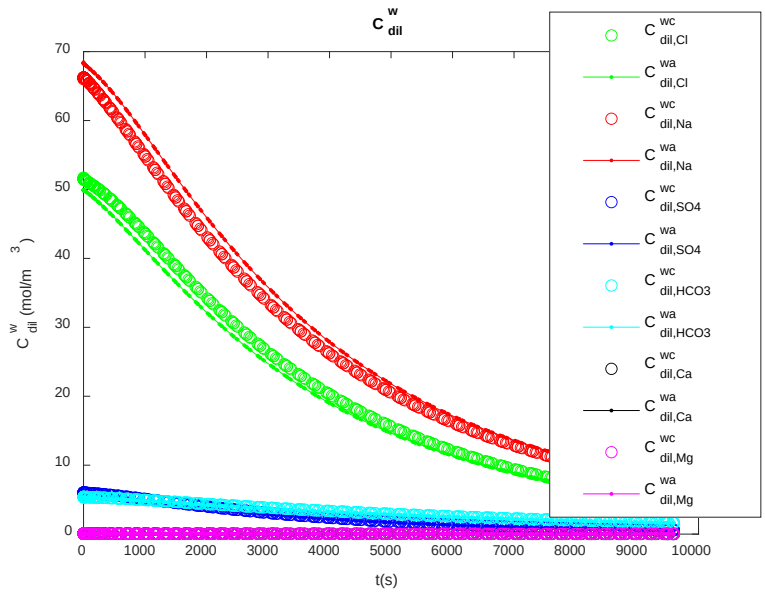
In the case of transport numbers, the general equations are:

$$t_i^{conc\text{ or }dil} = \frac{|z_i|u_i\ C_i^{conc\text{ or }dil}}{\sum_i |z_i|u_i\ C_i^{conc\text{ or }dil}} \quad (11)$$

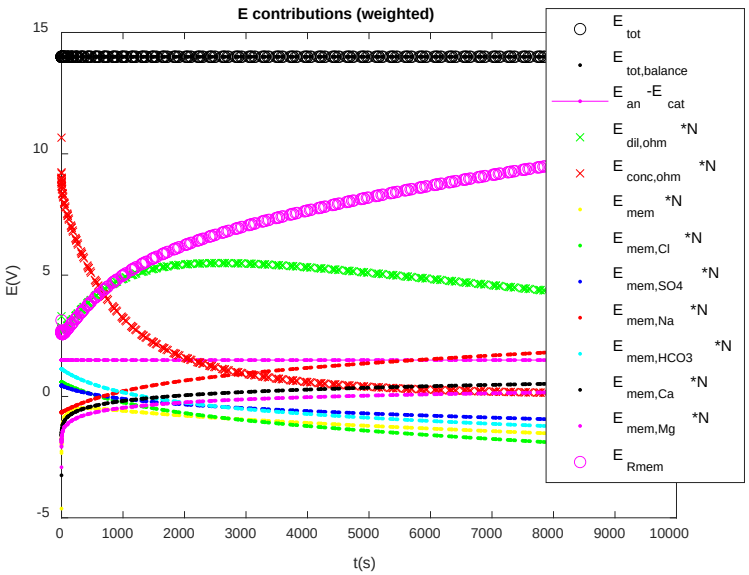
$$t_{app,i,contra\text{ or }co}^{ma\text{ or }mc} = \frac{|z_i|y_i^{contra\text{ or }co} C_{conc\text{ or }dil,i}^{wa\text{ or }wc}}{\sum_i |z_i|y_i^{contra\text{ or }co} C_{conc\text{ or }dil,i}^{wa\text{ or }wc}} \quad (12)$$

where $y_i$ is a term related to ionic mobility in the membranes (if it were in solution, the notation would be $u_i$), and $C_i$ is the ion concentration in the concentrate or dilute solution. This concentration may vary depending on whether it is in the membrane or in the solution [18].

The mass balances for the concentrate and dilute



e)



f).

**Figure 1(cont.).** Intensity, membrane compositionc and potential profiles obtained for a sample with an initial conductivity of 6 mS/cm.

tanks can be expressed as follows:

$$\frac{C^0_{conc,i}V^T_{conc}}{dt} = Q_{conc}\left(C_{conc,i} - C^0_{conc,i}\right) \quad (13)$$

$$\frac{C^0_{dil,i}V^T_{dil}}{dt} = Q_{dil}\left(C_{dil,i} - C^0_{dil,i}\right) \quad (14)$$

where $V^T_{dil}$ and $V^T_{conc}$ are the volumes of the dilute and concentrate tanks, respectively ($m^3$).

## Electrical potential difference in the electrodialysis stack

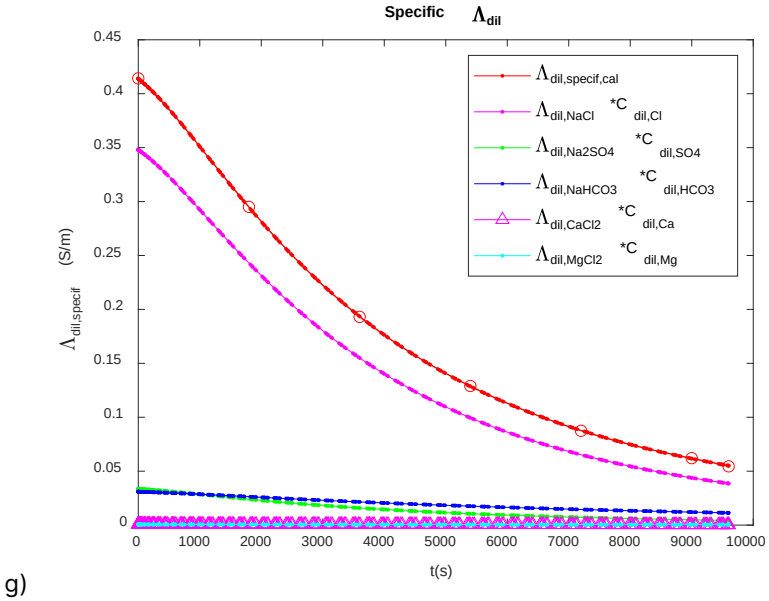
The current intensity ($I$) that flows through the electrodialyzer is related to the applied electrical potential. The total electrical potential drop for an electrodialyzer can be obtained as follows:

$$\varphi_{tot} = (\varphi_{an} - \varphi_{cat}) + N\left(\varphi^{dil}_{ohm} + \varphi^{conc}_{ohm} + \varphi_{mem}\right) + \\ + R_{mem} \cdot \frac{I}{A} \quad (15)$$

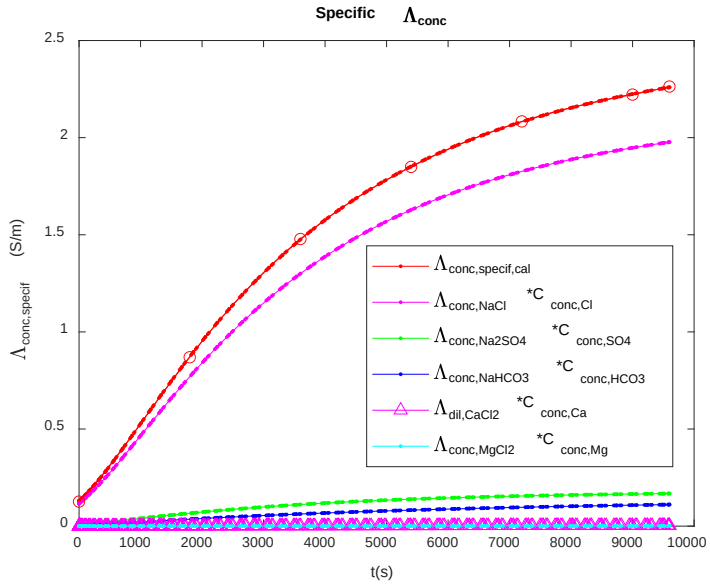
$$\text{with: } \varphi^{dil}_{ohm} = \frac{L\,I}{\Lambda_{dil}\,A};\ \varphi^{\text{conc}}_{\text{ohm}} = \frac{\text{L I}}{\Lambda_{\text{conc}}\,\text{A}} \quad (16)$$

$$\varphi_{mem} = \sum_i^{ions} \frac{RT}{z_i F}\, ln\left(\frac{C^{wc}_{conc,i}}{C^{wc}_{dil,i}}\frac{C^{wa}_{conc,i}}{C^{wa}_{dil,i}}\right) \quad (17)$$

where $\varphi_{an}$ and $\varphi_{cat}$ are the anode and cathode potentials, respectively (V), $\varphi^{dil}{}_{ohm}$ is the ohmic drop in the dilute compartment (V), $\varphi^{conc}{}_{ohm}$ is the ohmic drop in the



g)



h)

**Figure 1.(cont.).** Intensity, membrane compositionc and potential profiles obtained for a sample with an initial conductivity of 6 mS/cm.

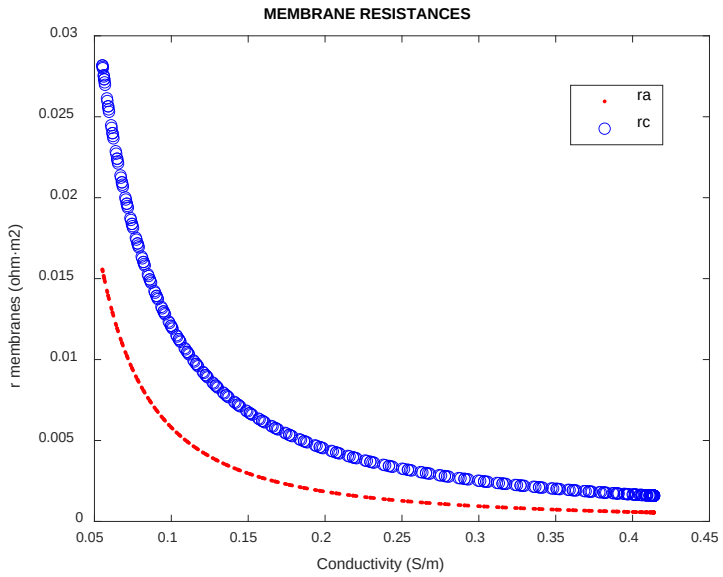
concentrate compartment (V), $\varphi_{mem}$ is the total membrane potential at each unit cell (V) due to the presence of all the ions present in the water, considering ideal mixture, $\Lambda_{dil}$ and $\Lambda_{conc}$ are the total specific conductivities (S/m) of the concentrated or diluted solution taking into account all the individual salts present in the solution (Table 1), respectively, $L$ is the membrane gap, and $R_{mem} \cdot I/A$ is the term associated with the total resistance contributed by all the membranes (N+1 CEM, and N AEM), which has been obtained by correlation the experimental intensity values (obtained in A 3D printed reactor [18]) with the conductivity of the diluted solution [eq. 18] by using the proposed model and a proprietary version of Particle Swarm Optimization (PSO) implemented in MatLab®, that has been successfully used for the optimal design of different unit operations [19].

$$R_{mem} = Nra + (N+1)rc \tag{18}$$

with: $ra = 58.04\Lambda_{dil}^{-1.66}$; $rc = 120.46\Lambda_{dil}^{-1.42}$ and $\Lambda_{dil} = \sum_{s}^{Salts} \Lambda_s \, C_{dil,s}$.

## RESULTS

To solve the obtained algebraic system of differential equations, additional equations and parameters are



i)

**Figure 1.(cont.).** Specific conductivities and membrane resistences profiles obtained for a sample with an initial conductivity of 6 mS/cm.

required (Tables 1-3), such as the characteristic parameter y, related to ion mobility in the membrane, the ion mobility in the solution u; the Falkenhagen equation for the molar conductivity of each salt of the solution (and its parameters $B_0$, $B_1$ and $B_2$), among others. Figures 1 show the main profiles obtained for the simulation of a case study with an initial conductivity of 6 mS/cm (concentration of the concentrated and diluted streams, intensity and, the different contributions of the stack voltage). As can be seen, the proposed model satisfactorily represents the experimental trends, analyzing the different evolutions over time, especially in the initial section up to approximately 3000 s, when a conductivity of less than 2.5 mS/cm is reached, which is the limit allowed for safe reuse of regenerated water in irrigation. However, future work should incorporate e.g. the non-ideality of the liquid mixture by using the corresponding activity coefficients in the calculation of the membrane potential.

**Table 1.** Parameters for Falkenhagen equation, with $U$= 4 Å. $\Lambda_{salt} = \Lambda_0 - (B_1\Lambda_0 + B_2)\frac{C_{salt}^{0.5}}{1+B_0 U C_{salt}^{0.5}}$.

## ABSTRACT

Bioprocess modelling, optimisation and scale-up are central components for improving sustainable manufacturing within pharmaceutical and chemical industries. However, developing accurate bioprocess digital twins remains a challenging process. Conventional mechanistic models are difficult to construct because of limited mechanistic understanding and large complexity of cellular metabolisms. While data-driven models have gained popularity, they often require large amounts of experimental data that is often time consuming to obtain and lack any quantitative description of the process. Hybrid modelling methods have emerged as promising alternatives however fail to provide physical insight to the root cause of model error. This work therefore presents a promising solution by developing a data-efficient symbolic regression (SR) based framework to enable the automated discovery of interpretable bioprocess models. A universal kinetic model backbone was used to capture overall process behaviour, while SR was applied to strategically uncover the structures of critical kinetic terms within the backbone. Two frameworks, embedding SR directly into the kinetic model backbone or identifying time-varying parameter profiles prior to SR, were benchmarked using an in-silico yeast fermentation case study. The results demonstrated that independently identifying individual kinetic terms was crucial for recovering the ground-truth model, while refining SR-generated candidates through a novel local iterative structural correction strategy significantly improved convergence to the true kinetic expressions, surpassing model-based design of experiments in data efficiency. This study therefore enables automated yet interpretable model construction for small-data bioprocess applications, paving the way towards augmented intelligence driven bioprocess modelling and accelerating digital twin development for process optimisation and control.

## INTRODUCTION

Accurate bioprocess models are critical for control, optimisation and accelerating the transition from laboratory experiments to production scale operations. Mechanistic models are widely adapted for modelling bioprocess kinetics due to their interpretability and ability for providing insight into the governing reaction kinetics. Represented using ordinary differential equations, they are derived using prior knowledge of underlying chemical reactions that occur within the biological cell. Typical strategies to construct mechanistic models for biochemical reaction networks include using the Monod and adapted Monod kinetic structures. This approach finds prominent application within bioprocess modelling and is widely used to simulate the evolution of key biological states over time. However, identifying the correct underlying mechanistic structure is often a difficult task due to the large network of complex metabolic pathways that contribute to apparent stochastic behaviour.

In response to the challenges faced with mechanistic approaches, data-driven modelling has gained popularity as a viable solution in literature. Black-box models can use large datasets gained from running experiments to make accurate kinetic predictions without requiring prior knowledge of underlying reaction mechanisms. Machine learning-based models have seen success in modelling chemical and biochemical reaction kinetics [1]

however, their practical applications remain limited. This is because data-driven models often require large amounts of data which is a scarce resource in bioprocess industry due to large expenses and risks involved when running experiments on novel systems.

Recently, hybrid modelling has emerged as a promising alternative to address the challenges with both mechanistic and data-driven modelling by combining machine learning techniques with mechanistic knowledge. Prior knowledge is embedded using a mechanistic backbone while the data-driven component leverages data to account for model error that may arise from any incomplete physical understanding. In this way, hybrid modelling has been able to demonstrate advantages by making accurate predictions for complex biochemical reaction kinetics [2] and offer a suitable platform to model the dynamics of similar biological strains by applying transfer learning [3]. However, despite the success in literature, there exist various practical challenges when applying hybrid modelling methods for modelling novel biological strains. The prominent disadvantage lies with providing no mechanistic insight into the root cause of model error, that is essential for in applications that require a high degree of explainability and limits human understanding of underlying reaction kinetics.

Motivated by the need for deeper mechanistic understanding, automated model structure identification methods have been proposed in literature for overcoming the limitations of hybrid modelling. Among these methods the sparse identification of nonlinear dynamics (SINDy) has gained most attention and has seen successful application for identifying accurate model structures for chemical reaction systems [4]. By leveraging sparse regression techniques, SINDy algorithm can construct kinetic rate equations using a library of predefined candidate functions found most likely within literature. However, application for biochemical processes remains limited by the requirement for a suitably large library of candidate functions that is particularly challenging to obtain if there exists no prior physical knowledge of biological strains. This has motivated the development of more flexible model structure identification techniques such as symbolic regression (SR) that uses genetic programming to explore a much broader solution space. the advantage of SR is that the models identified are a function of only predefined operators and variables and not limited by imposed structural forms. Presently SR has been successful in discovering chemical rate equations without a-priori [5] and simple unstructured bioprocess models [6] however the application for complex biochemical systems remains relatively unexplored due to significant challenges to guarantee interpretability of resultant models for real-world biological systems.

Therefore, to address the described challenges, this work utilises symbolic regression (SR) to develop an automated model structure identification framework that can uncover underlying kinetic information with high data-efficiency. Through this approach, is it possible to simultaneously accelerate the development of accurate bioprocess models while also deepening our mechanistic understanding of emerging processes.

## METHODOLOGY

### Symbolic regression and information criteria

Symbolic regression (SR) is a data-driven technique that leverages genetic programming to simultaneously identify both functional form and numerical constants that best describe a dataset. SR explores a solution space of equations represented as expression trees built from predefined mathematical operators and variables without imposing a set structural form. At each iteration, a set of expressions are drawn at random from an initialised population and undergo tournament selection process. The expressions are by default ranked according to their mean squared error or a fitness function of the user's definition where the highest scoring models proceed to the next iteration with a chance of undergoing mutation or crossover. In this work, SR was implemented using the PySR package, which combines the evolutionary search with gradient-based optimisation in an iterative evolve–simplify–optimise process. During this cycle, candidate equations are periodically simplified to remove redundancy, and their numerical constants are refined using local gradient-based methods. Rather than producing a single model, this approach generates a set of candidate equations across varying levels of complexity, forming a Pareto front that captures the trade-off between model simplicity and fitting accuracy.

Because symbolic regression produces many candidate models, this work adopts the corrected Akaike Information Criterion (AICc) as a systematic method for model selection, balancing goodness of fit with model simplicity. AICc evaluates models based on their residual error, number of parameters, and sample size, applying an additional correction term that increasingly penalises overly complex models when data is limited. This makes it particularly suitable for bioprocess applications, where experimental data is often scarce. By selecting the model with the lowest AICc, the framework identifies the best trade-off between accuracy and parsimony, reducing overfitting and providing a consistent, objective approach to choosing the most plausible model without relying on prior mechanistic assumptions.

### Approach 1 - Concentration space

Specifically, SR was implemented in two approaches and both methods were compared within this work. The first framework was designed to incorporate concentration profiles within the SR model discovery process by

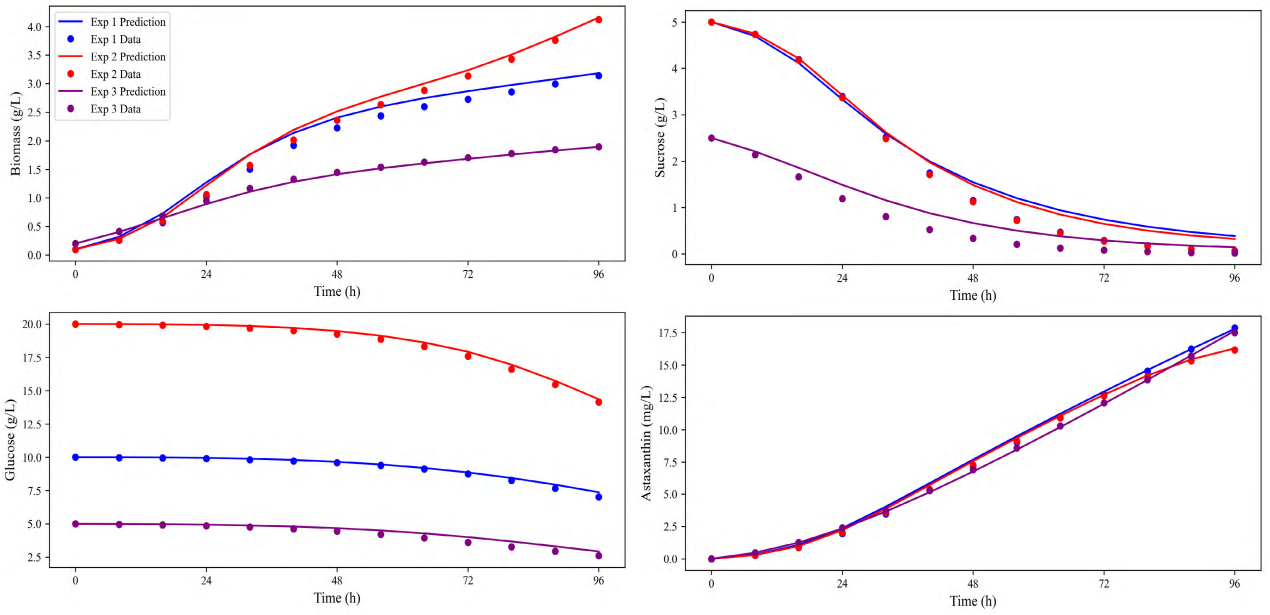

**Figure 1.** Fitting performance of the complete kinetic model using expressions discovered by SR for $\mu_{m1}$ and $\mu_{m2}$. Colours blue, red and purple represent experiment 1, 2, and 3 respectively. (a), (b), (c) and (d) shows the fitting result for concentrations of biomass, sucrose, glucose and astaxanthin, respectively.

embedding SR expressions directly into the kinetic model, ensuring that candidate models are evaluated based on how well they reproduce observed concentration dynamics. In this method, symbolic expressions representing key kinetic terms are iteratively generated and inserted into the model, and the resulting system is solved using numerical integration to simulate state variable evolution under experimental conditions. Model performance is assessed by comparing predicted and experimental concentration profiles, with better-fitting models guiding the evolutionary search process. Through repeated refinement, this approach produces a set of candidate models that balance accuracy and complexity, with the final selection made using the AICc criterion to identify the most plausible representation of the underlying system dynamics.

### Approach 2 - Gradient space

The second framework identifies kinetic model structure by initially treating key lumped parameters as time-varying quantities, estimated directly from experimental data alongside constant parameters within a nonlinear ODE-based model. This is achieved through an optimisation problem that minimises the error between model predictions and experimental observations while incorporating a regularisation term to ensure smooth, physically realistic parameter evolution over time.

Once these time-resolved parameter profiles are obtained across all experiments, they are used as target data for SR, which searches for analytical expressions that relate the parameters to the system's state variables. Candidate expressions are evaluated based on how well they reproduce the estimated parameter trajectories, and an iterative evolutionary process generates a set of models representing different accuracy–complexity trade-offs. Finally, the AICc criterion is applied to select the most plausible expressions, ensuring an optimal balance between model fit and simplicity.

## CASE STUDY

To evaluate whether SR could recover accurate kinetic information (i.e. ground-truth kinetic model structure), a case study was constructed using a yeast-based fermentation process for astaxanthin production. Using a kinetic model developed in our previous work [7], three in-silico experiments were generated at different initial conditions of biomass and substrate concentration to act as experimental data. The ground truth kinetic model is proposed in Equation 1.

$$\frac{dX}{dt} = \frac{\mu_{m1} S_1 X}{(S_1 + K_{c1} X)\cdot(1 + k_1 S_2)} + \frac{\mu_{m2} S_2 X}{(S_2 + K_{c2} X)\cdot(1 + k_2 S_1)} - \mu_d X \quad (1a)$$

$$\frac{dS_1}{dt} = \frac{-Y_{S1} \mu_{m1} S_1 X}{(S_1 + K_{c1} X)\cdot(1 + k_1 S_2)} \quad (1b)$$

$$\frac{dS_2}{dt} = \frac{-Y_{S2} \mu_{m2} S_2 X}{(S_2 + K_{c2} X)\cdot(1 + k_2 S_1)} \quad (1c)$$

$$\frac{dP}{dt} = \frac{\alpha_1 \mu_{m1} S_1 X}{(S_1 + K_{c1} X)\cdot(1 + k_1 S_2)} + \frac{\alpha_2 \mu_{m2} S_2 X}{(S_2 + K_{c2} X)\cdot(1 + k_2 S_1)} + \beta X - k_d X^2 \quad (1d)$$

where $X, S_1, S_2$, and $P$ denote concentrations of biomass, two substrates, and astaxanthin, respectively.

To effectively discover the kinetic information of

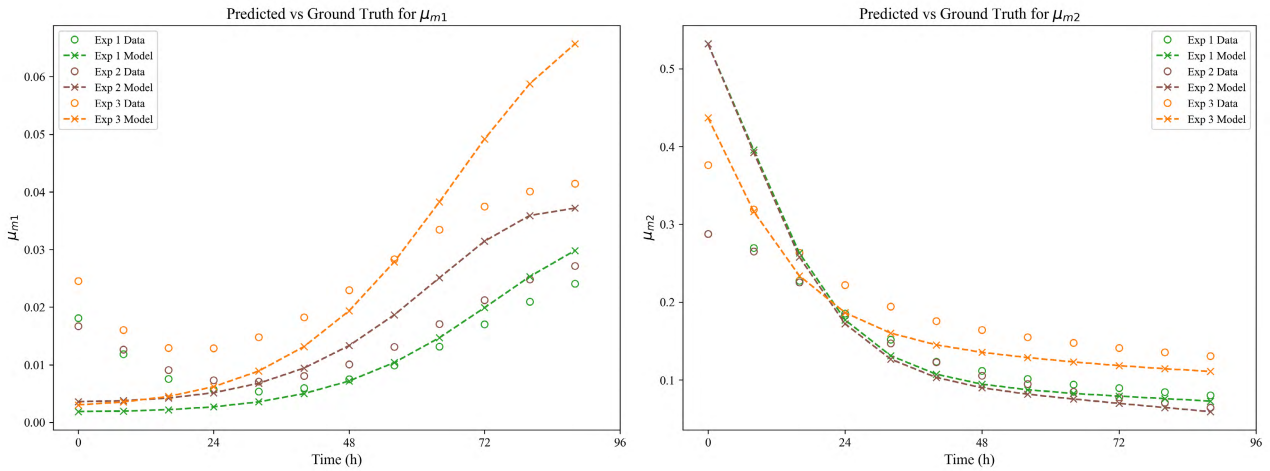

**Figure 2.** Comparison of the trends of $\mu_{m1}$ (a) and $\mu_{m2}$ (b) over time. Colours green, brown and orange represent experiments 1, 2, and 3 respectively.

this in-silico case study, a typical Monod model shown in Equation 2 was initially used to simulate a scenario where no prior strain-specific physical knowledge was available. SR was therefore applied to recover ground truth knowledge by automatically modifying and improving the Monod model structure and retrieve the expressions of two key kinetic parameters $\mu_{m1}$ and $\mu_{m2}$ in Equation 2.

$$\frac{dX}{dt} = \frac{\mu_{m1} S_1 X}{S_1 + K_{s1}} + \frac{\mu_{m2} S_2 X}{S_2 + K_{s2}} - \mu_d X \quad (2a)$$

$$\frac{dS_1}{dt} = \frac{-Y_{S1} \mu_{m1} S_1 X}{S_1 + K_{s1}} \quad (2b)$$

$$\frac{dS_2}{dt} = \frac{-Y_{S2} \mu_{m2} S_2 X}{S_2 + K_{s2}} \quad (2c)$$

$$\frac{dP}{dt} = \frac{Y_{P1} \mu_{m1} S_1 X}{S_1 + K_{s1}} + \frac{Y_{P2} \mu_{m2} S_2 X}{S_2 + K_{s2}} + \beta X - k_d X^2 \quad (2d)$$

Using this case study, if the expressions identified by SR can transform the kinetic backbone into the ground truth kinetic model by identifying the true expressions for $\mu_{m1}$ and $\mu_{m2}$ as shown in equation 3, it can be said that the proposed framework has the potential to systematically uncover novel relationships for emerging bioprocesses where prior mechanistic understanding is incomplete.

$$\mu_{m1,goal} = \frac{\mu_{m1} \cdot (S_1 + k_{S1})}{(S_1 + K_{c1} X) \cdot (1 + k_1 S_2)} \quad (3a)$$

$$\mu_{m2,goal} = \frac{\mu_{m2} \cdot (S_2 + k_{S2})}{(S_2 + K_{c2} X) \cdot (1 + k_2 S_1)} \quad (3b)$$

# RESULTS AND DISCUSSION

## Results of Approach 1

The results, presented in figure 1, showed that the generated models were able to accurately simulate state variable concentrations for each experiment. This was reflected in a low mean absolute percentage error (MAPE) value of 8.9% averaged across each experiment and each of the four state profiles (biomass, sucrose, glucose and astaxanthin concentration).

Despite success in simulating the concentration profiles, the framework of approach 1 was unable to uncover the exact ground truth model structures. It was discovered that, even though SR was tasked with discovering only two lumped terms, the potential solution space remained extensive and many models that had a strong fitting toward the experimental data exhibited significant structural divergence from the ground truth nevertheless. Further analysis deemed that the discrepancy stemmed from the failure to reproduce the temporal evolution of the specific growth rate terms $\mu_{m1}$ and $\mu_{m2}$ themselves because subtle differences in the gradient space can be diminished after integration, leading to different gradient profiles producing similar integral profiles. Figure 2 displays the profiles of $\mu_{m1}$ and $\mu_{m2}$ over time and highlights the discrepancy between the ground truth and predicted profiles from SR models.

## Results of Approach 2

The results, presented in figure 3, showed that the models generated using Approach 2 were also able to accurately simulate the state variable concentrations dynamics and reduce the model error (MAPE) by 60% with an average value of 3.5%.

Importantly, the fitting in the gradient space depicting the profiles of $\mu_{m1}$ and $\mu_{m2}$ through time, shown in figure 4, experienced a significant improvement. the models generated by SR were able to almost exactly reproduce the ground truth profiles with MAPE values of 0.08% and 0.39% for $\mu_{m1}$ and $\mu_{m2}$ respectively, averaged across all three experiments. Ultimately this led to the recovery of the ground truth expressions for both parameters. It should be noted that, for simple model structures such as $\mu_{m2}$, SR was able to identify the correct physical structure

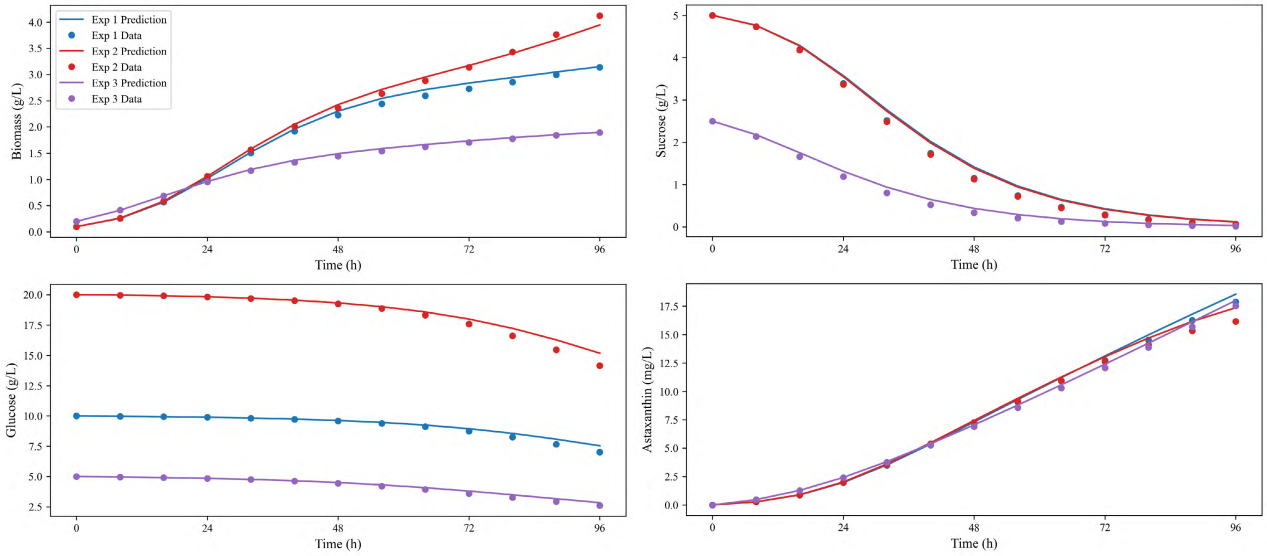

**Figure 3.** Fitting performance of the complete kinetic model using expressions discovered by SR for $\mu_{m1}$ and $\mu_{m2}$. Colours blue, red and purple represent experiment 1, 2, and 3 respectively. (a), (b), (c) and (d) shows the fitting result for concentrations of biomass, sucrose, glucose and astaxanthin, respectively.

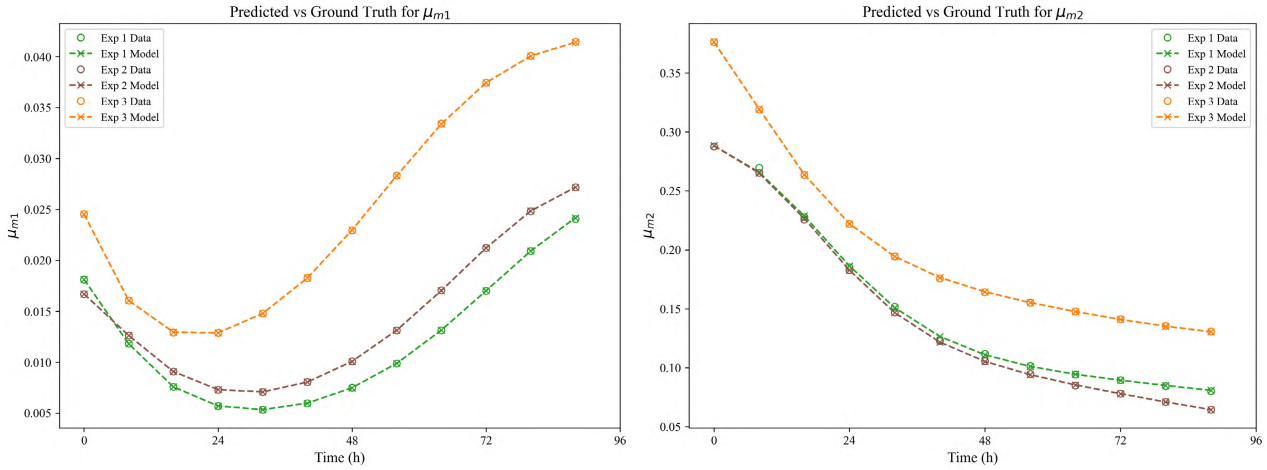

**Figure 4.** Comparison of the trends of $\mu_{m1}$ (a) and $\mu_{m2}$ (b) over time. Colours green, brown and orange represent experiments 1, 2, and 3 respectively.

without the need of running additional experiments. However, for complex model structures such as $\mu_{m1}$, as evidenced by their evolution over time, SR was unable to find the ground truth expressions on the first iteration due to the large solution space of possible expressions. Nonetheless, by iteratively freezing and mutating specific terms within the best expression selected using AICc, the SR generated expressions were able to converge to the ground truth structure.

## CONCLUSION

This study presents a symbolic regression–based framework for automated kinetic model structure identification that aims to improve mechanistic understanding of bioprocess systems while maintaining interpretability. By integrating symbolic regression with a general kinetic model backbone, two complementary strategies were explored, revealing that while the concentration-based approach could accurately reproduce system dynamics, it struggled to distinguish between structurally different models. In contrast, the gradient-based approach proved more effective and computationally efficient, successfully recovering underlying kinetic expressions when combined with AICc-based model selection and targeted refinement strategies.

Although the framework shows strong potential for data-efficient and interpretable model discovery, limitations remain, including the lack of validation under noisy data, untested performance on more complex systems, and challenges associated with limited experimental data in real-world scenarios. Despite this, the framework remains valuable as a knowledge discovery tool, capable of revealing meaningful relationships that can guide hypothesis generation even when exact model identification is not possible.

A key strength of the approach is its flexibility for expert involvement, aligning with augmented intelligence principles. Domain knowledge can be incorporated to guide model development, constrain the search space, and improve model plausibility, while quantitative tools such as information criteria can assess the impact of these interventions. Future work will focus on integrating such human-in-the-loop strategies, alongside methods like sparse regression, to further enhance the efficiency and interpretability of bioprocess model discovery.

# Modelling Pressure Effects in Boiling Brazed Aluminum Heat Exchangers: A Software Comparison

**Hamza Karim[a], Rim Khodr[a], Rodolphe Sardeing[b] and Gaëtan Becker[a]***

[a] Alfa Laval Golbey, 25 bis rue du Fort, 88190 Golbey, France

## ABSTRACT

Brazed aluminum heat exchangers (BAHX) are key cryogenic equipment, but their simulation is sensitive to phase change modelling. This work benchmarks ProSec, CO-ProSec Reaction, and Aspen EDR on an ethylene-chiller BAHX using ethane in thermosiphon mode. ProSec's interpolation scheme of tabulated data is validated against CO-ProSec Reaction's approach that employs a thermodynamic model for the evaluation of thermodynamic and physical properties; an initial 25% pressure drop gap is traced to different void-fraction models (slip vs homogeneous). Against Aspen EDR, default duty/quality are ~15% higher; differences are mainly due to nucleate-boiling treatment and distributor pressure drop modelling. Harmonizing options reduces duty mismatch to ~5%.

**Keywords**: Energy, Modelling and Simulations, Cryogenics, Brazed Aluminum Heat Exchanger

## INTRODUCTION

Brazed Aluminum heat Exchangers (BAHX) are one of the most widely used equipment in various industries. They are a core technology in air separation units, industrial gas processing, natural gas treatment and liquefaction (LNG), petrochemical and refinery services.

BAHX are valued for their high thermal efficiency, low weight, compact footprint and limited routine maintenance requirements. Their outstanding performance derives from an exceptionally large heat-transfer area per unit volume: typically area densities are on the order of 1000-1500 $m^2.m^{-3}$, which is much higher than conventional technologies, such as shell and tubes heat exchangers (40 to 70 $m^2.m^{-3}$). In addition, a single core can accommodate up to twenty streams enabling complex

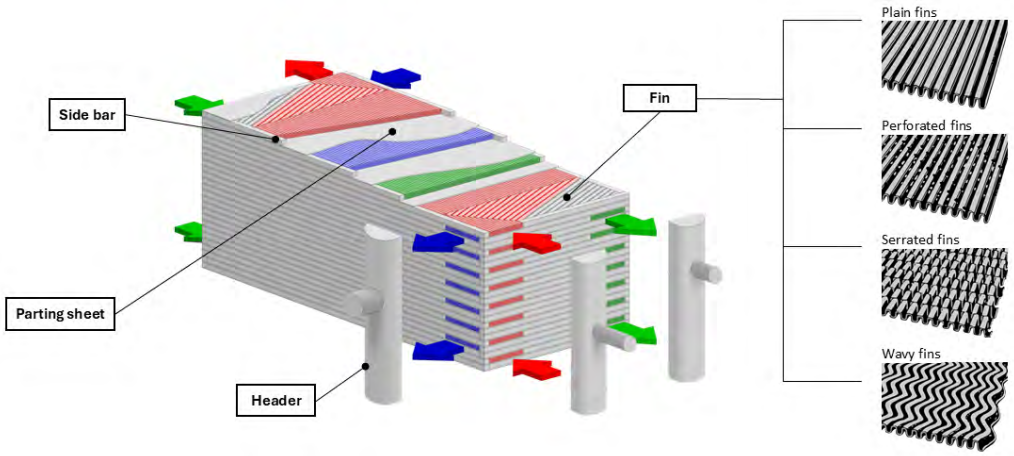

**Figure 1.** (left) Structure of a Brazed Aluminum Heat Exchanger, (right) Types of fins encountered in BAHX

thermal integration within one exchange and very small temperature approaches(2–5 °C) [1–4].

The geometry of a BAHX core is defined in detail by ALPEMA standards [2]. As schematically shown in **Figure 1**, a BAHX consists of a plate-fin core to which headers are attached. The headers distribute the process streams into the core, where the heat exchange takes place.

The core is built as a stack of passages, ranging from a few tens to more than one hundred layers. Each passage is dedicated to a given stream and comprises: (i) inlet distribution fins (distributors) to spread the incoming flow across the core width, (ii) heat-transfer fin sections where the fluid flows through the exchanger and exchanges heat with adjacent passages above and below, and (iii) side bars (closure bars) that seal the passage and contain the flow as shown in **Figure 2**. Adjacent passages are separated by thin parting sheets, across which passage-to-passage heat transfer occurs

To tailor the heat-transfer performances and pressure-drop behavior, several fin typologies are used beyond the standard straight fins, including perforated fins, serrated fins, and wavy fins.

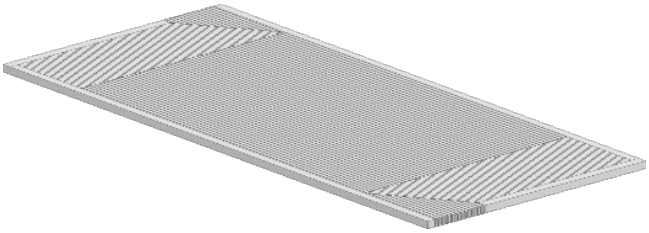

**Figure 2.** Schematic representation of a single passage

This construction makes BAHX intrinsically multiscale, structurally complex, and strongly heterogeneous, features that underpin their superior performance but also complicate modelling.

Indeed, the same features that make BAHX attractive also make their thermal prediction non-trivial. Strong stream-to-stream coupling, the influence of fin efficiency, axial conduction through parting sheets and side bars, sensitivity to maldistribution and phase change can all affect predicted temperature profiles, pinch locations, and duty. Consequently, selecting an appropriate simulation tool and understanding the modelling assumptions it embeds is essential for credible performance prediction and for robust design and troubleshooting.

To this end, we present a benchmark study comparing three different simulation tools on a representative case with a boiling stream. The first, ProSec, is an in-house software developed at Alfa Laval Golbey in collaboration with Fives ProSim, drawing on more than 30 years of research and industrial know-how. Based on robust numerical methods, ProSec simulate BAHX and analyze local profiles of numerous physical parameters (temperature, pressure, heat transfer coefficient, etc.) and allows the user to fine tune the design of the equipment to reach the best possible performances. It also accounts for pressure effects on thermodynamic properties through a bi-pressure interpolation scheme. The second, CO-ProSec Reaction (version 3.7.8), is a commercial version distributed by Fives ProSim [5]; it evaluates properties directly from thermodynamic models, offering a fully continuous treatment. The third tool, Plate-Fin in Aspen Exchanger Design & Rating (EDR) (version 14) distributed by AspenTech [6], adopts alternative modelling strategies together with its own heat-transfer and pressure-drop correlations . Due to the large diffusion of AspenTech's software in the industrial community, EDR is often the commercial software chosen to simulate heat exchangers. Therefore, comparisons with EDR is a necessary step for validating any development.

The remainder of this paper is organized as follows. Section 1 describes the pressure interpolation method implemented in ProSec. Section 2 introduces the case study used for the software comparison. Section 3 compares ProSec and CO-ProSec Reaction: both tools share the same correlations and numerical resolution framework, but CO-ProSec Reaction evaluates thermodynamic and transport properties from a thermodynamic model via Simulis Thermodynamics through a CAPE-OPEN interface, whereas ProSec relies on tabulated data. This comparison therefore isolates and validates the interpolation strategy. Section 4 presents a critical comparison between ProSec and Aspen EDR, with the objective of identifying the origin of the observed differences and critically discuss them.

## PRESSURE INTERPOLATION METHOD

In phase change operation, pressure variations directly govern the saturation temperature and affect vapor quality and enthalpy, thereby influencing the local thermal driving forces. This is important when a thermosiphon stream is present. In a thermosiphon loop, the circulation rate is not imposed by a pump; it results from the balance between the hydrostatic head in the downcomer and the pressure losses across the loop components (downcomer line, BAHX core, and return line).

**Figure 3** shows a typical temperature profile for a thermosiphon stream. The fluid enters the BAHX at approximately the saturation temperature at the surface of the liquid in the column. However, due to the hydrostatic pressure in the downcomer, the inlet pressure is higher and the liquid is typically subcooled with respect to the local saturation temperature. The temperature then increases (while static pressure decreases) until the local boiling point is reached, which depends on the pressure profile along the passage. Beyond this point, an evaporation zone develops and the thermodynamic state follows the saturation line as vaporization proceeds [7].

Accurate prediction of pressure drop and pressure-dependent thermodynamic properties is therefore required to reproduce the local thermal profile. This is particularly relevant for BAHX: while aluminum alloys generally retain high tensile strength at cryogenic temperatures compared with carbon steels, they can be relatively susceptible to fatigue damage under cyclic thermal loading [8]. Reliable local temperature profiles are thus important to assess whether significant thermal stresses may occur.

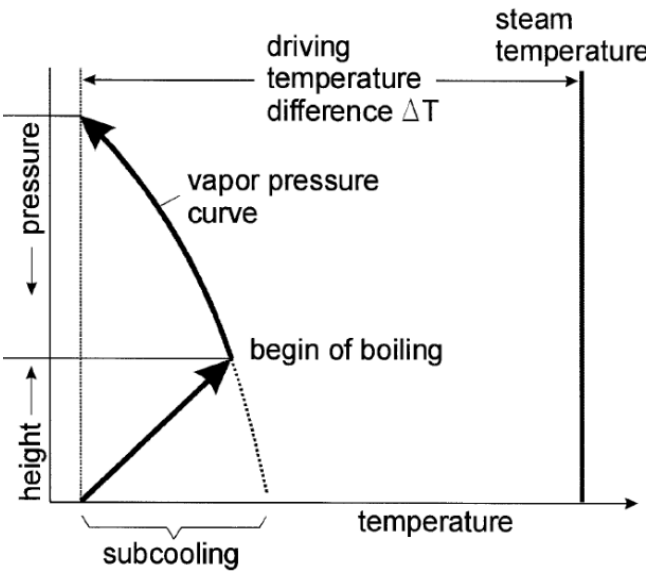

**Figure 3.** Characterisitic temperature profile for a thermosiphon stream [7]

In ProSec, the user provides for each stream tabulated values of temperature, $T$, vapor quality, $x$ and enthalpy, $h$ at two pressure levels $P_1$ and $P_2$. The program then evaluates the temperature and vapor quality at a specified enthalpy $h$ and pressure $P$ (with $P_1 \leq P \leq P_2$).

This is illustrated in **Figure 4**. In this example, the user provides two enthalpy tables, $(T, h_1)$ and $(T, h_2)$, corresponding to pressures $P_1$ and $P_2$. The objective is to determine the temperature $T(h,P)$. First, the interpolation factor $r$ is computed on a logarithmic pressure basis:

$$r = \frac{\ln(P/P_1)}{\ln(P_2/P_1)} \quad (1)$$

The bubble-point and dew-point enthalpies $(h_b, h_d)$ at pressure $P$ are then obtained by interpolation from the corresponding values at $P_1$ and $P_2$:

$$h_b = (1-r) \times h_{b_1} + r \times h_{b_2} \quad (2)$$

$$h_d = (1-r) \times h_{d_1} + r \times h_{d_2} \quad (3)$$

Next, the enthalpy $h$ is compared to $h_b$ and $h_d$ to identify the fluid region (liquid, vapor – liquid, or vapor). In the example shown in the figure, $h < h_b$ indicates that the fluid is in the liquid region at pressure $P$.

Two auxiliary enthalpies $h_m$ and $h_n$ are then defined at $P_1$ and $P_2$, respectively, such that the enthalpy shift between them is consistent with the corresponding saturation boundary (i.e, $h_n - h_m = h_{b_2} - h_{b_1}$ in the liquid region). Depending on the region, $h_m$ and $h_n$ are defined as follows:

liquid region:

$$h_m = h - (h_b - h_{b_1}) \quad (4)$$

$$h_n = h + (h_{b_2} - h_b) \quad (5)$$

vapor region:

$$h_m = h - (h_d - h_{d_1}) \quad (6)$$

$$h_n = h + (h_{d_2} - h_d) \quad (7)$$

vapor-liquid region:

$$h_m = h - (1-y)(h_b - h_{b_1}) - y(h_d - h_{d_1}) \quad (8)$$

$$h_n = h + (1-y)(h_{b_2} - h_b) + y(h_{d_2} - h_d) \quad (9)$$

$$y = \frac{h - h_b}{h_d - h_b} \quad (10)$$

Once $h_m$ and $h_n$ are known, the corresponding temperatures $T(h_m, P_1)$ and $T(h_n, P_2)$ are obtained by cubic spline interpolation of the tabulated data at $P_1$ and $P_2$. Finally, the temperature $T(h,P)$ is computed as:

$$T(h,P) = (1-r)T(h_m, P_1) + rT(h_n, P_2) \quad (11)$$

The same interpolation approach is used for the vapor quality $x$. This is only required when the fluid lies in the vapor–liquid region. In the liquid and vapor regions, the vapor quality is simply 0 and 1, respectively.

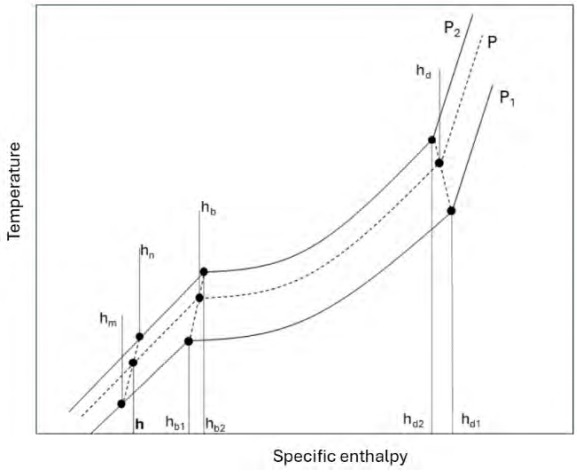

**Figure 4:** Schematic representation of the interpolation of the temperature between two sets of enthalpic profiles at $P_1$ and $P_2$ for a given enthalpy value, $h$ and pressure $P$ in the case of a diphasic mixture

## CASE STUDY: ETHYLENE PRODUCTION

Ethylene is a major building block of the chemical industry. It is widely used as a feedstock for plastics, fibers, and other organic chemicals that support key sectors such as packaging, transportation, and construction. Indeed, global ethylene consumption exceeded 150 million tonnes per year in 2017 [9].

Today, ethylene is produced mainly by steam cracking of ethane or naphtha. The overall process is commonly divided into three sections: (i) pyrolysis, where the feed is cracked in furnaces to form light olefins and the effluent is rapidly quenched to limit secondary reactions; (ii) compression and primary treatment, where the cracked gas is cooled, compressed in multiple stages, and purified (notably removal of water and acid gases) prior to cryogenic processing; and (iii) cryogenic product recovery, where chilling trains and distillation towers separate hydrogen/methane and $C_2$ components, and ultimately split ethylene from ethane, typically at very low temperatures [10].

The case study considered in this paper belongs to the cryogenic recovery section and focuses on ethylene chilling, a duty where BAHX technology is particularly well suited. In the investigated exchanger, an ethylene stream is cooled using ethane as a refrigerant operating in thermosiphon mode. The inlet conditions and operating parameters of both streams are summarized in **Table 1** Thermodynamic properties are evaluated using a Peng–Robinson equation of state coupled with the Soave Boston–Mathias alpha function.

Details of the BAHX internal geometry (core dimensions, stacking arrangement, and fin selection) are proprietary to Alfa Laval Golbey and are therefore not reported here. The exchanger uses in-house fins developed from extensive industrial experience. The corresponding hydraulic and thermal performances - expressed through the Fanning friction factor ($C_f$) and Colburn factor ($C_j$) - were characterized experimentally using an internal $C_f$–$C_j$ test bench, and these measured correlations are used as inputs to the simulations.

**Table 1:** Details of the streams input data used in the simulation of the BAHX

| Parameter | HOT (ethylene) | COLD (ethane) |
|---|---|---|
| $\dot{M}$ (kg.h$^{-1}$) | 157000 | 209000 |
| $T_{in}$ (°C) | -24.6 | -54.1 |
| $P_{in}$ (bar) | 10.44 | 4.012 |
| Flow Direction | Downward | Upward |

## COMPARAISON OF PROSEC WITH CO-PROSEC REACTION

**Table 2** compares the predicted exchanger performances obtained with ProSec and CO-ProSec Reaction for the thermosiphon stream. Overall, the agreement is very good: the outlet temperatures are virtually identical, and the outlet vapor fraction and exchanged duty differ by about 3%. In contrast, the predicted pressure drop shows a noticeable deviation, up to 25%. This difference is unexpected, since both tools are intended to use the same pressure drop correlations

**Table 2:** Global performances comparison between ProSec and CO-ProSec Reaction for the thermosiphon stream

| Parameter | ProSec | CO-ProSec Reaction |
|---|---|---|
| $T_{out}$ (°C) | -53.29 | -53.25 |
| $x_{out}$ (kg.kg$^{-1}$) | 0.565 | 0.547 |
| $Q$ (kW) | 14490.4 | 14036.5 |
| $DP$ (mbar) | 133.4 | 106.8 |

A plausible explanation is the different treatment of properties in the two tools. In ProSec, the influence of pressure on thermodynamic properties (temperature, quality, enthalpy) is accounted for, whereas transport properties (density, viscosity, thermal conductivity, and heat capacity) are interpolated only with respect to temperature. On the other hand, in CO-ProSec Reaction, properties are evaluated directly from the thermodynamic model at each mesh point using the local temperature and pressure. If pressure significantly affects transport properties - particularly density - then the converged pressure drop profile may differ, even when the same correlations are used.

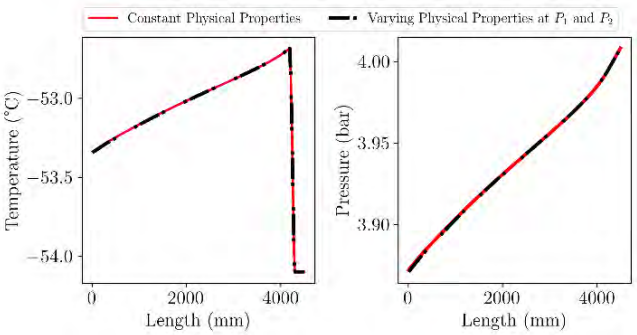

**Figure 5:** Influence of physical properties variations with respect to pressure on the BAHX performance

To test this hypothesis, an additional simulation was carried out in Aspen EDR, which allows interpolation of both thermodynamic and transport properties with respect to temperature and pressure (the user provides property tables at two pressure levels, and the program performs the interpolation)

Figure 5 compares two Aspen EDR cases. The black

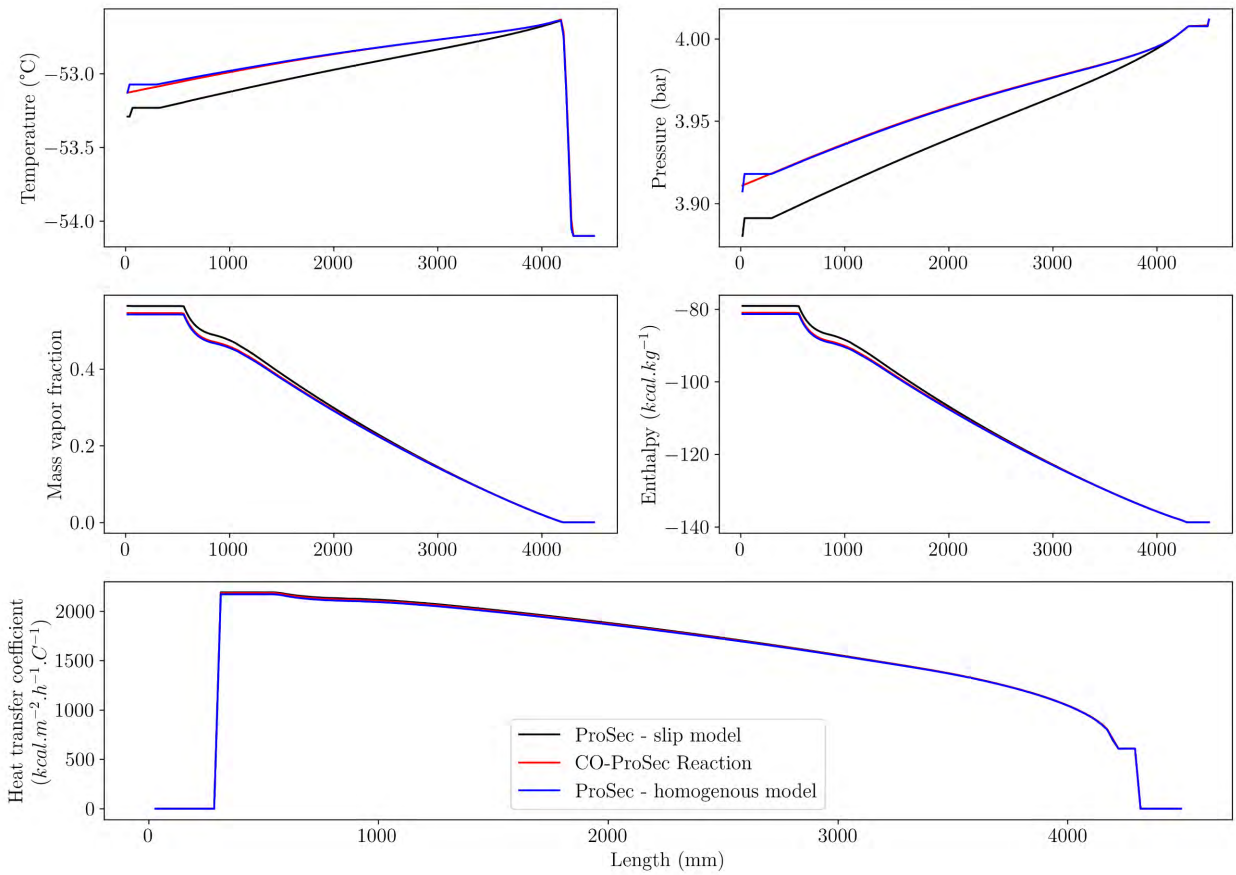

**Figure 6:** Comparison of the different profiles along the length of the BAHX between ProSec with slip model, CO-ProSec Reaction and ProSec with homogeneous model for the thermosiphon stream

curves correspond to identical transport properties at both pressure levels (mimicking a temperature-only dependence, as in ProSec). The red curves correspond to pressure-dependent transport properties (mimicking the CO-ProSec Reaction approach). In this case, the temperature and pressure profiles overlap, indicating that accounting for pressure dependence of transport properties has no measurable impact on the results. This is consistent with the small overall pressure drop (≈0.1 bar), for which pressure-induced variations of transport properties are expected to be negligible.

These findings indicate that the deviation must originate from another modelling difference between the two tools. To investigate further, the pressure profile was recomputed manually by separating the frictional and static contributions and applying the same frictional and gravitational formulations for both tools. The reconstructed profile matched the ProSec simulation closely, but not the CO-ProSec Reaction results. This pointed to a difference in the treatment of the two-phase static pressure drop.

The key parameter is the void fraction, defined as the volumetric fraction of vapor in the two-phase mixture. Void fraction is required to evaluate two-phase mixture density, and therefore directly affects the gravitational pressure drop [11, 12]. Numerous void-fraction models exist in the literature; they are commonly grouped into homogeneous (no-slip), slip-ratio based, and drift-flux approaches, each relying on different assumptions [12].

In ProSec, void fraction is computed using a slip-based correlation from the HTFS Handbook [13]. In contrast, CO-ProSec Reaction (version used in this study) uses a homogeneous model for void fraction in the computation of the static pressure drop. **Figure 6** compares the profiles along the exchanger length obtained with CO-ProSec Reaction (red curve) and with ProSec using the HTFS correlation (black curve). The pressure profiles show significant differences, which in turn affect the temperature, vapor quality, and enthalpy profiles through the coupling between pressure and saturation conditions in the two-phase region.

When ProSec was configured to use the homogeneous model (blue curve) for void fraction, its results became identical to those of CO-ProSec Reaction as shown in **Figure 6**. This provides strong confidence in the pressure interpolation approach implemented in ProSec: once

the two tools share the same void-fraction treatment, the simulations are consistent. It is also worth noting that since version 3.7.11, CO-ProSec Reaction implements the same void-fraction correlation as ProSec, which is a necessary step to ensure consistent modelling assumptions between the two tools.

This comparison highlights the importance of void-fraction modelling for two-phase flow in BAHX passages. Channel hydraulic diameters typically range from ~1 to 5 mm, whereas many widely used correlations were developed for larger, conventional channels. While two-phase flow in mini-channels has attracted increasing research attention [14, 15], further work is still needed -particularly studies that connect fundamental understanding to industrial geometries and operating conditions - to improve predictive capability in BAHX applications.

## COMPARAISON OF PROSEC WITH ASPEN EDR

As noted earlier, comparison with Aspen EDR is essential because it is widely used in industry; benchmarking against it therefore provides a relevant reference point for assessing any simulation approach. Aspen EDR employs its own numerical solution strategy as well as its own set of heat-transfer and pressure-drop correlations.

The first comparison was performed using the default settings in both ProSec and Aspen EDR. This choice is motivated by two practical reasons. First, in typical workflows, Aspen EDR users often rely on the default options for thermal and hydraulic calculations rather than tuning correlation sets or numerical controls. Second, quantifying agreement under default configurations provides a clear baseline from which the dominant sources of divergence can be identified and then reduced in a controlled manner.

As shown in **Table 3**, the default simulations exhibit non-negligible deviations. Aspen EDR predicts a heat duty and outlet vapor quality that are approximately 15% higher than those predicted by ProSec. Aspen EDR also predicts a higher total pressure drop. These differences indicate that the default modelling choices (heat transfer and pressure drop correlations) have a measurable impact on the predicted performance.

To interpret these discrepancies, axial profiles of the cold (boiling) stream - temperature, pressure, vapor quality, enthalpy, and heat-transfer coefficient - were extracted from both simulations and are compared in **Figure 7**. The differences are most apparent in the heat-transfer coefficient: Aspen EDR predicts higher values than ProSec, which directly drives higher local heat flux, a larger enthalpy rise, and therefore a higher outlet vapor quality and duty. This behavior is due to the default correlation choices for the heat transfer coefficient: Aspen EDR uses an HTFS boiling correlation, whereas ProSec uses an in-house boiling correlation (confidential).

**Table 3:** Comparison of the results of global performances between the different configurations of ProSec and Aspen EDR. See text for the meaning of different case studies

| | $T_{out}$ (°C) | $x_{out}$ (kg.kg$^{-1}$) | $Q$ (kW) | $DP$ (mbar) |
|---|---|---|---|---|
| ProSec - default | -53.29 | 0.565 | 14490 | 133.4 |
| EDR - default | -53.37 | 0.650 | 16612 | 145.8 |
| ProSec – HTFS85 | -53.29 | 0.544 | 13946 | 133.3 |
| EDR – NNB | -53.36 | 0.580 | 14968 | 144.9 |
| ProSec - DP | -53.36 | 0.554 | 14212 | 142.3 |

Differences are also observed in the pressure-drop prediction. Aspen EDR yields a larger pressure drop, which is mainly attributed to the treatment of the distributor pressure drop (see **Figure 7** pressure profile plot for the different zones inside the BAHX). Aspen EDR relies on HTFS handbook methods for distributor pressure drop, while ProSec uses correlations and practices derived from Alfa Laval Golbey's internal experience. A closer look at the pressure-drop breakdown in Aspen EDR indicates that it includes a static contribution in the distributors, whereas this contribution is not accounted for in ProSec. In the Alfa Laval workflow, a more detailed and comprehensive distributor pressure-drop evaluation (including static effects) is performed using a separate proprietary tool, which explains the difference in scope between the two ProSec and Aspen EDR calculations.

ProSec also offers the option to use the HTFS correlation for evaluating the heat-transfer coefficient. In practice, this option is mainly applied to condensing streams, as internal experience indicates that the in-house correlation is better suited to boiling flows. For consistency with Aspen EDR, the HTFS correlation was therefore applied to all streams in ProSec.

Interestingly, this change did not reduce the discrepancy between the two tools but increased it. Under this configuration, Aspen EDR predicts a duty about 20% higher than ProSec, as shown in **Table 3** (ProSec – HTFS85). **Figure 7** explains this trend: in ProSec, switching from the default correlation to HTFS85 reduces the predicted boiling heat-transfer coefficient, which lowers the duty and enlarges the gap with Aspen EDR.

Further examination of Aspen EDR documentation gave more information about the default correlation. In Aspen EDR, the default boiling model includes an additional nucleate boiling contribution to the overall heat transfer coefficient, whereas the HTFS correlation used in ProSec accounts essentially for the convective component only. In boiling flow inside channels, heat transfer is commonly described as the combination of convective

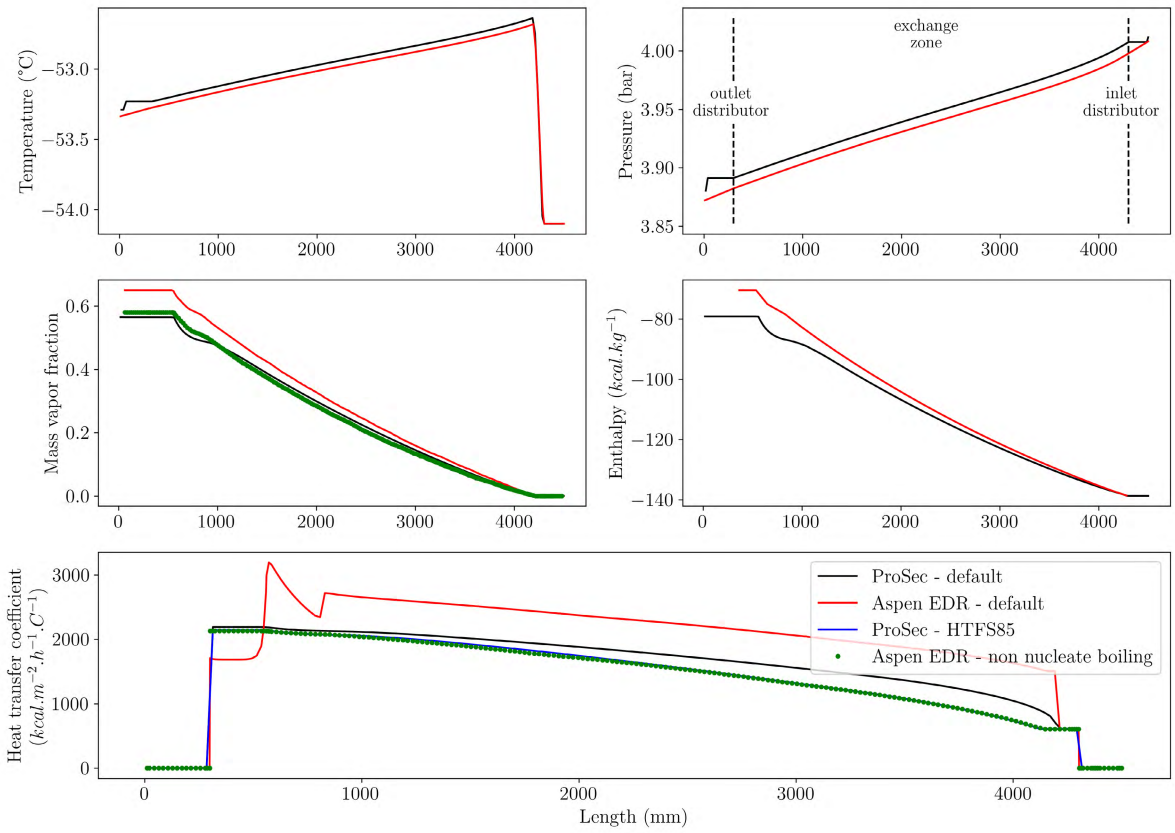

**Figure 7**. Comparison of the different profiles along the length of the BAHX between ProSec and Aspen EDR under their default settings for the thermosiphon stream. “PoSec – HTFS85” represents Prosec when using the HTFS correlation, “Aspen EDR – non nucleate boiling” is when the option of nucleate boiling is deactivated in Aspen EDR.

boiling and nucleate boiling, with their relative importance depending on heat flux, wall superheat, flow regime, and vapor quality. Nucleate boiling tends to be most influential at low to moderate qualities and sufficiently high wall superheat, while convective boiling becomes increasingly dominant as quality increases. For further information, interested readers are encouraged to read the following references [16–19].

Aspen EDR provides an option to disable the nucleate boiling contribution and retain only the convective component. The resulting case (EDR–NNB) is also reported in Table 3. When EDR–NNB is compared to ProSec – HTFS85, the duty difference decreases substantially (from ~20% to ~7%). This is also visible in Figure 7, where the heat transfer coefficient profiles of EDR – NNB and ProSec – HTFS85 nearly overlap.

To further reduce differences, the ProSec inlet pressure was adjusted so that the pressure at the beginning of the exchange zone matches that in the Aspen EDR simulation (case ProSec – DP). This alignment decreases the remaining gap, yielding a duty difference of about 5% (Table 3). Nevertheless, even when comparable pressure levels and cold-side boiling heat transfer coefficients are obtained, Aspen EDR still predicts a slightly higher duty.

This remaining difference is attributed to the treatment of the condensing hot stream, as shown in Figure 8. The two simulations predict similar heat transfer coefficients over most of the condensation range, except near the onset of condensation. In ProSec, the heat transfer coefficient is linearized between its value at a quality of 0.9 and the single-phase value to avoid numerical instabilities. In Aspen EDR, the two-phase correlation is retained up to the transition to single-phase flow. This reflects different modelling philosophies: ProSec prioritizes numerical robustness in the vicinity of phase-boundary transitions, where certain correlations can become ill-conditioned, whereas Aspen EDR maintains the two-phase correlation closer to the single-phase limit.

Overall, this alignment of modelling options shows that most of the initial discrepancies between ProSec and Aspen EDR can be traced to identifiable assumptions. Once these elements are harmonized, the two tools provide comparable trends and global performances.

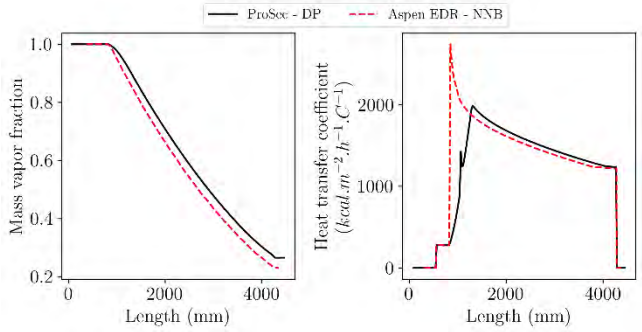

**Figure 8:** Mass vapor fraction and heat transfer coefficient profiles of the hot stream for both ProSec – DP and Aspen EDR – NNB simulations.

## CONCLUSION

This paper presented a benchmark of three BAHX simulation tools (ProSec, CO-ProSec Reaction and Aspen EDR) on a thermosiphon boiling case. ProSec's pressure-interpolation approach was validated against CO-ProSec Reaction; the initial 25% pressure-drop discrepancy was traced to different void-fraction models for the static two-phase contribution (slip model in ProSec versus homogeneous in CO-ProSec Reaction) and disappeared once the same model was used.

Comparison with Aspen EDR showed larger default deviations (≈15% higher duty and outlet quality, and higher pressure drop), mainly due to differences in boiling heat transfer modelling (nucleate contribution included by default in EDR) and in the treatment of distributor pressure drop. When nucleate boiling was disabled in EDR and pressures were aligned at the exchange-zone inlet, agreement improved to within ~5%, with remaining differences linked to condensation modelling near phase-boundary transitions.

Overall, the results emphasize that comparisons between BAHX simulation tools are only meaningful when the main physical assumptions are made consistent. More broadly, the work highlights the need for continued refinement and validation of two-phase correlations in BAHX passages with millimetric hydraulic diameters, where correlation choice can materially affect predicted performance and engineering conclusions.

## ABSTRACT

Model adaptation to production environment is critical for reliable Machine Learning Operations (MLOps), less attention is paid to developing systematic framework for updating the ML models when they fail under drift. This paper compares the transfer learning enabled model update strategies including ensemble transfer learning (ETL), all-layers transfer learning (ALTL), and last-layer transfer learning (LLTL) for updating the failed feedforward artificial neural network (ANN) model. The flue gas differential pressure across the air pre-heater unit installed in a 660 MW thermal power plant is analyzed as a case study since it mimics the batch processes due to load cycling in the power plant. Updating the failed ANN model by three transfer learning techniques reveals that ETL provides relatively higher predictive accuracy for the batch size of 5 days than those of LLTL and ALTL. However, ALTL is found to be suitable for effective update of the model trained on large batch size (8 days). A mixed trend is observed for computational requirement (hyperparameter tuning and model training) of model update techniques for different batch sizes. These empiric insights obtained from the batch process-based industrial case study can assist the MLOps practitioners in adapting the failed models to drifts for the improved monitoring of industrial processes.

## INTRODUCTION

The industrial operations have nonlinear characteristics, meaning that change in the process conditions over time and equipment changeover may result in changing patterns of correlations between the process variables. The “static” data-driven models trained on “fixed data-distributions” may not handle non-stationary data streams of industrial processes and are not suitable for their deployment for long-term monitoring tasks. This is attributed to data drift (shift in covariance due to change in data distributions between the input variables of process) and/or concept drift (the underlying relationships between the input and output variables of process are changed) that drive the model failure.

The data-driven models are retrained on the new data streams in order to maintain their predictive accuracy for new data-distributions. The potential caveat with this approach is the “catastrophic forgetting”, meaning that the model parameters have been tuned to the new dataset and may not predict well the historical data the model was trained on [1]. Initially, Geoffrey E. Hinton hypothesized that small changes in model parameters for their tuning to new data may collectively cancel out their effect on historical data [2]. However, McCloskey and Cohen [3] and Ratcliff [4] showed that sequential training of simple neural networks on disjoint sets of data results in significant forgetting even when the models are updated on small amount of new data.

To address the potential issue of catastrophic

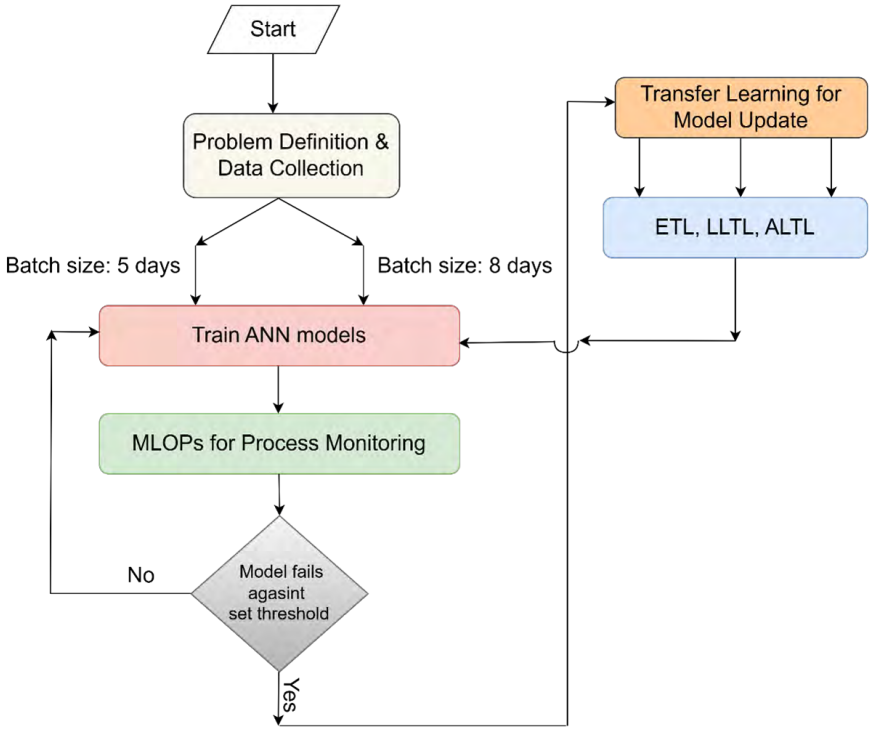

**Figure 1**. Schematic on transfer learning-based model update framework for process monitoring.

forgetting, continual learning approach is used in updating the model parameters and it balances the trade-off between the plasticity (learn new dynamics) and stability (retaining historical information) through experience replay and regularization techniques during the model update mechanism [5]. On the other hand, online learning retrains the model on a single or batch of data continuously once the model is productionised [6]. Online learning offer high adaptability to the model to the incoming data stream or concept drift; however, it suffers from catastrophic forgetting. Just-In-Time-Learning is another model update paradigm where a local model is trained on the incoming data stream and similar data queried from the historical data [7]. Just-In-Time-Learning offers high accuracy to approximate nonlinear dynamics of system. However, it has higher computational and memory requirement and may not extrapolate when system enters in the new operating model where historical data is not available. To enable the high predictive accuracy and reducing the computational expense for the models in production, transfer learning approach is also implemented where parameters of trained model (source domain maintained on historical data) are transferred for adapting them with the "target" domain (drift in data) through minimal requirement of data [8].

The literature studies identify the importance of updating the model for their adaptability to the changing industrial operations. In [9], the neural network parameters in all layers are tuned upon the detection of drift and resulting updated model was deployed for digital twin applications. In another study [10], the researchers have allocated the epoch budget and bounds on learning rate for updating the model parameters completely. Similarly, transfer learning is also implemented for model adaptation to source domain [11]. However, it is noted that much of research attention is paid to update the model parameters, the effect of batch-size on updating the model parameters by transfer learning-based model update techniques is not studied systematically. More importantly, it remains largely unknown how transfer learning driven model update techniques including ensemble transfer learning (ETL), all-layers transfer learning (ALTL), and last-layer transfer learning (LLTL) for neural networks in combination with batch size and how it would affect the predictive accuracy of the model. These fundamental issues about the selection of model update techniques considering plasticity vs stability and the computational expense are not investigated systematically to obtain mechanistic insights about addressing these issues.

Motivated by the current research gaps, this paper investigates the effect of batch size and transfer learning driven model update techniques (ETL, ALTL, LLTL) to address the concept drift for updating the feedforward ANN model. The flue gas differential pressure (DP) across the air preheater installed in a 660 MW thermal power plant is considered as a case study. Flue gas DP is correlated

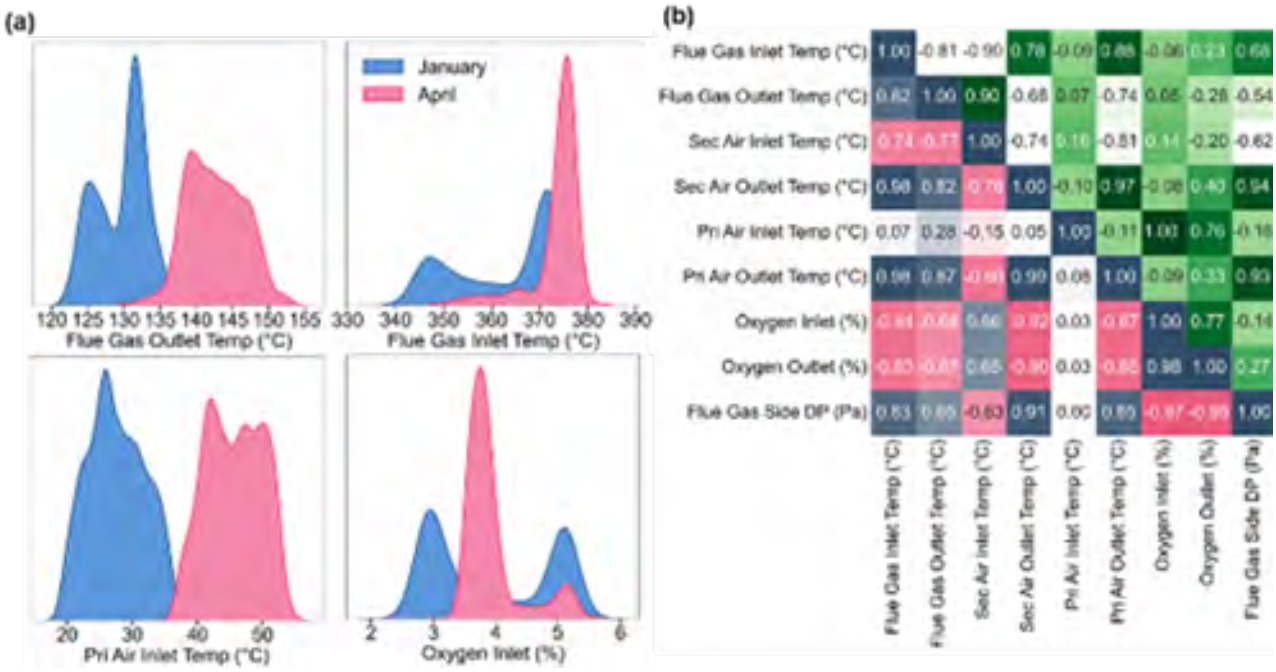

**Figure 2**. Characteristics of data collected for heat exchange across air preheater. (a) Data drift is observable in data collected for month of January and April. (b) Correlation structure between the operating variables is also changed for the two months (lower diagonal: January, upper diagonal: April) and data & concept drift is present in the collected data.

with load cycling (ramp-up and ramp down) and is treated as a batch process which is observable from the data visualizations. This allows to transfer the findings from this case study to the dynamics of batch processes which are carried out in various chemical engineering applications. A systematic comparison is made to reveal the effect of batch size on the predictive accuracy of updated model by three techniques, changes in the weight space of the updated models as well as their computational requirement. Moreover, the evolution in the feature importance is also investigated by SHapley Additive Explanations (SHAP) when the models are updated to reveal their stability for industrial monitoring tasks. These fundamental and empiric insights obtained through the industrial case study can assist the MLOps practitioners in adapting the failed models to drifts for the improved monitoring of industrial processes.

## METHOD

Figure 1 shows the transfer learning enabled model update framework developed in this work to monitor the flue gas DP across the air preheater. Two months of data is collected separately for the month of January and April for the model development on the two batch sizes of 5 days and 8 days. Initially, a set of two batches (for 5 days and 8 days each) is used to train ANN models under hyperparameters optimization (learning rate, number of neurons in the hidden layer). The models are evaluated on coefficient of determination ($R^2$) and root-mean-squared-error (RMSE) on the test data (20% of set). Later, the trained models are deployed as MLOps to predict the Flue Gas DP for the rest of batch data. When daily average error (RMSE and MAE) remains above the twice of test data (observed during model training) for three times consecutively, model update mechanism is triggered. A set of the batch data where model fails and the consecutive previous batch data (buffer data for model retraining) is used to update the model by transfer learning driven approaches (ETL, LLTL and ALTL). Later, the models trained by the three approaches are put into MLOps again to predict the rest of the collected data. This allows to compare the predictive accuracy of the model against the ground truth already available in the collected data. The stability of the models in terms of evolution of feature importance for the trained and updated models under different batches and model update approaches are investigated by SHAP framework. The feature evolution is affected by the process dynamics; however, they can be corrupted by the ineffective model update and mapping created in the model. The computational time consumed to train and update the models are also recorded to investigate the suitability of transfer learning enabled model update approaches for MLOps.

## RESULTS: MONITORING DIFFERENTIAL PRESSURE ACROSS AIR PREHEATER

### Data Characteristics

The operating variables across the air preheater for modelling flue gas DP (Pa) are as follows: flue gas inlet temperature (°C), flue gas outlet temperature (°C), secondary air inlet temperature (°C), secondary air outlet temperature (°C), primary air inlet temperature (°C), primary air outlet temperature (°C), and oxygen inlet (%), oxygen outlet (%). The historical operation data of the variables is collected at the averaging interval of 10 minutes and 8 minutes, respectively, for the month of January and April in order to explore the capacity and efficacy of models to handle different sampling frequency of data collection for the monitoring task. This allows us to mimic the real-life situation when sampling frequency of data collection is affected by data storage and maintenance costs and in turn investigate how the model responds to this transition yet ensuring acceptable predictive accuracy.

Figure 2(a) presents the data-distribution profiles of a few operating variables for the months of January and April. The asymmetric data-distribution as well as data drift are visually observable for the variables, and are further quantified by population stability index (PSI) and Cramér-von Mises (CvM). PSI ranges from 1.89 to 23.15 and CvM statistics from 72.4 to 658.9 with p-values less than 0.001 confirm drift in the data observed in two datasets sampled at multi time-scale sampling. Primary air inlet temperature exhibits the strongest data drift across both metrics (PSI=23.15, CvM=658.9) and flue gas DP (PSI=1.89) and oxygen outlet (CvM=72.4) show the relatively smaller data drift, yet noticeable for potential model failure. The correlation between the pair of variables (input-input & input-output) is computed for the two months separately (shown on Figure 2(b)) and reveals that correlation between the pair of variables is changed in the two datasets (data and concept drift are present in the data). This indicates different operating modes of operation are observed for the air preheater and this is useful for the monitoring evaluation capacity of the trained model once deployed in production.

### Training of ANN model and update under two different batch sizes

Feedforward ANN models are trained on a set of two batches of 5 days and 8 days separately, taken from the data of January. These two batch sizes are considered based on the operating characteristics of air pre-heater as influenced by power generation mode and soot deposition in the heat exchanger plates. During the training of model, hyperparameters of the ANN model (hidden layer neurons, learning size, number of hidden layers) are optimized and models are evaluated on the test data (20% of initial data). The model trained on set of 5-day batches yielded a test $R^2$ of 0.9824 (RMSE 0.0381), while the model on set of 8-day batches achieved a test $R^2$ of 0.9807 (RMSE 0.0385). After the training phase, the models trained on batch size of 5 days and 8 days are deployed in production to monitor flue gas DP across the air preheater. The monitoring accuracy of the two models is depicted on Figure 3(a, b) respectively. It is noted that the ANN model trained on batch size of 5 days exhibited relatively superior performance in predicting the Flue Gas DP in the month of January than those of ANN model trained on batch size of 8 days.

Between April 7 and 10, the two models crossed the human-defined error threshold, i.e., crossing twice the test error limit successively for three times. The mapping of actual and model-based responses (reference) is shown in the bottom of Figure 3(a, b). The failure of models on different sampling frequency of data collection reveals that the trained models do not scale well when data sampling frequency changes with respect to those the model was trained on. The failure of model can also be attributed to process dynamics and drift (data and concept) as depicted on Figure 2. The model failure triggers the model update procedure built on three techniques including ETL, ALTL, and LLTL and we carried it out for batch size of 5 days and 8 days separately (batch data where model fails and the consecutive previous batch). It is important to note here that during model update, only learning rate is optimized iteratively in the narrow range and without changing the model architecture. Later, the models trained on three model update techniques are put into MLOps to monitor Flue Gas DP across the air preheater for the rest of data of April.

The mapping of actual and model-based responses obtained from models trained by ETL, ALTL and LLTL is depicted on Figure 3(c, d) for the batch size of 5 days and 8 days respectively. Similarly, parity plots are also constructed to directly compare the actual and model-based responses as shown on Figure 3(e, f). The RMSE and MAE for ETL are as follows: 0.0564, 0.0414 (5-day), 0.0652, 0.0541 (8-day); ALTL: 0.0674, 0.0563 (5-day), 0.0384, 0.0315(8-day); and LLTL 0.0400, 0.0321 (5-day), 0.0537, 0.0438 (8-day). The visualization of actual and model-based responses in conjunction with errors computed for the models trained on three update techniques allows us to inspect local predictive performance of the trained model once productionized in industrial settings.

ETL approach seems to monitor flue gas DP with relatively more accuracy in comparison with ALTL and LLTL for the model trained on batch size of 5 days (Figure 3(a)). On the other hand, ALTL is found to have comparatively better predictive performance for the model trained on batch size of 8 days (Figure 3(b)). For small

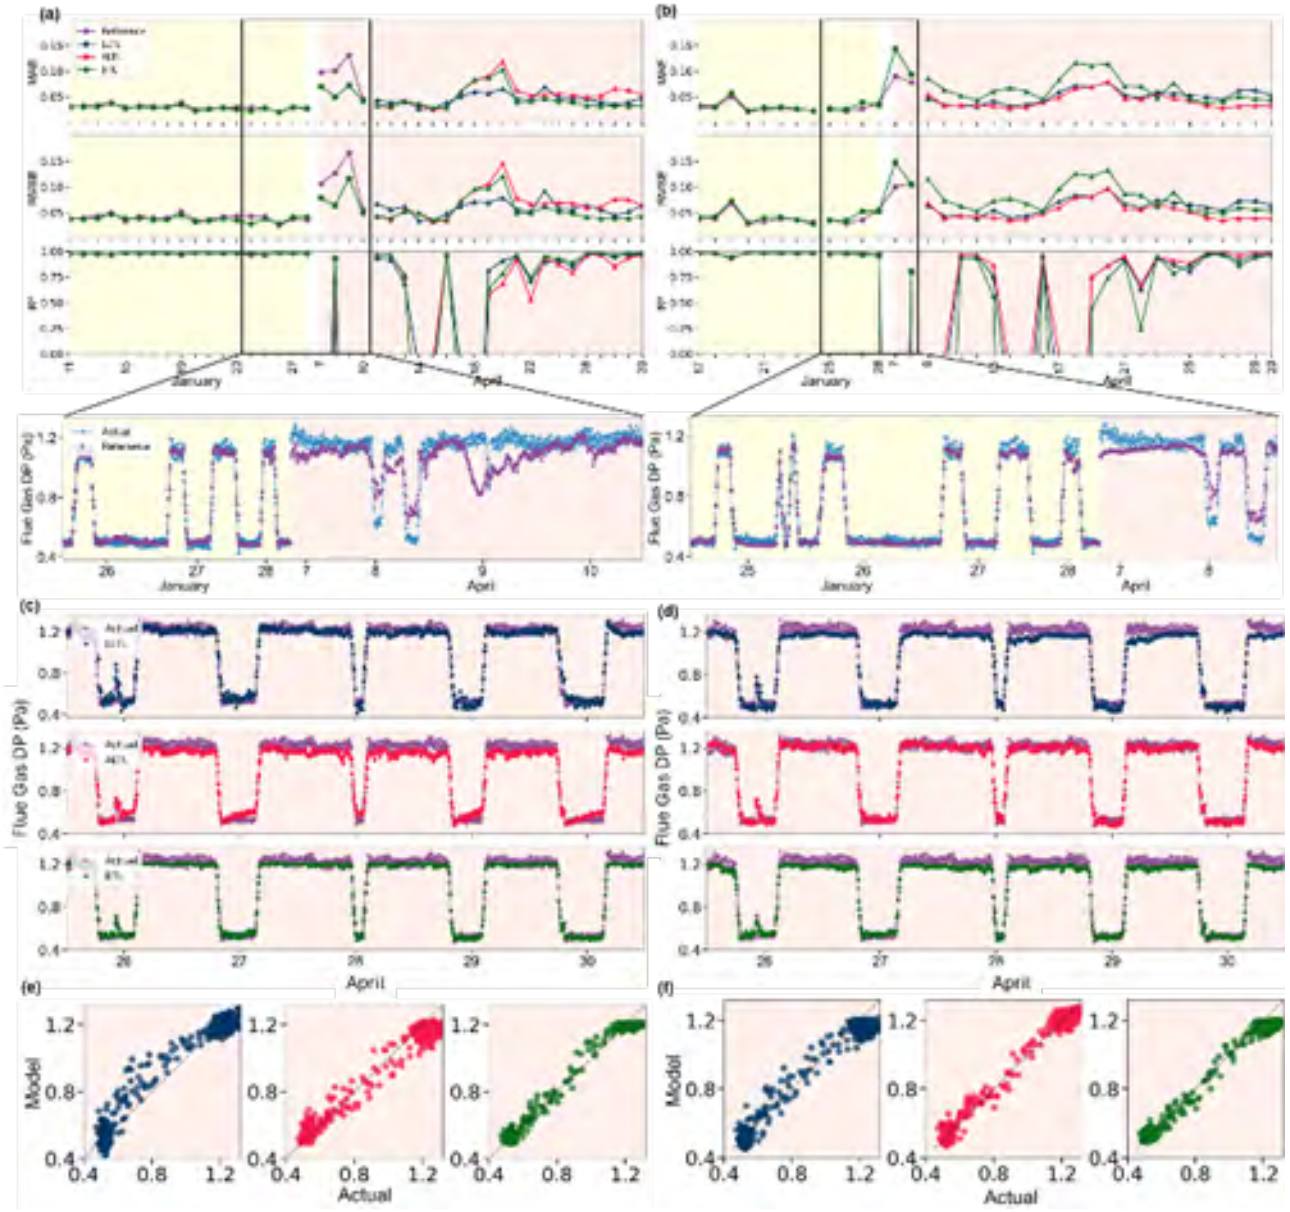

**Figure 3**. MLOps of ANN models trained on batch sizes of (a) 5 days and (b) 8 days to monitor flue gas DP across air preheater. The trained ANN model exhibited good monitoring performance in the month of January. However, they failed during 7-10 April and model update techniques are implemented. Actual and model-based responses are also mapped corresponding to the failure zone. Peformance of models updated by LLTL, ALTL, ETL techniques on remaining April data is shown in (c, d). (e, f) parity plot to compare actual and model-based response for three model update techniques in the remaining april data.

batch sizes, ensemble may average out the predictive responses and provide stable performance. However, when batch size increases, ALTL updates the model parameters across all layers and model is adapted with the recent data stream. This increases the risk of "forgetting" the operation history and model is poised to adapt with the recent operation dynamics.

## Insights about layer-wise weight space distribution after model update

The layer-wise weight space of the models updated with three techniques is retrieved and is visualised to obtain insights on how model parameters are tuned or varied after the model update phase corresponding to batch size of 5 days and 8 days. The weight-space distribution

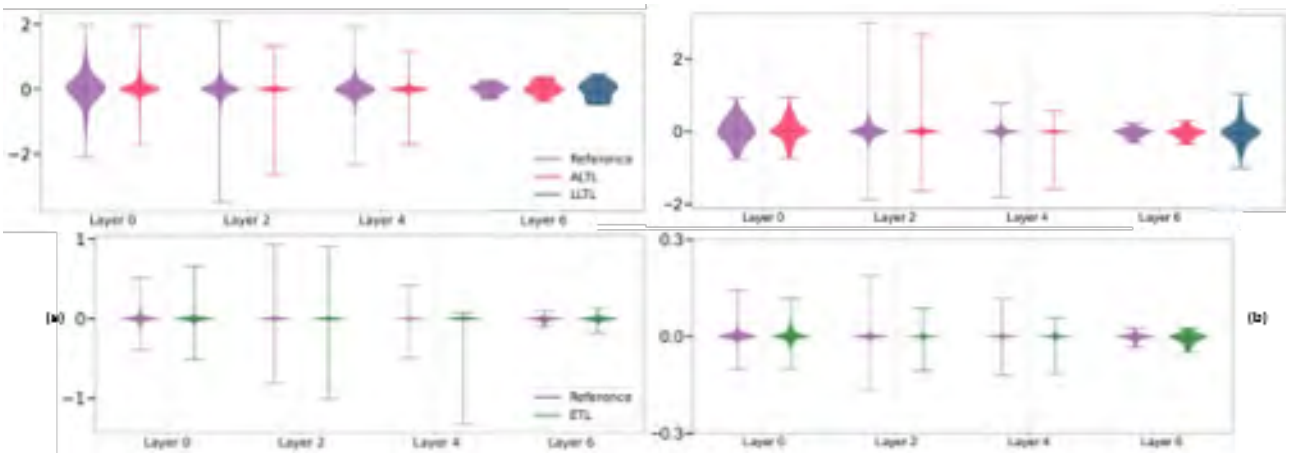

**Figure 4**. Weight space distribution changes with model update for the batch size of (a) 5 days, and (b) 8 days. In common, last-layer weight space is widened to adapt with data-drift.

is visualized as violin plot for each layer of ANN and is depicted on Figure 4(a, b) corresponding to batch size of 5 days and 8 days respectively. In general, it is found that weight space distribution for last-layer of ANN gets widened for the models trained on batch sizes of 5 days and 8 days. This can be attributed to back-propagation of error signal starting from last layer of ANN that tunes the model parameters. For ALTL, the weight space of hidden layers seems to be compressed than those of reference distribution (pre-trained model space) that can explain the improved generalization capability of the model while adapting with drift observed in the data distribution collected for the month of April. However, ensembles approach seems to depict mixed results in widening or compressing the weight space that can be explained by a number of ensembles digesting the data based on the batch sizes.

## Evolution of feature importance

The feature importance to predict flue gas DP is established by SHAP and is used to investigate the evolution in feature importance after the model update. The reference column represents the feature importance before the model update that serves as a baseline to compare the feature importance order after the model update. Secondary air outlet temperature is found to be the most significant feature affecting flue gas DP for models updated on batch size of 5 days and 8 days, respectively, as shown on Figure 5(a, b). After the model update, secondary air outlet temperature remains the most significant feature as established for models updated by LLTL, ALTL and ETL approaches. Multiple ETL columns explicitly track the sequential updates across successive batch intervals, where each column corresponds to a distinct version produced after an update and the resulting feature importance order. The consistent significant order of features, especially for most significant operating variable, by three model update techniques depicts the accuracy of feature importance analysis as well as stability of the trained models to capture the process dynamics. It also reveals that feature importance may remain the same even when concept and data drift are observed in the data (refer to Figure 2).

Although the magnitude of feature importance is varied for each model update approaches, the feature importance order remains nearly the same, especially for significant variables. This may depict the stable tuning of model parameters, irrespective of batch-sizes, and is also evident as stable error profiles depicted on Figure 3(a, b).

## Computational Performance of model update techniques

The computational time required to train a reference model as well as its update by three techniques for the batch size of 5 days and 8 days is recorded and is presented on Figure 6(a, b). For a reference model, comparatively larger computational time is observed (hyperparameter tuning time: 1113 s, training time: 28.4 s) for model trained on batch size of 8 days than those of model trained on 5 days (hyperparameter tuning time: 868 s, training time: 14.4 s). It can be attributed to non-smooth convergence to error minimum on the fewer batches. However, models trained on batch size of 5 days, in general, consumed large computational time for model update by LLTL, ALTL and ETL approaches than those of models trained on batch size of 8 days. This observation may reflect that stochastic error convergence in the baseline model training produces the parametric values that adapt quickly on new data streams as compared to smoothly converged models. A mixed trend is observed in comparing the computational time used for updating

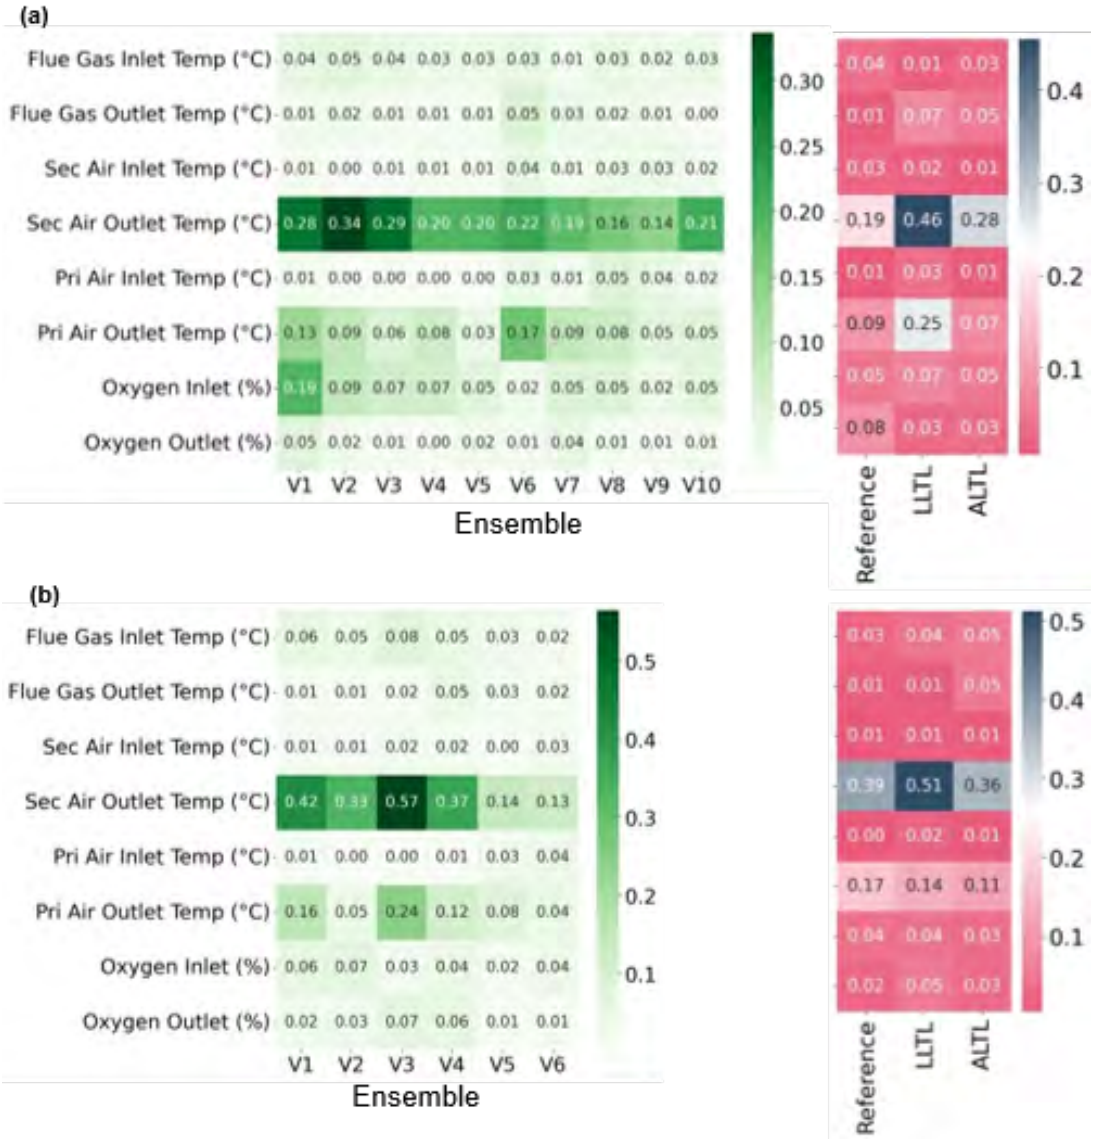

**Figure 5**. Evolution of SHAP-based feature importance with model update for ETL, LLTL and ALTL with respect to batch size of (a) 5 days and (b) 8 days. While Secondary Air Outlet Temperature (°C) is consistently the most dominant feature, but during periods of information scarcity, Primary Air Outlet Temperature (°C) exhibits a transient increase in importance to compensate for the lack of information of the new regime (V6 in (a) and V3 in (b)). Once sufficient data is accumulated, the model stabilizes, and Sec Air Outlet Temperature (°C) regains its primary significance.

the models for the same batch size. However, hyperparameter tuning time remains larger than those of training time irrespective of batch sizes.

## CONCLUSION

We provide insights into the selection of model update techniques when feedforward ANN model fails in MLOps due to drift (data and concept). The effect of batch size (5 days or 8 days) on the predictive accuracy of feed forward ANN model is investigated to monitor flue gas DP across air preheater (treated as batch process) installed in a 660 MW thermal power plant. We find that model failure is driven by drift and ensemble approach implemented for batch size of 5 days (small batch size) provides superior monitoring performance than those of LLTL and ALTL techniques. This can be attributed to widening of weight space across the layers of ANN models in the ensemble which is otherwise compressed for LLTL and ALTL techniques. The comparison of computational time requirements (hyperparameter tuning and model training) for model update techniques reveals that ETL

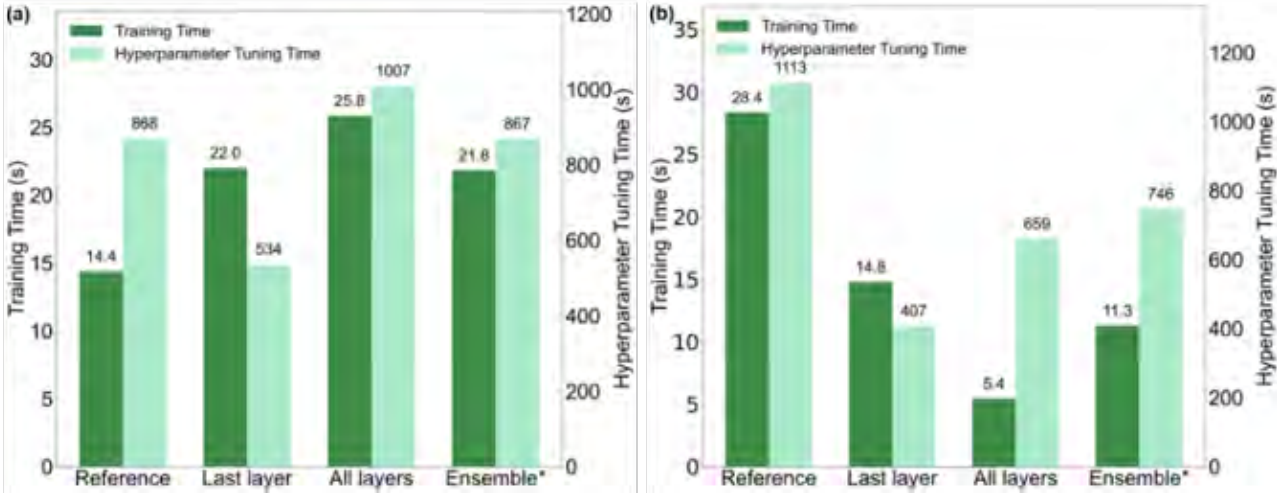

**Figure 6**. Comparing the computational time consumed for hyperparameter tuning and model training for batch size of (a) 5 days and (b) 8 days.

takes longer to update the model for the batch size of 5 days. However, ALTL, which depicts superior monitoring performance for the large batch size, takes the lowest time for updating the model once hyperparameters have been optimised. This aspect may have wider implications for MLOps practices since the models having stochastic error convergence profiles may quickly adapt with drift (data and concept) than the models which initially have smooth error convergence profiles. These fundamental but empiric insights obtained from model update for industrial batch processes highlight the role of batch size of data and the selection of model update techniques for industrial monitoring applications. These findings can also help troubleshoot the MLOps pipeline and dealing with failed ML model for adapting it to volatile industrial production environments.

## ABSTRACT

The conceptual design and performance of a novel Methylcyclohexane-Toluene-Hydrogen based chemical heat pump was studied using steady state simulations. The distillation operating parameters of the chemical heat pump were optimized to maximize the Coefficient of Performance based on heat quantity (COP) and its corresponding Coefficient of Performance based on electric work input ($COP_W$) was calculated. The best operating temperature ranges of the endothermic and exothermic reactor are 200°C-225°C and 250°C-275°C respectively. An endothermic temperature of 200°C and an exothermic temperature of 250°C results in a COP of 0.1357 and a $COP_W$ of 13.3. By integrating this chemical heat pump with a vapor compression heat pump COP increased to 0.1445 while $COP_W$ reduced to 4.9.

## INTRODUCTION

Chemical heat pumps convert low temperature heat to high temperature heat with only a small amount of electricity or work requirements. Organic chemical heat pumps are based on reversible organic reactions. The key unit operations in a chemical heat pump include an endothermic reactor, an exothermic reactor, and a distillation column [1]. Low temperature heat input (primarily waste heat) is given to the endothermic reactor and high temperature heat is released from the exothermic reactor. Because the reactions approach equilibrium, the distillation column separates the reactants from the products to establish the necessary driving forces. Ideally, the distillation column reboiler can be powered by waste heat at the same or lower temperature as the endothermic reactor.

The most researched organic chemical heat pump is the isopropanol + acetone based chemical heat pump. It is generally best used for lifting heat from about 80-90°C to about 150-210°C [1]. In this work, we examine a chemical set (methylcyclohexane and toluene) that could lift heat from about 200°C to about 250°C that has not been studied previously for chemical heat pump applications. Drying in textile and distillation in chemical industries are some of the processes that require heat in the range 200°C-250°C [2]. The methylcyclohexane and toluene based reversible system has been widely explored in other applications, such as a liquid organic hydrogen carrier. In that application, the hydrogen is stored in the form of methycyclohexane by using hydrogenation of toluene. Hydrogen is released during the dehydrogenation of methyl cyclohexane as shown:

$$C_7H_{14} \rightleftharpoons C_7H_8 + 3H_2 \quad (1)$$

Usman *et al.* [3] studied the dehydrogenation kinetics of methylcyclohexane in the temperature range of 340°C-380°C. Castano *et al.* [4] studied the toluene hydrogenation kinetics in the temperature range of 100°C-250°C. These studies provide evidence that the reversible reaction is feasible within the desired temperature ranges suitable for our proposed chemical heat pump application. Toluene and methylcyclohexane have a difference in boiling point by around 10°C, which enables their separation in a distillation column. Additionally, toluene and methylcyclohexane also meet the ozone depletion potential and global warming potential screening criteria as per [5].

In this work, we designed a novel methylcyclohexane–toluene–hydrogen (MTH) based chemical heat pump (CHP) and determined its key performance indicators using Aspen Plus process simulations.

## SYSTEM DESCRIPTION

The process scheme of the MTH-CHP is shown in Figure 1 with corresponding stream conditions in Table 1. It consists of an endothermic reactor, an exothermic reactor, a distillation column, recuperators, pumps and a compressor. The methylcyclohexane dehydrogenation takes place in the endothermic reactor and the toluene hydrogenation occurs in the exothermic reactor. Both the reactor effluents, containing all the chemicals, enter the distillation column for separation. The distillation column bottom consists of mostly toluene since it is the heaviest component. The distillate consists of hydrogen and methylcyclohexane. The hydrogen and methylcyclohexane need to be separated since hydrogen is required in

the exothermic reactor and methylcyclohexane is required in the endothermic reactor. A partial condenser facilitates this separation. Because the reactions happen in the gas phase, methylcyclohexane in the partial condenser liquid product and toluene at the distillation bottom and need to be fully vaporized (vaporizer 1 and 2 respectively). To reduce the heat duty of vaporizer 1, recuperator 3 is present to recover some of the heat from the distillate. Recuperator 1 and recuperator 2 recover heat from the endothermic and exothermic reactor outlet respectively.

The MTH-CHP requires waste heat at four different temperatures as shown in Figure 1. Out of all the four, the heat input at the endothermic reactor will have the highest temperature since the methylcyclohexane dehydrogenation is only feasible above 150°C at atmospheric pressure. The temperature of the reboiler, vaporizer 1 and vaporizer 2 is determined by the bubble point of the mixture at those pressure conditions.

# METHODOLOGY

## Modelling and simulation

A steady state simulation model was created using the software Aspen Plus V14. The PRMHV2 (Peng–Robinson equations of state with modified Huron–Vidal mixing rules) property method is chosen since the model phase equilibrium predictions are in close agreement with the NIST experimental data [10], as shown in Figure 2. The flow sheet was solved using Equation Oriented (EO) mode. Convergence was achieved by first solving the flowsheet in sequential modular mode with one or more loops broken (a.k.a. manual tearing), such that the solver converges but there is a small error in the global mass and energy balances. Then the loops are closed programmatically using the connections feature in EO, and the previous inaccurate solution is used as an excellent initial guess. The final converged EO solution satisfies all mass and energy balances.

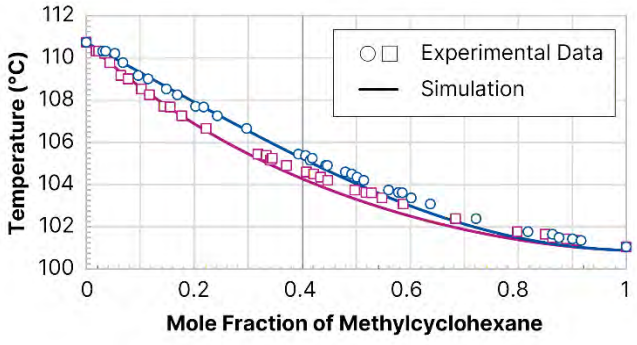

**Figure 2.** A comparison of the PRMHV2 vapor-liquid equilibria predictions for methylcylohexane and toluene vs. experimental data.

RADFRAC was chosen for modelling the distillation column in equilibrium made. The Design Spec feature in RADFRAC was used to meet the column top and bottom purity specs. The partial condenser temperature in RADFRAC was chosen as 35°C which maximized the separation between hydrogen and organics. The operating pressure of condenser is set as atmospheric. For both the endothermic and exothermic reactor, RGIBBS was used, which gives the maximum conversion possible since chemical equilibrium is assumed. The reactor assumes isothermal condition. 100% selectivity was assumed for both the reactors (in other words, we ignore potential side reactions not mentioned in this paper so as to achieve an optimistic performance bound). All the recuperators and vaporizers were modelled using HEATX and HEATER models respectively. The vapor fraction of vaporizer 1 is considered as 0.95 to reduce its heat duty, while the recuperator present in the downstream handles the remaining heat load. The approach temperature, defined as the temperature difference between hot inlet and cold outlet stream, is set to be 10°C for all the recuperators. The COMPR model was used for the compressor and the default isentropic efficiency of 0.72 was assumed. Pumps were modelled using PUMP with the default pump efficiency. Pumps and compressor are present to account for the pressure drops in the system. The pressure drop of the reactor, vaporizer, partial condenser and recuperators were assumed to be 0.1, 0.05, 0.05 and 0.025 bar respectively. A tray pressure drop of 0.005 bar per tray was considered [6].

For brevity, only the most relevant details are contained in this paper. The model has been released to the public as supplementary material (see link at end of article). Full details of the model and steam converged conditions of a representative case can be found there.

## Performance analysis

The $COP$ of MTH-CHP is calculated by the formula:

$$COP = \frac{Q_{exo}}{Q_{endo}+Q_{vap1}+Q_{vap2}+Q_r} \quad (2)$$

where $Q_{exo}$ is the rate of high temperature heat produced from the exothermic reactor, $Q_{endo}$ is the rate of the heat consumed in the endothermic reactor needed for the reaction and to raise the feed stream to reaction temperature, $Q_r$ is the reboiler heat duty, $Q_{vap1}$ is the heat duty of vaporizer 1 and $Q_{vap2}$ is the heat duty of vaporizer 2 (all in kW).

To enable the comparison with mechanical heat pumps, the $COP_w$ for a chemical heat pump is defined as follows:

$$COP_W = \frac{Q_{exo}}{W_{in}} \quad (3)$$

where $W_{in} = W_c + W_{p1} + W_{p2}$ and $W_c, W_{p1}, W_{p2}$ is the power

of compressor, pump 1 and pump 2 in kW.

## Optimization framework

The performance of MTH-CHP depends on many design parameters such as endothermic and exothermic reactor temperatures and distillation column parameters. Hence, multiparameter optimization is carried out to maximize the performance. The optimization problem is defined as follows:

$$\max_{d} COP$$

$f(x) = 0$ [all equations in Aspen Plus, & eq 2]

$g(x) \leq 0$ [all inequalities in Aspen Plus]

$L \leq d \leq U$ [all decision variable bounds]

The particle swarm optimization algorithm (PSO) was used for optimization using the method described in [7]. There are 6 total degrees of freedom. 4 degrees of freedom were taken as decision variables $d$ described in Table 2. The remaining 2 degrees of freedom are the total number of stages in the distillation column ($N_{stages}$), and the ratio of the molar flow rate of hydrogen to toluene at the exothermic reactor inlet ($r_{H2/tol}$). These two were fixed or taken as parameters. The objective function is theoretically maximized at infinite $N_{stages}$, and so reasonable upper bounds much be chosen as described later. Although out of the scope of this work, they can be decision variables if the objective function were based on economic or other metrics that balance capital ($N_{stages}$) versus operating ($r_{H2/tol}$) tradeoffs.

**Table 2** Decision variables considered for optimization.

| $d$ No | Description | Lower Bound | Upper Bound |
|---|---|---|---|
| 1 | Mole fraction of toluene in the partial condenser condensate stream | 0.01 | 0.99 |
| 2 | Mole fraction of methylcyclohexane in distillation bottom stream | 0.01 | 0.99 |
| 3 | Feed Tray Location of endothermic feed (tray 1 is partial condenser) | 2 | $N_{stages} - 1$ |
| 4 | Feed Tray Location of exothermic feed (tray 1 is partial condenser) | 2 | $N_{stages} - 1$ |

The number of particles considered for all runs is 40. The maximum number of iterations is set as 100. Each case was run for at least twice to ensure that the result was consistent. The arbitrary upper and lower bounds for $d_1$ and $d_2$ were wide enough such that $d_1$ and $d_2$ at the optimum was never at a bound.

**Table 3** $COP$ variation with number of stages at $T_{endo}$ = 200°C, $T_{exo}$ = 250°C, $r_{H2/tol}$ =3

| $N_{stages}$ | $d_3$ | $d_4$ | $COP$ |
|---|---|---|---|
| 5 | 4 | 2 | 0.1176 |
| 8 | 5 | 3 | 0.1181 |
| 10 | 7 | 3 | 0.1183 |
| 15 | 8 | 4 | 0.1183 |
| 20 | 9 | 2 | 0.1183 |

Prior to solving the full optimization problem, $N_{stages}$ was set to 10 based on a preliminary sensitivity study. In that preliminary study, $N_{stages}$ was varied around a base case of a "very good" design candidate with $T_{endo}$ = 200°C, $T_{exo}$ = 250°C, $d_1$ = 0.43 and $d_2$ = 0.45. The values for $d_1$ and $d_2$ were chosen in accordance with our previous work for a different chemical heat pump system where "sloppy distillation" is optimal from efficiency point of view [7]. $r_{H2/tol}$ was set as 3, which is stoichiometrically balanced (eq. 1). Then, for each value of $N_{stages}$ considered in the preliminary sensitivity study, the other two decision variables $d_3$ and $d_4$ were optimized using simple enumeration of the possible feed tray location combinations, to find the combination that yielded the maximum $COP$. It was found that the $COP$ increased with $N_{stages}$ up to 10 stages. $N_{stages} > 10$ did not improve the $COP$ meaningfully. The results are populated in Table 3. $N_{stages}$ is relatively small mainly because the vaporizer duty represents the largest quantity of heat load and reboiler duty is not the dominant term.

## RESULTS AND DISCUSSION

The optimization problem described in the previous section was solved for different $r_{H2/tol}$ of 3, 6, 9 and 12 and for $T_{endo}$ = 200°C, $T_{exo}$ = 250°C. Performance was recorded in terms of $COP$ and $COP_W$.

**Table 4** Solutions to the maximize $COP$ problem for each $r_{H2/tol}$ value taken as a parameter, with the corresponding $COP_W$ shown.

| $r_{H2/tol}$ | $COP$ | $COP_W$ |
|---|---|---|
| 3 | 0.1202 | 19.6 |
| 6 | 0.1341 | 16.7 |
| 9 | 0.1357 | 13.3 |
| 12 | 0.1357 | 10.4 |

Toluene hydrogenation which is the exothermic reaction is favored at higher $r_{H2/tol}$ and there is a $COP$ increase initially. However, the $COP$ does not increase

further when $r_{H2/tol}$ is above 9 because a major portion of the heat released from the exothermic reactor is used for heating the excess $H_2$ to exothermic reaction temperature. $COP_W$ reduces with higher $r_{H2/tol}$ due to higher work requirement in compressor. Based on these results, $r_{H2/tol}$ is fixed at 9 for further runs.

Finally, $T_{endo}$ and $T_{exo}$ were varied and the maximized $COP$ obtained by the optimization procedure described earlier and its corresponding $COP_w$ is populated in Table 5. Increasing the $T_{exo}$ for the same $T_{endo}$ reduces $COP$ because the heat liberation from the exothermic reactor ($Q_{exo}$) reduces at higher temperatures. The rate of methylcyclohexane dehydrogenation ($Q_{endo}$) increases with increase in endothermic reactor temperature and the rate of toluene hydrogenation decreases with increase in exothermic reactor temperature. This leads to more toluene and hydrogen in the system at higher endothermic and exothermic reactor temperatures. This causes increase in the compressor load and hence there is a drop in $COP_W$ at higher reactor temperatures. For the same reason, the toluene concentration in the partial condenser condensate increases, while the methylcyclohexane concentration in the distillation bottom decreases as the reactor temperature increases (Table 6). Energy flows per unit of product heat produced are shown in Table 7 for a representative case.

$T_{exo}$ of 300°C and above is not feasible for the MTH-CHP. This is because the sensible heat required to heat the feed inlet stream from 290°C to 300°C is more than the exothermic heat liberated at 300°C.

**Table 5** Variation of maximized $COP$ with $T_{endo}$ and $T_{exo}$

| $T_{endo}$, °C | $T_{exo}$, °C | $COP$ | $COP_W$ |
|---|---|---|---|
| 175 | 225 | 0.0632 | 18.3 |
| 200 | 250 | 0.1357 | 13.3 |
| 200 | 275 | 0.0766 | 4.5 |
| 225 | 275 | 0.1614 | 4.8 |

**Table 6:** Decision variable values for the maximized COP case

| $T_{endo}$, °C | $T_{exo}$, °C | $d_1$ | $d_2$ | $d_3$ | $d_4$ |
|---|---|---|---|---|---|
| 175 | 225 | 0.2307 | 0.7371 | 6 | 7 |
| 200 | 250 | 0.3798 | 0.4729 | 5 | 2 |
| 200 | 275 | 0.7490 | 0.1285 | 8 | 2 |
| 225 | 275 | 0.7607 | 0.1277 | 9 | 4 |

## Integration with vapor compression heat pump

The vaporizer 1 heat duty represents the majority of heat consumption as shown in Table 7. A design improvement of MTH-CHP could consist of including a conventional vapor compression heat pump. The function of a vapor compression heat pump is to take part of the partial condenser heat duty as its heat source and deliver heat at a higher temperature to vaporizer 1. Thus, this hybrid system not only reduces the hot utility demand of vaporizer 1, but also the cold utility demand of the partial condenser, although at the penalty of additional work/electricity requirements.

**Table 7**: Heat duties and electric power per unit of product heat delivered for $T_{endo}$ = 200°C, $T_{exo}$ = 250°C for the maximized COP case

| Ratio | Value |
|---|---|
| $Q_{vap1}/Q_{exo}$ | 5.38 |
| $Q_{vap2}/Q_{exo}$ | 0.38 |
| $Q_{endo}/Q_{exo}$ | 1.36 |
| $Q_r/Q_{exo}$ | 0.25 |
| $W_{in}/Q_{exo}$ | 0.08 |

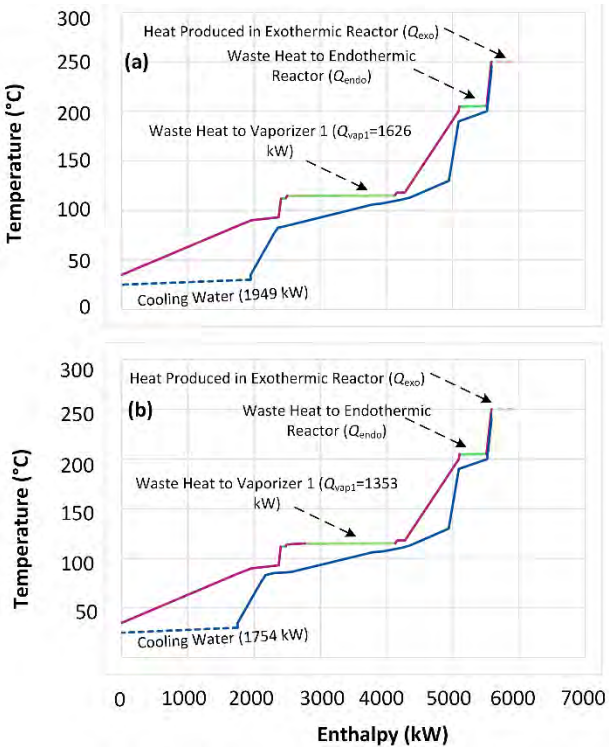

**Figure 3.** (a) Composite curve of MTH-CHP for $T_{endo}$ = 200°C, $T_{exo}$ = 250°C . (b) Composite curve of the hybrid heat pump design when 10% of the partial condenser heat duty is used as a heat source for the vapor compression heat pump. Both systems produce the same amount of exothermic heat, but the second system requires less waste heat consumption.

To look at the possibilities of mechanical heat pump integration, a composite curve was constructed for the MTH-CHP, using Aspen Energy analyzer. Figure 3a shows the composite curve of MTH-CHP without any heat integration for $T_{endo}$ of 200°C and $T_{exo}$ of 250°C. For this composite curve, a pinch temperature of 5°C was

chosen. Figure 3b shows what the composite curve would be if 10% of the partial condenser heat were upgraded and used for vaporizer 1 with a vapor compression heat pump, with a pinch temperature of 5°C. We assume a $COP_w$ of 3.5 for the vapor compression heat pump where the heat source temperature is around 85°C and heat sink temperature is around 115°C [8]. This increases the high-quality heat product generated per unit waste heat consumed by about 14%. This was repeated for 5% and 25% of partial condenser duty upgrading, with results summarized in Table 8.

**Table 8:** Performance result of hybrid heat pump

| Heat source of vapor compression heat pump | $COP$ | % Increase | $COP_W$ |
|---|---|---|---|
| 25% of condenser duty | 0.1955 | 44% | 1.4 |
| 10% of condenser duty | 0.1546 | 14% | 3.0 |
| 5% of condenser duty | 0.1445 | 6.5% | 4.9 |

The $COP$ presented in Table 8 reflects the result of heat integration already present as per Figure 1 as well as the contribution from the mechanical heat pump integration. The results show that this hybrid system allows the increase of $COP$ at the cost of $COP_w$. Increasing the scale of the vapor compression heat pump to 5% -10% of the partial condenser duty would result in $COP_w$ being in the same range as that of many mechanical heat pumps. Currently there is at least one mechanical heat pump at TRL 9 that can supply heat up to 280°C [9].

## CONCLUSIONS

The performance of novel chemical heat pump based on methylcyclohexane, hydrogen, toluene was studied. The most promising results are obtained at $T_{endo}$ of 200°C and $T_{exo}$ of 250°C, where we achieve a $COP$ of 0.136 and a $COP_w$ of 13. Increasing the temperature lift beyond 50°C significantly reduces the $COP$ for this chemical heat pump. Furthermore, a new configuration of hybrid system combining both chemical heat pump and mechanical vapor compression heat pump was studied. This configuration resulted in higher $COP$ at reduced $COP_w$. Very few commercial heat pumps currently operate within this range, and future economic assessments will determine whether this MTH-CHP is commercially viable.

## DIGITAL SUPPLEMENTARY MATERIAL

The aspen plus simulation file of the MTH-CHP is available in LAPSE at https://psecommunity.org/LAPSE:2026.0022.

## ABSTRACT

As the demand of freshwater continuous to rise, the water desalination can act as prominent solution to address the global water scarcity. However, significant environmental concerns arise as the process is mainly powered by fossil fuel, which contributes to greenhouse gas emissions and thus leading to global warming. This research intends to explore the potential of renewable energy sources to effectively reduce freshwater production cost. Specifically, it intends to estimate the power generated and freshwater production cost of a multi-effect distillation (MED) desalination process, powered by solar and wind energy sources in addition to a comparison against the performance of an MED process powered by fossil fuel based conventional steam boiler. The comparison of energy efficiency and freshwater production cost is conducted in two different UK locations: Wick in the north of Scotland and Watchet in the south of England. MED process model with both wind power and solar energy models are developed to estimate the freshwater production cost while assuring 12kg/s of freshwater for small coastal communities. The results ascertain that both energy sources are able to produce thermal energy required for the MED process. Statistically, for a full day, 4029 kWh and 16383 kWh amounts of electricity can be generated in Watchet and Wick, respectively. Referring to wind powered MED, the freshwater production cost in Watchet is estimated at $20.49 per $m^3$ of freshwater whereas it is reduced to $5.56/$m^3$ at Wick as due to stronger and more consistent wind speeds, which is less than a third of the Watchet freshwater production cost. However, solar powered MED shows a much smaller difference between the locations: $1.87/$m^3$ in Watchet and $3.11/$m^3$ in Wick. Based on the results of freshwater production cost, the solar energy for MED process is more efficient in Watchet, whereas wind energy for MED process is more efficient in Wick.

## 1. INTRODUCTION

As water demands continues to rise due to population growth, and agricultural demand, desalination process has become the main solution, especially in areas experiencing declining freshwater supplies. In the United Kingdom, high amount of rainfall has supported freshwater reservoirs and rivers. However, due to climate change, with warmer summers and less rainfall, the level of water in reservoir have been declined. Desalination process is considered as a long-term strategy to help meet water demand and provide a reliable source of clean water. Three desalination technology that are used for desalination processes are MED, multistage flash (MSF) and reverse osmosis (RO) [1]. Desalination is the removal of salts and impurities from seawater to produce safe water to drink. MED is a thermal process that uses multiple effects, which allows seawater to evaporate and

condense at progressively lower pressures and temperatures [2]. This process efficiently recycles heat between effects, which makes it more energy efficient. The Middle East and Africa regions dominates the global desalination market, by owning majority of the installed desalination technologies due to its dry climate, low amount of rainfall, high evaporation rates, and increasing water scarcity. The largest MED plant around the globe was constructed in Saudi Arabia called the Jubail Plant, which serves dual purpose facility by its combined cycled based power generation and MED plant that produces 800, 000 $\mathrm{m}^3$/day of freshwater [4].

There are few examples of articles regarding MED powered by Solar Energy, using Solar Collectors. Dilli and Kumar [7], presented an experimental performance evaluation of a solar powered MED system with a parallel feed configuration. The main target was to assess how real environmental and operational factors such as solar irradiance, temperature, pressure, and steam flow rate can affect the plant's desalination capacity and thermal performance. The researchers used a 10 $\mathrm{m}^3$/day of freshwater output solar MED plant. The MED system included four effects and was powered using solar heated steam. Experiments were conducted under variable solar irradiance conditions throughout the day. Parameters such as brine and distillate flow, evaporator pressure and temperature, and steam mass flow were measured simultaneously. The system achieved a maximum GOR of 3.6, indicating efficient heat reuse across effects. As solar irradiance increased by 24%, evaporation rates significantly increased. Freshwater production was higher in the afternoon despite higher morning solar irradiation, with higher steam production rates directly proportional to improved GOR and overall plant efficiency. This research offered valuable understanding of real world thermal performance, however, its limitations are the system's small scale and a lack of energy storage. The absence of backup storage means that productivity remains tightly linked to real time solar conditions.

Muftah et al. [11] explored how solar energy can be used to power MED plants to make freshwater in a more sustainable way. It focused on a plant in Zuara, Libya, and compared four different ways to run the system. The 1st method used solar energy only during daylight hours. The 2nd method was to combine solar power during the day with boiler operating at night. The 3rd method used solar power along with a thermal energy storage system to allow 24-hour process. The researchers developed a validated mathematical model based on real empirical data. The findings showed that the first method has a freshwater production cost of \$1.40/$\mathrm{m}^3$ and no emissions. Also, the second and third methods introduced a freshwater production cost of \$0.79/$\mathrm{m}^3$ with moderate emissions, and \$0.97/$\mathrm{m}^3$ with no emissions, respectively.

Blanco and Alarcón [5] presented the Aquasol Project, which was built in Spain as a pilot plant for research project funded by the EU to test and prove the technology of solar powered MED with combined hybrid heat source. The Aquasol developed a high capacity solar thermal desalination system that combines renewable energy with MED to reduce fossil fuel dependence and achieve no brine discharge. The main goal was to improve efficiency, reduce energy consumption, and enhance sustainability of seawater desalination at scale. The findings stated that at feed water flow rate of 8 $m^3$/h, the plant can produce 3 $m^3$/h of distilled water resulting a thermal power consumption of 190 $kW_{th}$. It achieved a PR over 9. These results emphasised that the pilot plant operated successfully showing both high freshwater output and very efficient thermal usage. The Aquasol plant highlighted the advantages of hybridisation in achieving high freshwater output, improved efficiency, and zero brine discharge due to a solar powered brine dryer. However, its reliance on fossil fuel backup weakens its long term sustainability.

There are few examples of articles below regarding MED powered by Wind Energy, using Wind Turbine. Rostami et al. [12] presented a hybrid desalination system that uses both waste heat and electricity from a wind turbine. It combined three desalination technologies: A humidification dehumidification unit, MED and MVC systems. The key aim was to minimise liquid brine discharge while improving freshwater productivity by exploiting waste heat, reducing reliance on external energy inputs. The system has a waste heat recovery subunit, which captures heat from the wind turbine cooling system. This recovered waste heat drives a closed air, open water HDH desalination unit. The 90% rejected brine from the HDH unit was fed into the 7 effect MED-MVC for further water recovery. This allowed to a maximise the freshwater productivity while minimising the brine discharge. The findings were that freshwater output increased by 18% across all wind speeds compared to prior layouts. In this regard, Specific Work Consumption (SWC) dropped from 33.41 to 21.27 kWh/ as wind speed increased. When compared to a RO system powered by electricity from wind turbine, this hybrid system of MED-MVC exhibited lower SWC and better recovery ratio, especially under higher wind conditions.

Khalilzadeh and Hossein Nezhad [10] proposed a desalination system that captures waste thermal energy from a 7.58 MW wind turbine to produce steam for a six-effect MED unit. The target was to enhance overall plant efficiency by turning waste turbine heat into freshwater, particularly in remote, wind-rich areas lacking potable water supplies. To capture waste heat from turbine's cooling system was fulfilled by the closed loop heat exchanger. The extracted heat generated steam at 100 ℃ at standard pressure, was fed in a 6 effect MED unit. The

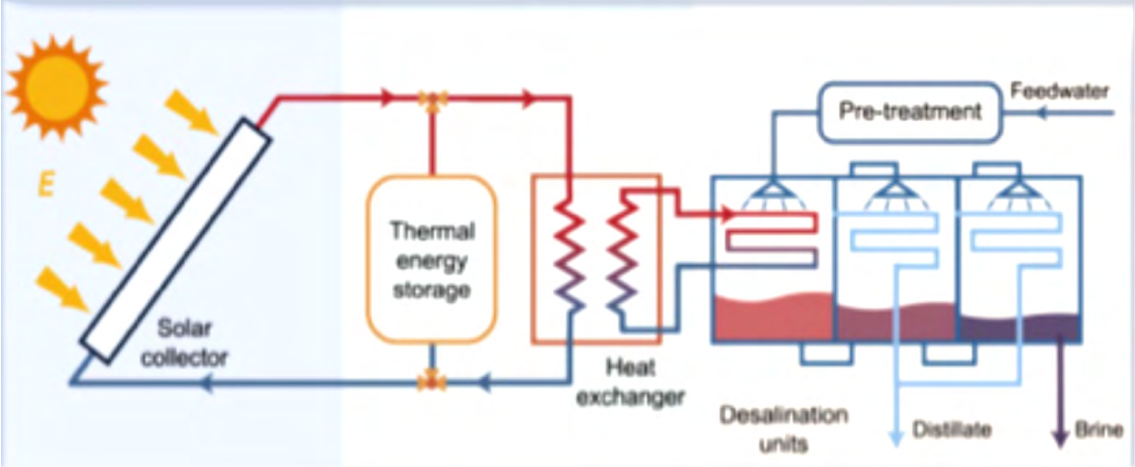

**Figure 1.** The concept of full model of Solar Powered MED [15]

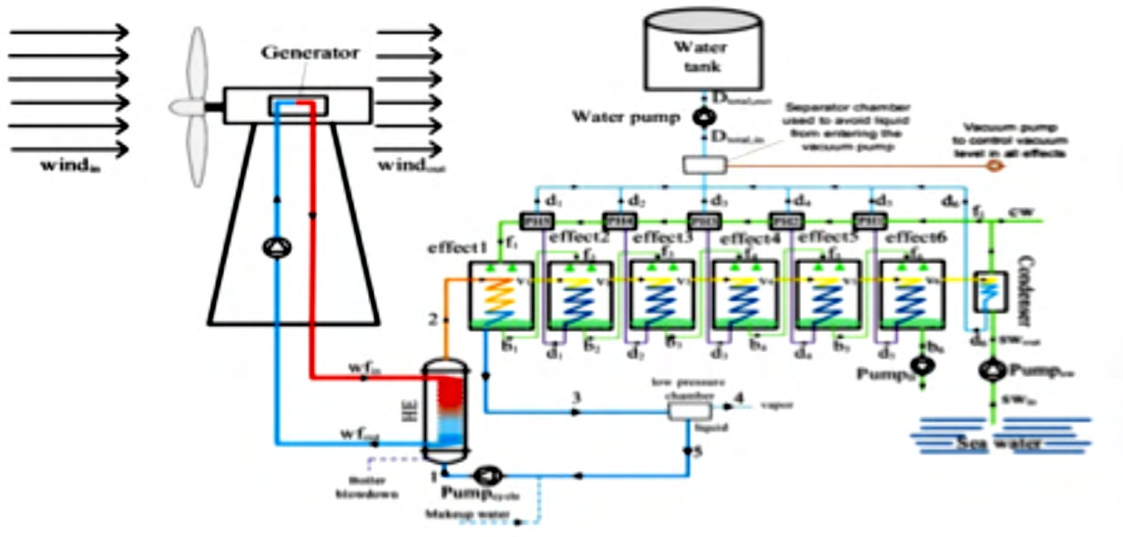

**Figure 2.** The concept of full model of Wind Powered MED [10]

power required for the pumps and pre-heaters were fulfilled by the electricity generated by the same turbine. The system produced 45 $m^3$/day of freshwater, with an estimated freshwater production cost of \$16.676/$m^3$, and a payback period of 6.33 years, based on its capital and operational costs.

## 2. MODEL OF SOLAR AND WIND POWERED MED

Solar irradiance is the total amount of light energy that reaches the Earth since it is the output of light energy that is received from the Sun. In UK, solar irradiance levels are moderate but still sufficient for effective solar energy production. In the North of Scotland, the solar irradiance can reach up to 71.8 W/$m^2$, whereas in the South of England, the solar irradiance can reach up to 128.4 W/$m^2$. Therefore, in this research, coastal towns from South of England called Watchet and coastal town in North of Scotland called Wick were selected for their data of Solar Irradiance and Wind Speed. Thermal energy from a solar collector is used to heat water, which acts as the Heat Transfer Fluid (HTF). The HTF flows through a temperature-controlled pipeline. If its temperature exceeds the required temperature, the fluid is transferred to a thermal energy storage tank. From the tank, the HTF at the appropriate temperature is then supplied to a heat exchanger, which is used in the MED process. Figure 1 shows the concept of this process.

Wind speed can be converted into either electrical energy by using Wind Turbines or thermal energy from the waste heat, which is lost from the wind turbine Generator and Gear components. Figure 2 shows the concept of this process.

## 3. METHODOLOGY

## 3.1 Model Equations

### 3.1.1 MED Process Equations

The MED mode equations produced by Filippini et al [9] is presented below. The MED model composes a set of algebraic and differential equations representing the thermodynamic and mass transport characteristics of a MED system. The model is based on fundamental mass and energy balance principles and includes equations for heat transfer, boiling point elevation, and salinity effects. Heat exchangers within pre-heaters and condensers is modelled using logarithmic mean temperature differences, with the model designed to simulate thermal performance under different input conditions.

Feed Flowrate

$$Mf = \frac{Ms.\lambda Ts}{Q_{sensible}+Q_{Latent}} \quad (1)$$

Sensible Heat in First Effect

$$Q_{sensible} = Mf \int_{t1}^{T1} cp\,(T1, x1)dt \quad (2)$$

Latent Heat in First Effect

$$Q_{Latent} = D1\,.\,\lambda(Tv1) \quad (3)$$

Temperature drop among effects

$$\Delta T = \frac{Ts - Tb}{n} \quad (4)$$

Temperature drop among pre-heaters

$$\Delta T = \Delta t \quad (5)$$

Feed temperature in first effect

$$t1 = tn + (n-1)\Delta t \quad (6)$$

Temperature of vapor phase

$$Tv = T - BPE\,(T, x) \quad (7)$$

Flowrate of flashed distillate

$$D_{flash,i} = \propto B_{i-1} \quad (8)$$

Fraction of distillate by flashing

$$\propto = \frac{cp\,(T_{mean} - x_{mean})\,\Delta T}{\lambda(T_{mean})} \quad (9)$$

Mean Temperature

$$T_{mean} = \frac{T1 + Tb}{2} \quad (10)$$

Mean Salinity

$$x_{mean} = \frac{xf + xb}{2} \quad (11)$$

Fraction of distillate by evaporation

$$\beta = \frac{\propto [xb(1-\propto)^n - xf]}{(xb - xf)[1 - (1-\propto)^n]} \quad (12)$$

Flowrate of evaporated distil

$$D_{i,boiled} = \beta M_D \quad (13)$$

Total distillate

$$D_i = D_{i,boiled} + D_{i,flashed} \quad (14)$$

Rejected brine flowrate

$$B_i = B_{i-1} - D_i \quad (15)$$

Salinity profile in the effects

$$x_i = \frac{x_{i-1}B_{i-1}}{B_i} \quad (16)$$

Area of i-th effects

$$A_{ev,i} = \frac{Q_i}{U_{ev,i}\,.\Delta T_{ev,i}} \quad (17)$$

Heat load in i-th effect

$$Q_i = D_{boiled,i-1}\,.\,\lambda(T_{v,i-1}) \quad (18)$$

Temperature drop in Heat Exchanger

$$\Delta T_{ev,i} = \Delta T - BPE_{i-1} \quad (19)$$

Area of i-th pre – heater

$$Mf\,.\int_{t_{i+1}}^{t_i} cp(t, xf)dt = U_{ph,i}\,.A_{ph,i}\,.\Delta t_{log,i} \quad (20)$$

Logarithmic temperature difference in pre-heaters

$$\Delta t_{log,i} = \frac{\Delta t}{log\,(\frac{Tv_i - t_{i+1}}{Tv_i - t_i})} \quad (21)$$

Area of Final Condenser

$$Q_{COND} = U_{COND}\,.A_{COND}\,.\Delta T_{log,COND} \quad (22)$$

Heat load in final condenser

$$Q_{COND} = D_n\,.\lambda(Tv_n) \quad (23)$$

Logarithmic Temperature difference in final condenser

$$\Delta T_{log,COND} = \frac{tn - Tw}{log\,(\frac{Tv_n - Tw}{Tv_n - tn})} \quad (24)$$

### 3.1.2 Solar Collector Process Equations

The Solar model equations presented below. The solar thermal model is formulated to calculate the thermal energy produced from solar irradiance and from the storage tank which will be transferred to be used in the MED model. It is composed of a set of algebraic equations describing collector performance, and the total energy gained by solar irradiance and thermal storage.

Solar Thermal power gained from Solar collectors

$$Q_{solar} = N_{collector}\,.A_{Collector}.\eta_{Collector}\,.\frac{I}{1000} \quad (25)$$

Total Heat supplied to MED

$$Q_{MED} = Q_{solar} + Q_{storage} \quad (26)$$

Heat Required by MED for desalination to work

$$Q_{Required} = \dot{X}_{Freshwater} \cdot \lambda_{Evap} \cdot C_p \cdot \Delta T \quad (27)$$

Energy Balance of Thermal Tank

$$\frac{dE_{storage}}{dt} = Q_{storage} - Q_{Charge} - Q_{Loss} \quad (28)$$

Thermal Tank Temperature with Stored HTF

$$T_{Tank} = \frac{T_{Ambient} + E_{storage}}{\rho_{HTF} \cdot C_p \cdot V_{Tank}} \quad (29)$$

Temperature of HTF from Thermal Tank

$$T_{Storage} = T_{Tank} \quad (30)$$

Temperature of HTF from Solar Collectors

$$T_{Collector} = T_{Exit_HX} \cdot \frac{Q_{solar}}{\dot{m}_{HTF} \cdot C_p} \quad (31)$$

Heat Charged into Thermal tank from excess HTF from Solar collector

$$Q_{Charge} = A \cdot \eta_{Collector} \cdot \frac{I}{1000} \quad (32)$$

Number of Collectors based on Desired Freshwater

### 3.1.3 Wind Turbines Process Equations

The Wind model equations presented below. The wind energy model developed for this work is based on the electrical and thermal energy outputs from wind turbines. It uses a series of algebraic formulations. The model captures mechanical power generation, gear and generator losses, and waste heat recovery, with them being useful for thermal applications.

Rotor Swept Area of Wind Turbine

$$A_{Rotor} = \pi \cdot r^2 \quad (35)$$

Max power available in the wind

$$P_{Wind_Max} = \frac{1}{2} \cdot \rho_{Air} \cdot A \cdot \frac{V^3}{1000} \quad (36)$$

Mechanical power extracted by wind turbines

$$P_{Turbine} = N_{Turbine} \cdot P_c \cdot P_{Wind_Max} \quad (37)$$

Electrical power output after losses

$$P_{Electric} = P_{Turbine} \cdot \eta_{Gear} \cdot \eta_{Generator} \quad (38)$$

Waste heat generated

$$Q_{Waste} = P_{Turbine} \cdot (1 - \eta_{Gear}) + \eta_{Gear} \cdot (1 - \eta_{Generator}) \quad (39)$$

Overall efficiency of wind to electric system

$$\eta_{Systems} = \frac{P_{Electric}}{P_{Wind_Max}} \quad (40)$$

Temperature Rise in HTF due to Waste heat

$$\Delta T_{HTF} = \frac{Q_{Waste}}{\dot{m}_{HTF} \cdot C_p} \quad (41)$$

Required thermal energy to produce desired freshwater output

$$Q_{Required} = \dot{X}_{Freshwater} \cdot \lambda_{Vaporisation} \cdot C_p \cdot \Delta T \quad (42)$$

Number of Wind Turbine based on Desired Freshwater

$$N_{collector} = \frac{Q_{Required}}{Q_{Waste}} \quad (43)$$

Mass Balance of HTF

$$\dot{m}_{HTF,in} = \dot{m}_{HTF,Out} \quad (44)$$

### 3.1.4 Economic Model Equations

The economic equation model below is developed by Al-Obaidi et al. [3] will be used to calculate the cost of freshwater produced from Solar Powered MED process, Wind Powered MED process and Steam Generated MED process. The economic equation model provides the equation whereas the Table 1 provides economic parameters to be used for the economic equations.

Freshwater Cost

$$FWC_{MED} = \frac{TAC}{\dot{X}_{Freshwater} \cdot THY \cdot 3600} \quad (45)$$

Total Annual Cost

$$TAC = AOC + CRF \cdot TCC \quad (46)$$

Total Capital Cost

$$TCC = Capex_{Direct} + Capex_{Indirect} \quad (47)$$

Direct CAPEX

$$Capex_{Direct} = Capex_{Equipment} + Capex_{Civil_Work} \quad (48)$$

Indirect CAPEX

$$Capex_{Indirect} = 0.25 \cdot Capex_{Direct} \quad (49)$$

Equipment Cost

$$Capex_{Equipment} = C_{Intake} + C_{MED} + C_{Cond} \quad (50)$$

Civil work Cost

$$Capex_{Civil_Work} = 0.15 \cdot Capex_{Equipment} \quad (51)$$

Seawater Intake and Pre – treatment Cost

$$C_{Intake} = \frac{K_{Intake} \cdot 24.3600 \cdot \dot{m}_{Seawater}}{\rho} \quad (52)$$

MED Plant Cost

$$C_{MED} = K_{MED} \cdot C_{mat_MED} \cdot (A_{MED})^{0.64} \quad (53)$$

Final Condenser Cost

$$C_{Cond} = K_{Cond} \cdot C_{mat_Cond} \cdot (A_{Cond})^{0.8} \quad (54)$$

Annual Operating Cost

$$AOC = AOC_{Chem} + AOC_{Lab} + AOC_{Pow} + AOC_{Man} + AOC_{Steam} \quad (55)$$

Cost of Chemical Treatment

$$AOC_{Chem} = \frac{C_{Chem} \cdot THY \cdot 3600 \cdot \dot{m}_{Seawater}}{\rho} \quad (56)$$

Cost of Human Labour

$$AOC_{Lab} = \frac{C_{Lab} \cdot THY \cdot 3600 \cdot X_{Freshwater}}{\rho} \quad (57)$$

Cost of Power

$$AOC_{Power} = \frac{C_{Power} \cdot THY \cdot 100 \cdot X_{Freshwater}}{\rho \cdot \eta} \cdot f(\Delta P) \quad (58)$$

Cost of Manutention

$$AOC_{Man} = 0.002 \cdot TCC \quad (59)$$

Cost of External Steam

$$AOC_{Steam} = \frac{C_{Steam} \cdot THY \cdot (T_s - 40) \cdot \dot{m}_{Steam}}{80} + 0.005 \cdot TCC \quad (60)$$

Capital Recovery Factor

$$CRF = \frac{Ir(1+Ir)^{life}}{(1+Ir)^{life} - 1} \quad (61)$$

**Table 1:** Economic Parameters Developed by Al-Obaidi et al. [3]

| Variables | Unit | Value | Description |
|---|---|---|---|
| THY | Hr/Yr | 8760 | Total Hour Per Year |
| $K_{Intake}$ | \$day/$m^3$ | 50 | Seawater Intake |
| $K_{MED}$ | - | 1.4 | Coeff of MED |
| $K_{Cond}$ | - | 2.8 | Coeff of Condenser |
| $C_{Chem}$ | \$/$m^3$ | 0.024 | Chemical Treatment |
| $C_{Lab}$ | \$/$m^3$ | 0.05 | Labour |
| $C_{Power}$ | \$/kWh | 0.09 | Power |
| $C_{Steam}$ | \$/kg | 0.004 | External Steam |
| $C_{mat_MED}$ | \$/$m^2$ | 3644 | Material of MED |
| $C_{mat_Cond}$ | \$/$m^2$ | 500 | Material of Condenser |
| $Ir$ | - | 0.07 | Interest Rate |
| $life$ | Yr | 25 | Life of the Plant |
| $f(\Delta P)$ | - | 3571 | Pressure Losses |
| $\eta$ | - | 0.75 | Efficiency of Power Generation |

The parameters in Table 2 are taken from Filippini et al [9]. These value are fixed inputs that are used for the gPROM simulation. They MED model uses 10 effects, which improves thermal efficiency by reusing heat. The low Top brine Temperature (Tn from last effect) indicates MED is optimised for low temperature heat sources. Higher water quality (Tw) suggests effective salt separation by MED. The Mev shows that vapour is not being mechanically compressed to raise the pressure and temperature.

The Solar Collector Specifications are provided in Table 3. These are fixed inputs that are used for the gPROM simulation. The area is large, which allows more solar energy to be absorbed. The efficiency is quite high suggesting most of sunlight being converted into thermal energy rather than being lost. The high absorptivity helps to maintain high thermal performance especially when the solar irradiance is low.

**Table 2:** MED unit Parameters Used in gPROMS developed by Filippini et al. [9]

| Variables | Units | Values |
|---|---|---|
| Number Of Stages | - | 10 |
| Tn | - | 40 |
| Xn | - | 60000 |
| Tw | ppm | 25 |
| Tphn | - | 36 |
| Pm | - | 1300 |
| Pcrit | kpa | 22089 |
| Tcrit | kpa | 647.286 |
| Mev | Kg/s | 0 |

**Table 3:** Data Specification of a Solar Collector [13]

| Variables | Units | Values |
|---|---|---|
| Area | $m^2$ | 10.1 |
| Efficiency | % | 83.8 |
| Absorption | % | 96 |
| Max Pressure | bar | 10 |
| Cost of 1 Solar Collector | \$ | 635 |

The Wind Turbine Specification are provided in Table 4. These are fixed inputs that are used for the gPROM simulation. The diameter of rotor suggests that bigger the diameter, the more power generated. The gear and generator efficiency indicates both components are very efficient with minimal energy loss. The power coefficient is the efficiency of converting wind energy to mechanical energy by the rotor.

**Table 4:** Data Specification of a Wind Turbine [14]

| Variables | Units | Values |
|---|---|---|
| Diameter of Rotor | m | 52 |
| Efficiency Of Gear | % | 98 |
| Efficiency Of Generator | % | 90 |
| Power Coefficient | % | 59.3 |
| Cost of 1 Wind Turbine | \$ | 38100 |

The Data specification of the steam boiler is provided in Table 5. These are fixed inputs that are used for the gPROM simulation for the Steam Boiler Powered MED process. The steam Min-Max is the value of how much steam in kg/s can be produced by the boiler.

**Table 5:** Data Specification of Steam Boiler [6]

| Variables | Units | Values |
|---|---|---|
| Steam Min - Max | Kg/s | 0.347 - 7.78 |
| Max Temperature | °C | 235 |
| Max Pressure | bar | 30 |
| Cost of Steam Boiler | $ | 100, 000 |

Finally, the Data specification of the thermal tank is provided in Table 6. These are fixed inputs that are used for the gPROMS simulation which is combined with the Solar code. The insulation is made up of foam and its thickness is 25mm to reduce heat loss.

**Table 6:** Data Specification of Thermal Tank [8]

| Variables | Units | Values |
|---|---|---|
| Volume Capacity | L | 7000 |
| Cost of Storage Tank | $ | 4360 |
| Insulation | mm | 25 |

## 4. RESULTS AND DISCUSSION

### 4.1 Economical Results

Based on the analysis, the initial investment almost fully determines the Levelized Cost of Water (LCOW). The Annual Operating Cost (AOC) remains below 3% of the total annualised cost for all renewable installations. This indicates that even though the energy source is free, the primary economic barrier in the UK is still the high initial cost of producing it. Wind power is particularly location-sensitive. Watchet's lower average wind speed (5.1 m/s) requires a large 1, 588 turbines to meet the system's heat demand, increasing the capital cost to $86.97 million. The turbine count in Wick decreases by 74% when speeds approach 8.0 m/s, resulting in a far more affordable water cost of $5.56/m³ instead of $20.49. Although the 25-year payback time helps keep the price gap acceptable, Wick requires almost twice as much land area as Watchet to produce the same 12 kg/s.

The research shows that the initial investment of wind power industry is where the two locations economic differences are most noticeable. The main factor driving Watchet's costs, is the high CAPEX recovery $7.58M/yr, which results directly from the need for 1, 588 turbines to compensate for lower wind speeds. Whereas, Wick, shows better resource efficiency; the higher wind speeds require less infrastructure, which enables the annualised CAPEX recovery to drop dramatically to $2.06M/yr. This shows how natural resources directly reduces the project's financial expense. Additionally, when considering all renewable energy sources, the Annual Operating Cost represents a small fraction of the total annualized cost, typically staying under 5%. This suggests that the financial feasibility of these desalination plants is mainly influenced by the upfront installation costs rather than ongoing maintenance expenses. While solar costs tend to be more stable, Wick notes a rise in the annualised repayment from $0.69 million to $1.15 million—because a larger collector field is needed in northern areas to meet the same thermal demand, due to reduced solar irradiance.

Table 7 provides the freshwater production cost ($/m³) for Wick and Watchet, while Figure 3 depicts a breakdown of annualised cost, CAPEX against OPEX.

**Table 7:** Freshwater production cost ($/m3) for Wick and Watchet

| Parameters | Watchet Solar | Watchet Wind | Wick Solar | Wick Wind |
|---|---|---|---|---|
| Units | 7, 255 | 1, 588 | 13, 055 | 412 |
| Area, $m^2$ | 73, 275 | - | 131, 855 | - |
| TCC, $M | 6.62 | 86.97 | 11.92 | 22.56 |
| TCC MED, $M | 1.4 | 1.35 | 6.27 | 1.39 |
| AOC, $k/yr | 17.77 | 173.95 | 28.36 | 45.13 |
| AOC MED, $k/yr | 7.35 | 2.74 | 7.42 | 2.82 |
| TAC, $M/yr | 0.71 | 7.75 | 1.18 | 2.10 |
| Cost of Freshwater, $/$m^3$ | 1.89 | 20.49 | 3.12 | 5.56 |

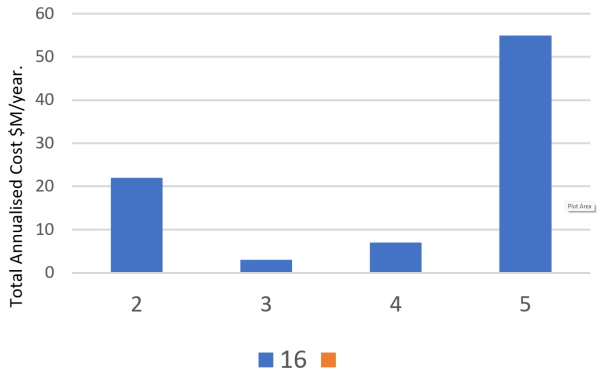

**Figure 3.** Breakdown of Annualised Cost, CAPEX vs OPEX

4.1.1 Comparison of Solar Powered freshwater production cost between Simulated Results and Case Study

The freshwater production costs for solar powered MED plants vary significantly between the case study of Libya, Muftah et al [11], and the current results for Watchet, and Wick. In Libya, the cost of freshwater is

around \$0.97 $m^3$, which is lower than the costs calculated for the UK locations This relatively low cost can be due to lower capital cost, such as, the costs of materials, equipment, and installation. Plus, labour and operational costs in Libya are considerably less expensive compared to the UK, reducing the overall expenses of the plant. In contrast, Watchet freshwater cost, \$1.87 $m^3$and Wick freshwater costs \$3.11 $m^3$, which reflects the higher economic and operational costs of the UK. Capital costs are higher due to more expensive equipment and installation procedures. Labor costs, including skilled technicians and maintenance, are costly in UK, increasing the operational expenses. The UK also imposes stricter environmental, safety, and quality regulations, which lead to additional compliance costs that must be factored into the project budget. The case study at Libya, they used large solar collectors with an area of $72m^2$, which costs \$6600 each, whereas, I used solar collectors with an areas of $10.1m^2$, which costs \$635 each. Despite, the lower cost of solar collectors, the cost of freshwater production calculated was higher than the results retrieved from Muftah et al [9]. In Libya, the solar irradiance is much higher compared to UK, so each solar collector in Libya can generate more thermal energy efficiently, reducing the numbers of collectors needed per unit of freshwater produced. Whereas, in UK, lower solar irradiance, requires more solar collectors to generate the same amount of thermal energy which increases the operational and capital costs leading to higher freshwater cost. To demonstrate the validity of the current simulation, the model was compared against the solar-MED case study in Libya by Muftah et al. [11] and the wind-MED study by Khalilzadeh and Hossein Nezhad [10]. While the calculated costs for Watchet of \$1.89/$m^3$, and Wick of \$3.12/$m^3$, are higher than the Libyan result of \$0.97/$m^3$, this difference validates the model's sensitivity to geographic and economic factors rather than indicating an error. Reassessing the resource requirements reveals that in Libya, the higher solar irradiance means fewer solar collectors are required to produce the same amount of freshwater, in contrast, the UK it has lower solar irradiance which requires 7, 255 collectors in Watchet and 13, 055 in Wick to meet the 12 kg/s demand, resulting in a TCC ranging from \$6.6M to \$11.9M. Furthermore, the model's validity is confirmed in the wind industry, where Wick's \$5.56/$m^3$, cost is far less than the \$16.68/$m^3$, reported in research by Khalilzadeh [10]. The switch from a 6-effect MED system used by Khalilzadeh [10] to the more effective 10-effect MED design used in this work, which achieves a higher Gained Output Ratio (GOR) and increased waste heat utilization, provides technical backing for this improvement. Using a 25-year lifecycle and a CRF of 0.0858, the model correctly shows that although the UK has higher initial costs, long-term payback of high-efficiency systems makes renewable water production potentially cost-effective.

### 4.1.2 Comparison of Wind Powered freshwater production cost between Simulated Results and Case Study

The freshwater cost powered by Wind Energy in Watchet is \$20.49 $m^3$ and in Wick it costs \$5.56 $m^3$ whereas, the Khalilzadeh and Hossein Nezhad [10] case study produces freshwater powered by Wind Energy which costs \$16.68$m^3$. The cost of freshwater in Watchet was 23% higher than the case study which can be due to less consistent wind in Watchet compared to Wick and case study location. This shows that more turbines were required to produce the same amount of thermal energy, increasing the TCC and AOC of Watchet. The cost of freshwater in Wick was cheaper than the case study as my MED model uses 10 effects, which may have caused to achieve a higher thermal efficiency compared to the 6 effect MED process used in the case study. Adding more effects in MED desalination improves the recovery ratio and reduces specific energy consumption, which allows more freshwater to be produced per unit of energy. This increased efficiency can contribute to lowering the overall cost of freshwater in my project compared to the pilot plant. Plus, the higher number of effects allows better utilisation of available waste heat, reducing the operational costs. Plus, the wind speed is major factor, as higher wind speed leads higher power output, which leads to more waste heat available for the MED process. Wick has lower cost of freshwater compared to the case study is because, the case study Muftah et al [11], has a short payback period of 6.33 years, which requires the initial investment of the capital cost to be recovered over a small period. This results in a higher annualised cost, which forces the freshwater cost to be higher because each year the cost of freshwater has to cover large fraction of the initial investment.

## 5. CONCLUSIONS

This research aligned with the inclination of transition from fossil fuels for seawater desalination into Renewable energy such as Solar and Wind energy. To conduct this research, specific models of MED, Solar and Wind energy were developed. Specifically, the freshwater production costs of MED powered by Solar and Wind energy were estimated for Watchet and Wick cities in the UK with a comparison against the freshwater production cost to MED powered by Conventional Steam boiler. The results demonstrated that using Watchet and Wick dataset of solar irradiance and wind speed, both energy sources were able to produce thermal energy required to heat the HTF of MED process. However, Solar energy for MED process is more efficient in Watchet, whereas Wind energy for MED process is more effective in Wick. Watchet is located South of England where there is high solar irradiance. Whereas, Wick is located in North of

Scotland which has a climate of strong and consistent wind speeds throughout the year and has low solar irradiance and is mainly cloudy especially in winter season. By using the same 750 kW turbine for both Watchet and Wick, we can ensure that the cost difference is caused strictly by the wind speeds, not the infrastructure. This demonstrates that Wick is more cost-effective due to its natural resources rather than only having a better infrastructure. It simplifies the study and keeps the focus on how location affects the cost of freshwater.

## ABSTRACT

A recurrent neural network (RNN) model for a $CO_2$ methanation reactor was developed based on synthetic data generated from a validated mechanistic model of the same unit. The model was used to predict the main properties of the reactor – methane productivity and hotspot temperature – during a dynamic operation of the unit. The dynamic profile of feedstock availability was simulated taking into account the $H_2$ flow that can be produced from PV-powered water electrolysis using solar irradiation profiles over a year in Milan, Italy. The dataset therefore consists of 366 data instances (one for each day), each composed of one datapoint per minute of sunlight. The best agreement between the predictions from the RNN and the target output values from the mechanistic model was found using a shallow RNN of 20 hidden-layer neurons, trained with a batch size of 10 and an 80/20 training-testing split. This showed that RNNs can constitute a reliable tool for dynamic surrogate modelling of energy conversion reactors. The surrogate model was embedded in an energy system model to provide dynamic predictions of the energy conversion efficiency in the reactor, providing a more realistic performance assessment compared to the average efficiency models commonly used in the literature.

## INTRODUCTION

The global transition towards decarbonised energy systems is reshaping the design and operation of chemical reactors within integrated energy networks. As renewable technologies become central to energy production, their inherent intermittency introduces temporal fluctuations that destabilise the conventional steady-state operation of chemical processes [1]. This shift demands new modelling approaches capable of capturing transient dynamics to ensure process efficiency, stability, and safety under variable operating conditions.

Among the technologies driving decarbonisation, the catalytic methanation of carbon dioxide ($CO_2$) has gained relevance within Power-to-Gas (PtG) systems. This process converts renewable hydrogen and captured $CO_2$ into synthetic natural gas (SNG), which can be injected into existing gas grids or used as a carbon-neutral fuel [2]. By enabling renewable energy storage and carbon utilisation, $CO_2$ methanation provides a key link between the renewable power and gas sectors. However, the highly exothermic nature of the reaction ($\Delta H_{298K} = -165.0 \frac{kJ}{mol}$) poses challenges for heat management and reactor stability, particularly under the intermittent and variable conditions imposed by renewable power fluctuations [3]. These dynamic changes in feed composition, flowrate, and temperature cannot be reliably represented through steady-state modelling approaches.

In this context, dynamic reactor modelling has emerged as a critical tool for understanding and optimising $CO_2$ methanation under varying conditions. By explicitly accounting for temporal variations in system inputs, dynamic modelling enables the prediction of phenomena such as transient temperature evolution, heat accumulation, and reaction rate fluctuations, providing the founda-

tion for safe and efficient reactor operation in non-stationary regimes [4]. Nevertheless, traditional mechanistic models, despite their physical accuracy, are computationally demanding due to the need to solve complex coupled differential equations across multiple spatial and temporal scales.

To overcome these limitations, recent advances in machine learning have opened new pathways for developing data-driven models that replicate mechanistic behaviour with significantly lower computational cost [5]. Recurrent neural networks (RNNs), in particular, have demonstrated great potential for modelling sequential and time-dependent chemical processes by capturing the effect of dynamic inputs on dynamically operated reactors [6].

This study develops and applies an RNN model trained on data from a validated mechanistic simulation to reproduce the dynamic behaviour of a $CO_2$ methanation reactor fed with hydrogen produced via photovoltaic-powered electrolysis. The main objective is to quantify the impact of seasonal renewable fluctuations on reactor performance and stability, providing a computationally efficient modelling framework to support future Power-to-Gas technologies.

While the tool of RNNs has been used in the literature to construct hybrid, discrepancy-based models [6, 7], i.e., dynamic mechanistic models where the machine learning tool is used to bridge the gap between the first-principles equations and the real-life phenomenon, this work aims at using the machine learning tool to construct a fully black-box model for the dynamic calculation of key performance variables in a chemical reactor as a function of present and past values of one or more selected input variables. This with the aim to realise a model as efficient as possible for the design of an energy conversion reactor capable of dealing with non-constant input quantities.

## METHODS

The methodology adopted in this study consists of three main steps. First, a mechanistic reactor model was developed and validated to generate a synthetic dataset to support the machine learning model development. Subsequently, a surrogate dynamic model based on recurrent neural networks was designed and trained using this dataset. Finally, the model outputs were integrated into a black-box $CO_2$ methanation model to assess the dynamic behaviour of a PtG system and evaluate the performance and applicability of the predicted results.

### Mechanistic reactor modelling

The kinetic expression for the $CO_2$ methanation reaction is derived from the work of Pétremand *et al.* (2025) [8]. Additionally, the behaviour of the system around the thermodynamic equilibrium is characterised by adding two kinetic expressions for the methanation of CO and the water-gas shift reaction from the work of Xu and Froment (1989) [9]. The rates of these reactions are only significant when the composition of the system is slightly different from that at the thermodynamic equilibrium, but not enough for the rate of $CO_2$ methanation to bridge such gap on its own. For the rest of the integration, their influence is negligible.

**Table 1:** Reactions in the kinetic model for CO methanation.

| Reaction | Equation |
|---|---|
| $CO_2$ methanation | $CO_2 + 4H_2 \rightleftharpoons CH_4 + 3H_2O$ |
| CO methanation | $CO + 3H_2 \rightleftharpoons CH_4 + 2H_2O$ |
| Water-gas shift | $CO + H_2O \rightleftharpoons CO_2 + H_2$ |

The $CO_2$ methanation reactor considered in this study is a plate-type unit operating at 8 bar and thermally regulated with boiling water at 230 °C. The feed consists of biogas with a $CO_2$:CH4 ratio of 1:1, and hydrogen is supplied to achieve an inlet molar $H_2/CO_2$ ratio of 4. The dynamic behaviour of the reactor is represented using a one-dimensional dynamic model in which mass balances are pseudohomogeneous, while heat balances are heterogeneous.

The gas-phase component balance is expressed in Equation (1):

$$\frac{\partial F_i}{\partial t} + v_g \frac{\partial F_i}{\partial z} = v_g A \mathcal{D}_i \frac{\partial^2 c_i}{\partial z^2} + \rho_c (1-\varepsilon_b) v_g A \sum_{j=1}^{N_R} \nu_{ij} r_j \quad (1)$$

The energy balance equations for the gas and solid phases, respectively, are expressed in Equations (2) and (3):

$$\rho_g \hat{c}_{P_{mix}} \left(\frac{\partial T}{\partial t} + v_g \frac{\partial T}{\partial z}\right) = v_g A \frac{\partial}{\partial z}\left(\Lambda \frac{\partial T}{\partial z}\right) - v_g a_s h_s (T - T_s) - v_g a_e U (T - T_e) \quad (2)$$

$$(1-\varepsilon_b)\rho_s c_s \frac{\partial T_s}{\partial t} = -(1-\varepsilon_b)\rho_s \sum_{j=1}^{N_R} \Delta h_j^R r_j + v_g a_s h_s (T - T_s) \quad (3)$$

At the reactor inlet, the Danckwerts boundary conditions are applied, while zero-gradient Neumann conditions are imposed at the outlet by setting the second derivative of concentration and temperature to zero.

Hydrogen production from photovoltaic-powered electrolysis is determined using the efficiency $\eta_{el}$ of the proton exchange membrane (PEM) electrolyser, defined as:

$$F_{H_2} = \frac{\eta_{el} W_{el}}{HHV_{H_2}} \quad (4)$$

In this formulation, the electrical power $W_{el}$ corresponds to the installed photovoltaic capacity derived

from satellite observations for Milan, Italy, and an efficiency of 75% was assumed for the electrolyser.

## Artificial neural network development

An artificial neural network (ANN) is a machine learning model that processes information through interconnected computational units known as neurons. Each neuron processes input signals ($x$), turning them into outputs ($y$) through two steps:

1. A linear combination of weights $W$ and biases $b$;
2. A nonlinear activation function $\theta$.

In the simplest ANN architecture, called a feed-forward neural network (FFNN), the neurons are organised in subsequent layers. The inputs to the network are processed by an input layer, one or more hidden layers, and one output layer [10].

The network parameters are initialised randomly, then updated iteratively to minimise the error between the actual and predicted outputs, in a procedure called training. Each iteration of the procedure is called epoch, and the training ends when a sufficient agreement between the training outputs and the network prediction is reached.

This study employs a recurrent neural network (RNN), which extends the conventional feedforward architecture by incorporating feedback connections to process sequential data and capture temporal dependencies relevant to reactor dynamics. A gated recurrent unit (GRU) network is used, as its gating mechanisms preserve information over longer time sequences through the hyperbolic tangent (tanh) and the sigmoid ($\sigma$) activation functions [11]. The GRU is defined by its gating mechanism, which at each time step $k$ computes the reset gate $\boldsymbol{r}^{(k)}$, update gate $\boldsymbol{z}^{(k)}$, candidate gate $\boldsymbol{g}^{(k)}$, and the hidden state $\boldsymbol{h}^{(k)}$ (in the following equations, $\circ$ represents element-wise multiplication):

$$\boldsymbol{r}^{(k)} = \sigma\left(\boldsymbol{W}_r \boldsymbol{x}^{(k)} + \boldsymbol{R}_r \boldsymbol{h}^{(k-1)} + \boldsymbol{b}_r\right) \tag{5}$$

$$\boldsymbol{z}^{(k)} = \sigma\left(\boldsymbol{W}_z \boldsymbol{x}^{(k)} + \boldsymbol{R}_z \boldsymbol{h}^{(k-1)} + \boldsymbol{b}_z\right) \tag{6}$$

$$\boldsymbol{g}^{(k)} = \tanh\left(\boldsymbol{W}_g \boldsymbol{x}^{(k)} + \boldsymbol{r}^{(k)} \circ \left(\boldsymbol{R}_g \boldsymbol{h}^{(k-1)} + \boldsymbol{b}_g\right)\right) \tag{7}$$

$$\boldsymbol{h}^{(k)} = \left(\boldsymbol{1} - \boldsymbol{z}^{(k)}\right) \circ \boldsymbol{g}^{(k)} + \boldsymbol{z}^{(k)} \circ \boldsymbol{h}^{(k-1)} \tag{8}$$

Afterwards, the GRU hidden layer is linked to a fully connected output layer defined by its own weight vector and bias, yielding the network output $\boldsymbol{y}^{k}$:

$$\boldsymbol{y}^{(k)} = \boldsymbol{W}_y \boldsymbol{h}^{(k)} + \boldsymbol{b}_y \tag{9}$$

The RNN tool was used to produce a surrogate, data-driven model of the reactor where the only input feature is the hydrogen inlet flowrate, while the $CO_2$ is assumed to always be fed in stoichiometric amounts according to the Sabatier reaction ($CO_2$ methanation, Table 1). As output features, three performance variables for the methanation reactor were chosen in the hotspot temperature, the methane output flowrate, and the methane purity at the outlet.

As this study assesses a regression task, the predicted outputs are assessed against the target values using the mean squared error (MSE), which quantifies the average squared difference between the predictions $y_i$ and target values $\hat{y}_i$:

$$\mathcal{L}_{MSE} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \tag{10}$$

## Integration into an energy system model

The trained RNN was integrated into a model for the design of a system to provide a constant supply of $H_2$ to satisfy the yearly energy demand from fuel-cell-powered vehicles. In this model, it is assumed that $H_2$ is primarily used in decarbonised mobility. When $H_2$ is available in excess, it is stored in the form of methane. Then, methane is reformed to produce hydrogen when $H_2$ supply is not sufficient [12] The energy demand is assumed as a problem datum and marked as $W_{req}$. The model equates $W_{req}$ with the energy converted from solar to calculate the minimum PV panel surface required to meet the demand.

The energy from the PV panels is stored and converted according to three steps:

1. **electrolysis** to produce $H_2$,
2. **methanation** to convert the $H_2$ into $CH_4$,
3. **reforming** to reconvert the methane to hydrogen for use on vehicles.

Each of these steps is characterised by an efficiency value, resulting in the following equation for the conversion of the available energy $W_{av}$:

$$W_f = W_{av} \bullet \eta_{el} \bullet \eta_{meth} \bullet \eta_{ref} \tag{11}$$

While the efficiencies connected to the electrolysis and reforming steps are assumed constant ($\eta_{el} = 0.75, \eta_{ref} = 0.7$), the value of $\eta_{meth}$ can either be a constant empirical value of 0.7, or calculated for each day individually with the help of the RNN model (in which case it is denoted by $\eta_{RNN}$):

$$\eta_{RNN} = \frac{F_{CH_4}^{out} \bullet HHV_{CH_4}}{F_{H_2}^{in} \bullet HHV_{H_2}} \tag{12}$$

The available energy for conversion is determined from the solar irradiation intensity $I$ in the dataset:

$$W_{av} = I \bullet S_{PV} \tag{13}$$

The equivalence between $W_{req}$ and $W_f$ is then used to determine the required PV panel surface $S_{PV}$. Results are compared between the constant assumption of $\eta_{meth} = 0.7$ and the average of the daily values derived from the RNN model ($\eta_{RNN}$).

## RESULTS AND DISCUSSION

### Mechanistic reactor model validation

The mechanistic model was validated by reproducing the transient and steady-state behaviour of the reactor reported by Moioli *et al.* (2024) [13]. The transient thermal behaviour of the $CO_2$ methanation reactor was evaluated by analysing the temperature profiles every second minute during start-up. The modelling case used for the validation shown in Figure 1 has been obtained at a coolant temperature of 230°C, reactor pressure of 8 bar, and with an inlet composed of hydrogen and biogas in stoichiometric ratio, with the molar ratio of CO and $CH_4$ in the biogas assumed to be 1/1. The case in the figure refers to a step change in the inlet flowrate from 0% to 50% of the nominal design conditions of the reactor (3000 $h^{-1}$).

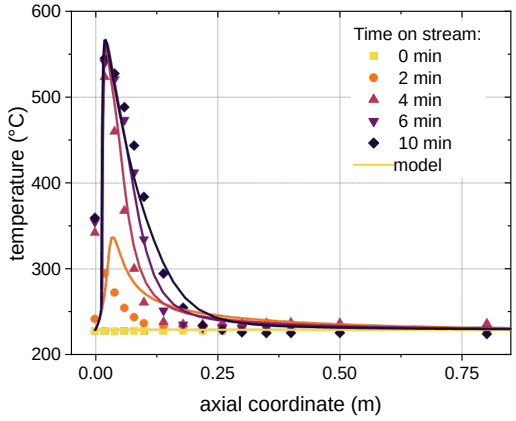

**Figure 1:** Temperature profile of the reactor during start-up at 50% load. Continuous lines represent the model results, scattered points the experimental data from [13].

At time-zero, the catalyst bed is preheated to 230°C. Upon feeding of $CO_2$, the reaction is initiated immediately, generating a hotspot whose axial width and peak temperature increase over time, reaching steady-state in under ten minutes. The mechanistic model successfully reproduces the start-up dynamics, closely matching the experimental observations. The discrepancies between the experimental and modelled profiles can be attributed to the difference between the catalysts used in the pilot-scale plant and in the work of Pétremand *et al.* [8].

The mechanistic model was subsequently validated through four simulations of the $CO_2$ methanation reactor, assessing its response to load variations, temperature evolution, concentration profiles, and axial temperature behaviour under different feed gas temperatures. In all cases, the reactor exhibited rapid thermal adaptation to changing operating conditions, and the model successfully reproduced key experimental reaction dynamics, including hotspot development and the attainment of grid-compliant methane. Overall, the simulated responses demonstrate the reliability and flexibility of the mechanistic model, confirming its suitability for generating representative training data.

### RNN development and performance evaluation

The RNN was trained using three target variables: hotspot temperature, methane dry molar fraction, and methane molar flow. These descriptors were selected as key indicators because they represent the thermal behaviour of the reactor, product quality, and productivity under fluctuating hydrogen supply. To ensure balanced learning across variables of different magnitudes, a standardisation procedure that transforms all target variables into a comparable numerical range was applied:

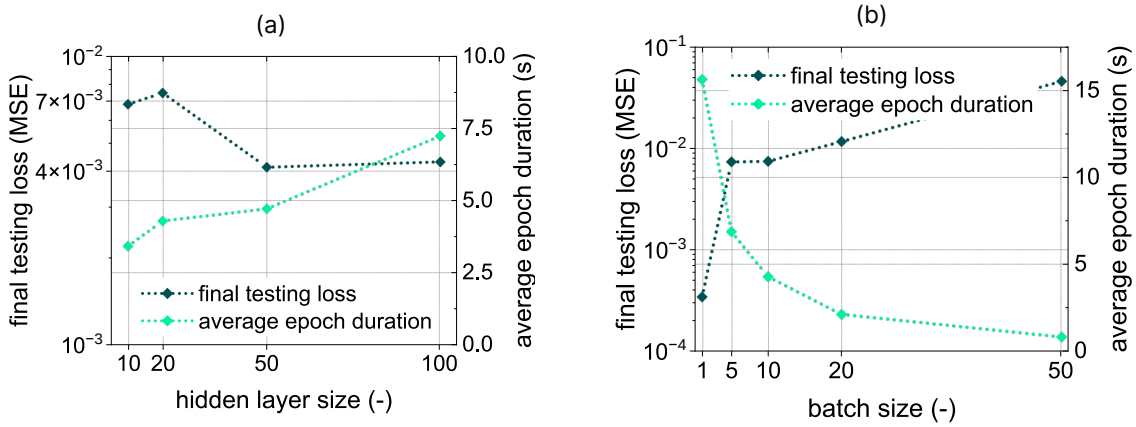

**Figure 2:** Effect of the number of neurons in the hidden layer (a) and of the training batch size (b) on the final performance of the RNN on the testing dataset – measured by mean squared error – and on the time required for the training.

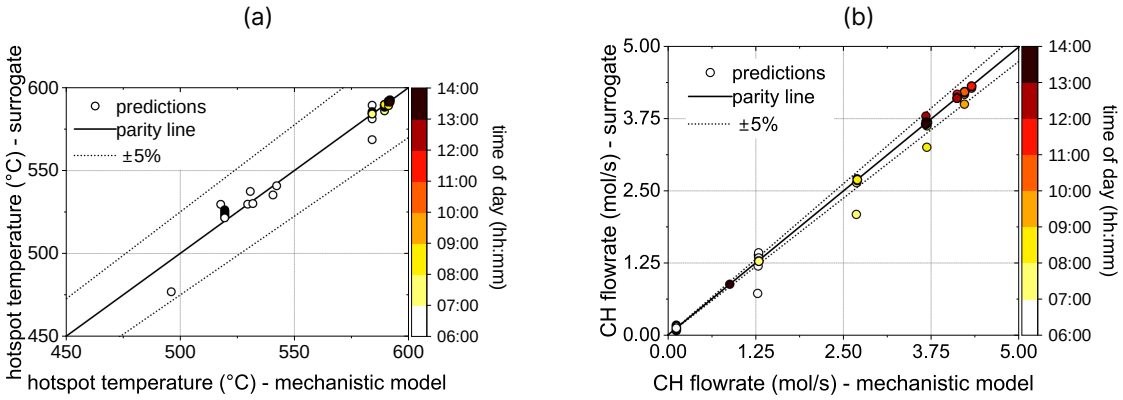

**Figure 3:** Parity plot for the hotspot temperature [°C] (a) and for the methane flowrate [mol/s] (b), comparing the values predicted by the RNN-based model (y axis) with those from the mechanistic model (x axis).

$$x_{i,sc} = \frac{(x_i - \mu_i)}{\sigma_i} \quad (14)$$

Where $\mu_i$ is the mean and $\sigma_i$ the standard deviation of feature $i$ across all datapoints. The scaling of the dataset allowed for stable convergence and close agreement between the predictions and the mechanistic model.

A sensitivity analysis was then performed to evaluate the influence of the hidden layer size, and batch size on model performance, whose results are reported in Figure 2. An increase in the hidden layer size did not lead to a clear improvement in the performance, but rather to a slight increase in the time needed for training. In machine learning theory, it is well established that increasing the number of neurons in hidden layers generally improves the accuracy of a neural network, but also that an excessive parametrisation may increase the risk of overfitting [6, 11]. The layer size for the following evaluations was therefore limited to 20 as a compromise to achieve relative accuracy while maintaining a low risk of overfitting and a manageable training time.

The sensitivity analysis on the batch size showed a clear trade-off between computational time and prediction accuracy: larger batch sizes reduced epoch duration but increased the testing loss. A batch size of 10 was adopted for the following evaluations, due to lower values also increasing the risk of overfitting.

The parity plots presented in Figure 3 offer an effective visual assessment of the model performance by comparing predicted values with their corresponding reference data for both output variables: the hotspot temperature, in °C, and the methane output of the reactor, in mol/s. Again, a strong agreement is shown between the predictions from the RNN model and those from the mechanistic model.

The parity plots show most data points lying close to the parity line, indicating that the RNN accurately reproduces the nonlinear behaviour of the mechanistic model under dynamic conditions. The highest deviations appear for the methane output at the extremes of the daytime range (lighter yellow datapoints), reflecting a reduced accuracy when the reactor operates at very low space velocities. These discrepancies remain limited and do not significantly affect overall predictive performance.

The parity plots confirm that the RNN captures both the steady-state and transient responses of the $CO_2$ methanation reactor with high fidelity.

Figure 4 compares the entire daily profile of the outlet flowrate of methane predicted by the mechanistic ground truth model and the RNN-based model, respectively. The strong agreement shown in the parity plot in Figure 2b between the predictions by the RNN and the mechanistic model is again made visible, confirming the ability of the network to capture the variation of key performance variables following a change in the hydrogen supply to the $CO_2$ methanation reactor.

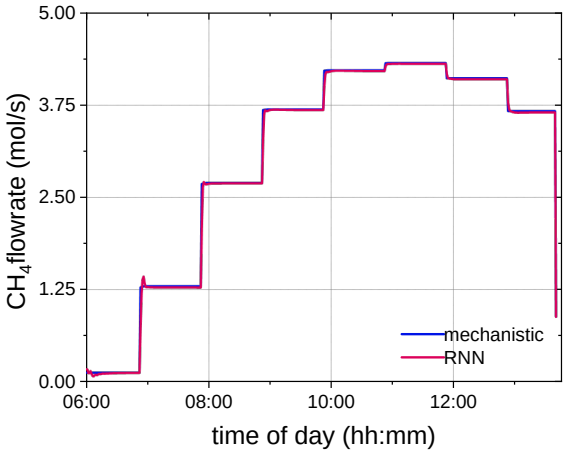

**Figure 4:** Comparison between the methane flowrate values [mol/s] predicted by the mechanistic model and the RNN-based model.

**Table 2:** Comparison of technical indicators obtained from the power-to-gas energy system using three modelling approaches.

| | Constant efficiency | Average RNN efficiency |
|---|---|---|
| PV surface required $[\mathrm{m}^2]$ | 1001 | 989 |
| Active days per year of the storage system $[\mathrm{d}]$ | 257 | 254 |
| Required amount of energy carrier ($CH_4$) per year $[\mathrm{ton}]$ | 9.20 | 8.98 |
| Required amount of biogas per year $\left[\frac{\mathrm{m}^3}{\mathrm{h}}\right]$ | 0.732 | 0.718 |

## Integration into the energy system model

The recurrent neural network was integrated into the energy system model by applying the daily power-to-gas efficiency profile calculated in Equation (12). These daily efficiency values were incorporated into the macroscopic energy balance described in Equation (11), linking the dynamic reactor behaviour with the overall energy system evaluation. For comparison, the RNN results were assessed against those obtained using a constant efficiency value for the methanation block, as commonly done in energy system analysis [14]. The results are summarised in Table 2.

When comparing the constant efficiency evaluations with the ones conducted using a dynamic efficiency profile, some notable differences are found. First, the higher efficiencies calculated by the RNN model result in a 1.2% lower surface of PV panels needed to meet the energy demands, and a lower need for the energy storage system, which is used 3 days fewer than what calculated using the standard efficiency value.

This reduces the amount required over a year for both the energy carrier (-2.4%) and the biogas (-1.9%), leading to a more efficient use of resources.

These results show that integrating a dynamic efficiency profile, calculated with the help of a model, directly improves the energy balance and storage behaviour of the system model, whereas assuming constant efficiencies fails to capture the daily variations in performance. Including these variations provides a more realistic representation of the response of the PtG system to the intermittency typical of renewable energy sources.

# CONCLUSIONS

This study developed and evaluated a recurrent neural network (RNN) framework for the dynamic modelling of a $CO_2$ methanation reactor powered by renewable hydrogen. The research aimed to bridge the gap between detailed mechanistic modelling, which provides high physical fidelity but is computationally intensive, and data-driven modelling, which enables fast, flexible, and adaptive simulations. The methodology consisted of three main stages: mechanistic model validation, RNN development, and a system evaluation within a Power-to-Gas (PtG) configuration.

In the first stage, a one-dimensional mechanistic reactor model using pseudohomogeneous component balances and heterogeneous energy balances was developed and validated with established $CO_2$ methanation kinetics. The model successfully reproduced the steady-state and transient responses reported in the literature [13], including the rapid thermal adaptation to load changes in the reactor, the evolution of the hotspot, and the corresponding concentration profiles. This validation confirmed the model as a reliable tool generating dynamic data representative of operating conditions influenced by fluctuating hydrogen inputs.

The second stage focused on developing and training the RNN using synthetic data produced by the mechanistic simulations. The hotspot temperature, methane dry molar fraction, and methane molar flow were selected to represent the thermal behaviour of the reactor, product quality, and productivity. Standardisation was essential to achieve balanced learning and stable convergence. A sensitivity analysis of network architecture showed that an increase in parametrisation (hidden layer size, network depth) had a limited influence on predictive accuracy, whereas the evaluation of the batch size revealed a clear trade-off between computational time and model performance. The final architecture, consisting of one hidden layer with 20 neurons and trained using a batch size of 10, provided the best balance between accuracy and efficiency. The trained RNN reproduced the nonlinear reactor dynamics with high fidelity, as demonstrated by strong agreement between predicted and mechanistic model outputs.

In the third stage, the RNN was integrated into a black-box PtG model to evaluate the system performance under daily and seasonal variability in hydrogen production from photovoltaic electrolysis. Compared to a constant efficiency assumption, the inclusion of dynamic daily efficiencies significantly altered the predicted behaviour of the chemical storage system. The dynamic case showed substantial decreases in the operating days needed to meet the energy demand, with a consequent decrease in the usage of methane and biogas, and in the PV panel surface required, demonstrating that simplified

efficiency assumptions notably overestimate the operational demands of the system.

Overall, this work demonstrates that RNNs offer an effective and computationally efficient surrogate for dynamic reactor modelling. The framework developed here constitutes a practical methodological approach that combines the accuracy of mechanistic models with the speed of data-driven ones, supporting future efforts in developing efficient optimisation and control strategies for flexible, renewable-driven chemical processes.

## TABLE OF VARIABLES

### Mechanistic model

| | | |
|---|---|---|
| $A$ | reactor cross-section | $m^2$ |
| $a_s$ | specific surface for interphase heat exchange | $m^{-1}$ |
| $c_i$ | concentration of species $i$ | $mol/m^3$ |
| $\hat{c}_{P_{mix}}$ | mass-specific heat of gas mixture | $J/kg \cdot K$ |
| $c_s$ | specific heat of solids | $J/kg \cdot K$ |
| $\mathcal{D}_i$ | axial dispersion coefficient of species $i$ | $m^2/s$ |
| $F_i$ | molar flowrate of component $i$ | $kmol/s$ |
| $HHV_i$ | higher heating value of species $i$ | $J/mol$ |
| $h_s$ | interphase heat exchange coefficient | $W/m^2 \cdot K$ |
| $\dot{m}$ | total mass flowrate | $kg/s$ |
| $r_j$ | rate of reaction $j$ | $kmol/m^3 \cdot s$ |
| $T$ | temperature | $K$ |
| $T_e$ | coolant temperature | $K$ |
| $T_s$ | temperature of solid phase | $K$ |
| $t$ | time | $s$ |
| $U$ | global heat transfer coefficient | $W/m^2 \cdot K$ |
| $v_G$ | gas velocity | $m/s$ |
| $W_{el}$ | available electrical power | $W$ |
| $z$ | axial reactor coordinate | $m$ |
| $\Delta h_j^R$ | enthalpy of reaction $j$ | $J/mol$ |
| $\varepsilon_b$ | bed void fraction | - |
| $\eta_{el}$ | electrolyser efficiency | - |
| $\nu_{ij}$ | stoichiometric coefficient of species $i$ in reaction $j$ | - |
| $\rho_C$ | catalyst density | $kg/m^3$ |

### Surrogate model

| | |
|---|---|
| $\boldsymbol{b}_g$ | bias of gate $g$/output layer $y$ |
| $\boldsymbol{g}^{(k)}$ | candidate gate output at timestep $k$ |
| $\boldsymbol{h}^{(k)}$ | network hidden state at timestep $k$ |
| $\boldsymbol{R}_g$ | recurrent weights of gate $g$ |
| $\boldsymbol{r}^{(k)}$ | reset gate output at timestep $k$ |
| $\tanh(\bullet)$ | hyperbolic tangent activation function |
| $\boldsymbol{x}^{(k)}$ | network input at timestep $k$ |
| $\boldsymbol{y}^{(k)}$ | network output at timestep $k$ |
| $\boldsymbol{W}_g$ | input weights of gate $g$/output layer $y$ |
| $\boldsymbol{z}^{(k)}$ | update gate output at timestep $k$ |
| $\sigma(\bullet)$ | sigmoid activation function |

### Energy system model

| | | |
|---|---|---|
| $F_i^{in}$ | inlet flowrate of component $i$ | $kmol/s$ |
| $F_i^{out}$ | outlet flowrate of component $i$ | $kmol/s$ |
| $I$ | solar intensity | $W/m^2$ |
| $S_{PV}$ | total surface of PV panels | $m^2$ |
| $W_{av}$ | available power from PV plant | $W$ |
| $W_f$ | enthalpy content of final product | $W$ |
| $\eta_{el}$ | electrolyser efficiency | - |
| $\eta_{meth}$ | thermal efficiency of methanation (constant hypothesis) | - |
| $\eta_{RNN}$ | thermal efficiency of methanation (from surrogate model) | - |

## ABSTRACT

Rapid, sustainable redesign of large functional molecules demands efficient exploration of vast chemical spaces. Chemical language models (CLMs), especially transformers, can learn long-range structure-property relationships and enable fast candidate generation after training. However, inverse molecular design is ill-posed – many structures can meet the same target – and conditioned generation often decodes to invalid or off-spec molecules. To address this challenge, we propose a CLM-based inverse design framework that optimises latent representations toward target properties and explicitly evaluates round-trip fidelity, i.e., whether decoded candidates remain on-target after decoding and forward re-evaluation. To improve reliability, we introduce post-decoding beam re-ranking using round-trip consistency and a predictor-guided minimal-edit repair step that corrects invalid near-misses while preserving closeness to the target property. We demonstrate the approach on surfactant critical micelle concentration (CMC) design, benchmarking existing large pretrained CLMs against our lightweight domain-trained CLM. The framework produces a high proportion of valid and diverse molecules (~90%) while maintaining target property error near 1%. Moreover, atom-level saliency analysis confirms that the generated structures follow established surfactant design rules, supporting interpretable structure–property control. Overall, the framework provides an efficient and broadly applicable solution to reliable inverse design of novel functional molecules.

**Keywords**: Inverse molecular design, chemical language models, transformers, interpretable AI, surfactants

## 1. INTRODUCTION

Across home and personal care, food, and speciality chemicals, many formulation industries face a portfolio-level redesign challenge driven by sustainability targets and tighter timelines [1]. Large fractions of core ingredient families – including surfactants – must be updated while preserving cost and performance. Yet developing new functional molecules remains slow and expensive: synthesis-test-validate cycles are labour-intensive, and even high-throughput workflows remain constrained by synthesis, characterisation, and safety testing [2]. Virtual screening can prioritise candidates, but for large, flexible amphiphiles, simple descriptor filters can be weakly informative while high-fidelity simulation becomes computationally intractable at scale [3]. This motivates tools that rapidly propose a small, diverse set of chemically valid, on-target candidates for portfolio-scale redesign.

Machine learning offers a route to accelerate both property prediction and molecular generation. In this work we use SMILES strings, which represent molecules as compact token sequences compatible with modern sequence models [4]. For the forward task, structure-property prediction is commonly addressed using descriptor/fingerprint-based regressors, kernel methods, graph neural networks, and other supervised deep learning models [5]. The reverse task – finding structures that meet target properties – is ill-posed: many distinct molecules can satisfy the same specification. Existing inverse-design approaches include brute-force screening, Bayesian optimisation over enumerated libraries and evolutionary-inspired mutations to strings or graphs [6, 7] but maintaining validity and reliable property control remains challenging over large combinatorial spaces.

To overcome these limitations, a more scalable approach is latent-space optimisation, where embeddings

represent molecules. A differentiable model learns to map the embeddings to the properties, and gradients are used to steer the embeddings toward the target property [8]. Autoregressive decoding generates a candidate token-by-token, each token conditioned on the previously generated tokens and the conditioning signal – a prompt or latent embedding – while beam search maintains the top-scoring partial sequences until an end-of-sequence token is produced. Sequence models, such as recurrent neural networks (RNNs) [9] and long short-term memory (LSTM) [10] networks, have been effective in de novo drug and organic molecule design. Transformers model long-range interactions via self-attention, which is valuable for large molecules whose properties depend on distributed motifs (e.g., head-tail interactions), and benefit from large-scale pretraining on unlabelled molecular structure corpora [11]. Chemical language transformers have been used in crystal property prediction [12], small-molecule inverse design and property prediction [13], and polymer inverse design and property prediction [14]. For surfactants, however, systematic transformer-based inverse design remains comparatively underexplored: recent studies use reinforcement learning [15] for inverse surfactant design and foundation models for phase-diagram prediction [16]. Overall, best practices for transformer-driven large-molecule inverse design remains an open area of research.

Most importantly, when a generator is conditioned – via a prompt or latent embedding – to meet a specified target, candidates must still satisfy the target after decoding and re-evaluation with the forward property predictor. Therefore, a core contribution of this research is to formalise and quantify this requirement as the round-trip fidelity. This behaviour is seldom reported in inverse-design studies [6] yet is critical for practical adoption, or else there is a risk of wasting experimental validation later. Accordingly, this work formalises, diagnoses, and mitigates round-trip fidelity failures for surfactant inverse design. We introduce two control strategies: (1) post-decoding re-ranking of beam candidates using round-trip consistency, and (2) predictor-guided minimal-edit repair that converts invalid near-miss SMILES into valid molecules while preserving property fidelity. We demonstrate the approach on a surfactant critical micelle concentration (CMC) design case study, benchmarking pretrained chemical language models and a lightweight domain-trained CLM, analysing novelty/diversity and atom-level saliency consistency with established surfactant structure–property design rules.

The remainder of this paper is organised as follows: Section 2 presents the model, latent optimisation, round-trip metrics, re-ranking, and repair; Section 3 describes the dataset and CMC case study; Section 4 reports the results; and Section 5 concludes with future directions.

## 2. METHODOLOGY

We first outline the backbone of our framework. A transformer-based encoder-decoder model was implemented with a property regressor to enable inverse molecular design. The encoder maps discrete molecular structures, represented as tokenised SMILES strings, to a continuous embedding space. A regressor maps this embedding to the molecular properties of interest, and the decoder reconstructs SMILES from the embeddings. Inverse design is performed by optimising over the latent embedding space to match the target property, decoding the optimised embedding to candidate SMILES, then applying round-trip validation, re-ranking, validity screening, and minimal-edit repair to improve reliability.

### 2.1. Constructing the Chemical Language Transformer Model

Building on this, our encoder-decoder transformer model was constructed for molecular representation and generation, trained from scratch on a large, unlabelled, augmented domain-specific dataset of molecule structures. The *HuggingFace* [17] *EncoderDecoderModel* class was used to build and manage the transformer architecture, enabling integration of our tokenisers, embedding layers, and downstream decoding pipelines.

SMILES strings are tokenised using byte-pair encoding trained on a large surfactant-like corpus (Section 3) to capture repeated chemical motifs and shorten sequences for long amphiphiles. Sequences are padded/truncated to a maximum length of 128. The model architecture consisted of two transformer stacks: a 2-layer encoder and a 2-layer decoder, each with 2 attention heads and an embedding size of 32. The number of transformer stacks (i.e., 8, 4, 2) and the embedding size (i.e., 128, 64, 32) were reduced until an elbow point was observed in SMILES reconstruction accuracy.

### 2.2. Property Regressor and Multitask Model Structure

Within this architecture, the encoder produces a contextual embedding that captures general chemical syntax, motifs and patterns. As illustrated in Figure 1, this shared representation then feeds the two heads of the multitask model structure: a decoder for SMILES reconstruction and a regressor that maps the embedding to the molecular properties of interest.

Let $\boldsymbol{Z} \in \mathbb{R}^{L \times d}$ denote the encoder output (contextual token embeddings). To predict the property of interest, $\boldsymbol{Z}$ is flattened to a vector $\boldsymbol{z} \in \mathbb{R}^{L \cdot d}$, concatenated with any relevant covariate conditions $\boldsymbol{c}$ (e.g., temperature) and then passed to a differentiable regressor $r([\boldsymbol{z}; \boldsymbol{c}]) \mapsto \hat{y}$. In this work, we use a linear regressor, while partial least squares (PLS) will later be used for compression and manifold-based optimisation (Section 2.6).

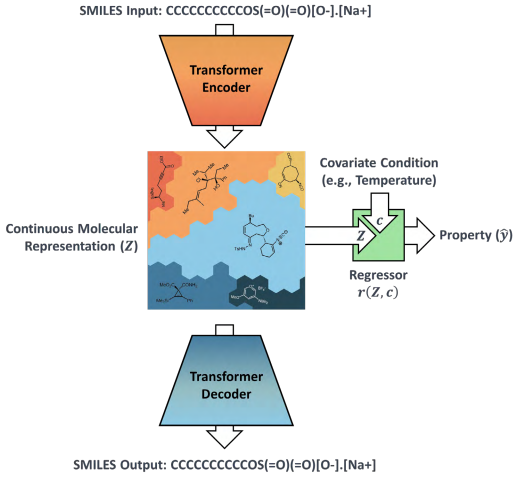

**Figure 1.** Multitask transformer architecture: a SMILES is encoded as an embedding that is then reconstructed or used to predict the molecular property under a covariate.

## 2.3. Transformer Pretraining and Multitask Finetuning

Training proceeded in two stages. The encoder–decoder was first pretrained on the large unlabelled surfactant-like corpus for SMILES reconstruction. It was then finetuned on a smaller labelled dataset using a multitask loss combining reconstruction and regression:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{recon}} + \lambda_{\text{reg}} \cdot \mathcal{L}_{\text{reg}} \tag{1}$$

Where $\mathcal{L}_{\text{recon}}$ is the cross-entropy loss between the predicted and ground-truth SMILES tokens, and $\mathcal{L}_{\text{reg}} = (\boldsymbol{y} - \hat{\boldsymbol{y}})^2$ is the mean squared error between the predicted, $\hat{\boldsymbol{y}}$, and true property, $\boldsymbol{y}$, values, and $\lambda_{\text{reg}} = 1$ is a weighting coefficient. Pretraining (~28 hours) and finetuning (~30 minutes) were performed on V100 (20 GB) and RTX 4060 (8 GB) GPUs, respectively.

## 2.4. Inverse Design via Latent Embedding Optimisation

Once the transformer-regressor was trained, we then performed inverse molecular design by optimising in the continuous embedding space to identify candidate molecules with a desired target property, as illustrated in Figure 2. Given a target value $y_{\text{target}}$, inverse design seeks an embedding, $\boldsymbol{Z} \in \mathbb{R}^{L \times d}$, whose predicted property matches the target, $y_{\text{target}} \approx r([\boldsymbol{z}; \boldsymbol{c}])$, as shown in Eqn. 2a. We use gradient-based optimisation and encourage diversity using a swarm of candidates $\{\boldsymbol{Z}^{(n)}\}$ optimised in parallel. Two penalties, $P(\boldsymbol{z})$, defined in Eqn. 2b were added to the total loss: (i) a quadratic repulsion term and (ii) a penalty on a point's squared Mahalanobis distance, $D_M$, [18], to the centre of the training dataset distribution.

$$\mathcal{L}^{(n)} = \left(r([\boldsymbol{c}; \boldsymbol{z}]) - y_{\text{target}}\right)^2 + P(\boldsymbol{z}) \tag{2a}$$

$$P(\boldsymbol{z}) = \lambda_1 \sum_{n \neq m} \left\| \boldsymbol{z}^{(n)} - \boldsymbol{z}^{(m)} \right\|_2^2 + \lambda_2 D_M(\boldsymbol{z}^{(n)}, \bar{\boldsymbol{z}}) \tag{2b}$$

$$D_M(\boldsymbol{z}, \bar{\boldsymbol{z}}) = (\boldsymbol{z} - \bar{\boldsymbol{z}})^{\mathrm{T}} \boldsymbol{\Sigma}^{-1} (\boldsymbol{z} - \bar{\boldsymbol{z}}) \tag{2c}$$

The squared Mahalanobis distance, $D_M$, is defined in Eqn. 2c, where $\boldsymbol{\Sigma} \in \mathbb{R}^{L \cdot d \times L \cdot d}$ is the covariance matrix, and $\bar{\boldsymbol{z}} \in \mathbb{R}^{L \cdot d}$ is the mean flattened embedding over the training dataset. Pairwise quadratic repulsion spreads swarm members apart regardless of direction, discouraging collapse to a single solution. Mahalanobis distance is distribution-aware, pulling designs toward chemically plausible regions of the embedding space supported by the training dataset, accounting for anisotropy and correlated dimensions.

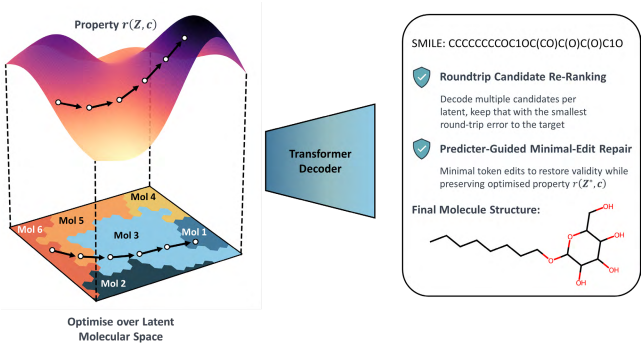

**Figure 2.** Inverse-design workflow: optimise over a learned property surface, $r(\boldsymbol{z}; \boldsymbol{c})$, toward the target, decode to SMILES, re-rank by round-trip error, and repair invalid near-misses.

## 2.5. Round-Trip Consistency Metric

After optimisation, each candidate embedding is decoded to SMILES. Because decoding may not preserve the intended latent state, we perform a round-trip check: for each optimised embedding, $\boldsymbol{Z}^*$, we (1) decode $\boldsymbol{Z}^*$ to generate a SMILES string $\boldsymbol{s}$, (2) re-encode $\boldsymbol{s}$ using the encoder to obtain the round-trip optimised embedding, $\boldsymbol{Z}^*_{\text{rt}}$, and then (3) flatten both embeddings and predict their properties using the regressor: $\hat{y}^* = r([\boldsymbol{z}^*; \boldsymbol{c}]), \hat{y}^*_{\text{rt}} = r([\boldsymbol{z}^*_{\text{rt}}; \boldsymbol{c}])$. Two consistency metrics were defined. The first was the round-trip MAPE between $\hat{y}^*_{\text{rt}}$ and $y_{\text{target}}$, quantifying how well the decoded molecule retained the desired property. To quantify how much the decoder perturbed the embedding representation, the second was the percentage Euclidean distance (PED) between $\boldsymbol{Z}^*$ and $\boldsymbol{Z}^*_{\text{rt}}$, defined in Eqn. 3. A high PED signals structural inconsistency introduced during decoding.

$$\text{PED} = 100 \times \frac{\|\boldsymbol{Z}^* - \boldsymbol{Z}^*_{\text{rt}}\|_2}{\|\boldsymbol{Z}^*\|_2} \tag{3}$$

To reduce decoding sensitivity, we use beam search to generate multiple candidates and re-rank candidates using round-trip consistency, selecting low-drift and/or low-error candidates, as reported in Section 4.

## 2.6. Latent-Manifold Optimisation

We perform inverse design in a latent space that captures the dominant directions of variation relevant to the target property. This was achieved by projecting the full embedding into a low-dimensional manifold and optimising within this space. To learn a suitable manifold, partial least squares (PLS) regression was fitted on the flattened embedding vectors, $\boldsymbol{z} \in \mathbb{R}^{L \cdot d}$, and the target property, $y$. This yields the linear projection in Eqn. 4a, with rotations $\mathbf{R} \in \mathbb{R}^{L \cdot d \times k}$, loadings $\mathbf{P} \in \mathbb{R}^{L \cdot d \times k}$, and scores $\boldsymbol{t} \in \mathbb{R}^{k}$, such that $\boldsymbol{t}$ lies in a $k$-dimensional subspace aligned with property-relevant variation. We reduced $k$ until an elbow point in SMILES reconstruction and property prediction accuracy was observed. A linear head was then fitted on the scores concatenated with the covariate condition, as shown in Eqn. 4b.

$$\boldsymbol{t} = (\boldsymbol{z} - \bar{\boldsymbol{z}})\mathbf{R} \tag{4a}$$

$$\hat{y} = r([\boldsymbol{t}; \boldsymbol{c}]) \tag{4b}$$

At inverse design time, $\boldsymbol{c}$ was fixed and $\boldsymbol{t} \in \mathbb{R}^{k}$ was optimised subject to the property loss and penalty terms described before (e.g., swarm repulsion and distribution-aware tether), now in the latent score space. Afterwards, the optimised scores were then mapped back to a flattened embedding vector using Eqn. 5, reshaped back to a matrix and decoded to SMILES.

$$\boldsymbol{z}^{*} = \bar{\boldsymbol{z}} + \boldsymbol{t}^{*}\mathbf{P}^{\mathrm{T}} \tag{5}$$

To improve reconstruction fidelity, the multitask transformer can optionally be finetuned on the manifold-projected embeddings to better align the decoder with the subspace geometry.

## 2.7. Predictor-Guided Minimal-Edit Repair

Invalid SMILES are handled with a lightweight repair step. We first apply simple deterministic normalisations (e.g., minor punctuation/bracket fixes) and test validity with RDKit sanitisation. If still invalid, we perform a bounded search over minimal token edits (prioritising punctuation-like tokens commonly responsible for SMILES failures, expanding to atom tokens only if needed). Valid repaired candidates are scored by proximity to $y_{\mathrm{target}}$ and the closest candidate is returned.

# 3. SURFACTANT CASE STUDY AND DATASET PREPARATION

We evaluated the framework on surfactant critical micelle concentration (CMC) design – a nonlinear, emergent property influenced by both molecular structure and environmental conditions such as temperature.

The labelled dataset contains 965 surfactant SMILES with experimentally measured CMC values and temperatures [19]. CMC (mM) is log-transformed, and the dataset is split into train/validation/test = 70/15/15. To construct a domain-relevant pretraining corpus, each labelled surfactant was augmented with structurally similar molecules retrieved from PubChem [20] using a Tanimoto fingerprint similarity threshold of 0.60 yielding >15 million unique valid SMILES. All SMILES were sanitised and canonicalised using RDKit to remove invalid structures and duplicates. A BPE tokeniser was trained on this augmented corpus to compress frequent motifs (e.g., headgroups and alkyl segments), improving sequence efficiency for long amphiphiles.

# 4. RESULTS AND DISCUSSION

## 4.1. Property Prediction and Reconstruction Performance

**Table 1.** Comparison transformer models' performance.

| Model | Parameters (million) | Train $R^2$ | Test $R^2$ | Reconstruction Similarity |
|---|---|---|---|---|
| ChemBERTa | 77 | 0.85 | 0.83 | - |
| SMI-TED | 289 | 0.95 | 0.81 | 80% |
| MolT5 | 250 | **0.94** | **0.80** | 84% |
| Our CLM | **0.43** | 0.89 | **0.80** | **89%** |

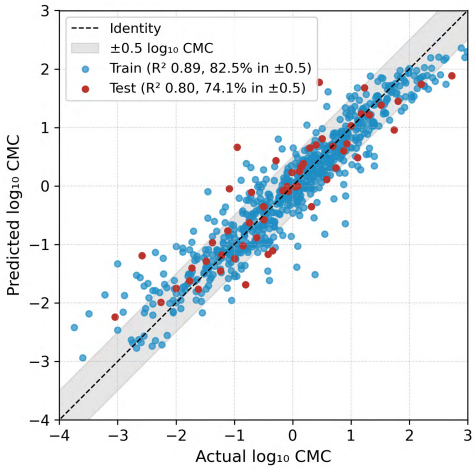

**Figure 3.** Predicted vs experimental $\log_{10}$ CMC. Shaded band marks ±0.5 $\log_{10}$ CMC with 82.5% and 74.1% of the training and testing points falling within this tolerance.

We first verified that the models used in the inverse-design loop provide (1) sufficient CMC prediction accuracy and (2) adequate encode–decode reconstruction, since round-trip evaluation depends on decoding candidates and re-evaluating them. Table 1 compares three pretrained chemical language models (ChemBERTa [11], SMI-TED [21], MolT5 [22]) to our CLM trained on an augmented surfactant dataset. Across models, property prediction test performance is similar ($R^2 \approx 0.80$–$0.83$), but

reconstruction is weaker for the pretrained models (80–84% exact matches) than for our CLM (89%), consistent with domain mismatch on long, motif-rich surfactant SMILES. Despite being much smaller (0.43M parameters), our CLM provides adequate accuracy. Figure 3 illustrates the train/test parity using our CLM where 74.1% of test points fall within ±0.5 $\log_{10}$ CMC, meeting typical industrial screening tolerances. Therefore, henceforth, we will use our CLM.

## 4.2. Diagnosing and Mitigating Round-Trip Inconsistencies

We evaluated inverse design on 50 target $\log_{10}$ CMC values evenly spaced from −2 to +2 at 25 °C. For each target, we optimise a latent embedding to match the target under the forward regressor, decode to SMILES, and re-evaluate the decoded molecule. A consistent failure mode emerged: embeddings could be optimised to match the target, yet decoded molecules were often off-target. To diagnose the cause, we calculated embedding drift as defined in Eqn. 3. Figure 4 shows drift occurs primarily on the first decode–re-encode (e.g., PED ≈ 33% after round-trip 1, falling to ~0% by round-trip 3), consistent with greedy decoding "snapping" to a nearby high-probability molecule that is stable under subsequent round-trips but not the intended latent optimum.

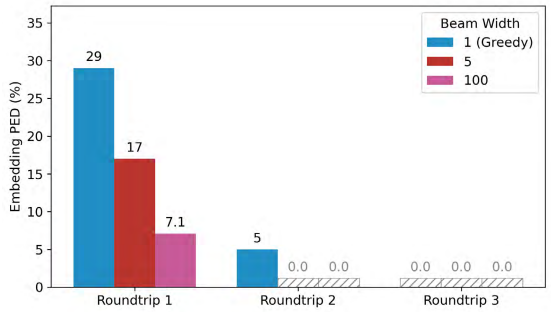

**Figure 4.** Impact of beam width on round-trip embedding stability, where PED is percentage Euclidian distance.

To mitigate snapping, we use beam search and a post-decoding re-ranking step: generate candidates (beam widths 1, 5, 100), re-encode each, and select the candidate with the smallest PED. Re-ranking improves both fidelity and stability: at beam width 100, average round-trip MAPE decreases from 20% to 5.1% and PED decreases from 29% to 7.1%. With re-ranking in place, decoder fine-tuning further improves round-trip fidelity (MAPE 5.1% → 0.7%), showing that round-trip accuracy – rarely reported in prior work – is crucial to ensure that the designed molecules reflect the optimisation objectives.

## 4.3. Molecular Structure Validity

SMILES validity remains a bottleneck: many near-target candidates are invalid due to small syntactic/chemical errors. Table 2 summarises the fidelity–validity trade-off under three post-processing strategies applied after decoding.

**Table 2.** Effect of validity filtering and SMILES repair on the round-trip target error.

| | Round-Trip MAPE (%) | SMILES Validity (%) |
|---|---|---|
| No Post-Processing | 0.7 | 6% |
| With Validity Filtering | 56% | 14% |
| Property-Guided Repair | **1.1%** | **90%** |

Beam-decoded candidates were initially selected by target property error – this is reported as the no post-processing result in Table 2 – yielding low error (MAPE 0.7%) but very low validity (6%). Instead, from each beam of decoded sequences, we retained only chemically valid SMILES (i.e., via RDKit sanitisation). Within this valid subset, we selected the molecule with the lowest round-trip drift relative to the optimised embedding. This increased validity to 14% but introduced a trade-off: the reduced candidate pool inflated target property deviation, with round-trip MAPE rising from 0.7% to 56%. This highlights a tension between enforcing strict validity and maintaining property fidelity; ideally, validity should be enforced during decoding, or by using less aggressive sanitisation techniques. We addressed this with predictor-guided minimal-edit repair: invalid near-misses are minimally edited to restore validity, then re-ranked by round-trip drift, recovering ~84% of invalid outputs and achieving 90% validity with a round-trip MAPE of 1.1%.

## 4.4. Property Trends and Design Interpretability

We finally check that the designed molecules are chemically plausible and interpretable. Figure 5 shows representative designs across the target range, paired with nearest neighbours from the training set. No exact matches to the training set were observed; average nearest-neighbour Tanimoto similarity was 0.31, and adjacent-target designs remain diverse (average Tanimoto 0.20). To our knowledge, all of the generated surfactants were entirely novel. The generated molecules follow established surfactant trends: molecules generated under lower CMC targets favour longer hydrophobic tails, while molecules generated under higher CMC targets favoured shorter tails and more polar/ionic headgroups (e.g., amines, ammonium salts, carboxylates) [23].

It is essential to understand why a model makes a specific prediction and which substructures influence the property of interest. To this end, gradient-based atom-level saliency [24] was carried out in this work. The saliency scores are visualised in Figure 5, where atoms with score > 0 that locally increase $\hat{y}$ are shaded red, while atoms with score < 0 that locally decrease $\hat{y}$ are shaded

blue. Saliency agrees with existing surfactant design rules: hydrophobic alkyl tails decrease CMC (blue), while polar/ionic headgroups increase CMC (red) [23]. Branching/heteroatoms in the tail tend to raise CMC, while linker effects (ethers/esters) are modest and context dependent. Furthermore, these saliency motifs align between designed and nearest-neighbour structures (e.g., the same headgroup and the same tail segments receive similar signs), reinforcing that the model has learned chemically meaningful structure-property relationships.

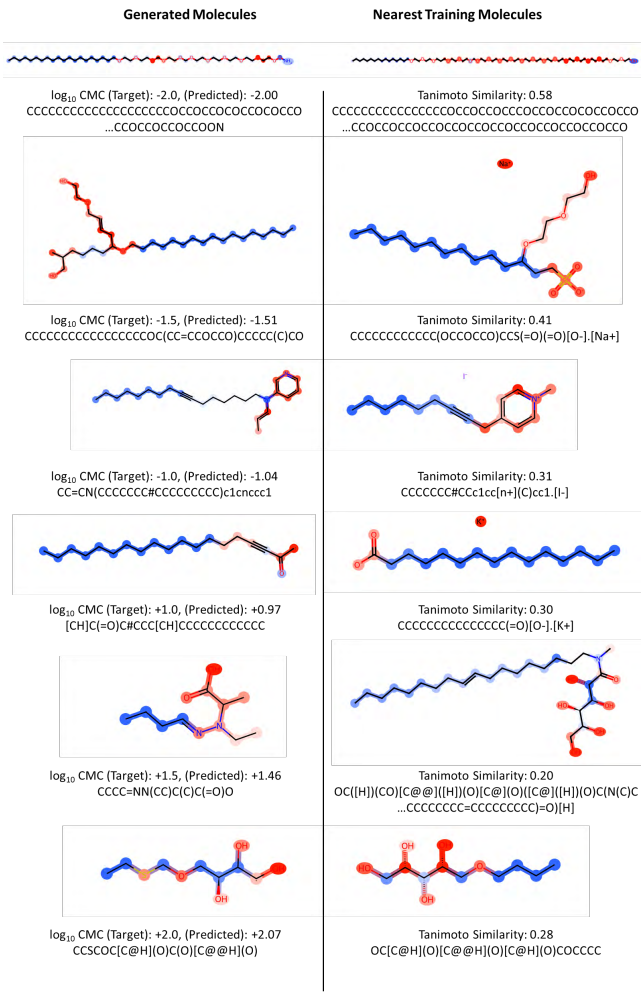

**Figure 5.** Representative generated surfactants across the target $\log_{10}$ CMC range (left) paired with nearest training-set analogues by Tanimoto similarity (right). Bonds/atoms are coloured by attribution to predicted CMC (blue: decreases CMC; red: increases CMC; intensity: magnitude).

## 5. CONCLUSION

In this work, we presented a transformer-based chemical language model (CLM) workflow for inverse design that optimises latent embeddings toward a target property under round-trip fidelity, i.e., that decoded candidates remain on-target after decoding and forward evaluation. Reliability is substantially improved by two control strategies: post-decoding re-ranking to reduce decoding-induced drift, and predictor-guided minimal-edit repair to convert invalid near-misses into valid molecules while preserving property fidelity. On a surfactant CMC design task, re-ranking reduced round-trip error to <1%, and repair increased SMILES validity to ~90% while keeping property error near ~1%.

Using 15M surfactant-like PubChem SMILES for pretraining, our lightweight CLM achieved test $R^2 = 0.80$ with strong reconstruction despite being orders of magnitude smaller than foundation CLMs (0.43M vs. 289M parameters). Saliency analysis produced chemically meaningful attributions consistent with surfactant design trends, supporting that the model captures interpretable structure–property relationships. Future work will extend the framework to multi-objective design and broader chemical classes and will integrate synthesisability constraints more explicitly. A key open question is where constraints should be imposed for best reliability: via constrained decoding or after decoding (re-ranking and repair).

## ABSTRACT

The availability of temperature-dependent physicochemical property data forms the cornerstone of process simulation, optimization, and sustainable molecular and product design. However, a critical data gap persists, as experimental measurements are accessible for only a small subset of known chemicals. This renders experimental characterization resource-prohibitive, often compelling reliance on empirical estimation methods. Moreover, although many models offer single-point predictions at fixed temperatures, accurately modeling continuous temperature-dependent behavior remains challenging. Conventional methods frequently overlook intermediate variations, resulting in limited extrapolation capability. To overcome these limitations, we introduce a mechanism-guided hybrid modeling framework that integrates physical insights into data-driven models. This framework is built on two strategies. Strategy I targets trend correction by generating a continuous representation from discrete single-point predictions, incorporating descriptors and slopes. Strategy Ⅱ addresses bias removal by anchoring a baseline to a high-accuracy point estimate and fitting the remaining deviations. The framework's effectiveness is evidenced by evaluations across ten thermophysical properties: Strategy I achieves MSE reductions of 19.23% and 20.33% for the quantitative structure-property relationship and group contribution methods, respectively. Strategy II provides a more substantial improvement, attaining an 81.63% MSE reduction for the gradient boosting decision tree regression model. This work demonstrates that incorporating trend and slope constraints facilitates physically consistent, bias-corrected, and accurate predictions, offering a scalable approach to bridge the data gap and accelerate computer-aided engineering and design.

**Keywords**: Temperature-dependent property prediction, Hybrid modeling, Mechanistic constraints, Machine learning, Slope-based correction, Bias correction

## 1. INTRODUCTION

The characteristics of organic compounds, especially the physical properties related to energy and phase behavior, are of great significance in the field of process engineering and serve as the foundation for process design and optimization. However, due to the scarcity of experimental data and the high cost of conducting experimental measurements, property prediction models thus represent the most viable and practical means to estimate the required properties in the initial design phase.

Benefiting from the relative abundance of standardized data points, single-point prediction models (such as boiling point and critical temperature) have seen significant development. In stark contrast, the development of models for temperature-dependent properties remains a notably under-explored area. This research gap is not only due to the scarcity of comprehensive experimental

data but, more fundamentally, to the significant increase in modeling complexity. Predicting a single value, by comparison, constitutes a fundamentally simpler task than learning a continuous temperature-dependent function. The latter demands models that can simultaneously capture the interplay of molecular structure and thermal dynamics, adhere to underlying physical laws, and maintain generalizability across both chemical space and continuous temperature domains. This pronounced complexity, coupled with the scarcity of comprehensive data, has therefore intensified the need for accurate and efficient models capable of estimating thermophysical properties for compounds lacking experimental measurements.

The most classic predictive models include: group contribution (GC) models[1], quantitative structure-property relationship (QSPR) models[2], and machine learning (ML)models[3]. In the prediction of temperature-dependent properties, GC models are often used to regress the coefficients of thermodynamic approximation or correlation functions. This workflow and its essentials are well captured by early foundational work [4]. Early temperature-dependent predictive models include:

(1)Heat capacity polynomial

$$C_p = [\sum(a) - 37.93] + [\sum(b) + 0.210]T + [\sum(c) - 3.91 \times 10^{-4}]T^2 + [\sum(d) + 2.06 \times 10^{-7}]T^3 \quad (1)$$

(2)Liquid-viscosity (Andrade-type) relation

$$\eta_L = mw \times \exp\left\{\frac{\sum(\eta_a) - 597.82}{T} + \sum(\eta_b) - 11.202\right\} \quad (2)$$

For models without explicit functional forms, a standard approach to predicting temperature-dependent properties is to treat temperature as an additional input feature, concatenated with molecular descriptors or structural information. This approach is widely used in various modeling contexts. For instance, in QSPR modeling, Sosnowska et al. [5] integrated QSPR-predicted enthalpy of vaporization into the Clausius-Clapeyron equation to characterize the temperature-dependent vapor pressure of persistent organic pollutants. This data-driven strategy has enabled predictions even under extreme conditions, as demonstrated by Yin et al. [6], who predicted gas heat capacity across an exceptionally wide temperature range. Similarly, tree-based ensemble methods such as gradient boosting regression trees and light gradient boosting machine have been employed to predict liquid heat capacity [7] and solubility [8] across varying temperatures by treating temperature as an input variable.

These models share a fundamental limitation in handling temperature-dependent properties: the prevalent methodology essentially treats data points from the same compound at different temperatures merely as an expanded dataset, processing each (temperature, property) pair as an independent sample. This approach inherently disregards the intrinsic physical continuity of the temperature-property curve. Consequently, conventional models trained on such discrete (structure, temperature) pairs fail to learn the underlying continuous functional relationship, resulting in physically inconsistent predictions that often exhibit incorrect curve shapes and poor extrapolation beyond the training temperature domain.

The above theoretical limitations are clearly reflected in practical predictions. As shown in Figure 1, the GC model, constrained by its fixed functional form, fails to accurately capture experimental trends: Figure 1A demonstrates its constant-trend prediction for heat capacity that deviates from the experimental data, while Figure 1B and 1C show increasingly amplified errors as the temperature range extends. Figure 1D further illustrates its overall failure to follow the actual property trend.

In contrast, while QSPR models offer greater flexibility, they introduce a different challenge due to their purely data-driven nature. As shown in Figure 2, all four subfigures (A-D) display abrupt, physically unsupported changes in predictions. Notably, Figures 2B and 2C exhibit nearly non-monotonic segments that contradict fundamental thermodynamic principles.

## 2. PROPOSED HYBRID MODELING FRAMEWORK

### 2.1 Strategy I – Trend-Guided modeling

**Table 1:** Linearity assessment of ten temperature dependent thermophysical properties. Data were obtained from the pure component analysis module of Aspen Plus. For each property, the $R^2$ value is averaged across all substances, where each substance's $R^2$ is calculated from the linear regression of property values over temperature points.

| Property (abbreviation) | Mean $R^2$ | Count Of $R^2$<0.95 |
|---|---|---|
| Heat capacity($C_p$) | 0.9768 | 27* |
| Heat of vaporization($\Delta Hvap$) | 0.9843 | 8 |
| Internal energy($U$) | 0.9932 | 0 |
| Liquid density($\rho_L$) | 0.9904 | 0 |
| Pure component enthalpy($H$) | 0.9948 | 0 |
| Pure component exergy($Ex$) | 0.9909 | 0 |
| Gibbs free energy($G$) | 0.9964 | 0 |
| Isentropic exponent($\gamma$) | 0.9927 | 0 |
| Vapor pressure($P_{vap}$) | 0.9942 | 0 |
| Volume($V$) | 0.9731 | 4 |

*17 substances with $R^2$ between 0.9 and 0.95, 6 substances with $R^2$ between 0.8 and 0.9, and 4

substances with $R^2$ below 0.8.

As demonstrated in the table above, fitting a linear trend to the experimental data for ten temperature-dependent properties reveals a strong linear relationship in all cases, with an average coefficient of determination ($R^2$) exceeding 0.97. (Note that vapor pressure data was log-transformed prior to fitting.) Consequently, high-accuracy predictions at two physically meaningful temperature points, such as the critical temperature ($T_c$) and the normal boiling point ($T_b$), are employed to estimate the property's temperature-dependent tendency.

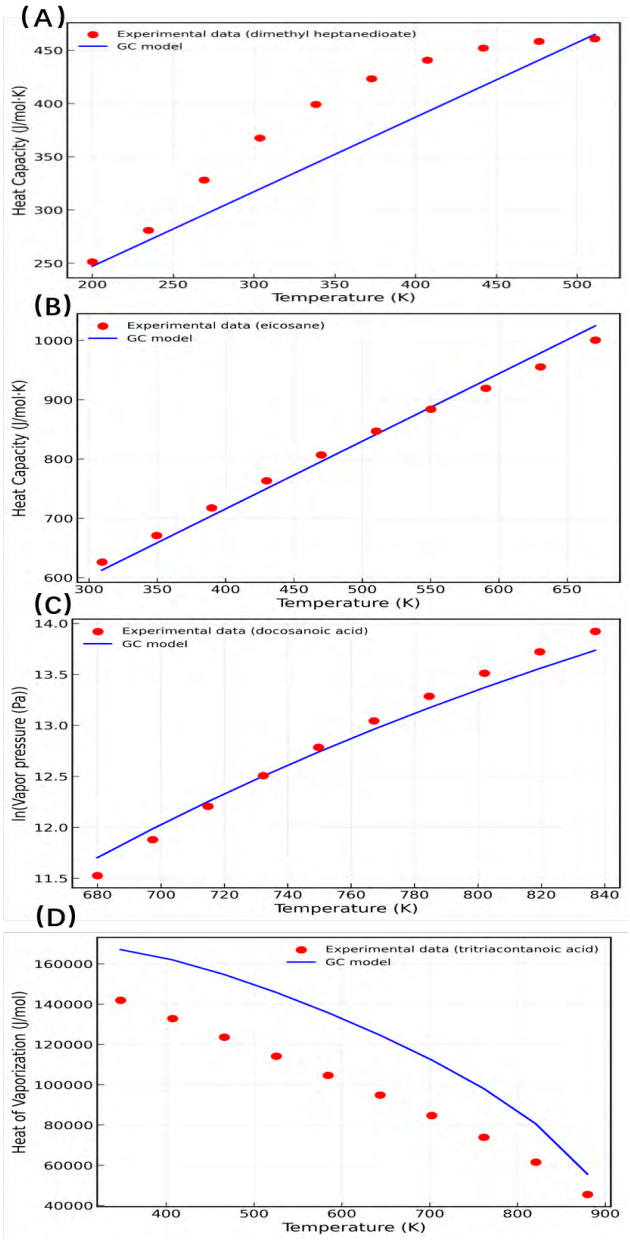

**Figure 1.** Prediction Performance of the GC Model for Thermodynamic Properties.(A, B) Heat capacity[9]. (C)Vapor pressure[10].(D)Heat of vaporization[9]. Model details are available in the Supplementary Information.

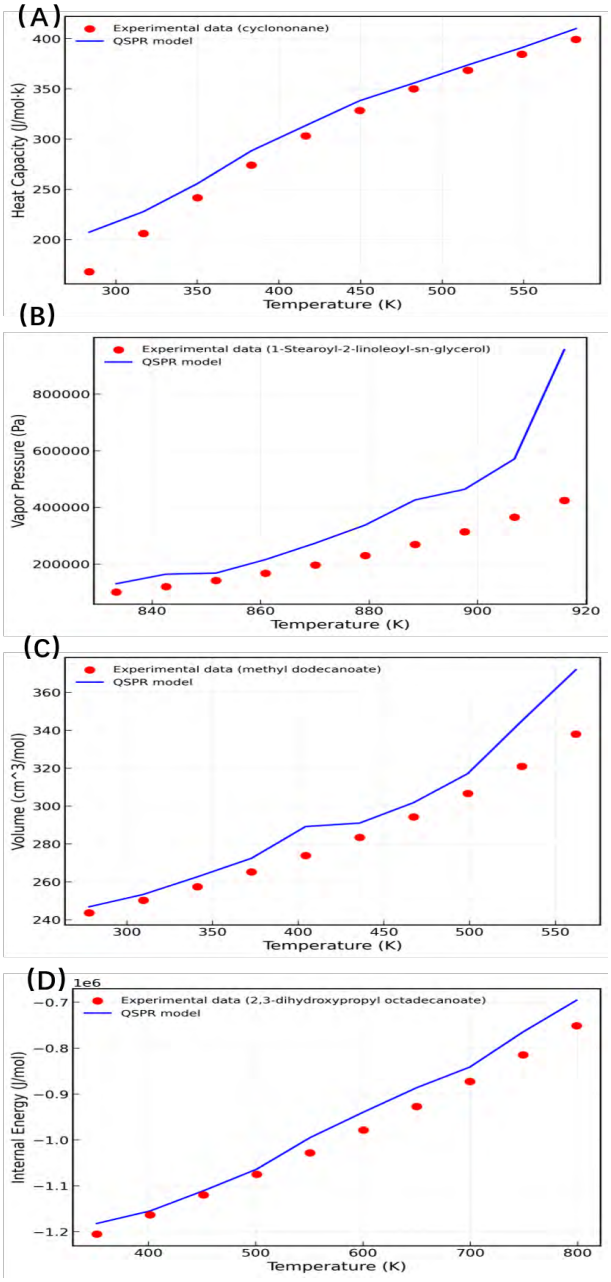

**Figure 2.** Prediction Performance of the QSPR Model for Thermodynamic Properties.(A) Heat capacity.(B)Vapor pressure.(C) Volume. (D) Internal Energy. Molecular descriptors derived from 2D structures downloaded from PubChem were used as input features. After data cleaning, appropriate descriptors were selected, and a random forest regression model was employed. Model details are available in the Supplementary Information.

### 2.1.1 Application of strategy I for explicit models

As presented in Figure 3, the modeling of temperature dependence for explicit models is accomplished through the following two-step framework:

Step 1: Construct four foundational models from molecular structure: two for predicting the reference

temperatures $T_1$ and $T_2$, and two for estimating the corresponding properties $y_{r1}$ and $y_{r2}$ at these points. The slope between these reference points is then derived as follows:

$$tendency = \frac{y_{r2}-y_{r1}}{T_2-T_1} \quad (3)$$

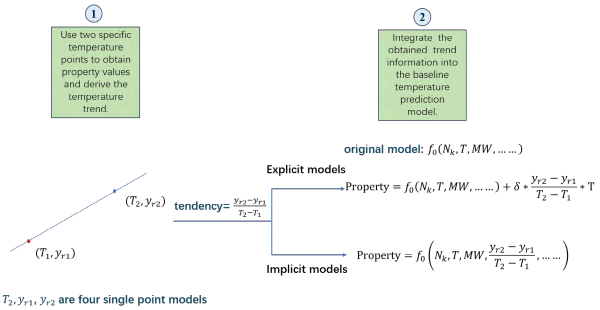

**Figure 3.** Flowchart of the Trend-Guided Hybrid Modeling Framework. Step 1: Construct models to predict two reference temperature points and their corresponding target properties, then use these four models to derive the predicted slope. Step 2: For existing models with an explicit expression, incorporate this slope as an additional temperature interaction term. For models without an explicit expression, use the slope as an additional input feature.

Step 2: Incorporate this slope into a baseline explicit model by introducing a temperature correction term. The augmented model takes the form:

$$\hat{y} = f_0(N_k, T, MW, \dots\dots) + \delta * \frac{y_{r2}-y_{r1}}{T_2-T_1} * \mathrm{T} \quad (4)$$

Here, $f_0(N_k, T, MW, \dots\dots)$denotes the original mechanistic or empirical model. Its temperature-inclined correction is introduced via a term weighted by a coefficient $\delta$ and scaled by the temperature T. This design allows the model to adaptively capture temperature-driven behavior.

### 2.1.2 Application of strategy I for ML models

The temperature-dependent modeling for ML models follows a two-step procedure:

Step 1: Construct four foundational models from molecular structure: two for predicting the reference temperatures $T_1$ and $T_2$, and two for estimating the corresponding properties $y_{r1}$ and $y_{r2}$ at these points. The slope between these reference points is then derived as follows:

$$tendency = \frac{y_{r2}-y_{r1}}{T_2-T_1} \quad (5)$$

Step 2: Incorporate the temperature tendency by adding the slope as a new input feature to the original data-driven model. This allows the model to learn temperature-dependent relationships directly, while its architecture remains unmodified. The resulting enhanced model formulation is:

$$\hat{y} = f_0\left(N_k, T, MW, \dots\dots, \frac{y_{r2}-y_{r1}}{T_2-T_1}\right) \quad (6)$$

Here, $f_0(N_k, T, MW, \dots\dots)$represents the original implicit model that learns structure-property relationships directly from data.

### 2.1.3 Physical significance

The physical significance of Strategy I stems from its fundamental departure from discrete-point prediction. By introducing a "temperature tendency" derived directly from experimental data points, the method incorporates prior physical intuition about continuous, smooth property evolution. This data-driven yet physics-aware approach not only improves robustness against experimental noise but also ensures more reliable extrapolation and interpolation. Crucially, it bridges the gap between discrete experimental observations and continuous theoretical physical models.

## 2.2 Strategy II –Bias-Corrected hybrid modeling

The conceptual foundation of Strategy II originates from a critical observation regarding purely data-driven machine learning methods. While these algorithms excel at identifying complex patterns, we propose that a more effective approach is to first establish a predictive baseline model, rather than feeding all data directly into a black-box model. This baseline, which uses linear regression with group features as inputs, captures the fundamental trend; subsequently, a GBDT model is applied specifically to learn the deviations between the baseline predictions and the actual measured values. This two-step process is illustrated in the flowchart of Figure 4.

### 2.2.1 Baseline model construction

Supported by the linearity assessment of ten temperature-dependent thermophysical properties (Table 1), a linear model is adopted as the baseline. Two preliminary models are first built to predict a reference temperature, $T_1$, and the corresponding property value at that temperature, $y_{\mathrm{r1}}$, directly from molecular structure. This reference prediction, $y_{\mathrm{r1}}$, serves as the intercept of the linear baseline model. The slope of the baseline is then determined using group contribution methods, giving the following expression for the baseline prediction $\hat{y}$:

$$\hat{y} = y_{\mathrm{r1}} + \sum_K A_K N_K (T - T_1) \quad (7)$$

Here, $y_{\mathrm{r1}}$ is the reference prediction for the property at temperature $T_1$, $A_K$ denotes the group contribution coefficients, $N_K$ represents the counts of molecular groups, and $T - T_1$ is the temperature deviation from the reference point.

### 2.2.2 Bias learning and compensation

Although the baseline model is physically reasonable, it cannot fully capture all complex, nonlinear relationships. To address this limitation, the deviation between the baseline prediction and the actual experimental value is calculated as $b = y - \hat{y}$. A machine learning model is subsequently employed to predict this systematic bias:

$$\hat{b} = f_1(N_k, T, MW \dots \dots) \tag{8}$$

This model, $f_1$, learns the residual errors of the baseline using a set of features including molecular descriptors, temperature, and molecular weight. The final, refined prediction is obtained by compensating the baseline output with the predicted bias:

$$\check{y} = \hat{y} + b \tag{9}$$

This step combines the robustness of the physical baseline with the flexibility of machine learning, enabling the hybrid model to capture nonlinear deviations that the baseline alone cannot represent.

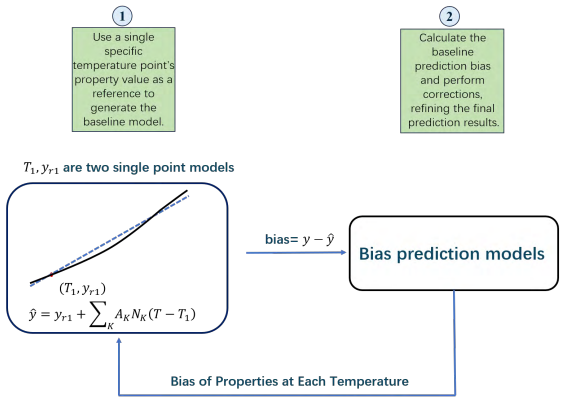

**Figure 4.** Flowchart of the Bias-Corrected Hybrid Modeling Framework. Step 1: Construct a prediction model for a reference temperature point and its corresponding target property to serve as an anchor point. Then, using the group contribution method, regress a straight line through this anchor point, where the method determines the slope. This line is taken as the predictive prior model for the property. Step 2: Calculate the deviation between the predictions of this prior model and the actual observed values. By predicting this deviation, apply a feedback compensation to the baseline model.

### 2.2.3 Physical significance

This hybrid methodology offers distinct advantages over purely black-box machine learning. Its primary strength lies in enforcing physically realistic predictions by anchoring them to a group-contribution baseline that adheres to thermodynamic principles. This constraint mitigates the generation of unrealistic outcomes—a common issue in purely data-driven models, particularly during extrapolation beyond the training domain. The framework also enhances interpretability: the baseline provides a physically meaningful starting point, while the machine learning component is dedicated to modeling only the residual deviations from this baseline. This separation allows researchers to distinguish between the fundamental physical relationships embedded in the baseline and the more complex, data-driven patterns captured by the machine learning model. Furthermore, by decomposing the problem into these two complementary tasks, the approach achieves greater data efficiency and robustness, as the machine learning model is tasked specifically with correcting the baseline's limitations rather than learning the entire underlying relationship from scratch.

## 3. RESULTS AND DISCUSSION

### 3.1 Data and evaluation framework

**Table 2:** Summary of experimental data points for the ten evaluated temperature-dependent properties, For each substance, data was collected at 10 different temperature points. Experimental data were obtained from Aspen Plus.

| Property | Symbol | Datapoints |
|---|---|---|
| $C_p$ | $J/mol \cdot k$ | 2070 |
| $\Delta Hvap$ | $J/mol$ | 2040 |
| $U$ | $J/mol$ | 2070 |
| $\rho_L$ | $g/ml$ | 2070 |
| $H$ | $J/mol$ | 2070 |
| $Ex$ | $J/mol$ | 2050 |
| $G$ | $J/mol$ | 2050 |
| $\gamma$ | 1 | 2070 |
| $P_{vap}$ | $Pa$ | 2090 |
| $V$ | $cm^3/mol$ | 2080 |

To evaluate the proposed enhancement strategies, we conducted a systematic performance comparison across several modeling frameworks. In this notation, the suffix "_SI" indicates the application of Strategy I, and "_SII" indicates Strategy II. Using this labeling scheme, we compared the following model variants: GC vs. GC_SI, GBDT vs. GBDT_SII, and QSPR vs. QSPR_ SI. All model variants are clearly identified with these labels in the subsequent results and discussion sections.

Table 2 summarizes the experimental data points for the ten evaluated temperature-dependent properties. For each substance, data were collected at ten distinct temperature points to comprehensively capture the property's behavior across a temperature range. These experimental data, serving as the foundation for all evaluations, were sourced from Aspen Plus—a widely used process simulation tool known for providing reliable thermophysical property data for diverse compounds.

**Table 3.** Overall predictive performance of original and enhanced models for ten thermophysical properties. Original models are labeled as GC, GBDT, and QSPR; models enhanced by Strategy I and Strategy II are denoted by the suffixes "_SI" and "_SII", respectively. For specific models and raw data, please refer to the digital supplementary material.

| Properties | | GC | GC_SI | GBDT | GBDT_SII | QSPR | QSPR_SI |
|---|---|---|---|---|---|---|---|
| $C_p$ | $R^2$ | 0.9918 | 0.9924 | 0.9971 | 0.9981 | 0.9994 | 0.9994 |
| | $MSE$ | 16.08 | 14.89 | 5.60 | 3.66 | 1.19 | 1.14 |
| $P_{vap}$ | $R^2$ | 0.9033 | 0.9194 | 0.8476 | 0.9914 | 0.9886 | 0.9901 |
| | $MSE$ | 63.04 | 52.58 | 99.36 | 5.59 | 7.41 | 6.43 |
| $\Delta Hvap$ | $R^2$ | 0.9260 | 0.9534 | 0.9713 | 0.9941 | 0.9929 | 0.9961 |
| | $MSE$ | 64.55 | 40.66 | 24.98 | 5.14 | 6.15 | 3.40 |
| $V$ | $R^2$ | | | 0.9931 | 0.9985 | 0.9991 | 0.9992 |
| | $MSE$ | | | 331.45 | 73.67 | 41.83 | 37.78 |
| $U$ | $R^2$ | | | 0.9965 | 0.9996 | 0.9991 | 0.9992 |
| | $MSE$ | | | 50.58 | 6.36 | 12.59 | 11.51 |
| $H$ | $R^2$ | | | 0.9965 | 0.9996 | 0.9991 | 0.9992 |
| | $MSE$ | | | 49.85 | 6.18 | 13.17 | 11.00 |
| $Ex$ | $R^2$ | | | 0.9728 | 0.9987 | 0.9992 | 0.9992 |
| | $MSE$ | | | 119.77 | 5.90 | 3.59 | 3.53 |
| $\gamma$ | $R^2$ | | | 0.9600 | 0.9956 | 0.9931 | 0.9955 |
| | $MSE$ | | | 354.26 | 39.37 | 61.24 | 40.08 |
| $\rho_L$ | $R^2$ | | | 0.9636 | 0.9957 | 0.9932 | 0.9950 |
| | $MSE$ | | | 67.49 | 8.00 | 12.53 | 9.23 |
| $G$ | $R^2$ | | | 0.9843 | 0.9975 | 0.9957 | 0.9971 |
| | $MSE$ | | | 50.27 | 8.05 | 13.80 | 9.27 |

## 3.2 Comparative performance analysis

Model performance was quantitatively assessed using the $R^2$ to evaluate the overall goodness of fit and the $MSE$ to measure the magnitude of absolute error.

The overall performance of the models in predicting the ten target properties is summarized in Table 3. Note that results from the GC-based model are only reported for heat capacity, vapor pressure, and heat of vaporization; for the remaining properties, no established GC models were available, and those entries are left blank. Based on the results in Table 3, a consistent improvement is observed across all original models after incorporating the proposed strategies, evidenced by increased $R^2$ values and reduced MSE. This dual improvement reflects both a better overall fit and a systematic reduction in prediction errors, thereby statistically validating the effectiveness of Strategy I and Strategy II.

**Table 4:** MSE improvement results using Strategy I and Strategy II: Percentage improvement in MSE relative to the original model for each property. Blank entries indicate cases where the corresponding strategy-model combination was not applicable. Original models are denoted as GC, gradient boosting decision tree regression (GBDT), and QSPR; models enhanced with Strategy I and Strategy II are labeled with the suffixes "_SI" and "_SII", respectively.

| Properties | GC_SI | GBDT_SII | QSPR_SI |
|---|---|---|---|
| $C_p$ | 7.40% | 34.64% | 4.20% |
| $P_{vap}$ | 16.59% | 94.37% | 13.23% |
| $\Delta Hvap$ | 37.01% | 79.42% | 44.72% |
| $V$ | | 77.77% | 9.68% |
| $U$ | | 87.42% | 8.58% |
| $H$ | | 87.60% | 16.48% |
| $Ex$ | | 95.07% | 1.67% |
| $\gamma$ | | 88.89% | 34.55% |
| $\rho_L$ | | 88.15% | 26.34% |
| $G$ | | 83.99% | 32.83% |
| Mean | 20.33% | 81.63% | 19.23% |

To further quantify the improvement, we compared the percentage reduction in MSE before and after applying the proposed strategies. As shown in Table 4, the strategies yield substantial and broadly consistent error reduction across most models. With Strategy I, the average MSE decreased by 19.23% for QSPR-based models and by 20.33% for GC models. For GBDT models, Strategy II delivered the most pronounced improvement, achieving an 81.63% reduction in MSE. These results underscore the efficacy of the Bias-Corrected Hybrid Modeling Framework for complex data-driven modeling tasks.

## 3.3 Model interpretation and physical insights

Figure 5 compares the original and enhanced models across three temperature-dependent properties. In Figure 5A, the GC model—originally constrained by a fixed linear form—exhibits markedly improved alignment with the experimental trend after incorporating Strategy I, yielding more flexible predictions that reduce deviations at both ends of the temperature range. Figure 5B shows that for the QSPR model, Strategy I preserves its inherent capacity to capture nonlinearity while imposing a physically guided constraint that suppresses unphysical, abrupt variations. The remaining panels consistently illustrate the advantages gained by integrating the proposed physics-informed features, further confirming the general effectiveness of the enhancement strategies.

The comparative results highlight a consistent advantage of incorporating physical knowledge into data-driven models. While purely statistical approaches learn patterns directly from the data, they lack awareness of the underlying thermodynamic structure governing temperature-dependent properties. The proposed strategies address this gap by embedding mechanistic priors into the learning process, enabling the hybrid framework to recover physically meaningful trends that conventional models often fail to capture. As illustrated by the predictions, many original models struggle to reproduce the experimental temperature variation because they are trained across multiple compounds using a global loss function that produces parameter sets representing statistical compromises. This leads to persistent prediction gaps for specific compounds—systematic biases that cannot be eliminated without incorporating physical mechanisms.

The physics-informed strategies introduced in this work effectively resolve these issues by embedding fundamental temperature-dependent behavior into the predictive process. In particular, Strategy I incorporates a physically interpretable slope term extracted from high-accuracy reference points such as $T_b$ and $T_c$. This slope simultaneously acts as a physics-informed feature—encoding the direction and magnitude of temperature effects—and as a molecularly grounded descriptor, since it reflects influences such as intermolecular forces, molecular weight, functional group contributions, and polarizability. By doing so, Strategy I transforms the learning task from predicting an unconstrained surface in (structure, T) → property space to predicting deviations around a physically anchored linearized manifold, analogous to embedding a first-order thermodynamic Taylor expansion as a prior.

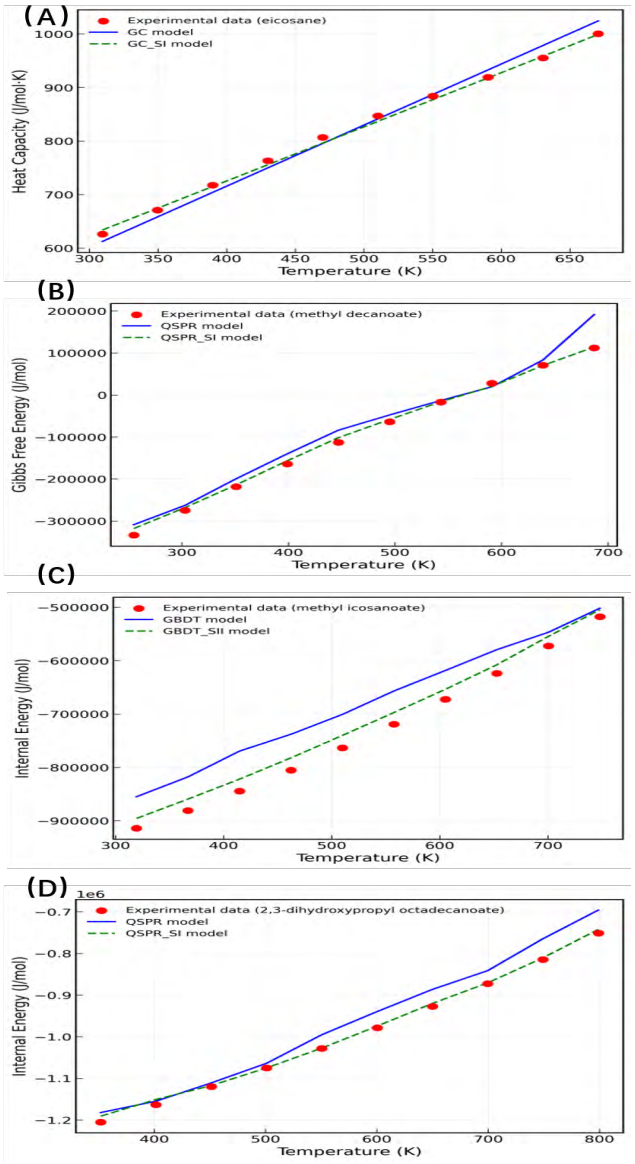

**Figure 5.** (A) GC vs. GC_SI for heat capacity. (B) QSPR vs. QSPR_SI for internal energy. (C) GBDT vs. GBDT_SII for internal energy. (D) QSPR vs. QSPR_SI for Gibbs free energy. (The suffix "_SI" denotes enhancement by Strategy I, "_SII" by Strategy II). For specific models and raw data, please refer to the digital supplementary material.

Similarly, Strategy II leverages a baseline GC model that encodes known physical relationships between

molecular groups and temperature tendencies. Although the baseline is approximate, it captures the dominant trend with clear physical interpretability, while the machine-learning component predicts only the deviation from this baseline. This decomposition substantially reduces the learning difficulty: the ML model focuses solely on complex residual patterns rather than the entire thermodynamic mapping. The baseline also prevents thermodynamic inconsistencies, such as incorrect concavity or unphysical changes in slope. As a result, the overall error decreases because ML is used to refine the nonlinear residual structure rather than reconstruct the entire temperature dependence from scratch. This approach closely mirrors the "Δ-learning" philosophy used in quantum chemistry machine learning, and our framework adopts the same logic for temperature-dependent thermophysical properties.

## 4 CONCLUSIONS

This paper presents a predictive framework for temperature-dependent properties that advances existing methodologies by addressing a fundamental limitation: the prevalent treatment of experimental data as discrete points rather than as manifestations of an underlying continuous function. By incorporating physically meaningful temperature trends and systematically correcting biases within data-driven workflows, the framework enables models to learn complete temperature-dependent functional relationships. Beyond predictive accuracy, it ensures thermodynamic consistency, enhances interpretability, and improves extrapolation reliability—attributes that are critical for process simulation, optimization, and computer-aided molecular design.

## DIGITAL SUPPLEMENTARY MATERIAL

The complete source code, datasets, and implementation details for all models presented in this study have been made openly available. The repository contains the input features for all 10 properties across 200+ compounds, the code for all comparison models. The TRGPACK repository can be accessed at: https://github.com/SZ-ZJU/TRGPACK.

## ABSTRACT

Accurately predicting chemical reaction yields can accelerate reaction optimization by prioritizing promising conditions; however, the complexity of multicomponent reactions and the limited availability of high-quality datasets remain significant challenges. While machine learning has achieved substantial progress in molecular property prediction, reaction-level modeling requires representations that capture three-dimensional structures, intercomponent interactions, and mechanistically critical features. In this study, we investigate the effective extension of molecular pretraining to reaction yield prediction from two complementary perspectives. First, we apply a reaction-aware architectural design based on molecular representation models pretrained via partial denoising to multicomponent reactions. Each reaction component is encoded as a three-dimensional stereoisomer embedding and concatenated into a reaction-level representation, with multi-head attention modeling intercomponent dependencies. We show that this approach achieves robust performance and generalizes well to reactions involving previously unseen components. Second, we design an architecture that extracts intermolecular relational embeddings through mechanistically meaningful pre-supervised learning using electron source-sink annotations derived from reaction mechanisms, followed by an active fine-tuning process. This mechanism-aware extension leverages large-scale reaction data to provide informative inductive bias and improves performance in data-constrained settings. We further confirm that this approach outperforms models that simply combine individual molecular embeddings, as it directly captures chemically meaningful information relevant to reaction outcomes. These results suggest promising directions for developing machine-learning models for reaction yield prediction that are more closely aligned with underlying chemical mechanisms.

**Keywords**: Deep learning, Reaction yield, Transfer learning

## 1. INTRODUCTION

Chemical reactions play a central role in diverse fields, including the synthesis of new compounds, process optimization, and materials development. Accurate prediction of chemical reaction outcomes can significantly reduce experimental costs and enable more efficient optimization strategies. However, reaction outcome prediction remains highly challenging due to the complex interplay of numerous factors, such as reaction conditions, catalysts, and the structural properties of reactants. Consequently, predicting reaction outcomes a priori, without performing physical experiments, remains an open and difficult problem.

Meanwhile, recent advances in deep learning have demonstrated strong performance in single-molecule property prediction tasks [1, 2], and the rapid growth of large-scale chemical reaction databases [3-5] has highlighted the potential of data-driven approaches to advance reaction modeling. Inspired by natural language processing, the BERT architecture has been applied to reaction yield prediction through large-scale pretraining on reaction corpora such as the Pistachio dataset[4]. The

resulting YieldBERT [6] model has shown superior performance compared to existing data-driven methods and has been widely adopted as a benchmark in subsequent studies [7]. However, as molecules are represented as linearized SMILES strings, key structural characteristics—such as explicit atomic connectivity and three-dimensional conformational information—are not directly encoded, which may limit the ability of such models to fully capture the chemical features governing reaction.

At the single-molecule level, numerous graph-based approaches have been developed to better capture intrinsic molecular characteristics [2, 8]. By representing molecules as graphs, these methods naturally encode atomic connectivity and, in some cases, incorporate three-dimensional coordinates into molecular embeddings. Pretraining strategies based on denoising techniques [2] have demonstrated the ability to learn physically meaningful representations beyond simple masking-based objectives. At the same time, reaction modeling inherently involves multiple interacting molecular species, and existing studies often address this challenge by aggregating or concatenating embeddings from individual molecules; however, it remains unclear whether such straightforward combinations are sufficient to fully capture complex inter-molecular interactions.

Accordingly, in this work we investigate reaction yield prediction using approaches specifically designed to address two essential aspects: intrinsic molecular representations that capture graph structure and three-dimensional conformational information, and data representations and architectures that explicitly model intermolecular interactions. First, we adapt and extend a denoising-based molecular property prediction model to reaction-level prediction, focusing on capturing intrinsic structural characteristics of individual molecules. This approach demonstrates stable generalization in scenarios involving unseen products. Second, from a complementary perspective, we incorporate mechanistically relevant supervision by leveraging electron source-sink annotations derived from reaction mechanisms. Rather than treating interactions implicitly, the model is pretrained to identify atomic sites that play decisive roles in electron flow, and this mechanistic information is subsequently integrated into reaction-level embeddings during fine-tuning. Taken together, these results suggest that explicitly reflecting fundamental mechanistic aspects of chemical reactions, rather than relying solely on molecular aggregation or architectural complexity, provides a promising direction for developing more chemically informed machine-learning models for reaction yield prediction.

# 2. METHODS

## 2.1 Structure-Aware Molecular Representation for Reaction Yield Prediction

### 2.1.1 Overview

To incorporate three-dimensional molecular conformations and chemically meaningful representations for reaction, without performing expensive geometry optimization, we build upon the fractional denoising molecular pretraining framework, denoted as Frad, introduced by Ni *et al* [2]. Frad is a denoising-based pretraining approach based on TorchMD-Net [9] that learns structure-aware molecular representations by reconstructing molecular conformation perturbed from their equilibrium geometries. A key feature of Frad is a chemically aware noise (CAN) designed to capture physically relevant perturbations, including rotations and vibrational modes. This enables the model to encode conformational variability beyond small harmonic distortion and has been shown to produce molecular embeddings that improve molecular property prediction and remain robust to the quality of input geometry, including those generated using inexpensive classical methods. In this work, the pretrained Frad encoder is extended from single molecule property prediction to reaction-level modeling and reaction yield prediction on benchmark reaction datasets. Each reaction is represented as a set of molecular components, and their embeddings are aggregated to obtain a reaction-level representation, while treating the relationship between reaction components implicitly.

### 2.1.2 Input Construction and Model Architecture

Reactions are represented using three-dimensional structure-based encoding produced by the pretrained Frad molecular encoder, in which each molecular component is treated as an independent molecular graph. To accommodate reactions with a variable number of components, a dummy molecular graph with atomic number zero and fixed coordinates at (0, 0, 0) is introduced to represent missing species. This allows all reactions to be expressed in a consistent input format. Each component-specific graph is then processed independently by the pretrained encoder to generate a fixed-dimensional molecular embeddings. To adapt the Frad designed only for single-molecule for reaction-level modeling, the component embeddings are concatenated in a fixed order and pass through a multi-head attention module. This attention mechanism serves as a learnable aggregation function that adaptatively capture correlations among reaction constituents. The resulting interaction-aware representation is subsequently passed through two multi-layer perceptron (MLP) layers to produce a scalar prediction of the reaction yield (see Figure 1).

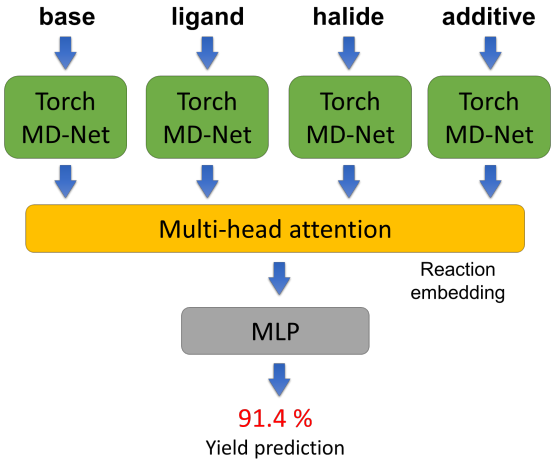

**Figure 1.** Reaction yield prediction using structure-aware molecular representations (SA-YIELD).

### 2.1.3 Datasets and Evaluation Protocol

Model performance for reaction yield prediction in this section is evaluated on the Buchwald-Hartwig coupling dataset [3], which was generated through high-throughput experimentation (HTE). Each reaction is defined by its constituent molecular components and represented using SMILES strings. In the HTE study, reaction conditions, such as concentration and temperature, are fixed across the dataset and are therefore not included as model inputs. The reactions involve four molecular components: aryl halide, ligand, base, and additive.

Reactions with zero yield frequently do not produce an isolable product, and including the product information as model input may introduce information leakage. To avoid this, each reaction instance is defined using only the four reactant-side components—aryl halide, ligand, base, and additive—while excluding the product from the input representation. This formulation ensures that yield prediction is based solely on information available prior to reaction execution and aligns with realistic experimental design constraints.

Model performance is evaluated under different generalization settings: random and component-wise unseen splits. For random split setting, reactions are randomly divided into training, validation, and test sets with a 6:2:2 ratio. To assess extrapolation to unseen molecular components, component-wise hold-out splits are applied. For bases and ligands, which consist of three and four distinct species, respectively, splits are generated by holding out one component at a time for testing, while using the remaining two bases and three ligands for training. For aryl halides and additives, which exhibit greater chemical diversity, unseen splits are generated by randomly selecting one quarter of the component combinations as the test set. Performance metrics reported for unseen component prediction are obtained by averaging results across all corresponding splits.

## 2.2 Interaction-Aware Pretraining Approach via Supergraph Representation

### 2.2.1 Overview

Many reaction prediction models form reaction representations by combining features derived from individual components, leaving cross-component relationship to be inferred implicitly from yield supervision. While the structure-aware formulation in Section 2.1 enriches molecular embeddings with conformation information, it similarly does not incorporate explicit mechanism derived relation across reaction components. In many cases, reaction outcomes depend on how specific atomic sites across different molecules participate in bond formation and electron transfer. Even for the same molecular species, the atoms involved in bond formation or braking can vary depending on the co-reactants, which limits what can be inferred from representations learned for each molecule in isolation.

To address this limitation, we introduce a mechanism-derived reaction modelling framework that incorporate explicit relational structure and supervision. First, reactions are represented using a pairwise supergraph formulation in which molecular components are decomposed into all combinatorial pairs. Second, electron source-sink annotations derived from reaction mechanisms are used as a pretraining objective to introduce mechanism-inspired relational bias into the learned representation. The pretrained model is then fine-tuned on a smaller reaction yield dataset, during which the predicted source-sink probabilities are incorporated to adaptively modulate how atomic information is aggregated into supergraph embedding, rather than relying on uniform pooling.

### 2.2.2 Supergraph Representation for interaction awareness

To encode intermolecular relationship explicitly, reactions are represented using a hierarchical, relation-centric supergraph formulation rather than as an aggregation of individual molecular embeddings. The model architecture is adapted from the HiMol [11] hierarchical graph framework, which augments atom-level graph with higher-order (e.g., fragment- or molecular-level) structural nodes to enable information exchange across multiple scales via deep message-passing neural network (D-MPNN)[12].

In the work, the hierarchical representation is extended from single molecules to reactions by constructing pairwise molecular supergraph. For a reaction involving multiple molecular components, all combinatorial molecular pairs are enumerated, and each pair is encoded as an independent supergraph. Within each supergraph, atom-level nodes capture local chemical structure, while higher-level nodes aggregate information at molecular-

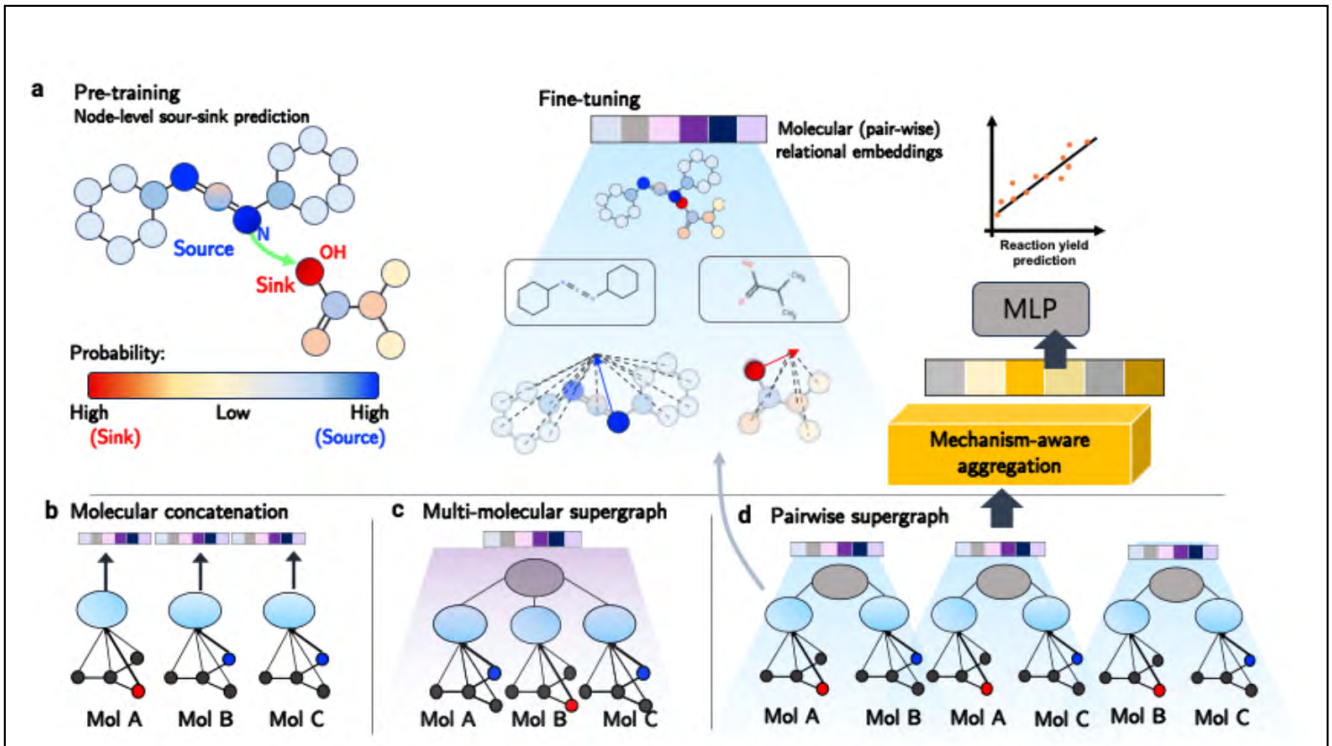

**Figure 2.** Mechanism-aware relational modeling for reaction yield prediction. (a) Source-sink pretraining and fine-tuning: predicted atom-level source-sink probabilities are used to weight atomic contributions during pooling when constructing pairwise relational embeddings for yield prediction. (b) Molecular concatenation baseline. (c) Multi-molecular supergraph. (d) Pairwise (combinatorial) supergraph formulation with mechanism-aware aggregation.

and reaction-levels. Message passing is then performed across all hierarchical levels of nodes, enabling information flow among atom-, molecular-, and reaction-level representations.

This pairwise construction is motivated by the observation that, even in multicomponent reactions, mechanistically relevant relationships are more naturally and effectively represented as pairwise interactions between specific components rather than as uniformly distributed multimolecular correlations. Key mechanistic process, such as electron flow and bond rearrangement, typically arises from interactions between two reacting species at a time, rather than from simultaneous many-body effects. Representing reactions using a pairwise supergraphs therefore provides a closer abstraction of the underlying reaction mechanism and aligns direclty with the pretraining objective, which is designed to capture electron source-sink relationships defined between interacting molecular pairs.

For reaction-level, embeddings extracted from all molecular pairs are integrated via a masked attention pooling. This aggregation yields a fixed-dimensional reaction representation and allows different molecular pairs to be weighted adaptively. A schematic overview of the pairwise supergraph representation and its integration into a reaction-level embedding is shown in Figure 2.

### 2.2.3 Source–Sink–Aware Pretraining and Active Finetuning for Reaction Yield Prediction

Reaction yield datasets are often limited in size, which constrains the ability of supervised models to learn complex intermolecular relationships reliably from yield labels alone. To mitigate this limitation, a transfer learning strategy is employed in which the pairwise supergraph encoder is first trained on a source-sink prediction task to introduce chemically motivated inductive bias, and is subsequently transferred to downstream reaction yield prediction.

Pretraining is performed using the Mech-USPTO-31k dataset [10], which provides reaction mechanisms annotated in an arrow-pushing format and include atomic- or bond-level labels identifying electron sources and sinks based on electron pair transfer. These annotations provide atom-level supervision that depends on the joint context of reacting molecular pairs and are therefore well aligned with the pairwise supergraph representation. Source-sink prediction is formulated as a node-level classification tasks on pairwise supergraphs, encouraging the model to assign higher likelihood to atomic sites associated with electron transfer in a reaction context.

Following pretraining, the model is fine-tuned on a liquid-phase amide coupling dataset reported by Zhang *et al* [13]. This dataset comprises reaction between

amines and carboxylic acids conducted in solvents in the presence of base and and coupling agent. During fine-tuning, pretrained parameters are used as initialization, and the source–sink prediction head, trained during pretraining as a classification objective with cross-entropy loss, is directly reused to generate softmax-normalized atom-level probabilities. These probabilities are employed as node-wise weighting factors during supergraph embedding aggregation, biasing the pooled representation toward atomic regions inferred to be more mechanistically relevant to electron transfer. The resulting weighted pairwise embeddings are then aggregated to form the final reaction-level representation for yield prediction. It is worth noting that the full distribution of source-sink probabilities is retained during pooling rather than selecting a single reactive atom, which improves robustness when reactive sites are distributed across multiple atoms or are uncertain at the atom level.

This pretraining-fine-tuning strategy allows mechanism-derived information learned from large-scale reaction data to influence downstream yield prediction indirectly, without requiring mechanistic annotations in the yield datasets. Figure 2 summarize our workflow.

### 2.3 Implementation Details

All experiments for the structure-aware reaction models (Section 2.1) were conducted on an NVIDIA A100 GPU, with batch size of 32 and the learning rate $5\times10^{-5}$. Each molecular component embedding had dimension 256, matching the dimensionality of the pretrained Frad encoder. Unless otherwise stated, all remaining hyperparameters, including the optimizer, scheduler, and activation functions, were kept identical to those used in the original Frad implementation [2]. All Frad encoders were initialized from checkpoints pretrained on the PCQM4Mv2 dataset. Reaction-level representations used a four-head multi-head self-attention module, with component embedding used as query, key, and value. Attention outputs were concatenated before being passed to the subsequent fully connected layers. Each task was trained independently and required approximately 12 hours to complete.

Experiments for the pairwise supergraph model with source-sink pretraining (Section 2.2) were conducted on a single NVIDIA RTX 4090 GPU. For source-sink pretraining on Mech-USPTO-31k, a random 0.85:0.15 train-validation split was used with AdamW optimizer (learning rate $1x10^{-4}$, batch size 256). Source-sink prediction was formulated as a graph-wise node selection task, where each atom in a given (super)graph is treated as a candidate class and the number of classes thus varies with graph size. Two parallel heads (source and sink) are trained with cross-entropy loss (with non-reactive nodes masked), and predictions are obtained by taking the argmax over atoms for each head. For yield prediction, the pretrained model was fine-tuned on the amide coupling dataset[13] using a random 0.85:0.15 split, learning rate $1\times10^{-6}$ and batch size 16. Reactions were represented as a hierarchical graph with atom-, molecule-, and molecule-pair-level nodes, using a five-layer D-MPNN backbone, with embeddings projected to dimension 256. Pairwise embeddings were aggregated using masked four-head attention pooling. During fine-tuning, predicted source-sink probabilities were used for probability-weighted pooling. Dropout rates of 0.1 (encoder) and 0.5 (yield head) were applied.

## 3. RESULTS

### 3.1 Reaction Yield Prediction with Structure-Aware Molecular Representations

This section evaluates whether incorporating three-dimensional, structure-aware molecular representation improve reaction yield prediction, with particular emphasis on generalization to reactions involving previously unseen components. The proposed structure-aware reaction model (SA-YIELD), described in Section 2.1, is evaluated on Buchwald-Hartwig coupling reaction dataset.

First, we note that SA-YIELD achieves a MAE of 4.18 under a random split setting. This performance is comparable to that reported for Yield-BERT [5], which achieves an average MAE of approximately 4.0 on the same dataset. Considering that Yield-BERT relies on representations pretrained on reaction SMILES from the USPTO patent corpus (approximately 3.7 million reactions), these results indicate that incorporating structure-aware molecular representations at the reaction level can achieve competitive yield prediction accuracy without requiring geometries derived from crystal structures or large-scale reaction pretraining.

Next, we compare the SA-YIELD to representative baseline models, sequence-based Yield-BERT [5] and structure-aware CRYSTAL-YIELD7. All performance of components splits are summarized in Table 1. In this setting, prediction accuracy decreases substantially for all models, as it assesses extrapolation to reactions containing held-out components. For example, the MAE is approximately 4 in random split, whereas it increases into a substantially higher range for reactions involving unseen components, reaching their largest values for unseen aryl halides up to 24.

This behavior reflects the fact that aryl halides span a broader chemical space and play a central role in determining reactivity in Buchwald–Hartwig couplings. As primary electrophilic partners, they directly determine the identity of the reacting electrophile and play a central role in bond formation. Withholding such components therefore induces a pronounced shift in the underlying yield distribution, which limits extrapolation based solely on patterns learned from the remaining reaction

components. This effect is substantially more pronounced than for other reaction partners, such as ligands, and exposes limitations in models that encode reactants in isolation, without explicitly accounting for how reactivity depends on interacting reaction partners.

Despite these challenges, SA-YIELD consistently achieve the lowest MAE across all unseen-component categories. The average MAE is reduced from 24.4 for Yield-BERT and 15.65 for CRYSTAL-YIELD to 13.5, with the largest improvement observed for aryl halides—the most challenging unseen component, where SA–YIELD achieves an MAE of 18.8. Comparisons between models with (SA-YIELD) and without pretraining (SA-YIELD-RAW) indicate that these gains primarily arise from reaction-level architectural design choices rather than from denoising-based molecular pretraining alone.

While the Frad framework effectively captures three-dimensional molecular structure, molecular-level pretraining alone provides limited benefit for extrapolative prediction. This suggests that accurately modeling reaction outcomes requires representations that go beyond intrinsic molecular features. This motivates a shift toward reaction-level architectures and supervision strategies that explicitly reflect reaction mechanisms, which we explore in the following section.

**Table 1:** Reaction yield prediction performance on the Buchwald-Hartwig coupling dataset under component-wise unseen splits. Reported values are mean absolute error (MAE) in yield percentage points (mean ± s. e. across splits where applicable)

| Model | Base | Ligand | Halide | Additive | Average |
|---|---|---|---|---|---|
| Yield-BERT | 24.3 ± 1.6 | 24.3 ± 1.4 | 24.7 ± 2.1 | 24.1 ± 0.7 | 24.4 |
| CRYSTAL-YIELD | 13.4 ± 0.3 | 11.7 ± 2.2 | 21.3 ± 3.3 | 16.2 ± 0.4 | 15.65 |
| SA-YIELD | 11.8 ± 1.6 | 11.3 ± 2.6 | 18.8 ± 0.8 | 12.1 ± 1.3 | 13.5 |
| SA-YIELD-RAW | 11.5 ± 1.5 | 11.7 ± 3.0 | 19.5 ± 1.4 | 12.1 ± 1.3 | 13.7 |

## 3.2 Reaction Yield Prediction from explicit relation embedding

### 3.2.1 Source-Sink Pretraining Performance

To assess the effectiveness of mechanism-aware pretraining, the pretrained model was evaluated on the electron source-sink identification task defined by the Mech-USPTO-31k dataset. The evaluation follows the first-step source-sink labeling scheme described in Section2.2.3. Consistent with the dataset formulation, source–sink prediction is treated as a graph-wise node selection problem, in which each atomic node within a pairwise molecular supergraph is assigned a relative score, and the source and sink atoms are identified by selecting the highest-scoring nodes for each role. These scores are normalized via a softmax operation during training with cross-entropy loss, allowing the model to learn a single source and a single sink atom per supergraph.

As summarized in Table 2, our model demonstrates high accuracy in both source and sink predictions. On the test set comprising 4, 705 reactions, 4, 288 cases (91.2%) ere correctly predicted for both source and sink components. Partial predictions were observed in 264 cases with only the source correctly identified and in 137 cases with only the sink correctly identified, indicating greater difficulty in sink-site prediction. Notably, only 16 reactions (0.3%) were misclassified for both sites, highlighting the robustness of the model in distinguishing reactive and non-reactive atomic positions. This reliability allows the predicted source–sink signals to be used for active fine-tuning. Rather than treating source-sink prediction as a standalone objective, the present model incorporates source-sink supervision within a pairwise molecular supergraph architecture that explicitly encodes interactions between reacting species. In this framework, source-sink prediction is not an endpoint, but a means of biasing learned representations toward interaction-dependent atomic features.

**Table 2:** Prediction Outcomes on the Test Set

| Outcome | Counts | % |
|---|---|---|
| Both correct | 4288 | 91.1 |
| Source only | 264 | 5.6 |
| Sink only | 137 | 2.9 |
| None | 16 | 0.3 |

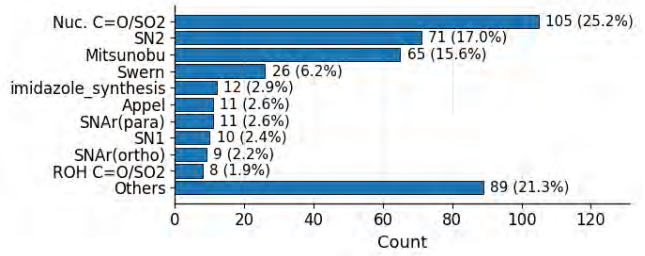

**Figure 3.** Reaction-Class Distribution of Failed Predictions

To examine the limitations of the pre-training approach, we analyzed the reaction classes associated with prediction errors, including both complete and partial mispredictions (Figure 3). Prediction errors were frequently observed in nucleophilic attacks on (thio)carbonyl or sulfonyl groups, $S_N2$ reactions, and Mitsunobu-type transformations, accounting for 105 (25.2%), 71 (17.0%), and 65 cases (15.6%), respectively. As discussed in Ref 10, $S_N2$ reactions are inherently challenging to annotate using discrete electron-flow representations, as bond formation and cleavage occur concertedly and multiple mechanistic interpretations can be chemically

plausible. In nucleophilic attack reactions involving (thio)carbonyl or sulfonyl groups, misassignments frequently involved intramolecular sites rather than external nucleophiles, reflecting a fundamental limitation of the molecular representation, as the 2D graph encoding does not capture steric accessibility or approach geometry. For Mitsunobu reactions, detailed inspection revealed that a substantial fraction of errors originated from the symmetric structure of diethyl azodicarboxylate, in which two nitrogen atoms are chemically equivalent, and the model frequently selected the alternative symmetric site that was treated as incorrect under the current labeling scheme despite being mechanistically equivalent. These observations indicate that many Mitsunobu-related mispredictions arise from annotation artifacts rather than genuine mechanistic failures, suggesting that the effective prediction accuracy of our model is likely higher than the nominal value reported here.

Despite these limitations, the pretrained model exhibits informative probabilistic behavior. Even when the highest predicted source or sink probability does not coincide with the ground-truth, the model frequently assigns relatively high probabilities to other chemically plausible atomic sites. Because the downstream framework does not rely on discrete source-sink assignments but instead incorporate the full probability distribution during the pooling, such partially correct predictions can still contribute useful interaction-relevant information.

### 3.2.2 Effect of Mechanism-Aware Pretraining and Active Finetuning

Reaction yield prediction performance on the amide coupling dataset is summarized in Table 3, comparing different reaction embedding strategies with and without mechanism-aware pretraining. Three embedding formulations are evaluated. Molecular concatenation aggregates independently encoded molecular embeddings without explicit intermolecular message passing and serves as a non-relational baseline. Multi-molecular supergraph encodes all reaction components within a single graph, enabling message passing across all atoms simultaneously. Pairwise supergraph, as described in Section 2.2.2, constructs relational embeddings by encoding molecular components as combinatorial molecular pairs. The first two settings are included as ablation baselines to assess the effect of explicitly modeling pairwise intermolecular relationships.

When trained without source-sink pretraining, the model based on molecular concatenation achieve slightly better performance than the pairwise supergraph. In this setting, reaction yield labels alone provide limited information about which molecular pairs and atomic regions are responsible for determining the reaction outcome. As a result, the model is unable to reliably identify and exploit pair-specific interaction patterns from the amide coupling dataset, which contains on the order of 500 reactions. which limits the effectiveness of relational representations and can lead to degraded generalization performance.

In contrast, when the pairwise supergraph encoder is initialized using source-sink pretraining and actively leveraging the mechanistic information, a substantial improvement in prediction accuracy is observed. This improvement reflects the ability of the large-scale pretraining to bias the model toward interaction-dependent atomic features that are relevant to reaction outcomes. Because source-sink annotations encode electron-transfer roles that arise from interactions between specific reacting species, the resulting inductive bias is naturally aligned with pairwise relational representations and cannot be readily captured by models that operate solely on independently encoded molecules.

Finally, comparison between relational formulations shows that the pairwise (combinatorial) supergraph outperforms the multi-molecular supergraph when combined with mechanism-aware pretraining. This behavior is consistent with the structure of the source-sink supervision, which is defined at the level of interacting molecular pairs rather than across all reaction components simultaneously. Encoding all molecules within a single supergraph can dilute pair-specific information, whereas the pairwise construction preserves interaction-specific contexts prior to aggregation. In summary, these results confirm that the proposed framework effectively pretrains mechanistically meaningful interaction information and selectively deploys it during fine-tuning, providing a principled and data-efficient strategy for yield prediction.

**Table 3:** Effect of embedding strategy and source-sink pretraining on amide coupling yield prediction. Reported values are MAE on the held-out test set

| Embedding strategy | No pre-training | With pre-training |
|---|---|---|
| Molecular concatenation | 0.17 | - |
| Multi-molecular supergraph | - | 0.16 |
| Pairwise supergraph | 0.19 | 0.14 |

## 4. CONCLUSION

In this study, two complementary approaches for reaction yield prediction were developed and evaluated, incorporating three-dimensional molecular structure and mechanism-derived relational information. First, a denoising-based molecular representation model pretrained on three-dimensional conformational data was extended from single-molecule property prediction to reaction-level modeling. This structure-aware formulation improved robustness under component-wise extrapolation, although molecular-level pretraining alone provided limited gains when transferred directly to reaction yield

prediction.

Second, a mechanism-aware framework was introduced that represents reactions using a pairwise supergraph formulation and leverages electron source-sink annotations for pretraining. By biasing representations toward interaction-dependent atomic regions associated with electron transfer, this approach improved yield prediction in data-constrained settings and outperformed direct training without such pretraining. These results indicate that reaction-level learning benefits from aligning representation granularity and pretraining tasks with mechanistically motivated constructs.

The findings suggest that yield prediction models benefit from moving beyond aggregation of isolated molecular features and instead incorporating interaction-specific, mechanism-derived information. While the present study used two-dimensional graph representations for mechanistic pretraining and was limited by available dataset scale, it establishes a basis for integrating three-dimensional structure and richer mechanistic annotations in future work.

## ABSTRACT

The present work aims to demonstrate the synergy achieved through the integration of biomass gasification with a direct air capture (DAC) system to maximize overall $CO_2$ removal capacity, while simultaneously converting waste into value-added products (hydrogen) and supplying the energy required for DAC operation (BG-$H_2$P-DAC). The proposed configuration is modeled using Aspen Plus to investigate the synergistic interactions and key performance indicators of the BG-$H_2$P-DAC system. Parametric analyses are conducted by varying gasification temperature, air inlet flow rate, and amine concentration and flow rate. The results indicate that increasing the monoethanolamine (MEA) concentration from 10% to 40% leads to a gradual decline in $CO_2$ capture efficiency, accompanied by a reduction in $CO_2$ slip. The system achieves a net specific electricity consumption of 0.0293 MWh/t $CO_2$, confirming that the electricity generated from the integrated steam power cycle is sufficient to fully offset the electrical requirements of the DAC process. The regeneration heat requirement at a steam temperature of 150 °C is 1.32 MWh/t $CO_2$, which represents the total net thermal demand of the DAC unit.

**Keywords**: Carbon Capture, Aspen Plus, Energy, Hydrogen, Environment

## INTRODUCTION

Deep decarbonization pathways aimed at limiting the world's surface temperature increases to no more than 1.5°C have placed significant pressure on the global energy system. One promising avenue to achieve this target is by deploying the renewable sources for clean energy alongside negative emission technologies (NETs).

Sustainable biomass plays a vital role towards the transition to decarbonized economy with broad applications [1]. Gasification of biomass features an effective technology to enhance thermochemical efficiency and curtailing environmental impact. The benefits result from the syngas production composes of hydrogen that serves as the primary fuel in the combustion process. Which render vital potential for multiple products such as methanol, hydrogen, power, and freshwater production[2].

Direct Air Capture (DAC) has emerged as a game changing NET due to its ability to capture $CO_2$ directly from the atmosphere (demand-side) [3], in contrast to other carbon capture technologies that primarily focus on the supply-side. DAC operates by removing $CO_2$ directly from ambient air through chemical processes using liquid solvents or solid sorbents usually requiring high and low regeneration temperatures.

Few studies have explored the potential of integrating biomass gasification, DAC couple/hybrid with other technologies. A novel integrated sustainable aviation fuel (SAF) production system combining DAC, $CO_2$ electrolysis, and biomass gasification was proposed and evaluated by [3]. The system achieved an overall energy efficiency of 54.7 % and a negative global warming potential estimated at -339.7 g $CO_2$-e/MJ SAF. In another study, [4] designed a high-temperature direct air capture (HTDAC) system integrated with Fischer-Tropsch synthesis (FTS) for renewable jet fuel production. The proposed configuration resulted in a fuel specific energy consumption about 122 MJ/kg jet fuel with DAC accounting for about 16 % of the total energy demand. From a thermodynamic perspective, the theoretical minimum energy required to separate $CO_2$ from air using a DAC

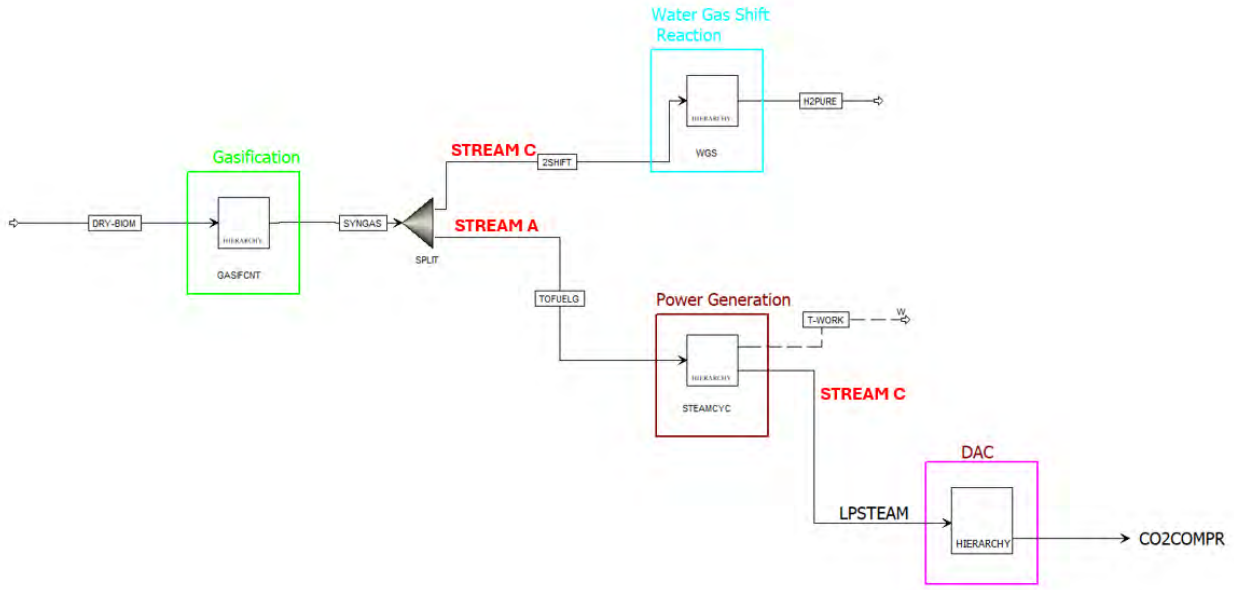

**Figure 1:** Hierarchies block in the Aspen Plus interface for BG-PH2-DAC system.

system and deliver it in pure form at 1 atm has been reported to be approximately 0.5 GJ per tonne of $CO_2$ [5]. The integration of nuclear small modular reactor (SMR) with a low-temperature solid sorbent DAC system was evaluated by [6]. Based on the DAC plant's output and energy requirement, a thermal input of 51.25 MW was required necessitating the SMR to supply 100°C steam at this capacity. Utilizing this amount corresponds to an estimated 15% reduction in electricity generation. An innovative low-$CO_2$ emission system that integrates biomass gasification, monoethanolamine (MEA)-based $CO_2$ capture, and methanol synthesis for waste-to-energy and power-to-fuel applications was proposed by [7]. This system generates 75 MW of electricity with the capture unit exhibits a capture efficiency of 59.24 % requiring 1.92 MW of power per kilogram of $CO_2$ captured. While extensive research has been conducted on various technology integration configurations, limited research has focused on integrated application of biomass gasification combined cycle systems for simultaneous power and hydrogen production coupled with DAC (BG-$PH_2$-DAC).

## Research contribution

Biomass gasification has been evident to make a significant contribution to achieve net-zero/negative emissions [8, 9]. Synergizing biomass gasification with a combine cycle system has been proven to enhance power generation efficiency and environmental performance compared to a conventional coal fired power plant [10].

A major challenges associate with DAC lies in its high $CO_2$ capture cost [11] and substantial demand of low carbon thermal and electrical energy [6]. Where, electricity is required to operate fans and auxiliary equipment, while a considerable amount of heat to regenerate the capture medium and release the captured $CO_2$. Despite its considerable mitigation potential, the large-scale commercialisation and deploying DAC of systems remain challenging. Although recent improvements have brought DAC closer to commercial feasibility, high regeneration energy and substantial energy requirement continue to represent a critical barrier to widespread adoption [5, 12].

The ability of biomass gasification to generate power in its downstream processes offer a significant advantage for integrated industrial ecosystem that include DAC. Present work demonstrates this synergy at a computational level (technology readiness level 2) serving as a preliminary contribution toward the development of a smart industrial ecosystem. Furthermore, this work highlights how the low-carbon energy required for DAC can be accommodated by the power produce from gasification system. The high-purity hydrogen produced via the water-gas shift reaction in biomass gasification enhances the efficiency of industrial ecosystems by enabling multiple energy vectors from renewable biomass sources.

# METHODOLOGY

## Process description

A simplified diagram of BG-$PH_2$-DAC system proposed in this study is illustrated in Figure 1. The diagram shows the hierarchical blocks used in Aspen Plus simulation consisting of biomass gasification, water gas shift (WGS), steam cycle and DAC processes. In this work, enriched air is employed as the gasification agent to produce syngas. A study has confirmed that using air as a gasification agent can produce high-purity $H_2$ [13], demonstrating the technical feasibility of this approach. Based on Figure 1, the syngas is controlled and divided into multiple streams for the co-production of electricity (Stream A), low pressure steam (Stream B) and hydrogen (Stream C). For Stream A, the syngas is cooled before entering the combustion unit, where it is burned with compressed air. The hot combustion gases drive a gas turbine and waste heat is recovered through a series of heat exchangers to generate power in combine cycle. At the down-stream process, energy required by the DAC is accommodated by generated power (assume as a pseudo stream/connection) and bleed steam is used for solvent regeneration at stripper. For Stream C, the syngas undergoes a water-gas shift reaction to increase its hydrogen content.

## Model development

### Biomass integrated gasification combine cycle coupled with water gas shift (BG-$PH_2$) process

A simplified biomass integrated gasification combine cycle model is adapted from a study conducted by [14], while WGS process is based on the simplified model developed in [15, 16]. Biomass gasification is modelled in Aspen Plus using a non-conventional solid approach combined with equilibrium-based reactors. The process consists of biomass decomposition, gasification, particulate removal, and syngas cleaning prior to its use in a combined cycle gas turbine. In gasification model, woodchip is used as fuel with their proximate and ultimate composition is based on [13, 17]. Based on the experimental study conducted by [13], utilization of woodchips as fuel source can produce almost $H_2$ purity of ≥ 99.977 vol.%

The WGS reactor converts CO and steam into $H_2$ and $CO_2$ through the reversible chemical reaction: $CO + H_2O \rightleftarrows CO_2 + H_2$. During this process, raw syngas is mixed with steam to achieve high purity $H_2$. The cooled syngas mixer then enters the RStoic reactor containing iron-based catalyst where perfect mixing is assumed for modelling purposes. For simplification, a single-stage WGS reactor is employed in this study following the process suggested by [16]. This process involves high temperature stage between 300 – 500°C. Finally, the tail gas stream ($CO_2$ + unconverted gases) is removed by the scrubber and high purity $H_2$ is released on the top scrubber column. Details of the model development and Aspen Plus unit operations involved is presented in Appendixes S1 and S2.

### Direct air capture with $CO_2$ compression

The DAC model is developed and adapted from [5, 11, 18] utilizing the mature MEA absorption process modified to suit DAC environmental conditions. This technology is deployed as it holds a promise as a low-cost and scalable solution for DAC [19]. Details of the model development and Aspen Plus unit operations involved is presented in Appendixes S1 and S2.

### Hybrid BG-PH2-DAC

The individual models are interconnected as illustrated in Figure 1. A splitter unit operation is used to divide the syngas between $H_2$ production and power generation at 50% ratio. For steam supply to the reboiler, a MHeatX unit operation is employed. In the stripper column (Radfrac), reboiler option is disable as steam is supplied externally from a low-pressure steam. The individual models are validated independently before being integrated to ease the convergence process.

# RESULT AND DISCUSSION

## Synergistic analysis of BG-PH2-DAC

Synergistic analysis through sensitivity evaluation is conducted by manipulating several operating variables such as gasification temperature, air inlet (at DAC), and amine solvent concentration and flowrate. The analysis is conducted based on nominal operating condition of BG-$PH_2$-DAC plant as tabulated in Appendix S2.

Figures 2(a)-(b) show the strong influence of gasifier temperature on syngas composition and the subsequent enhancement of hydrogen yield through the WGS reaction during biomass gasification. In Figure (a), increasing the gasifier temperature from 300 °C to around 700 °C markedly increases the $H_2$ and CO mole fractions, indicating enhanced devolatilization, char gasification, and endothermic reactions such as steam reforming [20] and the Boudouard reaction [21]. The $H_2$ mole fraction reaches a maximum at approximately 700 °C, beyond which it slightly declines, suggesting the increasing dominance of competing high-temperature reactions and which shift the equilibrium[20]. In contrast, [20] obtained the highest $H_2$ fraction at 800 °C, suggesting the existence of optimal condition for efficient $H_2$ production. The $CO_2$ shows a decreasing trend with temperature, reflecting its consumption in gasification and affect of the endothermic character of Boudouard reaction [22].

After the WGS reactor (Figure 2(b)), $H_2$ started to produce at 300 °C and increased drastically until 700 °C, with $H_2$ mole fraction significantly increasing and stabilizing at around 34–35% for temperatures above 700 °C, while $CO_2$ correspondingly increases due to CO conversion. This plateau indicates that the WGS reaction approaches equilibrium and all methane had been converted into hydrogen. Similar trend was observed in the

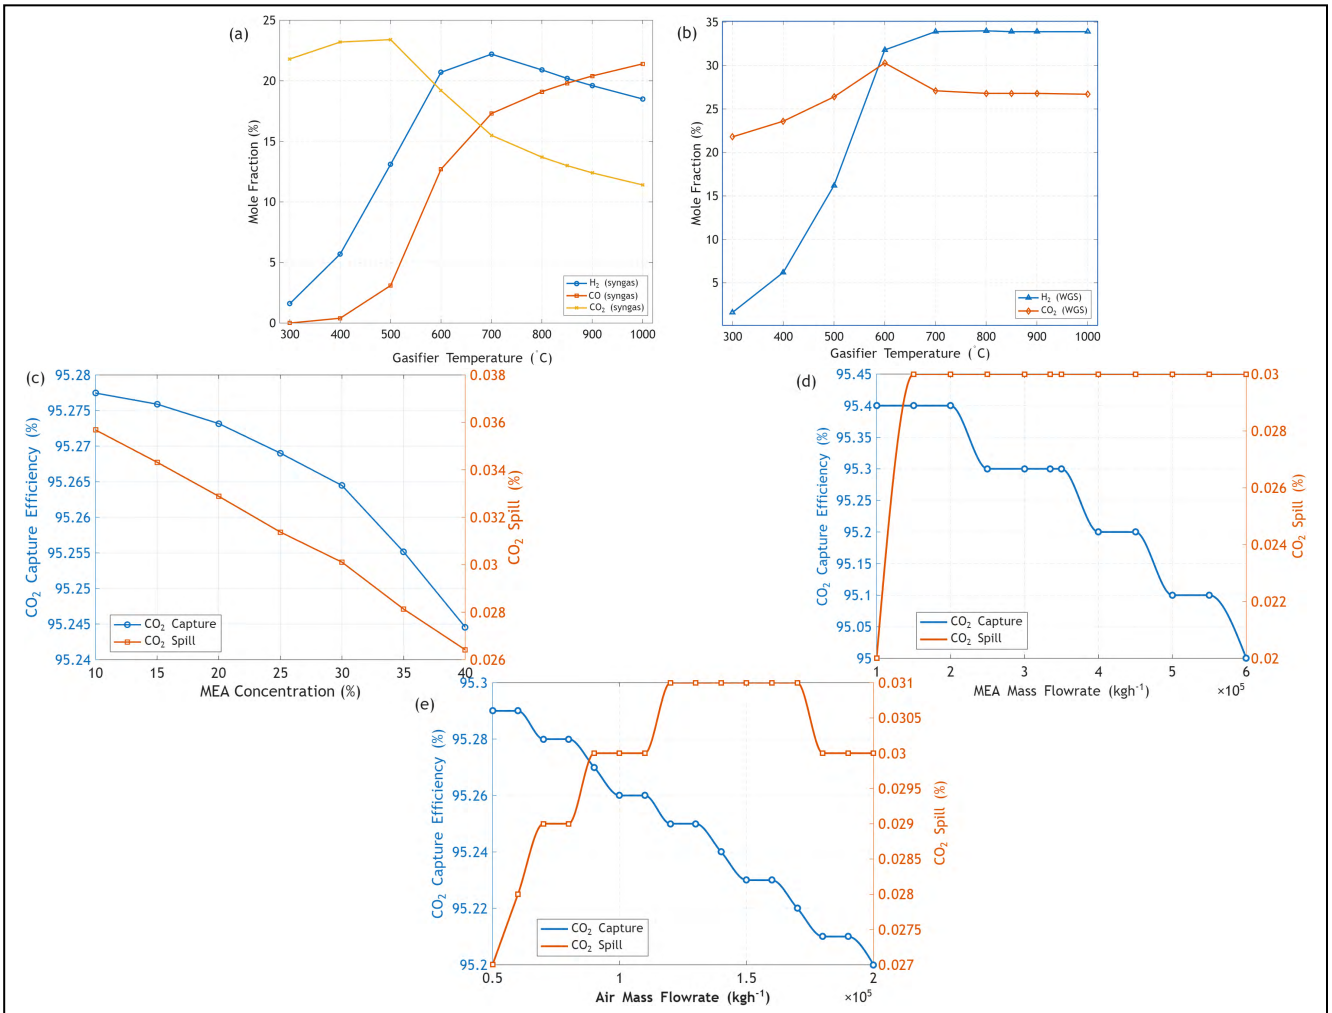

**Figure 2.** Synergisitc effect of BG-PH$_2$-DAC BG at nominal operating condition, in which a single parameter is varied (x-axis) while all other operating conditions are maintained constant. (a) Variation of gasification temperatue with syngas composition, (b) Variation of gasification temperature with gas composition after WGS, (c) Variation of MEA concentration with $CO_2$ capture rate and $CO_2$ spill (top absorber), (d) Variation of MEA mass flowrate with $CO_2$ capture rate and $CO_2$ spill (top absorber), (e) Variation of air mass flowrate with $CO_2$ capture rate and $CO_2$ spill.

study conducted by [15].

Figures 2 (c)–(e) present a synergistic analysis of the downstream process (DAC), highlighting the sensitivity of $CO_2$ capture efficiency and $CO_2$ slip (off-gas at absorber column) to key operating variables. In Figure 2(c), increasing the MEA concentration from 10% to 40% results in a gradual decline in $CO_2$ capture efficiency, accompanied by a reduction in $CO_2$ slip. This trend suggests that while higher MEA concentrations enhance the solvent's $CO_2$ absorption capacity, mass transfer limitations and high liquid-to-gas volumetric flow ratio may hinder overall capture efficiency under DAC conditions [23]. Additionally, higher lean loading (i.e. higher MEA concentration) can lead to low productivity (low capture efficiency) due to increased pressure drop within the column [11]. Figure 2(d) shows the effect of MEA mass flow rate, where an increase initially sustains high capture efficiency within the range of 95.0 – 95.4%. This behavior indicates that, within this specific range of MEA flowrate, the flowrate ensures complete wetting of the packing and effective gas–liquid contact for reaction and capture [23]. Meanwhile, $CO_2$ slip remains relatively stable, implying that solvent availability is no longer the limiting factor. As illustrated in Figure 2(e), increasing air mass flow rate exhibits minimal impact on capture efficiency, exhibiting a slight decreasing trend accompanied by a corresponding increase in $CO_2$ slip. This trend indicates that higher air flow rates may minimize the required contactor inlet area [23], though this may subsequently diminish the capture efficiency. This interpretation is based on the qualitative trend rather than a quantitative approach.

## Key performance analysis of BG-PH2-DAC

Table 1 summarizes the key performance indicators of the integrated BG-$PH_2$-DAC system operating under nominal conditions (Appendix 2). The system demonstrates marginal hydrogen production, achieving a specific $H_2$ yield of 0.0292 kg $H_2$/biomass with an almost complete hydrogen purity (~100%). This indicates efficient syngas conversion and effective downstream purification. Simultaneously, the process generates 66.25 kg$CO_2$/biomass, of which approximately 98% is successfully captured, highlighting the strong integration between biomass gasification, hydrogen production, and DAC subsystem.

The specific $CO_2$ capture energy requirement is quantified at 4.74 MJ/kg $CO_2$, indicating a moderate thermal energy intensity for solvent regeneration. This result is consistent with the findings of [24] who reported a regeneration duty of approximately 4.0 MJ/kg $CO_2$ when increasing the reboiler temperature from 123 to 150 °C. This minor deviation can be attributed to differences in solvent operating conditions and process integration strategies. In terms of power generation, the system delivers a gross electrical output of approximately 6.5 MWe, corresponding to a specific gross power output of 0.302 MWh/t $CO_2$.

As the present work employed a simplified BG-$PH_2$-DAC plant design, the electricity consumption for the air contactor is adopted from [6] at 0.232 MWh/t $CO_2$. Electricity consumption for $CO_2$ compression is calculated at 0.04 MWh/t $CO_2$ with auxiliary pumping at 0.0007 MWh/t $CO_2$. This results in a total DAC electricity demand of 0.2727 MWh/t $CO_2$. It can be observed that the pumping energy requirement in this study is slightly lower than the 0.007 MWh/t $CO_2$ reported in [24], as only a single pump is considered in the present configuration. Larger discrepancies are noted in $CO_2$ compression work, where other studies reported higher values of 0.0944 MWh/t $CO_2$ (0.34 MJ/kg $CO_2$) [25] and 0.132 MWh/t $CO_2$ (0.475 MJ/kg $CO_2$) [26].These differences are primarily attributed to variations in compressor design assumptions and isentropic efficiencies. Overall, the electrical energy demand (for DAC) reported here is comparable with the value reported by [27] with a difference of 0.0327 MWh/t $CO_2$. As a benchmark, a standalone DAC system typically requires about 1.4 MWh/t $CO_2$ under the external supply of power and heat sources [24].

The resulting net specific electricity of 0.0293 MWh/t $CO_2$ confirms that the electricity generated from the integrated combined power cycle is sufficient to fully offset the electrical requirements of the DAC process. This internal energy integration substantially enhances overall system efficiency and reinforces the feasibility of the BG-$PH_2$-DAC configuration. In this work, net specific electricity is defined as the gross power generated from the steam cycle minus the total electrical demand of the DAC unit. On the thermal side, the desorption heat requirement at a steam temperature of 150 °C is 1.32 MWh/t $CO_2$, which constitutes the total net thermal demand of the DAC unit. This value is slightly higher than the 1.14 MWh/t $CO_2$ reported in the literature [27], reflecting differences in solvent regeneration conditions and heat integration assumptions. Overall, the combination of high $CO_2$ capture efficiency, high-purity $H_2$ production, and effective internal energy utilization underscores the technical viability and energetic coherence of the BG-$PH_2$-DAC system.

## CONCLUSION

This study provides a preliminary insight for the BG-$PH_2$-DAC system that aim to anchor the decarbonization effort while producing multiple energy vectors. A simplified configuration proposed in this work evident the feasibility of integrated system to sufficiently accommodate electricity and thermal energy within the system. Existing work can be enhanced by considering comprehensive plant design with the integration of pressure swing adsorption and detailed combined cycle system to reflect actual operation design.

## ABSTRACT

The rapid integration of renewable energy sources is increasing the volatility and non-stationarity of modern power systems, posing significant challenges for data-driven forecasting models. In particular, concept drift and uncertainty in exogenous inputs such as weather forecasts can severely degrade predictive performance over time. This work proposes a lightweight two-layer forecasting framework that decouples prediction from adaptation. A traditional offline regression model is augmented by an online meta-learner that continuously generates adaptive meta-features, enabling the system to respond to structural changes and noisy inputs without repeated retraining. The framework is evaluated on two real-world case studies. First, concept drift is addressed in nuclear power production forecasting, where abrupt and gradual capacity changes are inferred through an online meta-learner. Second, feature uncertainty is mitigated in day-ahead solar production forecasting by correcting noisy weather forecast inputs. Across both scenarios, the proposed approach consistently outperforms single-layer baselines, reducing root mean squared error by up to 10% and maintaining robust performance over multi-year horizons without retraining. The results demonstrate that meta-learning provides a practical and computationally efficient mechanism for improving forecast robustness in non-stationary energy systems, with applicability to a wide range of power-system forecasting problems.

**Keywords**: Algorithms, Big Data, Modelling, Artificial Intelligence, Energy

## INTRODUCTION

The increasing penetration of renewable energy sources is fundamentally changing the operating conditions of modern power systems. Weather-dependent generation, evolving market mechanisms, and policy-driven structural changes are introducing significant non-stationarity into electricity production and demand time series. Accurate forecasting remains essential for grid operation, market participation, and emerging carbon-aware applications [1, 2], yet conventional data-driven models often struggle when historical patterns no longer hold.

Supervised learning models trained offline remain widely used in energy forecasting applications [3]. While advanced deep learning architectures and sliding-window gradient boosting ensembles represent the current state-of-the-art for raw predictive accuracy, their high computational overhead and requirement for continuous retraining limit their scalability in real-time operational environments. However, these models implicitly assume stationarity in the underlying data-generating process. Violations of this assumption lead to systematic degradation of predictive performance over time, motivating the development of adaptive forecasting strategies.

### Concept Drift and Adaptive Forecasting

Concept drift refers to changes in the statistical relationship between input variables and target outputs over time as described by Tsymbal [4], who formalised the concept and identified several drift patterns, including abrupt, gradual, and incremental drift. In energy systems, concept drift arises from structural events such as power plant commissioning or decommissioning, fuel

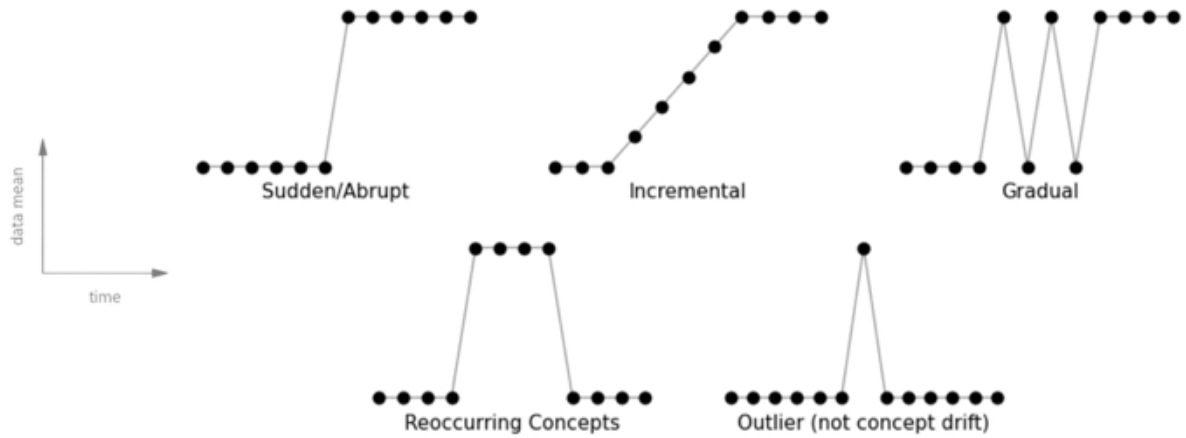

**Figure 1.** – Canonical drift patterns

switching, and regulatory interventions.

These drift types are illustrated schematically in **Figure 1**, which provides a conceptual reference for the experimental scenarios studied later in this work, and illustrates typical concept drift patterns, motivating the need for adaptive forecasting strategies capable of handling both abrupt and gradual changes.

Several approaches have been proposed to address concept drift in regression problems, including sliding-window retraining [5], weighted learning [6], and fully online adaptation [7]. While effective, retraining-based methods are computationally expensive, fully online learners may suffer from instability. On the other hand, Ensemble-based adaptive methods offer a compromise by combining robustness and adaptability.

Adaptive ensemble methods have gained significant attention for non-stationary data streams. Gomes et al. [8] introduced the Adaptive Random Forest (ARF), which integrates online bagging, per-tree drift detection, and background learners to enable localised adaptation. ARF has been successfully applied to a variety of streaming regression problems [9].

Efficient open-source implementations of these methods are provided by modern streaming machine-learning libraries, such as the River library in Python [10], facilitating their deployment in operational forecasting systems.

## Uncertainty in Exogenous Inputs

In addition to structural drift, which refers to physical changes in the system (like equipment aging) rather than the statistical shifts of concept drift, forecasting accuracy is strongly affected by uncertainty in exogenous inputs. Renewable generation forecasting, particularly for solar and wind power, relies heavily on meteorological predictions that are inherently uncertain. Errors and biases in weather forecasts propagate directly into production forecasts, often resulting in large prediction errors [11].

Various strategies have been proposed to mitigate this effect, including probabilistic forecasting [12], noise injection during training [13], and ensemble-based uncertainty modelling [14]. More recently, meta-learning approaches have been explored to correct biased, noisy, or missing inputs online without retraining the main forecasting model [15].

## Contribution

This paper proposes a two-layer meta-learning framework designed to address both concept drift and feature uncertainty without repeated retraining of the main forecasting model. The key contributions are:

1. A unified two-layer architecture that separates prediction and adaptation through meta-feature generation.
2. An online meta-learning strategy that adapts to structural changes and noisy inputs in streaming data.
3. Validation on real-world energy datasets covering both capacity-driven concept drift and weather-driven feature uncertainty.

# METHODOLOGY

The proposed framework combines an online meta-learner with a base forecaster that undergoes offline training. In the present implementation, the base forecaster is a linear regression model trained using ordinary least squares (implemented using river [0.23.0], scikit-learn [1.7.2]). All experiments were conducted in Python [3.12.10]. The model is trained once on historical data, and its coefficients remain fixed during the evaluation

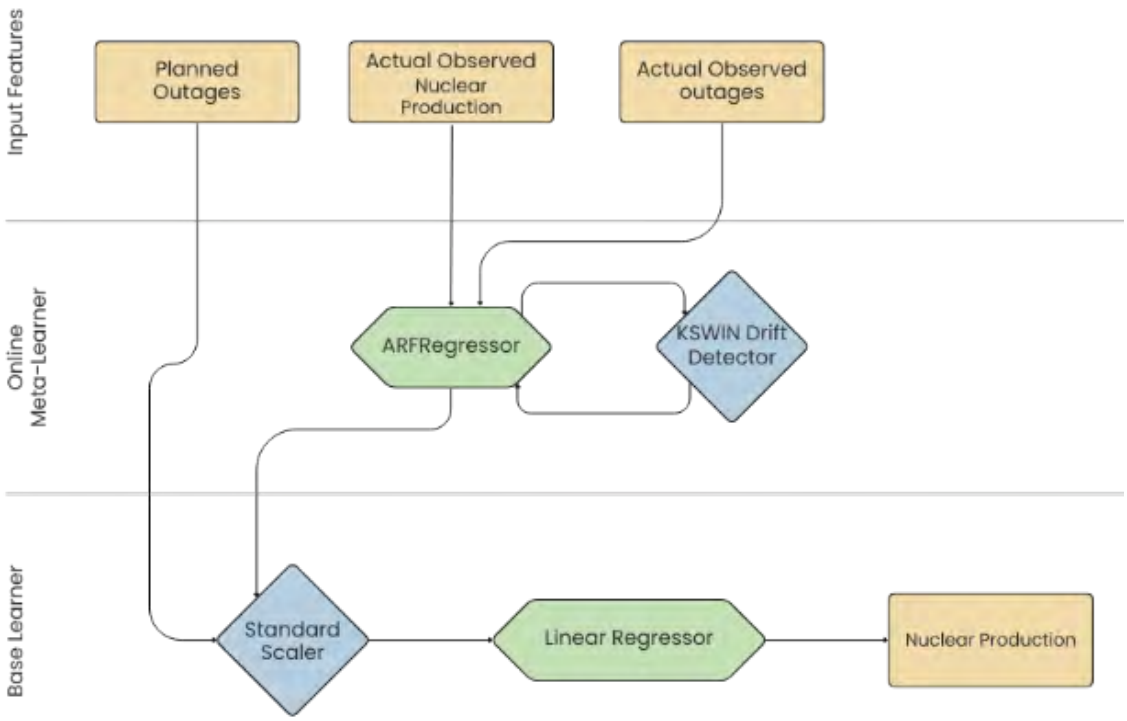

**Figure 2.** – Graphical representation of the two-layer framework, with an online meta-learner estimating operational capacity, which is appended to the offline forecaster as a meta-feature

period. The choice of a simple regression model for the base forecaster was deliberate. While modern forecasting often employs complex ensembles, utilizing a static offline baseline allows the isolated impact of the adaptive meta-feature to be measured cleanly, proving that our lightweight layer can rescue legacy models without the need for computationally expensive sliding-window retraining. This designation signifies that the model is pretrained on historical data and its internal weights remain fixed throughout the deployment phase. To enable adaptation without retraining the forecaster, the system augments the input with meta-features generated online.

Predictions $\hat{y}_t$ at time $t$ are computed as:

$$\hat{y}_t = f(x_t, m_t),$$

where $x_t$denotes the original feature vector and $m_t$ is a meta-feature generated by:

$$m_t = g(z_t),$$

with $g(\cdot)$ representing the meta-learner and $z_t$ auxiliary information such as recent observations, forecast errors, or uncertain inputs. During deployment, the framework operates sequentially on the data stream. At each time step, the meta-learner receives the most recent observations and updates its internal state. The resulting meta-feature is appended to the original feature vector and passed to the fixed offline forecaster, which produces the final prediction. This streaming workflow enables continuous adaptation without modifying the parameters of the base forecasting model.

The overall architecture of the proposed two-layer framework is shown in **Figure 2**, which illustrates the interaction between the fixed offline forecaster and the online meta-learner. The separation of prediction and adaptation is central to the proposed approach and enables efficient handling of non-stationarity. In the nuclear forecasting case study (see below), the meta-learner estimates a latent variable representing the effective operational capacity of the nuclear fleet. This estimate is derived incrementally from the production time series and the outage signal available in the data stream. At each time step, the Adaptive Random Forest updates its estimate using the newly observed production value, producing a capacity-related feature that reflects the current operational state of the system. This estimate is then appended to the original feature vector as a single additional input to the offline forecaster.

The meta-learner is implemented using an Adaptive Random Forest operating in streaming mode as described by Gomes et al. [7]. The Adaptive Random Forest implementation used in this work is based on the River library [10]. Across both case studies the ARFRegressor always uses the default (n_models=10) unless otherwise stated. In the first case study, we override the default detector with KSWIN, whereas in the second case study, we

use the default ARF configuration, which includes ADWIN detectors. The detectors act to identify distributional changes and trigger local model updates. Unless otherwise specified, the remaining hyperparameters follow the default configuration provided in the River implementation. Internal drift detection mechanisms allow individual trees within the ensemble to adapt locally, while the forecaster remains fixed, reducing computational overhead compared to retraining-based approaches. Models are compared using a set of metrics, including the coefficient of determination ($R^2$), the Root Mean Squared Error (RMSE), the Mean Absolute Error (MAE), the Mean Squared Error (MSE) and the Symmetric Mean Absolute Percentage Error (sMAPE).

All experiments were implemented in Python using the River streaming machine learning library (version 0.23.0). To ensure exact reproducibility of the Adaptive Random Forest's stochastic processes, the global random seed was fixed at 42 across all experiments. The full experimental workflow, including data preprocessing and model configuration, follows the methodology described above and can be reproduced using the same datasets and parameter settings.

### Case Study I: Concept Drift in Nuclear Power Forecasting

The first case study evaluates the framework under structural concept drift in nuclear power production. Nuclear generation is generally stable but subject to abrupt changes due to plant shutdowns, making it a suitable testbed for drift handling.

The meta-learner is tasked with estimating the operational capacity of the nuclear fleet, a latent variable not directly observable from production data alone. This estimated capacity is provided as a meta-feature to an offline regression model trained prior to major structural changes. Experiments were conducted on national-level nuclear production data for Germany, Switzerland, and the Netherlands, sourced from the ENTSO-E transparency platform [17]. The dataset consists of hourly aggregated production measurements spanning the period 2018–2024. Production values were aligned with outage information obtained from the European Energy Exchange (EEX). The resulting time series was cleaned for missing values and resampled to hourly resolution to ensure temporal consistency across all variables.

### Case Study II: Feature Uncertainty in Solar Power Forecasting

The second case study addresses feature uncertainty in day-ahead solar power forecasting. Solar generation forecasts rely heavily on weather predictions, which are inherently uncertain and may exhibit systematic bias.

In this scenario, the meta-learner operates as a feature uncertainty corrector. It learns the relationship between forecasted and observed solar radiation in an online fashion and outputs corrected radiation estimates as meta-features. The forecaster uses these corrected inputs to predict solar production.

The framework was evaluated on aggregated Swiss solar production data using three configurations: a baseline model trained on forecasted weather (using data from 2023-01-01 to 2024-01-01), the proposed two-layer model with corrected features, and an upper-bound model trained on observed weather over the same training interval. Solar radiation forecasts were obtained from the Visual Crossing Weather API and correspond to day-ahead meteorological predictions. Observed solar radiation values were aligned with the forecasts at hourly resolution. The forecasting model uses the radiation forecast together with the meta-corrected radiation estimate produced by the meta-learner.

## RESULTS AND DISCUSSION

### Structural concept drift: Nuclear Power Production

Nuclear power production constitutes a particularly challenging forecasting problem under concept drift. Unlike renewable generation, which is primarily driven by stochastic exogenous variables, nuclear production is dominated by structural constraints, namely installed capacity and plant availability. When these constraints change due to policy decisions or outages, the mapping between historical inputs and future outputs is fundamentally altered.

This effect is particularly evident in Germany, where the progressive nuclear phase-out resulted in multiple abrupt capacity reductions over the study period. The timing and magnitude of these events are shown in **Figure 3**, which highlights the strongly non-stationary nature of the production time series. Switzerland and the Netherlands exhibit milder forms of drift, characterised by gradual capacity changes and shorter outage periods.

These three countries, therefore, provide a spectrum of drift regimes, allowing the robustness of the proposed framework to be assessed under increasing levels of structural disruption.

We compared our proposed Two-Layer Framework (TLF) against a Single-Layer (SL) baseline defined as an offline linear regression model using only the outage signal as input. In the TLF, an online Adaptive Random Forest meta-learner estimates a latent capacity-related feature from the data stream (hourly resolution), and a second, offline linear regression main model predicts production using both outage and the meta-learner's output. Models were trained on 2018-01-01 to 2020-01-01 and evaluated on 2020-01-01 to 2024-01-01. Forecasts were generated sequentially in a walk-forward evaluation setting. At each time step in the test period, the meta-

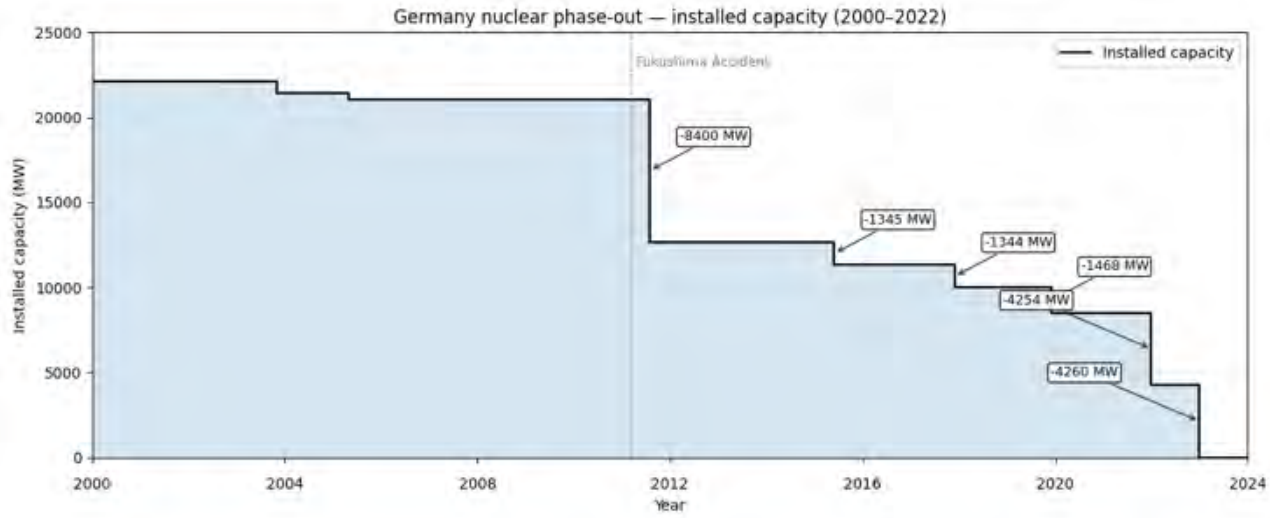

**Figure 3.** – Timeline for Germany's nuclear power plants phase-out culminating in April 2023. Source : Mez et al. [16].

learner was updated using the newly observed production value before the next prediction was produced.

Model performance was evaluated using several complementary error metrics, including RMSE, MAE, sMAPE, and the coefficient of determination ($R^2$). These metrics capture both absolute prediction accuracy and relative forecasting performance across different production scales. A quantitative comparison of forecasting performance is reported in **Table 1**, which aggregates RMSE, MAE, sMAPE and $R^2$ metrics for Germany, Switzerland, and the Netherlands.

**Table 1** – Performance comparison of a single-layer (SL) traditional model and our two-layer framework with meta-learner (TLF) for Germany (DE), Switzerland (CH) and the Netherlands (NL).

| Country | Model | $R^2$ [-] | RMSE [MW] | MAE [MW] | sMAPE [%] |
|---|---|---|---|---|---|
| **DE** | **SL** | -1.5547 | 4525 | 3714 | 71.8 |
| | **TLF** | 0.9824 | 375 | 293 | 40.0 |
| **CH** | **SL** | 0.6966 | 369 | 348 | 14.4 |
| | **TLF** | 0.9732 | 110 | 34 | 1.8 |
| **NL** | **SL** | 0.9644 | 26 | 10 | 12.3 |
| | **TLF** | 0.9698 | 24 | 6 | 9.5 |

**Table 1** shows that the two-layer framework consistently outperforms the single-layer baseline in the presence of concept drift. In the Netherlands, where structural changes are limited, both models achieve similar performance, indicating that the meta-learning layer does not degrade accuracy under quasi-stationary conditions. This is an important result, as it demonstrates that the proposed approach introduces no penalty when adaptation is not strictly required.

In Switzerland, where gradual capacity changes and recurring outages occur, the two-layer framework yields a clear improvement over the baseline. RMSE reductions on the order of several percentage points are observed, alongside a noticeable increase in $R^2$. This indicates that the meta-learner is able to track slow structural changes effectively, providing the forecaster with a more accurate representation of the system's operational state.

Germany represents the most challenging case. Here, the baseline model rapidly loses predictive power following major shutdown events, as it continues to rely on outdated capacity assumptions. As shown in **Table 1**, the baseline model for Germany yields a severely negative $R^2$ (-1.5547). It is important to note that the coefficient of determination ($R^2$) measures the model goodness-of-fit and is not strictly equivalent to the squared Pearson correlation coefficient ($r^2$). Consequently, $R^2$ is not bounded at zero and can drop below -1 when a model's predictions perform substantially worse than simply predicting the historical mean of the observed data. In this case, because the static baseline model continuously relies on outdated capacity assumptions after abrupt phase-out events, its predictions exhibit extreme systematic bias, mathematically resulting in this highly negative value. The two-layer framework significantly mitigates this degradation, achieving substantially lower error metrics over extended periods. While performance still deteriorates during extreme shutdown phases, the meta-learning approach preserves a meaningful level of predictive accuracy where the baseline effectively fails.

While aggregate metrics provide a useful summary,

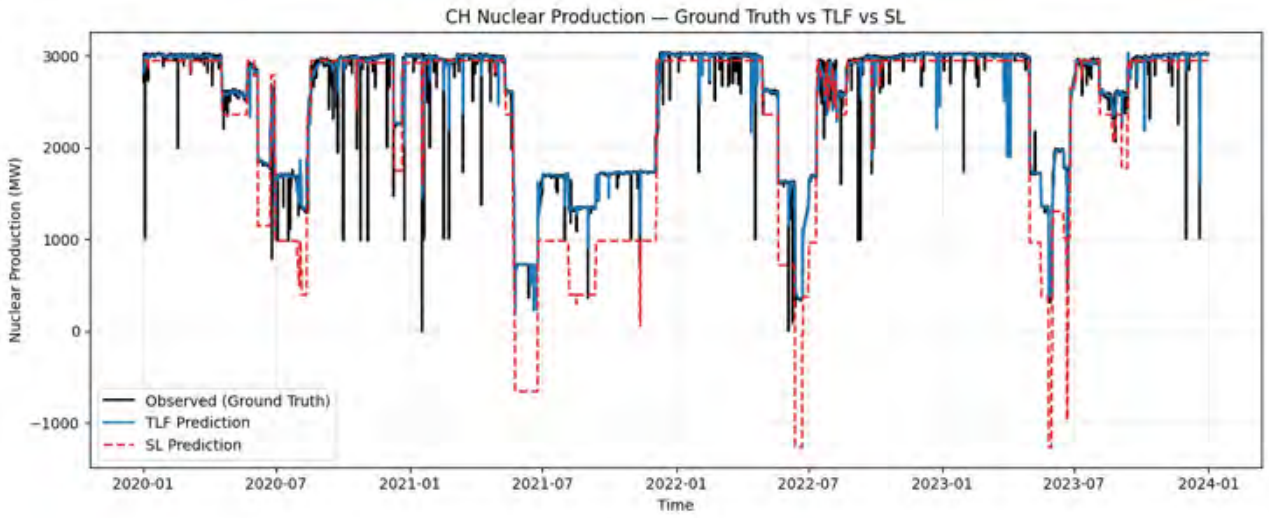

**Figure 4.** – Predictions of the Swiss nuclear production using the two-layer framework. The model tracks structural change better than the single-layer baseline.

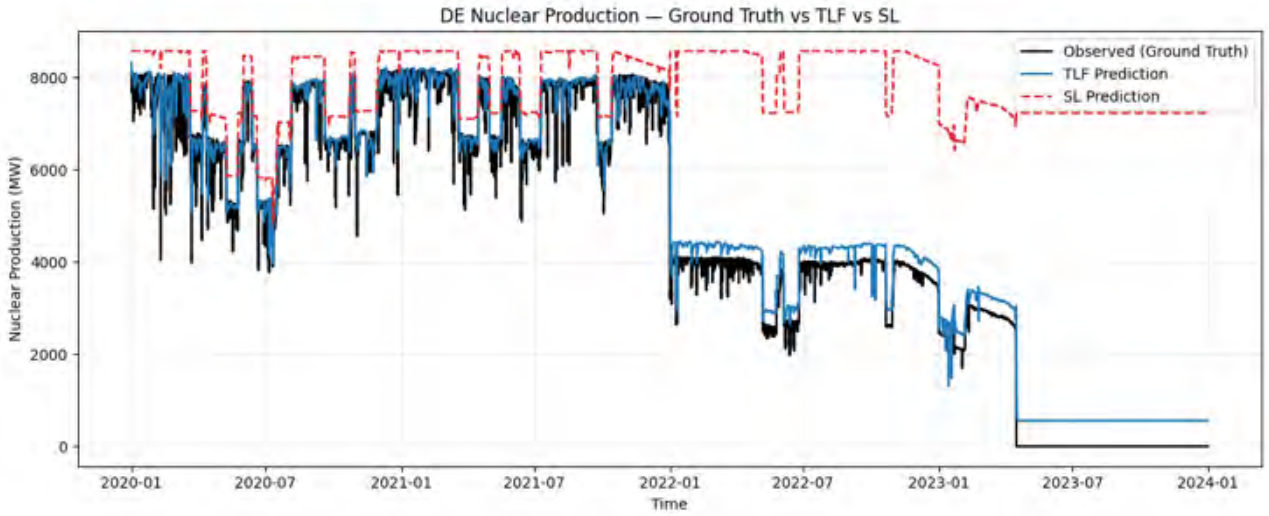

**Figure 5.** – Predictions of the German nuclear production using the two-layer framework. Despite improvements over the baseline, large abrupt capacity shutdowns remain challenging.

they obscure the temporal dynamics of adaptation. These dynamics are illustrated in **Figures 4 and 5**, which show predicted and observed nuclear production for Switzerland and Germany, respectively.

**Figure 4** demonstrates how the two-layer framework maintains close alignment with observed production over time, even as capacity evolves. In contrast, the baseline model exhibits systematic bias during extended outage periods, reflecting its inability to adapt to changing structural constraints.

**Figure 5** provides a more nuanced picture. Following abrupt shutdown events, both models experience an immediate increase in error. However, the two-layer framework adapts more rapidly, reducing bias and variance over subsequent time steps. This behaviour reflects the ability of the Adaptive Random Forest meta-learner to detect distributional change and update its internal representation accordingly.

Importantly, the results also reveal the **limits of adaptation**. When nuclear capacity approaches zero, the latent-variable assumption underpinning the meta-learner becomes invalid. In such cases, the model cannot fully recover, highlighting a fundamental limitation of any approach that relies on historical production patterns. This observation is critical and underscores the importance of explicitly acknowledging failure modes in adaptive forecasting systems.

From an engineering perspective, these results demonstrate that the proposed framework offers a practical alternative to frequent retraining. Structural capacity

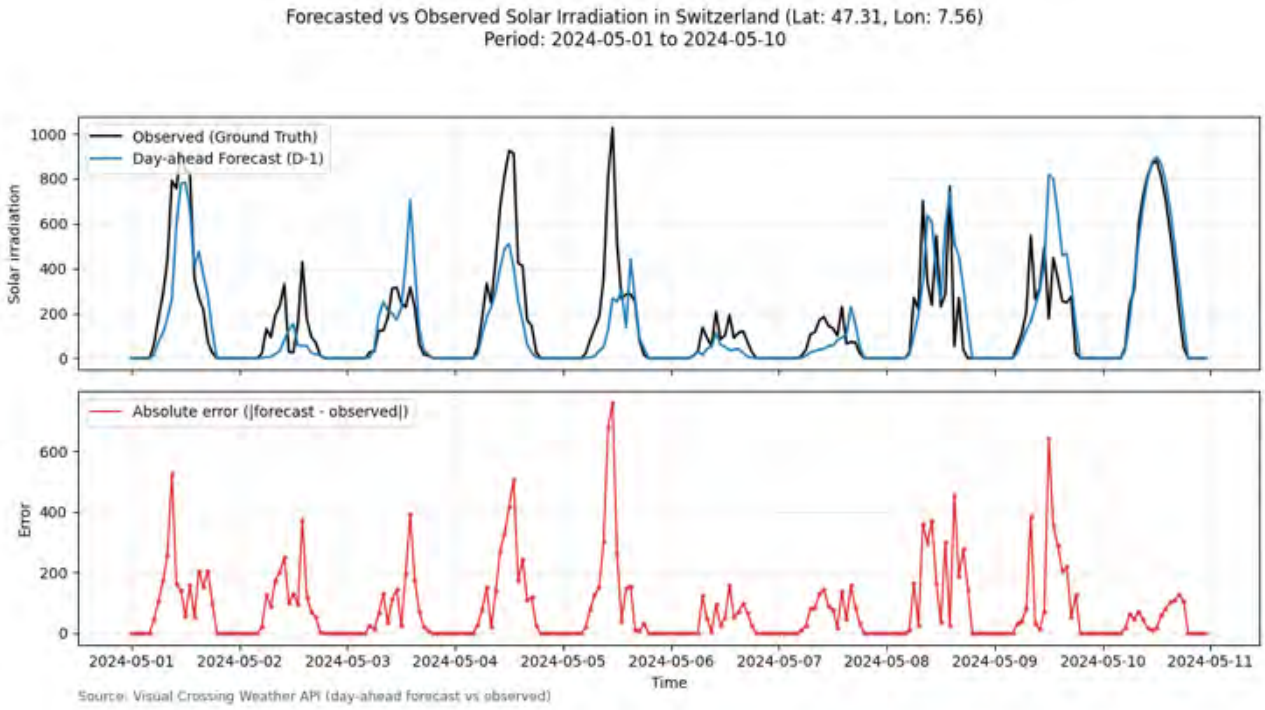

**Figure 6.** – Forecasted vs. observed solar irradiation in Switzerland (Lat: 47.31, Lon: 7.56) over the period May 1 to May 10, 2024. Data source: Visual Crossing Weather API. The top panel shows day-ahead forecasts (blue) deviating from observations (black), while the bottom panel tracks the absolute error, demonstrating recurrent inaccuracies.

changes are handled internally by the meta-learner, reducing the need for manual intervention or model redevelopment. This is particularly relevant for operational forecasting systems managing multiple assets or regions simultaneously.

Moreover, the results suggest that the two-layer approach is especially well suited to **moderate-to-strong drift regimes**, where structural changes occur but do not completely invalidate the historical relationship between inputs and outputs.

## Feature uncertainty: Solar Power Production

In contrast to nuclear power, solar power production is dominated by uncertainty in exogenous inputs, particularly weather forecasts. Even when the underlying physical relationship between irradiance and production remains stable, errors in meteorological predictions introduce noise and bias that directly affect forecast accuracy.

This effect is illustrated in **Figure 6**, which compares forecasted and observed solar radiation. The figure reveals both random dispersion and systematic deviations, indicating that forecast errors are neither negligible nor purely stochastic.

Forecasting performance is summarized in **Table 2**. We compare the Baseline model against our Two-Layer Framework, as well as an "Upper Bound" (Oracle) model. The Upper Bound model was trained and tested using observed (perfect) weather data rather than forecasts; it represents the theoretical limit of performance achievable if meteorological predictions were error-free.

**Table 2** – Performance comparison of the Baseline, Two-Layer, and Upper Bound models for Swiss solar production forecasting (Test set: 01.01.24 to 01.01.25). Metrics are computed on hourly aggregated data.

| Model | $R^2$ [-] | RMSE [MW] | MAE [MW] |
|---|---|---|---|
| **Baseline** | 0.7183 | 436.52 | 215.84 |
| **Two-Layer** | 0.7711 | 393.50 | 198.43 |
| **Upperbound** | 0.7740 | 391.34 | 185.34 |

**Table 2** shows that the baseline model suffers from elevated RMSE and MAE due to error propagation from uncertain inputs. Introducing the meta-learning layer leads to a consistent reduction in both metrics, with RMSE improvements approaching 10%(reducing from

437 to 394 MW). While the two-layer framework does not fully match the upper-bound model, it recovers a substantial fraction of the lost performance.

This result is particularly significant, as it demonstrates that meaningful gains can be achieved **without access to perfect information** and without retraining the main forecasting model.

Beyond average error metrics, the two-layer framework also exhibits improved behaviour during extreme events. The analysis shows that large forecast errors are disproportionately reduced, indicating that the meta-learner is especially effective at correcting severe input deviations.

This observation is consistent with the ensemble nature of the Adaptive Random Forest, which can capture nonlinear relationships between forecasted and observed weather variables. As a result, the meta-learning layer acts as a dynamic error filter, attenuating the impact of extreme weather forecast inaccuracies.

Comparing the solar and nuclear case studies reveals an important distinction between **structural non-stationarity** and **stochastic uncertainty**. In the solar case, the underlying system remains stable, and the meta-learner operates primarily as a noise corrector. In the nuclear case, the system itself evolves, requiring the meta-learner to infer latent structural variables.

Despite these differences, the same two-layer architecture proves effective in both settings. This highlights the generality of the proposed framework and supports the claim that decoupling prediction and adaptation is a powerful design principle for energy forecasting under non-stationarity.

## Overall Discussion and Lessons Learned

Across both case studies, several key insights emerge:

1. **Adaptation without retraining is feasible** for a wide range of non-stationary energy forecasting problems.
2. **Meta-features provide a flexible interface** between adaptive components and fixed forecasters.
3. The framework performs best under **partial but persistent non-stationarity**, while extreme regime shifts remain challenging.
4. The computational efficiency of the approach makes it attractive for large-scale operational deployment.

These findings position the proposed two-layer framework as a practical compromise between static models and fully online learning systems.

# CONCLUSIONS

This paper proposes a two-layer meta-learning framework for energy forecasting under non-stationary conditions, addressing both structural concept drift and uncertainty in exogenous inputs. By decoupling prediction from adaptation, the framework enables lightweight online adjustment without retraining the main forecasting model.

Results from real-world case studies demonstrate that the proposed approach consistently improves forecasting robustness across heterogeneous settings. In nuclear power production forecasting, the meta-learning layer effectively tracked capacity-driven structural changes, substantially reducing error relative to static baselines and maintaining meaningful predictive performance under moderate and strong drift. In solar power forecasting, the framework mitigated error propagation from uncertain weather inputs, recovering a significant portion of the performance gap to an upper-bound model trained on observed meteorological data.

An important outcome of this work is the demonstration that adaptation can be localised within a meta-layer, avoiding the computational cost and operational complexity associated with frequent retraining or fully online learning. This makes the proposed framework particularly suitable for large-scale operational forecasting systems.

The framework's limitations become apparent under extreme regime shifts that fundamentally invalidate historical relationships, and the present work is restricted to point forecasting. Future research will therefore focus on extending the approach to probabilistic forecasting, improving robustness to extreme structural breaks, and evaluating its applicability to additional energy system use cases.

Overall, the results indicate that two-layer meta-learning provides a practical and effective strategy for improving energy forecasting performance in evolving power systems.

## ABSTRACT

Direct air capture is gaining significant interest due to its potential to achieve carbon-negative emissions. With the aim to reduce the energy consumption and in line with the electrification of chemical processes, the absorption direct air capture system is integrated into a bipolar membrane electrodialysis cell stack for solvent regeneration and carbon dioxide release. The scheme solution is characterized by carbon dioxide bubbles inside the cell reducing efficiency so that other regeneration schemes have been proposed in the literature. A direct comparison of those is missing in the existing state of the art: the present work wants to fill this gap. In addition to the above process, the reaction of the rich solution with a weak organic acid and the use of both nanofiltration and reverse osmosis membranes are considered in other process schemes. The three case studies are modelled in Aspen Plus software with the aim to compare the energy consumption and total cost while the environmental impact is evaluated with the life cycle assessment methodology. Results show that the best capture process from economic and environmental point of views is that using only a bipolar membrane electrodialysis for solvent regeneration and carbon dioxide release despite a higher energy consumption for the cell stack. Here total capture cost and environmental impact are respectively 480 $/ton$CO_2$ and -0.9593 kg$CO_2$eq/kg$CO_2$ while the energy requirement in the BPMED stack is 408 kJ/mol$CO_2$.

## INTRODUCTION

Climate phenomena have caused profound social, economic and environmental damage, highlighting the urgency for systemic solutions. There is a strong scientific consensus that anthropogenic greenhouse gas emissions, particularly carbon dioxide (CO2), are the primary drivers of climate change. Hene, CO2 needs to be actively removed from the environment using carbon dioxide removal technologies (CDR). In this context, direct air capture (DAC) is a crucial and emerging carbon dioxide removal (CDR) technology for achieving net-zero emissions by balancing atmospheric CO2 release with removal. Different DAC technologies have been developed in the current state-of-the art such as absorption, adsorption, ion exchange resin, mineral carbonation, membrane, cryogenic separation [1]. These are mainly based on the use of thermal energy for regeneration of the capture agent [1, 2]. Recently, significant attention of the research community has been focused on electrochemical methods for regeneration: electrodialysis, electrolysis, proton coupled electron transfer, electro swing adsorption have been investigated [3, 4]. In the electrodialysis based process an absorption-based direct air capture column is connected to an electrodialysis stack for the release of CO2 and regeneration of the alkaline solvent recycled back to the absorption column [5]. Several research have been presented in the literature for this process scheme in order to evaluate the cost and the energy consumption as those reported by Sabatino et al.

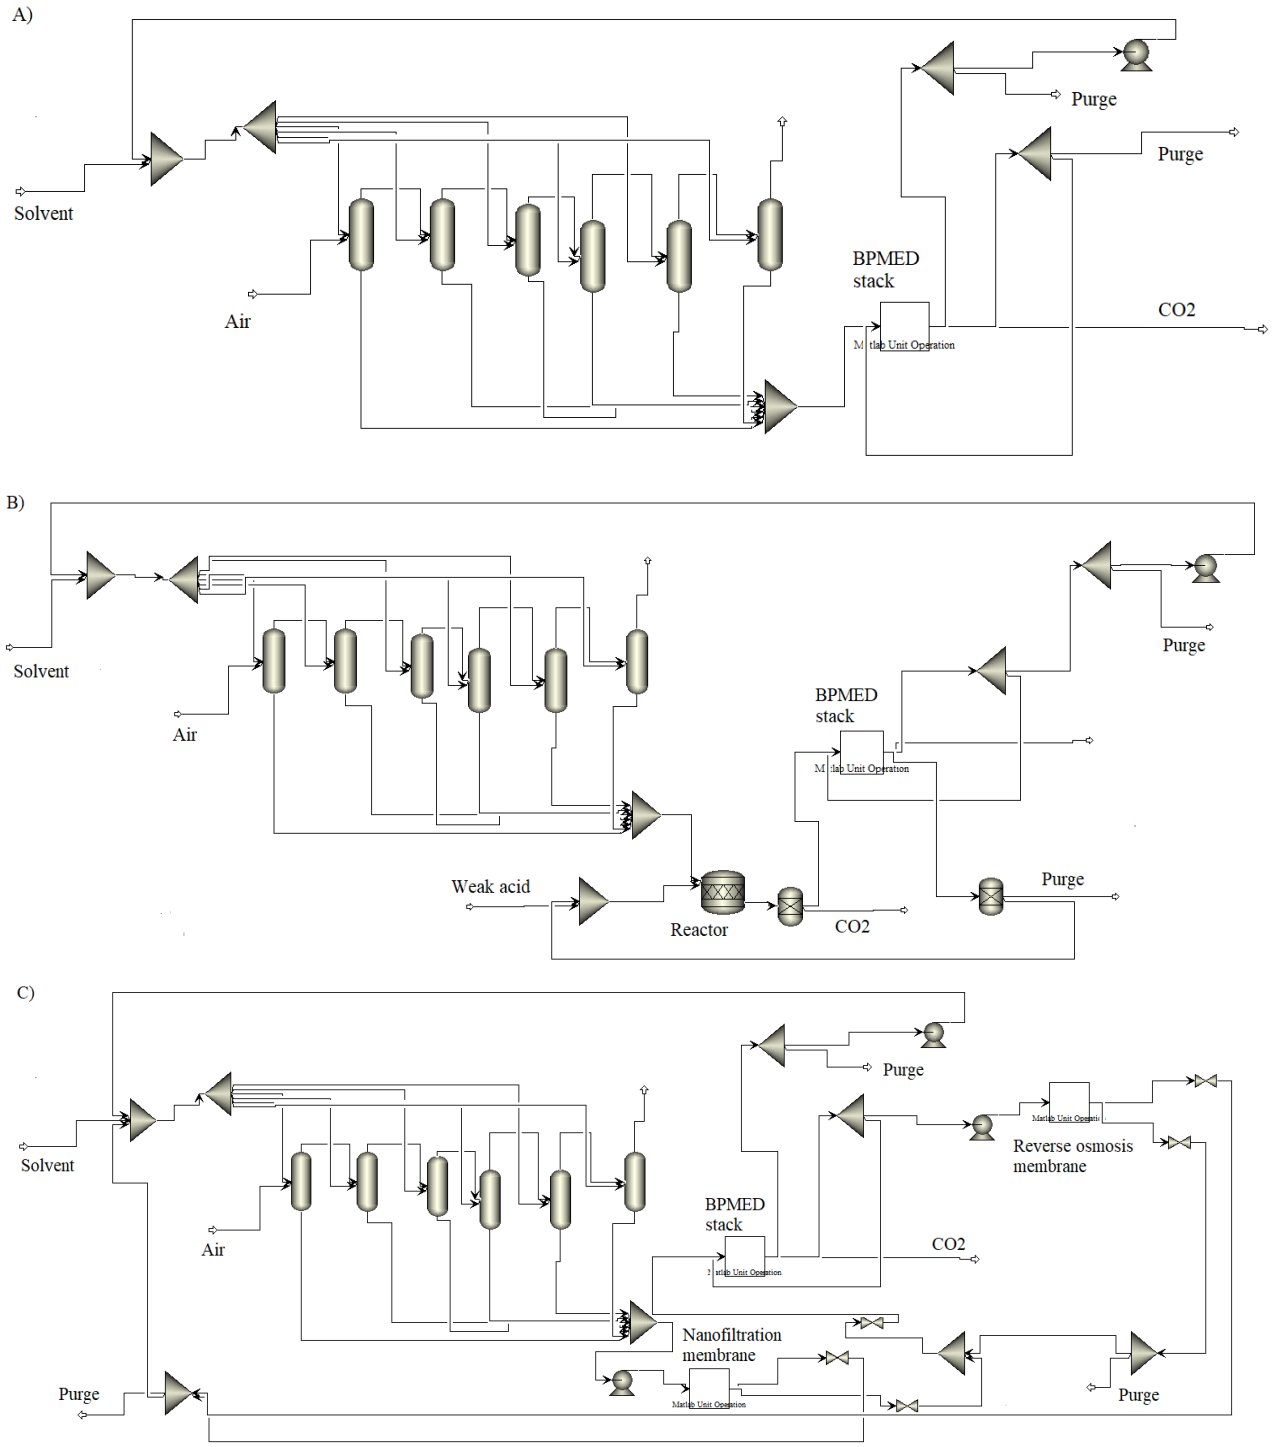

**Figure 1:** Process flowsheet of the investigated process: a) conventional; b) based on reaction between bicarbonates/carbonates and weak acid; c) based on BPMED with nanofiltration and reverse osmosis membrane

[6, 7], Young et al. [8], Leonzio and Shah [4], Leonzio et al. [9]. However, this process scheme can suffer from CO2 bubble formation inside the cell causing an increase of electrical energy demand. CO2 bubbles can, in fact, obstruct flow channels, block active membrane area, increase local resistance, exacerbate mass-transport limitations, current crowding and local heating [10]. To overcome this problem, in a previous work we proposed a system where carbonates and bicarbonates from the absorption column react with an organic weak acid to

release $CO_2$, producing its acid salt that is sent to the electrodialysis stack for both acid and alkaline solvent regeneration [11]. However, many other different alternatives have been proposed by Kemp et al. [12] to regenerate the capture solution and these are all based on the electrification of the process (direct and indirect protonation, nanofiltration and direct protonation, nanofiltration and indirect protonation, regeneration with CO2 electroreduction for product generation, CO2 electroreduction for product generation only, chiller crystallisation and direct protonation, nanofiltration and reverse osmosis, system with filtration unit and pH adjustment of electrodialysis feed stream, system with filtration unit and electrodialysis, schematic of electrodialysis unit with gas diffusion electrode). For the best our knowledge, a direct comparison of these solutions is not present in the literature yet. Therefore, the present research wants to overcome this gap. In particular, in this research, we aim to compare the following direct air capture technologies based on the use of an absorption column but with the regeneration of the rich solution by using a bipolar membrane electrodialysis stack, reacting carbonates and bicarbonates with a weak organic acid (formic acid or a mixture between formic and acetic acid) and by using nanofiltration and reverse osmosis technology. The proposed process schemes are simulated in detail and the material and energy balances are used to conduct an economic and environmental analysis finding the total capture cost and environmental burden.

## MODELLING

### Description of the capture plant

Three different process schemes are compared in this work: "conventional" scenario with the DAC absorption column connected to the BPMED stack, "reaction between bicarbonates/carbonates and weak acid" scenario where the BPMED stack is used for the regeneration of the acid salt obtained with the reaction between bicarbonates/carbonates and formic and/or acetic acid, "nanofiltration and reverse osmosis" scenario where these membranes are used to concentrate bicarbonates/carbonates sent to the BPMED connected to the DAC absorption column. These schemes are shown respectively in Figure 1a, 1b, 1c. In all process schemes, six absorption columns, in a cross-flow configuration, are considered according to the Carbon Engineering plant [6, 7]. An ambient air flow rate of 150 ton/h and a liquid flow rate according to a liquid to gas ratio equal to 0.6 are considered in the feed [6]. The liquid flow rate is based on a mixture of an aqueous solution of potassium hydroxide (KOH) (1 M) and potassium carbonate ($K_2CO_3$) (0.01 M), the latter added with the aim to reduce toxicity and corrosivity [13, 14]. From the absorption columns, the rich solution with carbonates and bicarbonates is sent to the BPMED stack for solvent regeneration and $CO_2$ release in the "conventional" scenario. In the "reaction between bicarbonates/carbonates and weak acid" scenario, the rich solution from the absorption column is sent to a reactor for the reaction with formic acid, in one case, and formic/acetic acid mixture, in the other case. Here, CO2 is released while the acid salt is sent to the BPMED stack for the regeneration of both acid and absorption solvent. In the "nanofiltration and reverse osmosis" scenario, the rich solution from the absorption column, is sent to the nanofiltration unit to concentrate carbonates sent to the BPMED stack, while the permeate solution rich in hydroxide ions is recycled back to the absorption column. In the same scheme, the brine stream from the BPMED is sent to the reverse osmosis unit to concentrate bicarbonates recycled back to the BPMED while the permeate rich in hydroxide ions is sent to the absorption column. All processes are modelled in Aspen Plus software by using RadFrac packed absorption columns, stoichiometric reactor and Matlab Cape Unit operation for the BPMED stack, nanofiltration and reverse osmosis membranes. For the BPMED cell stack, material balance equations, equilibrium equations and electroneutrality equations are used to solve the system and find the product stream composition. The following parameters are defined: membrane area equal to 1.785 m2 and current density equal to 800 A/cm2 [6], number of cells of 105. For membranes, by fixing the rejection factor for each compound and using material balances allow to find the product stream composition and needed membrane area. For the nanofiltration unit water permeability and transmembrane pressure are fixed to $9 \cdot 10^{-11}$ m/(Pas) and $5.4 \cdot 10^{6}$ Pa [15, 16]. For the reverse osmosis unit water permeability and transmembrane pressure are fixed to $1 \cdot 10^{-10}$ m/(Pas) and 1.1•10 Pa [15, 16]. The electrolyte Non-Random Two-Liquid (e-NRTL) thermodynamic model is used for the simulation in Aspen Plus of the overall capture plant [6, 7].

### Energetic and economic analysis

Regarding the energetic analysis, the needed electric power for the BPMED is evaluated with the following correlations (See Eq. 1-4) [6, 7]:

$$E_{cell} = i \cdot R_{cell} + E_{BP} \quad (1)$$

$$R_{cell} = R_{base} + R_{CEM} + R_{acid} + R_{BP} \quad (2)$$

$$R_{base/acid} = \frac{\delta}{\sigma_{base/acid}} \quad (3)$$

$$P_{cell} = i \cdot A \cdot N_{cell} \cdot E_{cell} \quad (4)$$

with $E_{cell}$ the voltage drop across the BPMED cell, $E_{BP}$ the water-splitting potential of the BPM (equal to 0.829 V for ΔpH of 14 [6]) (V), $R_{cell}$ the electrical resistance of a unit area of a single cell ($\Omega m^2$), i the current density ($A/m^2$), $R_{base}$, $R_{acid}$, $R_{CEM}$ and $R_{BP}$ respectively the resistance

of basic and acid solution and cation and bipolar membrane (these two last are respectively equal to $1.5 \bullet 10^{-4}$ $\Omega m^2$ and $5.2 \bullet 10^{-4}$ $\Omega m^2$ [6]) ($\Omega m^2$), $\sigma_{base/acid}$ the electrical conductivity of acid and base solutions, δ the distance between the BPM and cation membrane (1.5 mm [6]) (m), A the membrane area ($m^2$), $N_{cell}$ the number of cells, $P_{cell}$ the power of the BPMED unit (W). In the economic analysis the $CO_2$ capture cost is evaluated from the sum of capital (CAPEX) and operating (OPEX) costs. The CAPEX in the form of total overnight capital (TOC) ($) is evaluated on the basis of the bare erected cost (BEC), as the sum of the purchase cost of all plant components, taken from the literature and from Aspen Plus Economic Analyzer (APEA): absorption columns from Sabatino et al. [6, 7], reactor and pump from APEA, BPMED stack from Virruso et al. [17]. For the total cost of membranes in the stack, an ion exchange membrane cost and bipolar membrane cost respectively are assumed at 145 $/m^2$ and 1300 $/m^2$ [18]. For nanofiltration and reverse osmosis, a value of 134 $/m2 and 170 $/m2 is respectively assumed [19, 20]. In particular, the total overnight capital (TOC) is evaluated in accordance with NETL guidelines [21]. The OPEX is evaluated as the sum of fixed and variable operating and maintenance cost (O&M) ($/year). In the variable O&M cost, the cost of raw materials and utilities is taken into account assuming a price for aqueous hydroxide solvent of 580 $/ton [22], potassium carbonate of 600 $/ton, sustainable formic acid from $CO_2$ of 1738 $/ton [23], sustainable acetic acid from $CO_2$ of 1170 $/ton [24] and renewable electricity from wind onshore in the UK of 0.05 $/kWh [25]. The specific $CO_2$ capture cost is the sum TOC and OPEC divided the amount of captured $CO_2$.

## Environmental analysis

The LCA is conducted with OpenLCA software (version 1.11) and Ecoinvent database 3.9 accordingly with ISO 14040-14044 [26, 27]. This methodology includes four phases (goal and scope definition, life cycle inventory, life cycle impact assessment (LCIA) and life cycle interpretation). The goal of the study is the comparison of the three investigated processes from an environmental point of view with the scope to understand which of them is the most favorable. To this aim the functional unit is 1 tonCO2 that is captured with cradle-to-gate system boundary (the end use of captured $CO_2$ is not considered in the analysis). In the inventory phase, inventory data (e.g. material and energy balances) for the processes are defined as taken from the simulation in Aspen Plus. For formic acid and acetic acid, a sustainable production process from $CO_2$ is considered as that reported in Cuevas-Castillo et al. [23] and Regis et al. [24]. After these stages, the LCI results are organized into the usual LCA impact categories and then into the impact indicators at the midpoint level. The life cycle impact assessment is performed with the ReCiPe Midpoint (H) 2016 to obtain a general overview of the impact of the studied process on the climate change impact category [28]. In the interpretation phase, a comparison of the obtained results is carried out.

# RESULTS AND DISCUSSION

## Results of process modelling

In all simulations, the kinetic model of the absorption column is validated with the experimental data of Keith et al. [13] while the BPMED is validated with Sabatino et al. [6, 7] data.

From the developed simulations, the energy consumption (especially that in the BPMED stack) and the material balances are obtained and compared in each investigated process scheme.

For the same amount of air and solvent flow rate fed into the process, the energy consumption in the BPMED and the amount of captured CO2 are respectively of 2314 kWh/tonCO2 and 1142 tonCO2/year for the conventional process, 1907 kWh/tonCO2 and 959 tonCO2/year for the process using formic acid reacting with the rich solution, 1943 kWh/tonCO2 and 949 tonCO2/year for the process using the mixture formic/acetic acid reacting with the rich solution, 2468 kWh/tonCO2 and 1253 tonCO2/year for the process using a nanofiltration with reverse osmosis membrane.

The higher efficiency of the system regenerating CO2 from the electrodialysis of carbonates and bicarbonates is due the fact that in this system the total dissolved organic carbon is conserved while in the acid reaction-based process CO2 is produced not after a redistribution of carbonates because it is a chemical transformation.

Moreover, it is clear that the process with the highest electricity consumption in the BPMED stack is that using membranes due to the higher concentrate rich solution from which a higher amount of CO2 is captured compared to other case studies. Considering the energy consumption of pumps in both membranes, the overall energy needs is higher and with a value of 3752 kWh/tonCO2. Then, despite the higher amount of CO2 that is captured, the process based on the use of membranes has a higher energy requirement.

It is interesting to see that both processes based on CO2 recovery from rich solution through the BPMED stack are characterized by a greater value of energy consumption in the cell stack due to the CO2 bubble formation. A higher value is for the process with membranes due to a higher concentrate solution (435 kJ/molCO2 vs 408 kJ/mol$CO_2$ for the process using only the electrolytic stack).

The process with the lowest energy consumption is that based on the reaction between formic acid and

bicarbonates/carbonates: the BPMED stack requires 336 kJ/molCO2. The lower energy consumption for the system using formic acid is due to a very low specific energy required to regenerate this acid from its salt: the range is between 0.3 and 0.8 kWh/kg of formic acid [29]. On the other hand, the energy consumption for recovery of acetic acid from its salt can be up to 15.7 kWh/kg of acetic acid [30]. Then the presence of acetic acid in the mixture increases the energy demand for CO2 capture.

Overall, for the process based on the regeneration of CO2 via BPMED, values of these electrical consumptions are in agreement with that reported in the literature by Sabatino et al. [6, 7] and Eisaman et al. [30] where energy consumption up to 3789 kWh/tonCO2 are reported when varying current density and composition of the rich solution. Similar values are reported by Vallejo Castano et al. [32], Shu et al. [33] analyzing the same process under different sensitivity analyses. For the other two processes, a direct comparison with the literature cannot be conducted because a similar process has not been considered for CO2 capture from the air yet.

## Results of economic analysis

Results of the economic analysis show that the process based on only BPMED stack costs 480 $/tonCO2, that based on membranes costs 1179 $/tonCO2 while the others based on formic acid reaction and formic/acetic acid reaction cost respectively 510 $/tonCO2 and 519 $/tonCO2. It is clear that the process using membranes is the most expensive (59% more than that based on the regeneration using only BPMED that is the cheapest one), despite the highest amount of captured CO2 (1253 tonCO2/year). This is due to the highest impact of nanofiltration cost on total capital cost (due to a higher treated flow rate, 292 modules with 37 m2 of area are needed for the specific separation while 4 modules of reverse osmosis membrane with an area of 40 m2 are required).

A deeper analysis shows that the system using membranes has the highest values of TOC, total fixed and variable O&M respectively of 0.55 M$/year (437 $/tonCO2), 0.65 M$/year (520 $/tonCO2) and 0.28 M$/year (222 $/tonCO2). For the process scheme using a BPMED stack for the regeneration TOC, total fixed and variable O&M costs are 0.19 M$/year (165 $/tonCO2), 0.18 M$/year (161 $/tonCO2) and 0.17 M$/year (153 $/tonCO2). TOC, total fixed and variable O&M costs are respectively 0.22 M$/year (229 $/tonCO2), 0.1 M$/year (111 $/tonCO2) and 0.16 M$/year (170 $/tonCO2) for the process using formic acid reacting with the rich solution. On the other hand, TOC, total fixed and variable O&M costs for the process using a mixture acid solution are respectively 0.22 M$/year (231 $/tonCO2), 0.1 M$/year (112 $/tonCO2) and 0.17 M$/year (176 $/tonCO2).

It is evident that despite a higher operating costs (due to the higher energy consumption) compared to the process based on acid reaction, the process with the use of only BPEM stack for CO2 regeneration has the lowest capital cost due to the lower amount of used equipment. On the other hand, the process with nanofiltration and reverse osmosis has the highest values of capital and operating costs compared to all solutions.

The cost for the process based on only BPMED is in line (e.g. the same order of magnitude) with studies reported in the literature from Sabatino et al. [6, 7], Iizuka et al. [34]. For the other processes a comparison with the literature can not be done as similar works have not been considered.

## Results of environmental analysis

It is possible to see that values of climate change for the process with the use of only BPMED, using formic acid and formic/acetic acid reaction and based on membranes are respectively equal to -0.9593 kgCO2eq/kgCO2, -0.9378 kgCO2eq/kgCO2 and -0.9238 kgCO2eq/kgCO2, -0.9327 kgCO2eq/kgCO2. Then, recovering CO2 from carbonates via BPMED ensures the lowest environmental burden in terms of climate change, followed by the process whit a reaction between bicarbonates/carbonates and formic acid, by the system using membranes and then followed by the process with a reaction between bicarbonates/carbonates with the acetic/formic acid mixture.

A breakdown of results shows that the most significant input on total climate change is the electricity consumption for the conventional and membrane based processes (28.53 kgCO2eq/tonCO2 and 46.25 kgCO2eq/tonCo2 respectively), while for the other processes based on chemical reaction to release CO2, the potassium carbonate production has the highest impact (35.14 kgCO2eq/tonCO2 for the process using only formic acid and 35.52 kgCO2eq/tonCO2 for the process using the mixture acetic/formic acid).

Results for the system based on electrodialysis of carbonates are in agreement with the literature [4]. For the other systems, a direct comparison with the state-of-the-art is not possible.

# CONCLUSIONS

With the aim of electrifying chemical processes for CO2 capture from the air, different schemes are proposed and investigated in this work. The DAC absorption column is related to a BPMED stack in one case, to a BPMED stack and nanofiltration and reverse osmosis membranes in another case study and to a reactor for the reaction between the rich solution and formic acid and formic/acetic acid mixture in the other two case studies.

All processes are simulated in Aspen Plus to have material and energy balances required to conduct an economic and environmental analysis, finding the total

capture cost and the climate change impact.

A similar comparison analysis has not been considered in literature yet, underlining the novelty of the process.

Results show that the best process for the regeneration of solvent and release of CO2 is that based on the use of BPMED stack characterized by 480 $/tonCO2 and -0.9593 kgCO2eq/kgCO2. On the other hand, due to the higher impact of membrane cost, the process with the nanofiltration and reverse osmosis has the highest costs (1179 $/tonCO2) and relatively higher environmental burden (-0.9327 kgCO2eq/kgCO2).

## ABSTRACT

Polystyrene (PS) recycling remains limited despite large waste volumes, largely because many routes struggle to recover high-value chemicals at scale. This work develops a full process concept that upgrades PS through low-pressure hydrothermal processing (HTP) and directs the resulting aromatic oil to separation and downstream conversion. The superstructure includes HTP at 30 bar and 350°C, three distillation columns for toluene/ethylbenzene/styrene splits, ethylbenzene dehydrogenation to boost styrene yield, steam reforming of the heavier $C_{9+}$ fraction to syngas, and an ICI-type (Imperial Chemical Industries) methanol loop with inter-bed quench. The integrated flowsheet was simulated in Aspen Plus V14 using a consistent NRTL-RK (Non-Random Two-Liquid-Redlich–Kwong) property framework. Deep-vacuum operation (≈100–400 mbar) was applied where needed to limit styrene polymerization. Sensitivity and optimization focused on meeting a syngas stoichiometric number near 2; the best case occurred at ~998.8°C and 20.2 bar with ~37.8 t/h steam. Normalized to the polystyrene feed, the model predicts ~0.13 kg toluene, 0.16 kg styrene, and 1.27 kg methanol per kg PS, with only trace benzene/ethanol, at a water-to-PS ratio of ~3.77 kg/kg. When heat recovery is excluded, the overall heat demand corresponds to ~84 MJ per kg of PS processed. The flowsheet is technically consistent, but heat integration and a full TEA/LCA (Techno-economic Assessment/Life-cycle Assessment) will ultimately determine its viability.

## INTRODUCTION

The amount of generated plastic waste has surpassed 400 million tonnes annually and is growing at an alarming pace. Only 9% of this generated waste is recycled, and 12% is burned, while the rest is landfilled [1]. In this vein, polystyrene (PS) constitutes 7 wt% of worldwide plastic trash, equating to about 28 million tonnes generated each year [1]. However, around 1% of the PS-generated waste is recycled due to constraints in conversion techniques [2]. PS is generally used in the food packaging industry. Among polystyrene waste streams, expanded polystyrene (EPS; 'Styrofoam') is especially problematic because its intrinsic material properties promote environmental release. Its very low density and brittle morphology facilitate wind-driven dispersal from collection points and landfills, while minor mechanical stress readily causes fracture and fragmentation. As a result, EPS can rapidly generate microplastics that persist and spread over wide areas, making improved capture and controlled recycling or upgrading routes particularly important for mitigating this pathway [3].

Several studies in the literature showed that hydrothermal processing (HTP) is a promising way to convert PS into a wide range of chemicals in the literature. Gentilcore *et al.* have developed a low-pressure hydrothermal processing method to convert PS into oils, achieving an impressive yield of 96–99% oil with only 1–2% char at pressures of 2–3 MPa based on their experiments. They suggest and implement a reversible kinetic model involving monomers and poly-aromatics, confirm predictions, co-process PS with polyolefins, and assess greater

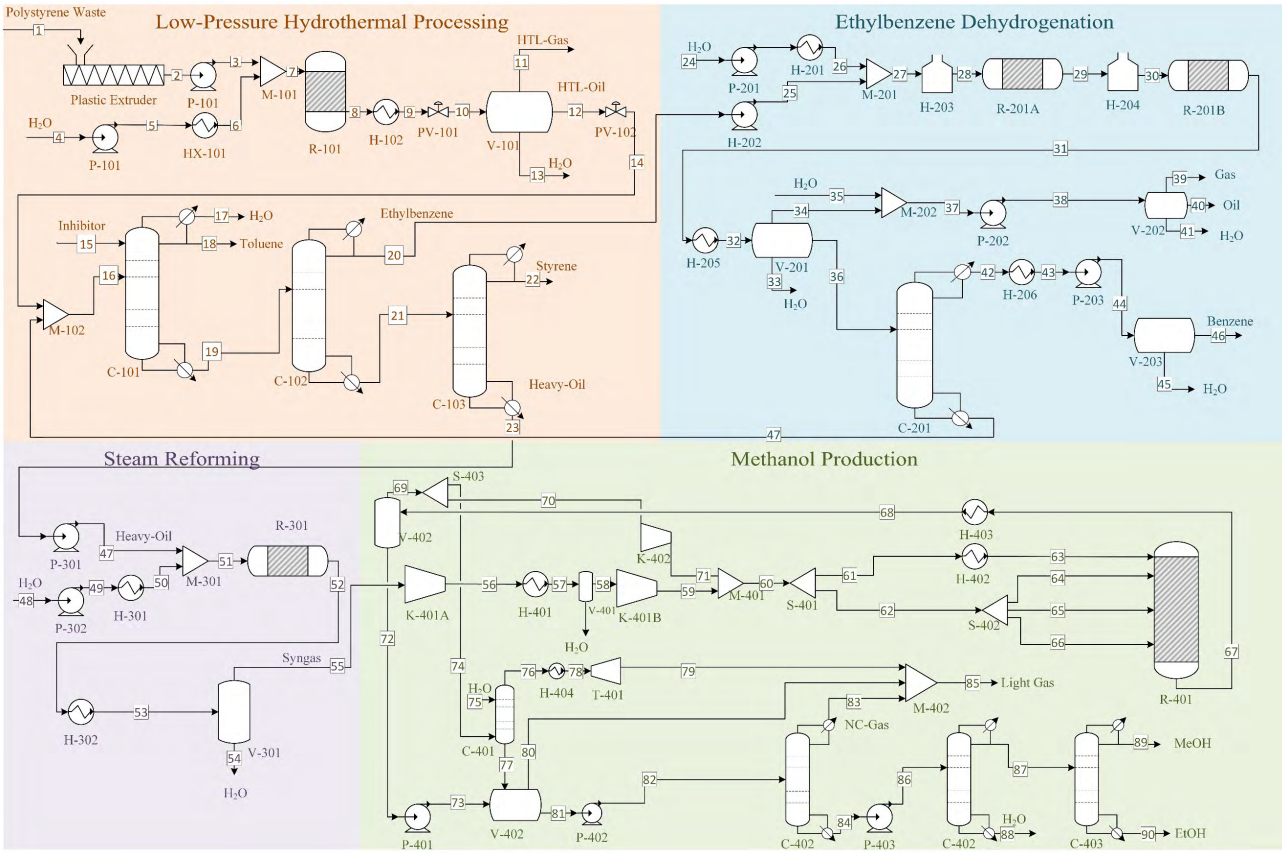

**Figure 1.** Superstructure design for polystyrene waste into value-added chemicals through low-pressure hydrothermal processing, ethylbenzene dehydrogenation, steam reforming, and the methanol production unit

energy recovery along with reduced environmental impacts compared to pyrolysis/incineration and landfilling [4]. The composition of the generated oil has become the basis for our simulation. It mostly contains monomers ($C_7$-$C_9$), dimers ($C_{10}$-$C_{17}$), and heavy aromatics ($C_{16}$-$C_{20+}$). In the present work, we propose a novel conceptual design of a process that converts the oil into styrene and convenient co-products like toluene and methanol, shown in Figure 1. Toluene and styrene (monomer) are valuable products of the reactor and can be separated using distillation columns.

Ethylbenzene, as the other fraction of the generated oil (15–20 wt%), can be transformed into styrene through the process of dehydrogenation, resulting in an increased yield of styrene, the most valuable product in our process. The remaining components of the composition can be converted into syngas via the steam reforming process. The produced syngas serves as the precursor for methanol production in our design concept, noting that methanol can further be converted to additional plastic precursors through well-known methanol-to-olefins processes.

Compared with mechanical recycling, solvent-based recovery, pyrolysis, and gasification, this study adopts low-pressure hydrothermal processing because it produces a high oil yield with low char formation and generates an aromatic-rich stream suitable for downstream upgrading [4]. In the present design, toluene, styrene, and methanol were selected as the main target products due to their high economic value and substantial production volumes. In addition, the heavy oil fraction ($C_{9+}$) accounted for about 65% of the produced oil, making it the dominant intermediate stream. Direct purification of this fraction is less attractive, so it was routed to steam reforming for syngas generation and then to methanol synthesis.

This is the first such study to present a complete design concept, addressing some particular challenges such as determining designs for difficult separation processes, and the relationships of important design parameters and operating conditions on key performance indicators like yield, efficiency, energy use, and environmental impact.

We use Aspen Plus to simulate the process and compute the mass and energy flows for the complete process. Optimization techniques are used to help identify design parameters that achieve maximum yield or other important objectives. This demonstrates a pathway

for the recycling of PS waste, which could contribute to a more sustainable industry environment.

# METHODS

## Process Description

Figure 1 presents the superstructure process flow diagram for the conversion of polystyrene (PS) waste into value-added chemicals across four processing units. As shown, PS waste is transformed into toluene, ethylbenzene, styrene monomer, benzene, syngas, methanol, and ethanol via low-pressure hydrothermal processing, ethylbenzene dehydrogenation, steam reforming, and a methanol synthesis section. The integrated process was simulated in Aspen Plus V14.

### Low-pressure Hydrothermal Processing

In the introduced process, PS waste (stream 1) and water (stream 4) are mixed and enter the low-pressure (at 30 bar and 350°C) hydrothermal reactor to produce an aromatic-rich oil that serves as the primary feed to downstream separation and conversion units. The reactor products contain mostly aromatic hydrocarbons from $C_7$ to $C_{20+}$, which are going to be separated in three distillation columns from C-101 to C-103.

In modern styrene plants (ethylbenzene dehydrogenation process), the crude product is separated by vacuum distillation to avoid excessive temperatures that could polymerize styrene [5]. Then, all of the columns in the first and second units operate under deep vacuum (on the order of 100–400 mbar top pressure) to keep bottom temperatures low and minimize styrene polymerization. Even in a vacuum condition, styrene is prone to free-radical polymerization, especially at elevated temperatures. Polymerization is exothermic and self-accelerating; at ambient temperature, styrene reacts slowly, but rates increase rapidly with heat. In fact, the rate of styrene polymerization (uninhibited) roughly doubles for every 10°C rise [6]. In practice, polymerization inhibitors are always used when handling styrene (and other vinyl aromatic fractions). In this process, 4-hydroxy-TEMPO (2, 2, 6, 6-tetramethylpiperidine 1-oxyl) is used as an inhibitor to suppress undesired free-radical polymerization of styrene. This inhibitor showed a great thermal stability based on thermogravimetric analysis [7].

Toluene (stream 18) and styrene (stream 22) are considered the main products in the separation unit. Ethylbenzene (stream 20) is used as the feedstock for the downstream process of ethylbenzene dehydrogenation to produce more styrene. This configuration leverages hydrothermal depolymerization to create a flexible liquid platform, while assigning downstream pathways according to product value and integration opportunities.

### Ethylbenzene Dehydrogenation

Ethylbenzene is purified (stream 20) as an aromatic fraction from upgraded HTP oil and can be directed to a traditional styrene production unit. The feed is vaporized and diluted with process steam, preheated using hot reactor effluent, and subsequently raised to the desired inlet temperature in a fired heater. Dehydrogenation to styrene and hydrogen is conducted in a series of low-pressure, adiabatic vapor-phase reactors. The endothermic and equilibrium-limited nature of the reaction favors conversion at elevated temperatures and lower ethylbenzene partial pressure; steam primarily serves as a diluent to shift equilibrium and mitigate the production of by-products such as benzene, toluene, light gases, and $CO_x$, which become more pronounced under extreme conditions. The temperature decrease between beds is mitigated by interstage reheating, followed by cooling of the effluent for phase separation and recovery of unreacted ethylbenzene for recycling (stream 47).

### Steam Reforming

Heavier oil containing $C_{9+}$ (stream 23) is used in the process of steam reforming for syngas production. The oil is vaporized and exposed to steam over a reforming catalyst at an elevated temperature (around 1000°C) and regulated pressure to transform hydrocarbons into a syngas mixture. The main products are $H_2$ and CO, while $CO_2$ and leftover $CH_4$ (stream 55) are produced via the water–gas shift reaction and incomplete reforming. The steam-to-carbon ratio, temperature, and pressure are established to reduce the formation of coke and methane while optimizing the stoichiometric number ratio (SN) for the following methanol synthesis.

### Methanol Production

Syngas (stream 55) from the upstream reforming section is provided to a methanol synthesis loop that is based on the low-pressure process of the Imperial Chemical Industries (ICI) process. Before entering the catalytic reactor, the fresh gas is compressed in two stages to approximately 80 bar, combined with recycled converter gas to regulate the inlet temperature, and partially preheated. To regulate the exotherm and maintain equilibrium in each bed, divided fractions of cool syngas are injected between catalyst beds in a four-bed quench reactor. The crude methanol (stream 67) is recovered in a knockout cylinder after the reactor effluent is chilled and partially condensed at 260°C and 76 bar. The unreacted gas (stream 70) is recompressed for recycling, while a portion (stream 74) is water-scrubbed to recover residual methanol. A minor purge is implemented to prevent inert build-up.

### Modelling and Simulation

The integrated process described in the previous section was simulated in Aspen Plus V14. NRTL-RK (Non-Random Two-Liquid-Redlich–Kwong) was used across

HTP, ethylbenzene dehydrogenation, steam reforming, and methanol synthesis to keep one consistent thermodynamic framework. NRTL captures non-ideal liquid behavior in water–organics and aromatic mixtures, while RK provides a reasonable vapor-phase model for high-temperature, high-pressure gas streams.

In the proposed design, different reactor models were selected according to the available mechanistic information and the objective of each unit. The hydrothermal processing step was modeled with an RYIELD reactor because it involves complex reaction pathways and lacks detailed kinetic data, so the model was based on experimental product yields. In contrast, RPLUG reactors were used for ethylbenzene dehydrogenation and methanol synthesis because reliable kinetic expressions are available. Steam reforming was modeled with an REQUIL reactor because the heavy $C_{9+}$ fraction was treated as a lumped feed, and the main aim was to estimate equilibrium syngas composition for methanol production.

An RYIELD reactor model (R-101) was chosen for the hydrothermal processing based on experimental data from Gentilcore et al. [4]. Three RADFRAC models in equilibrium mode (from C-101 to C-103) were selected to purify toluene, ethylbenzene, and styrene, respectively. A sensitivity analysis was considered for each distillation column to vary the feed-stage number and calculate the reboiler heat duty. The feed-stage number of each distillation column was determined based on the minimum reboiler heat duty.

Ethylbenzene was mixed with steam in the ratio of 1:11 (EB: ST) to minimize coke formation and higher efficiency based on the available experimental data [8]. The temperature of both furnaces (H-203 and H-204) was set to 620°C to balance the conversion and selectivity, and serve as a catalyst-activity benchmark [9]. Two RPLUG models were selected to kinetically simulate ethylbenzene conversion. The kinetic equations and parameters proposed by Elnashaie *et al*. were validated based on the experimental data [10]. These reactions are presented as follows:

Main reaction:

$$(C_6H_5)CH_2CH_3 \leftrightarrow (C_6H_5CH)CH_2 + H_2 \quad (1)$$

Side reactions:

$$(C_6H_5)CH_2CH_3 \rightarrow C_6H_6 + C_2H_4 \quad (2)$$

$$(C_6H_5)CH_2CH_3 + H_2 \rightarrow (C_6H_5)CH_3 + CH_4 \quad (3)$$

$$2H_2O + C_2H_4 \rightarrow 2CO + 4H_2 \quad (4)$$

$$H_2O + CH_4 \rightarrow CO + 3H_2 \quad (5)$$

$$H_2O + CO \rightarrow CO_2 + H_2 \quad (6)$$

The selectivity of styrene is defined as follows:

$$Selectivity = \frac{F_{ST,out} - F_{ST,in}}{F_{EB,in} - F_{EB,out}} \quad (7)$$

Where $F_{ST,\,out}$ and $F_{ST,\,in}$ are molar flow rates of styrene inside (first bed) and outside (second bed) of the reactor, respectively. Moreover, the products of this reactor cooled down to separate water, light gases, and oily material in V-201. A RADFRAC model equilibrium-mode(C-201) was chosen to purify the generated benzene as a by-product in this process.

To optimize the ethylbenzene dehydrogenation section for styrene production, two targets were considered: styrene selectivity and the styrene molar flow rate at the end of the second bed. Because economics are not assessed here, neither metric alone is sufficient to define a practical optimum. In principle, the styrene molar flow rate would continue to increase with reactor length, whereas the highest selectivity would occur with a vanishing second-bed volume, since byproduct formation rises as conversion is pushed further. These issues happen when considering only maximum selectivity or styrene molar flow rate for the optimization. To balance these competing trends, the objective function was defined as the product of styrene selectivity and styrene molar flow rate. The optimization was then applied to the effluent of the second bed, R-201B (stream 31), to identify operating conditions that improve styrene output while limiting the loss of selectivity to side reactions.

An R-Equil reactor model was used for energy and mass balance of the process of steam reforming. The general formula for the steam reforming of the oil was defined as follows:

$$C_nH_m + nH_2O \leftrightarrow nCO + (n + \frac{m}{2})H_2 \quad (8)$$

The desired syngas must have a stoichiometric number (SN) close to 2 (on a molar basis). For methanol synthesis, an SN close to 2 corresponds to a near-stoichiometric hydrogen availability for converting COx to MeOH, while accounting for the CO2 “hydrogen penalty” associated with RWGS. In industrial loop design, values around 2.0–2.1 are commonly reported as optimal: if SN is higher than this range, excess H2 tends to accumulate in the recycle and must be removed by a larger purge, reducing loop efficiency; if SN is lower than 2, the make-up gas becomes hydrogen-limited, which typically lowers per-pass MeOH yield and increases water formation and recycle/purge requirements. Therefore, SN close to 2 was used here as a design target for the make-up gas composition, reflecting established catalyst-operability and loop-design practice rather than an economic optimum. Stoichiometric number (SN) is defined as follows:

$$SN = \frac{H_2 - CO_2}{CO + CO_2} \quad (9)$$

Where $H_2$, $CO_2$, and CO are the molar flowrates of each component in stream 55. Reactor (R-301) temperature, pressure, and injected steam flow rate (stream 48) were the variables in the process of steam reforming. These

variables were used in Aspen Plus to optimize the required syngas for methanol production to achieve the SN equal to two and the highest hydrogen to methane ratio.

Synthesis gas was pressurized in a 2-stage compressor (K-401 A and B) up to 80 bar. The introduced reactor in this process is based on the ICI method, which is described in the previous section. The following equations belong to the methanol reactor (R-401):

$$CO_2 + 3H_2 \leftrightarrow CH_3OH + H_2O \quad (10)$$

$$CO_2 + H_2 \leftrightarrow CO + H_2O \quad (11)$$

$$2CO + 4H_2 \rightarrow C_2H_5OH + H_2O \quad (12)$$

$$2CH_3OH \rightarrow CH_3OCH_3 + H_2O \quad (13)$$

Four PLUG reactors were considered to simulate the process of methanol production using kinetic equations in the literature [11]. To evaluate the accuracy of the results, the model was validated based on experimental data [12]. In addition, a separate optimization block was introduced to maximize methanol production by varying the dimensions of the catalyst beds. The methanol loop was modelled as four insulated beds (i.e., zero external heat duty). Because the main synthesis reactions are exothermic, operating at high temperature can shift the equilibrium away from methanol and may even promote net methanol consumption at sufficiently high conversion and temperature. The bed sizes, therefore, cannot be increased arbitrarily; each bed must be long enough to achieve meaningful conversion, but not so long that the temperature rise drives the system into an unfavourable equilibrium region. Since the reactor consists of a single shell (one diameter) with multiple beds of different lengths, several geometrical combinations could deliver similar methanol molar flow rates when economics are not considered. To obtain a unique and comparable solution at this stage, the reactor diameter was fixed at 5 m, and the length of each bed was treated as the decision variable to identify the configuration that maximizes the methanol molar flow rate.

Table 1 summarizes the decision variables for each unit that were adjusted to determine the unit's optimal operating conditions for product maximization.

## RESULTS AND DISCUSSION

### Validation of Kinetic Mechanisms

Table 2 compares the outlet molar flow rates from the Aspen Plus kinetic model with the corresponding industrial plant data for ethylbenzene dehydrogenation. The simulation reproduces the key species reasonably well: ethylbenzene is predicted within 6.9% and styrene within 10.4%, indicating that the implemented kinetics capture the main conversion and selectivity trends. Benzene is also close (11.1%), whereas toluene shows the largest deviation (28.5%), likely reflecting its low concentration and higher sensitivity to side reactions and operating details not fully represented in the model.

**Table 1:** Decision variables for optimization

| Variable | Lower Bound | Upper bound |
|---|---|---|
| **Ethylbenzene Dehydrogenation** | | |
| R-201A Diameter | 0.9 m | 7 m |
| R-201B Diameter | 0.9 m | 7 m |
| R-201A Length | 2 m | 9 m |
| R-201B Length | 2m | 6 m |
| Stream 27 Pressure | 0.4 bar | 8 bar |
| **Steam Reforming Conditions** | | |
| R-301 Pressure | 20 bar | 35 bar |
| R-301 Temperature | 800°C | 1000°C |
| Steam Flowrate | 15, 000 kg/hr | 80, 000 kg/hr |
| **Methanol Reactor Bed Lengths** | | |
| R-401 First Bed | 1 m | 2 m |
| R-401 Second Bed | 2 m | 5 m |
| R-401 Third Bed | 1 m | 3 m |
| R-401 Fourth Bed | 1 m | 3 m |

Table 3 compares the reactor outlet composition and temperature from the Aspen Plus kinetic model with industrial plant data. Overall agreement is good: methanol is predicted within 5.3% relative error, while the main inerts and light gases are captured with small-to-moderate deviations ($N_2$: 0.34%, $CH_4$: 10.5%, CO: 13.2%). The outlet temperature is reproduced within 2.35%, indicating that the heat release and reaction rate levels are broadly consistent. The largest mismatch is observed for $CO_2$ (22.7%), suggesting higher sensitivity to the CO/$CO_2$ shift balance under the selected kinetics and operating conditions.

**Table 2:** Validation of the methanol synthesis reactor model against industrial data

| Outlet Component (kmol/h) | Industrial Data [10] | Aspen Plus (This Model) | Error (%) |
|---|---|---|---|
| Benzene | 1.5 | 1.35 | 11.11 |
| Toluene | 2.03 | 1.58 | 28.48 |
| Ethylbenzene | 19.45 | 18.20 | 6.86 |
| Styrene | 15.57 | 17.37 | 10.36 |

### Sensitivity and Optimization

Figure 2 illustrates a three-dimensional sensitivity map of the syngas stoichiometric number (SN) for the steam reforming of hydrothermal-processed heavy oil, characterized by a lumped $C_9$–$C_{20+}$ proportion. The horizontal axes represent reactor pressure and reactor temperature, while the vertical axis indicates the resultant SN. Each point represents a steady-state scenario achieved by altering the controllable variables: reactor

temperature, reactor pressure, and the syngas to oil ratio introduced into the reactor. The point color denotes the steam flow rate to oil ratio, as specified by the color scale. It is worth mentioning that heavier fractions (e.g., $C_{19}$ and $C_{20}$) cannot fully convert into syngas in the steam reformer at pressures lower than 20 bar. Therefore, we put 20 bars for the lower bound in the optimization block, as shown in Table 1.

**Table 3:** Comparison of industrial and simulated outlet flowrates for ethylbenzene dehydrogenation

| Outlet Component | Industrial Data [12] | Aspen Plus (This Model) | Error (%) |
|---|---|---|---|
| MeOH (mol%) | 4.74 | 4.99 | 5.3 |
| $CO_2$ (mol%) | 2.83 | 2.19 | 22.7 |
| CO (mol%) | 1.88 | 1.63 | 13.2 |
| $CH_4$ (mol%) | 12.86 | 11.50 | 10.6 |
| $N_2$ (mol%) | 2.35 | 2.34 | 0.3 |
| Outlet T (K) | 544.7 | 531.89 | 2.4 |

The results reveal significant sensitivity of SN to both pressure and temperature, highlighting a distinct interaction between the two variables. The highest stoichiometric number occurs at 520°C, 50 bar, and 10 steam to oil ratio. For any given temperature and pressure, the vertical dispersion of points suggests that syngas injection presents a viable method to adjust SN without changing the main operational parameters. Elevated steam flow is often associated with increased SN, which corresponds with the effects of steam on reforming and water-gas shift processes.

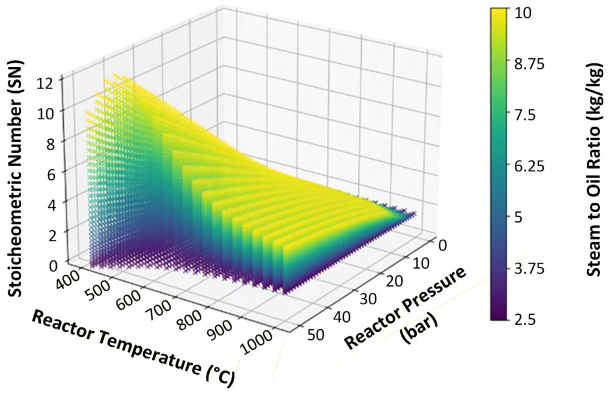

**Figure 2.** Sensitivity analysis of syngas stoichiometric number (SN) in steam reforming of hydrothermal-processed heavy oil ($C_9$–$C_{20+}$) as a function of reactor temperature, pressure, and syngas injection (steam flow rate as colour scale).

Figure 3 shows the sensitivity of the $H_2/CH_4$ molar ratio to the total required heat duty ($Q_t$) to oil flow rate ratio, across the evaluated operating cases. Points are colour-coded by reactor pressure (20–50 bar), highlighting how pressurisation shifts the $H_2/CH_4$–$Q_t$ relationship. All of the points indicate a stoichiometric number between 2 and 2.01. The dataset follows a strongly non-linear trend: $H_2/CH_4$ remains low and changes gradually at lower heat duties, then increases sharply beyond roughly 7.5-8 of $Q_t$ to oil flow rate ratio. To minimize the accumulation of methane in the methanol reactor, it is important to find the optimum point with the lowest methane in the syngas.

Table 4 summarizes the optimized operating and design variables that maximize the production of the two main value-added products, styrene and methanol, for the specified feedstock flow rate. The reported values represent the best-performing configuration under the present model assumptions and constraints, and they provide a consistent basis for comparing the two synthesis sections within the overall process.

Table 5 shows the summary of the input and output of the proposed process flow diagram. It also suggests that the proposed design has the possibility of further investigation through economic analysis, energy evaluation, and life cycle assessment.

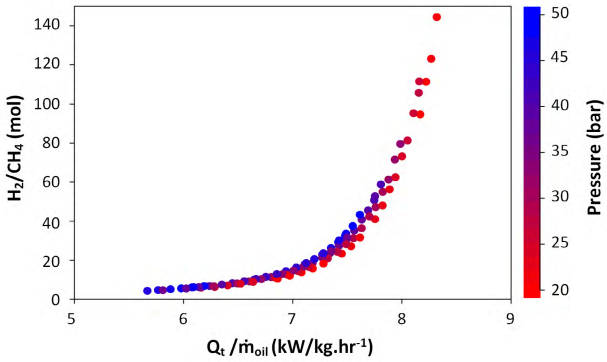

**Figure 3.** Sensitivity of $H_2/CH_4$ ratio to the total required heat duty, considering the reactor pressure at SN≈2

Following preliminary heat integration, the process required 85.01 MW of hot utility and 70.93 MW of cold utility. These values remained high mainly because the final distillation column (C-403), used to separate only 49 kg/h of ethanol, imposed substantial energy demands, with condenser and reboiler duties of 23.06 MW and 23 MW, respectively. After removing the final methanol distillation column and carrying out a new heat integration, the external utility demand decreased to 59.76 MW for heating and 47.4 MW for cooling. This reduction is significant because purchased heat represents the main variable operating cost of the process. Based on 12 tonne/h of polystyrene feed, 59.76 MW is equivalent to 4.98 $MWh_{th}$ per tonne of PS. Assuming steam is generated from natural gas at an efficiency of about 80%, the

corresponding fuel demand is 6.23 $MWh_{fuel}$ per tonne of PS [13]. Using an EU non-household natural gas price of 6.24 €/100 kWh, excluding VAT, the estimated fuel cost is about 389 €/tonne PS [14]. In addition, direct combustion emissions, estimated using the IPCC emission factor for natural gas, reach about 1.26 tonne $CO_2$/tonne PS. At a carbon price of 67.89 €/tonne $CO_2$, this adds roughly 85 €/tonne PS, giving a combined heat and carbon cost of about 474 €/tonne PS. Although this improves the economic position of the process, profitability still depends strongly on product value, particularly the netbacks of styrene and toluene, as well as capital control in the heat exchanger network and separation section.

**Table 4:** Decision variables for optimization

| Variable | Optimal Value |
|---|---|
| **Ethylbenzene Dehydrogenation** | |
| R-201A Diameter | 1.31 m |
| R-201B Diameter | 0.98 m |
| R-201A Length | 2.60 m |
| R-201B Length | 3.55 m |
| Stream 27 Pressure | 3.03 bar |
| **Steam Reforming Conditions** | |
| R-301 Pressure | 20.2 bar |
| R-301 Temperature | 989°C |
| Steam Flowrate | 37, 780 kg/hr |
| **Methanol Reactor Bed Lengths** | |
| R-401 First Bed | 1.23 m |
| R-401 Second Bed | 2.45 m |
| R-401 Third Bed | 1.86 m |
| R-401 Fourth Bed | 1.71 m |

**Table 5:** Main Process Inputs, Utility Requirements (before heat integration), and Product Outputs

| Variable | Final Value |
|---|---|
| **Inputs to Process** | |
| Polystyrene Waste | 12, 000 kg/hr |
| Total Water | 45, 300 kg/hr |
| Required Heat | 148 MW |
| Required Cooling | 134. MW |
| **Outputs from Process** | |
| Toluene | 1, 600 kg/hr |
| Benzene | 10.2 kg/hr |
| Styrene | 1910 kg/hr |
| Methanol | 15, 200 kg/hr |
| Ethanol | 49 kg/hr |

## CONCLUSIONS

An integrated route for upgrading polystyrene waste via low-pressure hydrothermal processing was modelled in Aspen Plus and connected to separation, ethylbenzene dehydrogenation, steam reforming, and an ICI-type methanol loop. In the reforming section, the syngas stoichiometric number (SN) was highly sensitive to the temperature–pressure, and steam flow rate combination. The optimized case (≈1000°C, 20.2 bar, 37, 800 kg/h steam) hit SN~2 while limiting methane carry-over; it provides an ideal syngas for methanol production. At steady state, 12, 000 kg/hr PS could yield about 1, 603 kg/hr toluene, 1, 909 kg/h styrene, and 15, 193 kg/hr methanol, with minor benzene and ethanol, but the gross energy demand is still 279.7 MW when heat recovery is excluded. The concept looks technically sound; the next step is heat integration and a full techno-economic and LCA check.

# Uncertainty Prioritisation for Water-Energy-Food-Land Nexus Optimisation

**Md Shamsul Alam[a], I. David L. Bogle[a], Vivek Dua[a]***

[a] Department of Chemical Engineering, The Sargent Centre for Process Systems Engineering, University College London, Torrington Place, WC1E 7JE, London, UK

## ABSTRACT

The interdependence among energy, water, food, and land sectors has been addressed through the concept of Energy-Water-Food-Land nexus (EWFLN), where interconnections between different sectors generate complex feedback loops. In the field of EWFLN, transitioning from deterministic to stochastic approach is considered as the natural choice for policy makers. Working with a large number of uncertain parameters can make a stochastic system complex. Therefore, Identification of the significant uncertain parameters in the system would create a more acceptable model before transforming from a deterministic to a stochastic approach. This study incorporates uncertainty prioritisation in the mathematical model for the optimisation of EWFLN. The specific objectives of this study include creating a mathematical model, determining and prioritising uncertain parameters, and prescribing appropriate policy recommendations. This study points out clearly which specific parameters should be taken into consideration for risk hedging. The sensitivity analysis results present a quantitative hierarchical ranking of uncertain parameters based on their influence on the objective function. The results demonstrate that energy price, solar radiation flux and crop yield are the most sensitive among them all. Moreover, it provides information about prioritised uncertain parameters to the policy makers to avoid dangerous risk of food, water, and energy scarcity.

**Keywords**: Resource allocation, uncertain parameter, stochastic approach

## INTRODUCTION

The existence of human beings is under threat without proper utilisation of basic lifesaving resources like food, water, and energy. Food is produced by the agriculture, livestock, and aquaculture sectors. On the whole, production of food cannot be dispensed without water and energy. Therefore, for ensuring food security, energy and water security must also be ensured. EWFLN, a widely used scholarly concept, demonstrates complex interactions [1, 2, 3], which can be used in an innovative way to manage optimal resources in a sustainable way [4]. According to the UN World Water Development report 2024, the agricultural sector consumes 70% of global freshwater while the domestic sector accounts for approximately 10-12% [5]. However, the International Renewable Energy Agency and Food and Agriculture Organisation [6] report that the food system including 'production to table' accounts for about 30% of total global energy consumption.

In this study of optimisation of biomass energy production in the water-food-energy-land nexus system, it is inevitable to have uncertainties in the determination of parameters due to insufficient information, variations of natural resources, fluctuations of socio-economic conditions as well as subjective judgment [7, 8]. Different authors have used different techniques to manage uncertainties in the parameters in the field of optimisation of EWFLN. This optimisation framework, combined with scenario analysis of population growth, has been designed to assess EWFLN systems in the study of Peña-Torres et al. [9].

Xie et al. [10] studied an inexact stochastic-fuzzy programming model with a view to allocating irrigation water and land resources with multiple uncertainties such as surface water and groundwater availability, the amount of random effective rainfall and the imprecise water requirements of crops. The results revealed that

water allocation is explicitly affected by uncertainties, and the results also provided information for the adjustment or justification of the existing water and land resources management. Cansino-Loeza, Tovar-Facio and Ponce-Ortega [11] provided a mathematical model for disadvantaged rural areas for their availability of basic needs to produce water, food and energy sustainably with provision for determining the mix of technology consistent with demand and nutritional requirements. This work incorporates mixed integer stochastic linear program with population change, water and energy demand change as uncertain parameters. The results provided positive feedback that enables the community to be self-sufficient and provides a balanced diet for inhabitants using renewable technologies considering waste treatment.

After reviewing all the literature, the authors believe that prioritisation of uncertainty in the EWFLN has not been fully explored and addressed. Therefore, prioritisation of uncertain parameters through sensitivity analysis will be presented and its impact will be discussed in this study.

## NOMENCLATURE

| Index | Description |
|---|---|
| $o$ | Sources of water |
| $a$ | Agriculture sectors |
| $L$ | Livestock sectors |
| $mt$ | Livestock types |
| $c$ | Crop types |
| $d$ | Domestic sectors |
| $t$ | Time period in months |
| $A$ | Water and energy consuming sectors |
| $p$ | Biomass gasification power plant |
| $sc$ | Sectors such as agriculture, livestock, domestic, energy, water |
| $al$ | Agriculture and livestock sector |

| Acronym | Description |
|---|---|
| $Actors$ | Water and energy consuming sectors |
| $AgL$ | Agriculture and livestock |
| $ARW_A$ | Effective area for rainwater harvesting in the sectors |
| $ASolarSector_A$ | Effective area for solar panel in the sectors |
| $ASolaroofSurAgMax_a$ | Maximum limit of effective area of solar panel installed in surface water pumping location |
| $\alpha F$ | Water efficiency coefficient for energy generation |
| $CostNexus$ | Total cost in all sectors |
| $AgL^{dom}_{al,d,t}$ | Raw food sent to domestic from agriculture and livestock sector |
| $AgL^{ext}_{al,t}$ | Raw food sent to market from agriculture and livestock sector |
| $ALndagb_a$ | Area of land dedicated for crop production in agriculture sector |
| $ConfCrpToBmas_c$ | Conversion factor: crop to biomass |
| $CofeedToMeat_{mt}$ | Monthly amount feed required to produce unit amount of meat |
| $Cost_{sc}$ | Cost in an individual sector |
| $E^{To-Actor}_{A,t}$ | Monthly amount of energy supplied to actors |
| $E^{\text{Plant}-Actor}_{p,A,t}$ | Energy distribution to actors from power plant |
| $E^{Solar-Actor}_{A,t}$ | Energy distribution to actors from solar panel |
| $E^{Solar-Ext}_{A,t}$ | Monthly energy sold from solar panel to external grid |
| $ProfitNexus$ | Overall nexus profit |
| $\alpha AgWst_c$ | Fuel efficiency coefficient for energy production |
| $F^{Rain-Actor}_{A,t}$ | Water harvested in all sectors such as domestic, livestock |
| $WRnflux_{A,t}$ | Rainwater precipitation flux in the sectors |
| $FoodDemand^{dom}_{d,t}$ | Amount of food required in domestic sector |
| $F^{To-Actor}_{A,t}$ | Total water Input to a sector |
| $F^{WSource-Actor}_{o,A,t}$ | Monthly water distribution from a water source to actors |
| $F^{Wsource-\text{plant}}_{p,t}$ | Monthly water distribution in power plant |

| | |
|---|---|
| $GRfood_{al,t}^{AgL}$ | Production of raw food such as crop from agriculture and meat from livestock |
| $GE_{p,t}$ | Monthly energy generation in a gasification power plant |
| $GE_{A,t}^{Solar-Actor}$ | Solar energy generation in the sectors |
| $MI_{sc}$ | Amount of input resource sold in a sector |
| $MR_{sc}$ | Amount of resource sold by an individual sector |
| $MAgWst_{c}$ | Amount of biomass type c fed for energy generation per month |
| $MCrp_{a,c,s}$ | Amount of crop produced in agriculture sector in a season |
| $MAgWaste_{a,c,s}$ | Amount of crop waste produced in agriculture sector in a season |
| $MFeed_{mt,t}$ | Monthly amount of feed required for meat production in livestock sector |
| $MLiv_{mt,t}$ | Monthly amount of meat production in livestock sector |
| $SRflux_{t}$ | Solar radiation flux in month t |
| $Wsource$ | Water source such as river, deep well |
| $RevNexus$ | Total revenue from all sectors |
| $Rev_{sc}$ | Revenue in an individual sector |
| $UCostI_{sc}$ | Unit cost of input in a sector |
| $UCostWatAg$ | Cost of water (per $m^3$) consumed in agriculture sector |
| $UPR_{sc}$ | Price of resource output from individual sector |
| $UPWatAg$ | Price of water (per $m^3$) distributed to agriculture sector |
| $UPEngyToExt$ | Price of energy sold to external power grid |
| $URCrp_{c}$ | Price of crop type c |
| $URAgWaste_{c}$ | Price of agriculture waste (per ton) |
| $CofPrdAg_{c}$ | Yield of crop |
| $Z$ | Overall profit of the nexus |

# METHODS

This section includes superstructure, the mathematical model for maximising profit of the nexus, and the solution method. The superstructure includes addition of modular gasification biomass energy plant, solar power system in all sectors, water sources including rainwater and their overarching input/output network.

## Mathematical model

### Objective function

Maximisation of overall profit, expressed in terms of revenue minus cost, of the nexus is a single objective function for this study.

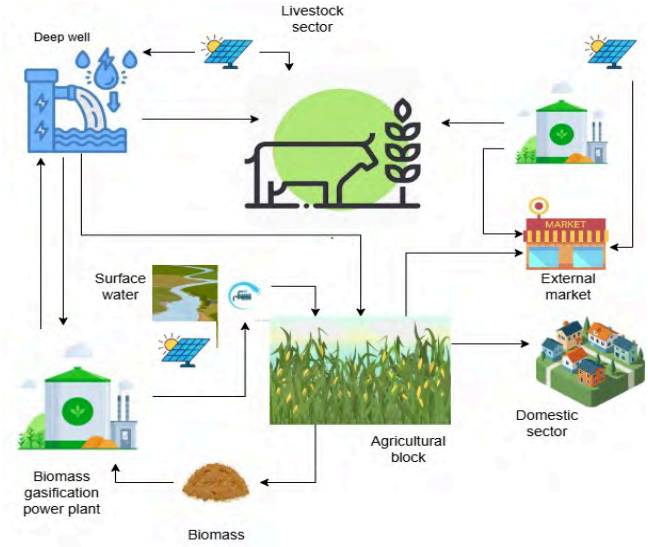

**Figure 1.** Superstructure of EWFLN

$$Max\ Z = RevNexus - CostNexus \quad (1)$$

$$RevNexus = \sum_{sc} Rev_{sc} \quad (2)$$

$$CostNexus = \sum_{sc} Cost_{sc} \quad (3)$$

$$Rev_{sc} = UPR_{sc}.MR_{sc} \quad (4)$$

$$Cost_{sc} = UCostI_{sc}.MI_{sc} \quad (5)$$

### Water mass balance

In this mathematical model, the term 'actors' is defined as the sectors in the nexus which consume resources delivered by other sectors of the nexus. The amount of water distributed in actors is equal to the amount of water sent from water sources and the amount of rainwater harvested in that sector.

$$F_{A,t}^{To-Actor} = \sum_{o} F_{o,A,t}^{WSource-Actor} + F_{A,t}^{Rain-Actor} \quad (6)$$

$$F_{A,t}^{Rain-Actor} = ARW_A . WRnflux_{A,t} \quad (7)$$

## Energy balance

Amount of energy generation in a biomass gasification power plant is expressed in terms of amount of water and biomass utilised for this purpose.

$$GE_{p,t} = \alpha F . F_{p,t}^{Wsource-\text{plant}} \quad (8)$$

$$GE_{p,t} = \alpha AgWst_c . MAgWst_c \quad (9)$$

Total energy in consuming bodies (actors) is equal to the amount of energy flow from generation units to actors and the amount of solar energy generated in that sector.

$$E_{A,t}^{To-Actor} = \sum_{p} E_{p,A,t}^{\text{Plant}-Actor} + E_{A,t}^{Solar-Actor} \quad (10)$$

$$GE_{A,t}^{Solar-Actor} = ASolarSector_A . SRflux_t \quad (11)$$

$$GE_{A,t}^{Solar-Actor} = E_{A,t}^{Solar-Actor} + E_{A,t}^{Solar-Ext} \quad (12)$$

## Food mass balance in agriculture and livestock sectors

Crops from agriculture sectors and meat from livestock sectors are sources of food which are distributed to domestic sectors and external markets. Production of crops, biomass from crops, and meat are linearly related to the respective production coefficient factors.

$$MCrp_{a,c,s} = CofPrdAg_c . ALndagb_a \quad (13)$$

$$MAgWaste_{a,c,s} = MCrp_{a,c,s} . ConfCrpToBmas_c \quad (14)$$

$$MFeed_{mt,t} = CofeedToMeat_{mt} . MLiv_{mt,t} \quad (15)$$

$$AgL_{al,d,t}^{dom} = FoodDemand_{d,t}^{dom} \quad (16)$$

$$GRfood_{al,t}^{AgL} = AgL_{al,d,t}^{dom} + AgL_{al,t}^{ext} \quad (17)$$

## Solution method

The model is implemented in four mouza (clusters of land) with four domestic sectors in Kazla union, Sariakandi upazila of Bogura districts of Bangladesh. Data was collected and implemented in GAMS software with CPLEX v.22.1.0.0 as solver for the LP. After running the model we have shortlisted the important parameters which can affect the objective function through looking at the shadow price of equations and the reduced cost of decision variables. In such a way we have screened out parameters which have no impact on the objective function and sorted 46 parameters which might have importance in shifting the value of the objective function. Then we have taken each parameter one at a time and run the model with ±20% deviation from the base parameter value and the percentage shift in the objective function is calculated. In this way we have sorted important parameters and prioritised them sequentially. Out of these, we have selected the three most sensitive parameters for further analysis. With these three most important parameters, we have made 125 joint independent scenarios; each parameter having five scenarios. The scenarios L20, L10, Bse, H10, and H20 are 20% lower, 10% lower, 10% higher, and 20% higher than the base scenario 'Bse' respectively. Thus, we have run the model with 125 scenarios to find the impact of uncertain parameters on the objective function.

# RESULTS

In Table 1 and Figure 2, the term "swing" refers to the percentage change of overall nexus profit resulting from changes in parameter value relative to the base parameter value. The swing of a parameter is from 20% lower and 20% higher than the base parameter value. The most sensitive parameters are 1) UPEngyToExt 2) SRFlux(t) (Figure 2, table 1) which decrease the energy sector's parameters. The second range of parameter falls are in the agriculture sector's parameters which are more than three times lower than the energy sector parameters and include 1) CofPrdAg(c) 2) URCrp(c) and 2) AIndagb(a). The third range is cost parameters which affect negatively the overall nexus profit and include 1) UCostLabr 2) UnituseLabr 3)UPWatAg, and 4) UCostWatAg. The fourth category affect minutely the overall nexus profit and include 1) ASolaroofSurAgMax(a) 2) ConfCrptoBmas(c) 3) URAgWaste(c). The range of prioritised parameters start with the first prioritised parameter "UPEngytoExt" and end with the twelfth prioritised parameter "URAgWaste(c)". In this study, we have not considered the parameters as prioritised which have a percentage swing of less than 1. The percentage swing of the most prioritised parameters, UPEngyToExt, SRflux(t) and CofPrdAg(c), are 36, 35 and 10% respectively. In practice, UPEngyToExt, SRflux(t) and CofPrdAg(c) are independent, and variation of any of them does not have any relationship with variation of other parameters. Now, we shall analyse how variation of these three independent parameters combined affects the overall profit of the nexus.

Figure 3 shows a range of values of overall profit resulting from 125 joint uncertain parameter scenarios of the three parameters. The lowest profit is in the LLL (lowest value of all 3 parameters) joint scenario which is 17.43 million USD while the highest profit is observed in HHH (Highest value of all 3 parameters) joint parameter

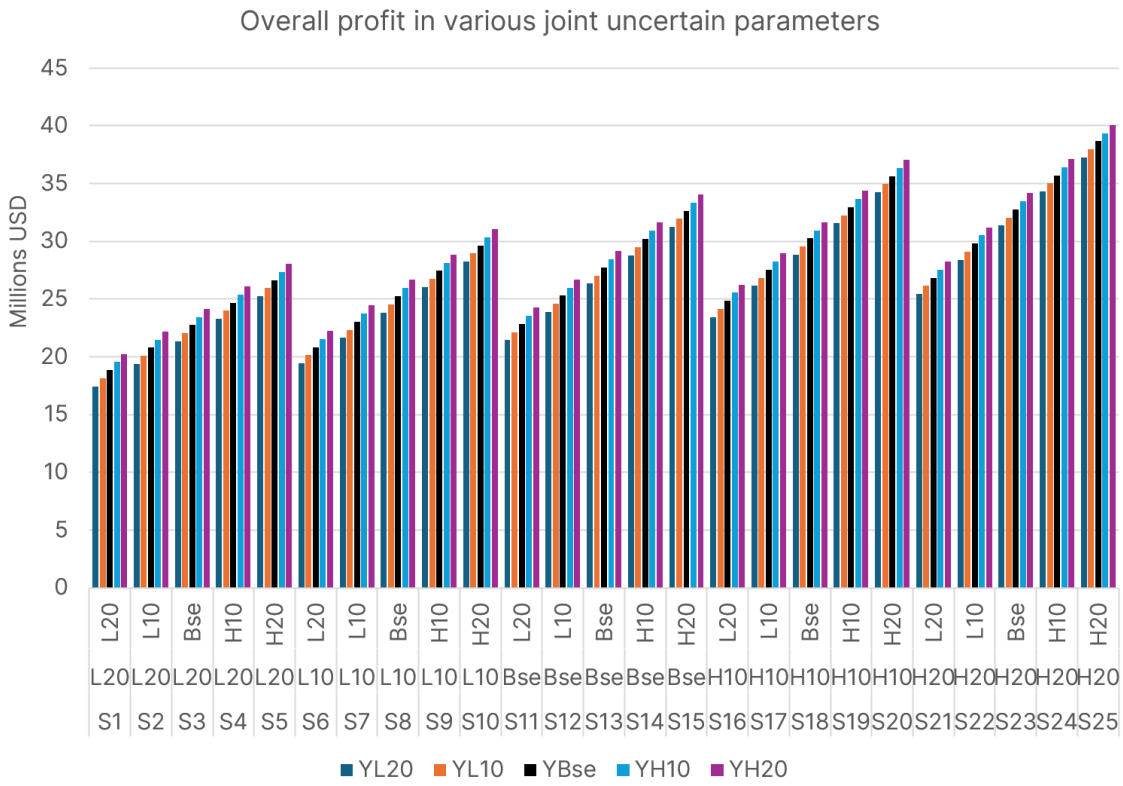

**Figure 3.** Overall profit of the nexus in different scenarios

scenario which is 40 million USD. The results indicate that the maximum profit(from HHH scenario) is approximately 2.3 times the minimum profit (from LLL scenario).

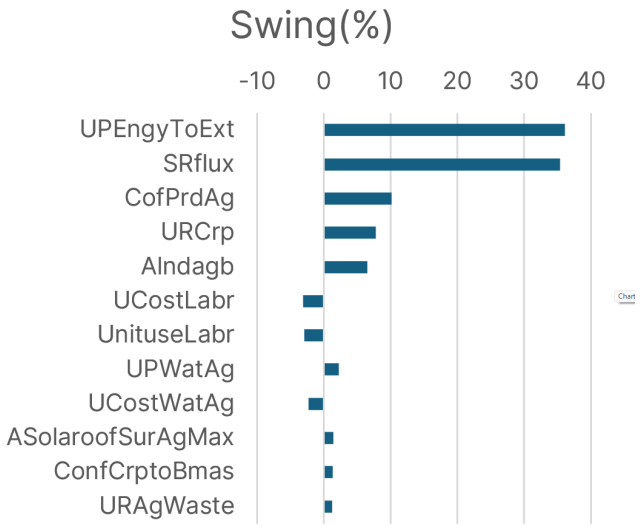

**Figure 2.** Tornado graph for sensitivity analysis

**Table 1.** Prioritised parameters

| Serial | Parameters | Swing (%) |
|---|---|---|
| 1 | UPEngyToExt | 36.08876914 |
| 2 | Flux | 35.35711568 |
| 3 | CofPrdAg | 10.12992412 |
| 4 | URCrp | 7.798400723 |
| 5 | AIndagb | 6.551808129 |
| 6 | UCostLabr | -3.087921957 |
| 7 | UnituseLabr | -2.921180162 |
| 8 | UPWatAg | 2.267019713 |

| 10 | ASolaroofSurAgMax | 1.490959063 |
| 11 | ConfCrptoBmas | 1.335354998 |
| 12 | URAgWaste | 1.240125902 |

## CONCLUSION

Uncertainty prioritisation is an important field of study in the realm of stochastic optimisation. This study provides a structured uncertainty prioritisation in the framework of the optimisation of EWFLN by maximising

the overall nexus profit as objective function. Within a range of candidate parameters in the mathematical model of EWFLN, we conducted a one-at-a-time (OAT) sensitivity analysis which revealed 12 important prioritised parameters. We have observed that the three parameters such as UPEngytoExt, SRflux(t) and CofCrpPrd(c) are the most sensitive parameters within these 12 parameters in this study. Therefore, with three parameters, each with 5 scenarios, 125 discrete joint parameter scenarios are constructed. Solving the optimisation model with each scenario has generated scenario wise overall nexus profit results. Visualised in the bar chart (Fig 3), the results show that the profit response is not the same across the joint scenario space. Three parameters are in the positive direction of profit maximisation; the lowest profit is 17.43 million USD while the highest profit is 40.00 million USD.

Practically, these findings focus on targeted uncertain parameters: the top ranked parameters are the most valuable for improvement of the objective function. Moreover, they are significantly important for risk hedging. The limitation includes the independence assumption among the three most prioritised parameters, discretized uncertainty ranges and reliance on OAT impact and observation of the list file (of GAMS code) for initial screening out. The future work should consider correlated uncertainties, probabilistic weighting of scenarios and stochastic optimisation incorporating these prioritised uncertain parameters.

## ABSTRACT

The global transition toward sustainable energy has intensified research into biofuels, with bioprocess optimization playing a central role in achieving decarbonization goals. Biobutanol, in particular, is a high-value molecule for sustainable fuel applications due to its superior energy density and compatibility with existing infrastructure. However, model-based optimization of its production is hindered by traditional semi-structured kinetic models that often suffer from limited predictive robustness. To address this challenge, within this study we developed a hybrid modeling framework for *Clostridium saccharoperbutylacetonicum* that integrates mechanistic mass-balance equations with Gaussian Processes (GPs) aiming to describe the biobutanol formation rate. Here, we investigate the effect of data normalization techniques on hybrid model's prediction capabilities comparing min-max normalization, z-score normalization, and no transformation. For each data treatment strategy, 8, 000 hybrid models were trained using experimental fermentation datasets, and ensemble predictors were constructed to mitigate variability and enhance generalization. Results demonstrate that hybrid models significantly outperform parametric baselines, with the ensemble approach leveling the performance differences across all pretreatment techniques. Ensembles achieved validation RMSE reductions of approximately 10.1% to 10.4%, which are two times higher than the best individual models regardless of the scaling method used. Despite similar RMSE reductions, prediction envelopes varied along data transformations revealing tradeoffs between uncertainty and coverage. Notably, targeted hybridization of the butanol reaction rate propagated performance improvements to other states, such as glucose and biomass. These findings suggest that for hybrid modeling, ensemble design provides greater benefits for robustness than any data normalization technique.

## 1. INTRODUCTION

Driven by the sustainable development goals, research into optimizing bioprocesses for bio-based fuels has shifted toward digitalized frameworks. Recent advancements in sensing technologies and computational power have enabled the integration of sophisticated modeling and simulation tools into biomanufacturing [1]. These developments, together with modern modeling and simulation tools, have catalyzed digitalization of biomanufacturing processes. In this context, hybrid modelling stands as a powerful paradigm, combining parametric (i.e. mechanistic representations) with non-parametric (i.e. data-driven) methods to mitigate their respective limitations [2] and accelerate advanced optimal design and operation within process system engineering [3].

Despite hybrid model's enhanced prediction capabilities, their formulation requires biological and operational data as inputs to inform the data-driven subcomponents. Traditionally, machine learning and computer science literature has stated that normalization techniques such as z-score normalization and min-max normalization have great influence on model performance of

data-driven techniques [4, 5]. Several studies have confirmed this especially when dealing with metabolomic data [6–8]. However, the effect of data transformation techniques in the performance of hybrid models remains largely unexplored [9].

This work evaluates the influence of data transformation techniques on the predictive robustness of hybrid models applied to Acetone-Butanol-Ethanol (ABE) fermentation. Herein, different hybrid model's structures are developed to improve state predictions of ABE fermentation by *Clostridium saccharoperbutylacetonicum*, with a particular focus on biobutanol as a key molecule for sustainable biofuel applications [10]. Although semi-structured kinetic models for butanol fermentation are well established, they are frequently overparameterized, which limits both structural and practical identifiability and degrades predictive robustness. Therefore, a hybrid modeling framework is here proposed, coupling mechanistic mass-balance equations with Gaussian Processes (GPs) used to represent the biobutanol formation rate. Furthermore, this study evaluates how different data transformation techniques affect hybrid model's performance of individual and ensemble models. This work is structured into four sections. Section 1 presents the case study and the goals of this contribution. Section 2 outlines modeling details, including data transformations. Section 3 analyzes the results, focused on performance of the various hybrid models. Section 4 presents conclusions and a summary of the key findings.

## 2. MODELING DETAILS

### 2.1 Experimental Data and Data preprocessing

This study utilized four fermentation datasets of *C. saccharoperbutylacetonicum* using glucose as the primary carbon source [11]. Data was extracted from the figures from the original paper [11]. Experimental measurements included glucose, acetone, acetate, butyrate, biomass, and butanol. Data were structured into three training sets and one validation set to rigorously evaluate predictive performance across different experimental runs. To ensure high-quality inputs for the hybrid model, raw signals underwent outlier detection and correction using a moving median window and Savitzky-Golay smoothing, respectively [12].

### 2.2 Data Transformation Techniques

Data was transformed using min-max normalization and z-score normalization, which are shown in Eq (2) and Eq (3), respectively:

$$X_{min-max} = \frac{X - min(X)}{max(X) - min(X)} \quad (2)$$

$$X_{z-score} = \frac{X - \bar{X}}{\sigma(X)} \quad (3)$$

Where $X$ represents a vector of data, $\bar{X}$ represents their average values, and $\sigma(X)$ represents the vector's standard deviation. The transformation was applied to both inputs and outputs of the data-driven component. As a base line, data without transformation was also used.

### 2.3 Hybrid Model Formulation

The proposed hybrid model architecture uses Shinto's ABE parametric model as a baseline [11]. The mass balances in batch conditions consist of 19 reaction rates, 16 states and 46 parameters. Only 6 metabolites were experimentally monitored: glucose, acetone, acetate, biomass, butyrate, and butanol all expressed in Mm. For the hybrid model, Butanol's reaction rate $r_{butanol}$ (mM/h) was replaced by a GP, as seen in Eq(1):

$$\frac{dButanol}{dt} = r_{butanol} = GP(W) \quad (1)$$

Where $W$ represents the features used as inputs for the GPs. Initial Glucose concentration along instantaneous glucose and acetone concentrations were used as features for training the GPs and making predictions.

### 2.4 Training Strategy and Evaluation

For each data transformation technique, a predictor ensemble strategy was proposed. Experimental data are employed to train the Gaussian Process (GP) models, while model-based inputs (outputs from ODEs) are used for evaluating hybrid model's performance in both training and validation sets. Specifically, at each integration step, the ODE solver provided a set of predicted concentrations as inputs to the GP to facilitate dynamic simulation. After integrating the responses, they were algebraically averaged to make predictions. This ensemble approach served to enhance predictive robustness and mitigate potential overfitting [13, 14]. For each data transformation technique, 8000 hybrid models were trained to ensure robustness. This number of models was chosen by manual inspection and sensitivity analysis as a tradeoff between the possibility of finding models with good performance and balancing computation times. Root Mean Squared Error (RMSE) for all variables relative to experimental data quantified model performance. For each hybrid model, RMSE reduction was calculated taking the full parametric Shinto model as baseline. RMSE reduction is defined in Eq. (4).

$$RMSE_{red} = \frac{RMSE_{Parametric\ Model} - RMSE_{Hybrid\ Model}}{RMSE_{Parametric\ Model}} \quad (4)$$

The optimal predictor ensemble size was the number of models that maximized the objective function defined in Eq. (5) using the predictor average.

$$max\ (Prediction_{Enhancement} - Overfitting) \quad (5)$$

$$Prediction_{Enhancement} = (RMSE_{red,train} + RMSE_{red,valid})$$

$$Overfitting = |RMSE_{red,train} - RMSE_{red,valid}|$$

**Table 1**. RMSE reduction on training and validation sets when compared against parametric model and number of optimal models for the ensemble predictor.

| Data Transformation technique | Ensemble Model | | | Best individual Model | |
|---|---|---|---|---|---|
| | %RMSE reduction training | %RMSE reduction validation | Number of optimal models Ensembled | %RMSE reduction training | %RMSE reduction validation |
| No transformation | 16.3 | 10.2 | 28 | 22.3 | 2.2 |
| Min-Max normalization | 18.2 | 10.4 | 8 | 20.8 | 4.5 |
| Z-score normalization | 16.5 | 10.1 | 13 | 21.6 | 6.6 |

This formulation balances two competing objectives: the first term maximizes the total error reduction across both training and validation sets, while the second term imposes a penalty for overfitting during calibration and for poor generalization performance.

Moreover, prediction envelopes and relative deviations of average values were used for approximating prediction uncertainty.

## 2.5 Computational Hardware Details

All computations were performed on an Intel® Core™ i9-14900HX CPU 2.20GHz, with 24 cores, 32 GB of RAM, and a 16 GB NVIDIA GeForce RTX 4090 GPU. Calculations were performed in MATLAB 2024a®.

# 3. RESULTS

Hybrid models' performance outperformed the parametric model baseline. The best individual model reduced RMSE by up to 21.6% (training) and 6.6% (validation), using z-score normalization, while ensemble models achieved reductions up to 18.2% and 10.4%, for training and validation respectively, using min-max normalization. Table 1 presents RMSE reduction for training and validation, as well as the number of optimal models used by the ensemble when using each data transformation technique.

There are differences in performance of the best individual models in the validation set, however, the ensemble approach increased generalization capabilities across the three techniques, leveling their performance. For ensemble models, performance across the different data transformation techniques was very similar for both training and validation. In training, no-transformation and z-score normalization yielded RMSE reductions of around 16.5%, with min-max normalization achieving higher performance, presenting reductions up to 18.2%. However, in validation there was no significant difference between the pretreatment techniques: 10.2% (no-transformation), 10.1% (z-score), and 10.4% (min-max).

Optimal ensemble size requirements varied, 28 models for no-transformation, 8 for min-max normalization, and 13 for z-score normalization. Training time was also comparable across methods, with 8000 models requiring 80–84 hours for calibration and less than 30 seconds for prediction in all cases. On the other hand, it's notable that out of 8000 calibrations, optimal ensemble sizes represent less than 1% of the total models calibrated. Moreover, when calibrating 4000 models, ensemble sizes varied between 4 and 9 (less than 1%). This lower number of models also deteriorated prediction capabilities, with RMSE reductions of the validation set being around 6-7%.

Figure 1 presents the behavior of the different ensemble predictors obtained using the three data transformation techniques. As expected from the results from Table 1, the behavior is very similar between them, which suggests that the ensemble approach is able to capture the dynamics of different models and minimize their differences while enhancing the predictive power. It is important to note that although butanol's reaction rate was hybridized, performance improved in other key states, such as glucose and biomass, since butanol concentration affects them. For these metabolites, individual RMSE reductions in the validation set ranged between 4% through 14%. Figure 2 presents the predictor confidence intervals, shown as envelopes of butanol prediction of the individual models used for the ensemble approach at each time-step. The hybrid model using data without transformation presents the widest predictor confidence intervals, due to having more than twice individual models when compared to z-score or more than triple when using min-max normalization. It is observed that confidence intervals are not symmetric, showcasing that the individual models' error is not distributed evenly. This might be attributed to both the non-parametric techniques as well as structural deficiencies in the parametric components of the model.

Moreover, when using no transformation, the ensemble envelope contains 94% of the experimental data, in contrast to 86% and 78% when using min-max and z-score normalization. This highlights that while their

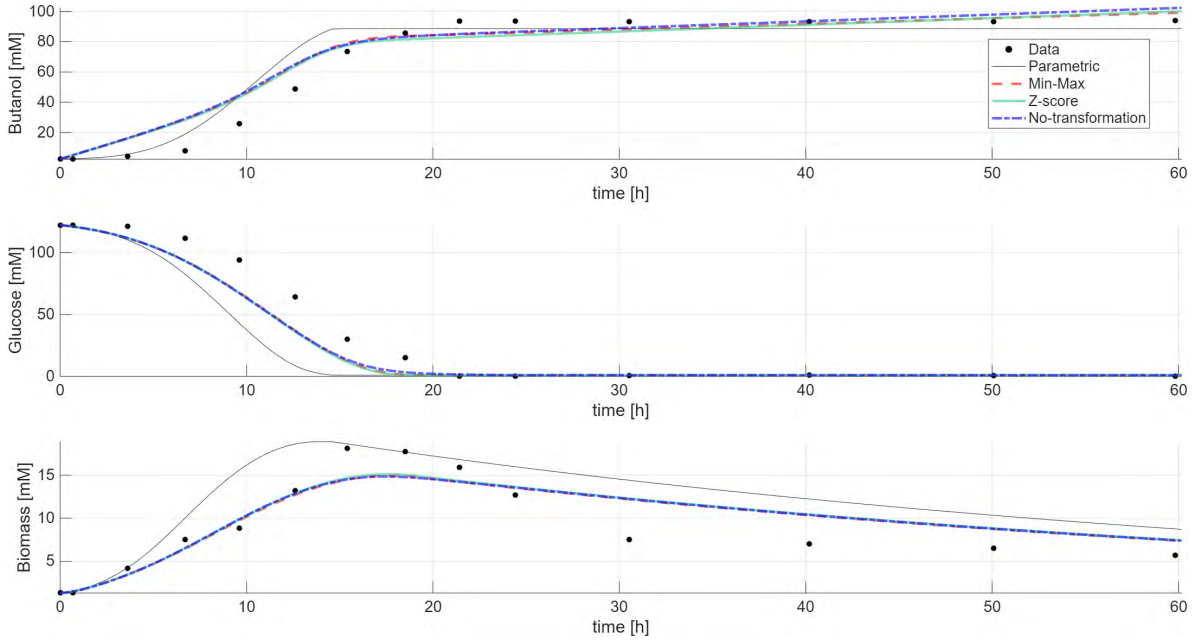

**Figure 1**. Ensemble hybrid models' behavior in the validation experiment according to each type of data transformation technique compared against real experimental data and the parametric model: a) butanol, b) glucose, c) biomass.

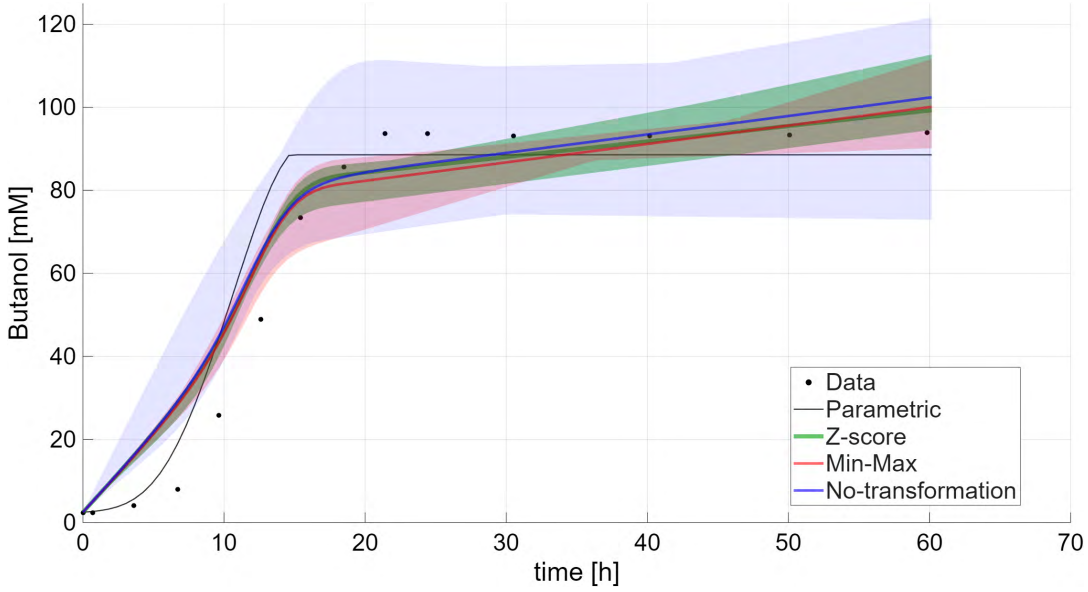

**Figure 2**. Hybrid models' prediction intervals for butanol in the validation set.

average predictions are similar, their uncertainty varies significantly. On the other hand, butanol's envelope of predictions also affects other variables, as seen in Figure 3 and Figure 4 for glucose and biomass in the validation set, respectively. As seen, prediction intervals follow the same trends as those for butanol.

Table 2 presents the average absolute and relative deviations using the different normalization techniques for the three metabolites. The absolute deviations remain relatively low for all metabolites, with min-max normalization and z-score normalization presenting deviations of less than 1 mM for glucose and biomass, and around 5 mM for butanol. These deviations are on average less than 5% of the predicted values, with the exception of biomass' deviation when using min-max normalization. On the other hand, using no data transformation results in higher absolute and relative deviations, being up to five times those obtained by the normalization techniques. This is in part due to ensemble size: when using no data transformation, the optimal ensemble is

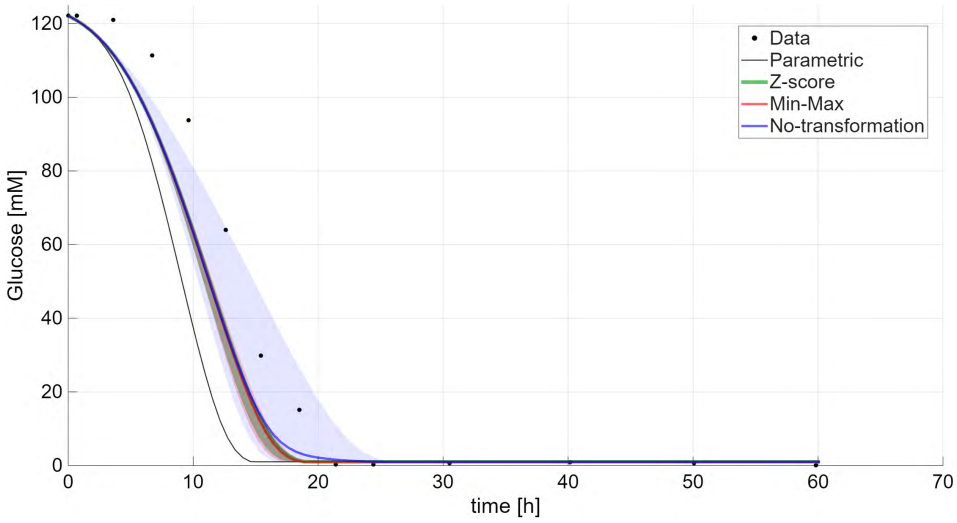

**Figure 3**. Hybrid models' prediction intervals for glucose in the validation set

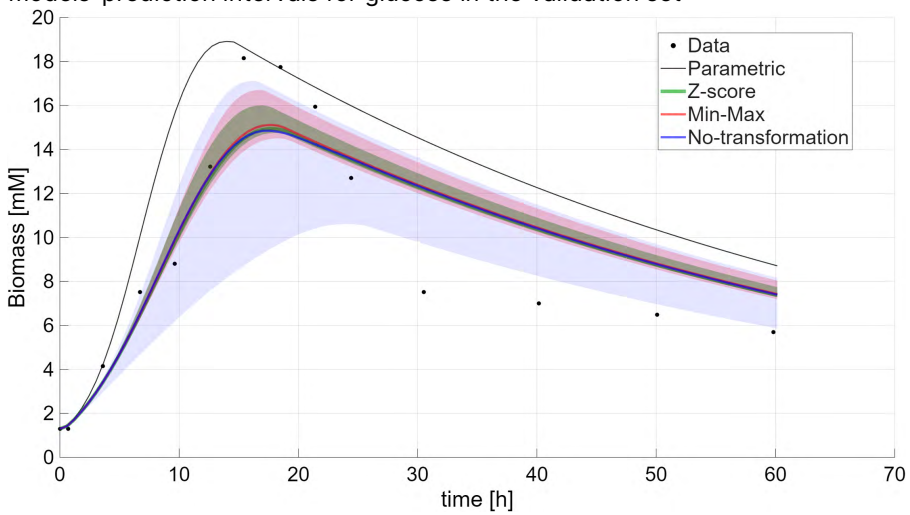

**Figure 4**. Hybrid models' prediction intervals for biomass in the validation set

**Table 2**. Average absolute and relative deviations (%) of the prediction envelopes from the average predicted value by the ensemble model

| | Absolute deviation (mM) | | | Relative deviation (%) | | |
|---|---|---|---|---|---|---|
| **Metabolite** | **Min-Max** | **Z-score** | **No-transformation** | **Min-Max** | **Z-score** | **No-transformation** |
| Glucose | 0.674 | 0.535 | 3.736 | 5.85 | 4.03 | 24.80 |
| Butanol | 5.594 | 5.200 | 17.414 | 4.72 | 4.40 | 12.27 |
| Biomass | 0.620 | 0.367 | 1.901 | 5.67 | 4.03 | 24.84 |

twice as large as the ensemble obtained using z-score normalization and more than three times as the one obtained when using min-max.

However, as seen in Figure 2, Figure 3 and Figure 4, the prediction envelope is not symmetric, as such, the models present zones where they have different relative deviations. This asymmetry can be explained by the fact that GPs numeric errors don't propagate linearly towards the rest of the states. Figure 5 and Figure 6 present the relative deviation of the prediction envelope as a function of time in the validation experiment for biomass and butanol respectively, with the continuous lines representing the average values. Figure 5 shows that when using z-score and min-max normalization, for biomass model deviation is low, with maximum individual values around 10% deviation. In contrast, when using no-pretreatment, relative deviations are higher, up to +20% and -40%. Similarly, Figure 6 shows that when using no transformation, butanol's relative deviation can vary by as much as +60% and -20% in the early stages of the fermentation, with lower values towards the end (+20% through -20%). On the other hand, when using z-score

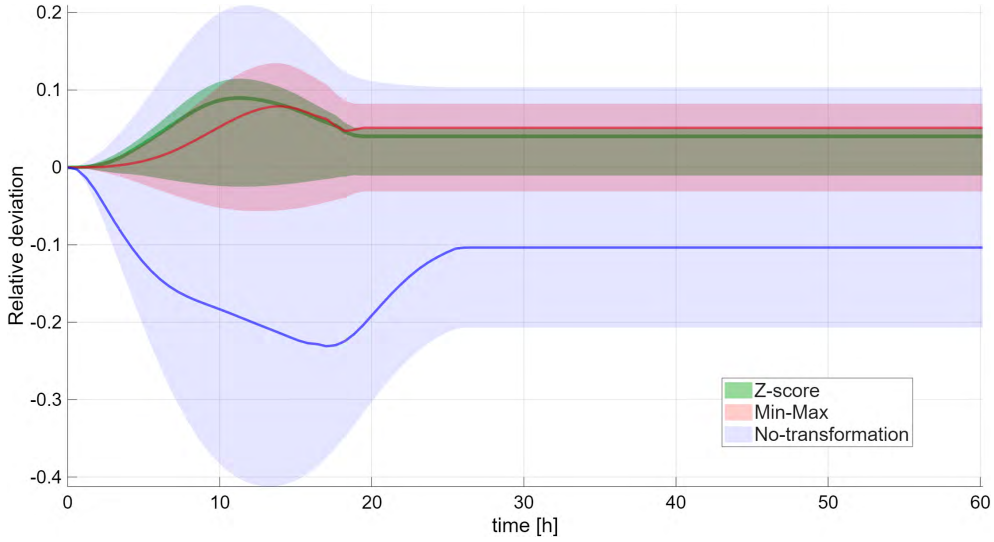

**Figure 5**. Hybrid models' prediction relative deviation for biomass in the validation set. Lines represent average prediction interval's width

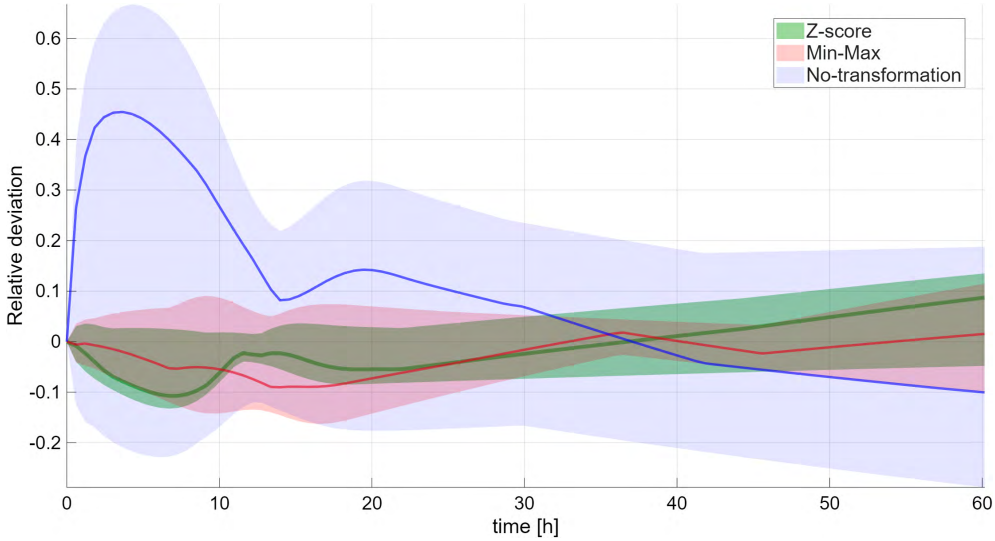

**Figure 6**. Hybrid models' prediction relative deviation for butanol in the validation set. Lines represent average prediction interval's width

and min-max normalization, predictions remain less dispersed, with relative deviations between -15% in the early stages of the fermentation and +15% towards the end. Higher deviations in early stages might be explained due to complexities for measuring metabolites and biomass at low concentrations, especially during lag phase and early exponential growth. Moreover, due to low values, high relative deviations might come from low absolute deviations, amplifying numerical error. As such, specific reaction rates change rapidly and error propagation might greatly affect prediction accuracy of the GPs, propagating uncertainty in a feedback loop.

Moreover, as observed in Figure 5 and Figure 6, hybridizing one reaction rate might enhance predictive capabilities, but also propagates uncertainty towards other metabolites and states in the system. As such, hybridization strategies should evaluate models as a whole in kinetic coupled systems, to enhance overall process understanding.

## 4. CONCLUSIONS

This study investigated the influence of data transformation techniques on the predictive robustness of hybrid models for ABE fermentation. The integration of Gaussian Processes into a mechanistic mass-balance framework successfully addressed the limitations of traditional kinetic models, specifically mitigating the issues of overparameterization and limited practical identifiability.

Main takeaways from this study are:

- **Ensemble-driven robustness:** while individual model performance was highly sensitive to data pretreatment—with z-score normalization yielding the most accurate single candidates, the implementation of an ensemble strategy effectively leveled these disparities. The ensemble approach achieved consistent validation RMSE reductions of approximately 10.1% to 10.4%, ggregardless of the normalization technique applied.
- **Prediction uncertainty vs. Coverage:** the analysis of prediction intervals (**Figure 5** and **Figure 6**) revealed trade-offs. Normalization techniques (z-score, min-max) provided superior narrower prediction intervals, particularly during the kinetically dynamic early fermentation stages, maintaining relative deviations within ±15%. In contrast, models trained on raw data exhibited significant volatility during the exponential phase (deviations up to +60%) but offered wider uncertainty envelopes that encapsulated 94% of experimental data, compared to ~80% for normalized models. Consequently, despite having similar performance indexes, uncertainty and coverage differ between data transformation techniques, making model selection more complex than just performance indexes.
- **Kinetic propagation:** although the hybridization specifically targeted the biobutanol formation rate, accuracy gains and conversely, uncertainty propagated to interconnected state variables such as glucose and biomass. This confirms that the hybrid framework functions as a cohesive dynamic system, where refining a single critical reaction rate improves the global fidelity of the bioprocess digital twin.

Finally, while normalization remains important for narrowing early-phase uncertainty intervals in individual predictors, the ensemble design serves as the primary driver of generalization and robustness. Future development of hybrid bioprocess models should therefore prioritize ensemble models over the exhaustive optimization of data scaling protocols.

## ABSTRACT

Environmental concerns caused by $CO_2$ emissions has attracted much attention by researchers worldwide. $CO_2$ can be captured from large single sources such as power plants to reduce the $CO_2$ emission. Solvent-based post-combustion carbon capture (PCC) process for large scale biomass-fired power plant could achieve negative carbon emission. However, capture level is commonly set at 90% in many studies. The small fraction of residual $CO_2$ is still a large amount due to the high flue gas flowrate. In this study, a piperazine-based PCC process at 95% capture level for biomass-fired power plant was studied. The process was simulated in Aspen Plus® V11, validated and scaled up. The energy performance results showed that when the capture level is increased to 95%, the reboiler duty rises to 4.07 GJ/t$CO_2$, corresponding to an increase of approximately 13.7% compared to the 90% case. This additional regeneration energy demand is offset by the reduction in residual $CO_2$ emissions from flue gas or 0.23 million tons extra $CO_2$ captured each year (from 3.86 million tons $CO_2$/year to 4.09 million tons $CO_2$/year). It is feasible for improving negative emission performance in BECCS systems. More analysis (e.g. different configurations and economic analysis) will be performed to further discuss the high capture level process.

**Keywords**: carbon capture, chemical absorption, process simulation, technical assessment, negative emission technologies

## 1. INTRODUCTION

### 1.1 Background and motivation

Biomass energy with carbon capture and storage (BECCS) has been widely recognized as a negative emission technology in which renewable energy generation is combined with permanent removal of atmospheric carbon dioxide. BECCS is increasingly considered as an essential component in long-term carbon emission reducing strategies.

From process engineering, the effectiveness of BECCS is mainly dependent on the efficiency of the solvent-based PCC system. While a capture level of 90% is commonly adopted in PCC studies from the IEA report [1], the remaining $CO_2$ in the treated flue gas still represents a direct emission to the atmosphere. Reducing the residual $CO_2$ concentration through higher capture levels becomes increasingly relevant for BECCS applications that aim to achieve meaningful negative emissions.

### 1.2 Literature review

The solvent-based PCC is widely used from Wang et al. [2]. The process is based on chemical absorption to capture $CO_2$ from the flue gas. In most system studies, a capture level of 90% is typically adopted as the default design point. It avoids the steep energy penalty and equipment scale-up associated with very high capture level. In Canepa et al. [3], MEA-based PCC process for combined cycle gas turbine (CCGT) power plant was studied under 90% capture level. Exhaust gas recirculation (EGR) technology was proposed to reduce the flue gas flowrate to solvent-based PCC plant, therefore reducing sizes of key equipment (mainly absorber) energy consumption for solvent regeneration. Luo and Wang [4] analysed the solvent-based PCC for nature gas combined cycle (NGCC) power plant. They found that carbon capture becomes economically justified only when the carbon price exceeds about €100–120 per ton $CO_2$. Higher fuel and $CO_2$ transport costs will further increase the required carbon price to maintain high capture levels. Hu et al. [5] applied the PCC using MEA for treating flue

gas from thermal cracking furnace in ethylene manufacturing under the same capture level. Through integrating excess process heat can supply regeneration energy and reduce $CO_2$ capture cost from about \$80/t$CO_2$ to \$70/t$CO_2$

Study of Michailos and Gibbins [6] explored solvent-based PCC process to facilitate 95–99% capture level from CCGT flue gas. The results show that there are significant differences in performance and energy consumption under different capture levels. The increasing capture level above 90% is technically possible but often comes with higher costs and higher energy consumption used, especially for post-combustion systems. Many studies historically capture level around 85–90%, leaving residual emissions uncaptured.

BECCS studies commonly treat solvent-based PCC as a key enabling block. IEAGHG has discussed higher capture rates for biomass as a method for lower residual emissions, while also noting that solvent-based PCC can face a high cost and energy penalty as capture level increases beyond typical benchmarks. More recent work has started to examine biomass-fired power plant with PCC configurations and solvent choices in more detail. For example, Ren et al. [7] investigated techno-economic performance and optimisation of piperazine-based PCC and $CO_2$ compression for large-scale supercritical biomass-fired power plants, discussing solvent choice and configuration effects specifically for biomass contexts.

### 1.3 Novelty of this study

Several studies on the solvent-based PCC process under 90% capture level has been discussed in the literature review section. For large-scale biomass-fired power plants, even a relatively small fraction of residual $CO_2$ can translate into a substantial emission due to the high flue gas flow rate. For the flue gas from a 550 MW biomass-fired power plant, increasing the capture level from 90% to 95% raises the daily amount of captured $CO_2$ nearly 700 tonnes. The capture cost of DAC commonly exceeds USD 600 per tonne. This additional captured amount shows great potential. Within this context, a capture level of 95% sets as the critical engineering setting. It could reduce the residual $CO_2$ emissions compared with the widely adopted 90% level, while remaining within a range that may still be technically achievable using advanced solvents and well-designed solvent-based PCC systems. The energy performance of solvent-based PCC process operating at such high capture levels has not been systematically assessed for biomass-fired power plants.

## 2. PROCESS DESCRIPTION

In this study, a standard solvent-based PCC process is considered for application to a large-scale biomass-fired power plant. The process configuration follows a conventional closed-loop absorption–regeneration system using piperazine (PZ) as the reactive solvent and is representative of industrial PCC designs targeting high $CO_2$ capture level. The flowsheet diagram of solvent-based PCC is shown in the Figure 1.

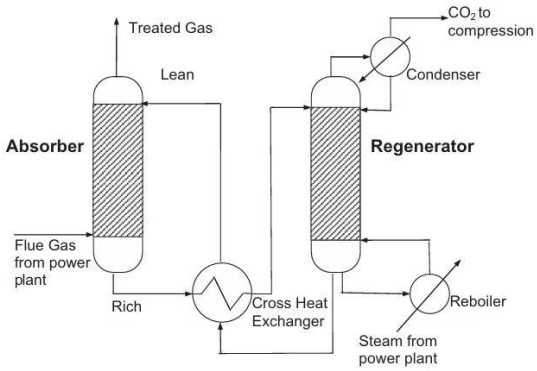

**Figure 1.** The process of standard PCC process from Lawal et al. [8]

The overall process consists of an absorber, a stripper equipped with a reboiler, solvent circulation pumps, and a set of heat exchangers for temperature control and heat recovery. Flue gas exiting the biomass-fired power plant is introduced at the bottom of the absorber. As Lawal et al. [8] and Otitoju et al. [9] mentioned, the gas flows upward through the packed bed, where it comes into counter-current contact with lean PZ solvent introduced at the top of the column. $CO_2$ is removed from the flue gas through combined gas–liquid mass transfer and chemical reaction with the solvent, resulting in a treated gas stream with reduced $CO_2$ concentration leaving the top of the absorber.

The $CO_2$-rich solvent collected at the bottom of the absorber is pumped to the regeneration section. Steam generated in the reboiler raises the temperature of the solvent, reversing the absorption reactions and releasing $CO_2$ from the liquid phase. The regenerated lean solvent exits the bottom of the stripper and is routed back to the absorber after cooling.

The solvent used in this study is 30 wt% PZ. Relative to MEA, PZ exhibits higher $CO_2$ absorption capacity and faster reaction kinetics, allowing operation at higher rich loadings. PZ solvent has better performance when targeting high capture levels, as they reduce the extent of solvent circulation and absorber height required to achieve a given removal target.

## 3. MODEL DEVELOPMENT, MODEL VALIDATION AND SCALE-UP

### 3.1 Model development

In this study, the DAC process using PZ was developed in Aspen Plus ® V11. The absorber and stripper are all rate-based models using RadFrac Block in the software. The reactions and physical properties used for rate-based model was the same as Otitoju et al. [9]. The details are not shown here due to page limit.

## 3.2 Model validation

The developed PCC model was validated by pilot-scale experimental data. The experimental cases were chosen from the pilot plant experimental results in the University of Texas at Austin from Otitoju et al. [9]. The flue gas conditions were stabled as 0.165 $m^3/s$ and 12 vol% of $CO_2$ in flue gas. The pilot plant consists of a packed-bed absorber and stripper equipped with structured packing. The absorber was designed as packed columns with a diameter of 0.427 m and a total height of 6.1 m. The column contained two 3.05 m sections of Mellapak 2X packing. In the present study, Mellapak 2X packing was selected in the simulation [7].

Model validation used five experimental cases operated under different conditions. These cases were selected with different operating parameters, including variations in liquid-to-gas (L/G) ratio, lean solvent loading, and solvent circulation rate from Dugas [10]. The $CO_2$ capture level was selected as the primary output variable for validation. For each experimental case, the simulated capture level was compared with the corresponding experimental value, and the relative error was calculated. As shown in the Figure 2, across the five validation cases, the relative error between model prediction results and experimental data remained within ±10%. This level of agreement indicates that the rate-based model can simulate the $CO_2$ absorption process with reliability. The validation results therefore support the use of the developed model for subsequent scale-up and high capture level analysis.

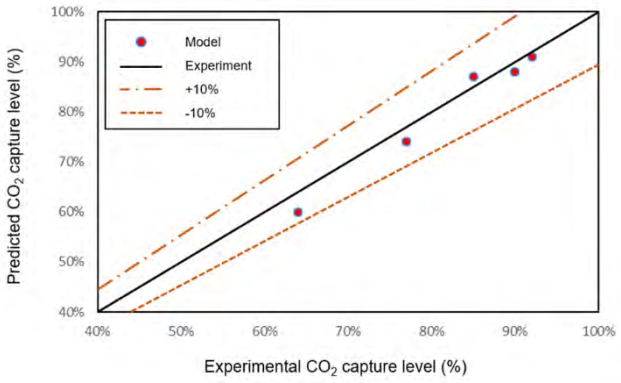

**Figure 2.** Experimental data versus model prediction for $CO_2$ capture level for the 5 experimental cases

3.3 Model scale-up

Following model validation at pilot scale, the PCC model was scaled up to deal with the flue gas from a large biomass-fired power plant with an electrical output of 550 MW. The solvent composition was maintained at 30 wt% PZ. The scale-up of the absorber and stripper was performed using established packed-column scale up design principles. The absorber diameter was determined based on flue gas flowrate as 647.5 kg/s and hydrodynamic constraints using the Generalized Pressure Drop Correlation (GPDC) [9]. This approach makes sure that column operation remains below flooding limits while maintaining acceptable pressure drop under large flue gas flowrates from biomass-fired power plants.

Table 1 presents the dimensions of the absorber and stripper calculated using the GPDC method and compares the cases operating at 90% and 95% capture levels. As shown in the Table 1, increasing the capture level requires the absorber to remove a larger fraction of $CO_2$ from the flue gas. To achieve this, a higher solvent circulation rate and a longer effective contact time between the gas and liquid phases are required, which leads to an increase in absorber size compared with the 90% capture case. The higher solvent flow rate also results in an increased regeneration demand, which in turn increases the required size of the stripper.

**Table 1:** Comparison of 90% capture level scale up simulation results with 95%

| Scale up results | 90% capture level | 95% capture level |
|---|---|---|
| Absorbers | | |
| Diameter (m) | 10.4 | 11.9 |
| Packing height (m) | 25 | 28 |
| Stripper | | |
| Diameter (m) | 8 | 10 |
| Packing height (m) | 20 | 20 |

## 4. SENSITIVITY ANALYSIS

The influence of lean solvent loading on the energy performance of the PZ-based PCC process was analysed using the validated standard PCC model. Two capture levels, 90% and 95%, were considered in order to examine how the operating strategy affects reboiler duty under different removal targets. For each capture level, the lean loading was varied with same specified overall $CO_2$ capture level.

As shown in Figure 3, the reboiler duty exhibits the relationship with lean loading for both capture levels. At relatively low lean loading, deeper solvent regeneration is required to maintain the target $CO_2$ removal, which leads to a higher reboiler duty. As lean loading increases, the regeneration requirement is gradually relaxed, resulting in a decrease in reboiler duty. However, beyond a certain lean loading range, further increases in lean loading cause the reboiler duty to rise again. This trend can be

explained by the corresponding change in solvent circulation rate. Figure 4 shows that the solvent flow rate increases continuously with increasing lean loading for both capture levels. At higher lean loading, a larger solvent circulation rate is required for same $CO_2$ removal efficiency, as the driving force for absorption in the absorber is reduced. The increased circulation rate leads to higher sensible and latent heat requirements in the regeneration section, which offsets the benefit of reduced regeneration depth and results in an overall increase in reboiler duty.

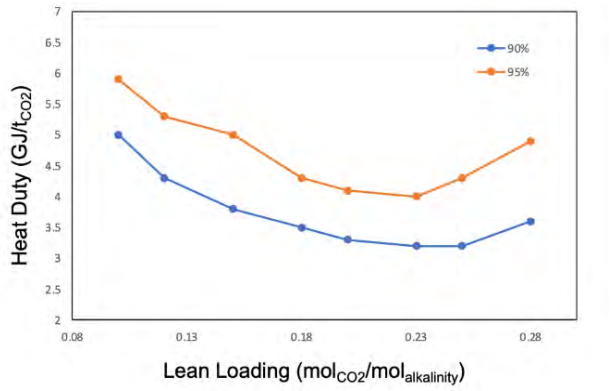

**Figure 3.** Energy consumption at various lean loadings for different capture level (%)

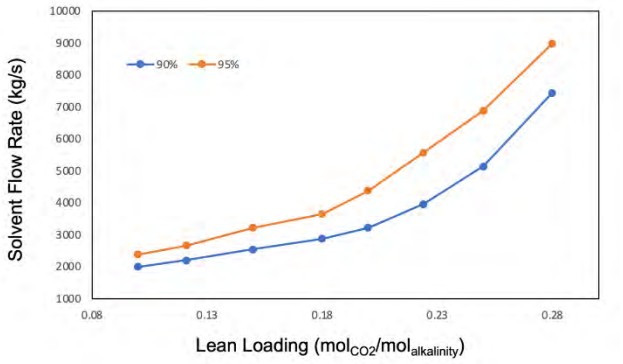

**Figure 4.** Solvent flow rate at various lean loading for different capture level (%)

For the 90% capture case, the minimum reboiler duty of approximately 3.5 GJ/t$CO_2$ is achieved at a lean loading of around 0.22–0.24 mol $CO_2$/mol alkalinity. A similar trend is observed for the 95% capture case, although the reboiler duty becomes higher across the entire lean loading range due to the higher regeneration requirement. The minimum reboiler duty for the 95% capture case is approximately 4.0 GJ/t$CO_2$, occurring at a similar lean loading range.

Comparing these two capture levels, the results showed that increasing the capture level from 90% to 95% systematically shifts the energy performance curve upward. This is attributed to the combined effects of deeper solvent regeneration and higher solvent circulation rates required at the higher capture level.

Overall, the sensitivity analysis shows that lean loading is important in determining the regeneration energy demand of the PCC process using PZ. An optimal lean loading range exists where the trade-off between regeneration depth and solvent circulation is balanced. Although operating at 95% capture inevitably increases the reboiler duty, the additional energy requirement remains moderate within the identified optimal lean loading range, supporting the feasibility of high capture operation in BECCS applications.

## 5. RESULTS FROM ENERGY ASSESSMENT

The energy performance of the PZ-based PCC process was evaluated by comparing operation at 90% and 95% $CO_2$ capture levels. The specific reboiler duty, expressed in GJ/t$CO_2$, was used as the primary performance indicator, as solvent regeneration represents the dominant energy consumption in the process.

Figure 5 presents the variation of reboiler duty with capture level. At a capture level of 90%, the reboiler duty is 3.58 GJ/t$CO_2$ [7]. When the capture level is increased to 95%, the reboiler duty rises to 4.07 GJ/t$CO_2$, corresponding to an increase of approximately 13.7%. This result confirms that achieving higher $CO_2$ removal requires additional thermal energy for solvent regeneration.

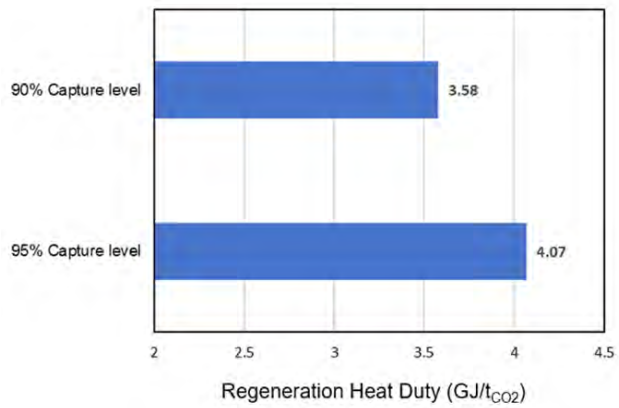

**Figure 5.** Regeneration heat duty of different configurations of PCC processes using PZ

From a process perspective, the increase in reboiler duty can be explained by the combined effects of deeper solvent regeneration and changes in column operation. To achieve a higher capture level, the lean solvent leaving the stripper must reach a lower $CO_2$ loading, which directly increases the thermal requirement in the reboiler. At the same time, the absorber must provide sufficient contact time and solvent capacity to remove a larger

fraction of $CO_2$ from the flue gas. This is reflected in the increased absorber dimensions and solvent circulation rates observed for the 95% capture case compared with the 90% case. The higher solvent circulation rate required at 95% capture also affects the regeneration section. An increased liquid flow to the stripper leads to a larger stripper size and higher sensible and latent heat demands during regeneration. These effects together contribute to the observed increase in reboiler duty. The results showed that higher capture efficiency can be achieved, but with the increasing cost of regeneration energy demand.

Despite this increase, the additional energy requirement is still acceptable. For the flue gas from the 550MW biomass-fired power plant as 647.5 kg/s, the increasing capture level as 5% could capture additional 7.55kg/s of $CO_2$. It results in an annual captured amount over 0.23 Mt. In other words, at 90% capture level, such a solvent-based PCC would capture 3.86 Mt $CO_2$ each year. At 95% capture level, such a solvent-based PCC would capture 4.09 Mt $CO_2$ each year. An increase of 13.7% in reboiler duty represents a relatively small penalty when considered against the substantial reduction in residual $CO_2$ emissions achieved by moving from 90% to 95% capture. In the context of BECCS, where the objective is to maximise net negative emissions, reducing residual emissions from the treated flue gas is particularly important. Existing biomass-fired power plants and PCC infrastructure do not require complete reconstruction. This indicates that the higher capture level does not introduce impractical equipment requirements under the operating assumptions considered. Consequently, the additional regeneration energy associated with 95% capture can be regarded as acceptable for BECCS applications, provided that the objective is to minimise residual emissions and enhance negative emission performance.

## 6. CONCLUSION AND RECOMMENDATIONS FOR FUTURE WORK

Operating a PZ-based PCC process at a 95% capture level is technically feasible and does not incur a prohibitive energy penalty relative to the commonly used 90% benchmark. The additional captured $CO_2$ by setting at 95% capture level is about 653 tonnes per day, corresponding to an annual increase of more than 0.23 Mt (from 3.86 Mt $CO_2$ to 4.09 Mt $CO_2$). The reboiler duty rises to 4.07 GJ/t$CO_2$, corresponding to an increase of approximately 13.7% than 90% case. These results provide the necessary research foundation for the subsequent integration of the BECCS system with direct air capture technology. This study will first conduct further configurations, such as utilizing advanced flash stripper (AFS), intercooling system and rich-split process. This study will also perform economic optimizations for the system. Optimal design and operation for high capture level biomass-fired power plant process using PZ can be achieved.

# Differentiable Programming for Cyclic Adsorption Processes

**Alex Glover[ab], Maria M. Papathanasiou[ab], and Ronny Pini[ab]***

## ABSTRACT

The design of cyclic adsorption processes is computationally expensive as it involves screening many process designs, each of which involve a time-consuming simulation to reach cyclic steady state. In this work, we demonstrate how differentiable programming can be used to accelerate both the simulation and attainment of cyclic steady state for a four-step pressure vacuum swing adsorption (PVSA) process to concentrate carbon dioxide from flue gas. A mechanistic one-dimensional dynamic adsorption model was implemented in JAX, enabling automatic differentiation and just-in-time compilation for efficient solution and accurate sensitivity evaluation. The latter was exploited to implement a Newton-based direct determination method for accelerated convergence to cyclic steady state, avoiding repeated cycle simulations. Across 4096 designs sampled in a six-dimensional design space, the direct determination method converged in an average of 4.6 iterations, compared to 145 cycles required by successive substitution. When combined with the computational gains from the JAX framework, this resulted in an overall speed-up of over 20 times relative to the conventional MATLAB-based implementation.

**Keywords**: Differentiable Programming, JAX, cyclic adsorption processes, mechanistic modelling, gradient-enhanced acceleration

## INTRODUCTION

Cyclic adsorption processes are used throughout a range of industrial settings for gas separations and have seen an increase in interest for their use in carbon capture applications. In these processes, a solid adsorbent is used to selectively adsorb components of a gas stream, due to differences in adsorption capacity. The adsorbent is regenerated through changing the column conditions such as with a decrease in pressure and/or an increase in temperature. Thus, adsorption processes consist of a sequence of distinct steps, which repeat in a cyclic manner.

Computational process models are a powerful and widely used tool for screening potential designs, where operating parameters such as the pressure set points, or duration of the steps are varied to optimise the process performance [1]. Such models describe the dynamic behaviour of these processes through systems of partial differential equations (PDEs) which represent mass, energy and momentum balances. Despite the inherently dynamic nature of adsorption processes, they are typically designed to operate at cyclic steady state (CSS): an operating point where one cycle behaves identically to the next. Therefore, determination of this CSS is a key part of evaluating every candidate process design. Typical methods involve simulating the process for multiple cycles, from startup conditions, until CSS is reached. Depending on the process and operating conditions, this procedure may require tens, hundreds or thousands of cycles to converge [2, 3]. In isolation, this procedure often requires just a few minutes of CPU time to evaluate the performance of the design at CSS. However, process design and optimisation studies typically evaluate thousands of designs due to having several operational parameters to evaluate simultaneously. Thus, for one process, the design may require hundreds or thousands of CPU hours [4, 5]. The computational demand becomes even larger when different cycle configurations or adsorbents are compared, or if uncertainty quantification is required, as the total number of high-fidelity simulations increases substantially, leading to a large cumulative computational cost even when parallel resources are

available, limiting the use of high-fidelity process models. As such, many authors have turned to short-cut models, where axial gradients are neglected[6, 7] or trained machine learning surrogates using data from high-fidelity process models [8, 9].

The conventional approach to reach CSS described above relies on successive substitution, in which the final state of one cycle is used as the initial condition for the next, which benefits from simulating the process dynamics. However, there have been several methods developed within the literature to accelerate the determination of CSS. Gradient-based methods, where the Jacobian matrix of the output state of the cycle with respect to the input state is used in a Newton iteration, have been used to converge to the CSS in fewer iterations [3, 10–12]. However, the evaluation of these gradients, typically through solving the forward sensitivity or adjoint ordinary differential equations [13, 14], require an added computational requirement at each iteration. Quasi-Newton methods, which do not require a full Jacobian evaluation at each iteration have been used to reduce this demand [10, 15]. Gradient-free approaches, such as algebraic methods introduced by Subraveti et al. [2], where the next iteration is based on the three preceding inputs have been used for the fixed point iteration. Machine learning models have also been trained to predict CSS [16]. Rather than the conventional method of solving the PDE system using the method of lines and integrating the resulting ordinary differential equations (ODEs), the full discretization of the PDE system (in both the spatial and time domain) reduces the system of equations to a set of algebraic equations, which can be combined with the CSS criterion to avoid repeated simulation [17]. However, authors have reported convergence difficulty with this method [12]. To address this issue, Tsay et al. developed a pseudo-transient model based on the fully discretized system to simulate and optimize cyclic processes[18].

Differentiable programming offers a promising alternative for addressing the above challenges by enabling the efficient computation of exact gradients of model outputs with respect to inputs. Recent advances in differentiable frameworks, such as Google's JAX and MIT's Julia, have made automatic differentiation techniques accessible to develop end-to-end differentiable mechanistic models. Such models have been applied to crystallisation processes, computational fluid dynamics, chemical reaction networks and molecular dynamics simulations[19–22].

In this work, we exploit these capabilities to develop a differentiable model of a pressure vacuum swing adsorption (PVSA) process for carbon capture. Due to the high computational effort required for the design and optimisation from the repeated simulations to obtain CSS, this study explores the use of JAX to accelerate process simulations. The first method for the acceleration of the solution of the ODE system is using just-in-time compilation and automatic differentiation within the ODE solver. By leveraging exact sensitivities, the second method implements a Newton-based direct determination method for rapid convergence to CSS [3], through a discrete sensitivity method.

## METHODOLOGY

### Mechanistic Adsorption Model

The case study for this work is a four-step pressure vacuum swing adsorption process for the separation of a 15% carbon dioxide in nitrogen feed, using Zeolite 13X as the adsorbent (Figure 1). This case study has been chosen for this work as it has been a system of interest throughout many optimisation studies, and due to its relevancy to post-combustion carbon capture applications [5, 23–25]. The process model describes the coupled heat and mass transfer in the adsorption bed through a system of partial differential and algebraic equations. The following assumptions are made in deriving the model equations:

- Only spatial gradients in the axial direction of the column are considered.
- The gas phase is ideal.
- Thermal equilibrium between the solid, adsorbed and gas phases.
- Constant heat capacities of all phases.
- Constant density of solid phase and the column wall.
- Constant column void fraction and adsorbent particle size.
- Constant mass dispersion coefficient and effective thermal conductivity.
- The pressure drop along the column is described by Darcy's law.

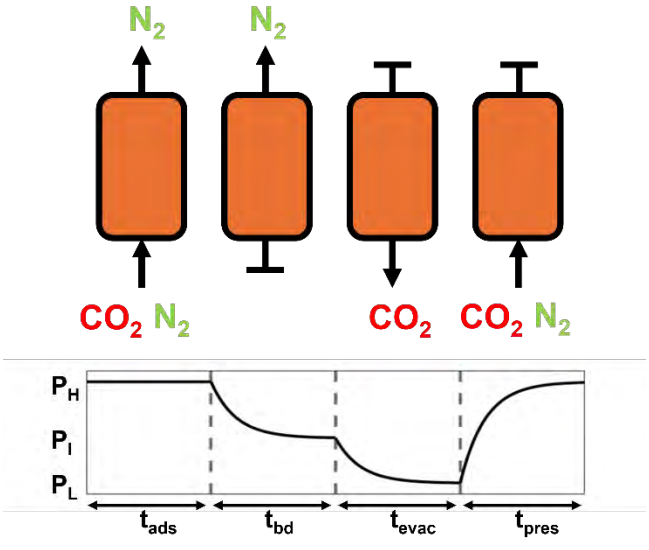

**Figure 1.** Schematic of the four step PVSA cycle. The four

**Table 1:** Adsorption model equations

Overall Material Balance

$$\frac{\partial p}{\partial t} - \frac{p}{T}\frac{\partial T}{\partial t} = -T\frac{\partial}{\partial z}\left(\frac{pv}{T}\right) - RT\frac{\rho_b}{\epsilon}\sum_{i=1}^{n_c}\frac{\partial q_i}{\partial t}$$

Component Material Balance

$$\frac{\partial y_i}{\partial t} = \frac{T}{p}D_L\frac{\partial}{\partial z}\left(\frac{p}{T}\frac{\partial y_i}{\partial z}\right) - \frac{T}{p}\left(\frac{\partial}{\partial z}\left(\frac{y_i pv}{T}\right) - y_i\frac{\partial}{\partial z}\left(\frac{pv}{T}\right)\right) - \frac{RT}{p}\frac{\rho_b}{\epsilon}\left(y_i\sum_{i=1}^{n_c}\frac{\partial q_i}{\partial t} - \frac{\partial q_i}{\partial t}\right)$$

Column Energy Balance

$$\left(C_{p,g}\frac{P}{RT} + \frac{\rho_b}{\epsilon}\left(C_{p,s} + C_{p,a}\sum_{i=1}^{n_c} q_i\right)\right)\frac{\partial T}{\partial t} = \frac{K_z}{\epsilon}\frac{\partial^2 T}{\partial z^2} - \frac{C_{p,g}}{R}\left(\frac{\partial}{\partial z}(pv) - T\frac{\partial}{\partial z}\left(\frac{pv}{T}\right)\right) - \frac{\rho_b}{\epsilon}\sum_{i=1}^{n_c}\left(T\left(C_{p,a} - C_{p,g}\right) - \left(-\Delta H_i\right)\right)\frac{\partial q_i}{\partial t} - \frac{2h_{in}}{\epsilon r_{in}}(T - T_w)$$

Column Wall Energy Balance

$$\rho_w C_{p,w}\frac{\partial T_w}{\partial t} = K_w\frac{\partial^2 T_w}{\partial z^2} + \frac{2r_{in}h_{in}}{r_{out}^2 - r_{in}^2}(T - T_w) - \frac{2r_{out}h_{out}}{r_{out}^2 - r_{in}^2}(T_w - T_a)$$

Steady State Momentum Balance (Darcy's Law)

$$-\frac{\partial P}{\partial z} = \frac{150}{4r_p^2}\left(\frac{1-\epsilon}{\epsilon}\right)^2\mu v$$

Linear Driving Force

$$\frac{\partial q_i}{\partial t} = k_i(q_i^* - q_i)$$

Adsorption Equilibrium (Dual Site Langmuir)

$$q_i^* = \frac{q_{b,i}b_i c_i}{1 + \sum_{i=1}^{n_c} b_i c_i} + \frac{q_{d,i}d_i c_i}{1 + \sum_{i=1}^{n_c} d_i c_i}$$

$$b_i = b_{i,0}e^{-\frac{U_{b,i}}{RT}}$$

$$d_i = d_{i,0}e^{-\frac{U_{d,i}}{RT}}$$

steps include adsorption, forward blowdown, reverse evacuation and forward pressurisation

The one-dimensional PDE model which describes the heat and mass balances within the column is illustrated in Table 1. Auxiliary equations include the adsorption isotherms which describe the thermodynamic equilibrium between the gas and the adsorbed phase. For the Zeolite 13X adsorbent used in this work, the extended dual-site Langmuir model is used to quantify this relationship for the carbon dioxide and nitrogen mixture. The parameters used for this model are the same as those reported in Ward and Pini [5]. For each step of the four-step cycle, the PDE system is solved with the boundary conditions relevant to the step, as described in [5]. The diagram in Figure 1 illustrates this 4-step cycle with the pressure profile given below. The cycle begins with adsorption at the high pressure set point. Blowdown to the intermediate pressure set point removes most of the adsorbed nitrogen. The carbon dioxide product is extracted in the evacuation step before the column is repressurized with the feed.

## Numerical Solution and Sensitivities

A finite volume discretization (10 finite volumes) of the spatial domain of PDE system was used to reduce the system to a set of ODEs that were then solved sequentially for each step of the cycle. Due to stiffness of the

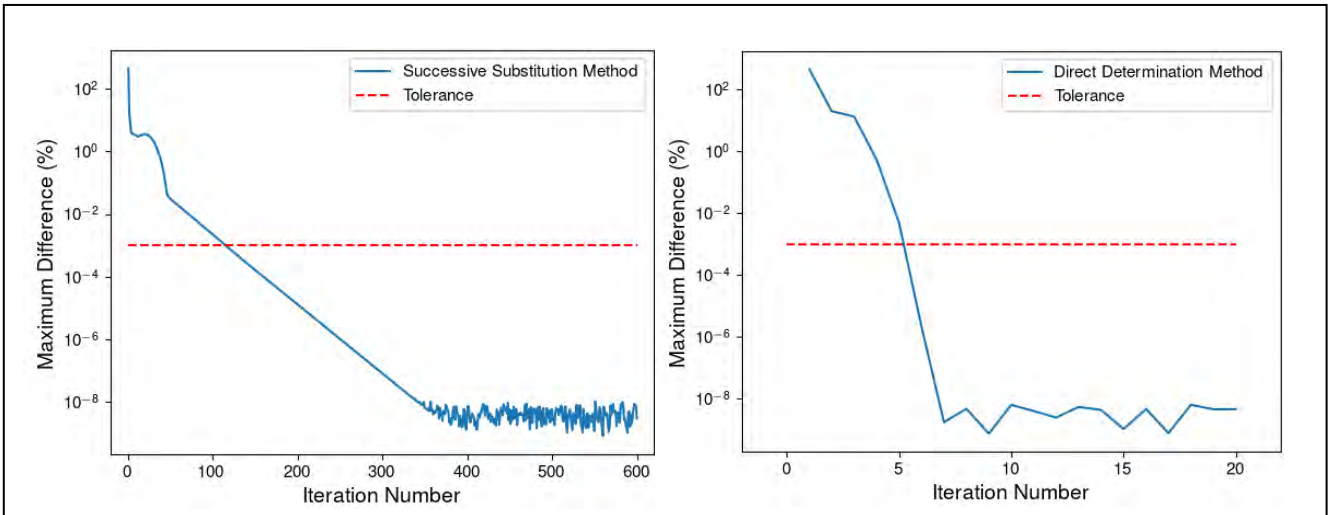

**Figure 2.** Convergence to cyclic steady state for successive substitution (left) and direct determination (right) methods.

ODEs, arising from diffusion, heat conduction, and adsorption source terms, we emplan implicit time integration scheme. Specifically, a numerical differentiation formula (NDF) method similar to MATLAB's ode15s solver was implemented in JAX [26]. This implementation uses automatic differentiation (AD) to efficiently evaluate the Jacobian of the state gradients with respect to the state variables: a key part of the implicit solver.

Sensitivities of the system states with respect to the initial conditions are required for the direct determination of CSS. Rather than using continuous sensitivity equations, a discrete forward sensitivity method was used, in which sensitivities are obtained by differentiating the numerical integration scheme itself. This ensures that the computed gradients are consistent with the discrete trajectory produced by the time integrator and enables the reuse of Jacobian information already computed by the implicit solve. The use of automatic differentiation within the JAX differentiable framework makes the evaluation of sensitivities computationally effective for the use of the direct determination method for reaching CSS in adsorption processes. All the simulations were performed on an Intel Core i5-10500 CPU with 8GB of RAM.

## Direct Determination of Cyclic Steady State

The CSS is defined as a point where each cycle operates identically to the next. In mathematical models this can be monitored through the convergence of the overall mass balance, the key performance indicators, or the values of the state variables themselves. In this work, we define the cycle error as the difference between the vector of state variables at the start and end of a cycle (Equation 1). The state variable vector $\boldsymbol{x}$ includes the pressure, column temperature, wall temperature, gas phase mole fraction and adsorbed quantity at every finite volume element. The subscript $k$ represents the iteration number, with $\boldsymbol{x}_k^0$ denoting the initial state of the cycle and $\boldsymbol{x}_k$ the final state.

$$\boldsymbol{e}_k = \boldsymbol{x}_k - \boldsymbol{x}_k^0 \tag{1}$$

The CSS is reached when the max norm (also known as the $L^\infty$) of this error (normalised to the input state) is less than $10^{-5}$. To attain the CSS, the successive substitution method uses the final state of the cycle as the initial state for the next cycle, following the dynamics of the process (Equation 2).

$$\boldsymbol{x}_{k+1}^0 = \boldsymbol{x}_k \tag{2}$$

As the design of adsorption processes is typically at the CSS and the dynamics are not of interest, the direct determination method described by Croft and LeVan is used, where a Newton iteration, based on the gradient of the error vector with respect to the initial state is used for the initial state of the next iterate (Equation 3).

$$\boldsymbol{x}_{k+1}^0 = \boldsymbol{x}_k^0 - \frac{\partial \boldsymbol{e}_k}{\partial \boldsymbol{x}_k^0}^{-1} \boldsymbol{e}_k \tag{3}$$

Within the literature, authors have mentioned the computational burden of solving for the sensitivities as a bottleneck for the implementation of this method [27]. The availability of gradients, accurate to the state solution integration, which can be computed efficiently in the JAX ecosystem, allows for the implementation of gradient-based methods.

## RESULTS AND DISCUSSION

Convergence f the successive substitution and direct determination methods was compared for the PVSA process, with the initial condition corresponding to a bed saturated with the feed gas. The design parameters were taken from the optimal cost design reported by Ward and

Pini [5].

For the successive substitution method, convergence to the specified CSS tolerance required 116 cycles (Figure 2, left plot). Beyond this point, further cycling continued to reduce the error, but at a significantly slower rate. To reach an error level comparable to the numerical tolerance of the ODE solver, nearly 350 full process cycles were required. This slow asymptotic convergence behaviour is characteristic of successive substitution, which exhibits linear convergence near the fixed-point. In contrast, the direct determination method only required 6 Newton iterations, with solver level accuracy being achieved within 7 iterations (Figure 2, right plot). Compared to the fixed-point iteration, close to quadratic convergence is expected for this direct determination method as it includes the Newton iteration.

The convergence properties of cyclic adsorption processes can be characterised by the dominant Floquet multiplier, which is also known as the spectral radius, and is the largest eigenvalue of the Jacobian matrix for the cycle, $\frac{\partial \boldsymbol{x}_k}{\partial \boldsymbol{x}_k^0}$. When this value is less than unity, the CSS is stable, but as this value approaches one, the cycle dynamics become increasingly sluggish, such that more iterations are required to reach CSS when the successive substitution method is used. For the adsorption process considered in this work, the dominant Floquet multiplier was calculated as 0.952 at the CSS. For processes exhibiting even slower cycle dynamics, often seen in air purification PSA processes, systems with strongly adsorbing impurities, or rapid PSAs cycles, the direct determination method is therefore expected to yield even greater performance compared to the successive substitution method. Conversely, processes with temperature swings and longer cycle times, such as direct air capture processes, typically exhibit faster cycle dynamics such that fewer cycle simulations are required to reach CSS when using the successive substitution method.

While the single-design study illustrates the potential of the direct determination method, practical process design and optimisation studies require reliable performance of this method across a wide range of operating conditions. To assess robustness and scalability, both methods were therefore applied to a set of 4096 designs generated using Sobol sampling in a six-dimensional design space. The sampled parameters include the step durations for the adsorption, blowdown and evacuation steps, the high and intermediate pressure set points and the feed velocity. These parameters are commonly selected in adsorption process optimisation studies, where the low-pressure set-point is fixed at 0.05 bar, and 20s for the pressurisation time. The bounds of the design parameters are given in Table 2.

**Table 2:** Bounds for design parameters.

| Parameter | Lower Bound | Upper Bound |
|---|---|---|
| $t_{ads}\ [s]$ | 20 | 100 |
| $P_H\ [bar]$ | 1 | 10 |
| $v_F\ [ms^{-1}]$ | 0.1 | 2 |
| $t_{bd}\ [s]$ | 30 | 100 |
| $P_I\ [bar]$ | 0.07 | 3 |
| $t_{evac}\ [s]$ | 30 | 100 |

For each design, the CSS was computed using three different approaches:

1. Successive substitution in JAX
2. Direct determination in JAX
3. Successive substitution in MATLAB which is representative of standard practice.

For all implementations, simulations were run to the same CSS criteria. Between the two successive substitution methods, the solution method differs only in the evaluations of the Jacobian within the implicit ODE solver, which are computed through automatic differentiation in JAX and via numerical approximation in MATLAB. The comparison with an equivalent model in MATLAB was included to benchmark performance against the current standard approach for modelling cyclic adsorption processes. For the direct determination method, the ODE solver was modified such that the Jacobian was evaluated at every accepted time step, rather than being reused over multiple steps when the sensitivities are not required.

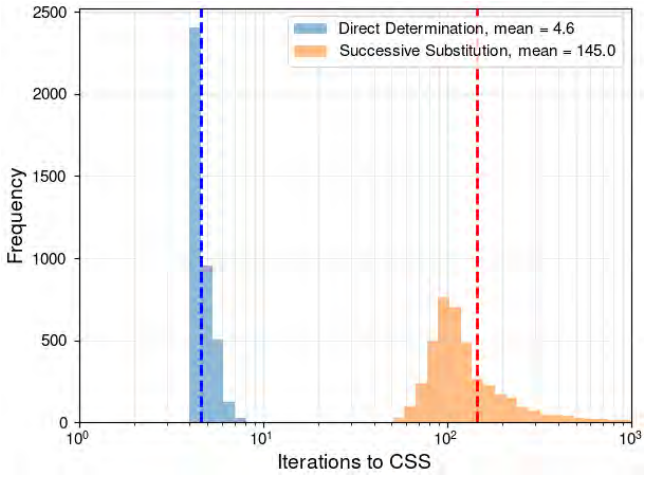

**Figure 3.** Distribution of iterations required to reach cyclic steady state for the 4096 Sobol-sampled designs, for the two methods. The number of iterations are plotted on a logarithmic axis.

Figure 3 shows the histogram of iterations required to reach CSS for the successive substitution and the direct determination methods across all Sobol-sampled designs. For every design, both methods converged to the same CSS, as verified by identical purity and recovery

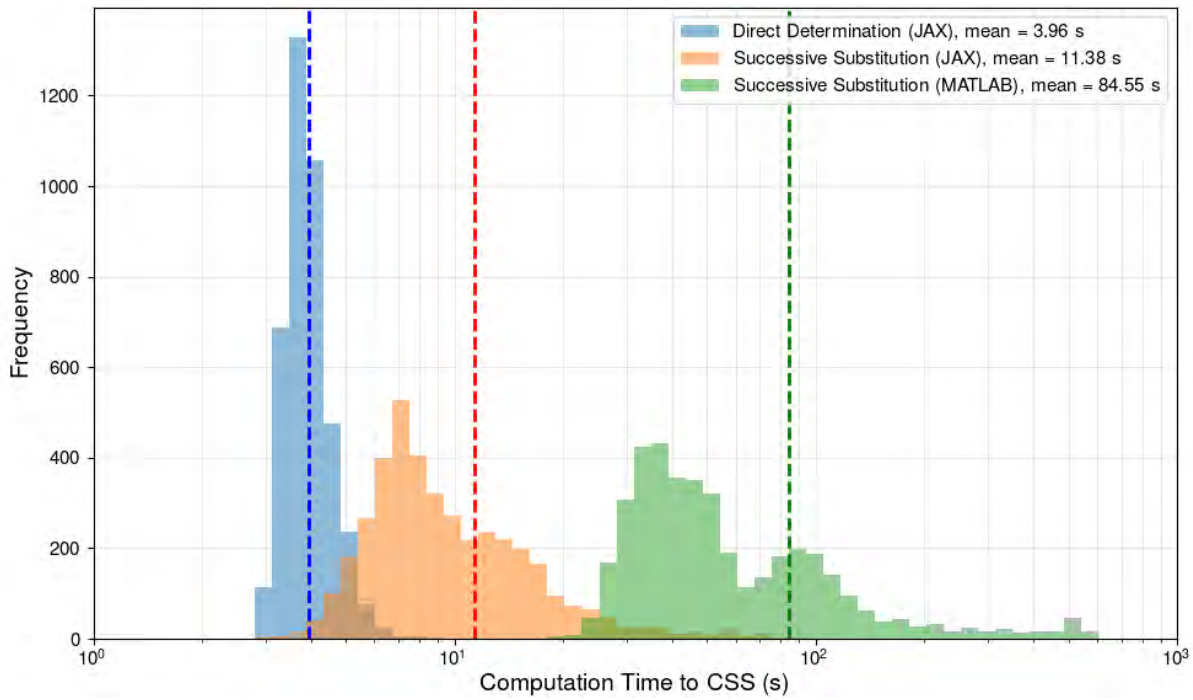

**Figure 4.** Distribution of CPU time required to reach cyclic steady state for 4096 Sobol-sampled designs, for each of the three approaches. The simulation time is plotted on a logarithmic axis

values at convergence. On average, the direct determination method converged to CSS in 4.6 iterations compared with 145 cycles for the successive substitution method. The spread of iterations was substantially larger for the successive substitution method. Most of the direct determination simulations converged in 4 iterations, with very few requiring more than 6. However, the successive substitution method required between 50 and 1000 iterations across the sampled design space. This behaviour highlights the robustness of direct determination which avoids the need to explicitly follow slow cycle dynamics to CSS.

In this work, the direct determination method was shown to attain CSS with significantly fewer iterations than the successive substitution method. This reduction in iteration count comes at the cost of additional computation per iteration due to the evaluation of state sensitivities. As such, computational time was also compared for the methods across all Sobol-sampled designs (Figure 4). For the process considered here, the direct determination method achieved convergence to CSS approximately three times faster than the successive substitution on average, requiring less than 4 seconds of CPU time per design. For processes with faster cycle dynamics, where fewer successive substitution iterations are required, the relative benefit of direct determination may be reduced. However, the automatic differentiation in JAX allows for this method to be accessible, accurate and efficient.

Also shown in Figure 4 is the comparison with the "standard" MATLAB implementation. The same solution method in JAX compared to MATLAB achieved nearly an eightfold reduction in solution time due to the just-in-time compilation and automatic differentiation available in JAX. These results the one-off compilation cost of 26 seconds for the JAX just-in-time compilation, which is incurred only during the first solution of the ODE system. For optimisation studies that require evaluating lots of model designs, this compilation overhead is negligible compared to the total computational cost.

## CONCLUSIONS

In this work, a mechanistic model of a cyclic adsorption process for post combustion capture was developed within the JAX differentiable framework. A key limitation of adsorption process modelling is the computational time required to evaluate the dynamic process model as it typically involves solving a system of semi-discretized PDEs several hundred times to simulate the process from startup to cyclic steady state. This cost is exacerbated in design and optimisation studies where thousands of candidate designs must be evaluated. The differentiable model was used to accelerate the solution of the resulting ODE system, and to enable the efficient computation of accurate sensitivities. These sensitivities were exploited to implement a Newton-based direct determination method to accelerate the convergence to the cyclic

state, in which gradients of the final state of the cycle with respect to the initial state were used. This was made effective due to the automatic differentiation tools within the JAX environment.

Both the direct determination method and the traditional successive substitution method which simulates the actual dynamics of the process were compared for 4096 Sobol samples in a six-dimensional design space. Both methods converged to the same CSS, with the direct determination method requiring over an order of magnitude fewer iterations due to the quadratic convergence of the Newton method. Despite the additional computational effort required per iteration for sensitivity evaluation, the overall time to reach cyclic steady state was significantly reduced, with the direct determination method achieving convergence approximately three times faster on average compared to the successive substitution method.

Performance gains were also obtained during the solution of the ODE system for the JAX framework when compared to an equivalent MATLAB implementation which is representative of the current modelling practice. The combination of the direct determination method and the efficient ODE solution yielded a total speed-up of over 20 times compared to the MATLAB implementation. These results demonstrate that differentiable programming is a useful tool for accelerating the design of adsorption processes. As well as gradient-based methods for the determination of CSS, this framework is further extendable to gradient-based optimisation.

## ABSTRACT

Manufacturing kinetically stable products remains a challenge in the agrochemical industry. Current agrochemical formulation design relies on semi-empirical and trial-and-error methods. The inconsistency is caused by the lack of a mechanistic understanding of the formulation, making the design a black-box optimisation problem. In addition, validating the ground truth of the high-dimensional design space is expensive, driving chemists to explore possible solutions using data-driven methods. We proposed a Bayesian optimisation framework employing a Gaussian process as the surrogate model to intelligently guide the screening of the design space. The uniqueness of our framework is the application to the classification task to increase the number of hits of stable formulation recipes. The framework was tested on a provided industry dataset with a focus on emulsifiable concentrates. The performance reached a comparable accuracy with only ~25% of the data being sampled and hit more stable formulations than a Monte Carlo search. Our framework accelerates the discovery of stable recipes and guides formulation screening.

## INTRODUCTION

Developing stable and effective agrochemical formulations – specifically Emulsifiable Concentrates (EC) remains a challenging bottleneck in product development. The formulation design space is high-dimensional and is characterised by limited mechanistic understanding of the complex chemical interactions between active ingredients, surfactants, and solvents when diluted in water [1]. Conventionally, these complexities are addressed through iterative trial-and-error campaigns [2]. However, these methods are inefficient for exploring vast compositional design spaces and often fail to identify optimal formulations within tight industrial timelines. Moreover, the identification of subsequent candidate formulations is non-trivial. As empirical models often fail to generalise, researchers are forced into unguided experimental loops that waste materials and stall development.

Modelling this black-box function presents common constraints in chemical engineering: the gradient information ($\nabla f$) of the chemical interaction is usually unknown; thus, gradient descent methods cannot be applied [3]. Another challenge is that the cost of evaluations (experimental validation) is also expensive in labour and time to verify the function sufficiently.

To address these limitations, we present a data-driven, closed-loop Bayesian optimisation (BO) framework that systematically accelerates the formulation development process. Unlike the traditional design of experiments (DoE), our approach employs BO to actively learn the composition-stability relationship. By treating the formulation problem as a classification task (homogeneous vs. inhomogeneous), the framework iteratively proposes the next set of experimental candidates to maximise the probability of identifying a homogeneous recipe.

## METHODOLOGY

Mathematically, the challenge can be formulated into $\mathrm{x}^{*} \in \arg\max_{\mathrm{x}\in\mathrm{X}} \mathrm{f}(\mathrm{x})$ where the design space is represented by $\mathcal{X} \subset R^{d}$, and the black-box function is

represented by matching the input $x$ with output $f(x)$. Modelling the black-box function $f$ is usually expensive in the chemical engineering field, due to the following constraints:

- **No analytical form.** The underlying physics/chemical reactions between materials are difficult to evaluate and express in closed-form equations.
- **Derivative-free.** The gradient information $\nabla f(x)$ is unknown. The gradient descent approach can't be applied.
- **Expensive evaluations.** Conducting experiments to verify the function can be costly.

## Bayesian Optimisation

BO is a sample-efficient, iterative strategy designed for the global optimisation of expensive, black-box objective functions. Unlike Random Search or traditional DoE, which typically rely on static, pre-determined sampling plans, BO is inherently adaptive. It intelligently guides subsequent experiments by balancing the model's explored region (exploitation) with the unexplored region (exploration) [4]. This allows the algorithm to focus the search on the most promising areas of the design space, achieving the optimal solution with significantly fewer experimental runs than conventional methods.

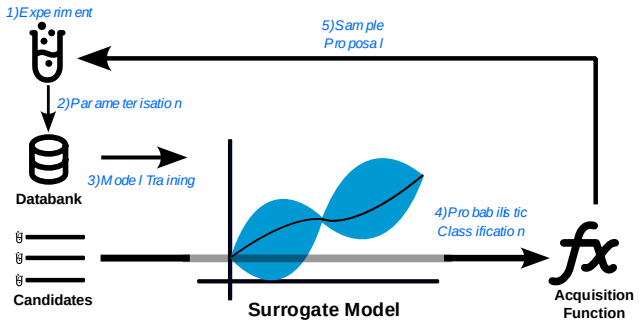

**Figure 1.** The iterative cycle of BO.

The BO procedure is an iterative strategy designed to optimise computationally expensive black-box functions. The workflow is characterised by the following stages:

(1) **Initial Sampling:** An initial set of experimental observations is collected.

(2) **Data Parameterisation:** The raw experimental inputs and corresponding outputs are transformed into a structured database for mathematical modelling.

(3) **Surrogate Model Construction:** A probabilistic surrogate model—most commonly a Gaussian Process (GP)—is trained on the available dataset to approximate the underlying objective function.

(4) **Acquisition Function Evaluation:** An acquisition function is employed to balance the exploration-exploitation trade-off. It utilises the surrogate model's mean predictions and associated predictive uncertainty to identify the most promising candidate for the next iteration.

(5) **Iterative Optimisation:** The suggested candidate is experimentally validated, the resulting data is appended to the training set, and the model is updated. This cycle repeats until a predefined termination criterion is reached.

The BO contains two core components: a surrogate model and an acquisition function. The surrogate model acts as the inference tool of the optimisation process, updating the probabilistic model given sampled data $\mathcal{D}_t = \{(x_i, y_i)\}_{i=1}^{t}$. The acquisition function is the decision maker, selecting the next point $x_{t+1}$ to sample by balancing exploitation (sampling regions known to be more promising) and exploration (sampling regions with higher uncertainty) using a predefined hyperparameter.

A **Gaussian process** is usually considered as the gold standard surrogate model as they provide reliable uncertainty estimates, analytic tractability and sample efficiency [4]. The Gaussian process is defined by a mean function $m(x)$ and a covariance function (also known as the kernel) $k(x, x')$:

$$f(x) \sim \mathcal{GP}(m(x), k(x, x')), \tag{1}$$

both mean functions $m(x)$ and covariance function $k(x, x')$ are the prior beliefs of the objective function. They are critical in training as they assume the smoothness and periodicity, before any data is observed by the model. The mean function is usually considered to be $m(x) = 0$, while the selection of the covariance function is trickier. The Matérn kernel family offers a good balance between smoothness and noise-handling. The Matérn kernel $k_{a,h}: \mathcal{X}: \mathcal{X}$ is defined by:

$$k_{a,h}(x, x') = \frac{1}{2^{\alpha-1}\,\Gamma(\alpha)} \left( \frac{\sqrt{2\alpha}||x - x'||}{h} \right)^{\alpha} K_{\alpha} \left( \frac{\sqrt{2\alpha}||x - x'||}{h} \right)^{\alpha}, \tag{2}$$

Where $\Gamma$ is the gamma function, and $K_a$ is the modified Bessel function of the second kind of order $\alpha$ [5]. More details of the Gaussian process can be found in [6].

The other core component of BO is the acquisition function. In this work, we employed the Upper Confidence Bound (UCB) as the acquisition function. The UCB is defined as:

$$\alpha_{UCB}(x) = \mu(x) + \kappa \cdot \sigma(x), \tag{3}$$

where $\mu(x)$ and $\sigma(x)$ are the mean and standard deviation of the prediction from the surrogate model, respectively,

and $\kappa$ is a predefined hyperparameter to balance exploitation and exploration. Compared to other acquisition functions, UCB is mathematically straightforward, intuitive, and based solely on the prediction and its uncertainty.

## Space-Filling Designs

Space-filling designs aim to encourage the diversity included in the dataset, resulting in not only saving computational calculations but also leading to a more sophisticated model in interpolation/extrapolation by providing a better coverage or representation of the design space [7], [8]. In this work, we considered 3 space-filling design methods with random sampling.

**Latin Hypercube Sampling** (LHS) is a space-filling design strategy that improves upon simple random sampling by ensuring one-dimensional uniformity. For each of the $k$ input variables, the range is divided into $n$ equally spaced intervals, with exactly one observation per interval. Mathematically, a design point $d_{ij}$ (representing the $i$-th run and $j$-th factor) is calculated using the formula $d_{ij} = \frac{l_{ij}+(n-1)/2+u_{ij}}{n}$, while $l_{ij}$ is a value from a permutation of $n$ levels (specifically taken as $-(n-1)/2$ to $(n-1)/2$) which determines the specific interval, and $u_{ij}$ is a random number between 0 and 1 that provides a random position within that interval. This stratification ensures that the variance of the LHS estimator is lower than that of simple random sampling, specifically by subtracting the variance contributions of the main effects. As one of the most popular space-filling design strategies, LHS offers a reduction of the variance of the sample mean compared to random sampling and provides better coverage of the range of each input [9].

**Sobol Sequence** is a quasi-random number generator which offers lower discrepancy compared to a random number generator. A pseudo-random number generator can cause the data points to cluster together, leaving a large area unexplored. Unlike random sampling, where the discrepancy decreases probabilistically, Sobol sequences are constructed using radical inversion in base-2 to ensure the discrepancy decreases, resulting in a faster conversion rate [10].

Neither the LHS nor the Sobol sequence directly select samples from the existing database; instead, they generate a list of theoretical coordinates to sample. To sample from the existence database, samples are selected by comparing the distance between each data point to match the theoretical points proposed by both generators with the same dimension. Euclidean distance $d(p,q) = ||p-q||^2 = \sum_{i=1}^{m}(p_i - q_i)^2$ is used to measure the distance between data points pairwise.

**Maximin distance design** is more intuitive. By starting with a random sample, the algorithm iteratively selected samples that maximise the minimum Euclidean distance (can be substituted by other distance measures) from the sampled data points. This algorithm ensures that no data point will be close to other data points pairwise, thus ensuring a maximum spread of the samples.

# CASE STUDY

To evaluate our framework, we utilise an experimental dataset provided by Syngenta. The data was generated using a customised automated robotic platform specifically designed for high-throughput formulation design and screening. Our goal is to validate the framework using an experimental dataset by sampling only a proportion of the data and testing the model with unseen data points. In the context of this case study, our optimisation objective is to maximise the probability of identifying a kinetically stable (homogeneous) formulation using BO. The underlying objective is to optimise for the most stable formulation composition. The optimisation variable defining our design space is the continuous weight percentages of the raw materials comprising the formulation product. Consequently, unguided formulation screening is time and cost-intensive; thus, we employed BO to accelerate the screening process.

## Formulation Composition and Design Space

The dataset focuses on EC formulations. These formulations consist of a mixture of active ingredients (AI), solvents, and emulsifiers. To ensure a robust evaluation across a diverse chemical space, a total of 25 raw materials were tested:

- Active ingredients: Five unique AI and control formulations containing no active ingredients.
- Solvent Systems: Five unique solvent systems, comprising blends of two or three solvents (from 11 unique solvents) at various ratios.
- Emulsifier Systems: A primary anionic emulsifier along with six different co-emulsifier systems, each a blend of two emulsifiers selected from a pool of nine non-ionic emulsifiers.

## Data Acquisition

Following preparation, the EC formulations were diluted in water at a 1:100 ratio to simulate practical manufacturing conditions. Kinetic (short-term) homogeneity was assessed 24 hours after dilution using a high-throughput image module.

To maximise information gain and capture subtle stability characteristics, the photography module utilised a multi-exposure technique. Each final data point is a concatenated image with a resolution of 9328 ×2550 pixels. These high-resolution images are an aggregation of 13 separate captures taken at varying exposures and

| Category | Components | Count | Percentage/Details |
|---|---|---|---|
| **Dataset Statistics** | Total Samples ($N$) | 811 | 100% |
| | Homogeneous | 341 | 42.05% |
| | Inhomogeneous | 470 | 57.95% |
| **Formulation Components** | Active Ingredients (AI) | 5 | Plus AI-free controls |
| | Solvent Systems | 5 | 11 unique solvents |
| | Emulsifier Systems | 6 | 9 unique emulsifiers |
| **Total Unique Materials** | | **25** | |

**Table 1.** A detailed description of the dataset and label distributions.

laser intensities.

## Data Labelling & Distribution

The labels of all the formulations are evaluated via an automated image analysis tool designed to classify formulations based solely on visual characteristics. This tool achieved a binary classification accuracy of 94.83%, providing a highly reliable and scalable method for processing large image batches.

As summarised in Table 1, the final dataset consists of 811 samples. The distribution is relatively balanced, with 341 samples (42.05%) labelled as homogeneous and 470 samples (57.95%) labelled as inhomogeneous.

The model's input is compositional data, consisting of the weight percentages of each unique material. The input has been transformed using the centred log ratio (CLR) transformation and a standard scaler to make the model more sophisticated. The CLR transformation is used to handle the feature of compositional data (all data points have a constant sum) and preserves the mean distances [11]. The dataset was partitioned into two subsets using a 70:30 ratio. Seventy per cent of the data constituted the sampling pool, from which all initial and subsequent samples were drawn. The remaining 30% functioned as a held-out test set to evaluate model performance.

## Optimisation Strategy

Since we are working on a classification rather than a regression model, we employed a different approach than Gaussian process regression. The construction and training of Gaussian process models are carried out using the Python library GPflow [12]. A Gaussian process classifier (GPC) can be slightly different to a regression task. A latent function must be applied to convert the output to the desired likelihood, which is a Bernoulli likelihood for a binary classification problem.

We have chosen Matérn kernel with $\alpha = 5/2$ (also known as the Matérn 5/2 kernel) as it provides a smoother result than other common hyperparameters. The GP models' other parameters, such as length scale and variance will be optimised by the GPflow library. The hyperparameter $\kappa$ of UCB was chosen to be 1.5 to balance exploitation and exploration.

## RESULT

We applied our framework to the provided dataset with an initial sample size of 100 and ran 50 iterations. As illustrated in Figure 2(a), the diverse sampling strategies fluctuate in performance but generally demonstrate the ability to achieve high predictive accuracy with significantly reduced data requirements. While the baseline model required 500 random samples to achieve an F1 score of 71.9%, the BO framework achieved comparable F1 scores (ranging between 0.6 and 0.8) with only 100 to 150 samples. Among the space-filling designs, the Sobol Sequence demonstrated strong potential, peaking above the baseline in the final iterations. This framework reduced the experimental burden by approximately 70% compared to the baseline random sampling required to achieve the same F1 score.

This underperformance may be attributed to the tendency of Maximin distance designs to prioritise the boundaries of the design space. Consequently, the central regions remain undersampled, leading to poorer generalisation in those areas compared to Sobol or Random initialisation.

Figure 2(b) details the efficiency of the framework in locating stable (homogeneous) formulations. The effectiveness of the BO approach is evident when compared to the Monte Carlo baseline (grey dashed line), which represents a pure random search without model guidance. The figure shows that the Gaussian model using random sampling achieves the highest hit rate (35 found), while demonstrating no superiority over LHS (33 Maximin distance (26 found). Whereas all Gaussian models found more homogeneous samples than a pure random search (19 found).

The result demonstrates the advantages of our framework, as all four different initial samplers captured more homogeneous formulations than the Monte Carlo method. This highlights the limitations of traditional trial-and-error approaches, which suffer from inconsistency and the inability to intelligently guide the search toward promising compositional regions.

**(b)**

**Figure 2. (a)** The change of the F1 score over iterations. The grey dashed line is the baseline model trained using a Gaussian process with random sampling with 500 sampled data points, which leads to an F1 score of 71.9%. **(b)** The cumulative number of homogeneous formulations identified over 50 iterations using different initial sampling strategies compared to a Monte Carlo baseline.

## CONCLUSIONS AND FUTURE WORK

This study presented a data-driven, closed-loop BO framework designed to address the inefficiencies in traditional trial-and-error practice for agrochemical formulation design. By treating the formulation design of EC as a binary classification task (homogeneous vs. found), the Sobol sequence (30 found), and outperforming inhomogeneous, we successfully demonstrated the framework's ability to navigate a high-dimensional design space with limited mechanistic understanding using Gaussian process models.

The next step will be applying the framework to a larger dataset to validate its performance against a dataset with higher dimensions and more samples. In addition, the idea can be applied to a multi-class classification task, but perhaps with slightly different approaches.

## DIGITAL SUPPLEMENTARY MATERIAL

Due to commercial confidentiality, specific compositional data cannot be provided. However, we have included representative images captured by the camera module of the automated formulation system: https://github.com/yipeizhao/ESCAPE-material.

## ACKNOWLEDGEMENTS

This is an iCASE awarded project, sponsored by Syngenta and the UK Engineering and Physical Sciences Research Council (EPSRC) under the grand code EP/Y528808/1.

## ABSTRACT

Biopharmaceutical manufacturing requires systematic identification, understanding and control of critical process parameters (CPPs) and critical quality attributes (CQAs) While deterministic machine learning models have proven valuable for describing complex systems and providing insights into process behaviour, the extension to probabilistic frameworks allows for the capture of intrinsic biological and process variability, improving robustness, understanding and safety. This work introduces a framework for autoregressive variational Bayesian neural networks (BNNs) that integrate uncertainty quantification into data-driven modelling. The approach is demonstrated on a multicolumn countercurrent solvent gradient purification (MCSGP) process for monoclonal antibody purification. The BNN is trained autoregressively on high fidelity data generated using a detailed mechanistic process model data. A heteroscedastic variance head is included to model signal-dependent observation noise, while the epistemic uncertainty is captured through stochastic network parameters. Model performance is assessed using both deterministic accuracy metrics - MSE and probabilistic scores namely coverage and continuous ranked probability scores (CRPS). Results show that the proposed method accurately recovers noiseless concentration profiles while maintaining well calibrated predictive distributions. Additionally, the framework is tested under multiple noise regimes to test robustness of the proposed approach.

## INTRODUCTION

Biologics, such as monoclonal antibodies (mAbs), play a central role in the treatment of diseases, including cancers and autoimmune disorders. The commercial importance of mAbs is substantial, with six of the top ten best pharmaceutical products being mAb-based therapies [1]. As a result, there is an increasing demand for cost minimisation and high production efficiency, while regulators are pushing for transparency, robustness and explainability through initiatives such as Quality by Design (QbD) and the drive towards Biopharma 4.0. In this context, process modelling provides a valuable tool for supporting design, operation and decision making, by improving understanding and operability of complex bioprocesses.

Data-driven modelling allows engineers with access to process data and often limited mechanistic process knowledge to model unknown phenomena. This is pertinent in upstream bioprocessing where many underlying mechanisms remain partially characterised. In downstream processing, where process knowledge is richer, data-driven modelling can offer significant improvement in computational time for inference, making them attractive for online monitoring, optimisation, and control. However, in the pursuit of Biopharma 4.0, deterministic model inference alone is insufficient to support risk-aware decision making. Biological systems are often characterised by substantial inherent variability and therefore process decisions must account for uncertainty to satisfy stringent regulatory constraints and ensure consistent product quality.

In this setting, Bayesian Neural Networks (BNNs) offer a promising solution, by retaining the predictive

capabilities of artificial neural networks, while providing uncertainty estimates via probabilistic inference. In contrast to deterministic models, BNNs provide predictive distributions rather than point estimates, enabling quantification of uncertainty. This includes aleatoric uncertainty arising from measurement noise or process variability, and epistemic uncertainty associated with limited data and uncertainty in model parameters. Gaussian Processes (GP) are commonly utilised for this purpose, however lack scalability in dynamic systems such as bioprocessing [2].

Many algorithms exist for the training of BNNs, with Markov Chain Monte Carlo (MCMC) methods often being regarded as the gold standard [3]. Despite their wide application, these exact methods can be slow to converge and may become computationally prohibitive for large networks. Approximate inference methods offer a scalable alternative that is compatible with gradient based optimisation. In this work, the applicability of variational inference for autoregressive BNNs in bioprocess modelling is assessed using ion-exchange chromatography as a use case. The proposed framework is designed to enable probabilistic prediction and decompose aleatoric and epistemic uncertainties. This distinction is important, as only epistemic uncertainty can be reduced by more data and targeted experimentation, whereas the aleatoric uncertainty represents intrinsic process variability that must instead be managed through robust operation and control.

## THE USE CASE OF MULTICOLUMN COUNTERCURRENT SOLVENT GRADIENT PURIFICATION (MCSGP) PROCESS

The case study of interest is the twin-column Multicolumn Countercurrent Solvent Gradient Purification (MCSGP) process presented by Aumann and Morbidelli [4]. The process is an ion exchange chromatography used as a purification step in mAb production. The system separates three components, namely the product, the weak impurities, and the strong impurities.

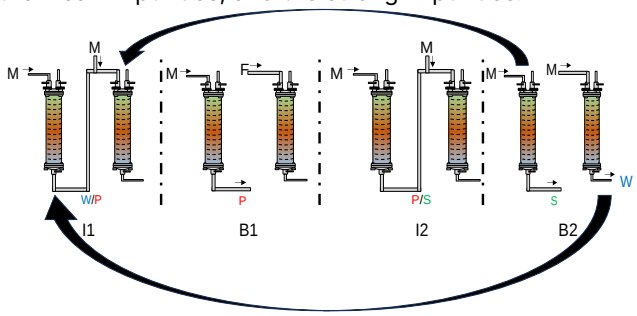

**Figure 1**: Diagram of MCSGP operating cycle

Operation proceeds through four phases: Two interconnected (I1 and I2) and two batch (B1 and B2) (Figure 1). During the interconnected phases, outlet streams containing off specification product fractions are recycled between columns to enhance recovery, while batch phases allow for the elution of high purity product. Strong and weak impurity fractions are discarded. After the cycle shown in Figure 1, the roles of the columns reverse and the process is repeated.

A high fidelity, experimentally validated, process model, originally developed by Müller-Späth et al. [5] was utilised to generate data of the MCSGP process. This lumped kinetic model, comprises over 4000 ordinary differential equations [6], after spatial discretization, representing a computational bottleneck for real time applications and uncertainty quantification (UQ).

## METHODOLOGY

### Data Generation and Process Model

Data is generated according to the strategy proposed by Michalopoulou et al. [7]. In which Sobol sampling is used to sample nine design variables through ranges presented in Table 1.

**Table 1**: Inputs and Bounds for Data Generation

| Variable | Lower Bound | Upper Bound | Units |
|---|---|---|---|
| Weak Feed Concentration | 0.05 | 0.08 | mg/ml |
| Product Feed Concentration | 0.3 | 0.5 | mg/ml |
| Strong Feed Concentration | 0.03 | 0.05 | mg/ml |
| Batch Flowrates | 0.1 | 1.0 | ml/min |
| I1 Flowrate | 0.1 | 1.0 | ml/min |
| I2 Flowrate | 0.1 | 1.0 | ml/min |
| Modifier Feed Concentration | 1.0 | 3.0 | mg/ml |
| Initial Modifier Concentration Phase I1 column 1 | 2.0 | 3.0 | mg/ml |
| Initial Modifier Concentration Phase I1 column 2 | 0.8 | 1.2 | mg/ml |

The model is simulated to Cyclic Steady State (CSS) and input-output data, consisting of these nine design variables and the output concentrations of each species for a full CSS cycle is taken to create the dataset. For quantifying aleatoric uncertainty in this methodology, heteroscedastic noise is added to the measured concentrations of species.

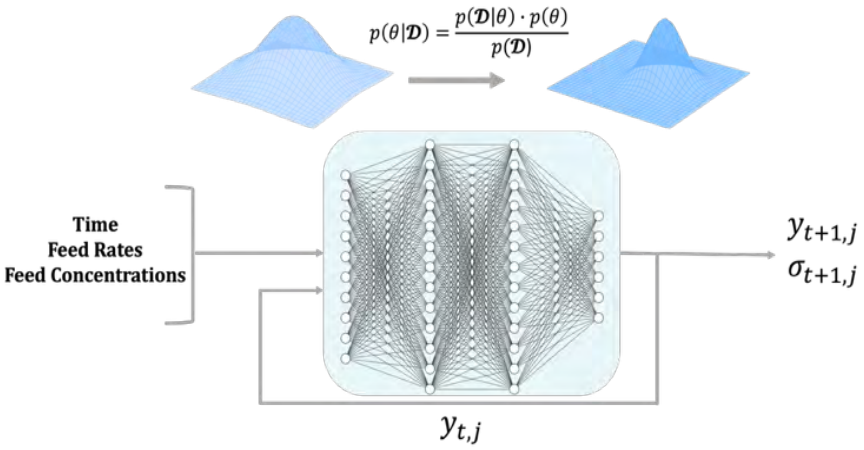

**Figure 2**. Autoregressive Bayesian Neural Network Architecture

## Autoregressive Bayesian Neural Network

A dataset of multivariate time sequences $\left\{\left(x_{1:T}^{(n)}, y_{1:T}^{(n)}\right)\right\}_{n=1}^{N}$, where $x_t \in \mathbb{R}^{d_x}$ are exogenous inputs and $y_t \in \mathbb{R}^{d_y}$ are the targets, is constructed. The model is trained autoregressively to predict $\hat{y}_t^{(n)} = f_\theta\left(x_{t-C:t}^{(n)}, \hat{y}_{t-C:t-1}^{(n)}\right)$. Using a fixed context length $C$. Predictions are generated sequentially, with the previous $C$ predicted outputs fed back as inputs for subsequent time steps.

The predictor, $f_\theta$, is a Bayesian neural network with a factorised Gaussian variational posterior over weights and biases. For each layer $\ell$, the posterior is parameterised as shown in Eq. (1) and (2).

$$q(W_\ell) = \mathcal{N}\left(\mu_{W_\ell}, \sigma_{W_\ell}^2\right) \quad (1)$$

$$q(b_\ell) = \mathcal{N}\left(\mu_{b_\ell}, \sigma_{b_\ell}^2\right) \quad (2)$$

Where $W_\ell$ and $b_\ell$ denote the weights and biases of layer $\ell$ of the network. The standard deviations are parameterised via Eq. (3).

$$\sigma = log(1 + exp(\rho)) \quad (3)$$

With, $\rho$, a learned parameter for each weight and bias, to ensure positivity and improved training stability. The BNN includes a heteroscedastic variance head that predicts the log-variance, $log\left(\sigma_{t,j}^2\right) \forall j = 1, \ldots, d_y$, for each output dimension at each timestep. A schematic of the network is displayed in Figure 2.

## Variational Inference

The training of the BNN approximates the posterior distribution over network parameters ($\theta$) given by Eq. (4)

$$p(\theta|\mathcal{D}) = \frac{p(\mathcal{D}|\theta)p(\theta)}{p(\mathcal{D})} \quad (4)$$

Where, $p(\mathcal{D})$ is the evidence or the marginal likelihood shown in Eq. (5).

$$p(\mathcal{D}) = \int p(\mathcal{D}|\theta)p(\theta)\, d\theta \quad (5)$$

Which requires integration over all possible parameter realisations and is non-conjugate and therefore intractable to compute analytically requiring an approximate inference algorithm. In this case variational inference was chosen as it can be seamlessly integrated into gradient descent optimisation algorithms.

Variational inference introduces a parameterised variational distribution and seeks a member of this family that is the closest to the true posterior, defined by Eq. (6) the Kullback-Leibler (KL) divergence.

$$q_\phi^*(\theta) = \arg\min_{q_\phi} D_{KL}\left(q_\phi(\theta) \,\middle|\, p(\theta \mid \mathcal{D})\right) \quad (6)$$

Direct evaluation of Eq. (6) is infeasible, as it requires the unknown posterior, therefore optimisation is performed indirectly by maximising the evidence lower bound (ELBO) defined in Eq. (7).

$$\mathcal{L}_{\mathcal{ELBO}} = \mathbb{E}_{q_\phi(\theta)}[\log p(\mathcal{D} \mid \theta)] - \mathrm{KL}\left(q_\phi(\theta)|p(\theta)\right) \quad (7)$$

The ELBO defines a lower bound on the log-evidence and is related to the intractable KL divergence in Eq. (8).

$$log\ p(\mathcal{D}) = \mathcal{L}_{\mathcal{ELBO}} + \mathrm{KL}\left(q_\phi(\theta)||p(\theta|\mathcal{D})\right) \quad (8)$$

Since the KL divergence on the right-hand side of Eq. (8) is non-negative, maximising the ELBO is the equivalent to minimising the KL divergence between the variational approximation and the true posterior. The ELBO consists of two competing terms, the expected log-likelihood term that encourages the model to explain the observed data, while the KL term acts as a regulariser towards the prior distribution.

The variational loss function applied in this algorithm is defined by Eq. (9).

$$\mathcal{L} = -E_{q(\theta)}\left[\sum_{t=C+1}^{T} \log p\left(\hat{y}_t \mid \hat{\mu}_t, \hat{\sigma}_t^{\,2}\right)\right] + \beta\,\mathrm{KL}(\mathrm{q}(\theta)||\mathrm{p}(\theta)) \quad (9)$$

To enable gradient based optimisation of the ELBO, the expectation with respect to the variational posterior is approximated using Monte Carlo sampling combined with the reparameterization trick [8]. Specifically, for layer $\ell$, weights and biases are sampled from Eq. (10) and Eq. (11).

$$W_\ell = \mu_{W_\ell} + \sigma_{W_\ell}\epsilon_\ell \quad (10)$$

$$b_\ell = \mu_{b_\ell} + \sigma_{b_\ell}\epsilon'_\ell \quad (11)$$

Where $\epsilon \sim \mathcal{N}(0, \mathrm{I})$. This formulation expresses the stochastic network parameters as deterministic functions of the variational parameters and auxiliary noise variables ($\epsilon$), allowing the Monte Carlo estimated ELBO to be computed via automatic differentiation.

## Model Training

The training data consists of 400 cyclic steady state sequences generated from the mechanistic model, with the nine varied design variables and three output concentration profiles. A further 200 sequences are used for validation, and 90 sequences are held out for testing and visualisation.

The BNN receives 13 input features at each time step. These consist of the nine design variables, the most recent prediction of the three outlet concentrations, and time. The network contains three fully connected hidden layers with sizes 64, 64 and 32, respectively, each followed by ReLU activations. The architecture and model hyperparameters were optimised using Tree Structured Parzen Estimator based Bayesian Optimisation [9]. The final output layer consists of six neurons, predicting the mean and heteroscedastic noise estimate for each concentration.

During training the KL divergence term is computed independently for each layer and scaled by the batch size to avoid batch-size dependence or the variational objective. To improve optimisation stability, the KL weight $\beta$, is linearly annealed from 0 to 1 during an initial warmup phase. After warmup, full variational regularisation is applied.

The ELBO is approximated using $\mathcal{K}$ Monte Carlo samples of the network parameters. For each particle independent random keys are used to sample weights and biases, producing $\mathcal{K}$ autoregressive rollouts.

During training teacher forcing is employed to stabilise the learning. At each time step, the history value fed back to the model is chosen according to Eq. (11).

$$y_t^{hist} = \begin{cases} y_t, & with\ \text{probability}\ \ p_{TF} \\ \hat{\mu}_t, & with\ \text{probability}\ (1 - p_{TF}) \end{cases} \quad (11)$$

Where $p_{TF}$ is the probability of teacher forcing. This probability is annealed linearly over a fraction of the total optimisation steps in training, gradually transitioning from fully guided rollouts towards fully self-predicted trajectories.

When physical bounds are supplied the predictive mean is mapped through a sigmoid transformation (Eq. 12)

$$\hat{\mu}_t = \mathrm{a} + (b - a)\sigma(\hat{\mu}_t^{raw}) \quad (12)$$

Where a and b represent the lower and upper bounds and $\sigma(\cdot)$ is the sigmoid function. In this case bounds are chosen as [0, 1] mg/ml. This deterministic and differentiable mapping enforces hard constraints on the mean prediction while preserving gradient based optimisation of the variational loss. Since epistemic uncertainty arises from variability in the network parameters, constraining the sampled mean predictions also constrains the resulting epistemic uncertainty distribution. In contrast, the heteroscedastic variance head remains unbounded, allowing the model to freely represent the aleatoric noise.

## Model Inference

At inference time, predictive uncertainty is obtained via Monte Carlo sampling of the learned variational posterior. In all experiments, 1000 parameter samples are drawn. For each sample, a full autoregressive rollout of the concentration trajectories is generated.

The predictive mean is computed as the mean trajectories across all samples. Epistemic uncertainty is quantified as the variability across these sampled mean predictions. This sampling-based formulation allows the predictive distribution to be non-Gaussian and enables direct estimation of prediction quantiles.

Aleatoric uncertainty is obtained from the heteroscedastic output head. Since the variance prediction itself depends on stochastic network parameters, the aleatoric estimate exhibits epistemic uncertainty as a second order effect. The total predictive uncertainty is therefore composed of both epistemic and aleatoric contribution, combined under a conditional independence assumption.

## Computation

In this work the BNN architecture and training algorithm were constructed using JAX, to enable efficient automatic differentiation and hardware acceleration [10]. Just-in-time (JIT) compilation was used extensively to optimise the autoregressive rollout and ELBO computation, allowing entire sequence scans to be compiled into fused kernels. Vectorisation was performed across batches and Monte Carlo particles to enable efficient parallel evaluation of stochastic network samples during training and inference. Gradient descent was performed with AdamW using the Optax suite [11], [12]. All experiments are performed using an NVIDIA RTX 4090 GPU.

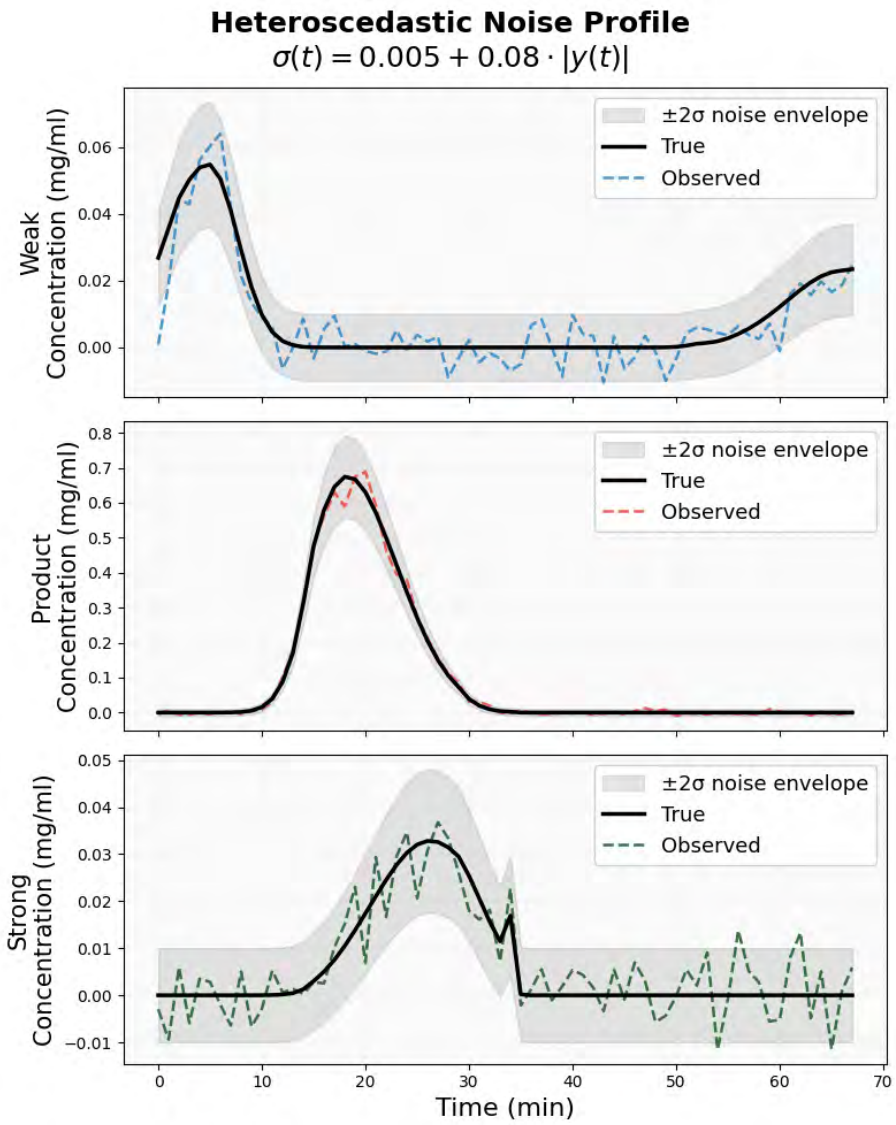

**Figure 3**. Nominal heteroscedastic noise profiles applied to outlet concentrations.

## RESULTS AND DISCUSSION

### Nominal Test Case

The nominal test case takes the train, test and validation sets and applies noise to the outputs before training and testing. The noise model in this scenario is Gaussian heteroscedastic noise with noise standard deviation defined as a sum of a constant baseline component and a signal magnitude dependent component given by Eq. (13)

$$y_{t,j}^{noisy} = y_{t,j} + \epsilon_{t,j},\ \epsilon_{t,j} \sim \mathcal{N}\left(0, \left(\sigma_0 + \alpha|y_{t,j}|\right)^2\right) \quad (13)$$

Where $\sigma_0$ represent the baseline noise and $\alpha$ controls the signal dependent noise, and where $j$ represents each component. For this nominal case $\sigma_0 = 0.005, \alpha = 0.08$ was used, an example profile is shown in Figure 3.

Validation metrics of deterministic prediction accuracy and uncertainty quantification capability are displayed in Table 3. The mean squared error (MSE) quantifies the accuracy of the predictive mean, while the empirical coverage, the frequency at which the model's predicted intervals contain the observed values, evaluates the calibration of the predictive intervals. The continuous ranked probability score (CRPS) [13] is a proper scoring rule that assess the difference between the predicted and observed cumulative distributions.

Figure 4 displays a representative outlet concentration prediction profile from the test set. The predictive means closely follow the true, noiseless, profiles. While the predictive uncertainty bands capture the epistemic and aleatoric uncertainty throughout time. A subset of

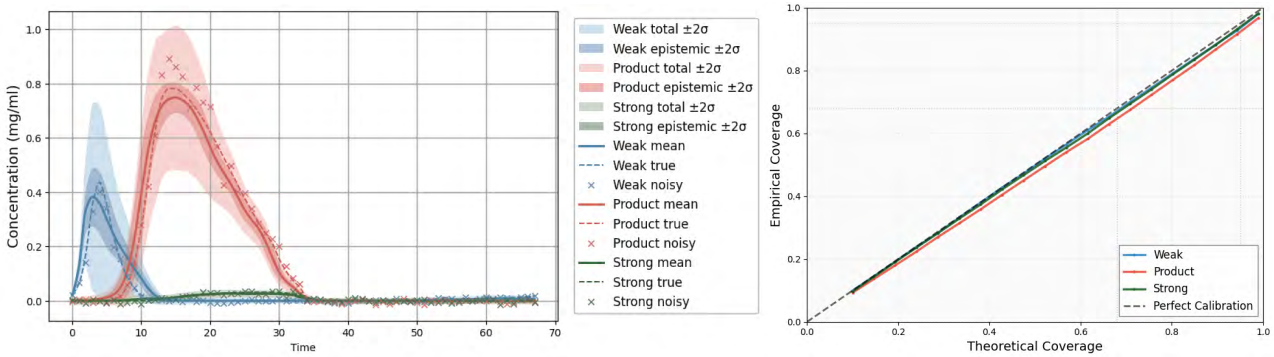

**Figure 4.** Left**:** Predicted outlet concentration profiles for representative test sequence. Right: Calibration plots for nominal case, over all test set sequences.

noisy realisations are marked with a cross to demonstrate the capability of the model to capture the heteroscedastic noise.

**Table 2**: Validation Metrics for Nominal Case

| Metric | Weak Impurities | Product | Strong Impurities | Units |
|---|---|---|---|---|
| MSE | 6.32e-4 | 1.79e-3 | 1.37e-4 | $[mg/ml]^2$ |
| 95% Coverage | 93.4% | 92.2% | 93.8% | - |
| CRPS | 5.99e-3 | 1.13e-2 | 4.03e-3 | mg/ml |

The probabilistic calibration of the predictive distributions is assessed via calibration curves shown in Figure 4, across all sequences in the test set, for each component. The empirical coverage closely matches the nominal confidence levels across all components, with slight overconfidence in the product profiles. Overall, the nominal test case demonstrates that the predictive distribution from the BNN achieves accurate predictions and is able to filter noise to predict close to true noiseless values with low MSE, within its predicted epistemic uncertainty. While the noise levels are accurately captured by the heteroscedastic head, with a mean absolute error in noise levels of 8e-4.

## Secondary Noise Model

To better reflect realistic UV sensor behaviour typically observed in chromatographic systems, and test the algorithm in different, more complex and realistic noise regimes, a secondary noise model is introduced. Unlike the nominal case, which assumes temporally independent noise observations, this model incorporates additional structure, including temporal correlation and baseline drift. In this case there is an additive noise given by Eq. (14)

$$y_{t,j}^{noisy} = y_{t,j} + \epsilon_{t,j} \tag{14}$$

Where $\epsilon_{t,j}$ is composed of three contributions:

(i) The heteroscedastic white noise displayed in Eq. (15)

$$\epsilon_{het,t,j} \sim \mathcal{N}\left(0, \left(\sigma_0 + \alpha|y_{t,j}|\right)^2\right) \tag{15}$$

(ii) Temporally correlated first order autoregressive noise ($AR(1)$) shown in Eq. (16)

$$\epsilon_{ar,t,j} = \rho\epsilon_{ar,t-1,j} + \eta_{t,j},$$
$$\eta_{t,j} \sim \mathcal{N}\left(0, (\sigma_{ar})^2\right) \tag{16}$$

Where $\rho \in (-1, 1)$ controls the strength of temporal correlation and $\sigma_{ar}$ determines the magnitude of the correlated noise.

(iii) Baseline drift modelled as a random walk given by Eq. (17)

$$d_{t,j} = d_{t-1,j} + \xi_{t,j} \tag{17}$$

with $\xi_{\{t,j\}}$ denoting a zero mean Gaussian increment.

Figure 5 illustrates the new noise profiles on an example sequence. This test case uses: $\sigma_0 = 0.002, \alpha = 0.02, \rho = 0.95, \sigma_{ar} = 0.002.$

The model architecture, training epochs and data set size are identical to the nominal test case for comparability. Quantitative validation metrics obtained under the secondary regime are reported in Table 3. Compared to the nominal case, point prediction error increases modestly across all components, reflecting the increased complexity in filtering temporally correlated noise and baseline drift. Despite this, the empirical 95% coverage remains close to the nominal level across all components, indicating that the predictive uncertainty adapts to the new noise regime. The increase in CRPS reflects a reduced predictive sharpness and increased uncertainty, which is consistent with the more challenging noise model.

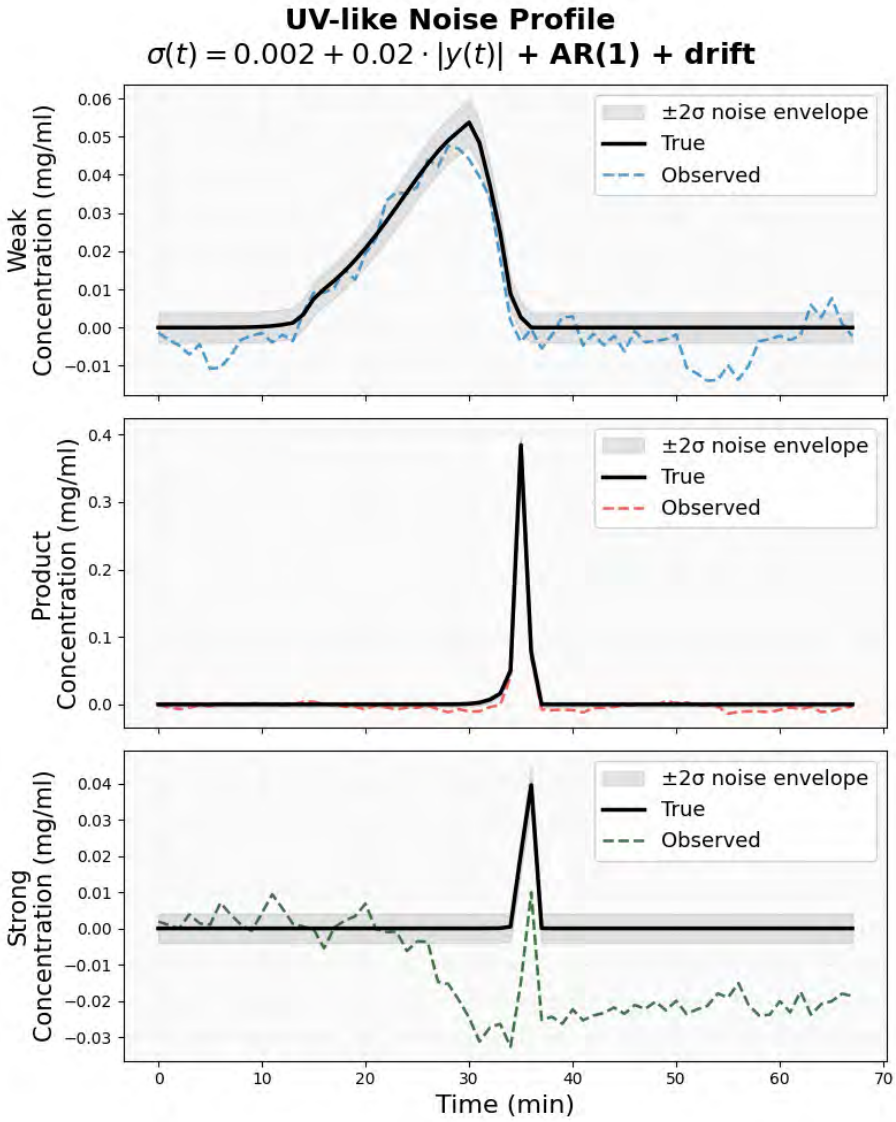

**Figure 5.** Secondary noise model profiles applied to outlet concentrations.

Figure 6 shows a representative prediction under the secondary noise model. Despite the added complexity of the noise regime, the predictive mean is still able to track the noiseless truth, while the uncertainty bands adapt to the new regime. The predictive uncertainty increases in regions effected by baseline drift, reflecting reduced confidence in the inferred signal.

The right-hand side of Figure 6 shows the calibration of the network remains tight across all components, with slight overconfidence in some regions.

**Table 3**: Validation Metrics for Secondary Case

| Metric | Weak Impurities | Product | Strong Impurities | Units |
|---|---|---|---|---|
| MSE | 7.54e-4 | 2.73e-3 | 2.40e-4 | $[mg/ml]^2$ |
| 95% Coverage | 91.8% | 92.6% | 90.6% | - |
| CRPS | 1.14e-2 | 1.85e-2 | 9.23e-3 | mg/ml |

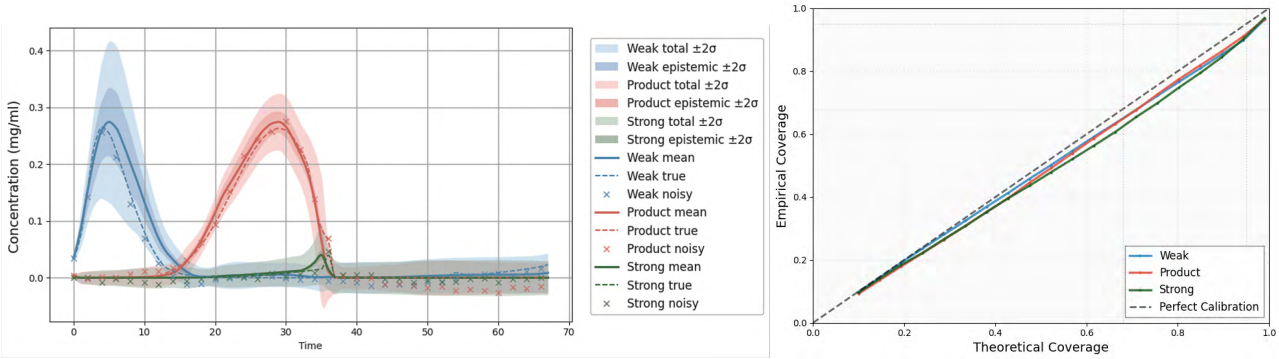

**Figure 6.** Left: Predicted outlet concentration profiles for representative test sequence, under secondary noise model. Right: Calibration plots for secondary case, over all test set sequences.

## CONCLUSION AND OUTLOOK

This work has demonstrated the applicability of autoregressive Bayesian neural networks trained via variational inference for modelling and uncertainty quantification in downstream bioprocessing operations. Using the MCSGP case study, the proposed framework was shown to produce accurate predictive means while also providing well calibrated uncertainties. The decomposition of predictive uncertainty into epistemic and aleatoric components enables meaningful interpretation of model confidence.

The nominal test case demonstrated that the BNN is able to accurately recover noiseless concentration profiles from heteroscedastic observations, while maintaining reliable uncertainty calibration. The introduction of a secondary, more complex, noise model showed the framework remains robust under more challenging, but practically relevant conditions.

A key strength of the proposed approach is the autoregressive formulation, which allows the model to generate predictions sequentially without reliance on cyclic steady state conditions. Looking forward, the framework will be tested under fully dynamic operation or transient disturbances, allowing deployment in online monitoring, optimisation or control.

A particularly promising direction in the application of the framework is in upstream bioprocessing, where biological variability arising from cellular mechanisms introduces substantially higher uncertainty than downstream steps. Eventually, targeting an uncertainty-aware holistic modelling pipeline connecting the upstream and downstream processing units.

Training data requirements remain a key limitation for Bayesian Neural Networks over using Gaussian Processes. Future work will explore smaller models and lower training data availability, to demonstrate applicability in the data sparse environments often found in bioprocessing. Particularly looking at the effect of training data availability on epistemic uncertainty estimates.

## ABSTRACT

The pharmaceutical industry is placing growing emphasis on sophisticated process modeling to enhance the efficiency of drug design and production pipelines. Optimal control over these models can significantly improve manufacturing performance by lowering costs, boosting productivity, and ensuring rigorous quality compliance. However, the intricate nature and heavy computational load of these models often require the adoption of more practical or simplified alternative strategies for optimisation such as simulation-based approaches. In this work, we introduce a simulation-based framework including a "top-level" gradient-based mathematical programming optimisation model coupled with a "low-level" simulation scheme, to optimise multi-scale drug substance manufacturing flowsheets. The proposed framework optimises critical quality attributes, such as yield and purity, including green metrics such as process mass intensity, aligning with digital platforms (e.g. gPROMS) used in the pharmaceutical industry. By constructing Pareto fronts, we capture the balance between conflicting objectives, providing valuable insight for informed decision-making. The results indicate that this simulation-based approach can effectively optimise complex process behaviors while improving computational efficiency as no preliminary data is needed. By applying the framework to a real-world case study, we demonstrate its potential in optimising complex pharmaceutical manufacturing flowsheets.

**Keywords**: Optimisation, Simulation, Algorithms, Industry 4.0, Process Operations

## INTRODUCTION

The pharmaceutical industry has undergone substantial transformation over the past decades, driven in large part by advances in process modelling that have accelerated drug development and manufacturing. Mechanistic flowsheet models are often highly complex, comprising tightly coupled unit operations, nonlinear dynamics, and numerous decision variables [3, 4]. Optimising such flowsheets with traditional optimisation methods, such as gradient-based approaches, is therefore challenging. To address these challenges, different kinds of methods such as surrogate-based [2] or simulation-based techniques [1] have been developed, enabling the optimisation of highly complex flowsheets with increased dimensionality.

Surrogate-based optimisation methods require *a priori* data to train surrogate models that approximate the underlying process behaviour, often necessitating substantial offline computational time. In contrast, simulation-based optimisation approaches do not require an explicit surrogate model to be trained in advance, instead relying directly on repeated evaluations of the high-fidelity process model during the optimisation procedure. However, these heuristic approaches often suffer from stochasticity, or limited convergence guarantees [1, 7].

Motivated by the need to combine data-free simulation-based optimisation with the advanced optimisation capabilities of surrogate-based methods, we propose a simulation-optimisation framework for pharmaceutical manufacturing flowsheets that integrates with the GAMS optimisation language (via gamspy) and aligns with commonly used software in the pharmaceutical industry (e.g. gPROMS, via gO:Python).

The rest of the manuscript is structured as follows. In the methodology section, the general workflow and mathematical model of the "top-level" mathematical programming component are presented, followed by the

computational methodology section that presents the proposed algorithm. The drug substance manufacturing Case Study is then presented while the results of the application of the proposed methodology on the Case Study are latter discussed. Concluding remarks are highlighted at the end of the manuscript.

## METHODOLOGY

The objective of the proposed framework is to optimise the operating conditions of complex pharmaceutical manufacturing processes using a simulation–optimisation strategy. A mechanistic flowsheet model representing the pharmaceutical manufacturing process was developed internally and its predictive capability was validated against experimental data. Although the experimental data cannot be disclosed for confidentiality reasons, the validated flowsheet model is considered representative of the process and can therefore be used to generate reliable in silico experiments. The optimisation objective is to determine the operating conditions of the manufacturing process, such as temperatures and solution volumes, that achieve multi-objective optimisation of key performance indicators including yield, purity, and sustainability metrics. However, the mechanistic flowsheet model is highly complex and computationally intensive, which makes direct optimisation intractable.

To address this challenge, we propose a simulation–optimisation framework that combines a high-fidelity simulator with a gradient-based mathematical programming model. The mechanistic flowsheet model is repeatedly queried to evaluate the values of the critical quality attributes and their sensitivities with respect to the decision variables. At each iteration, these quantities are extracted from the simulator and treated as fixed parameters in the top-level Linear Programming (LP) optimisation model presented below [5]. The framework is formulated in a general manner and can therefore be applied to any mechanistic flowsheet model.

### Nomenclature

**Indices**

| | |
|---|---|
| m | Features (m = $m_1$, $m_2$, ..., M) |
| k | Iterations (k = $k_1$, $k_2$, ..., K) |
| r | Responses (r = $r_1$, $r_2$, ..., R) |

**Sets**

| | |
|---|---|
| V | Set including principal response *r* |
| $\bar{O}$ | Set of responses *r* to be maximised |
| $\underline{O}$ | Set of responses *r* to be minimised |

**Parameters**

| | |
|---|---|
| $T_r$ | Threshold level for response *r* |
| $\bar{Y}_{kr}(X'_{mk})$ | Value of response *r* obtained by simulation at iteration *k* |
| $X'_{mk}$ | Value of $X_m$ used in simulation iteration *k* |
| $\partial\bar{Y}_r / \partial X'_{mk}$ | Partial derivative of $Y_r$ with respect to $X_m$ obtained at iteration *k* |
| μ | Parameter determing the explored region |
| $\alpha_r$ | Weight for response *r* in the objective function |

**Variables**

| | |
|---|---|
| $X_m$ | Optimal value of feature *m* |
| $Y_r$ | Objective value of response *r* |
| $\delta_r$ | Slack variable for response *r* |

### Constraints

The objective value of response *r* is approximated using a first-order Taylor expansion of the solution obtained at the previous iteration *k-1* (Eqs. (1, 2)).

$$Y_r \geq \bar{Y}_{kr}(X'_{mk}) + \sum_m \frac{\partial \bar{Y}_r}{\partial X'_{mk}}(X_m - X'_{mk}) \; \forall r \in \underline{O}, k = k-1 \quad (1)$$

$$Y_r \leq \bar{Y}_{kr}(X'_{mk}) + \sum_m \frac{\partial \bar{Y}_r}{\partial X'_{mk}}(X_m - X'_{mk}) \; \forall r \in \bar{O}, k = k-1 \quad (2)$$

The objective value of a non-primary response *r* to be minimised needs to be below a certain threshold with the addition of a slack variable $\delta_r$ (Eq. (3)), that is minimised in the objective function.

$$Y_r \leq T_r + \delta_r \; \forall r \in \underline{O} \setminus V \quad (3)$$

The objective value of a non-primary response *r* to be maximised needs to be above a certain threshold with the extraction of a slack variable $\delta_r$ (Eq. (3)), that is minimised in the objective function.

$$Y_r \geq T_r - \delta_r \; \forall r \in \bar{O} \setminus V \quad (4)$$

For the Taylor expansion to be valid as well as to prevent the optimisation from extrapolating too far from the previous iteration, the concept of trust region is used [5]. The trust region is a local domain that the optimisation is allowed to explore. A small $\mu$ (10%) is chosen to determine the range of the region explored (Eq. (5)).

$$X'_{m,k-1}(1-\mu) \leq X_m \leq X'_{m,k-1}(1+\mu) \; \forall m \quad (5)$$

The slack variable $\delta_r$ needs to be positive for every response r.

$$\delta_r \geq 0 \; \forall r \in R \quad (6)$$

### Objective function

In the objective function, a principal response *r* is optimised, while the remaining responses are incorporated through the slack variables $\delta_r$ (Eq. (7)).

$$\max_{X_m} \sum_{r \in V} Y_r - \sum_{r \in R \setminus V} a_r \cdot \delta_r \quad (7)$$

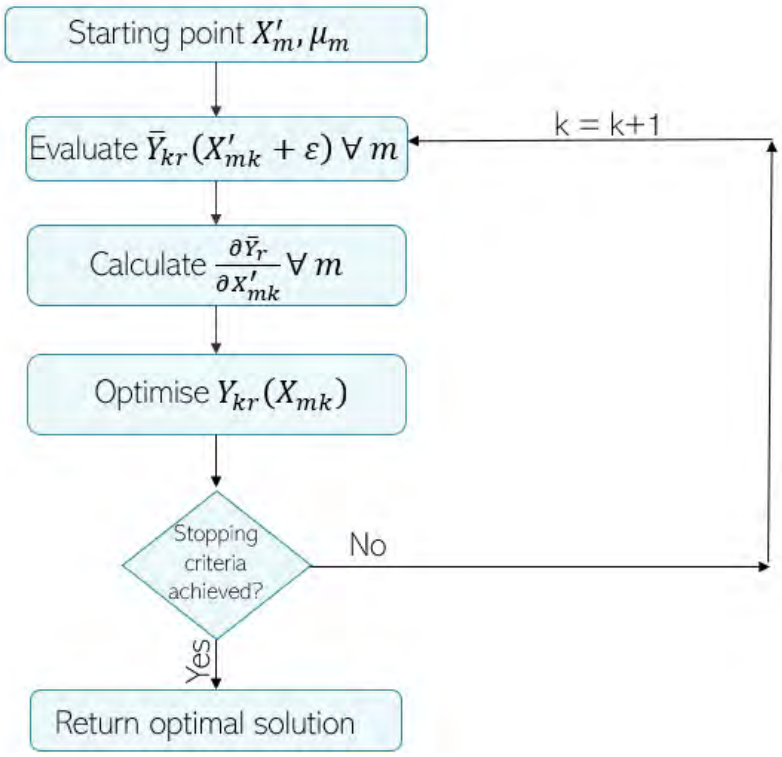

**Figure 1.** Proposed algorithm.

## COMPUTATIONAL METHODOLOGY

Figure 1 illustrates the proposed computational methodology. Starting from a random initial point, a mechanistic flowsheet model is used to evaluate the values of the objectives. By introducing a small perturbation (ε) and re-performing the simulation for every perturbated feature m, the derivatives $\partial \bar{Y}_r / \partial X'_{mk}$ can be estimated using the finite differences method (Eq. 8).

$$\frac{\partial \bar{Y}_{kr}}{\partial X'_{mk}} = \frac{\bar{Y}_{kr}(X'_{mk}+\varepsilon) - \bar{Y}_{kr}(X'_{mk})}{\varepsilon}\ \forall r, m, k \qquad (8)$$

The information is then used in the Linear Programming (LP) mathematical model described in the methodology section from which the optimal values of the decision are decided. These are fed back into the flowsheet for the next simulation, thereby forming an iterative simulation–optimisation loop that continues until convergence criteria are satisfied. The iterative procedure is terminated when at least one of the following stopping criteria is satisfied: (i) a prescribed maximum number of iterations is reached or (ii) over T consecutive iterations, the changes in all response values remain below a specified tolerance, implying practical convergence of the solution.

## CASE STUDY

The proposed framework is designed to efficiently optimise complex industrial processes and is demonstrated through a pharmaceutical manufacturing Case Study. The system model represents an API production flowsheet (Figure 2), comprising a dynamic batch reactor, a liquid–liquid extraction unit, and a crystallisation stage. In the reaction step, an exothermic process partially dissolves suspended solids, forming two liquid phases: a product-rich organic layer and an impurity-rich aqueous layer. The phases are separated, followed by repeated washing of the aqueous phase. Product recovery is completed through solvent addition, seeding, and controlled cooling during crystallisation. The integrated flowsheet model consists of over 25, 000 equations, including both algebraic and differential components. A total of 22 decision variables spanning reaction, extraction, and crystallisation stages are optimised with respect to Yield, Impurity D and Process Mass Intensity (PMI) [6]. The decision variables are distributed across the main stages of the manufacturing process. Specifically, 11 variables correspond to the reaction stage (A1–A4, B1–B5, E1–E2), 3 variables are associated with the extraction stage (C1–C3), and 8 variables relate to the crystallisation stage (D1–D8). These variables represent key operating conditions of the flowsheet, including quantities of solvents or reactants, operating temperatures, addition or residence times, and mixing conditions. For more details on the Sensitivity Analysis for the Case Study the reader is

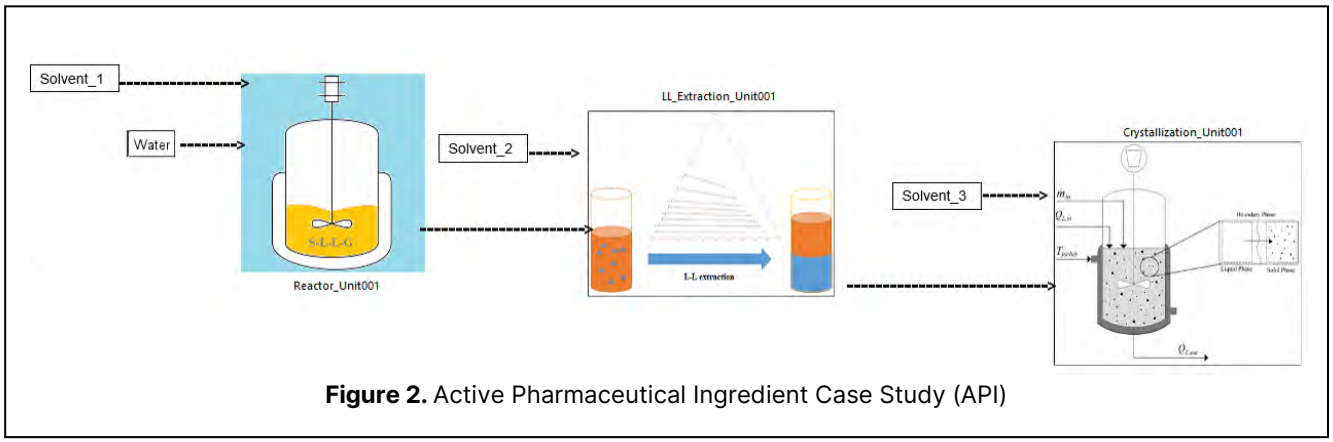

**Figure 2.** Active Pharmaceutical Ingredient Case Study (API)

referred to [8, 9].

## RESULTS AND DISCUSSION

The proposed approach has been applied to the Case Study presented in the previous section. The goal of the multi-objective optimisation was to maximise Yield while keeping the Impurity D levels below a threshold ($T_{ImpurityD} \leq 0.0215\ \%w/w$). The maximum number of iterations is set to 50, with the convergence window $T = 3$ consecutive iterations.

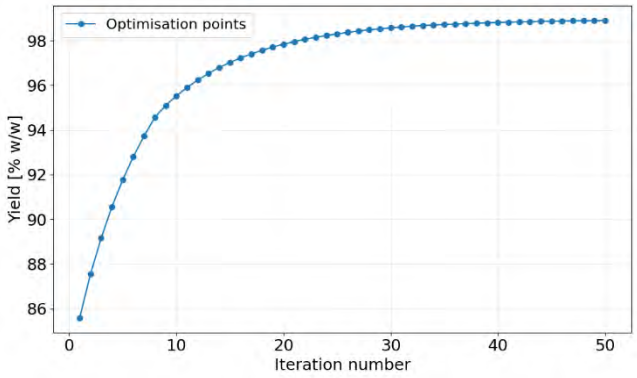

**Figure 3.a:** Yield [% w/w] vs Iteration number

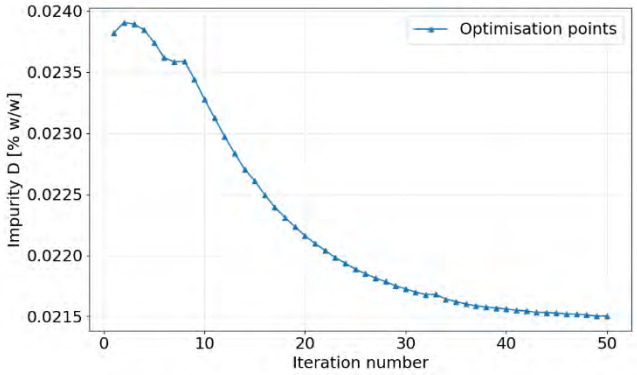

**Figure 3.b:** Impurity D [% w/w] vs Iteration number

Figures 3a and 3b demonstrate the profile of the validated $\bar{Y}_r$ from the mechanistic flowsheet model for responses Yield and Impurity D respectively. Starting from a random sample (Yield ≈ 86 % w/w, Impurity D ≈ 0.024 %w/w), the proposed algorithm managed to get to a value of Yield ≈ 98.9% w/w while respecting the Impurity D threshold. Yield reaches its maximum value early in the applied algorithm, whereas Impurity D requires the full iteration limit to satisfy the convergence threshold.

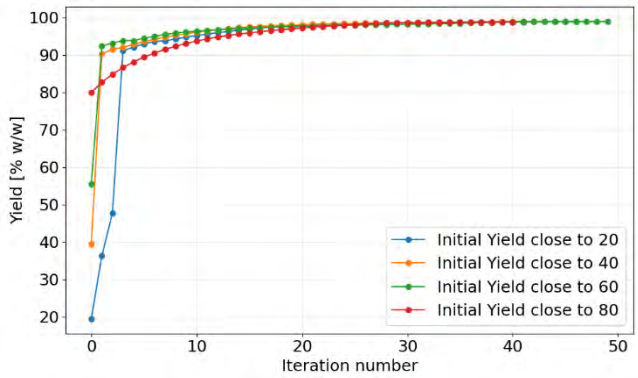

**Figure 4.a:** Yield [% w/w] vs Iteration number for different initial samples

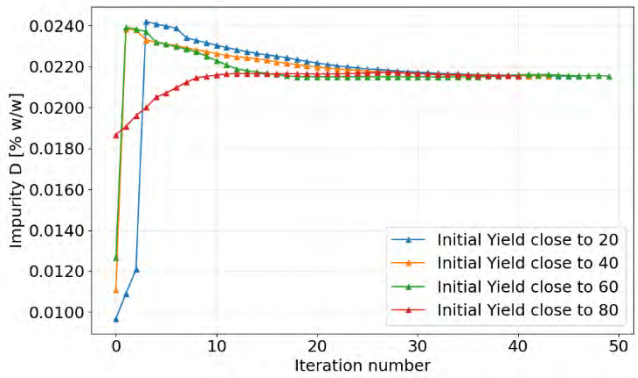

**Figure 4.b:** Impurity D [% w/w] vs Iteration number for different initial samples

To demonstrate the effectiveness of the algorithm in different initial points, we choose 4 representative scenarios to start the proposed approach. Those scenarios correspond to initial samples with Yield values close to

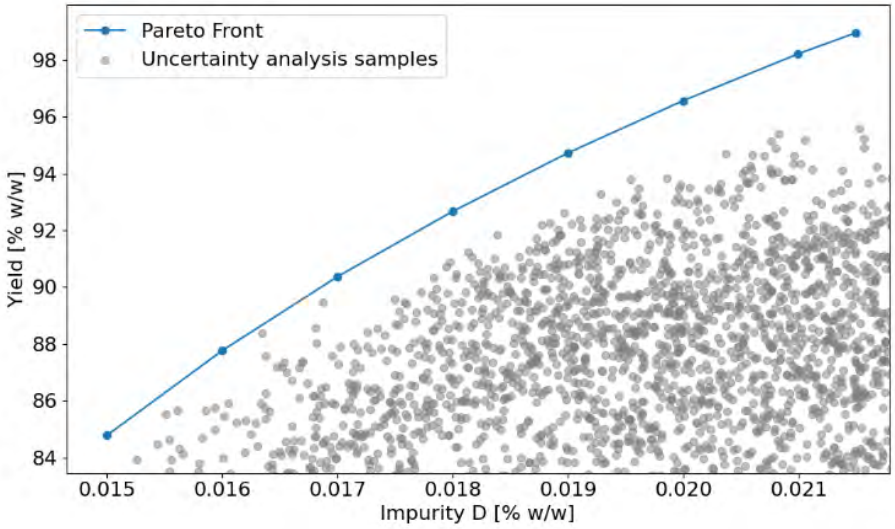

**Figure 5.a:** Pareto Front: Yield [% w/w] vs Impurity D [%w/w]

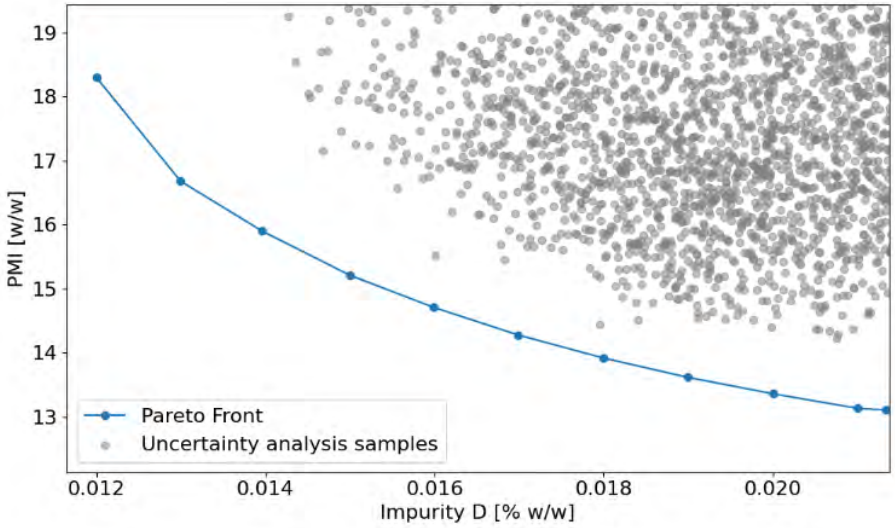

**Figure 5.b:** Pareto Front: PMI [w/w] vs Impurity D [%w/w]

20, 40, 60 and 80 %w/w. As depicted in Figures 4a and 4b, the algorithm can obtain almost identical solutions when terminated, with the number of iterations needed varying between 40 to 50.

Motivated by industrial requirements to evaluate trade-offs between competing objectives, we apply the proposed methodology to generate Pareto fronts that map the space of optimal compromises. These fronts provide actionable insight into objective interactions, enabling more informed decisions. By adjusting the threshold for Impurity D and applying the proposed approach for multiple values, we can derive a spectrum of optimal validated Yield values with respect to Impurity D thresholds. This is demonstrated in Figure 5a where the gray samples result from an uncertainty analysis carried out in gPROMS software using quasi-random Sobol sampling over 5, 000 uncertainty scenarios. The blue points are the samples derived from the proposed approach and represent the limits between the feasible and non-feasible space.

Figure 5b illustrates the results of the proposed approach applied to a different optimisation scheme: Minimisation of PMI while keeping Impurity D up to a threshold. These objectives are competing (as the case of Yield and Impurity D) meaning that it is difficult to have a low value of PMI along with high purity in the same sample. However, the proposed approach managed to achieve up to 33.8% improved samples compared to the ones obtained from the uncertainty analysis.

Each point on the Pareto front represents a validated operating condition obtained from the mechanistic flowsheet model. These points correspond to feasible

solutions where improvement in one objective cannot be achieved without deteriorating at least the other. These fronts serve as a valuable tool for decision-making, to understand the limits imposed by the process. The final selection of an operating point depends on the preferences of the decision maker, such as the relative importance assigned to product quality, process efficiency, or sustainability metrics.

## CONCLUDING REMARKS

In this study, we proposed a simulation-optimisation framework for complex system models in the pharmaceutical industry. The framework integrates mathematical programming principles with a simulation-based approach to enable systematic exploration of process trade-offs. The applicability of the proposed approach is demonstrated by an industrial case study characterised by an existing mechanistic flowsheet model. The results demonstrate that the approach can efficiently identify Pareto-optimal operating conditions for multi-objective optimisation.

## ABSTRACT

The need to reduce greenhouse gas emissions and diversify energy sources has driven the development of hydrogen ($H_2$) as a leading carbon-free energy vector with high gravimetric energy density (33.3 kWh/kg) for stationary and transport applications. However, its storage and transportation remain challenging. Therefore, ammonia emerges as a promising hydrogen carrier due to its high energy density and ease of liquefaction and transport. This work presents the development of a phenomenological based mathematical model for an ammonia electrolysis cell operating in a zero-gap configuration with an anion exchange membrane. The model considers the contributions of different overpotentials (activation, ohmic, concentration) and incorporates empirical and semi-phenomenological expressions adjusted to experimental data from Zhang et al [1]. The model shows both qualitative and quantitative agreement with experimental measurements, achieving a determination coefficient ($R^2$) of 0.9874. Beyond electrochemical modeling, the cell model is integrated into a nonlinear programming (NLP) optimization framework to minimize the total annualized cost (TAC) of the system. For hydrogen production of 1250 kg/h, the optimal solution corresponds to 353 K, 0.82 A/cm$^2$, and 1302 cells, yielding a TAC of about 45.0 MUSD/year.

**Keywords**: Hydrogen production, Ammonia electrolysis, Zero gap cell, Mathematical model, Optimization

## INTRODUCTION

Hydrogen ($H_2$) is widely regarded as a promising energy vector due to its high gravimetric energy density and carbon-free end use [2]. However, its low volumetric energy density and wide flammability range pose challenges for storage and long-distance transportation, requiring energy-intensive solutions such as high-pressure compression or cryogenic liquefaction [2-3].

A promising alternative to overcome these limitations involves storing hydrogen in chemical compounds that can be easily transported and stored, with hydrogen released on demand through chemical or electrochemical processes. Among the available hydrogen carriers, ammonia ($NH_3$) stands out due to its high hydrogen content (17 wt.%), relatively mild liquefaction conditions (~10 bar at ambient temperature), and well-established global infrastructure [4-5].

In this context, ammonia electrolysis has emerged as an attractive pathway for hydrogen production, offering a significant thermodynamic advantage over conventional water electrolysis [5]. Recent studies highlight that anion exchange membrane (AEM) electrolyzers are particularly suitable for ammonia electrolysis due to their chemical compatibility with $NH_3$ and their ability to operate under alkaline conditions. Furthermore, zero-gap cell configurations have been identified as the most promising architecture, as they minimize internal ohmic losses while enabling compact and scalable designs for industrial deployment [6]. However, despite the growing number of experimental studies, the availability of mathematical models for system-level analysis and scale-up remains limited.

The present work addresses this gap by developing a mathematical model of an anion exchange membrane ammonia electrolyzer within a compact zero-gap configuration.

The Methods section describes the electrolyzer configuration, the modeling approach and assumptions, the parameter estimation procedure, and the formulation

of the optimization problem, minimizing the total annualized cost (TAC). The model was parameterized using experimental data from the literature and optimized using nonlinear programming (NLP) to minimize the total annualized cost (TAC), evaluating the trade-off between the number of cells and the applied current density for large-scale hydrogen production. The Results section presents the model fitting, followed by the optimal operating and design conditions obtained from the TAC minimization. Finally, the main findings and implications are summarized in the Conclusions.

## METHODS

A typical anion exchange membrane (AEM) electrolyzer cell consists of an anion exchange membrane sandwiched between an anode and a cathode, both comprising catalyst and gas diffusion layers, as well as bipolar plates containing engraved flow channels (Figure 1).

In the present system, an aqueous KOH solution is supplied to the cathode, while a mixture of $NH_3$ and KOH is fed to the anode. At the cathode, water is reduced to hydrogen and hydroxide ions via the hydrogen evolution reaction. The hydroxide ions migrate through the AEM toward the anode, where ammonia electro-oxidation produces nitrogen and water. The generated gaseous products are removed through the respective flow channels.

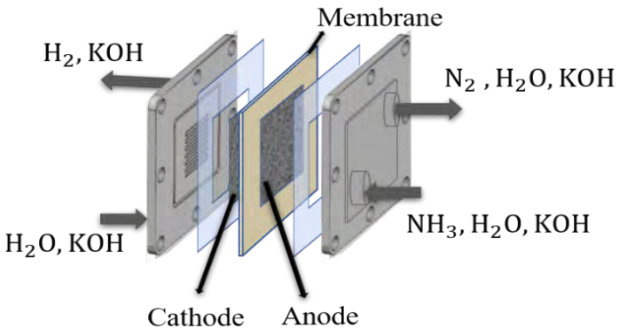

**Figure 1**. Conceptual schematic of the anion exchange membrane ammonia electrolysis cell.

### Mathematical modeling

In contrast to previously reported ammonia electrolysis models that focus either on detailed reaction mechanisms or highly resolved transport phenomena [7-8], the present work adopts a physics-based zero-dimensional modeling approach that is suitable for system-level analysis and optimization. The electrolyzer is treated as a lumped system and spatial gradients of temperature, concentration, and current density are neglected. The model formulation is based on global electrochemical relations and simplified thermal and pressure descriptions, under the following assumptions:

1. Steady-state operation at constant temperature and pressure;
2. Catalyst layers are treated as interfacial surfaces;
3. Ohmic losses are described using Ohm's law;
4. The electrolyte is an aqueous KOH solution;
5. Identical active areas and uniform current density at both electrodes;
6. Gaseous species behave as ideal gases and are uniformly distributed;
7. Uniform pressure along gas flow channels;
8. Electrolyte ohmic resistance in the electrode gap is neglected due to the zero-gap configuration;
9. Gas bubble coverage effects are not explicitly modeled, as forced electrolyte flow and the zero-gap architecture promote rapid bubble detachment.

The model builds upon established formulations previously developed for anion exchange membrane water electrolysis (AEMWE) [9–12] and alkaline water electrolysis (AWE) [13-15].

The cell voltage is calculated as the sum the reversible cell potential ($V_{rev}$) and the different overpotential contributions, namely activation ($\eta_{act}$), concentration ($\eta_{con}$), and ohmic ($\eta_{ohm}$) overpotentials, as expressed in Equation 1.

$$V_{cell} = V_{rev} + \eta_{act} + \eta_{con} + \eta_{ohm} \quad (1)$$

The reversible cell potential is calculated using the Nernst equation as expressed in Equation 2:

$$V_{rev} = V_{rev}^{0} + \frac{R \cdot T}{z \cdot F} \ln \frac{a_{H_2}^{3} \cdot a_{N_2}}{a_{NH_3}^{2}} \quad (2)$$

Where $R$ is the universal gas constant, $F$ is Faraday's constant, $a_k$ denotes the thermodynamic activity of species $k$, and $z$ is the number of electrons transferred in the overall ammonia electrolysis reaction. The standard reversible potential ($V_{rev}^{0}$) is obtained from the semi-empirical correlation proposed by Estejab et al. [16]. The thermodynamic activities of hydrogen and nitrogen are assumed to be equal to their respective partial pressures, which are calculated following the procedure described in [13].

The activity of ammonia is assumed to be equal to that of the alkaline electrolyte composed solely of KOH, since the ammonia concentration employed is relatively low. The activity of water in aqueous KOH solutions is calculated according to the correlation reported by Balej [17].

The activation overpotential is expressed as the sum of the anodic and cathodic activation contributions, derived from the Butler-Volmer formulation, and written in logarithmic form as Equation 3:

$$\eta_{act} = \frac{2.3 \cdot R \cdot T}{z \cdot \alpha_{cat} \cdot F} \log \frac{i}{i_{cat}^{0}} + \frac{2.3 \cdot R \cdot T}{z \cdot \alpha_{ano} \cdot F} \log \frac{i}{i_{ano}^{0}} \quad (3)$$

where $i$ is the operating current density, $i_{cat}^{0}$ e $i_{ano}^{0}$ are the exchange current densities at the cathode and anode, respectively, and $\alpha_{cat}$ and $\alpha_{ano}$ are the corresponding charge transfer coefficients. The exchange current densities are modeled as temperature-dependent quantities

following an Arrhenius-type relationship (Equations 4-5):

$$i_{cat}^{0} = i_{cat,ref}^{0} \cdot \exp\left[-\frac{\Delta G_{cat}}{R} \cdot \left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right] \quad (4)$$

$$i_{ano}^{0} = i_{ano,ref}^{0} \cdot \exp\left[-\frac{\Delta G_{ano}}{R} \cdot \left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right] \quad (5)$$

where $i_{cat,ref}^{0}$ and $i_{ano,ref}^{0}$ represent the exchange current densities at reference temperature $T_{ref}$, and $\Delta G_{cat}$ and $\Delta G_{ano}$ denote the activation free energies associated with the cathodic and anodic reactions, respectively.

In the present model, the charge transfer coefficients $\alpha_{cat}$ and $\alpha_{ano}$ are assumed to be temperature-dependent. Similar behavior has been reported in previous electrochemical modeling studies [9–11]. In this work, empirical correlations as functions of temperature were obtained by regression of experimental polarization data and are described by third-order polynomial expression. The nonlinear temperature dependence of $\alpha$ observed for ammonia electrolysis contrasts with the commonly assumed linear behavior in water electrolysis and reflects the higher mechanistic complexity of the ammonia oxidation reaction.

The concentration overpotential is derived from the Nernst equation combined with Fick's law to account for mass transport limitations associated with gas diffusion through the porous electrodes. Following an approach from Chang et al. [11], the concentration overpotential is expressed as Equation 6:

$$\eta_{conc} = \frac{2.3 \cdot R \cdot T}{n_{cat} \cdot F} \log \frac{C_{H_2,cat}}{C_{H_2,low}} + \frac{2.3 \cdot R \cdot T}{n_{ano} \cdot F} \log \frac{C_{N_2,ano}}{C_{N_2,low}} \quad (6)$$

where $C_{N_2,ano}$ and $C_{H_2,cat}$ are the concentrations of hydrogen and nitrogen, respectively, at the membrane–electrolyte interface, while $C_{N_2,low}$ and $C_{H_2,low}$ denote the reference concentrations at working conditions. The parameters $n_{cat} = 2$ and $n_{ano} = 6$, represent the number of electrons required to produce one mole of $H_2$ and $N_2$, respectively.

The ohmic overpotential accounts for electrodes and membrane resistances within the electrolyzer and is calculated by modeling the different cell components as electrical resistances connected in series. The effective cell resistance ($R_{cell}$) is obtained as the sum of the electrode resistances ($R_{electrodes}$), and the separator resistance, which in the present case corresponds to the anion exchange membrane ($R_{membrane}$). Accordingly, the ohmic overpotential is given by Ohm's law (Equation 7):

$$\eta_{ohm} = I \cdot R_{cell} \quad (7)$$

The total electrode resistance is calculated according to the Equation 8:

$$R_{electrodes} = \rho_{ef,cat} \cdot \frac{\delta_{cat}}{A_e} + \rho_{ef,ano} \cdot \frac{\delta_{ano}}{A_e} \quad (8)$$

where $\rho_{ef,cat}$ and $\rho_{ef,ano}$ are the effective resistivities of the cathode and anode, respectively, $\delta_{cat}$ and $\delta_{ano}$ are the corresponding electrode thicknesses, and $A_e$ is the active electrode area. The expressions used to calculate the effective resistivities are taken from the correlations reported in [13].

The membrane resistance is given by Equation 9:

$$R_m = \frac{\delta_m}{\sigma_m \cdot A_m} \quad (9)$$

where $\delta_m$ is the membrane thickness, $A_m$ is the active membrane area, and $\sigma_m$ is the ionic conductivity of the membrane material.

## Experimental data and parameter estimation

Experimental polarization data reported by Zhang et al. [1] were used to estimate the model parameters. The experiments were conducted in a zero-gap membrane electrode assembly (MEA) electrolyzer with an active area of 5 $cm^2$, operating between 323 and 363 K. The anode was supplied with an aqueous solution containing 3 M KOH and 3 M $NH_3$, while the cathode was fed with 3 M KOH, both at a flow rate of 3 mL/min and atmospheric pressure.

Model parameters, including anodic and cathodic exchange current densities, activation energies, and membrane thickness, were estimated through nonlinear least-squares regression. Parameter estimation was performed using a routine developed in Python (Python Software Foundation, USA), employing the curve_fit function from the SciPy library together with NumPy [18]. The optimization was carried out using the Trust-Region Reflective algorithm.

## Model performance metrics

Model performance was evaluated by calculating the determination coefficient ($R^2$), mean absolute error (MAE), mean absolute percentage error (MAPE), and root mean square error (RMSE). Parameter uncertainty and identifiability was assessed using the bootstrap method, confirming the robustness of the estimated parameters.

## Optimization framework

To evaluate the techno-economic performance of the zero-gap ammonia electrolyzer and its scale-up to plant level, the developed electrochemical model was embedded into a nonlinear optimization framework to minimize the total annual cost (TAC), implemented in Python using the Pyomo package (version 6.10.0) [19]. The formulation accounts for electrochemical, thermal, and economic trade-offs, enabling the identification of optimal operating and design conditions.

The TAC (Equation 10) accounts for both capital and operating expenditures associated with the electrolyzer system.

Capital expenditure (CAPEX, Equation 11) was assumed to be proportional to the number of cells (N), the cost of a cell per area ($C_{cell}$), and the cell area ($A_{cell}$).

Operating expenditure (OPEX, Equation 12) includes

electricity and steam consumption. The capital recovery factor (CRF, Equation 13) was calculated assuming a plant lifetime ($n$) of 20 years and interest rate ($j$) of 10%. The parameters used to calculate the expenditures are list in Table 1.

$$\mathrm{TAC} = \mathrm{CRF} \bullet \mathrm{CAPEX} + \mathrm{OPEX} \quad (10)$$

$$\mathrm{CAPEX} = \mathrm{N} \bullet \mathrm{C_{cell}} \bullet \mathrm{A_{cell}} \quad (11)$$

$$\mathrm{OPEX} = \mathrm{C_{elect}} \bullet \mathrm{P} \bullet \mathrm{h_{op}} + \mathrm{C_{steam}} \bullet \mathrm{Q_t} \bullet \mathrm{h_{op}} \quad (12)$$

$$\mathrm{CRF} = \frac{\mathrm{j(1+j)^n}}{\mathrm{(1+j)^n - 1}} \quad (13)$$

where $C_{elect}$ is the electricity cost (USD/MWh), $P$ is the total electrical power (MW), $h_{op}$ is the annual operating time (h/year), $C_{steam}$ is the steam cost (USD/GJ) and $Q_t$ is the total thermal demand (GJ).

The thermal energy required to heat the electrolyte was estimated using a surrogate model derived from process simulations performed in Aspen Plus v.12, using a temperature-dependent polynomial correlation. These simulations were used to calculate the specific heat requirement per unit mass of electrolyte solution, $Q_{spec}$(GJ/kg), under representative operating conditions.

Within the optimization framework, the total thermal demand was then obtained by scaling the specific heat requirement with the electrolyte mass flow per cell and the total number of cells, Equation 14:

$$Q_t = Q_{spec} \bullet \dot{m}_{sol} \bullet N \quad (14)$$

where $\dot{m}_{sol}$ is the electrolyte mass flow rate per cell.

**Table 1.** Main parameters of the optimization problem.

| Parameter | Value | Reference |
|---|---|---|
| $\mathrm{h_{op}}$ (h/year) | 8000 | Adopted |
| $\mathrm{C_{cell}}$ (USD/m$^2$) | 16200 | [20] |
| $\mathrm{C_{steam}}$ (USD/GJ) | 12.85 | [21] |
| $\mathrm{C_{elect}}$ (USD/MWh) | 136.95 | [21] |
| $\mathrm{A_{cell}}$ (m$^2$) | 3.14 | [1] |

The main decision variables of the optimization problem are:

- Current density, $i$ (A/cm$^2$);
- Number of cells, N;
- Operating temperature, T (K).

These variables simultaneously control the electrochemical performance of the cell and the overall plant sizing, directly affecting hydrogen production, energy consumption, and total system cost.

The optimization problem was formulated as the minimization of TAC, subject to electrochemical, physical, thermal, operational, and hydrogen production constraints, as expressed in Equations 15-20.

$$\min \mathrm{TAC}, (\text{Equation 10}) \quad (15)$$

$$\text{s. t. cell voltage equation}, Eq.(1) \quad (16)$$

$$\mathrm{H_2\ production}: \frac{\mathrm{I}}{2 \bullet \mathrm{F}} MM_{H_2} \geq 1250\ \mathrm{kg/h} \quad (17)$$

$$\mathrm{T^l} \leq \mathrm{T} \leq \mathrm{T^u} \quad (18)$$

$$\mathrm{N^l} \leq \mathrm{N} \leq \mathrm{N^u} \quad (19)$$

$$\mathrm{i^l} \leq \mathrm{i} \leq \mathrm{i^u} \quad (20)$$

where T is the operating temperature of the electrochemical cell, which was allowed to vary between $\mathrm{T^l}$=323 K and $\mathrm{T^u}$=353 K. The current density $i$ was evaluated in the range $\mathrm{i^l}$=0 to $\mathrm{i^u}$=2 A/cm$^2$, and the number of electrochemical cells was varied between $\mathrm{N^l}$=0 and $\mathrm{N^u}$=400 000.

A minimum hydrogen production target of 1250 kg/h was imposed to represent large-scale centralized production, consistent with the hydrogen demand of multiple refueling stations, where a single station typically consumes about 1000 kg/day of hydrogen.

The resulting nonlinear programming (NLP) problem was solved using the IPOPT solver [22], which is well suited for constrained nonlinear optimization with continuous decision variables.

## RESULTS

### Modeling results

The model parameters were estimated through nonlinear regression using the experimental polarization data. The regressed model was then compared with the experimental measurements to assess its ability to reproduce the observed electrochemical behavior.

Figure 2 presents the experimental polarization curves together with the corresponding model predictions at different operating temperatures between 323 and 353 K. Over this temperature range, the model reproduces the experimental cell voltages with good agreement across the investigated current density domain. At higher temperatures beyond the analyzed range, deviations are expected due to the reduced ammonia solubility at elevated temperatures, which affects mass transport phenomena.

Statistical goodness-of-fit indicators as $R^2$= 0.9874, and MAE=0.0126, MAPE= 2.72%, and RMSE = 0.0155, indicate a strong agreement between the regressed model and the experimental data within the range of operating

conditions considered.

The estimated parameters are reported in Table 2. The obtained values for the exchange current densities at reference temperature, fall within ranges commonly reported in the literature for alkaline electrolysis [9], [13], [23], varying between $10^{-3}$ and $10^{-11}$ A/cm$^2$, supporting the physical consistency of the proposed modeling approach. Similarly, the estimated activation free energies are close to values previously reported in the literature [23], [24].

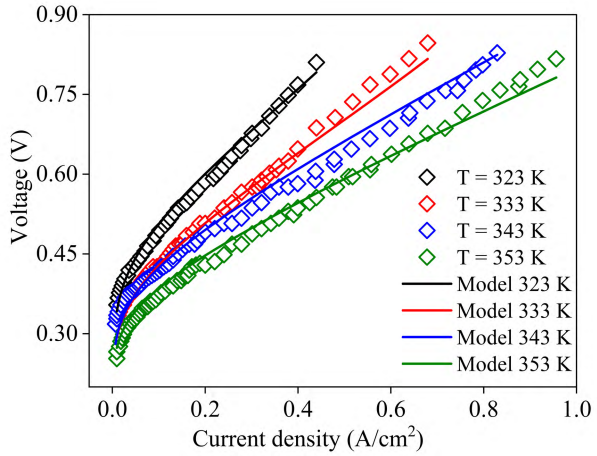

**Figure 2**. Comparison of experimental data with model predictions.

**Table 2.** Estimated model parameters from non-linear regression.

| Parameters | Value |
|---|---|
| $i^0_{ano,ref}$ (A/cm$^2$) | $7.64 \cdot 10^{-7}$ |
| $\Delta G_{ano}$ (J/mol) | 24935.61 |
| $i^0_{cat,ref}$ (A/cm$^2$) | $3.32 \cdot 10^{-5}$ |
| $\Delta G_{cat}$ (J/mol) | 16524.13 |
| $\delta_m$ (cm) | 0.0034 |

## Optimization results

Solving the nonlinear optimization problem resulted in a unique set of operating and design conditions that minimize TAC while satisfying the minimum hydrogen production constraint. Figure 3 illustrates the variation of TAC with current density for the different operating temperatures considered. A well-defined minimum is observed at 353 K, indicating that this temperature provides the most favorable trade-off between improved electrochemical performance and increased thermal and operating costs.

At the optimal temperature of 353 K, the optimal current density was found to be 0.82 A/cm$^2$. This value represents a compromise between higher hydrogen production rates and the increase in activation, concentration, and ohmic overpotentials at elevated current densities. The resulting optimal cell voltage is approximately 0.81 V, leading to a total plant electrical power consumption of about 27.1 MW. The optimal current density and cell voltage obtained in this work are in good agreement with limits reported for ammonia electrolysis, which indicate that economically viable operation requires current densities close to 1 A/cm$^2$ while maintaining the applied cell potential below approximately 1 V [25].

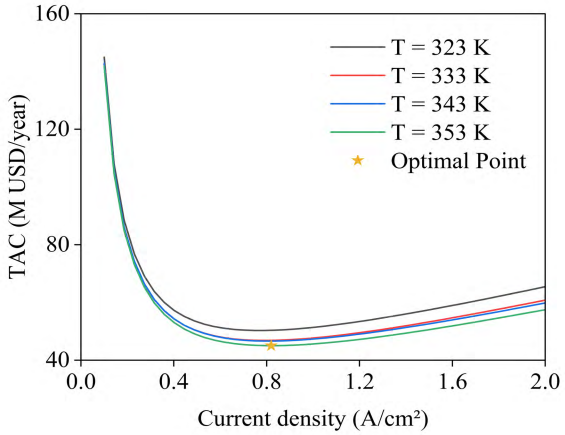

**Figure 3**. Variation of TAC at different temperatures.

The corresponding optimal number of cells was determined to be $N$ = 1302, as illustrated in Figure 4 at 353 K.

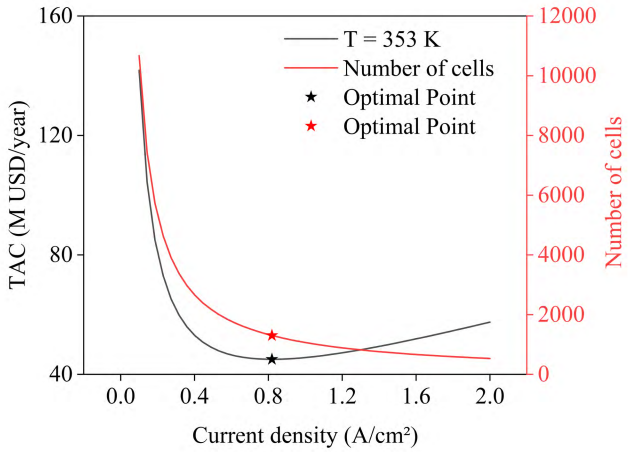

**Figure 4**. Optimization of TAC and number of cells at 353 K.

The estimated capital expenditure (CAPEX) under optimal conditions amounts to approximately 132.5 million USD, dominated by the installed electrochemical active area. The annual operating expenditure (OPEX) was calculated as approximately 29.5 million USD/year, primarily driven by electricity and steam consumption. The resulting minimum TAC is approximately 45.0 million

USD/year. Under these optimal conditions, the system achieves the target hydrogen production rate of 1250 kg/h. The estimated cost of hydrogen production is approximately 4.5 USD/kg $H_2$, excluding ammonia feedstock cost, and it falls within the range reported values for alkaline water electrolysis [26]. A complete techno-economic assessment including ammonia supply, storage, logistics, and sensitivity analysis is left for future work.

## CONCLUSIONS

This work developed a mathematical model of a zero-gap AEM ammonia electrolyzer integrated into a techno-economic optimization framework. The model was fitted to experimental polarization data and describes the main factors affecting cell voltage, energy efficiency, and hydrogen production, showing good agreement ($R^2$ = 0.9874). For the base case, optimal configuration corresponds to a temperature of 353 K, a current density of 0.82 A/cm$^2$, and 1302 cells, resulting in a TAC of about 45.0 MUSD/year.

## ABSTRACT

Simulation and modeling technologies play an increasingly critical role in enhancing feedstock utilization, improving product quality, and enhancing enterprise competitiveness in the refining industry. Molecular-level kinetic models for refining processes typically involve highly detailed and complex data, significantly increasing computational costs. Additionally, the data granularity within these models fails to align with the practical requirements of industrial production. To address these, this study proposes the Reaction Network Coarse-Graining Integration (RNCGI) algorithm to achieve flexible adjustments to model complexity and data granularity. Species with similar molecular structures and kinetic behaviors within the reaction network are identified and integrated. Subsequently, a kinetic parameter mapping approach is developed to preserve the critical reaction behaviors. Finally, the reaction coarse-graining process significantly reduces the number of reactions within the network. The RNCGI algorithm was validated using the naphtha catalytic reforming process. The original complete network with 206 species nodes was integrated into two versions with different data granularities: a medium-scale network with 42 nodes and a small-scale network with 5 nodes. Both coarse-grained networks calculated the product composition accurately and provided clearer insights into core species transformation mechanisms compared to the original network. Additionally, the RNCGI algorithm ensures the completeness of reaction routes. By flexibly handling detailed data in molecular-level models, this work preserves the necessary complexity of models tailored to industrial needs, supporting the development of refinery-wide production planning and scheduling strategies.

## INTRODUCTION

In response to the rising challenge of declining crude oil quality and stringent carbon reduction targets, the petroleum refining industry is undergoing transformative upgrades toward intelligent operations [1]. Mechanistic simulation and modeling technologies enable the construction of detailed process models that accurately predict critical process indicators, such as product composition. These comprehensive refining models improve product quality while enhancing enterprise competitiveness [2].

Reaction kinetic models form the core foundation of refinery process modeling, and the accurate simulation of key industrial indicators serves as a fundamental criterion for model validation. While the widely employed lumped models [3, 4] offer a simplified representation of reaction processes, their oversimplification leads to poor extrapolation performance when feedstock composition varies. To enhance simulation accuracy, the concept of molecular management [5, 6] has been introduced, facilitating the development of refined molecular-level kinetic models [7, 8, 9] and enabling a comprehensive analysis of reaction mechanisms. However, the number of species and reactions within the refined models significantly increase, which leads to a dramatic rise in computational costs. Moreover, the microscopic granularity of molecular-level models often fails to align with the macroscopic data requirements of practical operations, thereby constraining their applicability for industrial production.

Effective reaction kinetic models should balance industrial applicability with the appropriate level of

complexity, retaining only the components necessary to fulfill process demands. Reaction mechanism reduction is a promising method to lower computation costs and improve model interpretability. A common approach involves identifying less important species or reactions and subsequently removing them from the reaction networks. Chen et al. [10] focused on reaction network structures and applied molecular-level oil characterization data to classify and remove species, thereby significantly reducing computation time. Considering both network structures and simulation results, Fang et al. [11] developed the Network Flow Analysis Algorithm (NFAA) to rank the importance of species and reactions, enabling reaction reduction and parameter adjustments. However, few studies focus on the mismatch in data granularity between molecular-level models and practical production. To address this, we propose an information integration method as an alternative to conventional information reduction in this study. The Reaction Network Coarse-Graining Integration (RNCGI) algorithm was developed to identify and integrate species or reactions exhibiting similar kinetic behaviors. This method facilitates both size reduction and data granularity adjustments in reaction networks. A reaction network of the naphtha catalytic reforming process was employed to validate the RNCGI algorithm. The results demonstrate that the algorithm can flexibly adjust the size and data granularity of the reaction network while ensuring high simulation accuracy. The coarse-grained network, with significantly reduced complexity, preserves the key routes and provides a clear representation of the core species transformation mechanisms.

## METHODS

### The Reaction Network Coarse-Graining Integration (RNCGI) Algorithm

From the perspective of network science, the kinetic model of a refining process can be transformed into a directed weighted reaction network $G = (V, E, w)$. $V$ represents the node set, corresponding to species in the model. $E$ denotes the directed edge set, corresponding to the reactions, and each edge is directed from reactants to resultants. Each directed edge is assigned a weight $w$, which quantifies the connection strength between nodes and corresponds to the reaction kinetic information in the model. To achieve scale reduction and data granularity adjustment of complex networks, we have developed the Reaction Network Coarse-Graining Integration (RNCGI) algorithm. Taking the original reaction network as the input, the algorithm generates a coarse-grained reaction network through three sequential steps: node coarse-graining, kinetic parameter mapping, and edge coarse-graining. Assuming that all reactions in the original complex network are first-order reversible reactions, the flowchart of the RNCGI algorithm is illustrated in Fig. 1, including the following three steps. The corresponding pseudo-code is presented in Fig. 2.

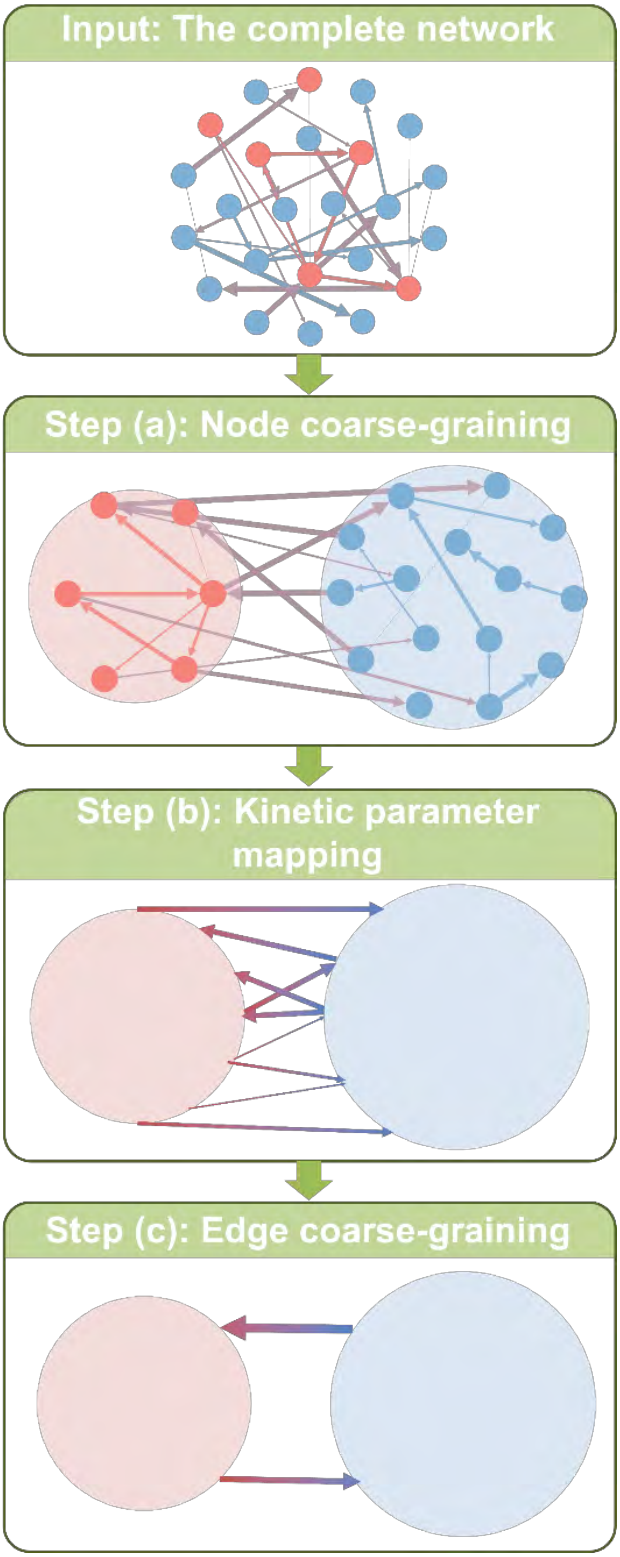

**Figure 1.** Flowchart of the RNCGI algorithm

**Algorithm 1** The Reaction Network Coarse-Graining Integration (RNCGI) Algorithm

**Input:** The original complete reaction network and the kinetic model $Comp = \{V^{comp}, E^{comp}, k^{comp}, C_{V^{comp}}^{t_0}\}$

**Output:** The coarse-grained reaction network and the kinetic model $Coa = \{V^{coa}, E^{coa}, k^{coa}, C_{V^{coa}}^{t_0}\}$

$V$---species nodes in the network

$E$---reaction edges in the network

$k$---kinetic parameters in the kinetic model

$C_V^{t_0}$---molar concentrations of species nodes $V$ in the feedstock

Superscript: $comp$---the original complete reaction network and the kinetic model $Comp$

$coa$---the coarse-graining reaction network and kinetic model $Coa$

Function $Coa$ = RNCGI($Comp$)

1. Node coarse-graining

$A = \{a_1, a_2, \dots, a_n\}$ $\{a_1, a_2, \dots, a_n\} \in V^{comp}$ ▷ Define the node coarse-graining rules and generate $A \in V^{coa}$

$C_A^{t_0} = \sum_{i=1}^{n} C_{a_i}^{t_0}$ ▷ Adjust the feedstock composition $C_{a_i}^{t_0}$ at time $t_0$ and generate $C_A^{t_0} \in C_{V^{coa}}^{t_0}$

2. Kinetic parameter mapping

for a reaction $a_i \rightleftharpoons b_j$ with $r = -k_{+,a_i,b_j}^{comp} \times C_{a_i} + k_{-,a_i,b_j}^{comp} \times C_{b_j}$ ▷ The calculation equation for reaction rate $r$

$C_{a_i}^{mean} = \frac{\sum_{p=1}^{N-1}(t_{p+1}-t_p)\times C_{a_i}^{p+1}}{t_N - t_1}$ ▷ Calculate the time-weighted average molar concentrations $C_{a_i}^{mean}$

$\tilde{k}_{+,a_i,b_j}^{coa} = \frac{k_{+,a_i,b_j}^{comp} \times C_{a_i}^{mean}}{C_A^{mean}} = \frac{k_{+,a_i,b_j}^{comp} \times C_{a_i}^{mean}}{\sum_{i=1}^{n} C_{a_i}^{mean}}$

$\tilde{k}_{-,a_i,b_j}^{coa} = \frac{k_{-,a_i,b_j}^{comp} \times C_{b_j}^{mean}}{C_B^{mean}} = \frac{k_{-,a_i,b_j}^{comp} \times C_{b_j}^{mean}}{\sum_{j=1}^{m} C_{b_j}^{mean}}$ ▷ Mapping equation for rate constants $\tilde{k}_{+,a_i,b_j}^{coa}$ and $\tilde{k}_{-,a_i,b_j}^{coa}$ that account for concentration changes due to node coarse-graining

end

3. Edge coarse-graining

for all reaction edges between $a_i$ and $b_j$, where $a_i \in A$ and $b_j \in B$

replace all reactions $a_i \rightleftharpoons b_j$ with a single new reaction $A \rightleftharpoons B$ ▷ Edge coarse-graining and generate $E^{coa}$

$k_{+,A,B}^{coa} = \sum_{i=1}^{n}\sum_{j=1}^{m} \tilde{k}_{+,a_i,b_j}^{coa} + \sum_{i=1}^{n}\sum_{j=1}^{m} \tilde{k}_{-,b_j,a_i}^{coa}$

$k_{-,A,B}^{coa} = \sum_{i=1}^{n}\sum_{j=1}^{m} \tilde{k}_{-,a_i,b_j}^{coa} + \sum_{i=1}^{n}\sum_{j=1}^{m} \tilde{k}_{+,b_j,a_i}^{coa}$ ▷ Calculate the rate constants for $Coa$ and generate $\{k_{+,A,B}^{coa}, k_{-,A,B}^{coa}\} \in k^{coa}$

end

Return $Coa = \{V^{coa}, E^{coa}, k^{coa}, C_{V^{coa}}^{t_0}\}$

**Figure 2:** The corresponding pseudo-code for the RNCGI algorithm.

Step (a): Node coarse-graining. The first step of the RNCGI algorithm is to identify which nodes in the original complex network can be integrated into a single new node in the coarse-grained network, which is to define the node coarse-graining rules. All species nodes constitute the species library of this reaction system. Multi-dimensional structural features of species, such as the number and linkage pattern of aromatic rings, naphthenic rings and side-chain carbons, serve as classification criteria for these species nodes. The dominant reaction mechanisms and industrial production requirements enable the identification of critical versus secondary structural features. When the node set $\{a_1, a_2, \dots, a_n\}$ in the original network is integrated into a single new node $A$, the reactions among nodes $\{a_1, a_2, \dots, a_n\}$ are neglected.

Species nodes sharing identical critical structural features but differing only in minor secondary structural features are likely to exhibit similar reaction behaviors, and can therefore be grouped into the same category and integrated into a single node. This approach minimizes the network scale while preserving the dominant species transformation mechanisms, and aligns the network with the data granularity required for practical industrial production. For example, n-decane can undergo cyclization to form naphthene isomers with varying side-chain structures, which can subsequently be dehydrogenated to produce the corresponding aromatic isomers (Fig. 3(a)). Considering the similar reaction mechanisms of species with different side-chain structures, the naphthene and aromatic isomers can be integrated into new nodes, respectively (Fig. 3(b)). In contrast, the molecular structures of paraffins and naphthenes differ

significantly. Therefore, integrating these two types of nodes could lead to the interrupted reaction routes and the loss of important reaction categories, such as cyclization, in the coarse-grained network (Fig. 3(c)).

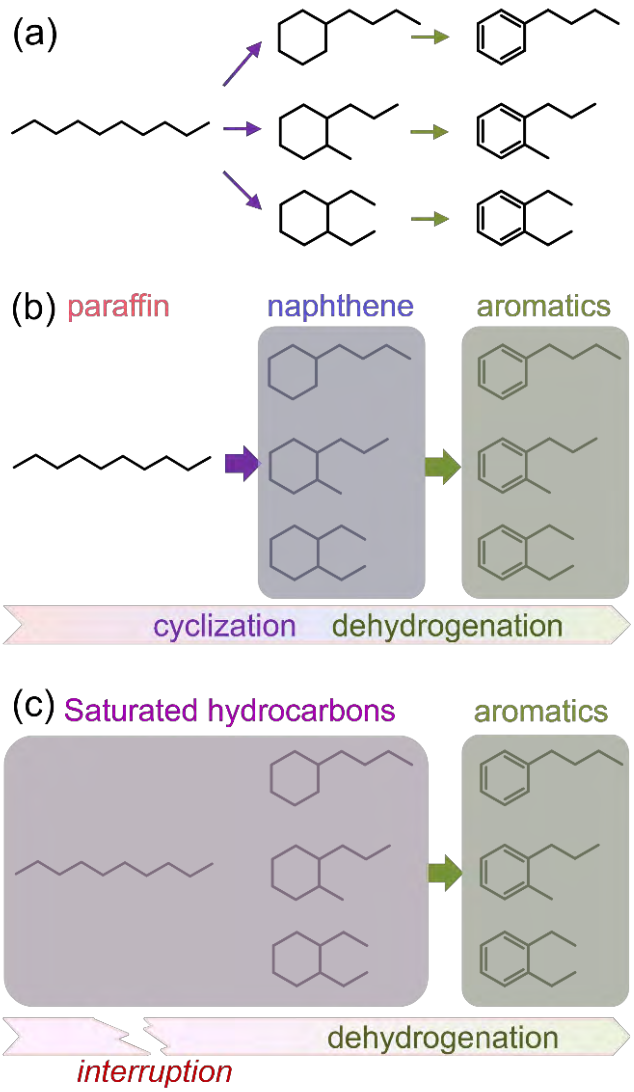

**Figure 3.** Examples of different node coarse-graining rules. (a) the original reaction routes; (b) the complete routes derived by appropriate node coarse-graining rules; (c) the interrupted routes derived by inappropriate rules

Once the node coarse-graining rules are defined, it is necessary to adjust the feedstock composition at time $t_0$. The molar concentration of node $A$ in the feedstock of the coarse-grained network is equal to the sum of the molar concentrations of the integrated nodes $\{a_1, a_2, \ldots, a_n\}$ in the original network (Equation 1).

$$C_A^{t_0} = \sum_{i=1}^{n} C_{a_i}^{t_0} \tag{1}$$

Step (b): Kinetic parameter mapping. The molar concentrations of the species nodes are altered due to the node coarse-graining step, thereby introducing perturbations in the reaction behaviors. Consequently, the kinetic parameters of the coarse-grained network could be mapped from those of the original network to preserve the accuracy of overall kinetic behaviors. Suppose the original species node sets $\{a_1, a_2, \ldots, a_n\}$ and $\{b_1, b_2, \ldots, b_m\}$ are integrated respectively into new species nodes $A$ and $B$. For a first-order reaction involving species $a_i$ and $b_j$ (Equation 2), the reaction rate $r$ is calculated in the original network as Equation 3. $C_{a_i}$ and $C_{b_j}$ are the molar concentrations of $a_i$ and $b_j$. Theoretically, to preserve the reaction rates after node coarse-graining, the forward and reverse rate constants $k^{coa}_{+,a_i,b_j}$ and $k^{coa}_{-,a_i,b_j}$ at time $t_x$ in the coarse-graining network should satisfy the mapping relationships in Equation 4 with respect to the original forward and reverse rate constants $k^{comp}_{+,a_i,b_j}$ and $k^{comp}_{-,a_i,b_j}$. $n$ and $m$ are the number of species integrated into the nodes $A$ and $B$, respectively. As the molar concentrations $C^{t_x}_{a_i}$ and $C^{t_x}_{b_j}$ vary dynamically with time $t_x$, the theoretical values of $k^{coa}_{+,a_i,b_j}$ and $k^{coa}_{-,a_i,b_j}$ are inherently time-dependent. To effectively preserve the key characteristics of reaction behaviors, the time-weighted average molar concentrations $C^{mean}_{a_i}$ at N discrete time points (Equation 5) are used to calculate the approximate rate constants $\tilde{k}^{coa}_{+,a_i,b_j}$ and $\tilde{k}^{coa}_{-,a_i,b_j}$ in the coarse-grained network (Equation 6).

$$a_i \rightleftharpoons b_j \tag{2}$$

$$r = -k^{comp}_{+,a_i,b_j} \cdot C_{a_i} + k^{comp}_{-,a_i,b_j} \cdot C_{b_j} \tag{3}$$

$$k^{coa}_{+,a_i,b_j} = \frac{k^{comp}_{+,a_i,b_j} \cdot C^{t_x}_{a_i}}{C^{t_x}_{A}} = \frac{k^{comp}_{+,a_i,b_j} \cdot C^{t_x}_{a_i}}{\sum_{i=1}^{n} C^{t_x}_{a_i}} \tag{4-1}$$

$$k^{coa}_{-,a_i,b_j} = \frac{k^{comp}_{-,a_i,b_j} \cdot C^{t_x}_{b_j}}{C^{t_x}_{B}} = \frac{k^{comp}_{-,a_i,b_j} \cdot C^{t_x}_{b_j}}{\sum_{i=1}^{m} C^{t_x}_{b_j}} \tag{4-2}$$

$$C^{mean}_{a_i} = \frac{\sum_{p=1}^{N-1} (t_{p+1} - t_p) \cdot C^{p+1}_{a_i}}{t_N - t_1} \tag{5}$$

$$\tilde{k}^{coa}_{+,a_i,b_j} = \frac{k^{comp}_{+,a_i,b_j} \cdot C^{mean}_{a_i}}{C^{mean}_{A}} = \frac{k^{comp}_{+,a_i,b_j} \cdot C^{mean}_{a_i}}{\sum_{i=1}^{n} C^{mean}_{a_i}} \tag{6-1}$$

$$\tilde{k}^{coa}_{-,a_i,b_j} = \frac{k^{comp}_{-,a_i,b_j} \cdot C^{mean}_{b_j}}{C^{mean}_{B}} = \frac{k^{comp}_{-,a_i,b_j} \cdot C^{mean}_{b_j}}{\sum_{i=1}^{m} C^{mean}_{b_j}} \tag{6-2}$$

Step (c): Edge coarse-graining. After node coarse-graining, multiple edges may exist between the same pair of nodes in the network, corresponding to multiple identical reactions. To ensure the simplicity and consistency of the coarse-grained network, these edges are integrated into a single representative edge directed from node $A$ to $B$, which represents the reaction in Equation 7. Considering the directions of all the integrated edges, the forward and reverse rate constants for the coarse-grained new reaction $k^{coa}_{+,A,B}$ and $k^{coa}_{-,A,B}$ are calculated by

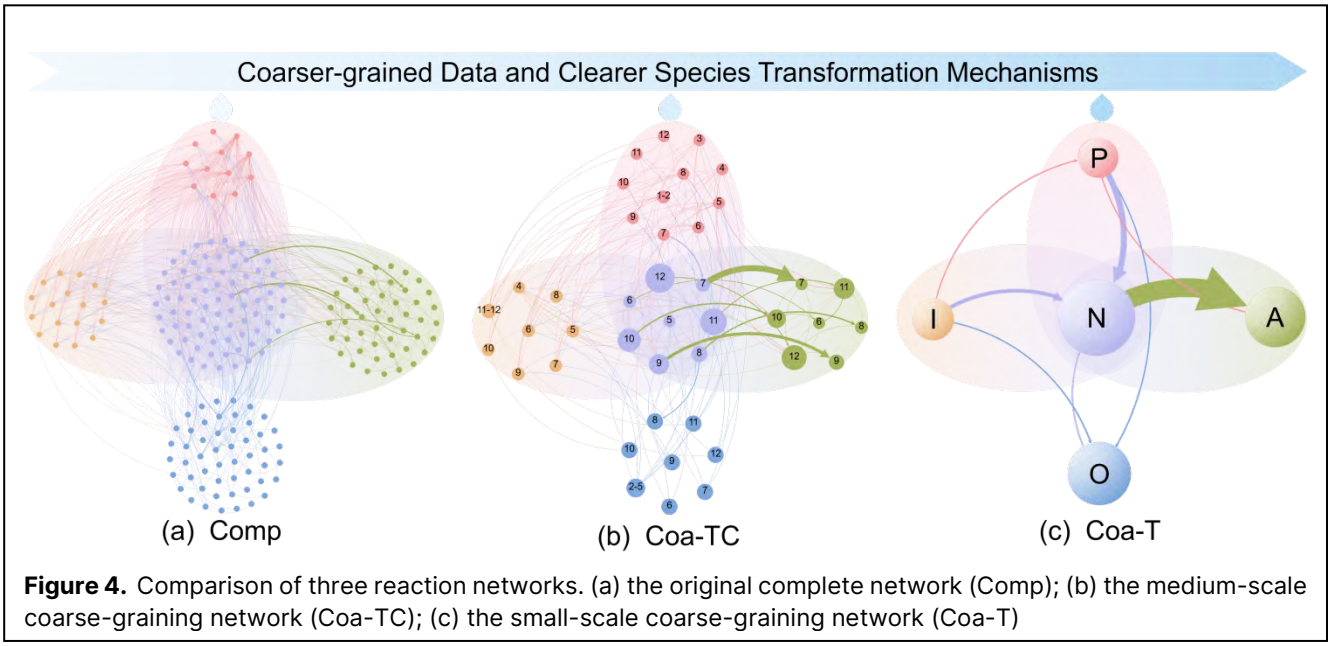

**Figure 4.** Comparison of three reaction networks. (a) the original complete network (Comp); (b) the medium-scale coarse-graining network (Coa-TC); (c) the small-scale coarse-graining network (Coa-T)

aggregating the respective rate contributions (Equation 8). $\tilde{k}^{coa}_{+,b_j,a_i}$ and $\tilde{k}^{coa}_{-,b_j,a_i}$ denote the approximate forward and reverse rate constants, respectively, after kinetic parameter adjustment for the reaction where $b_j$ serves as a reactant and $a_i$ as a resultant.

$$A \rightleftharpoons B \tag{7}$$

$$k^{coa}_{+,A,B} = \sum_{i=1}^{n}\sum_{j=1}^{m}\tilde{k}^{coa}_{+,a_i,b_j} + \sum_{i=1}^{n}\sum_{j=1}^{m}\tilde{k}^{coa}_{-,b_j,a_i} \tag{8-1}$$

$$k^{coa}_{-,A,B} = \sum_{i=1}^{n}\sum_{j=1}^{m}\tilde{k}^{coa}_{-,a_i,b_j} + \sum_{i=1}^{n}\sum_{j=1}^{m}\tilde{k}^{coa}_{+,b_j,a_i} \tag{8-2}$$

## Example: The Catalytic Reforming Reaction Network

Catalytic reforming of naphtha is a crucial process for increasing the octane number of gasoline and producing high-value-added aromatics. Taking a self-constructed molecular-level catalytic reforming network as an example, the RNCGI algorithm was employed to derive coarse-grained networks at different levels of data granularity. The original complex network (Comp) consists of 206 species nodes and 674 reaction edges, in which molecular structures of species are described via the structure-oriented lumping (SOL) method. The edge weight in the network represents the cumulative molar flow rate $CF_h^0$ (Equation 9) of the corresponding reaction $h$ throughout the complete reaction extent. $\nu_0$ is the constant volumetric flow rate, $r_h$ is the reaction rate (Equation 3), and $t$ is the reaction time.

$$CF_h^0 = \nu_0 \int_0^t r_h \, \mathrm{d}t \tag{9}$$

The catalytic reforming process primarily involves species with carbon numbers ranging from C1 to C12, and the detailed composition of these light components could be determined using advanced oil characterization techniques. The two-dimensional PIONA (paraffin, isoparaffin, olefin, naphthene, and aromatic) compositions of feedstocks and products represent key industrial parameters in the reforming process. Based on practical purposes, species with the same PIONA type and carbons in the Comp network can be integrated into a single new node, while neglecting more detailed structural information from the SOL method. The RNCGI algorithm results in a coarse-grained network, termed Coa-TC (type and carbon-based coarse-graining).

On the other hand, coarser-grained data, such as the aromatic yield, are key considerations in the development of production planning and plant-wide scheduling strategies. To address this, the RNCGI algorithm allows for flexible adjustment of data granularity, using only PIONA types as the basis for node coarse-graining. This approach results in a coarser-grained network, Coa-T.

# RESULTS AND DISCUSSIONS

## Network Scale and Kinetic Accuracy

Fig. 4 shows the scales of the Comp, Coa-TC, and Coa-T networks. In the Coa-TC network (Fig. 4(b)), species nodes are distinguished by the PIONA types and carbon numbers. The node colors represent different PIONA types, serial numbers indicate the carbon numbers, and node sizes reflect the number of original nodes that are integrated into the corresponding coarse-grained node. The Coa-TC network consists of 42 species nodes and 131 reaction edges, accounting for only about 20% of the complexity of the original Comp network. Furthermore, the species concentrations within all nodes directly correspond to the two-dimensional PIONA composition, ensuring the clear representation of feedstocks and products. At different temperatures, the product components

calculated by the Coa-TC network are in good agreement with the original values in the Comp network, with the maximum absolute error less than 1.5% (Fig. 5). This demonstrates that the RNCGI algorithm ensures the accuracy of the coarse-grained network.

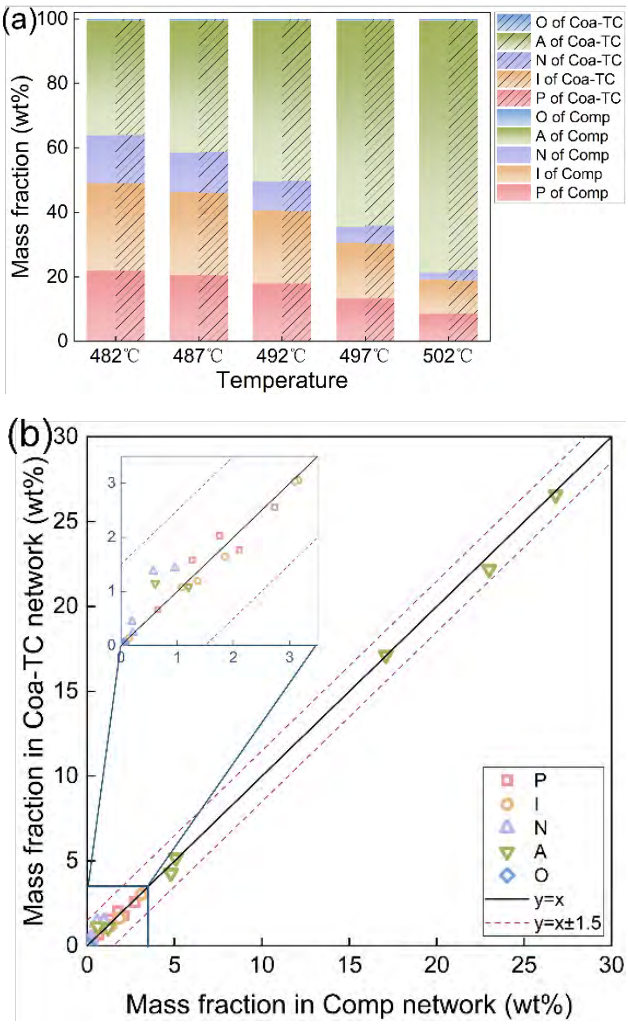

**Figure 5.** The Calculation results of the Coa-TC network (a) PIONA compositions at different temperatures; (b) two-dimensional PIONA compositions at 502 ℃

In contrast, the Coa-T network only consists of five species nodes (P, I, N, A, O) and eight reaction edges (Fig. 4(c)). In the Coa-T network, the calculated PIONA compositions across different temperatures show strong consistency with those obtained from the Comp network, with absolute errors maintained within 5% (Fig. 6). Compared to the Comp network, the Coa-T network exhibits a significantly reduced scale while better enhancing alignment with industrial needs for aromatics production, providing a simplified and accurate foundation for plant-wide scheduling and process optimization.

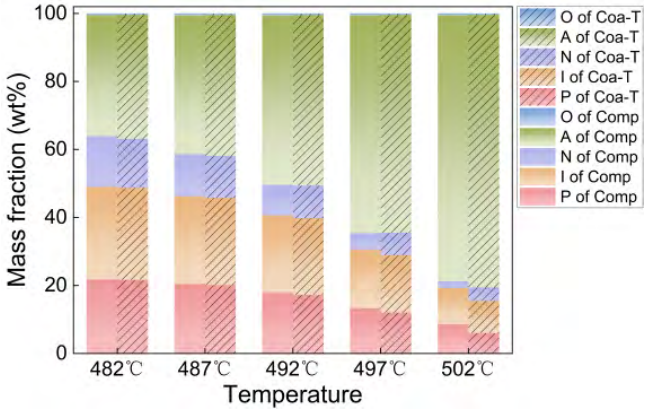

**Figure 6.** The Calculation results of the Coa-T network

## Species Transformation Mechanisms

One of the primary objectives of catalytic reforming is to produce aromatics. The aromatic content in the product increases significantly with rising temperatures. Fig. 4 compare the data granularity and species transformation mechanisms among the Comp, Coa-TC, and Coa-T networks. Across different levels of data granularity, these networks reveal a consistent reaction route for the accumulation of aromatics: chain alkanes undergo cyclization to form naphthenes, which are subsequently aromatized. In this route, chain alkanes, naphthenes and aromatics serve as the main reactants, intermediates and products, respectively. Furthermore, the essential species transformation mechanisms, from chain alkanes to naphthenes and finally to aromatics, become more clearly evident in the coarser-graining network structures (shaded area in Fig. 4).

Additionally, the RNCGI algorithm demonstrates superior performance compared to traditional information reduction methods in reducing reaction networks while maintaining simulation accuracy. Table 1 evaluates reduced networks derived from different algorithms with respect to network scale and simulation accuracy. The reaction deletion (RD) network is obtained by using the NFAA algorithm [11], which ranks reaction importance and remove reactions with low importance. When the RD network is reduced to 198 species nodes and 278 reaction edges, the calculated mass fractions of iso-paraffins and aromatics with 9 carbons (denoted as I7 and A7, respectively) in the product exhibit significant deviations compared to the Comp network. In contrast, the Coa-TC network, generated using the RNCGI algorithm, contains fewer species nodes and reaction edges while achieving higher simulation accuracy compared to the RD network. This enhanced performance is attributed to the kinetic information integration in the RNCGI algorithm, which preserves critical reaction routes while reducing the overall network scale.

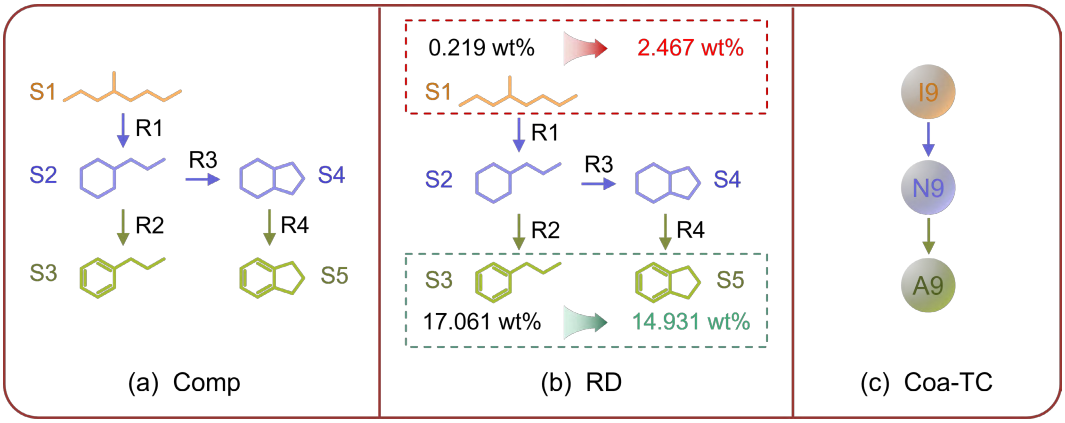

**Figure 7.** Comparison of speceis transformation mechanisms within different networks. (a) reaction routes in the Comp network; (b) reaction routes in the RD network; (c) reaction routes in the Coa-TC network

**Table 1.** The scale and simulation accuracy of reduced networks derived from different algorithms

| Metrics | | Networks | |
|---|---|---|---|
| | | Coa-TC | RD |
| Absolute error | I9 | 0.087 wt% | 2.417wt% |
| | A9 | 0.094 wt% | 2.299wt% |
| Network scale | Node number | 42 | 198 |
| | Edge number | 131 | 278 |

From the perspective of species transformation mechanisms, the generation of A9 in the Comp network primarily proceeds via cyclization and aromatization of species with the same carbon number (Fig. 7(a)). In the RD network (Fig. 7(b)), the cyclization reaction of I9 (reaction R1) is removed. The interruption of this route reduces the content of intermediate naphthene species (S2), thereby diminishing the reaction flow rates of its subsequent aromatization and side-chain cyclization reactions. These affected kinetic behaviors lead to a decreased production of aromatic species (S3 and S5), while the iso-paraffin species (S1) accumulate excessively due to the interruption of transformation routes. In contrast, the RNCGI algorithm replaces information deletion with an information integration strategy, preserving critical reaction routes in the Coa-TC network (Fig. 7(c)). This approach ensures accurate kinetic behaviors even with a significant reduction in network scale.

## CONCLUSIONS

This study proposes a novel reaction network coarse-graining integration (RNCGI) algorithm, which comprehensively considers the accuracy, simplicity, and applicability of reaction models. The node coarse-graining rules are constructed specific to various industrial demands, and kinetic parameters mapping and reaction coarse-graining are followed to derive a coarse-grained network. In comparison to the original Comp network, the resulted Coa-TC and Coa-T networks exhibit a significantly reduced scale and a data granularity that is more closely aligned with real industrial production. Therefore, these coarse-grained networks enable the rapid and accurate calculation of critical industrial indicators. The RNCGI algorithm employs information integration instead of deletion, consistently preserving key reaction routes across various degrees of coarse-grained networks. By avoiding reaction routes interruption, this approach ensures the reliability of species transformation mechanisms within the network.

Future work will likely focus on integrating this algorithm into the refinery-wide scheduling and optimization software in a modular form, providing practical support for achieving comprehensive automation in modern refinery operations.

## ABSTRACT

Chemical processes are characterized by high complexity and inherent hazards, necessitating systematic and comprehensive risk assessment methodologies. However, traditional risk assessment approaches are often limited to static analyses and small-scale models, resulting in insufficient coverage and a lack of detailed, unit-level insights. This paper proposes an automated Bayesian network–based dynamic risk assessment (DRA) framework for full-process risk analysis in chemical plants. The proposed method automatically extracts knowledge from established risk analysis documents, such as HAZOP reports, and integrates it with dynamic process monitoring data, expert knowledge, and reliability databases. By effectively leveraging multi-source heterogeneous data, an equipment-level causal inference network is constructed automatically, addressing the high labor demand and limited scalability of conventional DRA approaches. The proposed framework is validated through an industrial FCC case study at a large petrochemical enterprise in Zhejiang, China. The results demonstrate that the method can effectively construct Bayesian causal networks for chemical processes and quantitatively evaluate both the likelihood and severity of accident consequences under various failure scenarios, thereby enabling systematic and dynamic risk assessment of chemical processes.

**Keywords**: dynamic risk assessment, Bayesian network, multi-source heterogeneous data, automated construction

## 1. INTRODUCTION

Chemical processes are inherently complex and fraught with various risks due to their dynamic nature and the involvement of hazardous materials. Traditionally, risk assessments in these environments have been static, relying on predefined assumptions and historical data. However, as industrial systems grow more complex and real-time monitoring becomes more prevalent, these conventional approaches are no longer sufficient to capture the dynamic behavior and evolving risks that can occur during operation.

Dynamic risk assessment (DRA) has emerged as a more suitable methodology to address these challenges. The main goal of DRA is to provide a real-time, adaptable framework for assessing the risks associated with chemical processes. This approach continuously updates risk levels based on variations in operating conditions, equipment degradation, human–machine interactions, and control system performance. By incorporating time-dependent factors, DRA offers a more comprehensive understanding of risk propagation and its evolution over time, enabling better decision-making in high-risk environments.

According to the definition by Khan et al.[1], DRA is a methodology that updates process risk estimates based on the performance of control systems, protection barriers, inspection and maintenance activities, human factors, and operational procedures. A key distinction between DRA and traditional risk assessment lies in the explicit incorporation of time-dependent factors. Importantly, risk analysis should quantify both the probability and the consequences of hazardous scenarios. Approaches that focus exclusively on occurrence probability without assessing consequence severity result in incomplete and potentially misleading risk evaluations.

In 2006, Meel and Seider[2] developed an integrated framework combining precursor information with real-time failure data to dynamically assess accident sequences, marking one of the earliest practical applications of DRA in chemical process safety.

Building upon tree-based models, subsequent research increasingly focused on dynamic risk assessment. Kalantarnia et al.[3] advanced DRA by integrating Bayesian failure modeling with consequence analysis. Their framework consists of two key modules: (i) an accident analysis module, which incorporates real-time process parameters into dynamic probability estimation using fault tree analysis; and (ii) a probability updating module, which iteratively updates probabilities through Bayesian inference as new data become available.

Between 2000 and 2009, Bayesian networks (BN) were widely adopted in DRA due to their natural compatibility with probabilistic updating and causal reasoning. Montani et al.[4] introduced dynamic Bayesian networks (DBN) and developed the DBNet tool to automatically convert dynamic fault trees into DBNs, representing a significant milestone in BN-based DRA. Kohda and Cui et al.[5] proposed a DBN-based dynamic reconfiguration method for safety monitoring systems, using time slices to model operational states and sensor reliability degradation. More recently, Shan et al.[6] employed fuzzy Bayesian networks (FBN) to quantify gas pipeline leakage risk, while Guo et al.[7] proposed a fuzzy dynamic Bayesian network (FDBN) framework for uncertainty propagation in DRA.

Machine learning methods have been increasingly applied to DRA. Adedigba et al.[8] used artificial neural networks (ANNs) for real-time accident probability prediction, while Wang et al.[9] applied long short-term memory (LSTM) networks for real-time risk forecasting. Other techniques, such as principal component analysis (PCA)[10] and support vector machines (SVM)[11], have also been explored.

Existing DRA methodologies mainly depend on Event Tree Analysis (ETA), Fault Tree Analysis (FTA), and Bow-Tie Analysis. Despite their effectiveness, most current approaches suffer from several limitations: incomplete risk characterization, limited network scale, and high reliance on expert knowledge. In particular, the construction of BN structures and the assignment of initial probabilities often require substantial manual effort, which hinders scalability and industrial applicability.

Although these studies collectively illustrate the evolution of DRA methodologies, most existing approaches still rely heavily on manual model construction and expert-driven probability assignment. This limitation is particularly pronounced for methods such as FBN, which are highly dependent on expert judgment. To address these challenges, this paper proposes an automated framework for extracting knowledge from multi-source heterogeneous data and constructing BN for DRA.

## 2. PRELIMINARIES

This section introduces the key techniques and algorithms employed in the proposed framework, including time-series Transformer-based causal discovery, sentence Transformer for heterogeneous textual data, and Bayesian parameter estimation. These techniques jointly enable the automated construction of a Bayesian causal network for DRA.

### 2.1 Time-Series Transformer-Baesd Causal Discovery

Causal discovery from process data plays a critical role in constructing the structural framework of a causal BN. In complex chemical process such as Fluid Catalytic Cracking (FCC), process variables are strongly coupled, dynamically evolving, and often influenced by delayed and indirect interactions. Traditional correlation-based methods are insufficient to capture such causal relationships.

In this work, causal discovery is performed using a time-series Transformer model[12] applied to DCS historical data. Transformer architectures, originally developed for sequence modeling, are particularly well suited for capturing long-range temporal dependencies and nonlinear interactions among multivariate time-series signals. By leveraging self-attention mechanisms, the model can learn how past values of one variable contribute to the future evolution of another.

Specifically, Granger causality is estimated within the Transformer framework: a variable $X$ is considered to Granger-cause another variable $Y$ if incorporating the historical information of $X$ significantly improves the prediction of $Y$ compared to using the history of $Y$ alone. By evaluating such predictive contributions across all monitored variables, a directed causal graph is obtained, which serves as the initial structure of the BN. This data-driven approach enables scalable and automated identification of causal relationships in large-scale industrial systems without relying solely on expert-defined structures.

### 2.2 Sentence Transformer

To bridge the semantic gap between Bayesian network node descriptions expressed in unstructured natural language and reliability database entries provided in structured textual form, this study employs the Sentence-BERT (SBERT) framework for semantic vector representation. Conventional BERT models typically adopt a cross-encoder architecture for sentence similarity tasks, in which sentence pairs are jointly encoded. Although effective, this approach incurs high computational cost and is therefore unsuitable for large-scale database matching

and real-time retrieval. SBERT addresses this limitation by reformulating pretrained BERT models into a Siamese architecture with shared weights, allowing each sentence to be encoded independently into a fixed-dimensional embedding.

Given a Bayesian network node description $A$ and a candidate database entry $B$, SBERT processes the two texts separately and generates contextualized token-level representations using BERT encoders. A pooling operation is then applied to aggregate token embeddings into a sentence-level vector. In this work, mean pooling is adopted, where the final sentence embedding $u$ is computed as the average of all token embeddings:

$$u = \frac{1}{N}\sum_{i=1}^{N} h_i \quad (3)$$

where $hi$ denotes the embedding of the $i$th token and $N$ is the sentence length.

To ensure that the resulting embeddings exhibit meaningful geometric properties in the semantic space, SBERT is typically fine-tuned using a supervised classification objective. For a sentence pair ($A$, $B$), the corresponding embeddings $u$ and $v$ are concatenated with their absolute difference, and fed into a Softmax classifier trained on semantic entailment, contradiction, and neutrality labels. This training strategy encourages semantically similar sentences to be mapped closer together in the embedding space while pushing dissimilar sentences further apart.

During inference, Bayesian network node names and reliability database entries are mapped into high-dimensional vectors and their semantic correspondence is quantified using cosine similarity:

$$sim(A,B) = \frac{u \cdot v}{\|u\| \cdot \|v\|} \quad (4)$$

The resulting similarity score ranges from [−1, 1], with higher values indicating stronger semantic similarity. This approach not only captures direct lexical overlap but also effectively identifies implicit semantic associations, such as those between instrumentation tags and their corresponding process semantics, thereby enabling robust matching between Bayesian network nodes and heterogeneous reliability data sources.

### 2.3 Bayesian Parameter Estimation

Parameter learning for conditional probability tables (CPTs) in BN is performed using Bayesian inference with Dirichlet priors. A commonly used baseline approach is maximum likelihood estimation (MLE), which estimates probabilities by simple frequency counting. For example, if node $X$ has parent $Y$, and the dataset contains $N$ instances where $Y$=High, among which $X$=Alarm occurs $n$ times, then:

$$P(X = Alarm|Y = High) = \frac{n}{N} \quad (4)$$

However, MLE suffers from the zero-frequency problem. If a critical event has not occurred in the dataset, MLE assigns it a probability of zero. In process safety applications, “not observed” does not imply “impossible, ” and MLE completely ignores prior knowledge from reliability databases such as OREDA.

To overcome these limitations and integrate prior knowledge with observational data, Bayesian estimation is adopted. In discrete BN, node states follow a multinomial distribution, whose conjugate prior is the Dirichlet distribution. This approach is commonly referred to as Dirichlet smoothing.

A key parameter in Bayesian estimation is the Equivalent Sample Size (ESS), which quantifies the confidence placed in prior probabilities. ESS represents the number of virtual observations implied by the prior. Given a prior probability $P_{prior}(X_i = k|Pa_i = j)$ , the corresponding pseudo-count is:

$$a_{ijk} = P_{prior}(X_i = k|Pa_i = j) \times ESS \quad (1)$$

The updated CPT is then computed as:

$$\theta_{ijk} = \frac{N_{ijk}+\alpha_{ijk}}{N_{ij}+\alpha_{ij}} \quad (2)$$

where $N_{ijk}$ is the observed count from process data and $\alpha_{ij}$ is the sum of pseudo-counts. When large amounts of data are available, the influence of the prior diminishes. When data are scarce, the prior prevents zero-probability artifacts.

## 3. PROPOSED FRAMEWORK

This chapter provides a detailed description of the complete implementation workflow of the proposed automated dynamic risk assessment framework. The framework is designed to address two fundamental limitations of conventional risk assessment approaches: first, the subjectivity and high labor cost associated with manual construction of BN; and second, the inherent latency of static risk data, which fails to reflect the real-time operating state of chemical processes. As illustrated in Fig. 3, the implementation workflow is tightly integrated, starting from preprocessing of DCS data, proceeding through causal discovery and multi-source heterogeneous data extraction, and ultimately achieving the automated construction of a risk-oriented causal network for chemical processes.

### 3.1 Data Preprocessing and Transformer-Based Causal Discovery

The first stage of the framework aims to automatically extract the topology of the BN from the vast amount of Distributed Control System (DCS) data in chemical processes.

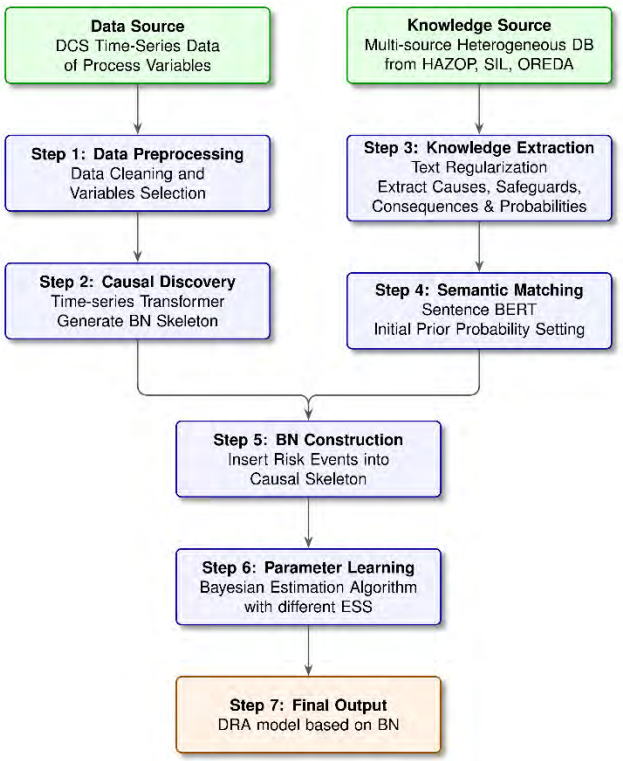

**Figure 1.** Framework of automated Bayesian causal network construction.

Initial preprocessing of the raw DCS time-series data involves selecting the key variables that have a critical impact on the safety of the process. In real-world chemical production plants, a single plant consists of thousands of instrument points that indicate the parameters of different systems and equipment. During the risk assessment process, some variables are closely related to the safe operation of the plant, while others are used to indicate production efficiency. In our risk analysis, we focus primarily on those variables that are tightly connected to production safety.

To extract these key variables, we collect a list of key variables from the HAZOP analysis table. The structure of the HAZOP analysis table is shown in Table 1. The HAZOP analysis report provides risk data on the occurrence probabilities of causes and consequences for a specific unit's risk scenarios, which are determined through brainstorming sessions by an expert panel. In the HAZOP analysis process, expert panels analyze all nodes in the P&ID diagrams and evaluate the risks in the process based on deviations observed in DCS data. We extract high-risk variables identified by the expert group during the HAZOP analysis, and then select these variables from the thousands of DCS data points for causal discovery.

After preprocessing, the study employs a Time-series Transformer model to capture generalized Granger causality relationships between process variables and construct the structural backbone of the BN. The Transformer architecture utilizes a self-attention mechanism to compute an attention weight matrix that quantifies the influence of historical states of variable $j$ on the future state of variable $i$. This influence is expressed as the attention weight $\alpha_{ij}$. By setting a significance threshold $\delta$, if $\alpha_{ij}>\delta$, a causal link from node $j$ to node $i$ is determined. The algorithm iterates through all pairs of process variables, generating an adjacency matrix that describes the global causal relationships of the system. This matrix is directly transformed into a directed acyclic graph (DAG) of the Bayesian network, successfully identifying implicit control loop couplings. This approach not only significantly reduces the time cost of manual network construction but also ensures the objectivity and accuracy of the network structure.

## 3.2 Mapping Risk Events from HAZOP to BN

Relying solely on node identifiers is insufficient to fully capture all the risks in a chemical process. To comprehensively reflect all risks and their evolution paths within the system, we match key node identifiers from the HAZOP report to potential causes and consequences of deviations, as well as the protective measures within the risk evolution paths. Using text normalization techniques, specific matching rules are established to link the risk causes, consequences, and protective measures from the HAZOP analysis table to the deviations of key variables. This enables the exploration of the risk evolution path, where risk sources cause deviations in key variables, bypass protective measures, and ultimately lead to severe consequences. This process forms a Bayesian network that incorporates risk causes, consequences, protective measures, DCS variables, and risk outcomes.

## 3.3 Automated Extraction of Risk Data for BN Initialization

To accurately obtain the occurrence probabilities of causes and consequences, as well as the Probability of Failure on Demand (PFD) of protection layers, the method extracts failure data from the OREDA database, SIL verification reports, and HAZOP analysis reports, constructing a comprehensive and targeted database. SIL verification reports provide failure probability analyses of protection measures for a specific unit, confirmed through expert discussions based on national standards, industry guidelines, and expert experience, thus providing targeted reliability data for protection layers. HAZOP analysis reports contain risk data on the occurrence probabilities of causes and consequences for unit-specific risk scenarios, determined through expert brainstorming sessions and analyzed according to the HAZOP procedure and expert judgment, offering targeted risk assessment data. The OREDA database, a widely used Norwegian reliability database, supplements failure probability data and risk assessment information that may not be

**Table 1:** Structure Example of a HAZOP table

| Designator | Deviation | Cause | Protection Layer | Consequence | Probability | Severity |
|---|---|---|---|---|---|---|
| FI10101 | High | HV10101 closed on failure | The feed will be cut off by interlock TICA10101. | Resulting in regenerator overtemperature. | 3 | 5 |
| TI10103 | High | R0102 broke down | The settler is equipped with multiple-point temperature display. | The wax oil solidified, causing a pipeline blockage. | 2 | 2 |
| PIC10104 | Low | P0101 broke down | P0101 one as main, one as standby. | The knockout drum was damaged due to overpressure. | 3 | 5 |

captured in the SIL verification or HAZOP reports.

In the process of filling the BN with information from the database, a pre-classified Sentence-BERT (SBERT) algorithm is used to match entries, eliminating the need for manual risk probability assessment. The specific matching algorithm, as described in section 2.2, first classifies risk events into causes, protection measures, and consequences. This classification is pre-labeled according to the HAZOP analysis table during the insertion of causal events in section 3.2. The protection measures are further categorized by different equipment types, and the corresponding PFDs are matched from the database. Based on the risk event names in the Bayesian network, failure entries from the risk database are matched, allowing for the assignment of initial probabilities to risk events and completing the initialization of the Bayesian network.

### 3.4 Parameter Learning

After completing the initialization of the Bayesian network, parameter learning is performed using the Bayesian inference algorithm described in section 2.3. The initial probability distribution for risk event nodes is derived from data in the risk database, while a normal distribution is used as the initial probability distribution for critical node data. Actual accident occurrence data and DCS data are used as observational samples for parameter learning, allowing for the refinement of probability distributions and conditional probability tables (CPT) to better reflect real conditions.

### 3.5 Bayesian Inference

After the topology construction and parameter learning of the Bayesian causal network are completed, the network can be used for probabilistic inference. This network integrates risk event evidence with real-time DCS data streams to perform DRA. The inference can be performed in two modes, forward prognostic inference and backward diagnostic inference. By inputting observational data for a subset of nodes and evidence of initiating risk sources, the probabilities of different consequences can be inferred, enabling dynamic risk assessment. Conversely, given evidence of observed consequences, backward inference can be performed to trace and identify the most likely underlying causes that led to those outcomes.

## 4. CASE STUDY

The proposed automated Bayesian causal network construction method was applied to the fluid catalytic cracking process of a petrochemical enterprise in Zhejiang, China, to validate the feasibility of the approach.
