## PREFACE

**Introduction** ..... **xxiii**
Solomon F. Brown

**Peer Review Policy** ..... **xxiv**

**International Scientific Committee** ..... **xxvi**

## PEER REVIEWED CONFERENCE PROCEEDINGS

### Section 1: CAPE in Circular Economy

**Circular Zero Liquid Discharge Systems with Renewable Energy Integration: A Technoeconomic Assessment** ..... **2**
Fatima Mansour, Sabla Y. Alnouri, Sabah Solim, Ali Al-Sharshani, and Dhabia Al-Mohannadi

**Development of a Novel Microwave-assisted Process that Converts Mixed Plastic Waste to Olefins and Aromatics** ..... **11**
Aseel Al-Sakkaf, Chunlin Luo, Yuxin Wang, and Srinivas Palanki

**Process-Informed Design of Electrochemical Cells for Urea Production: A Techno-Economic and Systems Engineering Approach** ..... **18**
Zhimian Hao, Shilong Fu, Chengtian Cui, Ruud Kortlever, Ruud van Ommen, and Ana Somoza-Tornos

**Computed-Aided Design of an Intensified Process for the Sustainable Production of Biodiesel from Waste Cooking** ..... **25**
Tania G. Salgado-Rodríguez, Fernando I. Gómez-Castro, and Nelly Ramírez-Corona

**Integrated Multiproduct Facility for the Green Production of Chemicals and Food from Apples** ..... **31**
Vanessa Villazón-León, Carlos Sanz, Adrián Bonilla-Petriciolet, and Mariano Martín

**Hybrid Modeling of a Sewage-Sludge Gasifier using Flowsheet Simulation and Machine Learning** ..... **37**
Malte Lutz, William Würpel, Fabian E. Habicht, Burcu Aker, and Jan C. Schöneberger

**Lifetime-Adjusted LCA of Biochemical and Thermochemical Circular Plastic Pathways** ..... **45**
Alexandra Krestnikova and Gonzalo Guillén-Gosálbez

**Optimization of Circular Supply Chains for Electric Vehicle Batteries** ..... **52**
Kaapo Kopra and Iiro Harjunkoski

**Integration of carbon dioxide capture in a wine effluent biorefinery through the use of deep eutectic solvents** ..... **59**
Carlos E. Guzmán Martínez, Valeria Caltzontzin Rabell, Sergio I. Martínez Guido, Salvador Hernández, and Claudia Gutiérrez Antonio

**Techno-economic feasibility of gallium recovery from semiconductor wastewater** ..... **68**
Kilian Kozerke, Thomas Eberius, and Nathanial J. Cooper

**Integrated solvent and process design with technoeconomic and lifecycle assessment for solvent-based recycling of end-of-life vehicle plastics** ..... **77**
Riccardo Standish, Jian Yin, Jakob Burger, Mirjana Minceva, Hannah Mangold, Christian Holtze, Markus Schoerner, Bernhard von Vacano, Amparo Galindo, George Jackson, and Claire S. Adjiman

**From Waste to Clean Energy: Techno-Economic and Circular Assessment of Biomass-Based Hydrogen Production and Ammonia Storage through Syngas Chemical Looping** ..... **87**

**Advancing Circularity in Biopharma: Leveraging Industrial Symbiosis for Resource Efficiency** ..... **94**
Miriam Sarkis, Andrea Bernardi, Cleo Kontoravdi, and Maria M. Papathanasiou

**Beyond Decarbonization: Quantifying Circularity in Energy System Planning** ..... **100**
Javiera Vergara-Zambrano and Styliani Avraamidou

**Hybrid Modelling of Segmented Flow Extraction Process for Digital Twin Development in Critical Metals Recovery** ..... **108**
Arun Pankajakshan, Konstantinos Katsoulas, Malik Olasinde, Cong Chao, Eric S. Fraga, Panagiota Angeli, and Federico Galvanin

**Life Cycle Modeling towards Regional Symbiosis for Valorizing Mixed-Lignocellulosic Biomass from Agriculture and Forestry** ..... **117**
Yasunori Kikuchi, Nobuhide Takahashi, and Satoshi Ohara

**Design and Assessment of Regional Symbiosis: A Case Study of Plant-oil Production in Japan** ..... **125**
Yukito Watanabe, Yuichiro Kanematsu, Hiro Tabata, Heng Yi Teah, Kousuke Hiromori, and Yasunori Kikuchi

**OpenAD-lib: Open-Source Framework for Uncertainty-Aware Anaerobic Digestion Digital Twins** ..... **131**
Benaissa Dekhici, Rohit Murali, and Michael Short

**Achieving Net-Zero Emissions in Industrial Parks Through Optimized Symbiotic Exchanges and Carbon Capture Utilization** ..... **143**

**Sustainable thermochemical conversion of waste plastics to olefins with reduced emissions** ..... **152**

**Techno-Economic Assessment and Optimisation of Self-Sufficient Biomethane Systems for Regional Decarbonisation** ..... **161**
Meshkat Dolat, Benaissa Dekhici, and Michael Short

**Dynamic material flow analysis of iridium circularity in proton exchange membrane water electrolysers in Japan** ..... **169**
Shu Yamaki, Ayumi Yamaki, Heng Yi Teah, Yuichiro Kanematsu, and Yasunori Kikuchi

**Value-Based Assessment for Strategic Selection and Optimization of POME Valorization Pathways** ..... **175**
Yiwei Gao, Heng Yi Teah, Yuichiro Kanematsu, and Yasunori Kikuchi

**Chemical Additives in Plastics: Understanding the Reactions, Fate, and Releases during Pyrolysis** ..... **183**
Ronald Borja-Roman, Andres Castellar-Freile, John D. Chea, Monica Rodriguez Morris, Gerardo J. Ruiz-Mercado, and Kirti M. Yenkie

**Banana peel as a Source of Polyphenols: Perspectives of Sustainability** ..... **192**
Kajal Chaudhary and Soumyajit SEN GUPTA

**A Whole Systems Thinking Model Towards Optimal Decarbonization Strategies for China's Cement Sector** ..... **198**
Yushu Wang, Wenli Du, Minglei Yang, and Vassilis M. Charitopoulos

**A Decision-Support Framework for Process Design of Sustainable Aviation Fuel Production via Integrated Biorefineries** ..... **205**
Vibhu Baibhav, Daniel Florez-Orrego, and Francois Maréchal

**Modeling standardized industrial profiles for the optimization of eco-industrial parks** ..... **215**
Dilafruz Mavlanova, Marianne Boix, Rachid Ouaret, and Stephane Negny

**Understanding Environmental Impacts of Lithium-Ion Battery Recycling** ..... **222**

Marco Vaccari, Leonardo Tognotti, and Monica Puccini

**Accelerating Design of Chemical Recycling of Plastic Waste through Digitalization: A Bubbling Fluidized Bed Reactor Case Study ..... 229**
Stefano Iannello, Vassilis M. Charitopoulos, and Massimiliano Materazzi

**Principal Component Analysis (PCA) for Evaluation of Fatty Acid Monoalkyl Ester (FAME) Quality towards Sustainable Biodiesel Production from Indonesian Microalgae Strains ..... 236**
Dea Nilam Mustika and Dimitrios I. Gerogiorgis

## Section 2: CAPE in Clean Energy Systems

**A MIBLP model for a Northern European negative-emission hydrogen supply chain with CCS in the North Sea 244**
Matthias Maier, Sungho Shin, Simon Roussanaly, and Thomas A. Adams II

**Integration of exergy and economic optimization for green hydrogen and power co-generation based on sorbent-enhanced biogas reforming with CO2 capture ..... 252**
Arthur-Maximilian Báthori and Calin-Cristian Cormos

**Green Hydrogen Supply Chain Design Towards Social Sustainability: A Case Study in Brazil..... 259**
Leonardo Santana, Fernando Pessoa, and Ana Barbosa-Póvoa

**Sustainable Design of an Integrated Seawater-Based Green Hydrogen Production Process .....267**
Antonio Torres-Ayala, Eduardo Sánchez-Ramírez, Marcelino Carrera-Rodríguez, and Juan Gabriel Segovia-Hernández

**Net Carbon Balance (NCB): a Better Way to Evaluate and Optimize Carbon Capture Technologies ..... 274**
André F. Young, Aline R. Eckstein, Leonardo D. Ferreira, Vítor M. Sermoud, and Ingrid A. de Oliveira

**Multi-Scale Design for Clean Energy Systems: Industrial Electrification and Flexible Operation of Ammonia Synthesis ..... 282**
Nicholas N. Kalamaris and Christos T. Maravelias

**Optimizing Renewable Energy Storage Systems to Accelerate Sustainable Data Center Deployment ..... 289**
Matthew J. Palys and Prodromos Daoutidis

**Temporal aggregation bias in model-based Direct Air Capture performance under weather variability .....297**
Eleni Chalasti, Gbemi Oluleye, Maria M. Papathanasiou, and Ronny Pini

**Dynamic Optimization of an Adsorption Heat Storage to satisfy the Heat Demand of a House ..... 306**
Alix Untrau, Lorenz T. Biegler, and Sabine Sochard

**Direct iron reduction system analysis with mixture of hydrogen feed.....314**
Marwa Mortadi, Carl Haikarainen, Guanwei Zhou, and Henrik Saxén

**Optimization of Site-wide Heat-Integrated Utility Systems with Heat Pumps using MILP..... 320**
Thorben Hochhaus, Marcus Grünewald, and Julia Riese

**Investigating the Effects of Heat Ingress and Tank Motion on the Ullage Space of a Partially Filled Liquid Hydrogen Tank Using CFD ..... 328**
Anna Pakarinen and Anders Brink

**Development of a methodology for heat pump-based heat integration in batch processes..... 334**
Johannes Wloch, Marcus Grünewald, and Julia Riese

**Pareto-Optimal Pathways for Refinery Decarbonization: Retrofit of Small Modular Nuclear Reactors..... 342**
Aditya S Khatu, Sampriti Chattopadhyay, and Ana I Torres

**Exploring the Thermal Coupling of Solid Oxide Electrolysis and Ammonia Synthesis: A Plantwide Energy Integration Assessment ..... 352**
Alessandra Macchi, Federica Longobardi, Régis Anghilante, Andrea Isella, and Davide Manca

**Techno-Economic Assessment of Decarbonization Pathways for Methanol and Formaldehyde Production: A Superstructure Optimization Approach ..... 360**
Rafailia Mitraki, Muhammad Salman, and Grégoire Léonard

**Integrated Operating Strategies and Parameter Optimization for PEM Electrolyzers in Power-to-X Energy Systems**
**Luka Bornemanna*, Yifan Wangb, and Martin Kaltschmitta ..... 369**
Luka Bornemann, Yifan Wang, and Martin Kaltschmitt

**Evaluating the Potential of Sustainable Aviation Fuel for Decarbonization of the Aviation Sector: An Agent-based Model ..... 378**
Geeta Joshi, Tejeswi Ramprasad, Harmandeep Singh, Narayanan Rajaraman, Vikrant Urade, Arnoud Higler, and Rajagopalan Srinivasan

**A Data-Driven Optimization Framework for the Design and Operation of Adaptive and Resilient Energy Supply Chain Networks under Uncertainty ..... 386**
Halil Iseri, Funda Iseri, Mahmoud El-Halwagi, Eleftherios Iakovou, and Efstratios Pistikopoulos

**Powering AI Beyond the Grid: Optimal allocation and Behind the Meter Investment Portfolios for Data Centers396**
Mohamed Abdelhady, Eleftherios Iakovou, and Efstratios N. Pistikopoulos

**Evaluating the potential of e-fuels for decarbonizing European truck transport: A techno-economic and life cycle approach ..... 404**
Marion Andritz, Severin Sendlhofer, Rafailia Mitraki, Grégoire Léonard, and Christoph Markowitsch

**Integration of computer aided design and emerging technology development based on a series of scale-up demonstration tests; Case study of thermal energy storage .....413**
Shoma Fujii and Yasunori Kikuchi

**Optimizing Heat Storage Integration for Solar Thermal Systems in Industrial Process Heat Networks.....419**
Håvard Falch, Henri Tande Espen, and Rahul Anantharaman

**Energy planning towards absolute environmental sustainability: identifying key demand-side sufficiency levers to stay within planetary boundaries using sensitivity analysis tool ..... 424**
Nicolas Ghuys, Diederik Coppitters, Anne van den oever, Mahdi Kchaou, Hervé Jeanmart, and Francesco Contino

**Assessing the potential of vehicle-to-grid (V2G) systems using dynamic simulation and life cycle assessment ..... 432**
Ayumi Yamaki and Yasunori Kikuchi

**Techno-economic assessment of green ammonia plants with multi-scale capacity ..... 440**
Ruitao Sun and Jie Li

**Terawatts for Petabytes: Exploring the impact of AI data centres on Europe's net zero goals ..... 446**
Mohammad Hemmati and Vassilis M. Charitopoulos

**Simulation of Methanol Production from Biogas: Impact of Feedstock Composition and Stoichiometric Number Adjustment ..... 454**
Muhammad Zulkefal, Magne Hillestad, Truls Gundersen, and Bjørn Austbø

**Strategic Design of CO2-Reuse Pathways for Sustainable Aviation Fuel: A Game-Theoretic Techno-Economic Analysis..... 462**
Andrés I. Cárdenas, Víctor A. Soria, and Ana I. Torres

**Feasibility of Integrating Sugarcane-Derived Biogas into the Allam–Fetvedt Cycle for BECCS Power Generation ..... 470**
João Pedro B. Vasconcelos, Miguel D. Carvalho, and Jean F. Leal Silva

**Optimising Waste-to-Energy Power Generation in Trinidad and Tobago ..... 477**
Sherard Sadeek, Thomas Hart, Arun Mangra, Daniel Chernick, Andrew Ross, Dhurjati Prasad Chakrabarti, Maria M. Papathanasiou, and Keeran Ward

**Harnessing waste heat in the optimal operation of power-to-X energy systems using detailed process models ..... 483**
Yifan Wang, Luka Bornemann, and Niklas von der Assen

**Comparative Life Cycle Assessment of Electrochemical and Conventional Regeneration Pathways in KOH-Based Direct Air Capture Systems ..... 492**
Georgia Ioanna Prokopou, Zoi Drakopoulou, Dominik Bongartz, and Alexander Mitsos

**Comparative Techno-economic and Environmental Evaluation of Single-Step vs. Dual-Step CO2-to-Methanol Processes using Multiobjective Optimization ..... 500**
Biswarup Mondal, Johannes Leipold, and Achim Kienle

**A Multi-Objective Optimization and Superstructure-Based Decision-Support Tool for Regional Low-Carbon Hydrogen Roadmaps: Methodology and Application to a region of Spain ..... 507**
Silvia Moreno, Alejandro Aragón-García, Ángel L. Villanueva-Perales, Bernabé Alonso-Fariñas, and Pedro Haro

**Electrified refineries in the Power Flow Network ..... 514**
Sampriti Chattopadhyay, Ana I. Torres, Ignacio E. Grossmann, and Saif R Kazi

**Techno-economic Analysis of Alternatives for Carbon Capture and Utilization and Green Ammonia Production from a Cement Plant Flue Gas ..... 526**
Miguel A. Pedro, Ana S. Amorim, and Henrique A. Matos

**CFD-based optimal design of a portable and stackable alkaline water electrolyser for hydrogen production ... 534**
Akepogu Venkateshwarlu, Gianluca Li-Puma, and Brahim Benyahia

**Modeling and experimental validation of a flat-conduit dense-phase receiver for concentrated solar power ... 543**
Mustapha Hamdan, Malak Hamdan, Bogdan Dorneanu, and Harvey Arellano-Garcia

## Section 3: CAPEing with Uncertain Futures

**The Value of Multi-Stage Stochastic Programming in Power Grid Capacity Expansion Planning ..... 550**
Sergio Bugosen, Tomas Valencia, Jean-Paul Watson, Chrysanthos E. Gounaris, and Carl D. Laird

**Designing in an Unpredictable World: Novel Methods for Uncertainty Characterization, Quantification, and Optimization in Process Engineering ..... 558**
Diederik Coppitters, Antoine Laterre, Mahdi Kchaou, Kevin Verleysen, Panagiotis Tsirikoglou, Jerome Stock, Matthias Weigold, Konstantinos Kyprianidis, Ward De Paepe, and Francesco Contino

**Enhancing Interpretability of Stochastic Programming Solutions: A Multiparametric Approach ..... 567**
Parth Brahmbhatt and Styliani Avraamidou

**Exploring Robust Early-Stage Decisions in Energy Transitions Using Near-Optimal Pathways and Multi-Armed Bandits ..... 574**
Mahdi Kchaou, Diederik Coppitters, and Francesco Contino

**Optimization-based Design, Simulation and Data-Driven Learning for Resilient Manufacturing Systems ..... 583**
Miriam Sarkis and Efstratios Pistikopoulos

**A Machine Learning Implementation for Fermentation Quality Prediction in Wine Manufacturing ..... 592**

Matthew A.J. Hill and Dimitrios I. Gerogiorgis

**Global Optimization of Robust AC OPF** ..... **602**
Yuhui Yin and Vassilis M. Charitopoulos

## Section 4: Pharmaceutical and Biotechnological Systems

**Uncertainty-Aware Model Validation Framework for Pharmaceutical Process Development** ..... **611**
Kensaku Matsunami, Yash Barhate, and Zoltan K. Nagy

**Comparison of Centralised and Decentralised Pharmaceutical Manufacturing Paradigms: An Agent-Based Simulation Study** ..... **618**
Farshid Babaei, Mohammad Salehian, David Robins, Cameron J. Brown, Daniel Markl, Alastair J. Florence, and Solomon Brown

**Developing predictive models for batch cooling crystallization of APIs with limited data availability** ..... **625**
Mauro Davanzo, Emanuele Tomba, Enrico Carlassare, Riccardo Motterle, Massimiliano Barolo, Zoltan K. Nagy, and Fabrizio Bezzo

**An in silico/in vitro approach for uncertainty-aware hybrid models for template-induced protein crystallisation systems** ..... **631**
Daniele Pessina, Jerry Y. Y. Heng, and Maria M. Papathanasiou

**Capturing mixing effects on aggregation kinetics of monoclonal antibodies during viral inactivation** ..... **640**
T. Marella, F. Cenci, P. Thompson, M. Muhieddine, and F. Bezzo

**A Generative AI Approach to Inverse Design for Continuous Pharmaceutical Manufacturing** ..... **648**
Consuelo Del Pilar Vega-Zambrano and Vassilis M. Charitopoulos

**Development of Symbolic Regression-Based ATR-FTIR Calibration Models** ..... **655**
Fernando A. R. D. Lima, Inga S. Nordhus, Marcellus G. F. de Moraes, M. Enis Leblebici, Argimiro R. Secchi, Mauricio B. de Souza Jr., and Idelfonso Nogueira

**Beyond Solid-Phase: Comparative Assessment of Liquid Phase Oligonucleotide Synthesis with Single- and Dual-Stage Diafiltration** ..... **664**
Alberto Saccardo, Rachel Ha, Zoe Fang, and Benoît Chachuat

**In silico solvent selection for green and cost-effective pregabalin crystallisation** ..... **672**
Matthew Blair and Dimitrios I. Gerogiorgis

**Molecular Similarity Coefficient in Chemical Design and Analysis** ..... **681**
Youquan Xu, Zhijiang Shao, Abdulelah S. Alshehri, Mansour S. Alhoshan, and Anjan K. Tula

**Pareto Front Guided Sampling for Efficient Bioprocess Experimentation** ..... **692**
Stricker Samuel, Lucas Francisco dos Santos, Claus Wirnsperger, Alessandro Butté, Antonio del Rio Chanona, Mehmet Mercangöz, and Gonzalo Guillén Gosálbez

**Sensitivity-Based Comparison of Resource Competition Models for Optogenetic Gene Circuit Design** ..... **702**
Pratham Kapavarapu, Satyajeet S. Bhonsale, Simen Akkermans, and Jan F.M. Van Impe

**Genome to Production: A Multiscale Model for Bioprocess Design** ..... **709**
Rajiv Kailasanathan, Mohammad Reza Boskabadi, Abhishek Sivaram, and Seyed Soheil Mansouri

**Modelling & optimization of recombinant protein production in a microbial cultivation with tunable induction** ..... **714**
Philipp Pably, I Gede Eka Perdana Putra, Gerd Seibold, Jakob K. Huusom, and Julian Kager

**Automatic kLa determination in stirred tank reactors by model-based design of experiments** ..... **721**
Ana Helena V. Caetano, Krist V. Gernaey, and Julian Kager

**Decarbonizing API Manufacturing: Conceptual Design and Scale-up Analysis of Continuous-Flow Electrosynthesis for Ibuprofen Production** ..... **727**
Tuse Asrav, Merlin Alvarado-Morales, and Gürkan Sin

**A Multi-Level Hybrid EKF–Machine Learning Soft Sensor for Robust Bioprocess Monitoring** ..... **733**
Mohammad Reza Boskabadi, Rajiv Kailasanathan, Luis Ricardez-Sandoval, and Seyed Soheil Mansouri

**Understanding the Impact of Ribbon Splitting on Tablet Properties Using a Hybrid Mechanistic–Machine Learning Framework** ..... **742**
Shumaiya Ferdoush, Mohammad Shahab, Xinle Zhang, Jayden A. Pierce, Emma Jeffries, Adaugo Ufomba, Zoltan K. Nagy, Gintaras V. Reklaitis, and Marcial Gonzalez

**Physics-Informed Neural Networks for NIR Spectroscopy Analysis of Pharmaceutical Tablet Properties** ..... **751**
Xinle Zhang, Shumaiya Furdoush, Marcial Gonzalez, and Gintaras V. Reklaitis

**Probabilistic design spaces from small DoEs – A boundary-focused workflow using quantile surrogates** ..... **756**
Tobias Overgaard, Emmanouil Papadakis, Maria-Ona Bertran, and Maria M. Papathanasiou

**Influence of Surface Properties on Poly(3-hydroxybutyrate) Biodegradation Dynamics: Experimental and Modelling Insights Using Aspergillus fumigatus** ..... **763**

**Combined PBM-PBPK Modeling for Optimized Integrated Oral Solid Dosage Form and Dosing Strategy Design** **769**
Meng-Hua Yang, Francesco Rossi, Gintaras V. Reklaitis, and Zoltan K. Nagy

**Experiments & Modelling of Batch Fermentation of Fusarium venenatum on Glucose-Fructose Mixtures** ..... **776**
Tom Vinestock and Miao Guo

**Towards Digital Threads for FAIR, Trustworthy, and Human-Centric Bioprocess Development** ..... **783**
Jonas M. Karsten, Ernesto C. Martínez, and Mariano N. Cruz Bournazou

**Safe and Sustainable by Design Pharmaceuticals through Combined Computer-Aided Retrosynthesis, Techno-Economic Analysis, and Life Cycle Assessment** ..... **791**
Shang Gao and Brahim Benyahia

## Section 5: Modelling and Simulation

**An Open-Source IDAES Framework for Simulating Inductively Heated Adsorption Processes** ..... **802**
Sudip Sharma and Thomas A. Adams II

**Development of a Predictive Model for Microbial Growth under Variable Conditions Using a Multilayer Perceptron Neural Network: Application to Candida guilliermondii** ..... **810**
Jazmín Cortez-González, Juan Gabriel Segovia-Hernández, Salvador Hernández, Varinia López-Ramírez, Arturo Hernández-Aguirre, and Rodolfo Murrieta-Dueñas

**Dynamic optimization of glucose feed in cell cultivation for monoclonal antibody production process design balancing productivity and impurity generation** ..... **816**
Kosuke Nemoto, Yuki Yoshiyama, Mizuki Morisasa, Junshin Iwabuchi, Yusuke Hayashi, Sara Badr, and Hirokazu Sugiyama

**Development of ANN-based models for dye removal through electrochemical advanced oxidation techniques** **822**
Zaira J. Mosqueda-Huerta, Oscar D. Lara-Montaño, Juan Manuel Peralta-Hernández, and Fernando I. Gómez-Castro

**Model Screening and Identifiability Analysis of Methanol Synthesis Kinetics: Information-Guided Evaluation of Operating Conditions** ..... **828**
Eblagh Ahmad, Biasin Alberto, Nardi Luca, and Federico Galvanin

**A Process Modeling Approach for Water and Energy Optimization in Geologic Hydrogen Extraction ..... 838**
Caroline Kaitano and Thokozani Majozi

**Optimal Simulation of an Electrodialysis Reactor for the Desalination and Regeneration of Multi-Ionic Wastewater ..... 846**
Vicent Ayala-Andreu, Miguel A. Montiel, Vicente Montiel, and Juan A. Labarta

**A Data-Efficient Symbolic Regression Framework for Automated Interpretable Bioprocess Modelling ..... 855**
Luca Riezzo, Alexander Rogers, Harry Kay, and Dongda Zhang

**Modelling Pressure Effects in Boiling Brazed Aluminum Heat Exchangers: A Software Comparison .....861**
Hamza Karim, Rim Khodr, Rodolphe Sardeing, and Gaëtan Becker

**From Drift to Adaptation to the failed ML model: Transfer Learning in Industrial MLOps ..... 870**
Waqar Muhammad Ashraf, Talha Ansar, Fahad Ahmed, Jawad Hussain, Muhammad Mujtaba Abbas, and Vivek Dua

**Design of a Chemical Heat Pump based on Methylcyclohexane, Toluene and Hydrogen ..... 879**
Rajalakshmi Krishnadoss, Félix Le Bot, and Thomas A. Adams II

**An Integrated Process of Multi Effect Distillation Based Desalination with Renewable Energies: Evaluation of Power Generation Efficiency and Freshwater Production Cost..... 886**
Mohammed Adam, Mudhar A. Al-Obaidi, and I. M. Mujtaba

**Dynamic Modelling of Renewable-driven CO2 Methanation using Recurrent Neural Networks ..... 895**
M. Andrea Pappagallo, Diego A. Romero Lombo, Mattia Vallerio, and Emanuele Moioli

**Chemical Language Transformers for the Inverse Design of Novel Surfactants..... 903**
Alexander W. Rogers, Ruediger Zillmer, Amanda Lane, Adam Kowalski, and Dongda Zhang

**A Modeling Framework Integrating Data Trends and Reference Information for Predicting Temperature-Dependent Thermophysical Properties .....910**
Shuai Zhang, Abdulelah S. Alshehri, Mansour S. Alhoshan, and Anjan Tula

**Exploring Molecular Pretraining and Mechanism-Aware Modeling for Reaction Yield Prediction .....919**
Yongkyu Lee, Won Bo Lee, and Lauren Ye Seol Lee

**Synergistic integration of direct air capture in bioenergy systems.....927**
Nor Syuriaty Jaafar, Norhuda Abdul Manaf, Noor Fatina Emelin Nor Fadzil, and Nilay Shah

**An Adaptive Framework for Robust Energy Forecasting under Concept Drift and Feature Uncertainty ..... 934**
Francesco Marcato, Alessio Santecchia, Manuel Ruivo de Oliveira, Francesco Silvestri, and Rafael Castro-Amoedo

**Analysis and comparison of technologies for the regeneration of a capture solution in DAC absorption systems ..... 943**
Grazia Leonzio and Nilay Shah

**From Plastic Waste to Platform Chemicals: Aspen Plus Modeling of Polystyrene Conversion Through Hydrothermal Processing into Value-added Chemicals ..... 950**
MohammadSina HajiHashemi, Corinna Schulze-Netzer, and Thomas A. Adams II

**Uncertainty Prioritisation for Water-Energy-Food-Land Nexus Optimisation..... 958**
Md Shamsul Alam, I. David L. Bogle, and Vivek Dua

**Data Transformation Techniques and its Influence in Hybrid Model Performance ..... 964**
Juan Federico Herrera-Ruiz, Carlos Eduardo Robles-Rodriguez, Cesar Arturo Aceves-Lara, Javier Fontalvo, and Oscar Andrés Prado-Rubio

**Simulation and analysis of carbon capture process using piperazine for large scale biomass-fired power plant 972**
Shengyuan Huang, Olajide Otitoju, Yao Zhang, and Meihong Wang

**Differentiable Programming for Cyclic Adsorption Processes ..... 978**
Alex Glover, Maria M. Papathanasiou, and Ronny Pini

**Bayesian Optimization Framework for Agrochemical Formulation Design ..... 986**
Yipei Zhao, Robin Wesley, and Joan Cordiner

**Variational Bayesian Neural Networks for Modelling and Uncertainty Quantification in Bioprocessing..... 992**
George Spencer, Harini Narayanan, Claus Wirnsperger, Alessandro Butté, Cleo Kontoravdi, and Maria M. Papathanasiou

**Multi-objective simulation-based optimisation of pharmaceutical process systems .....1001**
Artemis Tsochatzidi, Francesca Cenci, Magdalini Aroniada, and Lazaros G. Papageorgiou

**Modeling, Simulation, and Optimization of an Anion Exchange Membrane Cell for Ammonia Electrolysis .....1007**
Laureen E. Hernández Lefrán, Leonardo A. Cáceres Avilez, Antonio E. Bresciani, Claudio A. Oller do Nascimento, and Rita M. Brito Alves

**A Coarse-Graining Algorithm for Complex Chemical Reaction Networks .....1014**
Yi Tao and Tong Qiu

**Automated Construction of Bayesian Networks of Chemical Process for Dynamic Risk Assessment .....1022**
Kai Yin, Hao Kang, and Jinsong Zhao

**CO2 Conversion: Three-Dimensional Modelling of Gas Diffusion Electrodes ..... 1030**
Cristina González-Fernández, Camilo Peralta, Jose Antonio Abarca, Esther Santos, Guillermo Díaz-Sainz, and Ángel Irabien

**Comparative analysis of waste tyre gasification using biogas-air/O2 and steam-air/O2 mixtures..... 1036**

**Multiscale Modeling of PHBV Production: Explicit Polymerization Modeling and Improved Prediction of Chain Length Distributions..... 1043**
Stefan Hempfling, Rudolph Kok, Stefanie Duvigneau, Achim Kienle, and Robert Dürr

**Evaluating Extrapolation of Modular Hybrid Process Models for Pilot-Scale Batch Separation Processes..... 1050**
Søren Villumsen, Jakob K. Huusom, Xiaodong Liang, and Jens Abildskov

**Exploiting Input-Space Separation in Kolmogorov–Arnold Networks to Prevent Catastrophic Forgetting in Industrial NIR Systems ..... 1058**
Imam M. Iqbal, Isabell Viedt, and Leon Urbas

**Renewables to X: Micro-Reactor Pathways towards Methanol and Dimethyl Ether Production ..... 1064**
David T. Hren and Andreja Nemet

**Dynamic modeling of fouling development during dead-end filtration of dusty superheated steam .....1073**
Felipe de Oliveira, Wijtze Nijhuis, Marcel Meinders, and Edwin Zondervan

**Robust Design of Transient Flow Experiments for the Identification of Kinetic Models in Flow Reactor Systems with Catalyst Deactivation..... 1080**
Jinwen Cui and Federico Galvanin

**Process modelling and multi-objective optimisation of solid sorbent-based direct air capture..... 1088**
Toluleke E. Akinola and Meihong Wang

**Uncertainty Quantification of Stochastic Gene Expression..... 1095**
Francisca Pizarro Galleguillos, Satyajeet S. Bhonsale, and Jan F.M. Van Impe

**Practical Identifiability and Optimal Experiment Design for Hybrid Cybernetic Models: An E.Coli Case Study . 1102**
Stylianos Floros, Satyajeet S. Bhonsale, Simen Akkermans, and Jan F.M. Van Impe

**Semi-Supervised Generative Augmentation Improves Surfactant Surface Tension Prediction from Limited Experimental Data ..... 1111**
Gabriela C. Theis Marchan, Kyle Territo, and Jose A. Romagnoli

**A CFD Analysis of Dielectric Fluid Performance in Thermal Management of Li-ion Cells .....1119**
Margarita G. Correa-Ibarra, Jorge A. Alfaro-Ayala, Jose de J. Ramirez-Minguela, Zeferino Gamiño-Arroyo, and Agustin R. Uribe-Ramirez

**Simulation of Fixed-Bed Reactor System for Combined Ca–Cu Chemical Looping with Integrated Combustion and CO2 Capture ..... 1127**
Levente Biró, Norbert-Botond Mihály, and Ana-Maria Cormos

**Comparison of Various Hydrogen Flux Trajectories in a Catalytic Membrane Reactor Operating Dehydrogenation of Ethylbenzene to Styrene..... 1135**
Nabeel S. Abo-Ghander

**A Neural Model of Pinch-Based Multicomponent Distillation for Applications in Flowsheet Synthesis..... 1145**

Jessica V. Scheffer, Serena Delgado, Olivier Authier, Valentin Loubière, Franchine Ni, Christophe Castel, and Jean-Marc Commenge

**An End-to-End Pure Component Property Prediction Framework Based on a Hierarchical Molecular Fragmentation Method ..... 1634**
Jianfeng Jiao and Jie Li

**Global Optimization of a Hydrodealkylation Flowsheet through Spatial Decomposition with SNoGloDe ..... 1643**
Madeline Leppla, Georgia Stinchfield, Norman Tran, and Carl D. Laird

**Superstructure Framework for Feasibility and Flexibility Analysis Methods in Modular Plant Design ..... 1650**
Julian Pamperin, Jonathan Mädler, Amy Koch, Isabel Viedth, and Leon Urbas

**Process Flowsheet Synthesis via Quantum Reinforcement Learning with Improved Scalability ..... 1659**
Austin Braniff, Fengqi You, and Yuhe Tian

**A Unified Multi-Scale TCN Framework for Batch Manufacturing Soft Sensing and Monitoring ..... 1666**
Yee Hung Hong and Zhao Jinsong

**Optimizing the Solubility of Organic Molecules in Mixed Solvents Using Bayesian Optimization and Multicomponent Directed-Message Passing Neural Networks ..... 1679**
Simona Buzzi, Ulderico Di Caprio, Dominik Bongartz, and Florence Vermeire

**Coupling Analytical Derivatives with Adjoint Automatic Differentiation in a Modular Process Simulator ..... 1687**
Andrés Piña-Martinez and Jean-Marc Commenge

**Hand-crafted Feature Fusion for Deep Learning-Based Instance Segmentation in Microfluidics ..... 1696**
Wenle Xu, Lin Sheng, Qichen Shang, Mengqi Liu, Tong Qiu, Kai Wang, and Guangsheng Luo

**Methodology to assess the integrity of Water and Energy Integration Systems (WEIS) models using the ThermWatt computational tool ..... 1705**
Miguel Castro Oliveira, Rita Castro Oliveira, and Henrique A. Matos

**Targeted Olfactory Molecule Generation for Vanilla Scents Using Generative Flow Networks ..... 1713**
Bruno C. L. Rodrigues, Paul J. Groening, Laura Sisson, Mumin Enis Leblebici, and Idelfonso B. R. Nogueira

**A Strategy for Limiting the Effects of Nonconvexities in Mixed-Integer Nonlinear Programming Reformulation of Nonconvex Generalized Disjunctive Programs ..... 1721**
Miloš Bogataj, Chiara Železnik, and Zdravko Kravanja

**Beyond Tennessee Eastman: Benchmarking Deep Anomaly Detection on Real-World Pilot-Scale Continuous Distillation Data ..... 1728**
Fabian Hartung, Aparna Muraleedharan, Marius Kloft, and Jakob Burger

**From P&ID Drawings to Process Graphs: A Multimodal Language Model Approach ..... 1737**
Baikai Zhu, Samuel Duong, Javal Vyas, and Mehmet Mercangöz

**Task-Conditioned Hierarchical Representations for Controllable AI-Assisted Process Synthesis ..... 1746**
Ali Tarik Karagoz, Omar Alqusair, and Jie Li

**Recommendation System for Prediction of Adsorption Properties using Kernelized Probabilistic Matrix Factorization ..... 1754**
Gnaneshwar Sampathirao, Sasidhar Gumma, and Nabil Magbool Jan

**Optimizing MIP-Heuristics: Generic Formulation and Code ..... 1761**
Sophie Hildebrandt, Meik Franke, Edwin Zondervan, and Guido Sand

**A Large Language Model Enhanced Fault Diagnosis Framework for Chemical Processes ..... 1769**

Jingkang Liang and Gürkan Sin

**A Unified Python/JAX Framework for Thermodynamic Modeling, Nonlinear Solvers, and DAE Solution of Hydrocarbon Systems** ..... **1776**
Carlos C. Sanz and Galo Le Roux

**Digital Twin Supported FAIR Electronic Lab Notebooks for Simulated Experiments** ..... **1786**
Amy Koch, Isabell Viedt, and Leon Urbas

**Nonconvex Robust Optimization for Process Design with Artificial Neural Networks Embedded** ..... **1793**
Diego Izquierdo González, Basit Adeogun, Yuhui Yin, and Vassilis M. Charitopoulos

**Using Active Learning to Efficiently Calibrate Foundation Models on Raman Spectra in Upstream Bioprocess Fermentations** ..... **1801**
Christoph Lange, Ernesto Martínez, Peter Neubauer, and Mariano Nicolas Cruz Bournazou

**Utilizing Machine Learning for Phenomena-based Synthesis of Intensified Process Flowsheets** ..... **1809**
Omar Alqusair and Jie Li

**Separation of Concern Capabilities of Information Model Candidates for Modular Plant System Engineering Lines** ..... **1817**
Tobias Kock, Isabell Viedt, Amy Koch, and Leon Urbas

**A Framework for Flexible Start/Stop Operation of Electrified Chemical Processes** ..... **1825**
Samuel Mercer and Michael Baldea

**PhoSim V.0 - Towards A Digital Twin for an Industrial Wet-Process Phosphoric Acid Production** ..... **1833**
Ilias Bouchkira, Sanae Elmisaoui, and Abderrazak Latifi

**MatStudio: A Human-in-the-Loop Framework for Microstructure Segmentation with SAM-Guided Refinement** ..... **1841**
Yao Xue, Yanhu Wang, and Antonios Armaou

**Hybrid Multi-Task Learning for Sustainability-Aware Pharmaceutical Molecular Design** ..... **1847**
Yiming Ma, Shang Gao, and Brahim Benyahia

**Machine Learning-Assisted Multi-PAT Data Fusion for Physics Consistent Crystallization Monitoring** ..... **1856**
Yiming Ma, Xuming Yuan, and Brahim Benyahia

**Analysis of Ultrasound-Assisted Transesterification for Sustainable Biodiesel Production via Inline Raman spectroscopy** ..... **1866**
Ilias Bouchkira and Adel Mhamdi

**Evaluating and adapting modelling strategies for data-driven prediction of solvent effects on reaction barriers** ..... **1876**
Daeun Shin, Lingfeng Gui, Jonggeol Na, Won Bo Lee, and Lauren Ye Seol Lee

**GlycoPy: An Equation-Oriented and Object-Oriented Python Framework for Process Modeling, Optimization and Optimal Control** ..... **1884**
Yingjie Ma, Jing Guo, and Richard D. Braatz

**Automated workflow for the configuration of modular plants and HAZOP analysis by utilizing DEXPI P&ID** ..... **1891**
Mathias Schmitz, Janis Weber, and Norbert Kockmann

**Deep Learning for Fourier-Transform Infrared Spectroscopy Analysis: Polymer Identification and Oxidative Degradation Detection** ..... **1899**

**Accelerating Efficient Dimethyl Ether Synthesis through Machine Learning-Based Process Optimization** ..... **1908**

Mitra Jafari, Jefferson Santos da Silva, Wilson Sousa Mercês Neto, Lucas Fonseca Couto, Bogdan Dorneanu, Karen Valverde Pontes, and Harvey Arellano-Garcia

**Decomposition of MINLP Formulations in Process Family Design using Progressive Hedging ..... 1916**
Ali Asger, Bernard Knueven, and Carl Laird

**Physics Constrained Machine Learning for Modeling and Optimization of Chemical Process Systems .....1925**
Rahul Golder, Bimol Nath Roy, and M. M. Faruque Hasan

## Section 7: Process Design, Scheduling and Optimisation

**Effect of the feed composition on the performance of a double-dividing wall distillation column.....1933**
Carlos E. Guzmán-Martínez, Araceli G. Romero-Izquierdo, Claudia Gutiérrez-Antonio, Salvador Hernández, Massimiliano Errico, and Fernando I. Gómez-Castro

**System-Level CO2 Allocation under Supply Constraints in Industrial Clusters ..... 1943**
Razan Sawaly, Ahmad Abushaikha, and Tareq Al-ansari

**Virtual Plant–Model Pair as a Step Towards Real-Time Optimization of a Simulated Moving Bed System ..... 1950**
Guilherme C. Amaral, Alexandre F. P. Ferreira, Ana M. Ribeiro, Idelfonso B. R. Nogueira, and Diogo Rodrigues

**Rolling-Horizon Scheduling for Dynamic Market-Driven Operation of an Air Separation Plant.....1958**
Kieran McKenzie and Christopher L. E. Swartz

**Deep Kernel Learning with Kolmogorov–Arnold Networks for Bayesian Optimization .....1967**
Zhongtao Shang, Zhihong Yuan, Lifeng Zhang, and Yiyang Dai

**Machine Learning and Adaptive Sampling Powered Feasible Path Algorithm for Black-box Optimization .....1974**
Zixuan Zhang, Xiaowei Song, Jiaming Li, Yujiao Zeng, Yaling Nie, Min Zhu, Dongyun Lu, Yibo Zhang, Xin Xiao, and Jie Li

**Work and Heat Exchanger Networks as a General Energy-Integration Strategy for Chemical Processes .....1986**
José A. Caballero, Zinet Mekidiche-Martínez, and Juan A. Labarta

**Designing a Load-Flexible Renewable Ammonia Plant for Variable Green Hydrogen Supply.....1992**
Niklas Groll and Gürkan Sin

**A framework for dynamic rescheduling under disruptions and resource constraints..... 2001**
David Robins, Farshid Babaei, Joan Cordiner, and Solomon F. Brown

**Optimization of Large-Scale Lycopene Production from Tomato Waste: A Comparative Study of Different Processing Technologies.....2008**
Nereyda V. Hernández-Camacho, Fernando I. Gómez-Castro, Mariano Martín, Ehecatl A. del Rio-Chanona, and Oscar D. Lara-Montaño

**Auxiliary flexibility in an integrated green steel plant participating in Day-ahead and Intra-day electricity markets .....2015**
Santeri Vaara and Iiro Harjunkoski

**Development of a process modeling library for the design and optimization of beverage production plants... 2023**
Valentin Becher, Christian Prommesberger, Ulrike Paap, Anna Afanasev, Anna Bechtold, and Jörg Zacharias

**Discrete multi-criteria optimisation of a modular heterogeneous electrolysis system ..... 2029**
Hannes Lange, Lukas Furtner, Michael Große, Isabell Viedt, and Leon Urbas

**Optimizing Flexible Operation of Grid-Connected Electrolyzers: Storage Capacity as the Key to Economic Viability ..... 2036**
Julian Pamperin, Hannes Lange, Michael Große, and Leon Urbas

**Comparative Techno-Economic Assessment of Hybrid-Green Ammonia Layouts for Available-to-Date Decarbonization of the Fertilizer Industry** ..... **2045**
Andrea Isella and Davide Manca

**Optimizing Steam flux for Energy efficiency in Ammonia Recovery during Sodium carbonate production** ..... **2051**
Ediane S. Alves, Mohamad A. Chahine, Denis Guillaume, and Julien Gornay

**Structural Constraints with the P-graph Framework: Application to an Ammonia Synthesis Process** ..... **2058**
Darrick Hillaby, Andrés Piña Martinez, Jean-François Portha, and Laurent Falk

**High Performance Heat Pumps Using Tailored Refrigerants** ..... **2066**
Finlay M. Sandham, Andrew Muumbo, Kenneth Mathew, Sarthak Sinha, and Smitha Gopinath

**Generative AI for the optimal design of seawater desalination processes** ..... **2074**
Valentin ZARLENGA, Antonio ROCHA AZEVEDO, Alvaro MARTINEZ-TRIANA, and Thibaut NEVEUX

**Assessing the Impact of Solvent Recycling in Cooling Crystallization using Computer-Aided Molecular and Process Design** ..... **2082**
Gaurav Seth, Saman Naseri Boroujeni, Shubhani Paliwal, Amparo Galindo, George Jackson, and Claire S. Adjiman

**Reinforcement Learning-driven Process Intensification Synthesis – Design and Optimization of Reaction/Separation Systems** ..... **2091**
Dylan Nice, Daniel Wenck Ribeiro, Kristina Savitskaya, Rahul Bindlish, Efstratios N. Pistikopoulos, and Yuhe Tian

**A Graph Reinforcement Learning Framework for Batch Process Scheduling in State-Task Networks** ..... **2099**
Syu-Ning Johnn, Victor-Alexandru Darvariu, and Vassilis M. Charitopoulos

**Two-stage stochastic programming optimization of natural gas pipeline network under cost and carbon emission reduction** ..... **2107**
Huiyu Hao and Bohong Wang

**Optimization-based design of distillation processes with embedded pressure drop and HETP correlations** .... **2115**
Sina Bertram, Jonas Schnurr, and Mirko Skiborowski

**Data-Driven Multi-Objective Optimization of Energy, Environmental, and Economic Performances in Manufacturing with Physics-Consistent Deep Learning** ..... **2123**
Hyeonrok Choi, Jaewook Lee, Won Yang, and Seong-il Kim

**Joint Optimization of Feedstock Procurement and Production Planning in AD: A Deep Learning-Integrated Stochastic Programming Framework** ..... **2131**
Ruosi Zhang and Michael Short

**A Method for Uniquely Determining Robust Operating Conditions in Simulated Moving Bed Chromatography** **2140**
Kensuke Suzuki, Tomoyuki Yajima, and Yoshiaki Kawajiri

**Design of Fluid Distribution Devices Using Topology Optimization** ..... **2145**
Osamu Tonomura, Shunya Doi, Naohiro Akashi, and Ken-ichiro Sotowa

**An Extended Superstructure Formulation for Non-Isobaric Flowsheet Synthesis** ..... **2152**
Harrison A. Fraser, Smitha Gopinath, Jan Sefcik, George Jackson, Amparo Galindo, and Claire S. Adjiman

**Superstructure Optimization of CCUS Value Chain: Case Study on Sohar Freezone in Oman** ..... **2161**
Shaima Al-Salmani and Muhammad Abdul Qyyum

**Design Optimization of Shell-and-Tube Heat Exchangers Under Operational Uncertainty: A Comparative Study Across Three Paradigms** ..... **2170**
Fernando Israel Gómez-Castro, Sergio Iván Martínez-Guido, Claudia Gutiérrez-Antonio, and Oscar Daniel Lara-Montaño

**Reactor network synthesis of enzymatic cascades using superstructure optimization ..... 2176**
Swastik Chandra, Leandros Paschalidis, Siv Kinau, and Mirko Skiborowski

**Designing Multi-Objective Optimization Models for Vaccine Supply Chains: Economic, Environmental, and Social Trade-offs in the COVID-19 Context ..... 2183**
Jonathan Jair Cuevas Lopez, Sofía De-León Almaraz, Alberto A. Aguilar Lasserre, and Catherine Azzaro-Pantel

**Multiperiod optimisation of a European CCS supply chain under capture-cost uncertainty..... 2191**
José A. Álvarez-Menchero, Rubén Ruiz-Femenia, Raquel Salcedo-Díaz, and José A. Caballero

**Optimal Operation of an Alkaline Electrolyzer in an Industrial Setting Using Effective Linearization Techniques ..... 2201**
Jonaed Bin Mustafa Kamal, Loukas Kyriakidis, Saskia Bublitz, Bogdan Dorneanu, and Harvey Arellano-Garcia

**Set-based Formulations for the State Task Network Scheduling Problem ..... 2209**
David A. Liñán, Georgia Stinchfield, Carl D. Laird, and Jan Kronqvist

**Ammonia as Fuel for Gas Turbines – The Impact of Heat Integrated Partial Decomposition ..... 2218**
Julian Straus, John C. Morud, and Elettra Vantaggiato

**Research on Dynamic Scheduling of Multi-line Polyolefin Production Based on Deep Reinforcement Learning 2226**
Zhineng Tao, Tong Qiu, Zhenzhi Gong, Fenglian Dong, Zhi Wei, and Yunlong Guan

**Multi-Objective Optimisation of Pressure Swing Adsorption Systems via Symbolic Regression ..... 2234**
Carine Menezes REBELLO, Amilton Barbosa BOTELHO JUNIOR, Anderson Rapello DOS SANTOS, and Idelfonso B. R. NOGUEIRA

**GPU-Accelerated Nonlinear Multi-Period AC Optimal Power Flow for Large-Scale Power–Hydrogen Systems 2243**
Geunseo Song, Dirk Lauinger, Sungho Shin, and Jonggeol Na

**Foundation Model-Guided Optimization of Chemical Reaction Spaces for Autonomous Experimentation..... 2252**
Youhyun Kim and Jonggeol Na

**Techno-Economic Optimization of Electrified Airports as Collaborative Energy Hubs ..... 2261**
Mohammadreza Babaei, Stavros Vouros, Konstantinos Kyprianidis, and John D. Hedengren

**Particle Swarm Optimization for simultaneous design and optimization of heat pumps considering Mixed Integer problems ..... 2272**
Beatriz C. da Silva, Ana M. Ribeiro, Alírio E. Rodrigues, Alexandre F.P. Ferreira, Diogo Rodrigues, and Idelfonso B.R. Nogueira

**Techno-economic analysis of hydrogen refueling station with on-site production from a novel blue H2 and N2 production system..... 2280**
Adrian R. Irhamna and George M. Bollas

**Distributed low-carbon hydrogen for freight corridors: siting hydrogen refueling station with onsite production on New England highways ..... 2288**
Adrian R. Irhamna, Burcu Beykal, and George M. Bollas

**Superstructure Modelling of Membrane Systems for the Optimization and Flexible Design of Post-combustion Carbon Capture Processes ..... 2297**
Stefania Bempeli and Marina Micari

**Multi-scenario Optimization of Groundwater-Sourced Water Production Networks With Daily Well Shutdown Requirements..... 2303**
Pedro H. CALLIL-SOARES, René P. SCHNEIDER, and Galo A. CARRILLO LE ROUX

**Towards the Resilient Design of Power-to-Ammonia Systems via Linear Optimization Tools..... 2311**

José M. Pires, João Fortunato, Henrique A. Matos, and Diogo A. C. Narciso

**Transfer Learning–Enhanced Deep Probabilistic Surrogates for Scalable Multi-Fidelity Bayesian Optimisation in Process Design ..... 2320**
Jaewook Lee, Ethan Errington, and Miao Guo

**Optimal Biogas Utilization Planning in a Pig Farm Under Sustainability Indicators ..... 2327**
Jaime David Ponce-Rocha, Martín Picón-Núñez, César Ramírez-Márquez, José María Ponce-Ortega, and Ricardo Morales-Rodriguez

**Process design for the recovery of valuable organic compounds from pyrolysis oil aqueous phase ..... 2334**
Matteo Gilardi, Filippo Bisotti, Stefan Schmidt, Rune Myrstad, Camilla Otterlei, Trung Trinh, and Bernd Wittgens

**Intensified liquid-liquid process design for critical metals extraction from e-waste ..... 2340**
Konstantinos Katsoulas, Arun Pankajakshan, Malik Olasinde, Cong Chao, Federico Galvanin, Panagiota Angeli, and Eric S. Fraga

**Sensitivity of MPC Performance to Component Scaling in a Battery–Hydrogen Storage System ..... 2349**

**A novel decomposition-based approach to solve heterogeneous capacitated vehicle routing problems ..... 2355**
Vakil Vamsi Krishna, Mangesh Kapadi, Pankaj Verma, and Shamik Misra

**Network Design Optimization for Biomethane Feed-in from Decentralized Production Sites ..... 2362**

**Simulation-Optimization vs. MILP Approaches for Real-Time Scheduling of Multiproduct Batch Plants ..... 2370**
Engelbert Pasieka and Sebastian Engell

**Design and Optimization of Supply Chain for Citrus Biorefineries: A Regional Approach for Waste Valorization in Brazil ..... 2377**
Marilia G. L. Cavenaghi, Larissa T. Bruschi, and Moises T. dos Santos

**Logistics Management of Agri-Industrial Waste for Energy Valorization in Uruguay ..... 2386**
Milena Lagarmilla, Ivan Guchin, Mauro Gambetta, Darío Huelmo, Adrián Ferrari, and Soledad Gutierrez

## Section 8: Process Control and Operation

**Design and Control of Heat Pump Assisted Distillation Processes for Flexible E-methanol Production ..... 2393**
Lucas A.T. Poker, Marija Saric, Jan Wilco Dijkstra, Vladimir Dikic, and Anton A. Kiss

**Long-Cycle Operation for Residue Hydrotreating Processes with Bayesian Optimization ..... 2400**
Pengcheng Zhu, Han Wang, Gang Chen, Bo Chen, Fei Zhao, and Xi Chen

**Decentralized Causal Monitoring in High-Dimensional Systems: Revealing the Topological Drivers behind Fault Detection Performance ..... 2406**
Rodrigo Paredes and Marco S. Reis

**Control Structure Design of Novel Microwave-Catalyzed Process for Simultaneous Production of Ammonia and Ethylene ..... 2418**
Md Mizanur Rahman, Omar Almaraz, Snehitha Baddam, Jianli Hu, and Srinivas Palanki

**Towards Safety-Intelligent Cyber-Physical Systems: A Real-time Monitoring and Control Framework ..... 2425**
Zhane Ann Tizon, Yuanxing Liu, Sahithi Srijana Akundi, Austin Braniff, Beatriz Dantas, Yuhe Tian, Faisal I. Khan, and Efstratios N. Pistikopoulos

**Extremum seeking control by perturb and observe applied to dividing wall column pilot ..... 2433**
Ivar J. Halvorsen, Bart M. A. Bergers, Giovanni Merlo, Leontine I.M. Aarnoudse, Mark A.M. Haring, and Sigurd Skogestad

**Managing Renewable Energy Uncertainty in Green Hydrogen Production Systems** ..... **2441**
Matteo Lea Casagrande, Andrea Isella, and Davide Manca

**Forecasting Time-to-Cyclic Steady State in Periodic Bioprocesses via a Multi-Feature k-Nearest Neighbours Framework** ..... **2449**
Yasser Algoufily, Foteini Michalopoulou, Maria M. Papathanasiou, and Mehmet Mercangöz

**Enhancing Control in Chemical Processes using Reinforcement from Human Feedback** ..... **2457**
Hilde Gerold, Dean Bradner, and Sergio Lucia

**Open-Source Optimization Algorithm for the Simulated Moving Bed Process using CasADi** ..... **2466**
João Nunes, Ana M. Ribeiro, Alexandre Ferreira, Diogo Rodrigues, and Alírio E. Rodrigues

# Introduction

**Solomon Brown, Maria Papathanasiou, David Bogle, Joan Cordiner, Michael Fairweather (eds.)**

The 36th European Symposium on Computer Aided Process Engineering (ESCAPE|36) was held in the UK from Sunday 21 June to Wednesday 24 June 2026 at the University of Sheffield. The organisation was led by members of the University's School of Chemical, Materials and Biological Engineering, in collaboration with the Institution of Chemical Engineers (IChemE) and the Grantham Centre for Sustainable Futures.

Since it began, ESCAPE has become a prestigious platform for the process systems engineering community to connect with experts, share innovative ideas, and explore latest advancements. Spread across four days, researchers, industry professionals, and students, will enjoy a wide range of presentations, posters, plenary speakers, workshops, panel discussions, networking opportunities, and social events.

In an era defined by climate challenges, resource constraints, and rapid technological advancement, the need for sustainable practices has never been more urgent or complex. The main theme of this year's conference, Resilient Sustainability through CAPE, reflects the shift toward integrating resilience through design and the critical role computer-aided process engineering has when developing innovative tools and adaptive, efficient systems that can withstand uncertainty while minimising environmental impact. This conference brings together leading minds to explore how advanced modelling, simulation, optimisation, and data-driven decision-making can drive sustainable transformation across sectors.

ESCAPE|36 received 687 abstract submissions, of which 654 were invited for a 5-to-8 page full paper or a 2-page short paper after a first round review. Upon rigorous re-review of all papers submitted, 331 conference papers have been published in full open access by PSE Press as a volume of the *Systems & Control Transactions* series. Another 162 contributions being made available as short papers separately.

The scientific contributions were organised into oral sessions, poster presentations, workshops and demonstrations, within nine thematic areas:

1. CAPE in Circular Economy
2. CAPE in Clean Energy Systems
3. CAPEing with Uncertain Futures
4. Pharmaceutical and Biotechnological Systems
5. Modelling and Simulation
6. Concepts, Methods and Tools
7. Process Design, Scheduling and Optimisation
8. Process Control and Operation
9. CAPE in Education, Knowledge Transfer and Entrepreneurship

We would like to extend our sincere thanks to all authors, reviewers, topic coordinators, plenary and keynote speakers, and members of the Scientific and Organizing Committees. We gratefully acknowledge the University of Sheffield and the IChemE for their support and express our heartfelt appreciation to our numerous sponsors. This edition marks the second volume with PSE Press as the official publisher of the ESCAPE proceedings (full papers volume) – continuing this important collaboration in promoting high-quality, open access dissemination of PSE research.

We hope this volume captures the scientific excellence, collaborative spirit, and forward-looking vision that defined ESCAPE|36 and continue to serve as a valuable reference for researchers and practitioners in the years ahead.

# Peer Review Policy

## TERMINOLOGY

- **Conference Paper:** This is a peer-reviewed research paper describing an **original** research contribution and published in the conference proceedings.

## APPLICATION

- All conference papers are subject to peer review.

## PUBLICATIONS

- All conference papers which have passed peer review and have been accepted by the conference chairs will be published in the conference proceedings.

## PEER REVIEW PROCESS

### Initial Screening

The conference chairs will screen the initial submissions (one-page abstracts) of contributed papers. At their option, chairs may choose to reject these submissions for any reason, but the primary reasons for rejection at this stage are (a) subject does not match conference themes and topics; (b) in appropriate, unprofessional, unethical, or dishonest material; (c) duplicate submissions; (d) abandoned submissions; (e) multiple submissions from same presenter; (f) obvious poor quality; (g) reasonable suspicion of machine-generated text; (h) need to limit acceptances because of conference space constraints. Chairs may also transfer papers between sessions at this stage.

Conference chairs will then invite authors of the one-page abstracts that have passed the initial screening to submit a conference paper for peer review.

### Conference Paper Peer Review

Conference chairs act as editors. They will assign peer reviewers to assess the quality of the conference papers and manage the peer review process for each paper. Peer reviewers are generally selected from the International Scientific Committee who are scientists, engineers, or researchers with technical expertise in the conference topic. Peer reviewers must be considered technical experts in their field, hold a PhD, and have published peer reviewed scientific works previously. Each work must be reviewed by a minimum of two peer-reviewers.

A “single-blind” peer review system is used, in which the peer reviewers have access to the identities of the authors, but the authors are never given the identities of the peer reviewers. This is consistent with most journal peer-review procedures in our field.

Peer reviewers will be given a set of quality criteria that may include scientific and technical quality, quality of writing, originality and novelty, appropriateness for the conference topic and theme, interest to the community, and other factors of merit. Peer reviewers are expected to be rigorous and critical in their technical assessments and adhere to the highest standards in the field in order to ensure high quality. Peer reviewers are asked to comment on their assigned conference papers and issue a recommendation to the conference chairs based on this quality criteria. Reviewers may recommend one of the following:

- **Accept Paper.** No technical changes are necessary before publication. Only typographical, spelling, grammar, or other minor changes are necessary which do not require technical review.
- **Accept Paper with Minor Revisions.** Some minor technical issues need to be addressed either through technical changes to the manuscript or through rebuttal to reviewer comments. The reviewer does not believe the issues are significant enough to require additional technical review by the reviewers. The reviewer has provided enough commentary such that the editor can decide if the minor issues have been addressed in a future revision.
- **Reject Without Reconsideration.** The technical issues are so significant that it is unlikely that an acceptable

manuscript could be produced by the deadline; or, the manuscript is out of scope, inappropriate, or computer-generated.

Peer reviewers may be asked to provide numerical scores or rankings, as well as provide written comments intended for the chairs and/or the authors. Peer reviewers are encouraged to provide specific and constructive feedback that will aid the authors in improving the work and provide advice to the chairs.

The conference chairs are responsible for making the final decision on each paper and may require several rounds of author changes if necessary to meet quality standards. Conference chairs are not required to follow the recommendations of the peer reviewers in making these decisions. It is possible that conference chairs will choose to not accept some papers that still pass through rigorous technical peer review, especially when limited by available space or when papers do not sufficiently promote conference objectives. Conference chairs may also transfer papers between sessions as desired.

## CONFLICTS OF INTEREST AND ETHICAL GUIDELINES

The chairs and peer reviewers must ensure they do not have a conflict of interest that may bias their decisions, such as ensuring that authors are at “arm’s length” and have no financial conflicts of interest. Peer reviewers and chairs must disclose if they have such a conflict of interest with a specific submission, and if so, a different chair and/or peer reviewer should be assigned to handle that submission.

To help determine conflicts of interest, and for all other ethical guidelines, we use the Systems and Control Transactions ethical guidelines described at: https://psecommunity.org/contributor-guidelines

## ABSTRACT

The transition toward circular economy principles in water treatment requires advanced process systems engineering tools to evaluate the trade-offs between environmental sustainability and economic viability, particularly for energy-intensive Zero Liquid Discharge (ZLD) systems. While classic ZLD systems treat concentrated brine as waste, circular ZLD (CZLD) systems incorporate salt recovery technologies that generate marketable salt product. This study presents a comprehensive technoeconomic assessment framework for CZLD systems integrated with renewable energy. The framework is developed to evaluate different CZLD configurations that generate saleable sodium chloride. The assessment methodology integrates solar photovoltaic systems with increasing capacities (100-1400 kW) to analyze renewable energy penetration and energy storage requirements. The renewable energy integration model incorporates hierarchical energy dispatch algorithms prioritizing direct solar utilization, battery storage, and grid backup systems. Solar PV integration demonstrates renewable fractions ranging from 15-100%, with corresponding emissions reductions of up to 72% compared to grid-powered baselines. The technoeconomic analysis reveals a critical trade-off: while renewable integration substantially reduces carbon emissions, it significantly increases operational costs due to higher solar costs compared to subsidized grid electricity. However, configurations with substantial salt revenue generation maintain economic viability even under complete renewable operation. Beyond configuration screening, this work makes three specific contributions to process systems engineering: (i) a hierarchical energy-dispatch model for intermittent solar integration in energy-intensive separations; (ii) a revenue-function formulation that embeds salt valorization into ZLD process economics, shifting the design objective from cost minimization to net revenue maximization; and (iii) systematic identification of the thermodynamic basis for membrane–thermal hybrid superiority through analysis of osmotic pressure versus latent heat energy barriers across 26 configurations. These contributions establish a reproducible framework applicable to brine management in resource-constrained industrial settings.

**Keywords**: circular water system, zero liquid discharge, zero liquid, resource recovery

## INTRODUCTION

Global water stress affects over 2 billion people, with industrial sectors consuming approximately 20% of freshwater resources while generating increasingly saline effluents. Traditional treatment paradigms achieving 70-90% recovery leave substantial volumes requiring disposal, creating environmental liabilities and regulatory challenges. Zero liquid discharge technologies present compelling alternatives by maximizing water recovery beyond 99%, yet implementation barriers persist due to energy requirements reaching 20-80 kWh/m$^3$ and treatment costs spanning 2-15 \$/m$^3$ [1].

Recent technological advances enable transformation of ZLD systems through circular economy integration. Salt crystallization and purification technologies

convert waste brines into marketable products, fundamentally altering system economics. Simultaneous renewable energy deployment addresses sustainability concerns, particularly in regions with abundant solar resources coinciding with water scarcity [2]. As a result, ZLD technology adoption has accelerated over the past decade, driven by regulatory tightening and increasing water scarcity.

ZLD process design methodologies have evolved from single-technology studies toward multi-stage hybrid systems. [3] establish that membrane-based ZLD is thermodynamically more efficient than thermal alternatives for feeds below 150, 000 mg/L TDS, while [4] quantify the theoretical minimum energy for ZLD at 3–5 kWh/m³, establishing benchmarks against which practical configurations should be compared. Renewable energy integration with desalination has been extensively reviewed by [2], yet the specific challenge of solar coupling with thermal-intensive ZLD operations remains understudied. [5] show that solar-integrated MED systems operating with thermal energy storage achieve substantially higher renewable fractions than daytime-only configurations, underscoring the importance of storage design in solar-thermal desalination. Salt valorization in ZLD systems is an emerging field with significant economic implications. [6] conduct a techno-economic assessment comparing two ZLD configurations, one producing mixed solid salt and one producing high-purity NaCl, and found that while pure NaCl recovery incurs 1.4× higher energy consumption, it yields 1.52× greater profitability, demonstrating the economic premium of product-grade salt separation. At the ion separation stage enabling such purity, [7] demonstrate that monovalent-selective nanofiltration can preferentially pass monovalent ions while rejecting divalent species, providing a pre-crystallization fractionation pathway. However, systematic frameworks for optimizing these integrated systems remain underdeveloped.

The present work addresses this gap through three distinct contributions to the process systems engineering field. First, a configuration generation algorithm is developed that applies thermodynamic feasibility constraints (including maximum inlet TDS thresholds and process sequencing rules) as an a priori screening step across viable configuration design space, analogous to superstructure-based process synthesis methods but adapted for rapid feasibility assessment. Second, a hierarchical renewable energy dispatch model is formulated that prioritizes direct solar utilization, battery storage, and grid supplementation sequentially, extending established industrial microgrid energy management heuristics to the intermittent solar energy profiles. Third, a multi-criteria performance framework is introduced that applies parallel coordinate visualization to map a six-dimensional performance space (spanning energy consumption, treatment cost, salt revenue, net revenue, carbon emissions, and renewable fraction) across configurations, enabling systematic identification of Pareto-optimal design regions and partitioning of the configuration space into context-sensitive application archetypes. Together, these contributions reframe CZLD design from a single-technology selection problem into a systematic process synthesis and integration challenge, directly advancing circular water treatment systems.

# METHODOLOGY

## System configuration development

The technoeconomic framework evaluates CZLD configurations through systematic technology combination. Process units span four categories: pretreatment (chemical precipitation, nanofiltration), concentration (reverse osmosis, electrodialysis), thermal processing (multi-effect distillation, multi-stage flash, brine concentrators), and crystallization systems for sodium chloride recovery. Each configuration undergoes mass and energy balance calculations to determine feasibility boundaries.

Feed water characteristics assume 35, 000 mg/L total dissolved solids, representative of industrial brines. Technology sequencing is subject to a technical viability check ensuring that inlet feed concentration does not exceed maximum allowable limit. Sequential staging ensures progressive concentration while respecting operational limits.

## Solar integration model

Renewable energy integration employs dynamic allocation algorithms matching solar generation profiles with process demands. The model incorporates direct solar utilization during generation periods, battery storage for load shifting (assumed to be five times the cost premium), and grid supplementation for unmet demands

Solar availability assumes 13.75 hours/day peak generation (Qatar conditions) [8], with photovoltaic costs at 0.06 $/kWh [9] versus 0.035 $/kWh grid electricity [10]. Energy allocation prioritizes direct consumption, followed by stored energy deployment during non-generation periods.

## Economic and environmental assessment

Economic evaluation incorporates capital expenditure, operational costs, and revenue streams from recovered salt products. Salt pricing correlates with purity levels: high-grade NaCl (>95%) commands 0.15-0.25 $/kg, medium-grade (90-95%) achieves 0.05-0.15 $/kg, while mixed salts yield 0.02-0.08 $/kg [11]. Net treatment costs account for salt revenues, providing comprehensive economic assessment.

Environmental metrics quantify carbon emissions based on energy sources. Grid electricity generated from natural gas assumes 0.2 kg $CO_2$/kWh emission factor [12], while solar generation via photovoltaics produces lifecycle emissions of 0.048 kg $CO_2$/kWh [13].

## RESULTS AND ANALYSIS

### Energy-economic performance trade-offs

Comprehensive evaluation reveals significant performance variations across CZLD configurations. Energy consumption spans 16.1-89.2 kWh/m³, with membrane-dominant systems achieving highest efficiency while thermal processes maximize salt quality. Figure 1 illustrates the energy-economic landscape, identifying optimal configurations balancing competing objectives.

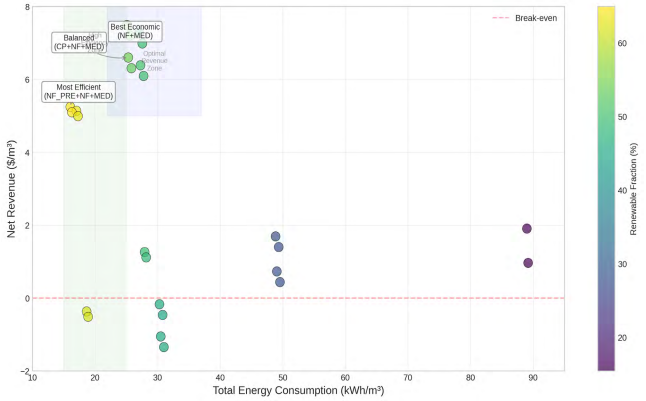

**Figure 1.** CZLD configuration performance showing energy-economic trade-offs with renewable fraction.

Analysis identifies three distinct performance clusters: (i) high-efficiency membrane systems (16-20 kWh/m³) with moderate revenues (5-6 $/m³), (ii) balanced membrane-thermal hybrids (25-30 kWh/m³) maximizing net revenue (6-7.5 $/m³), and (iii) thermal-intensive configurations (50-90 kWh/m³) with variable economics depending on salt quality. The optimal configuration (NF + MED + Crystallizer + Polish) generates 7.49 $/m³ net revenue at 25.1 kWh/m³ consumption, demonstrating synergies between selective separation and thermal concentration.

Detailed examination of the evaluated configurations reveals systematic performance patterns based on technology combinations. Configurations employing chemical precipitation pretreatment (CP) demonstrate 8-12% higher energy consumption compared to membrane-only pretreatment due to mixing and flocculation requirements. Electrodialysis-based concentration stages (ED) consume 18-22 kWh/m³ for brine concentration, positioning them between reverse osmosis and thermal technologies. The relationship between water recovery rate and specific energy consumption exhibits nonlinear behavior across configuration types.

Table 1 provides a summary of key performance metrics for selected configurations.

**Table 1:** Performance metrics for selected high-revenue CZLD configurations under base conditions.

| Configuration | Energy (kWh/m³) | Total Cost ($/m³) | Salt Rev. ($/m³) | Net Rev. ($/m³) | Emissions (kg $CO_2$) |
|---|---|---|---|---|---|
| NF + MED + Crystallizer | 25.1 | 1.48 | 8.97 | 7.49 | 2.50 |
| RO + MED + Crystallizer | 25.6 | 1.77 | 8.97 | 7.20 | 2.55 |
| CP + NF + MED + Crystallizer | 25.3 | 2.36 | 8.96 | 6.60 | 2.53 |
| NF_PRE + NF + MED + Crystallizer | 16.1 | 3.72 | 8.97 | 5.25 | 1.61 |

### Solar integrations and emissions reduction

Photovoltaic integration demonstrates substantial environmental benefits across all configurations. Renewable fractions vary from 15% for energy-intensive thermal systems to over 70% for more efficient configurations. Figures 2 and 3 compare emissions performance between grid-powered and solar-integrated scenarios, quantifying achievable reductions through renewable deployment.

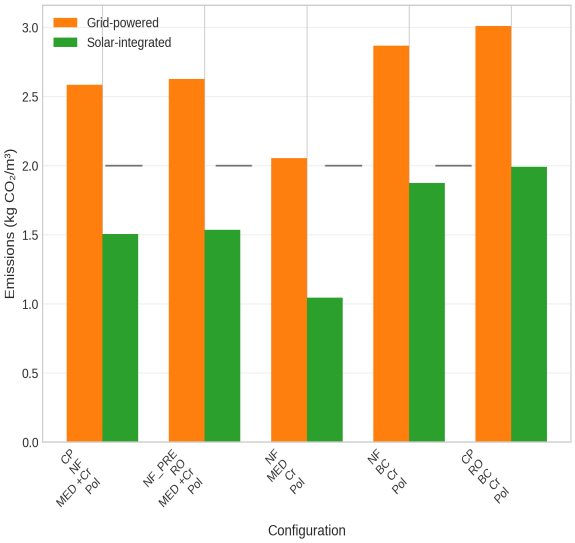

**Figure 2.** Emission comparison between grid powered and solar integrated configurations.

The selected configurations represent distinct operational archetypes: highly efficient membrane dominant systems (NF_PRE + NF + MED at 16.1 kWh/m³), optimal hybrid configurations (NF + MED + Crystallizer at 25.1 kWh/m³, CP + NF + MED at 25.3 kWh/m³), and more

energy-intensive alternatives with brine concentrators and crystallizers. Emissions reductions range from 1.0 to 1.55 kg $CO_2/m^3$ across the displayed configurations, representing 38-50% decreases relative to grid-only baselines. Notably, the most efficient achieves the lowest absolute emissions in both scenarios (2.58 kg $CO_2/m^3$ grid, 1.52 kg $CO_2/m^3$ solar) but demonstrates smaller absolute reduction (1.06 kg $CO_2/m^3$) compared to higher-energy configurations with emission performance as follows: 3.01 kg $CO_2/m^3$ grid, 2.01 kg $CO_2/m^3$ solar, 1.00 kg $CO_2/m^3$ reduction. This pattern reflects the dual influence of baseline energy consumption and renewable fraction achieved—lower-energy systems have less emissions to reduce, while higher-energy systems can achieve larger absolute reductions despite lower renewable penetration percentages.

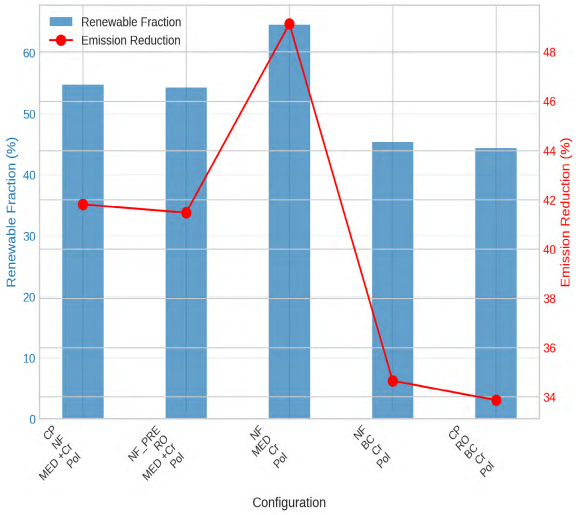

**Figure 3.** Solar integration performance metrics across selected configurations.

Emission reductions correlate strongly with process energy profiles and renewable fraction achieved. Membrane-based configurations demonstrate highest renewable integration potential (50-65%) due to consistent power demands matching solar generation profiles. Thermal processes, despite higher absolute consumption, benefit from load shifting through strategic battery deployment, achieving 40-55% renewable operation. Economic analysis reveals solar premium of 71% over grid electricity offset by emission reductions exceeding 40% for optimized configurations.

Figure 3 indicates that renewable integration potential is non-uniform with membrane dominant configurations achieving renewable fractions of 54-58%, while more energy-intensive systems demonstrate lower penetration at 44-46% despite identical available solar capacity. The emission reduction trend line demonstrates a striking nonlinear relationship: configurations achieving 54-58% renewable fraction deliver 42-49% emissions reductions, exhibiting near-proportional correlation, while the drop to 44-46% renewable fraction corresponds to disproportionately lower 34-35% emissions reductions. This nonlinearity reflects the combined influence of reduced renewable displacement and the carbon intensity differential between grid and solar lifecycle emissions.

## Salt recovery economics

Salt valorization transforms CZLD economics from cost-minimization to revenue-maximization paradigms. Crystallization with polishing generates high-purity NaCl (>95%) commanding an average premium price of 0.25 $/kg, while mixed salt byproducts contribute additional revenue at 0.05 $/kg. Figure 4 illustrates the relationship between salt revenue generation and treatment costs across configuration types. Blue dots represent configurations using chemical precipitation as pretreatment. The orange dots represent configurations using nanofiltration as pretreatment. Green dots are configurations with no pretreatment (direct processing).

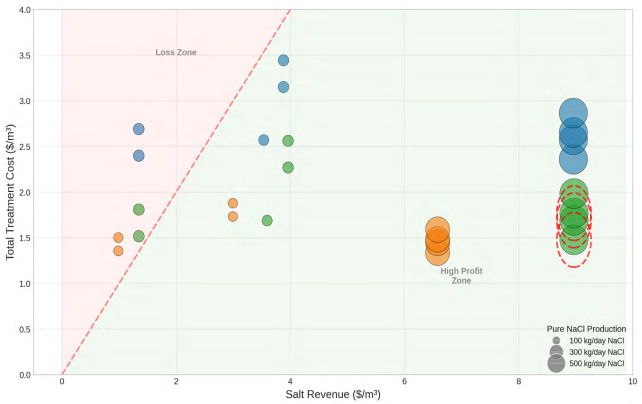

**Figure 4.** Salt recovery economics showing revenue potential versus treatment costs.

The diagonal clustering of configurations reveals a strong positive correlation between salt recovery capacity and overall economic viability, with configurations generating >7 $/m³ salt revenue consistently achieving positive net revenues of 5-7.5 $/m³. The scatter pattern demonstrates three distinct groupings: (i) low-revenue membrane-only systems (0-2 $/m³ salt revenue) operating at net costs of 2-4 $/m³, highlighting the economic burden of treatment without resource recovery; (ii) intermediate crystallization systems (4-6 $/m³ salt revenue) approaching break-even economics; and (iii) optimized crystallization configurations with polishing (7-9 $/m³ salt revenue) achieving substantial net revenues. The slope of the configuration clusters indicates that each additional dollar of salt revenue translates to approximately 0.85-0.90 $/m³ improvement in net revenue, with the slight offset representing the marginal energy and capital costs associated with crystallization and

purification processes.

Thus, salt revenue can significantly offset treatment costs for optimal configurations. Thermal concentration coupled with crystallization maximizes product quality, generating 468 kg/day pure NaCl and 2, 954 kg/day mixed salts for 1, 000 $m^3$/day treatment capacity. Market analysis confirms regional demand exceeding 500, 000 tons/year in Qatar alone [14], meaning that the implementation of CZLD systems could eliminate salt imports while advancing circular economy objectives through waste-to-resource transformation.

## Thermodynamic efficiency analysis

While energy consumption provides a practical basis for comparing configurations, it conflates work and heat inputs of fundamentally different thermodynamic quality, and does not situate results relative to the theoretical limits of separation. To address this, the present results are contextualized using a second-law framework. [15] establish the minimum specific exergy of separation for a saline feed at approximately 1.06 kWh/$m^3$ at seawater salinity, representing the thermodynamic lower bound irrespective of technology pathway. Against this benchmark, the best-performing configuration in the present study (NF + MED + crystallizer, 25.1 kWh/$m^3$) operates at a second-law efficiency of approximately 4.2%, consistent with published values for industrial-scale MED systems, which typically range from 3–6% [16]. Membrane-dominant configurations in this study approach 6–7% second-law efficiency, reflecting the lower irreversibility of pressure-driven versus thermally-driven separation. The observed spread of 4–7% across the 26 configurations confirms that substantial thermodynamic improvement potential remains, primarily through heat recovery within thermal stages and pressure energy recovery in membrane modules. It should be noted that the present analysis treats electrical and thermal energy inputs on a kWh basis without explicit exergy weighting; full exergy accounting, including the chemical exergy of recovered NaCl product streams, would further differentiate configurations by the thermodynamic value of outputs and is reserved for future work.

## Sensitivity analysis

Salt price sensitivity is the dominant source of economic uncertainty. For the optimal configuration (NF + MED + NaCl Cr + NaCl Polish), all recovered salt is high-purity NaCl (3, 588 kg/day at 100 $m^3$/day feed), and the base case assumes the upper bound of the high-grade price range at 0.25 $/kg. This represents an optimistic but commercially justified assumption given that the NaCl Polish step delivers a >95% purity product. Applying the lower bound of the high-grade price range (0.15 $/kg), a 40% price reduction, cuts salt revenue from 8.97 to 5.38 $/$m^3$, reducing net revenue at 100 kW solar penetration from 7.32 to 3.73 $/$m^3$. This remains profitable but represents a substantial compression of economic margin. At the midpoint price of 0.20 $/kg, net revenue settles at approximately 5.05 $/$m^3$, which constitutes a reasonable central estimate. Configurations relying on brine crystallizers, which produce mixed salts at 0.02–0.08 $/kg, are already near or below breakeven at base case pricing and carry no meaningful upside from product purity improvements, making them economically dominated regardless of price scenario. The qualitative ranking of configurations is therefore preserved across the full high-grade price range, though the absolute magnitude of net revenue is sensitive to realized market price.

Energy cost sensitivity is of secondary magnitude but varies with solar penetration level. At 100 kW solar capacity, the lowest penetration modeled, energy cost for the optimal configuration is 0.62 $/$m^3$, representing approximately 38% of total treatment cost of 1.65 $/$m^3$. A 50% increase in the grid tariff from 0.035 to 0.053 $/kWh raises treatment cost by approximately 0.31 $/$m^3$, reducing net revenue from 7.32 to ~7.01 $/$m^3$ at the base case salt price. However, at the lower bound salt price of 0.15 $/kg, this same energy cost increase reduces net revenue further from 3.73 to 3.42 $/$m^3$, illustrating that energy and salt price sensitivities interact: configurations operating at compressed salt revenue margins are disproportionately exposed to energy cost increases. At higher solar penetration levels, grid supplementation constitutes a smaller share of total energy supply and this sensitivity diminishes accordingly. Process efficiency parameters, including membrane rejection rates, thermal process performance ratios, and energy conversion efficiencies, govern energy consumption and water recovery rather than salt product purity, and their influence on net revenue is therefore, for the purposes of this analysis, bounded by the energy cost sensitivity established above. The qualitative configuration ranking, membrane-thermal hybrids with high-purity crystallization outperforming purely thermal or purely membrane alternatives, does not change across the price perturbations examined. A full simulation-based parametric sensitivity analysis across the complete solar penetration range, including systematic quantification of process efficiency uncertainty, is reserved for the future work.

## Multi-criteria assessment

Optimal configuration selection requires balancing multiple competing objectives including energy efficiency, economic performance, environmental impact, and operational reliability. Figure 5 illustrates the performance trends of key metrics across different configurations (indicated by the pink dots). The parallel axes display normalized performance metrics spanning energy consumption (kWh/$m^3$), total treatment cost ($/$m^3$), salt revenue generation ($/$m^3$), net revenue ($/$m^3$), carbon

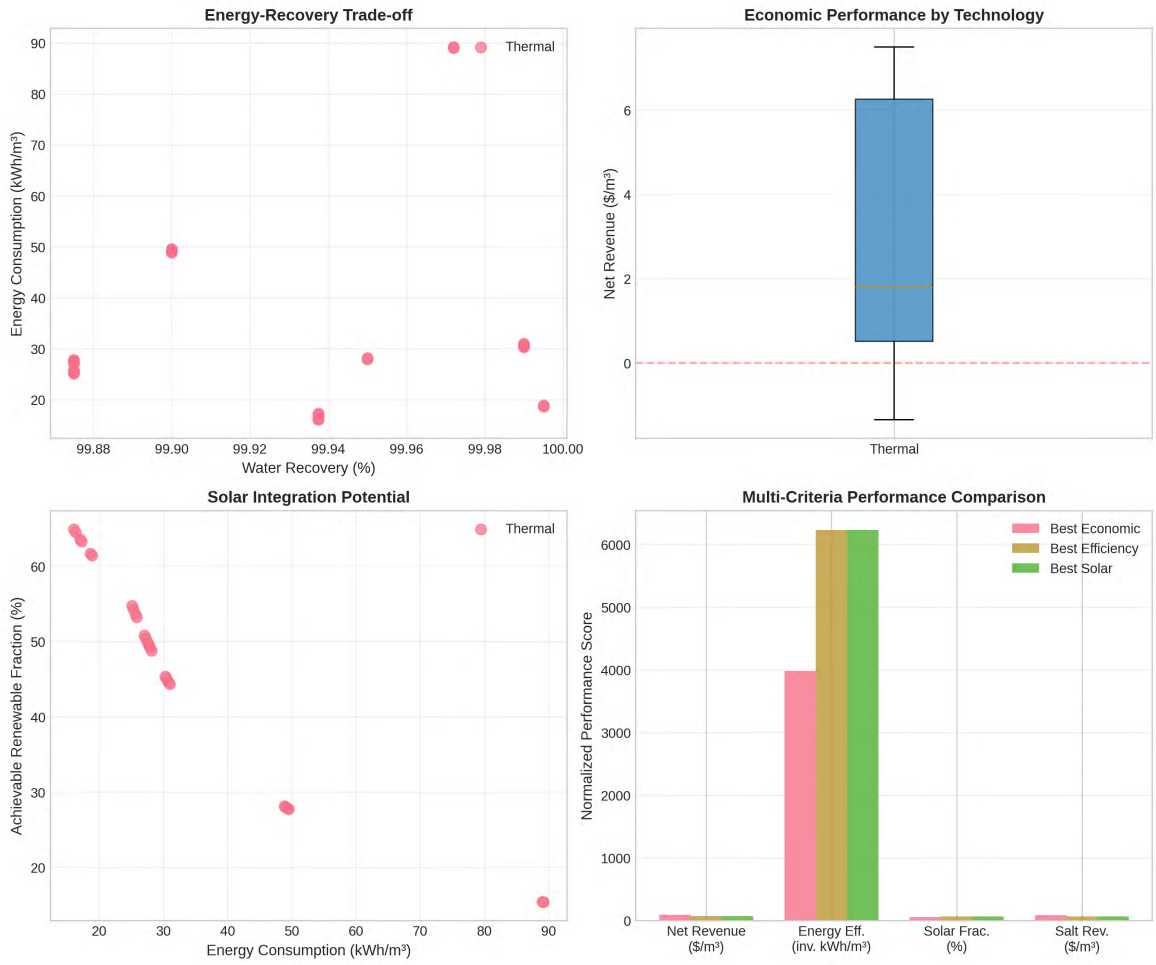

**Figure 5.** Multi-criteria performance matrix showing (a) energy-recovery trade-offs, (b) economic performance distribution, (c) solar integration potential, and (d) normalized comparison of top configurations.

emissions (kg $CO_2$/m³), and renewable energy fraction (%). Each pink line represents a distinct configuration, with line patterns revealing the inherent trade-offs and synergies across objectives. Configurations achieving low energy consumption (left side, 16-25 kWh/m³) typically exhibit moderate salt revenues (6-8 $/m³) and higher renewable fractions (50-65%), while energy-intensive configurations (70-90 kWh/m³) demonstrate variable economic performance depending on crystallization integration.

For revenue maximization, NF + MED + Crystallizer configuration dominates with 7.49 $/m³ net revenue. Energy minimization favors NF_PRE + NF + MED at 16.1 kWh/m³ consumption. Balanced performance emerges from CP + NF + MED configuration, achieving 6.60 $/m³ revenue at 25.3 kWh/m³ with 54% renewable fraction.

The visualization reveals no single dominant configuration across all criteria, confirming the necessity of context-specific optimization based on regional priorities. Notably, the optimal configurations identified in earlier analyses (NF + MED + Crystallizer, CP + NF + MED + Crystallizer) appear as lines maintaining favorable positions across multiple axes, demonstrating balanced performance. The convergence of lines at high salt revenue values (8-9 $/m³) indicates that crystallization-equipped systems achieve similar revenue generation regardless of energy pathway, while divergence in the renewable fraction axis reflects fundamental differences in the energy consumption between membrane-based and thermal-intensive processing routes.

## DISCUSSION

The findings of this study highlight several fundamental insights that advance the understanding of Circular Zero Liquid Discharge (CZLD) systems and their integration with renewable energy. The diverse performance observed across configurations underscores that CZLD is not a singular technology but a design space shaped by thermodynamic constraints, process integration strategies, and market economics. This variability reaffirms that there is no “one-size-fits-all” approach; instead,

optimal configurations emerge from careful matching of feed characteristics, separation objectives, and local energy-market conditions.

The technical analysis of the configurations reveals critical technical insights into the fundamental trade-offs governing circular water treatment systems. A key insight is that all configurations achieve similar high-water recovery (>99.5%), but energy consumption varies widely (16-90 kWh/m³). The stark variation in energy consumption directly correlates with the thermodynamic barriers each technology must overcome. Membrane processes operating near osmotic pressure limits require 16-30 kWh/m³ primarily for pressurization, while thermal systems consuming 50-90 kWh/m³ must supply latent heat of vaporization to achieve phase change. The optimal performers (NF + MED + Crystallizer at 25.1 kWh/m³ generating 7.49 $/m³ revenue) leverage synergistic coupling where nanofiltration selectively removes divalent ions at lower energy penalties than reverse osmosis, producing a monovalent-rich stream ideal for MED thermal concentration and subsequent crystallization into high-purity (>95%) NaCl.

Thus, one of the clearest outcomes is the dominance of membrane–thermal hybrid configurations. This matches well-documented industry trends showing that hybridization can reduce specific energy consumption by up to 40–60% relative to purely thermal ZLD systems. From a process integration perspective, the superior performance of hybrid configurations stems from strategic placement of separation barriers such as using membrane processes for initial volume reduction (50-70% water removal at 2-6 kWh/m³) before engaging energy-intensive thermal systems (70-99.9% recovery at 15-70 kWh/m³) minimizes the volume subjected to high-energy treatment, explaining why pure thermal systems (BC, BCr alone at 80-90 kWh/m³) prove economically inferior despite achieving similar recovery rates. To further contextualize these energy differences within a rigorous thermodynamic framework, the observed energy consumption values are benchmarked against the theoretical minimum exergy of separation for the present feed conditions. This technical understanding indicates that future optimization should focus on intermediate precipitation steps to remove sparingly soluble salts before thermal stages, potentially reducing energy consumption by an additional 20-30%. The benchmarking of these energy values against the theoretical minimum exergy of separation for the present feed conditions confirms that all configurations operate at second-law efficiencies of 4.8–7.5%, consistent with published values for industrial-scale membrane-thermal hybrid systems and indicative of substantial remaining thermodynamic improvement potential.

The strong revenue contribution from salt recovery highlights a paradigm shift in ZLD economics. Historically, ZLD has been framed as a compliance-driven, cost-intensive environmental obligation. Introducing resource recovery transforms the system into a productive industrial asset capable of offsetting treatment costs or even achieving positive net revenues. The results indicate that for regions with high salt demand, such as Gulf countries, where industrial salt consumption can exceed several hundred thousand tons annually, CZLD plants have the potential to establish localized salt supply chains, reducing reliance on imports and contributing to national resource security. This reframing supports broader circular economy strategies and diversification of industrial inputs. The sensitivity analysis further confirms that while absolute net revenue is sensitive to realized NaCl market price, the qualitative dominance of high-purity crystallization configurations is preserved across the full reported price range, supporting the robustness of these economic conclusions.

Renewable energy integration further enriches the system design space by coupling water, waste, and energy flows. The analysis shows that solar integration can achieve renewable fractions ranging from 15% to 70%, depending largely on the configuration's load profile. Membrane-based systems, with relatively uniform and lower power requirements, exhibit strong alignment with solar generation availability, leading to higher renewable penetration and smoother load matching. Thermal systems, however, exhibit high-power, nonuniform demand patterns requiring substantial battery buffering to reach similar renewable fractions. This highlights a key operational constraint: the degree to which CZLD systems can decarbonize is not only a function of total energy consumption but also of energy temporal dynamics.

Furthermore, the nonlinear relationship between renewable fraction and emissions reduction reveals the influence of system-scale inefficiencies such as battery cycling losses and inverter inefficiencies. Thus, while renewable energy offers meaningful environmental gains (up to 72% reduction in emissions relative to grid-only operation), these benefits diminish for high-energy thermal systems unless paired with optimized storage strategies. Future research should explore alternative load-management tools such as thermal energy storage, flexible scheduling, or hybrid renewable portfolios that combine solar with other intermittent resources.

The multi-criteria assessment emphasizes the inherent trade-offs in CZLD design. Maximum revenue configurations do not minimize energy use, and lowest-energy systems do not maximize salt recovery or renewable fraction. Decision-making must therefore be context-sensitive, weighing environmental priorities, capital availability, operational risk tolerance, and market conditions. The results suggest three broad application archetypes:

- Energy-Minimizing Designs for regions with limited

power capacity or high energy prices;

- Revenue-Maximizing Designs for regions with high salt demand or favorable salt-market conditions;
- Balanced Hybrid Designs suitable for industrial clusters seeking cost-effective, decarbonized water recovery solutions.

From a systems perspective, CZLD facilities hold strategic potential in industrial symbiosis frameworks, where recovered water, salts, and thermal energy streams can directly feed neighboring industries such as chlor-alkali plants, cooling towers, or district cooling systems. This extends the value chain beyond individual plants into regional industrial ecosystems, supporting broader sustainability and economic diversification goals.

While this study provides a robust basis for CZLD feasibility, real-world deployment requires addressing practical considerations such as brine variability, operational fouling, crystallizer control strategies, and long-term battery degradation. Pilot-scale validation remains an essential next step, especially for hybrid configurations that rely on tight coupling of membrane and thermal processes. Moreover, policy levers such as carbon pricing, renewable energy incentives, or circular-economy mandates could significantly shift the economic balance in favor of CZLD, accelerating adoption in water-stressed regions.

Overall, the transition from conventional ZLD to CZLD reframes industrial brine from an environmental liability to a recoverable resource, directly aligning with circular economy principles. By generating high-purity salts, reducing freshwater dependency, and integrating low-carbon solar energy, CZLD systems close material and energy loops that traditionally remained linear. Moreover, the recovered salt streams can supply local industrial users, enabling industrial symbiosis and reducing reliance on imported materials. These findings demonstrate that CZLD is not simply a treatment technology but a circular value-creation platform that enables economic, environmental, and resource-efficiency gains across the water-energy-materials nexus, if implemented strategically.

## CONCLUSION

This research establishes comprehensive techno-economic assessment frameworks for solar-integrated CZLD systems, demonstrating economic viability through strategic salt valorization. Configuration analyses indicate that membrane-thermal hybrid systems are optimal solutions, generating net revenues exceeding 7 $/m³ while achieving >99% water recovery. Solar integration reduces emissions with achievable renewable fractions of 15-65% depending on process configuration.

Key findings include: (i) multi-effect distillation with crystallization maximizes economic performance at 25-30 kWh/m³ consumption and (ii) high-purity salt recovery profitably offsets treatment costs transforming waste management to resource generation.

Results provide quantitative guidance for industrial practitioners and policymakers advancing circular economy principles in water management. Future research should explore dynamic optimization under uncertainty, pilot-scale validation of promising configurations, and integration with broader industrial symbiosis networks. The framework establishes pathways for sustainable water management in resource-constrained environments through technology integration and business model transformation.

## ABSTRACT

Plastic waste represents an abundant and underutilized resource that can be converted into valuable products through microwave-assisted pyrolysis. In this research, a novel microwave-assisted processing plant that converts mixed plastic waste to olefins and aromatics is developed and simulated on Aspen Plus (v.14) guided by laboratory-scale experimental data. The experimental results show that at a bulk temperature of 400$^{o}$C and ambient pressure, approximately 95% of a solid waste plastic feed comprised of equal portions of polypropylene and polyethylene is converted to gases, with nearly two-thirds of the resulting effluent gas composed of olefins. Simulation results show that 2889.1 kg/h propylene, 2088.0 kg/h ethylene and 96.3 kg/h aromatics (benzene and toluene) are produced as main products from 8000 kg/h of mixed plastic feed. High-purity propane and ethane streams were also recovered and sold as byproducts. A technoeconomic analysis is subsequently conducted, revealing that the proposed novel plant achieves a positive net present value of USD 61.6 million at a processing capacity of 8000 kg/h of mixed plastic waste feed. The levelized cost of propylene production is also calculated to be USD 481.1 per ton, estimated while keeping the price of the other coproducts fixed at their average market selling price. Such results confirm the economic feasibility of the microwave-assisted novel plant at the investigated scale.

## INTRODUCTION

Olefins, such as propylene and ethylene, are important feedstocks, used primarily in the manufacture of polymers such as polyethylene and polypropylene. The global production of propylene is projected to reach 191 million metric ton (Mt) by 2030, while ethylene is expected to exceed 407 Mt by the same year [1, 2]. Conventional routes used to produce olefins include steam cracking (SC), which is an energy intensive process that cracks large hydrocarbon fractions, such as naphtha, into smaller molecules, at elevated temperatures of around 800$^{o}$C [3]. The heat required for the process is typically supplied by the combustion of fossil-based fuels, and industrial steam crackers with gas-fired furnaces are reported to emit globally about 366 Mt of carbon dioxide ($CO_2$) annually [3]. Statistics show that around 65% of the global propylene production is derived from SC, but the production of propylene from steam crackers is highly dependent on several factors, including the composition of the feedstock [4]. However, with the shifting to ethane-based feed, the amount of the propylene produced through this pathway as a byproduct is declining rapidly, which led to a propylene gap that needs to be bridged by other technologies, such as propane dehydrogenation (PDH) using the OLEFLEX by UOP Honeywell [5]. However, both naphtha cracking as well as PDH utilize fossil fuels and conventional heating methods, which are considered inefficient from an energy point of view and produce significant quantities of greenhouse gases. For these reasons there is current interest in producing light olefins from alternative feedstocks that involve waste plastics and explore alternative heating strategies that are energy efficient to improve process sustainability.

Several researchers have investigated plastic waste upcycling using microwave-assisted heating to convert plastic waste into high-value products, such as olefins

and aromatics, attempting to increase recycling rates and promoting a circular plastic economy [6, 7]. Microwave-assisted heating has emerged as a transformative and advantageous electrified heating method compared to conventional thermal heating routes. Unlike conventional heating methods, microwaves heat the material uniformly, and this volumetric and selective heating enables faster processing times, lowers energy losses hence increases efficiency, and allows precise control over temperature gradients [8].

In this research, a novel microwave-assisted process to convert mixed plastic waste into olefins and aromatics is designed. First, experimental data is obtained in a laboratory-scale microwave reactor that converts a mixture of polypropylene and polyethylene to olefins and aromatics. Then, this data is utilized to develop and simulate the novel process on Aspen Plus (v.14) that produces mainly olefins and aromatics at an industry scale. The objective of this research is to investigate the economic feasibility of this proposed novel scheme. Heat integration tools are implemented in the designed plant to reduce the required external hot and cold utilities. A detailed technoeconomic analysis (TEA) study is performed on Aspen Process Economic Analyzer (APEA) to evaluate important economic indicators, including the net present value (NPV) and levelized cost of propylene production (LCoP) to assess the economic feasibility of the microwave-assisted novel process.

## MICROWAVE-ASSISTED PLASTIC PYROLYSIS

In the laboratory, the plastic waste feed to the microwave reactor consists of equal portions of polypropylene and polyethylene obtained from real-world post-consumer plastic waste, each accounting for 50% of the total feed. Because the process is catalyzed, a 4 wt.% Ru/α-$Fe_2O_3$ catalyst was synthesized via the wetness impregnation technique as described in a previous related publication [7]. The plastic particles, after being crushed and sieved to small particle size, were mixed with the metal-oxide catalyst at a 1:1 mass ratio before being charged into a quartz tube reactor. The microwave-assisted pyrolysis of the plastic waste mixture at lab-scale was conducted in a microwave system which utilizes a Sairem microwave control system (Sairem Corp., Peachtree Corners, GA, USA) having a 2.45 GHz solid-state generator, which can provide up to 1 kW of maximum forward power. The system used is also equipped with a TE10 mono-mode cavity which serves as an applicator [6, 7]. The temperature of the reacting bed was measured using an infrared pyrometer, which regulated incident microwave power, and the external surface temperatures were independently monitored using an infrared thermometer (Micro Epsilon America, IL, USA). Prior to microwave irradiation, the system, being the plastic/catalyst mixture, was purged with nitrogen at 50 mL/min for a period of 30 min. The mixed plastic waste was then converted under microwave-assisted irradiation, and the gaseous effluent of the system was collected in sampling gas bag, with nitrogen as the carrier gas. The gaseous stream was analyzed in a four-channel Inficon Fusion micro-gas chromatograph (Inficon, NY, USA) and the gas phase product yields were quantified and reported. The system is equipped with the following analytical columns: Rt-Molsieve 5A ($O_2$, $N_2$, $H_2$, CO, $CH_4$), Rt-U-Bond ($CO_2$, $C_2$ hydrocarbons), Alumina-$Na_2SO_4$ ($C_3$–$C_4$ hydrocarbons), and Rxi-1ms (aromatic species such as benzene and toluene) [6, 7].

Table 1 summarizes the gas-phase compositions of the lab-scale microwave reactor outlet. It was observed that 94.8% of the solid plastic waste feed was converted to gas phase at a bulk temperature of 400°C and ambient pressure. The outlet consists of significant fractions of propylene and ethylene, which make up almost two-thirds of the gas products, while aromatics components (i.e., benzene and toluene) comprise 1.2% of the gaseous stream. These experimental data are utilized to develop a novel process flowsheet that produces polymer-grade (PG) propylene and ethylene which can be used as key feedstocks to produce polypropylene, polypropylene, and other high-value polyolefins. The aromatics stream is recovered as a mixed stream of benzene and toluene. Since alkanes, namely propane and ethane, make up 9% of the gaseous stream and are readily obtained as part of the PG propylene and PG ethylene purification process, respectively, they are also recovered to be sold as by-products since they can be used in various industrial applications.

## DEVELOPMENT OF SIMULATION MODEL

Figure 1 presents an illustration of the novel microwave-assisted process for mixed plastic waste conversion. In the process flow diagram (PFD) that is developed for this study, the feed is specified to be 8000 kg/h of mixed plastic waste, comprising equal portions of polypropylene and polyethylene. Initially, the feed is directed to two single-screw extruders for feed processing before it enters the microwave reactor. The extruder configuration is representative of standard industrial units, featuring a 150 mm diameter and a 5 m length. Each extruder is capable of a processing capacity of 4000 kg/h [9].

**Table 1:** Gas Composition of Microwave Reactor Outlet.

| Component | Gas composition (wt.%) |
|---|---|
| Hydrogen | 1.4 |
| Methane | 10.2 |
| Ethylene | 25.9 |
| Ethane | 6.2 |
| Acetylene | 0.3 |
| Propane | 2.8 |
| Propylene | 36.4 |
| Butane and butene(s) | 15.6 |
| Benzene | 1.0 |
| Toluene | 0.2 |
| Total | 100 |
| Gas Percent | 94.8% |

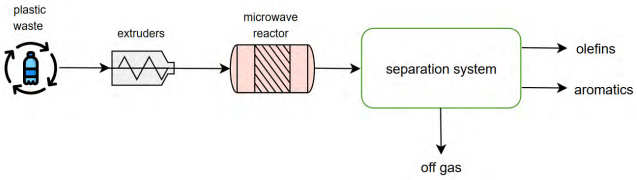

**Figure 1.** Illustration of microwave-assisted conversion of mixed plastic waste to olefins and aromatics.

The feed plastic mixture is pyrolyzed in the microwave reactor, and it is assumed in this study that the large-scale reactor will produce the same product stream as that observed in the lab-scale reactor. The separation train is modeled in Aspen Plus for the purification and recovery of the product streams as summarized in Figure 2. The hot reactor effluent, exiting at 400$^{o}$C and ambient pressure, is first routed to a heat exchanger, where it is cooled down and its temperature is reduced before it enters the train of separation. The resulting cooled stream undergoes multi-stage compression, increasing the pressure from near-atmospheric conditions to 15 bar, before being introduced to the first distillation column. This column separates the heavy hydrocarbon fractions (S1)

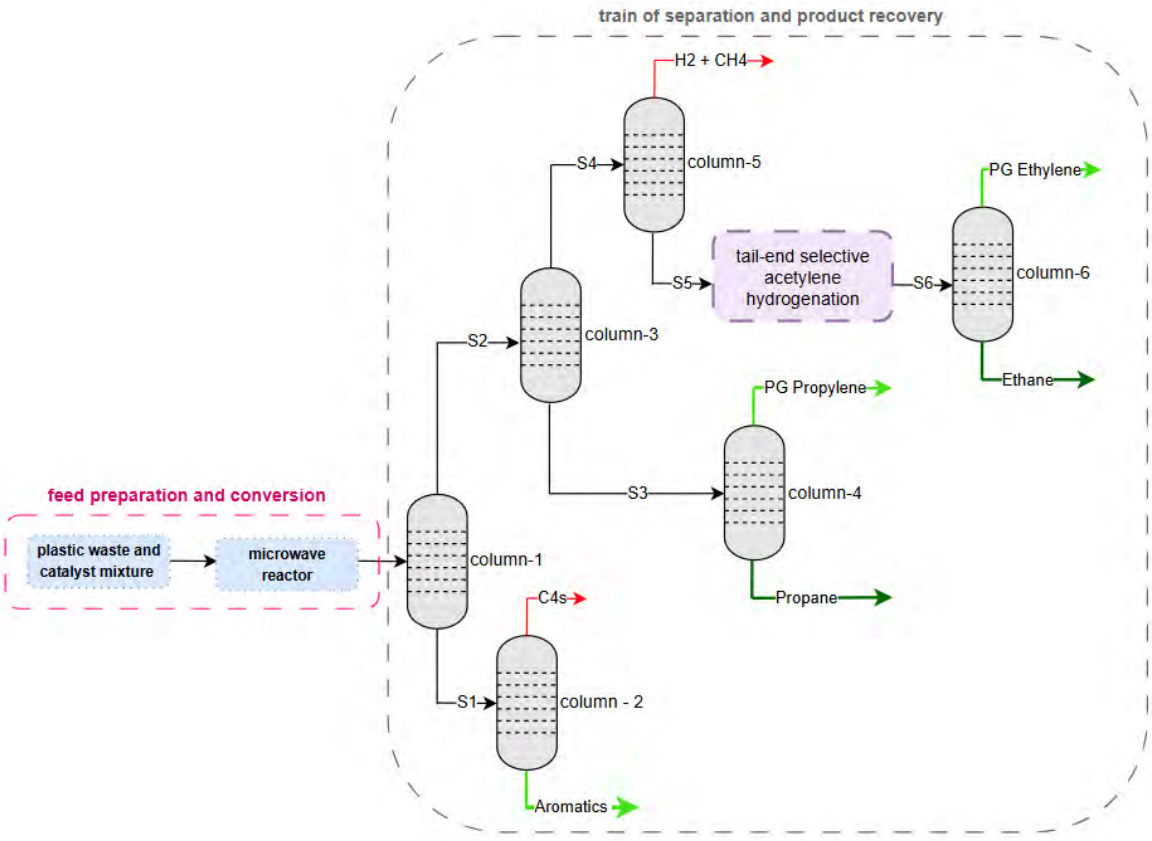

**Figure 2.** Train of seperation and recovered streams of the simulated novel microwave-assisted process. The main product streams are labeled *PG Propylene*, *PG Ethylene*, and *Aromatics*. The two byproduct streams are labeled

from the lighter components (S2). The heavy components stream (S1) is directed to another distillation column that effectively separates the aromatics mixture of benzene and toluene as a bottom product, which is composed of 14.4 mol% toluene and 84.9 mol% benzene at a rate of 96.3 kg/h. The top product stream of the distillation column consists primarily of a mixture of $C_4$ hydrocarbons and is utilized as an on-site fuel source. The stream which contains the propylene, propane, and lighter components (S2) is sent to another compressor to increase its pressure to 30 bar and then enters a cryogenic column which separates the propylene/propane mixture (S3) from the lighter fractions (S4). The propylene/propane mixture (S3) undergoes heat exchange and is expanded to 14 bar, which is a typical operating pressure of the propylene/propane splitter, before being redirected to the column for separating the two components. Because this separation is energy-intensive, the column operating pressure is selected to avoid the need for cryogenic cooling, thereby reducing the overall cost of the column. The column efficiently separates PG propylene, with a high purity of 99.85 mol% as the top product stream, and 96.7 mol% propane as a bottom product stream. The flowrates of the PG propylene and propane streams are 2889.1 and 222.7 kg/h, respectively.

In parallel, the pressure of the light ends stream (S4) is reduced to 25 bar before it is fed into a second cryogenic column to remove the C2-rich mixture (S5) from the mixture of hydrogen and methane. Similar to the C4-rich stream, the stream composed of predominantly hydrogen and methane is also used as on-site fuel. Because the C2-rich stream (S5) contains 1.01 mol% acetylene, it must be removed before ethylene purification, and a tail-end selective acetylene hydrogenation process is implemented for this purpose. The C2-rich stream (S5) has a pressure of 25 bar, which lies in the range of the reported operating pressures for acetylene hydrogenation [10]. The stream (S5) subsequently mixes with hydrogen to enable acetylene conversion via selective hydrogenation. The heated mixture enters the selective hydrogenation system, where the acetylene is converted across two beds: a lead bed and a guard bed, with interstitial heat exchangers installed to limit temperature rise which result due to the highly exothermic nature of the process [10]. The effluent stream of the hydrogenation system (S6) is cooled down before entering the ethylene/ethane splitter. The final column separates PG ethylene with 99.91 mol% purity containing < 1 ppm of acetylene, satisfying the recommended threshold for PG ethylene. The bottom product of this column is 97.9 mol% ethane, which is sold as a byproduct alongside the propane recovered as the bottom stream of the propylene/propane splitter. These byproducts can be used downstream, where they are further cracked into high-value olefins. The flowrates of the PG ethylene and ethane streams amount to 2088.0 and 509.5 kg/h, respectively. Figure 2 shows the schematic of the entire plant, including the detailed train of separation, which enables product recovery and purification.

## COLUMNS COMPOSITION PROFILES

In Aspen Plus, the specifications of the distillation columns, such as the reflux ratio, feed stage location, and required number of equilibrium stages are first estimated using the DSTWU shortcut columns. The parameters obtained from the DSTWU columns are then used as inputs for the more rigorous RadFrac distillation column [9]. The propylene and ethylene recovered in the process need to meet specific purity requirements to qualify as PG olefins. Therefore, the propylene/propane and ethylene/ethane columns are optimized carefully, by selecting the optimal stage number and reflux ratio to achieve the required minimum purity. Figure 3 shows the composition profile of the propylene/propane splitter plotted as a function of stage number in the simulated plant. From the plot, it can be observed that the vapor mole fraction of propylene at the topmost stage, stage 1, is 0.9985 and the liquid mole fraction of propane at stage 130 is 0.9671.

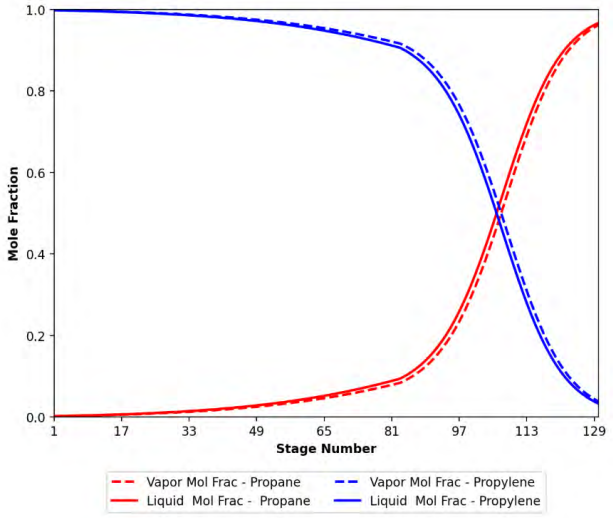

**Figure 3.** Composition profile in the propylene/propane splitter.

Figure 4 presents the molar composition profile in the ethylene/ethane splitter as a function of stage number. Polymer-grade ethylene is separated as the top product stream, and the vapor mole fraction of ethylene in stage 1 is 0.9991. Conversely, the liquid mole fraction of ethane in the bottommost stage, namely stage 82, is 0.9787. Moreover, in both distillation columns, partial-vapor condensers are employed since recovery of the

distillate in the liquid phase is not required. This configuration results in energy savings and a more cost-effective separation process.

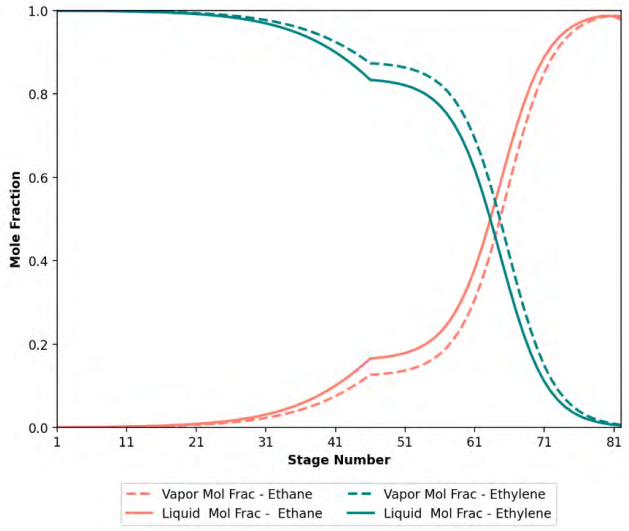

**Figure 4.** Composition profile in the ethylene/ethane splitter.

## TECHNOECONOMIC ANALYSIS

The designed distillation train successfully achieved the required separations, yielding three main product streams and two byproduct streams. The economic evaluation of the simulated novel scheme is then conducted on APEA to assess the economic feasibility of the microwave-assisted novel plant. Since microwave-assisted processes are still in the developmental stage, a contingency factor of 26% is used for the economic study and the economic life of the project is taken to be 15 years [9]. In addition, a tax rate of 21% is assumed, and the raw material, products, and utility escalations are taken to be 1% per year. The cost of the microwave reactor is estimated using the numbering up approach and entered into APEA as a quoted item. Similarly, the costs of the single-screw extruders are also entered as quoted items in the software based on industry prices [9]. However, the costs of the remaining equipment are obtained by mapping the units from the developed PFD in Aspen Plus to APEA, where the software automatically performs equipment sizing and cost estimation. The cost of electricity in the economic evaluation is taken to be USD 0.06 per kWh as per the recommendation of the U.S. Department of Energy (DOE), while the cost of the other utilities is obtained from previous published TEA studies [9]. Using these economic assumptions, the TEA is carried out, and the total capital investment of the simulated novel plant is determined to be USD 48.1 million. Meanwhile, the total operating expenditure (OPEX) amounted to USD 18.8 million per year, with the raw material cost calculated to be USD 8.8 million per year. Since three main product streams are recovered and sold alongside two byproducts, the total product sales amount to USD 38.0 million per year.

Because microwave-assisted heating relies heavily on electricity, the total utility cost for the plant is high and is calculated to be USD 5.6 million per year. To investigate the contribution of each utility to the overall utility cost, Figure 5 presents a pie chart illustrating the distribution of costs among the five utilities used. As observed from the plot, electricity ranks first, representing just over half of the total utility cost, demonstrating the high electricity demand of the microwave-assisted novel process. The high contribution of electricity to the total utility cost highlights its role as the dominant factor among all utilities. The electricity cost is then followed by approximately 31% for refrigeration, which is primarily required for the cryogenic columns used in the separation of the light fractions and the purification and recovery of the PG ethylene stream. Low pressure steam (LP steam) comprises approximately 16% of the utility cost and is primarily used in the reboilers of the distillation columns as well as providing the necessary heat in the heat exchangers throughout the plant. Cooling water contributes minimally to the total utility cost, accounting for roughly 1% of the cost, while high pressure steam (HP steam) represents merely < 1% of the utility cost. It is rather crucial to investigate the utility cost distribution to identify the major cost drivers and prioritize opportunities for efficiency improvements.

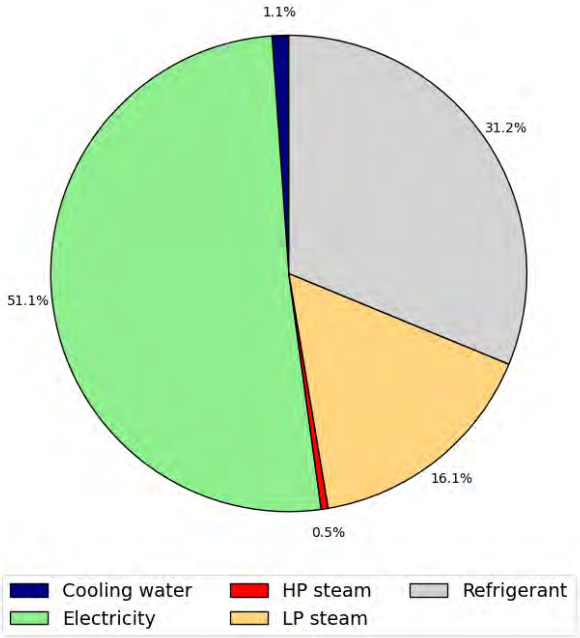

**Figure 5.** Total utility cost breakdown.

The NPV of the designed plant totals to USD 61.6 million, confirming the economic potential of the proposed novel plant for mixed plastic waste conversion at the investigated scale. Since propylene exhibits the highest yield among all product streams, the levelized cost of production is attributed to and calculated for propylene alone. In this case, revenues from the remaining four product streams are treated as credits that offset the total production cost. The LCoP is calculated using a discounted cash flow (DCF) analysis, assuming a 10% internal rate of return (IRR) over the 15-year plant lifespan, with the condition that the NPV at the estimated LCoP value amounts to zero. Thus, the LCoP is estimated to be USD 481.1 per ton, and the detailed TEA results of the proposed novel microwave-assisted simulated plant are summarised in Table 2.

**Table 2:** Economic Summary for the Simulated Novel Process.

| Parameter and unit | Value |
|---|---|
| Total capital investment (million USD) | 48.1 |
| Operating cost (million USD/year) | 18.8 |
| Raw material cost (million USD/year) | 8.8 |
| Utility cost (million USD/year) | 5.6 |
| Product sales (million USD/year) | 38.0 |
| NPV (million USD) | 61.6 |
| LCoP (USD/ton) | 481.1 |

Since the OPEX has a substantial impact on the plant's economics, a sensitivity analysis is performed on the raw material and electricity costs, as they are the main cost drivers, to demonstrate the effect of changing these costs on the OPEX. Figure 6 presents the effect of changing the cost of the electricity and raw material on the OPEX. From this figure, the following can be observed: when the electricity cost is increased by 50%, the OPEX increases by 8.2% and conversely, a 50% reduction in the electricity cost leads to a consequent reduction of 8.2% in the OPEX. In comparison, changes in the raw material cost appears to have a more pronounced effect, where a 50% increase in the raw material cost results in a 25.3% rise in the OPEX, while a 50% decrease leads to a corresponding 25.3% reduction in the OPEX.

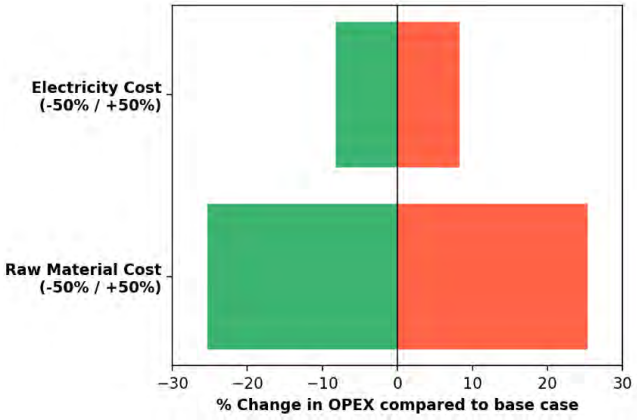

**Figure 6.** Effect of changing the cost of electricity and raw material on the OPEX.

## CONCLUSIONS

The novel process presented in this work utilizes microwave-assisted heating to convert mixed plastic waste of polyethylene and polypropylene into olefins and aromatics at a bulk temperature of 400$^{o}$C and atmospheric pressure. Experimental results from the conversion of mixed plastic waste to valuable products in a lab-scale microwave reactor are used to develop the flowsheet in Aspen Plus. The simulated separation train enabled the recovery of three main streams of high-value products, namely PG propylene, PG ethylene, as well as a mixed aromatics stream of benzene and toluene. In addition, propane and ethane are also recovered as high-purity by-product streams and can be sold to downstream cracking plants for further conversion into higher-value products. Economic evaluation confirmed the potential of the simulated novel plant at the investigated scale, with a positive NPV of USD 61.6 million in the economic lifetime and a LCoP of USD 481.1 per ton. Such results demonstrate the technoeconomic feasibility of producing valuable products from mixed plastic waste through microwave-assisted heating, highlighting the potential for efficient plastic waste recycling and the opportunity to contribute to a circular plastics economy.

PE and PP are the two most common plastics in use today. An initial 50/50 mixture of PP and PE was considered in this research to account for these two common plastics and a technoeconomic analysis was conducted to see if this process is economically feasible. However, mixed plastic waste could have other components, or the ratio of PE and PP could be different. Ideally, one would like a flexible plant that could take many different ratios and types of plastics and convert them to higher-value olefins profitably. Alternatively, one would have to take a mixed plastic waste and add either PE or PP to it so that the ratio of PE and PP is in a range that makes the production of olefins from the feed profitable, despite the extra cost of adjusting the feed composition. The

methods developed here provide the framework for this profitability analysis and is the subject of our current research.

## ABSTRACT

Conventional urea production is a centralized and fossil-intensive process associated with significant greenhouse-gas (GHG) emissions and limited flexibility for deep decarbonization. As an alternative, the Integrated COnversion of NItrate and Carbonate steams (ICONIC) project is developing innovative electrochemical urea (e-urea), via the co-electroreduction of nitrogen and carbon sources using renewable power. While recent research advances in electrocatalysis have demonstrated promising Faradaic efficiencies (FE) toward urea, the design of electrochemical systems involves inherent trade-offs between key performance indicators (KPIs) such as current density, cell voltage, and FE. Crucially, the implications of electrolyzer-level performance on plant-level economics and environmental impacts remain poorly understood. To address this gap, we integrate process modelling with techno-economic and life-cycle assessment (TEA–LCA) to evaluate the trade-offs of KPIs from a process systems perspective. Lab-scale electrolyzer KPIs are transformed into process-level environmental/economic metric, using Python-based electrolyzer modelling and Aspen Plus downstream simulations. Fossil urea is used as a benchmark, and production scenarios are evaluated for wind-powered operation in the Netherlands and solar-powered operation in Spain. The results identify quantitative performance targets for electrolyzer design and demonstrate that urea recovery in the downstream are decisive bottlenecks. This work reveals the essentials for expanding the system boundary beyond the electrolyzer cell, as to identify R&D prioritization and deployment strategies during early-stage technology development and lays the groundwork for scalable and low-carbon urea production.

## 1 INTRODUCTION

Nitrogen mismanagement presents a dual global challenge. On the one hand, excess nitrogen species released into aquatic environments cause coastal eutrophication. On the other hand, the agriculture sector remains heavily dependent on nitrogen fertilizers, such as urea, and faces challenges regarding supply security. For example, the European Union (EU) needs to import approximately 6 Mt urea annually from Asia, Africa and other regions [1].

Conventional urea production relies on centralized Haber–Bosch ammonia synthesis followed by thermal urea formation by Bosch-Meiser process. This pathway is fossil-dependent, energy-intensive and poorly compatible with variable renewable electricity, resulting in substantial $CO_2$ emissions and limited potential for deep decarbonization [2, 3].

To address these challenges, the Integrated COnversion of NItrate and Carbonate steams (ICONIC) project positions electrochemical urea (e-urea) as an alternative [4]. By coupling renewable electricity with

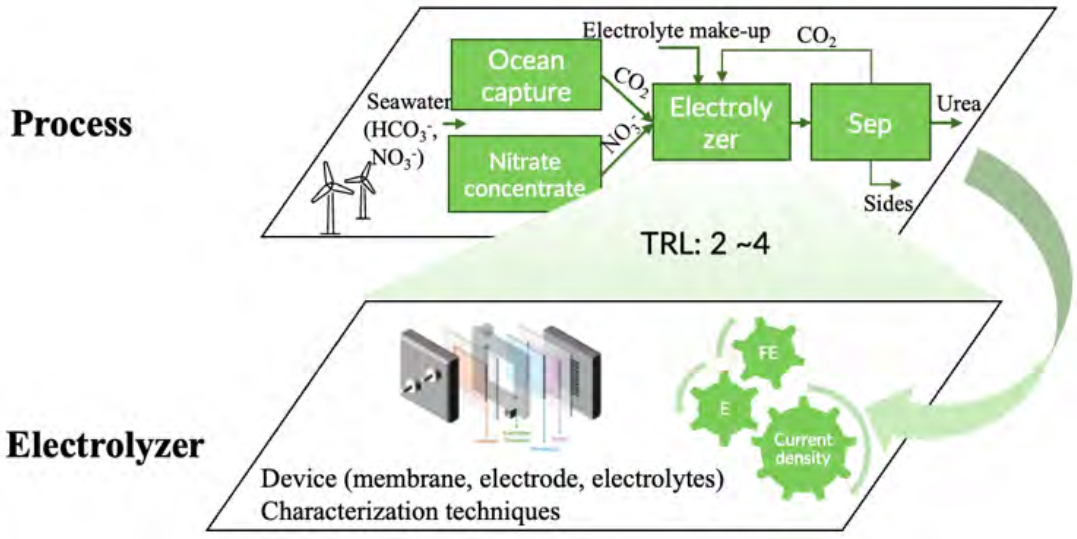

**Figure 1.** Process-informed KPI framework for electrochemical cells.

electrochemical C–N bond formation from nitrate and $CO_2$, ICONIC envisions a distributed, electricity-driven pathway in which e-urea directly substitutes fossil urea in existing markets.

ICONIC's e-urea is currently at technology readiness level (TRL) 2-4 and will soon face the *Valley of Death* challenge from R&D to commercialization. In recent years, research on e-urea has expanded rapidly [5], with reported FE approaching 75% in 2023 [3] and 90% in 2025 [6] but all in low current density with low yield of urea. However, most research scopes are limited to 'point view' for the development of electrocatalysts, membranes, and electrolyzer concepts for cell-level performance metrics [5], with limited consideration of system-level integration.

At higher TRLs, where demonstration activities dominate, fundamental changes to process concepts become increasingly risky, costly, and difficult to implement [7]. Conversely, at low to intermediate TRLs, system-level redesign remains feasible and can substantially influence long-term cost and environmental performance. This makes early-stage, process-informed analysis particularly valuable on cost and risk management.

Specifically, e-urea synthesis faces a critical gap: electrolyzer KPIs are rarely linked quantitatively to plant-level cost, GHG emissions, and deployment choices such as separation strategy and electricity mix (distinguished by location [8]). Without such linkage, it is difficult to define realistic performance targets that guide fundamental research toward commercial relevance.

This study addresses the following research question: What electrolyzer KPI targets (FE, current density, and electrolyzer cost) are required for ICONIC e-urea to become economically and environmentally competitive with fossil urea? Process models are employed to systematically propagate electrolyzer performance to plant-level metrics. Following this, this work aims to identify key technology bottlenecks at an early stage and provide guidance for R&D and scale-up decisions.

## 2 METHODOLOGY

This study adopts a process systems engineering (PSE) methodology to target the KPIs of electrolyser for ICONIC e-urea production. A steady-state process model is developed to represent the full value chain, including $CO_2$ capture, electrochemical C–N conversion, and downstream product recovery. The electrolyzer is parameterised using experimental data as the baseline operating point. Future technology development is explored through parametric variation of these KPIs to reflect potential improvements in catalysts, membranes, and cell design.

Mass and energy balances by process simulations are used to quantify system-level electricity demand and electrolyzer sizing. These results are subsequently integrated into a techno-economic assessment to evaluate levelized e-urea cost and identify cost and energy drivers. By systematically mapping electrolyser-level KPIs to process-level performance, the framework derives process-informed performance targets for early-stage technology development.

### 2.1. Process description

The system boundary extends beyond the electrolyzer to capture the full cradle-to-gate e-urea process. The ICONIC concept comprises:

- Nitrate separation from aqueous streams;

- $CO_2$ capture from ocean carbonate sources;
- C–N co-electrolysis in a BPM-based flow cell;
- Downstream purification to obtain solid urea.

$CO_2$ is supplied via ocean capture, which exploits the ocean carbonate buffer system as a large, naturally equilibrated carbon reservoir. Seawater is electrochemically acidified to shift dissolved inorganic carbon ($HCO_3^-/CO_3^{2-}$) toward dissolved $CO_2$, which is subsequently released and separated as a concentrated $CO_2$ stream. The treated stream is neutralised prior to discharge. The energy consumption for ocean capture is reported at 11.3 GJ/t-$CO_2$ [9].

The downstream purification consists of steam stripping for ammonia recovery, followed by evaporation for water removal, crystallisation of urea, and solid–liquid separation by filtration as to obtain the solid urea product. This flowsheet reflects mature industrial practice and enables systematic evaluation of energy consumption to purify the urea from the liquid phase following the electrolyzer.

Process modelling is used to link electrolyzer performance to system-level economic and environmental impacts. Process model covers all modules except the nitrate pre-treatment, where energy consumption is assumed as negligible while achieving a nitrate concentration of 0.1M $NO_3^-$, which is commonly used for the C-N electrolyzer operation [5].

## 2.2 Electrolyzer Modelling

The electrolyzer is modelled in Python using mass and energy balances for a three-compartment BPM flow-cell (cathode, anode, membrane). The electrolyser model is informed by experimental research conducted at TU Delft using a small-scale flow-cell electrolyser for the co-electrolysis of $CO_2$ and nitrate to urea. Current experimental result (FE, current density, and cell voltage) is used as the initial operating point for the process model. To represent future scale-up and technology maturation, improved electrolyser performance is systematically explored through parametric variation of these KPIs, reflecting plausible advancements in catalyst activity, membrane performance, and cell design. Scale-up is represented via modular replication of identical cells, assuming preservation of cell-level performance.

Given inputs include the urea production rate, nitrate and $CO_2$ conversion, FE, and current density; the model outputs are the required electrode area, energy balance (cell voltage), mass balance (outlet stream compositions).

## 2.3 Downstream Process Simulation

Downstream separation is simulated in Aspen Plus to recover urea from the dilute aqueous product stream produced by electrochemical C–N co-electrolysis. As no established industrial separation route exists for urea recovery at such low concentrations, representative downstream configurations are designed as engineering case studies to systematically evaluate energy and cost associated with urea recovery. The base case consists of steam stripping for $NH_3$ recovery, followed by multi-effect evaporation, urea crystallisation, and solid–liquid separation by filtration, providing a conservative thermally driven reference.

As to reduce the energy consumption, alternative process configurations incorporate pre-concentration (e.g. reverse osmosis, RO) and heat-pump (HP) assisted evaporation [10, 11].

## 2.4 Techno-Economic and Life-Cycle Assessment

The functional unit is 1 kg of urea on a cradle-to-gate, covering raw material supply, co-electrolysis and urea recovery. Fossil urea is used as a benchmark (0.38 $/kg-urea; 1.38 kg $CO_2$/kg-urea). ICONIC targets a production cost at 1 €/kg-urea.

Electrolyzer CAPEX and electricity price can be two important drivers for e-chemicals [12, 13]. ICONIC electrolyzer CAPEX for C/N co-electrolysis for e-urea is assumed to range from 5, 000 $/m² (base) to 2, 500 $/m² (optimistic), reflecting inheritance from both $CO_2$ reduction reaction (CO2RR) at 900–1800 $/m² [13] and nitrogen reduction reaction (NRR) technologies (4000–7500 $/m² by 2050) [12].

Electricity cost and carbon intensity are strongly location-dependent and therefore explicitly considered through the selection of two representative production locations. The Netherlands (NL) is chosen to represent a system dominated by offshore wind power, characterised by relatively low-carbon but moderate-cost electricity. Spain (ES) is selected to represent a solar-dominated system with lower electricity costs but a higher carbon intensity. Both base and optimistic scenarios are evaluated for each location to systematically assess the combined effects of electricity price and electrolyzer cost on the economic performance of e-urea production (Table 1).

**Table 1.** Scenarios of locations and electrolyzer costs for e-urea production.

| Scenarios | Energy cost ($/kWh) | Carbon intensity ($gCO_2$/kWh) | Electrolyzer cost ($/m²) |
|---|---|---|---|
| NL base (wind) | 0.07 | 12 | 5000 |
| ES base (solar) | 0.04 | 33 | 5000 |
| NL optimistic (wind) | 0.03 | 12 | 2500 |
| ES optimistic (solar) | 0.01 | 33 | 2500 |

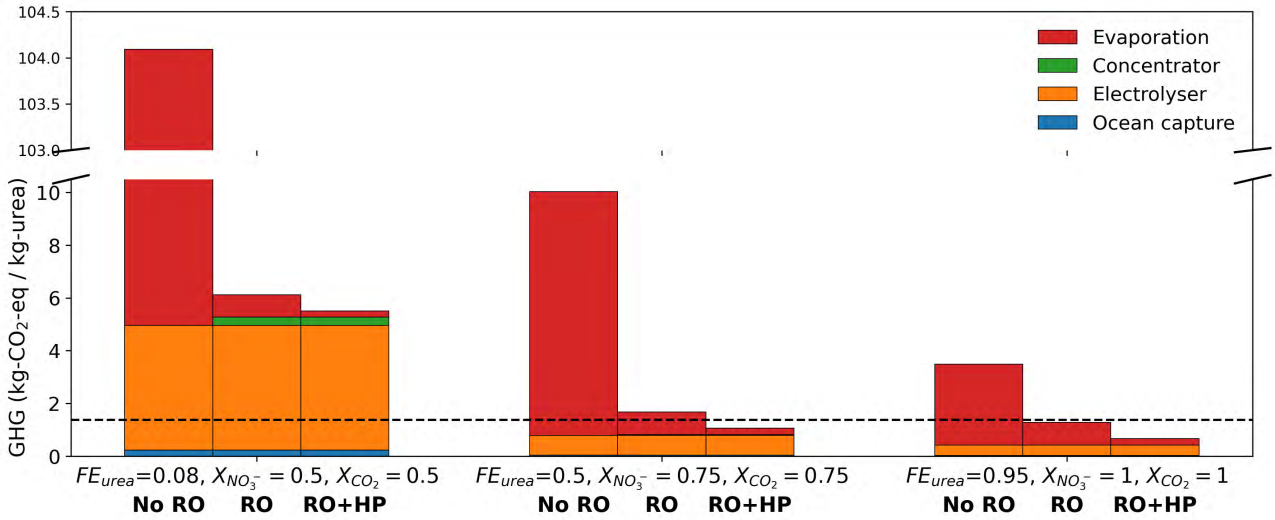

**Figure 2.** GHG breakdowns with the improvement of electrolyzer and different downstream design options. FE_urea is the FE to urea; X_NO3- and X_CO2 is the conversion.

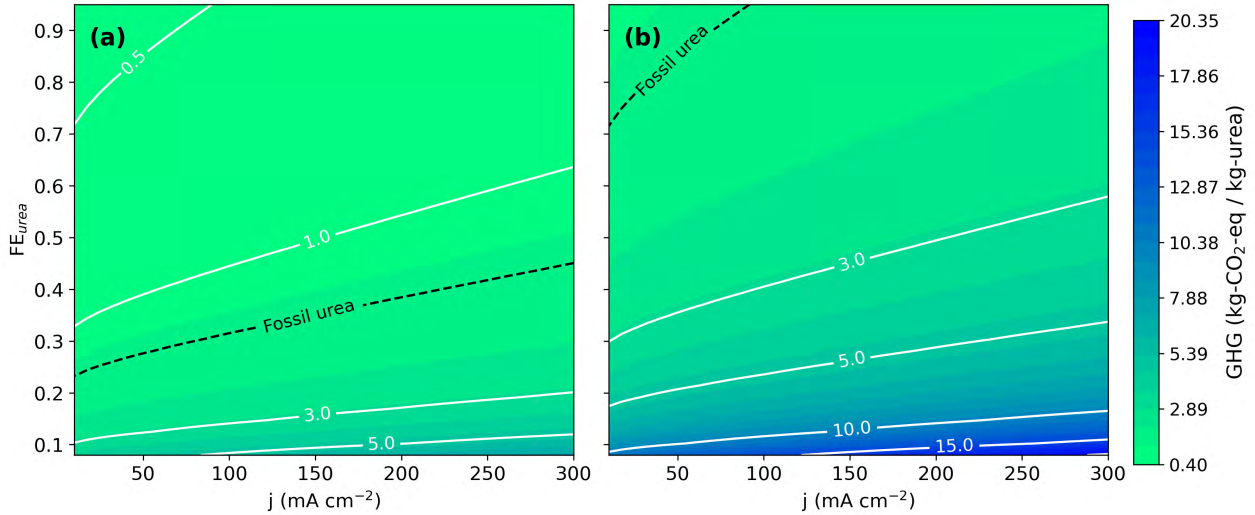

**Figure 3**. Targeting electrolyzer cell KPIs by comparing GHG emissions of e-urea to fossil urea: (a) wind-powered operation in the Netherlands and (b) solar-powered operation in Spain. RO pre-concentration and HP-assisted evaporation are included. Complete nitrate and $CO_2$ conversion is assumed.

# 3 RESULTS AND DISCUSSIONS

## 3.1 GHG Emissions

Figure 2 presents the GHG breakdowns for e-urea production by ocean capture for $CO_2$, electrolyzer, urea concentrator, downstream separation under the improving electrolyzer performances. The dashed line indicates the GHG intensity of fossil urea for reference.

For each electrolyzer case, three downstream separation configurations are considered:

- No RO, where urea recovery mainly relies on thermal evaporation.
- RO, where reverse osmosis (RO) is deployed to concentrate urea prior to evaporation.
- RO+HP, where RO is combined with heat-pump-assisted evaporation.

Notably, downstream evaporation dominates GHG emissions, primarily due to the extremely dilute urea concentration (0.02–0.3 wt%) exiting the electrolyzer. Even with near-ideal electrolyzer performance (the right 'no RO' in Figure 2) and the benefits of renewable electricity, the intensive evaporation energy alone can result in more GHG emissions than fossil urea. The results show that, without pre-concentration, downstream purification dominates total GHG emissions, whereas RO and RO+HP

substantially reduce the thermal energy demand and associated emissions.

Introducing RO concentration can reduce thermal energy demand by up to ~90%. HP-assisted evaporation can further cut thermal duty by additionally 90%. RO and HP substantially expand the feasible operating window for electrolyzer KPIs.

Comparing to the GHG of fossil urea, Figure 3 presents sensitivity analysis for the feasible operating window for electrolyzer. Lower current density and higher FE to urea are environmentally preferred. Under wind power in NL, e-urea achieves lower GHG emissions than fossil urea at FE > 0.4. In ES, higher FE (>0.7) and moderate current densities (and j < 100 mA/cm²) are required due to the higher carbon intensity of solar electricity than wind (**Table 1**).

## 3.2 Techno-Economic Assessment

Figure 4 illustrates the effect of electrolyzer current density on e-urea production cost. Increasing current density reduces electrolyser CAPEX due to the reduction of required electrolyzer area, while simultaneously increases electricity-related OPEX. As a result, the total production cost exhibits a shallow minimum at intermediate current densities (≈50–100 mA·cm⁻²). The dashed lines indicate the fossil urea benchmark and the ICONIC target cost for comparison.

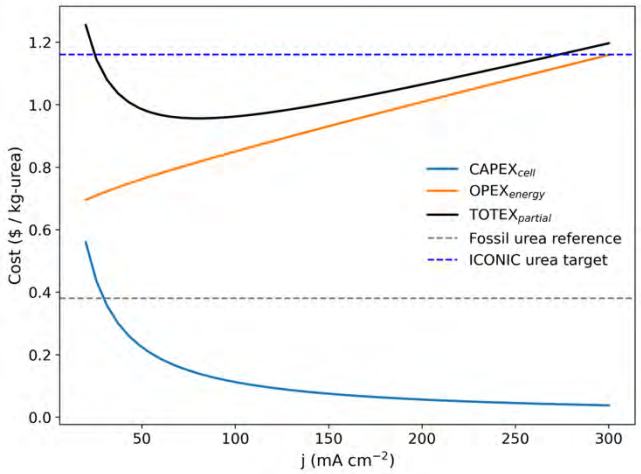

**Figure 4.** Cost of urea with respect to current density.

Figure 4 shows e-urea is more than twice costly than fossil urea, while a proper operating window ranging from 30 to 270 $mA \cdot cm^{-2}$can still achieve the ICONIC target at 1 €/kg-urea.

As shown in Figure 5, sensitivity analysis shows a

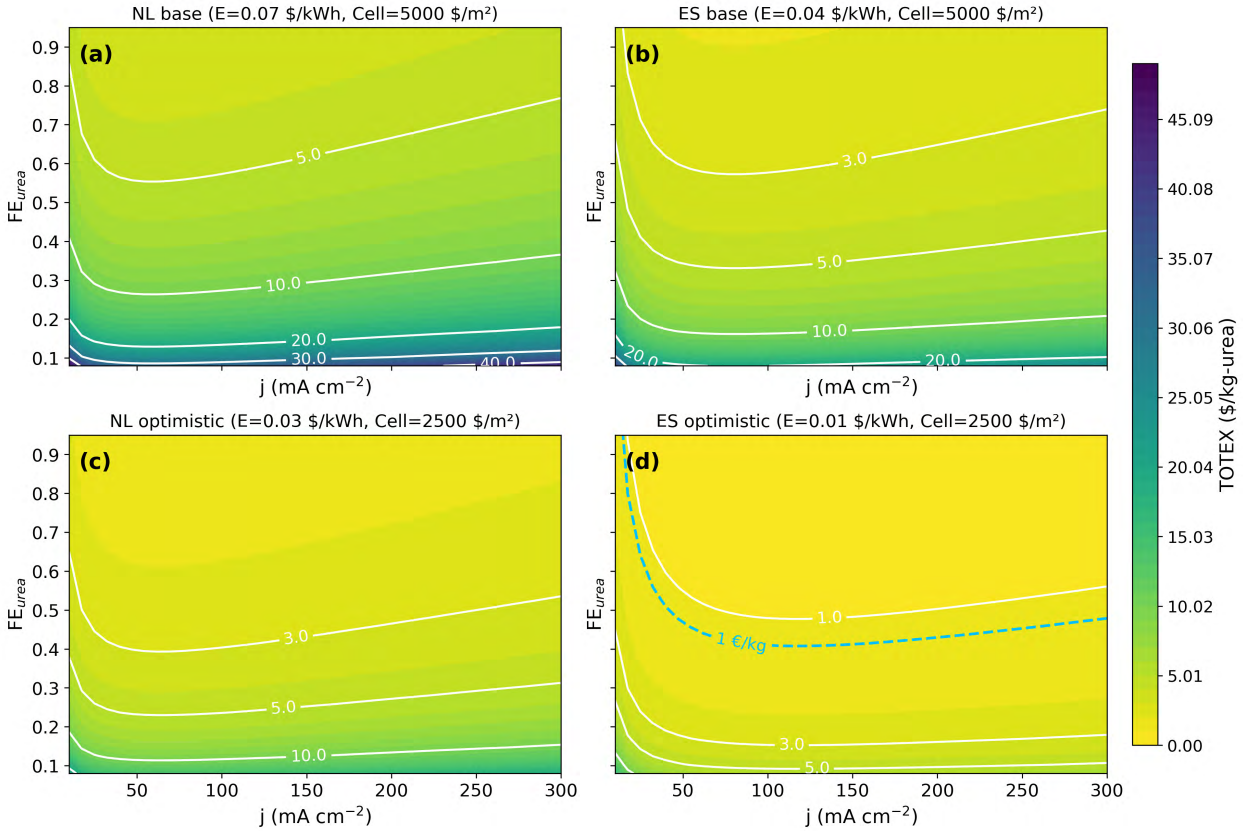

**Figure 5.** Targeting electrolyzer cell KPIs by the production cost of e-urea. (a) NL – base; (b) ES – base; (c) NL – optimistic; (d) ES – optimistic. RO pre-concentration and HP-assisted evaporation are included. Complete nitrate and $CO_2$ conversion is assumed.

higher FE always reduces cost and a proper current density range: 50–100 mA/cm² can further reduce the cost. In the base scenario, neither NL nor ES achieves cost parity with fossil urea. However, under optimistic ES conditions (FE > 0.4, j > 50 mA/cm²), ICONIC e-urea approaches (~1 $/kg-urea), compared to the ICONIC target at 1 €/kg-urea.

## CONCLUSION CONCLUSIONS AND FUTURE OUTLOOK

This study demonstrates that it is challenging for e-urea to environmentally and economically compete with fossil urea, if the electrolyzer alone is considered**.** Key insights for the electrolysis include:

- Faradaic efficiency: higher FE is always preferred, as it lowers specific energy (kWh/kg-urea), reduces side-product formation, and shrinks downstream duty.
- Current density: Moderate targets (~50–100 $mA{\cdot}cm^{-2}$) are preferred, as it balances CAPEX and OPEX.
- Electrolyzer cost: Achieving competitiveness requires CAPEX well below 5, 000 $/m², with a medium-term target of ~2, 500 $/m².

Notably, downstream (upstream) processes of electrolyzer matters. The dominant bottleneck is dilute urea from electrolyzer outlet for the downstream, which is directly related to the low $NO_3^-$ concentration at 0.1 M in the electrolyzer inlet for the upstream (the concentration of $NO_3^-$ in coastal water is even much lower, so upstream for $NO_3^-$ separation also matters). Novel energy-efficient recovery and heat integration can significantly expand the feasible design space for electrolyzer KPIs.

As per location, manufacturing in the Netherlands results in lower GHG emissions but remains economically less viable than production in Spain.

Future research should shift beyond catalysts and membranes for electrolyzer toward process-level innovations, including electrolyzer configurations that directly concentrate urea and advanced liquid-phase urea recovery technologies. By linking lab-scale KPIs to system-level performance, this TEA–LCA framework provides actionable guidance for scaling up e-urea production in early stage and enhance the resilience of the fertilizer supply chain.

## ACKNOWLEDGEMENTS

Authors gratefully acknowledge Prof. Tony Kiss and Dr. Tamara Jankovic for the insightful discussions on the design options for downstream separation from diluted solution, and Qing Li for the discussions on heat pump-assisted distillation. This work received the financial support from European Union: ICONIC (101115204) project.

## ABSTRACT

The utilization of low-quality vegetable oils as raw materials helps to reduce the production costs of biodiesel. Waste cooking oils are examples of this type of raw material, having a high content of free fatty acids. While biodiesel is a sustainable alternative to fossil fuels, conventional production methods face challenges due to low reaction rates and high energy demands. This study investigates pathways for biodiesel production from waste cooking oil using process intensification technologies in combination with biowaste-derived heterogeneous catalyst. Conventional and intensified (reactive distillation-based) processes are compared using Aspen Plus simulations as an analysis tool, focusing on the production of biodiesel from waste cooking oil (WCO) using CaO as a catalyst. According to the results, the conventional method at 60°C and 6:1 methanol-oil ratio achieves 95% conversion but suffers from high methanol use and long reaction times (65 min). The intensified process at 65–70°C reduces energy needs by more than 29%, requiring shorter residence time while enhancing efficiency. Overall, it demonstrates that intensified and sustainable biodiesel production can reduce environmental footprints and support the transition to cleaner energy systems. This work emphasizes the transition from traditional processing routes to innovative, intensified technologies for sustainable fuel production within the framework of the circular economy.

**Keywords**: reactive distillation, process design, biodiesel, waste cooking oil

## INTRODUCTION

Recently, the global energy demand climbed 63% between 2010 and 2019, reaching 14, 406 Mtoe due to population expansion and modern lifestyle changes. The International Energy Agency (IEA) projects a further 20% increase by 2050. Thus, the transition to renewable energy sources, particularly biofuels, has become more urgent than ever [1]. Biofuels (bioethanol, biodiesel, biogas, etcetera) produced from different organic feedstocks such as food, municipal, and agricultural waste might provide an alternative solution to overcome the global challenges faced by the excessive use of fossil fuels, including economy, reservoir depletion, and pollution [2].

Biodiesel is a very attractive option to overcome the energy crisis, since it is derived from renewable feedstocks, which may lead to more sustainable production schemes. Moreover, its use as energy source may provide substantial reductions in greenhouse gas emissions [3].

Lipidic waste such as waste cooking oils (WCOs), and slaughterhouse waste are potential feedstocks for biodiesel production. The waste cooking oil is inexpensive and widely available due to its numerous sources (restaurants, food processing industries, fast food outlets, and households), which makes it a potential alternative as raw material. The utilization of waste cooking oil to produce biofuels is helpful to deal with the energy crisis, food safety, and environmental problems because of the renewable, non-toxic, and clean combustion alternative of such derivatives [2].

An industrial-scale biodiesel production facility usually employs alkali catalysts for transesterification. However, the use of alkaline catalyst may lead to undesired side reactions for raw materials with high composition of free fatty acids. In these cases, esterification can convert

FFA into fatty acid methyl esters (FAMEs) using an acid catalyst such as sulfuric acid as a pretreatment step [5]. Therefore, an additional process is required when changing the feedstock from refined vegetable oil to WCO to decrease FFA in the raw material before transesterification.

A heterogeneous catalyst derived from biowaste, specifically eggshells, has been used to improve the environmental and operational performance of biodiesel production. Environmental assessment has indicated that CaO-based heterogeneous catalyst significantly reduces impacts on human health and ecosystems while maintaining high biodiesel yields. Compared to conventional catalysts, biowaste-derived CaO provides a sustainable alternative, balancing high conversion efficiency with reduced environmental impacts and aligning with circular economy principles. [6]

Process intensification seeks to transform the industry through integrated design, which aims at reducing the mass and heat transfer resistances while overcoming thermodynamic limitations through integrated designs and operation. In retches enchainment years, PI has attracted considerable academic interest as a potential mean for process improvement, to meet the increasing demands for sustainable production [7]. A clear example of intensified equipment is given by the reactive distillation columns.

The concept of reactive distillation combines these two important functions for the enhancement of the process. The separation of the product from the reaction mixture may not need a separate distillation step, which saves energy for heating and material.

When considering the characteristics of the transesterification reaction, a multifunctional reactor combining chemical reaction and distillation in a single column is a promising way. The simultaneous separation and reaction inside the column allow the equilibrium-limited reaction to take place more completely and reduce the separation cost of unreacted reactants [8].

The design of the reactive distillation focuses on the identification of the characteristics and operating conditions of the separation systems, which are significantly more complex than those involved in ordinary distillation. However, its advantages may compensate this additional complexity, considerably enhancing the performance of the process and its economic and environmental indicators.

Although production of biodiesel is technically feasible, strategies must be sought to make it cost-competitive with fossil diesel, implementing strategies that make more efficient its production. One of the key alternatives that allows for reducing production costs is the use of low-cost raw materials, as well as the implementation of intensified technologies [2]. Therefore, the objective of this research is to evaluate the implementation of intensified technologies to improve process efficiency and reduce energy impact in the production of biodiesel with heterogeneous catalysis.

## CASE STUDY

The biodiesel production processes studied in this work use waste cooking oil as raw material. The designs of the processes have been obtained by simulation in the commercial software Aspen Plus. The first steps in developing the process simulation were defining components and selecting appropriate thermodynamic models. In addition, unit operations and operating conditions, input conditions and plant capacity must be all selected and specified.

Based on the aforementioned information, a process feeding of 2900 kg/h of waste cooking oil has been proposed; this is an estimated amount generated annually in Mexico. [9] Table 1 presents the lipidic profile employed to represent the oil. Likewise, numerous studies have reported the interaction parameters between glycerol, methanol, and water. Some authors have studied the behavior of liquid-liquid equilibria, which are fundamental to the design of biodiesel purification processes, comparing experimental data with calculations provided by thermodynamic models. In the study by Tomassetti et al. [10], who measured liquid-liquid equilibrium, the UNIQUAC model accurately follows the LLE of biodiesel + glycerol and biodiesel + water, while the UNIFAC model can predict values with most of the experimental data for the FAMEs + glycerol system. The use of the UNIFAC L-L model is also reaffirmed by Souza et al. [11]. In the study of Pasha et al., the non-random two-liquid (NRTL) model was selected as the property package due to the presence of polar compounds and the non-ideal nature of the transesterification reaction system, with methyl esters being of primary interest [12]. NRTL has been chosen for most stages of the process studied in this work. UNIFAC-LL is used for phase separation equipment in the presence of ethyl esters with glycerol and methanol.

**Table 1:** Lipid composition of waste cooking oil.[13]

| Fatty acids (6% wt) | Triglicerides (94% wt) |
|---|---|
| Palmitc acid (12.3% wt) | Trypalmitin (12.3% wt) |
| Oleic acid (24% wt) | Triolein (24% wt) |
| Linoleic acid (56.6% wt) | Trilinolein (56.6% wt) |
| Linoleic acid (7.1% wt) | Trilinolenin (7.1% wt) |

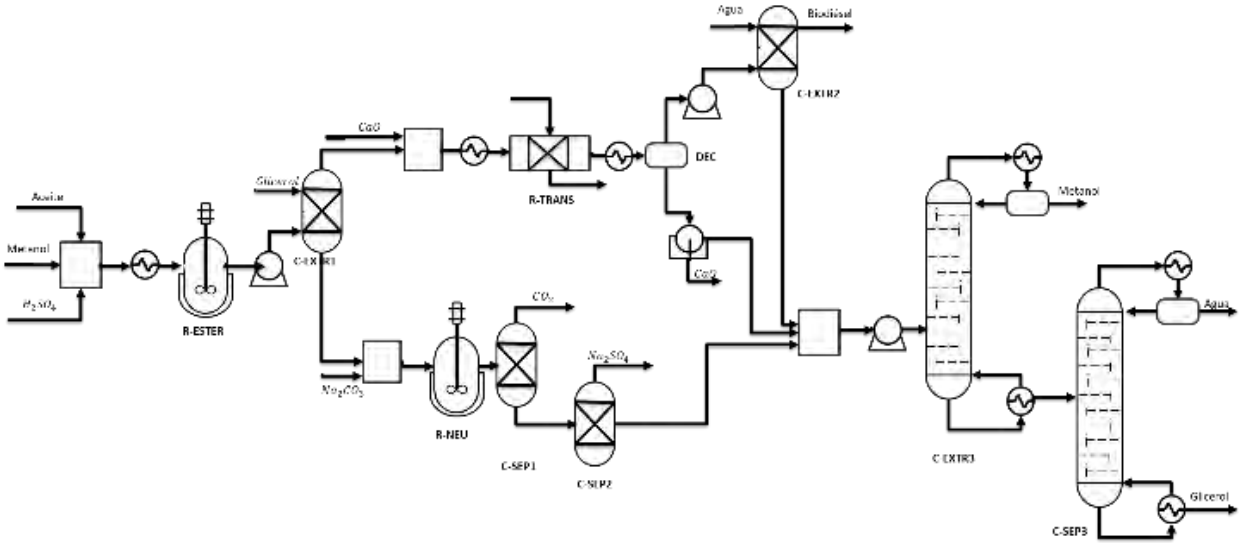

**Figure 1.** General conventional process treatment.

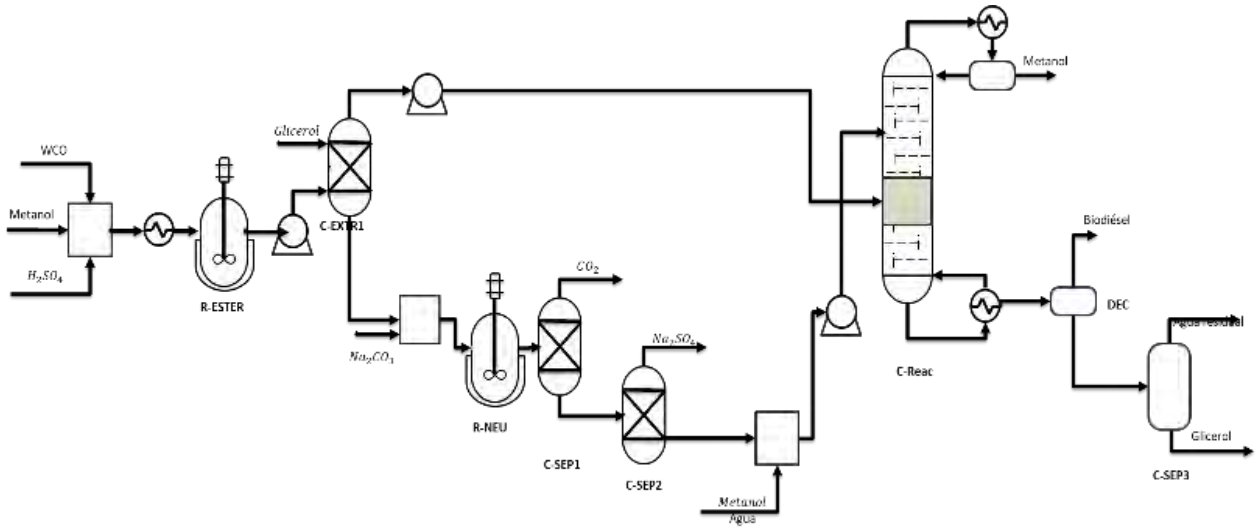

**Figure 2.** General intensification process treatment.

## Conventional process

Figure 1 shows the conventional process proposed to produced biodiesel. The waste cooking oil pretreatment stage is implemented; this step is catalyzed by a sulfuric acid. At the outlet of the esterification reactor, the triglycerides together with the excess alcohol and the catalyst. The mixture passes to an extraction column where the triglycerides are separated from the alcohol and the catalyst, so it can move on to the neutralization stage and recover part of the alcohol. Downstream of the esterification reactor, there is a neutralization reactor, where the catalyst is neutralized, and the resulting salts are separated. The second reactive zone is where the transesterification of triglycerides to methyl esters take place. A plug flow reactor is used, where water is used as cooling fluid. With the help of a decanter, the biodiesel phase and the aqueous phase are separated; this last phase includes methanol, glycerol and water. The oily phase goes into an extraction column where the biodiesel is washed and separated from the impurities to finally obtain the refined biofuel. On the other hand, the aqueous phase is directed to two distillation columns where most of the methanol and glycerol present in the stream are recovered. Sensitivity analysis has been applied to the process equipment with available degrees of freedom, mainly the reactors and distillation columns, to obtain the best values operating variables, aiming to keeps costs down and maintain product quality. The goal was to maintain 99 % purity for both the glycerol recovery and the biodiesel.

## Intensified process

Figure 2 shows the proposed intensified process. The initial step is the same of the conventional process, where the esterification reaction followed by the neutralization of the resulting mixture take place. Upon completion, the triglycerides exiting the extraction column are fed directly into the reactive distillation column. A fraction of the methanol originally allocated for esterification is redirected to facilitate the transesterification stage. The core of the process occurs within a reactive distillation column designed, a sensitivity analysis was performed to determine the operating parameters, using the minimum thermal load as the primary criterion while maintaining the required purity in the condenser, where the excess methanol is recovered. It was decided to maintain a reflux ratio variation ranging from 1.5 to 3.5, which are average values commonly found in the literature [14]. The design considered 18 equilibrium stages and a feed composition of 6:1, six parts methanol to one-part triglycerides. The reaction zone is concentrated within two specific reactive stages, the stages 7 to 9, containing a solid calcium oxide (CaO) catalyst. The sensitivity analysis was conducted by evaluating combinations of the number of stages and the feed tray locations. The column yields two distinct output streams, the top stream recovering the methanol, where this alcohol is collected as distillate for potential recycling into the system. The bottom stream consists of a mixture of fatty acid methyl esters (biodiesel), glycerol, and a residual percentage of unreacted triglycerides.

Final purification is achieved through a two-step separation sequence. First, the bottoms stream is sent to a decanter for primary biodiesel recovery, where two phases contained in the mixture, organic and inorganic, are separated. The operating conditions were 1 atm of pressure and 30°C of temperature. Subsequently, the remaining mixture is processed in a flash tank where the glycerol is recovered. This equipment was chosen with a view to obtaining the highest flow in the bottom stream, with the lowest thermal load in the column and recovering most of the glycerol. In addition to the difference in volatility of the components.

## RESULTS

The production of biodiesel through the transesterification of waste cooking oil with methanol in a reactive distillation has been investigated in this work. Once the initial oil passes through the esterification reactor, the initial free fatty acid content goes from 6% to less than 0.9% by weight.

The simulations result for biodiesel production via conventional and intensified processes are presented in Table 2 and 3. The key findings highlight the advantages of process intensification in terms of material efficiency, energy, and product yield.

**Table 2:** Reactant feed streams

| Materials (kg/h) | CP | IP |
|---|---|---|
| Methanol | 1342 | 992 |

| | Flow rate (kg/h) | 3, 675.71 | - |
| | Methanol purity (%mass) | 99 | - |
| **Equipment** | **Variable** | **CP** | **IP** |
| Glycerol column | Number of plates | 6 | 1 |
| | Feed plate | 2 | 1 |
| | Flow rate (kg/h) | 3, 182 | 414 |
| | Methanol purity (%mass) | 99 | 99 |

**Table 5:** Energy requirements of the process.

| Equipment | CP (kW) | IP (kW) |
|---|---|---|
| Esterification reactor | 1.9 | 1.9 |
| Transesterification reactor | 848.6 | - |
| Reactive distillation column | - | 1, 736.13 |
| Biodiesel separation | 792.5 | 157.4 |
| Methanol column | 1650.2 | - |
| Glycerol column | 15, 801.3 | 51.5 |
| Total | 19, 094.5 | 1946.9 |

When comparing the two processes, improvement in feedstock utilization yield is observed, increasing from 94 % with a conventional plug flow reactor (PFR) to 95 % with the reactive distillation. Furthermore, the transesterification reaction produces glycerol, a commercially valuable by product, yielding 288.25 kg/ hr in the intensified process and 288.19 kg/ hr in the conventional route. Since the conventional process generates a high-volume entering the first distillation column, it consequently requires significantly higher energy for purification. Regarding methanol consumption, the intensified process uses substantially less, which translates not only into raw material savings but also a direct reduction in condenser duty. While the reduction in the number of stages influenced the holdup, increasing the reaction rate. The most significant improvement in seen in the reboiler energy savings, around 66%. This is due to the heat integration by the transesterification reaction within the reactive column, where the heat is utilized directly for phase separation, unlike the sequence used in conventional distillation. Consequently, this results in an overall energy savings of 29% when comparing the complete intensified process to the conventional one.

The conventional process requires cooling services for the PFR, and water for biodiesel washing and methanol separation. The intensified process reduces wastewater generation. In the reactive distillation column, the methanol is recovered, simplifying the separation of the final product and by-products. This reduces energy costs, as there is no need for extraction equipment for biodiesel washing in the intensified scheme.

## CONCLUSIONS

The design of two biodiesel production processes has been carried out in a simulation environment, allowing the analysis for the complete process to be carried out. Based on the results, the most convenient configuration for biodiesel production employs an intensified system. This configuration can produce high biodiesel yields by incorporating a pretreatment stage that significantly reduces free fatty acids, as well as the choice of favorable operating conditions.

The intensified process offered better performance in terms of biodiesel yield and energy consumption compared with the conventional one. The results demonstrated the benefits of adopting intensified processes in the transition toward more sustainable fuel production systems.

Ultimately, this study establishes that intensified biodiesel production, when integrated with renewable feedstocks and catalysts, plays a critical role in the global transition to low-carbon fuels. Advancing these technologies toward large-scale implementation will depend on coordinated progress in engineering efficiency, economic viability, and regulatory support. Such an integration ensures that biodiesel productions align with the broader goals of resource scarcity reduction and the establishment of sustainable energy systems.

## ABSTRACT

An integrated multiproduct facility for the valorization of apple pomace in the green production of high value-added chemicals such as phenolic compounds and pectin, bioethanol, as well as apple juice, was optimally designed. The process includes green extraction technologies relying on subcritical water extraction and ethanol produced on-site through fermentation of residues. Two scenarios were evaluated: one based on purchasing the ethanol and another with on-site ethanol production. The units of the process were modeled using first principles. The process superstructure was formulated as a mixed-integer nonlinear programming problem, solved by decomposition. Investment and production costs of both alternatives were similar, with unit production requirements ranging from 1.09 €/L to 1.13 €/L. The discounted payback periods were 6.7 years and 6.4 years for the on-site ethanol production and purchased ethanol scenarios, respectively, while the internal rates of return were 36.4 and 37.8% for both processes, respectively. Both scenarios showed economic profitability with higher returns under the purchased ethanol scenario, but the on-site production scenario allowed waste reduction, self-sufficiency and ethanol reuse. A green extraction process based on subcritical water for the pectin extraction and the solvent recycling avoided the use of conventional acids and promoted the circular economy. The findings of this project demonstrated the potential of apple pomace as a valuable feedstock for integrated biorefinery applications in the agri-food sector.

**Keywords**: Integrated facility, Apples, Mathematical optimization, Apple pomace, Value-added products

## INTRODUCTION

Food waste represents an important challenge leading to environmental problems due to the high volumes of residues generated (59 million tons alone in Europe in 2024) and the reduction of the supply chain efficiency [1]. Food waste valorization is an opportunity to mitigate this problem. Within this context, the beverage and juice processing industry not only generates large amounts of residues but also discards products with high value-added that could be recovered and reused. Fruit byproducts contain pectin, phenolic compounds, and fermentable sugars that can be transformed into value-added products and bioenergy contributing to the circular economy [2]. Orange peels spent coffee grounds, apple pomace, and olive oil residues have been used to produce value-added products [3].

The extraction process (i.e., the use of solvents, supercritical fluids or steam) to produce value-added products is a critical step. To evaluate and scale up the process, techno-economic analysis of the process using simulation-based approaches for comparing technologies is a promising tool [4]. Optimization-based design enables simultaneous synthesis, and mass and energy integration analyses. This allows the reduction of the need for external chemicals and utilities within the process. Polyphenols, oils, essential oils and pectin are the main value-added products extracted from food wastes. Furthermore, green solvents and end-use chemicals have been produced from these biomasses. This framework has been extended to the apple residues valorization.

The extraction of apple juice produces high volumes of apple pomace that can be valorized. The optimization of the process is carried out by developing a design of experiments for determining the optimal operating conditions. Apple pomace contains pectin, antioxidants and

polyphenols. Therefore, the development of cleaner extraction technologies such as subcritical water, microwave-assisted, supercritical $CO_2$, and ultrasound-assisted contribute to improve process efficiency and reduce solvent consumption.

Different approaches using commercial simulation software (i.e., SuperPro or Aspen Plus) to produce polyphenols, and to compare the biogas, pectin and bio-oil production have been reported in the literature. Vukušić et al. [5] have developed a pilot plant biorefinery analysis for producing apple juice, pellets, ethanol and pectin from apples. Okoro et al. [6] compared the production of lactic acid, xylitol and hydroxymethyl furfural using an optimization approach (NSGA-II algorithm within Aspen Plus). However, an integration of the facility has not been conducted. Commercial simulation software has limitations to model different biomass processing stages. Furthermore, their databases lack chemicals and properties needed to perform accurate modeling of processes.

In this study, an integrated facility was optimized to produce apple juice, high value-added products (e.g., pectin, phenolic compounds, and ethanol used as a solvent in extraction processes) based on circular economy concepts and using a mathematical optimization model. An economic analysis was carried out to assess economic feasibility of the facility under two scenarios: one producing ethanol on-site and another purchasing it externally. This framework promotes more sustainable strategies within the agri-food sector and contributes to maximizing economic benefits and efficiency.

## PROCESS DESCRIPTION

The extraction processes for the pectin and phenolic compounds recovery require high volumes of solvents, which can be covered by the full utilization of apple residues for producing green ethanol by fermentation. The process has been divided into four sections as shown in Figure 1.

The apple juice production involves washing, milling, and pressing the fruit using pectinase enzyme to achieve higher yields in juice extraction. A clarification process is carried out to hydrolyze the pectin (responsible for cloudiness) with a conversion of 0.99 using 0.05 kg of immobilized pectinase per liter of juice for 6 hours at 30 °C. A stirred tank reactor operating for 30 min at ambient temperature in the presence of bentonite and gelatin enables the coagulation of protein complexes, tannins and suspended solids. Pasteurization is carried out using a continuous high-temperature short-time pasteurizer at 85 °C before bottling.

The apple residues generated during juice production are fed to a dryer (DR-01), followed by a mill (M-02) and pre-treating unit using ethanol for 20 min at 50 °C, ensuring the phenolic compounds extraction. The solid content is sent to the section of pectin extraction containing 30% moisture by weight. A flash separation unit enables the ethanol recovery before being reused. This unit operates at 90 °C. A molecular sieve (T-01), which operates at 70 °C, isolates phenolic compounds with 99.9% purity.

The pectin extraction is carried out in a stirred reactor (TK-04) through a subcritical water extraction process at 150 °C and 4.6 bar, with a yield of 0.17 g of pectin per gram of pomace. In the TK-04, cellulose and hemicellulose hydrolysis to fermentable sugars is achieved, with yields of 50 and 70%, respectively [7]. The pectin recovery is carried out employing ethanol at 95% purity in a stirred reactor (TK-05) operating for 20 min at 30 °C. The pectin is extracted as a gel and washed using ethanol to remove impurities. The solid pectin containing 10% moisture is isolated from the liquid phase using a press. Finally, a dryer (DR-02) reduces pectin humidity to 5%, before milling and storage.

The ethanol-rich streams from the extraction processes units are sent to the distillation column (DC-01) as a liquid at saturation conditions, for the ethanol recovery at 95% purity. The fermentation unit (R-01) is fed with the distillation column bottoms and operates at 38 °C for 24 h with 0.7 g of inoculum per liter of solution [8]. The main substrates assumed in the fermentation were xylose and glucose, with conversion rates of 0.83 and 0.955, respectively. The reactions involved in this process are shown below according to the data from the NREL database.

$$C_6H_{12}O_6 \longrightarrow 2C_2H_5OH + 2CO_2 \quad (1)$$

$$3C_5H_{10}O_5 \longrightarrow 5C_2H_5OH + 5CO_2 \quad (2)$$

$$C_6H_{12}O_6 + 1.2NH_3 \longrightarrow 6CH_{0.56}O_{0.5}N_{0.2} + 2.4H_2O + 0.3O_2 \quad (3)$$

$$C_5H_{10}O_5 + NH_3 \longrightarrow 5CH_{0.56}O_{0.5}N_{0.2} + 2H_2O + 0.25O_2 \quad (4)$$

A molecular sieve was used for the bioethanol purification up to 95% weight. The bed of the molecular sieve is regenerated with air at 70 °C and continuous operation is enabled by two parallel beds. The stream from the molecular sieve is mixed with the top of the distillation column and is recycled to the process, whereas the remaining ethanol is purified to meet fuel-grade purity requirements.

The scenario that considers purchased ethanol, shares the first three stages (juice production, phenolic compounds extraction and pectin recovery) and differs in the last stage, where only ethanol is recovered at 95% purity using a distillation column and the distillate is mixed with make-up ethanol and recycled to meet the plant's ethanol demand.

## MODELING AND SOLUTION PROCEDURE

The units were modeled using first principles (i.e.,

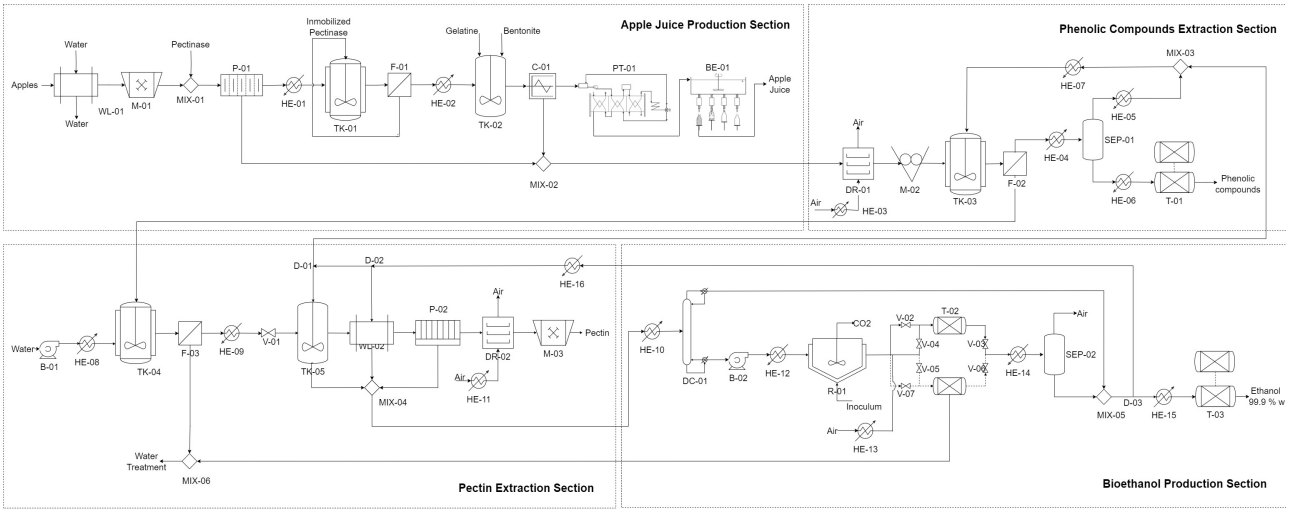

**Figure 1.** Flow diagram of the integrated facility divided by sections.

energy and mass balances), experimental kinetics, process yields, vapor-liquid equilibria and power consumption of equipment. The distillation column was modeled employing the CHEMCAD process simulator. The flash separator units were modeled employing vapor-liquid equilibrium relationships and the Antoine equation for the vapor pressure calculations. The problem was solved by maximizing a profit function comprising the product revenues, the cost of raw materials and utilities as follows:

$$Z = \sum_{i=Products} C_i \bullet flow(i) - \sum_{r=Raw\ materials} C_r \bullet flow(r) - \sum_{k=Mechanical\ equipment} C_e \bullet W(k) - \sum C_{Wa} \bullet Wa_{utility} - \sum C_{Steam} \bullet Steam_{utility} \quad (5)$$

where $C_{Steam}$ is the cost of process steam, $C_{Wa}$ is the water cost, $C_e$ corresponds to electricity cost, $W$ is the power consumption of mechanical equipment, $C_r$ denotes the raw materials costs, and $C_i$ represents the selling prices of the products obtained.

The superstructure of alternatives was represented by a mixed integer nonlinear programming (MINLP) model. Two scenarios (i.e., one producing ethanol on-site, and another purchasing it) were modeled by two nonlinear programming (NLP) formulations written in GAMS. The scenario involving the purchasing ethanol production is composed of 3, 854 equations and 4, 812 variables, while the scenario involving ethanol production on-site is composed of 4, 763 equations and 5, 979 variables. The problems were solved using a multistart optimization framework, selecting CONOPT as the preferred solver. After modelling all equipment, an economic evaluation was carried out.

## RESULTS

The facility capacity was assumed to be 2000 kg/h of apples which corresponds to 40% of the production of the annual production in the region of Castilla y León, Spain [9]. The facility operates 24 h a day for 334 days in a year, considering a month for maintenance. A scaling study was carried out to evaluate economic feasibility.

### Mass and Energy Balances

The energy and mass balances results for both scenarios are reported in Table 1. The needs for raw materials are equal in both cases, as they are associated with the production of apple juice. Ethanol is produced on-site under the first scenario, resulting in an additional amount of solvent generated (i.e., 16.61 L per $m^3$ of apple juice). However, in the purchased ethanol scenario, a total of 134 L of ethanol is needed to be acquired. Producing ethanol contributes to the circular economy principles, avoids dependence on external resources and promotes sustainable waste management practices.

Apple juice accounted for the largest production volume, exceeding 10, 000 $m^3$ per year. However, its selling price is low. A total of 3 t per year of phenolic compounds were produced, but they are high-priced, accounting for a substantial economic profit. Pectin was produced by 148 t per year, and its value is relatively high.

The first scenario requires 120.04 kWh of electricity per $m^3$ of apple juice, twice the energy requirements of the second scenario (67.58 kWh per $m^3$ of apple juice). This difference is due to the high energy consumption of the fermentation and ethanol recovery units. Cooling water and ammonia needs are similar in both scenarios. A

reduction in steam requirements in the ethanol purification process under the first scenario was achieved using the molecular sieve. Ethanol losses in this purification unit remained minimal (1%).

This study proposes the use of subcritical water for the pectin extraction, avoiding the need for sulfuric acid or citric acid and neutralizing agents compared to previous works [10]. This sustainable alternative also reduces operational risks without compromising process yields.

**Table 1:** Energy and material balances results for the study cases.

| | Produced on-site ethanol | Purchased ethanol |
|---|---|---|
| Apples (t/year) | 16, 032 | 16, 032 |
| Water ($m^3/m^3$ juice) | 9.05 | 9.05 |
| Gelatin ($kg/m^3$ juice) | 0.05 | 0.05 |
| Bentonite ($kg/m^3$ juice) | 0.18 | 0.18 |
| Pectinase ($kg/m^3$ juice) | 0.22 | 0.22 |
| Inoculum ($kg/m^3$ juice) | 3.97 | |
| Ethanol consumed ($L/m^3$ juice) | - | 134 |
| Ammonia ($kg/m^3$ juice) | 0.31 | - |
| Apple juice ($m^3$/year) | 10, 895.11 | 10, 895.11 |
| Phenolic compounds ($kg/m^3$ juice) | 0.29 | 0.29 |
| Pectin ($kg/m^3$ juice) | 13.67 | 13.67 |
| Ethanol produced ($L/m^3$ juice) | 16.61 | |
| Power consumption ($kWh/m^3$ juice) | 120.04 | 67.58 |
| Steam ($kg/m^3$ juice) | 20, 634.10 | 20, 631.50 |
| Cooling water ($m^3/m^3$ juice) | 780.57 | 785.08 |
| Ammonia ($kg/m^3$ juice) | 75.21 | 75.21 |

## Economic Evaluation

An economic evaluation was conducted to compare the profitability of producing ethanol as a solvent on-site with purchasing it from the market. Investment and production costs were calculated, and a sensitivity analysis were performed to estimate several economic indicators. These indicators were evaluated by varying the ethanol market price. In addition, scale-up and scale down studies were carried out to assess the effect of production capacity.

Investment costs were estimated using the factorial method described by Towler and Sinnott [11] and employing correlations reported in the literature to estimate the equipment costs [12]. Figure 2 shows that investment costs are largely dominated by the ethanol recovery and production section, which represents around 50% of the total investment in both scenarios. This is because the distillation column and heat exchangers are expensive units, meaning that avoiding on-site ethanol production does not significantly reduce the investment. In the remaining stages, phenolic compound recovery involves higher investment costs than juice production, which partly explains the limited industrial adoption of waste valorization strategies without economic incentives.

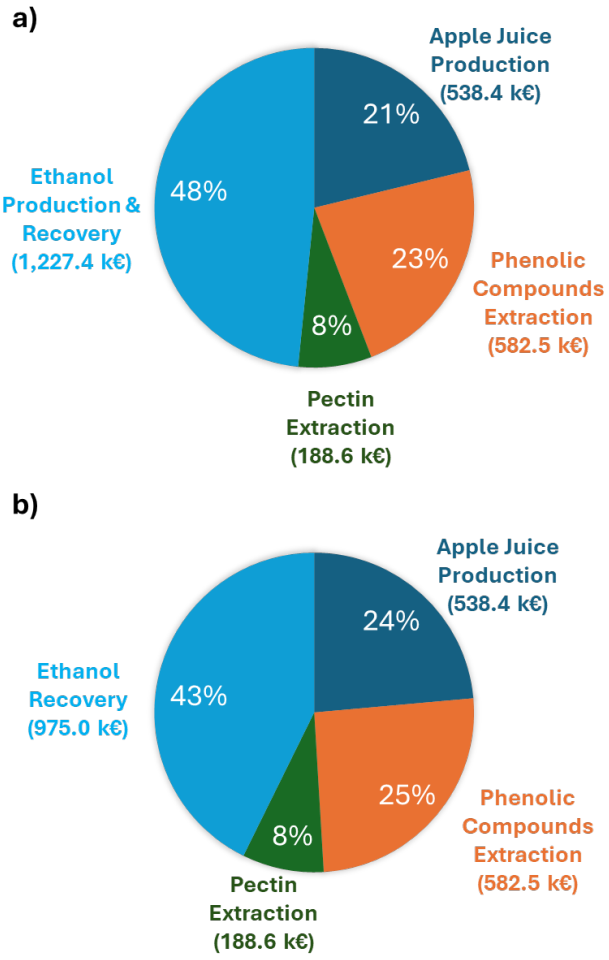

**Figure 2.** Investment cost distribution by stage for the on-site ethanol production scenario (a) and purchased ethanol scenario (b).

Production costs are classified into variable and fixed costs and were estimated following the procedure described in Towler and Sinnott [11]. Figure 3 shows that raw materials and utilities account for more than 70% of the total operating costs and therefore represent the highest expenditure in both scenarios. Purchasing ethanol slightly reduces utility consumption but increases raw material costs, resulting in only minor overall cost differences between both alternatives. Overall, both processes are economically viable, with unit production costs between 1.09 and 1.13 €/L, well below the market price of apple juice in Spain (1.5 €/L). In this way, due to

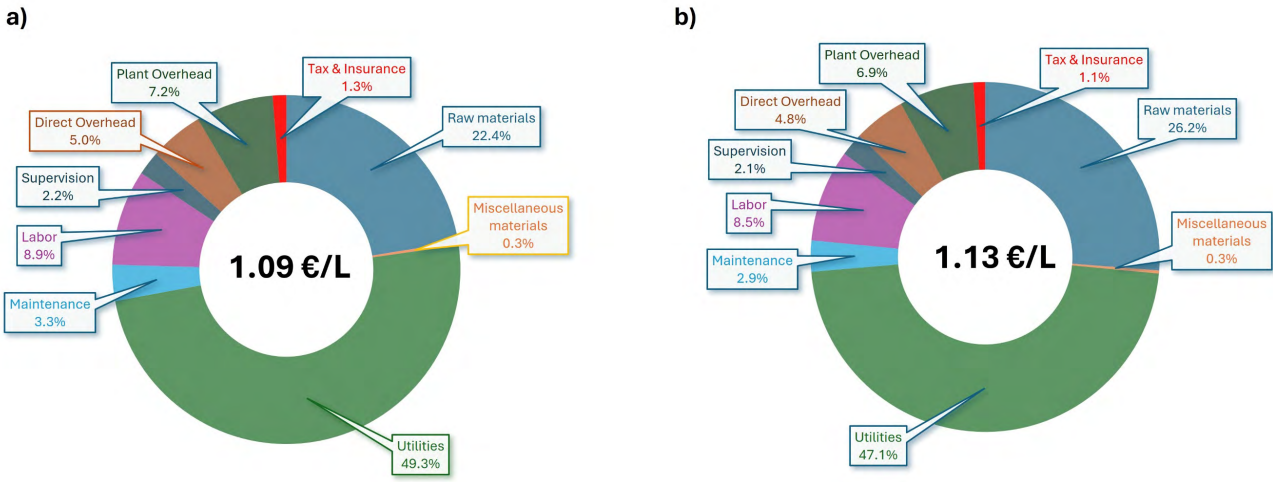

**Figure 3.** Breakdown of the production costs for the (a) ethanol produced on-site and (b) purchased ethanol (0.5 €/kg).

the difficulty in identifying the most attractive scenario, a sensitivity analysis is carried out using the internal rate of return (IRR) and the discounted payback period (DPP) indicators while considering several ethanol market prices (0, 25-1 €/kg). The results show that at low ethanol prices, purchasing ethanol is economically preferable, as it leads to higher internal rates of return and shorter payback periods. However, as ethanol prices and production capacity increase, on-site ethanol production becomes more competitive, lowering unit production costs and offsetting the higher investment.

The scaling results showed that purchasing ethanol is always cheaper from an investment point of view, whereas production costs are slightly higher in the ethanol on-site production scenario, regardless of production capacity. Nevertheless, these results are consistent with the conclusions drawn from the sensitivity analysis.

## CONCLUSIONS

The optimization of an integrated facility to produce juice, phenolic compounds, pectin, and ethanol as a green solvent from apples was conducted. The scenario with on-site ethanol production promotes circular economy concepts and reduces the external dependence on solvents for the extraction processes. Both scenarios showed similar profitability despite ethanol production consumes substantial electricity in fermentation and ethanol recovery stages. However, the plant configuration is determined by the production or waste processing capacity. In general, the scenario based on purchasing ethanol from the market remains economically favorable. However, at large plant capacities and when ethanol prices increase above 0.5 €/kg, on-site ethanol production becomes a competitive alternative. Under these conditions, producing ethanol in situ not only mitigates exposure to external market fluctuations but also enhances process sustainability. In addition, the subcritical water extraction process avoids the need for acids and neutralizing agents. This study highlights the potential of apple pomace as a valuable feedstock for the development of sustainable and economically viable valorization pathways, supporting the transition to resource-efficient and sustainable agri-food systems.

## ABSTRACT

This work presents a hybrid modelling approach for a downdraft sewage sludge gasifier within the Shit2Power (S2P) process. The gasifier is represented in CHEMCAD NXT by a series of four standard reactors that combine stoichiometric and equilibrium models with a data-driven correction step to account for deviations from ideal Gibbs equilibrium. Reaction conversions in the correction reactor are fitted to experimental synthesis gas compositions reported by Werle (2014) [7] for 30 operating points with varying equivalence ratios and reactor inlet air temperatures. The calibrated hybrid reactor model is evaluated against these data and shows conservative agreement for the combustible gas components of the synthesis gas. To overcome the limitations of linear interpolation between fitted operating points, several machine learning approaches are evaluated to predict the reaction conversions, and boosted neural networks are selected as a compromise between prediction accuracy and smooth behaviour in the operating window. After implementation in the CHEMCAD flowsheet, sensitivity studies with respect to equivalence ratio and reactor inlet air temperature show good agreement between predicted and fitted gas compositions, considering the limited data available. This demonstrates that the combination of flowsheet simulation and machine learning provides a promising framework for modelling sewage sludge gasification in the S2P process, but that significantly more experimental and training data are needed for practical application.

## 1 INTRODUCTION

Across Europe, wastewater treatment facilities are adapting sludge-management strategies in response to evolving regulatory requirements and circular-economy objectives. The revised EU Urban Wastewater Treatment Directive (UWWTD) [1], in force since 1 January 2025, tightens requirements for nutrient removal and introduces quaternary treatment for micropollutant removal, while setting an energy-neutrality target for larger plants by 2045. These measures increase operational complexity and energy demand, strengthening the need for robust and compliant sludge treatment pathways.

In parallel, phosphorus has been classified as a Critical Raw Material at EU level and several countries are moving toward binding recovery obligations. This reinforces the strategic relevance of recovering phosphorus from sewage sludge, particularly via thermal routes that concentrate phosphorus in solid residues and facilitate downstream separation.

Together, these developments accelerate the shift away from land application and mixed-incineration toward mono-thermal, resource-oriented solutions. For many operators - especially small to medium plants - decentralized on-site concepts are favorable, as they reduce transport needs, mitigate dependency on constrained external capacities, and allow solutions tailored to local sludge characteristics.

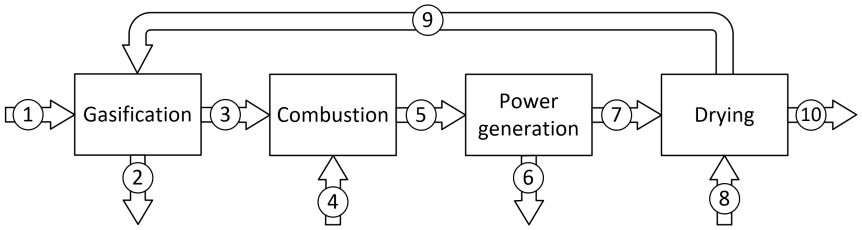

**Figure 1.** Block diagram of the Shit2Power process with the streams (1) air, (2) ash, (3) synthesis gas, (4) air, (5) hot flue gas, (6) electrical energy, (7) flue gas, (8) dewatered sewage sludge, (9) dried sludge, and (10) exhaust gas.

### 1.1 Shit2Power process

Shit2Power GmbH is developing a modular sludge-to-energy technology designed for decentralized deployment and plug-and-play integration at wastewater treatment plants. As shown in Figure 1, the system follows a four-module setup - sludge drying, gasification, synthesis gas combustion, and power generation - implemented as an energy-integrated process.

Dewatered sludge is first dried to a moisture content to less than 15 % using internally recovered heat. The dried feed is then converted in a dedicated gasifier under sub-stoichiometric air supply, producing a combustible synthesis gas (primarily $H_2$, CO, $CH_4$, $CO_2$ and $N_2$) and a solid ash fraction. The synthesis gas is subsequently oxidized in a purpose-designed combustion chamber, and the released thermal energy is converted to electricity in an ORC-based power generation unit. A defined part of the heat is recirculated to the dryer to enable self-sustaining operation, while surplus heat can be made available for site-specific external use.

### 1.2 Process simulation

In order to predict optimal operation regimes and to develop process control strategies, the Shit2Power (S2P) process is simulated using the CHEMCAD process simulation software from Datacor Inc. While the majority of the process steps can be adequately represented by physical models, no standard approach is available to model the complex reactions that govern the gasification process. To address this, the present study employs a hybrid approach that integrates first-principal models with data-driven models.

## 2 MODEL DEVELOPPEMENT

This section provides a comprehensive overview of the physical and chemical principles relevant to the gasification process. In addition, it offers a detailed description of the structure and sequence of the flowsheet simulation. The concept of the hybrid reactor model is derived, and the selected machine learning approach is described.

### 2.1 Gasification chemistry

Gasification is a thermo-chemical conversion process that transforms carbonaceous solids into a combustible synthesis gas under sub-stoichiometric oxygen supply. The primary components of the gas are hydrogen ($H_2$), carbon monoxide (CO), methane ($CH_4$), carbon dioxide ($CO_2$), and nitrogen ($N_2$). Additionally, this process leads to the formation of water vapor ($H_2O$) and other minor species, including tars ($C_xH_x$), ammonia ($NH_3$), hydrogen sulfide ($H_2S$), and hydrogen chloride (HCl). These species are of significance for the subsequent stages of gas cleaning and material selection because they can reduce the technical lifetime considerably. [2]

#### 2.1.1 Reactor type and key reactions

In the present work, a downdraft fixed-bed gasifier is considered, which has been found to be suitable for a decentralized application with a thermal power well below 1 MW in prior investigations [3]. The dried sludge is introduced at the upper end of the reactor and moves downward through the bed, while air is injected into the reactor. The resulting gas stream follows the same direction. [2]

Four distinct reaction zones can be identified. In the drying zone (i), residual moisture is evaporated at temperatures between 100 °C and 200 °C in an oxygen-free environment. In the pyrolysis zone (ii), thermal decomposition occurs between approximately 150 °C and 500 °C mostly in the absence of oxygen. This process converts the sludge into char (C), gases (CO, $CO_2$, $H_2$, $H_2O$, $CH_4$), tars and ash. In the oxidation zone (iii), exothermic reactions with oxygen occur at temperatures of up to 1000 °C, resulting in the formation of carbon dioxide ($CO_2$), carbon monoxide (CO), and water ($H_2O$). These reactions provide the necessary heat for the endothermic reactions in the pyrolysis zone and the final stage of the gasification process, known as the reduction zone (iv). Here, a series of endothermic reactions lead to temperatures ranging from 500 °C to 700 °C. These reactions include the Boudouard, water–gas, hydrogasification, and water–gas shift reactions. Together, these reactions increase the calorific value of the gas by forming $H_2$, CO, and $CH_4$. [2, 3, 4]

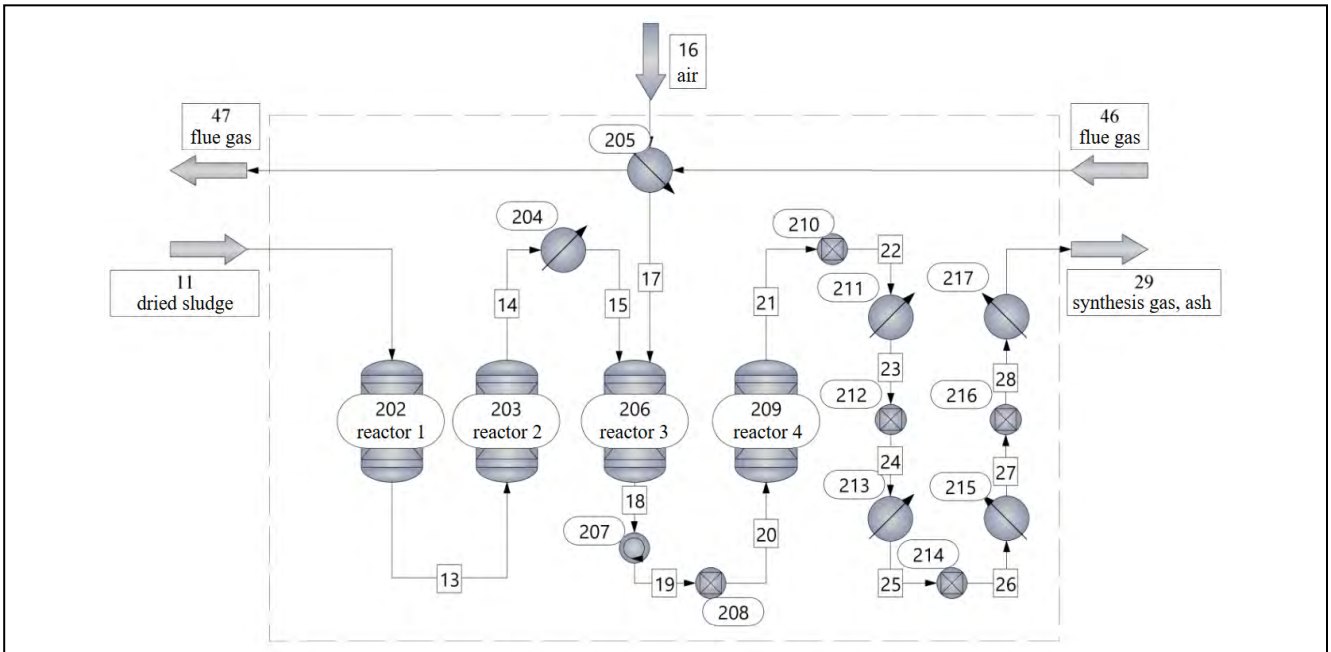

**Figure 2.** Image of the hybrid reactor model in the CHEMCAD simulation.

### 2.1.2 Operating parameters

Key factors influencing the gasification process in the described reactor configuration are the equivalence ratio (ER), the temperature of the supplied air, and the sludge properties - dry-matter content, lower heating value, and chemical composition. Within these variables, equivalence ratio and supply air temperature during operation can be influenced by the operator. The ER is defined as the ratio of the actual air supply to the air supply required for complete stoichiometric combustion. In the gasification of sewage sludge, the equivalence ratio is typically in the range of 0.15 to 0.35 [5, 6].

## 2.2 Flowsheet model

The flowsheet simulation is executed with CHEMCAD NXT (version 1.1.3.18169, Datacor Inc.), which employs a block-oriented representation of the plant, using unit operations to depict the processes. For each unit operation, mass and energy balances are solved using thermodynamic property models and, where applicable, equilibrium calculations. The tool holds a comprehensive library of thermodynamic models and pure component and mixture property data. The resulting process model is solved numerically using a sequential calculation approach.

### 2.2.1 Sewage sludge component

The sewage sludge, which serves as the primary input for the S2P process, is modeled as a mixture of water, inert ash (implemented as SiO2), and water- and ash-free (waf) sewage sludge. In the process of creating the waf sewage sludge component in CHEMCAD, the lower heating value and the elemental composition (carbon, hydrogen, oxygen, nitrogen, sulfur, chlorine) are taken into account.

For all simulations conducted as part of this study, the sewage sludge SS1 from Werle (2014) [7] is used.

### 2.2.2 Hybrid reactor model

Due to the highly complex reaction process involved in thermochemical gasification, it is not possible to rigorously model all reactions. Therefore, a hybrid reactor model that integrates a physical and a data-driven approach is developed.

As shown in Figure 2, a series of four CHEMCAD standard reactors is employed. The feed streams are dried sewage sludge (11) and preheated gasification air (16). The outputs of this process consist of a mixture of synthesis gas, ash and other by-products (29), which are separated in a subsequent simulation step.

The initial reactor employed is a stoichiometric reactor (202), in which the sewage sludge is completely broken down into its elementary components. These act as reactants for the following three reactors.

The second reactor is an equilibrium reactor (203). Here, relevant side reactions take place, producing the following by-products: ammonia, hydrogen sulfide, and hydrochloric acid. In the remaining two reactors of the hybrid reactor model, these substances are considered inert. [8]

In reactor (206), adiabatic minimization of Gibbs free energy results in a product gas containing the following main components: hydrogen, carbon monoxide, carbon dioxide, methane, and nitrogen. Tars are neglected. The quantity of oxygen present is governed

through the settings of a feedback controller (208). The airflow (16) is preheated using a heat exchanger (205). The heat required for this process is extracted from the combustion chambers flue gas flow (46) .

However, complete minimization of the free Gibbs energy during gasification is not achieved in reality. Consequently, the deviations in the synthesis gas composition must be adjusted to experimental results. To do this, the fourth equilibrium reactor (209) is employed, embodying the data-driven modeling approach. Five reverse reactions (equation 1 – 5) are incorporated in this reactor, which cause the products of the Gibbs reactor to react back.

$$\text{R1: } 2\,CO \xrightarrow{X_{R1}} C + CO_2 \quad (1)$$

$$\text{R2: } CH_4 \xrightarrow{X_{R2}} C + 2\,H_2 \quad (2)$$

$$\text{R3: } CO + H_2 \xrightarrow{X_{R3}} C + H_2O \quad (3)$$

$$\text{R4: } 3\,H_2O + CO \xrightarrow{X_{R4}} CH_4 + H_2O \quad (4)$$

$$\text{R5: } H_2 + CO_2 \xrightarrow{X_{R5}} CO + H_2O \quad (5)$$

Reactors 1, 2, and 4 are calculated isothermally, with each heat duty subsequently being taken into account in the energy balance of the synthesis gas stream via four heat exchangers (211, 213, 215, 217) and controller blocks (208, 210, 212, 214, 216). Heat exchanger (204) is inactive. It can be used to introduce the temperature at which the Gibbs equilibrium is calculated as an additional degree of freedom for the data reconciliation.

### 2.2.3 Data Reconciliation

In the calibration of the reactor model, the reaction conversions $X_{Ri}$ in reactor 4 (209) (reactions 1 - 5) are adjusted to align the simulated synthesis gas concentrations with the experimental measurements. In addition to the combustible components - hydrogen, methane, and carbon monoxide - the non-combustible gas components nitrogen and carbon dioxide are also taken into account at this point. Werle (2014) [7] provides experimental data for 30 operating points as a function of the gasification air temperature (T = 25, 100, 150, 200, and 250 °C) and the equivalence ratio (ER = 0.12, 0.14, 0.16, 0.18, 0.23, and 0.27). The conversion rates are fitted using CHEMCAD's proprietary data reconciliation tool. In this optimization task multiple restarts are used in order to overcome local minima.

The results of the data reconciliation can be found in Fig. 6 and Fig. 7, where calculated and experimental compositions are compared. The resulting errors are shown in Table 1. In general, the simulated molar fractions of the primary synthesis gas components are lower than the experimental values. The model underestimates the content of the calorific gases, thereby providing conservative predictions. The errors are smallest at the boundaries of the investigated equivalence ratio range and largest in the central region. The most significant discrepancies emerge for the $CO_2$ molar fraction, exhibiting a relative error of 50 % (absolute error of 7.6 mol%). However, the impact on the overall process assessment is mitigated by the negligible contribution of $CO_2$ to the syngas lower heating value. The authors are aware that the amount of data used is very limited and that for a more robust model more data points are required.

**Table 1:** Errors between experimental [7] and fitted synthesis gas concentrations.

| Parameter | Rel. error, avg. [%] | Absolute error [mol%] | | |
|---|---|---|---|---|
| | | avg. | min. | max. |
| $y_{H2}$ | 6 | 0.4 | < 0.01 | 1.6 |
| $y_{CO}$ | 29 | 7.7 | 2.8 | 13.4 |
| $y_{CO2}$ | 50 | 7.6 | 3.5 | 10.5 |
| $y_{CH4}$ | 6 | 0.1 | < 0.01 | 0.2 |
| $y_{N2}$ | 29 | 15.0 | 7.5 | 21.4 |

## 2.3 Machine learning approach

Only a limited number of 30 operating points are available from the literature data [7]. Therefore, interpolation is necessary to investigate intermediate operating points. After conducting initial tests with linear interpolation, this study focuses on implementing and evaluating a machine learning (ML) approach. This approach has several advantages over linear interpolation:

- No requirement for a structured data grid
- Simplified data handling and improved usability
- Easier integration of additional sewage sludge parameters
- Representation of nonlinear relationships
- Potential for extrapolation, given a sufficient data basis

### 2.3.1 Training and test data

The training data for the machine learning model consists of the inputs equivalence ratio and reactor inlet air temperature, and the outputs are the conversion rates $X_{R1}$ to $X_{R5}$ of reactions R1 to R5 (see eq. 1 - 5). The conversion rates were obtained by calibrating the reactor model to the synthesis gas compositions that were experimentally determined (see section 2.2.3).

In the interest of expanding the functionality of the reactor model, it is also possible to introduce additional inputs, provided that a suitable data basis is available. For instance, if data from other sewage sludges is available, the sewage sludge composition and the lower heating value can be considered.

The resulting dataset consists of 30 samples structured in an evaluable CSV file. The sample size is very

limited for training a neural network. Consequently, the present study places its primary emphasis on the methodology of hybrid modelling.

### 2.3.2 Model screening

The commercial machine learning software JMP Pro was used for model selection. Following the importation of the training data, a model comparison of the widely used machine learning methodologies (Neural Boosted, Boosted Tree, Bootstrap Forest, Support Vector Machines, Fit Least Squares, Fit Stepwise, Generalized Regression Lasso, K Nearest Neighbors) was conducted automatically. For each of these algorithms, JMP Pro generated five individual models with ER and reactor inlet air temperature as inputs and a chemical reaction conversion ($X_{Ri}$) as the output.

### 2.3.3 Integration in CHEMCAD

The utilization of a VBA function module facilitates the implementation of the machine learning model into the flowsheet simulation. The so-called VBA unit is designed to execute VBA code during the simulation process, thereby allowing it to access the inputs for the machine learning model from the simulation and subsequently send the outputs back to CHEMCAD. The machine learning model itself can be implemented in two ways: either directly as VBA code or via a Python interface, controlled from the VBA unit.

## 3 RESULTS AND DISCUSSION

This section shows the result of the selection of the most suitable ML model. Subsequently, the performance of the hybrid reactor model is examined and discussed.

### 3.1 Data analysis and model selection

In order to conduct a meaningful comparison of the machine learning approaches, Figure 3 shows the $R^2$ values of the best-performing algorithms, which are Boosted Tree (BT), boosted neural network (NB), and Support Vector Machine (SVM). For each approach, the five different models were considered; together, they provide predictions for all five outputs.

It is evident that there are substantial issues with all models in terms of their capacity to accurately predict the outputs $X_{R2}$ and $X_{R5}$. The $R^2$ values for $X_{R2}$ range between 0.0833 (FLS) and 0.2927 (BT), and for $X_{R5}$ between 0.1918 (NB) and 0.5816 (BT). These values are very low. This finding suggests the absence of dependencies between the corresponding training values, indicating a data issue. The remaining outputs, $X_{R1}$, $X_{R3}$, and $X_{R4}$, can be predicted with a reasonable degree of accuracy. The boosted tree shows the best performance, with an average $R^2$ of 0.7302, followed by the boosted neural network with an average $R^2$ of 0.609.

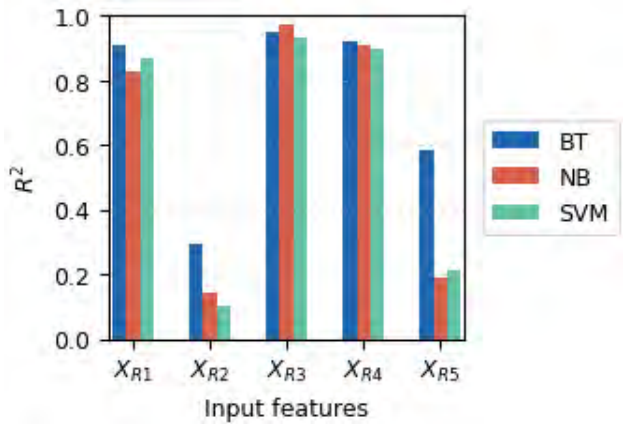

**Figure 3.** Comparison of $R^2$ for the predictions of $X_{R1}$ to $X_{R5}$; for each value one of the following machine learning approaches was used: boosted tree (BT), boosted neural network (NB), and support vector machine (SVM).

In order to evaluate the suitability of the two best machine learning approaches, Figure 4 presents $X_{R2}$ as a function of ER and the reactor inlet air temperature (T). In contrast to the smooth curve of the boosted neural network, the boosted tree exhibits pronounced discontinuities. The $X_{R2}$ value shows sudden rises or falls around the points of the training data. This behaviour indicates that the use of the boosted tree is not suitable for the reactor model, as it does not permit reliable interpolation between the fitted chemical conversions $X_{R1}$ to $X_{R5}$.

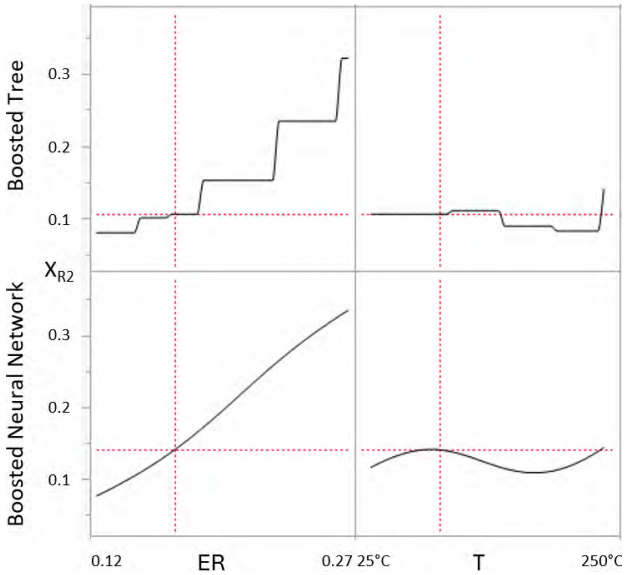

**Figure 4.** Comparison of the $X_{R2}$ curve for a boosted tree and a boosted neural network as a function of ER and the reactor supply air temperature.

Consequently, boosted neural networks was selected for implementation in this study. The number of layers and neurons is documented in Table 2, along with the $R^2$ values for training and validation. The validation

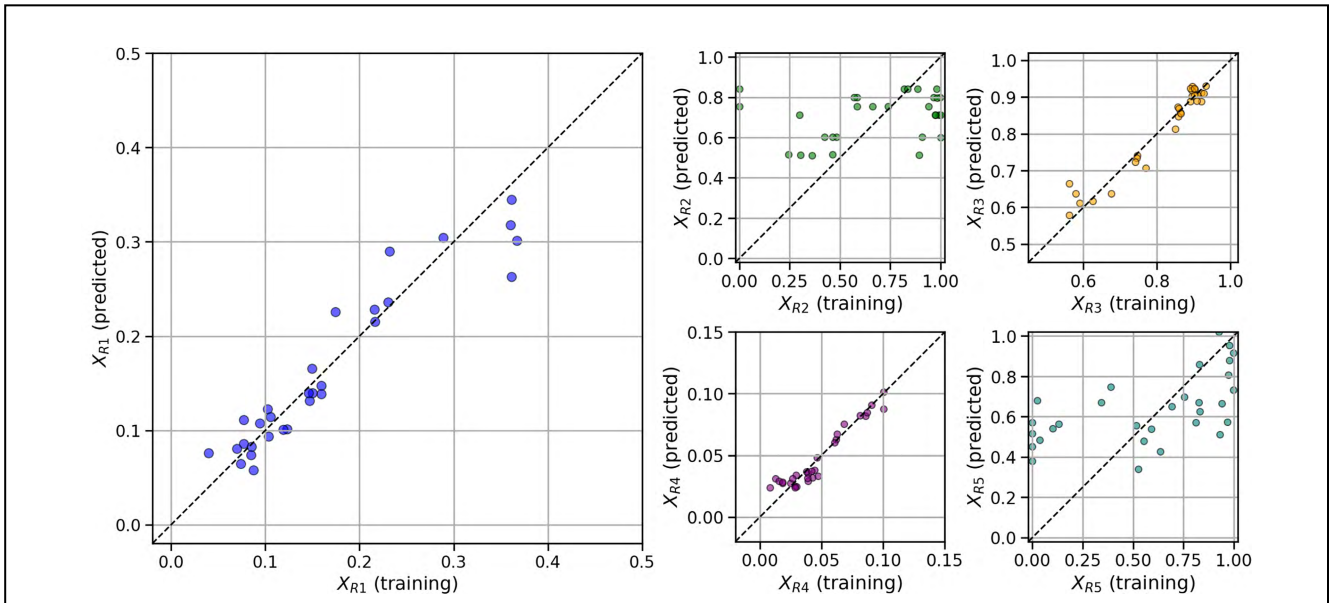

**Figure 5.** Comparison of $X_{R1}$ to $X_{R5}$ training data with the prediction values of the boosted neural networks.

was performed using random holdback, which did not indicate any overfitting for the evaluated models. The hyperbolic tangent (tanh) function was utilised as the activation function. Furthermore, Figure 5 compares the chemical conversions $X_{R1}$ to $X_{R5}$ from the training data with the predicted values of the boosted neural networks.

As already indicated by the data in Table 2, the conversions $X_{R2}$ and $X_{R5}$ cannot be predicted accurately (see Figure 5). It is notable, that these conversions range from 0 to 1, while the others scatter in a much smaller range. In a future work this difference in range will be analyzed more in detail.

**Table 2:** Documentation of the architecture and performance of the boosted neural networks $X_{R1}$ to $X_{R5}$ containing the number of layers, neurons, and R2 of the training and validation.

| Model | Number of | | $R^2$ | |
|---|---|---|---|---|
| | layer | neurons | train. | valid. |
| $X_{R1}$ | 3 | 60 | 0.8259 | 0.9049 |
| $X_{R2}$ | 3 | 6 | 0.1458 | 0.1083 |
| $X_{R3}$ | 3 | 60 | 0.9710 | 0.9028 |
| $X_{R4}$ | 3 | 60 | 0.9098 | 0.8177 |
| $X_{R5}$ | 3 | 21 | 0.1918 | 0.2323 |

## 3.2 Performance of the hybrid reactor model

After the implementation of the five boosted neural networks in the CHEMCAD flowsheet, a series of sensitivity studies was performed. The ER and the reactor inlet air temperature were varied, and the composition of the synthesis gas was logged. The results are shown in Figures 6 and 7, with the left-hand side showing examples of the curves at the highest (250 °C) and lowest (25 °C) temperatures over the variable ER and the right-hand side displays the curves as a function of the reactor inlet air temperature and an ER of 0.12 and 0.27. In order to facilitate comparison between these graphs, both the values as determined through experimentation [7], and the composition based on the fitted chemical conversions, which act as training data for the neural network, are displayed. The dashed lines in the figure represent the composition of the synthesis gas, which can be simulated by using linear interpolation between the fitted data points. It is evident that the predicted concentration curves align closely with the fitted concentrations, particularly in consideration of the limited dataset. Furthermore, an error calculation was performed between the fitted and predicted concentrations for all 30 operating points, not solely the visualized ones. The results of this calculation are presented in Table 3.

**Table 3:** Average errors between the fitted and predicted concentrations of $H_2$, CO, $CH_4$, $CO_2$, and $N_2$.

| | $H_2$ | CO | $CH_4$ | $CO_2$ | $N_2$ |
|---|---|---|---|---|---|
| Rel. error [%] | 11.4 | 4.7 | 8.4 | 5.7 | 1.6 |
| Abs. error [mol%] | 0.72 | 0.84 | 0.10 | 0.43 | 1.12 |

The data shows that the absolute errors, despite the relatively large relative errors of up to 11.4% ($H_2$), are between 0.10 mol% ($CH_4$) and 1.12 mol%. Given the limited data available, these errors are considered minor, and they suggest that the machine learning-optimized hybrid reactor model can plausibly simulate the synthesis gas composition.

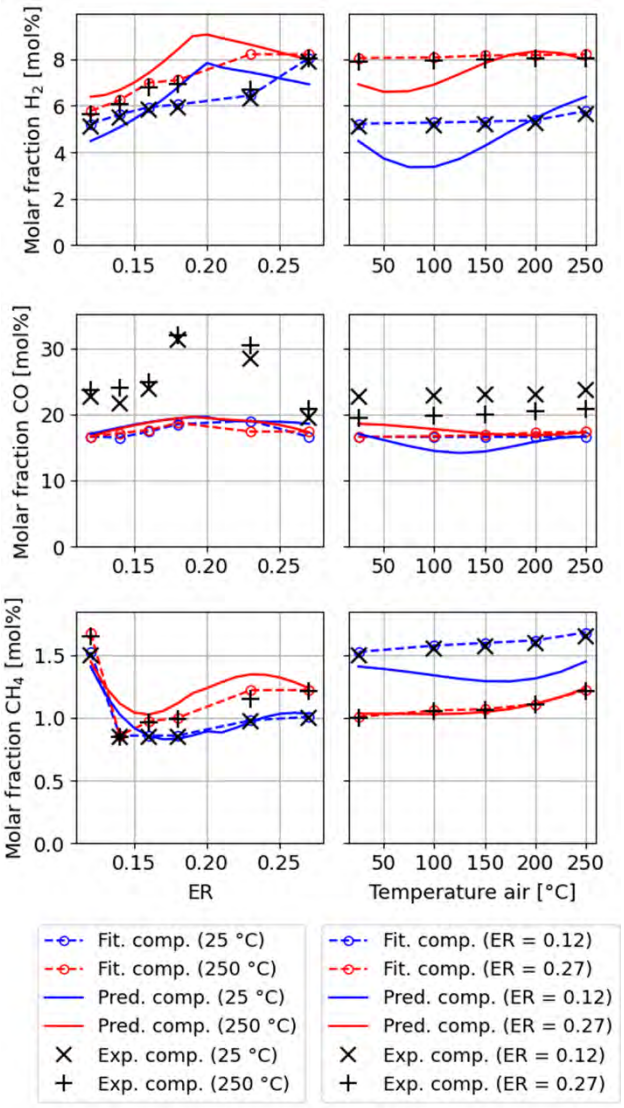

**Figure 6.** Concentration curve of the oxidizable gases $H_2$, CO, and $CH_4$ as a function of ER (left) and reactor inlet air temperature (right); comparison of experimental, fitted, and predicted concentrations.

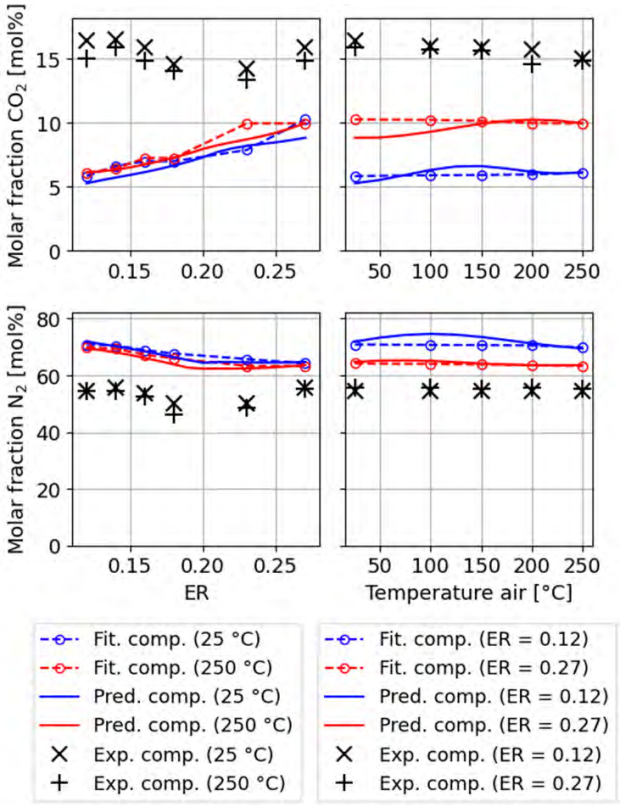

**Figure 7.** Concentration curve of the non-oxidizable gases $CO_2$ and $N_2$ as a function of ER (left) and reactor inlet air temperature (right); comparison of experimental, fitted, and predicted concentrations.

## 4 CONCLUSIONS

The present study develops and evaluates a hybrid modelling approach for a downdraft sewage sludge gasifier within the Shit2Power process. A four-reactor concept is implemented in CHEMCAD, in which a sequence of standard reactor models is combined with a data-driven correction step to account for the deviation from ideal Gibbs equilibrium. The correction is based on reaction conversions fitted to synthesis gas compositions [7]. This enables the model to reproduce the behavior of real sewage sludge gasifiers with conservative estimates of the energy content of the resulting syngas.

On this basis, several machine learning approaches were systematically compared regarding their suitability to predict the reaction conversions in the hybrid reactor model. Although boosted trees achieved the highest average coefficient of determination ($R^2$), they exhibited pronounced discontinuities and were therefore deemed unsuitable for interpolation between experimental operating points. Boosted neural networks were ultimately selected as the most appropriate compromise between prediction accuracy and smoothness, providing satisfactory representations for three of the five reaction conversions, given the small training dataset of 30 samples. After integration into the CHEMCAD flowsheet simulation, the resulting hybrid reactor model reproduces the fitted synthesis gas compositions with good agreement, while maintaining the overall mass and energy balances.

Overall, the results show that the combination of rigorous flowsheet simulation and machine learning provides a promising framework for modelling complex thermochemical conversion processes such as sewage sludge gasification. Within the Shit2Power concept, the hybrid reactor model provides a robust basis for a digital representation of the gasification reactor and enables future work on process optimization, advanced control, and evaluation of varying sewage sludge characteristics.

## DIGITAL SUPPLEMENTARY MATERIAL

The VBA code, which includes the interface between the Python machine learning model and the CHEMCAD simulation, can be viewed in the Living Archive for Process Systems Engineering under ID LAPSE:2026.0012.

## ACKNOWLEDGEMENTS

We would like to express our gratitude to the German Federal Ministry for Economic Affairs and Climate Action and the European Social Fund, which provided financial support for the research conducted for this study through the exist Gründungsstipendium.

## ABSTRACT

The transition from a linear, fossil-based polymer economy to a circular bio-economy is critical for mitigating resource depletion and greenhouse gas emissions. This study provides a rigorous comparison of two biomass-to-plastic pathways: a biochemical route (PLA via enzymatic hydrolysis) and a thermochemical route (bio-PE via gasification and MTO). Based on Aspen Plus simulations and a "lifetime-adjusted" lifecycle assessment framework, we evaluate the environmental performance of these routes in the transition from linear to circular systems. Unlike standard "cut-off" methods, the lifetime-adjusted model accounts for virgin make-up and molecular retention across multiple recycling cycles. Results indicate that at current 15% recycling rates, PLA exhibits the lowest global warming potential due to significant biogenic carbon sequestration. However, as recycling rates reach 75%, process efficiency becomes the dominant factor; the precise biochemical recycling of PLA continues to outperform mechanical HDPE recycling, whereas the energy-intensive thermochemical bio-PE route loses its competitive advantage. Our sensitivity analysis reveals that LCA modeling choices significantly diverge at intermediate recycling rates, resulting in different values for environmental impact. Ultimately, while bioplastics serve as a vital agent for $CO_2$ sequestration during the transition to circularity, long-term sustainability necessitates a shift toward "recyclable-by-design" materials.

## INTRODUCTION

Currently, polymer production is mostly based on fossil feedstocks, leading to burdens, such as pollution, resource depletion and green house gas emissions [1]. Nonetheless, production volumes continue to rise, especially driven by the plastic packaging sector, which made up over 30% of the global plastic demand in 2019 [2], where recycled plastics remain the exception, with recycling rates reaching 15% at most [3]. The sector's reliance on linear manufacturing and single-use packaging threatens to intensify its environmental crisis [1], highlighting the need for a circular plastics economy, leveraging various renewable technologies [4].

Biomass, especially agricultural residues such as wheat straw, emerges as a promising renewable feedstock for $CO_2$ sequestration, and has multiple processing pathways: biochemical and thermochemical. Polylactic acid (PLA) is currently leading the global bioplastic production [5] as a versatile packaging material and follows a biochemical processing path, using hydrolysis and subsequent fermentation to produce lactic acid [6]. Meanwhile bio-polyethylene (bio-PE) is a "drop-in" plastic, that can be produced thermochemically via biomass gasification [7] and methanol-to-olefins (MTO) technology [8]. However, bioplastics alone will not solve the environmental crisis in the plastics sector and can contribute to added strain on land use [4].

A possible solution for a more sustainable polymer economy is combining chemical recycling, with renewable feedstocks, which saves virgin resources and facilitates the shift away from fossil-dependence. While bioplastics are currently mostly landfilled, they have great potential for chemical depolymerization, conserving their polymer quality, as opposed to mechanical recycling. PLA can be recycled using enzymatic hydrolysis, which is a very precise, single step biochemical process [9]. Similar to its production, bio-PE can be recycled

thermochemically by polymer gasification and MTO [10, 11]. While previous studies have evaluated these pathways in isolation, a rigorous comparison of these technologies is missing to our best knowledge.

Furthermore, standard lifecycle assessment (LCA) "cut-off" methods often fail to capture the long-term value of molecular retention and do not account for the impact of virgin make-up. This leads to comparisons of isolated processes that neglect the synergies between chemical recycling and the use of renewable makeup, where the latter can bring additional benefits relative to the standard consumption of fossil make up in circular routes. This assumption fails to accurately quantify the true impact of plastics based on the recycling rate, the virgin make-up and the end-of-life treatment of the losses. In contrast, this paper uses a "lifetime- adjusted" framework, following the work of Nicholson et al. [12], to evaluate the global warming potential (GWP) of these technologies as they transition from linear to circular systems and assess the difference between the cut-off model and lifetime-adjusted model for impact calculation.

# PROCESS DESCRIPTION & SIMULATION

## Biochemical Pathway

The simulations are carried out in Aspen Plus V15. ELECNRTL is used as the property model, and missing model parameter values are taken from NREL's Physical Property Database for Biofuels Components [13] or estimated with the UNIFAC method. The considered substances are modeled as conventional substances, with the exception of biomass, enzymes, PLA, and calcium lactate, which are modeled as solids. The reactors are modeled with RSTOIC units, except for the polymerization of the lactide, where a batch is used. The flashes and distillation columns are modeled using FLASH2 and RADFRAC respectively. The process flowsheets and inventories can be found in the SI.

Production begins with steam explosion of wheat straw (160°C, 0.62 MPa) [14] to hydrolyze hemicellulose into xylose, followed by organosolv pretreatment (170°C, 65% ethanol, 0.5% $H_2SO_4$) to solubilize lignin [15]. The remaining cellulose is enzymatically hydrolyzed (50°C) to glucose [16].

These sugars are fermented (37°C, pH 7) into lactic acid (LA) with 90% yield and 99.5% optical purity [17]. Neutralization with lime forms calcium lactate, which is acidified with sulfuric acid to liberate LA and remove gypsum [18, 19]. Purification utilizes reactive distillation via esterification and hydrolysis, achieving commercial concentrations of 85-88% [20].

PLA polymerization follows the continuous ring-opening polymerization (ROP) route. LA is dehydrated (130°C, 0.5 atm) to a prepolymer, then thermally depolymerized (180°C, 0.1 atm) to cyclic lactide. Purified lactide undergoes ROP in the melt using a tin octanoate catalyst (180°C, 4h) with 95% conversion [21, 22]. Residual monomers are devolatilized and recycled.

Enzymatic recycling employs PLA-depolymerases to degrade the polymer back to monomers [23]. PLA is hydrolyzed in water (70°C, 230 g/L solids) [24], followed by neutralization and acidification as described for LA production from biomass conversion above. Finally, reverse osmosis recovers LA at target purity, closing the material loop [25].

## Thermochemical Pathway

For the thermochemical benchmark, existing work and inventories were used, as shown in the SI. The process is based on high-TRL biomass gasification [7] followed by a MTO [8, 10] route to produce bio-PE. Circularity is achieved via polymer gasification, returning the waste plastic to syngas [11]. This route is characterized by higher energy intensity and a higher number of steps but benefits from seamless integration into existing infrastructure.

# METHODOLOGY

## Lifetime-adjusted LCA

The LCA follows ISO 14040/14044 standards [26] using Ecoinvent 3.10 [27] as the background system and process simulation outputs as foreground data. Calculations are performed in Brightway2 [28], utilizing the IPCC 2021 climate change method for GWP over a time horizon of 100 years and including hydrogen and biogenic carbon.

Beyond the standard cut-off approach, we implement a lifetime-adjusted impact framework following Nicholson et al. [12]. This approach calculates the number of material lifetimes $L$ based on the process yield of polymer recycling ($a$), the recycling rate ($b$), and the fraction of recycled monomer in the new material ($c$), which make up the total fraction of recyclate $\Phi$, following equation (1). The polymer recycling yield is process-specific and taken from the respective inventories of enzymatic hydrolysis ($a$ = 95%) and polymer gasification ($a$ = 81%). The recycling rate describes how much plastic is collected for recycling. The fraction of recycled monomer in the new material was assumed to be one for both PLA and bio-PE, as the chemical recycling process produces polymers of "virgin-like" quality, such that no other virgin material is required.

$$\frac{ab}{c} = \Phi \tag{1}$$

It is assumed that anything not recycled ($1-\Phi$) ends up in waste streams, that ultimately are treated by municipal waste incineration. The number of lifetimes $L$ is used to scale the products environmental impact $x_L$, ensuring each product shares the burden of virgin production $x_v$ and recycling $x_r$ across all cycles $n$ in the

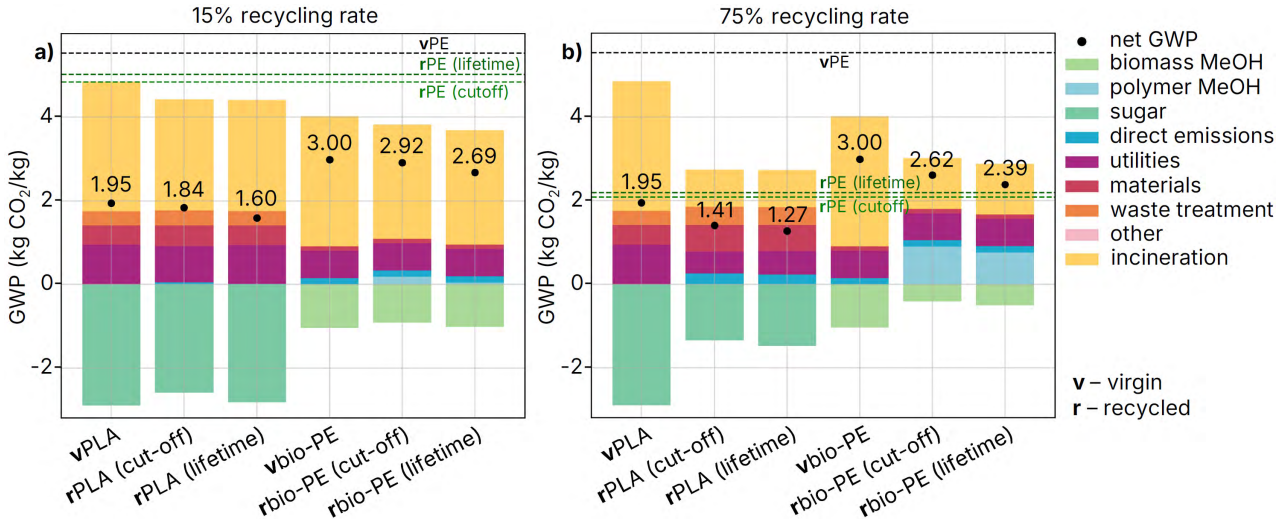

**Figure 1. a)** Breakdown of average GWP impacts for virgin and recycled PLA, bio-PE, and fossil-PE across different life-cycle calculation models (cut-off vs. lifetime-adjusted) at 15% recycling rate. **b)** Breakdown of average GWP impacts for virgin and recycled PLA, bio-PE, and fossil-PE across different life-cycle calculation models (cut-off vs. lifetime-adjusted) at 75% recycling rate.

production and recycling cascade as can be seen in equations (2) and (3).

$$L = \sum_{n=0}^{\infty}\left(\frac{ab}{c}\right)^{n} = \frac{c}{c-ab}\text{, for } \frac{ab}{c} < 1 \quad (2)$$

$$x_L = \frac{x_v+(L-1)x_r}{L} \quad (3)$$

One limitation of the lifetime calculation, however, is that the amount of monomer recovered from chemical recycling ($ab$) must be less than the amount used to resynthesize the equivalent amount of polymer product ($c$), as seen in equation (2). Hence parameter $c$ is also fixed at one for mechanically recycled conventional PE.

While many studies compare the cut-off impacts of a conventional material with its recycled counterpart, this approach assumes that all plastic is recycled. With our current recycling rates of just 15%, our study applies an averaged impact of circular plastics accounting for a virgin make-up, as shown in equation (4).

$$x_{average} = \Phi\, x_r + (1-\Phi)x_v \quad (4)$$

The model further accounts for end-of-life treatment of losses, distinguishing between material entering the loop and virgin makeup. Equations (5) and (6) present the contribution of the end-of-life treatment $x_{eol}$ to the overall impacts in both the cut-off and lifetime adjusted models. As Nicholson's model only assumes the same life-time adjusted impact over all levels in the cascade for the material entering the loop, the fraction that is virgin but then lost, needs to be accounted separately. For an extended derivation, please consult the SI.

$$x_{cut-off} = \Phi\, x_r + (1-\Phi)x_v\ + (1-\Phi)x_{eol} \quad (5)$$

$$x_{lifetime} = \Phi x_L + (1-\Phi)\Phi x_L + (1-\Phi)^2 x_v + (1-\Phi)x_{eol} \quad (6)$$

By comparing both models and benchmarking against linear impacts of fossil high-density polyethylene (HDPE) and mechanically recycled HDPE across varying recycling rates, we highlight how different calculation methods can steer policy decisions. The inventories for HDPE from naphtha cracking, henceforth called conventional PE, and from mechanical recycling (recycled conventional PE) were taken from Ecoinvent 3.10. While the use phase is excluded due to lack of data, the comparative results across plastic types remain robust.

## RESULTS & DISCUSSION

### Impacts at current state of recycling

Figure 1 a) shows the breakdown of the averaged GWP impacts for the biochemical pathway, represented by virgin and recycled PLA, as well as the impacts from the thermochemical production path for virgin and recycled bio-PE at current recycling rates of 15%. In the case of both virgin polymers, waste incineration has the biggest contribution to the total GWP. However, PLA is able to offset most of this impact with the production of the sugars, which uses biomass, resulting in a negative contribution. The negative contribution stems from the fact that biomass uses $CO_2$ from the atmosphere during its growth, such that this take-up is subtracted from the total process and end-of-life emissions and can be viewed as a carbon credit. On the other hand, bio-PE from gasification also uses biomass and even to higher extents, but the production of methanol involves many more steps and much more energy, resulting in a smaller offset.

Nonetheless, both bioplastics are outperforming conventional virgin and even recycled PE at these lower recycling rates in terms of lower environmental burden.

At the lower recycling rate, the contribution of virgin material and the losses to be incinerated are quite high, explaining the small relative improvement of the bioplastics when they are recycled with respect to the virgin material. All the same, recycling bioplastics presents an environmental benefit, as the amount of material getting incinerated decreases in both cases, bio- and thermochemical, of recycling.

Comparing the two impact calculation methods, one observes that for both bioplastics applying the lifetime-adjusted framework results in 13% and 8% lower GWP for recycled PLA and bio-PE respectively. This stems from accounting for the first cycle of the virgin material that has negative carbon credits and hence decreases the impact of the plastics, even when recycled. Similarly, the averaged impacts of conventional PE in the recycling scenario differ depending on the calculation method. GWP of conventional PE when recycled is underestimated, as the contribution of the virgin material is disregarded.

## Impacts at higher recycling rates

Following the lifecycle analysis of bioplastics at low recycling rates, we investigate how these impacts change with an increased rate of collection. Figure 1 b) shows the impact breakdown for both bioplastics, PLA and bio-PE, in the linear and circular scenarios, when the recycling rate increases to 75%.

As expected, when more plastic is recycled the GWP decreases for all types of plastic in the circular scenario. Now the contribution of the virgin material decreases and hence the carbon credits decrease, as less biomass is used. At the same time, much less plastic is lost and incinerated, such that the burden from the end-of-life treatment decreases as well, resulting in lower impacts. These end-of-life impacts differ between PLA and bio-PE as their monomer yields, and hence the fraction of recyclate is different. In this scenario, recycling plastics becomes much more beneficial, however it becomes evident, that while recycling PLA via enzymatic hydrolysis still outperforms the mechanical recycling of conventional PE, the gasification of bio-PE does not yield any environmental benefits anymore. This is due to the lower monomer yield and higher energy consumption from the gasification process, so as recycling rates increase, the more precise and less energy intensive biochemical pathway offers better performance than the thermochemical path.

One also observes that the difference in impacts for the recycled material between the two recycling rates is even more significant for conventional PE than for the bioplastics, because of the big difference between virgin and recycled impacts.

Further, the differences in GWP of the recycled materials from the two calculation methods are not as pronounced anymore. This is also explained by the decreasing impact of the virgin material, suggesting that at higher recycling rates the choice of calculation method becomes less relevant. At 75% recycling rate the difference is still significant, however moving towards a circular future this might not be the case anymore, warranting a sensitivity analysis.

## Sensitivity to recycling rates

Given the decreasing influence of the impact calculation model, a sensitivity analysis with respect to the recycling rate was performed for PLA and conventional PE using both models, as shown in Figure 2. The GWP of the virgin plastics that are being incinerated remains unchanged across different recycling rates as they never enter the material loop and are hence independent of the rate of recycling.

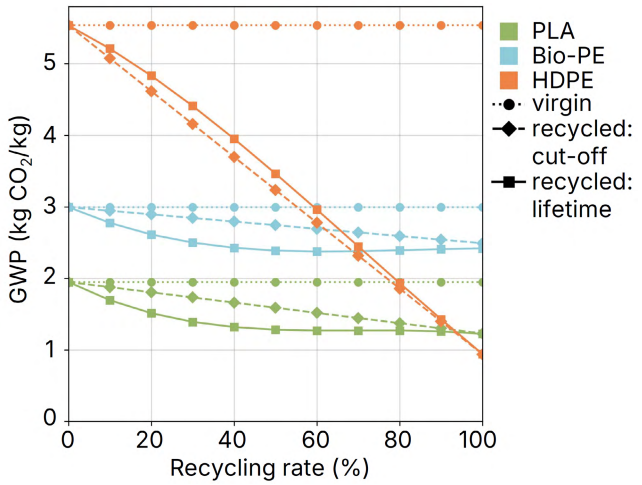

**Figure 2.** Sensitivity analysis of GWP impacts of virgin conventional PE (orange), virgin bio-PE (blue) and virgin PLA (green), as well as impacts when recycled, calculated with the cut-off (diamond) and the lifetime-adjusted (square) methods, across all possible recycling rates.

## Modeling choice

Focusing on the scenarios where the plastics are recycled, we notice that naturally, at 0% recycling rate all impacts for the recycled plastic are equal to the impact of the respective virgin plastic regardless of the model, as no recycling means that all material is ultimately incinerated, corresponding to a linear economic scenario. As the recycling rates increase, the impacts of the more circular scenarios decrease and a difference between the impact calculation models becomes noticeable. This divergence between the two models increases, as the cut-off model follows a linear trend as per equation (5), while

the lifetime-adjusted model traces a non-linear path, due to the consideration of the virgin material in the lifetime-adjusted impacts as per equations (3) and (6). The disparity starts decreasing after a recycling rate of about 40%, as with a higher fraction of the recyclate the influence of the virgin material and the end-of-life treatment decreases and the source of the carbon becomes less relevant. At 100% collection rate there is virtually no virgin material and no losses, except to account for the deficit during the depolymerization process. This means that the source of carbon is now irrelevant and the limiting factor becomes the process efficiency and not the feedstock, such that the impacts of both models converge at the cradle-to-gate impact of recycling the material $x_r$. These observations suggest that for a certain range of recycling rates, the usually applied cut-off method may overestimate impacts for bioplastics and underestimate them for fossil plastics within a circular economy.

### Technology choice

Comparing the biopolymers and conventional PE, the feedstock plays a major role at low recycling rates, so that bioplastic whether virgin or recycled, has much lower GWP than conventional PE derived from cracking naphtha, due to the carbon credits from biomass consumption. At higher recycling rates, however, the difference quickly diminishes. As the difference between virgin and purely recycled impacts of conventional PE is so high, the impact decreases more steeply than for PLA or bio-PE. The trends between PLA and bio-PE are very similar with the difference that bio-PEs impacts are higher across all recycling rates. Nonetheless, recycling rates of nearly 80% are needed for mechanically recycled conventional PE to beat virgin PLA in terms of GWP, and nearly 95% of plastic need to be collected for recycled conventional PE to have lower environmental impacts than the biochemically recycled PLA, as the impact of the virgin material can be neglected and the process itself becomes the main constraint. This suggests that ultimately, in a perfectly circular economy, the source of carbon would be virtually irrelevant and bioplastic would offer no environmental advantage over fossil plastic when both are fully recycled, a very ideal unlikely case. However, with current recycling rates of 15% we are far away from this goal, so as long as there is plastic loss the carbon credits from biomass derived plastics offer a necessary buffer to mitigate long-term environmental damage.

While this work has focused on environmental impacts in terms of global warming potential, there are other indicators that are relevant in sustainability assessments. Previous studies show that bioplastics such as PLA can have higher impacts in other categories like human toxicity and eutrophication, due to the agricultural phase and the use of fertilizers [29, 30]. This in turn highlights the importance of plastic recycling to mitigate the impacts from virgin resource extraction. Though there are many studies, their differing methodologies result in a big variation of insights, warranting further analysis under a harmonized framework [30].

## CONCLUSION

A lifecycle assessment comparing the biochemical and thermochemical pathways for biomass valorization to PLA and bio-PE respectively was performed. Two impact calculation models (cut-off and lifetime adjusted) were used to evaluate the average GWP impact when considering the virgin make-up in a circular economy. The analysis showcased the environmental advantage of both processing pathways at current recycling rates of 15%, with PLA having the lowest impact, due to its highly-targeted biomass conversion and energy economy. At higher recycling rates (75%), impacts for the circular materials decrease, such that biomass and polymer gasification to produce PE cannot compete anymore, owing to the lower depolymerization yield and higher energy consumption during methanol production. Meanwhile PLA recycled via enzymatic hydrolysis remains superior to mechanically recycled conventional PE in terms of GWP.

The lifetime-adjusted framework offers a more accurate estimation of life cycle impacts in a circular economy, as it accounts for the first lifecycle of the virgin material and therefore attributes the corresponding carbon credit or penalty to the averaged impact. However, towards maximum recycling rates the models converge, as the impact of the virgin material becomes negligible and the process impact becomes the main limitation, such that mechanically recycled PE shows a lower GWP than recycled PLA.

At high recycling rates the source of carbon becomes irrelevant, making bioplastics less appealing for decarbonizing the plastic sector. However, we are very far from reaching the goal of these high recycling rates and continue to leak plastic from the closed material loop. While this remains the case, bioplastics offer the necessary carbon offset and facilitate the transition to our circular future, by mitigating damage caused by excess $CO_2$ emissions already now.

Nonetheless this study has shown that in the long-term depending solely on bioplastics is not enough, as aside from the heavy burden on land use, recycling can offer better environmental benefits. This means the research community's focus should move towards the development of materials that are recyclable-by-design and processes that facilitate that beyond identifying the most suitable renewable feedstock.

## ABSTRACT

The increasing popularity of electric vehicles (EVs) leads to an expected rise in the quantity of end-of-life lithium-ion batteries (LIBs) that require efficient management. This paper presents a State Task Network (STN) based optimization model to analyze and optimize the supply chain for LIBs, allowing for the selection of optimal processing routes, facility locations, capacities and re-integration of recovered materials, as well as analyzing the possible trade-offs between different end-of-life management strategies. Based on available data from the literature, the model is demonstrated with the LIB supply chain considering both primary production and different end-of-life strategies for spent LIBs (recycling and reuse). The case study reveals that mechanical pretreatment followed by hydrometallurgical recycling is the optimal pathway and it outperforms the linear supply chain in both costs and emissions. The cost optimal solution opts for more centralized collection and disassembly, whereas when minimizing the total greenhouse gas emissions, the optimal collection and disassembly center locations are decentralized. The model can aid in the design of circular supply chains to select and locate the optimal processes and to examine how the network should evolve over time.

**Keywords**: Batteries, GAMS, Optimization, Supply Chain, Circular Economy

## INTRODUCTION

The recent energy transition to renewable energy sources has resulted in increased demand for metals such as lithium, cobalt, nickel and manganese that are needed to produce lithium-ion batteries (LIBs) used mainly in electric vehicles (EVs). At the same time, the natural mineral deposits are reaching critical concentrations of these valuable metals and thus increasing the environmental impacts associated with metals extraction via the conventional primary production routes [1]. As only a limited fraction of LIBs are currently recycled [2], a wider adoption of recycling processes and advancements in circular economy (CE) could help alleviate future supply-demand disparities for battery materials, reduce environmental burdens, and lower the production costs by decreasing the required amount of primary production of battery metals.

The concept of circular economy (CE) has been gaining popularity in businesses, government and the research community [3]. In contrast with linear production systems, the aim of circular economy is that materials never become waste. It is based on the following principles: to eliminate waste and pollution, to circulate products and materials and to regenerate nature [4]. Aligned with the principles of CE, end-of-life (EOL) EV LIBs can be managed through several alternatives to disposal: reuse in second-life applications, remanufacturing suitable battery cells, and recycling to recover valuable materials from EOL LIBs. The general structure of the circular LIB system is presented in Figure 1.

A vast amount of research has focused on designing recycling processes for LIBs to recover valuable materials and facilitate closed-loop recycling of battery materials. Currently, mechanical pretreatment processes, hydrometallurgical processes and pyrometallurgical processes are conducted on an industrial scale, whereas emerging direct recycling processes are currently on a pilot or laboratory scale level and thus lack industrial maturity [5].

- Mechanical pre-treatment: involves discharging, crushing and separation stages for the LIBs to

obtain black mass powder which contains valuable metals, mainly from the cathode active material.

- Hydrometallurgical recycling: the black mass is leached, and the battery metals are selectively separated and purified.
- Pyrometallurgical recycling: the spent LIBs are fed into a high-temperature process to produce a metal alloy as well as a slag phase as a byproduct.

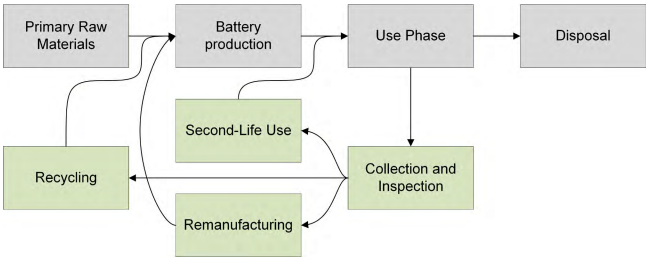

**Figure 1.** Schematic representation of the circular LIB system.

## METHODOLOGY

The need for systematic methods to assess and optimize circular economy networks has been recognized in the process systems engineering literature [3]. Recent examples include the design and optimization of circular economy networks for polyethylene terephthalate (PET) [6] and the optimization of circular food supply chains [7].

Ahmed et al. [6] proposed a State Task Network (STN) modeling approach for the optimal design of circular economy networks and applied it to a case study on polyethylene terephthalate (PET) networks with a one-year assessment period. Baratsas et al. [7] presented a systems engineering framework for the optimization of circular food supply chains using a Resource Task Network (RTN) representation. Finally, Iakovou et al. [8] presented an RTN-based approach for the optimal design of reverse logistics networks for photovoltaic recycling.

The multi-period modeling of the supply chain for batteries is crucial, especially given the growing availability of EOL materials. By modeling the entire supply chain, we can examine how different end-of-life management strategies can be efficiently integrated with the primary production processes.

### Model formulation

The optimization model is based on the State Task Network representation first introduced by [9] for short-term scheduling of batch processes. The State Task Network representation allows for flexible representation of production processes where materials are represented as states that are transformed in processes referred to as tasks. Thus, the framework allows for the preparation of a superstructure, which includes all the possible production processes that can be used to produce the required products in the supply chain. As the STN formulation inherently allows for material circulation in the network, a complete supply chain network can be represented which includes both primary production processes and all possible processes to treat end-of-life batteries, as well as the possible reintegration routes in the supply chain.

The goal is to be able to present the holistic supply chain model for lithium-ion batteries that allows the investigation of optimal EOL LIB treatment options and how the recover materials can be integrated back into the different stages of the battery production supply chain.

### Sets, Parameters and Variables

The nomenclature used in the optimization model is summarized in Tables 1-3.

**Table 1:** Sets used in the optimization model.

| | |
|---|---|
| $c \in C$ | Capacity selection |
| $d \in D$ | Delay time periods |
| $i \in I$ | Processing tasks |
| $l \in L$ | Locations |
| $s \in S$ | Materials |
| $t \in T$ | Time periods |
| $S^F \subset S$ | Subset for final products |
| $S^V \subset S$ | Subset for primary raw materials |

**Table 2:** Parameters used in the optimization model.

| | |
|---|---|
| $Cap_{i,c}^{Max}$ | Maximum capacity for processing task |
| $Cap_{i,c}^{Min}$ | Minimum capacity for processing task |
| $CostP_{s,t}$ | Cost of purchased materials |
| $CostS_{s,t}$ | Cost of sold/sink materials |
| $CTrans$ | Transportation cost |
| $Dem_{l,s,t}$ | Material demand |
| $Dist_{l,l'}$ | Distance between locations |
| $E_i$ | Emissions of processing tasks |
| $EPur_s$ | Material procurement emissions |
| $ETrans$ | Transportation emissions |
| $FC_{i,c,t}$ | Fixed costs of processing tasks |
| $Sink_{s,t}^{Max}$ | Maximum sink for materials |
| $Supply_{s,t}^{Max}$ | Maximum supply of materials |
| $VC_{i,t}$ | Variable costs of processing tasks |
| $\rho_{s,i}$ | Conversion of materials in processing tasks |
| $\rho_{s,i}^{+}$ | Generation of material s in i, $(\rho_{s,i} > 0)$ |
| $\rho_{s,i}^{-}$ | Consumption of material s in i, $(\rho_{s,i} < 0)$ |
| $\alpha_{i,d}$ | Fraction of outputs from process i released after delay d |

**Table 3**: Variables used in the optimization model.

| | |
|---|---|
| $B_{i,l,t}$ | Flow through processing task i at location l during time period t. |
| $P_{l,s,t}$ | Purchasing of material s in location l during time period t. |
| $S_{l,s,t}$ | Selling/sink of material s in location l during time period t. |
| $Tr_{l,l',s,t}$ | Transportation of material s from location l to location l' during time period t. |
| $Y_{i,l,t,c}$ | 1 if processing task i with capacity level c is selected at location l during time period t, 0 otherwise. |

## Objective Functions

To evaluate the potential trade-offs between economic performance, environmental impacts, and supply chain circularity, three objective functions are considered: supply chain costs, greenhouse gas emissions generated and the consumption of primary raw materials.

First, the total supply chain costs are minimized that consists of fixed and variable processing costs, transportation costs, and material purchasing costs and revenues generated from selling materials.

$$\min \sum_i \sum_l \sum_t B_{i,l,t} \cdot VC_{i,t} + \sum_i \sum_l \sum_t \sum_c Y_{i,l,t,c} \cdot FC_{i,c,t} + \sum_l \sum_{l'} \sum_s \sum_t CTrans \cdot Tr_{l,l',s,t} \cdot \mathrm{Dist}_{l,l'} + \sum_l \sum_s \sum_t (P_{l,s,t} \cdot CostP_{s,t} - \mathrm{S}_{l,s,t} \cdot CostS_{s,t}) \quad (1)$$

Second, the environmental sustainability of the supply chain is addressed by minimizing the total emissions that consists of process emissions, transportation emissions and emissions related to material procurement.

$$\min \sum_i \sum_l \sum_t B_{i,l,t} \cdot E_i + \sum_l \sum_{l'} \sum_s \sum_t ETrans \cdot Tr_{l,l',s,t} \cdot Dist_{l,l'} + \sum_l \sum_s \sum_t P_{l,s,t} \cdot EPur_s \quad (2)$$

Finally, as proposed in [6], the total purchasing of primary raw materials is minimized and is considered as a proxy for material circularity in the supply chain.

$$\min \sum_l \sum_{s^v} \sum_t P_{l,s,t} \quad (3)$$

## Constraints

Net flow through each processing task cannot exceed the maximum production capacity at the selected capacity level.

$$B_{i,l,t} \leq \sum_C Y_{i,l,t,c} \cdot Cap_{i,c}^{Max} \; \forall i,l,t \quad (4)$$

Net flow through each processing tasks must exceed the minimum production capacity level.

$$B_{i,l,t} \geq \sum_C Y_{i,l,t,c} \cdot Cap_{i,c}^{Min} \; \forall i,l,t \quad (5)$$

Material purchases in the supply chain cannot exceed the maximum supply of materials.

$$\sum_l P_{l,s,t} \leq Supply_{s,t}^{Max} \; \forall s,t \quad (6)$$

Material sales in the supply chain cannot exceed the maximum allowed sink of materials.

$$\sum_l S_{l,s,t} \leq Sink_{s,t}^{Max} \; \forall s,t \quad (7)$$

The demand for the final products must be satisfied in the supply chain. In a circular system, the final products are consumed by the demand zones.

$$\sum_i -B_{i,l,t} \cdot \rho_{s,i}^{-} = Dem_{l,s,t} \; \forall l, s^F, t \quad (8)$$

The mass balance at all locations and all time periods is formulated based on material generation or consumption, transportation and the purchasing or selling of materials. As in the case of electric vehicle batteries, the use phase introduces a time delay before the material becomes available for end-of-life processes. Accordingly, the material generation term is modified to model this delay as a fractional release, where each task with a delay generates materials in predetermined fractions.

$$\sum_i \sum_d B_{i,l,t-d} \cdot \rho_{s,i}^{+} \cdot \alpha_{i,d} + P_{l,s,t} + \sum_{l'} Tr_{l',l,s,t} = \sum_i -B_{i,l,t} \cdot \rho_{s,i}^{-} + S_{l,s,t} + \sum_{l'} Tr_{l,l',s,t} \; \forall s,l,t \quad (9)$$

For each processing task and each time period, at most one capacity level can be selected.

$$\sum_c Y_{i,l,t,c} \leq 1 \; \forall i,l,t \quad (10)$$

The selected production capacity of the processing tasks at time t cannot be lower than at previous time period t-1.

$$\sum_c Y_{i,l,t,c} \cdot Cap_{i,c}^{Max} \geq \sum_c Y_{i,l,t-1,c} \cdot Cap_{i,c}^{Max} \; \forall i,l,t \quad (11)$$

Thus, the objective functions defined in Eqs. (1-3) are used to study trade-offs in circular supply chain design, and the resulting MILP formulation can be expressed as:

$$\begin{aligned} &\min Z \\ &s.t. \; Eq.(4-11) \\ &B_{i,l,t}, P_{l,s,t}, S_{l,s,t}, Tr_{l,l',s,t} \geq 0, Y_{i,l,t,c} \in \{0,1\} \end{aligned} \quad (12)$$

By constraining the material flows through selected echelons and by fixing the location of existing facility locations in the supply chain, the model facilitates "what if" analyses and enables the investigation of different scenarios.

# CASE STUDY

To illustrate the proposed optimization model for circular supply chain design, a representative case study of NMC622 LIBs used in EVs is considered. The case study investigates the high-value metals present in the cathode active material of the LIBs: refined lithium, cobalt, nickel and manganese, while other materials in the lithium-ion battery cells and packs are considered to be inert. Model parameters are chosen to reflect typical

economic, environmental and process conditions that are reported in the literature ([10-12]). The case study considers 10 uniformly randomly generated locations within a 1000 x 1000 km grid, each associated with identical demand for LIBs with an annual demand growth rate of 1.5%. The supply chain is optimized for the time period of 30 years, assuming that no end-of-life LIBs are available at the initial time period. The main assumptions of the case study are summarized in Table 4, and Figure 2 presents the candidate locations and locations fixed in the linear reference scenario.

**Table 4:** The main assumptions used in the case study.

| Parameter | Value |
|---|---|
| Cell chemistry | NMC622 |
| Cell specific energy | 0.218 kWh/kg |
| CAM to Cell ratio | 0.324 |
| Cell to pack ratio | 0.6 |
| Lifespan of EV batteries | 10 years |
| Lifespan of reused batteries | 4 years |

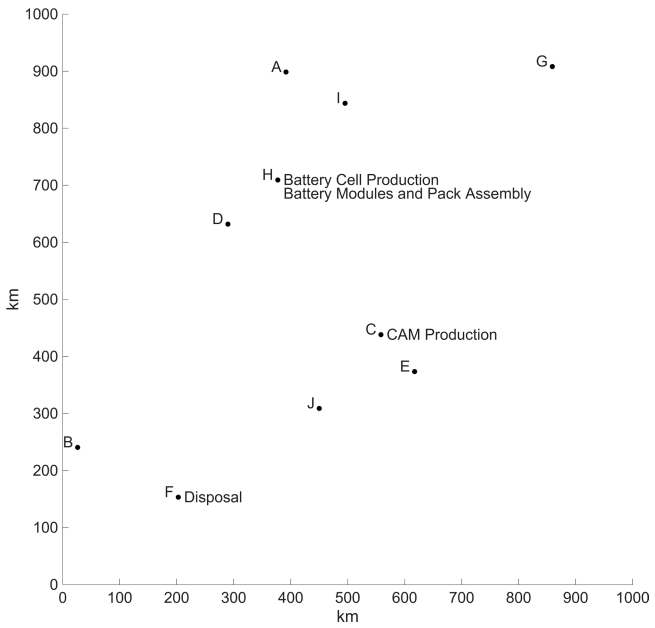

**Figure 2.** Representation of the case study showing fixed battery production sites (C, F, H) and candidate locations.

In the case study, the production of LIB packs begins with the production of cathode active material (CAM) which consumes refined lithium, cobalt, nickel and manganese to produce the CAM. The CAM is then supplied to the cell production phase, which manufactures battery cells that are then assembled into battery modules and finally into battery packs in the assembly process. From the assembly, the produced battery packs are transported to demand zones where the battery packs are used in electric vehicles. For the case study, a fixed lifetime of 10 years is assumed before the batteries become available for end-of-life treatment processes. Figure 3 illustrates the superstructure of the studied network.

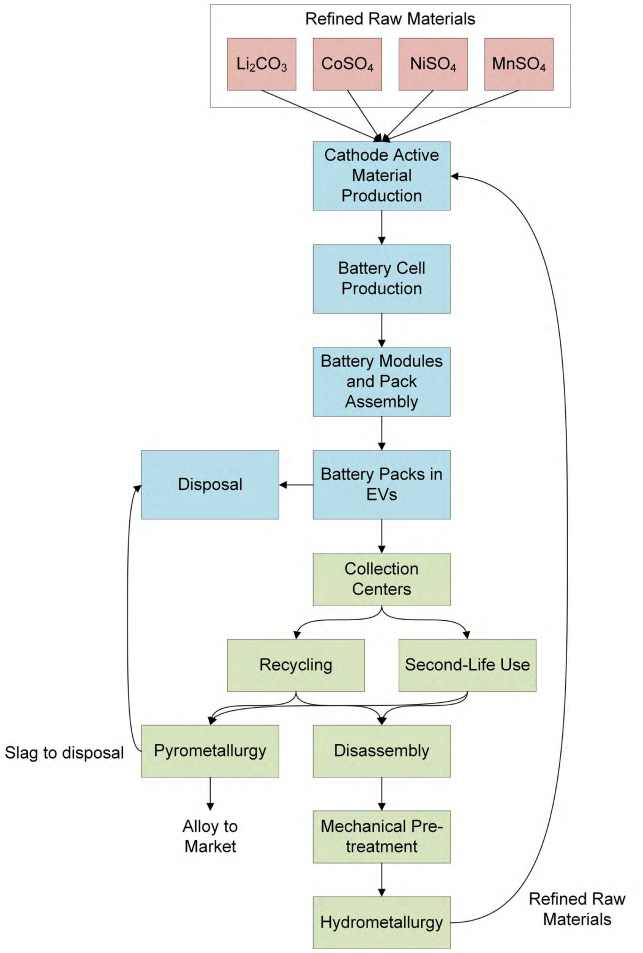

**Figure 3.** Superstructure representation of the circular LIB network, focusing on the high-value refined battery metals present in cathode active material (CAM).

In the linear reference scenario, all EOL LIB packs are transported to the disposal facility located at F. In the recycling scenario, EOL LIB packs can be collected at collection and sorting centers, and either processed directly in pyrometallurgical recycling facilities or first disassembled into battery cells, followed by mechanical pretreatment to obtain black mass. The black mass can be subsequently treated in hydrometallurgical recycling facilities to recover refined battery materials that can be used in the CAM production. Finally, in the circular scenario, the EOL battery packs can be processed using the same recycling pathways, or a maximum of 20% can be sent to location F to be reused as stationary energy storage. Here we assume a fixed lifetime of 4 years as energy storage after which the LIBs are treated in downstream recycling processes. The analyzed scenarios in the case

study are summarized in Table 5.

**Table 5:** Studied scenarios in the case study.

| Scenario | Description |
|---|---|
| Linear | Linear benchmark supply chain, where EOL LIBs are transported to disposal. |
| Recycling | EOL LIBs can be processed in recycling processes. |
| Circular | EOL LIBs can be processed in recycling processes and a fraction reused in stationary energy storage applications. |

## RESULTS AND DISCUSSION

The optimization model is implemented in GAMS and solved using CPLEX solver version 22.1.1. The evaluated scenarios (Table 5) were run with all three objective functions (Equations 1-3) to assess the trade-offs in the optimal supply chain design. Further multi-objective optimization and pareto analysis was not conducted at this stage.

### Cost optimal solution

Compared with the linear supply chain, the recycling scenario reduced the total cost by 4.4% in the time periods studied. The optimal strategy was to use hydrometallurgical recycling for spent LIBs as it allows for cost savings due to smaller quantity of required raw material purchases. The cost-optimal supply chain uses centralized collection and disassembly and, at the final time period, requires three collection centers, three disassembly centers and a mechanical pretreatment center and a hydrometallurgical facility, as shown in Figure 4. Mechanical pretreatment and hydrometallurgical recycling are located at the same location as the CAM production to avoid transportation of the refined battery metals.

In the circular scenario, when the possibility of second-life use of LIBs was allowed, the optimal solution included using a fraction of the LIBs as energy storage in the allowed location F to generate more revenue, resulting in total supply chain cost decrease of 10.8% compared to the linear supply chain.

### Emission optimal solution

When the total supply chain emissions were minimized, the hydrometallurgical processing route was also selected, to reduce the supply chain emissions from raw material procurement. However, in contrast with the cost optimal strategy, the supply chain shifts towards a decentralized collection and disassembly to avoid emissions generated via transportation. The optimal supply chain for the recycling scenario consisted of collection and disassembly facilities at all locations, three mechanical pretreatment facilities at locations C, F, and H and a hydrometallurgical recycling facility at location C, as presented in Figure 5. In the circular scenario, the model did not allocate any collected batteries to secondary use, as no environmental benefit was assigned to reuse.

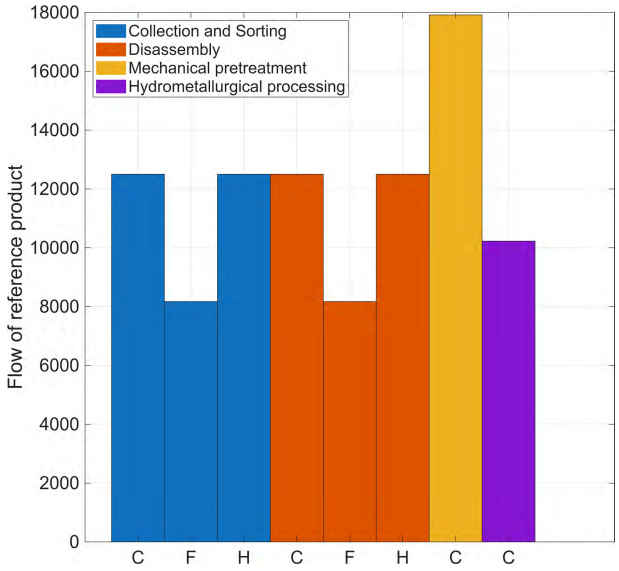

**Figure 4.** Cost optimal capacities at the final period for the recycling scenario.

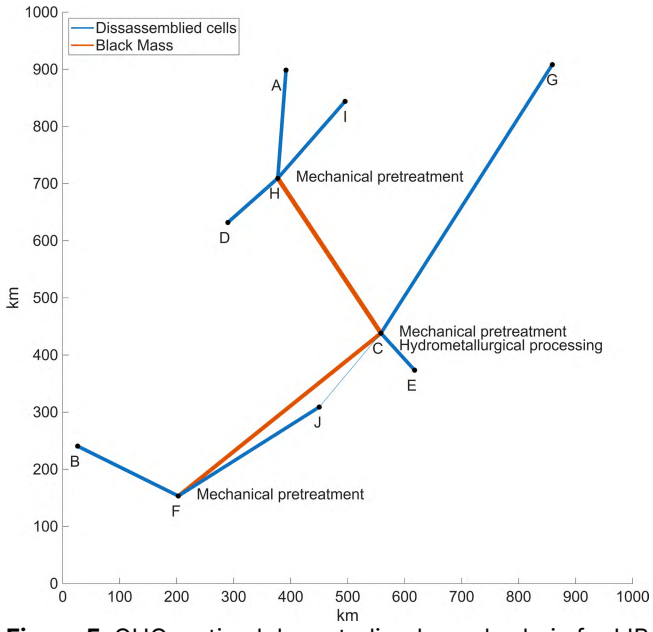

**Figure 5.** GHG-optimal decentralized supply chain for LIB recycling.

### Raw material optimal solution

For the studied generic pyrometallurgical and hydrometallurgical processes, the optimal solution for minimizing primary raw material procurement was to utilize the hydrometallurgical recycling route in all scenarios where recycling was permitted by the model constraints. By recycling EOL LIBs, the supply chain reduced its total refined battery materials consumption by 55% over the

studied time periods.

## CONCLUSIONS AND FUTURE WORK

The significant rise in the popularity of electric vehicles results in the increasing demand for lithium-ion batteries, consequently increasing the amount of EOL LIBs, which require efficient management. Thus, an optimization model is proposed as a tool to design and optimize the circular supply chain network for LIBs. The State Task Network based optimization framework allows for the optimal design of facility locations, technologies, capacities and the reintegration of recovered materials back into the different stages of the supply chain.

The results from the illustrative case study tested with literature data showed that both in terms of costs and emissions, the hydrometallurgical process is preferred. With the circular scenario, the optimal strategy was to utilize a fraction of the collected LIBs as stationary energy storage to generate more revenue. The case study revealed that the cost optimal solution prefers centralized collection, while the GHG optimal network prefers decentralized collection and mechanical pretreatment for LIBs. The preliminary results align well with the identified spoke-and-hub network recognized to reduce costs in LIB recycling [13].

Future work could involve developing a more realistic case study as well as studying different cathode active materials used in EVs. Also, considering the full bill of materials enables the optimization and assessment of the circularity of electrolytes and other materials present in LIBs.

## ABSTRACT

The wine industry generates large volumes of organic effluents, whose inadequate management poses significant environmental challenges but also offers opportunities for resource recovery. In this work, an integrated biorefinery scheme for the valorization of winery effluents is proposed and evaluated through steady-state simulation in Aspen Plus®. The biorefinery converts winery wastewater into a portfolio of value-added chemicals and biofuels, including levulinic acid, propylene glycol, formic acid, light gases, naphtha, sustainable aviation fuel, green diesel, and bioethanol, while enabling water recovery and carbon dioxide management. Two alternative $CO_2$ capture routes are analyzed and compared: a conventional CaO-based carbonation–calcination process and an innovative absorption system using deep eutectic solvents (DES), specifically choline chloride–urea. Technical performance is assessed through chemical oxygen demand (COD) removal, recovery, conversion, yield, and product mass ratios. Economic feasibility is evaluated using profit-based indicators, while environmental performance is quantified through $CO_2$-equivalent emissions associated with utility consumption. Results show that the proposed biorefinery achieves a COD removal efficiency of 99.99%, producing treated water compliant with Mexican regulations for internal reuse. The DES-based configuration reduces raw material costs by 48.86%, enables hydrogen recovery as an additional valuable product, and increases overall profit by 2.86% compared to the CaO-based scheme. Although the relative reduction in total $CO_2$ emissions is modest (≈0.5%), the DES configuration achieves an absolute annual reduction of 2, 198 t $CO_2$. Overall, the results demonstrate that integrating DES-based $CO_2$ capture into winery effluent biorefineries enhances economic performance and supports circular economy principles through waste valorization, water reuse, and emissions mitigation.

**Keywords**: Deep Eutectic Solvents, biorefinery, wine effluents, techno-economic analysis

## INTRODUCTION

The wine industry plays an essential role in the global economy, with sales ranging between €25.8 and €31.4 billion [1]. Mexico, ranked 32nd among the world's wine producers, contributed approximately 400, 000 hectoliters in 2022 [2]. Moreover, the wine industry stands out due to the considerable volumes of organic effluents generated during pretreatment, fermentation, clarification, and bottling operations. On average, 2–4 liters of effluent are generated per liter of wine produced, underscoring the need for sustainable management strategies. In this context, waste valorization offers a significant opportunity [3].

The wine effluents contain high concentrations of carbohydrates, alcohols, and organic matter. Because of their rich organic and mineral content, winery effluents are often reused for irrigation or discharged into water bodies and surrounding environments. However, if not properly treated, their high organic load and seasonal variability pose serious environmental risks. The impacts extend beyond aquatic systems to terrestrial ones. On land, effluents can cause salinization, acidification, structural soil damage, and unpleasant odors, while reducing

mineral availability, microbial diversity, and biological productivity. In aquatic systems, they can lead to turbidity, eutrophication, oxygen depletion, decreased photosynthesis, and toxic effects on aquatic life [3]. Nonetheless, their organic content also makes these effluents a promising feedstock for biorefinery systems. Due to this, several strategies have been analyzed to treat and valorize effluents derived from the wine industry. Among the analyzed processes, the valorization of wine effluents through biorefinery schemes is highlighted.

A biorefinery integrates a set of processes designed to convert wine effluents into value-added products, chemicals, biofuels, and bioenergy. In this processing scheme, the inclusion of carbon capture technologies aligns with circular-economy principles, promoting closed-loop systems that minimize waste and emissions. Among the available $CO_2$-capture approaches, absorption with chemical solvents is one of the most efficient and technologically mature. However, conventional amine-based solvents such as monoethanolamine (MEA) have significant drawbacks, including high regeneration energy requirements, solvent degradation, and environmental toxicity. As an alternative, deep eutectic solvents (DES) have emerged as a new generation of environmentally friendly solvents with outstanding physicochemical properties.

Various DES formulations have been explored, such as choline chloride/ethanolamine, choline chloride/L-arginine/glycerol, and choline chloride/1, 2-propanediol. Notably, the combination of choline chloride and urea forms a liquid solvent known as choline chloride:urea (ChCl:U) or reline, which demonstrates a high capacity for selectively absorbing $CO_2$ from gas mixtures [4].

Therefore, the research aim is to design and evaluate a conceptual process that integrates deep eutectic solvents-based $CO_2$ absorption with a biorefinery scheme. This scheme treats winery effluents to produce levulinic acid, sustainable aviation fuel (SAF), naphtha, light gas, formic acid, green diesel, propylene glycol, dipropylene glycol, and bioethanol. Additionally, in this biorefinery, water can be recovered to quality levels permissible under Mexican regulations.

## METHODOLOGY

In general, the procedure implemented to develop the proposed biorefinery is summarized in the block flowchart shown in Figure 1.

First, the case study is defined in terms of the effluent composition and its mass flow rate. Subsequently, the target products are established, together with the unit operations required for their recovery and/or production; this stage corresponds to the conceptual process design.

To satisfy the $CO_2$ capture requirement within the proposed biorefinery, two alternative capture routes are developed. The first route integrates $CO_2$ capture using deep eutectic solvents (DESs), whereas the second route is based on CaO as the capturing agent. Each route is incorporated into the overall process flowsheet to meet the $CO_2$ capture demand of the system. Consequently, these alternatives define two different biorefinery schemes, each one characterized by its corresponding $CO_2$ capture technology.

The kinetic and thermodynamic information reported in the literature is compiled and used to support the process modeling. Afterwards, the manipulated variables for each unit operation are identified, and the complete biorefinery is modeled and simulated under steady-state conditions using Aspen Plus® V15. Finally, technical, economic, and environmental assessments are carried out to evaluate the overall performance of the proposed biorefinery.

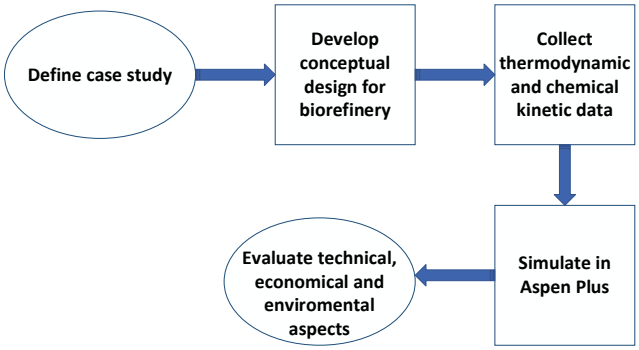

**Figure 1.** Methodological strategy

The technical evaluation aims to quantify the capacity of the biorefinery to remove contaminants from the effluent. This assessment is performed using the Chemical Oxygen Demand (COD) as a key indicator, calculated directly in Aspen Plus. Specifically, the technical performance is quantified through the relative reduction between the initial COD of the wine effluent and the COD of the treated water. In addition, several technical indicators are computed to characterize the overall process performance, namely: component recovery (rec), conversion (cv), yield (Yd), and product mass ratio (pmr), as defined by Equations (1)–(4) [5].

$$rec = \frac{oms}{fms} \tag{1}$$

$$cv = \frac{\dot{r}_{in} - \dot{r}_{out}}{\dot{r}_{in}} \tag{2}$$

$$yd = \frac{pmf}{tpm} \tag{3}$$

$$pmr = \frac{mp}{rmm} \tag{4}$$

Where: rec = component recuperation, oms = output mass flow (kg/h), fms = feed mass flow (kg/h) cv =conversion, $r_{in}$ = reactant input to process (mol/h), $r_{out}$ = reactant output to process (mol/h), Yd = Yield, pmf = moles of desired product formed (mol), tpm = theoretical product moles (mol), pmr = product mass ratio, mp = product mass flow (kg/h), rmm = raw material mass flow (kg/h)

The economic evaluation is based on the estimation of the process profit (PFT), defined as the difference between incomes and outcomes. Incomes correspond to product sales, whereas outcomes include raw material costs, total utility costs, and equipment-related costs. Equipment costs are estimated using the Guthrie method [6]. Since equipment investment represents a time-independent cost, an annualization factor (k) is incorporated to express this contribution on an annual basis [6]. The mathematical framework for the economic assessment is described by Equations (5)–(12). The parameters required to solve Equations (5)–(12), including Guthrie constants, are taken from Tourton et al. [6]. Utility prices were obtained from the Aspen Plus® V15 database. It is important to note that Guthrie parameters were originally developed in 2001; therefore, equipment costs were updated to 2025 values using the Marshall and Swift index and Equation (10) [6].

Finally, the environmental evaluation focuses on the environmental burden associated with utility consumption. The main indicator employed is the total $CO_2$-equivalent emissions, defined by Equation (13) and based on US-EPA-RULE-E9-5711. This parameter is also calculated using Aspen Plus.

$$PFT = (Ah)(Psale - RMC - UC_T) - (k)(EC) \quad (5)$$

$$Psale = \sum_{1}^{j}\left((mp_j)(pp_j)\right) \quad (6)$$

$$RMC = \sum_{1}^{g}\left((mp_g)(pp_g)\right) \quad (7)$$

$$UC_T = \sum_{1}^{i}(UC_i) \quad (8)$$

$$k = \frac{y(1+y)^h}{(1+y)^h - 1} \quad (9)$$

$$EC = C_2 = C_1\left(\frac{I_2}{I_1}\right) \quad (10)$$

$$C_{BM} = C_p^o(B_1 + B_2F_MF_P) \quad (11)$$

$$log_{10}C_p^o = \left(K_1 + K_2log_{10}(A) + K_3\left(log_{10}(A)\right)^2\right) \quad (12)$$

$$TCO_2e = \sum_{1}^{l}(CO_2e_l) \quad (13)$$

Where: PFT = profit (USD/year), Ah = hours per year (8766 h/year), PSALE = Product sales (USD/h), RMC = Raw material cost (USD/h), UCT = Total utilities cost (USD/h), k = annualization factor, EC = Equipment cost (USD), mp = product mass flow (kg/h), rmm = raw material mass flow (kg/h), pp = product price (USD/kg), prmm = raw material mass price (USD/kg), UC = Utility cost, y = interest rate (10 %), h = Life period of each technology (20 years), $C_p^o$= purchased cost for condition (USD), A = the capacity or size parameter for the equipment, ($K_1$, $K_2$, $K_3$, $B_1$, $B_2$) = Guthrie constants, FM = Material factor, FP = Pressure factor, CBM = bare module cost (USD), $C_1$ = Purchased cost to base time (USD), $C_2$ = Purchased cost to time when cost is desired (USD), $I_1$ = Cost index to base time, $I_2$ = Cost index to time when cost is desired, $TCO_2e$= Total $CO_2$ equivalent (ton $CO_2$ equivalent/year), $CO_2e_l$= $CO_2$ equivalent per utility (ton $CO_2$ equivalent/year). Subscripts: j = product stream, g = raw material stream, i = utility.

## RESULTS

As previously mentioned, Mexico reported a wine production of 400, 000 hectoliters in 2022 [2]. According to Buitrón et al. [3], the wine industry generates between 0.2 and 4 L of wastewater per liter of wine produced. For the definition of the study case, the average value within this range was adopted, resulting in 2.1 L of wastewater per liter of wine. Therefore, the annual volume of wine effluent released in Mexico was estimated at 8.4 × $10^7$ L·year$^{-1}$, which corresponds to 9, 589.04 L·h$^{-1}$. For modeling purposes, this value was rounded and, assuming the effluent density is close to that of water (as water is the predominant component), the study case was defined as a mass flow rate of 10, 000 kg·h$^{-1}$.

According to Buitrón et. al. [3] winery effluent is composed of several components; however, the most abundant are water, solids, ethanol, and glucose. On the other hand, De Iseppi et al. [7] report that the solid fraction is constituted by 25 wt% lees, 25 wt% lignin, 25 wt% cellulose, and 25 wt% hemicellulose, mainly. It is important to mention that wine lees are dead yeast that are deposited and discarded at the clarification step of wine production. Table 1 shows the effluent characterization.

Regarding the thermodynamic model, it is not possible to use only one for the entire biorefinery; this is because the process uses several components, which have different characteristics such as organic or inorganic nature, in different amounts; therefore, thermodynamics models for each section are defined by Carlson algorithm [8]. Those used in the entire process are NRTL, BK10, and PENG-ROBINSON.

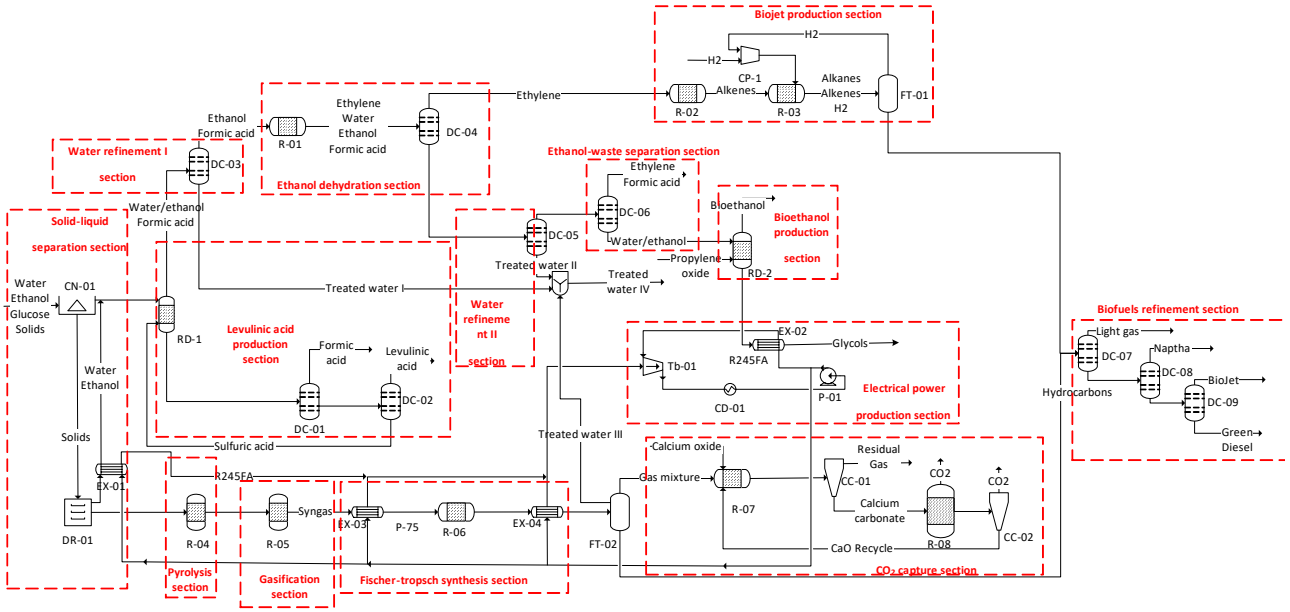

**Figure 2.** Biorefinery process flowsheet for the CaO-based $CO_2$ capture configuration.

**Table 1:** Winery effluent characterization

| Winery effluent | Value |
|---|---|
| Mass flow (kg/h) | 10, 000 |
| Water (wt%) | 71.76 |
| Ethanol (wt%) | 7.39 |
| Glucose (wt%) | 5.26 |
| Solids (wt%) | 15.59 |
| DQO (PPM) | 210, 052 |

The overall biorefinery scheme is presented in Figure 2. For clarity, the flowsheet is divided into several process sections. Figure 2 represents both the CaO-based and DES-based configurations; however, the only difference between them lies in the $CO_2$ capture section. For the DES configuration, the corresponding $CO_2$ capture section is shown separately in Figure 3, where $CO_2$ is captured using DESs [9].

The biorefinery process (Figure 2) begins with the separation of suspended solids from the bulk effluent. This step is performed using a centrifuge, and the recovered solids are routed to an independent processing pathway. The clarified liquid stream, mainly composed of glucose, ethanol, and water, is subsequently fed to a reactive distillation column (RD-01). In this unit, glucose is first converted to 5-hydroxymethylfurfural (5-HMF) and then further transformed into levulinic acid and formic acid. These reactions correspond to R1 and R2, respectively, while the kinetic parameters employed in the model are summarized in Table 2. The reaction system is catalyzed by $H_2SO_4$. Finally, the resulting acid mixture is purified using two conventional distillation columns (DC-01 and DC-02), enabling catalyst recovery and recycling.

$$C_6H_{12}O_6 \rightarrow C_6H_6O_3 + 3H_2O \quad \text{(R1)}$$

$$C_6H_6O_3 + 2H_2O \rightarrow CH_2O_2 + C_5H_8O_3 \quad \text{(R2)}$$

**Table 2:** Kinetic parameters for levulinic acid production [10]

| Reaction | **Reaction R1** | **Reaction R2** |
|---|---|---|
| Preexponential factor ($s^{-1}$) | $2.09x10^7$ | 27, 261.3 |
| Activation energy (kJ/mol) | 86.33 | 56.95 |

An overhead stream containing water, ethanol, and formic acid is withdrawn from RD-01. This stream is then fed to a third distillation column (DC-03), where ethanol and formic acid are recovered as the distillate, while treated water is obtained as the bottom product. The ethanol-rich stream is subsequently sent to reactor R-01, where ethanol is dehydrated to produce ethylene and water.

The ethylene produced in R-01 is purified in distillation column DC-04. The overhead stream, rich in ethylene, is sent to reactor R-02, where the polymerization step is carried out. The bottom stream from DC-04, containing heavier compounds and impurities, is directed to DC-05 for further treatment.

In R-02, the reaction yields a hydrocarbon mixture mainly composed of alkanes. This stream is subsequently hydrogenated to ensure full saturation of the products. Unreacted hydrogen is recovered in a flash tank (FT-01) and recycled, while the resulting hydrocarbon stream is

routed to the biofuels upgrading section.

Regarding the waste stream from DC-04, the water content is separated as the bottom product of DC-05, generating a second treated-water stream. The distillate from DC-05 is further processed in DC-06. In this column, ethylene and formic acid are recovered as the overhead product, whereas an ethanol–water mixture is obtained as the bottom stream.

The ethanol–water mixture is subsequently used as feedstock for bioethanol production. Ethanol dehydration is performed in a reactive distillation unit, where water reacts with propylene oxide to form propylene glycol. In addition, a side reaction between propylene oxide and propylene glycol leads to the formation of dipropylene glycol. These reactions correspond to R3 and R4, respectively, and the kinetic parameters employed are summarized in Table 3.

$$C_3H_6O + H_2O \rightarrow C_3H_8O_2 \quad \text{(R3)}$$

$$C_3H_6O + C_3H_8O_2 \rightarrow C_6H_{14}O_3 \quad \text{(R4)}$$

**Table 3:** Bioethanol production. Reactive dehydration parameters [11]

| Reaction | **Reaction R3** | **Reaction R4** |
|---|---|---|
| Preexponential factor ($s^{-1}$) | $9.6x10^7$ | 75, 362 |
| Activation energy (kJ/mol) | $9.6x10^6$ | 82, 899 |

The solid fraction separated from the effluent is dried in DR-01. The generated vapor is condensed prior to being recycled to RD-01.

The dried solids are subsequently subjected to pyrolysis in reactor R-04, yielding bio-oil and biochar. These products are then routed to the gasification section (R-05), where they are converted into syngas. The produced syngas is upgraded via a Fischer–Tropsch (FT) synthesis in reactor R-06 [12], generating a broad hydrocarbon distribution ranging from C1 to C30. However, water and $CO_2$ are also formed as by-products. Therefore, the multiphase effluent from R-06 is sent to a flash tank (FT-02), which separates the stream into three phases. The aqueous phase is recovered as the third treated-water stream in the overall process. The hydrocarbon phase is directed to the biofuels refinement section, while the gas phase, mainly composed of $CO_2$, along with methane and hydrogen, is routed to the $CO_2$ capture section.

In the CaO-based capture configuration, the gas stream is fed to reactor R-07, where a selective carbonation reaction takes place. In this step, calcium oxide reacts with $CO_2$ to form calcium carbonate ($CaCO_3$), as described by reaction R5. The kinetic model employs an activation energy of 0.3699 kJ/mol and a pre-exponential factor of 10.2 $s^{-1}$ [13].

$$CaO + CO_2 \rightarrow CaCO_3 \quad \text{(R5)}$$

After $CO_2$ capture, the remaining gas stream, rich in methane and hydrogen, is recovered as a potential fuel product using cyclone CC-01. In parallel, the calcium carbonate particles are sent to reactor R-08, where calcination is performed to release the previously captured $CO_2$ and regenerate CaO. The resulting stream exiting R-08 is routed to a second cyclone (CC-02) to separate residual $CO_2$ from the regenerated solid. Finally, the recovered CaO is recycled back to reactor R-07.

The biofuels upgrading section consists of three distillation columns. Light gases are recovered as the overhead stream from DC-07, naphtha is obtained as the distillate from DC-08, and sustainable aviation fuel is recovered as the overhead stream from DC-09. The bottom product of DC-09 corresponds to green diesel.

Electrical power generation is achieved through an organic Rankine cycle (ORC) employing R245fa as the working fluid. The ORC recovers waste heat from different sections of the biorefinery through heat exchangers, including streams associated with DR-01, R-05, R-06, and RD-02.

In addition to the CaO-based configuration, a DES-based $CO_2$ capture alternative is assessed. The only difference between both biorefinery schemes lies in the $CO_2$ capture section. In the DES configuration, the gas mixture from FT-02 is fed to the bottom of an absorption column (AC-01), while a deep eutectic solvent (DES) is introduced from the top. The DES consists of choline chloride:urea and is used in a 1:1 DES:water ratio. The solvent selectively absorbs carbon-containing compounds, enabling hydrogen recovery as the overhead product, which is considered a valuable co-product.

The $CO_2$-loaded (exhausted) solvent stream (Ex-DES) is subsequently sent to flash tanks FL-03 and FL-04 for solvent regeneration and $CO_2$ release. The overhead stream from FL-04 corresponds to a residual gas containing approximately 80 mol% $CO_2$. The process flowsheet of the DES-based $CO_2$ capture configuration is presented in Figure 3.

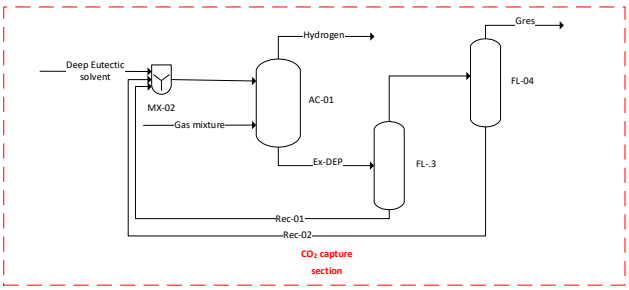

**Figure 3**. Process flowsheet for the DES-based $CO_2$ capture configuration.

The product slate obtained for each biorefinery configuration is summarized in Table 4. The reported water product corresponds to the total amount of treated water, obtained as the sum of all treated-water streams generated throughout the process. The resulting treated-water stream exhibits a COD of 19.1 ppm.

As shown in Table 4, the overall product yields are identical for both biorefinery configurations; the only differences are associated with the waste and hydrogen streams. In both the CaO-based and DES-based schemes, the waste stream is mainly composed of (i) the ethylene–formic acid stream generated in the ethanol/waste separation section, in addition to (ii) a residual gas stream and (iii) a $CO_2$-rich stream.

In both configurations, treated water is the dominant product, accounting for 70.5% of the total output. This is followed by sustainable aviation fuel, levulinic acid, naphtha, and light gases, contributing 4.13%, 2.20%, 2.10%, and 1.53%, respectively. The primary difference between the two schemes lies in the relative proportions of waste and hydrogen streams. In the CaO-based configuration, waste streams account for 17.21% of the total products, whereas in the DES-based configuration this fraction is reduced to 16.20%. As a result, hydrogen emerges as an additional valuable product in the DES-based scheme, representing 1.16% of the overall product distribution.

**Table 4:** Products obtained from the different schemes.

| **Product (kg/h)** | **CaO** | **DES** |
|---|---|---|
| Scheme | Figure 2 | Figure 3 |
| Water | 7,094.84 | 7,094.84 |
| Levulinic acid | 221.57 | 221.57 |
| Light gases | 153.62 | 153.62 |
| Naphtha | 211 | 211 |
| Sustainable aviation fuel | 415 | 415 |
| Green diesel | 74.8 | 74.8 |
| Bioethanol | 6.93 | 6.93 |
| Di/Propylene glycol | 49.3 | 49.3 |
| Formic acid | 96.4 | 96.4 |
| Waste | 1,730.26 | 1,631.49 |
| Hydrogen | ----- | 117.01 |

The chemical oxygen demand (COD) removal capacity is defined as the relative reduction between the initial COD of the winery effluent and the final COD of the treated-water product. Based on this definition, the proposed biorefinery achieves a COD reduction of 99.99%, fully complying with the maximum COD limits established by Mexican regulations for water intended for human use (COD < 70 ppm), as specified in NOM-001-SEMARNAT-2021 and NOM-127-SSA1-2021. Nevertheless, even if the treated water were to reach excellent quality (e.g., COD ≈ 0 ppm), NOM-127-SSA1-2021 does not allow its direct use for drinking purposes. Instead, the treated-water stream is suitable for internal reuse, such as recycled water within vineyard operations.

Regarding technical performance indicators, recovery is calculated exclusively for water and ethanol, as these are considered the relevant products of the biorefinery. Water recovery reaches 98.87% (Eq. (1)), based on the water content in the winery effluent as the input and the total treated water produced by the biorefinery as the output. In terms of sectional contributions, 84.73% of the recovered water is obtained from treated-water stream I, 13.56% from treated-water stream II, and the remaining fraction is generated within the Fischer–Tropsch section.

Ethanol recovery is relatively low (0.95%), as ethanol is produced solely as a bioethanol stream. It is important to emphasize that this outcome does not indicate an inefficient biorefinery configuration. Rather, it reflects the intentional process design, where ethanol contained in the winery effluent is primarily valorized as a feedstock for sustainable aviation fuel production pathway. Thus, only a small fraction of ethanol is available for recovery.

**Table 5:** Technical indicators

| Wastes | 0.173 | 0.1631 |

The product ratios reported in Table 5 provide valuable input for subsequent systems-level analyses, including supply chain development. These ratios can be directly incorporated into mathematical models to represent process outputs, thereby avoiding the introduction

of complex nonlinearities that typically arise when embedding detailed process simulations into optimization frameworks.

The main economic indicators of the proposed biorefinery are summarized in Table 6. A comparative assessment of the economic indicators for the CaO- and DES-based configurations reveals a significant reduction of 48.86% in raw material costs when CaO is replaced by DES. This reduction is primarily attributed to the internal generation of hydrogen within the $CO_2$ capture section, which supplies the hydrogen required for alkene hydrogenation in the alcohol-to-jet pathway. Specifically, hydrogen is produced in unit AC-01. In contrast, in the CaO-based configuration, hydrogen must be purchased as a raw material, accounting for 50.16% of the total raw material cost. The DES-based scheme also exhibits a 2.45% increase in product sales relative to the CaO-based configuration. This improvement is mainly associated with hydrogen recovery as a valuable product. In the CaO scheme, hydrogen is effectively wasted due to the lack of purification capability. In the DES-based process, hydrogen becomes the third most abundant product, following levulinic acid and sustainable aviation fuel, contributing 91.22% and 3.39% of the product distribution, respectively.

**Table 6:** Economic indicators

| | **CaO** | **DES** |
|---|---|---|
| Scheme | Figure 2 | Figure 3 |
| Raw material (USD/y) | $1,138,265.10 | $582,134.16 |
| Products (USD/y) | $255,625,939.62 | $261,888,720.64 |
| Utilities (USD/y) | $21,848,553.72 | $21,901,820.16 |
| Equipment cost (USD) | $50,954,841.13 | $53,374,306.62 |
| Annualized equipment cost (USD/y) | $5,985,136.52 | $6,269,326.03 |
| Total annual cost (USD/y) | $28,971,887.65 | $28,753,280.34 |
| Profit (USD/y) | $226,654,024.68 | $233,135,440.3 |

Despite these advantages, utility and equipment costs increase by 0.24% and 4.75%, respectively, in the DES-based configuration compared to the CaO-based scheme. The higher equipment cost is mainly driven by the inclusion of a compressor required to feed $CO_2$ to unit AC-01 and a heat exchanger used to pretreat the DES prior to absorption, operating at 20 atm and 15 °C. In the DES-based scheme, the compressor and heat exchanger represent 2.67% and 2.09% of the total equipment cost, respectively. By comparison, all equipment associated with $CO_2$ capture in the CaO-based scheme accounts for only 0.57% of the total equipment cost.

Regarding utility costs, the $CO_2$ capture section in the CaO-based configuration requires $32.97 USD $h^{-1}$, while the DES-based configuration requires $38.76 USD $h^{-1}$. These values correspond to 1.32% and 1.55% of the total utility costs of each process, respectively, explaining the observed 0.24% increase. In the CaO-based scheme, utility consumption is mainly associated with reactors R-07 and R-08, whereas in the DES-based scheme it includes the compressor feeding AC-01, the heat exchanger, and flash tanks FL-03 and FL-04.

Overall, the total annual cost is reduced by 0.75% in the DES-based configuration relative to the CaO-based scheme. As a result, the difference between revenues and operating costs leads to a 2.86% increase in profit for the DES-based process.

Table 7 summarizes the selected environmental indicators used for $CO_2$ quantification. In terms of $CO_2$-equivalent emissions associated with utilities, the DES-based scheme achieves a reduction of 0.48% compared to the CaO-based configuration. Although the CaO-based scheme releases a substantial amount of $CO_2$ due to $CaCO_3$ calcination during CaO regeneration, the DES-based scheme is unable to significantly reduce overall emissions. This limitation is mainly attributed to the large flowrate of exhausted DES (12.17 t $h^{-1}$) and the energy-intensive desorption step, which requires heating and handling a high mass of solvent, resulting in $CO_2$ emissions comparable to those of the CaO-based process.

**Table 7:** Environmental indicators

| | **CaO** | **DES** |
|---|---|---|
| Scheme | Figure 2 | Figure 3 |
| $CO_2$e utilities (Ton $CO_2$/y) | 431,843.59 | 429,766.75 |
| $CO_2$ streams (Ton $CO_2$/y) | 12,015.37 | 11,894.15 |
| Total | 443,858.96 | 441,660.90 |

The $CO_2$ streams correspond to the desorption stages in which both CaO- and DES-based systems release the captured $CO_2$. The DES-based configuration exhibits a slightly lower $CO_2$ release, with a reduction of 1.01% compared to the CaO-based scheme. This behavior is attributed to partial $CO_2$ retention within the DES matrix, whereas in the CaO-based process $CO_2$ is almost entirely released during regeneration.

Although the relative difference in total $CO_2$ emissions between the CaO- and DES-based configurations is modest (approximately 0.5%), the absolute impact is significant. The DES-based process enables an annual reduction of 2, 198 t $CO_2$, highlighting its environmental

relevance despite the small percentage difference.

## CONCLUSIONS

This study demonstrates the technical and economic feasibility of producing value-added chemicals and biofuels from winery effluents through the modelling and simulation of an integrated biorefinery scheme. The proposed process enables the recovery of levulinic acid, propylene glycol, formic acid, and biofuels, including light gases, naphtha, sustainable aviation fuel, green diesel, and bioethanol, transforming an agro-industrial waste stream into a diversified portfolio of marketable products.

From a circular economy perspective, the proposed biorefinery closes material and energy loops by simultaneously valorizing organic matter, recovering water for internal reuse, and separating $CO_2$ emissions from hydrogen mixtures through the incorporation of deep eutectic solvents (DES) as a capture and utilization strategy. This approach reduces dependency on external raw materials, lowers total annual costs, and enhances profitability by integrating hydrogen as an additional value-added product. Moreover, the DES-based configuration contributes to emissions mitigation, reinforcing the environmental performance of the system while maintaining economic competitiveness. For the selected case study, in Baja California, Mexico, the biorefinery achieves attractive economic indicators and complies with national environmental and water quality regulations. In particular, a COD removal efficiency of 99.99% allows the recovery of treated water suitable for internal reuse, in accordance with NOM-001-SEMARNAT-2021 and NOM-127-SSA1-2021.

Overall, the proposed scheme exemplifies a circular and sustainable pathway for winery effluent management; this proposal allows shifting from waste treatment to resource recovery, and highlighting the role of integrated biorefineries as enabling technologies for the transition toward low-carbon and circular agro-industrial systems.

## ABSTRACT

Gallium is a critical material with increasing demand driven by compound semiconductors such as gallium nitride (GaN) and gallium arsenide (GaAs) used in power electronics and optoelectronics and a highly concentrated supply chain, with 98 % of refined production occurring in China. While recycling remains limited, GaAs semiconductor manufacturing generates wastewater that can contain gallium concentrations ranging from 1–35 mg·L$^{-1}$, representing an underutilized secondary resource. This study evaluates the technical and economic feasibility of recovering gallium from GaAs semiconductor wastewater across an input range of 10–100 m$^3$·d$^{-1}$ using process modelling and a techno-economic analysis comparing two alternative separation routes: ion exchange (IX) and solvent extraction (SX). Using a real-world industrial wastewater composition, IX achieves a higher overall recovery than single-stage SX (80.40 % vs. 62.54 %), which translates into consistently lower levelized costs of gallium. The resulting levelized cost decreases from 563 to 144 €·kg$^{-1}$ for IX and from 701 to 161 €·kg$^{-1}$ for SX. The results demonstrate that separation step efficiency is the dominant determinant of economic performance and show that gallium recovery from semiconductor wastewater can be economically viable at fab-relevant scale. The analysis provides a proof-of-concept for integrating gallium recovery into semiconductor wastewater management and highlights its potential contribution to resource security and circular material supply.

**Keywords**: Gallium recovery, GaAs semiconductor wastewater, techno-economic analysis, ion exchange, solvent extraction, critical raw material, circular economy

## INTRODUCTION

The compound semiconductor industry is a key enabler of renewable energy and low-carbon technologies through materials such as gallium arsenide (GaAs) and gallium nitride (GaN), which enable high-efficiency power electronics and optoelectronic devices [1]. Semiconductor applications include photovoltaics, power conversion in wind and solar technologies and the electrification of transport [1].

As demand increases, gallium has become a critical material with highly concentrated supply chains, as 98% of refined production occurs in China [2]. As a companion metal primarily derived from bauxite processing and aluminum refining, independent scale-up is challenging. Global demand is projected to exceed 3000 t by 2050 [3], yet total potential capacity in 2024 was only 1100 t and primary production output was around 760 t.

Recent export restrictions have exposed the fragility of this dependency, with gallium prices rising from below 185 € kg$^{-1}$ in 2020 to more than 460 € kg$^{-1}$ in 2023 [4]. These developments highlight the urgency of developing alternative and secondary gallium sources to enhance supply resilience and reduce exposure to geopolitical and regulatory disruptions.

Recycling of gallium remains negligible and is largely confined to production scrap, while end-of-life recovery is virtually absent [1]. Industrial wastewater from semiconductor manufacturing represents a promising yet underexplored secondary source of gallium. In particular, GaAs wastewater from wafer manufacturing has shown gallium concentrations of up to 35 mg L$^{-1}$ [5]. Recent material flow analyses indicate that dominant gallium losses in both wafer- and device-oriented compound semiconductor manufacturing arise from the same unit

operations, particularly substrate processing and back-grinding, implying comparable gallium-bearing wastewater streams across these sectors [6]. A material flow analysis identified wafer and device production as major loss hotspots, accounting for 19 ± 5 % and 26 ± 5 % of gallium losses within the production system, respectively, and highlights wastewater treatment as a key leverage point for reducing these losses, revealing a substantial untapped recovery potential of both economic and environmental relevance [7].

To address this gap, this study compares two separation technologies: ion exchange (IX, e.g., chelating resins) and solvent extraction (SX, e.g., organophosphorus extractants). IX is the current state-of-the-art method and is already applied on a large industrial scale to recover gallium from Bayer® liquor, an alkaline process stream generated during alumina production, owing to its high selectivity and operational stability [8]. However, while IX dominates industrial gallium recovery from alkaline process streams, solvent extraction remains chemically well suited for acidic, arsenic-bearing solutions and is frequently reported in the literature on GaAs-related aqueous process solutions. For such systems, including scrap-derived leachates and simulated process solutions representative of GaAs manufacturing, both IX and SX have been tested mainly at laboratory scale, achieving high gallium recovery yields of up to 99 % and successful arsenic removal [9, 10].

Despite this demonstrated technical potential, neither technology has been implemented at scale for fab wastewaters, largely due to dilute gallium concentrations and complex co-contaminant matrices that undermine economic viability [5]. At the same time, recent laboratory studies report high selectivity and recovery for GaAs-representative acidic solutions, and emerging downstream conversion concepts offer additional enabling options; however, their implications for full-scale process design, cost drivers, and break-even conditions remain insufficiently quantified [9, 11, 12].

This work develops a system-level process model and techno-economic analysis to translate reported separation performance into scaled process designs and quantify cost drivers, break-even conditions, and design trade-offs across IX and SX. The results provide actionable design guidance for fab integration of resource recovery and water reuse and support policymakers and commodity strategists with quantitative evidence on circular supply options that can reduce dependence on highly concentrated primary gallium supply chains.

## MATERIALS AND METHODS

### Framework for the case study

This work develops and applies a techno-economic analysis (TEA) to evaluate the economic viability of gallium recovery from GaAs semiconductor wastewater. This section defines the case study, system boundaries, and modelling framework used to quantitatively compare two alternative recovery routes—ion exchange and solvent extraction.

First, process models, which include mass and energy balances to track gallium and key co-contaminants, are developed for each recovery train, identifying the major pretreatment, separation, and conversion steps for the two alternative separation technologies considered. The process models calculate gallium production rates, energy and additive demands, equipment quantities and sizes, and material replacement requirements, which are subsequently used as inputs to the techno-economic analysis. Next, a system-level TEA model calculates the levelized cost of gallium (LCOGa).

Key technical and economic inputs (feed composition, operating setpoints, performance parameters, costs and lifetime assumptions) are summarized in Tables 1–2 and applied consistently across both routes to ensure comparability. The TEA reports LCOGa and its decomposition into capital, operating, replacement, and labour cost contributions.

The case study is defined using measured wastewater compositions reported for real GaAs wafer manufacturing effluents. All economic parameters (electricity price, labour cost, and industrial cost indices) are referenced to a German industrial context, reflecting a representative European semiconductor manufacturing location. Gallium and arsenic concentrations of 34.6 mg $L^{-1}$ and 35.3 mg $L^{-1}$, respectively, together with an acidic pH of 3.8, were taken from semiconductor wastewater characterized by Jain et al. and are used to define the representative feed composition in this work [5].

The wastewater is assumed to be available at continuous flow rates typical for industrial semiconductor fabrication facilities, reflecting segregated process wastewaters from shared unit operations such as back-grinding and etching that occur across both wafer and device manufacturing [6]. A throughput range of 10–100 $m^3$ $d^{-1}$ was selected based on reported industrial effluent volumes and is applied consistently for equipment sizing, and cost correlations [13]. Additional aggregate water quality parameters, including total dissolved solids (TDS) and total suspended solids (TSS), were adopted from GaAs semiconductor wastewater treatment studies reported by Li et al. [14]. While Table 1 reports the key parameters used to define the case study, the process modelling accounts for the full wastewater composition reported in the literature.

As previously noted, this study examines IX and SX as the two alternative separation technologies for gallium recovery from GaAs semiconductor wastewater. In this work, the IX route is modelled using a chelating ion exchange resin (Diaion CR11) [12], while the SX route

employs an organophosphorus extractant (Cyanex 272) diluted in kerosene [9], consistent with experimental studies on gallium recovery from acidic GaAs-derived process solutions.

**Table 1:** Key feed characteristics and operating conditions defining the GaAs semiconductor wastewater case study

| Parameter | Unit | Value | Source |
|---|---|---|---|
| Volume flow | $m^3\ d^{-1}$ | 10–100 | [13] |
| Temperature | °C | 25 | [13] |
| pH | | 3.8 | [5] |
| Gallium | $mg\ L^{-1}$ | 34.6 | [5] |
| Arsenic | $mg\ L^{-1}$ | 35.3 | [5] |
| Total dissolved solids | $mg\ L^{-1}$ | 1500 | [14] |
| Total suspended solids | $mg\ L^{-1}$ | 30 | [14] |

These two separation technologies are evaluated as alternative recovery routes under identical wastewater feed definitions and system boundaries, enabling a consistent techno-economic comparison. The selected wastewater dataset therefore serves as a well-documented blueprint case for system-level modelling of gallium recovery from semiconductor wastewater.

This study targets the recovery of gallium with a purity of 99.99 % (4N). This grade is the standard commercial form of commodity gallium and is subsequently refined to high-purity (6N to 7N) for semiconductor device fabrication. Using this framework, the levelized cost of 4N gallium production is compared against current market prices, which were approximately 423 € $kg^{-1}$ in 2024 [4].

## Techno-economic analysis

The objective function to be minimized is the LCOGa, defined as the total annual cost of the system $TC$ divided by the total annual production of 4N gallium, $m_{\mathrm{Ga,ann}}$ ($kg{\cdot}a^{-1}$):

$$LCOGa = \frac{TC}{m_{Ga,ann}} \tag{1}$$

The total annual gallium production is a function of the wastewater feed flow rate ($Q_{\mathrm{feed}}$), the initial gallium concentration ($c_{\mathrm{Ga}}$), the plant availability factor ($y$), and the overall recovery rate ($TR$), which is calculated from the process models developed in this work:

$$m_{Ga,ann} = Q_{feed} \times c_{Ga} \times TR \times y \times 365\ days \tag{2}$$

The total annualized cost of the gallium recovery system is defined as:

$$TC = AF \times CapEx + OpEx + Rep + LC \tag{3}$$

where $CapEx$ represents the capital expenditure required to install the gallium recovery process train, $AF$ is the annualization factor, $OpEx$ denotes the annual operating expenses, $Rep$ accounts for annualized replacement costs of materials and equipment with finite lifetimes, $LC$ represents labour costs associated with plant operation.

The formula for the annualization factor is dependent on the annual discount rate, $r$, and the project lifetime in years, $n$:

$$AF = \frac{r(1+r)^n}{(1+r)^n - 1} \tag{4}$$

Capital expenditures are calculated by summing purchased equipment costs across all process steps and applying step-specific Lang factors $f_{Lang,s}$, to convert purchased costs to installed costs (accounting for installation, piping, instrumentation, for example):

$$CapEx = \sum_s (f_{Lang,s} \times \sum C_{equip,s}) \tag{5}$$

Here, $\sum C_{\mathrm{equip},s}$ is the total purchased cost of all equipment items assigned to process step $s$, and is the corresponding step-specific Lang factor.

Operating expenditures comprise electricity costs, chemical/additive consumption, and operations & maintenance (O&M) costs. Electricity costs are calculated from the annual electricity demand $E_{\mathrm{ann}}$ and the electricity price $EP$, while chemical costs depend on the annual consumption $m_{k,\,\mathrm{ann}}$ and unit price $AP_k$ of each chemical or additive $k$. O&M costs are approximated as a fixed fraction $OM$ of installed $CapEx$:

$$OpEx = E_{ann} \times EP + \sum_k (m_{k,ann} \times AP_k) + OM \times CapEx \tag{6}$$

Annual replacement costs $Rep$ account for equipment and materials with finite lifetimes. They are calculated by annualizing the purchased cost of each replaceable item $C_{\mathrm{equip},i}$ over its expected lifetime $\tau_i$:

$$Rep = \sum_i \frac{C_{equip,i}}{\tau_i} \tag{7}$$

The annual labour cost contribution, $LC$, is calculated as:

$$LC = C_{FTE} \times f_{FTE} \tag{8}$$

where $C_{\mathrm{FTE}}$ is the annual fully loaded cost of one full-time equivalent (FTE) employee, including salary, social charges, overhead, and benefits, and $f_{\mathrm{FTE}}$ is the fraction of a full-time equivalent required for operation of the gallium recovery process.

Values for the key parameters used in the analysis can be found in Table 2. It is worth noting that performance figures for the RO98pHt membrane, IX resin, SX, and electrowinning (EW) are sourced from experimental studies.

**Table 2:** Key parameters for the techno-economic analysis and the values associated with them.

| Parameter symbol | Description | Value | Source |
|---|---|---|---|
| n | Plant lifetime | 20 | [15] |
| y | Availability factor | 0.95 | [15] |
| r | Discount factor | 0.08 | [16] |
| OM | Annual rate cost of operations and maintenance | 0.02 | [16] |
| EP | Electricity price [€ $kWh^{-1}$] | 0.1648 | [17] |
| $C_{FTE}$ | Annual labour cost [€ $a^{-1}$] | 69, 164 | [18] |
| $f_{FTE}$ | Fraction of an FTE | 0.25 | [19] |
| $f_{Lang}$ | Lang factor | 1.4 – 4.9 | [20–22] |
| $AP_{HCL}$ | Cost of hydrochloric acid feedstock [€ $kg^{-1}$] | 0.15 | [23] |
| $AP_{H2SO4}$ | Cost of sulfuric acid feedstock [€ $kg^{-1}$] | 0.13 | [23] |
| $AP_{NaOH}$ | Cost of sodium hydroxide feedstock [€ $kg^{-1}$] | 0.3 | [24] |
| $C_{IX}$ | IX resin cost [€ $kg^{-1}$] | 138.91 | [25] |
| $\tau_{IX}$ | IX resin lifetime [y] | 5 | [26] |
| $C_{SX}$ | SX extractant cost [€ $kg^{-1}$] | 10 | [27] |
| $f_{makeup}$ | SX make up rate [% $a^{-1}$] | 15 | [28] |
| $SEC_{EW}$ | EW energy [kWh $kg^{-1}$ Ga] | 9.05 | [11] |
| $C_{RO98pHT}$ | RO98pHt membrane cost [€ $pc^{-1}$] | 1, 088 | [29] |

# RESULTS AND DISCUSSION

## Process trains and models

Process trains for each separation technology, IX and SX, were developed to recover 4N gallium from GaAs semiconductor wastewater. As shown schematically in Figure 1, both trains share an identical pretreatment and concentration front-end and a shared downstream conversion block; they differ only in the separation step. This structure enables a controlled comparison in which route-level differences in recovery and cost are dominated by separation performance and its implications for downstream conditioning.

The process begins with filtration to reduce suspended solids and mitigate downstream fouling while preserving dissolved species, including Ga [20]. Reverse osmosis (RO) is then used as a concentrator to reduce the flow volume and increase gallium concentration, improving the feasibility of selective recovery at comparatively small, fab-relevant module throughputs. The RO design uses a commercial spiral-wound membrane configuration (RO98pHt), which has demonstrated high rejection of multivalent ions and dissolved metals in acidic, metal-bearing waters [30]. In the process model, RO is implemented as a volumetric split with component-specific partitioning of gallium (and other tracked species) between permeate and concentrate. The permeate stream is treated as a reuse or discharge stream depending on site-specific integration, while the concentrate is routed to chemical conditioning [31].

The RO concentrate is adjusted to pH 2 using hydrochloric acid to ensure a stable operating window compatible with both separation routes and to avoid premature hydroxide precipitation. This setpoint follows reported operating conditions for gallium recovery in acidic solutions and provides a consistent basis for comparing IX and SX under the same feed chemistry. [9, 12, 23]

In the IX process train, $Ga^{3+}$ is selectively complexed on a chelating resin and subsequently recovered through an acid wash. This step yields a gallium-rich product stream, while the treated aqueous stream leaving the column constitutes a gallium-depleted waste stream. Diaion CR-11 is used as the baseline resin and it is regenerated using 0.1 M $H_2SO_4$, consistent with reported gallium recovery from GaAs-derived feeds and supported by manufacturer specifications and literature data [12].

In the SX process train, gallium is transferred from the aqueous phase into an organic phase consisting of Cyanex 272 diluted in kerosene via pH-dependent complex formation, and subsequently stripped into an aqueous recovery solution using 0.5 M HCl, consistent with experimental studies on simulated GaAs waste etching solutions and hydrometallurgical practice [9]. Solvent make-up is explicitly included in the model to account for extractant losses and operability constraints relevant to industrial scale-up. The IX and SX recovery streams differ in acid chemistry (sulfate versus chloride), which propagates to downstream neutralization requirements and associated reagent demand.

After separation and regeneration, the gallium-rich recovery streams are not directly suitable for electrowinning due to their low gallium concentration, acidic chemistry, and residual matrix components, which would lead to severe hydrogen evolution and poor current efficiency. To enable efficient electroreduction, gallium is therefore first precipitated as gallium hydroxide by alkalinization using sodium hydroxide, effecting a solid–liquid separation that concentrates gallium while removing the bulk aqueous matrix and associated impurities [8].

The precipitate is then subjected to alkaline leaching to generate a gallium-rich electrolyte suitable for electroreduction [11]. This step is essential because direct

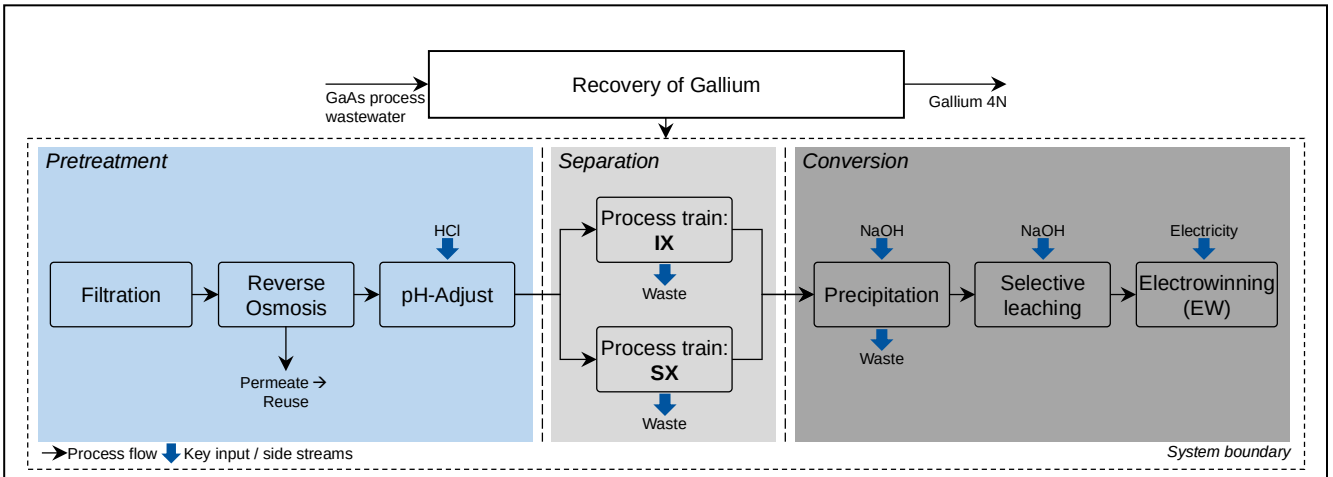

**Figure 1:** Schematic diagram of the processing trains developed and analyzed for recovery of 4N gallium from GaAs process wastewater, structured into pretreatment, separation, and conversion blocks. Pretreatment comprises filtration followed by reverse osmosis (RO), operated as a volumetric split to concentrate gallium in the retentate while generating a permeate stream assumed available for reuse. The RO concentrate is chemically conditioned by pH adjustment to establish an acidic matrix suitable for selective gallium separation.
Two alternative separation technologies are considered: (i) ion exchange (IX), in which gallium is selectively adsorbed on a chelating resin and recovered by acid elution; and (ii) solvent extraction (SX), in which gallium is transferred into an organic phase and subsequently stripped into an aqueous recovery stream. In both cases, the gallium-rich stream is routed to a shared conversion train comprising precipitation, alkaline leaching, and electrowinning to produce 4N gallium using a titanium cathode. The dashed box indicates the system boundary. Black arrows denote the main process flow, while blue arrows indicate key chemical and utility inputs as well as qualitative side streams.

electrowinning from acidic recovery solutions would be kinetically unfavorable and dominated by hydrogen evolution.

Final recovery is achieved by electrowinning using a titanium cathode, following the cyclone electrowinning concept reported by Xu et al [11]. In this process, forced electrolyte circulation enhances mass transfer and suppresses concentration polarization, enabling stable deposition of metallic gallium from alkaline solutions. The deposited metallic gallium is mechanically separated, washed, and vacuum-dried to remove residual electrolyte and moisture, yielding 4N gallium as the final product, which represents the standard commercial grade and serves as feedstock for subsequent high-purity upgrading. [11]

**Table 3:** The fraction of gallium recovered using each process train for both technologies.

| Process train | Recovery fraction |
|---|---|
| IX | 80.4 % |
| SX | 62.54 % |

Overall gallium recovery for each train is computed from the stepwise recovery fractions across RO, separation, precipitation, leaching, and electrowinning, with the corresponding recovery values reported in Table 3. Because both routes share the same front-end and downstream conversion, differences in overall recovery are dominated by separation performance: IX achieves a single-pass recovery of 96.9 %, whereas single-stage SX is limited to 77.3 %, resulting in overall recoveries of 80.40 % and 62.54 %, respectively. In the baseline, the SX route is modelled as a single extraction/stripping stage following Chen et al., such that higher recovery would require additional stages and increased solvent inventory, implying a cost–recovery trade-off [9]. In contrast, the IX basis follows Cheng et al. and provides higher effective single-pass recovery due to strong $Ga^{3+}$ affinity and efficient elution, thereby reducing separation-stage losses [12].

## Techno-economic performance

The process models assume an unpressurized feed, with all unit operations sized explicitly using flow-dependent design equations and operating setpoints. Given the comparatively small target throughputs considered in this study (baseline feed flow rates of 10–100 $m^3\ d^{-1}$), a bottom-up costing approach is adopted based on explicit equipment sizing and vendor or literature pricing [32]. Generic large-plant cost correlations are not applied, as they are sparse or non-representative at this scale [20].

Waste and side streams (e.g., spent regenerant, RO permeate, spent electrolyte) are quantified for mass-balance closure, disposal costs for these streams are not charged to the recovery system in the baseline TEA. This

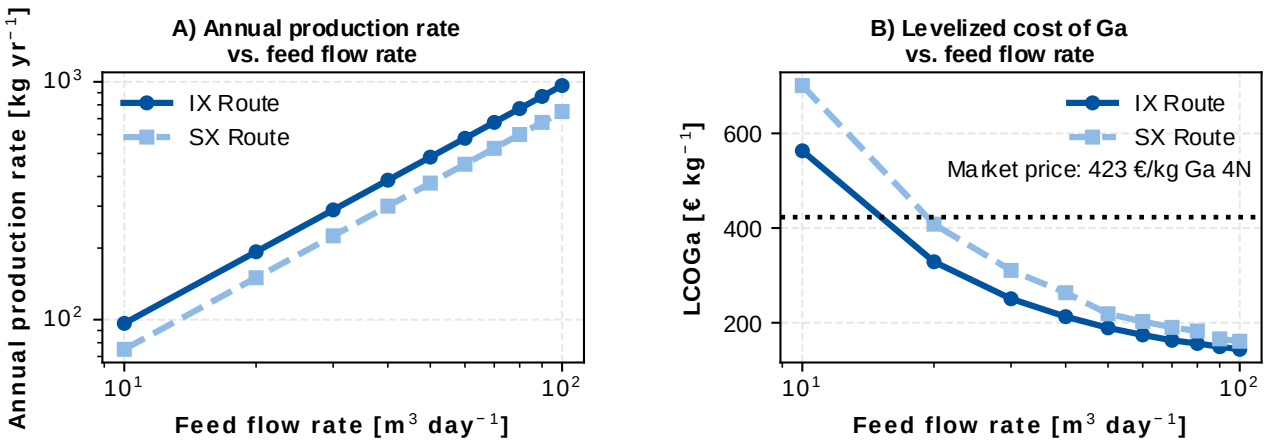

**Figure 2:** Baseline techno-economic results for gallium recovery from GaAs semiconductor wastewater comparing ion exchange (IX) and solvent extraction (SX) over feed flow rates of Q = 10–100 m³ d⁻¹. (A) Annual production rate (kg yr⁻¹) versus feed flow rate (log–log), showing near-linear scaling with throughput at fixed feed composition and route-dependent yield differences arising from different overall recovery. (B) Levelized cost of gallium (€/kg 4N Ga) versus feed flow rate (log-x), including a reference market price for 4N gallium (423 €/kg).

framing represents an incremental "bolt-on" recovery module at a fab site with existing wastewater treatment infrastructure; stand-alone deployment would require explicit treatment/disposal costing and may shift the economic results [33].

The production rate shown in Figure 2A scales linearly with the feed flow rate. The factors determining annual production in these designs are primarily the total recovery and conversion yields across the process train (Table 3), which depend on separation performance (recovery and selectivity), reaction yields, and operational setpoints, rather than on the absolute volume of feed processed. Accordingly, the model applies fixed recovery fractions for each route in the baseline case, resulting in proportional scaling of annual production with Q. At the baseline composition ($c_{Ga}$ = 34.6 mg $L^{-1}$), the IX route produces 96 kg per year at Q = 10 m³ per day and 965 kg per year at Q = 100 m³ per day, whereas the SX route produces 75 kg per year and 750 kg per year at the same throughputs. This difference in yield is not merely a production metric: because the LCOGa is normalized per kilogram of product, a lower total recovery reduces the denominator (kilograms of gallium produced per cubic meter processed) and therefore increases the cost in euros per kilogram, even if the processing cost per cubic meter were unchanged.

The levelized cost trends are shown in Figure 2B. LCOGa decreases steeply with throughput for both routes, falling from 563 to 144 € $kg^{-1}$ for IX and from 701 to 161 € $kg^{-1}$ for SX when scaling Q from 10 to 100 m³ per day. The IX route is consistently lower in cost because it combines a higher overall recovery with a more favourable operating-cost structure at scale. This effect is particularly evident at Q = 100 m³ $d^{-1}$, where operating expenses account for a larger fraction of total cost for SX, approximately 43%, compared to approximately 24% for IX, as shown in Figure 3. This is consistent with the additional consumables and operational burdens associated with the SX route in the baseline model.

To assess economic viability, the LCOGa curves are compared against a representative market price for 4N gallium of 423 € $kg^{-1}$. Both routes reach economic viability within the evaluated throughput range. Interpolation of the base-case LCOGa curves yields break-even throughput thresholds of approximately Q* = 14.2 m³ $d^{-1}$ for IX and Q* = 19.3 m³ $d^{-1}$ for SX under baseline assumptions. These thresholds provide a practical screening criterion for deployment: below Q* the recovery module is not viable at baseline performance, whereas above Q* it becomes viable without requiring optimistic price assumptions.

Figure 3 decomposes LCOGa into CapEx, OpEx, replacement, and labour to better understand the major cost drivers of the LCOGa. At Q = 10 $m^3 \cdot d^{-1}$, labour and annualized CapEx dominate for both routes (~30 % each), consistent with a small-plant regime where fixed and semi-fixed costs are spread over limited production. At Q = 100 $m^3 \cdot d^{-1}$, labour becomes less significant (~12–13 %), while CapEx and OpEx dominate, explaining the strong decline in $€ \cdot kg^{-1}$ with scale.

In this bottom-up model, most variable consumptions (electricity, reagents, membrane area, and separation materials) scale approximately with treated volume, so returns to scale arise mainly from dilution of fixed/semi-fixed costs rather than improved specific consumptions. Parts of the installed equipment are also

discretely sized (e.g., standard pumps/ancillaries), such that selected items can cover a wide operating window and contribute similar installed costs at Q = 10 and 100 $m^3 \cdot d^{-1}$, producing stepwise CapEx behaviour. Consequently, within the two-train comparison, the most effective levers to reduce LCOGa are higher overall recovery TR (dominated by separation) and reductions in labour intensity and replacement burden.

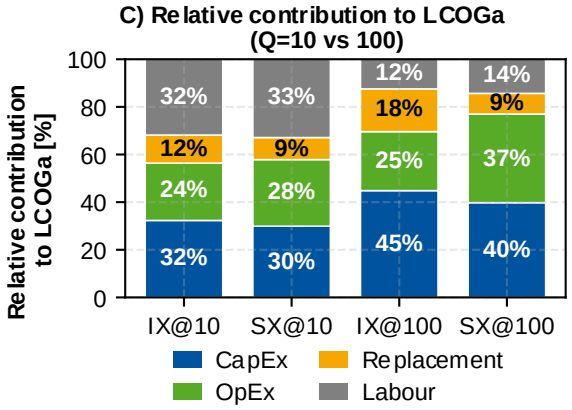

**Figure 3**: (C) Relative contribution of aggregated cost centres to the levelized cost of gallium (LCOGa) at two representative scales (Q = 10 and 100 $m^3\ d^{-1}$) for both routes

Deployment implications follow directly from the controlled IX vs. SX comparison. First, throughput and feed concentration jointly determine viability, as production scales with Q and $c_{Ga}$ at fixed recovery (Eq. 2). Second, within the two-train comparison the dominant technical lever is overall recovery TR, driven primarily by the separation step; higher SX recovery would require additional stages and solvent inventory, introducing a clear cost–recovery trade-off. Third, the strong cost decline with scale indicates two regimes: at low feed flow rates, fixed and semi-fixed costs (labour, annualised equipment) dominate, whereas at higher feed flow rates consumables and energy become increasingly important.

## CONCLUSION

This study assessed the techno-economic feasibility of recovering 4N gallium from GaAs semiconductor wastewater ($c_{Ga}$ = 34.6 $mg \cdot L^{-1}$, pH = 3.8) across a throughput range of 10–100 $m^3 \cdot d^{-1}$. Under identical system boundaries with shared pretreatment and downstream conversion, ion exchange (IX) achieves higher overall recovery than single-stage solvent extraction (SX) (80.40 % vs. 62.54 %), resulting in consistently lower LCOGa across the evaluated range (144–563 $€ \cdot kg^{-1}$ for IX vs. 161–701 $€ \cdot kg^{-1}$ for SX). This performance gap is driven primarily by the markedly higher single-pass separation efficiency of IX (96.9% vs. 77.3% for SX), which dominates recovery losses and propagates directly into total plant recovery and cost. Compared against a representative 4N gallium market price of 423 $€ \cdot kg^{-1}$, the corresponding break-even throughputs are Q* ≈ 14.2 $m^3 \cdot d^{-1}$ for IX and 19.3 $m^3 \cdot d^{-1}$ for SX, providing a transferable proof-of-concept blueprint for bolt-on integration of gallium recovery into semiconductor fabrication facilities.

Future work should quantify environmental performance and investigate the cost–recovery trade-offs of multi-stage SX configurations to overcome single-stage limitations. In parallel, sensitivity analyses should be used to test the robustness and transferability of these findings across different wastewater flow rates, gallium concentrations, and semiconductor wastewater chemistries, and to explore their implications for wider deployment of gallium recovery across the semiconductor industry.

## ABSTRACT

The accumulation of automotive plastic waste poses a growing environmental threat; while recycling has the potential to address this, its use remains limited by the complexity of the materials used in vehicle components. Specifically, the presence of mixtures of polypropylene (PP), polyethylene (PE), and polyoxymethylene (POM) in the materials makes mechanical recycling challenging due to the difficulty of separation. To address the inefficiency of current end-of-life management, we present a systematic computational framework integrating computer-aided molecular and process design (CAMPD) with technoeconomic assessment (TEA) and life cycle analysis (LCA) to design a solvent-based recycling process capable of producing near-virgin quality resins. This framework involves utilizing the SAFT-$\gamma$ Mie equation of state to predict thermodynamic properties and employing nonlinear programming (NLP) to perform process optimization. From an evaluation of 875 solvent candidates, we identify 72 feasible solvent combinations, amongst which cymene and cyclohexanone is the most promising solvent pair to separate polyolefins selectively and dissolve POM, enabling reduced dissolution temperatures and minimized unit capital costs. TEA and LCA indicate that the proposed process is highly competitive, as all feasible designs yield a minimum selling price (MSP) below the market price of virgin polymers and achieve global warming potentials (GWP) significantly lower than those of virgin polymer production. Sensitivity analysis confirms the robustness of the design, showing that both economic viability and environmental competitiveness relative to virgin production are maintained, even under conservative solvent loss scenarios of up to 5%. These findings suggest that solvent-based recycling offers a commercially viable pathway to meet emerging EU circularity mandates for the automotive sector.

## INTRODUCTION

Automotive plastic waste has emerged as a critical environmental concern in Europe. With a fleet of approximately 285.6 million vehicles, roughly 6.5 million reach their end of life annually [1]. The automotive sector is a major consumer of polymers, with more than 2.2 million tons of plastics being used in vehicles introduced to the EU market each year. Key engineering polymers in this sector include polypropylene (PP), polyethylene (PE), and polyoxymethylene (POM) [2]. Despite this significant material footprint, current end-of-life management is inefficient; less than 19% of automotive plastic waste is recycled, while the vast majority is directed to incineration or landfill [2].

Current mechanical recycling approaches often

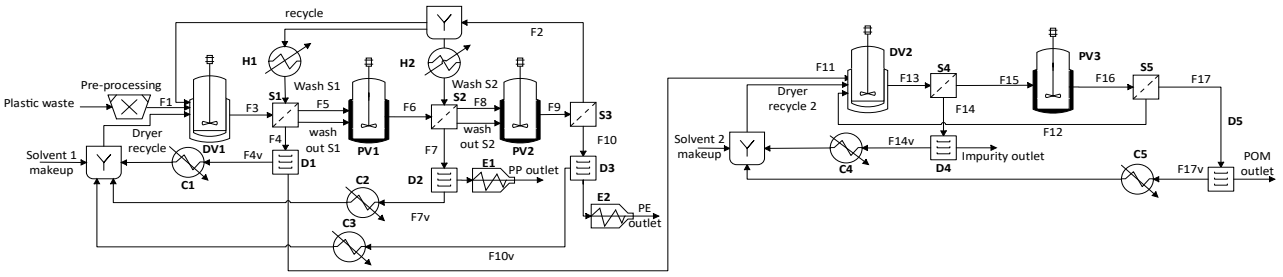

**Figure 1:** Process flow diagram of the plastic waste recycling process considered in the current work.

yield downgraded materials with compromised performance due to polymer chain scission, contamination from additives, and the presence of glass fibers [3]. These limitations severely restrict the reuse of recycled plastics in high-performance automotive applications. The new EU circularity rules, however, mandate at least 20% recycled plastic in new vehicle types within six years [1], creating an urgent need for technologies capable of producing recycled resins comparable in quality to virgin materials.

In this context, solvent-based recycling offers a promising solution. By selectively dissolving target polymers, this method can effectively remove contaminants and precipitate near-virgin quality materials [4]. This technology is particularly suitable for PE and PP, whose inert backbones make chemical depolymerization impractical [5]. However, the design of solvent-based polymer recycling processes is complex, requiring the identification of solvent systems that can achieve high selectivity and purity while maintaining economic viability [6].

Recent computational efforts have sought to streamline the design of these processes. Notably, Ikegwu et al. [7] developed a fast computational framework for designing solvent-based recycling systems, specifically targeting the recovery of multilayer packaging films via the solvent-targeted recovery and precipitation (STRAP) methodology. Their work demonstrated the potential of computational screening to identify solvents for distinct polymer layers. However, their analysis also highlighted the significant difficulty of separating chemically similar polyolefins; they reported finding very few viable solvent candidates capable of effectively separating PE from PP under fixed processing conditions.

This scarcity of obvious candidates underscores the need for more integrated approaches to molecular and process design. While broad screening is effective for identifying solvents with high solubility, successfully separating PE, PP, and POM requires further optimization of dissolution and precipitation operating conditions. Rigorous optimization of process temperatures and recycle rates may render a solvent inviable for the multicomponent mixture, even if it shows low or high solubility for the single solute [8].

Building on the challenges identified in the literature, we move beyond standard screening to systematically optimize the process conditions for 875 solvent combinations (one solvent for each dissolution step) through a novel computer-aided molecular and process design (CAMPD) framework specific to the ternary separation of automotive PE, PP, and POM waste.

We propose a process flowsheet comprising sequential dissolution/precipitation steps with solvent recycle. To identify the optimal design, we employ an enumeration strategy coupled with rigorous nonlinear programming (NLP). For each solvent combination, we solve a dedicated NLP problem to convergence using a model of the process that combines mass and energy balances with the predictive SAFT-$\gamma$ Mie [9, 10] equation of state to evaluate the thermodynamic properties of the multicomponent mixtures. This allows us to identify specific temperature and concentration ranges where separation is thermodynamically and economically feasible; screening methods might overlook some of these designs as they lack the flexibility to adapt operating points to each solvent/solvent mixture.

We integrate the CAMPD framework with detailed technoeconomic assessment (TEA) and life cycle analysis (LCA) to provide a holistic evaluation of the trade-offs between total annualized cost (TAC) and environmental metrics, including global warming potential (GWP), cumulative energy demand (CED), and the ReCiPe and Eco-indicator 99 (EI99) endpoint indicators. Furthermore, we determine the minimum selling price (MSP) and internal rate of return (IRR) to assess the financial viability of the process. Additionally, we perform sensitivity analyses to quantify the impact of the solvent loss rate, a highly influential and uncertain parameter, on the MSP and GWP.

The paper is structured as follows: the Design Methodology section covers the problem definition, process flowsheet, CAMPD formulation, and TEA and LCA methods. The Results and Discussion section analyzes the optimization results in conjunction with economic and environmental assessments. The paper closes with final conclusions.

## DESIGN METHODOLOGY

### Problem definition

The process configuration, shown in Figure 1, entails

the sequential separation and recovery of 3 polymer product streams, PE, PP and POM. A 3000 ton/year plastic waste stream made up of 45 wt% PE, 45 wt% PP and 10 wt% POM is pre-processed and introduced into dissolution vessel DV1, where PE and PP are selectively dissolved in Solvent 1 to separate them from POM and insoluble impurities. The slurry is passed to filtration unit S1, where the POM and impurities are removed. A portion of the lean solvent recycle stream, *F2*, is utilized to wash the filter cake, thereby recovering the majority of the liquid PE and PP and improving polymer purity. The resulting filter cake is dried in D1 to recover Solvent 1 within the POM matrix; this solvent is subsequently condensed in C1 and recycled to DV1.

The filtrate from S1, stream *F5*, and the S1 wash outlet are fed to the precipitation vessel PV1. Here, cooling is applied to selectively precipitate the PP. The solid PP is recovered in filter S2, where the filter cake is washed with a fraction of the lean solvent, stream *F2*, to recover residual liquid PE. The cake from S2, stream *F7*, is dried in D2 for solvent recovery (condensed in C2 and recycled) and is then extruded to produce near-virgin PP.

The filtrate from S2, stream *F8,* combined with the S2 wash outlet, enters precipitation vessel PV2, where cooling is applied to precipitate PE and any remaining liquid PP. Filtration is employed in S3 to produce a PE-rich cake, *F10*. This cake is dried in D3 to recover solvent (condensed in C3 and recycled), producing a PE outlet stream that is extruded in E2 to form near-virgin PE.

For the final recovery stage, the POM-containing stream, *F11*, is fed to dissolution vessel DV2 for POM to be dissolved in Solvent 2, separating it from the remaining insoluble impurities. These impurities are removed in filter S4 and fed to dryer D4 for solvent recovery (condensed in C4 and recycled to DV2). The filtrate from S4, stream *F15*, is directed to a precipitation stage where cooling is applied to recover the solid POM. In unit S5, the solid POM is separated by filtration, and the cake is dried – enabling the recovery of Solvent 2 – before being extruded in E3 to produce near-virgin POM.

## Modeling Framework and Optimization constraints

The models of each process unit, including the relevant material and energy balances, are implemented in gPROMS Process 2025.2.0. Thermodynamic properties, including phase equilibria and enthalpy calculations, are evaluated using the SAFT-γ Mie equation of state implementation within gProperties 2.10, utilizing group contribution parameters developed by Haslam et al. [11] and Paliwal et al. [12].

### Process constraints

To ensure the formation of a processable solution and to prevent gel formation, upper bounds are imposed on the total polymer mass fractions in the dissolution outlet streams *F3* and *F13* [13]:

$$\sum_{pol\in\{PP,PE,POM\}} w^{L}_{F3,pol} \le 0.3, \tag{1}$$

$$\sum_{pol\in\{PP,PE,POM\}} w^{L}_{F13,pol} \le 0.3. \tag{2}$$

In DV1, the operating temperature, $T_{F3}$, is determined by imposing solid-liquid equilibrium (SLE) equation on PP [13]. To ensure selective dissolution, where PP dissolves while PE remains in the liquid phase and POM remains solid, we enforce specific lower and upper bounds on $T_{F3}$:

$$T^{\mathrm{SLE}}_{PE,F3} \le T_{F3} \le T^{\mathrm{SLE}}_{POM,F3}, \tag{3}$$

where $T^{\mathrm{SLE}}_{PE,F3}$ and $T^{\mathrm{SLE}}_{POM,F3}$ are the SLE temperatures of PE and POM at $\boldsymbol{x}^{L}_{F3}$, the liquid composition of stream *F3* (with $T^{\mathrm{SLE}}_{POM,F3}$ computed at $x^{L}_{F3,\mathrm{POM}} = 10^{-20}$).
Additionally, to guarantee that the polymer-solvent mixture forms a single stable liquid phase in DV1, a logical stability function $\tilde{S}_l(T_3, P_3, \boldsymbol{x}^{L}_{3})$ is constrained to 1. A value of 1 indicates that a temperature-pressure flash calculation at the specified conditions detects only one stable (liquid) phase, while 0 indicates the presence of another fluid phase (a vapor or a second liquid). A similar function $\tilde{S}_l(T_{13}, P_{13}, \boldsymbol{x}^{L}_{13})$ is constrained to 1 to ensure the polymers and solvent form a single stable liquid phase in DV2.

In PV1, the operating temperature, $T_{F6}$, is also obtained by imposing SLE equation for PP. To prevent the co-precipitation of PE, a lower limit on $T_{F6}$ is enforced:

$$T_{F6} \ge T^{\mathrm{SLE}}_{PE,F6}, \tag{4}$$

where $T^{SLE}_{PE,F6}$ is the SLE temperature of PE at $\boldsymbol{x}^{L}_{F6}$, the molar liquid composition of stream *F6*. In PV2, the design objective is to fully recover PE and any residual PP. Consequently, the operating temperature ($T_{F9}$) must be sufficiently low to ensure full precipitation but must remain above the solvent's freezing point to avoid crystallization:

$$T_{F9} \le T^{\mathrm{SLE}}_{PE,F9}; \quad T_{F9} \le T^{\mathrm{SLE}}_{PP,F9}; \quad T^{\mathrm{fus}}_{sol} \le T_{F9} \tag{5, 6, 7}$$

where $T^{\mathrm{SLE}}_{PE,F9}$ and $T^{\mathrm{SLE}}_{PP,F9}$ are computed for a trace mole fraction of $10^{-20}$ and $T^{\mathrm{fus}}_{sol}$ is the solvent temperature of fusion.

Finally, because the polymers are thermally sensitive, strict upper limits must be applied to the temperatures of dryers D1, D2, D3, and D5. These temperatures must remain below the polymer temperature of fusion ($T^{fus}_{pol}$) and below or equal to the solvent bubble point ($T^{b}_{sol}$) to prevent overpressurization:

$$T_{F4} \le T^{\mathrm{fus}}_{POM} - 5; \; T_{F4} \le T^{\mathrm{b}}_{sol}; \tag{8, 9}$$

$$T_{F7} \le T^{\mathrm{fus}}_{PP} - 5; \; T_{F7} \le T^{\mathrm{b}}_{sol}; \tag{10, 11}$$

$$T_{F10} \leq T_{PE}^{\text{fus}} - 5;\ T_{F10} \leq T_{sol}^{\text{b}} \quad (12, 13)$$

$$T_{F14} \leq T_{sol}^{\text{b}}; \quad (14)$$

$$T_{F17} \leq T_{POM}^{\text{fus}} - 5;\ T_{F17} \leq T_{sol}^{\text{b}}; \quad (15, 16)$$

where $T_{F4}, T_{F7}$ and $T_{F10}$ correspond to the temperatures of dryers D1, D2 and D3, respectively. The temperature of dryer D4, $T_{F14}$, can be above the temperature of fusion of the polymers as the filter cake from S1, *F4*, consists primarily of insoluble impurities. A safety margin of 5 K has been applied to the lower bounds.

### Optimization variables and specifications

The optimization problem is constrained by strict product quality specifications, which require a minimum recovery of 95% for each polymer component (PP, PE, and POM) relative to the initial feed stream (*F1*), along with a minimum product purity of 99% by weight. The set of decision variables includes the identities of solvents 1 and 2, the weight fractions of PP in the dissolution outlet (*F3*) and precipitation outlet (*F6*), denoted as $w_{F3,PP,liquid}$ and $w_{F6,PP,liquid}$, respectively, as well as the operating temperatures of the dryers $(T_{F4}, T_{F7}, T_{F10}, T_{F17})$ and the split fractions of the pure solvent stream (*F2*) utilized for washing the filter cakes in units S1 $(\text{WF}_{S1})$ and S2 $(\text{WF}_{S2})$.

## CAMPD formulation

The process model and thermodynamic constraints are integrated within a CAMPD framework. This is in principle a mixed integer problem, but it is tackled here via enumeration of the integer variables and solution of the resulting NLP problem for each combination. The solvent candidates are selected from two predefined lists, $\mathcal{L}_1$ (for Polyolefins) and $\mathcal{L}_2$ (for POM). Each solvent $l_1$ and $l_2$ is characterized by a vector of functional group numbers, $\boldsymbol{n}_{l_1}$ and $\boldsymbol{n}_{l_2}$, using the sets $G_1$ and $G_2$ of SAFT-γ Mie groups (see Table 1). The solvents selected include commonly used in solvent-based recycling processes and solvents with promising RED values according to Hansen Solubility Parameters (HSPs) [14]. Two binary variables, $y_{l_1}$ and $y_{l_2}$, are introduced to denote whether the solvent candidates $l_1$ and $l_2$ are selected and are defined such that only one solvent from each list can be chosen:

$$\sum_{l_1 \in \mathcal{L}_1} y_{l_1} = 1; \qquad \sum_{l_2 \in \mathcal{L}_2} y_{l_2} = 1. \quad (17, 18)$$

Assignment constraints are used to set the values of the SAFT-γ Mie group numbers. The number of groups of type $g_i$ in solvent $l_i$ is given by

$$n_{g_i} = \sum\nolimits_{l_i \in \mathcal{L}_i} y_{l_i} n_{g_i,l_i}. \quad (19, 20)$$

The solution strategy is implemented via a Python script that enumerates the solvent combinations and passes them to gPROMS via gO:RUN, where the NLP is solved using NLPSQP.

The problem is formulated using the sum of the scaled TAC (economic metric), $\widehat{\text{TAC}}$, and scaled ReCiPe Endpoint indicator (environmental metric), $\widehat{\text{ReCiPe}}$, as the objective function. The two scaled metrics are given equal weight. Normalization is performed using scalarization-based multiobjective optimization (cf. SI).

**Table 1:** Solvent lists and SAFT-γ Mie groups involved in the two solvent lists.

| List | Solvents | SAFT-γ Mie groups |
|---|---|---|
| $\mathcal{L}_1$ | Benzene, butane, cumene, cyclohexane, cyclohexanone, cymene, decalin, n-decane, dibutoxymethane, dimethylcyclohexane, n-dodecane, diisopropylbenzene, ethyl acetate, ethylbenzene, hexane, isopropylxylene, MEK, mesitylene, methylcyclohexane, n-octane, n-pentane, propane, toluene, n-undecane, xylene. | $G_1 = \{$CH3, CH2, cCH, cCH2, cCO, mO, aCH, aCCH, aCCH3, aCCH2, COO, CH3CO$\}$ |
| $\mathcal{L}_2$ | $\mathcal{L}_1$ + acetone, benzyl alcohol, butyl acetate, CPME, 1-decanol, ethyl isobutyrate, ethylene glycol, 1-octanol and thymol. | $G_2 = G_1 \cup \{$CH3COCH3, aCOH, OH, CH2OH, CH$\}$ |

## TEA and LCA methodology

The TEA analysis is performed using the methodologies established by Towler and Sinnott [15] to compute the TAC, MSP, and IRR. The TAC is calculated as

$$\text{TAC} = \text{OPEX} + \frac{[i(1+i)^n]}{[(1+i)^n - 1]} \times \text{CAPEX}; \quad (21)$$

where $i$ represents the discount rate, set at 20% [16], and $n$ denotes the plant life, assumed to be 20 years [17]. The operating expenditure (OPEX) is divided into variable and fixed categories. Variable costs include steam generated from natural gas, grid electricity, cooling water supplied via cooling towers, solvent makeup, and waste incineration. Fixed costs comprise pre-treatment, salaries, maintenance, benefits, overheads, land rent, tax, and insurance. Further details on the TEA methodology are provided in the SI.

The LCA is conducted on a cradle-to-gate basis, accounting for all impacts associated with production up to the factory gate. The analysis is performed using the openLCA 2.3.1 software with background data from the Ecoinvent v3.6 database [18]. The life cycle inventory (LCI) is generated using the process model developed in gPROMS, supplemented by external sources for specific inputs. Data for the GWP, EI99, and CED of solvent

**Table 2:** Best 5 and worst 5 Solvent Pairs (SP) ranked from lowest to highest objective value (obj=$\widehat{\text{TAC}}$+ $\widehat{\text{ReCiPe}}$.)

| Label | Solvent 1 + Solvent 2 | TAC/M$/y | ReCiPe/- | $T_{F3}$/K | $T_{F13}$/K | $F_{F3,sol}$ /kton/y | $F_{F13,sol}$ /kton/y |
|---|---|---|---|---|---|---|---|

production is obtained from Finechem [19, 20]. The ReCiPe values for solvent production are estimated using the correlation developed by Dieterich et al. [21] between EI99 and ReCiPe endpoint indicators for solvent production. Further details on the LCA methodology are provided in the SI.

## RESULTS AND DISCUSSION

### Optimization results

Through the optimization framework, we systematically evaluate 875 potential solvent combinations, out of which 72 are identified as feasible candidates satisfying all thermodynamic stability and process constraints. Among these, the combination of cymene+cyclohexanone emerges as the best-performing candidate, minimizing the performance objective within the investigated search space. This configuration results in a 13.43% reduction in TAC and 6.84% lower ReCiPe compared to n-dodecane+1-decanol, the lowest-ranked design. Lower OPEX and environmental burdens are achieved due to lower operating temperatures in the dissolution vessels ($T_{F3}$=389.47 K and $T_{F13}$=415.43 K) compared to competing designs.

The top-performing candidates (SP1–SP5) all utilize the aromatic solvents cymene and ethylbenzene for the polyolefin dissolution/precipitation loop, with alkanes, cyclics, and aromatics favored in the POM separation section. Conversely, the poorest performing combinations (SP68–SP72) employ dibutoxymethane and alkanes for the PE/PP process, while relying on alcohols for POM dissolution. These inferior candidates require operating temperatures in DV2 near the polymer's fusion point (see SI), resulting in higher thermal energy demand.

Regarding solvent use, the top 5 SPs use similar amounts of solvent to the bottom 5 SPs when considering both the PE/PP and POM processes. The differences in TAC can be largely attributed to the cost of the filter units, as shown in Figure 2, which is highly dependent on solvent choice. Filter cost is influenced not only by the solvent flow rate but also by its viscosity [22]. Further details on the filter costing methodology and viscosity calculations are provided in the SI.

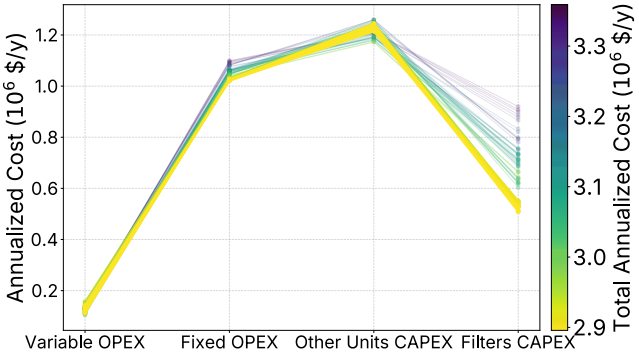

**Figure 2.** Parallel-coordinates plot illustrating the differences in variable and fixed OPEX, other unit, and filter CAPEX. Each line corresponds to one of the 72 SPs, colour-coded by TAC.

To evaluate the trade-offs between conflicting design criteria, we show a parallel coordinates plot (Figure 3). The analysis reveals strong consistency across the environmental metrics; solvents that perform well in GWP also tend to rank highly in CED, EI99, and ReCiPe, with only slight overlap in ranking lines observed between EI99 and ReCiPe for the poorest performers. This suggests that minimizing a single environmental indicator is generally a reliable proxy for overall sustainability in this process.

However, we observe a notable discrepancy between the economic metric (TAC) and these environmental indicators. As the plant is small-scale, we calculate that CAPEX accounts for approximately 60% of the TAC for most solvents (see SI). Consequently, if the economic metric is chosen as the sole objective, designs involving

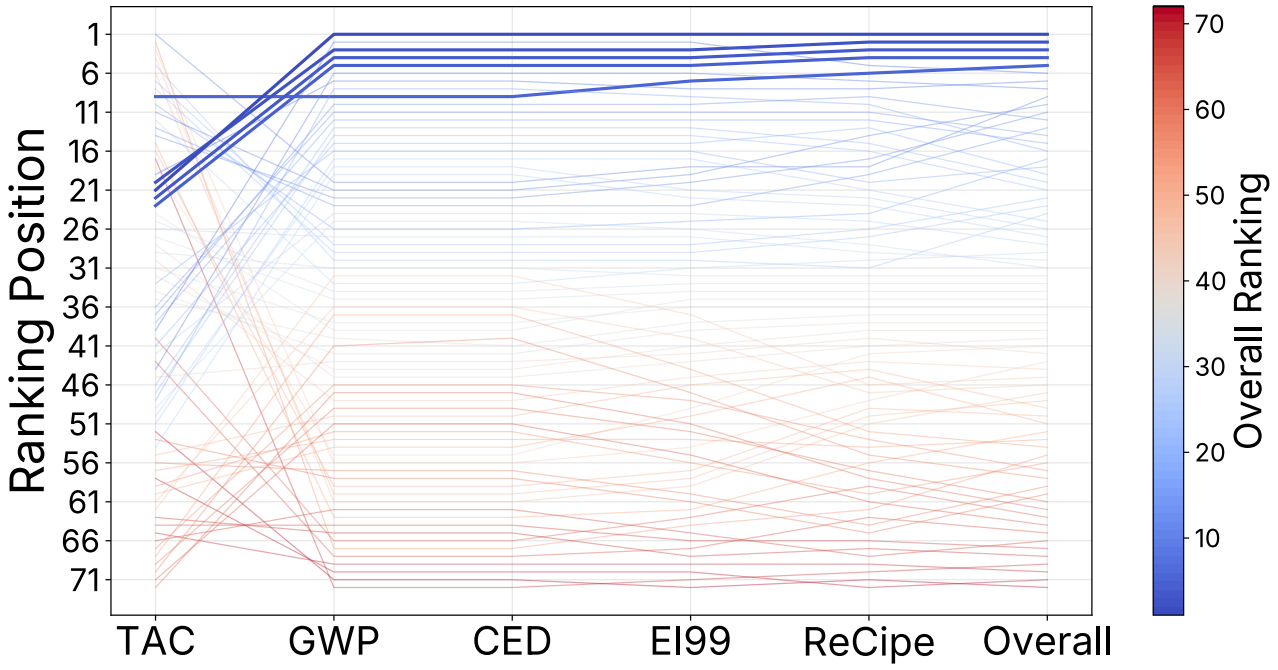

**Figure 3.** Parallel-coordinates plot displaying the ranking consistency of the 72 feasible solvent candidates across economic (TAC) and environmental (GWP, CED, EI99, ReCiPe) performance metrics. The vertical axes represent the ranking position (1 = best, 72 = worst). Blue lines indicate top-tier candidates, and red lines indicate lower-ranked candidates based on the objective function.

lower solvent inventories are favored to minimize vessel sizes, even if those solvents possess high specific heat capacities and are thus associated with significant energy demand. In contrast, we find that environmental performance is predominantly dependent on utility use (steam and electricity). Therefore, environmental metrics favor solvents that operate at lower temperatures, possess lower heat capacities and enthalpies of vaporization, regardless of the equipment size required. These trade-offs highlight the importance of considering both economic and environmental performance metrics to identify optimal designs.

## TEA and LCA results

In Figure 4, we present the unified techno-economic and environmental assessment (MSP vs. GWP) for all 72 feasible designs. The results demonstrate that the proposed solvent-based recycling process is highly competitive against virgin polymer production. Specifically, we observe that all evaluated designs yield an MSP below the current European market price for virgin polymers. The highest MSP calculated is $1.34/kg, which remains comfortably below the market floor of $1.50/kg for virgin polypropylene [23].

The environmental analysis confirms that all 72 designs achieve a GWP lower than the $CO_2$ emissions associated with virgin PP and LDPE production [24] (comparative data for virgin POM was unavailable). We identify a cluster of optimal designs near the lower-left boundary of the plot, representing the set of non-dominated solutions that offer both minimal cost and minimal environmental impact. As expected, higher IRRs are observed for designs with lower MSPs. Crucially, we find that all designs exceed the standard hurdle rate of 20% required to cover the cost of capital, and the majority surpass the 18-23% threshold typically required to justify investment in novel chemical technologies [25], indicating strong potential for commercial viability. Although only one weight vector was used in the objective function, the figure shows that markedly different performance can be achieved and points to the value of multi-objective optimization to explore the space of solutions further.

We evaluate the robustness of the process by varying the solvent loss rate from the baseline value of 0.002% [26] up to 5%. In Figure 5 the impact of these losses on the breakdown of GWP contributors is shown. In this analysis, the contributions from solvent production and waste disposal are scaled to reflect the increased makeup requirements and incineration of waste solvent, while holding other contributions fixed. As can be seen, at a 5% loss rate, the solvent and disposal contributions become approximately equal; however, they remain lower than the contributions from power, heating and pre-processing. Overall, even at this worst-case loss rate

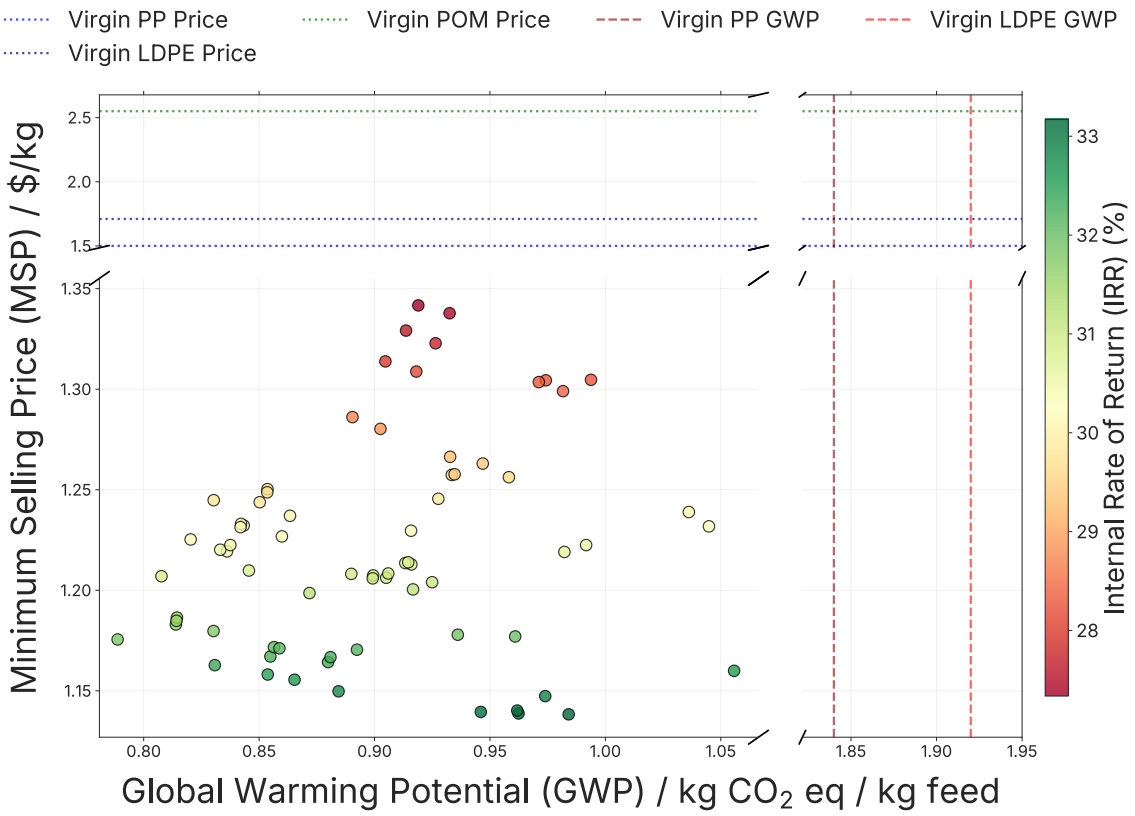

**Figure 4.** Scatter plot of MSP versus GWP for the 72 feasible solvent combinations. The color scale indicates the IRR.

(5%), the total system GWP remains below the carbon intensity of virgin PE and PP production.

In Figure 6, we evaluate the economic sensitivity of the process to solvent loss rates ranging from 0.002% to 5%. Variations in this parameter directly influence variable OPEX, increasing solvent makeup requirements and associated incineration costs. The data indicates that at 5% solvent loss, the MSP for the majority of design configurations exceeds the market price of virgin PP ($1.50/kg). Notably, however, solvent pair SP2 (ethylbenzene + cyclohexanone) exhibits significant economic resilience, achieving an MSP of $1.49/kg, thereby marginally retaining profitability relative to virgin PP even under maximum loss conditions.

Moreover, all evaluated designs remain substantially more cost-effective than virgin POM ($2.55/kg), while a significant proportion maintain competitiveness against virgin LDPE ($1.71/kg). Given that the weighted average market value of the polymers is approximately $1.70/kg, we confirm that several designs preserve economic viability across the full spectrum of operational efficiencies. When coupled with anticipated fiscal incentives for plastic recycling, these findings suggest the process is poised to retain robust competitiveness under diverse operational scenarios.

## CONCLUSIONS

In this work, we have developed and applied an integrated CAMPD-TEA-LCA framework to design a solvent-based recycling plant for a three-component automotive plastic waste (PP/PE/POM). We have evaluated 875 solvent combinations and identified 72 feasible candidates that satisfy process and thermodynamic constraints, capable of separating chemically similar polyolefins from engineering plastics.

Our analysis highlights a notable tension between economic and environmental design drivers. We have found that while economic performance (TAC) is dominated by CAPEX (approx. 60%) and favors solvents that minimize equipment volume and solvent viscosity, environmental metrics are driven by utility consumption and favor solvents with lower heat capacities and enthalpies of vaporization. We have identified cymene + cyclohexanone as the best-performing solvent pair, effectively balancing these trade-offs by leveraging lower operating temperatures, solvent circulation rates, and transport properties to minimize both thermal energy demand and

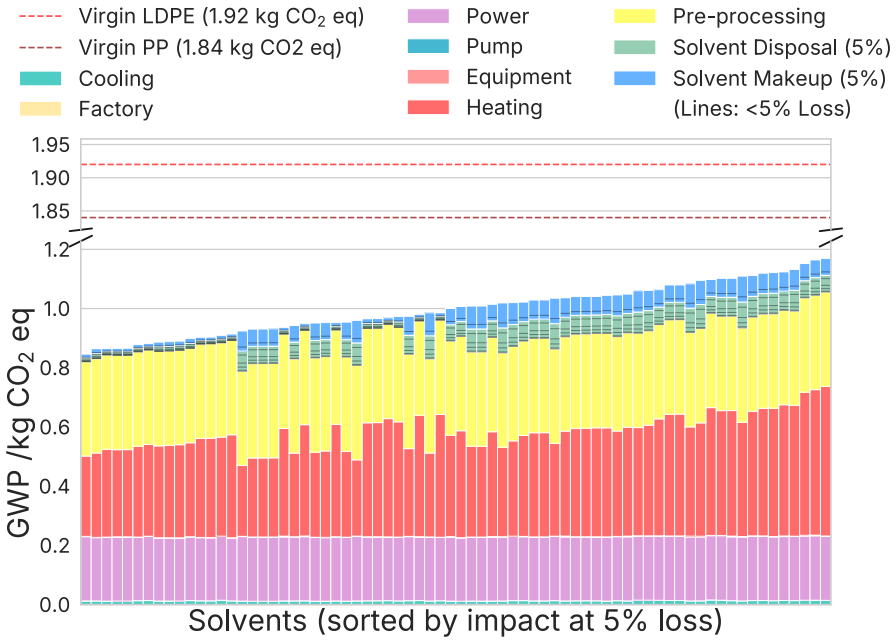

**Figure 5.** Sensitivity analysis of GWP to solvent loss rates ranging from 0.002% to 5%. The stacked bars illustrate the changing contributions of utilities, solvent makeup, and disposal, while the black lines indicate the total GWP values.

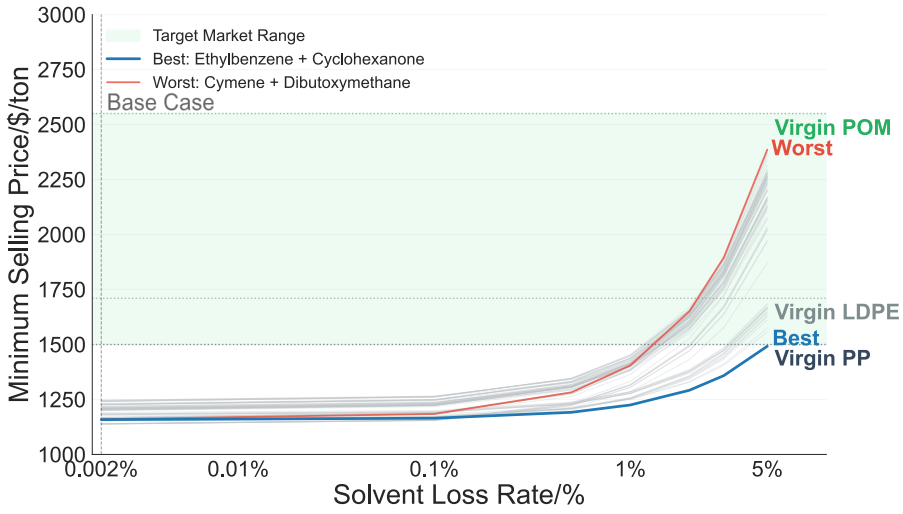

**Figure 6.** Sensitivity analysis of MSP to solvent loss rates. The calculated MSPs are compared against market price benchmarks for virgin PP, LDPE, and POM to assess economic competitiveness under varying operating conditions.

equipment size.

Techno-economic analysis has indicated that the process is financially attractive, with IRRs consistently exceeding the 20% hurdle rate for novel technologies. Furthermore, the environmental benefits are substantial, with carbon footprints remaining below those of virgin production even under worst-case scenarios of solvent loss (5%). We conclude that solvent-based recycling represents a robust, scalable solution for closing the loop on automotive plastics, providing a necessary technological enabler for the industry to meet the 20% recycled content mandate for new vehicles.

In future work, we plan to formulate a CAMPD problem to construct optimal solvent structures from functional groups via mixed-integer nonlinear programming, allowing for a significantly broader search space to be explored. Furthermore, we will incorporate heat integration to minimize energy demands and conduct

experiments to validate the simulated unit operations and conduct multi-objective optimization.

## ABSTRACT

The biopharmaceutical sector has traditionally focused on cost-efficient process design and capacity planning to meet rising demand. Recently, sustainability pressures have increased, driving efforts to reduce the environmental footprint of manufacturing and supply chains; however, strict quality and sterilization requirements can limit the implementation of fully circular resource-use strategies. In this space, adopting an industrial-cluster systems view could unlock opportunities to improve sustainability of industrial clusters through coordinated material and energy exchange, supporting resource efficiency at cluster level and still meet sector-specific quality/sterilization requirements. In this work, we present life cycle assessment (LCA)-based comparative analyses to investigate the potential of industrial symbiosis within monoclonal antibody (mAb) manufacturing, whereby LCA process models are based on comprehensive techno-economic analyses that quantify resource inputs and waste streams. The presented results discuss impact reduction pathways including integrating renewable wind-based electricity, low-grade waste heat use, heat recovery through incineration and mechanical recycling of single-use plastics. The compound reductions of industrial symbiosis and energy source decarbonization are estimated, corresponding to 75% reductions in GWP potential, 70% in fossil resource scarcity and 60% in water use, thus highlighting the benefit of adopting a large-scale system view rather than siloed approaches.

**Keywords**: Life Cycle Analysis, Modelling, SimaPro, Environment, Industrial Symbiosis

## INTRODUCTION

With sustainability becoming a growing priority in the pharmaceutical sector, manufacturers are pressured to quantify and mitigate footprints where possible, whilst continuing to meet product demands at global scale. Pharmaceutical manufacturing is typically water- and energy-intensive and generate significant wastewater flows, particularly in the case of multi-use (MU) stainless steel technologies. Aiming for improved flexibility, scalability and shorter set-up timelines, the sector is moving towards single-use (SU) based technologies, which in turn result in less water-related impacts, but significant increase of solid waste from the use and disposal of consumables such as plastics bioreactor, storage, mixing bags, tubes and filters.

Life cycle assessment (LCA) is an established systematic tool for comparative assessments and standardization of footprint quantification and related uncertainty, to identify more sustainable process designs. LCA[1, 2] studies comparing the MU vs SU alternatives have highlighted that footprints are largely process/product-dependent, thus requiring a case-by-case analysis to support decision-making.

LCA effectively helps pinpoint the critical resources consumed and waste flows that impact the environment through the quantification of direct and indirect emissions. Additionally, it offers the capability of assessing through what-if analyses the impact of sourcing and waste treatment decisions, given its large database of options across geographical regions, production and treatment processes. From an industrial symbiosis point of view, this translates into a systematic way to compare resource exchange pathways across industrial sectors and facilities and compute overall footprints of the integrated system.

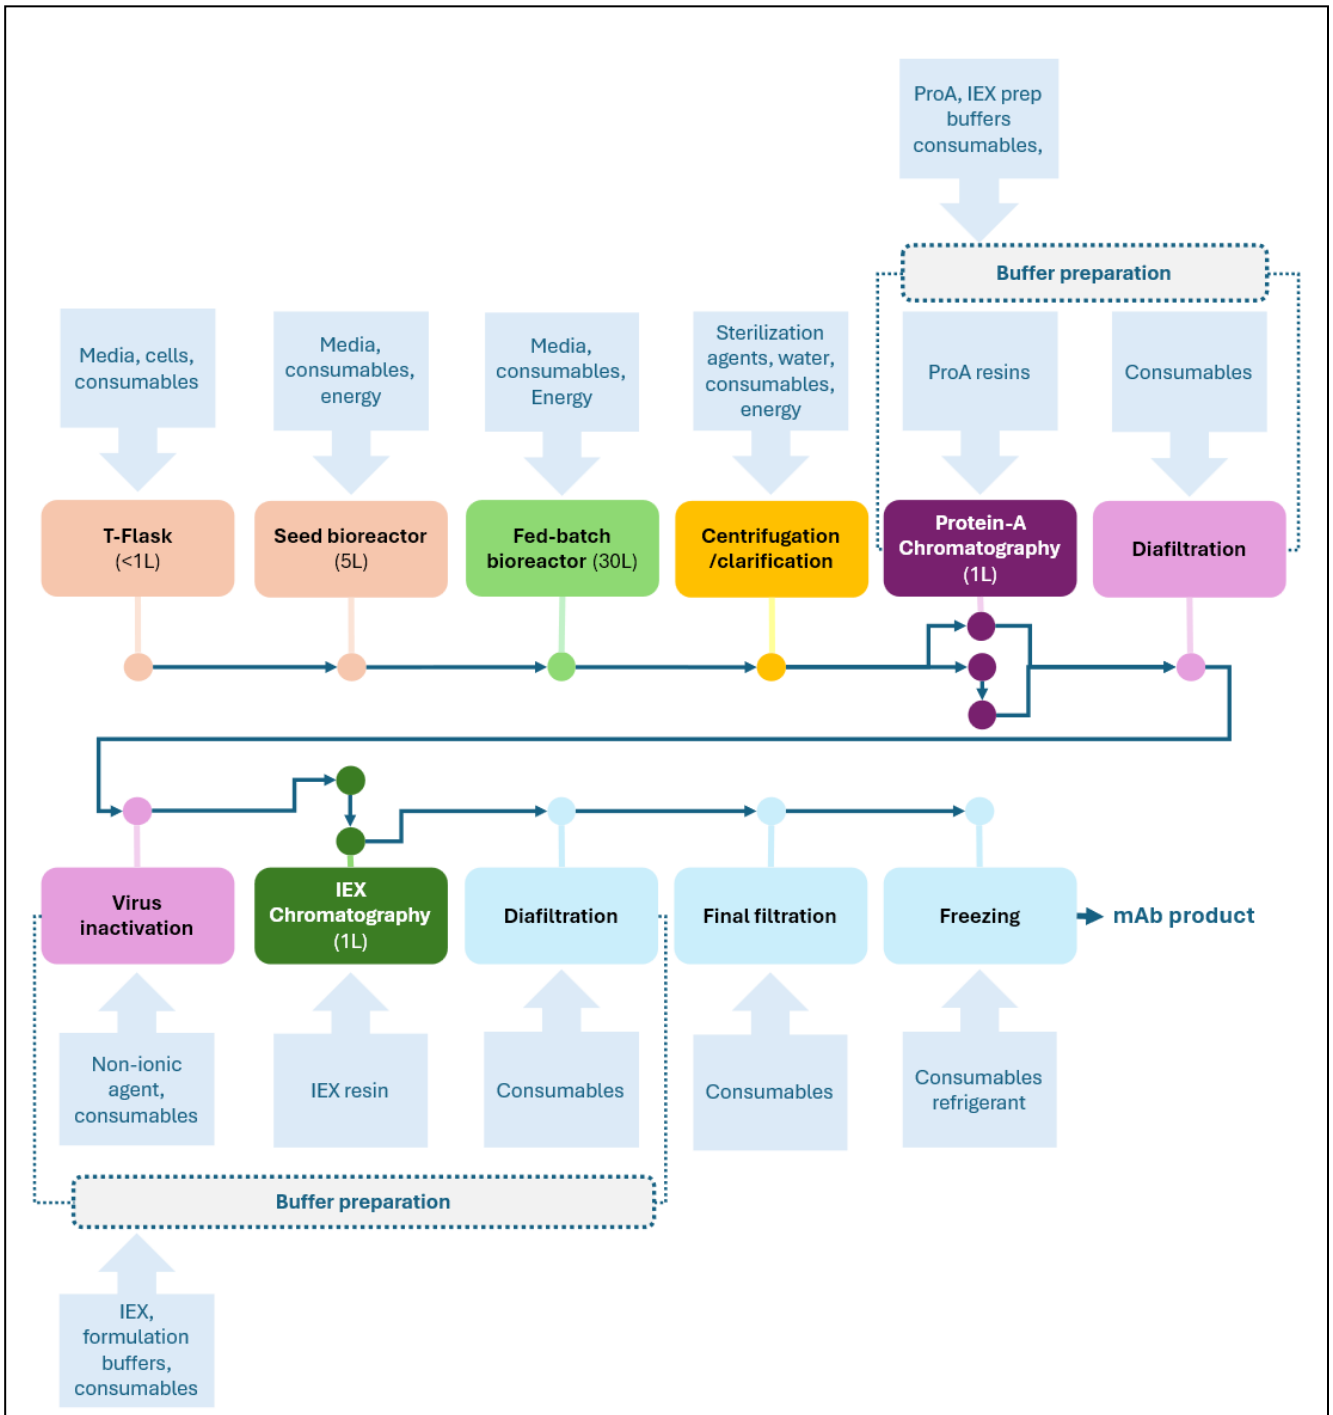

**Figure 1:** mAB process flowsheet illustrating equipment volumes, unit sequence and resource inputs.

Hence, in this work footprint reduction sourcing and treatment strategies are investigated, including (i) low-grade heat use in manufacturing, (ii) plastics waste incineration, (iii) incineration with energy recovery, (iv) mechanical recycling, with the aim of gaining an understanding promising pathways towards reducing impacts in biopharmaceutical manufacturing processes, specifically monoclonal antibody (mAb) production.

Effectively, the pathway-specific data presented in this work can serve as inputs within optimization-based tools to be developed for the support systematic decision-making with respect to optimal resource exchange across sectors and cost-footprint trade-off analyses in industrial planning problems.

## METHODS

The framework presented in this work represents an

extension of previously published work[3], where candidate mAb process designs are generated through superstructure-based optimization and assessed via techno-economic and LCA. Here, we present further footprint analyses considering alternative sourcing and waste treatment options within the LCA analysis tool.

## Process flowsheet

We consider the purity-constrained process design for mAb production[3]. Techno-economic modelling in SuperPro Designer (Intelligen), enabled the simulation of the 30-L scale platform. Figure 1 illustrates the process steps within the process sections including (i) inoculum preparation, (ii) cell culture, (iii) primary recovery, (iv) Protein A chromatography, (v) viral inactivation, (vi) IEX chromatography, (vii) filling, (viii) buffer prep and hold, which supplies buffer-based purification/separation steps. Additionally, sequential and parallel equipment units in parallel are highlighted. For reference, detailed process description and the resulting input/output materials for the LCA process models are provided in Sarkis et al. (2025)[3].

## Life cycle analysis models

Environmental performance of the mAb process is assessed using LCA, in accordance with the ISO 14040/14044 standards[4].

### Goal and scope

The aim of the LCA is to determine the environmental footprint of producing mAb, hence the functional unit corresponds to 1 gram of mAb produced by a 30L pilot scale process. A cradle-to-gate LCA is performed, thus including raw material production and activities up until the mAb product is sold. As a result, the disposal of single-use plastic equipment is considered as this is part of the activities within the production process. It is worth noting that plastics consumption is estimated based on the material composition of the single-use bags, thus not considering packaging.

### Life cycle inventories

Materials and energy flows for the mAb production are obtained from the techno-economic models and form the foreground life cycle inventory (LCI) data, which is presented in Appendix C of Sarkis et al. (2025) [3]. and linked to the background LCI data, within EcoInvent v3.10, through Simapro[5]. The limited data availability for some resources used in the biopharmaceutical production process required a set of assumptions, including the selection of proxies for certain chemical components, including ethylene vinyl alcohol (EVOH), sodium hydrophospate and sodium dihydrophosphate. Additionally, stoichiometric modelling is integrated for TRIS-based solvents. Critically, plastics-based resources are integrated in the LCA model using mass compositions of each consumable, which therefore results in the LCA model not accounting for the production process of the consumables and the related indirect environmental impacts.

End-of-life alternatives for the plastic waste comprise landfill, incineration, and mechanical recycling. Landfill and incineration are available in Ecoinvent for polypropylene and for mixed plastic waste, while two new processes have been created for the mechanical recycling of Polyethylene and Nylon-6, considering the LCIs reported in Ruggeri et al.[6] and Tonsi et al.[7] respectively.

### Life-cycle impact assessment

To illustrate the methodology in this work we focus on three midpoint indicators: global warming potential (GWP), fossil fuel scarcity, and water use. GWP and fossil fuel scarcity are estimated using the ReCiPe2016[8] life-cycle impact assessment (LCIA) methodology, while the impact of water use is characterised in terms of water scarcity using the latest consensus-based LCIA methodology AWARE[9].

### Uncertainty quantification

Uncertainty in the LCA results related to the background LCI data is quantified through Monte Carlo sampling. Specifically, uncertainty of LCI within Ecoinvent is defined based on a pedigree matrix, which gives a score between 1 and 5, with 1 representing the highest quality, to five criteria: completeness, reliability, temporal correlation, geographic correlation, and technological correlation. These scores are translated into log-normal distributions of the LCIs.

In this work, the uncertainty analysis was performed using the tool included into Simapro, which uses Monte Carlo method to sample considering 1000 runs for each scenario. The uncertainty was characterised for GWP and fossil resource scarcity, while it has not been quantified for the water use as it is artificially inflated by the sampling method. Specifically, in background processes such as hydropower, where large amount of water enters and exit the system in equal amount the net water consumption is zero. However, these flows are sampled independently and may lead to large imbalances that are not physically meaningful.

## Scenario analysis

In this work, the LCA models comparing different sourcing and waste treatment strategies are developed to investigate the potential for industrial symbiosis for biopharmaceutical manufacturing. Figure 2 provides a representation of the scenarios considered, which are described below:

a. **Business as usual (BAU):** plastics are purchased from their respective markets, heat requirement is met with industrial steam production, electricity is provided by the UK national grid, waste plastics are incinerated.

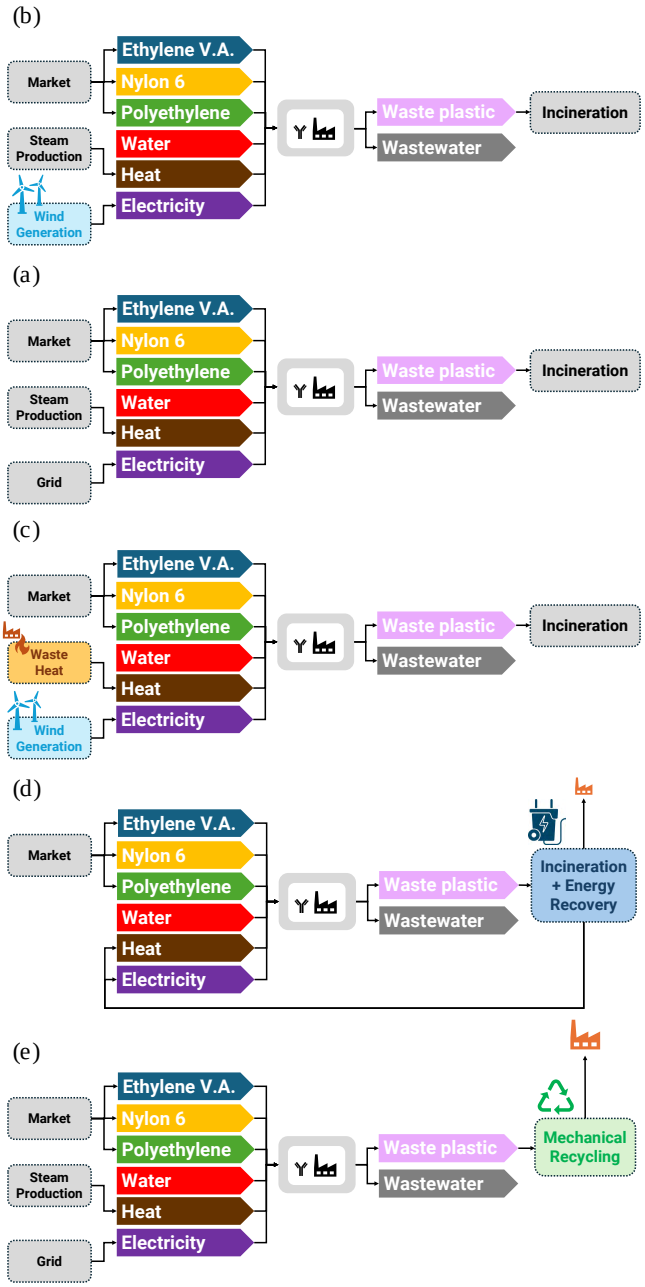

**Figure 2.** Footprint mitigation and symbiotic routes considered: (a) business as usual, (b) Scenario 1, (c) Scenario 2, (d) Scenario 3, (e) Scenario 4.

b. **Scenario 1**: electricity is generated through renewables, in this case an onshore wind energy
c. **Scenario 2**: electricity is provided by onshore wind energy and heat is derived from low-grade waste heat sources.
d. **Scenario 3:** waste plastics are incinerated in an energy from waste (EfW) plant, producing heat and electricity, either sold to other plants or reused within the mAb manufacturing process.
e. **Scenario 4:** mechanical recycling of Ethylene and Nylon, producing lower grade plastics that can purchased by other industries.

## RESULTS AND DISCUSSION

Figure 3 shows the environmental impacts associated with producing 1 g of mAb in a 30 L pilot-scale process. Global warming potential (GWP), fossil resource scarcity, and water use are presented in Figures 3a, 3b, and 3c, respectively. Stacked bar charts highlight the main environmental hotspots, while net impacts are indicated by white squares. Uncertainty bars for GWP and fossil resource scarcity represent the 5% and 95% percentiles obtained from Monte Carlo simulations. In the business-as-usual case (Figure 3a) the environmental hotspots for GWP correspond to plastics use (~50%), comprising EVA, Nylon and Polyethylene, the use of electricity and heat (~25%) and the end-of-life incineration of the plastics (~20%). Thus, switching to wind-based energy as captured in Scenario 1 only provides reductions up to (~10%) of the overall GWP footprint, whilst plastics-related impacts remain significant. This is even more evident with respect to fossil fuel scarcity, where in the BAU case plastics-disposal is not a contributor to resource scarcity itself, whilst plastics use is even more critical (66%). Here, switching to wind-based energy reduces the impact by 11% (Figure 3b).

To fully decarbonize the energy requirements of the plant, Scenario 2 also introduces the switch to waste-heat sources from other industries within the industrial cluster, thus effectively corresponding to a symbiotic exchange. In this scenario, the impact from heat generation is removed, resulting in GWP reductions of ~22% (Figure 3a) and fossil resource scarcity of 23% (Figure 3b). Whilst energy requirements are tackled through the wind-energy and low-grade heat exchange proposed in Scenario 2, waste plastics account for the remainder of GWP and the fossil fuel scarcity impacts.

Hence, in Scenario 3 the option of recovering energy from the incineration process of plastics is investigated. This corresponds to the case where the energy recovered could be used (i) internally to feed into the heating and electricity requirements of the process or (ii) sold to industrial partners as part of the symbiotic system. As can be seen in Figure 3a, the resulting reduction is displayed in terms of credits gained (EfW – Heat, EfW – Electricity) and corresponds to nearly 15% of the overall GWP. It is worth mentioning that these credits are calculated based on current state of the UK grid. If grids become greener, the share of renewables increase, the credits would decrease. Hence, this translates in a long-term uncertainty in the benefits of Scenario 3, as these credits are highly dependent on the carbon intensity of the grid and will likely decrease with time. The case for fossil fuel scarcity is similar (Figure 3b), with overall impact reduction (15%) achieved through credits gained for

avoided energy production, quantified through EfW – Heat and Electricity.

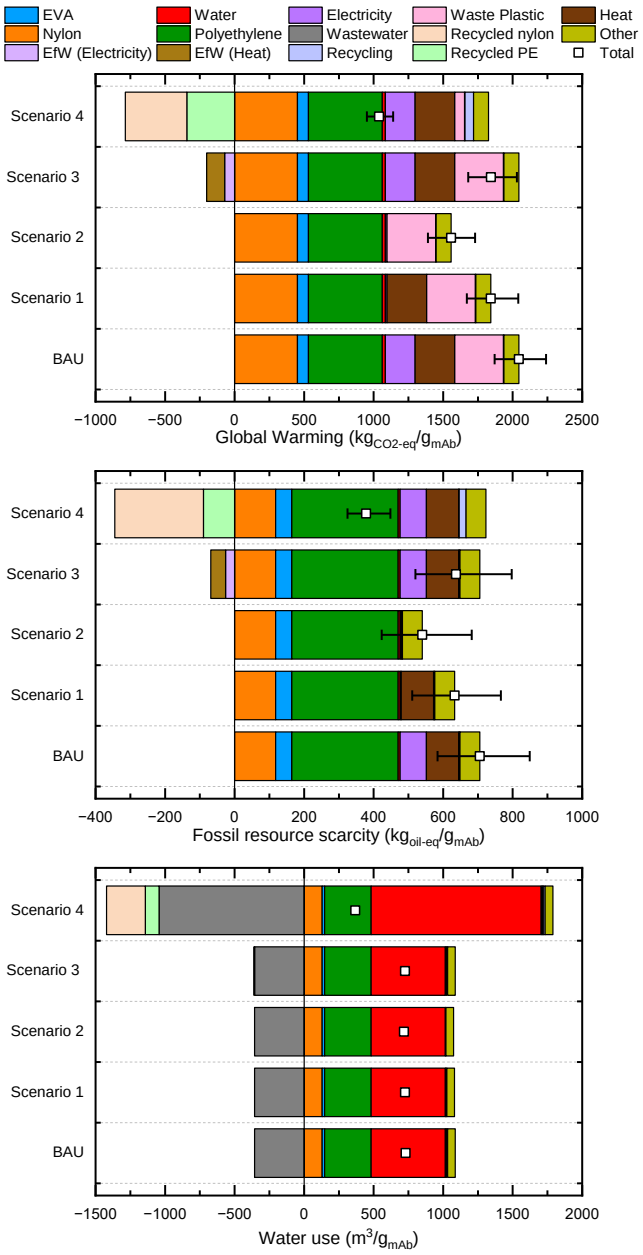

**Figure 3.** (a) Global warming potential, (b) Fossil fuel scarcity, (c) water depletion for the production of 1 $g_{mAb}$. Error bars represent the 5% and 95% percentile.

Finally, Scenario 4 considers mechanical recycling of the consumables used. The process includes shredding, water separation, washing, extrusion, and pellet production, and results in downcycled plastic material that does not meet the quality standards required for biopharmaceutical manufacturing. Therefore, the recovered plastic is assumed to be sold to other industries, generating credits for avoided virgin plastic production within the symbiotic system.

Impacts associated with mechanical recycling—mainly driven by electricity, heat, and water requirements—are shown in lavender in Figure 3. As shown in Figure 3a and 3b, the additional contributions to overall GWP and fossil resource scarcity are small compared to the electricity and heat impacts of the mAb production process. In contrast, credits from avoided plastic production are substantial, leading to ~52% reductions in overall GWP and ~47% reductions in overall fossil resource scarcity.

In terms of water use, mechanical recycling requires a large amount of water, nearly doubling direct water demand. However, after wastewater treatment, most of this water is released back to the environment. In the base case, indirect water demand associated with plastic production accounts for ~40% of total water demand. As a result, credits from avoided plastic production led to an overall ~50% reduction in net water use within the symbiotic system.

The results suggest that mechanical recycling is more promising than energy from waste in a symbiotic system. Additionally, combining mechanical recycling with wind electricity and waste heat utilization, could result in ~75% reduction in GWP and fossil fuel scarcity, and ~60% reduction in water use compared to the base case. However, it is important to note that the feasibility and efficiency of mechanical recycling depend on if and how well plastic consumables can be separated into monomaterial streams. In this work we are considering a 20 and 30% material loss for Polyethylene and Nylon[6, 7], but future work should aim at quantifying consumables-specific efficiency.

Chemical recycling techniques, such as pyrolysis, gasification, plasma-based decomposition could produce virgin-like materials, thus reducing the reliance of the biopharmaceutical industry on fossil-based products, and process unsorted mixed plastic waste that could not be mechanically recycled[10]. Although promising, low TRL level and high dependency on feedstock composition require consumable-specific modelling to develop even a preliminary LCA model of chemical recycling alternative processes and will be addressed in future research effort (Figure 4).

Overall, for the scenarios considered, this work demonstrates the benefits of adopting proactive strategies for footprint mitigation, primarily through industrial symbiosis to improve integrated system sustainability rather than adopting a siloed approach.

This motivates future research avenues in studying feasible resource exchanges through optimization-based system-system integration, with challenges emerging from potentially asynchronous operational cycles, resource transport and storage constraints.

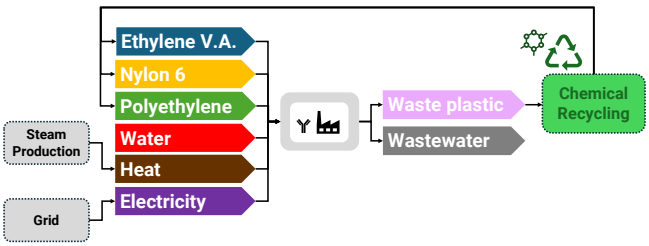

**Figure 4.** Footprint mitigation route through chemical recycling.

## CONCLUSION

Industrial symbiosis offers opportunities to improve sustainability of industrial clusters through collective efforts and resource exchange. Through the systematic analysis presented in this study, its potential within biopharmaceutical industry has been explored, with a focus on a case study from mAb manufacturing relying on single-use and multi-use equipment. These result in emissions from both plastics consumption and disposal and energy and water use. To mitigate these, life cycle assessment models are presented to quantify footprint breakdown and uncertainty in footprint estimation and compare alternative supplier and waste treatment options representing industrial symbiosis solutions. The findings demonstrate how amongst the scenario considered, mechanical recycling is a promising option as it directly tackles the impact from waste plastics disposal, through instead the recovery of lower-grade plastics flows thus resulting in avoided emissions from low-grade plastics production elsewhere. Results further demonstrate that a combination of plastics recycling, low-grade heat supply and renewable electricity greatly reduces overall impacts, suggesting that adopting industrial cluster-wide system approach could greatly reduce footprints through smart resource exchanges.

## ABSTRACT

While the transition from traditional energy sources to renewable energy is necessary to reduce greenhouse gas (GHG) emissions, it introduces new challenges related to material use, both in quantity and type, potentially leading to resource scarcity, biodiversity loss, and waste accumulation. Therefore, incorporating circular economy (CE) principles into the design and planning of energy systems becomes essential. Despite the growing recognition of circularity, current assessments in energy systems focus on economic performance and GHG emissions. In this work, we propose a metric for quantifying circularity of energy systems based on the CE assessment framework MICRON, addressing the gap between CE metrics and energy systems planning. The framework is adapted to energy systems by accounting for the specific characteristics of energy technologies and by incorporating metrics associated with critical material use, scarcity, and durability. Its applicability is demonstrated through a case study of energy system planning at the University of Wisconsin-Madison, considering a grid-connected system with solar, wind, and lithium-ion battery technologies. Results show that wind-only portfolios achieve higher overall circularity scores than solar-only and hybrid systems, reflecting the higher efficiency and availability of wind energy. Hybrid systems exhibit higher durability and more efficient material use by avoiding system oversizing. Regarding decarbonization strategies, reducing grid reliance and associated emissions does not necessarily improve circularity, as energy storage is required to ensure reliability. Storage systems increase material demand, the share of critical materials, and replacement frequency. Finally, a sensitivity analysis was performed, highlighting that end-of-life recovery is a key factor influencing circularity.

**Keywords**: Renewable and Sustainable Energy, Energy Systems, Circular Economy, Energy Planning

## INTRODUCTION

The increasing energy demand, along with the environmental impacts of traditional energy sources, highlight the need for an energy transition. While moving from fossil fuels to renewable energy is essential to reduce greenhouse gas (GHG) emissions, focusing solely on emissions can be insufficient and overlook other environmental sustainability aspects. A sustainable energy transition must simultaneously consider, amongst others, resource efficiency, material use, land footprint, waste generation, energy security, and socioeconomic impacts, in addition to GHG emissions [1]. However, current energy transition policies and decarbonization strategies mostly focus on the closure of fossil fuel power plants and the deployment of new infrastructure, often without accounting for material demand, the increased reliance on critical materials, and the associated waste generation [2].

Clean energy technologies, including solar photovoltaics (PV), wind turbines, and power storage systems, require significant mineral resources and introduce new challenges related to resource scarcity, biodiversity loss, land use changes, and waste generation at the end of their lifetime, a concern that is amplified by their relatively short lifetimes compared to fossil fuel plants [3, 4]. For instance, a 100 MW wind power plant requires nearly 67, 850 tons of materials, including composites and polymers that are difficult to recycle [5]. Similarly, the projected 1.75 TW of installed PV capacity in the United States by

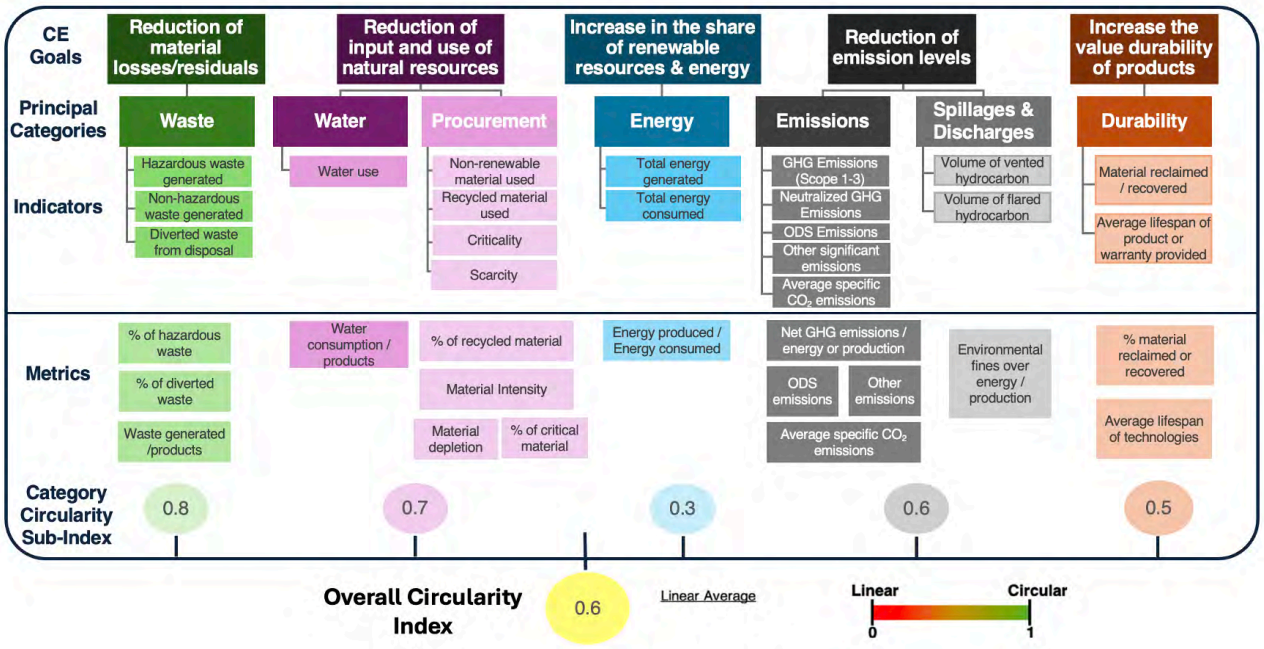

**Figure 1.** Schematic of MICRON CE assestment framework for energy systems, with arbitrary values on category-based circularity sub-indices.

2050 will demand nearly 97 million tons of virgin materials and generate over 8 million tons of lifecycle waste [6]. Therefore, integrating circular economy (CE) principles into the design and planning of energy systems becomes essential to reduce material demand and carbon intensity, and address end-of-life (EoL) management challenges. Without a circular approach, the energy transition risks replacing carbon emissions challenges with new environmental burdens, such as material scarcity and waste accumulation [7].

## Circular Economy Metrics for Energy Systems

Progress toward CE can be measured using indicators defined at different scales, including product (micro), system (meso), and economy-wide (macro) levels. The Material Circularity Indicator (MCI) [8] evaluates material inputs and outputs at the product level, while the circularity index [9] accounts for recovered EoL material and its energy requirements at a system level. The global circularity metric [10] is an economy-wide indicator that measures the percentage of materials reused or cycled back into the global economy relative to the total material inputs. The Circular Economic Value (CEV) [11] is a system-level indicator addressing the reduction of virgin materials and waste generation. Material Flow Analysis (MFA) [12] provides a flow-based system-level framework to track material stocks and flows across processes and sectors, and recycling rates [13] are process- or material-specific metrics commonly used to evaluate EoL management performance.

When applied to energy systems, these CE metrics exhibit several limitations. Most indicators focus on mass flows and do not capture broader system interactions or the dynamic characteristics of energy infrastructures. Energy systems are often treated as inputs or waste streams rather than as systems requiring dedicated circularity metrics. Common energy-related indicators include energy productivity and energy consumption [14]. Moreover, despite increasing recognition of the need for circularity, current energy systems assessments focus on economic performance and GHG emissions reduction. For renewable energy technologies, operational emissions are negligible, and the sustainability concerns arise from the upstream and downstream stages, i.e., material extraction, and EoL management [15].

In response to these shortcomings, recent studies have introduced CE metrics tailored to specific energy sectors. Serrano-Arevalo et al. [16] integrated three CE indicators into an energy planning optimization problem. The metrics proposed were relative material impact, absolute material impact, and energy self-sufficiency [14], accounting for the material requirements and analyzing the producer-consumer relationship. The results showed that incorporating CE indicators led to significant changes in optimal system configurations, yielding additional reductions of 12% in $CO_2$-eq emissions compared to approaches based solely on emissions minimization. These findings demonstrate that circularity-oriented metrics can guide the selection of technology

combinations that reduce non-renewable resource use and environmental burdens. Similarly, Xin et al. [15] introduced a framework to evaluate the circularity of EV battery systems, including 15 indicators across three categories: material flow, end-of-life, and energy. The findings show that the material outflow significantly influences the circularity score, highlighting the need to improve collection and recycling rates of equipment at end-of-life.

Despite these advances, to our knowledge, no integrative assessment exists to holistically evaluate circularity performance across energy infrastructures. A circularity metric for energy systems should evaluate CE goals across all circularity dimensions, accounting for material scarcity and criticality, as well as EoL management, including downstream effects [16]. To address this gap, this study proposes an integrated metric to assess and quantify CE in energy systems based on the MICRON CE framework [17], accounting for the specific characteristics of energy technologies.

# METHODS

## The MICRON CE framework

The MICRON (MIcro CircuIaR ecOnomy iNdex) framework, developed by Baratsas et.al. [17], is a quantitative CE assessment tool based on the Global Reporting Initiative (GRI) standards at a micro-level. The framework defines circularity scores from 0 to 1, where 0 represents a fully linear system and 1 a perfect circular system. MICRON was designed around five CE goals: i) reduction of material losses, ii) reduction of input and use of natural resources, iii) increase in the share of renewable resources, iv) reduction of emissions and pollutants, and v) increase the durability of products. Based on these goals, seven principal categories (waste, water, procurement, energy, emissions, spillages, and durability) are defined, each associated with assessment indicators and quantitative metrics. These metrics are used to derive the Category-based Circularity Index. The linear average of the category-based indices constitutes the Overall Circularity Index. MICRON was originally developed for the automotive, energy and utilities, manufacturing and service sector, and has also been applied to the recycling of food packaging and transportation fuel systems [18-19].

## Adapting MICRON for energy systems

In this work, we have adapted the MICRON framework for its application to energy systems, accounting for the specific characteristics of energy technologies. Figure 1 shows the schematic of the MICRON framework for energy systems, indicating the principal categories and their associated metrics. The main contributions of this work are: i) the addition of three indicators under the procurement principal category to capture material-related challenges of renewable energy, ii) the adaptation of the durability metric to account for systems that have technologies with different lifetimes and replacement frequencies, and iii) the demonstration of the framework's applicability through a case study of energy system planning at the University of Wisconsin-Madison. The complete set of metrics considered is included in Table 1.

**Table 1:** CE metrics for energy systems.

| Principal Category | Metric |
|---|---|
| Waste | **1a**. Waste Generated [ton]/Energy Produced [MWh]<br>**1b.** % Hazardous Waste over Total Waste Generated<br>**1c.** % Diverted Waste over Total Waste Generated |
| Water | **2a.** Water use [L]/Energy Produced [MWh] |
| Procurement | **3a.** % Recycled Material Used<br>**3b.** Material intensity [ton/MWh]<br>**3c.** % Critical Material Used<br>**3d.** Abiotic Depletion Potential [Sb-eq] |
| Energy | **4a.** % Renewable Energy over Total Energy Produced<br>**4b.** Energy Return of Investment (EROI) [-] |
| GHG Emissions | **5a.** Net Total Emissions [kg CO2-eq]/Energy Produced [MWh]<br>**5b.** Ozone Depleting Substances (ODS) [metric tons CFC-11]/Energy Produced [MWh]<br>**5c.** NOX, SOX Emissions [ton Nox+SOx]/Energy Produced [MWh] |
| Durability | **6a**. % Material to be Reclaimed/Recover<br>**6b.** Average Lifetime of the System [years]<br>**6c.** Average Remaining Lifetime [years] |

## Material-related procurement metrics

The deployment of new infrastructure implies an intense use of resources, both in terms of quantity and type. We have included material intensity, criticality, and scarcity as metrics in the procurement category to account for this characteristic.

1) Material intensity: It is defined as the amount of material required by the system relative to the energy produced.

$$SMI = \frac{M_{syst}^{tot}}{E_{syst}^{tot}} \quad (1)$$

**Figure 2.** Schematic of the CE assestment for energy systems using MICRON.

Where $M_{syst}^{tot}$ is the mass of material required by the system and $E_{syst}^{tot}$ is the energy produced by the installed technologies.

2) Criticality: Captures the percentage of critical material used relative to the system's total material requirements.

$$CR = \frac{M_{syst}^{crit}}{M_{syst}^{tot}} = \frac{\sum_{y\in Y}\sum_{t\in T}\sum_{i\in I_t} Exp_{t,y}\cdot m_{t,i}\cdot x_i}{\sum_{y\in Y}\sum_{t\in T}\sum_{i\in I_t} Exp_{t,y}\cdot m_{t,i}} \quad (2)$$

where $M_{syst}^{crit}$ is the amount of critical material required by the system, $Exp_{t,y}$ is the capacity of technology $t$ installed in year $y$, $m_{t,i}$ is the mass of material $i$ per unit of technology $t$ and $x_i$ is a binary parameter equal to 1 if the material $i$ is classified as critical and 0 otherwise. The classification of critical materials follows the assessments developed by the U.S. Department of Energy (DOE) and the European Union [16-17].

3) Material Scarcity: It is evaluated using the abiotic depletion potential (ADP) factor, which measures the reduction of finite, non-living natural resources due to human extraction. The ADP of a resource is defined as the ratio of its annual production to the square of its ultimate reserve, normalized by the same ratio for a reference resource [18].

$$SR = \sum_{y\in Y}\sum_{t\in T}\sum_{i\in I} Exp_{t,y}\cdot m_{t,i}\cdot ADP_i \quad (3)$$

where $ADP_i$ is the abiotic depletion potential of resource/material $i$.

## Durability metrics

For energy systems, durability must be addressed at the portfolio level rather than by comparing single technologies. A high-durability system implies it has technologies that have long lifetimes, lower replacement frequency and low material turnover, whereas a low durability system involves frequent replacement and short lifetime technologies. In this study, the durability of an energy system is measured using the average lifetime of the system, the average remaining lifetime, and the remaining capacity. In this way, both the lifetime of the system and the potential use of the system beyond the modeling horizon are considered.

The Average Lifetime of the System (ALS) is defined as

$$ALS = \frac{\sum_{y\in Y}\sum_{t\in T} Exp_{t,y}\cdot L_t}{\sum_{y\in Y}\sum_{t\in T} Exp_{t,y}} \quad (4)$$

where $L_t$ is the lifetime of technology $t$.

On the other hand, the average remaining lifetime (ARL) is defined as

$$ARL = \frac{\sum_{y\in Y}\sum_{t\in T} Exp_{t,y}\cdot RL_{t,y_f}}{\sum_{y\in Y}\sum_{t\in T} Exp_{t,y}} \quad (5)$$

where $RL_{t,y}$ is the remaining lifetime at the end the of planning horizon (year $y_f$) defined as $\max(0, L_t - (y_f - y))$.

Finally, the remaining capacity (RC) at the end of the modeling horizon is calculated as

$$SR = \sum_{t\in T} Exp_{t,y}\cdot RL_{t,y_f} \quad (6)$$

Technology lifetime determines the replacement and end-of-life decisions, influencing the three metrics. This allows the framework to account for energy portfolios with technologies with different lifetimes and the installation year decisions.

## Other categories

The remaining categories, including water, waste, energy, emissions and spillages, are adopted from the original MICRON framework, and adapted for energy systems by normalizing with respect to the energy produced.

# CASE STUDY

The framework is applied to a case study that considers the energy transition at the University of Wisconsin-Madison to evaluate how decarbonization strategies affect circularity. The analysis focuses on the planning of the electricity system at a campus scale over a 25-year horizon (2025-2050). A cost-minimizing energy planning model developed in [19] is used to determine capacity expansion and energy dispatch decisions. The model represents a grid connected system with solar, wind, and lithium-ion battery storage technologies. Grid reliance is included to account for the GHG emissions operational targets and is defined as the share of the total electricity

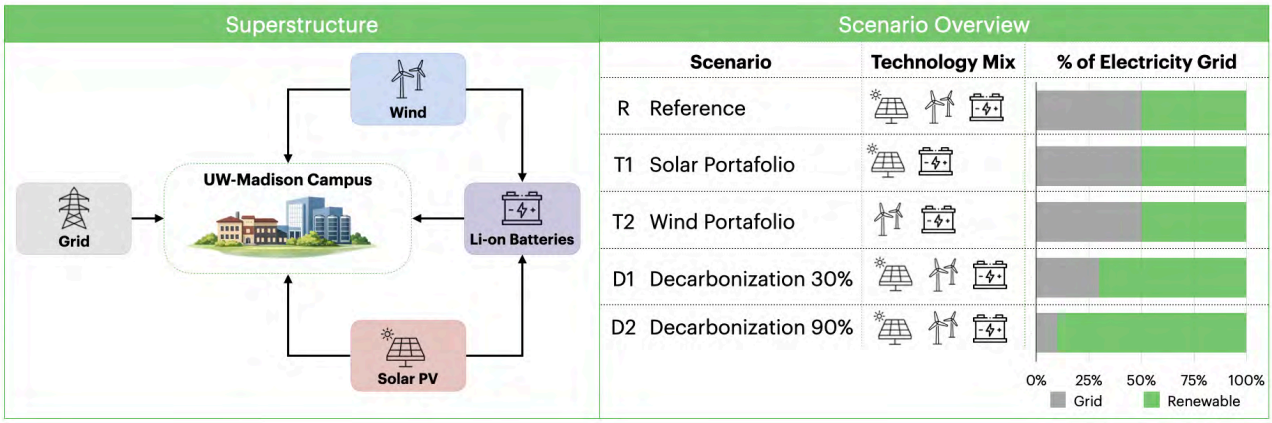

**Figure 3.** Summary of the case study including superstructure and scenarios studied.

**Table 2:** Summary of results for different technology portfolios.

| Scenario | Technology Portfolio | % Grid Electricity | Storage Use | Total Costs | Scope 2 Emissions | Scope 3 Emissions | Total GHG Emissions | Circularity Overall |
|---|---|---|---|---|---|---|---|---|
| | | | | MM USD | ton $CO_2$-eq | ton $CO_2$-eq | ton $CO_2$-eq | Index |
| R | Solar-Wind | 50% | No | 1,378 | 829 | 168 | 997 | 0.61 |
| T1 | Solar | 50% | No | 6,252 | 791 | 950 | 1,742 | 0.39 |
| T2 | Wind | 50% | No | 1,391 | 801 | 949 | 949 | 0.66 |
| D1 | Solar-Wind | 30% | Yes | 1,629 | 539 | 259 | 798 | 0.56 |
| D2 | Solar-Wind | 10% | Yes | 2,892 | 273 | 580 | 853 | 0.55 |

demand supplied by the grid. Circularity is quantified using the MICRON framework as a post-processing step. The overall modeling and assessment framework is illustrated in Figure 2.

The scenarios evaluated and the superstructure of the problem are summarized in Figure 3. A reference configuration is defined and used to compare the impact of technology portfolio (Scenarios T1-T2) and increasing decarbonization stringency through reduced grid reliance (Scenarios D1-D2). All scenarios assume identical electricity demand, technology performance parameters, and cost assumptions. As an initial approach, no recycling of technologies is considered, i.e., all waste is sent to landfill. Later, the effect of recycling is studied in the sensitivity analysis.

## RESULTS & DISCUSSION

Table 2 summarizes the system's costs, GHG emissions and the overall circularity index for the scenarios analyzed. The reference scenario shows a circularity index of 0.61 with a cumulative capacity of solar PV of 96 MW and 116 MW for wind. Compared to other portfolios, the solar only case (scenario T1) exhibits the lowest circularity (0.30) and the highest GHG emissions. Meeting the demand with only solar energy required approximately 1, 580 MW of capacity, which substantially increases the material requirements and indirect GHG (Scope 3) emissions. Additionally, as the system does not include energy storage system, there is a significant curtailment of excess energy generation, reducing the system performance and penalizing the circularity score. Conversely, the only wind portfolio achieves the highest circularity (0.66) among the three configurations. The higher efficiency of wind turbines and greater availability of the resource, improve the water and procurement, energy and emissions sub-indices, translating in a higher overall circularity index. These results indicates that resource availability and efficiency are as important as material composition for circularity.

Analyzing the effect of grid reliance, we can see that lower grid reliance decreases operational emissions (Scope 2), but it can reduce overall circularity. This reduction is driven by two factors. First, reducing grid reliance requires the addition of energy storage, represented here by lithium batteries, which increases the share of critical materials and scarcity. Second, achieving higher self-sufficiency systems requires larger deployment of renewable energy, raising total material demand and associated indirect (Scope 3) emissions. Overall, the results show that reducing operational emissions (scope 2) that not always reduce overall emissions. Therefore,

the reduction in operational emissions can be downside by the increased impact of material extraction and waste generation. It is important to notice that the systems studied do not have Scope 1 emission for Scope 1 as it does not include any technology with fuel consumption.

Figure 4 shows the circularity subindex values for each scenario. Differences are primarily driven by the material-related categories. In terms of subindices, the reference scenario is relative balanced, with the highest score for Durability. This performance is explained by the hybrid option, which reduces oversizing of the system and storage while maintaining reliability. Scenario T1 has the lowest scores in Water & Procurement and Energy, due to the oversized solar PV system and energy curtailment. Scenarios D1 and D2 show low Durability scores due to the relatively short lifetime of batteries which requires more frequent replacement compared to wind turbines or PV panels. Consequently, improvements in Emissions sub-index are offset by effects of deployment and EoL, reducing overall circularity. These findings suggest that decarbonization strategies focusing solely on emission reduction may shift into a material burden. All scenarios analyzed have similar Waste sub-index scores, as no recycling of technologies is considered.

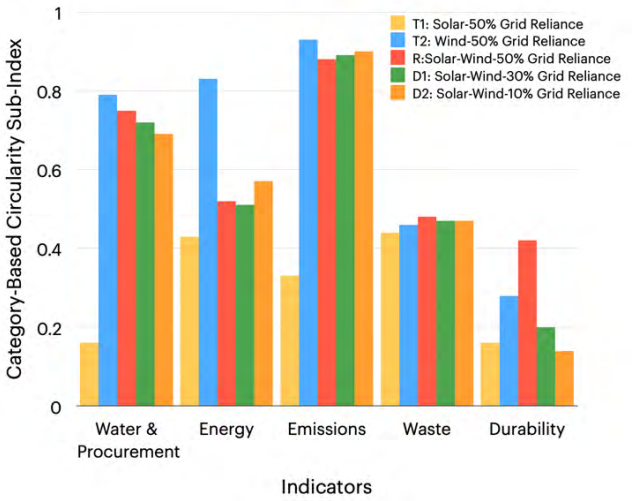

**Figure 4.** Circularity Sub-Index values for different scenarios analyzed.

## Sensitivity Analysis

A single parameter sensitivity analysis was performed to identify the key drivers of circularity. Each parameter is varied individually around the reference scenario (R) while all other parameters are kept constant. The parameters analyzed included the share of critical material, material scarcity, material intensity, % of recycled material used, and % of material recovered at the EoL. Figure 5 shows the corresponding effect, a ± 25% variation was applied to each parameter. Results indicate that the percentage of material recovered has the largest influence on circularity; in contrast, no change was seen for amount of recycled material used during manufacturing. This highlights the importance of EoL management of renewable technology to achieve a sustainable energy transition. On the other hand, small changes were seen for the percentage of critical material and scarcity, suggesting that it is important to focus on the type of material used and not only on the amount.

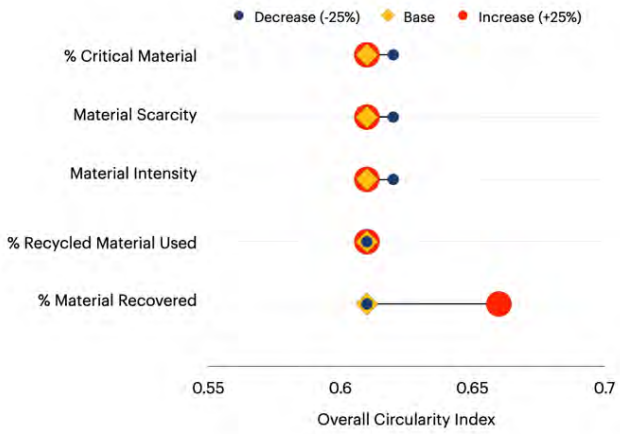

**Figure 5.** Single-parameter sensitivity analysis on the overall circularity index.

## CONCLUSIONS

This study proposed an integrated metric to assess and quantify circularity in energy systems based on the MICRON CE framework. The framework was adapted to account for the specific characteristics of energy technologies by incorporating metrics related to critical material, scarcity, material intensity and durability. The proposed metric was applied to evaluate circularity in an electricity planning problem at the University of Wisconsin-Madison.

While the scenarios studied showed similar GHG emissions, they differ in material use, durability and the overall circularity index. This demonstrates that GHG emissions alone are insufficient to characterize sustainability in the design and planning of energy systems. The results also show that lowering grid reliance, hence reducing operational emissions, does not necessarily improve circularity. The reduction of operational emissions can be offset by higher material requirements and increased waste generation.

The percentage of material recovered influences improvements in circularity. Therefore, future work will focus on evaluating the circularity of different recycling pathways for energy systems and integrating the circularity metric as a design criterion in an optimization planning problem, enabling the systematic design of energy systems that balance decarbonization and circularity objectives.

## ABSTRACT

Critical metals are indispensable in renewable, low-carbon, and hydrogen technologies due to their unique catalytic and electrochemical properties. They are primarily sourced through mining, which is associated with significant environmental impacts and geopolitical risks due to the uneven global distribution of ore deposits. As a result, efficient recovery of these metals from secondary sources such as electronic waste has become increasingly important. In this context, liquid-liquid extraction (LLE) has emerged as a promising separation technique due to its high selectivity and scalability. The development of intensified, continuous-flow LLE in small channels offers further advantages in terms of mass transfer efficiency, solvent utilization, and process sustainability, making it an attractive approach for the recovery of critical metals. A flow pattern known as segmented flow further enhances mass transfer in LLE in small channels. This work presents a hybrid modelling approach for developing a predictive model of a segmented flow LLE process, intended for digital twin implementation in critical metals recovery. Within the hybrid modelling framework, mass transfer is modelled using a lumped approach, which allows to treat mass transfer independently from flow hydrodynamics. Further, hydrodynamic and mass transfer models are developed in parallel using Gaussian process (GP)-based active learning (AL) and model-based design of experiments (MBDoE), respectively. Prior knowledge of flow regimes is used in developing the hydrodynamic model. The method was tested in an *in silico* case study and shown to efficiently develop reliable models for segmented flow extraction in small channels.

**Keywords**: hybrid modelling, active learning, model-based design of experiments, critical metals, extraction, segmented flow

## INTRODUCTION

Critical metals are essential to the functioning of modern technological systems, with applications ranging from lithium-ion batteries in smartphones and laptops to rare earth elements (REEs) used in permanent magnets for wind turbines and electric vehicles. These vital metals are used in many sectors including communications, renewable energy, transport and life sciences (Department for Business & Trade, 2026). The primary sources of critical metals are economically viable ore deposits, whose distribution across the globe is greatly uneven. In addition, the process of mining to obtain critical metals from their ore deposits is a highly resource-intensive process and can cause enormous damage to the environment. As a result, the supply of critical metals is increasingly vulnerable due to geopolitical, environmental and economic constraints. This risk in supply chain has pushed the recovery of critical metals from secondary sources such as electronic waste (e-waste) (Sun et al., 2017).

The recovery of critical metals from e-waste usually proceeds through pyrometallurgical or hydrometallurgical routes. Hydrometallurgical routes are preferred due to their flexibility, high recovery rate and sustainable nature. Hydrometallurgical processes essentially involve dissolving e-waste in acid solutions followed by selective separation of critical metals via liquid-liquid extraction (LLE). LLE involves contacting two immiscible liquids to selectively transfer solutes between them. Intensified, continuous flow LLE in small channels offers further

advantages such as enhanced mass transfer, less material consumption, precise control of operating conditions, real-time monitoring and ease of automation and digitization. Based on the way in which the immiscible liquids are contacted, in small channels, LLE can proceed through different flow patterns. One of the possible flow patterns is segmented flow which is a two-phase flow pattern in which one immiscible liquid forms discrete segments within a continuous phase of the other liquid (Garstecki et al., 2006; Mac Giolla Eain et al., 2013). Segmented flow is particularly attractive due its regular hydrodynamics and enhanced mass transfer, supporting the development of predictive models and advanced process control. Consequently, implementing digital twins of segmented flow LLE in small channels can accelerate the development of critical metals recovery from e-waste. A digital twin is a software model (Ljung, 1999) of a physical system which interacts with the physical system continuously and acts as a reliable virtual entity of the real world described by the physical system. Compared to the traditional simulation models, digital twins are adaptive and responsive real time simulations enabled via fast computation, advanced sensing and automation. Digital twins are becoming increasingly important to automate decision making related to productivity, cost, energy consumption, and sustainability for complicated systems. The core of such digital twins are mathematical models of physical systems, which are instrumental for simulation and prediction.

The aim of this study is in developing a digital twin model of a segmented flow LLE system for recovering critical metals from e-waste. The geometry of segmented flow pattern and the resulting hydrodynamic characteristics strongly influence the mass transfer between the two liquid phases. Consequently, modelling segmented flow requires to develop both hydrodynamic and mass transfer models.

Hydrodynamic modelling of segmented flow in small channels has traditionally relied on a combination of mechanistic and semi-empirical approaches. Mechanistic models, based on computational fluid dynamics (CFD) simulations, offer detailed insight but are computationally expensive. Semi-empirical models, on the other hand, use fitted correlations for flow parameters and are typically calibrated for specific fluid systems and operating conditions. They often fail to reliably predict system behaviour under new operating conditions which limit their application as digital twins. In this work we combine two powerful modelling techniques – probabilistic modelling via Gaussian processes (GPs) and model-based design of experiments (MBDoE) (Geremia et al., 2026) methods to develop a hybrid modelling framework for the segmented flow. In the proposed framework, hydrodynamic models are developed using GP and active learning (AL) (Lewis & Catlett, 1994), while MBDoE methods are employed to precisely estimate the parameters of the mass transfer model. The framework is tested on a simulated case study and is further shown to be effective in developing hybrid models of segmented flow LLE processes.

## 2. BACKGROUND AND METHODOLOGY

As shown in Fig. 1, segmented flow in small channels is characterised by repeated volumes of one phase (dispersed phase) in a continuous volume formed by the other phase (continuous phase). The dispersed phase is called plug and the continuous phase volume between two plugs is called slug. A single plug and slug constitute a unit cell. The size of plug, slug and unit cell are characterised by their lengths $L_p, L_s$ and $L_u$, respectively. Moreover, plugs are assumed to be cylindrical in shape with two hemispherical caps attached at both ends.

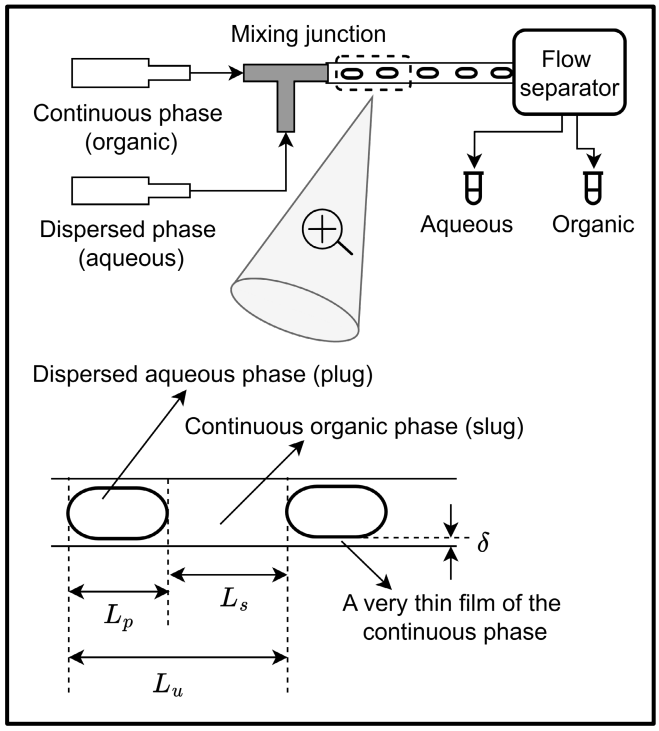

**Figure 1.** Schematic showing a segmented flow contactor set up, the segmented flow pattern and hydrodynamic characteristics of the segmented flow pattern.

In this work we consider a segmented flow LLE process in which the mass transfer by extraction happens from the dispersed aqueous phase to the continuous organic phase. Typically, the rate of mass transfer is affected by three main factors – the velocity and mixing patterns within each of the phases, the concentration driving forces and the interfacial area available for mass transfer. These three factors are influenced by several variables. Some of them for example, the design of the

mixing junctions (T-shaped junction or Y shaped junction, rectangular or circular cross section), the channel diameter and length and the properties of the contacted liquids are fixed for a specific system. While some variables such as the mixture velocity, the flow rate fraction of any of the two phases or the initial concentration of metals in the aqueous phase can be varied to study their effects on the plug-slug geometries as well as on the rate of mass transfer.

## 2.1 Fundamentals of modelling segmented flow extraction in small channels

Mathematical models of segmented flow LLE in small channels consist of a hydrodynamic model, a model for the pressure drop and a mass transfer model. Important hydrodynamic parameters related to segmented flow LLE are: a) primary flow geometries such as $L_p, L_s$ and $L_u$, b) film thickness ($\delta$), c) the dispersed phase holdup ($\varepsilon_d$) and d) the specific interfacial area ($a$). As shown in Fig. 1, a thin film of the continuous phase separates the slugs from the channel wall. The dispersed phase holdup is the volume fraction of the dispersed phase within one unit cell of the segmented flow:

$$\varepsilon_{\mathrm{d}} = \frac{\text{volume of dispersed phase in one unit cell}}{\text{total volume of the unit cell}} \tag{1}$$

The specific interfacial area is the area available for mass transfer per volume of the unit cell, and is defined as:

$$a = \frac{\text{total surface area of the dispersed phase}}{\text{total volume of the unit cell}} \tag{2}$$

The hydrodynamic modelling involves developing mathematical relationships between the inputs or the operating conditions to the primary flow geometries as well as to the film thickness. Typically, the relationship between inputs and film thickness is modelled using physics-based correlations such as Bretherton-type scaling laws, often extended to account for fluid properties and operating conditions (Mac Giolla Eain et al., 2013). Such correlations are often functions of dimensionless numbers such as the capillary number and the Weber number, depending on whether the flow is in the visco-capillary regime or in the visco-inertial regime (Mac Giolla Eain et al., 2013). Given $L_p, L_s, L_u$ and $\delta$, and assuming a plug geometry consisting of a cylindrical core with two hemispherical caps, expressions for $\varepsilon_d$ and $a$ can be derived using simple geometric relations. The rate of mass transfer between the dispersed phase and the continuous phase depends on the driving force, i.e., the metal concentration difference between the two phases, and the interfacial area available for mass transfer. Assuming an ideal plug flow behaviour (producing plugs of same dimension with no axial mixing) and negligible concentration gradient along the radial direction, the mass transfer along the channel length can be described by:

$$u_{\mathrm{mix}} \frac{\mathrm{d}C_{\mathrm{aq}}}{\mathrm{d}z} = -\frac{K_{\mathrm{aq}} a}{\varepsilon_{\mathrm{d}}} \left(C_{\mathrm{aq}}(z) - C_{\mathrm{aq}}^{\mathrm{eq}}\right) \tag{3}$$

In Eq. (3), $u_{mix}, K_{aq}, C_{aq}(z)$ and $C_{aq}^{eq}$ are the mixture velocity, aqueous phase mass transfer coefficient, concentration of metal in the aqueous phase at a distance $z$ from the channel inlet and the equilibrium concentration of metal, respectively. The mixture velocity is defined as the ratio of the total volumetric flow rate ($Q_T$) and the cross-sectional area of the channel with internal diameter $d_{\mathrm{int}}$. The total volumetric flow rate is defined as the sum of volumetric flow rates of the continuous phase ($Q_c$) and the dispersed phase ($Q_d$). The equilibrium concentration is defined as:

$$C_{\mathrm{aq}}^{\mathrm{eq}} = \frac{C_{\mathrm{aq}}^{\mathrm{in}}}{D(Q_{\mathrm{d}}/Q_{\mathrm{c}})+1} \tag{4}$$

In Eq. (4), $D, C_{aq}^{in}, Q_d$ and $Q_c$ are the distribution coefficient, initial concentration of metal in the aqueous phase, volumetric flow rate of the dispersed phase and the volumetric flow rate of the continuous phase, respectively. The distribution coefficient is usually evaluated from batch equilibrium experiments. Pressure drop is a key parameter in designing segmented flow contactors as it provides crucial information regarding energy consumption. However, it becomes more significant in designing scale-out segmented flow systems (Garciadiego Ortega et al., 2018) where multiple channels are involved. For this reason, in this study, a pressure drop model is not considered.

## 2.2 A hybrid modelling framework for segmented flow extraction in small channels

The mass transfer model in the form provided in Eq. (3) imposes two challenges. The first is its direct dependency on hydrodynamic terms such as the specific interfacial area and the dispersed phase holdup. This prevents the independent development (estimation and validation) of the mass transfer model as the predictive quality of the mass transfer model strongly depends on the accurate evaluation of $\varepsilon_{\mathrm{d}}$ and $a$ using the hydrodynamic model. Secondly, the aqueous phase mass transfer coefficient $K_{\mathrm{aq}}$ in Eq. (3) relates the mass flux through the interface to the concentration driving force. Consequently, when the interfacial area changes (i.e., the plug shape changes), for example due to variations in the flow rate, the value of mass transfer coefficient changes. For this reason, it is a local property that depends on the specific hydrodynamic conditions and cannot be uniquely estimated as a single model parameter over a range of operating conditions. As a solution to both the challenges, we lump the mass transfer coefficient, the specific interfacial area and the dispersed phase holdup into a single parameter $k'$ given by:

$$k' = K_{\mathrm{aq}} a / \varepsilon_{\mathrm{d}} \tag{5}$$

The lumped parameter $k'$ physically signifies mass transfer per unit interfacial area per unit volume of the dispersed phase. This parameter can be treated as constant (Garciadiego-Ortega et al., 2020) across a wide range of operating conditions that affect the primary plug-slug geometries, and subsequently the interfacial area and holdup. However, the parameter $k'$ can be affected by the mixture velocity, which promotes internal circulation within the plugs and slugs and enhances mass transfer even without changing the plug geometry. Therefore, analogously to the Arrhenius equation describing the temperature dependency of reaction rate constants, we employ a simple scaling rule to account for velocity dependency of $k'$, given by:

$$k' = k'_0\left(\frac{u_{\text{mix}}}{u_{\text{mix}}^{\text{ref}}}\right)^p \tag{6}$$

In Eq. (6), $k'_0$ is the lumped mass transfer coefficient corresponding to a reference mixture velocity $u_{mix}^{ref}$. The exponent $p$ in Eq. (6) represents the combined sensitivity of the effective mass transfer rate to mixture velocity, accounting for velocity-induced changes in interfacial area, phase holdup, and local mass transfer. By substituting Eq. (5) and (6) in Eq. (3), the mass transfer model can be modified as:

$$u_{\text{mix}}\frac{\mathrm{d}C_{\text{aq}}}{\mathrm{d}z} = -k'_0\left(\frac{u_{\text{mix}}}{u_{\text{mix}}^{\text{ref}}}\right)^p\left(C_{\text{aq}}(z) - C_{\text{aq}}^{\text{eq}}\right) \tag{7}$$

Now, Eq. (7) contains two parameters $k'_0$ and $p$ that can be uniquely estimated so that Eq. (7) holds true for a wide range of operating conditions. This approach allows the mass transfer model to be developed independently of the hydrodynamic model. We suggest the application of closed loop experimentation via optimal feedback loop (with minimum data points) to develop both hydrodynamic and mass transfer model. To this end, we employ GP modelling via AL for the development of hydrodynamic model and MBDoE for the mass transfer model development. Details of these methods are given below.

### 2.2.1 Gaussian processes and active learning for hydrodynamic model development

Consider a small channel segmented flow LLE system in which the aqueous phase forms the plug and the organic phase forms the slug. Let the system is affected by two inputs – mixture velocity and the continuous phase flow rate fraction ($\phi_c$), which is defined as the ratio of continuous phase volumetric flow rate over the total volumetric flow rate. Now, an experiment $i$ is identified by the input vector $\mathbf{u}_i = [u_{i1}, u_{i2}]$ and the outputs - $\mathbf{y}_{h_i} = \left[y_{h_{i1}}, y_{h_{i2}}\right]$ and $y_{m_i}$. Here, $u_{i1}$ and $u_{i2}$ respectively denote the values of mixture velocity and continuous phase flow rate fraction that define experiment $i$. Similarly, $y_{h_{i1}}, y_{h_{i2}}$ and $y_{m_i}$ respectively denote the observed values of plug length [m], unit cell length [m] and concentration of metal [mol/L] in the dispersed aqueous phase at the outlet of the channel of length $L_z$. It is assumed that the observations $y_{h_{i1}}, y_{h_{i2}}$ and $y_{m_i}$ are corrupted by independent and identically distributed Gaussian noise with zero mean and standard deviations of $\sigma_1, \sigma_2$ and $\sigma_c$, respectively.

Consider a dataset from $n$ experiments consisting of inputs $\mathbf{u}_1, \dots, \mathbf{u}_{\text{n}}$ and outputs $\mathbf{y}_{h_1}, \dots, \mathbf{y}_{h_n}$ and $y_{m_1}, \dots, y_{m_n}$. The relationship between $\mathbf{u}$ and $\mathbf{y}_h$, which is the relationship between the inputs and the primary plug-slug geometries is usually modelled as empirical correlations validated using polynomial regression. Disadvantages of this approach are the lack of proper quantification of the uncertainty in model predictions and the lack of accurate predictions under new operating conditions, which were not used in calibration. As a better approach that guarantees accurate estimation of prediction uncertainties, and that captures non-linear system behaviour, we model the relationship between $\mathbf{u}$ and $\mathbf{y}_h$ using a multiple-output GP model (Bonilla et al., 2007).

In a multiple-output GP modelling framework, several related output variables are modelled together by assuming each output having an underlying hidden function called the latent function. Mathematically, the observed value of output $l$ at input $\mathbf{u}_i$ can be represented as:

$$y_{h_{il}} = f_l(\mathbf{u}_i) + \epsilon_l, \epsilon_l \sim \mathcal{N}\left(0, \sigma_l^2\right) \tag{8}$$

In Eq. (8), $f_l$ is the latent function for output $l$ and $\epsilon_l$ is the error term. In the GP framework, the latent functions are treated as random functions drawn from a GP, meaning that for any set of inputs $\mathbf{u}_1, \dots, \mathbf{u}_n$, the latent function values follow a multivariate Gaussian distribution.

$$[f_{11}, \dots, f_{\text{n}1}, f_{12}, \dots, f_{\text{n}2}; \mathbf{u}_1, \dots, \mathbf{u}_{\text{n}}] \sim \mathcal{N}(\mathbf{m}, \mathbf{K}) \tag{9}$$

In Eq. (9), $\mathbf{m}$ and $\mathbf{K}$ represent the mean vector and the covariance matrix, respectively. The covariance between any two latent function values is given by:

$$Cov\left(f_l(\mathbf{u}), f_j(\mathbf{u}')\right) = \kappa_{lj}^f \kappa_u(\mathbf{u}, \mathbf{u}') \tag{10}$$

The RHS of Eq. (10) is called a kernel function. Essentially, it assigns covariance between the latent function values based on the covariance or similarities observed among inputs and outputs. According to Eq. (10), similarity between inputs is captured by $\kappa_u(\mathbf{u}, \mathbf{u}')$ whereas similarity between outputs is captured by $\kappa^f$. We employed the intrinsic coregionalization model (ICM) kernel proposed by Bonilla et al., (2007) for the product $\kappa_{lj}^f \kappa_u(\mathbf{u}, \mathbf{u}')$, with the radial basis function (RBF) kernel for $\kappa_u(\mathbf{u}, \mathbf{u}')$.

The GP model training involves estimating the optimal values of hyperparameters of the kernel function that minimises a loss function. We used the negative marginal log-likelihood as the loss function. Once trained with few points, the GP model can be used to predict the plug and unit length for any unseen input data point. Along with these predictions, the model also provides an estimate of

uncertainty associated with the predictions. This uncertainty will be largest in regions less explored, where the model is least confident. Therefore, selecting new experiments in the largest uncertainty region and retraining the model with those new data points helps to reduce the model prediction uncertainty over the experimental iterations. This iterative approach of training the model with informative data points is known as active learning (AL) (Lewis & Catlett, 1994). Mathematically, AL is an optimisation problem of the form:

$$\max_{\mathbf{u}_{\mathrm{lb}} \le \mathbf{u} \le \mathbf{u}_{\mathrm{ub}}} \psi\{\mathrm{Var}[f(\mathbf{u})]\} \tag{11}$$

where, $Var[f(\mathbf{u})]$ is the posterior predictive variance of the GP model at conditions defined by the vector $\mathbf{u}$ and $\psi$ is a scalar function of the variance vector. We have chosen $\psi$ as the $\ell^2$-norm of the variance vector. The AL procedure was applied iteratively to develop a reliable GP model that maps the mixture velocity and continuous phase flow rate fraction to the plug and unit lengths.

### 2.2.2 Model-based design of experiments for mass transfer model development

The development of mass transfer model presented in Eq. (7) essentially requires precise estimation of the two model parameters lumped in the $N_\theta$ (here, 2) dimensional vector $\theta = [k_0', p]$. Let us revisit the dataset formed from $n$ experiments. The mass transfer data consists of the set of inputs $\mathbf{u}_1, \ldots, \mathbf{u}_{\mathrm{n}}$ and outputs $y_{m_1}, \ldots, y_{m_n}$. Each input vector corresponds to an experimental condition specified by the values of mixture velocity and continuous phase flow rate fraction, while the output variables denote the metal concentration in the dispersed phase at the channel outlet. With the availability of such a dataset, a parameter estimation can be performed to obtain the best values of the model parameters that minimises the discrepancy between predicted and observed concentration values. We employed maximum likelihood method of parameter estimation to obtain the optimal parameter estimates $\hat{\theta}$.

The uncertainty in estimation of $\hat{\theta}$ can be quantified as the parameter covariance matrix $\mathbf{V}_\theta$, which in turn can be approximated as the inverse of observed Fisher information matrix $\mathbf{H}_\theta$ (Geremia et al., 2026).

$$\mathbf{H}_\theta = \left[\mathbf{V}_\theta^0\right]^{-1} + \sum_{\mathrm{i}=1}^{n} \mathbf{S}_{\mathrm{i}}^{\mathrm{T}} (\sigma_{\mathrm{c}}^2)^{-1} \mathbf{S}_{\mathrm{i}} \tag{12}$$

In Eq. (12), $\mathbf{S}_{\mathrm{i}}$ represents the parameter sensitivity matrix with dimensions equal to number of output variables times the number of model parameters. Since, we have the case with only one output variable, $\mathbf{S}_{\mathrm{i}}$ is a row vector whose elements represent the first derivatives of the output variable with respect to the model parameters, evaluated at the estimated parameter values and at the condition investigated in experiment $i$. The parameter covariance matrix $\mathbf{V}_\theta$ is evaluated as the inverse of $\mathbf{H}_\theta$. The statistical precision in which the parameters are estimated can be evaluated using a *t*-test. From the parameter covariance matrix, the test statistic *t*-value for the *t*-test can be computed for each parameter estimate as:

$$t_{\mathrm{i}} = \frac{\hat{\theta}_{\mathrm{i}}}{t_{N-N_\theta}(1-\alpha/2)\sqrt{\mathbf{V}_{\theta_{\mathrm{ii}}}}} \tag{13}$$

When the computed *t*-value for an estimate is greater than a reference *t*-value, $t_{ref} = t_{N-N_\theta}(1-\alpha/2)$, that parameter is identified as precisely estimated, otherwise the test fails and new experiments need to be designed to improve the statistical precision. This can be achieved by solving the MBDoE optimisation problem, which suggests new condition that minimises a scalar function $\xi$ of the expected parameter covariance matrix $\hat{\mathbf{V}}_\theta$.

$$\min_{\mathbf{u}_{\mathrm{lb}} \le \mathbf{u} \le \mathbf{u}_{\mathrm{ub}}} \xi\left[\hat{\mathbf{V}}_\theta(\mathbf{u})\right] \tag{14}$$

Popular choices of $\xi$ are the alphabetic design criteria with A-, D- and E-designs, respectively minimising the trace, determinant and maximum eigenvalue of the expected covariance matrix. Like AL, MBDoE can be also performed iteratively in closed loop until all the model parameters are precisely estimated.

## 2.3 Case study

A simulation study was designed to test the proposed hybrid modelling approach. For the simulation study, the extraction of uranium U(VI) by tributyl phosphate (TBP) (100 %) (Garciadiego-Ortega et al., 2020) in a channel of internal diameter 2 mm was selected as the case study. In their study, Garciadiego-Ortega et al. (2020) have developed the models provided in Eq. (15) and (16) to predict the dimensionless plug and slug lengths. They also validated these models over the range of operating conditions provided in Table 1.

**Table 1:** Experimental design space in terms of variable bounds.

| Input | Bounds |
|---|---|
| Mixture velocity ($cm/s$) | [1.062, 4.24] |
| Continuous phase flow rate fraction (–) | [0.2, 0.5] |

In this study, the models with the coefficients in Eq. 15 and 16 are assumed as the "true models" representing the hydrodynamic component of the segmented flow LLE system. The design space provided in Table 1 was chosen to be the design space in this simulation study.

$$\ln\left(\frac{L_{\mathrm{p}}}{d}\right) = -2.56 - 0.872\ln\left(\frac{Q_{\mathrm{c}}}{Q_{\mathrm{T}}}\right) - 0.36\ln\left(\frac{\mu_{\mathrm{d}}}{\mu_{\mathrm{c}}}\right) - 0.280\ln(\mathrm{Ca_c}) + 0.099\ln\left(\frac{\mathrm{Re_c}}{\mathrm{Ca_c}}\right) \tag{15}$$

$$\ln\left(1 - \frac{L_{\mathrm{p}}}{L_{\mathrm{u}}}\right) = -0.82 + 1.181\ln\left(\frac{Q_{\mathrm{c}}}{Q_{\mathrm{T}}}\right) - 0.099\ln\left(\frac{\mu_{\mathrm{d}}}{\mu_{\mathrm{c}}}\right) -$$

$$0.130 \ln(\mathrm{Ca}_c) \quad (16)$$

In their study, Garciadiego-Ortega et al. (2020) have used the following correlation proposed by Mac Giolla Eain et al., (2013) to calculate the film thickness:

$$\frac{2\delta}{d_{\text{int}}} = 0.35(\mathrm{Ca}_c)^{0.354}(\mathrm{We}_c)^{0.097} \quad (17)$$

According to Mac Giolla Eain et al., (2013), Eq. (17) is only valid within a specific range of operating conditions defined by the dimensionless numbers listed in Table 2. However, a subregion of the chosen design space in Table 1 resulted in values of the dimensionless numbers outside the feasible bounds provided in Table 2.

**Table 2:** Dimensionless numbers and their ranges over which the film thickness correlation in Eq. (17) is valid.

| Dimensionless number | Description | Desired range |
|---|---|---|
| Capillary (Ca) | $\mathrm{Ca}_c = \mu_c u_{mix}/\gamma$ | 0.002 – 0.119 |
| Weber (We) | $\mathrm{We}_c = \rho_c u_{mix}^2 d/\gamma$ | 0.047 – 0.697 |
| Reynolds (Re) | $\mathrm{Re}_c = \rho_c u_{mix} d/\mu_c$ | 14.46 – 100.96 |

Therefore, in the simulation study, the AL was solved as a constrained optimization problem with the constraint $0.047 \leq \mathrm{We} \leq 0.697$. Based on the work by Garciadiego-Ortega et al., (2020), the true values of the parameters of the lumped mass transfer model - $k_0'$ and $p$ were chosen as 0.055 and 0.8, respectively with $u_{mix}^{ref} = 1.062$ cm/s. For *in silico* data generation, it is assumed that the plug length, unit length and concentration data are corrupted by independent and identically distributed Gaussian noise with zero mean and standard deviations of 0.0004 m, 0.0004 m and 0.001 mol/L, respectively. The physical properties of the fluids such as viscosity ($\mu$), density ($\rho$) and interfacial tension ($\gamma$) required to calculate Eq. (15-17) and the dimensionless numbers in Table 2 as well as the value of the distribution coefficient $D$ were obtained from Garciadiego-Ortega et al., (2020). The channel length $L_z$ was assumed as 0.5 m.

## RESULTS AND DISCUSSION

Initial experiments to calibrate both the hydrodynamic and mass transfer models were generated using Latin hypercube sampling (LHS) applied in the design space provided in Table 1. Four initial experiments were designed using the LHS method. The outputs (plug length, unit length and metal concentration in the dispersed phase at the channel outlet) corresponding to these experiments were obtained by simulating the true models and adding noise to them. The initial hydrodynamic dataset was used to train the GP model, and the initial mass transfer dataset was used to estimate parameters of the lumped mass transfer model. The results of parameter estimation of the mass transfer model using the initial dataset (i.e., at the end of 4 DoE experiments) are shown in Table 3.

**Table 3:** Parameter estimation results after DoE and AL. The reference *t*-values after DoE and AL are 2.91 and 1.71 respectively.

| Parameter | Estimate | *t*-value | Evaluation |
|---|---|---|---|
| $k_0'$ | 0.060 ±0.03 | **1.98** | End of DoE |
| $p$ | 0.704 ±0.49 | **1.43** | |
| $k_0'$ | 0.058 ±0.005 | 10.39 | End of AL |
| $p$ | 0.734 ±0.08 | 8.35 | |

As shown in Table 3, the parameter estimates obtained from the initial DoE exhibited relatively large uncertainty. The *t*-values of the parameter estimates were smaller than the reference *t*-value (2.91). At this stage, one can perform either AL, MBDoE or a multi-objective optimization using AL and MBDoE to design next set of experiments for developing the segmented flow model. In this work, we focussed on the development of hydrodynamic model. Thus, after the DoE, a campaign of AL experiments, consisting of 20 new experiments were designed iteratively to reduce the prediction uncertainty of the GP model. In this simulated experimental campaign, AL was solved as a constrained optimization problem with the constraint equation $0.047 \leq \mathrm{We} \leq 0.697$.

The experiments designed in the AL campaign along with the initial LHS experiments are shown in Fig. 2. As shown in the Fig. 2, in the constrained AL problem, a low velocity region appeared to be infeasible as it resulted in Re and We below their validated range. A physical significance of this observation is that the correlation for film thickness provided in Eq. (17) applies to the visco-inertial regions, where the velocity or inertia force start to have an influence on the film thickness. However, at low velocity, this influence is negligible with capillary and viscous forces dominating (Mac Giolla Eain et al., 2013). Hence, even the small weighting of the Weber number is not appropriate in calculating film thickness at low velocities. As a result, this low velocity region proved to be the infeasible region in the constrained AL problem. It can be also inferred from Fig. 2 that the constrained AL problem always resulted in feasible solutions, however, very close to the feasible boundary. This is because AL picks new experiments in the less explored regions.

The experiment numbers showing the exact iteration of experiments are provided as labels in Fig. 2. It is also understood from Fig. 2 that the AL campaign was successful in exploring the design space. Further evidence of the good performance of the AL campaign in reducing the prediction uncertainty of the GP model is

provided in Fig. 3.

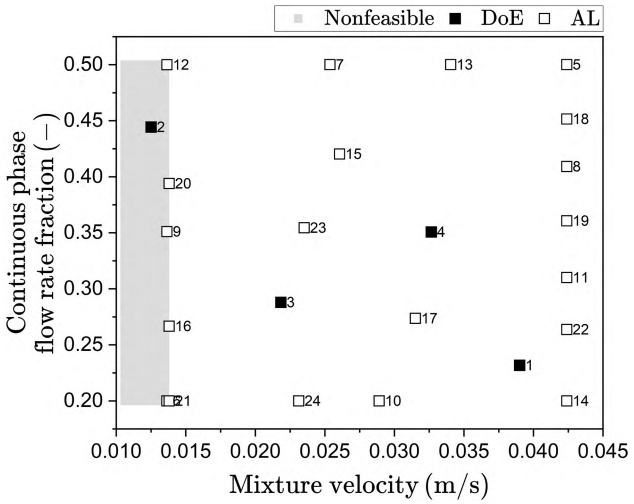

**Figure 2.** The simulated experimental campaign showing the DoE (filled squares) and AL (open squares) experiments. Labels adjacent to the scatter points denote the experiment number. The nonfeasible design space is shown using grey scatter points.

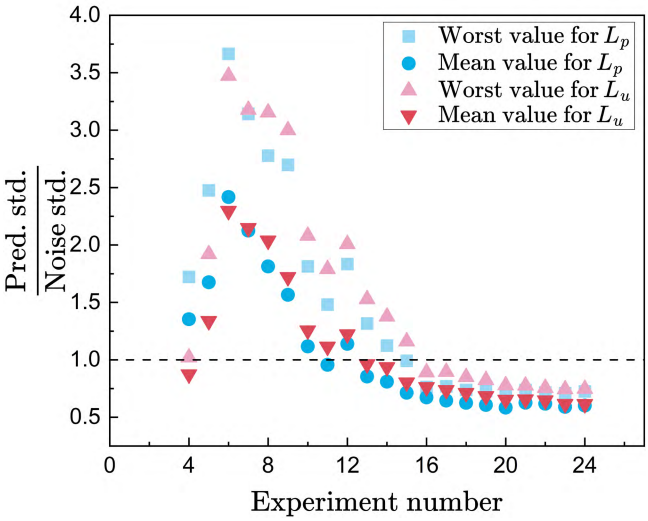

**Figure 3.** Convergence of the AL method in terms of the ratio of standard deviation of prediction to that of noise.

As shown in Fig. 3, for each output ($L_p$ and $L_u$), the ratio of GP predictive standard deviation to the corresponding observation noise standard deviation was used as a performance indicator of the AL method. Specifically, the worst and mean values of this ratio evaluated

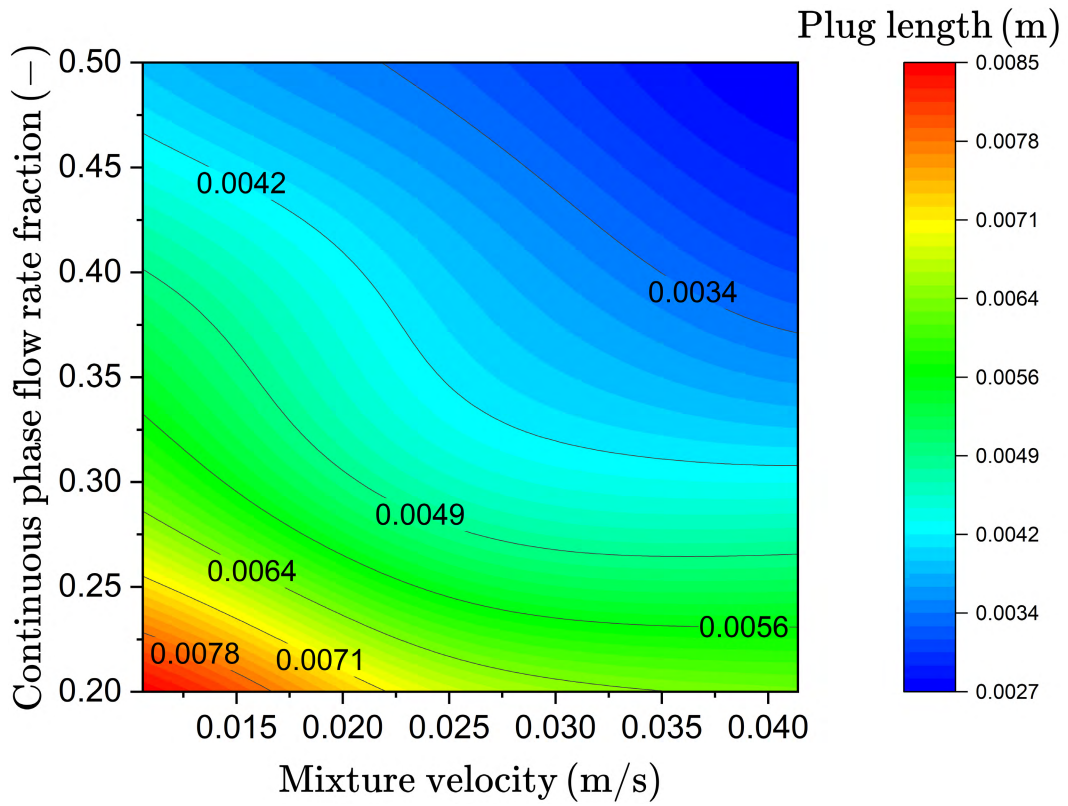

**Figure 4.** Prediction of plug length by the GP model developed using constrained AL method. The numbers on the contour lines represent the predicted values of plug length.

posteriori (after each design and execution) across the design space were used as the performance indicators. As expected, the ratio decreased gradually as new informative training point was picked in each iteration of the AL method. Ideally, one can stop performing the AL experimental campaign when the ratio of the standard deviations drops below 1 (marked by the dashed line in Fig. 3), indicating that the uncertainty in predicting $L_p$ and $L_u$ by the GP model can be fully explained by the uncertainty in the random nature of measurements.

Besides the prediction uncertainty, the prediction behaviour of the final GP model (after 20 AL experiments) developed through the constrained AL method is illustrated in Fig. 4.

As shown in Fig. 4, the plug length increases with decreasing mixture velocity and continuous phase flow rate fraction. A decrease in the continuous phase flow fraction increases the proportion of the dispersed phase in the channel, resulting in larger plugs. Also, as the mixture velocity decreases, the drag force which helps detach the plugs at the inlet decreases, again producing longer plugs (Garstecki et al., 2006). The behaviour of the GP model is quite appealing as its predictions of the plug length align well with known physical phenomena affecting plug formation and its size.

## CONCLUSION

A hybrid modelling approach has been proposed to develop a digital twin model of a segmented flow LLE process to recover critical metals. In the proposed method, a lumped mass transfer model was developed to decouple the mass transfer and hydrodynamic models. Furthermore, the proposed approach enables the closed-loop development of both hydrodynamic and mass transfer models via GP-based AL and MBDoE, respectively. When prior constraints regarding flow regimes or hydrodynamic characteristics are available, this knowledge can be incorporated to guide the development of the GP model describing hydrodynamic features such as plug and slug lengths. Although the approach decouples the hydrodynamic and mass transfer components of the segmented flow model, it allows both models to be developed simultaneously through multi-objective optimization of AL and MBDoE. The approach was tested on an *in silico* case study and proved to be very efficient in developing a combined data-driven and knowledge-based model of segmented flow LLE in small channels.

## ABSTRACT

Regional deployment of bioenergy and bio-based products is often constrained by the seasonality, heterogeneity, and dispersed availability of lignocellulosic biomass. This work demonstrates a computer-aided process engineering (CAPE) workflow that integrates experimental characterization, process modeling, and life cycle assessment (LCA) to support regional symbiosis design using mixed feedstocks from agriculture and forestry. A case study is developed for Tanegashima, a remote Japanese island where unused woody residues and sugarcane bagasse are locally available but temporally mismatched. Torrefaction is modeled in an autothermal configuration: char is the main product, while torrefaction gas and condensables are recovered for internal heat supply and any excess is treated as an energy coproduct. Laboratory measurements (220–400°C, 20°C interval) provide temperature-dependent yields of char, tar, aqueous condensate, and gas, alongside ultimate analysis and heating values of solids and representative gas composition. These data are translated into a mass–energy inventory for LCA foreground modeling up to pelletization. The functional unit is 1 t of wet biomass (40 wt% moisture) processed on-island. Results show that increasing temperature decreases solid yield but increases charification and heating value. Autothermal operation becomes feasible above approximately 340°C under a mid-level drying-energy assumption, and the threshold is highly sensitive to drying performance. Across assessed feedstocks and temperatures, life-cycle GHG emissions are negative when credits are given for substituting fossil coal and kerosene-equivalent fuels. The proposed workflow enables composition- and seasonality-aware screening of regional biomass portfolios under consistent inventory assumptions.

**Keywords**: torrefaction, mixed lignocellulosic biomass, autothermal operation, CAPE, life cycle assessment

## INTRODUCTION

Utilizing lignocellulosic biomass from forestry and agriculture can contribute to decarbonization and energy security, particularly in regions that rely on imported fossil fuels. In Japan, expanding the use of domestic woody biomass is discussed not only as a renewable energy measure but also as a route to revitalize forestry and local economies [1]. Realizing these benefits requires long-term alignment between forest management, labor availability, and roundwood demand; recent modeling work explicitly treats this as a "forest transition" problem that must be planned over multi-decade horizons [2]. At regional scale, the feasibility of bioenergy systems is therefore shaped as much by supply-side constraints as by conversion technology performance [3, 4].

Alongside forestry resources, agricultural residues can provide concentrated feedstocks with established

collection points. Sugarcane bagasse is produced at sugar mills during the crushing season, and its use has been studied as part of coordinated agricultural–industrial systems design [5] and as a lever for reducing greenhouse gas (GHG) emissions in sugar/ethanol production systems [6]. However, residue supply is seasonal and storage is not trivial: large bagasse stockpiles can pose risks related to dust emissions, leachate, and spontaneous heating [7]. In island contexts such as Tanegashima, where agricultural and forestry residues coexist but are temporally mismatched, combining feedstocks can help stabilize plant operation while improving local resource circulation [3, 4, 8].

Thermochemical pretreatment technologies are attractive for heterogeneous biomass because they can stabilize the feedstock and improve fuel quality. Torrefaction is an oxygen-deficient thermal treatment typically carried out over 200–300°C, although practical systems may operate into higher temperatures where mild pyrolysis becomes relevant. Reviews report that torrefaction reduces moisture and oxygen content, increases energy density, improves grindability, and enhances hydrophobicity, which can reduce biological degradation during storage and facilitate pelletization and co-firing [9]. Techno-economic assessments further highlight that process performance strongly depends on reactor configuration and heat integration, and that overall efficiency hinges on how moisture removal and volatile utilization are handled [10].

From a life-cycle perspective, torrefaction can improve energy efficiency per delivered megajoule but can also add process energy demand and associated impacts. In particular, the energy required for drying and water removal is frequently a dominant contributor and uncertainty driver in torrefied pellet life-cycle assessments [11, 12]. Autothermal operation—supplying process heat primarily from internally generated torrefaction gas and condensables (“torgas” and related volatiles)—is often proposed as a design target because it can reduce or eliminate external fuel demand. Sensitivity analyses indicate that the extent of by-product utilization is critical for both emissions and economics [12].

Computer-aided process engineering (CAPE) tools can support these decisions by generating consistent mass–energy inventories for alternative pathway options and by enabling composition-aware screening. Recent work demonstrated simulation-based design for regional biomass thermochemical conversion systems, integrating process modeling and LCA for improved environmental and socio-economic performance [13]. Building on this foundation, the present study focuses on autothermal dry torrefaction as a key pretreatment step for mixed lignocellulosic biomass and illustrates how experimental yield data can be translated into foreground inventories suitable for LCA and for future superstructure-based regional design.

The objective of this paper is to demonstrate a CAPE-supported workflow for designing regionally appropriate lignocellulosic resource utilization systems using Tanegashima as an illustrative case. Specifically, we (i) characterize temperature-dependent thermal decomposition behavior and product yields for wood chips and bagasse (220–400°C); (ii) formulate an autothermal torrefaction process model that converts experimental yields into a consistent mass–energy inventory up to pelletization; and (iii) evaluate life-cycle GHG emissions (LC-GHG) across feedstocks, temperatures, and operating assumptions, highlighting the conditions under which autothermal operation is feasible.

## MATERIALS AND METHODS

### Introduction to case study: Tanegashima

Tanegashima is a remote island in Kagoshima Prefecture, Japan, characterized by an islanded energy system and a regional economy where agriculture and forestry coexist. Prior studies have analyzed industrial symbiosis centered on a regional combined heat and power (CHP) plant using local resources [8] and have shown that designing the appropriate plant scale requires careful matching between sustainably available woody biomass supply and local heat/electricity demand [3]. A co-learning case study further emphasized that aligning technology choices with local constraints (resource availability, stakeholder preferences, and infrastructure) is essential for regional transformation [4].

In addition to forestry residues, Tanegashima hosts a sugar-mill industry that produces sugarcane bagasse as a coproduct. Coordinated integration of agricultural and industrial processes has been studied for sugarcane-derived production systems, highlighting how cultivar choice and mill operation influence material and energy flows [5]. Bagasse supply is concentrated in the crushing season, while forestry residues can be available more continuously but depend on long-term forest management and logistics. The coexistence of these two feedstocks motivates a mixed-biomass utilization strategy to stabilize conversion facilities and improve regional resilience.

### Thermal decomposition experiments and yield characterization

Thermal decomposition behavior was characterized under controlled inert conditions to provide process-relevant foreground data. Isothermal experiments were conducted using a thermogravimetric analyzer (TGA-51) with nitrogen carrier gas at 100 mL/min. Samples were heated to target temperatures between 220 and 400°C (20°C interval) and held isothermally for 120 min to observe mass-yield trajectories [14, 15]. These

| Impact category | LC-GHG (GWP100) | — | IPCC AR4 factors [19]. |
| Background data | IDEA v3.5.1 | — | Japan LCI database (industry standard). |

measurements provide a consistent basis for mapping temperature-dependent solid yield and for supporting yield-function fitting.

In addition, bench-scale carbonization experiments in an electric tubular furnace were performed for Japanese cedar wood chips and sugarcane bagasse sourced from Tanegashima to quantify product distributions. For each temperature, mass yields of solid char, tar, aqueous condensate (wood-vinegar-like fraction), and non-condensable gas were determined. Ultimate analysis (C/H/O) and HHV/LHV were obtained for raw feedstock and char, and representative gas composition ($CO_2$/CO/$CH_4$) was measured by gas chromatography (GC). These data allow estimation of by-product energy available for internal heat supply.

A mass–energy balance was constructed using measured compositions. For solids, carbon, hydrogen, and oxygen contents were directly measured. For the gas phase, the measured species were used to estimate the combustible fraction and the lower heating value of the gas mixture. Liquid products were separated into tar and aqueous fractions; because comprehensive speciation was outside the scope of this proceeding, their aggregate energy content was inferred from the overall energy balance using measured HHV/LHV of the feed and char and the estimated gas energy.

Although these experiments were performed at laboratory scale with inert carrier gas and differ from industrial reactors in heat and mass transfer, the measured yields and compositions are valuable anchors for process modeling. In the process model (Section 2.3), we treat experimental yields at 30 mins as primary inputs and represent scale-up-relevant uncertainties (e.g., drying energy and heat losses) through scenario ranges consistent with LCA literature [11].

## Autothermal dry torrefaction process modeling

**Figure 1** illustrates the process boundary for the modeled torrefaction system. The target configuration is autothermal dry torrefaction, in which process heat is supplied predominantly by combusting internally generated torrefaction gas and condensable by-products. The

model includes biomass acquisition and preprocessing (chipping/handling and transport), drying, torrefaction (220–400°C), solid cooling, grinding, and pelletization. Char is the main product, while by-products are used for internal heat demand and any surplus is treated as an energy coproduct.

Experimental temperature-dependent yields (char, tar, aqueous, and gas) are mapped to a steady-state mass flow model for a reference feed input. **Table 1** summarizes key modeling parameters and scenario settings (moisture content, drying energy per kg evaporated water, electricity demand for size reduction and pelletization, and heat recovery efficiency). Drying is represented by reducing feed moisture from the functional-unit basis (40 wt% wet basis) to a target moisture suitable for torrefaction. The required drying heat is calculated from the latent heat of vaporization and an "effective drying energy" factor that implicitly captures sensible heating, exhaust losses, and heat recovery performance; this factor is varied in three cases to reflect uncertainty (Section 2.4).

Autothermal feasibility is assessed by comparing recoverable by-product energy with process thermal demand. Let Q_demand be the sum of drying heat, reactor sensible/latent duties, and heat losses. Let Q_byprod be the usable heat from by-product combustion after accounting for combustion efficiency and heat recovery (Table 1). Autothermal operation is considered feasible if Q_byprod ≥ Q_demand (electricity excluded). This criterion provides a transparent link between measured yield distributions (which determine Q_byprod) and design/operation choices (which determine Q_demand).

Electricity use is included for material handling, grinding, and pelletization. When site-specific measurements are unavailable, electricity intensities are adopted from torrefied pellet and co-firing LCA studies and treated as scenario inputs [11, 16, 17]. This approach keeps the process model modular: measured thermochemical yields drive thermal balances, while mechanical-electric demands can be updated as site-specific data become available.

### Life cycle assessment (LCA)

The goal of the LCA is to quantify life-cycle greenhouse gas emissions associated with producing charcoal via autothermal dry torrefaction on Tanegashima and to compare outcomes across feedstocks (wood chip, bagasse, and mixed operation) and operating temperatures. The system boundary (**Figure 1**) covers biomass acquisition and preprocessing, drying, torrefaction, pelletization, and the use of products that substitute fossil fuels. The functional unit is the processing of 1 t of wet biomass (40 wt% moisture) delivered to the torrefaction system.

Foreground models for forestry operations and logistics are aligned with prior Tanegashima studies that evaluated woody biomass CHP and regional symbiosis under local supply constraints [3, 8]. For sugarcane bagasse, upstream burdens and allocation within the sugar-mill system follow Japanese case studies on sugarcane-derived production and GHG reduction options [5, 6]. Background processes for fuels, electricity, transport, and materials are taken from IDEA, and island-specific electricity assumptions can be applied following earlier Tanegashima LCA practice [8].

LC-GHG is calculated as the sum of upstream and on-site emissions minus substitution credits. Substitution is modeled on an energy basis: charcoal displaces general coal, while any externally available by-product energy displaces kerosene-equivalent fuel. This consequential framing is used to highlight mitigation potential in an island context where imported fossil fuels dominate. Sensitivity analysis is performed by varying the effective drying energy factor (3/6/9 MJ/kg-water) following the approach of torrefied pellet LCAs that explicitly tested drying assumptions [11].

## RESULTS AND DISCUSSION

### Process modeling results: yield and fuel quality trends

For both Japanese cedar wood chips and sugarcane bagasse, experimental results show consistent qualitative trends with increasing temperature. Solid yield decreases as temperature increases due to progressive devolatilization. In parallel, the degree of charification increases: carbon fraction rises, oxygen fraction falls, and the solid heating value increases. These patterns are consistent with the broader torrefaction and mild pyrolysis literature [9, 10].

Comparing feedstocks at the same temperature, wood chips generally exhibit higher solid yield, while bagasse tends to reach a higher charification degree (higher C fraction and lower O/C) at comparable severity. Such differences can be attributed to compositional and ash effects that influence devolatilization pathways. This observation reinforces the value of feedstock-specific (and ultimately composition-based) yield models for reliable process screening.

By-product streams (gas and condensables) increase with severity and underpin autothermal feasibility. Measured gas composition indicates that combustible species (CO, $CH_4$) become more prominent at higher temperatures, raising gas LHV and improving suitability for internal heat generation. When mapped into the process model, this shift increases Q_byprod, while decreasing solid yield reduces the energy retained in the main product. The trade-off between solid yield and autothermal heat availability therefore defines an operational "sweet spot" that depends strongly on drying and heat recovery assumptions.

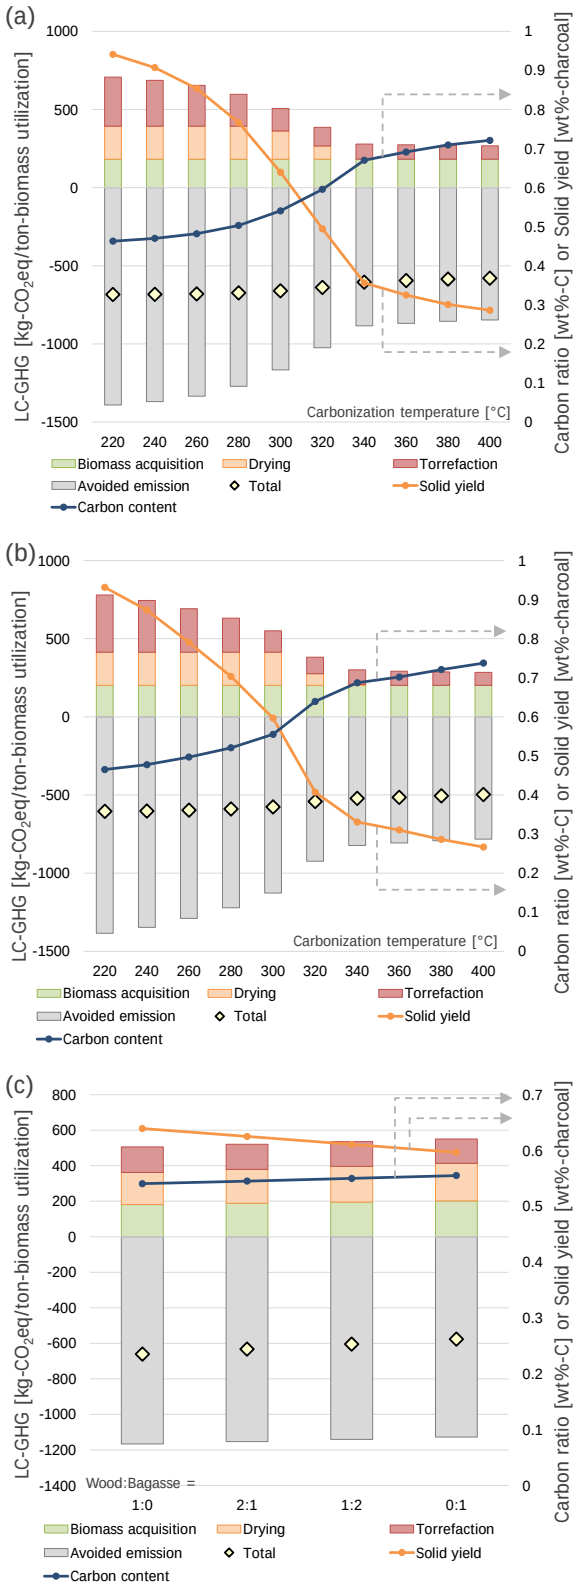

**Figure 2.** LC-GHG results (a) wood chip, (b) sugarcane bagasse, (c) combination of wood chip and bagasse.

## Life cycle GHG results

**Figure 2** summarizes LC-GHG results for (a) wood chips only, (b) bagasse only, and (c) combined operation.

For each case, the bar chart shows total LC-GHG per functional unit and the line plots indicate solid yield and degree of charification. The wood-only and bagasse-only cases show similar LC-GHG magnitudes across temperatures, suggesting that upstream differences are partially offset by differences in yield and product energy content when credits are applied.

A key operational result is the temperature threshold for autothermal feasibility. Under the baseline (middle) drying-energy case, autothermal operation—meeting all process heat demand with internally generated by-products (excluding electricity)—becomes feasible above approximately 340°C. Below this range, by-product energy is insufficient to cover drying and reactor duties, implying an external heat requirement. This threshold shifts with drying assumptions, consistent with the strong sensitivity to drying energy reported in prior torrefied pellet LCAs [11].

Across all assessed temperatures and feedstocks, total LC-GHG is negative when displacement credits are applied. The dominant driver is avoided emissions from coal substitution by charcoal on an energy basis. This result highlights the mitigation potential of converting locally available biomass into a storable, transportable solid fuel in an island context. It also clarifies the modeling dependence on the chosen use and substitution assumptions, motivating transparent reporting and scenario testing when LCAs are used for decision support.

## Discussion: implications for CAPE-supported regional design

The experimental mass–energy balances imply that, under baseline drying assumptions, autothermal feasibility is not obtained within the conventional torrefaction band (220–300°C). This does not necessarily mean that autothermal torrefaction is infeasible in practice. Instead, it emphasizes that drying and heat integration dominate the energy balance and that laboratory yields must be interpreted together with realistic process-scale drying performance and heat recovery. Adams et al. [11] explicitly varied drying energy in three cases and showed that drying assumptions can substantially change comparative outcomes; similarly, McNamee et al. highlighted that using torgas for process heat is a major lever for emission savings [12]. For Tanegashima, practical strategies such as air-drying prior to mechanical drying, using waste heat, or co-locating with heat sources could lower effective drying energy and shift the autothermal threshold.

Beyond autothermal operation, the by-product streams expand the design space for regional symbiosis. If process heat is supplied by an additional renewable source, gas and condensables need not be fully consumed internally and could be recovered as energy or upgraded products. In the Tanegashima context, demonstration activities have explored the use of torrefaction-derived fuels in practical energy applications; for example, finely ground char slurried with diesel (biomass-oil-mixture, BOM) was combusted in a commercial diesel engine to generate electricity [20]. While BOM fuel requires blending with fossil diesel and is therefore not a fully defossilized route, such demonstrations illustrate the value of flexible product portfolios and the need to evaluate multiple utilization options alongside LCA results.

Feedstock seasonality and storage are practical constraints. Bagasse is produced seasonally, and stockpiling can lead to dust, leachate, and spontaneous heating risks if unmanaged [7]. Torrefaction offers stabilization by reducing moisture and increasing hydrophobicity, enabling longer-term storage and more flexible use. For woody residues, mobilization depends on sustained forest management and logistics, which must be evaluated over long time horizons [2, 3]. A mixed-feedstock strategy can therefore improve plant utilization factors while sharing logistics and infrastructure across sectors, consistent with regional symbiosis concepts observed in Tanegashima case studies [4, 8].

From a CAPE standpoint, the main contribution is the translation of experimentally verified yields into consistent life-cycle inventories suitable for superstructure-based screening. By expressing conversion performance as temperature- and feedstock-dependent functions, the model enables rapid evaluation of alternative operating points, feedstock mixes, and product allocations under consistent assumptions. While this proceeding focuses on LC-GHG, the same inventories can be extended to additional impact categories, uncertainty propagation, and multi-objective trade-offs, supporting future CAPE-driven regional planning.

## CONCLUSION

This paper demonstrated a CAPE-supported workflow for designing and evaluating regional lignocellulosic biomass utilization based on autothermal dry torrefaction, using Tanegashima as a case study and focusing on Japanese cedar wood chips and sugarcane bagasse. Laboratory experiments (220–400°C) provided temperature-dependent yields and fuel-quality indicators for char and by-products, which were translated into a process inventory up to pelletization.

Process modeling and LCA showed a clear trade-off between solid yield and charification with increasing temperature. Under a baseline drying-energy assumption, autothermal operation becomes feasible above approximately 340°C, and the threshold is highly sensitive to drying performance. With substitution credits for coal and kerosene-equivalent fuels, LC-GHG results are negative across assessed feedstocks and temperatures, indicating substantial mitigation potential in an island context.

The results underline that drying energy and heat integration are decisive factors for both autothermal feasibility and LC-GHG outcomes. Future work will refine site-specific drying and heat-recovery assumptions, integrate the torrefaction model into a broader regional superstructure, and evaluate multi-product portfolios and seasonal feedstock allocation strategies with combined environmental and socio-economic objectives.

## ABSTRACT

This study conducted a life cycle assessment to assess and design regional symbiosis at plant-oil production. These industries face challenges including dependence on fossil fuels and the generation of underutilized by-products, while effective regional symbiosis requires the selection of diverse regional unused resources and assessment based on process models that consider future technological prospects. Mathematical models for plant-oil production were developed using industrial data from literature to calculate inventory data. The case study showed that introducing woody biomass combined heat and power reduced GHG emissions by 8% in the Cradle-to-Grave system boundary, while recycling technology for soap stock using Kolbe electrolysis achieved a 3% reduction. Regional analysis indicated that 33 prefectures in Japan could meet woody biomass demand through sustainable forestry management, potentially reducing GHG emissions in Japan by approximately 0.041%. These results suggest that regional symbiosis can enhance resource-use efficiency, reduce environmental impacts, and contribute to sustainable regions.

**Keywords**: Life Cycle Analysis, Modelling, Biomass, Energy, Materials

## INTRODUCTION

Japan has set a governmental target to achieve net-zero greenhouse gas emissions by 2050[1]. In Japan, annual greenhouse gas emission reduction targets have been steadily achieved; however, further reduction of environmental impacts will require mitigation efforts not only in large-scale industries such as power generation, petrochemicals, and steel production but also in small- and medium-scale industries operating in local regions.

Plant-based production systems, which are widely distributed across local regions of Japan, utilize plant-derived resources as feedstocks and produce plant-based products through processes such as pressing and refining. However, these processes remain highly dependent on fossil-derived energy and often generate large amounts of unused by-products, which represents a challenge for improving environmental impacts [2]. To address this issue, regional symbiosis has been proposed, in which neighboring industries mutually utilize underutilized by-products, energy, and other resources [3]. Life cycle assessment (LCA) has been widely applied to quantitatively evaluate the environmental impacts of such systems [4]. Nevertheless, previous studies have focused on limited industrial processes [5], and evaluation of technological options based on diverse regionally available resources remains insufficient.

The objective of this study is to evaluate and design regional symbiosis enabled by the introduction of new technologies into plant-oil production from a life cycle perspective. To assess the effects of technological implementation, we develop process models for both the existing plant-oil production process and newly introduced technologies and conduct life cycle assessment (LCA). Regional symbiosis can enable the utilization of underutilized regional resources that are difficult to exploit within individual industries, thereby improving resource efficiency and reducing dependence on fossil resources. Such systems have the potential to reduce regional environmental impacts while enhancing the

sustainability and socio-economic viability of local production systems.

In this study, plant-oil production is selected as the target industry. Plant-oil production facilities are widely distributed throughout Japan and already possess infrastructure for handling regional biomass resources, indicating their potential to serve as hubs for regional symbiosis. Previous studies have examined regional symbiosis using LCA, including the conceptual design of energy systems centered on sugar factories [6] and the design of energy hubs for pulp and paper mills [7]. However, evaluations based on process models that consider the selection of diverse regional resources, and the future potential of technological options remain limited. Consequently, design challenges and the environmental benefits associated with technological implementation for regional symbiosis in plant-oil production have not yet been fully clarified. As illustrated in **Figure 1**, this study assumes a regional symbiosis framework in which the introduction of new technologies utilizing regional resources into existing plant-oil production systems promotes resource circulation within the region.

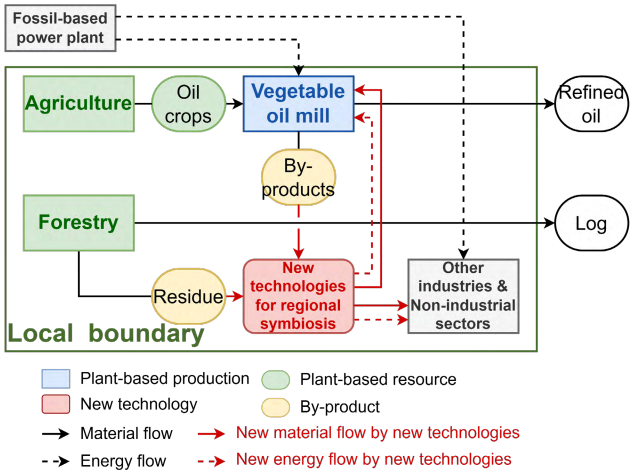

**Figure 1.** Future visions of regional symbiosis at plant-oil production

# METHOD

## Life Cycle Assessment

**Figure 2** illustrates the system boundary of the LCA case study, which assumes the introduction of a woody biomass combined heat and power (CHP) system using a steam turbine [8] and a resource recovery technology for neutralization residues soap stocks based on the Kolbe electrolysis reaction [9] into conventional plant-oil production. In the LCA, the functional unit was defined as the conversion of 1 kg of oil crops into the refined oil and a series of by-products. The system boundary was set as cradle-to-grave (excluding the use phase). The assessment indicator was greenhouse gas (GHG) emissions.

Regarding the end-of-life (EoL) of the main product (food), processes such as digestion, wastewater treatment, and sludge incineration are assumed; however, for simplicity, all carbon contained in the product was assumed to be uniformly released as $CO_2$. In contrast, plant resources were assumed to absorb $CO_2$ during cultivation, and by-products were regarded as substituting for conventional production and were therefore accounted for as negative emissions.

The production process and the newly introduced technologies were treated as foreground processes, and models were developed to enable the calculation of mass and energy balances required for the LCA. The production process model was formulated as a mathematical model capable of reproducing processes of different scales and operating conditions through parameter adjustment, based on empirical data extracted from the literature and interviews with companies. All other processes were treated as background processes, and data were obtained from IDEA ver. 3.5.1, the Japanese background LCA database [10].

## Process Modeling of Plant-oil Production

In the plant-oil production process, oil crops are separated into crude oil and oil meal through pressing and extraction. The crude oil then undergoes a degumming process, in which warm water is added to hydrate and remove hydratable phospholipids as gums. Subsequently, phosphoric acid is added to convert non-hydratable phospholipids remaining after water degumming into forms that can be more easily entrained into soapstock in the subsequent neutralization step. In the neutralization process, alkaline agents are added to remove free fatty acids as soapstock. In the bleaching process, pigments and other impurities are removed by adsorption using activated bleaching earth, and in the deodorization process, volatile and odorous compounds are removed by high-temperature steam stripping, resulting in the production of edible refined oil. The oil meal, on the other hand, undergoes a drying process and is obtained as a by-product used for animal feed [11, 12].

A mathematical model was developed based on actual industrial data extracted from the literature, including parameters such as chemical input ratios, separation ratios, and energy intensities. In addition, through interviews with companies, the model was refined to capture the specific characteristics of the industrial processes.

## Process Modeling of Emerging Technologies

### Woody Biomass CHP

Woody biomass CHP is an energy supply technology that uses wood chips as fuel. In this study, the supplied wood chips were assumed to be produced from underutilized woody resources such as thinned wood and waste wood, and a steam turbine-based CHP system

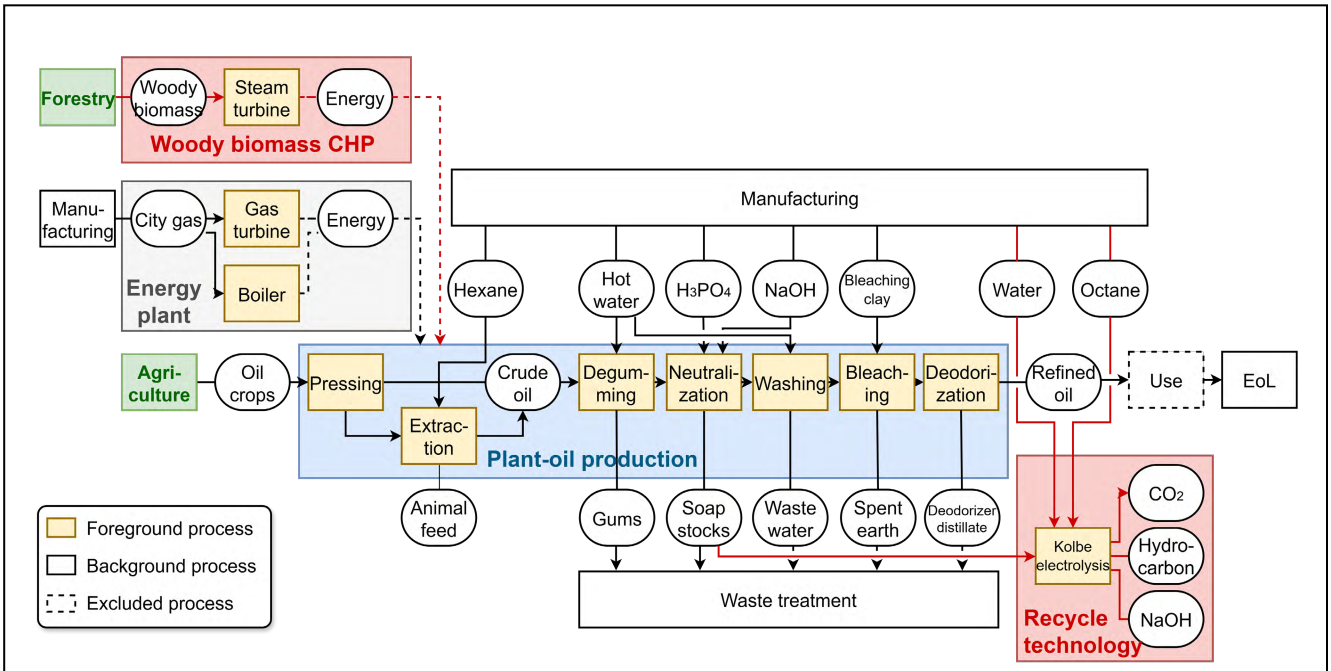

**Figure 2.** The system boundary for the cradle-to-grave assessment (excluding the refined oil use phase) of plant oil production and technology implementation. The system boundary includes, as conventional processes, oil crop cultivation, plant oil production processes, additive manufacturing, waste treatment, fossil-based energy supply, and EoL processes. In addition, as newly introduced technologies, the system includes woody biomass combined heat and power (CHP) and a recycling technology for neutralization residues using Kolbe electrolysis.
Yellow rectangles indicate foreground processes, while white rectangles represent background processes. The dotted rectangles denote processes excluded from the system boundary. Rounded rectangles indicate avoided processes, which represent conventional production substituted by the system.

was considered. The system was assumed to operate under a heat-led mode to meet the thermal demand of the process. When surplus electricity was generated, it was assumed to be exported to the grid, whereas when electricity was insufficient, it was assumed to be supplied from the grid. The fuel was assumed to be woody chips with a moisture content of 11%, produced from coniferous forests through harvesting, drying, and chipping processes. The electricity generation efficiency of the steam turbine was calculated as a function [13] of the power output, and the required amount of woody biomass was determined based on the energy demand of the process.

### Recycle Technology for Neutralization Residue

Soapstock, a residue generated in the neutralization process, poses a disposal challenge for many edible oil producers, and there is a strong demand for technologies that can both reduce environmental burdens and convert this residue into value-added products. At present, a laboratory-scale technology has been developed in which soapstock is diluted with water and subjected to electrolysis followed by separation, enabling the production of sodium hydroxide and fuel-grade hydrocarbons [9]. The overall reaction of the process is expressed by Eq. (1), yielding a 48 wt% aqueous sodium hydroxide solution and long-chain hydrocarbons for fuel, while carbon dioxide and hydrogen are purged as by-products.

$$2RCOONa + 2H_2O \rightarrow RR + 2NaOH + H_2 + 2CO_2$$

Based on experimental data and empirical data from other industrial processes, a conceptual design of the separation system including recycle streams was developed for industrial-scale implementation [14]. Material and energy balances were calculated using a process simulator. For thermal energy analysis, pinch analysis was applied [15], and the Grand composite curve was constructed. The minimum heating requirement derived from the analysis was assumed to represent the additional heat demand associated with the introduction of the resource recovery technology.

## RESULTS AND DISCUSSIONS

### Process Flow Analysis

Using the mathematical model, the material and energy balances of the plant oil production system were calculated as shown in **Figure 3**. The material flow analysis indicates that approximately 32% of the oil crops are converted into refined oil, while about 54% are converted into animal feed. The flow rate of soapstock, which serves as the feedstock for the resource recovery technology based on Kolbe electrolysis, corresponds to

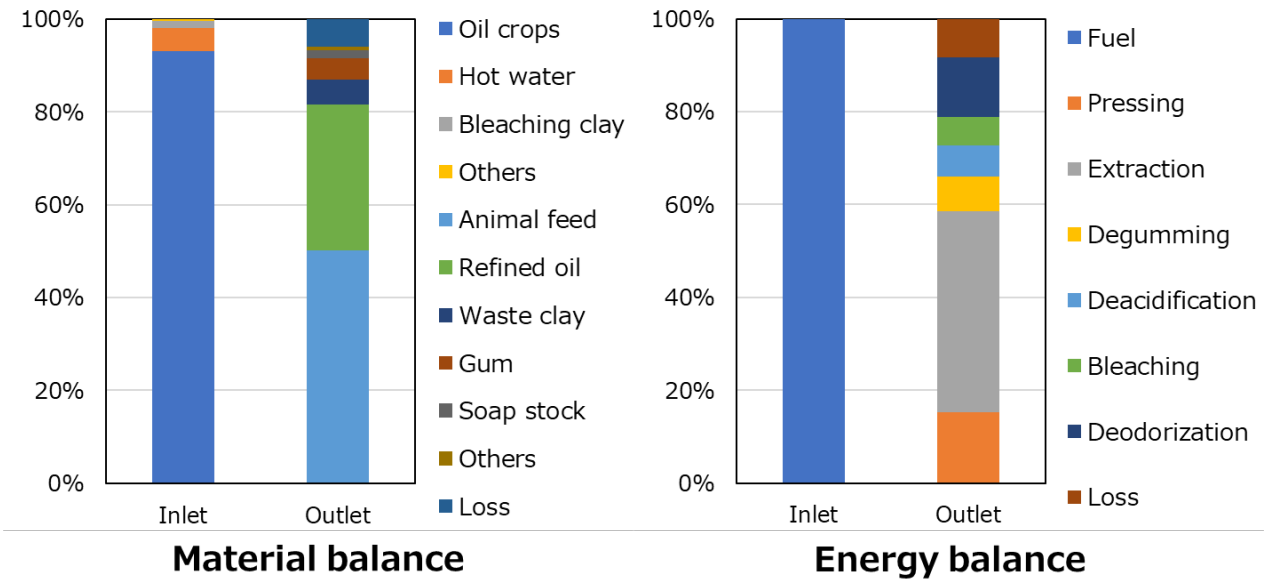

**Figure 3.** Material (left) and energy (right) balance calculated from flow analysis of plant-oil production based on mathematical model

approximately 1.8% of the oil crop input.

The energy flow analysis reveals that the overall heat-to-power ratio of the plant oil production process is approximately 3.4, indicating a heat-intensive system. A large share of the thermal energy demand arises in the extraction process, with particularly high heat consumption in the drying process for converting oilseed meal into animal feed. Regarding temperature levels of the thermal demand, the deodorization tower operates at approximately 210–240 °C, whereas most of the other processes require relatively low temperatures of around 70–90 °C, at which thermal degradation of plant oil is minimal.

## Life Cycle Assessment

**Figure 4** presents the GHG emission results for plant oil production with and without technology implementation. The conventional process results in approximately 1.32 kg-$CO_2$ eq per kg of oil crop. The introduction of woody biomass CHP reduces GHG emissions by 8%, the resource recovery technology by 3%, and the combined implementation of both technologies by 12%.

The reduction achieved by woody biomass CHP can be attributed to the decarbonization of the fuel supply, as the GHG emissions from biomass combustion are offset by $CO_2$ uptake during the growth of the woody biomass. In addition, because the CHP system is assumed to operate in a heat-led mode, surplus electricity that cannot be fully utilized within the plant oil production process is exported to the grid and substitutes for grid electricity, which is another major contributor to the emission reduction. For the resource recovery technology, soapstock is converted into sodium hydroxide and long-chain hydrocarbons for fuel. These products are assumed to substitute for their conventional counterparts, and the resulting substitution effects are reflected as avoided emissions.

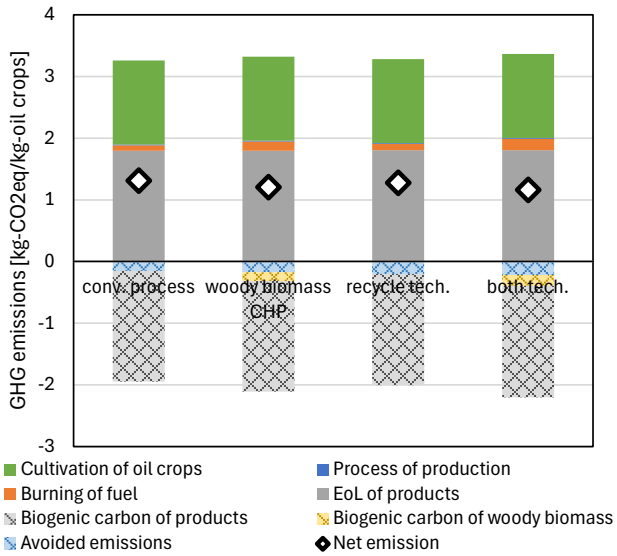

**Figure 4.** GHG emissions of plant-oil production and introduction of technology

## Regional Symbiosis with Forestry in Japan

Next, regional symbiosis between forestry and plant oil production was examined by comparing woody biomass availability and demand on a prefectural basis. The demand was defined as the woody biomass required if all existing plant oil factories in Japan were assumed to adopt the same process as the plant oil production model

and to introduce heat-led woody biomass CHP systems. The demand was calculated based on the plant oil production model and national statistics [16]. The supply, on the other hand, was defined as the required harvesting volume to equalize forest age-class distributions under a sustainable long-term forestry plan [17], assuming that woody biomass is supplied within the same prefecture where plant oil production facilities are located. As shown in **Figure 5**, in regions where the demand-to-supply ratio is less than or equal to 1, excluding Ibaraki, Osaka, and Kagawa etc. prefectures, the woody biomass demand does not exceed the required harvesting volume. This suggests that the utilization of woody biomass CHP can generate stable long-term demand for woody biomass as fuel and may contribute to promoting harvesting and replanting cycles based on long-term forestry plans.

Furthermore, because the CHP systems are assumed to operate in a heat-led mode, surplus electricity is generated from woody biomass CHP depending on the scale of the plant oil production facilities, as not all electricity can be fully consumed within the plants. When this surplus electricity is assumed to be supplied within the local region, it was found that, in all prefectures, the existing electricity demand substantially exceeds the amount of surplus electricity. This indicates that GHG emissions can be reduced by supplying woody biomass-derived energy to both the energy demand of plant oil production and a portion of regional electricity demand, thereby substituting for existing fossil-based energy.

Based on these assumptions, regional symbiosis of plant oil production could achieve an annual GHG emission reduction of approximately 4.19 × $10^5$ t-$CO_2$ eq nationwide, which corresponds to about 0.041% of Japan's annual GHG emissions [18].

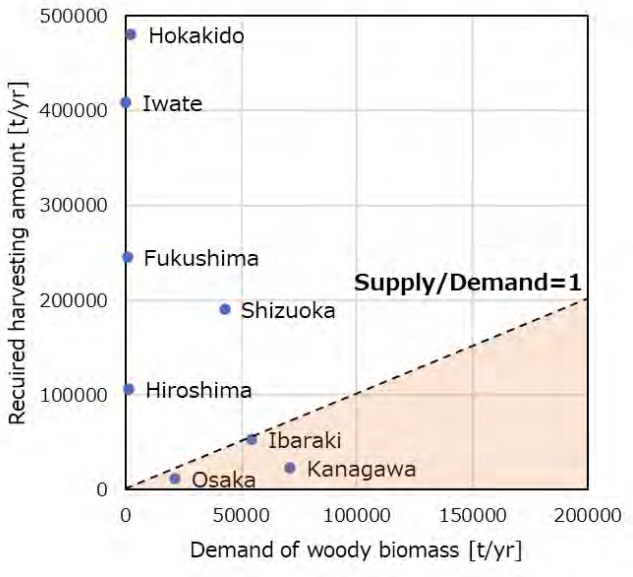

**Figure 5.** Comparison between woody biomass demand and required harvesting volume in Japan

## CONCLUSIONS

In this study, as a case study of regional symbiosis at plant-oil production, mathematical models of a plant oil production process and newly developed technologies were developed to consider their future potential, regional resource supply–demand balance, and geographical constraints. Using these models, LCA was conducted assuming the introduction of woody biomass CHP and a resource recovery technology for neutralization residues in plant oil production. The evaluation confirmed that regional symbiosis of plant-oil production can provide benefits such as environmental impact reduction.

Plant oil production is energy-intensive and is often located in rural areas. In Japan, where woody biomass from forestry is abundantly available, coupling plant oil production with woody biomass CHP represents a feasible pathway for regional symbiosis and decarbonization.

The recycle technology using Kolbe electrolysis process can effectively convert neutralization residues into valuable products; however, the total amount of such residues is relatively small compared to the quantity of refined oil, as indicated by the process model. Consequently, its overall contribution to emission reduction is limited, and its feasibility is expected to depend on the scale and conditions of individual production sites.

## ACKNOWLEDGEMENTS

## ABSTRACT

This paper presents OpenAD-lib, an open-source Python framework for anaerobic digestion (AD) digital twins, unifying mechanistic models, machine learning (ML) surrogates, and model predictive control (MPC) within a modular ecosystem. OpenAD-lib addresses the critical fragmentation in AD digitalisation by bridging mechanistic and data-driven paradigms under explicit uncertainty. By integrating uncertainty-aware feedstock characterisation with robust process control, the platform enables the transition from isolated research tools to fully integrated digital twins, delivering economic and environmental value in AD systems.

**Keywords**: Digitalisation, Bioenegry, Anaerobic digestion, Digital twins, Uncertainty quantification, Model Predictive Control, Machine learning, Open-source framework

## INTRODUCTION

Anaerobic digestion (AD) is critical to the UK's energy transition and circular economy, producing renewable biogas and nutrient-rich digestates that enhance soil health and carbon sequestration [5]. However, most AD facilities lack production-ready computational tools integrating mechanistic modelling with data-driven methods, resulting in passive monitoring, sub-optimal biogas recovery, and underutilised operational potential.

Since the introduction of Anaerobic Digestion Model No. 1 (ADM1) in 2002 [2], mechanistic AD modelling has advanced substantially, with ADM1 establishing the international reference standard for capturing complex substrate heterogeneity, microbial dynamics, and inhibitory mechanisms across 32 state variables [1]. However, four interconnected limitations impede sector digitalisation. First, the AD modelling landscape remains fragmented [5]. No unified platform integrates mechanistic models, ML surrogates, and control strategies. Practitioners assemble tools ad-hoc with divergent input/output conventions, and the absence of standardised feedstock descriptors across six documented characterisation methodologies for the ADM1 inputs [13] necessitates resource-intensive site-specific calibration, preventing model transfer between facilities. Second, existing tools deliver deterministic predictions without quantifying uncertainty or confidence bounds. Real-time operational decisions including biogas commitments and control setpoints require probabilistic guarantees rather than nominal estimates. Third, mechanistic and data-driven components operate in isolation. Recent advances including Long Short-Term Memory networks (LSTM) surrogates [9], Physics-Informed Machine Learning (PIML)[12], and multi-task Gaussian processes [4] (MTGP) demonstrate that hybrid approaches achieve both computational efficiency and mechanistic fidelity, yet no integrated commercial or open-source platform exists, forcing practitioners to choose between high-fidelity simulation or fast data-driven methods [5]. Finally, scattered AD models [4, 7, 9, 12] across disconnected repositories lack unified access, standardised comparison frameworks, and industrial-grade implementation practices required for operational deployment.

OpenAD-lib, developed within the Supergen Bioenergy Impact Hub (SBIH) [11] is an open-source Python framework that bridges mechanistic understanding with data-driven approaches under explicit uncertainty. The framework integrates feedstock characterisation, mechanistic models, ML surrogates, and control strategies in seamless workflows (unified platform), well-documented, comprehensively tested, and designed for industrial extensibility (production-ready), propagates uncertainty explicitly from feedstock characterisation

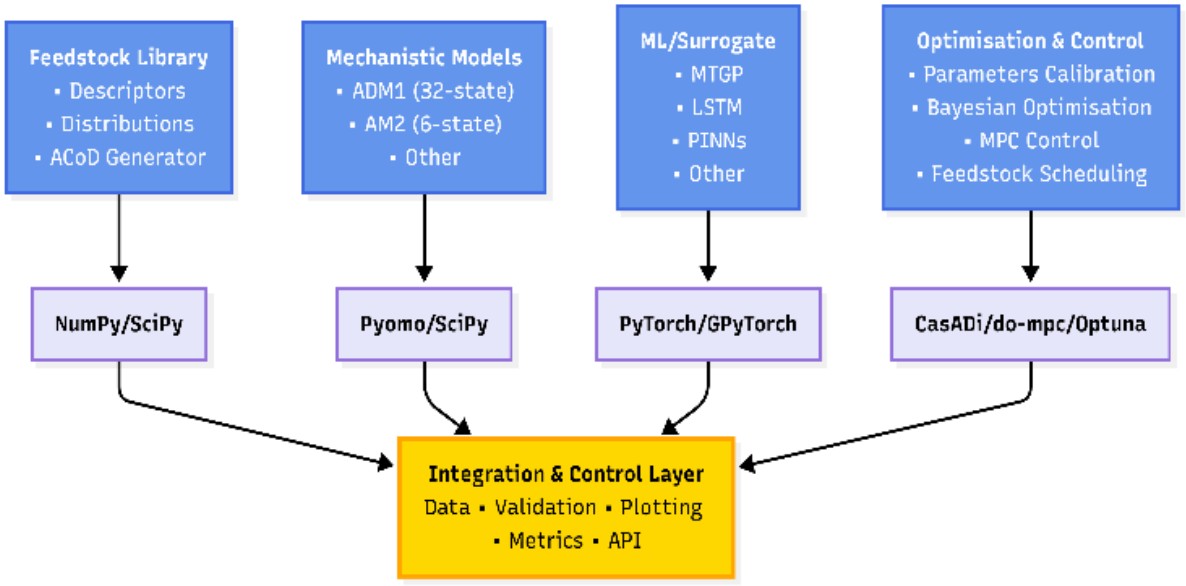

**Figure 1**. OpenAD-lib four-layer modular architecture.

through mechanistic simulation, surrogate approximation, and control optimisation to enable quantified confidence in operational decisions (uncertainty-aware by design), and enables users to select components (ADM1-only, surrogate-only, or hybrid approaches) matching their computational and accuracy requirements, avoiding unnecessary complexity while enabling gradual adoption (modular composability). Beyond AD, OpenAD-lib is designed for extensibility to complementary bioenergy pathways (gasification, pyrolysis) aligned with SBIH's partnership ecosystem.

The paper is organised as follows: Section 2 presents the software architecture, Section 3 describes key features and implementation, Section 4 demonstrates a case study, and Section 5 provides conclusions and future work.

## SOFTWARE ARCHITECTURE

OpenAD-lib implements a four-layer modular architecture that enables uncertainty propagation from feedstock characterisation through process prediction to optimisation and control. Figure 1 presents the layered technology stack of OpenAD-lib, demonstrating how the framework leverages Python's scientific computing ecosystem to integrate each layer within a cohesive software architecture. This layered design philosophy reflects a systems level approach to digitalisation of AD processes, enabling users to employ components independently or in combination to accommodate diverse use cases ranging from offline feasibility analysis to real-time adaptive control:

- **Layer 1 -Feedstock Characterisation Library:** Encodes statistical representations of feedstock properties.
- **Layer 2 -Mechanistic Modelling:** Wraps standard solvers for ADM1 (32-states) and AM2 (reduced-order only 6-states) simulations.
- **Layer 3 -ML/Surrogate Models:** Provides pre-configured PyTorch modules for fast inference.

### Layer 4- Optimisation and Control: Integrates optimization solvers for calibration and MPC.

The modular interconnection of these layers is orchestrated through a unified *Integration & Control Layer* that manages data flow and uncertainty propagation across all operational modes. The OpenAD-lib can be accecced in Github via the following link: https://github.com/benmola/OpenAD-lib

## IMPLEMENTATION AND KEY FEATURES

### Feedstock Characteristics Library

Reliable characterisation of feedstock properties is fundamental to predictive accuracy in AD modelling [6]. OpenAD-lib addresses this through a structured feedstock library that captures the variability inherent in real-world substrates and translates readily available measurements into the required inputs for the mechanistic models. The library integrates comprehensive representations of diverse feedstock types commonly encountered in typical UK AD sites.

**Table 1:** OpenAD-lib Feedstock Library: Data Coverage Summary

| Feedstock Category | Included Feedstocks |
|---|---|
| **Agricultural/ Energy Crops** | Maize Silage, Wholecrop Cereals, Grass, Fodder Beet |
| **Agro-industrial** | Rice Bran, Corn Gluten/Rapemeal, Crimped Wheat |
| **Food Processing** | Lactose (Whey), Apple Pomace, Potatoes |
| **Manure & Residues** | Chicken Litter, Animal Manure |

**Table 2:** Standardised descriptor set for uncertainty-aware feedstock characterisation.

| Symbol | Descriptor | Unit |
|---|---|---|
| TS | Total Solids | Mass % or kg $m^{-3}$ |
| VS | Volatile Solids | g $kg^{-1}$ TS or kg $m^{-3}$ |
| $COD_t$ | Total COD | kg COD $m^{-3}$ |
| $COD_{s,p}$ | Soluble / Particulate COD | kg COD $m^{-3}$ |
| BMP | Biochemical Methane Potential | NmL $CH_4$ $kg^{-1}$ VS |
| $f_{bio}$ | Biochemical Composition | g $kg^{-1}$ or kg $m^{-3}$ |
| $C:N$ | Carbon-to-Nitrogen Ratio | Molar ratio |
| TAN | Total Ammonia Nitrogen | g N $m^{-3}$ |
| $V_{vfa}$ | Volatile Fatty Acids | kg $m^{-3}$ |

## Feedstock Characterisation and Uncertainty Representation

The OpenAD-lib feedstock library consists of 12+ substrates consitsting of agricultural residues, energy crops, agro-industrial by-products and food waste streams as shown in Table 1. To capture the inherent variability of biological substrates, OpenAD-lib encodes feedstock properties using the standardised descriptor set detailed in Table 2. Unlike deterministic approaches, the framework models these inputs as probabilistic distributions ($x_{feedstock} \sim \mathcal{P}(\theta)$), parametrised via Maximum Likelihood Estimation (MLE) using data from multi-facility laboratory measurements, literature meta-analysis, and expert elicitation. To ensure physical consistency during ensemble generation, the library automatically assigns Beta distributions to bounded fractions (e.g., biodegradability coefficients) and Log-normal or Gamma distributions to strictly positive quantities (e.g., TS, VS, COD), thereby preventing non-physical sampling while facilitating the propagation of measurement uncertainty into downstream process control.

## Mechanistic Modelling

The mechanistic modelling layer simulates AD dynamics using coupled ordinary differential equation (ODE) systems [1]. OpenAD-lib adopts a multi-model approach, offering both comprehensive and reduced-order formulations to balance process fidelity with computational efficiency for varying application requirements. The complex nonlinear dynamics are represented by a general state-space mass balance equation [1]:

$$\dot{x} = D(x_{in} - x) + Kr(x) \quad (2)$$

where $x \in R^n$ is the state vector of concentrations were is n is the number of the model state variables. D is the dilution rate (scalar or diagonal matrix, $\frac{Q_{in}}{V}$ where $Q_{in}$ is the flow rate and V is the reactor volume). $x_{in}$ is the vector of influent concentrations. K is the stoichiometric matrix containing yield coefficients. r(x) is the vector of kinetic reaction rates (Monod/inhibition functions). The mechanistic layer provides Python wrappers for the ADM1 and the reduced-order AM2 model. The engine uses SciPy/Numpy for standard simulation and Pyomo/CasADi for symbolic gradient-based optimization tasks. OpenAD-lib implements the ADM1 as the primary high-fidelity representation. The implementation follows [2, 7] comprising a system of 32 ($x \in R^{32}$) coupled ODEs that describe seven biochemical pathways. ADM1 offers exceptional detail for hypothesis testing and steady-state design [2]. However, the requirement to estimate ~100 parameters and the computational stiffness of the 32-state system make it challenging for real-time control applications or scenarios requiring thousands of iterative simulations [1, 3]. To address the control-oriented limitations of ADM1, OpenAD-lib incorporates the Anaerobic Model for Control (AMOCO), hereafter referred to as the AM2 model [3]. AM2 aggregates the complex dynamics of ADM1 into a two-step biological process (acidogenesis and methanogenesis) governed by two lumped biomass populations. The AM2 dynamics follow the same general mass balance structure as in Eq (2), but with only 6 state variables ($x \in R^6$). A major barrier in applying mechanistic models is the complex mapping required to convert routine physicochemical measurements (e.g., TS, VS, COD) into the state variables required by ADM1/AM2. To resolve this, OpenAD-lib provides a standardised framework that mathematically transforms available feedstock data into stoichiometrically consistent ADM1 input fractions, ensuring mass conservation (COD, Nitrogen) across the model interface [6]. The framework also supports other widely-adopted characterisation protocols depending on available data fidelity [13]. For facilities operating with substrate mixtures, the library implements a mixing module that aggregates individual feedstock descriptors. Once

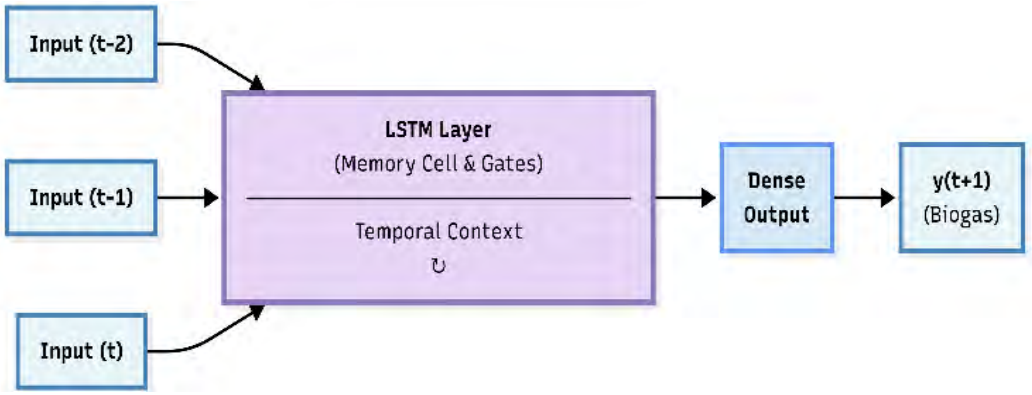

**Figure 2.** LSTM Architecture (Temporal Forecasting) [9].

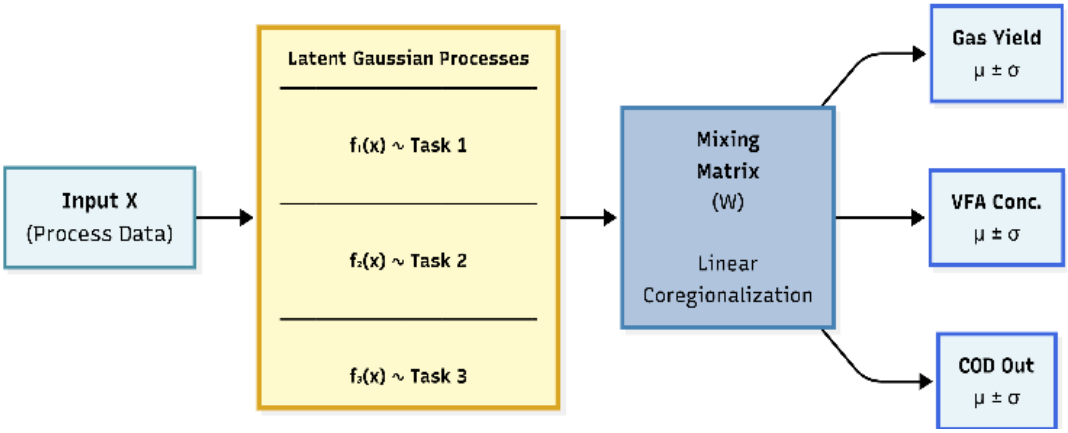

**Figure 3.** MTGP Architecture (Multi-OUTPUT & Uncertainty) [4].

characterised, the composite influent state vector $x_{mixture}$ is computed via weighted averaging based on volumetric or mass flow ratios ($w_i$) :

$$x_{mixture} = \sum_{i=1}^{N} w_i x_i \quad \text{with} \quad \sum_i w_i = 1 \tag{3}$$

This formulation preserves the mass balance of all state variables while naturally propagating the uncertainty from individual substrate characterisations to the final blended influent. By providing a single, standardised interface to multiple established characterisation protocols, OpenAD-lib removes the historical barrier whereby practitioners implemented ad-hoc, undocumented conversions from measurements to ADM1 inputs, often introducing unquantified error and reducing model transparency [6, 13].

## ML/Surrogate Models

The ML surrogate approximation problem is formulated as learning an efficient mapping:

$$\hat{y} = \mathcal{S}(x; \phi) \tag{4}$$

where $\mathcal{S}$ denotes the learned surrogate function parameterised by $\phi$ (e.g. neural network weights, Gaussian process hyperparameters), and the ML surrogate is trained to approximate outputs $\hat{y}$ (e.g. cumulative methane/biogas production, VFA concentration trajectory, digestate composition) given inputs $x$ (real system data such as feedstock composition and feeding, operating conditions). However, ML surrogates require hyperparameter tuning of the network and it remains a "black box" approach. OpenAD-lib serves as a repository for ML surrogates tailored to AD and biogas production forecasting. Currently, the framework implements two validated models: LSTM [9] and MTGP [4], both developed by the authors and natively integrated into the library. Future versions will progressively incorporate additional surrogate architectures from peer-reviewed studies in the AD and bioenergy domain. The LSTM (Figure 2) utilises a many-to-one architecture, ingesting a sliding window of historical operational data (e.g., 30 days) to explicitly model the retention time lag, predicting future yield based on past feeding trends [9]. In contrast, the MTGP (Figure 3) utilises a non-recurrent structure designed for robust state estimation. It maps current

process inputs to multiple correlated outputs (Gas, Stability, Effluent) through a set of shared latent Gaussian functions. Crucially, the MTGP output layer includes a covariance term, generating confidence intervals (shaded regions) that quantify the uncertainty of the prediction [4]. To address the computational stiffness of ODE solvers, OpenAD-lib provides native PyTorch modules that share the same API as the mechanistic models. To synergise the interpretability of mechanistic descriptions with the fitting power of deep learning, the library implements a Physics-Informed Machine Learning (PIML) framework. As illustrated in Figure 4, this hybrid approach integrates the "Mechanistic Model" (ADM1 or AM2) directly into the learning loop of the "ML Model." By embedding governing ODEs as physical regularisation terms or using mechanistic simulations to generate synthetic pre-training data, the framework constrains the neural network to biologically plausible solutions [12]. This interaction creates an "Improved Model" that balances the high fidelity of mass-balance equations with the computational speed of data- driven inference. The implementation supports "grey-box" configurations where the ML component compensates for unmodelled phenomena (e.g., temperature shocks) while the physical component guides extrapolation in data-sparse regimes, preventing the prediction of chemically impossible states (e.g., negative concentrations) outside the training domain.

## Optimisation and Control

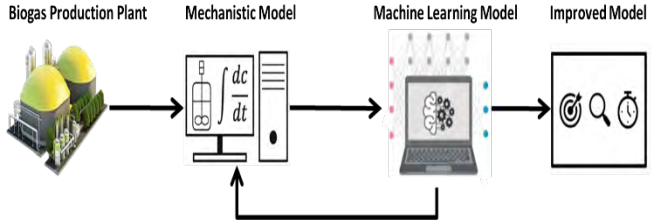

**Figure 4.** Physics-Informed Machine Learning workflow.

For real-time process optimisation and control, OpenAD-lib integrates a modular control layer designed to be model-agnostic. This architecture allows users to deploy any calibrated model, whether a mechanistic system (AM2, ADM1) or a data-driven surrogate (LSTM, MTGP) as the internal prediction engine ($f_{model}$) without altering the control logic.

### Automated Calibration and Tuning

Prior to deployment, the library leverages the *Optuna* framework [8], a state-of-the-art Bayesian optimisation library to automate parameter estimation. For mechanistic models, this involves identifying kinetic constants ($\mu_{max}, K_s$), while for ML surrogates, it tunes architectural hyperparameters (e.g., learning rate, hidden layers). The library utilises the Tree-structured Parzen Estimator (TPE), a Bayesian optimisation algorithm that constructs probabilistic density estimates of promising versus unpromising parameter regions [8]. TPE is chosen for its ability to converge in significantly fewer iterations than random search [8]. The objective is to minimise the deviation between simulated outputs and experimental time-series data:

$$J_{calib}(\Theta) = \sum_{t=1}^{T} ||y_{meas}(t) - y_{sim}(t, \Theta)||^2 \quad (4)$$

where θ is the vector of unknown kinetic parameters. This automated routine ensures that the internal model accurately reflects the biological reality of the specific digester before control authority is granted.

### Model Predictive Control (MPC) Formulation

The control layer wraps the *do-mpc* library [10] to solve nonlinear Optimal Control Problems (OCP). The controller discretises the process dynamics using orthogonal collocation on finite elements, ensuring numerical stability even for stiff biological systems (e.g., rapid pH changes). At each sampling instant $k$, the solver uses the calibrated prediction engine ($f_{model}$) to compute a sequence of optimal control inputs $u$ (e.g., dilution rate, feedstock blend) over a finite horizon $N_p$:

$$\min_{u} J_{MPC} = \sum_{k=0}^{N_p} \left(l(x_k, u_k)\right) + V\left(x_{N_p}\right) \quad (5)$$

### Subject to:

- **Model Dynamics:** $x_{k+1} = f_{model}(x_k, u_k)$ (Mechanistic ODEs or ML Inference)
- **Path Constraints**: $g(x_k) \leq 0$ (e.g., $pH > 6, VFA < 2000\ mg/L$)
- **Input Bounds:** $u_{min} \leq u_k \leq u_{max}$

where $l(x_k, u_k)$ is the running cost (penalising deviation from setpoints or maximising yield) and $V\left(x_{N_p}\right)$ represents the terminal cost, which penalises the final state deviation to ensure infinite-horizon stability. The optimisation problem is transcribed into a Non-Linear Programming (NLP) problem via CasADi and solved using IPOPT implemented within the do-mpc library [10]. The implementation natively supports two configurable control strategies: i) Yield Maximisation: the stage cost is defined to maximise energy recovery ($J = -Q_{gas}$), driving the system to the highest loading rate possible within stability constraints. ii) Setpoint Tracking: the controller minimises deviations from a reference trajectory ($J = ||y - y_{ref}||^2$), useful for maintaining effluent quality standards (e.g., COD limits).

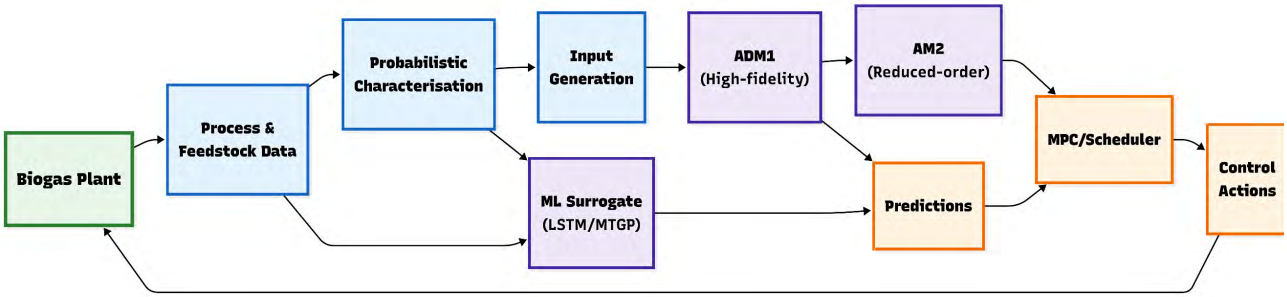

**Figure 5:** OpenAD-lib framework architecture showing the integrated workflow from feedstock characterization through mechanistic models, ML surrogates to control with closed-loop feedback.

## CASE STUDY

We present a comprehensive case study of a co-digestion biogas plant to showcase the 'plug-and-play' nature of the OpenAD-lib ecosystem. This digital twin integrates the entire process pipeline, transforming sparse feedstock inputs into optimised control trajectories. To

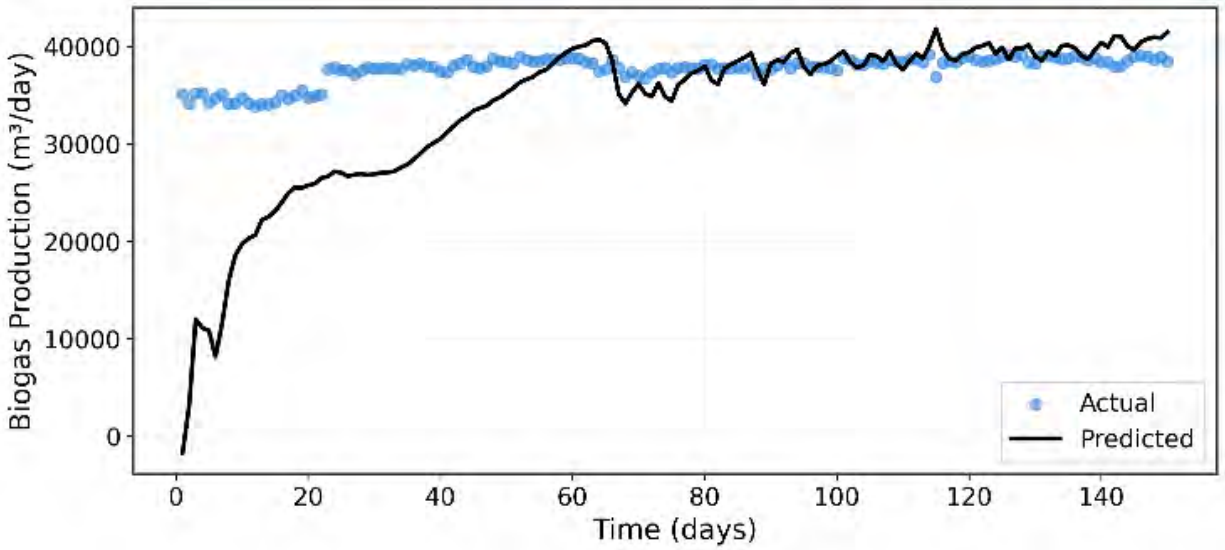

**Figure 7.** ADM1 mechanistic simulation validation.

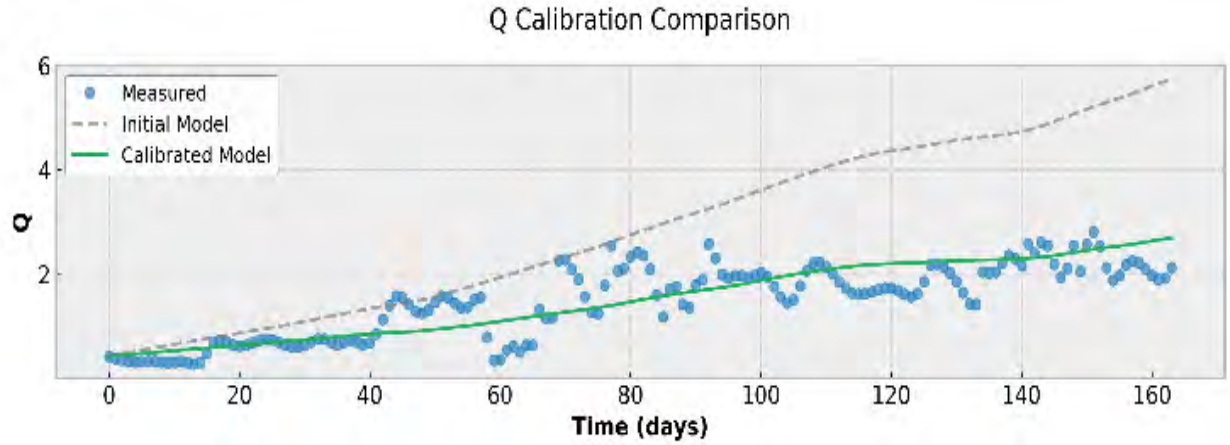

**Figure 8.** Tune simplified model to plant data with optimised parameters, before/after comparison.

validate the framework across varying degrees of information availability, the case study leverages a multi-source data strategy: it combines real-world sensor readings with synthetic data generated to simulate rare operational events, alongside standard datasets adopted from the original manuscripts of the ADM1/AM2 and MTGP /LSTM models [2, 3, 4, 9]. This hybrid approach ensures the digital twin is tested against both theoretical baselines and realistic operational noise. Figure 5 outlines the complete architecture and data flow of this integrated workflow.

## Phase 0: Probabilistic Feedstock Characterisation

This phase Handles sparse user measurements with library uncertainty filling. Figure 6 shows the probabilistic feedstock characterisation with sparse user measurements (3-8 samples) combined with library-filled distributions for TS, VS, BMP, and COD parameters.

```
import openad_lib as openad
# Initialize feedstock library
lib = openad.FeedstockLibrary()
# User provides LIMITED measurements (real-
istic scenario)
user_maize_data = {
 'ts': [310, 315, 308], # Only 3 TS measure-
ments from lab
 'bmp': [285, 300, 293, 290, 295, 292, 298,
294] # 8 BMP measurements
# Missing: vs, cod_total, proteins, lipids
}
# Library fills missing parameters automati-
cally
maize_prob = lib.get_probabilistic("Maize",
user_data=user_maize_data)
```

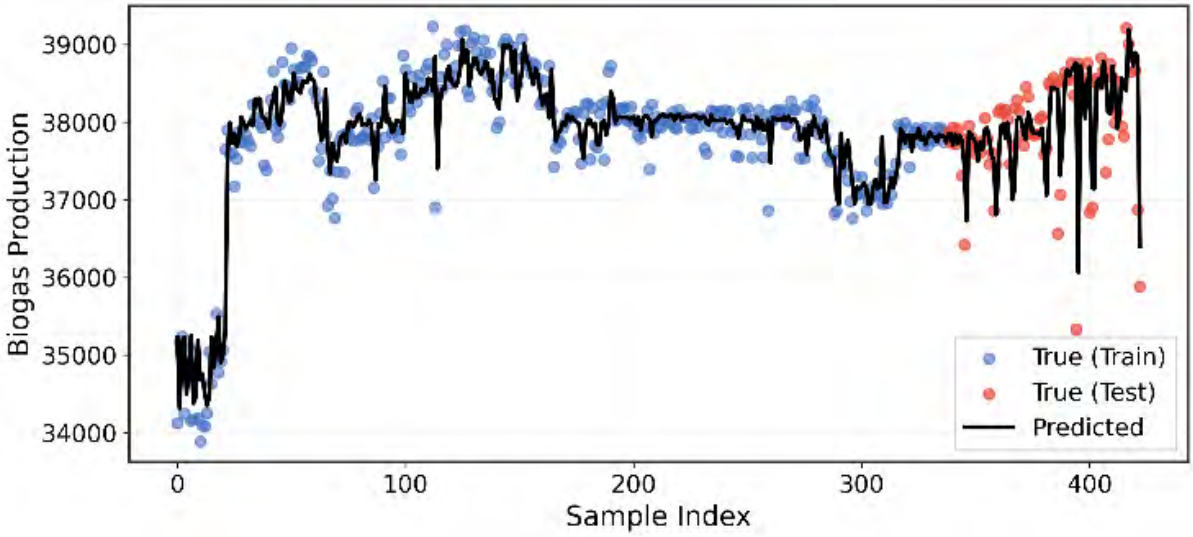

**Figure 9.** LSTM biogas production predictions.

```
# Generate ensemble for uncertainty propaga-
tion
maize_ensemble = maize_prob.sample(n=500,
random_state=42)
```

## Phase 1: ADM1 Mechanistic Baseline

After generating the ADM1 model inputs from the probabilistic characterisation we establish the physics-based understanding by running ADM1 simulations and compare the results of the measured and simulated outputs as shown in Figure 7.

```
# Generate influent from feedstock ratios
influent_df = openad.acod.generate_influ-
ent_data(feedstock_data)
# Run ADM1 simulation (32 states)
adm1_model = openad.ADM1Model()
results = adm1_model.simulate(influent_df)
# Evaluate performance
metrics = openad.utils.metrics.compute_met-
rics(y_true, y_pred)
```

## Phase 2: AM2 Parameters Calibration

In this step the AM2 model calibration using Optuna is achieved. Figure 8 show a comparison of pre-calibration predictions of biogas production showing poor fit versus post-calibration performance after 30 optimisation trials.

```
# Calibrate with Optuna (30 trials)
calibrator = openad.AM2Calibrator(am2_model)
best_params = calibrator.calibrate(
 params_to_tune=['m1', 'K1', 'm2', 'Ki',
'K2'], n_trials=30)
```

**Figure 8.** Tune simplified model to plant data with optimised parameters, before/after comparison.

## Phase 3A: LSTM Time Series Prediction

LSTM time-series prediction for biogas production with 30-day lookback window. Figure 9 show the results with training phase (blue, days 0-60) demonstrates model learning on historical feeding patterns. Test phase (orange, days 60-90) validates generalisation capability. LSTM architecture: input dimension = 6 (operational + feedstock features), hidden dimension = 24, training epochs = 30 as shown in the code below.

```
# Create LSTM model
lstm = openad.LSTMModel(input_dim=6, hid-
den_dim=24)
# Prepare time series with lags
X, y, dataset = lstm.prepare_time_se-
ries_data(data, features, target, n_in=1)
# Train and evaluate
lstm.train(X_train, y_train, epochs=30)
metrics = lstm.evaluate(X_test, y_test)
```

## Phase 3B: Multi-Task GP with Uncertainty

Next, multi-output prediction with confidence intervals using the MTGP of three correlated outputs with uncertainty quantification is shown. Figure 10 presentes the results of (a) soluble COD (SCOD_out) predictions with 95% confidence intervals (shaded region) achieving 94% empirical coverage; (b) VFA concentration predictions capturing process dynamics; (c) biogas production rate with mean ± 2σ bounds.

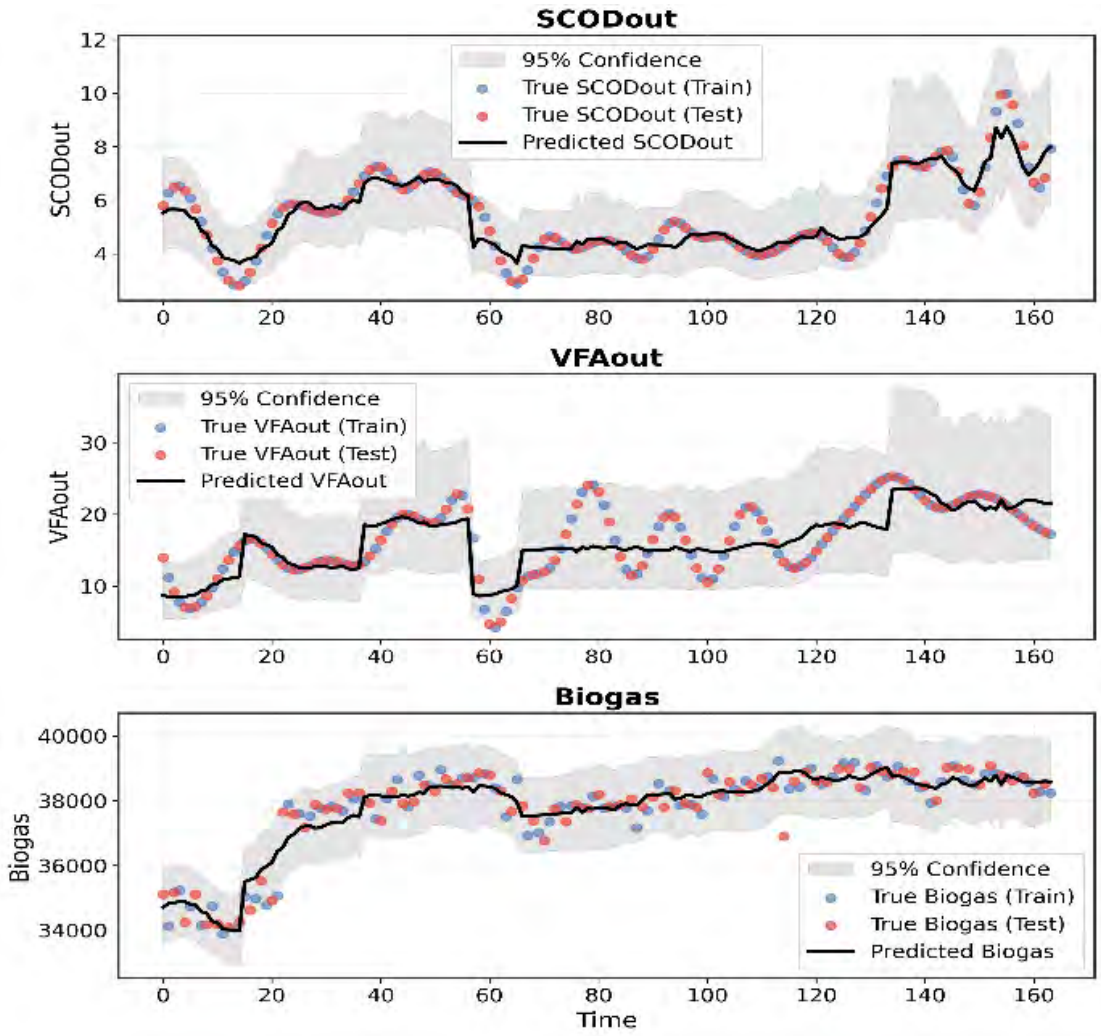

**Figure 10.** MTGP OF SCOD, VFA, and biogas with 95% confidence intervals.

```
# Initialize MTGP (3 outputs: SCOD, VFA, Bi-
ogas)
mtgp = openad.MultitaskGP(num_tasks=3,
num_latents=3)
# Train and predict with uncertainty
mtgp.train(X_train, Y_train, epochs=300)
mean, lower, upper = mtgp.predict(X_test,
return_std=True)
```

## Phase 4A: MPC Biogas Maximisation

For control, MPC for maximum biogas production. Tow-panel trajectory showing (Figure 11): (a) optimal dilution rate (control input) computed at each MPC step subject to process constraints; (b) biogas production increase from 0.001 L/d (baseline) to 0.03 L/d under optimal feeding strategy. MPC configuration: prediction horizon = 10 steps, control update frequency = 1 day, with AM2 internal model.

```
# Setup MPC controller
mpc = openad.AM2MPC(params)
mpc.setup_controller(
 horizon=10,
 objective_type='maximize_biogas',
 D_max=0.5
)
# Run closed-loop simulation
for k in range(30):
 u_opt, y_next =
mpc.run_step(S1in_val=S1in_k, pH_val=pH_k)
```

## Phase 4B: MPC VFA Tracking

MPC for VFA concentration setpoint tracking to maintain process stability. Figure 12 demonstrates: (a) VFA concentration regulated at 2.0 mmol/L target setpoint (dashed line) with tight tracking despite

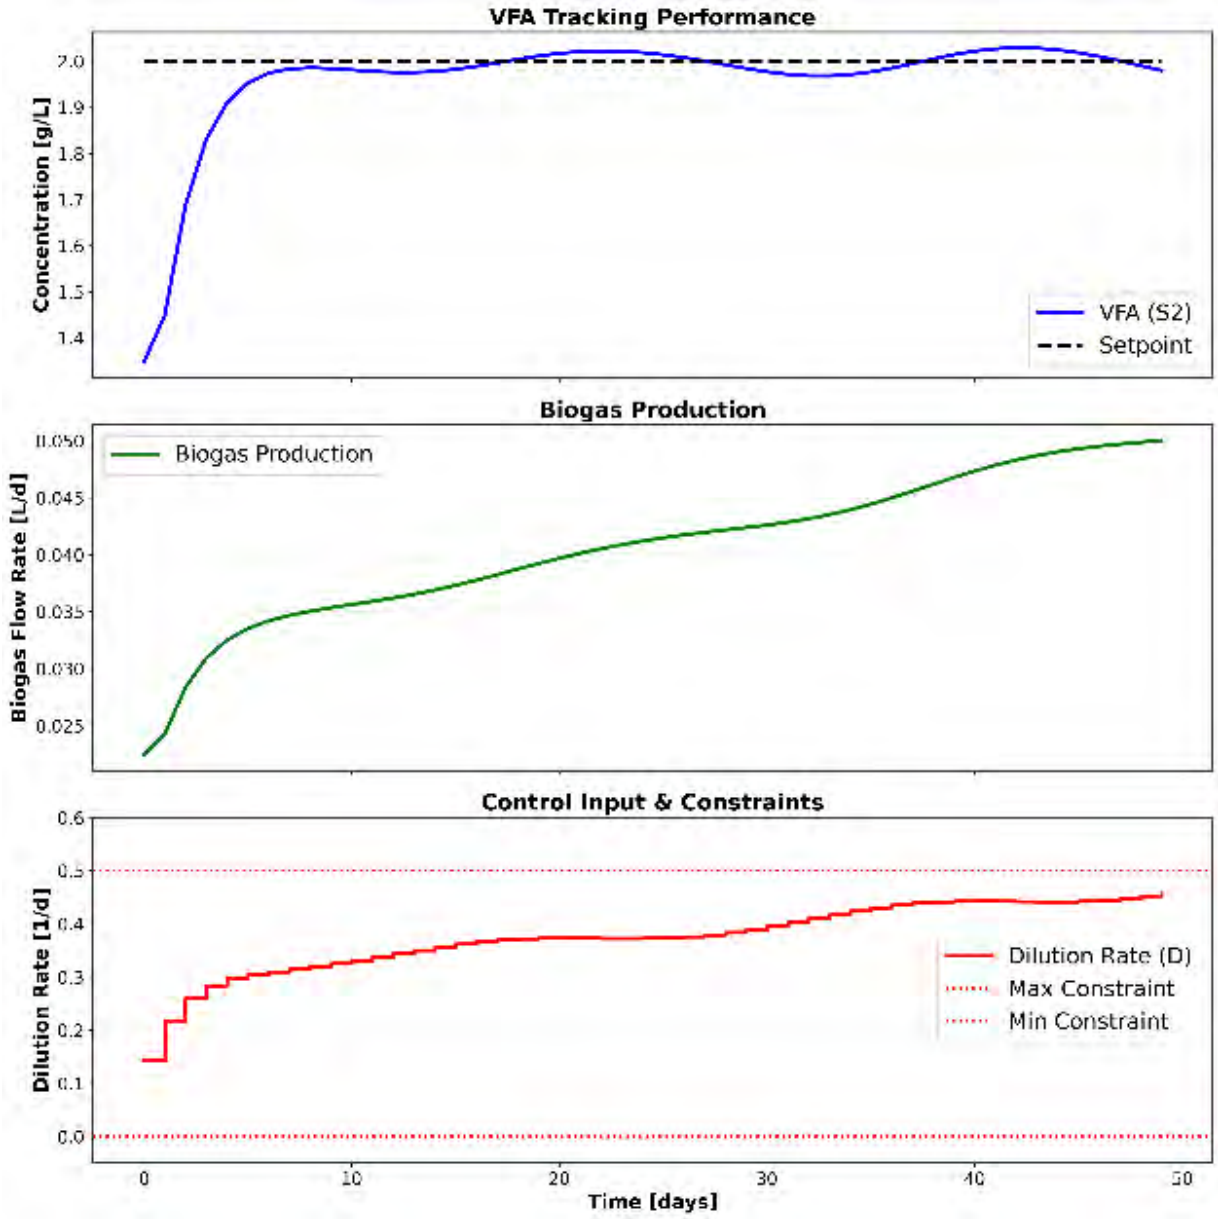

**Figure 11.** MPC for maximum biogas production.

feedstock composition disturbances; (b) control effort (dilution rate adjustments) showing smooth manipulated variable trajectory without excessive actuator action.

```
# Configure VFA tracking
mpc.setup_controller(
objective_type='track_vfa',
```

**Figure 12.** MPC for VFA concentration setpoint tracking to maintain process stability.

```
vfa_setpoint=2.0
)
# Run tracking simulation
for k in range(30):
  u_opt, y_next = mpc.run_step(...)
```

## CONCLUSION

OpenAD-lib addresses the digital gap in AD industry by unifying mechanistic understanding, data-driven methods, and uncertainty quantification. By providing a production-ready, open-source ecosystem, it enables the development of robust strategies for real-world AD application. Future iterations will extend to bioenergy

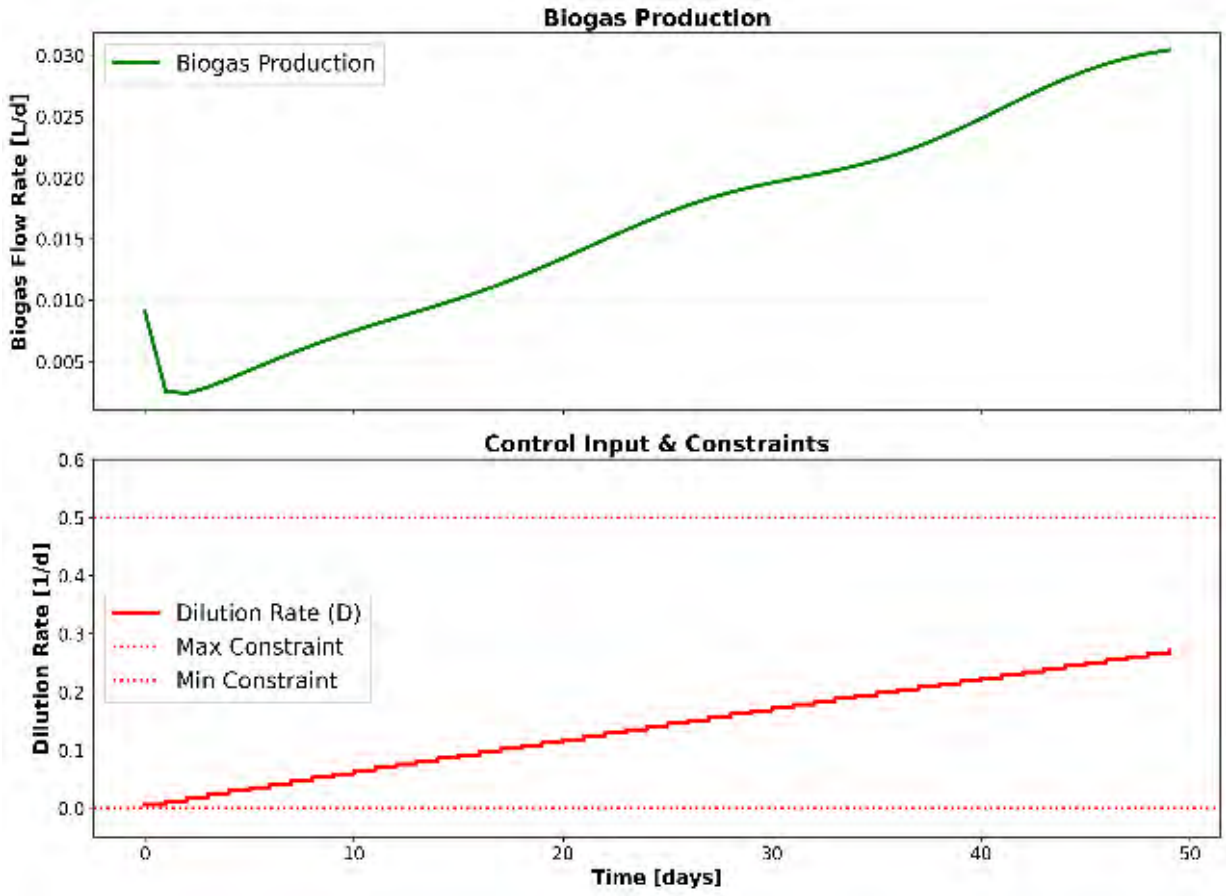

**Figure 12.** MPC for VFA concentration setpoint tracking to maintain process stability.

technologies (such as gasification and pyrolysis) demonstrating the platform's role in the wider bioenergy transition.

## ABSTRACT

Existing gas network infrastructure are important national energy assets, transporting mostly fossil-derived natural gas to end-users. Biomethane, methane derived from anaerobic digestion (AD) of organic matter, presents a potential route to replace fossil fuels with home-grown renewable gas. Combined with carbon capture and storage (CCS) of the $CO_2$ in the biogas potentially results in carbon negative energy. This work seeks to understand the feasibility of operating a part of the gas network isolated from the main natural gas network fully on biomethane in Scotland. We present an integrated techno-economic optimisation framework for designing self-sufficient biomethane islands, applied to the Inverness network. The model, implemented as a nonlinear program (NLP), maximises annual net profit from biomethane sales and Green Gas Support Scheme (GGSS) tariffs subject to practical constraints such as GGSS-compliance of ≥50 % waste-derived biomethane, seasonal supply, land/scale, demand balancing with centralised liquefied natural gas (LNG) storage, and a life-cycle global warming potential (GWP) metric. Three archetypes are analysed: Type A (crop-dominated, manure co-digestion), Type B (food/industrial wastes, grass/manure support), and Type C (distillery residues + grass/manure). In Inverness, feasible solutions include: Type A (2 large ~92, 000 $m^3$ digestion plants at ~23 ha/site producing 97.39 $Mm^3\,y^{-1}$ of gas; net revenue £13.4 M $y^{-1}$; GWP ~42.2 $ktCO_2e/y$), Type B (1 ~97, 000 $m^3$ plant at ~24 ha, producing 48.69 $Mm^3\,y^{-1}$ gas; net revenue £9.4 m $y^{-1}$; GWP ~48.0 $ktCO_2e/y$), and Type C (2 large ~110, 000 $m^3$ plants at ~27 ha, producing 97.4 $Mm^3\,y^{-1}$ of gas; net revenue £13.0 m $y^{-1}$; GWP ~47.2 $ktCO_2e/y$). Type B is most profitable per unit capacity due to gate-fee feedstocks but carries higher GWP (mostly from grass-silage cultivation). The model balances a combination of dynamic feeding of different recipes with using a centralised LNG storage to buffers seasonal deficits and maximise asset utilisation; optional $CO_2$ liquefaction (~87.7 kt $y^{-1}$ per large site at ~151 kWh $t^{-1}$) enables near/net-negative operation under low-carbon power. Our results find that the business model is feasible for Inverness and highlight the value of systems thinking and the need for policy reform (particularly lifting the 250 GWh $y^{-1}$ cap for GGSS and rewarding carbon intensity rather than just waste-derived methane) to unlock larger, efficient, low-emission regional systems.

## INTRODUCTION

Anaerobic digestion (AD) has become an increasingly important technology in the transition to low-carbon and circular energy systems, owing to its capacity to stabilise organic wastes, recover renewable biomethane, and reduce greenhouse-gas emissions from agriculture and food supply chains. The broader environmental and policy context for this transition is underscored by national targets for Net Zero, 2050 for the UK and 2045 for Scotland, which position renewable gas as a critical enabler of decarbonisation across heat, transport, and

industrial applications. The UK Biomass Strategy targets 30-40 TWh of biomethane by 2050, up from 6-8TWh [1], with the National Energy System Operator (NESO) suggesting 64 TWh by 2050[2]. The national gas infrastructure is an important national energy asset that risks decommissioning should fossil fuel natural gas decline as electrification of heating and transport dominate. Within these contexts, we seek to assess the feasibility, both technically and economically, of operating regional gas networks entirely on locally produced biomethane, integrating waste management, renewable energy conversion, and seasonal storage into a unified system design.

From a modelling perspective, AD has traditionally been described using mechanistic kinetic models, including simplified first-order approaches and more detailed models such as the ADM1. First-order kinetics remain widely applied in strategic decision-support settings due to their tractability and ability to capture degradation dynamics across co-digestion systems [3], but still need to assure control of methane yield, inhibition, and stability, for co-digestion by considering C/N ratios, solids loading, retention time and synergy effects. In our previous work [4], we developed a mixed-integer linear programming scheduling model to optimise feed scheduling for a single AD plant to optimise both electricity and biomethane gas-to-grid for maximising profit, considering co-digestion recipes, dynamic pricing, and gas storage. The model used a co-digestion model for understanding the gas yields from blending different feedstocks from [3] Additional literature indicates growing interest in hybrid frameworks that combine mechanistic understanding with optimisation and control, including the incorporation of price forecasting, nonlinear programming (NLP), and model predictive control (MPC) to manage temperature, substrate scheduling, and economic performance in AD systems [5].

At system level, optimisation frameworks have increasingly integrated logistics, crop availability, plant sizing, price signals, and life cycle assessments (LCA) [6], [7]. Despite this progress, relatively few studies integrate logistics, co-digestion modelling, economic optimisation, environmental performance, and policy constraints within a single modelling framework [8]. This gap is particularly relevant when systems must meet regulatory requirements such as the Green Gas Support Scheme (GGSS), which mandates that at least 50 % of biomethane be derived from eligible waste sources. This constraint strongly influences feedstock blending, reactor sizing, and plant economics due to the subsidy scheme. In practical deployment, additional challenges arise from seasonal demand variability, land availability, feedstock availability and transport distances, and the need for flexible gas-balancing infrastructure such as centralised bio-LNG storage, all of which directly affect the feasibility of establishing a self-sufficient regional gas system.

To address these challenges, working with gas networks and industrial partners, this work develops a unified NLP optimisation framework that integrates feedstock logistics, co-digestion performance, methane-release dynamics, LNG storage requirements, and life-cycle greenhouse gas emissions into a coherent decision-support tool to optimise the design and economics of AD sites that could realistically deliver flexible green gas to a part of the gas network. The framework is applied to the Inverness region as a detailed case study considering real feedstock availabilities and potential site locations, enabling the systematic evaluation of multiple plant archetypes under shared technical, economic, and policy constraints. The resulting analysis offers insight into the techno-economic viability of regional biomethane systems, the role of seasonal storage [9], and the implications of current UK policy structures for large-scale renewable-gas deployment.

## METHODS

We formulate an NLP in Pyomo [10] solved with IPOPT [11]. The model couples: (i) feedstock logistics with seasonality and a 50-mile catchment from identified potential site locations; (ii) co-digestion performance via first-order decay over solids retention time (SRT) and empirical blending correlations (C:N, biodegradability); (iii) demand balancing with potential for centralised bio-LNG storage on the network; (iv) GGSS constraints (≥50 % waste share; tiering of tariffs based on gas amounts); and (v) GWP covering cultivation, transport and parasitic energy. A scale-factor adjusts digestion volume/land for lower-energy wastes and GGSS compliance; excessive scaling is penalised in the objective.

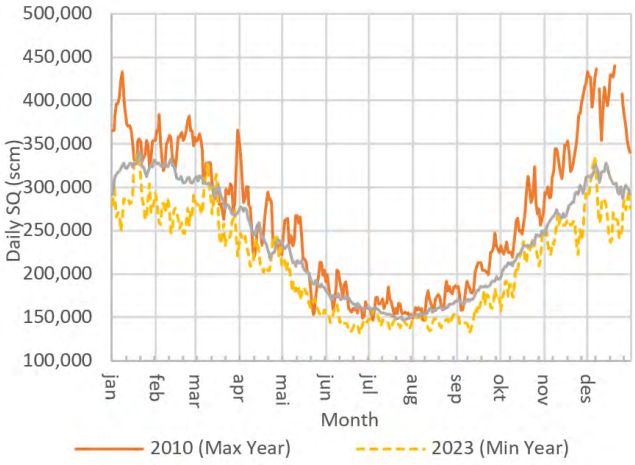

**Figure 1.** Inverness daily demand profiles (min/avg/max; 2010 as conservative 1-in-20 winter). Values are derived from the historic Scotland LDZ dataset.

### Mathematical Formulation

The NLP combines economic, operational, and policy-driven constraints to optimise the site design and feeding patterns to meet regional gas demands at maximum profit. The mathematical model is discretised in time for weekly demand for strategic scenario analysis and sufficiently detailed to capture the dynamic methane-release behaviour, seasonal balancing requirements, and regulatory conditions (particularly the ≥50 % waste-derived biomethane threshold specified by the GGSS).

The optimisation seeks to maximise the annual net profit of the biomethane island. Revenue is derived from biomethane sales to the gas grid and, where applicable, GGSS tariff payments; costs include feedstock procurement, transport logistics, annualised capital expenditure, operational expenditures, and scale-related penalties applied when plant size significantly exceeds benchmark industrial references. This leads to the following general objective:

$$\max_{\mathbf{x}} \Pi = \left(P_{\text{gas}} Q_{\text{bm}} + T_{\text{GGSS}} Q_{\text{bm}}^{\text{elig}}\right) - \left(C_{\text{feed}} + C_{\text{OPEX}} + C_{\text{CAPEX}}^{\text{ann}} + C_{\text{transport}} + \phi_{\text{scale}}\right) \quad (1)$$

where $Q_{\text{bm}}$ represents total biomethane production, $Q_{\text{bm}}^{\text{elig}}$ is the portion eligible for GGSS support, and $\phi_{\text{scale}}$is the nonlinear scaling penalty used to discourage unrealistic reactor upscaling beyond benchmark industrial AD site references.

A defining feature of the system is compliance with the GGSS requirement that at least 50 % of the biomethane energy content must originate from eligible wastes. Because each feedstock carries a distinct methane-yield potential, this constraint is expressed on an energy basis, ensuring that compliance cannot be met merely by mass-based blending:

$$\frac{\sum_{i \in \mathcal{W}} E_i Q_i}{\sum_{i \in \mathcal{F}} E_i Q_i} \geq 0.50 \quad (2)$$

where $E_i$ denotes the methane energy yield per tonne of substrate $i, Q_i$ its annual quantity, and $\mathcal{W}$ is the set of GGSS-eligible waste feedstocks from all feeds $\mathcal{F}$. This constraint is highly influential in determining plant scale, especially for crop-dominated (Type A) systems, and is responsible for driving the 35–62 % volume-expansion factors observed across Inverness scenarios.

To represent the time-dependent degradation behaviour of substrates, the model incorporates first-order kinetic decay, a widely used simplification in strategic AD planning [3]. This allows gas production to be traced over the effective SRT, enabling weekly matching between production and district gas demand:

$$M_{i,t} = \sum_{\tau=0}^{t} Q_{i,\tau}\, Y_i (1 - e^{-k_i (t-\tau)}), t \in \{1, \ldots, 52\} \quad (3)$$

where $M_{i,t}$ is methane released at week $t$ from substrate $i, Y_i$ is its specific methane yield, and $k_i$ a first-order rate constant. This reflects the dynamic gas-release effects, which are particularly important when high-moisture residues such as pot ale dominated blends.

The Inverness network exhibits pronounced winter peaks, requiring that surplus summer biomethane be liquefied and stored as bio-LNG for later reinjection. The required LNG capacity is defined as the maximum cumulative surplus over the annual horizon:

$$V_{\text{LNG}}^{\text{req}} = \max_{t \in [1,365]} \left(\sum_{\tau=1}^{t} Q_{\text{bm},\tau} - D_\tau\right) \cdot \rho_{\text{LNG}} \quad (4)$$

where $D_t$ is district demand and $\rho_{\text{LNG}}$ the gas-to-LNG volumetric conversion factor. This constraint is central to identifying feasible island-mode operation, ensuring that biomethane production and storage remain sufficient to meet peak-demand shortfalls.

## CASE STUDY

The case study in this work is a real gas network in Inverness, Scotland, with data obtained from our industrial partners. We use historical regional gas demands to define the demand profiles (see Figure 1), with the 2010 demand profile used as a conservative 1-in-20 winter standard to ensure the system is designed for robustness. We use an existing industrial site as a large-scale reference, with a 57 MW class site (~500 GWh $y^{-1}$ historically with a footprint of ~17 ha). For “real demand-scale” testing, the GGSS 250 GWh cap is relaxed while maintaining the ≥50 % waste rule; tiering is applied to eligible volumes. Available feedstocks are obtained from an existing national feedstock database from industrial partners, with their characteristics and availabilities shown in Table 1. GWP figures for crops are derived from [12]. GWP numbers provided in the results aggregates cultivation (dominant for grass silage), transport (feeds + digestate), and site parasitic load (CHP electricity, auxiliary use). $CH_4$ leakage is set to 0 % in the base cases but has been noted at ~3–4 % in empirical studies.

### Plant Archetypes

Three representative plant archetypes were defined to capture the main categories of feedstocks available within the 50-mile Inverness sourcing radius, obtained from industrial partners and to reflect typical UK AD deployment models. These archetypes differ in substrate composition, yield characteristics, infrastructure requirements, and their ease of compliance with the GGSS ≥50 % waste-derived biomethane rule.

**Energy-Crop-Dominated Systems (Type A):** These plants are based primarily on energy crops (wholecrop and cereal silages), co-digested with grass silage and cattle manure to ensure stable nutrient profiles. Energy crops provide relatively high and predictable methane yields, supporting flexible scheduling to match seasonal demand. However, because cultivated crops are not GGSS-eligible wastes, Type A systems must incorporate

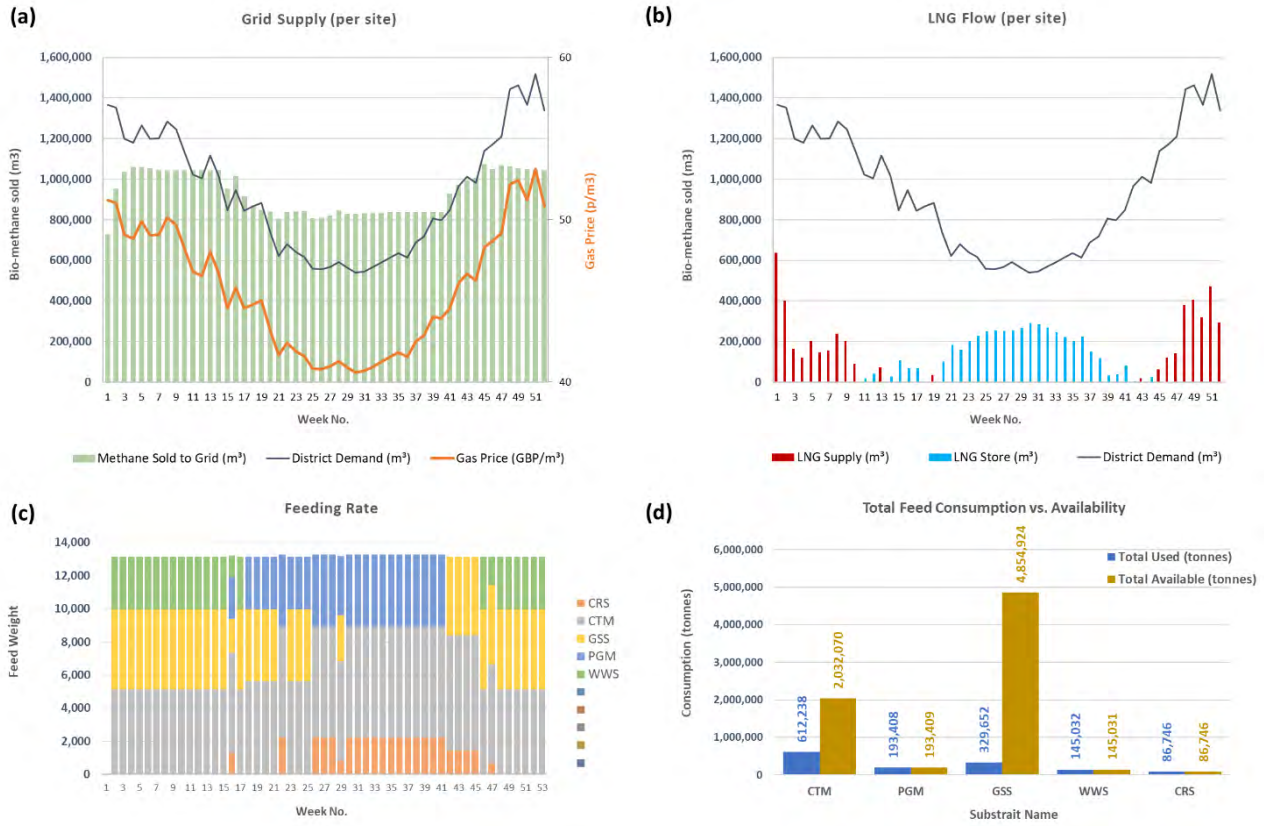

**Figure 2.** Operational performance – Type A plant (Inverness): (a) production vs demand; (b) LNG schedule; (c) blend ratios; (d) feed availability/use.

substantial manure volumes to meet the ≥50 % waste threshold, which drives the required 35 % scale increase (digester volume factor 1.35 in comparison to our reference industrial sites) observed in the Inverness configuration.

**Food- and Industrial-Waste-Based Systems (Type B):** These utilise household food waste (HFW) and industrial food waste (IFW), both of which count entirely toward the GGSS waste fraction. These substrates typically have low or negative net cost due to gate fees, enabling strong economic performance. However, their compositional variability necessitates co-digestion with grass silage and manure to maintain buffering capacity and prevent acidification. Feedstock availability limits Inverness to a single large-scale Type B plant, requiring 43 % larger digesters above benchmarks.

**Distillery-Residue-Based Systems (Type C):** These configurations are built around distillery by-products, particularly draff and pot ale, both abundant and fully waste-classified within the Inverness region. These substrates offer favourable co-digestion synergies with grass silage and manure, but raw pot ale's low solids content significantly reduces energy density. Consequently, Type C requires the largest scale increase of 62 % above the benchmark digester sizing, leading to higher digestion volumes and land requirements compared with Types A and B.

## RESULTS

### Type A: Crop-Dominated Configuration

The crop-based Type A scenario makes extensive use of energy crops (wholecrop and cereal silages), grass silage, and regionally abundant cattle manures. The optimisation determines that two large-scale AD plants constitute the maximum feasible configuration for Inverness under this scenario, with each site requiring a 35 % scale increase above the benchmark to comply GGSS requirements. This results in a digestion volume of approximately 92, 000 m³ per plant, with an associated land footprint of roughly 23 ha per site. The resulting biomethane output reaches 97.39 million m³ year$^{-1}$, of which 48.69 million m³ year$^{-1}$ is derived from waste feedstocks, meeting the GGSS threshold exactly. Table 2 summarises the techno-economic performance of the sites with annual sales of £86.2 million, feedstock costs of £38.9 million, annualised CAPEX of £19.1 million, and OPEX of £14.9 million yielding a net annual revenue of £13.4 million across the two-plant configuration to meet demands.

Figure 2a (Inverness Type A performance) shows

**Table 1:** Feedstocks for Type-A and Type-B plants in the selected area. Note EBMP is experimental biomethane potential and TBMP is theoretical biomethane potential. k is the rate constant, C/N is carbon to nitrogen ratio and GWP is the global warming potential associated with growing 1 tonne of the feedstock. Type-C feedstocks not shown to save space as these were not shown to be a part of the optimal configurations.

| Substrate | Abbr. | Available weight | Cost | Total Solids | Volatile Solids | EBMP | TBMP | C/N | k | GWP |
|---|---|---|---|---|---|---|---|---|---|---|
| | | Tonnes | £/t | $kg_{TS}$ / $t_{feed}$ | $kg_{VS}$ / $t_{TS}$ | $m^3CH_4$ / $t_{VS}$ | $m^3CH_4$ / $t_{VS}$ | - | $week^{-1}$ | - |
| Cattle Manure | CTM | 2,032,070 | 15 | 250 | 800 | 230 | 380 | 20 | 0.7 | 0 |
| Pig Manure | PGM | 193,409 | 10 | 250 | 800 | 250 | 410 | 14 | 1 | 0 |
| Grass Silage | GSS | 4,854,924 | 35 | 350 | 900 | 370 | 440 | 25 | 0.9 | 0.39 |
| Wholecrop Wheat Silage | WWS | 145,031 | 70 | 350 | 870 | 390 | 450 | 32 | 1 | 0.31 |
| Cereal Straw | CRS | 86,746 | 70 | 850 | 850 | 220 | 380 | 75 | 0.4 | 0 |
| Household Food Wast | HFW | 77,703 | 15 | 240 | 920 | 500 | 600 | 15 | 1.8 | 0 |
| Industrial Food Waste | IFW | 42,000 | 20 | 240 | 920 | 600 | 650 | 20 | 1.5 | 0 |

that production tracks seasonal demand through deliberate modulation of feedstock blends. Higher-yield crops are favoured during winter months, whereas lower-energy materials dominate during periods of suppressed demand. This allows the plants to maximise the digester volume usage and still hit the GGSS requirements across the year, while surpluses are still generated to maximise profit and still hit overall gas demands via gas storage. This flexible scheduling produces a yearly surplus of approximately 4.8 million $m^3$ $plant^{-1}$, which is redirected to the centralised LNG facility. The associated GWP for Type A totals ~42, 200 $tCO_2e$ $year^{-1}$, driven predominantly by grass-silage cultivation (33, 400 $tCO_2e$) and transport impacts (8, 800 $tCO_2e$).

## Type B: HFW and IFW Configuration

Type B shifts the focus to HFW and IFW, supported by grass silage and manure to maintain process stability. Due to limited volumes of food waste within the Inverness catchment, the optimisation identifies only one feasible large-scale site, which would need to be partnered with a Type A site to deliver the full region's gas demand. This plant requires a 43 % volume expansion over the industrial benchmark sizing, resulting in a total digestion volume of approximately 97, 000 $m^3$ and a land area of 24 ha.

Annual biomethane production in this configuration is 48.69 million $m^3$, with half (24.35 million $m^3$) derived from eligible waste streams. Despite being only half the scale of the Type A two-plant scenario, Type B shows strong economic performance, benefiting from the gate-fee revenues associated with food waste. As shown in Table 3, annual sales revenue reaches £43 million, with feedstock procurement costing only £16.2 million, significantly lower than in Type A. When combined with annualised CAPEX (£9.8 million) and OPEX (£7.6 million), this yields a net annual revenue of £9.4 million for a single facility.

Unlike Type A, the food-waste-dominated system exhibits less flexibility in modulating feedstock blends, resulting in a greater reliance on LNG storage to buffer seasonal mismatches. The Type B plant generates a larger relative surplus, approximately 6.4 million $m^3$ $year^{-1}$, equivalent to 13 % of total production. However, Type B also carries the highest GWP among the scenarios (48, 000 $tCO_2e$ $year^{-1}$), again dominated by emissions from grass-silage cultivation (~38, 700 $tCO_2e$) and transportation (9, 300 $tCO_2e$).

## Type C: Distillery Residue Configuration

The Type C scenario evaluates draff and pot-ale feedstocks from local distillery operations, supplemented by grass silage and manure. Feedstock availability supports the deployment of two large-scale plants, but low methane-potential substrates (particularly raw pot-ale) necessitate the largest scale expansion of the three scenarios: a 62 % increase (scale factor 1.62), giving a digestion volume of approximately 110, 000 $m^3$ per plant and a land requirement of 27 ha per site.

Combined annual biomethane production is 97.4 million $m^3$, with 48.7 million $m^3$ from eligible wastes. Total sales revenue reaches £85.8 million, with feedstock costs (£36 million), annualised CAPEX (£21 million), and OPEX (£16 million) resulting in a net revenue of £13 million $year^{-1}$, broadly comparable to Type A. Production under this scenario remains relatively stable throughout the year due to the low degree of flexibility offered by distillery residues. The system accordingly generates a larger annual surplus of ~7.2 million $m^3$ (15 %), which must be stored as LNG to satisfy winter deficits.

**Table 2:** Optimisation results- Estimated performance and economic metrics for Type-A 57MW AD plants in Inverness

| | | |
|---|---|---|
| Number of benchmark sites required | MW | 2 x 57 |
| Max. feasible number of sites | MW | 2 x 57 |
| Total estimated land required | ha | 2 x 23 |
| **Performance/Economic Metric** | **Unit** | **Total Sites Value** |
| Total biomethane Produced | $m^3$/yr | 97,385,400 |
| Waste-derived Volume | $m^3$/yr | 48,692,700 |
| Waste-derived Share | % | 50% |
| Total Sell | £m/yr | 86.2 |
| Total Feed Cost | £m/yr | 38.9 |
| Total CapEx | £m | 202.4 |
| Total OpEx | £m/yr | 14.9 |
| Annualised CapEx | £m/yr | 19.1 |
| Net Revenue | £m/yr | 13.4 |
| Volume Scale Factor | - | 1.35 |
| Total Digestion Vol. per plant | $m^3$ | 92,000 |

**Table 3:** Performance, cost, and LNG implications of the selected plant configuration for Inverness biomethane island

| Selected configuration | | (1xA) + (1xB) |
|---|---|---|
| Total land required | ha | (23 ha) + (24 ha) |
| Total annual costs | £m/yr | 69.9 |
| Total net revenue | £m/yr | 16.1 |
| Total GWP | $tCO_2e$ | 90,200 |
| Total LNG storage | $m^3$LNG | 18,500 |
| Cent. LNG facility total capital | £m | 67 |
| Cent. LNG facility Opex | £m | 2.0 |

The Type C configuration exhibits a total GWP of approximately 47, 200 $tCO_2e$ $year^{-1}$, with the majority (78 %) attributable to grass-silage cultivation and the remainder to logistics. Notably, the exclusion of pot-ale syrup, a higher-solids, higher-methane-potential variant, suggests that future scenarios including concentrated distillery co-products could significantly reduce both plant size and GWP.

## Optional $CO_2$ liquefaction (per large site)

For each large-scale Inverness AD facility, the biogenic $CO_2$ stream from upgrading can be processed via an optional on-site liquefaction unit. Our model estimates an annual $CO_2$ flow of ~87, 700 t $CO_2$ $year^{-1}$ per site, requiring ~£61 million in capital expenditure and ~£0.71 million $year^{-1}$ in O&M costs, with electricity demand of 151 kWh $t^{-1}$ $CO_2$. These energy requirements are treated as a parasitic load on the CHP system rather than external grid purchases, ensuring consistency with the broader techno-economic system boundary. Although optional, $CO_2$ liquefaction has the potential to shift AD systems toward near- or net-negative emissions, particularly when the captured $CO_2$ can be diverted for sequestration or utilised in local industrial markets.

The feasibility of implementing $CO_2$ liquefaction, however, depends heavily on future policy incentives and the evolution of $CO_2$ commodity pricing. The current GGSS framework does not reward $CO_2$ capture, meaning the investment must presently be justified solely on environmental grounds, as current UK $CO_2$ market prices do not provide a profitable investment case [13]. Shifting policy from a strict ≥50 % waste-content rule toward a carbon-intensity-based support mechanism would materially improve the economic case for $CO_2$ capture and valorisation. As emerging low-carbon markets develop, particularly in Scotland's food, beverage, and synthetic-fuel sectors, liquefied $CO_2$ could represent a meaningful future revenue stream, strengthening the long-term viability of regional biomethane systems.

# DISCUSSION

The optimisation results for Inverness reveal that system feasibility depends on the interplay between feedstock availability, GGSS constraints, and seasonal balancing needs. The most profitable solution identified in the report is a hybrid configuration comprising one Type A and one Type B plant based on feedstock availability. This combination leverages the high methane yield and operational stability of crop-supported co-digestion (Type A) together with the strong economic performance of food-waste-based digestion (Type B), achieving £16.1 million $year^{-1}$ in net revenue and requiring 18,500 $m^3$ of centralised LNG storage to meet winter peak demand. The details of the optimal system is given in Table 3.

This hybrid arrangement also moderates the limitations of the individual systems. By combining the two plant types, the system achieves a more favourable balance of economic efficiency and environmental performance, while reducing sensitivity to feedstock variability. Seasonal surplus remains critical across all scenarios, necessitating dedicated centralised LNG infrastructure.

## CONCLUSION

This work applied a unified techno-economic optimisation framework to assess the feasibility of an Inverness biomethane island. We showed that it is feasible in this region to meet all current gas demands within current policy and feedstock availability restrictions with a novel arrangements of technologies and feeding patterns, while still providing an attractive business case. Future work should examine hybrid designs that combine the economic strengths of Type B with the lower emissions and operational flexibility of crop- or distillery-based systems, as well as the potential of higher-value co-products such as pot-ale syrup to reduce required plant scale. Policy implications are significant: the 250 GWh $y^{-1}$ GGSS cap and binary ≥50 % waste rule limit optimal system design that do not encourage flexible operation. Shifting toward carbon-intensity-based incentives, alongside support for $CO_2$ capture, would better align economic and environmental outcomes and accelerate deployment.

## ABSTRACT

Achieving and sustaining net-zero greenhouse-gas emissions will require the long-term deployment of green hydrogen. Proton exchange membrane water electrolysers (PEMWEs) are attractive for variable renewable electricity (VRE) because of their fast dynamic response; however, they rely on iridium (Ir) anode catalysts, and Ir supply is severely constrained. Here, a Japan-specific dynamic material flow analysis (DMFA) model is developed for 2025–2100 to quantify Ir circularity in PEMWE deployment under a backcasting-oriented hydrogen production pathway. The model tracks Ir in anode catalysts only and represents: (i) Ir demand for new capacity additions and replacements, (ii) end-of-life (EoL) outflows governed by a Weibull lifetime distribution, and (iii) closed-loop recycling characterised by an overall recycling rate across collection, separation/preprocessing, and refining. Sensitivity analyses show that long-term primary Ir requirements are governed by the coupled effects of catalyst durability and recycling performance. Although lowering Ir loading reduces initial Ir intensity, accelerated degradation can increase replacement frequency and cumulative primary Ir demand unless recycling rate improves concurrently. Importantly, conclusions depend on the analysis horizon: Ir loading dominates cumulative demand up to 2050, whereas recycling becomes increasingly decisive toward 2100. These results highlight that Ir-thrifting catalyst designs must be evaluated jointly with durability under dynamic operation and recyclability to ensure scalable and continuous PEMWE deployment.

**Keywords**: Hydrogen, Proton Exchange Membrane Water Electrolyser, Material Flow Analysis, Iridium

## INTRODUCTION

Green hydrogen is expected to play a central role in decarbonizing industrial sectors where deep emissions reductions are difficult without major production cuts. Water electrolysis is a key pathway for green hydrogen production. Among electrolyser technologies, proton exchange membrane water electrolysers (PEMWEs) are attractive because their fast transient response is compatible with variable renewable electricity (VRE) such as photovoltaics [1]. However, state-of-the-art PEMWEs rely on iridium-based catalysts at the anode to sustain oxygen evolution in strongly acidic environments [2]. Iridium (Ir) is among the scarcest metals, with global annual production on the order of only about 8 t [3]. This scarcity has motivated extensive research into reducing Ir usage through lower catalyst loadings [4].

A critical challenge is that Ir-thrifting strategies can compromise durability. Several studies report accelerated degradation at low catalyst loading and under dynamic operation [5]. From a systems perspective, faster degradation shortens electrolyser lifetime, increases replacement frequency, and enlarges the end-of-life (EoL) flow requiring recycling. These effects can raise the risk of Ir dissipation along the recycling chain and ultimately undermine circularity. Therefore, evaluating Ir circularity requires a framework that links catalyst loading, degradation-driven lifetime, and recycling rather than treating them independently.

Dynamic material flow analysis (DMFA) provides a time-resolved approach for quantifying primary demand, in-use stock, and EoL flows of critical materials, thereby

informing recycling infrastructure planning and technology targets. Existing Ir-focused DMFA studies remain limited both globally [6–8] and at the country level [9], and many studies emphasize time horizons up to 2050, the net-zero target year for many countries. Net-zero, however, is not an endpoint: maintaining a net-zero state requires continued infrastructure renewal and resource management beyond 2050.

In this study, a Japan-specific DMFA model is developed for Ir in PEMWEs through 2100 and quantifies how catalyst properties (Ir loading and degradation rate) and recycling performance jointly govern long-term primary Ir requirements. Japan is a relevant case due to its industrial scale, potential demand for green hydrogen, and notable role in Ir-consuming products (e.g., spark plugs, crucibles), which together position Japan as an important node in the global Ir cycle. The analysis also highlights durability and recycling priorities that connect catalyst/material chemistry to long-term material circularity.

# MATERIALS AND METHODS

## Scenario and scope

This study adopts a Japan-focused decarbonisation scenario [10] in which only photovoltaic-derived VRE is available as the electricity supply, and PEMWEs are selected because of their operational responsiveness. The model period is 2025–2100, and commercial introduction of PEMWEs is assumed to begin in 2030. The system boundary includes only Ir in the PEMWE anode catalyst.

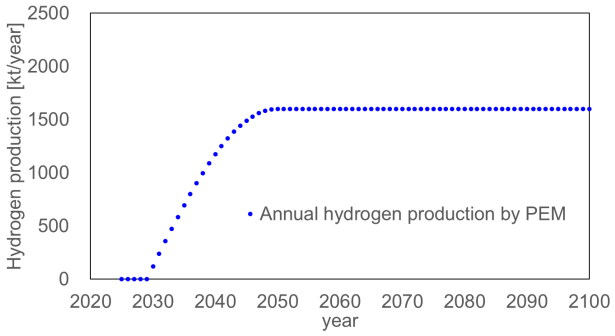

**Figure 1.** Scenario-based trajectory of annual hydrogen production in Japan from 2030 to 2100.

The objective is to estimate the primary Ir requirement needed to achieve and sustain the specified hydrogen production pathway. To isolate the effects of catalyst loading, durability, and recycling performance, technological progress is not explicitly represented. On the demand side, Japan's ongoing population decline and the expected contraction of domestic manufacturing motivate a simplified trajectory in which PEMWE-based hydrogen production increases to 1.6 Mt/year by 2050 and remains constant thereafter (**Figure 1**). This PEMWE contribution (1.6 Mt/year) is less than 10% of Japan's 2050 hydrogen target of 20 Mt.

## DMFA model

Annual Ir demand for PEMWE deployment in year $t$, $Ir_t^d$[g], is calculated from (i) the additional hydrogen production required between years $t-1$ and $t$, and (ii) Ir associated with end-of-life PEMWE equipment in year $t-1$. Let $H_t$[kg] be the annual target hydrogen production, $EI_t$[kWh/kg-$H_2$] the electrical energy intensity of PEM water electrolysis, $MI_t$ [g/kW] the Ir material intensity of new equipment (hereafter referred to as Ir loading), and $h$ [h/year] the annual operating hours. The required additional capacity $\Delta C_t$ is:

$$\Delta C_t = \max(0, H_t - H_{t-1}) EI_t / h \quad (1)$$

The corresponding Ir demand is:

$$Ir_t^d = \Delta C_t MI_t + Ir_{t-1}^w \quad (2)$$

where $Ir_{t-1}^w$ [g] denotes Ir contained in waste (retired) PEMWE equipment. Recycled Ir, $Ir_t^r$[g], is computed using an overall recycling rate $RR$ [–], defined as the yield across all processes required to return Ir to a state suitable for reuse in PEMWE manufacturing (collection, separation, and refining):

$$Ir_t^r = Ir_{t-1}^w RR \quad (3)$$

Primary Ir demand is then:

$$Ir_t^p = Ir_t^d - Ir_t^r \quad (4)$$

Recycled Ir is prioritized for PEMWE manufacturing, and any remaining demand is met by primary Ir.

## End-of-life outflow and lifetime distribution

The EoL outflow $Ir_t^w$ is determined by applying a lifetime distribution to historical inflows of Ir embedded in newly manufactured and replacement PEMWE anode catalysts. Specifically, $Ir_t^w$ is computed as the convolution of past inflows with the discrete retirement probability implied by a Weibull distribution. The Weibull shape parameter is fixed (**Table 1**), and the scale parameter is calibrated so that the resulting lifetime distribution is consistent with the lifetime $L$ defined below, enabling time-dependent replacement and recycling needs to be represented within a consistent stock–flow framework.

## Lifetime modeling and parameter settings

Previous DMFA studies mainly assume a uniform lifetime [6–8]. Here, lifetime is linked to electrochemical durability via the voltage degradation rate. End-of-life is defined using the US Department of Energy (DOE) criterion of a 10% voltage increase at fixed current density relative to beginning-of-life [12]. If the average degradation rate is $\gamma$ [%/kh], the corresponding lifetime $L$ [h] is:

$$L = \frac{10}{\gamma} \times 1000 \quad (5)$$

For example, $\gamma = 0.25$ [%/kh], the US DOE "2022 Status" value, corresponds to $L = 40,000$ h. This definition connects catalyst durability to replacement frequency, thereby linking catalyst chemistry/structure to long-term Ir circularity.

Because the scenario adopted in this analysis assumes photovoltaic-derived VRE as the power source, the average operating time was constrained to 2920 h/year (8 h/day). With respect to operational variability under VRE, it was assumed to have no effect on the hydrogen production stage; during operating hours, hydrogen production was assumed to proceed at a constant rate.

**Table 1:** Parameter settings for DMFA calculation.

| Fixed Parameters | Value |
|---|---|
| Weibull shape parameter | 5 |
| End of life voltage loss [%] | 10 |
| Average operation hour [h/year] | 2920 |
| Electrical efficiency [kWh/kg-$H_2$] | 51 |

## RESULTS AND DISCUSSION

### DMFA and sensitivity analysis results

**Figure 2** illustrates the time evolution of total Ir demand, primary Ir demand, and recycled Ir supply for an illustrative parameter set intended to reduce primary Ir dependence: Ir loading 0.05 g/kW (below the US DOE 2026 target), recycling rate 0.9 and degradation rate 0.25 %/kh corresponding to a 40, 000 h lifetime. Under these assumptions, the cumulative primary Ir demand by 2100 is limited to approximately 2.0 t, a level that could be secured by a single country.

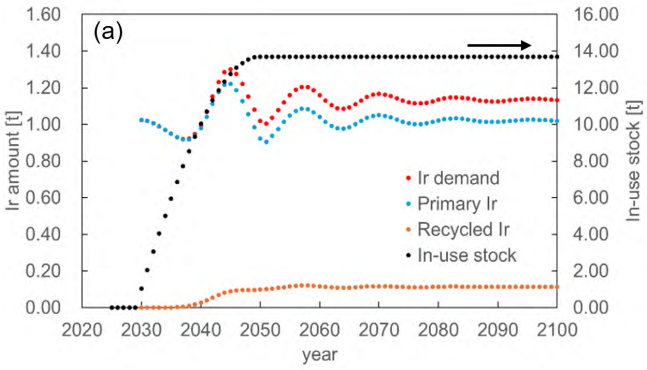

**Figure 2.** DMFA results (Ir loading = 0.05 g/kW, recycling rate = 0.9, degradation rate = 0.25 %/kh).

Utilizing this DMFA model, **Figure 3** presents the results of a sensitivity analysis in which Ir loading is held constant (0.05 g/kW) and the degradation rate and recycling rate are varied as input parameters, with cumulative primary Ir demand in 2100 as the output. Because global annual Ir production is approximately 8 t, it would be challenging for Japan alone to consume several tens of tons of Ir. **Figure 3** indicates that high recycling alone cannot compensate for rapid degradation, and conversely that durability gains deliver limited benefits when recycling losses are large. These results motivate Ir-reduction strategies that improve both durability and recycling performance rather than optimising lever in isolation.

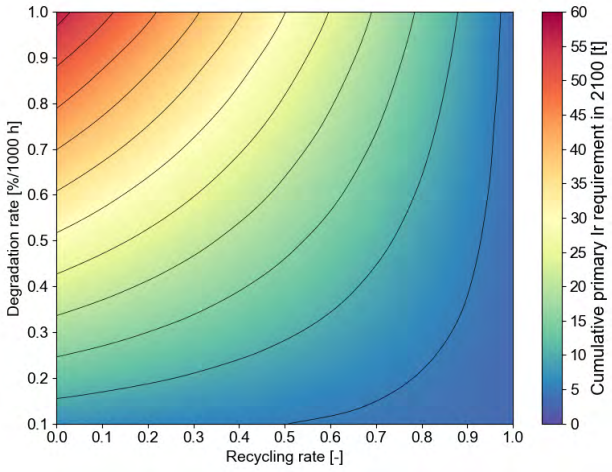

**Figure 3.** Results of sensitivity analysis on cumulative primary Ir demand in 2100 using recycling rate and degradation rate as parameters. Ir loading is fixed at 0.05 g/kW.

### Relationship between Ir loading and degradation rate

Several studies report that reducing Ir content can worsen degradation [5], implying that Ir loading and degradation rate should not be treated as independent. Accordingly, the relationship between Ir loading and degradation rate is parameterized using literature data: a linear function is derived based on Ir loading and degradation-rate data reported in the US DOE "2022 Status" [12], together with additional literature data [13] obtained at the same current density (2 A/cm²).

**Figure 4** and **Figure 5** show sensitivity results using Ir loading and recycling rate as input variables, with degradation rate determined from the parameterized Ir loading and degradation rate relationship. A non-monotonic response emerges: lowering Ir loading reduces Ir intensity per unit capacity, but it can also shorten lifetime by accelerating degradation, thereby increasing replacement frequency. Consequently, cumulative primary Ir demand can increase in a low-loading region when accelerated replacement outweighs the benefit of reduced initial Ir intensity. This is a critical systems-level implication of durability–loading trade-offs: Ir-thrifting strategies can

backfire if durability degradation dominates.

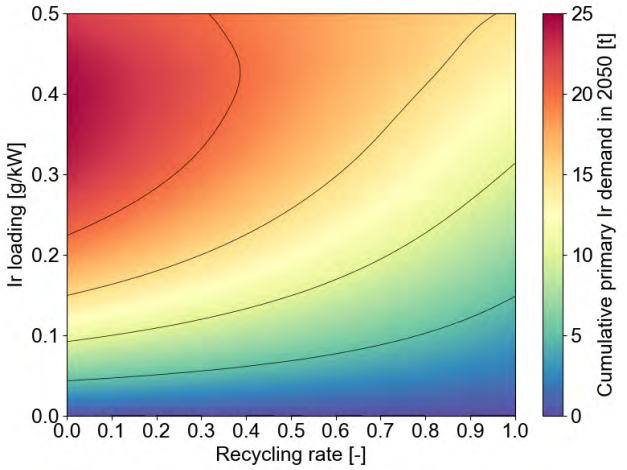

**Figure 4.** Results of sensitivity analysis on cumulative primary Ir demand in 2050 using recycling rate and Ir loading as parameters.

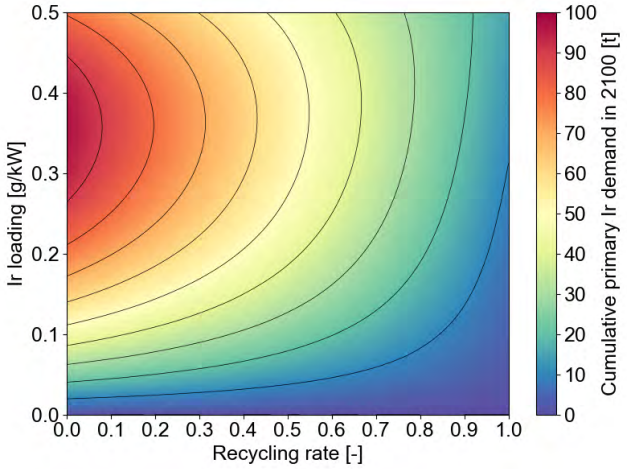

**Figure 5.** Results of sensitivity analysis on cumulative primary Ir demand in 2100 using recycling rate and Ir loading as parameters.

The analysis horizon strongly affects the apparent priority of interventions. Up to 2050, reducing Ir loading has a larger effect than increasing recycling rate, because the system is still building in-use stock and cumulative replacements are limited. By 2100, however, the system is dominated by replacement and recycling loops rather than initial stock build-out, and improving recycling rate becomes more decisive. Therefore, DMFA conclusions intended to inform carbon-neutrality planning should state the terminal year explicitly.

**Figure 6** illustrates the mechanism behind the increase in cumulative primary Ir demand observed in **Figure 4** and **5** despite reduced Ir loading. At a low recycling rate (0.1), comparing a higher loading case (0.50 g/kW) with a lower loading case (0.35 g/kW) shows that the higher-loading case has a larger in-use stock but benefits from a longer lifetime and therefore a lower EoL frequency. In contrast, the lower-loading case experiences more frequent replacements, which increases annual Ir demand over time and elevates cumulative primary Ir demand. Accordingly, catalyst development should target low Ir loading while maintaining durability under dynamic operation, and electrode designs should explicitly consider recyclability and separability to increase the overall recycling rate.

## Limitations of this study

First, the relationship between Ir loading and degradation rate depends on catalyst state, distribution, and electrode architecture, and it is not necessarily linear. Due to limited long-duration durability data under realistic dynamic operation, this study assumed a proportional relationship derived from available datasets. More comprehensive durability testing under VRE-relevant operating profiles is required.

Second, although the analysis extends to 2100, parameters are assumed constant over time to isolate effects, and long-term technological progress is not explicitly represented. This may overestimate Ir requirements if

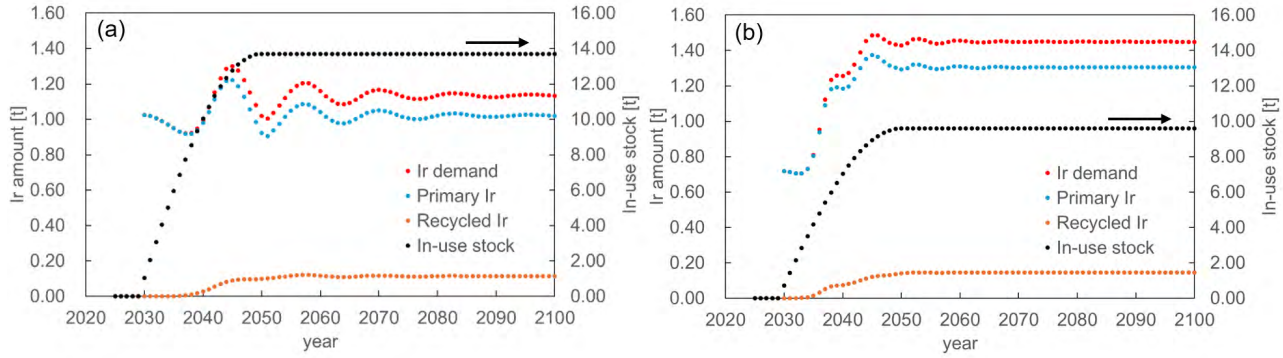

**Figure 6:** DMFA results considering the relationship between Ir loading and degradation (recycling rate = 0.1) (a) Ir loading = 0.5 g/kW; (b) Ir loading = 0.35 g/kW.

future innovations improve efficiency, durability, or recycling. Conversely, the scenario assumes that PEMWE-supplied hydrogen demand remains constant after 2050, which may underestimate Ir requirements if demand continues to grow.

Third, the system boundary includes only Ir in the anode catalyst and excludes other Ir uses and potential competition across sectors. Including cross-sectoral coupling could further constrain available Ir and alter feasible deployment pathways.

## CONCLUSIONS

This study developed a Japan-specific DMFA model to quantify long-term Ir circularity in PEMWE deployment through 2100, explicitly linking catalyst loading, degradation-driven lifetime, and the overall recycling rate. The results show that primary Ir dependence is governed by the coupled effects of durability and recycling: lowering Ir loading reduces initial Ir intensity, but it can increase cumulative primary Ir demand when it accelerates degradation and replacement frequency, particularly under low recycling rate. The time horizon further conditions these conclusions, with Ir loading effects dominating up to 2050 and recycling performance becoming increasingly decisive toward 2100.

These findings indicate that Ir-thrifting strategies must be pursued alongside (i) durability improvements under dynamic operation and (ii) improvements in the overall recycling rate across separation/pre-processing and refining to ensure scalable and sustainable PEMWE-based hydrogen deployment. In practice, robust Ir circularity requires integrated catalyst and electrode design for both stability and recyclability, together with strategic planning of recycling infrastructure.

## ABSTRACT

Palm oil mill effluent (POME) represents a major environmental burden in the palm oil industry while offering opportunities for resource recovery. This study develops and applies a value-based assessment framework to examine how technological choice influences the integrated environmental–economic performance of POME valorization. Biomethane production and bio-hydrogen production are selected as representative mature and emerging technologies, respectively. Life-cycle environmental performance is quantified using greenhouse gas (GHG) emissions midpoint indicator and natural resources endpoint indicator, reflecting broader environmental damages. A techno-economic assessment is performed to show the economic performance. In addition to conventional return of investment (ROI), the benefits of mitigating environmental impacts are accounted using the return of value (ROV) methodology. The results indicate that the attractiveness of POME valorization pathways depends strongly on how environmental gains are represented. Midpoint-based valuation shows the climate mitigation potential of the biomethane and bio-hydrogen, whereas endpoint-based valuation reveals higher environmental impacts for the energy-intensive hydrogen route, favoring the mature biomethane option in terms of integrated sustainability performance. This contrast demonstrates that technological maturity is reflected not only in cost structure and process stability but also in the balance between avoided impacts and newly introduced environmental burdens. Overall, the proposed value-based assessment framework enables environmental impacts and economic performance to be evaluated on a common value scale, providing a consistent basis for sustainability-oriented decision-making in POME valorization and supporting strategic planning for wastewater management and bio-economy development in the palm oil sector.

**Keywords**: Life Cycle Assessment, Wastewater valorization, Palm oil mill effluent, Bioenergy pathways, Value-based assessment

## INTRODUCTION

The palm oil industry plays a pivotal role in the global vegetable oil market, accounting for approximately 33% of global oils and fats production and nearly 40% of international edible oil trade [1]. However, the large-scale processing of fresh fruit bunches (FFB) into crude palm oil is highly water-intensive, particularly during sterilization and clarification stages, resulting in the generation of substantial quantities of POME. On average, approximately 0.1 tons of effluent per ton of produced crude palm oil is generated as POME. [2]. POME is characterized by high chemical oxygen demand (COD), biological oxygen demand (BOD), oil and grease content, and acidic pH [3]. If inadequately managed, conventional open-pond treatment systems can lead to severe water pollution and significant methane emissions, contributing to climate change [4]. To address these challenges, POME valorization has emerged as an important strategy to transform wastewater from an environmental burden into a valuable resource. Importantly, the POME valorization technologies span a wide range of technology readiness levels (TRLs). On one end, mature technologies have already been deployed at industrial scale, delivering

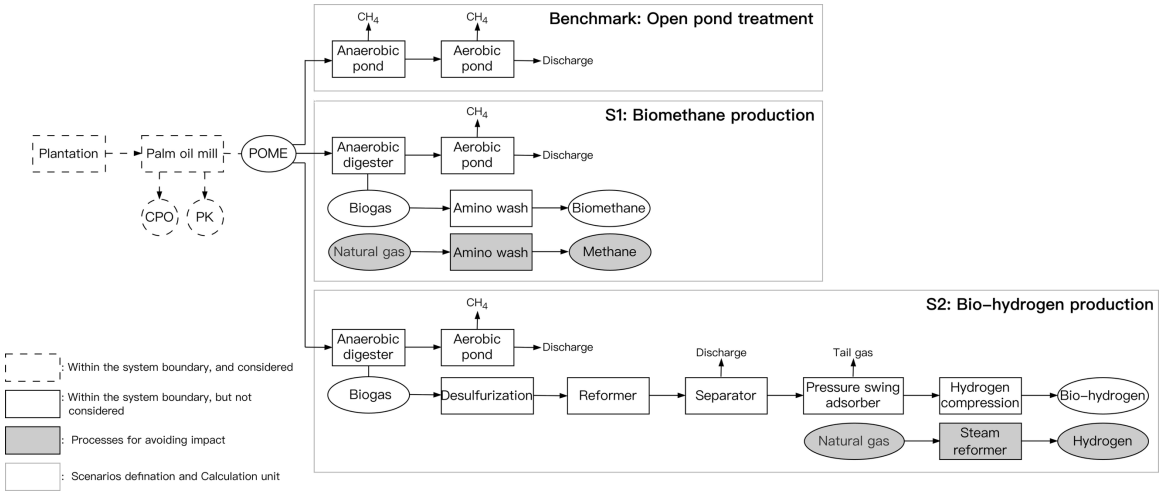

**Figure 1:** Cradle-to-gate system boundary of POME valorization pathways for benchmark and two valorization

near-term environmental benefits and relatively stable economic returns. On the other end, emerging technologies remain at pilot or laboratory stages, offering potentially higher long-term value but accompanied by greater technical uncertainty, higher costs, and less certain environmental performance. This coexistence of mature and emerging valorization options poses a critical challenge for decision-makers: how to systematically compare technologies with fundamentally different maturity levels on a consistent and transparent basis. Most existing studies evaluate single POME valorization pathways using either environmental indicators, such as life cycle greenhouse gas (GHG) emissions, or economic metrics, such as production cost and profitability, or evaluate these two aspects individually [5, 6]. However, these single-dimensional assessments fail to explicitly integrate environmental impacts with economic performance into a single level to enable holistic comparison across heterogeneous technologies.

This study aims to first characterize the life-cycle performance of POME valorization by examining two representative pathways corresponding to mature and emerging technologies. Building on this characterization, a value-based assessment framework is applied in which environmental impacts are represented in monetary value and added to the economic indicator. The objective is to elucidate how technological choice influences the integrated environmental–economic performance of POME valorization and to provide a quantitative basis for strategic technology selection in sustainable wastewater management and bio-economy development in the palm oil sector.

# METHOD

## Scenario Design and Settings

To reflect the technological heterogeneity of POME valorization options, this study selects two representative pathways in different levels of technological maturity. Biomethane production via anaerobic digestion is chosen as the mature technology because it has been widely implemented at industrial scale [7] and its relatively stable technical performance and production costs. In contrast, bio-hydrogen production from POME via steam reforming is selected as the emerging technology. Although hydrogen is associated with higher market value and strategic relevance for future low-carbon energy systems [8], this pathway remains at pilot or laboratory scale, leading to higher technical uncertainty and production costs. These two pathways are therefore used as representative cases to examine how differences in technological maturity and value potential influence the integrated environmental–economic performance of POME valorization.

The two scenarios are: S1, POME-to-biomethane with biogas capture and purification, and S2, POME-to-bio-hydrogen via steam reforming. A conventional open-pond treatment without methane removal is used as a benchmark for comparison.

## Life Cycle Assessment

This life cycle assessment (LCA) aims to evaluate environmental impact of POME treatment and valorization pathways. The process modeling is based on a mass and energy balance framework, in which each unit operation is represented by literature-based input–output data and linked to corresponding datasets in ecoinvent v3.11. The functional unit (FU) is defined as 1 t of POME utilization. The system boundary is illustrated in **Figure 1** and focuses on POME treatment and down-stream valorization processes. Upstream plantation and palm oil mill (POM) operations are not considered, and POME is considered as the sole feedstock entering the system. The

benchmark includes processes of anaerobic and aerobic ponds, and the treated effluent is discharged, while methane generated during treatment is emitted to the atmosphere without removal. In S1, POME is treated by an anaerobic digester (AD) followed by aerobic ponds. The biogas produced from anaerobic digestion is purified through an amino washing process to produce biomethane, which is assumed to substitute fossil-derived methane. In S2, the system boundary is further extended to include biogas desulfurization, steam reforming, gas separation, pressure swing adsorption, and hydrogen compression for bio-hydrogen production. The produced bio-hydrogen is assumed to substitute hydrogen derived from fossil-based methane.

Inventory datas for material, energy and process shown in **Table 1** are primarily derived from literature sources [5, 8]. These data are scaled to the defined FU using proportional coefficients, according to:

$$Flow_{FU} = Flow_{ref} \times \frac{FU}{FU_{ref}} \quad (1)$$

where $Flow_{FU}$is the inventory flow per FU, and $Flow_{ref}$ is the reference flow reported in the literature for a given FU $FU_{ref}$. All inventory flows are scaled linearly to the functional unit based on reported reference data, assuming steady-state operation and constant conversion efficiencies.

For the benchmark, the generated biogas is considered as direct emissions. For S1, inventory data include water and electricity input, and the purification process. A biomethane purification efficiency of 97% is assumed, while the remaining fraction is released as losses and accounted for in the emission calculation. For S2, additional material and energy inputs include monoethanolamine (MEA) for gas treatment and metal oxides (iron oxide, copper oxide, and nickel) as catalysts for reforming and downstream conversion. In this study, catalyst recovery and re-use are not considered. Steam consumption includes low-, medium-, and high-pressure steam, which are represented by an average energy intensity of 2.80 MJ/kg steam to calculate both steam demand and its associated environmental impacts. Tail gas is also generated from the pressure swing adsorption unit. The composition consists of 94.66 % $CO_2$, 2.00 % $H_2S$, 1.25 % water, 0.93 % $NH_3$, 0.40 % $CH_4$, 0.40 % $C_2H_7NO$, 0.21 % $H_2$, 0.11 % $C_{13}H_{25}O_7N_3S$, and 0.04 % CO [8]. It is assumed to be directly released, and only $CO_2$ (587 kg) and $CH_4$ (2.48 kg) are included in the GHGs calculation. Wastewater and digestate from two valorization pathways are estimated based on mass balance. For the fossil-derived alternatives, cradle-to-gate environmental impacts are adopted from ecoinvent v3.11 database, which includes natural gas production, amine washing, and steam reforming.

**Table 1:** Inventory data of each scenario.

| S1 | Material/Energy | Unit | Value |
|---|---|---|---|
| Input | POME | t | 1 |
| | Water | $m^3$ | 0.01 |
| | Electricity | kWh | 0.03 |
| | Biogas-to-biomethane purification (amine washing) | $m^3$ | 20.79 |
| Output | Biomethane | $m^3$ | 20.17 |
| | Digestate | t | 0.11 |
| | Wastewater | t | 0.89 |
| S2 | | | |
| Input | POME | t | 1 |
| | Monoethanolamine | kg | 0.03 |
| | Iron oxide | kg | 0.05 |
| | Copper oxide | kg | 0.08 |
| | Nickel | kg | 0.06 |
| | Water | kg | 17.50 |
| | Steam | kg | 570.43 |
| | Heat | MJ | 1693.50 |
| Output | Hydrogen | kg | 6.08 |
| | Tail gas | kg | 620.21 |
| | Wastewater | t | 0.59 |

Direct methane emissions from each stage are obtained by multiplying the corresponding treatment organic load by the emission factors for facultative and other treatment and for discharge to the water environment [4]. Chemical oxygen demand concentrations [5, 9] are assumed at three treatment stages: from palm oil mill to anaerobic digesters, from anaerobic digesters to aerobic digesters, and from aerobic digesters to final discharge. For the benchmark, where methane is not recovered, biogas produced in the anaerobic stage is assumed to be directly released to the atmosphere. Therefore, total methane emissions are calculated as the sum of emissions from all three treatment stages, resulting in 14.2 kg $CH_4$ per FU and representing a major source of GHG emissions. For S1, methane generated in the anaerobic stage is assumed to be captured as biogas. Direct emissions in S1 include those from the aerobic stages and the residual biogas released during purification, which is assumed to be 3% of the produced biogas, resulting in 1.7 kg $CH_4$. For S2, direct emissions include methane released during the mill-to-anaerobic digester stage and emissions associated with tail gas from hydrogen production. It is assumed that, apart from the above, no methane is released from other processes.

Two impact assessment methods are applied based

on the ReCiPe 2016 framework. First, the ReCiPe 2016 midpoint (H) method is used with a focus on global warming potential (GWP100), expressed as kg $CO_2$-eq, to quantify the climate change impact associated with POME treatment and conversion. Second, the ReCiPe 2016 endpoint (H) method is applied with a focus on the Natural Resources damage category, expressed in monetary units (USD), to represent resource depletion impacts. Background inventory data are all taken from ecoinvent 3.11, using datasets representative of Malaysia, one of the major palm oil–producing countries. These two results are subsequently used as two alternative representations of environmental gain in the value-based assessment, providing complementary perspectives on climate-related and resource-related impacts.

## Techno-economic assessment

Techno-economic assessment (TEA) is performed, which parameters are shown in **Table 2**. Production costs consist of capital costs and operating costs. Capital costs are annualized directly based on resource data [8, 10]. It should be noted that the techno-economic parameters differ significantly between the two pathways due to their different technology maturity levels. The objective of this study is not to normalize these differences, but to evaluate their influence on integrated environmental–economic performance under consistent functional unit and system boundary assumptions.

**Table 2:** Techno-economic analysis assumptions.

| | Economic parameters | Unit | Value |
|---|---|---|---|
| S1 | Lifetime | Year | 15 |
| | Annualized factor | | 0.096 |
| | Input/output rate | | 0.65 |
| | Total CAPEX | USD | 155000 |
| | Annual operating time | h/year | 4380 |
| | Annual OPEX | USD/year | 25600 |
| | Water selling price | USD/t | 0.79 |
| | Electricity selling price | USD/kWh | 0.09 |
| | Biomethane selling price | USD/$m^3$ | 0.55 |
| S2 | $H_2$ production | t/year | 963.34 |
| | Lifetime | Year | 20 |
| | Annualized factor | | 0.1 |
| | Hydrogen output | kg | 6.08 |
| | Total CAPEX | USD | 121080920 |
| | Annual OPEX | USD/year | 52717984.74 |
| | Hydrogen selling price | USD/kg | 19.68 |

The annualized capital cost is calculated as:

$$Annualized\ CAPEX = CAPEX_{tot} \times AF \quad (2)$$

where $CAPEX_{tot}$ is the total capital cost of the plant, and $AF$ is the annualized capital cost factor derived from the plant lifetime.

For S1, the capital cost allocated to the FU is then obtained based on the annual operating time and the output or input rate of the system:

$$CAPEX_{FU-S1} = \frac{Annualized\ CAPEX}{R \times t_{op}} \quad (3)$$

where $CAPEX_{FU-S1}$is the capital cost per FU for S1, $R$ is the output rate of the system (per hour), and $t_{op}$is the annual operating time (h·yr$^{-1}$).

For S2, the capital cost allocated to the FU is based on annual hydrogen production and hydrogen production per FU:

$$CAPEX_{FU-S2} = \frac{Annualized\ CAPEX \times\ H_2\ output}{Annual\ H_2\ production} \quad (4)$$

where $CAPEX_{FU-S2}$ is the capital cost per FU for S2, $H_2\ output$ is amount of hydrogen produced per FU, and $Annual\ H_2\ production$ is annual production of hydrogen.

For S1, operating costs are calculated based on the annual operating cost and the cost of input materials per FU:

$$OPEX_{FU-S1} = \frac{OPEX_{ann}}{R \times t_{op}} + \sum(Input_i \times Price_i) \quad (5)$$

where $OPEX_{FU}$is the operating cost per FU, $OPEX_{ann}$is the annual operating cost provided in the resource data, $R$ is the output rate of the system (per hour), and $t_{op}$is the annual operating time (h·yr$^{-1}$). $Input_i$is the quantity of input $i$ required per FU, and $Price_i$ is the corresponding unit price.

For S2, operating costs are calculated based on the annual operating cost, annual hydrogen production and hydrogen production per FU:

$$OPEX_{FU-S2} = \frac{Annualized\ OPEX \times\ H_2\ output}{Annual\ H_2\ production} \quad (6)$$

where $OPEX_{FU-S2}$is the operating cost per FU for S2, $H_2\ output$ is amount of hydrogen produced per FU, and $Annual\ H_2\ production$ is annual production of hydrogen. And cost of input materials and energy in S2 are included in $OPEX_{ann}$.

Product revenues are calculated as the market values of POME-derived products:

$$Total\ revenue = \sum(Product_j \times Price_j) \quad (7)$$

where $Product_j$ is the output quantity of product $j$ per FU, and $Price_j$is the corresponding market price.

The net economic value (NEV) is evaluated by subtracting total revenues (TR) with the sum of capital and operating costs per FU.

The benchmark is not included in the cost calculation, because this study focuses exclusively on the costs associated with valorizing an existing POME treatment facility.

## Value-based assessment

Unlike conventional investment analysis that considers only ROI, value-based assessment also incorporates environmental gains to represent the sustainability value of impact mitigation in a unified metric.

Firstly, the return of investment (ROI) is used to evaluate the conventional economic performance of each scenario. ROI is defined as:

$$ROI = \frac{Financial\ gain - Financial\ loss}{Total\ investment}$$

where $Financial\ gain$ represents the revenue obtained from product sales and $Financial\ loss$ includes capital and operating costs.

ROI is applied to quantify the economic attractiveness of each pathway without considering environmental externalities and serves as a reference to the integrated sustainability performance indicated by ROV.

The integrated sustainability performance is quantified using the ROV [11]:

$$ROV = \frac{Value\ gain - Value\ loss}{Total\ investment} \quad (8)$$

where $Value\ gain$ includes both financial and environmental gains from investment, while $Value\ loss$ represents the total cost, including both $CAPEX$ and $OPEX$.

Two approaches are applied to quantify environmental gains. Under the midpoint-based approach, environmental gain is estimated by multiplying the avoided GHG emissions by the projected Malaysian carbon price:

$$Enivironmental\ gain_{GHG} = \Delta GHG \times P_{carbon} \quad (9)$$

where $\Delta GHG$is the reduction from benchmark and including the avoided fossil-derived products in GWP100 and $P_{carbon}$is the carbon price (RM 35–45/t $CO_2$-eq) [12], we use the average 40 RM/t $CO_2$-eq, or 10 USD/t $CO_2$-eq.

Under the endpoint approach, environmental gain directly uses the Natural Resources damage category expressed in monetary units (USD). This value is derived from the ReCiPe2016 endpoint (H) method, which converts resource depletion into economic terms based on the marginal increase in future extraction costs caused by current resource use, thereby representing the damage to natural capital in value units.

The economic gain is calculated as NEV from product sales, while total investment includes $OPEX_{FU}$ and $CAPEX_{FU}$. The ROV indicator therefore integrates economic profitability and environmental externalities into a unified value metric, enabling direct comparison between POME valorization technologies.

# RESULTS AND DISCUSSION

The environmental impacts of the two scenarios are evaluated using two complementary approaches. **Figure 2a** presents the GHG emission results, with the conventional treatment used as a benchmark. Both S1 and S2 achieve net GHG reductions, which are 392.57 and 158.99 kg $CO_2$-eq, respectively. This indicates that diverting POME from direct discharge to valorization pathways can substantially mitigate climate impacts. For S1, the dominant contribution is the avoided GHG emissions associated with fossil-derived energy substitution through biomethane utilization, totally 447.38 kg $CO_2$-eq. This negative contribution outweighs the positive emissions arising from electricity use, biogas purification, and material inputs, resulting in a net GHG reduction. Direct methane emissions are relatively low because methane generated in the anaerobic stage is assumed to be captured and upgraded, with only minor losses during purification. In S2, avoided GHG emissions is 513.97 kg $CO_2$-eq, but this benefit is partially offset by process emissions. Steam and heat consumption for reforming and gas separation represent the largest positive contributors, followed by tail gas release. As a result, although S2 still achieves net GHG reduction compared with the benchmark, its total GHG benefit is smaller than that of S1. Overall, the GHG results highlight contrasting mitigation mechanisms: S1 mainly reduces emissions through methane capture and fossil energy substitution, whereas in S2 the avoided emissions from hydrogen substitution are largely offset by substantial process emissions. Therefore, biomethane is more effective than bio-hydrogen in reducing GHG emissions under current conditions.

**Figure 2b** shows the endpoint results for natural resources in terms of avoided damage, incurred damage, and net damage for the two valorization scenarios. For S1, the net damage is -6.17 USD, showing that the avoided damage associated with fossil-derived substitution exceeds the resource damage generated during processing. This result indicates that biomethane production provides a small net benefit in the natural resources indicator, as the resource savings from displaced fossil energy outweigh the additional resource use required for treatment and purification. In S1, the avoided damage associated with fossil-derived energy substitution slightly exceeds the resource damage generated during processing, resulting in a small negative net damage. This indicates that biomethane production leads to a marginal net benefit in the natural resources category, as the resource savings from displaced fossil energy offset the additional resource use required for treatment and upgrading. In contrast, the net damage of S2 is 12.41 USD, exhibiting a positive net damage. Although hydrogen substitution leads to a larger avoided damage than in S1, this benefit is more than offset by the substantial resource damage

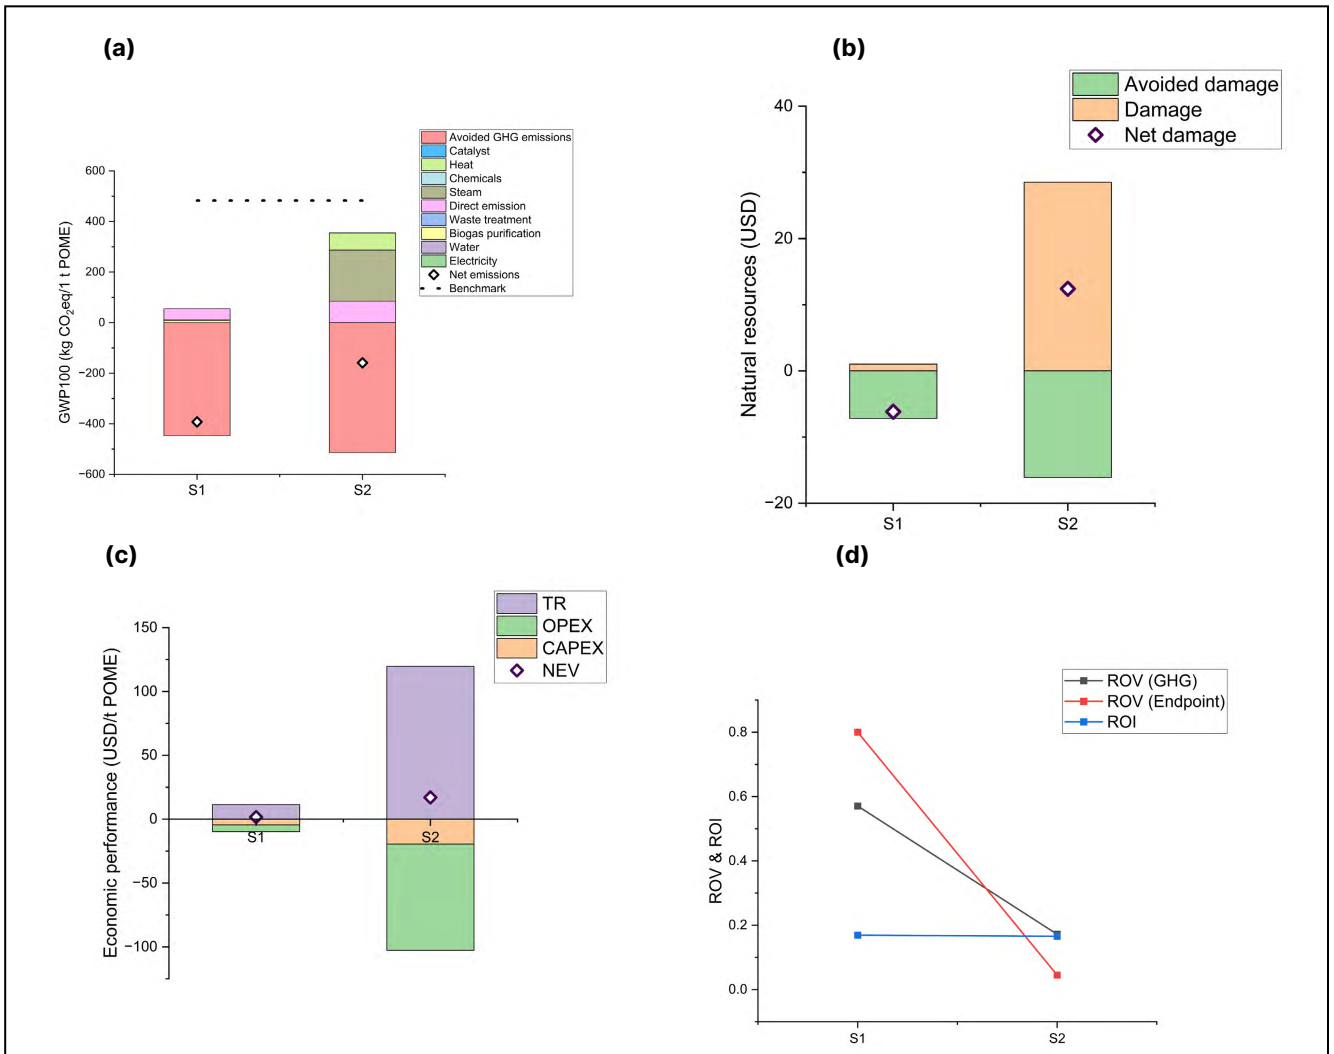

**Figure 2.** Integrated results of POME management scenarios (B–S2): (2a) GHG emissions (GWP100), (2b) endpoint indicator (Natural resources), (2c) economic performance (CAPEX, OPEX, TR, and NEV), and (2d) ROV based on GHG- and endpoint-derived environmental gains and financial gains and ROI only based on financial gains.

caused by conversion processes. Steam contributes significantly to the positive damage term. As a result, S2 shows an overall increase in natural resource impacts.

Overall, the environmental assessment indicates that biomethane production delivers more favorable environmental performance because the bio-hydrogen production is much more energy-intensive.

**Figure 2c** illustrates the economic performance of the two valorization scenarios in terms of capital expenditure (CAPEX), operating expenditure (OPEX), TR, and NEV. In S1, both CAPEX and OPEX are relatively low, reflecting the technological maturity of the biomethane pathway and its moderate energy and material requirements. The resulting TR from biomethane production slightly exceeds the total production cost, leading to a relatively low NEV. This indicates that biomethane production can approximately balance costs and revenues under the assumed conditions. In contrast, S2 exhibits substantially higher production costs, particularly in OPEX, which is mainly driven by intensive steam, heat, and chemical inputs required for hydrogen production. Although S2 achieves a much higher TR due to the higher market value of hydrogen, this revenue is largely offset by the elevated operating costs. As a result, the NEV of S2 remains positive but is only moderately higher than that of S1. Overall, the economic results suggest that S1 represents a low-risk and cost-stable option, whereas S2 offers higher revenue potential at the expense of significantly increased cost intensity.

**Figure 2d** compares the performance of the two valorization scenarios using ROI and ROV. In terms of conventional ROI, both scenarios exhibit similar profitability, with ROI values of 17% for S1 and 18% for S2. This indicates that biomethane and bio-hydrogen pathways provide comparable financial returns under the assumed market and cost conditions. When environmental gains

are incorporated using the midpoint impact approach (GHG-only), a clear differentiation emerges. The $ROV_{GHG}$ of S1 reaches 0.57, substantially higher than the value of 0.17 obtained for S2. This result reflects the stronger climate mitigation effect of biomethane production through effective methane capture and fossil energy substitution, whereas the larger process-related emissions in S2 reduce its net GHG-based value gain. A larger contrast is observed when environmental gains are evaluated using the endpoint-based approach. The $ROV_{endpoint}$ of S1 reaches 0.8, while that of S2 drops to 0.04. This indicates that, once broader environmental damage categories are considered, the integrated sustainability performance of biomethane production is markedly superior to that of bio-hydrogen production. The intensive energy and material requirements of the hydrogen pathway substantially increase its endpoint damages, which are not fully compensated by its higher economic return. Overall, the value-based assessment demonstrates that scenario ranking is highly sensitive to how environmental gains are represented, with S1 consistently favored when both climate-related and damage-oriented indicators are considered.

## CONCLUSIONS

This study applied a value-based assessment framework to examine how technological choice influences the integrated environmental–economic performance of POME valorization. By selecting biomethane production and bio-hydrogen production as representative mature and emerging technologies, the analysis first characterized their life-cycle environmental and economic profiles and then integrated these dimensions using the ROV.

The ROV results demonstrate that the attractiveness of POME valorization pathways depends strongly on how environmental gains are represented. When environmental performance is expressed through midpoint indicators focusing on GHG emissions, the bio-hydrogen pathway can appear competitive due to its high product value and credited climate benefits. In contrast, when endpoint indicator is applied to capture a broader environmental burden on natural resources, the biomethane pathway shows a superior integrated performance. This difference indicates that technological maturity is reflected not only in process reliability and cost structure, but also in the balance between avoided impacts and newly introduced environmental burdens. From a methodological perspective, value-based assessment offers a means to integrate LCA and TEA by expressing environmental impacts in value terms, but its interpretation is constrained by the assumptions underlying environmental valuation. GHG-based valuation depends on carbon price scenarios that presuppose the existence of policy instruments such as carbon taxes or markets, while endpoint-based resource valuation reflects theoretical damage costs rather than actual economic transactions. Several limitations should be acknowledged. In the economic assessment, labor employment and associated wage costs were not explicitly considered, which may lead to an underestimation of total production costs. In addition, catalyst recovery and reuse were not included, and tail gas was assumed to be directly emitted, which may overestimate environmental burdens for advanced configurations.

Overall, the proposed framework provides a quantitative basis for comparing mature and emerging POME valorization technologies on a common value scale. It supports strategic technology selection by revealing how technological maturity shapes integrated sustainability performance and offers a structured approach for guiding sustainable wastewater management and bio-economy development in the palm oil sector.

## ABSTRACT

Plastic pyrolysis is widely promoted as a techno-economic industrial scale recycling strategy. Nevertheless, the fate and reactivity of plastic chemical additives during pyrolysis are mostly overlooked in product quality and environmental release assessments. Here, we present an integrated modeling framework to elucidate the role of additives in plastic pyrolysis and evaluate the implications of their transformation products and environmental releases. Using high-density polyethylene (HDPE) as a case study, chemical additives of concern are selected based on occurrence, concentration data, and potential risk to human health and the environment. Bond dissociation energies are predicted using a machine learning model to identify dominant radical species formed under pyrolytic conditions. These additive-derived radicals are incorporated into an automatic chemical reaction mechanism generator that constructs kinetic models composed of elementary chemical reaction steps. These kinetic models are simulated using kinetic Monte Carlo (kMC) methods to predict product distributions and yields. The results show that common additives readily form stabilized alkyl and aryl radicals at energies accessible during pyrolysis, enabling their active participation in polymer degradation pathways. These interactions influence product formation and may contribute to the generation of environmentally relevant by-products. Overall, this study provides a mechanistic and risk-informed perspective on plastic pyrolysis, emphasizing the importance of explicitly accounting for additive chemistry in the development of safer and more sustainable chemical recycling technologies.**Disclaimer**: The views expressed in this work are those of the authors and do not necessarily represent the views or policies of the EPA.

## INTRODUCTION

Plastic pollution remains a critical global challenge due to rapidly increasing waste generation and the limited effectiveness of existing recycling technologies. Approximately 2.01 billion metric tons of municipal solid waste (MSW) are generated annually worldwide, a figure projected to rise to 3.4 billion metric tons by 2050 [1]. Plastics constitute a substantial fraction of this end-of-life (EoL) material stream, accounting for roughly 7–12% by weight in the United States [2]. Despite ongoing recovery efforts, only 9–10% of plastic MSW is recycled globally, while 12–19% is incinerated, and the majority is landfilled or released into the environment, leading to persistent accumulation and adverse environmental and human health impacts [3].

In this context, pyrolysis has emerged as a promising thermochemical upcycling strategy for converting plastic waste into fuels, monomers, and chemical feedstocks under oxygen-free conditions. However, plastics are chemically complex materials that contain not only polymer matrices but also a wide range of intentionally

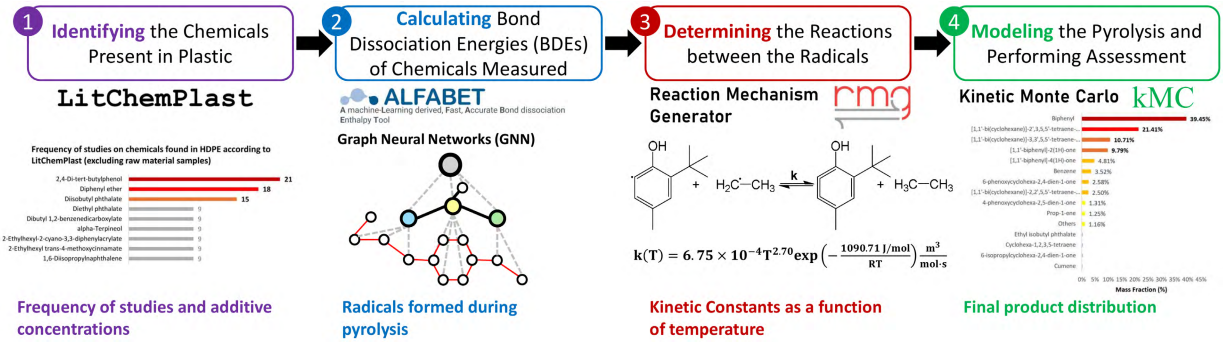

**Figure 1.** Proposed framework comprising the LitChemPlast database, the machine learning model ALFABET, the Reaction Mechanism Generator (RMG), and kinetic Monte Carlo (kMC) simulations to estimate the reactions, fate, and releases of chemical additives in plastic pyrolysis.

and non-intentionally added substances, including residual monomers, additives, and processing aids. Data from the LitChemPlast database show that over 3, 500 chemicals have been detected in plastics across 372 studies, with more than 16, 000 substances linked to plastic products, including over 4, 200 classified as hazardous [4]. Despite this complexity, most pyrolysis studies focus on polymer degradation, largely overlooking the fate and reactivity of additive-derived chemicals.

Mechanistic modeling approaches, including kinetic Monte Carlo (kMC) simulations, have been widely applied to describe polymer degradation and predict product distributions based on molecular-scale reaction kinetics [5]. However, polymer–additive interactions remain poorly characterized due to limited experimental data and incomplete reaction mechanisms, reducing the predictive capability of conventional models [6]. Machine learning (ML) offers a powerful means to address these limitations by enabling systematic identification of chemically plausible reaction pathways and reactive intermediates [7].

In this work, we integrate ML-based tools with kMC simulations to explicitly account for additive chemistry during plastic pyrolysis. Representative additives are selected based on occurrence and concentration data from the LitChemPlast database. Bond dissociation energies are predicted using ALFABET to identify dominant radical species formed under pyrolytic conditions [8], and their subsequent interactions are explored using the reaction mechanism generator (RMG) [9]. The resulting reaction networks are simulated using kMC to predict product distributions and yields and used to assess the environmental fate and impacts of pyrolysis-derived products. The framework is demonstrated through a case study of high-density polyethylene (HDPE) pyrolysis that incorporates three frequently reported additives (2, 4-di-tert-butylphenol, diphenyl ether, and diisobutyl phthalate).

## Methodology

This work introduces an integrated framework to predict product yields and the formation of chemicals of concern during plastic pyrolysis. Machine learning (ML) tools, coupled with kinetic Monte Carlo (kMC) simulations, capture additive-derived reaction pathways often neglected in conventional analyses. The framework identifies representative plastic-associated chemicals, predicts dominant radicals using bond dissociation energy (BDE) analysis, and constructs reaction networks that are used to determine the pyrolysis degradation products. Figure 1 outlines the workflow from chemical identification and radical generation to kMC-based product prediction.

### Identifying the Chemicals Present in Plastic

The LitChemPlast database is used to identify and quantify chemicals present in plastics. It compiles and harmonizes chemo-analytical measurements across multiple stages of the plastic life cycle, addressing the limited availability of publicly accessible data on plastic chemical composition. The database includes studies published between 1978 and 2021, identified through systematic searches via Web of Science and SciFinder followed by a two-stage screening process. Extracted data include bibliographic information, sample characteristics (product categories and polymer types), analytical methods, and measured chemicals, with concentrations standardized and reported in parts per million (ppm) [4].

In this study, the comprehensive state-of-the-art open database of chemical additives in plastics, LitChemPlast, is used to identify chemicals of concern with the highest reported occurrence and concentrations across different plastic types and applications. This information enables the selection of representative compounds that are most likely to participate in chemical reactions during the pyrolysis process and therefore influence reaction pathways and product formation.

### Calculating Bond Dissociation Energies (BDEs) of Chemicals Measured in Plastics

To predict radical formation during pyrolysis, bonds most susceptible to thermal cleavage must be identified. Bond dissociation energies (BDEs) quantify bond strength and are used to determine bond-breaking under pyrolytic conditions. A BDE is the energy required for homolytic cleavage of a bond (A–B) into radicals ($A\bullet$ and $B\bullet$) [10]. As thermodynamic parameters, BDEs inform reactivity, kinetics, and accessible pathways in radical-driven systems. Bond dissociation is shown in Equation (1), and BDEs are calculated from the enthalpies of formation ($\Delta_f H$) of the parent molecule and the resulting radicals (Equation (2)).

$$A - B \rightarrow A\bullet + B\bullet \quad (1)$$

$$BDE = \Delta_f H(A\bullet) + \Delta_f H(B\bullet) - \Delta_f H(A - B) \quad (2)$$

Experimental determination of BDEs is challenging and restricted to a few techniques, including radical kinetics, photoionization mass spectrometry, and the acidity–electron affinity thermochemical cycle. These methods require high-precision measurements, advanced instrumentation, and strict control, limiting their applicability, particularly for complex or transient species [11]. Quantum chemical approaches, such as density functional theory (DFT), provide accurate BDE estimates but are computationally intensive and sensitive to the level of theory options chosen.

To address these limitations, we employ ALFABET, a machine learning (ML)-based model that predicts homolytic BDEs of organic molecules with near-DFT accuracy at sub-second computational cost. ALFABET is trained on over 290, 000 DFT-calculated BDEs using a graph neural network that operates directly on molecular structures derived from simplified molecular input line entry system (SMILES) strings, eliminating manual feature engineering. The model achieves mean absolute errors of 2.4 kcal $mol^{-1}$ for in-distribution molecules and 3.4 kcal $mol^{-1}$ for out-of-distribution molecules, compared with DFT values of 2.1 kcal $mol^{-1}$ and 2.5 kcal $mol^{-1}$, respectively. This accuracy loss is compensated by a significant decrease in the CPU time per molecule, where DFT methods require 31.4 h while ALFABET 1 ms [8].

In this work, ALFABET is used to estimate the BDEs of compounds selected from the LitChemPlast database. For each compound, the lowest BDE is used to identify the most probable radical species formed during pyrolysis, which are subsequently incorporated into the reaction network to predict the content of additive-derived chemicals in pyrolysis products and environmental releases.

## Determining the Reactions between the Radicals Formed During Plastic Pyrolysis

The reaction network describing interactions between additive-derived radicals is constructed using the kinetic search module of the RMG. Starting from the radical species identified by the BDE analysis, RMG systematically enumerates chemically plausible elementary reactions and assigns temperature-dependent rate coefficients to each reaction. Pressure-independent kinetics are described using a modified Arrhenius expression as shown in equation (3).

$$k(T) = A\left(\frac{T}{T_0}\right)^n \exp\left(-\frac{E_0 + \alpha\Delta H_{\mathrm{rxn}}}{RT}\right) \quad (3)$$

Where $A$ is the pre-exponential factor, $n$ is the temperature exponent, $T_0$ is a reference temperature, $E_0$ is the activation energy for a thermoneutral reaction, $\Delta H_{\mathrm{rxn}}$ is the reaction enthalpy, $\alpha$ is the Evans-Polanyi coefficient, $R$ is the universal gas constant, and $T$ is the system temperature. The Evans-Polanyi corrections are not applied in this work; therefore, $\alpha$ and $\Delta H_{\mathrm{rxn}}$ are set to zero, and the reported activation energy corresponds directly to $E_0$.

When assigning kinetic parameters, RMG uses a hierarchical strategy prioritizing data reliability. Parameters are taken from user-provided seed mechanisms, followed by curated reaction libraries, matched training reactions, exact rule-based matches, and, when necessary, estimated average rates. When multiple sources exist within a category, parameters are ranked by level of theory or experimental evidence, with experimental data and high-level quantum calculations prioritized over lower-level estimates [9].

Using this structured approach, RMG generates a consistent and chemically informed reaction network describing radical–radical interactions during pyrolysis. The resulting elementary reactions and associated kinetic parameters are subsequently used as inputs to the kinetic Monte Carlo (kMC) simulations to predict product formation, concentrations, and yields.

## Modeling Pyrolysis using Stochastic Simulations

The kMC method is a stochastic simulation framework based on the stochastic simulation algorithm (SSA) originally developed by Gillespie. It enables the time-resolved simulation of chemically reacting systems by explicitly considering the probabilistic nature of individual reaction events [5]. As shown in Figure 2, implementing kMC requires kinetic and system-specific inputs, including reaction-specific pre-exponential factors and activation energies, as well as operating conditions such as temperature, system volume, and the initial populations of all chemical species. The kinetic inputs are obtained from the RMG results, and the process conditions are established based on previous plastic pyrolysis studies.

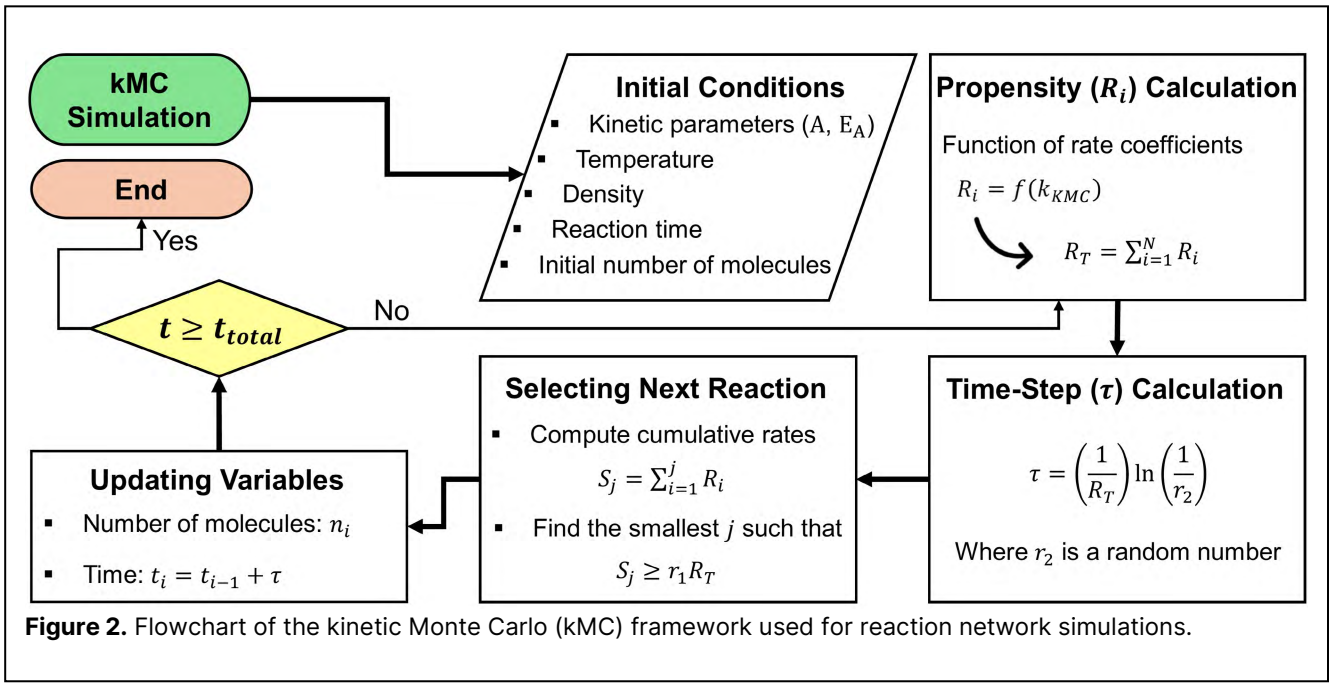

**Figure 2.** Flowchart of the kinetic Monte Carlo (kMC) framework used for reaction network simulations.

From these inputs, stochastic rate constants are derived from the corresponding macroscopic rate coefficients, accounting for reaction order and molecularity. Specifically, distinct expressions are used for first-order unimolecular reactions, second-order bimolecular reactions between identical species, and second-order bimolecular reactions between different species, as shown from equations (4) to (6), respectively, where $k_a^{\exp}, k_{aa}^{\exp}$, and $k_{ab}^{\exp}$ denote the macroscopic rate coefficients, $N_A$ is Avogadro's number, and $V$ is the control volume [12]. These stochastic rate constants are used to calculate the reaction propensities for each elementary reaction channel. Equation (7) shows the total propensity of the system ($R_T$), which is obtained by summing up the propensities of all reactions ($R_i$).

$$k^{MC} = k_a^{\exp} \tag{4}$$

$$k^{MC} = \frac{2k_{aa}^{\exp}}{V \cdot N_A} \tag{5}$$

$$k^{MC} = \frac{k_{ab}^{\exp}}{V \cdot N_A} \tag{6}$$

$$R_T = \sum_{i=1}^{N} R_i \tag{7}$$

The time to the next reaction event is sampled by generating a uniform random number $r_2 \in (0,1)$, which determines the stochastic time increment. A second random number $r_1 \in (0,1)$is then used to select the reaction event by identifying the first reaction whose cumulative propensity exceeds $r_1 \cdot R_T$. Following reaction selection, the populations of reactant and product species are updated according to the reaction stoichiometry. This procedure is repeated, allowing the reaction network to evolve stochastically over time while rigorously preserving the correct statistical distribution of reaction events.

Following the kMC simulations, time-resolved product distributions and final yields are obtained, and high-concentration products are prioritized for downstream analysis due to their relevance for environmental exposure and risk evaluation [13]. This study introduces a fully integrated, mechanistic framework that explicitly links additive-specific reaction chemistry to pyrolysis product formation and environmental releases, which is an aspect that has not been systematically addressed in prior pyrolysis modeling efforts. Whereas most existing models are constrained to polymer-only degradation due to the severe lack of kinetic data for additive-derived reactions, the present approach overcomes this limitation by combining ML-based reactivity prediction, automated reaction mechanism generation, and stochastic kinetic modeling. By doing so, this work enables, for the first time, predictive exploration of additive-driven degradation pathways, improves the reliability of pyrolysis outcome predictions, and supports early identification of environmentally relevant and potentially hazardous degradation products.

## RESULTS AND DISCUSSION

This section presents the validation of the proposed methodology through a case study on plastic pyrolysis. The most frequently reported chemicals associated with the selected plastic are identified, and their BDEs are used to determine the dominant radical species formed during thermal degradation. The interactions between additive-derived radicals are then analyzed to determine key reaction pathways and their influence on product

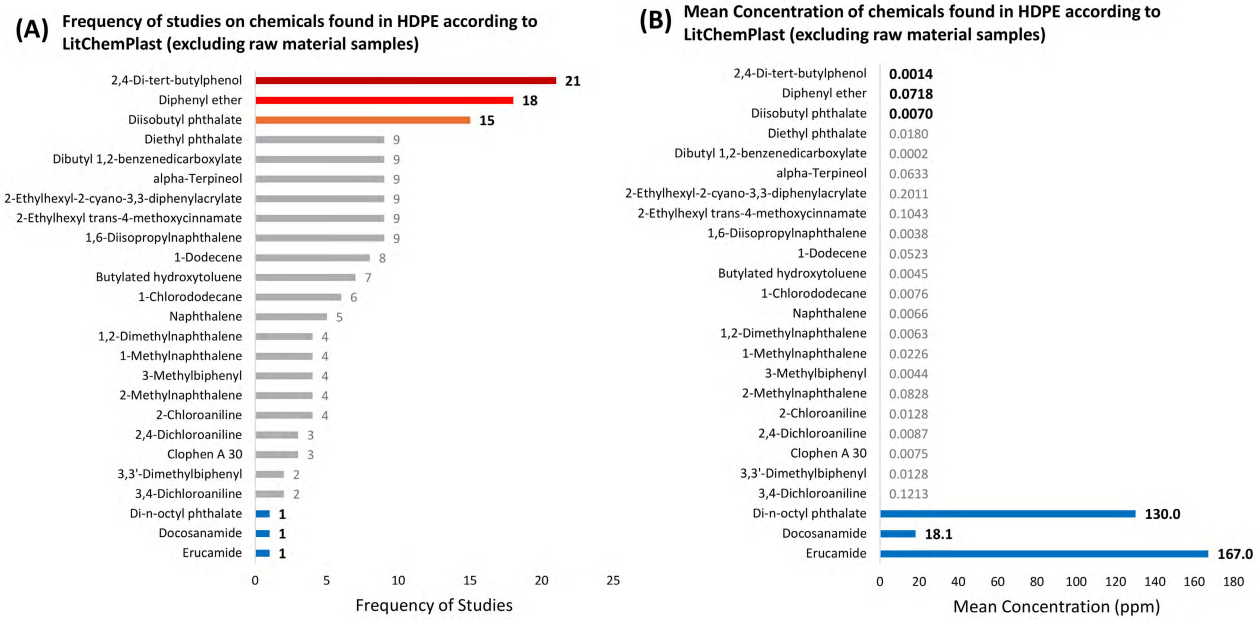

**Figure 3. A)** Frequency of studies and **B)** Mean concentration in parts per million (ppm) of additives found in HPDE according to the LitChemPlast database, excluding raw material samples.

formation. Based on these reactions, the resulting product distribution is predicted, and the environmental implications and fate of the released chemicals are subsequently assessed.

## Case Study: Pyrolysis HDPE with Chemical Additives

The case study used to validate the proposed methodology is based on the pyrolysis of HDPE, considering the chemical additives identified in different HDPE samples as reported in the LitChemPlast database. Figure 3 shows the frequency of studies reporting chemicals detected in HDPE and their corresponding mean concentrations, as compiled from the LitChemPlast database [4].

As shown in Figure 3A, the chemicals most frequently reported in HDPE samples are 2, 4-di-tert-butylphenol, diphenyl ether, and diisobutyl phthalate, identified in 21, 18, and 15 samples, respectively. Additive selection was primarily based on occurrence frequency across the LitChemPlast dataset to ensure that the case study compounds are broadly representative of HDPE samples.

In contrast, di-*n*-octyl phthalate, docosanamide, and erucamide were each detected in only a single sample but exhibited the highest concentrations (Figure 3B). While such high-concentration additives represent interesting case studies, their limited occurrence restricts statistical representativeness. Nevertheless, when present in specific EoL streams, their high concentration may significantly influence the emission risk profile: erucamide undergoes autocatalytic degradation below 90°C generating nitrile species and alkyl radicals [14], while di-n-octyl phthalate decomposes via ester bond cleavage to yield oxygenated aromatics [15]. These chemicals were excluded from this case study; however, the proposed framework is generalizable and can readily be applied to such scenarios.

**Table 1:** Chemical structure, description, SMILES string, and primary hazards of the most measured chemical compounds in HDPE samples.

| **Information** | **2, 4-di-tert-butylphenol** | **Diphenyl ether** | **Diisobutyl Phthalate** |
|---|---|---|---|
| Chemical Structure | | |  |
| Description | Antioxidant [16] | Degradation product [17] | Plasticizer[18] |
| SMILES String | CC(C)(C)c1ccc(O)c(C(C)(C)C)c1 | c1ccc(Oc2ccccc2)cc1 | CC(C)COC(=O)c1ccccc1C(=O)OCC(C)C |
| Primary Hazards | Corrosive, Irritant, Health Hazard, Environmental [16] | Irritant, Environmental hazard [17] | Health Hazard [18] |

Consequently, this work focuses on the three most frequently reported chemicals in HDPE (excluding raw material samples), as identified in the LitChemPlast database: 2, 4-di-tert-butylphenol, diphenyl ether, and

diisobutyl phthalate. Notably, all three compounds are associated with hazard classifications, including potential carcinogenicity and aquatic toxicity [16] [17] [18]. Table 1 summarizes their key characteristics, including their functional roles in HDPE and SMILES representations, which are subsequently used to compute the corresponding BDEs.

## Computing BDEs of Chemicals Measured

The calculated BDEs for the three compounds selected in the case study are summarized in Table 2. For each compound, the two lowest BDE values are reported to provide an overview of the energetically most accessible bond-cleavage pathways.

**Table 2:** The two lowest BDE values obtained with ALFABET for 2, 4-di-tert-butylphenol, diphenyl ether, and diisobutyl phthalate.

| Bond | 2, 4-di-tert-butylphenol | Diphenyl ether | Diisobutyl Phthalate |
|---|---|---|---|
| #1 |  Bond Type: C-C *BDE(ML):* 76.1kcal/mol |  Bond Type: C-O *BDE(ML):* 84.2kcal/mol |  Bond Type: C-C *BDE(ML):* 87.1kcal/mol |
| #2 |  Bond Type: C-C *BDE(ML):* 76.7kcal/mol |  Bond Type: C-H *BDE(ML):* 110.9kcal/mol |  Bond Type: C-C *BDE(ML):* 89.0kcal/mol |

Across all compounds, the lowest BDEs range from approximately 76.1 to 87.1 kcal mol$^{-1}$, indicating that radical formation from these additives is thermodynamically accessible under typical pyrolysis temperatures (≥ 400-600 °C), where thermal energies are sufficient to activate bond cleavage within this range.

For 2, 4-di-tert-butylphenol, the lowest BDEs (76.1 and 76.7 kcal mol$^{-1}$) correspond to C-C bond cleavage within the tert-butyl substituents. These values are approximately 10 kcal mol$^{-1}$ lower than the phenolic O-H bond dissociation energy (85.9 kcal mol$^{-1}$) and nearly 20 kcal mol$^{-1}$ lower than aromatic C-C bond cleavage (96.5 kcal mol$^{-1}$). This significant energetic preference indicates that pyrolysis is initiated predominantly through the formation of tert-butyl-derived alkyl radicals rather than phenoxy or aryl radicals.

In the case of diphenyl ether, the weakest bond is the aryl-O bond, with a BDE of 84.2 kcal mol$^{-1}$. This value is significantly lower than the aromatic C-H BDEs (110.9-112.0 kcal mol$^{-1}$), indicating that homolytic cleavage of the ether bond is the primary pathway for radical formation. The resulting phenyl and phenoxy radicals are stabilized by resonance and are known to participate in secondary reactions that lead to aromatic growth. Therefore, for the formation of alkyl radicals observed in 2, 4-di-tert-butylphenol, diphenyl ether predominantly contributes to aromatic radical species, which may affect the formation of polycyclic aromatic hydrocarbons and char during pyrolysis.

For diisobutyl phthalate, the lowest BDEs (87.1 and 89.0 kcal mol$^{-1}$) are associated with C-C bond cleavage in the isobutyl side chains. These values are 8-10 kcal mol$^{-1}$ lower than C-H bond dissociation energies in the ester backbone (95.9-96.7 kcal mol$^{-1}$), indicating that radical formation is dominated by the release of isobutyl radicals rather than direct fragmentation of the aromatic or ester part.

Overall, the BDE analysis demonstrates that additive-derived radicals are thermodynamically favored to form under pyrolytic conditions, and their nature strongly depends on the additive structure. These results provide a quantitative basis for including additive-derived radicals in the reaction network and support their potential role in modifying polymer degradation pathways, product distributions, and the formation of environmentally relevant by-products.

## Determining the Reactions between the Radicals Formed During the Plastic Pyrolysis

Based on the BDE analysis obtained using ALFABET, the radical species considered in the pyrolysis simulations are summarized in Table 3. For each additive, the lowest BDE value is selected as the most probable bond-cleavage pathway, resulting in two corresponding radical species that are incorporated into the reaction network. These additive-derived radicals constitute the initial reactive pool used for reaction network generation with the RMG.

To determine the interactions among radical species, binary interactions between all species are assumed. This assumption is widely used in kinetic modeling of pyrolysis and combustion systems, where bimolecular reactions dominate radical propagation, abstraction, and termination pathways. In contrast, higher-order reactions are statistically less probable under typical thermal decomposition conditions due to the low likelihood of simultaneous multi-body collisions. Consistent with this framework, the RMG constructs reaction networks primarily from unimolecular and bimolecular reaction steps based on established kinetic theory [19]. Considering this, Figure 4 summarizes the reaction space generated

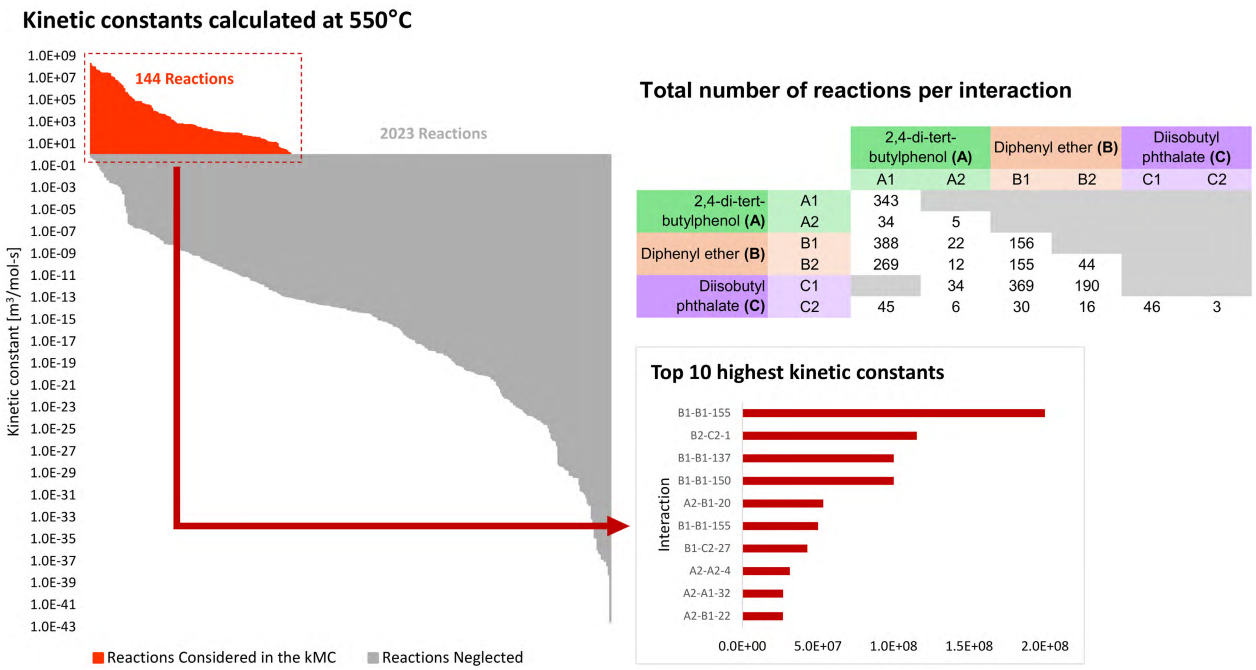

**Figure 4.** Total number of reactions generated for each radical-radical interaction, along with the corresponding kinetic parameters obtained from the Reaction Mechanism Generator (RMG). Of the 2,167 reactions identified, 144 are selected for inclusion in the kinetic Monte Carlo (kMC) simulations.

by RMG for interactions between additive-derived radicals and the subset retained for kMC simulations. 2, 167 elementary reactions are identified across all radical–radical interactions; however, only 144 reactions are selected based on their kinetic relevance at the pyrolysis temperature (550 °C). These retained reactions exhibit rate constant values several orders of magnitude higher than the remainder of the network, indicating that a relatively small subset of reactions dominates system kinetics.

The distribution of kinetic constants spans more than 40 orders of magnitude, with the fastest reactions primarily involving diphenyl ether-derived radicals (B-type), which account for the highest number of reaction pathways and the largest rate constants. The highest-rate reactions are predominantly radical–radical recombination or hydrogen abstraction events, consistent with expected high-temperature pyrolysis chemistry.

The reduction of the reaction network relies on the assumption that reactions with negligible rate constants do not significantly contribute to product formation within the simulated time scale. This filtering strategy preserves the chemically and kinetically dominant pathways while maintaining computational tractability, enabling efficient and physically meaningful kMC simulations of product formation.

**Table 3:** Radical species considered for generating the reaction network using the RMG.

| Original Compound | Radical ID | Chemical Structure | SMILES |
|---|---|---|---|
| 2, 4-di-tert-butylphenol | A1 |  | [C](C)(C)C1=CC(=C(C=C1)O)C(C)(C)C |
| 2, 4-di-tert-butylphenol | A2 | | [CH3] |
| Diphenyl ether | B1 | | C1=CC=C(C=C1)[O] |
| Diphenyl ether | B2 | | [c]1ccccc1 |
| Diisobutyl phthalate | C1 |  | CC(C)COC(=O)C1=CC=CC=C1C(=O)O[CH2]C[CH]C |
| Diisobutyl phthalate | C2 | | |

## Modeling the Reaction Network using Stochastic Simulations

Figure 5 presents the product distribution predicted by the kMC simulations, showing the final mass fractions

of the compounds.

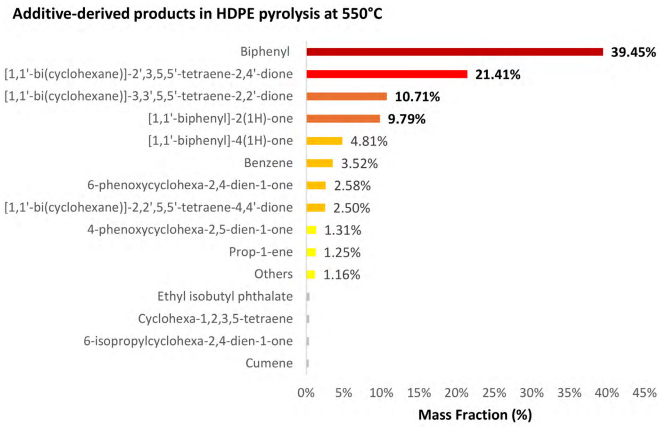

**Figure 5.** Product distribution predicted by the kMC simulation, considering just the chemicals derived from additives.

The kMC results show that product formation is dominated by a small number of aromatic and partially hydrogenated cyclic compounds, indicating that kinetically favored pathways govern system behavior. Biphenyl accounts for nearly 40 wt% of the additive-derived products, followed by phenolated ketones and cyclohexadienedione derivatives. These findings are consistent with the high stability and reactivity of aromatic radicals identified in the BDE and RMG analyses, especially those originating from diphenyl ether, which exhibits both high reaction connectivity and elevated rate constants.

The prominence of aromatic products suggests that additives can redirect polymer degradation toward aromatic-rich pathways, rather than acting as inert spectators during pyrolysis. This behavior contrasts with conventional polymer-only pyrolysis models, which typically predict product distributions dominated by aliphatic hydrocarbons. The formation of stabilized aromatic species early in the reaction network also explains their persistence at high concentrations in the final product mixture.

From an environmental perspective, several of the dominant products raise concerns. Biphenyl is persistent, hydrophobic, and toxic to aquatic organisms, with documented bioaccumulation potential [20]. Benzene, although produced at lower yields, is a well-established human carcinogen and a regulated air pollutant [21]. Phenolated ketones and cyclohexadienedione derivatives may serve as precursors to polycyclic aromatic hydrocarbons under secondary thermal or environmental conditions, contributing to mutagenic and carcinogenic risks. These results highlight that additive chemistry can significantly influence not only product yields but also the environmental risk profile of pyrolysis outputs.

Overall, these results show that plastic additives actively influence pyrolysis chemistry by serving as radical precursors that redirect degradation pathways and product formation. By integrating additive occurrence data with ML-based bond dissociation analysis, automated reaction mechanism generation, and kinetic Monte Carlo simulations, this study establishes a mechanistic link between additive chemistry, product distributions, and potential environmental impacts. Neglecting additive-derived reactions leads to systematic underprediction of aromatic and environmentally relevant by-products, limiting the reliability of polymer-only pyrolysis models. The proposed framework enables predictive assessment of pyrolysis outcomes and early identification of potentially hazardous degradation products, addressing key challenges associated with scarce kinetic data for additive reactions and supporting safer, more sustainable plastic recycling technologies.

## CONCLUSIONS

The framework established in this study offers a risk-informed perspective on plastic pyrolysis by shifting the analytical focus from isolated polymer matrices to consider the complex chemical interactions of additives within EoL streams. By leveraging the ALFABET model to predict bond dissociation energies with near-DFT accuracy at sub-second speeds, we have enabled a systematic, scalable assessment of additives present in commercial plastics. As thermal recycling strategies like pyrolysis are promoted globally, future kinetic and environmental assessments must move beyond polymer-only models to incorporate the additive-derived reaction pathways identified here. Ultimately, the generalization of this framework into a computational tool will be crucial for characterizing other polymers and complex mixtures, ensuring the production of safe, high-value chemical feedstock from plastic EoL material.

## ABSTRACT

The case of banana peel as a rich source of pharmaceutically important polyphenols is well-known. Our research focuses on techno-economic and environmental impact assessment of sourcing polyphenols from banana peel. Firstly, phenolic acids and flavonoids, the two major classes of polyphenols, are extracted from dried banana peel powder. The extraction process is carried out with different solvents with varying properties and different extraction techniques with differences in their working mechanism. These extraction protocols were compared on the basis of techno-economics. Distilled water was the most favored solvent in that regard. On the other hand, from the perspective of carbon dioxide emission potential, ethanol stood out as the best. Recovery of extraction solvent was considered and its impact, on techno-economics and emission potential of the protocols was analyzed. The exact nature of the impact was a strong function of the specific protocol and the target polyphenols.

**Keywords**: Extraction, Food & Agricultural Processes, Batch Process, Polyphenols, Techno-economics, Emission potential

## INTRODUCTION

Valorization of agro-food waste is key to waste management in a sustainable manner. While such waste products, so commonly available world-wide, has great value as fuel and fertilizer, they are also useful source of important chemicals, many of which have critical pharmaceutical applications owing to their anti-oxidant properties [1, 2]. Among pharmaceutically active intra-cellular metabolites of plants, polyphenols are most abundant of which phenolic acids and flavonoids are the major subclasses [3]. Accordingly, in this work, the aim is to evaluate various extraction strategies for obtaining phenolic acids and flavonoids from banana peel.

While there exists rich literature on evaluating performance of different extraction techniques, solvents as well as other factors (such as time, temperature, parameters of extraction agents such as microwave power, ultrasound power etc.) for polyphenols extraction from various natural sources [4, 5], studies on analyzing their sustainability perspectives are very rare. Thus, in this work, we aim to bridge this gap by performing analysis based on techno-economic and environmental impact for production of phenolics and flavonoids from banana peel.

## EXTRACTION PROTOCOLS

Banana peels, freshly obtained from the whole fruit was cut into pieces and dried in microwave oven to remove moisture (to around 85 %) which otherwise might interfere with solvent extraction efficiency. Our study involved optimizing critical extraction decisions in terms of techno-economics and environmental impact. With this motivation, the microwave-dried banana peel powder (BPP) was subjected to solvent extraction using five different solvents – distilled water (DW), methanol (Me), ethanol (Et), acetone (Ac) and acetic acid (AA). In terms of extraction solvent, the chosen solvents varied in terms of the key properties relevant for leaching – such as polarity (which impacts the type of polyphenols a solvent would extract), surface tension, viscosity, vapor pressure (these properties of solvent determine how good a solvent would perform in presence of ultrasound), dielectric properties (which impact suitability of solvents in microwave).

The extraction process was carried out with five different methods. Only these two factors which would fundamentally alter the extraction performance were varied.

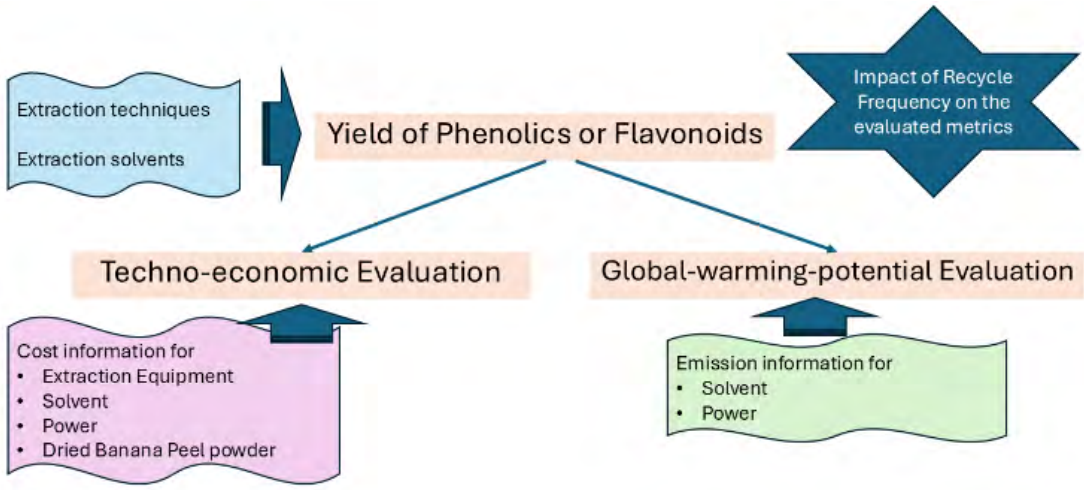

**Figure 1.** Scope of the Present Work and its Correlation with the Yield of Polyphenols and the Relevant Input Parameters.

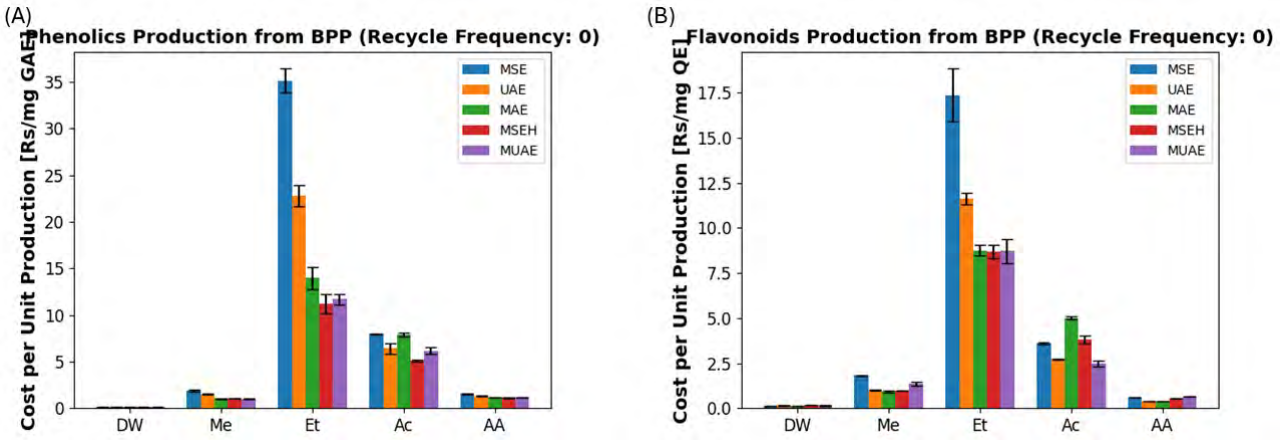

**Figure 2.** Variation in Cost per Unit Production of either type of Polyphenols for all the different Extraction Protocols: (A): Phenolics and (B): Flavonoids

Other potential factors like temperature, solvent amount, US power etc. were not independently varied. Among the five extraction techniques, for Magnetic Stirred-based Extraction (MSE), a simple leaching was conducted at room temperature (around $25^0$ C). Ultrasound and microwave have been reported to enhance the yield by helping rupture the cell walls of BPP [6, 7], thereby allowing the solvents an easy access to dissolve them. Thus, two of our techniques (UAE and MAE) employed these to incorporate these impacts. While temperature of extraction was maintained at $25^0$ C for UAE, microwave also increased the temperature of medium. The extraction temperature was maintained at $50^0$ C for MAE. Thus, we also had an extraction technique (Magnetic Stirred-based Extraction with Heating, i.e., MSEH) that would ensure $50^0$C operation with conventional heating – for a fair comparison between two modes of heating. Finally, for the case of MUAE operated at $50^0$ C, both the ultrasound and microwave effects acted in parallel. Extraction time was 30 times for all the scenarios and solvent to solid ratio was 10 mL/g. Total Phenolics Content (TPC) and Total Flavonoids Content (TFC) were computed with UV-Visible Spectrophotometer. While the lab-scale experiments were conducted using 50 mL solvent, for computations in this work, a scaling of 10 times was considered since 500 mL was maximum capacity of equipment with which we performed MAE and MUAE. Accordingly, for the scaled scenario, electricity demand was considered to be also 10 times (as against lab scale one) to ensure identical profile for stirring, US, MW, heating to keep efficiency of extraction same.

## METRIC FOR COMPARING VARIOUS EXTRACTION DECISION-ALTERNATIVES

**Figure 3.** Relative Contribution of various cost components for varioud extraction techniques with acetne as solvent (for the use of fresh solvent, i.e., recycle frequency = 0)

**Figure 4.** Relative Contribution of various cost components for varioud extraction techniques with acetne as solvent (for recycle frequency = 5)

In this section, we present and discuss about the basis on which techno-economic analysis was performed. We define Techno-Economic Metric (TEM) as a function of total cost incurred over a year for unit production of phenolics or flavonoids. Total cost was assumed to have four components – equipment cost (EC) required to procure extraction equipment as per the specific technique, solvent cost (SC) required to purchase necessary amount of a specific solvent, power cost (PC) necessary to meet the demand of electricity for stirring, heating, introducing ultrasound and microwave, as the case may be, and BPP cost (BPPC) incurred to procure the necessary amount of raw material. Among the four components, EC, being a capital cost, was annualized as per capital recovery factor. 300 days of operation was assumed over one year and 16 batches, over one day with each batch,

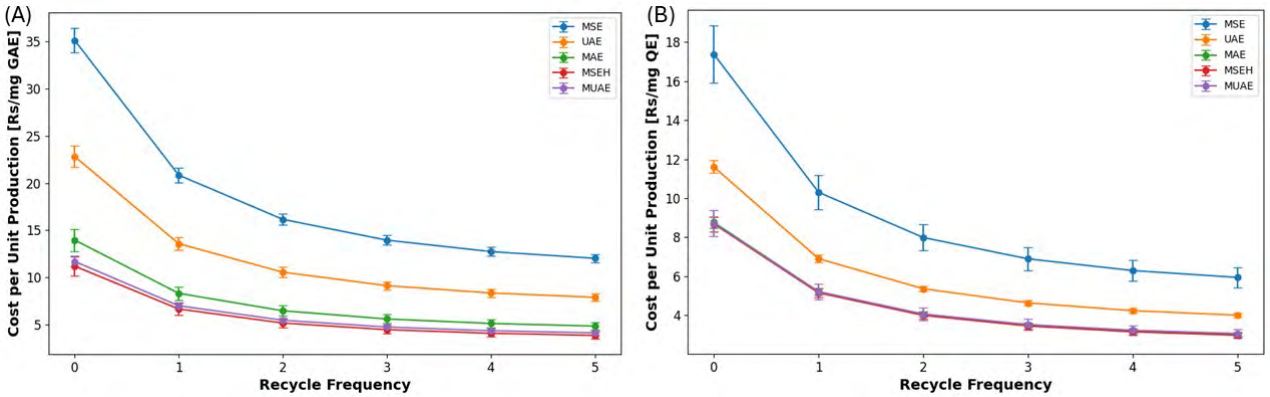

**Figure 5.** Variation in Cost per Unit Production of Polyphenols with Increase in Recycle Frequency: (A): Phenolics, (B): Flavonoids, considering ethanol as an example solvent

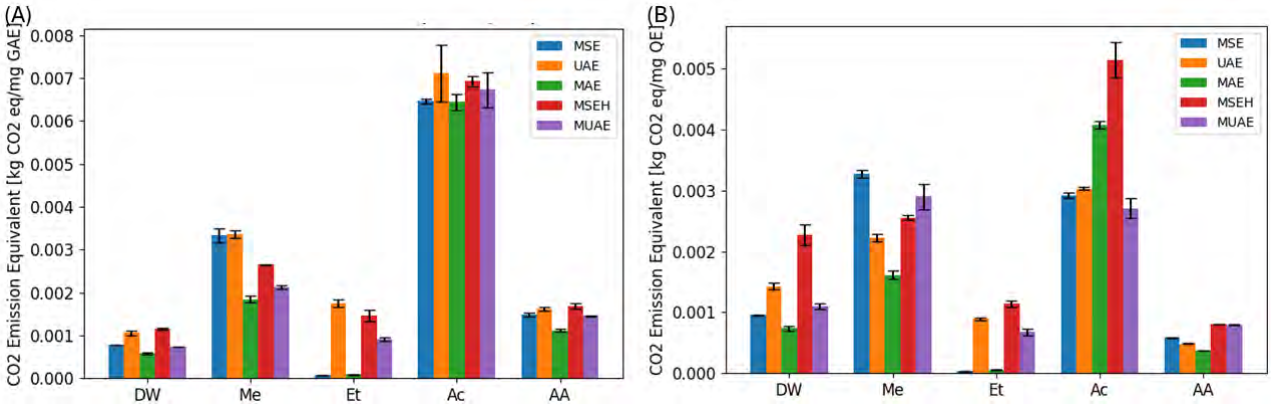

**Figure 6.** Variation in Emission per Unit Production of either type of Polyphenols for all the different Extraction Protocols: (A): Phenolics and (B): Flavonoids, using fresh solvent (n: 0).

employing 500 mL of a specific extraction solvent at a relative ratio of 10 ml/g solid.

Instances of solvent recovery was also considered. For such cases, the extra terms for cost for recovery scenario involved the purchase of a rotary evaporator, vacuum pump and recirculating chiller as well as the electricity needed for the recovery operation, while cost for fresh solvent got reduced. Detailed scheduling of extraction and recovery operation was ignored since labor cost was ignored.

Figure 1 presents a schematic of the scope of this study. Extraction yield of polyphenols is a strong function of the extraction protocols, i.e., technique and solvent. In conjunction with yield and relevant inputs related to cost of various contributing factors, we obtain cost of production (CP) per unit of a specific type of polyphenols, and that is considered as a metric of evaluation. Similarly, the CO2 emission potential for production of the organic solvents (as per standard values in literature [8-10] in addition with the electricity required during extraction, in conjunction with yield provide us a mean to compare the protocols as per emission from production (EP) for unit production of a specific type of polyphenols over the same operation period, as stated above. For DW, the emission was based on power demand in the distillation equipment. DW was not recovered as it would always be available in any lab facility at minimal cost.

It is to be noted that the recycle frequency plays an important role in our study. We consider six scenarios in this regard – recycle frequency of zero defining use of fresh solvent daily. For recycle frequency of ‘n”, the scenario assumes that extraction starts with fresh solvent on day 1 and then, for n consecutive days, solvents are continued to be recovered after each extraction operation. After n days, again the process is repeated with one day of operation with fresh solvent and n days again, with recovered solvent. Yield is assumed to be dropping similar to that reported in literature [11] by a factor of 0.9 for each recovery frequency. The trade-off that all these factors bear on CP and EP per unit production is important and discussed in due course.

## RESULTS AND DISCUSSIONS

Based on yield, it was noticed that for phenolics, DW

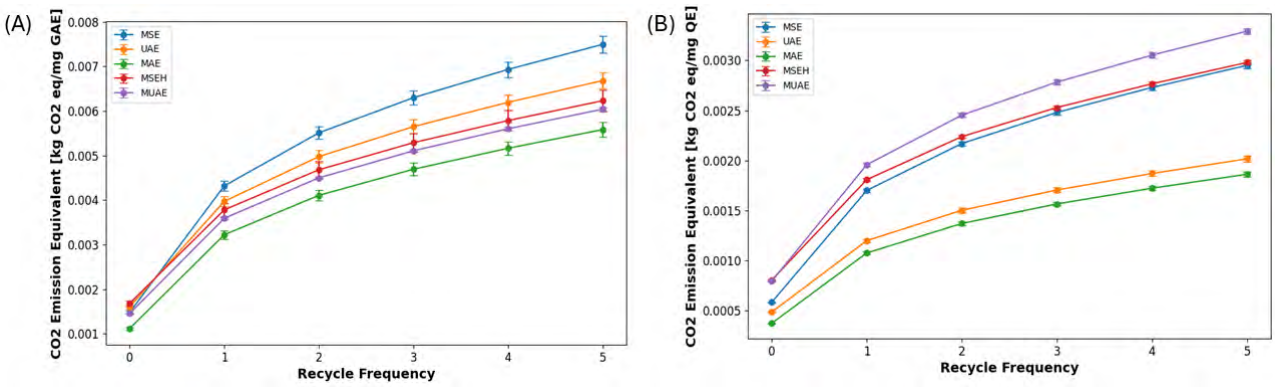

**Figure 7.** Variation in Emission per Unit Production of Polyphenols with Increase in Recycle Frequency: (A): Phenolics, (B): Flavonoids, considering acetic acid as an example solvent.

with MUAE was the most efficient, while for flavonoids, it was AA, with MAE. Variation in yield with extraction protocols closely followed prospective impact of most critical solvent properties, as relevant for a specific extraction technique. As stated earlier, the major focus of this present work is comparative evaluation of five extraction techniques and those many solvents from the perspectives of sustainability.

## Techno-economic Analysis

We firstly focus on the findings from a techno-economic evaluation. The trade-off between yield obtained by a certain protocol and the associated cost incurred is studied here. This study is important since without this, one would not know whether a protocol with low yield with a low cost is preferred over one with high yield at high cost.

From Figure 2, we notice that DW was the most favoured solvent for all the extraction techniques from the perspective of achieving a high enough yield of either type of polyphenols at low enough expenditure. Ethanol, being the most expensive solvent among all (for the AR/ACS grade, in India), was the least favoured. Among the extraction techniques, the relative superiority varied with the choice of solvent as well as the target polyphenol and there was no clear trend identical for all the solvents for either of the polyphenols. Figure 3 presents the relative contribution of the four cost components – for acetone, as an example. We notice that for all the techniques, solvent cost was the most dominant cost components. The findings were same (with difference only in % contribution values) for the other solvents. These % contribution were same for both the types of polyphenols since the cost for utilizing 500 mL solvent in extraction over one year as stated before would be same for either type of polyphenols.

## Impact of Recovery of Solvent

As the frequency of recycle increases, fresh solvent amount drops – this, its cost and emission would also drop. However, recycle of solvent also requires equipment for solvent recovery – thereby increasing equipment cost and power cost (for power, operating those extra equipment).

With the yield dropping and cost also majorly dropping (as solvent contribution was so dominant on process economics for extraction with fresh solvent), the net impact can be seen in Figure 5, wherein we noticed a drop in cost as n increases for all the scenarios. In terms of relative cost contribution, equipment and power now had more foothold as expected (Figure 4 as against Figure 3, for acetone as an example).

## Emission Potential of the Extraction Protocols

We also evaluated the EP for unit amount of polyphenols as shown in Figure 6 for fresh solvent. Like CP, EP was also, as expected, a strong function of extraction protocol. However, percentage change in EP was not that much significant across the techniques for any solvent, for majority of the instances. Among all the scenario, acetone's outlook was the poorest for phenolics and also for MAE and MSEH for flavonoids extraction. Ethanol with MSE was the most superior among all options.

Figure 7 reflects relative change in EP with increase in recycle frequency for acetic acid, as an example solvent. Even though emission due to solvent production dropped (for use of lower amount of fresh solvent), that due to power demand for solvent recovery increased. Moreover, with increase in recycle frequency, production of polyphenols also took a hot. As a result, we notice an increase in EP with recycle frequency for all the extraction techniques. A similar trend was observed for other solvents, as well.

## CONCLUSIONS

Comparative evaluation of extraction protocols

(technique and solvent) from the critical perspectives of techno-economics and emission potential was the major focus of this study. We found that the relative superiority of extraction protocols as per either of these perspectives differed as per choice of target polyphenols. While this work is an important step towards sustainability assessment for phytochemical extraction from agro-food waste, consideration of other environmental impact assessment indicators would be an important next step. Moreover, pareto-optimality of this two-objective (cost and environmental impact) would enable us to have a sounder decision-making for extraction protocol. Moreover, while this work has highlighted important findings for polyphenols extraction from a given quantity of banana peel (since volume of solution per batch was same), it would also be very informative to explore the optimal decisions for a certain demand profile of polyphenols.

## ABSTRACT

China's cement industry accounts for over half of global production and contributes 8% of global $CO_2$ emissions, making its decarbonization critical for achieving climate targets. While carbon capture and storage (CCS) and carbon capture and utilization (CCU) are essential deep decarbonization technologies, existing research has not adequately addressed the regional and temporal variations needed for optimal pathway selection across China's diverse provinces. This study develops a comprehensive whole-systems optimization model to design provincial-scale decarbonization pathways for China's cement industry from 2025 to 2060. The model reveals significant spatial and temporal heterogeneity in optimal technology combinations. Before 2050, traditional cement processes integrated with CCS (TCP-CCS) represent the dominant bridging technology for low-carbon transition. However, reaching carbon neutrality by 2060 necessitates an eventual shift toward widespread deployment of novel chemical processes combined with green hydrogen (NCP-H2) as the ultimate decarbonization pathway. Notably, regional natural gas prices significantly affect technology feasibility and deployment timing. The optimized transition pathway reduces unit clinker costs by approximately 58% compared to 2025 levels while successfully meeting the 2060 carbon neutrality target. This research framework provides quantitative decision support for policymakers to design cost-effective, province-specific decarbonization strategies that align with local resource endowments and economic conditions, ultimately advancing deep decarbonization across China's industrial sector.

**Keywords**: Cement decarbonization, Whole systems thinking, Supply chains, CCS, Green hydrogen, MILP

## INTRODUCTION

In the face of global warming, countries worldwide are pursuing economic development while striving for environmental sustainability [1-2]. The cement industry, as a cornerstone of the built environment, accounts for a significant percentage of global carbon emissions, making it a critical area for decarbonization [3]. China, the world's largest cement producer [4], plays a pivotal role in achieving both domestic and global cement industry carbon neutrality. Given that 58% of cement industry emissions originate from calcination processes [5], deep decarbonization cannot be achieved solely through alternative energy sources or equipment improvements. Even emerging methane reforming technology for carbonate decarbonization requires integration with renewable energy technologies such as green hydrogen and carbon capture and utilization (CCU) to achieve net-zero emissions [6-7]. Additionally, carbon capture and storage (CCS) pathways represent another important pathway for deep decarbonization [8]. A comprehensive comparison of economic and environmental performance for these technologies, along with their applicable conditions, is urgently needed.

While numerous studies have investigated carbon reduction methods for the cement industry across China [9], South Korea [10], Europe [11], and globally [12]. However, most studies only evaluate and compare different processes under single or uniform conditions, failing to consider how regional variations might affect technology

performance rankings and optimal application scenarios. Few studies have addressed regional heterogeneity through refined spatial modeling, with notable examples including comparative analyses across European countries. [13]. For China, significant resource disparities exist across regions, with varying geological resources, renewable energy potential, and cement demand [14]. A one-size-fits-all approach has clear limitations; each province needs to adopt appropriate decarbonization methods based on local conditions to meet the national 2060 carbon neutrality vision. However, research comparing green hydrogen and CCS technologies across different Chinese provinces remains limited.

Furthermore, given the long timeframe to 2060, considering dynamic changes in decarbonization technologies over time is imperative [15-16]. Most studies focus on technology deployment endpoints rather than how decarbonization pathways will evolve throughout the entire transition period, including specific deployment timing and sequencing [17]. These long-term, large-scale technological transformations will significantly impact overall economic and environmental performance, necessitating whole systems thinking models.

This study develops a comprehensive optimization model for China's provincial cement industry low-carbon transformation. It integrates regional heterogeneity including renewable energy resources, fossil fuel prices, electricity costs, $CO_2$ geological storage conditions, and cement demand variations, while considering inter-provincial transportation of materials. Under constraints regarding cement demand, carbon emission targets, and technological capacity limitations, the model minimizes the total discounted net cost of system to provide tailored transformation solutions for different regions and identify advantageous scenarios for different technologies. Through multiperiod spatially explicit optimization, the model considers annual capacity changes, production adjustments, and inventory management, providing optimal deployment timing and sequencing for low-carbon technologies. This research framework offers detailed transformation pathway planning for cement enterprises and provides policymakers with optimal solutions and policy recommendations for achieving carbon neutrality.

# MATHEMATICAL FORMULATION

## Objective Function

The model minimizes the total discounted net cost (TDNC) of system from 2025 to 2060:

$$\min \mathrm{TDNC} = \sum_t \mathrm{DF}_t \times \mathrm{TC}_t \tag{1}$$

$$\mathrm{DF}_t = \frac{1}{(1+\phi)^{t-1}} \quad \forall t \tag{2}$$

where $\mathrm{DF}_t$ the discount factor for year t (assuming 5% annual discount rate), and $\mathrm{TC}_t$ is the total cost in year t.

Total cost comprises capital costs (cement processes and energy facilities), fixed operating costs, and variable operating costs including material procurement, transportation, electricity/hydrogen trading, carbon tax, $CO_2$ storage, and inventory holding, retirement costs and offset by methanol revenue.

$$\begin{aligned}\mathrm{TC}_t = {} & \mathrm{C}_t^{cap,cem} + \mathrm{C}_t^{cap,ene} + \mathrm{C}_t^{fix,cem} + \mathrm{C}_t^{fix,ene} + \mathrm{C}_t^{mat} + \mathrm{C}_t^{inv} \\ & + \mathrm{C}_t^{trans} + \mathrm{C}_t^{ele} + \mathrm{C}_t^{H_2} + \mathrm{C}_t^{Ctax} + \mathrm{C}_t^{sto} + \mathrm{C}_t^{ret} - R_t^{MeOH} \quad \forall t\end{aligned} \tag{3}$$

## Material and Energy Balance Constraints

Material flows are constrained to adjacent provinces, with transportation between non-adjacent regions achieved through sequential routing via intermediate provinces.

$$\begin{aligned}&\mathrm{Trans}_{r,r',t}^{Coal} = \mathrm{Trans}_{r,r',t}^{CO_2} = \mathrm{Trans}_{r,r',t}^{cem} = 0 \\ &\forall t, (r,r') \notin ADJ, r = r'\end{aligned} \tag{4}$$

where *ADJ* denotes the set of adjacent province pairs.

The cement inventory balance ensures production plus net imports equals demand plus net exports, maintaining dynamic equilibrium across different years. Similar balance equations govern coal and $CO_2$ flows across provinces, enabling inter-provincial resource allocation and transportation optimization.

$$\begin{aligned}&I_{r,t}^{cem} = I_{r,t-1}^{cem} + \sum_i \mathrm{Pro}_{i,r,t} + \sum_{r' \in ADJ(r)} Trans_{r',r,t}^{cem} \\ &-\mathrm{dem}_{r,t} - \sum_{r' \in ADJ(r)} Trans_{r,r',t}^{cem} \quad \forall r,t\end{aligned} \tag{5}$$

Electric power balance:

$$\begin{aligned}&\sum_{j \in \{\mathrm{Wind,PV}\}} \left(\omega_j^{\mathrm{Ele}} \times \mathrm{Cap}_{j,r,t}^{ene} \times \mathrm{h}\right) \\ &+ Ele_{r,t}^{buy} = \sum_i \left(\alpha_{i,\mathrm{Ele}} \times \mathrm{Pro}_{i,r,t}\right) \\ &+ \left(\omega_{\mathrm{EC}}^{\mathrm{Ele}} \times \mathrm{Cap}_{EC,r,t}^{ene} \times \mathrm{h}\right) + Ele_{r,t}^{sell} \quad \forall \mathrm{r,t}\end{aligned} \tag{6}$$

Hydrogen balance:

$$\begin{aligned}&\omega_{\mathrm{EC}}^{\mathrm{H_2}} \times \mathrm{Cap}_{EC,r,t}^{ene} \times \mathrm{h} + H_{r,t}^{buy} = \\ &\sum_i \left(\alpha_i^{\mathrm{H_2}} \times \mathrm{Pro}_{i,r,t}\right) + H_{r,t}^{sell} \quad \forall \mathrm{r,t}\end{aligned} \tag{7}$$

where $h$ is 8760 hours. ω represents the electricity and hydrogen production coefficients per unit capacity of energy facilities (MWh/MW or ton $H_2$/MW). α represents the electricity and hydrogen consumption coefficients for cement production process $i$ (MWh/ton clinker or ton $H_2$/ton clinker).

## Capacity Evolution Constraints

The evolution of cement production capacity over time is calculated in Equations (8) and (9). These equations account for new investments, automatic lifetime retirements, and early decommissioning, ensuring a

dynamic balance of capacity.

$$\begin{aligned}&\mathrm{Cap}_{i,r,t}^{cem}=\mathrm{Cap}_{i,r,t-1}^{cem}+\mathrm{Cap}_{i,r,t}^{cem,new}\\&-\mathrm{Cap}_{i,r,t-te}^{cem,new}-\mathrm{Cap}_{i,r,t}^{cem,dec}\quad\forall i,r,t>1\end{aligned}\tag{8}$$

$$\mathrm{Cap}_{i,r,t}^{cem}=\mathrm{cap}_{i,r,0}^{cem}\quad\forall i,r,t=1\tag{9}$$

Equations (10) establish lower and upper bounds on new capacity additions, linking the continuous variable to the binary investment indicator.

$$\begin{aligned}&\mathrm{cap}_{i}^{Min}\times\mathrm{Build}_{i,r,t}\le\mathrm{Cap}_{i,r,t}^{cem,new}\\&\le\mathrm{cap}_{i}^{Max}\times\mathrm{Build}_{i,r,t}\quad\forall i,r,t\end{aligned}\tag{10}$$

$$\mathrm{cap}_{i}^{Max}=\lambda\times cap_{r}^{cem,totalMax}\tag{11}$$

where $\mathrm{Build}_{i,r,t}$ is a binary variable indicating whether process i is built in province r and year t, $cap_{r}^{cem,totalMax}$ represents the maximum allowable total cement capacity in province r, determined by historical data, $\mathrm{cap}_{i}^{Min}$ is the minimum economic capacity for process i, and $\mathrm{cap}_{i}^{Max}$ are the maximum economic capacity, calculated in Equation (11) as a fraction $\lambda$ of the total provincial limit.

Several constraints are imposed to limit capacity and production. Equation (12) constrains the aggregate cement production capacity across all technologies within each province. Equation (13) ensures that early decommissioning does not exceed existing capacity from the previous period. Equation (14) constrains clinker production to not exceed the installed capacity.

$$\sum_{i}\mathrm{Cap}_{i,r,t}^{cem}\le cap_{r}^{cem,totalMax}\quad\forall r,t\tag{12}$$

$$\mathrm{Cap}_{i,r,t}^{cem,dec}\le\mathrm{Cap}_{i,r,t-1}^{cem}\quad\forall i,r,t>1\tag{13}$$

$$\mathrm{Pro}_{i,r,t}\le\mathrm{Cap}_{i,r,t}^{cem}\quad\forall i,r,t\tag{14}$$

Similar power generation capacity constraints are employed, which for the sake of brevity are not explicitly introduced herein.

## $CO_2$ Management Constraints

$CO_2$ balance ensures sources (process emissions and inter-provincial imports) equal sinks (storage and exports).

$$\begin{aligned}&\sum_{i\in\{TCP-CCS,NCP-CCS\}}\left(\beta_{i}^{cem}\times\mathrm{Pro}_{i,r,t}\right)+\sum_{r'\in ADJ(r)}\mathrm{Trans}_{r',r,t}^{CO_2}\\&=\mathrm{CS}_{r,t}+\sum_{r'\in ADJ(r)}\mathrm{Trans}_{r,r',t}^{CO_2}\quad\forall r,t\end{aligned}\tag{15}$$

where $\beta_{i}$ is the emission factor of process i for clinker production.

The system emissions must not exceed carbon cap targets aligned with China's carbon neutrality pathway in each year t.

$$\mathrm{Emi}_{t}^{dir}=\sum_{i}\sum_{r}\beta_{i}^{cem}\times\mathrm{Pro}_{i,r,t}\quad\forall t\tag{16}$$

$$\mathrm{Emi}_{t}^{dir}\le tce_{t}^{Cap}\quad\forall t\tag{17}$$

# RESULTS

## Baseline Scenario Model Results

The MILP model was implemented in GAMS 48.1.0 on a desktop computer equipped with a 13th Gen Intel(R) Core (TM) i9-13900K CPU @ 3.00 GHz and 128 GB RAM, and was solved by the Gurobi 12.0.1 solver to obtain the globally optimal solution.

Based on data from various literature sources and institutions such as International Energy Statistics (IES) [18], China's cement clinker demand is projected to decline annually from approximately 1, 233 million tons (Mt) in 2025 to 563 Mt in 2060. Figure 1a demonstrates that the model's total cement clinker installed capacity remains relatively smooth and closely tracks total demand throughout the planning horizon. Furthermore, actual production levels closely approximate installed capacity, indicating high-capacity utilization rates and optimal model performance. The divergence between production and demand curves represents the model's strategic allocation of cement inventory.

Figures 1b and 1c present the total and unit clinker production costs for each year during the planning period (2025-2060), respectively. The black and red lines in Figures 1b and 1c represent pre-discount and post-discount cost values, respectively. While the black line shows an overall upward trend, the red line exhibits a downward trend. The red line is better highlighting both the advantages and necessity for enterprises to transition to low-carbon production. Although carbon tax prices increase annually, enterprises can reduce costs by adopting low-carbon processes. The red line in Figure 1c shows that unit clinker production cost decreases from 540 CNY/ton to 226 CNY/ton (comparing smooth curve values while ignoring peaks). Notably, the red line peaks around 2025, 2040, and 2050, indicating these years represent peak periods for decommissioning old processes and constructing new processes facilities. Figure 1e further proves this observation through its depiction of economic cost composition. This suggests China's cement industry will undergo three distinct low-carbon transformation periods by 2060.

As illustrated in Figure 1d, the low-carbon transformation of cement clinker production can be divided into three stages: from 2025 to 2050, traditional cement processes (TCP) will significantly decline until complete phase-out; from 2030 to 2050, traditional cement processes with carbon capture and storage systems (TCP-CCS) will serve as the primary decarbonization pathway; from 2040 onwards, novel cement processes with green

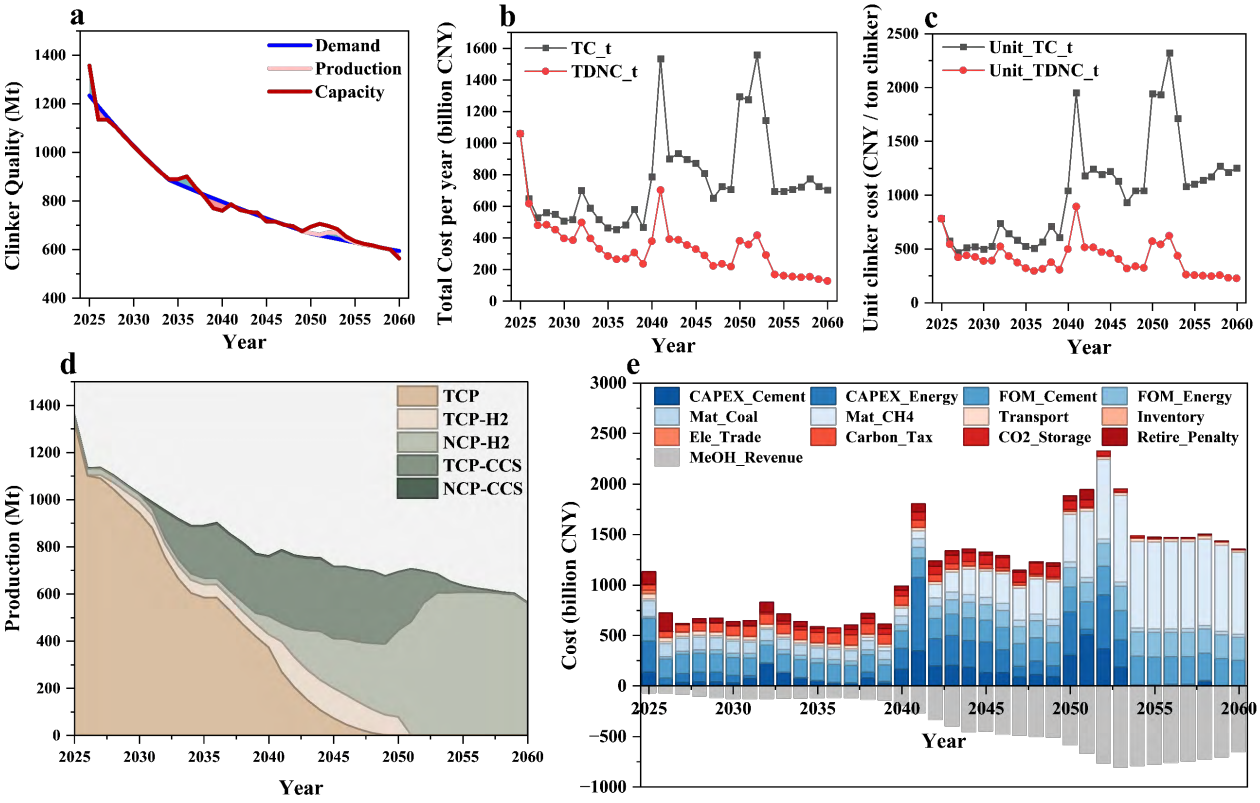

**Figure 1.** (a) Temporal evolution of cement clinker demand, production, and installed capacity. (b, c) Total cost and unit clinker cost trajectories over time, where the red line represents total discounted net cost and the black line represents pre-discount total cost. (d) Optimal cement decarbonization pathways from 2025 to 2060, where TCP denotes traditional cement process, NCP represents novel chemical process via methane reforming, TCP-H2 and NCP-H2 indicate integration with green hydrogen technology, and TCP-CCS and NCP-CCS represent integration with carbon capture and storage systems. (e) Economic cost composition across different years.

hydrogen (NCP-H2) will gradually demonstrate superior decarbonation advantages, becoming the dominant technology after 2050 and ultimately capturing nearly the entire cement clinker market. This progression occurs because NCP-H2 possesses stronger deep decarbonization capabilities compared to other processes, and its net-zero emission capacity makes it the optimal choice for meeting China's 2060 carbon neutrality target.

Meanwhile, Figure 1e also reveals that methanol revenue gradually increases after 2040, reaching a peak in 2053. After 2053, methanol revenue declines as cement clinker demand and process capacity decreases. Additionally, natural gas costs account for a substantial proportion of total costs because the NCP-H2 process requires natural gas as a raw material, meaning natural gas prices will significantly influence cement clinker production costs during this period.

## Regional Technology Deployment Pathways

Figure 2a illustrates the temporal evolution of low-carbon cement processes across different Chinese provinces. Figure 2b displays natural gas prices across different provinces, highlighting how regional price disparities result in different economic advantages for NCP-H2 and influence its adoption. The evolution of low-carbon cement processes in each province can be broadly categorized into three patterns:

Firstly, in provinces where natural gas prices remain below 5, 050 CNY per ton (represented by yellow bars), the NCP-H2 process demonstrates superior economics compared to TCP-CCS. These provinces show greater willingness to adopt NCP-H2 for low-carbon transformation, with provinces having lower natural gas prices transitioning from traditional cement processes (TCP) to NCP-H2 earlier in the planning horizon.

Secondly, in provinces where natural gas prices range from 5, 050 to 5, 500 CNY per ton (represented by light green bars), the economic advantage of NCP-H2 over TCP-CCS becomes marginal. Consequently, these provinces primarily utilize TCP-CCS for decarbonization before 2050, then transition to NCP-H2 in the post-2050 period to meet increasingly stringent carbon neutrality

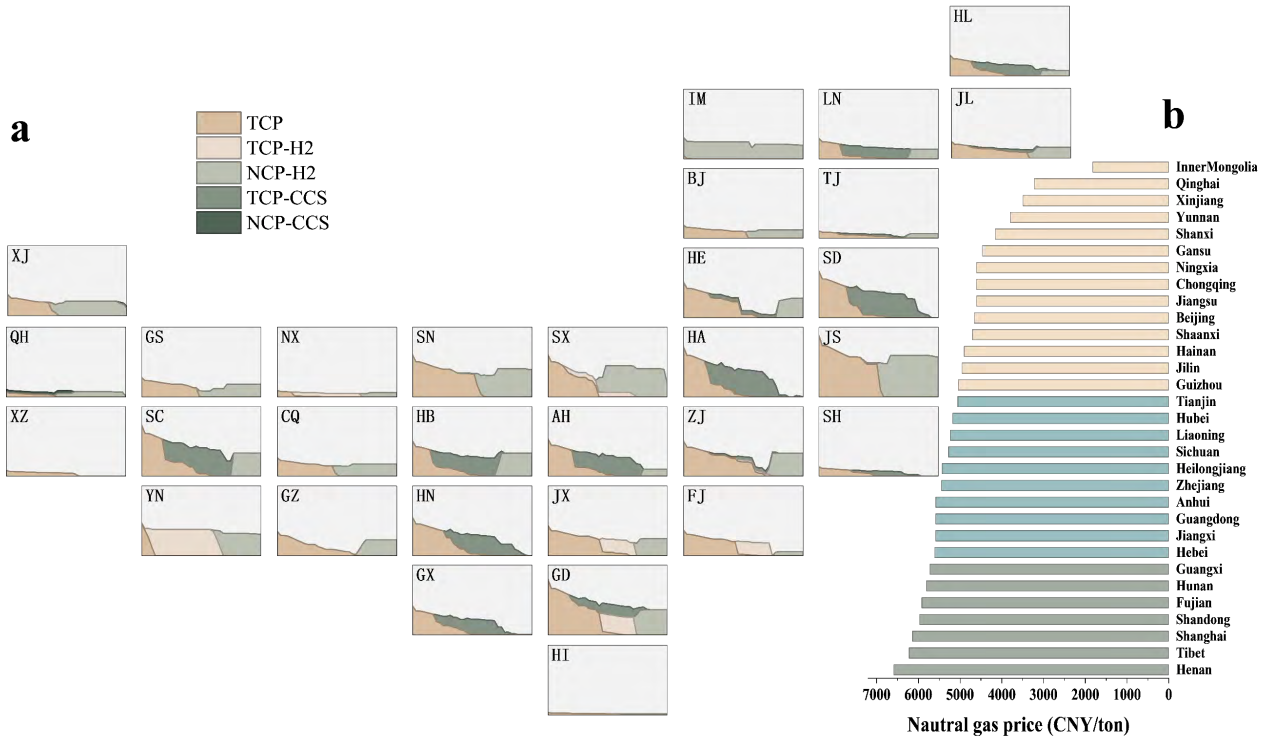

**Figure 2.** (a) Provincial cement decarbonization pathway trajectories across China (excluding Hong Kong, Macao, and Taiwan), with all subplots sharing identical x-axis (years 2025-2060) and y-axis (cement clinker production) scales. (b) Natural gas prices across Chinese provinces, categorized into three tiers (low, medium, high) represented by different colors. Provinces across different price tiers demonstrate markedly divergent decarbonization pathway trajectories.

requirements.

For provinces where natural gas prices exceed 5, 500 CNY per ton (represented by dark green bars), NCP-H2 loses its economic competitiveness entirely. These provinces rely exclusively on TCP-CCS throughout their decarbonization pathway. When local TCP-CCS clinker production capacity cannot satisfy demand, additional clinker is sourced from neighboring provinces through inter-provincial trade.

Several provinces exhibit unique decarbonization patterns worth noting. Yunnan (YN), benefiting from favorable solar radiation conditions conducive to photovoltaic development and green hydrogen production. Simultaneously, it faces substantial clinker demand that makes premature TCP retirement economically prohibitive. Therefore, it adopts TCP-H2 as a transitional process, offering a balanced compromise between cost and environmental performance. Meanwhile, Zhejiang (ZJ), Jiangxi (JX), and Fujian (FJ), constrained by insufficient geological capacity for $CO_2$ storage, demonstrate stronger preference for hydrogen-based processes (TCP-H2 or NCP-H2) rather than CCS-dependent processes.

## CONCLUSIONS

This study presents a comprehensive whole-system optimization model for China's cement industry decarbonization, incorporating spatial heterogeneity across provinces, cement technologies, renewable energy integration, and CCS. The model provides quantitative insights into optimal technology deployment pathways, identifying when, where, and which technologies should be adopted to achieve carbon neutrality cost-effectively.

The optimization results reveal the principles for selecting low-carbon transformation processes in China's cement industry. First, the low-carbon transformation of China's cement industry requires a gradual transition. Before 2050, the traditional cement process combined with CCS (TCP-CCS) is an important low-carbon transition process. However, to achieve the carbon neutrality target by 2060, the adoption of a novel methane reforming and green hydrogen process (NCP-H2) is the ultimate solution, as it is the only process with the potential for net-zero or even negative emissions. It is worth noting, natural gas prices are a significant factor influencing the NCP-H2 process and determining whether it can surpass TCP-CCS technology and be adopted by different

provinces.

The modeling framework developed in this study provides a template applicable to other hard-to-abate industrial sectors (steel, chemicals) facing similar decarbonization challenges, contributing to broader climate mitigation strategies in China and globally.

Future work should extend this framework to incorporate demand-side uncertainties through two-stage stochastic programming, integrate life cycle assessment across multiple environmental impact categories, and couple with techno-economic analysis for comprehensive sustainability evaluation.

## ABSTRACT

Sustainable aviation fuel (SAF) is a key pathway for mitigating greenhouse gas emissions in aviation, yet its large-scale deployment is constrained by high energy demand and production costs. Among available conversion routes, the hydroprocessed esters and fatty acids (HEFA) pathway is the most commercially mature, but it requires substantial hydrogen input and high-temperature heat, affecting both economic and environmental performance. This study presents a decision-support framework for SAF production via integrated biorefineries, using rapeseed oil extraction coupled with HEFA conversion as a case study. Detailed process simulations are combined with energy integration and mixed-integer linear programming optimization to enable system-level analysis. Material integration strategies include internal hydrogen generation via glycerol steam reforming and valorization of rapeseed meal through gasification for syngas production. Heat integration considers cross-process heat recovery and the application of high-temperature heat pumps to reduce external energy demand. The results demonstrate that coordinated optimization of heat and material flows significantly improves energy efficiency and reduces reliance on fossil utilities. The framework provides a practical tool for identifying economically and environmentally robust SAF production pathways by integrating feedstock conversion, co-product utilization, and utility optimization. These findings support strategic decision-making for next-generation biorefineries and strengthen circular economy principles in sustainable aviation fuel production.

**Keywords**: Sustainable Aviation Fuel (SAF), HEFA, Biorefinery, Process Integration, MILP Optimization

## INTRODUCTION

The aviation sector plays a critical role in enabling economic development and global connectivity, yet it is also a significant contributor to climate change [1]. While aviation accounts for approximately 2.5% of global carbon dioxide emissions, its contribution to total radiative forcing is estimated to be closer to 4% due to the altitude at which emissions are released [2]. Decarbonizing aviation is therefore both urgent and particularly challenging, given the sector's reliance on high-energy-density liquid fuels, stringent fuel specifications, and long aircraft lifetimes.

Sustainable Aviation Fuel (SAF) is widely recognized as the most viable near- to mid-term solution for reducing aviation emissions. SAFs are drop-in fuels with physicochemical properties similar to conventional jet fuel, allowing the use of existing aircraft fleets and fuel infrastructure. In contrast, non-drop-in alternatives such as hydrogen would require entirely new aircraft designs and energy supply chains [3]. Despite this, large-scale SAF deployment
remains constrained by high production costs, significant fossil energy consumption, and limitations associated with feedstock availability and logistics.

Current SAF studies are typically focused on fuel yield and product quality, while energy and utility systems are often neglected. As a result, SAF pathways often exhibit high demands for steam, electricity, and hydrogen, frequently supplied by fossil-based utilities, undermining both economic competitiveness and environmental performance.

Among the available SAF pathways, Hydroprocessing of Esters and Fatty Acids (HEFA) is the most mature and commercially deployed technology, accounting for more than 99% of current global SAF production from lipid-based biomass [4]. In the HEFA process, acylglycerols and free fatty acids are upgraded into drop-in hydrocarbons suitable for jet fuel applications. Triglycerides, which constitute the dominant fraction of lipid-based feedstocks, require extensive upgrading involving deoxygenation and saturation reactions. Oxygen removal proceeds through hydrodeoxygenation, decarbonylation, and decarboxylation pathways, yielding linear hydrocarbons typically in the C8–C18 carbon range [5]. Subsequent hydrocracking and isomerization steps are required to meet jet fuel cold-flow specifications, followed by product separation into jet fuel and co-products such as diesel, naphtha, and propane.

Hydrogen availability is a critical determinant of both the yield and carbon efficiency of the HEFA process. Higher hydrogen addition promotes hydrodeoxygenation and improves carbon retention by reducing CO and $CO_2$ formation, but it also substantially increases hydrogen demand. Consequently, the environmental benefits of HEFA-based SAF are strongly dependent on the hydrogen source. The use of fossil-derived hydrogen significantly limits achievable greenhouse gas reductions, particularly given the scale of hydrogen consumption required for jet fuel production. While on-site hydrogen production via water electrolysis is a potential solution, it is associated with high capital costs and challenges related to the intermittency of renewable electricity supply. An alternative approach involves producing hydrogen from biomass-derived intermediates, such as glycerol generated during triglyceride hydrolysis, enabling partial internal hydrogen supply and improved process integration [6–7].

Waste cooking oil (WCO) and animal fats are often considered preferred HEFA feedstocks due to their low associated life-cycle emissions and classification as waste-derived resources. However, large-scale deployment is constrained by limited and geographically dispersed supply, collection logistics, and variability in feedstock quality. As a result, waste-derived lipids alone are insufficient to meet projected SAF demand, particularly in Europe. To ensure stable and continuous SAF production, vegetable oils can therefore serve as complementary feedstocks when waste lipid supply is insufficient, as the generic triglyceride to jetfuel conversion pathway remains applicable with comparatively less feedstock pretreatment requirements.

Rapeseed is the most widely cultivated oilseed crop in Europe, driven primarily by demand for rapeseed oil [8], and benefits from an established agricultural and processing infrastructure. Rapeseed oil extraction also generates rapeseed meal as a major co-product [9]. Due to the presence of anti-nutritional compounds, rapeseed meal is currently utilized primarily as animal feed and is not suitable for direct human consumption [8, 10]. While this co-product is traditionally treated as a low-value output in fuel-oriented system assessments, it represents a significant source of biogenic carbon and energy.

Integrating rapeseed oil extraction with downstream HEFA upgrading enables a biorefinery configuration in which both the primary product and co-products are considered explicitly within a unified energy and material system. Such integration creates additional degrees of freedom for process and utility optimization that are not accessible in stand-alone fuel conversion pathways. In particular, coupling feedstock processing, fuel upgrading, and internal hydrogen generation allows systematic assessment of co-product utilization and waste heat recovery within a single modeling framework.

Accordingly, this study develops detailed ASPEN Plus process models for both HEFA-based SAF production and rapeseed oil extraction to enable consistent evaluation of mass and energy flows, utility requirements, and integration opportunities across the full value chain. The integrated modeling framework provides the basis for systematic analysis of heat integration, hydrogen sourcing strategies, and co-product valorization pathways, with the objective of improving overall energy efficiency, reducing dependence on fossil-based utilities, and enhancing carbon utilization within SAF production systems.

## METHODOLOGY

This study adopts a system-level approach to evaluate an integrated biorefinery configuration for sustainable aviation fuel (SAF) production. The methodology is structured to first describe the individual process models and subsequently assess their integration at the energy and material level within a unified biorefinery framework.

### Jet fuel production process model

An ASPEN Plus process model of the HEFA-based jet fuel production pathway was developed to evaluate mass and energy flows, hydrogen demand, and product yields. The model includes triglyceride hydrolysis, hydrogen production via glycerol steam reforming, hydrotreating, hydrocracking and isomerization, and final product separation.

Triglyceride hydrolysis was modeled to produce free fatty acids and glycerol. Reaction parameters were adapted from Iliuta et al. [11]. Figure 1 illustrates the ASPEN Plus flowsheet of the triglyceride hydrolysis section, including pressure reduction, power recovery, and phase separation into free fatty acids and glycerol. The hydrolysis product stream was expanded from 50 bar to 20 bar and subsequently to 1 bar. Power recovery from flashed

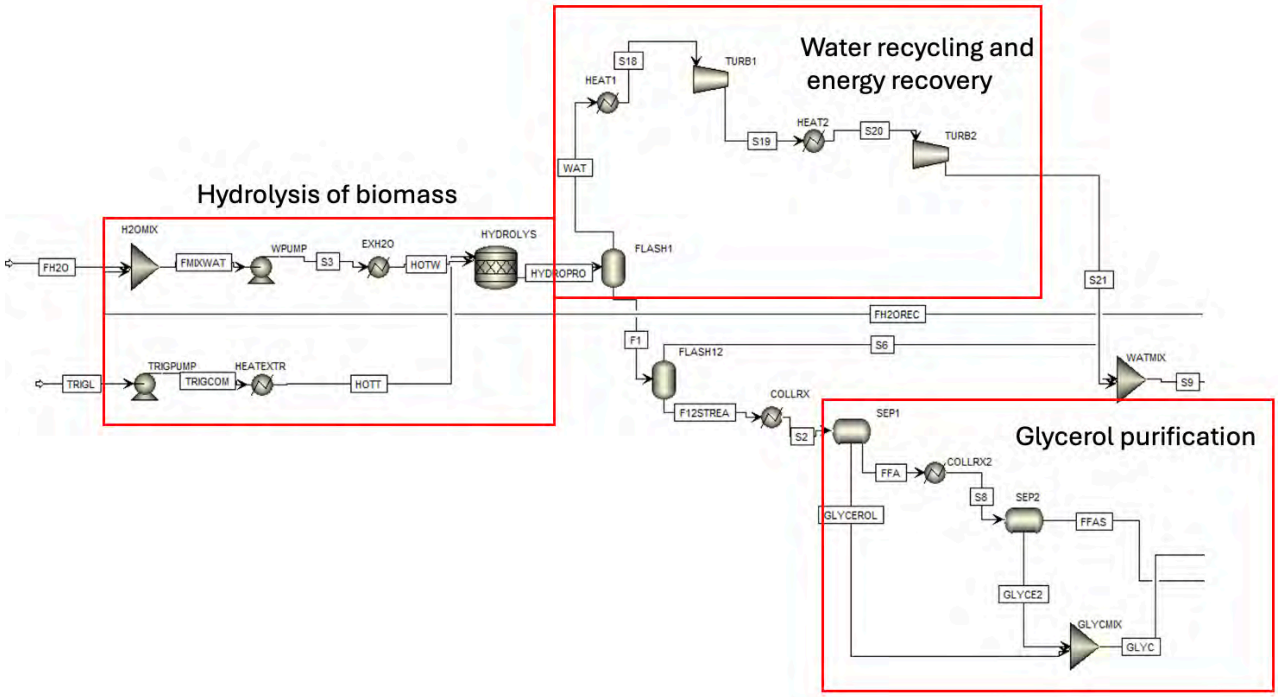

**Figure 1.** Process flowsheet of the triglyceride hydrolysis section, illustrating the production of free fatty acids and glycerol, pressure reduction stages, power recovery from flashed water vapor, and gravity-based phase separation.

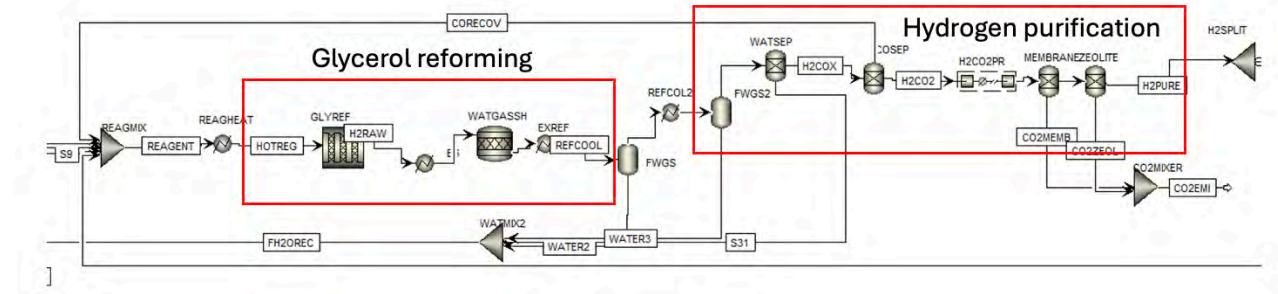

**Figure 2.** Process flowsheet of the glycerol steam reforming and downstream gas separation units used to produce hydrogen for deoxygenation, ismoerization and cracking steps.

water vapor at 20 bar was modeled using a two-stage turbine. Gravity-based separation of free fatty acids and glycerol was represented using decanter units, following an approach similar to biodiesel process models in Baibhav et al. [12].

The separated glycerol stream was sent to steam reforming for hydrogen production. Glycerol steam reforming was modeled using kinetic parameters obtained from Cheng et al. [13]. Figure 2 presents the ASPEN Plus model of the glycerol steam reforming section and the gas separation units. Downstream gas separation units were included to produce high-purity hydrogen suitable for use in subsequent upgrading reactions. The hydrogen produced via this pathway was supplied internally to the HEFA upgrading section.

Hydrotreating reactions were modeled considering the simultaneous occurrence of hydrodeoxygenation, decarbonylation, and decarboxylation pathways. These reactions convert saturated fatty acids into alkanes while producing water, carbon monoxide, or carbon dioxide, depending on the dominant pathway. The coexistence of these reactions reflects realistic operating conditions and catalyst behavior.

Hydrocracking and isomerization were modeled using RStoic reactors operating at 250 °C and 30 bar, with conversion levels and product yields adopted from Elias et al. [14]. Final product separation was performed using distillation columns, yielding propane, naphtha, diesel, and jet fuel fractions. The resulting jet fuel stream, along with co-products, was assessed in terms of mass and

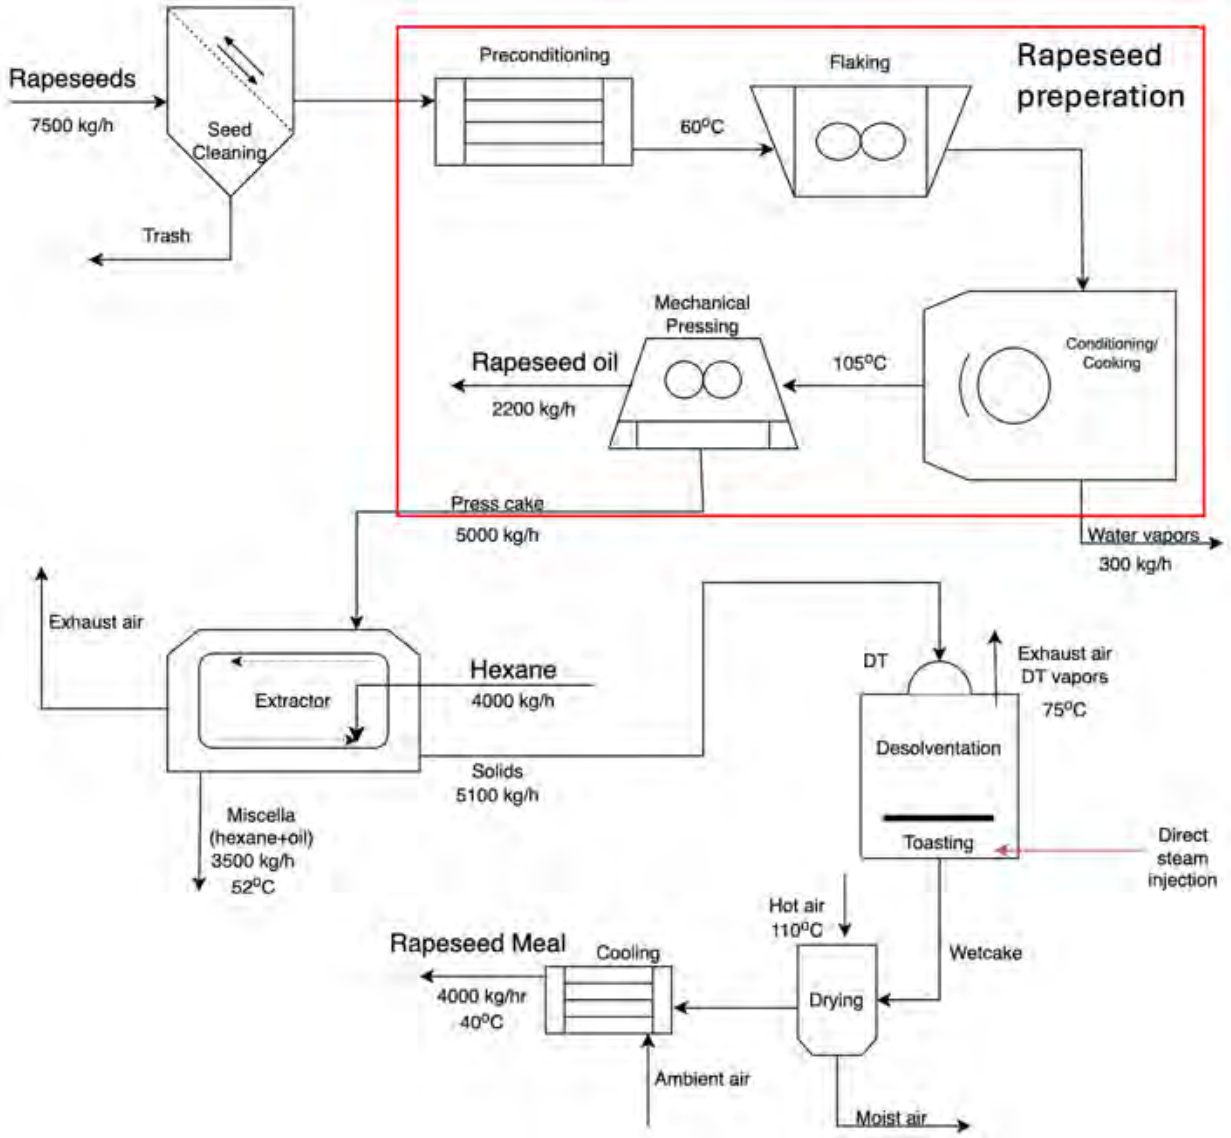

**Figure 3.** Process flow diagrams of the rapeseed preparation and oil extraction process. **(a)** Rapeseed preparation, crushing, and extraction process along with meal desolventization steps.

energy balances, providing the basis for subsequent process integration and system-level evaluation.

## Rapeseed oil production process model

Rapeseed oil production was modeled as an upstream unit operation to supply the lipid feedstock to the HEFA-based jetfuel production process. Unlike soybean oil extraction, which relies exclusively on solvent extraction, rapeseed oil production combines mechanical pressing and solvent-based extraction due to the higher oil content of rapeseed (approximately 40% w/w, compared to ~20% w/w for soybeans). A soybean crushing and oil extraction process previously developed in ASPEN Plus by Granjo et al. [15] was adapted in this study using rapeseed-specific operating conditions and parameters reported by Carré Patrick [16].

Figure 3a shows the process flow diagram of the rapeseed oil production system modeled in ASPEN Plus in this study. Rapeseeds are first cleaned to remove impurities and are then preheated to approximately 60 °C prior to flaking. The flaked seeds are subsequently conditioned at around 100 °C to reduce moisture content and improve oil release and are then fed to a mechanical press for primary oil extraction. Approximately 70% of the total oil content is recovered at this stage, while the remaining solid fraction (press cake) is directed to a solvent extraction unit for further oil recovery.

Hexane, the most widely used industrial solvent for oil extraction [9], is employed in this model to extract the remaining oil from the press cake. The solvent flow rate

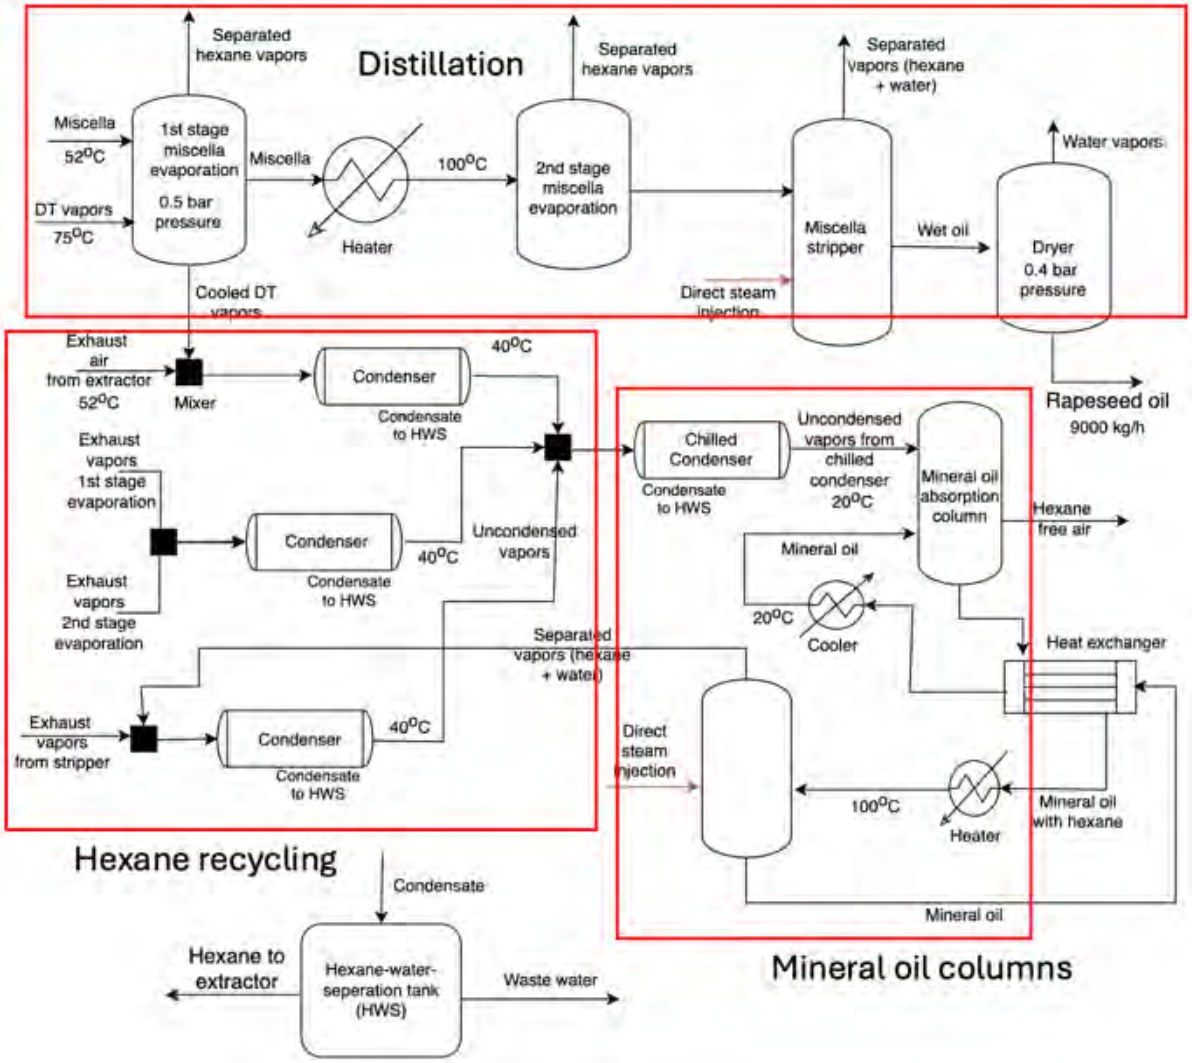

**Figure 3 Continued.** Process flow diagrams of the rapeseed preparation and oil extraction process. **(b)** Miscella distillation and hexane condensation along with mineral oil absorption steps.

corresponds to approximately 55% (w/w) of the incoming seed flow. In the extractor, hexane recovers the remaining 30% of the oil content and exits the unit via three outlet streams: extracted rapeseed cake, miscella (hexane–oil mixture), and exhaust air. In addition to miscella distillation, hexane is also recovered from the solid cake and exhaust air streams and recycled within the system. Overall, more than 99.9% of the added hexane is recovered [16-17], resulting in negligible solvent losses and limited contribution to operating costs and emissions.

Figure 3b presents the miscella distillation and hexane recovery section of the process. The miscella is treated through a two-stage evaporation system followed by a stripper, where direct steam injection is used to remove residual hexane. The crude oil is subsequently dried to remove moisture introduced during the stripping step and is sent for the refining process. The exhaust air from the extraction process is treated via a mineral oil absorption system to ensure hexane emissions remain below environmental regulatory limits [18]. Efficient absorption requires cooling the gas stream to approximately 20 °C, which is represented in the model by a refrigeration cycle producing chilled water. Absorbed hexane is recovered by direct steam injection into the heated mineral oil and recycled back to the extraction unit.

The solid press cake leaving the extractor, which is saturated with hexane, is sent to the desolventization–toasting–drying–cooling (DTDC) section to produce hexane-free rapeseed meal suitable for animal feed. The desolventization and toasting steps involve heating the meal to approximately 100 °C with direct steam injection, resulting in a DT exhaust stream containing hexane and water vapor. This exhaust is combined with extractor exhaust vapors and routed to the hexane recovery system.

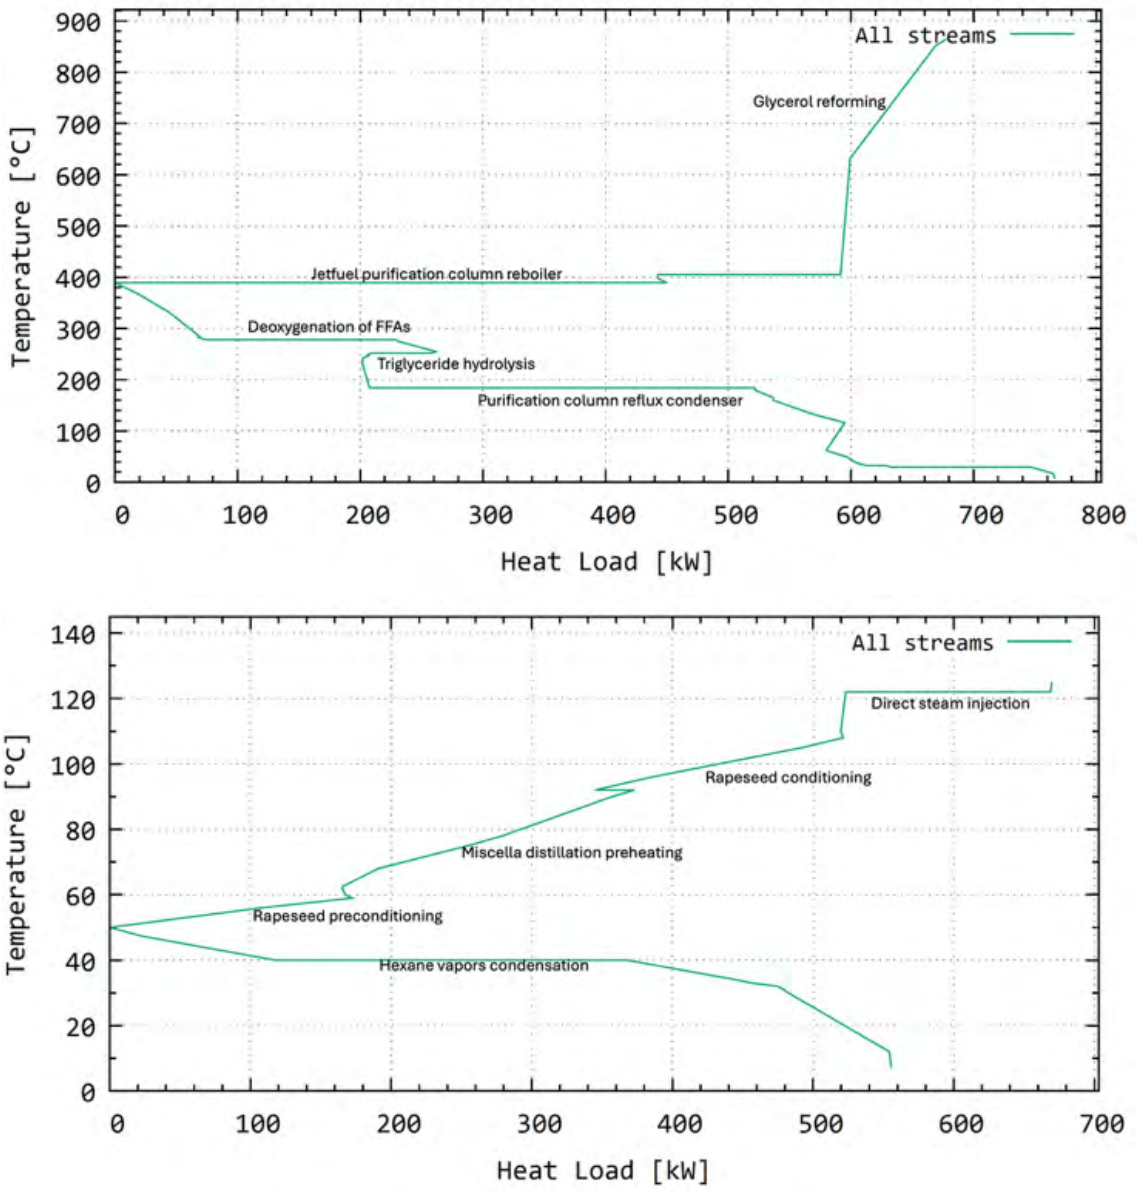

**Figure 4.** Grand composite curves of the jetfuel production and oil extraction process. (a, top) HEFA-based jet fuel production process (1 t $h^{-1}$ capacity) with glycerol reforming for hydrogen production. Process pinch point temperature of 389 ˚C shows waste heat recovery potential. (b, bottom) Rapeseed oil extraction process (7.5 t $h^{-1}$ crushing capacity) with a low-temperature pinch point at 50 °C.

Due to steam injection, the meal exiting the DT unit has a high moisture content. It therefore undergoes drying using hot air at approximately 105 °C, followed by cooling to around 40 °C using ambient air.

All recovered hexane streams were condensed and sent to a gravity–based hexane–water separation unit, with the recycled solvent returned to the extractor and the separated water directed to wastewater treatment. The extracted rapeseed oil undergoes subsequent refining, while rapeseed meal, produced as a major co-product, was explicitly considered within the integrated biorefinery framework for further valorization.

## Process integration and biorefinery

The mass and heat streams obtained from the ASPEN Plus process models were exported to OSMOSE, a system-level optimization platform developed at IPESE, EPFL [19–20], to evaluate energy integration and utility system design. Heat integration was first performed separately for the HEFA-based jet fuel production process

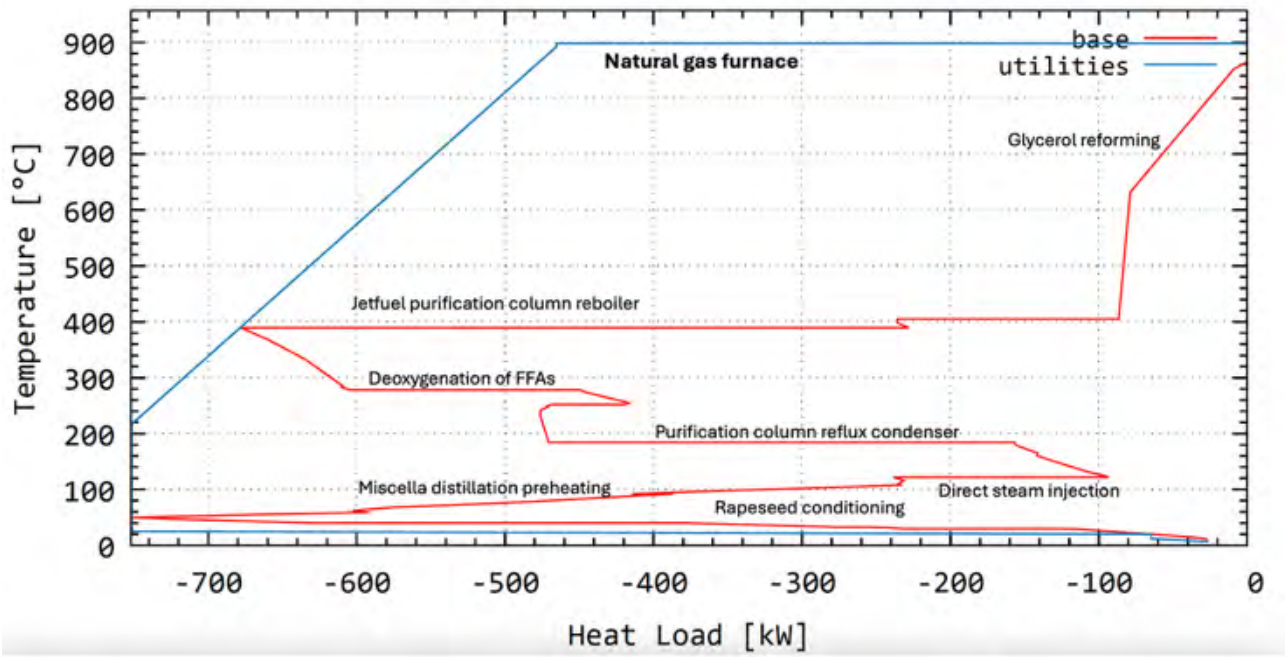

**Figure 5.** Integrated composite curve of the combined HEFA and rapeseed oil extraction processes. Thermal coupling between subsystems results in approximately 89% reduction in external heating requirement compared to stand-alone production.

and the rapeseed oil extraction process, and subsequently for the c ombined biorefinery configuration to assess potential symbiotic benefits.

The integration framework includes energy conversion technologies such as boilers, cooling water systems, refrigeration cycles, and heat pumps. A mixed-integer linear programming (MILP) formulation was implemented to determine the optimal utility configuration and operating strategy that minimizes total annualized system cost, accounting for both capital and operational expenditures while satisfying process integration constraints. Environmental constraints were incorporated to evaluate decarbonization pathways, including Scope 1 emissions associated with biogenic $CO_2$ release and natural gas consumption for process heating, as well as Scope 2 emissions linked to electricity use. In addition to heat integration, material integration between subsystems was evaluated, with emphasis on internally generated hydrogen and the valorization of rapeseed meal. Hydrogen produced via glycerol steam reforming was directly supplied to the HEFA upgrading section, reducing external hydrogen requirements. Rapeseed meal was assessed as an alternative energy and carbon carrier through steam gasification, and its use for syngas production was compared against its conventional use as animal feed.

The gasification process was modeled in ASPEN Plus as a sequence of drying, pyrolysis, reduction, and combustion reactions, following the methodology reported by Florez et al. [21]. The proximate composition of rapeseed meal was assumed to be 5.7% moisture, 13.5% fixed carbon, 74% volatile matter, and 6.8% ash, consistent with literature values [22–23]. Mass yields in the pyrolysis step and the resulting syngas composition were calculated using empirical correlations derived from the referenced model [21], providing the basis for integration within the overall biorefinery configuration. The resulting optimization framework enables a systematic assessment of cost–emission trade-offs while simultaneously evaluating heat and material integration options, allowing identification of biorefinery configurations that enhance energy efficiency, reduce external resource dependence, and improve carbon utilization within the SAF production system.

## RESULTS AND DISCUSSION

The described modeling framework was applied to evaluate the energetic performance of the rapeseed-based HEFA biorefinery. The analysis assumes a production capacity of 1 ton per hour of jet fuel and a rapeseed crushing capacity of 7.5 tons per hour for oil extraction. Results are presented sequentially, beginning with the individual subsystems, followed by their integration.

### Stand-alone process energy analysis

The grand composite curves (GCC) of the HEFA and rapeseed oil extraction processes are shown in Figure 4. The HEFA process (Figure 4a) has minimum heating

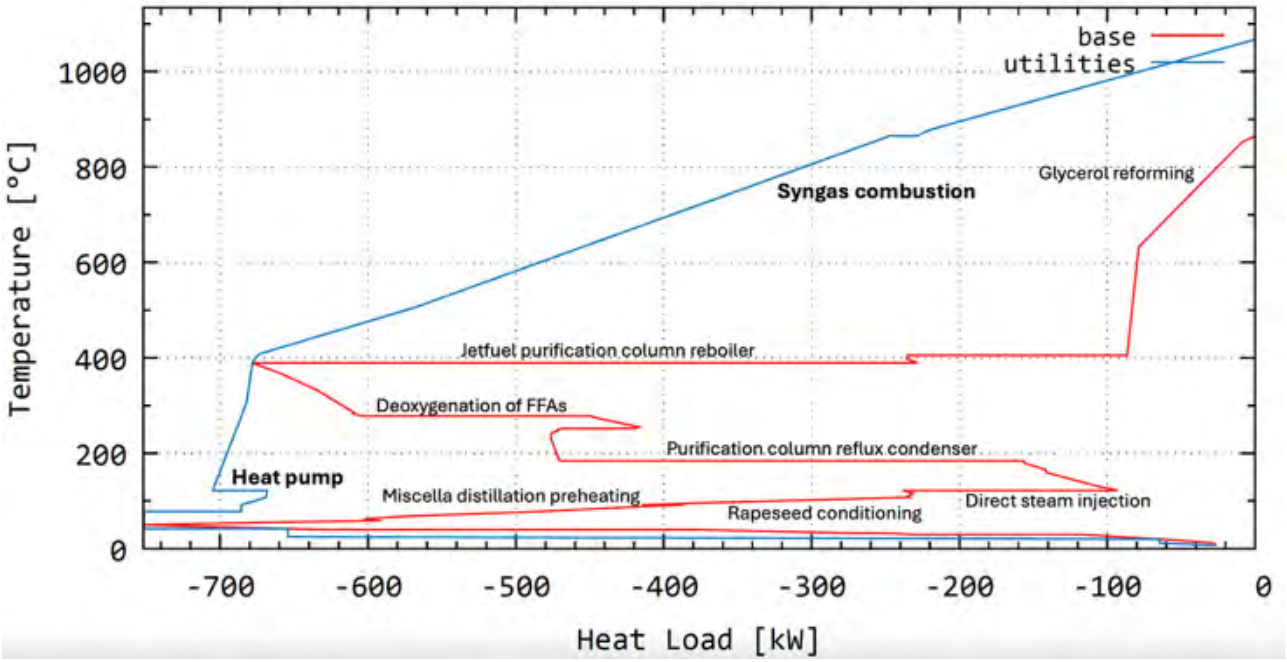

**Figure 6.** Integrated composite curve of the biorefinery configuration including HEFA production, rapeseed oil extraction, and rapeseed meal gasification. Conversion of 6.2% of the available rapeseed meal to syngas enables full thermal self-sufficiency of the integrated system.

requirements of 677 kWh for 1 ton of jetfuel production. Glycerol steam reforming, operating at 827 °C, supplies the hydrogen required for deoxygenation, isomerization, and hydrocracking. Recycling the diesel fraction from the distillation column back to the hydrocracking reactor increases overall jet fuel yield to 73%, corresponding to approximately 1.37 t $h^{-1}$ of biomass feedstock conversion. The pinch point temperature of 389 °C reflects the external heating requirements at elevated temperature levels with significant thermal demand primarily driven by reforming reactions and the distillation columns.

In contrast, the rapeseed oil extraction process shows a pinch point at 50 °C (Figure 4b). At a crushing capacity of 7.5 t $h^{-1}$, the process exhibits the same minimum heating requirement of 677 kW as the HEFA subsystem. This operation yields 2.2 t $h^{-1}$ of press oil, 0.9 t $h^{-1}$ of hexane-extracted oil, and 4 t $h^{-1}$ of rapeseed meal as a co-product. The dominant heat duties arise from seed conditioning, hexane recovery, and steam generation at 120 °C for direct injection.

The observed temperature-level mismatch between the two subsystems suggests strong potential for thermal symbiosis, with high-temperature waste heat from the HEFA process potentially satisfying heating requirements of the extraction section.

## Heat Integration of the Combined Biorefinery

Figure 5 shows the integrated composite curve of the combined jetfuel and oil extraction process. In this configuration, a natural gas furnace and cooling tower satisfy the residual external heating and cooling demands after internal heat recovery. A chilled-water-based refrigeration cycle is required to meet sub-ambient cooling demands associated with the mineral oil absorption process in the extraction section. The optimized furnace capacity is 746 kW, corresponding to an approximately 89% reduction in external heating demand compared to stand-alone operation of the rapeseed oil extraction process. The reduction in fossil-based heating demand directly lowers operational energy requirements and contributes to improved economic and environmental performance of the integrated HEFA biorefinery.

To further reduce external utility demand, integration with rapeseed meal gasification was evaluated. Figure 6 shows the integrated composite curve with the gasification subsystem included in the biorefinery configuration. The results indicate that only 6.2% of the available rapeseed meal must be converted to syngas to fully satisfy the remaining process heating demand. A two-stage heat pump upgrades low-temperature heat and generates steam at 120 °C required for the gasification process. Under this configuration, the biorefinery achieves full thermal self-sufficiency while preserving the majority of rapeseed meal for its conventional market application as animal feed. The combined heat and material integration strategy, therefore, eliminates fossil-based heating requirements and significantly improves the overall energy autonomy of the HEFA-based jet fuel

production system. Such system-level integration is therefore critical for enhancing the competitiveness of sustainable aviation fuel production pathways.

## Outlook and Extended Integration Opportunities

Beyond the discussed configurations, additional valorization pathways may further enhance system circularity and resource efficiency. Rapeseed straw, because of its relatively high calorific value [17], could be considered for direct combustion or co-combustion with other biomass resources to provide supplementary thermal energy. In addition, ash produced from the rapeseed meal gasification process, which is rich in phosphorus and contains significant quantities of potassium, calcium, and magnesium [23], presents potential for agricultural reuse as fertilizer. The application of biochar and nutrient-rich ash to rapeseed cultivation could strengthen the circular-economy framework of the HEFA-based jet fuel production system.

Since only a small fraction of rapeseed meal is required to achieve thermal self-sufficiency, the remaining high-temperature heat from syngas combustion could be further utilized for power generation through a Rankine cycle, potentially covering a significant share of the plant's electricity demand. Future work may also explore the integration of Power-to-Liquid (PtL) pathways for the utilization of biogenic $CO_2$ streams originating from the HEFA decarboxylation process. Potential strategies include seasonal or underground $CO_2$ storage in salt caverns [24], coupled with electrolysis-based hydrogen production during periods of excess renewable electricity. Such extensions could further enhance carbon efficiency and address the current limitations in the broader adoption of sustainable aviation fuels.

# CONCLUSION

This study presented a system-level evaluation of an integrated rapeseed-based biorefinery for sustainable aviation fuel production via the HEFA pathway. Standalone analysis of the individual subsystems revealed complementary thermal characteristics, with the HEFA process exhibiting a high pinch point temperature and the rapeseed oil extraction process showing a low-temperature pinch. This facilitated substantial cross-process heat recovery when the systems were integrated. Coupling the HEFA and oil extraction processes reduced external heating demand by up to 89% compared to operating the processes independently. Further integration through rapeseed meal gasification demonstrated that only a small fraction of the available biomass byproduct needs to be valorized to achieve thermal self-sufficiency of the combined biorefinery. Also, internally generated hydrogen from glycerol steam reforming reduced reliance on external hydrogen supply, enhancing overall resource efficiency.

These findings underscore the importance of simultaneously evaluating heat and material integration within a unified optimization framework. By leveraging inter-process symbiosis and flexible biomass allocation, the proposed configuration substantially lowers fossil utility dependence while maintaining co-product valorization pathways. System-level integration strategies of this kind are essential for improving the economic and environmental performance of sustainable aviation fuel production and for enabling its broader, large-scale deployment.

## ABSTRACT

The ecological transition demands innovative frameworks to reduce industrial resource consumption and environmental impacts. Industrial ecology, particularly through Eco-Industrial Parks (EIPs), provides a promising pathway by enabling exchanges of materials, energy, and water between firms. However, the deployment of EIPs is limited by the lack of standardized industrial profiles and transferable modeling approaches. This study develops a generic framework for representing industrial actors as standardized input–output black-box models, consolidating data on resource consumption, energy demand, by-products, and waste streams. These profiles are structured into a harmonized database to support resource-exchange analysis and scalable optimization across diverse contexts. Complementary mappings of processes and resources, as well as energy and heat demand profiles, enhance the feasibility of identifying synergies such as heat cascading and material reuse. The framework is designed to integrate with optimization approaches to evaluate trade-offs between economic and environmental objectives. The framework highlights the benefits of generalizing industrial profiles for robust and transferable EIP modeling, while also identifying gaps in the integration of social indicators, uncertainty analysis, and governance aspects. This work contributes a methodological foundation for supporting circular, low-carbon industrial systems and provides practical tools for the design and deployment of sustainable industrial zones.

**Keywords**: industrial ecology, eco-industrial park, resource exchanges, optimization

## INTRODUCTION

The ecological transition requires innovative strategies to reduce resource consumption and mitigate industrial environmental impacts. Industrial ecology, and particularly Eco-Industrial Parks (EIPs), has emerged as a promising framework for promoting circular resource use through exchanges of energy, water, and materials between companies. While several studies have demonstrated the economic feasibility of industrial symbiosis, there remains a lack of integration of environmental performance and model flexibility across various industrial contexts.

Industrial ecology (IE) provides the theoretical foundation for rethinking industrial systems as ecosystems in which resources circulate rather than follow a linear path. Chertow (2000) emphasized that the central principle of IE is the closing of loops that allows transforming waste from one process into a valuable input for another. This idea is operationalized in EIPs, where firms engage in industrial symbiosis through exchanges of materials, energy, water, and by-products to achieve both environmental and economic benefits [1].

The Kalundborg symbiosis in Denmark is the most widely cited and pioneering example of this approach. Over several decades, companies in Kalundborg developed a network of exchanges, such as the transfer of steam, surplus heat, gypsum, and wastewaterthat reduced costs, minimized environmental impacts, and demonstrated the feasibility of symbiosis in practice. This case illustrates how industrial systems can evolve organically towards resource efficiency and collaborative sustainability.

Recent works extend EIP thinking toward Hubs for Circularity (H4C), which integrate industrial, urban, and rural exchanges to reach near-zero emissions and enhance local welfare. This broader framing highlights the importance of considering not only intra-industrial

synergies but also urban heat recovery, agricultural waste valorization, and community-level benefits [2].

In Europe, Italy has pioneered regional EIP initiatives, particularly in Emilia-Romagna, where governance and institutional support are critical drivers of symbiotic networks. Similarly, in Spain, co-located industrial symbiosis networks have contributed to multiple UN Sustainable Development Goals (SDGs), including water savings, emission reductions, and job creation [3].

Despite successful examples, EIP design and operation are complex due to conflicting objectives, local versus global optima, and operational uncertainties. Kuznetsova and Zio propose a methodological framework treating EIPs as complex engineered systems comparable to smart grids, requiring multi-level optimization and robustness to uncertainties [4]. Mathematical programming, particularly mixed-integer linear programming (MILP), is widely applied to model optimal material and energy exchanges, balancing costs, emissions, and resource use.

Recent advances include:

- Multi-objective MILP models optimizing economic, environmental, and social performance in desert EIPs, such as the Ulan Buh Demonstration Park in Inner Mongolia.
- Stochastic and robust optimization frameworks to account for uncertainty in demand, waste availability, and energy prices within IS networks and H4Cs.
- Leader–slave optimization structures that reconcile global EIP objectives with local firm interests.

Such formulations increasingly integrate multi-resource networks (water, energy, materials, gases), though joint modeling across all domains remains limited. The literature demonstrates the evolution from classical EIP design to complex, multi-objective, and multi-scale frameworks. Key insights include: EIPs can deliver significant environmental and economic benefits but require systematic modeling under uncertainty. Simulation and visualization methods bridge the gap between technical models and stakeholder decision-making.

Despite progress, gaps remain in integrated multi-resource modeling, incorporation of social objectives (e.g., job creation, equity), and operational-level optimization beyond strategic design. This work builds upon these foundations by developing a generic framework for modeling network components in industrial resource exchanges, integrating black-box process representations with systemic indicators (e.g., MFA, Sankey diagrams) to improve adaptability across contexts.

## PROBLEM STATEMENT

The primary objective of this study is to support the deployment of industrial ecology by developing standardized industrial profiles that can be used as building blocks in a generic optimization framework for eco-industrial parks. The work involves reviewing existing literature and case studies, defining representative profiles for selected industrial sectors, and characterizing their typical processes in terms of resource consumption, energy demand, by-products, and waste streams.

These profiles are modeled using a black-box approach to identify potential resource exchanges and synergies between companies. Finally, the profiles are integrated into an adaptable optimization framework and applied to a case study, with the aim of evaluating both economic and environmental performances.

The purpose of this formulation is not to provide a site-specific optimal solution, but to demonstrate how standardized profiles reduce modeling effort and enable scalable optimization across heterogeneous industrial contexts. This research work aims to answer the following questions:

- What are the defining features of industrial profiles in terms of resource usage?
- How can these profiles be modeled in a way that supports generic optimization?
- What is the impact of using standardized profiles on the scalability and adaptability of eco-industrial models?

## METHODOLOGY

The methodology outlines the approach adopted to develop a generalized framework for modeling resource exchanges within eco-industrial parks. Within the scope of the French industry decarbonization program, this research addresses the need for a standardized database capable of integrating diverse industrial profiles across the country. The procedure involved structuring representative profiles into a harmonized format and designing a network model to support resource exchange analysis. This approach provides the foundation for evaluating eco-industrial park topologies in a way that is both generalizable and adaptable to local contexts.

This study is defined as quantitative and model-based, drawing on the frameworks of industrial ecology and optimization modeling. Industrial ecology provides the systemic perspective for analyzing material, energy, and water exchanges within industrial ecosystems [5], [7]. Within this methodological framework, EIPs operationalize industrial symbiosis by linking firms through complementary resource flows and assessing their performance with eco-efficiency indicators [8].

Case studies such as the Ulsan Eco-Industrial Park

**Table 1.** Representative enterprise types and their primary input–output flows.

| Category | Facility / Plant | Inputs | Outputs |
|---|---|---|---|
| Energy Utility | Combined Heat & Power (CHP) Plant | Fuel, Water | Electricity, Steam, Waste Heat |
| | Biomass Power Plant | Biomass | Electricity, Heat, Biochar |
| | Waste-to-Energy Plant | Municipal Waste | Electricity, Heat, Ash |
| | Hydrogen Production Plant | Electricity, Water | Hydrogen, Oxygen |
| Wastewater TP | Municipal Wastewater Treatment Plant | Wastewater, Electricity | Treated Water, Biogas, Sludge |
| Heavy Industry | Cement Factory | Limestone, Slag, Energy | Cement, Clinker, Heat |
| | Steel Manufacturing Plant | Iron Ore, Coal, Water | Steel, Slag, Waste Heat |
| | Glass Manufacturing Plant | Silica, Soda Ash, Energy | Glass Products, Heat |
| | Brick or Tile Factory | Clay, Ash | Bricks, Tiles |
| Chemical Industry | Chemical Processing Plant | Feedstocks, Steam, Water | Chemicals, Heat, Wastewater |
| | Plastic Recycling Facility | Plastic Waste, Energy | Recycled Plastic |
| | Paint or Coating Factory | Solvents, Chemicals | Paint, Coating |
| | Fertilizer Plant | Ammonia, $CO_2$ | Fertilizers, $CO_2$ Reuse |
| Agri-Food | Food Processing Plant | Raw Food, Water | Packaged Food, Organic Waste |
| | Brewery or Winery | Grains, Water | Beer/Wine, Spent Grains |
| | Slaughterhouse | Livestock | Animal Products, Fat Waste |
| | Dairy Plant | Milk, Steam, Water | Milk Products, Whey |
| Light Manufacturing | Textile Factory | Cotton, Dyes, Water | Fabrics, Dye Wastewater |
| | Paper Mill | Pulp, Water | Paper, Sludge |
| | Wood Workshop | Wood | Sawdust, Wood Products |
| | Electronics Assembly Plant | Electronic Components | Electronics, E-waste |
| Other industries | Urban Greenhouse / Vertical Farm | $CO_2$, Heat, Water | Vegetables, $CO_2$ Utilization |
| | Composting Facility | Food Waste, Green Waste | Compost |
| | Algae Production Facility | Wastewater, $CO_2$ | Algae, Biomass |
| | Biogas Plant (Anaerobic Digester) | Organic Waste | Biogas, Digestate |
| Small Business | Bakery | Flour, Water, Electricity | Bread, Waste Heat |
| | Laundromat | Water, Electricity | Hot Water Discharge |
| | Café / Restaurant | Water, Ingredients, Energy | Food Waste, Wastewater |

demonstrate how "designed" industrial symbiosis networks can evolve from research and development initiatives into practical business models, enabling systematic evaluation of exchanges across diverse enterprises [9].

Optimization modeling has been widely applied to EIPs to evaluate synergies and design efficient exchange networks [10]. Methods such as mixed-integer linear programming (MILP) and superstructure optimization enable systematic assessment of trade-offs between economic and environmental objectives, while metaheuristic approaches such as ant colony optimization (ACO) and agent-based modeling (ABM) have been proposed to handle the complexity of large-scale networks.

The objectives of this research are therefore fourfold:

- To develop generalized industrial profiles that abstract enterprises into standardized input–output black-box models;
- To model resource exchanges in EIPs through network superstructures that capture all feasible synergies;
- To design a harmonized dataset to support optimization across diverse industrial contexts;
- To evaluate the adaptability of this framework through application to a case study.

## MAPPING OF INDUSTRIAL PROFILES

### Industrial profiles and enterprises types

A substantial body of literature exists on material flow analysis (MFA) [1], circular economy implementation, and the optimization of industrial symbiosis [6]. These studies demonstrate the potential of resource exchanges within eco-industrial parks (EIPs) and provide valuable methodologies for flow quantification and network optimization. However, most of these works remain

**Table 2.** Process to Resources mapping

| Enterprise | Process | Resources Required |
|---|---|---|
| Steel Manufacturing | Blast Furnace | Iron ore, Coal, Coke, Oxygen, Heat |
| | Basic Oxygen Furnace | Oxygen, Scrap Metal, Heat |
| | Rolling | Electricity, Lubricants |
| | Waste Heat Recovery | Waste Gas, Heat Exchanger |
| | Slag Handling | Electricity, Water |
| Cement Factory | Raw Material Crushing | Limestone, Electricity |
| | Preheating | Waste Heat, Fuel |
| | Clinker Production | Fuel, Heat, Electricity |
| | Grinding & Packing | Electricity, Gypsum |
| Food Processing | Cleaning | Water, Electricity |
| | Cooking | Steam, Electricity, Ingredients |
| | Pasteurization | Steam, Water, Electricity |
| | Packaging | Plastic, Packaging Gas |

**Table 3.** Resources -> Process mapping

| Resource Input | Used In Process | Industry Examples |
|---|---|---|
| Steam | Sterilization | Food & Beverage<br>Pharmaceutical |
| | Boiling | Brewery, Food Processing<br>Food processing |
| | Evaporation | Sugar Refinery<br>Dairy |
| | Drying | Paper Mill, Textile, Chemical |
| | Heating reactors | Chemical Manufacturing, Petrochemical |
| | Steam Stripping | Petrochemical, Refining |

| | Steam cleaning | Dairy, Brewery |
| | Pasteurization | Dairy, Beverage |
| | Cooking | Canning, Packaged Food |
| | Distillation | Refinery, Spirits Production |
| | Preheating | Steel, Chemical |

context-specific, focusing on individual case studies or sectoral analyses, rather than proposing a generalized and reusable dataset of industrial profiles.

Currently, there is no consolidated datasheet that categorizes enterprises into standardized groups with generalized input/output flow data. This gap makes it difficult to design transferable models that can efficiently simulate exchanges between companies in different locations. Existing datasets are often fragmented (case-specific "stories" of companies or sectoral MFA studies), but they are not harmonized into a universal resource-exchange typology.

Industries in this study were first classified into representative categories (e.g., power plants, chemical industries, steel plants, bakeries, wastewater treatment facilities). The Enterprise Types sheet of the database defines the scope of participants, their primary inputs (fuels, raw materials, water), and outputs (electricity, steam, waste heat, by-products). This provides the foundation for a generic library of industrial actors in an EIP.

The Input-Output sheets consolidate resource balances by identifying primary inputs, main outputs, and secondary outputs such as waste heat, CO,ÇÇ, or solid residues. This abstraction ensures that industries with very different processes can be compared under the same modeling structure.

A datasheet (Table 1) has been created for each industry profile, providing a general view and supporting

**Table 4.** Energy and heat demand profiles of industries

| Enterprise Name | Process | Electricity Demand (Typical) | Heat/Steam Demand (Typical) | Estimated Temperature Range (°C) |
|---|---|---|---|---|
| Steel Manufacturing Plant | Raw material handling | Very High | High | 900–1800 |
| | Blast furnace | Very High | High | 900–1800 |
| | BOF | Very High | High | 900–1800 |
| | Rolling & finishing | Very High | High | 900–1800 |
| | Waste heat recovery | Very High | High | 900–1800 |
| Cement Factory | Crushing | High | Very High | 1200–1500 |
| | Preheating | High | Very High | 1200–1500 |
| | Clinker formation | High | Very High | 1200–1500 |
| | Grinding | High | Very High | 1200–1500 |
| | Packing | High | Very High | 1200–1500 |
| Chemical Processing Plant | Reactor operation | High | High | 100–300 |
| | Separation | High | High | 100–300 |
| | Distillation | High | High | 100–300 |
| | Storage | High | High | 100–300 |
| | Cooling | High | High | 100–300 |

the construction of a generic model. The sheets are structured around the following characteristics:

- Enterprise type (energy, chemical industry, heavy industry, etc.);
- Primary and secondary inputs and outputs of enterprises.

### Process-resource mapping

Two complementary sheets: Process→Resources and Resources→Process—map industrial processes to the resources they require and produce (Table 2, 3). For example, in steelmaking, the blast furnace consumes iron ore, coke, and oxygen, while emitting $CO_2$ and slags. This mapping ensures that exchanges can be matched based on technical feasibility.

## ENERGY AND HEAT PROFILES

To systematically evaluate exchange opportunities, the energy and heat requirements of industrial processes are characterized in terms of both demand level and temperature range. The Electricity–Heat Demand profile provides a comparative mapping of industries such as steel manufacturing, power generation, and food processing, indicating whether their electricity and heat consumption is low, medium, or very high.

In addition, typical operating temperature ranges are included to capture the quality of heat required or released. This parameterization is crucial for identifying feasible synergies: for instance, excess low-temperature steam from one process may be unsuitable for another process requiring high-grade heat, but could be matched to district heating or drying applications.

By grouping industries according to their energy demand intensity and thermal characteristics, the framework facilitates heat cascading strategies and improves the robustness of optimization models for eco-industrial parks.

## OPTIMIZATION AND MODELLING STRATEGIES

The standardized industrial profiles developed in this study are designed to be adaptable to a range of optimization and modeling approaches. This creates opportunities to strengthen the design and deployment of Eco-Industrial Parks (EIPs) by linking resource-exchange data to advanced decision-support tools.

Mathematical optimization methods, such as Mixed-Integer Linear Programming (MILP), are particularly well-suited for systematically identifying exchanges that minimize cost or emissions while respecting process constraints. By structuring industries as black-box profiles, the framework ensures compatibility with such models and facilitates scalable, scenario-based evaluation.

Based on previous works [6] and to demonstrate the compatibility of the proposed standardized industrial profiles with process-systems engineering approaches, this section outlines a generic optimization formulation for eco-industrial park (EIP) design based on these

profiles. The objective is not to solve a fully instantiated case-specific problem, but to illustrate how the standardized profiles can be directly embedded into a superstructure-based optimization framework.

Each industrial actor $i \in I$ is represented as a standardized black-box profile defined by its resource inputs, outputs, by-products, and energy demands. These profiles constitute the building blocks of a superstructure that enumerates all feasible resource exchanges between actors within the EIP.

Let $R$ denote the set of resources (e.g. water, steam, heat, materials), and $x_{ij}^r$ the continuous decision variable representing the flow of resource $r \in R$ exchanged from actor $i$ to actor $j$. Binary variables $y_{ij}^r$ indicate whether an exchange link is activated.

A generic cost–emission optimization problem can be formulated as:

$$\min \left( \sum_{i,j,r} C_{ij}^r x_{ij}^r \, , \; \sum_{i,j,r} EF^r x_{ij}^r \right)$$

subject to:

- Mass and energy balance constraints

$$\sum_j x_{ji}^r + S_i^r = \sum_j x_{ij}^r + D_i^r \forall i, r$$

where $S_i^r$ and $D_i^r$ denote standardized supply and demand parameters derived from the industrial profiles.

- Capacity constraints

$$0 \le x_{ij}^r \le \bar{X}_{ij}^r y_{ij}^r$$

- Technical compatibility constraints

$$x_{ij}^r = 0$$

$$\text{if profiles } i \text{ and } j \text{ are incompatible for resource } r$$

The standardized profiles provide harmonized bounds $\bar{X}_{ij}^r$, emission factors $EF^r$, and unit exchange costs $C_{ij}^r$, enabling the formulation to be instantiated across different territorial contexts without redefining the model structure.

This formulation illustrates how standardized profiles reduce model-building effort, facilitate scalability, and support comparative scenario analysis, while remaining fully compatible with classical MILP and multi-objective optimization approaches used in EIP design.

The standardized industrial profiles can be applied to generate and analyze generic resource-exchange scenarios representative of typical eco-industrial park configurations. Rather than focusing on a single site-specific case, the objective is to demonstrate how the profile-based approach supports systematic identification of symbiosis opportunities.

Based on the compiled profiles, industries are currently classified according to their dominant resource roles (producer, consumer, or prosumer) and thermal characteristics. This enabled the identification of recurrent exchange patterns, including:

- heat and steam cascading between high-temperature and low-temperature processes,
- by-product valorization chains across manufacturing and recycling activities,
- water reuse loops involving industrial and utility actors.

For instance, standardized profiles for energy-intensive processes (e.g. power generation, steelmaking) are matched with medium- and low-temperature demand profiles (e.g. food processing, district heating), revealing generic heat recovery configurations applicable across multiple industrial zones. Similarly, material by-products identified in standardized profiles enabled the construction of cascading exchange chains connecting primary production, transformation, and recycling actors.

These scenarios can be directly encoded as candidate exchange links in the optimization superstructure, reducing the search space while preserving technical realism. Compared to purely case-specific modeling, the standardized profile approach enables rapid scenario generation, cross-site comparison, and transferability of symbiosis configurations.

Looking forward, the main opportunity lies in combining these approaches: using standardized profiles as building blocks for multi-objective optimization, heuristic exploration, and dynamic modeling. This integration will not only improve technical robustness but also support decision-making by balancing economic, environmental, and social objectives. While the present framework relies on static categorizations of energy and heat demand (e.g., low, medium, high), this simplification corresponds to an aggregated representation aimed at enabling generic and transferable modeling across industrial sectors. However, real industrial systems often exhibit significant temporal variability due to batch operations, shift-based production, or seasonal fluctuations.

The proposed formulation can be naturally extended to account for such dynamics by introducing a multi-period MILP structure. In this case, the set of decision variables and parameters (e.g., resource flows, demands, and availabilities) can be indexed over discrete time intervals (e.g., hourly, daily, or seasonal periods). This allows capturing temporal mismatches between resource supply and demand, such as excess heat production during off-peak hours and consumption during peak periods.

Additional components such as storage units (e.g., thermal storage, tanks) and time-dependent operational constraints can also be integrated to ensure feasibility of exchanges over time. Importantly, the standardized industrial profiles developed in this work remain fully

compatible with this extension, as their input–output structure can be enriched with time-dependent parameters without modifying the underlying modeling framework.

This perspective opens the way toward more realistic and operational eco-industrial park designs, combining the scalability of standardized profiles with the accuracy of dynamic optimization.

## CONCLUSION

This study proposes a process-based framework to support the design and optimization of Eco-Industrial Parks (EIPs) through the development of generalized industrial profiles. By abstracting enterprises into standardized black-box models defined by their inputs and outputs, the framework makes it possible to compare diverse sectors under a common structure and to systematically identify potential exchanges of materials, energy, and water.

The results highlight that structuring industrial data in this way improves both the robustness and scalability of optimization models. It also enhances transferability across different contexts, making the framework suitable for regional and national applications in the deployment of industrial ecology. Furthermore, the use of systemic indicators such as Sankey diagrams and material flow analysis strengthens the capacity to communicate technical results to stakeholders, supporting collaborative decision-making.

While the present work has focused primarily on economic and environmental objectives, future developments should integrate social and governance dimensions, life cycle assessment (LCA), and explicit modeling of uncertainty. In combination with advanced optimization and simulation strategies, the proposed framework can thus serve as a practical tool for advancing circular, low-carbon industrial systems and supporting territorial decarbonization policies.

## ABSTRACT

The increasing deployment of lithium-ion batteries (LIBs) requires effective recycling strategies to reduce environmental impacts and dependence on critical raw materials. In this study, a comparative life cycle assessment (LCA) of two LIB recycling routes, a pyrometallurgical process (Pyro) and a hydrometallurgical process with co-precipitation (Hydro), was performed using a Python-based process modeling framework. The LCA was carried out using an attributional approach, with impacts referred to 1 kg of spent LIBs treated at the recycling facility inlet, considering a representative mix of battery formats and cathode chemistries. Results showed that, when normalized per kilogram of treated batteries, the Hydro route is more impactful than the Pyro one, particularly in terms of global warming potential. The Pyro process does not enable direct cathode regeneration but allows the recovery of high-purity metal salts, whereas the Hydro route enables the production of re-formed NMC-111 cathode material that exhibits lower environmental impacts than virgin cathode production. Overall, the study highlights how rigorous process modeling integrated with LCA enables a detailed and non-trivial assessment of LIB recycling sustainability, revealing trade-offs that are not evident from simplified or purely qualitative analyses.

**Keywords**: Life Cycle Analysis, Modelling and Simulations, Batteries, Process Operations, SimaPro

## INTRODUCTION

The rapid growth of electric mobility has led to a sharp increase in the deployment of lithium-ion batteries (LIBs). As a consequence, the management of spent LIBs has become a critical environmental and resource-security issue [1]. Spent LIBs contain significant amounts of valuable and critical raw materials (CRMs), including lithium (Li), cobalt (Co) and nickel (Ni), whose extraction is associated with high environmental burdens and supply risks. Recycling is expected to play a central role in mitigating these challenges by reducing reliance on primary resources and supporting circular economy strategies along the battery value chain [2]. However, the environmental performance of recycling technologies strongly depends on process design and operational conditions.

Among the recycling technologies proposed for LIBs, pyrometallurgical and hydrometallurgical routes represent the most mature industrial options [3]. Pyrometallurgical routes are characterized by high robustness and flexibility with respect to battery chemistry and format but typically exhibit high energy demand and limited selectivity toward Li recovery [4]. Hydrometallurgical routes, in contrast, rely on leaching and selective separation steps enabling higher recovery efficiencies for CRMs, at the cost of increased process complexity and reagent consumption [5].

Life Cycle Assessment (LCA) has therefore been widely adopted as a decision-support tool to evaluate the environmental implications of LIB recycling technologies. Several studies have shown that recycling does not automatically result in lower environmental impacts compared to primary material production, and that LCA outcomes are highly sensitive to methodological choices such as system boundaries and functional unit definition [6]. Comparisons based on the mass of treated battery waste may lead to different conclusions than those based on the quantity or quality of recovered materials, highlighting the importance of transparent and consistent assumptions [7].

In recent years, process modeling has emerged as a key element for improving the robustness of LCA studies

applied to battery recycling systems. Detailed mass and energy balances derived from process simulations enable the construction of consistent inventories and allow environmental results to be interpreted in direct relation to specific unit operations and material inputs [8]. This approach is particularly relevant for complex and evolving recycling technologies, where industrial-scale data are often limited and scenario-based analyses are required to explore potential optimization pathways [9].

Within this framework, the present study provides a comparative LCA of two LIB recycling routes: a pyrometallurgical process (Pyro) and a hydrometallurgical process with co-precipitation (Hydro) based on a unified process modeling approach. Material and energy balances obtained from a Python-based simulation model were implemented in SimaPro to assess the environmental impacts associated with each recycling strategy. By integrating process-level modeling and LCA, the study aims to clarify the main environmental trade-offs between the two technologies and to identify the process features that most strongly influence their sustainability performance.

## RECYCLING ROUTES AND PROCESS MODELING BACKGROUND

The two alternative recycling routes for LIBs considered in this study, Pyro and Hydro, were modeled in detail to quantify material and energy flows and to identify the main process features influencing their environmental performance [9]. A conceptual overview of the process workflow adopted in this work is provided in Figure 1.

### Pyrometallurgical recycling route (Pyro)

The Pyro route is based on a high-temperature smelting process, in which spent LIBs are treated in a furnace to recover a metallic alloy mainly composed of Ni, Co and copper. During smelting, organic components and graphite are oxidized and provide part of the thermal input, while Li, aluminum and other elements are largely transferred to the slag phase, making them not directly recovered as a valuable product in this route. The metallic alloy produced in the smelter is subsequently processed through a series of hydrometallurgical refining steps aimed at separating and purifying individual metal salts. These downstream refining steps allow the recovery of Ni and Co in the form of high-purity metal salts, which represent the main valuable outputs of the Pyro route. These operations involve leaching, precipitation and washing stages, requiring the use of alkaline reagents, in particular sodium hydroxide (NaOH), as well as additional water and energy inputs. Together with the high thermal energy demand of the smelting stage, these inputs contribute significantly to the overall material and energy balances of the Pyro route. The main advantage of this recycling strategy lay in its robustness and flexibility with respect to battery chemistry and format, as well as in its relatively simple process structure. However, this comes at the expense of high energy consumption and limited selectivity for Li recovery [3].

### Hydrometallurgical recycling route with co-precipitation (Hydro)

The Hydro route is instead based on a sequence of mechanical treatments, leaching and selective separation steps. After mechanical preprocessing, the black mass is subjected to acidic leaching to solubilize valuable metals. Impurities were removed through controlled precipitation, followed by a co-precipitation stage aimed at recovering a mixed metal precursor suitable for the synthesis of NMC-111 cathode material. In this route, the main valuable output is a mixed-metal precursor whose composition is

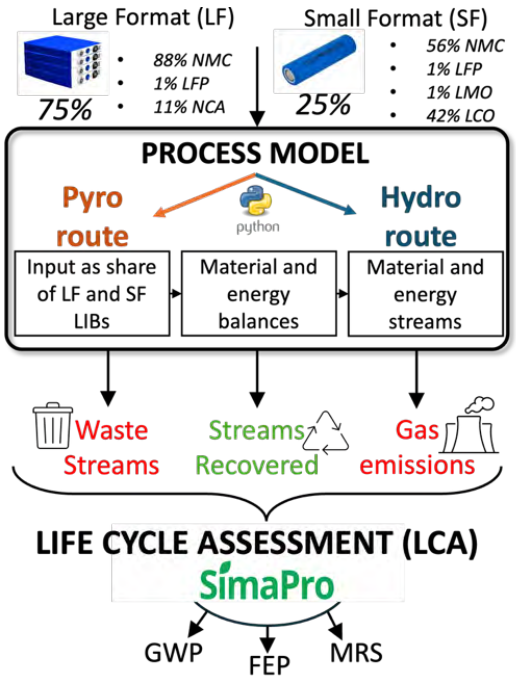

**Figure 1.** Conceptual framework for the LCA of LIB recycling: from Python-based LCI to results.

adjusted to match the target NMC-111 stoichiometry, requiring the controlled addition of Ni, Co and Mn salts during co-precipitation. Compared to the Pyro route, the Hydro process involved a higher number of unit operations and a more complex flowsheet. In addition to inorganic reagents, the process required the use of organic solvents, such as acetonitrile (ACN), in specific separation steps. These solvents are partially recovered and recycled, but their use contributes to auxiliary material consumption and to the generation of solvent-containing waste streams. The Hydro route allows a higher degree of selectivity in the recovery of CRMs, including Li. At the

same time, the increased complexity of the process results in additional material, water and energy inputs that are explicitly accounted for in the process model [3].

### Process modeling framework

Both recycling routes are simulated using a Python-based process modeling framework previously developed and described in detail in [9]. The model represents the main unit operations of each recycling route and calculates the corresponding material and energy balances under steady-state conditions. Model parameters are derived from literature data and industrial references, and the resulting balances are used as primary data for the subsequent LCA. To facilitate the integration of the process simulations into the LCA framework, individual unit operations were aggregated into process blocks representing the main sections of each recycling route. This aggregation allowed a transparent implementation of the recycling processes in SimaPro while preserving the link between process modeling assumptions and environmental results. The resulting system boundaries and block structure adopted for the LCA are illustrated in Figure 2.

## LIFE CYCLE ASSESSMENT METHODOLOGY

### Goal and scope definition

The LCA is performed to compare the environmental performance of the two LIB recycling routes, consistently with the process modeling framework developed in previous work. As evidenced in Figure 2, the analysis focuses exclusively on the recycling stage, with the aim of identifying and comparing the environmental burdens associated with the two alternative technological solutions. The functional unit defined is 1 kg of spent LIBs at the inlet of the recycling facility. This choice is deliberately adopted to ensure a consistent comparison between the two recycling routes, which differ significantly in terms of process configuration, material selectivity and recovery efficiency, and overall output products. Normalizing all results to the same amount of input battery waste allows the environmental impacts of the two processes to be directly compared without introducing additional allocation assumptions. A complementary comparison based on the mass of recovered NMC-111 cathode material was also carried out as a supporting analysis for the Hydro route only. In this case, the environmental impacts associated with the recycled cathode material are compared with those of a reference NMC-111 production process available in the SimaPro database. This comparison is not intended to define an alternative functional unit, but rather to provide additional context for the interpretation of the results related to material recovery.

### System boundaries and life cycle inventory

The system boundaries of the LCA include the recycling processes from the reception of spent LIBs at the recycling facility to the generation of recovered material streams and waste emissions. Battery use, collection and transport to the recycling facility are excluded from the analysis. The system boundaries and the aggregation of unit operations into process blocks adopted in the LCA model are illustrated in Figure 2. Life cycle inventory (LCI) data are derived from a Python-based process simulation model, which provided detailed material and energy balances for both recycling routes [9]. The process model quantified the associated input and output streams and the resulting mass and energy balances are subsequently implemented in SimaPro to build the LCI. An attributional approach was adopted for the LCA, using the Ecoinvent 3 database (cut-off by classification) as background data source. Recycling facilities are assumed to be located in Europe, in line with the industrial context considered in the process simulations. Consequently, European electricity mixes and region-specific energy carriers were used to model energy inputs. This assumption is particularly relevant for energy-intensive operations and has a significant influence on the overall environmental performance of the recycling routes.

### Life cycle impact assessment and impact categories

Life cycle impact assessment (LCIA) is carried out using the ReCiPe 2016 Midpoint (Hierarchist) method implemented in SimaPro. The method allows the transformation of inventory flows into a set of midpoint environmental impact indicators, providing a comprehensive assessment of the potential environmental burdens associated with the recycling processes. Although the full set of midpoint impact categories available in the selected method was calculated, only a subset of impact categories is reported and discussed in detail for clarity and relevance. The selection of the impact categories reported in Figure 3 reflects an interpretative and application-oriented choice, rather than compliance with product category rules or environmental product declaration criteria. In particular, Global Warming Potential (GWP) is included due to its direct relevance to European climate policies and regulations [2]. Mineral Resource Scarcity (MRS) is selected to reflect the primary objective of LIB recycling, namely the recovery of CRMs and the reduction of virgin resource extraction. Freshwater Eutrophication Potential (FEP) is considered to account for water-related impacts, which are particularly relevant for hydrometallurgical processes due to reagent use and wastewater generation. Finally, Ozone Depletion Potential (ODP) is included as an indicator of environmentally harmful emissions not strongly dependent on local conditions, in contrast to several ecotoxicity-related categories. This selection

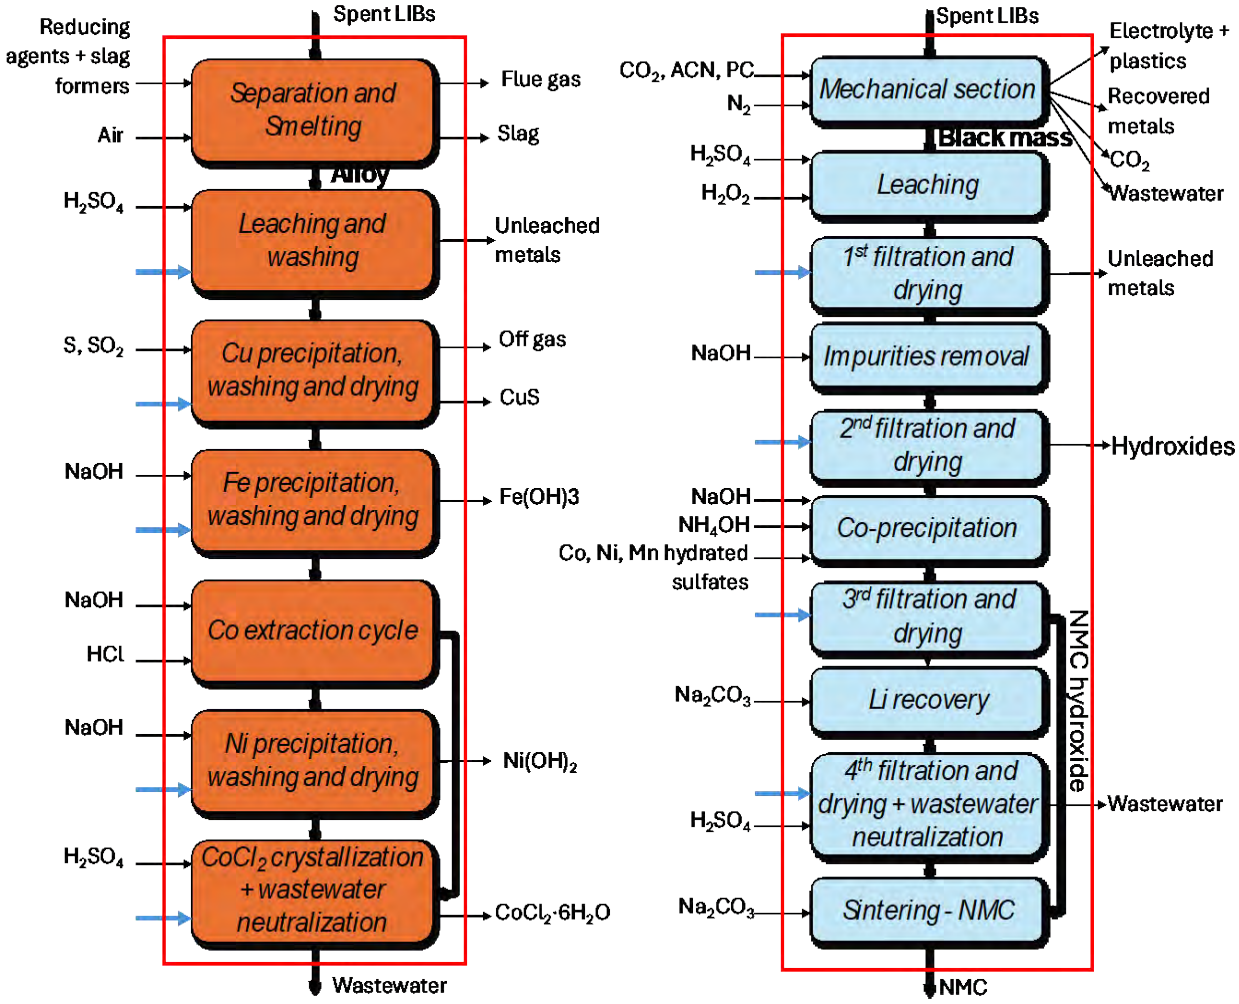

**Figure 2.** System boundaries for LCA analysis of the Pyro route (on the left) and of the Hydro route (on the right) highlighting the main material streams entering and exiting the blocks. The sequences of operations is taken from [9] and simplified/grouped according to SimaPro implementation. The blue arrows represent inlet washing water, while energy streams and transport input are not represented even if included in the analysis

enabled a clear and physically meaningful comparison between the two routes while avoiding redundancy and potential misinterpretation of highly location-dependent categories. This methodological framework enables a consistent interpretation of the contribution analysis and the quantitative comparisons presented in the following section.

## RESULTS AND DISCUSSION

### LCA results per kg of spent LIBs

Figure 3 reports a normalized contribution analysis of the Pyro and Hydro recycling routes. Impacts are normalized within each process and category to identify the most impactful unit operations within each route. As illustrated in Figure 1, the process feed consisted of a representative mix of LF and SF LIBs, characterized by different cathode chemistries, to reflect realistic industrial recycling conditions and to avoid results biased toward a single battery type. For all the impact categories considered, the two processes exhibited markedly different environmental profiles, reflecting both their technological characteristics and the associated material and energy inputs. For the Pyro route, Figure 3 clearly highlights the smelting stage as the dominant contributor to GWP. This result is consistent with the high-temperature nature of the process and the associated fuel consumption. In addition, the iron precipitation stage represents a relevant contribution in all displayed impact categories, reflecting the intensive use of alkaline reagents, particularly NaOH, required for impurity removal in downstream hydrometallurgical refining steps. Other unit operations

show comparatively minor contributions, indicating that environmental impacts in the Pyro route are strongly concentrated in a limited number of process blocks. In the Hydro route, the contribution analysis reveals a different impact distribution. The mechanical separation section and the co-precipitation stage emerge as the most impactful unit operations across the selected categories. The mechanical separation section is mainly associated with electricity consumption and solvent-related operations, including electrolyte separation based on ACN, which constitutes a major contributor to GWP. In contrast, the co-precipitation stage is dominated by the consumption of chemical reagents necessary to control metal ratios and achieve the desired cathode stoichiometry. Overall, the contribution analysis highlights a clear distinction between the main impact drivers of the two dominant unit operations in the Hydro route. Mechanical separation stages are primarily associated with energy-related contributions, mainly electricity consumption and solvent handling, whereas the co-precipitation stage is driven by material-related inputs linked to reagent consumption. This separation between energy- and material-driven contributions provides a process-level interpretation of the impact distribution observed in Figure 3.

While Figure 3 provides insight into the internal structure of environmental impacts for each recycling route, a quantitative comparison between Pyro and Hydro is reported in Table 1. When impacts are normalized to 1 kg of spent LIBs treated, the Hydro route exhibits a higher GWP than the Pyro route (3.97 vs. 3.61 kg $CO_2$ eq), mainly due to solvent use, reagent consumption and wastewater treatment requirements. A similar trend is observed for FEP, where the Hydro route shows markedly higher values, reflecting the intensive use of water and aqueous process streams. Consistently, the Pyro route shows MRS values that are approximately two orders of magnitude lower than those of the Hydro route. Although Li and Al are lost to the slag phase during smelting, the pyrometallurgical process recovers Ni and Co as high-purity salts, thereby reducing the demand for virgin CRMs. In contrast, the higher MRS observed for the Hydro route is mainly associated with the intentional use of Co, Ni and Mn sulphates to adjust the stoichiometry of the re-formed NMC-111 cathode, rather than with inefficiencies in metal recovery.

An important outcome of the combined analysis of Figure 3 and Table 1 concerns the potential for process optimization. In the Pyro route, the dominant contributions originate from the smelting stage, which is intrinsically linked to high-temperature operation and therefore difficult to mitigate without major process redesign. In contrast, the Hydro route exhibits impact hotspots associated with specific unit operations and material choices, such as solvent-based separations and reagent-intensive co-precipitation. This suggests that targeted modifications, including alternative solvents, improved solvent recovery or process simplification, could significantly reduce the environmental impacts of the Hydro route without compromising its material recovery performance.

**Table 1:** Quantitative comparison of Hydro and Pyro for 1 kg of spent LIBs treated

| Impact category | Unit | Hydro | Pyro |
|---|---|---|---|
| GWP | kg $CO_2$eq | 3.974 | 3.611 |
| ODP | kg CFC11eq | 1.63E-06 | 1.47E-06 |
| FEP | kg Peq | 1.77E-01 | 1.23E-03 |
| MRS | kg Cueq | 1.69E-01 | 8.25E-03 |

**Table 2:** Quantitative comparison of recycled and virgin NMC-111 cathode production (1 kg basis).

| Impact category | Unit | Hydro (recycled NMC-111) | Virgin NMC-111 |
|---|---|---|---|
| GWP | kg $CO_2$eq | 20.522 | 26.116 |
| ODP | kg CFC11eq | 8.42E-06 | 1.96E-05 |
| FEP | kg Peq | 9.11E-01 | 3.595 |
| MRS | kg Cueq | 8.74E-01 | 5.633 |

## Supporting comparison with virgin NMC-111 cathode production

To further contextualize the environmental performance of the Hydro recycling route, a supporting comparison was carried out between the production of recycled NMC-111 cathode material and a virgin NMC-111 cathode production process available in the SimaPro database. This comparison was not intended to introduce a second functional unit, but rather to provide an additional reference for interpreting the potential benefits of cathode material recovery. The virgin NMC-111 production process was selected from the Ecoinvent 3 database (cut-off by classification) and represents an industrial-scale synthesis of NMC-111 cathode material based on the use of primary raw materials. The process includes the upstream extraction and refining of Ni, manganese (Mn) and Co compounds, followed by precursor synthesis and high-temperature calcination to produce the final cathode material. Energy inputs and emissions were modeled using region-specific background processes consistent with the European context adopted in this study. Table 2 reports the quantitative comparison between the Hydro recycling route and the virgin NMC-111 production process for selected impact categories. The results show that, when normalized per kilo of production of NMC-111 from recycled materials the Hydro route leads to lower impacts with respect to virgin cathode production for the chosen indicators. This outcome reflects the avoidance of upstream mining and refining

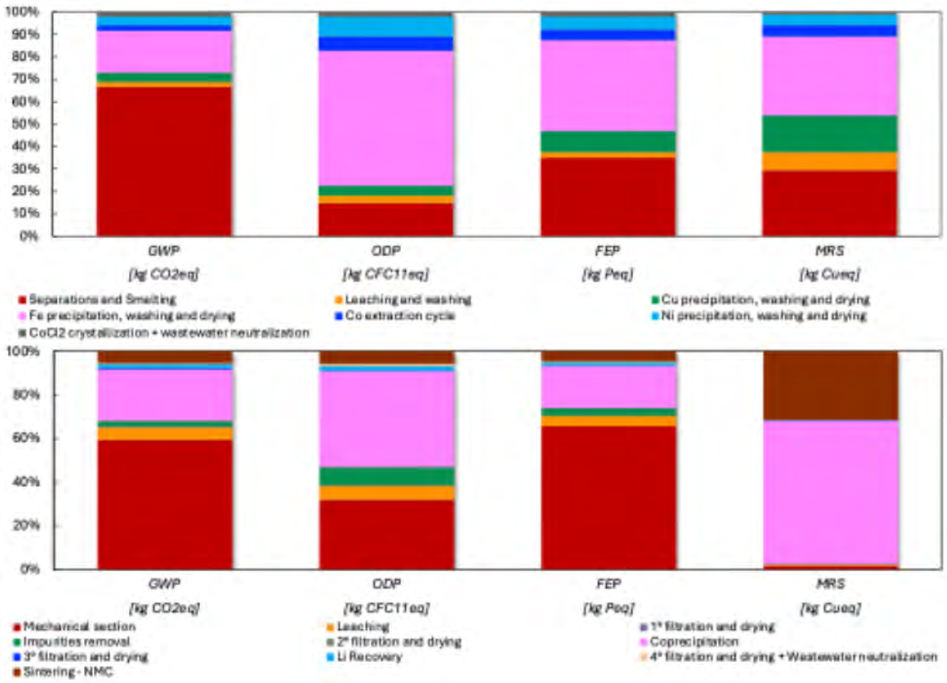

**Figure 3.** Normalized contribution analysis for Pyro (top) and Hydro (bottom) recycling routes, highlighting the relative contribution of the main unit operations, grouped as in Figure 2, to the selected impact categories.

stages for CRMs, which are among the most impact-intensive phases of virgin cathode production. These results support the interpretation that the environmental performance of Hydro recycling should not be assessed solely based on impacts per kilogram of treated waste, but also in relation to the quality and functionality of the recovered products. When evaluated from this perspective, Hydro recycling shows a clear potential to reduce the environmental burden associated with cathode material production, particularly in scenarios where process optimization measures are implemented.

Taken together, the results reported in Table 1 and Table 2 show that the environmental performance of Hydro recycling strongly depends on the selected reference basis. When impacts are expressed per kilogram of treated battery waste, the Hydro route appears more impactful due to its higher process complexity and material intensity. However, when the same process is evaluated in terms of its main functional output, namely the production of NMC-111 cathode material, Hydro recycling exhibits a clear environmental advantage over conventional production from primary raw materials.

## CONCLUSIONS

This work presented a comparative LCA of two LIB recycling routes, namely a pyrometallurgical process and a hydrometallurgical process with co-precipitation, based on detailed process modeling and consistent inventory data. The analysis was carried out using a single functional unit defined as 1 kg of spent LIBs at the recycling facility inlet, considering a representative mix of battery formats and chemistries. The results showed that the two recycling routes exhibit markedly different environmental profiles. The comparison highlighted that some impact-driving elements of the pyrometallurgical process are intrinsically linked to the technology and therefore difficult to mitigate. In contrast, the hydrometallurgical route offers a greater potential for environmental optimization, for instance through alternative solvent choices, improved solvent recovery or process simplification, without necessarily compromising material recovery performance. In addition, when compared to virgin NMC-111 cathode production, the hydrometallurgical recycling route can achieve lower environmental burdens, emphasizing the importance of evaluating recycling processes not only in terms of waste treatment efficiency, but also in relation to the quality and functionality of the recovered products. Overall, the study confirms that the environmental sustainability of LIB recycling strongly depends on process design choices, system boundaries and functional unit selection. The integration of process modeling and LCA proved to be a valuable approach for identifying critical operations and supporting informed optimization strategies.

Further improvements in data quality and the inclusion of industrial-scale operational data would allow more robust conclusions and support informed decision-making in the development of sustainable battery recycling technologies.

## ABSTRACT

The reliable identification of feasible and optimal operating conditions is a key challenge in the design and optimization of thermochemical conversion processes, where kinetics, limited data availability, and strict physical constraints coexist. In this work, a novel data-driven strategy based on Physics-Informed Neural Networks (PINNs) is proposed to explore the operability space of a bubbling fluidized bed (BFB) plastic pyrolysis process. The approach integrates mechanistic knowledge through explicit mass balance constraints with data-driven learning, enabling accurate prediction of and feasibility boundaries. An adaptive sampling framework is employed to iteratively augment the training dataset. The trained PINN surrogate is then used to predict feasible regions and perform constrained optimization aimed at minimizing tar production, which is one of the most problematic byproducts in plastic pyrolysis processes. Beyond classical optimality, a robustness-oriented uncertainty quantification methodology is introduced, combining local perturbations with feasibility filtering to assess the reliability of the optimal solution. Quantitative robustness metrics, including relative objective uncertainty, feasibility retention ratio, and an overall robustness index, are introduced and used to track convergence and select the most reliable operating point. Results show that the proposed framework efficiently converges to accurate feasibility regions and identifies operating conditions that balance optimal performance with robustness against uncertainty. This work provides a methodology for physics-driven process optimization and operability analysis, with potential applicability to a wide range of complex energy and chemical systems.

## INTRODUCTION

The rampant surge in plastic waste generation and lack of sustainable management practises have posed a substantial threat to the ecosystem and human health in the last two decades [1], and plastic waste production is projected to triple by 2050 reaching 1, 200 million metric tons [2]. Chemical recycling through advanced thermochemical technologies (ATTs), such as pyrolysis [3, 4], represent a promising pathway to tackle the plastic waste issue, allowing us to produce a broad spectrum of chemical feedstock for the manufacturing sector [5] and promoting the transition to a true circular economy [6, 7]. Plastics pyrolysis involves feedstock thermal decomposition at temperatures in the range of approximately 400 – 800 °C and in complete absence of oxidizing agents. This process promotes the formation of both gas and liquid products, whose relative amount depends on the reactor operating conditions. The pyrolysis gas is mainly composed of hydrogen and light hydrocarbons. After cleaning and refining, this gas can be used as chemical feedstock by the manufacturing industry. The liquid product, also known as pyrolysis oil, can be upgraded and used to produce olefins, paraffins and substitute fuels. To achieve these results, bubbling fluidized bed reactors (BFBR) are among the best reactor design for ATTs, due to their favourable operating flexibility, and enhanced heat and mass transfer [8]. However, when processing plastic waste, they are subject to hydrody-

namic instabilities due to the plastic melting and unwanted byproducts formation, such as tar and waxes, that can lead to products quality deviations and even early plant shutdown if not properly monitored during operation. This challenge raises the urgency of developing reliable modelling approaches to control BFBR for chemical recycling, de-risking their implementation at industrial scale and improving their performance. While physics-based or mechanistic models are successfully used in the design stage of industrial chemical reactors, their integration for predicting product quality and controlling operations comes at significant computing costs. The opposite approach involves using fully data-driven models, which can ultimately lead to similar issues as they completely lack physical understanding of the process. This work proposes a combination of established process-specific semi-empirical approaches and physics-informed machine learning algorithms to optimize BFBR for chemical recycling of plastic waste. The objective of this work is to find the optimal operating conditions that minimize the yield of tar produced during pyrolysis and elucidate design space trade-offs [9, 10, 11].

A mechanistic model of a fluidized bed reactor for plastic waste pyrolysis is employed, based on kinetics semi-empirical correlations obtained from the literature [12]. This model predicts the yield of the main pyrolysis products, including volatile matter, tar and char, which represent unreacted carbon. Although this model is relatively simple, in general directly embedding pure mechanistic models within an optimisation framework is computationally prohibiting and this motivates the use of surrogate models [13, 14]. Using adaptive sampling, we develop a Physics-Informed Neural Network (PINN) as a surrogate [15, 16], by minimizing simultaneously data loss and physics loss. In this work, the physics loss enforces the conservation of mass between inlet and outlet of the BFBR. The use of neural networks for feasible region identification has already been proven successful, as highlighted by Metta et al. (2020) [17]. Finally, we use the trained PINN within an optimization framework to quantify maximum operability limits [18] and identify the optimal operating conditions that minimize the tar yield.

# METHODOLOGY

## Mechanistic model of plastic pyrolysis in BFB

A mechanistic model $\mathcal{M}$ for plastic pyrolysis in a bubbling fluidized bed reactor is employed to describe the relationship between reactor operating conditions and product yields. The model is based on semi-empirical correlations obtained by Vitale et. al (2024) [12], capturing the dependence of temperature on the yield of volatiles, tar and char during pyrolysis of polypropylene, as follows:

$$\boldsymbol{y}(F,T) = \boldsymbol{A}T + \boldsymbol{B} \tag{1}$$

Where $\boldsymbol{y}$ is the vector of volatiles, tar and char mass flow rates $\dot{m}$, and the hydrogen-to-methane mass ratio $h$ in the pyrolysis gas ($H_2/CH_4$), while $\boldsymbol{A}$ and $\boldsymbol{B}$ are vectors of coefficients obtained from experimental data fitting. The parameter $h$ is a key indicator of gas quality and it is considered in this work as one of the criteria to determine the feasible operability region.

Although the mechanistic model employed in this work consists of linear semi-empirical correlations that are computationally inexpensive, the primary objective of this study is to develop a general algorithmic strategy for feasibility discovery through adaptive sampling and robustness-driven design using PINN.

The reactor system inputs are the plastic feed flow rate $F$ and operating temperature $T$, which also constitute the decision variables of the optimization problem. The BFB is considered to operate with nitrogen at twice the minimum fluidization condition. The set of operating conditions $\mathcal{D}$ of the BFB is given by the temperature range of 650 – 850 °C and the plastic feed mass flow rate range of 20 – 30 kg/h. The temperature limits are chosen in order to remain consistent with the experimental conditions used by the authors, while the flow rates are chosen to vary in a reasonable range for medium size BFB pyrolizers.

## PINN surrogate model

A PINN is developed to act as a surrogate for the mechanistic BFB model. The PINN maps the reactor inputs $F$ and $T$ to the vector of outputs including volatiles, tar and char mass flow rates, and $H_2/CH_4$. The neural network consists of a fully connected feedforward architecture with 1 hidden layer of 20 neurons and hyperbolic tangent activation functions. Several authors observed that a single hidden layer is a good function approximator, provided sufficient number of hidden neurons [17]. The PINN is trained by minimizing a composite loss function including three contributions, as shown in the equation below: a data loss term, a physics loss term, and an L2 regularization term to avoid overfitting. The loss terms are calculated using a MSE metric.

$$\mathcal{L}(\theta) = \frac{1}{N}\sum_{i=1}^{N}\|\hat{y}_i - y_i\| + \frac{1}{N}\sum_{i=1}^{N}\left\|\hat{\dot{m}}_{out,i} - F_i\right\| + \lambda_{L2}\sum_k \theta_k \tag{2}$$

Where *N* are the collocation points in the domain, $\hat{y}$ is the PINN prediction, $y$ is the output of the mechanistic model, $\lambda_{L2}$ is the regularization weight, $\theta_k$ is the $k^{th}$ trainable parameter of the PINN, and $\hat{\dot{m}}_{out}$ and $F$ are the overall mass flowrates at outlet and inlet of the BFB, respectively.

The physics loss enforces mass conservation by constraining the predicted outlet flow rate to match the inlet feed flow rate in real physical units. This constraint

embeds first-principles knowledge into the learning process and improves extrapolation behavior in sparsely sampled regions of the operating space. Input and output variables are standardized prior to training to ensure numerical stability.

## PINN-driven feasibility analysis

An initial training dataset of 100 points is generated using Latin Hypercube Sampling (LHS) over the predefined set of operating conditions for feed flow rate and reactor temperature. The corresponding mechanistic model outputs are used to initialize the PINN training. This initial step is summarized by the following equations:

$$\{x_i\}_{i=1}^{N_0} \sim LHS(\mathcal{D}) \tag{3}$$

$$y_i = \mathcal{M}(x_i) \tag{4}$$

To progressively improve surrogate accuracy in regions of interest, an adaptive sampling strategy is employed. At each adaptive iteration, the PINN is retrained using all available data, after which a dense pool of candidate points is generated within the operating conditions set using LHS. An acquisition function is defined and evaluated on this pool to identify new informative samples. The acquisition is chosen to encourage the PINN to learn regions with high physics residuals, where the surrogate violates mass conservation. The candidate point maximizing this acquisition function is selected, the corresponding output is evaluated using the mechanistic model and added to the training dataset. This approach encourages the PINN to learn regions of the space according to physics constrains. This is the main novelty aspect of the methodology developed in this work. The adaptive sampling algorithm at each iteration can be summarized by the following steps:

1. Train PINN

$$\theta = arg\,\min_{\theta} \mathcal{L}(\theta) \tag{5}$$

2. Generate a dense pool of candidate points

$$\{\tilde{\mathbf{x}}_j\}_{j=1}^{N_c} \sim LHS(\mathcal{D}) \tag{6}$$

3. Evaluate surrogate and physics residual

$$r_j = \left|\hat{m}_{out}(\tilde{\mathbf{x}}_j) - \tilde{F}_j\right| \tag{7}$$

4. Evaluate acquisition function

$$a(\tilde{\mathbf{x}}_j) = \frac{r_j}{max(r)} \tag{8}$$

5. Select new sample

$$x_{new} = arg\,\max_{\tilde{\mathbf{x}}_j} a(\tilde{\mathbf{x}}_j) \tag{9}$$

6. Update training dataset

$$\mathcal{D}_{k+1} = \mathcal{D}_k \cup \{x_{new}, \mathcal{M}(x_{new})\} \tag{10}$$

Subsequently, the process feasibility region is determined through a combination of physics and operational constraints, as follows:

$$\Omega = \left\{(F,T) \in \mathcal{D} \;\middle|\; \begin{matrix} r(F,T) \le \varepsilon \\ h_{min} \le \hat{h}(F,T) \le h_{max} \end{matrix}\right\} \tag{11}$$

The physics residual associated with mass conservation must remain below a prescribed tolerance. Moreover, the $H_2/CH_4$ is constrained to lie within a specified range, reflecting pyrolysis gas requirements for downstream utilization. The values of $\varepsilon, h_{min}$ and $h_{max}$ used to run the algorithm in this work are 1e-2, 0.4 and 0.6, respectively.

## Optimization and sensitivity analysis

The trained PINN surrogate is embedded within a constrained optimization framework to identify operating conditions that minimize tar production while satisfying feasibility constraints. The optimal operating point is selected as the feasible point with minimum tar within the feasible region, as follows:

$$x^* = arg\,\min_{(F,T)\in\Omega} \hat{m}_{tar}(x) \tag{12}$$

To quantify local uncertainty, a local perturbation analysis is performed on the optimum point. The perturbations were generated at each adaptive iteration from a normal distribution with zero mean, as follows:

$$\delta_p \sim \mathcal{N}(0, \sigma) \tag{13}$$

$$x_p^* = x^* + \delta_p \tag{14}$$

Where $x_p^*$ is the p$^{th}$ perturbated optimum point. Each perturbated sample is evaluated using the PINN and it is retained if satisfies the same feasibility constraints shown in Eq. 11. If $N_\delta$ and $N_{feas}$ are the number of perturbated samples and feasible perturbated samples for the tar mass flow rate, respectively, it is possible to define the following metrics:

$$FRR = \frac{N_{feas}}{N_\delta} \tag{15}$$

$$\sigma_{tar} = \frac{\Delta\hat{m}_{tar}}{\hat{m}_{tar}*} \tag{16}$$

Where $FRR$ is the feasibility retention ratio, $\sigma_{tar}$ is the relative uncertainty of the optimal tar value, and $\Delta\hat{m}_{tar}$ and $\hat{m}_{tar}*$ are the 95% confidence interval (CI) for the outlet tar mass flow rate and the optimum tar mass flow rate, respectively. A high value of $FRR$ indicates that small perturbations around the optimum remain feasible with high probability, while $\sigma_{tar}$ captures the sensitivity of the objective value to local perturbations around the optimum. Finally, an overall robustness index can be calculated as:

$$RI = (1 - \sigma_{tar})\, FRR \tag{17}$$

This metric simultaneously rewards small tar uncertainty and high retention of feasible perturbations. The best feasibility region and optimum are chosen to be those with the highest value of $RI$.

A block diagram of the entire algorithm is shown in Figure 1.

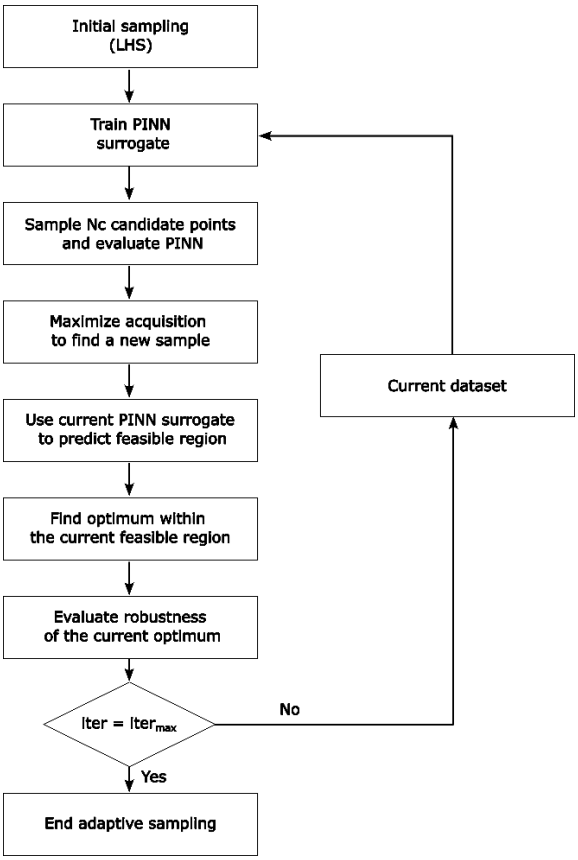

**Figure** 1. Adaptive sampling algorithm.

Table 1 presents the values of relevant parameters used to run the algorithm.

**Table 1:** Parameters used in this study.

| Parameter | Description | Value/Name |
|---|---|---|
| $F_{min}$, $F_{max}$ | Bounds of plastic mass feed flow rate | 20 - 30 kg/h |
| $T_{min}$, $T_{max}$ | Bounds of BFB temperature | 650 - 850 kg/h |
| $N_0$ | Number of initial design points (LHS) | 100 |
| $N_c$ | Number of samples in the dense pool of candidate points (LHS) | 5000 |
| iter | Maximum number of adaptive sampling iterations | 200 |
| $N_{layers}$ | Number of PINN hidden layers | 1 |
| $N_{neurons}$ | Number of PINN hidden neurons | 20 |
| η | Learning rate for Adam optimizer | 1e-3 |
| $N_{epochs}$ | Number of PINN training epochs | 7000 |
| ε | Mass balance residual tolerance | 1e-2 |
| $h_{min}$, $h_{max}$ | Bounds of $H_2/CH_4$ ratio | 0.4 – 0.6 |
| $N_δ$ | Number of perturbations per iteration | 5000 |
| σ | Standard deviation for perturbation | 0.3 |

## RESULTS AND DISCUSSION

### Feasible region identification and optimum

Figure 2 compares the feasible operating regions and tar flow rate iso-contours obtained at two different stages of the adaptive sampling procedure: the last iteration (200 adaptive points) and the iteration corresponding to the maximum robustness index (191 adaptive points).

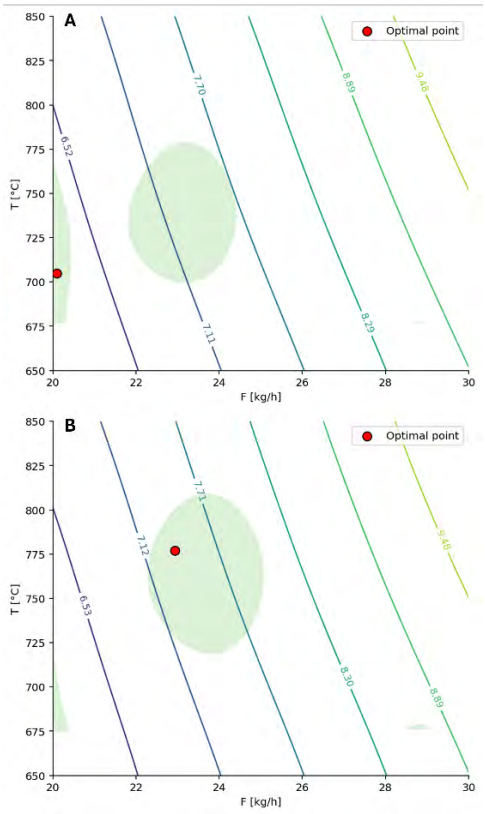

**Figure 2.** Feasible operating region with tar iso-contours and optimal point after 200 (A) and 191 adaptive samples (B).

Although both feasibility regions are obtained using the same PINN architecture and feasibility criteria, they reveal fundamentally different behaviors in terms of operability structure, and optimum point location. At the last iteration (Figure 2-A, iter = 200), the feasible region appears more fragmented, with greater disconnected areas. The shaded feasibility domain is narrow in the temperature direction. In contrast, at the robustness-optimal iteration (Figure 2-B, iter = 191), the feasible region shows smaller disconnected area at low feed flowrate values when compared with Figure 2-A. The smoother and more compact geometry suggests that the PINN has captured the feasibility constraints more consistently, resulting in a better-defined operating window. A key difference between the two figures lies in the location of the optimal operating point relative to the feasible region. In Figure 2-A, the optimal point lies very close to the feasibility boundary, particularly near the lower temperature and feed flow rate limits. In this case, even small uncertainties in the model predictions or minor disturbances in operating conditions could lead to constraint violation. However, in Figure 2-B, the optimal point is located farther from the boundary of the feasible region. This interior positioning provides a substantial operability margin, making the solution more resilient to uncertainty in process operation.

## Perturbation and robustness analysis

Table 2 compares the robustness index $RI$ and optimum for the two different adaptive sample numbers (191 and 200).

**Table 2.** Optimal solution and *RI* at the two iterations investigated.

| Iteration | RI | Optimal values |
|---|---|---|
| 191 | 0.538 | $\hat{F}^* = 22.93\ kg/h$<br>$\hat{T}^* = 777.14$ °C<br>$\hat{m}_{tar}^{\ *} = 7.37$ kg/h<br>$\hat{h}^* = 0.545$<br>$r = 2.96e-3$ |
| 200 | 0.157 | $\hat{F}^* = 20.10\ kg/h$<br>$\hat{T}^* = 704.75$ °C<br>$\hat{m}_{tar}^{\ *} = 6.17$ kg/h<br>$\hat{h}^* = 0.437$<br>$r = 3.13e-3$ |

The discussion in the previous section agrees with the values obtained for the $RI$. The robustness index integrates objective certainty and feasibility retention into a single metric, and its values are 0.157 and 0.538 at iteration 200 and 191, respectively. Figure 3 compares the uncertainty boundaries obtained by perturbing the optimal operating point identified at the iteration with the highest robustness index and at the final adaptive iteration. Each one represents feasible operating points generated by local perturbations around the nominal optimum and filtered by feasibility constraints as explained in the Methodology section, providing a direct visualization of local operability robustness.

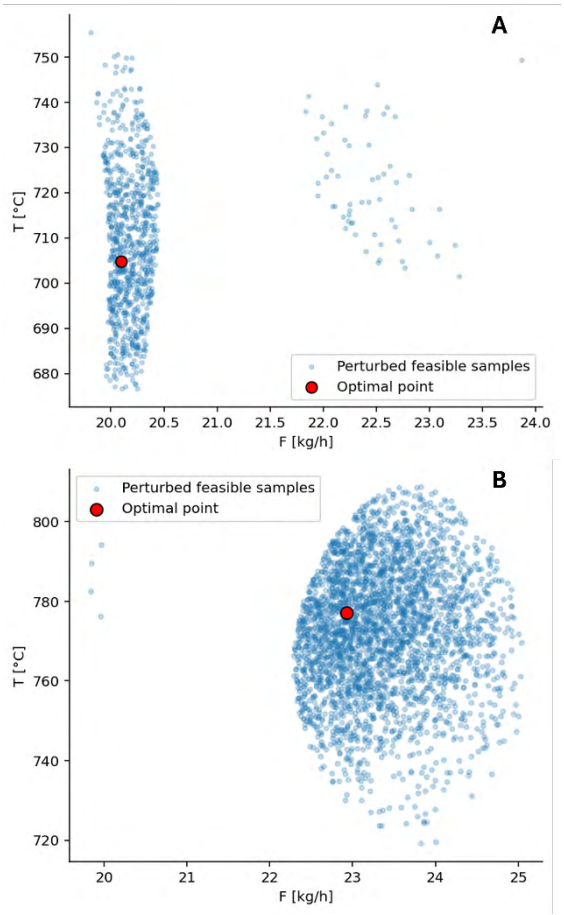

**Figure 3.** Optimum and feasible perturbed points after 200 (A) and 191 adaptive samples (B).

For the best-robustness iteration (Figure 3-B), feasible perturbations are more densely distributed around the optimum, indicating that small variations in feed rate and temperature may not readily violate feasibility constraints. In contrast, the final iteration exhibits a markedly different perturbation pattern (Figure 3-A). The feasible samples form a narrow, elongated region, particularly constrained in the feed rate dimension. While feasibility is retained under some perturbations, the admissible region collapses rapidly along one coordinate, suggesting that the optimal point lies close to a constraint. This explains the lower robustness index observed at the final iteration. Despite further adaptive refinement of the surrogate, this indicates increased sensitivity of feasibility to small input variations and highlights the risk of operating near constraint boundaries, even when the objective value appears to be favorable.

These results emphasize that continued adaptive sampling does not necessarily improve operational robustness but can lead to over-refinement around feasibility boundaries. While later iterations may sharpen these boundaries or marginally improve objective values, they can also drive the optimizer toward regions of higher sensitivity. Whereas the iteration with the highest robustness index achieves the best trade-off between performance and reliability.

## CONCLUSIONS

This work presents a novel physics-informed strategy based on PINNs to explore the design space and predict the feasibility region for a BFB pyrolysis process. Optimization and sensitivity analysis are also performed to find the optimum operating point, as well as investigate its robustness. By embedding fundamental mass balance constraints directly into the learning process, the proposed PINN framework achieves physically consistent predictions while maintaining flexibility in data-driven modeling. The introduction of an adaptive sampling scheme enables efficient exploration of the input space, progressively refining the surrogate model in regions of high violation of the mass balance constraint. This results in accurate operability maps that capture complex feasible regions without requiring exhaustive mechanistic simulations. A key contribution of this study is the explicit integration of robustness analysis into the optimization workflow. Local perturbations around candidate optima are used to quantify uncertainty in both operating variables and objective values, while feasibility filtering ensures that robustness is evaluated under strict process constraints. The combined use of relative objective uncertainty and feasibility retention ratio allows the definition of a robustness index that discriminates between purely optimal solutions and those that are reliably operable under uncertainty. The comparison between early and late adaptive iterations highlights that continued sampling does not necessarily improve robustness, highlighting the importance of robustness-aware criteria. The results show that the most robust operating point may emerge before full convergence of the feasible region, offering practical insights for reducing computational effort while maintaining reliability.

Overall, the proposed methodology provides a framework for feasibility prediction, constrained optimization, and robustness assessment in complex thermochemical systems. Its modular structure and physics-informed features make it readily extendable to higher-dimensional design spaces, additional constraints, and alternative reactor configurations. As this study is a proof of concept based on a semi-empirical literature model, its industrial applicability is currently limited. Future works should be directed towards validation using experimental and plant data.

## ABSTRACT

Biodiesel production from sustainably cultivated plant sources holds extremely high promise globally [6]. Microalgae have been intensely explored as a next-generation source for transport fuel production [9], as they combine attractive characteristics: rapid growth, high lipid content, and environmental benefits. Nevertheless, technical challenges abound regarding the feedstock potential, cultivation process, and its fatty acid mono-alkyl ester (FAME) properties. Performance evaluations for specific microalgal strains [2, 4, 10, 15] are thus of particular interest. The case of Indonesia is particularly significant due to the country's large size, population, biodiversity of terrestrial and marine plant species, and the variety of microalgae that can be harvested and used on an industrial scale for biodiesel production, especially in different media and cultivation methods. Many strains, such as *Botryococcus braunii*, *Chlorella* sp., *Chlamydomonas* sp., and *Nannochloropsis* sp., have a high identified potential [1, 5]. This paper presents the implementation of an established statistical methodology (Principal Component Analysis, PCA) to evaluate the potential of some nitrogen sources for sustainable biodiesel production from Indonesian microalgae strains.

**Keywords**: Biodiesel, Indonesia, Microalgae, Nitrogen, Principal Component Analysis

## INTRODUCTION

Biodiesel is an alternative fuel supply for diesel engines composed of FAME derived from renewable feedstock. Biodiesel has received much scientific attention since it offers comparable fuel characteristics [3, 5]. It is generally produced from a feedstock of vegetable oils, animal fats, and any renewable stock through a chemical reaction called transesterification [1]. Compared to the conservative fuels, biodiesel is more manageable, storable, and transportable due to its biodegradability, high flash point, improved cetane number, and reduced exhaust emission [3, 4]. Nonetheless, the production of biodiesel from second-generation feedstock has led to major conversation concerning the competition between food and fuel. Conversely, the third generation of biodiesel derived from microalgae does not vie with food crops for arable land and water resources.

Microalgae like *Botryococcus braunii*, *Chlorella* sp., *Chlamydomonas* sp., and *Nannochloropsis* sp., which are the most potential strains that are typically found in Indonesian freshwater, marine water, and brackish water systems, are one of the most promising feedstocks for biodiesel production due to their strong adaptability to a wide range of conditions and their characteristics of rapid growth, high oil content, and especially sequestration of atmospheric $CO_2$ (**Figure 1**) [2, 4, 9]. Microalgae are predicted to produce biodiesel with 15–300 times more oil and 10 times more per unit area of land than a typical terrestrial oleaginous crop used in the first and second generations of biodiesel [2, 9, 10, 14].

**Figure 1.** Geographical Representation of Microalgae Biodiversity Research Across Indonesia [3].

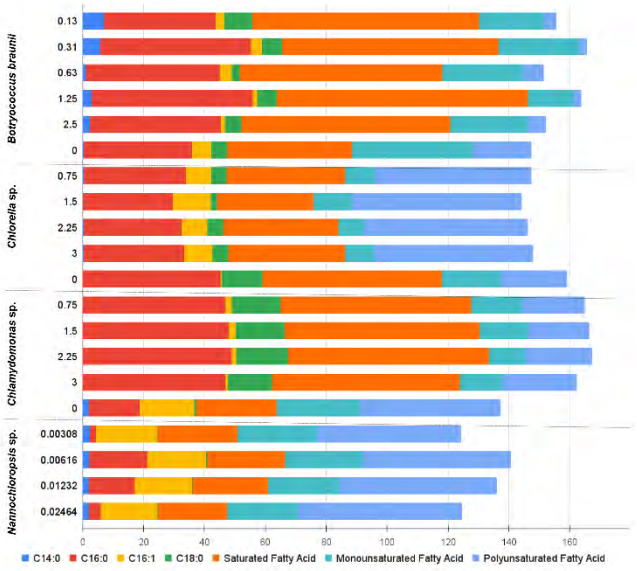

**Figure 2.** Fatty acid profiles across nitrogen concentration on *Botryococcus braunii, Chlorella* sp., *Chlamydomonas* sp., *Nannochloropsis* sp. [7, 16, 17].

Considering microalgae's potential and impact on the environment, numerous investigations have explored efforts to develop biodiesel production research, such as the different nitrogen sources' application impacts in microalgae cultivation [2, 4, 10, 15]. Nitrogen (N) is an essential core for microalgae's growth; it is a precipitant in all the structural and functional proteins such as chlorophylls, peptides, enzymes, energy transfer molecules, and genetic materials in algal cells. Nitrogen concentration in a culture medium strongly affects both cellular biochemical compositions and growth rate in microalgae, such as decreasing cell growth rate and raising the lipid or carbohydrate content, as well as reducing protein synthesis. It is shown in **Figure 2** that different nitrogen sources and concentrations significantly influenced the FAME of all four microalgal strains, although the proportions and trend of the response were highly dependent on the strain [7, 16, 17]. Changes were observed not only in the total fatty accumulation but also in the relative distribution of saturated (SFA), monounsaturated (MUFA), and polyunsaturated fatty acids (PUFA). These results demonstrate that nitrogen restriction systematically influences lipid metabolism; nevertheless, the consequent FAME profiles are specified by variation in species strategies, which underscores the value of aligning nitrogen use with the microalgae selection to achieve ideal lipid compositions.

In terms of using variations of microalgae, there are several nitrogen sources that can be used in the cultivation stage of biodiesel production, such as $KNO_3$, $NaNO_3$, $CO(NH_2)_2$, $NH_4HCO_3$, $(NH_4)_2CO_3$, $NH_4NO_3$, $NH_4Cl$, and $(NH_4)_2SO_4$. Different ways to choose nitrogen sources have different effects on the biodiesel production performance; for example, ammonium ($NH_4^+$) and nitrate ($NO_3^-$) with either limitation or starvation conditions have been reported as the critical culturing conditions affecting lipid accumulation in many microalgae [15].

The research on variable nitrogen supplementation in microalgae cultivation has increasingly understood how different nitrogen sources might influence biodiesel production and analyzed it based on the FAME properties they have to find out the biodiesel productivity and its overall lipid quality.

The study stated that nitrogen does not simply affect biomass accumulation but also drives substantial shifts in the FAME profile, which then ultimately determines the fuel performance, stability, and suitability for the large-scale application. Therefore, to accurately characterize these shifts and to identify which nitrogen sources offer the most favorable outcomes for sustainable biodiesel generation, a thorough study of statistical processing methodology using principal component analysis (PCA) is needed to pinpoint the most promising potential nitrogen inputs for sustainable biodiesel production from diverse microalgae strains [3].

Various PCA models concerning FAME characteristics are prevalent in **Figure 3**. This study investigated four strains: *Botryococcus braunii*, *Chlorella* sp., *Chlamydomonas* sp., and *Nannochloropsis* sp., which are the most promising for high lipid and oil production in Indonesia, based on several studies about Advanced Biodiesel Production, as shown in **Table 1**. PCA works as a multivariate statistical method that combines the information from several variables and reduces them in order to focus on the essential features and information needed, the indicators with maximum variables [6].

## METHODOLOGY

The PCA models we use are scree plot and biplot models. The scree plot model visualizes how much information each PC contributes to the dataset and plots it on the x-axis and the explained variance ratio on the y-axis; it helps us determine how many components should be retained from the graph. The scree plot in **Figure 4** showed us the amount of variances each principal component (PC) explains across all four microalgae strains. It is clear that PC1 and PC2 together explained most of the variance, which is sufficient for interpreting 85.9% of the overall data. The PCA biplot serves as a scatter plot to visualize the relationship between the zoriginal data and principal components.

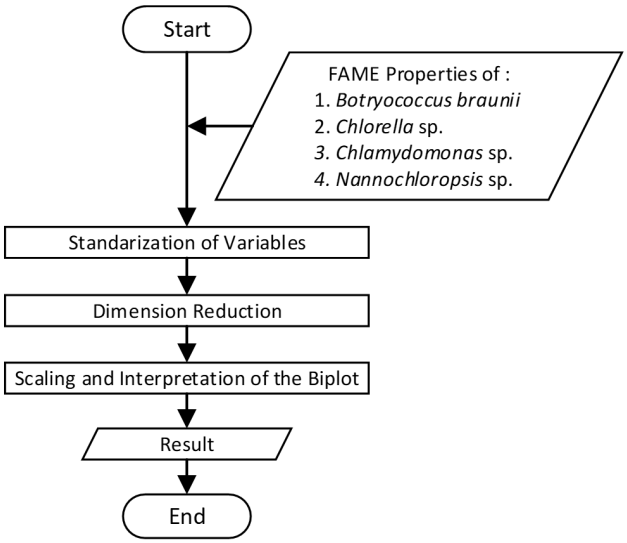

**Figure 3.** PCA Workflow on Different Nutrient Sources' Effects on Biodiesel Production from Indonesian Microalgae Strains [6].

The primary advantage of these approaches is the identification of the most effective nitrogen source for strain cultivation in biodiesel production. As shown in **Figure 5**, the PCA requires several steps to get the suitable and compatible variables for making the biplot: standardization of the variables, dimension reduction, scaling and interpreting the biplot, optional de-emphasizing of cases or variables in the biplot, and optional adding of supplementary variables to the biplot. Biplot in **Figure 5** demonstrates that microalgal species are clearly different from each other based on the FAME composition. PC1 displays the condition of lipid saturation very clearly, while PC2 illustrates the length of the chain and how it changes with monounsaturation. These distinctions show that each strain has its own technique of producing lipids and adjusting to its surroundings.

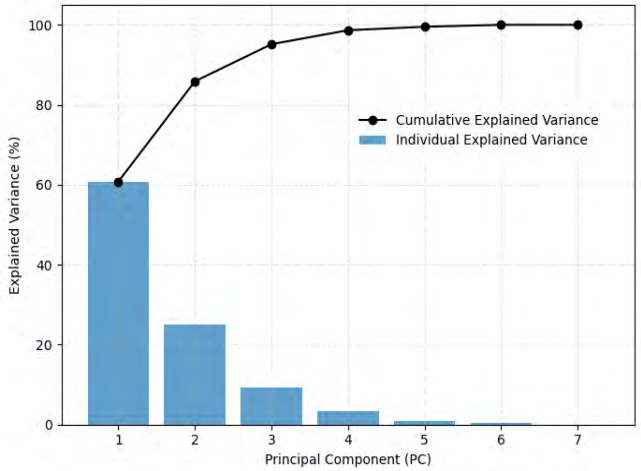

**Figure 4.** PCA scree plot highlighting Nitrogen concentration relationships between *Botryococcus braunii, Chlorella* sp., *Chlamydomonas* sp., and *Nannochloropsis* sp.

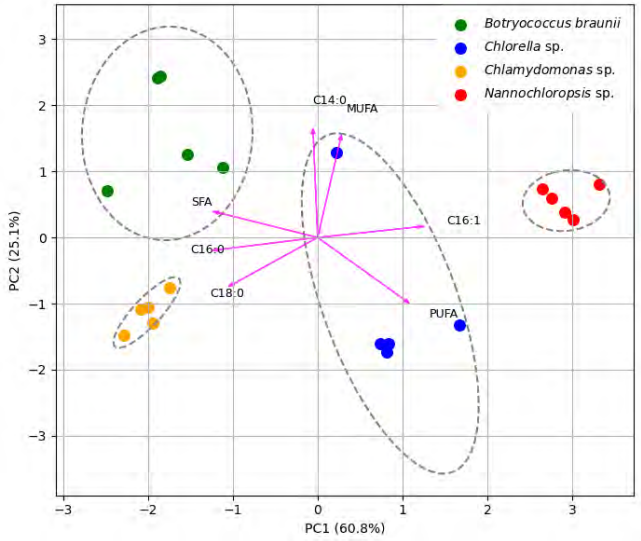

**Figure 5.** PCA biplot illustrating the relationships among *Botryococcus braunii*, *Chlorella* sp., *Chlamydomonas* sp., and Nannochloropsis sp. under different nitrogen concentrations, based on their FAME profiles.

This research focuses on the impact of nitrogen concentration and its linearity to the type of nitrogen used on Indonesian microalgae strains for bioethanol production. Therefore, the workflow we use reached the analytical point with the dataset we use from **Table 1** using the same scree plot and biplot method. In **Figure 6**, we use a similar scree plot to understand how much information we can gain from each dataset; we observe that PC1 explains the most variance, approximately 34.9%, indicating it captures the dominant pattern in the data. On the other hand, PC2 and PC3 make a big difference and contribute substantially with 26.1% and 19%. The explained variance therefore drops more gradually

after PC3 until it's almost negligible. There is a clear elbow around PC3 and PC4, which means the first two PCs are sufficient to represent most of the meaningful structure in the data.

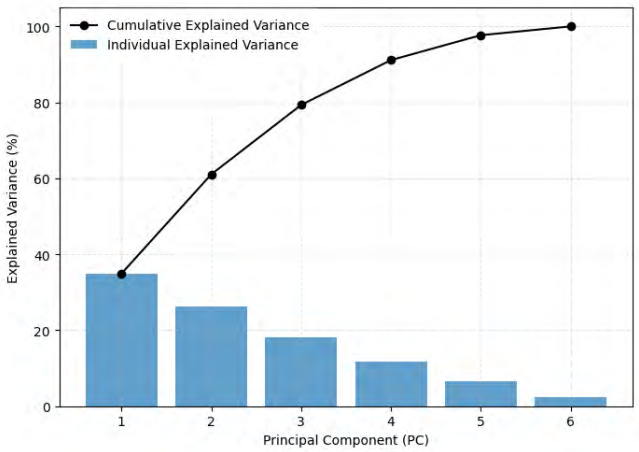

**Figure 6.** PCA scree plot showing the nitrogen source relationships among *Botryococcus braunii*, *Chlorella* sp., *Chlamydomonas* sp., and *Nannochloropsis* sp.

The FAME data from each strain included different FAME properties, including lauric acid (C12:0), tridecanoic acid (C13:0), tetradecanoic acid (C14:0), myristoleic acid (C14:1), trans-myristoleic acid (C14:1T), cis-myristoleic acid (C14:1C), pentadecanoic acid (C15:0), methyl pentadecanoic (C15:1), palmitic acid (C16:0), palmitoleic acid (C16:1), hexadecadienoic acid (C16:2), heptadecanoic acid (C17:0), heptadecenoic acid (C17:1), stearic acid (C18:0), elaidic acid (C18:1n9t), and oleic acid (C18:1n9c), as shown in **Table 1**. The main focus of this research is 4 different selected variables: lauric acid, tetradecanoic acid, palmitic acid, palmitoleic acid, stearic acid, and oleic acid. The lauric acid and tetradecanoic acid are medium-chain saturated fatty acids that increase biodiesel's cetane number and its combustion quality. Palmitic and stearic acid are long-chain saturated fatty acids that strongly increase the cetane number but significantly worsen the cold-flow behavior, such as higher cloud point, pour point, and Cold Filter Plugging Point (CFPP). Palmitoleic acid enhances cold-flow properties relative to saturated fats, while oleic acid is regarded as the optimal biodiesel component due to its strong balance between good cetane number, excellent cold-flow characteristics, and huge oxidative stability [11].

## RESULTS & DISCUSSION

Using the scree plot and biplot, we have visualized clear patterns in how four microalgae strains responded to different nitrogen sources. The PCA results showed clear separation patterns driven by both strain differences and the nitrogen source effect in **Figure 6** and **Figure 7.** The first principal component (PC1) shows that all four microalgae strains formed distinct clusters, indicating that the strains' identity is the dominant factor influencing the fatty acid composition. *Chlamydomonas* sp. was placed at the upper-right region of the score plot and reflected a slightly different behavior from the other strains, while the *Nannochloropsis* sp. formed a separate cluster in the upper-middle area. *Chlorella* sp. shows a tighter grouping in the lower-left area, which means that the lipid profile is more stable across different levels of nitrogen. On the other hand, *Botryococcus braunii* shows the most significant area along PC1, especially when $CO(NH_2)_2$ is present. The spread in this case means strain metabolism changes a lot depending on the nitrogen supply employed in the study.

The second main component (PC2) from **Table 1** data shows how different nitrogen sources are making any impact. Nitrogen sources like $NH_4NO_3$ and $NH_4Cl$ made the PC2 trend in Chlamydomonas sp. increase significantly, showing how much they affect this strain's lipid metabolism. On the other hand, $NaNO_3$ circumstances tended to diminish PC2 values in many species. **Figure 7**'s biplot analysis showed that saturated fatty acids like C12:0, C13:0, C16:0, and C18:0 were the main factors that caused separation along PC1. This supports their significance in telling species apart. At the same time, fatty acids like C17:1 and C15:0 had greater loadings on PC2, which shows that they are sensitive to changes in nitrogen.

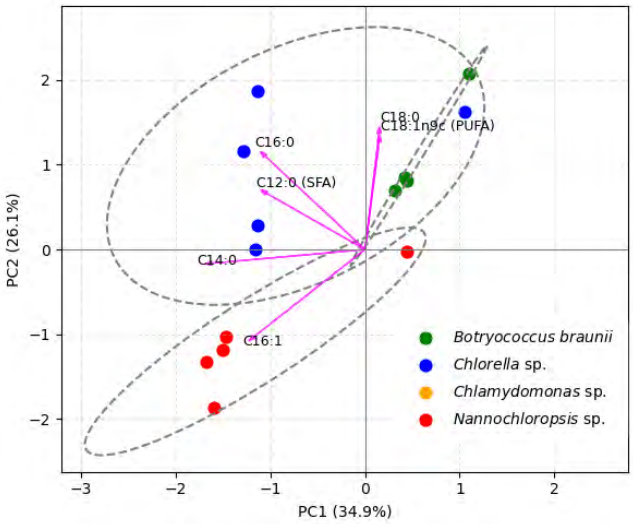

**Figure 7.** PCA biplot demonstrating the correlation among *Botryococcus braunii*, *Chlorella* sp., *Chlamydomonas Botryococcus braunii*, *Chlorella* sp., *Chlamydomonas* sp., and *Nannochloropsis* sp. under C12:0, C14:0, C16:1, C18:0, and C18:1N9C FAME properties.

The discussion in **Figure 6** and **Figure 7** analyzes all

four strains with the specific chosen FAME properties, such C12:0, C14:0, C16:0, C16:1, C18:0, SFA, and PUFA. These FAME properties are explicitly showing us the lipid quality and having the majority of the data from all 4 strains analyzed. The scree plot in **Figure 6** shows that the first two principal components (PC1 and PC2) account for 61.0% of total variances, which means these two components sufficiently summarize the major variability in Table 1 and justify the use of PC1 and PC2 plots for interpretation. The score plot above demonstrated that PC1 primarily separated all four strains' variables based on the inherent species-level differences. Chlamydomonas sp. formed a distinct cluster on the positive side of PC1, while *Nannochloropsis* sp. was very close to the negative side. The gap between the strains shows that there are significant differences in the fatty

acid properties. In contrast, *Botryococcus braunii* showed minimal dispersion, which means its fatty acid profile was relatively stable across the nitrogen treatments. On the other hand, *Chlorella* sp. indicated a steadier movement and metabolic response to different variants of nitrogen.

The biplot in **Figure 7** showed us further insight into the variables after integrating both sample positioning and contribution of fatty acids. C18:1n9c and C18:0 aligned strongly with the positive PC1 axis, indicating that these components were elevated particularly in *Chlamydomonas* sp. However, *Nannochloropsis* sp. seemed to be related with negative PC1 values, which were linked to greater amounts of shorter-chain fatty acids such C14:0 and C16:1. Along PC2, saturated fatty acids such as C12:0, C16:0, and partially C18:0, were positively aligned, reflecting the upward distribution of *Chlorella* sp., which means that these nitrogen sources caused more saturated lipids in this strain.

The combined PCA value shows that strains identity is the main thing that causes variance (PC1), though PC2 may reflect variation associated with the nitrogren treatments we used, as evidenced by the differential movement of all four strains along this axis. The results also point out the significant uniqneness of biochemical responses of each strain, *Chlamydomonas* sp. is characterized by longer-chain fatty acids, *Nannochloropsis* sp. by shorter-chain and monounsaturated fatty acids, and *Chlorella* sp. shows a deep sensitivity to nitrogen form through heightened saturated fatty acid accumulation. This multivariate method clearly shows how the amount of nitrogen changes the lipid makeup in different species.

## CONCLUSIONS

PCA on this research effectively shows the kind of strain and nitrogen source affect FAME in Indonesian microalgae relevant to the biodiesel production. While PC1 stipulated that essential strain-level differences were the major causes of variance, PC2 captured additional variability that may be associated with different nitrogen source effects on lipid metabolism. *Botryococcus braunii* exhibited minimal dispersion which indicates a steady fatty acid profile across nitrogen treatments. *Chlamydomonas* sp. was characterized by longer-chain fatty acids, *Nannochloropsis* sp. by shorter-chain and monounsaturated fatty acids, and *Chlorella* sp. shows sensitivity to nitrogen form through heightened saturated fatty acid accumulation. These strain-specific lipid characteristics are relevant to biodiesel quality parameters such as oxidative stability and fuel performance, it concluded that all four Indonesian strains have great potential to be used in biodiesel through an appropriate nitrogen treatment.

## ABSTRACT

Hydrogen from biomass gasification combined with carbon capture and storage (CCS) can lead to negative emissions and support Europe's energy transition. This study presents a mixed-integer bilinear optimization model for the cost-optimal design of a Northern European hydrogen supply chain with integrated CCS, focusing on exports from Norway to Germany and $CO_2$ sequestration in Norway. The model is formulated as a superstructure problem and implemented in Pyomo, considering multiple locations for infrastructure nodes and transport options for hydrogen, wood chips, and $CO_2$. The results show that shipping wood chips and $CO_2$ is generally more cost-effective than shipping compressed hydrogen. Supply chain costs range from 35–55 NOK/kg $H_2$, and net-negative emissions (scope 1 and scope 2) are achieved at $CO_2$ capture rates above approximately 30%.

**Keywords**: Superstructure optimization, mixed-integer bilinear problem, hydrogen supply chain, carbon capture and storage, negative emissions, hydrogen

## INTRODUCTION

The European Union is dependent on imports of fossil fuels today. Hydrogen could be an alternative fuel to natural gas, since it can be produced with low carbon emissions and does not produce $CO_2$ upon combustion. In 2022, the European Commission presented the REPowerEU plan that aims to import 10 million tonnes of renewable hydrogen into the EU by 2030 [2]. On the other end, Norway could become a large export nation for hydrogen by establishing a sustainable and resilient hydrogen supply chain between Norway and the EU. Moreover, Norway could develop international supply chains for carbon capture and storage in the near future. In August 2025, Northern Lights JV started operations of their storage facility in Kollsnes, Norway with plans to expand to store 5 million tonnes of $CO_2$ per year [3]. If hydrogen is produced from biomass gasification and the generated $CO_2$ is captured and permanently sequestered underground, this could even lead to negative emissions. In this study, we calculated the overall costs and emissions and investigated the structure of a cost-optimal supply chain for the export of hydrogen from Norway to Germany combined with carbon capture and storage (CCS) in Kollsnes, Norway.

## METHODOLOGY

We developed an optimization model using the python-based optimization framework Pyomo to find the cost-optimal supply chain for export of biomass gasification-based hydrogen from Norway to mainland Europe given a final hydrogen demand and a rate of $CO_2$ to be captured and sequestered. In previous work, we developed a supply chain model for hydrogen export from Norway to Wilhelmshaven, Germany [1], but it did not consider the possibility of CCS. The model allows for hydrogen production via biomass gasification in various Norwegian locations and in the import terminal in Germany. At the same time, both compressed hydrogen and wood chips can be shipped from Norway to Germany. In this work, we extended the existing model to include new

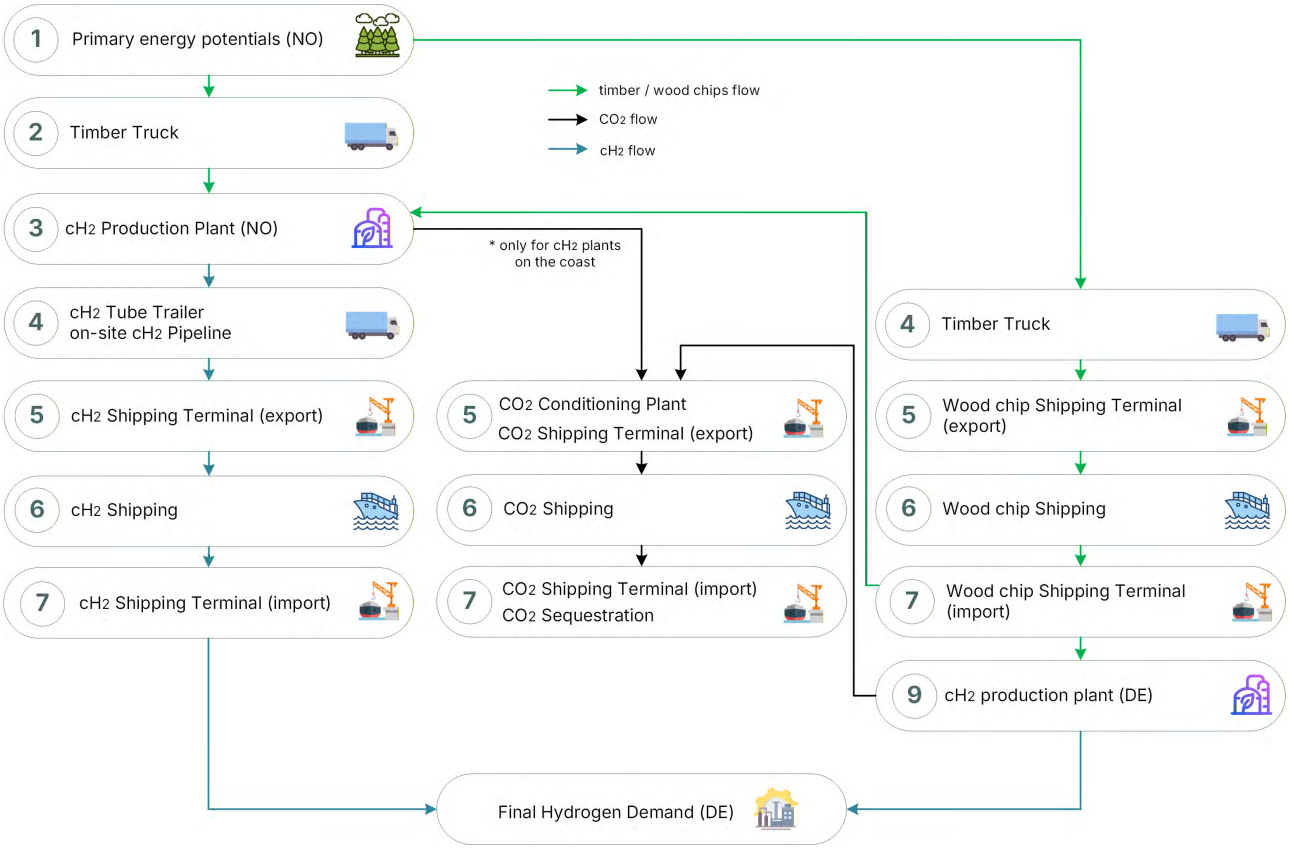

**Figure 1.** Superstructure design (modified from [1])

commercial CCS options. Since the previous study [1] used 2024 as the base year for currency value, we followed that system and defined NOK2024 as the default economic currency, using an exchange rate of 11.63 NOK/EUR. As for supply chain emissions, we only consider emissions from utilities. Applied emission factors are stated in the supplementary material. The model is categorized as a mixed integer bilinear problem (MIBLP) and was solved to its global optimum using the commercial solver Gurobi [4].

## Superstructure design

**Figure 1** shows the design of the superstructure graph, which defines the underlying logic of the model. Possible energy conversion routes are defined in the nodes and possible transport routes are defined in the edges. The superstructure graph (see **Figure 1**) is structured in a hierarchical flow-oriented manner, where energy carriers flow from top to bottom. Odd-numbered levels contain nodes, while even-numbered levels contain the edges connecting those nodes (see **Table 1**). At the first level, the model includes renewable biomass potentials at 1, 000 geographically specific locations randomly distributed across Norway (see [1]). At the second level, timber can be transported to hydrogen production facilities within Norway, which must be constructed by the model. At level three, hydrogen is produced through gasification of wood chips. The model permits the construction of hydrogen production plants at 40 randomly distributed geographic locations in Norway.

At level four, (a) timber may be transported from forest resources to existing timber shipping terminals and/or (b) compressed hydrogen may be transported from hydrogen production plants to hydrogen shipping terminals that must also be built. Hydrogen transport can occur either by compressed hydrogen tube trailer or by hydrogen pipeline; the latter is restricted to local transport (i.e., distances under 5 km).

At level five, the model allows construction of up to 20 compressed hydrogen shipping terminals distributed along the Norwegian coast. In addition, shipping terminals for liquefied $CO_2$ exports may be built at this level at locations where hydrogen production plants are constructed and $CO_2$ from gasification is captured (see **Figure 2**). At level six, (a) hydrogen can be shipped from Norwegian export terminals to hydrogen import terminals in mainland Europe, (b) wood chips can be shipped from export terminals to import terminals, and/or (c) $CO_2$ can

be shipped from $CO_2$ export terminals to $CO_2$ import terminals. These import terminals must be developed at level seven. For hydrogen, the model considers an import terminal in Wilhelmshaven, Germany. For wood chips, import terminals are considered in Kollsnes, Norway, and Wilhelmshaven, Germany. For $CO_2$, the model includes an import terminal in Kollsnes, Norway.

At level nine, a hydrogen production plant may be constructed at the wood-chip import terminal in Wilhelmshaven, Germany. Finally, the total amount of hydrogen imported plus the hydrogen produced in Wilhelmshaven must equal the value specified as an input parameter to the model.

The novelty of the work is a) the extension of the hydrogen supply chain model with the possibility of CCS and b) an improvement of the compressed hydrogen ($cH_2$) shipping model. In [1], the terminal times at the compressed hydrogen export terminals and the compressed hydrogen import terminals were pre-calculated using the relations reported in [5] and then implemented as a parameter in the model. Thereby, all terminals receive the same loading and unloading times. While this logic is a good approximation for simple, single-route supply chains, we found that a more distributed supply chain, as is investigated in this study, requires a more thorough approach. Thus, we implemented the terminal times for the $cH_2$ export terminals and $cH_2$ import terminals as decision variables in the model.

**Table 1:** Indices sets for nodes (modified from [1])

| Set | Description |
|---|---|
| $I_1$ | Timber production sites in Norway |
| $I_3$ | Biomass gasification hubs in Norway |
| $I_{5,cH_2}$ | Shipping terminals for export of $cH_2$ |
| $I_{5,CO_2}$ | Shipping terminals for export of $CO_2$ |
| $I_{5,CO_2,NO}$ | Subset of $I_{5,CO_2}$ with terminals in Norway |
| $I_{5,wc}$ | Shipping terminals for export of wood chips |
| $I_{7,cH_2}$ | Shipping terminals for import of $cH_2$ |
| $I_{7,wc}$ | Shipping terminals for import of wood chips |
| $I_{7,CO_2}$ | Shipping terminals for import of $CO_2$ |

## Optimization objective

The objective function is stated below, where $\theta$ is the set of meta parameters and $X$ are the decision variables in the supply chain graph. The model receives a set of meta parameters which contain data for nodes and edges upon model creation. For every run, the desired hydrogen supply and the desired amount of $CO_2$ to be sequestered must be declared.

$$p_{\text{supply chain}}(\theta, m^{cH_2,\text{demand}}, m^{CO_2\ \text{sequestered}}):$$
$$\min_X f_{\text{cost}}(X, \theta, m^{cH_2,\text{demand}}, m^{CO_2\ \text{sequestered}})$$

$$\begin{aligned} f_{\text{cost}}(X, \theta, m^{cH_2,\text{demand}}, m^{CO_2\ \text{sequestered}}) = & \underbrace{\sum_{i\in I_1} c_i^{\text{timber 01}}}_{\text{Timber production}} \\ & + \underbrace{c^{\text{timber truck}}}_{\text{Timber truck transport}} + \underbrace{\sum_{i\in I_3} c_i^{\text{gasification 03}}}_{\text{Gasification hub (NO)}} + \underbrace{c^{cH_2\ \text{tube trailer 04}}}_{cH_2\ \text{tube trailer}} \\ & + \underbrace{\sum_{i\in I_{5,cH_2}} c_i^{cH_2\ \text{terminal 05}}}_{cH_2\ \text{shipping terminal (export)}} + \underbrace{\sum_{i\in I_{5,CO_2}} c_i^{CO_2\ \text{terminal 05}}}_{CO_2\ \text{shipping terminal (export)}} \\ & + \underbrace{\sum_{i\in I_{5,wc}} c_i^{wc\ \text{terminal 05}}}_{wc\ \text{shipping terminal (export)}} \\ & + \underbrace{\sum_{i\in I_{5,cH_2}} \sum_{j\in I_{7,cH_2}} c_{ij}^{cH_2\ \text{shipping,var 06}} + c^{cH_2\ \text{shipping,fixed 06}}}_{cH_2\ \text{shipping}} \\ & + \underbrace{\sum_{i\in I_{5,CO_2}} \sum_{j\in I_{7,CO_2}} c_{ij}^{CO_2\ \text{shipping,var 06}} + c^{CO_2\ \text{shipping,fixed 06}}}_{CO_2\ \text{shipping}} \\ & + \underbrace{\sum_{i\in I_{5,wc}} \sum_{j\in I_{7,wc}} c_{ij}^{wc\ \text{shipping,var 06}} + c^{wc\ \text{shipping,fixed 06}}}_{\text{Wood chip shipping}} \\ & + \underbrace{\sum_{i\in I_{7,cH_2}} c_i^{cH_2\ \text{terminal cost 07}}}_{cH_2\ \text{shipping terminal (import)}} + \underbrace{\sum_{i\in I_{7,CO_2}} c_i^{CO_2\ \text{terminal 07}}}_{CO_2\ \text{shipping terminal (import)}} \\ & + \underbrace{\sum_{i\in I_{7,wc}} c_i^{wc\ \text{terminal 07}}}_{wc\ \text{shipping terminal (import)}} + \underbrace{\sum_{i\in I_{7,wc}} c_i^{\text{gasification 09}}}_{\text{Gasification hub (DE)}} \end{aligned}$$

## MODEL DESCRIPTION

Below, the amendment of nodes for $CO_2$ shipping terminals as well as $CO_2$ shipping edges is presented. For the modification of the $cH_2$ shipping structure, we direct the reader to the supplementary material.

### $CO_2$ export terminals

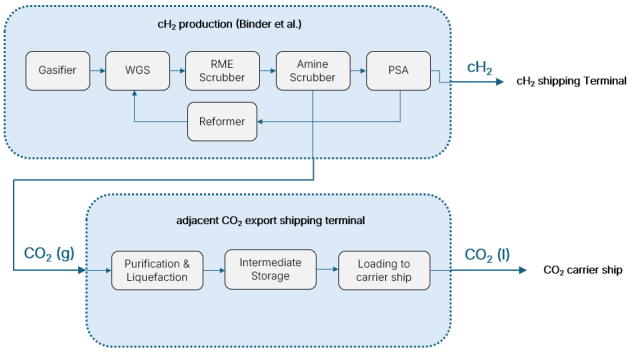

**Figure 2.** Flow chart of $CO_2$ export terminal

The superstructure nodes for shipping terminals for export of $CO_2$ are located at 20 evenly spread-out locations along the Norwegian coast as well as one node in Kollsnes and one node in Wilhelmshaven. At each $CO_2$ export terminal, a hydrogen production plant must be built, and the $CO_2$ throughput of the terminal can only be as

large as the $CO_2$ captured from that hydrogen production plant. We do not consider inland transport of liquified $CO_2$ from other hydrogen production plants to the terminal. Thus, the $CO_2$ export terminals only handle locally captured $CO_2$.

The processes diagram of the $CO_2$ export terminal is shown in **Figure 2**. Since the design of the hydrogen production plants already contains an amine scrubber prior to PSA for removal of $CO_2$ (see Binder et al. [6]), the objective of the $CO_2$ export terminal is a) to purify and liquefy the captured $CO_2$ stream, b) to store the liquefied $CO_2$ in an intermediate storage tank and c) to load the liquid $CO_2$ on incoming ships. As for Kollsnes, the terminal serves mathematically both as an export and an import terminal, since the model allows for hydrogen production combined with $CO_2$ capture and on-site sequestration. In this special case, the shipping of $CO_2$ is omitted.

Specific investment costs for $CO_2$ conditioning as a function on system size were obtained from Deng et al. [7]. Fixed operational costs for $CO_2$ conditioning as a function of system size were obtained from Bjerketvedt et al. [8]. Specific investment costs for the shipping terminal as well as utility consumptions were calculated using the iCCS tool developed by SINTEF Energy Research [9].

In the optimization model, the shipping terminals for the export of $CO_2$ are described by the variables for expansion size of terminal $i$ $m_i^{CO_2\ terminal\ 05}$ [kt $CO_2$ p.a.], expansion decision of terminal $i$ $z_i^{CO_2\ terminal\ 05}$ [-], fixed annual cost at terminal $i$ $c_i^{CO_2\ terminal,fixed\ 05}$ [kNOK2024 p.a.], total annual cost at terminal $i$ $c_i^{CO_2\ terminal\ 05}$ [kNOK2024 p.a.], and annual $CO_2$ emissions from operations at $CO_2$ export terminals $e^{CO_2\ terminal\ 05}$ [$tCO_{2eq}$ p.a.]. The $CO_2$ export shipping terminal $i$ can only process as much $CO_2$ as is created and captured at the biomass gasification plant $i$. The captured $CO_2$ at biomass gasification plants is directly related to its expansion size $m_i^{gasification}$ [kt $cH_2$ p.a.] via the conversion factor $e^{gasification,direct\ CO_2}$ [$kgCO_2/kgH_2$].

$$m_i^{CO_2\ terminal\ 05} \leq m_i^{gasification} \bullet e^{gasification,direct\ CO_2}\ \forall i \in I_{5,CO_2}$$

The expansion size of each terminal $i$ is also linked to the outflow of the terminal $i$. All of the $CO_2$ which is liquified must be exported by ship.

$$m_i^{CO_2\ terminal\ 05} = \sum_{j \in I_{7,CO_2}} m_{ij}^{CO_2\ shipping\ 06}\ \forall i \in I_{5,CO_2}$$

The $CO_2$ emissions from operations at the terminals arise from electricity consumption $m^{CO_2\ terminal,el\ cons\ 05}$ [MWh/kt $CO_2$] given the emission factor $e^{el,NO}$ [$tCO_{2eq}$/MWh] for terminals in Norway or the emission factor $e^{el,DE}$ [$tCO_{2eq}$/MWh] for terminals in Germany and are linked to the expansion size of the terminals.

$$e^{CO_2\ terminal\ 05} = \sum_{i \in I_{5,CO_2,NO}} m_i^{CO_2\ terminal\ 05} \bullet m^{CO_2\ terminal,el\ cons\ 05} \bullet e^{el,NO} + \sum_{i \in I_{5,CO_2,DE}} m_i^{CO_2\ terminal\ 05} \bullet m^{CO_2\ terminal,el\ cons\ 05} \bullet e^{el,DE}$$

The total annual cost at each terminal $i$ includes the fixed annual costs, electricity costs given the electricity price at terminal $i$ $c_i^{el}$ [kNOK2024/MWh] and an assumed 1 EUR/tonne $CO_2$ harbour cost.

$$c_i^{CO_2\ terminal\ 05} = c_i^{CO_2\ terminal,fixed\ 05} \bullet z_i^{CO_2\ terminal\ 05} + m_i^{CO_2\ terminal\ 05} \bullet m^{CO_2\ terminal,el\ cons\ 05} \bullet c_i^{el} + 11.63\ [NOK/t] \bullet m_i^{CO_2\ terminal\ 05}\ \forall i \in I_{5,CO_2}$$

The fixed annual costs include the investment and fixed operational costs for $CO_2$ conditioning, cost for buffer storage (i.e., 1.25 times the $CO_2$ ship size) and shipping terminal construction costs. The cost parameter is in general a nonlinear function of the expansion size and was linearized via a piecewise linear regression. In the model, a piecewise linear constraint was implemented to link the fixed annual costs to the terminal expansion size for all terminals $i \in I_{5,CO_2}$.

$$c_i^{CO_2\ terminal,fixed\ 05} = a_p \bullet m_i^{CO_2\ terminal\ 05} + b_p\ \forall i \in I_{5,CO_2}$$

where $a_p$ is the specific cost factor and $b_p$ is the offset for the piece $p_{lower} \leq m_i^{CO_2\ terminal\ 05} \leq p_{upper}$. The pieces of the cost function are defined by their breakpoints $p_{lower}$ and $p_{upper}$. The values for $a_p, b_p$ and the breakpoints can be found in **Table 2**.

**Table 2:** Piecewise cost function $CO_2$ export terminals

| Parameter | Values |
|---|---|
| $a_p$ [kNOK2024/kt] | 67.7, 60.9 |
| $b_p$ [kNOK2024/a] | 8612.6, 16917.4 |
| p [kt/a] | 0, 1217.5, 2500 |

## $CO_2$ import terminal

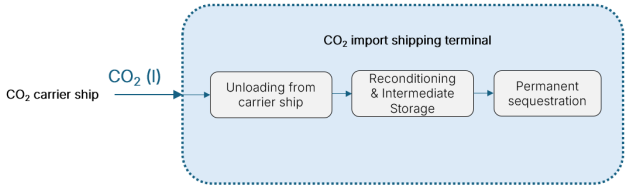

**Figure 3.** Flow chart of $CO_2$ import terminal

The superstructure node for the shipping terminal for the import of $CO_2$ is located in Kollsnes, Norway. The maximum amount of $CO_2$ to be sequestered from operations investigated in this study is 2.2 Mt/a $CO_2$,

corresponding to a theoretical 700 MW hydrogen supply chain with full $CO_2$ capture. This implies an annual wood chip consumption of 1.1 Mt p.a. for hydrogen production.

The processes diagram of the $CO_2$ export terminal is shown in **Figure 3**. The objective of the $CO_2$ import terminal is a) to unload the liquid $CO_2$ from the ship, b) to recondition and intermediately store the $CO_2$ in storage tanks and c) to sequester the $CO_2$ in a permanent underground reservoir. Data for investment costs for the terminal, utility consumption and a cost estimate of $CO_2$ sequestration was calculated with the iCCS tool developed by SINTEF Energy Research [9]. Fixed operational costs were taken from Bjerketvedt et al. [8].

In the optimization model, the shipping terminals for the import of $CO_2$ are described by the variables for expansion size of terminal $i$ $m_i^{CO_2\ terminal\ 07}$ [kt $CO_2$ p.a.], total annual cost at terminal $i$ $c_i^{CO_2\ terminal\ 07}$ [kNOK2024 p.a.], and annual $CO_2$ emissions from operations at $CO_2$ import terminals $e^{CO_2\ terminal\ 07}$ [$tCO_{2eq}$ p.a.]. The expansion size of each terminal $i$ is linked to the inflow of $CO_2$ to terminal $i$ via liquid $CO_2$ shipping.

$$m_i^{CO_2\ terminal\ 07} = \sum_{j \in I_{5,CO_2}} m_{ji}^{CO_2\ shipping\ 06} \quad \forall i \in I_{7,CO_2}$$

The $CO_2$ emissions from operations at the terminals arise from electricity consumption $m^{CO_2\ terminal,el\ cons\ 07}$ [MWh/kt $CO_2$] and are linked to the expansion size of the terminals.

$$e^{CO_2\ terminal\ 07} = \sum_{i \in I_{7,CO_2}} m_i^{CO_2\ terminal\ 07} \bullet m^{CO_2\ terminal,el\ cons\ 07} \bullet e^{el,NO}$$

The total annual costs consider investment costs, fixed operational cost, electricity costs as well as an assumed 1 EUR/tonne $CO_2$ harbour costs and an assumed 19.7 EUR/tonne $CO_2$ sequestration costs.

$$c_i^{CO_2\ terminal\ 07} = (0.3 + 0.51 + 1 + 19.7)\ [EUR/t] \bullet 11.63\ [NOK/EUR] \bullet m_i^{CO_2\ terminal\ 05} + m_i^{CO_2\ terminal\ 07} \bullet m^{CO_2\ terminal,el\ cons\ 07} \bullet c_i^{el} \quad \forall i \in I_{7,CO_2}$$

## $CO_2$ carrier ship

Since the Northern Lights project [3] is based on a 15 bar supply chain design, we adopted this assumption. The design of the ships which carry liquid $CO_2$ from the on-shore terminal to the off-shore sequestration site follows the design parameters outlined in the Northern Lights concept report [10], using a payload of 7500 $m^3$, ship speed of 14 knots, and operating pressure of 15 bar. The specific fuel consumption and investment costs were calculated based on data from Roussanaly at al. [9]. Fixed operational costs were assumed to be 5% of the ship's investment costs.

The $CO_2$ shipping edges connect the nodes for $CO_2$ shipping terminals (export) $i \in I_{5,CO_2}$ with the nodes for $CO_2$ shipping terminals (import) $i \in I_{7,CO_2}$. The edges are described by the variables for $CO_2$ shipping amount $m_{ij}^{CO_2\ shipping\ 06} \mid i \in I_{5,CO_2}, j \in I_{7,CO_2}$ [kt $CO_2$ p.a.], number of annual trips on the route $ij$ $n_{ij}^{CO_2\ shipping\ trips\ 06} \mid i \in I_{5,CO_2}, j \in I_{7,CO_2}$ [-], variable cost on the route $ij$ $c_{ij}^{CO_2\ shipping,var\ 06} \mid i \in I_{5,CO_2}, j \in I_{7,CO_2}$ [kNOK2024 p.a.], number of $CO_2$ ships in the fleet $n^{CO_2\ shipping\ ships\ 06}$ [-], fixed annual costs of the fleet $c^{CO_2\ shipping,fixed\ 06}$ [kNOK2024 p.a.], and annual $CO_2$ emissions from $CO_2$ shipping $e^{CO_2\ shipping\ 06}$ [$tCO_{2eq}$ p.a.].

The number of ships in the fleet must be greater than the required number of ships (float) in the fleet. The number of ships required in the fleet is calculated as the sum of ships required on each route. We assume that a ship can sail different routes throughout the year. The number of ships required on route $ij$ is calculated as the number of trips required on the route $ij$ divided by number of trips a ship can do per year on route $ij$. The number of trips required on the route $ij$ is defined as the shipping amount $m_{ij}^{CO_2\ shipping\ 06}$ divided by the payload of the ship $m^{CO_2\ ship,payload}$ [tonnes $CO_2$]. The number of trips a ship can do per year on route $ij$ is calculated as the maximum annual ship utilization $t^{CO_2\ ship,annual}$ [h/a] divided by the trip time. The trip time is calculated as the time for sailing on route $ij$ from the export terminal to the import terminal and back to the export terminal given the distance $d_{ij}^{CO_2\ shipping\ 06}$ [km] and a speed of $v^{CO_2\ ship}$ [km/day] plus the time spent at terminal $t^{CO_2\ shipping,terminal}$ [h/trip]. The time spent at each terminal is assumed to be 12h. The shipping distances $d_{ij}^{CO_2\ shipping\ 06}$ [km] were pre-calculated using the methodology presented in [1].

$$n^{CO_2\ shipping\ ships\ 06} \geq \sum_{i \in I_{5,CO_2}} \sum_{j \in I_{7,CO_2}} m_{ij}^{CO_2\ shipping\ 06} / (m^{CO_2\ ship,payload} \bullet t^{CO_2\ ship,annual}) \bullet 1000\ [t/kt] \bullet (d_{ij}^{CO_2\ shipping\ 06} \bullet 2 \bullet 24\ [h/day] / v^{cH_2\ ship} + t^{CO_2\ shipping,terminal})$$

The number of trips conducted on route $ij$ (integer) must be greater than or equal to the number of trips required on route $ij$.

$$n_{ij}^{CO_2\ shipping\ trips\ 06} \geq m_{ij}^{CO_2\ shipping\ 06} / m^{CO_2\ ship,payload} \bullet 1000\ [t/kt] \quad \forall i \in I_{5,CO_2}, \forall j \in I_{7,CO_2}$$

The variable cost on route $ij$ is calculated as the product of the number of trips conducted on route $ij$ and the specific trip cost on route $ij$ $c_{ij}^{CO_2\ shipping,trip\ 06}$ [kNOK2024/trip]. The specific trip cost is calculated as the product of specific fuel consumption during sailing $m^{CO_2\ shipping,fuel}$ [g/$tCO_2$/km] and the bunkering cost for ship fuel. We assume that the ship runs on LNG and consumes 6.87 g/$tCO_2$/km fuel [9] with a bunkering cost $c^{LNG}$

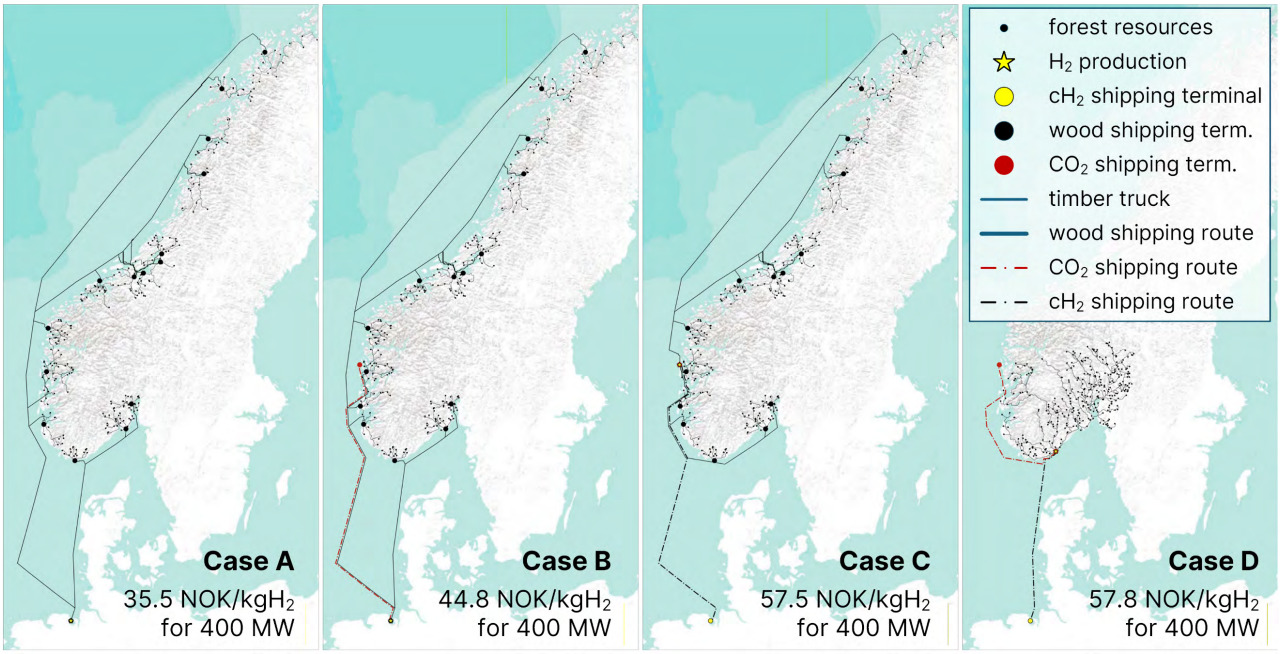

**Figure 4**. Comparison of supply chain structure results for different cases.

of 7.6 kNOK2024/tonne [11].

$$c_{ij}^{CO_2\ shipping,var\ 06} = n_{ij}^{CO_2\ shipping\ trips\ 06} \bullet c_{ij}^{CO_2\ shipping,trip\ 06} \ \forall i \in I_{5,CO_2}, \forall j \in I_{7,CO_2}$$

$$c_{ij}^{CO_2\ shipping,trip\ 06} = m^{CO_2\ shipping,fuel\ 06} \bullet d_{ij}^{CO_2\ shipping\ 06} \bullet m^{CO_2\ ship,payload} \bullet c^{LNG}/1000/1000 \ \forall i \in I_{5,CO_2}, \forall j \in I_{7,CO_2}$$

The fixed annual costs of the fleet are calculated as the product of the number of ships in the fleet times the fixed annual costs per $CO_2$ ship $c^{CO_2\ shipping,fixed,ship\ 06}$ [kNOK2024/a]. This cost factor includes investment costs, staff costs, insurance and maintenance costs and is based on a previous study [5].

$$c^{CO_2\ shipping,fixed\ 06} = n^{CO_2\ shipping\ ships\ 06} \bullet c^{CO_2\ shipping,fixed,ship\ 06}$$

The annual $CO_2$ emissions from $CO_2$ shipping are calculated as the product of annual fuel consumption on all $CO_2$ shipping routes times the emission factor for LNG fuel $e^{LNG}$ [kg$CO_{2eq}$/kg].

$$e^{CO_2\ shipping\ 06} = \sum_{i \in I_{5,CO_2}} \sum_{j \in I_{7,CO_2}} m^{CO_2\ shipping,fuel\ 06} \bullet d_{ij}^{CO_2\ shipping\ 06} \bullet m^{CO_2\ ship,payload}/1000/1000 \bullet n_{ij}^{CO_2\ shipping\ trips\ 06} \bullet e^{LNG}$$

# RESULTS

## Case comparison

**Figure 4** shows the optimal supply chain design for a final hydrogen demand of 400 MW and different system constraints. The following cases were investigated:

- **Case A:** The model was run with no additional constraints. The solution is the cost-optimal supply chain without CCS.
- **Case B:** The model was run with the additional constraint that all of the direct $CO_2$ generated at hydrogen production must be captured and sequestered in Kollsnes.
- **Case C:** The model was run with the additional constraints that a) all of the direct $CO_2$ generated at hydrogen production must be captured and sequestered in Kollsnes and b) hydrogen must be produced in Norway and exported via compressed hydrogen shipping.
- **Case D:** The model was run with the additional constraints that a) all of the direct $CO_2$ generated at hydrogen production must be captured and sequestered in Kollsnes and b) hydrogen must be produced in Norway and exported via compressed hydrogen shipping and c) the $cH_2$ export shipping terminal in the very south of Norway (i.e., Grimstad) must be built out.

It can be seen that the most cost-effective supply chain design is shipping wood chips from various locations along the Norwegian coast to Germany and producing hydrogen there. In Case B, the optimizer chooses to build out a hydrogen production plant at the wood chip

import terminal in Germany and to ship the captured and liquefied $CO_2$ from Germany to Kollsnes, omitting $cH_2$ shipping. In Case C, hydrogen production in Norway and export of compressed hydrogen is mandated. Unlike the other cases, shipping of $CO_2$ is omitted by building a hydrogen production plant in Kollsnes, where the captured $CO_2$ is stored directly. Wood chips are shipped from the entire Norwegian coast to Kollsnes to serve as feedstock for hydrogen production. In that way, the $CO_2$ shipping supply chain is replaced by a $cH_2$ shipping supply chain, which increases the overall supply chain costs by 12.6 NOK/kg $H_2$ or 28%. This clearly shows that establishing a supply chain for shipping of liquid $CO_2$ is economically superior to establishing a supply chain for compressed hydrogen shipping. In Case D, by moving the hydrogen production to the south of Norway, the length of the $cH_2$ shipping route is decreased, reducing the $cH_2$ shipping costs. On the other hand, shipping of $CO_2$ from Grimstad to Kollsnes is required. However, this solution is only insignificantly more expensive than Case C, showing that more than one practical solution with very similar hydrogen supply costs exists.

Case B, which is the cost optimal supply chain for hydrogen export combined with carbon capture, has supply chain costs of 44.8 NOK per kg$H_2$ produced and delivered, with corresponding cradle-to-product net emissions of -7.6 kg$CO_{2eq}$/kg$H_2$ (scope 1 plus scope 2). Given these values, we calculated the cost of $CO_2$ (CCA) avoided using

$$\mathrm{CCA} = \frac{c_{\mathrm{cH_2,B}} - c_{\mathrm{ref}}}{e_{\mathrm{ref}} - e_{\mathrm{cH_2,B}}},$$

where $c_{cH_2,B}$ and $e_{cH_2,B}$ describe the specific costs and emissions case B, while $c_{\mathrm{ref}}$ and $e_{\mathrm{ref}}$ describe the specific costs and emissions for the reference system, which was defined as natural gas combustion. Herein, we assumed specific emissions for the reference system of 201 kg$CO_2$/MWh (LHV) [12] and approximated the natural gas price (LHV) from the natural gas price (HHV) $\mathrm{p_{ng,HHV}}$ using a factor of 0.9. Assuming a natural gas price of 20 €/MWh (LHV), the cost of $CO_2$ avoided is 218 €/tonne $CO_2$. Assuming a natural gas price of 60 €/MWh (LHV), the cost of $CO_2$ avoided is 114 €/tonne $CO_2$

## Sensitivity analysis

Figure 5 shows the sensitivity analysis of the supply chain costs and emissions in the cost-optimal supply chain given different final hydrogen demands and different $CO_2$ sequestration rates. It can be seen that the estimated supply chain costs lay between 35 and 55 NOK/kg $H_2$. While increasing $CO_2$ sequestration rates lead to higher hydrogen supply costs, increasing hydrogen demand leads to lower hydrogen supply costs. Especially for small hydrogen demands lower than 150 MW and high $CO_2$ sequestration rates, the hydrogen supply costs are very high.

The specific emissions are only a function of $CO_2$ sequestration rate and are not significantly affected by the final hydrogen demand. Herein, all direct and indirect supply chains emissions were summed up, and the sequestered $CO_2$ was counted as negative emissions. A capture rate above 30% is required in order to achieve a negative emission hydrogen supply chain.

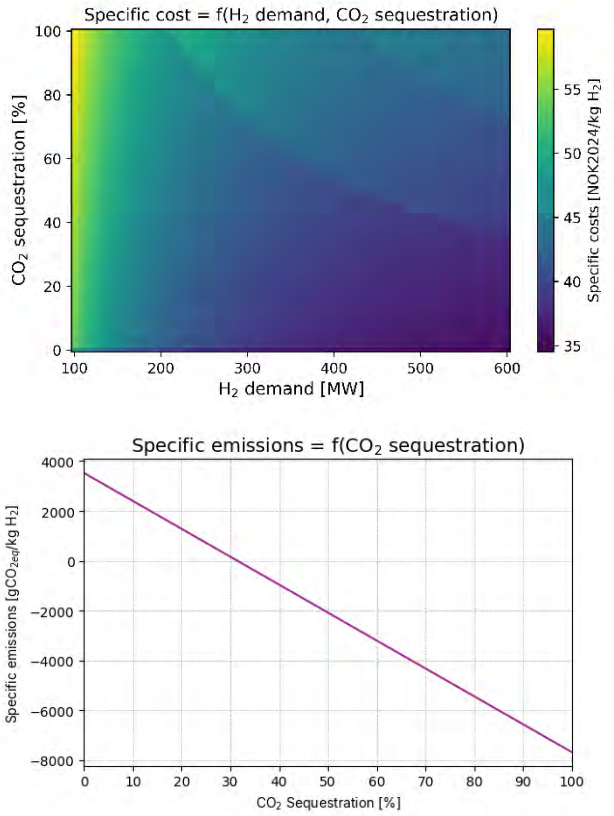

**Figure** 5. Sensitivity analysis (upper: specific supply chain costs, lower: specific supply chain emissions)

## CONCLUSION

This work demonstrates that negative-emission hydrogen supply chains based on biomass gasification combined with CCS can be designed in a cost-effective manner in the Northern European context. Moreover, we note that our analysis does not account for potential additional revenues that could be received from private and public financial incentives from achieving net-negative emissions. We found that even though shipping of $CO_2$ could be omitted by producing hydrogen in Kollsnes and sequestering $CO_2$ at the same location while shipping compressed hydrogen to Germany, it is significantly more cost-effective to produce the hydrogen in Germany and ship the $CO_2$ to Kollsnes.

While low cost of $CO_2$ avoided can be achieved with

the supply chains investigated in this study, supply chains focusing on different energy carriers might lead to even better CCAs. Future research should investigate the possibilities of integrating alternative energy carriers such as ammonia or methanol. Moreover, the calculation of the size of the intermediate $cH_2$ storage is based on average ship arrival times and the sizing for buffer storage for $CO_2$ is based on conventional assumptions. While these assumptions allow the model to be in bilinear space, the validity of these assumptions should be confirmed in future work.

## ABSTRACT

In the urgent effort to reduce greenhouse gas (GHG) emissions in the industrial sector, biogas-derived green hydrogen and power co-generation represents a promising solution. Biogas, a renewable and carbon-neutral resource, provides a flexible feedstock for decentralized energy systems, particularly in regions with well-developed agricultural or waste biomass infrastructure. This approach allows the deployment of cost-efficient systems aligned with climate targets and industrial decarbonization roadmaps. Compared to steam methane reforming (SMR), sorbent-enhanced SMR (SE-SMR) with integrated calcium looping (CaL) $CO_2$ capture reduces process emissions while enhancing hydrogen yield. This study investigates the economic and exergy-based implications of partially splitting hydrogen from a SE-SMR-CaL system producing 50, 000 $Nm^3/h$ of $H_2$ from desulfurized biogas. Following heat integration using the PINCH methodology, an electrically self-sufficient base case was established. Economic and exergy analyses were conducted in Excel, with cash flow allocation based on exergy contributions. An automated optimization routine identified competitive levelized costs of electricity (LCOE) and hydrogen (LCOH). Results show that increasing the hydrogen split to power generation maintains nearly constant LCOE (<1% variation) while reducing overall exergy efficiency. Partial hydrogen splitting achieves LCOE below 30.5 €/MWh at the expense of increased LCOH, highlighting a trade-off between electricity and hydrogen economics in flexible, multi-vector systems. The workflow demonstrates that incorporating electricity generation into a sorbent-enhanced hydrogen production system using air combustion is technically and economically feasible.

## INTRODUCTION

Low carbon technologies and carbon neutrality are key considerations in discussions of a future in which humanity lives in a sustainable manner with respect to available resources. The main challenged addressed in the context of sustainability is anthropogenically induced climate change, which has led to the implementation of a number of significant and ambitious policies worldwide [1]. At the core of these policies is the carbon element, primarily in the form of carbon dioxide ($CO_2$), a greenhouse gas emitted through various anthropogenic activities, including energy production, the bulk chemical industry, and transportation. By mitigating (or offsetting) $CO_2$ emissions by choosing renewable raw materials and/or electricity sources, short- to mid-term solutions can be developed that benefit from the use of existing infrastructure [2]. In this context, carbon capture, utilization and storage (CCUS) technologies emerge as carbon sinks by either completely sequestering (via storage) or off-setting (via utilization) the $CO_2$ footprint of a given technology. However, the transition to carbon-free energy vectors, such as hydrogen and ammonia, represents a long-term solution [3] that requires substantially greater research, development and deployment efforts than previously discussed approaches to increase the

technology readiness level (TRL) and accelerate industrial deployment.

In this context [4], the present work evaluates the techno-economic and exergy-based implications of partially splitting hydrogen ($H_2$) from a sorbent-enhanced steam methane reforming (SE-SMR) plant, coupled with calcium looping technology (CaL) [5] with a design capacity of 50, 000 Nm3/h of high-purity $H_2$ for electricity generation. In line with the considerations discussed above, desulfurized biogas is employed as the raw material for hydrogen production [6], offering a sustainable energy pathway for the deployment of an innovative, cost-efficient, and decarbonized system that aligns with climate targets and industrial decarbonization roadmaps. By employing process modelling and simulation using ChemCAD, techno-economic and exergy analyses using Excel, and automation using Visual Basic for Applications (VBA), a robust framework was developed for evaluating multi-product renewable energy systems. In particular, an optimal range for the hydrogen split fraction was identified, within which competitive levelized costs of electricity (LCOH) and hydrogen (LCOH) can be achieved under realistic economic bounds.

## PLANT CONFIGURATION, DESIGN ASSUMPTIONS, EXERGY AND ECONOMIC ANALYSIS METHODOLOGY

The plant (Figure 1) is designed to produce 50, 000 $Nm^3/h$ of $H_2$ using desulfurized biogas, while also providing inherent carbon sequestration through carbonation-calcination cycles. The resulting hydrogen-enriched gas stream from the reformer is further purified via pressure-swing adsorption (PSA). A flexible fraction of pure $H_2$ is diverted to generate electricity through air combustion for high-pressure (HP) steam generation in a Rankine cycle, while the remainder is compressed and stored for downstream utilization (e.g., chemical applications). The SE-SMR-CaL process employs a dual circulating fluidized bed system, enabling continuous operation with high $CO_2$ capture efficiency and stable hydrogen production. The process produces high-purity hydrogen and $CO_2$ streams, with the latter being further processed to meet sequestration or utilization criteria, primarily through water removal using triethylene glycol (TEG) dehydration. In this study, the net power output considers the electricity required for oxygen production from the air separation unit (ASU) and for compressing pure $H_2$, $CO_2$, and streams within the TEG unit. After heat integration of the available hot streams using the PINCH methodology to maximize heat recovery (Figure 2), an electrically self-sufficient base case was established.

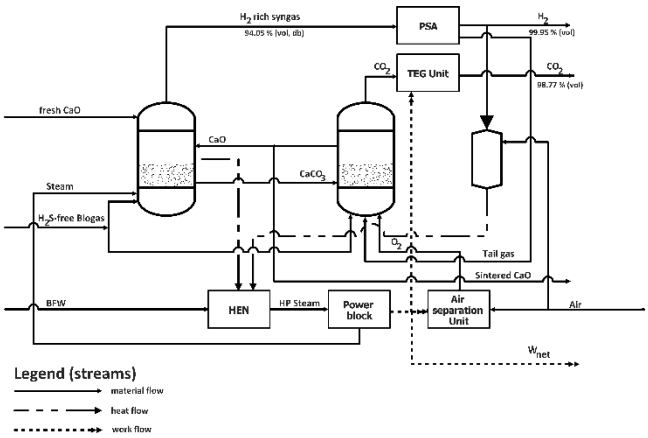

**Figure 1.** Schematic design of the SE-SMR-CaL plant.

The chemically reactive system within the reformer is described by the following reactions:

$r_1$ $CH_4 + H_2O \leftrightarrow CO + 3H_2$ $\Delta H_1 = 206.1$ kJ/mol (1)

$r_2$ $CO + H_2O \leftrightarrow CO_2 + H_2$ $\Delta H_2 = -41.1$ kJ/mol (2)

$r_3$ $CH_4 + 2H_2O \leftrightarrow CO_2 + 4H_2$ $\Delta H_3 = 165.0$ kJ/mol (3)

$r_4$ $CaO + CO_2 \leftrightarrow CaCO_3$ $\Delta H_4 = -178.0$ kJ/mol (4)

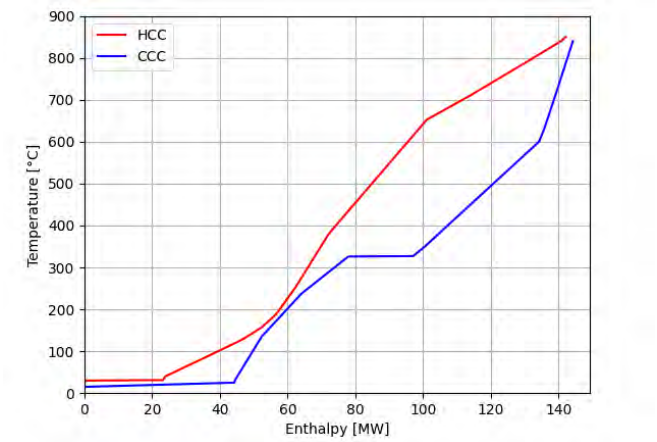

**Figure 2.** Thermal integration analysis of the SE-SMR-CaL plant.

The reformer was modelled as a kinetic reactor, with the following reaction rates and additional expressions implemented using VBA within ChemCAD [7, 8]:

$$r_1 = \frac{\frac{k_1}{p_{H_2}^{2.5}} \cdot \left(p_{CH_4} \cdot p_{H_2O} - \frac{p_{H_2}^3 \cdot p_{CO}}{K_1}\right)}{\left(1 + K_{CO} \cdot p_{CO} + K_{H_2} \cdot p_{H_2} + K_{CH_4} \cdot p_{CH_4} + \frac{K_{H_2O} \cdot p_{H_2O}}{p_{H_2}}\right)^2} \quad (5)$$

$$r_2 = \frac{\frac{k_2}{p_{H_2}} \cdot \left(p_{CO} \cdot p_{H_2O} - \frac{p_{H_2} \cdot p_{CO_2}}{K_2}\right)}{\left(1 + K_{CO} \cdot p_{CO} + K_{H_2} \cdot p_{H_2} + K_{CH_4} \cdot p_{CH_4} + \frac{K_{H_2O} \cdot p_{H_2O}}{p_{H_2}}\right)^2} \quad (6)$$

$$r_3 = \frac{\frac{k_3}{p_{H_2}^{3.5}} \cdot \left(p_{CH_4} \cdot p_{H_2O}^2 - \frac{p_{H_2}^4 \cdot p_{CO_2}}{K_3}\right)}{\left(1 + K_{CO} \cdot p_{CO} + K_{H_2} \cdot p_{H_2} + K_{CH_4} \cdot p_{CH_4} + \frac{K_{H_2O} \cdot p_{H_2O}}{p_{H_2}}\right)^2} \quad (7)$$

$$r_4 = \frac{3k_4}{\bar{R}_p} \cdot (1 - \bar{X}_{CaO})^{\frac{2}{3}} \cdot \left(\frac{p_{CO_2} - p_{CO_2,eq}}{RT}\right)^{0.66} \quad (8)$$

$$p_{CO_2,eq} = 1.01325 * 10^{\left(\frac{-8308}{T} + 7.079\right)} \quad (9)$$

$$k_i = k_i^0 \cdot e^{-\frac{E_i}{RT}} \quad (10)$$

$$K_j = K_J^0 \cdot e^{-\frac{\Delta H_J}{RT}} \quad (11)$$

The kinetic and thermodynamic parameters employed in expressions (5)-(11) are summarized in Table 1, while general modelling assumptions of the SE-SMR plant are summarized in Table 2.

**Table 1:** Kinetic and thermodynamic parameters employed for reformer modelling.

Exergy efficiencies (ε) are defined according to the fuel (F)-product (P) paradigm [9], accounting for the physical and chemical contributions of inlet and outlet streams within a given control volume, defined such that the boundary temperature equals the environmental temperature. In this study, pre-treated biogas, oxygen from the ASU, required boiler feed water (BFW) for steam reforming, and fresh CaO are considered fuels, while the purified $H_2$, captured and processed $CO_2$, and net electricity output are treated as products. Exergy losses are attributed to $CO_2$ emissions from the TEG unit, removed sintered sorbent stream, and process water discharged as condensate streams.

$$\varepsilon = \frac{\dot{E}_P}{\dot{E}_F} = 1 - \frac{\dot{E}_D + \dot{E}_L}{\dot{E}_F} \quad (12)$$

$$e^{PH} = (h - h_0) - T_0 * (s - s_0) \quad (13)$$

$$\overline{e}^{CH} = \sum_1^k x_k * \overline{e}_k^{CH} + \overline{R}T_0 * \sum_1^k x_k * ln\,(x_k) \quad (14)$$

$$\dot{E} = \dot{m} * \left(e^{PH} + e^{CH}\right) \quad (15)$$

To facilitate the computation of chemical exergy using ChemCAD's thermodynamic packages, a custom unit operation was developed to duplicate a stream with a specified composition at a given temperature and pressure and bring it to the restricted dead state (RDS) by flashing it at $T_0$ = 25 °C and $p_0$ = 1 bar. All RDS streams are subsequently mixed to verify the mass balance of the overall plant.

The economic analysis focuses around the estimation of the following relevant economic performance indicators:

Capital expenditure of a process unit ($C_E$) with capacity Q is calculated using the cost correlation approach [10], which considers base cost of the evaluated subsystem ($C_B$), its corresponding base production size ($Q_B$) and a technological maturity exponent (M):

$$C_E = C_B * \left(\frac{Q}{Q_B}\right)^M \quad (16)$$

The reference data ($C_B$, $Q_B$ and M) were extracted from the literature and the outdated values were updated to the present-day conditions by usage of Chemical Engineering Plant Cost Index (CEPCI):

$$\frac{Cost_{y1}}{Cost_{y2}} = \frac{CEPCI_{y1}}{CEPCI_{y2}} \quad (17)$$

Operational and maintenance (O&M) costs account for both fixed costs (e.g., maintenance, labour, and administrative expenses) and variable costs (e.g., feedstock chemicals, catalyst replacement, cold utilities, and costs associated with $CO_2$ transport and storage) over the operational lifetime of the plant.

The levelized cost of hydrogen (LCOH) was calculated as the sum of the annualized capital cost ($CC_{Annualized}$), assuming straight-line depreciation, and the operational and maintenance (O&M) costs, divided by the annual hydrogen thermal output ($Q_{H2,\,Annual}$):

$$LCOH = \frac{CC_{Annualized} + O\&M}{Q_{H_{2,Annual}}} \quad (17)$$

The Levelized cost of electricity (LCOE) was computed in a similar manner than levelized cost of hydrogen (LCOH), with additional consideration for the correlation factors that account for the combined energy output (hydrogen and net power) of the plant.

Varying the hydrogen split fraction decreases the required capacity for the hydrogen compression system while increasing the power block capacity, impacting capital expenditures and, consequently, levelized costs. The optimization focuses on determining the net present value (NPV) of the overall plant, accounting for changes in the cost correlation method and allocating the cash flow factor based on the exergy values of the produced hydrogen and electricity.

Excel Solver is used to determine the levelized costs of electricity (LCOE) and hydrogen (LCOH) that yield an NPV of zero, subject to non-negativity constraints:

Find LCOE, LCOH such that: NPV(LCOE, LCOH) = 0, subject to LCOE ≥ 0, LCOH ≥ 0, NPV ≥ 0.

Automation is achieved by employing the sensitivity study tool and data maps within ChemCAD to extract the relevant thermodynamic data of the main material streams (specific enthalpy, specific entropy, stream composition, stream mass rate) and unit operation parameters (e.g., compressor power, divider split fraction), in combination with a VBA subroutine that links each sensitivity study run to an instance of Excel Solver:

```
Sub RunExcelSolverFromChemCAD()
 Dim xlApp As Object
 Dim xlWB As Object
 Set  xlApp  =  CreateObject("Excel.Applica-
tion")
 xlApp.Visible = False
 Set        xlWB        =        xlApp.Work-
books.Open("path_to_solver")
 xlApp.RUN "RunSolverAuto"
 xlWB.Close SaveChanges:=True
 xlApp.Quit
 Set xlWB = Nothing
 Set xlApp = Nothing
End Sub
```

## RESULTS AND DISCUSSION

The mathematical model of the plant was validated primarily by analyzing the dry volumetric composition of the simulated reformer gaseous output with respect to available experimental data [12, 13] (Table 3).

**Table 3:** Validation of the kinetic reformer model.

| Parameter | Simulation | Experimental |
|---|---|---|
| % $CH_4$ | 2.15 | 2-2.5 |
| % CO + $CO_2$ + $N_2$ | 3.8 | 3-4 |
| % $H_2$ | 94.05 | 94-94.5 |
| $CH_4$ conversion | 90.77 | 90 |

As shown, the simulation data are in range and close agreement to the experimental data, with relative errors for hydrogen composition and methane conversion below 0.5%. This underlines the reliability of the model and the robust behaviour of the kinetically modelled reformer. A more detailed model validation is presented in a previous work of the authors [11] which serves as the basis of the current optimization study, including sorbent deactivation [14] as a function of the number of looping cycles and several arguments for the sorbent make-up fraction and selected mean sorbent conversion within the reformer.

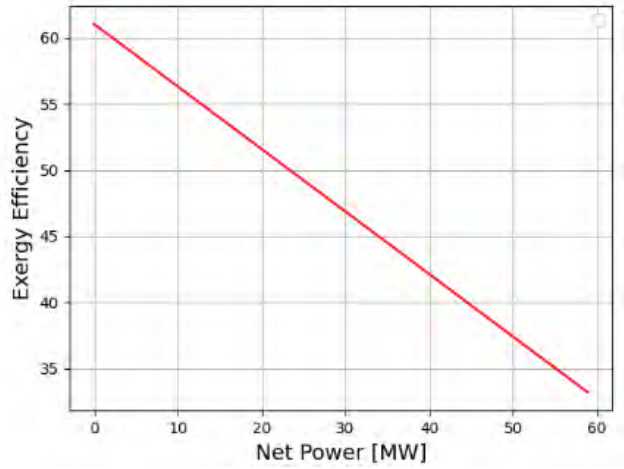

**Figure 3.** Plant exergy efficiency variation with hydrogen split fraction.

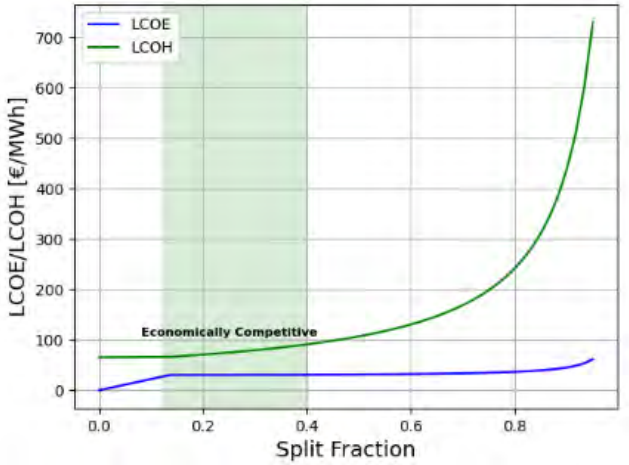

**Figure 4.** LCOE and LCOH dependence of hydrogen split fraction in the first sensitivity analysis.

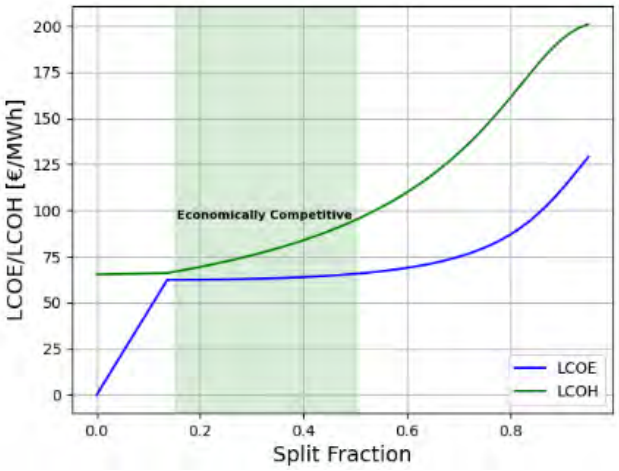

**Figure 5.** LCOE and LCOH dependence of hydrogen split fraction in the second sensitivity analysis.

Once the steady-state output of the reformer was validated, two successive sensitivity analyses were conducted in ChemCAD, employing the previously mentioned data map and Excel solver configuration. Both runs indicated that as the hydrogen split fraction for electricity generation increases up to about 0.40, the levelized cost of electricity (LCOE) remains essentially constant, varying by less than 1%, while the overall system exergy efficiency declines. This highlights an important compromise between electricity generation and exergy efficiency. The observed linear decrease in exergy efficiency (Figure 3) is expected, as the high chemical exergy of the pure hydrogen stream is inefficiently utilized to generate steam and, subsequently, electricity through combustion, an inherent exergy sink, and a Rankine cycle, operating at constant efficiency across all split fractions.

The optimization results reveal two distinct operational regimes. In the first case (Figure 4), a plateau in electricity cost is observed where LCOE remains below 30.5 €/MWh, while the LCOH steadily increases from 80 to 100 €/MWh in a linear manner. Beyond this split-fraction range, the LCOH rises exponentially up to 700 €/MWh, highlighting a threshold where hydrogen production becomes economically prohibitive. In this regime, the economic burden is primarily borne by hydrogen production, as electricity costs remain stable up to a split fraction of 0.85.

In the second optimization study (Figure 5), the solver was initialized to previously obtained values [11], with both LCOE and LCOH starting around 60-70 €/MWh. In this case, LCOE remains approximately constant across a wider range of hydrogen split fractions (up to about 0.55), while LCOH increases gradually to 100 €/MWh and, at high split fractions, only reaches about 200 €/MWh. These findings indicate that while affordable electricity prices can be maintained across a broad operational range, hydrogen costs are highly

sensitive to the split fraction beyond certain thresholds. In essence, the system preserves economically competitive electricity prices across a wide operating range by progressively transferring the cost burden to hydrogen production as the split fraction increases.

The results further indicate an important trade-off between electricity and hydrogen economics. Allowing for a moderate increase in electricity costs (approximately 50% compared to the first operational regime) enables hydrogen production costs to remain stable over a wider range of hydrogen split fractions. This defines a flexible operating window, extending up to a split fraction of 0.55, within which the plant can simultaneously supply moderately priced electricity and economically competitive hydrogen. The application of exergy-based allocation to the cash flow factor enhances the interpretation of these results by revealing the relative efficiency and economic contribution of each product, thereby supporting more robust design and investment decisions for integrated multi-vector energy systems.

From a global market perspective, the LCOE achieved in the most competitive scenarios (< 30.5 €/MWh) is below typical world averages for newly commissioned renewable generation such as solar PV (about 40–60 €/MWh [15]) and onshore wind (about 42 €/MWh [16]). Even the higher-cost case (about 60–70 €/MWh) remain within the range of real-world LCOE values, indicating that the proposed system is economically feasible and competitive in multiple energy markets.

## CONCLUSIONS

This study shows that partial hydrogen splitting can be optimized to balance electricity affordability and hydrogen production costs, highlighting a clear trade-off between electricity and hydrogen economics. Two distinct operational cases were identified, showing that low-cost electricity can be maintained across a range of split fractions while hydrogen costs remain economically competitive. As a key finding, despite the overall variability in LCOH, operating at a hydrogen split fraction between 0.4 and 0.5 provides a reliable and economically competitive range for hydrogen production.

The proposed methodology provides a reproducible and adaptable framework for evaluating multi-product renewable energy systems, which can be extended to alternative hydrogen-to-power pathways, including fuel cells, supporting the development of sustainable and flexible hybrid energy strategies.

## ABSTRACT

When designing and planning Green Hydrogen Supply Chains (GHSCs), sustainability considerations are increasingly recognized as essential, particularly in light of decarbonization goals and climate policy targets. Existing research has largely focused on economic and environmental however, social sustainability aspects remain significantly underexplored. This work aims to develop a mathematical programming model to design a GHSC, considering simultaneously economic and social aspects. Solar PV, wind power, and PPA (wind) as energy sources are integrated, while transportation options include the construction of new pipelines, compared to the use of existing highways for trucks carrying liquefied or compressed hydrogen to deliver hydrogen to an oil refinery. The model is applied to a case study conducted in the Brazilian state of Bahia, where different social indicators will be explored, characterizing the case study context while allowing generalization to other contexts. Results allow us to establish a trade-off analysis between economic and social concerns, offering valuable insights for both policymakers and companies, supporting strategies that strike a balance between economic competitiveness and regional social development.

**Keywords**: Supply Chain, Hydrogen, Optimization, Social Sustainability, Brazil case study

## INTRODUCTION

Green hydrogen produced without $CO_2$ emissions, namely electrolytic hydrogen, has emerged as a key enabler for the decarbonization of hard-to-abate sectors [1]. It is widely recognized in literature as a promising solution to support the achievement of the United Nations Sustainable Development Goals (SDGs). However, despite its potential, the large-scale deployment of green hydrogen still requires policy support and subsidies to overcome cost barriers and enable market uptake [2]. In this context, national hydrogen strategies and roadmaps have been proposed and continuously updated to facilitate the development and deployment of green hydrogen supply chains (GHSCs) [3].

Nevertheless, the design and planning of GHSCs must go beyond purely techno-economic considerations and explicitly account for sustainability metrics. Although several studies have proposed mathematical programming models for GHSC design, relatively few have critically examined how environmental, economic, and social dimensions are jointly addressed within these frameworks [4]. In particular, a significant gap persists in the assessment of social sustainability, as social aspects remain largely underrepresented in optimization-based formulations, often treated qualitatively or excluded altogether [4, 5].

This gap is especially concerning given that the development of green hydrogen is explicitly framed as a pathway toward sustainable and inclusive energy transitions. Beyond reducing greenhouse gas emissions, such transitions must also proactively address potential social risks, including neocolonial patterns of resource extraction, uneven distribution of economic benefits, exclusion of local communities, water scarcity, and land-use conflicts. Recent studies emphasize that the integration of energy justice principles is essential for the equitable and socially robust development of GHSCs [6].

Accordingly, socio-economic factors, encompassing income levels, employment generation, fiscal contributions, subsidies, and broader social development indicators such as the Human Development Index, have

emerged as critical elements in sustainability assessments [7]. Despite their relevance, these dimensions are rarely incorporated explicitly into optimization-based HSC design models, remaining largely disconnected from strategic planning and investment decisions [4].

In the context of a developing country such as Brazil, the inclusion of a social sustainability assessment is particularly important. While Brazil seeks to position itself as a competitive producer of low-cost green hydrogen, decision-making processes must also account for regional inequalities and development needs [8]. These objectives are often conflicting, highlighting the need for integrated modeling approaches. To address this challenge, this study proposes a bi-objective mixed-integer linear programming (MILP) model for the strategic design of a GHSC in Brazil, explicitly integrating economic performance and location-dependent socio-economic indicators into the decision-making process.

## LITERATURE REVIEW

Kim and Moon (2008) were the first to address a social criterion for HSC design using MILP, by considering cost and safety in the design of hydrogen infrastructure [9]. Since then, the models normally use safety to access the social aspects of the HSC, optimizing risk-related factors. This risk-based interpretation of the social dimension has become the dominant perspective in the literature [4].

Almaraz et al. (2013) was one of the precursors to the proposal of sustainable HSC, highlighting the importance of considering the triple bottom line in sustainability in the strategic stage of any new design to ensure system efficiency. However, the social aspects are restricted to the risks linked to the activities of each stage of the HSC [10].

Fazli-Khalaf et al. (2020) implemented in their modeling the maximization of social responsibility, considering among their criteria the generation of employment opportunities, reduction of health damage, and promotion of sustainable and balanced development between regions. Despite this broader interpretation of social sustainability, the adopted indicators remain highly aggregated and are not explicitly linked to regional socio-economic conditions or location-specific vulnerability [11].

In the Brazilian context, recent MILP-based studies on HSC optimization, such as da Silva et al. (2024), Santana et al (2025), and Camelo et al. (2025), focus primarily on economic and technical performance, without explicitly incorporating social or socio-economic criteria [12-14]. This highlights a persistent gap in the integration of location-dependent social indicators into strategic HSC design models.

To address this gap, the present study incorporates four socio-economic indicators into a bi-objective MILP framework, explicitly linking regional socio-economic conditions to strategic supply chain design decisions.

## PROBLEM STATEMENT

As a deterministic capacitated facility location problem, this work aims to design optimal investments that consider both economic and social aspects in the GHSC to meet the demand of Bahia's oil refinery, as shown in the superstructure in Figure 1.

**Given:**

(i) A predefined hydrogen demand cluster $j$ (representing the refinery).

(ii) Possible facility locations $i$ (12 locations in Bahia).

(iii)Scenarios involving energy sources $e$ (solar, wind, or PPA), production technology $p$ (PEM), and transportation methods $l$ (liquid tanker, tube trailer, or pipelines).

**Determine the optimal:**

(i) Hydrogen production plant location.

(ii)The transportation method for the production plant to the demand cluster.

**Objective:** Minimize the Levelized Cost of hydrogen (LCOH) while maximizing social impact (SOCimp) for different social indexes.

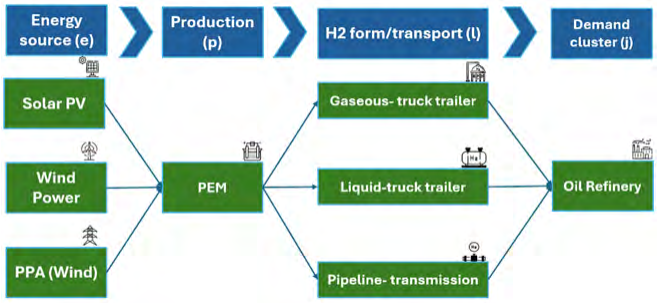

**Figure 1.** Superstructure of the Green Hydrogen Supply Chain Model.

The demand cluster requires 200 MW (29 kt/year) of hydrogen, according to a previous study [14]. The geographic disposition of the candidate site productions and the demand cluster is shown in Figure 2. Energy sources include solar PV, Wind power, and purchase power agreements of wind farms (PPA-wind). A hub-based configuration is adopted, in which a single production site is selected to supply the entire demand cluster. This assumption reflects the economies of scale and allows isolating location-dependent trade-offs between cost and social performance, which is essential for assessing the influence of regional socio-economic indicators in strategic decision-making.

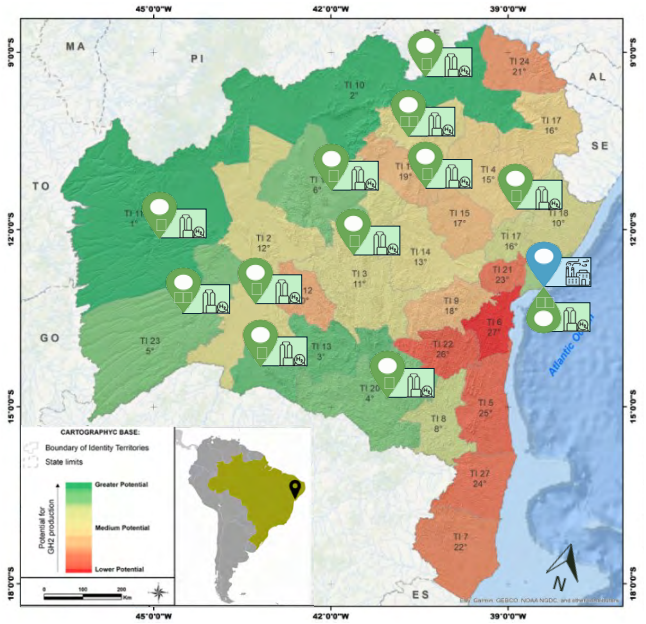

**Figure 2.** Geographic Location of Candidate Production Sites (green) and Demand Cluster (blue) in Bahia, Brazil.

## METHODOLOGY

The study follows three main steps. First, a bi-objective MILP model is formulated to represent strategic decisions on hydrogen production site selection and transport mode selection, minimizing economic costs and maximizing social impact. Second, the model is parametrized using local socio-economic data from the Green Hydrogen Atlas of Bahia and complementary statistical sources [15]. At the same time, technical and cost coefficients are obtained from peer-reviewed literature. Finally, the optimization problem is implemented in Python and solved using the Gurobi solver, applying the ε-constraint method to generate discrete Pareto fronts.

## OPTIMIZATION FRAMEWORK

### Mathematical modeling

A basic mathematical formulation of this work is based on previous models by Santana et al. (2025), was developed just to test the social component of such networks. The social objective is inspired by the work of Mota et al. (2018) [16, 17].

### Sets:

$i$: Production site location

$j$: Demand cluster location

$e$: Energy source type

$p$: Production technology type

$l$: Transport mode

### Parameters:

$a^{p,l}$: Literature parameter for production technology $p$ and energy source $e$, or transport mode $l$.

$b^{p,l}$: Literature parameter for production technology $p$ and energy source $e$, or transport mode $l$.

$c^{p,l}$: Literature parameter for production technology $p$ and energy source $e$, or transport mode $l$.

$d^{l}$: Literature parameter for transport mode $l$.

$EP^{e}$: Electricity price of energy source $e$

$L^{l}_{ij}$: Distance between production plant $i$ and demand cluster $j$ per transport mode $l$.

$FTE^{e,p,l}$: Full time employment per energy source $e$, or production technology $p$, or transport mode $l$.

$SV^{si}$: Regional social index value for index $s$

$SV^{s,ref}$: Reference social index value for index $s$

$\mu^{s}_{i}$: Regional factors based on social indexes $s$

### Variables:

$x_i$: Plant capacity of production plant $i$ (MW)

$Y_i$: Binary variable, 1 if the site $i$ is activated, 0 otherwise.

$T_{li}$: Binary variable, 1 if the transportation mode $l$ is activated at location $i$, 0 otherwise.

In this specific case study, as only one production location may be selected among all candidates, variable $x_i$ becomes $x_i = 200Y_i$.

### Equations:

The model considers that the flow between production site and demand cluster is equal to the plant capacity $x_i$, thus the levelized cost of hydrogen for producing at site $i$ and transport to demand cluster $j$, are:

$$LCOH^{p}(x_i) = \sum_{i=1}^{n}(a^{p}x_i + b^{p}EP^{e}Y_i + c^{p}Y_i) \quad (1)$$

$$LCOH^{l}(x_i) = \sum_{i=1}^{n}(a^{l}L^{l}_{ij}T_i + b^{l}T_i + c^{l}x_i + d^{l}T_i) \quad (2)$$

Regional social factor definition:

$$\mu^{s}_{i} = \frac{SV^{s,ref}}{SV^{si}} \quad (3)$$

Social impact of installing a production plant in a location $i$:

$$SOCimp_i = \mu^{s}_{i}x_i(FTE^{e} + FTE^{p} + FTE^{l}L^{l}_{ij}) \quad (4)$$

### Constraints:

Hydrogen production from all selected plants must equal the supply chain demand:

$$\sum_i x_i = D \quad (5)$$

**Table 1:** Regression Parameters for Levelized Cost of Hydrogen (LCOH) Calculation.

| | a | b | c | d | Ref |
|---|---|---|---|---|---|
| $p$ (PEM) | -0.0249 | 13.3604 | 2.1039 | 0 | [17] |
| $l$ (Pipeline) | 0.2176 | -7.105x10^-15 | 0 | 0 | [12] |
| $l$ (Liq truck) | 0.0006 | 0.1203 | -0.0078 | 3.5535 | [18] |
| $l$ (Gas truck) | 0.0031 | 0.3231 | 0 | 0 | [18] |

**Table 2:** Employment Factors (FTE) for Different Supply Chain Echelons [19].

| | Employment factor (FTE) | Unit |
|---|---|---|
| $e$ (Wind) | 0.4 | FTE/MW |
| $e$ (Solar) | 0.12 | FTE/MW |
| $e$ (PPA-Wind) | 0.0 | FTE/MW |
| $p$ (PEM) | 0.9 | FTE/MW |
| $l$ (Pipeline) | 0.04 | FTE/km |
| $l$ (Liq truck) | 2 | FTE/(GW*km) |
| $l$ (Gas truck) | 0.3 | FTE/(GW*km) |

**Table 3:** Candidate Production Sites: Characteristics, Distances, and Socio-Economic Indicators [15;20-21].

| Site ($i$) | Location | Energy source ($e$) | Transport mode distance (km) | | GDP (kBRL per inhabitant) | IFDM | SoVI | Salary (BRL) |
|---|---|---|---|---|---|---|---|---|
| | | | Pipe | Road | | | | |

| | | **Reference value (Bahia's average)** | | | *19.54* | *0.5564* | *0.419* | *1865* |

Hydrogen production is an integer variable:

$$x_i \in z^+, \forall i \quad (6)$$

Hydrogen production is constrained by its maximum capacity and is dependent on whether the plant is selected:

$$x_i \leq D\, Y_i, \forall i \quad (7)$$

Binary decision variables $Y_i$ and $T_{li}$ indicates whether a specific production site and transport mode is selected:

$$Y_i \in \{0,1\}, \forall i \quad (8)$$

$$T_{li} \in \{0,1\}, \forall i \quad (9)$$

Only one transportation mode may be selected if a location is active:

$$\sum_i t_{il} = Y_i, \forall i \quad (10)$$

## Objective functions:

Minimize the Supply chain's LCOH:

$$Min\ LCOH = LCOH^p(x_i) + LCOH^l(x_i) \quad (12)$$

Maximize the Supply chain's social impact:

$$Max\ SOCimp\,(x_i) = \sum_{i=1}^{n} x_i \mu_i^s (FTE^e + FTE^p + FTE^l L_{ij}^l) \quad (13)$$

## Multiobjective optimization strategy:

The bi-objective problem is solved using the ε-constraint method. The economic objective is minimized to obtain the minimum economic cost and the corresponding social impact. Then, the social objective is maximized to obtain the maximum attainable social impact. So, a set

of ε values is generated between these two extremes, and the economic objective is minimized subject to:

$$SOCimp \geq \varepsilon_k \quad (14)$$

In this study, a discrete Pareto frontier is constructed using five ε values uniformly distributed between the economic and social extremes.

## Model parametrization

The literature parameters: $a^{p,l}$; $b^{p,l}$; $c^{p,l}$; $d^{l}$, are displayed in table 1. The production parameters are derived from Santana et al. (2024), which quantified the impact of various variables on the levelized cost of hydrogen (LCOH) for different plant capacity scales [17]. This parameter set incorporates costs associated with electricity, water pre-treatment, PEM electrolyzer system, initial compression, and gaseous storage buffering.

Based on the published data, a bilinear function was regressed to estimate the LCOH as a function of two key variables: plant capacity (MW) and electricity price (US$/MWh). This formulation captures the main influencing factors identified in the reference study. In the present model, the electricity price is an exogenous variable, fixed and defined specifically for each location $i$.

The parameters for transportation and subsequent conditioning costs (gaseous or liquefied form) were sourced from the meta-analysis by Santos (2024) [18]. This work provides a comprehensive review of hydrogen production, storage, and transportation technologies, detailing their cost and greenhouse gas emission profiles. Given that initial compression costs are already internalized within the production parameters, the transportation and conditioning costs applied here refer to subsequent logistical steps. Originally, non-linear or scale-incompatible parameters were adapted and linearized where necessary to align with the scope and structure of the current model.

The employment parameters were sourced from Ganter et al. (2024), who synthesized the job creation potential for each echelon of the hydrogen supply chain. Their synthesis was based on a combination of data from academic publications, industry sources, and anonymous industry surveys and is presented in table 2 [19]. For PPA-wind is assumed to have no Job creation once the energy production isn't in the same region of hydrogen's.

The selection of potential plant locations $i$ was based on the results of the Green Hydrogen Atlas of Bahia study [15]. This study applied an Analytic Hierarchy Process (AHP)-based multicriteria analysis to rank the most suitable regions within the Brazilian state of Bahia for green hydrogen production. The selection of the energy source type e for each locality $i$ was performed by integrating data from the Atlas with information from the Brazilian National Electric System Operator [20].

Due to budget constraints, a single plant installation is to be considered in this case. Also, the technology to be installed is a single one, and it will be an electrolyser.

The distances between production locations $i$ and demand points $j$ were calculated as follows: for pipeline transport, straight-line distances were obtained via Google Earth, with a 5% markup applied to account for potential route deviations. For truck transport (liquid or gaseous), road distances were acquired using Google Maps, and the electricity price is based on literature data, being $0.05 per kWh for solar PV; $0.03 per kWh for onshore wind power and assume as premised by Mughal and Sajid, 2025 the electricity cost of PPA-Wind equal to solar PV ($0.05 per kWh) [21, 22].

The data for social indices were either directly obtained or calculated from the values presented in the Green Hydrogen Atlas for the Municipal Development Index (IFDM), Social Vulnerability Index (SoVI), and Gross Domestic Product (GDP) [15]. Income data, however, were sourced directly from the Superintendency of Economic and Social Studies of Bahia (SEI) [23].

Table 3 presents the selected plant locations, distances, and social indices.

# RESULTS AND DISCUSSION

The results highlight a trade-off between economic efficiency and social sustainability in the design of a GHSC in Bahia. Using an ε-constraint multi-objective MILP formulation with a single-sourcing structure, the resulting Pareto fronts are inherently discrete, with each non-dominated solution corresponding to a specific combination of production site, energy source, and transport mode.

Table 4 presents the trade-off between levelized cost (LCOH) and social impact when the Municipal GDP is used as the social indicator. The Pareto-efficient solutions range from the cost-optimal site (4-Serrinha) to the socially optimal one (6-Barreiras), illustrating the additional cost associated with investing in municipalities with lower economic activity to boost local development.

**Table 4:** Pareto-Optimal Solutions for the GDP-based Social Indicator.

| Site ($i$) | Energy source ($e$) | Transport mode ($l$) | LCOH ($/kg) | Social impact (GDP) |
|---|---|---|---|---|
| 4 | Wind | Gas truck | 1.92 | 128 |
| 5 | Wind | Liq truck | 3.54 | 357 |
| 6 | Solar | Liq Truck | 6.42 | 1037 |

For the Municipal Development Index (IFDM), Table 5 summarizes the Pareto-optimal solutions obtained when maximizing its social impact. The sequence of selected sites demonstrates how the model shifts

investment towards locations with greater infrastructural and social needs as the social constraint is tightened, with a corresponding increase in LCOH.

**Table 5:** Pareto-Optimal Solutions for the IFDM-based Social Indicator.

| Site ($i$) | Energy source ($e$) | Transport mode ($l$) | LCOH ($/kg) | Social impact (IFDM) |
|---|---|---|---|---|
| 4 | Wind | Gas truck | 1.92 | 259 |
| 8 | Wind | Liq truck | 3.44 | 352 |
| 3 | Wind | Liq Truck | 3.51 | 424 |
| 7 | Wind | Liq truck | 3.64 | 564 |
| 6 | Solar | Liq Truck | 6.42 | 571 |

In turn, Table 6 details the compromise solutions identified when the optimization incorporates the minimization of Social Vulnerability (SoVI). The results show a progression towards sites with higher social fragility, underscoring the potential role of green hydrogen projects in addressing regional vulnerabilities, although at a higher production cost.

**Table 6:** Pareto-Optimal Solutions for the SoVI-based Social Indicator.

| Site ($i$) | Energy source ($e$) | Transport mode ($l$) | LCOH ($/kg) | Social impact (SoVI) |
|---|---|---|---|---|
| 4 | Wind | Gas truck | 1.92 | 298 |
| 8 | Wind | Liq truck | 3.44 | 408 |
| 3 | Wind | Liq truck | 3.51 | 473 |
| 2 | Solar | Liq truck | 6.37 | 559 |

Finally, the Pareto-optimal configurations for the social indicator based on the local Average Salary are presented in Table 7. The solutions reveal a trade-off where selecting sites with lower average wages (aiming to improve local income) leads to higher supply chain costs, highlighting a key equity-efficiency tension in strategic planning.

**Table 7:** Pareto-Optimal Solutions for the Salary-based Social Indicator.

| Site ($i$) | Energy source ($e$) | Transport mode ($l$) | LCOH ($/kg) | Social impact (Salary) |
|---|---|---|---|---|
| 4 | Wind | Gas truck | 1.92 | 238 |
| 8 | Wind | Liq truck | 3.44 | 366 |
| 11 | Wind | Liq truck | 3.46 | 415 |
| 6 | Solar | Liq truck | 6.42 | 555 |

Across all social indicators, the economically optimal solution consistently selects Serrinha (site 4), supplied by wind power and connected to the refinery via compressed hydrogen trucks (Gas truck), achieving the lowest LCOH of 1.92 USD/kg$H_2$. This configuration benefits from short transport distances and low electricity costs but yields the lowest social impact. These results indicate that, in the case of Bahia, cost-minimizing strategies tend to concentrate investments in already consolidated regions, offering limited contributions to broader regional social development goals.

As social requirements become more restrictive, the model shifts the production location and systematically adopts liquefied hydrogen transport (Liq truck), despite its higher cost, due to its significantly higher FTE factor per distance. Intermediate Pareto-efficient solutions, such as Juazeiro (site 5, Table 4), Jacobina (site 8, Tables 5, 6, 7), and Seabra (site 3, Tables 5 and 6), present LCOH values between 3.4 and 3.6 USD/kg$H_2$, while delivering substantially higher social impacts.

On the other hand, the socially optimal solutions for indicators like GDP, IFDM, and Salary are consistently associated with Barreiras (site 6, powered by solar PV and relying on Liq truck), achieving the highest social impact scores (Tables 4, 5, 7). However, these configurations present the highest LCOH, approximately 6.4 USD/kg$H_2$, reflecting longer transport distances and higher electricity costs. This outcome reveals a structural tension: regions with the greatest potential for social benefits are often those facing logistical and energy cost disadvantages, limiting their competitiveness under purely market-driven conditions.

Although each social indicator emphasizes different dimensions of local development, consistent qualitative patterns emerge. GDP-based results favor municipalities with lower economic activity, while IFDM and Salary indicators shift solutions toward regions with greater development needs. The Social Vulnerability Index (SoVI) further reorients the Pareto frontier toward socially fragile municipalities, such as Bom Jesus da Lapa (site 2, Table 6), even at the expense of higher hydrogen production costs.

From a policy perspective, the results suggest that achieving socially inclusive GHSCs requires targeted interventions, such as regional incentives, subsidies, or infrastructure investments in inland regions. Without such measures, cost-driven solutions are likely to prevail, limiting the social benefits of hydrogen deployment. For supply chain planners and investors, the intermediate Pareto-efficient solutions detailed in the tables offer viable compromise strategies that balance economic competitiveness with measurable social contributions, aligning with emerging ESG-oriented investment frameworks.

## CONCLUSION

This work proposed a bi-objective MILP framework

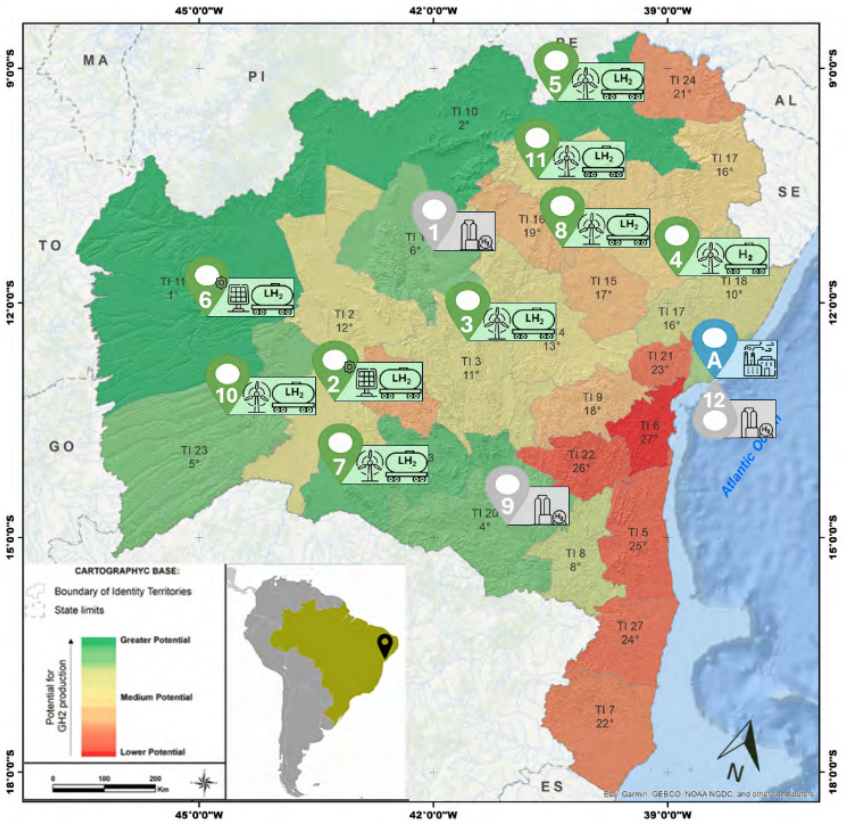

**Figure 3.** Snapshot of the Pareto-optimal site selections for green hydrogen production in Bahia.

for the strategic design of GHSCs that explicitly integrates economic performance and location-dependent social sustainability indicators. By incorporating regional socio-economic metrics into the optimization process, the model enables a transparent assessment of trade-offs between cost efficiency and social impact. The case study in Bahia, Brazil, demonstrates that cost-minimizing solutions tend to favor already developed regions, while socially oriented solutions shift investments toward inland municipalities with greater development needs, at the expense of higher hydrogen costs. The resulting Pareto fronts provide actionable insights for policymakers and investors by identifying compromise solutions that balance competitiveness and social contribution. Although the analysis is restricted to a single production hub, the proposed framework is flexible and can be extended to multi-facility, multi-period, and uncertainty-aware formulations, supporting broader applications in sustainable hydrogen planning. The model proposed is a basic model that will be further developed to include further detailed characteristics of the GHSC, such as fugitive emissions and multiple demand clusters and technologies for hydrogen production.

## ABSTRACT

Green hydrogen constitutes a strategic energy vector for achieving the Sustainable Development Goals (SDGs 7, 9, 12, and 13) due to its high energy density, flexibility for renewable energy storage, and direct emission-free operation. However, its production critically depends on the supply of high-purity water, which is unsustainable in the context of a projected 40% global water deficit by 2030. Given that more than 97% of available water is saline, integrating desalination processes with electrolysis constitutes an essential strategy for transitioning toward circular economy models in water resource management. This work presents the conceptual design, detailed modeling, and optimization of an integrated process for the sustainable production of green hydrogen from saline water. The system couples a desalination technology (Solar Distillation) with two electrolysis technologies (AEL and SOEC), modeled through physicochemical, electrochemical, and thermodynamic principles. The objective is to determine technological configurations, materials, and operating conditions that maximize the energy efficiency and minimize the LCOH, contributing to the development of viable routes within the energy transition and circular economy. The results shows that the viability of a integrated Seawater Green Hydrogen system with a detail model is possible. In contrast to black-box models, this model yielded a detailed, geometrically accurate simulation that captures phenomenological effects. It enables the development of processes that contribute to the energy transition, reduce freshwater consumption, and assess their economic viability. The sensitivity analysis revealed promising solutions, with LCOH values ranging from 4.22 to 7.10 USD/kg and overall energy efficiencies between 67% and 82%.

## 1. INTRODUCTION

Green hydrogen, produced through electrolysis powered by renewable energy, represents a key technology for decarbonizing hard-to-abate industrial and energy sectors, in accordance with SDGs 7 (Affordable and Clean Energy) and 13 (Climate Action) [1, 2]. However, its production depends on the supply of ultrapure water, which poses a critical challenge in the context of water stress and the need to transition toward systems that promote circular water use.

By 2030, the European Union aims to reach an annual hydrogen production of 10 million metric tons. From a stoichiometric standpoint, this target demands 89 million metric tons of water, excluding supplementary requirements like cooling systems [3]. For comparison, the average domestic water consumption in nations like Germany and the United Kingdom is currently 120 and 140 liters per capita per day (lcd), respectively [4]. Based on the current EU population (~450 million) [5], the total domestic water use amounts to 19, 700 million metric tons annually. Therefore, scaling up hydrogen production would introduce an additional water demand of 0.45 % per year. Although this increase might not pose a systemic threat to Europe's total water reserves, it constitutes a substantial volume. This demand becomes

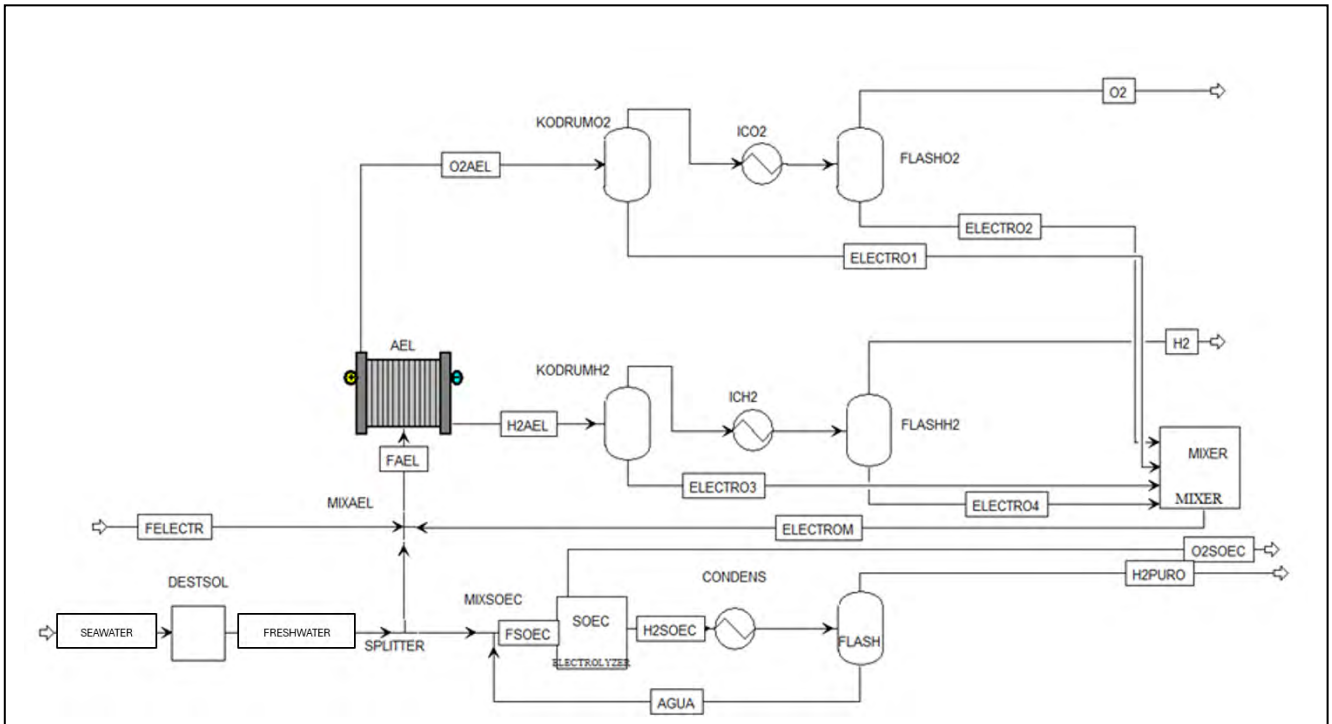

**Figure 1.** Hydrogen production process flowsheet.

particularly challenging in decentralized, water-stressed regions with limited freshwater availability, making the integration of seawater desalination a strategic necessity for sustainable deployment in these regions.

Integrating desalination technologies with advanced electrolysis systems avoids the use of potable water and improves the sustainability of the energy-hydrogen–water cycle [2, 6].

While desalination and electrolysis are mature technologies individually, their thermal and mass integration presents non-trivial challenges. Most technoeconomic studies rely on "black-box" models that fix the efficiency of the electrolyzer regardless of operating conditions. However, the specific energy consumption of an Alkaline Electrolyzer (AEL) is sensitive to the void fraction generated by bubbles at high current densities, a phenomenon that cannot be captured without a phenomenological approach. Furthermore, traditional experimental optimization is time-consuming and capital-intensive, limiting the ability to screen novel electrode materials or geometric configurations.

This analysis forms the basis for future multi-objective optimization steps, addresses the geometric gaps by developing a rigorous simulation framework that couples electrochemical kinetics with a detailed thermodynamic property package (Aspen Plus) and a desalinisation system. Unlike standard models, this tool allows for the "virtual prototyping" of the cell simultaneously varying geometric parameters (gap, area) and electrolyte concentrations, using both empirical correlation and fundamental equations-based optimization of the coupled water-hydrogen nexus before physical piloting.

## 2. METHODOLOGY

The process simulation strategy relies on a hybrid architecture. The mass and energy balances, along with the electrochemical equations, are solved in a Python environment, which dynamically queries Aspen Plus V14 to retrieve physicochemical properties using the [e-NRTL / Pitzer] method.

The process consists of a coupled desalination-electrolysis system, beginning with a seawater desalination unit. Subsequently, a splitter separates the water supply into an AEL line and a SOEC line, as shown in Figure 1. After each electrolyzer produces hydrogen, the separation units purify and recirculate the water and electrolyte.

### 2.1 Electrochemical Modeling

Mathematical models were developed in an open-source language for Alkaline (AEL) electrolysis technology and Solid Oxide technology, incorporating mass and energy balances, electrochemical models for overpotentials, ionic transport, and equations for thermodynamic behavior under different materials, and operating conditions.

The cell voltage ($V_{cell}$) is the primary performance indicator in this type of analysis, and is calculated by summing the reversible potential and the overpotentials, as defined in Eq. (1) reported by Abdin et al. (2017) [7] report in their model:

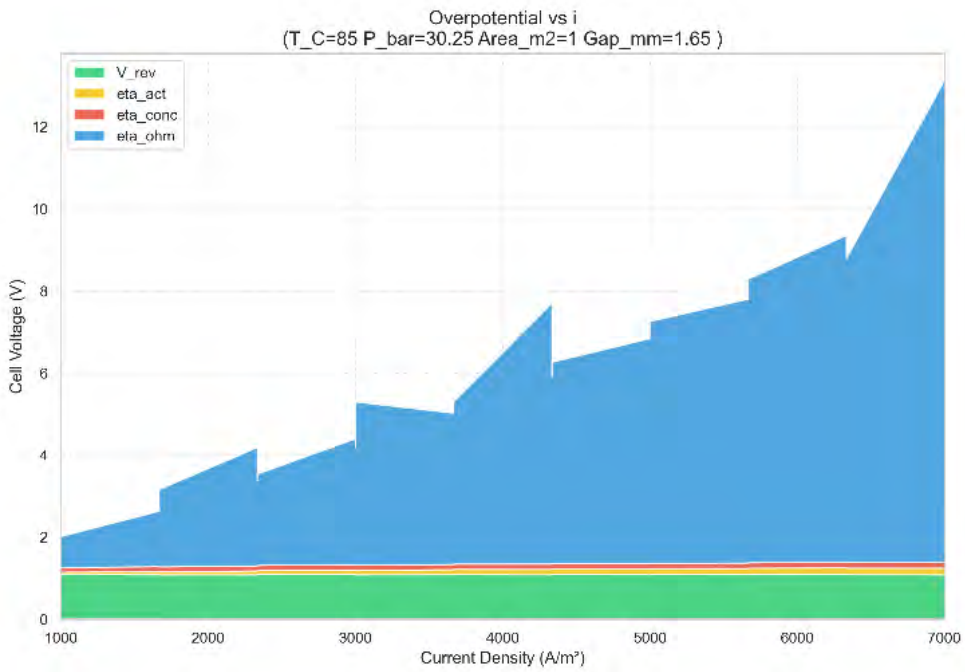

**Figure 2.** Contribution of overpotentials to the total cell voltage for Ni-Mo and Ni-Co electrodes.

$$V_{cell} = V_{oc} + \eta_{act} + \eta_{ohm} + \eta_{conc} \quad (1)$$

The overpotential includes in a explicit way the effect of physic, geometric and transport variables such as the ohmic overpotential ($\eta_{ohm}$) in Eq. (2) or the activation overpotential ($\eta_{act}$) in Eq. (3) shows:

$$\eta_{ohm} = I_{cell}\left(\frac{\delta_{anode}\rho_{ref}^{anode}}{A_{anode}(1-\varepsilon_{anode})^{1.5}} + \frac{\delta_{cathode}\rho_{ref}^{cathode}}{A_{cathode}(1-\varepsilon_{cathode})^{1.5}} + \frac{1}{\kappa_{electrolyte}A_{anode}}\left[(l_{anode-membrane} - \beta_{\text{anode}}) + \left(\frac{\beta_{anode}}{(1-\theta_{anode})^{m_{brug}}}\right)\right] + \frac{1}{\kappa_{electrolyte}A_{cathode}}\left[(l_{cathode-membrane} - \beta_{\text{cathode}}) + \left(\frac{\beta_{cathode}}{(1-\theta_{cathode})^{m_{brug}}}\right)\right] + \frac{\delta_{membrane}\tau_{membrane}^{2}}{\kappa_{electrolyte}\omega_{membrane}\varepsilon_{membrane}A_{membrane}}\right) \quad (2)$$

$$\eta_{act} = \frac{RT_{cell}}{a_{cathode}F_c} ln\left[\left(\frac{i}{2i_{exch}^{cathode}(1-\theta_{cathode})^{m_{brug}}}\right) + \sqrt{\left(\frac{i}{2i_{exch}^{cathode}(1-\theta_{cathode})^{m_{brug}}}\right)^{2} + 1}\right] + \frac{RT_{cell}}{a_{anode}F_c} ln\left[\left(\frac{i}{2i_{exch}^{anode}(1-\theta_{anode})^{m_{brug}}}\right) + \sqrt{\left(\frac{i}{2i_{exch}^{anode}(1-\theta_{anode})^{m_{brug}}}\right)^{2} + 1}\right] \quad (3)$$

The ($\eta_{ohm}$) accounts for the contribution of electrode gap ($l$), the bubble coverage ($\theta$) effect on electrolyte conductivity (third and fourth term of sum) and membrane electric resistance (fifth term of sum) to name some variables. This rigorous treatment allows the model to predict the sharp voltage increase at high current densities due to bubble accumulation, a critical factor for sizing the circulation pumps and optimizing the operating pressure and current density. The production of Hydrogen was estimated with Eq. (4):

$$\dot{N}_{H_2}^{cathode,gen} = \frac{I_{cell}}{2F_c} \quad (4)$$

## 2.2 Desalinisation system

The desalination subsystem was modeled to ensure the water requirements of electrolysis were met, allowing for future evaluation of their energy integration under water efficiency criteria. This part of the process was developed with a Solar Still technology proposed by Abdel-Rehim & Lasheen (2005) [8].

This model allows estimating the necessary surface area of the solar still to supply water production, taking into account heat transfer under specific climatic conditions (solar resource, wind speed and ambient temperature), as well as energy and mass balances.

## 2.3 Separation units

The separation train (flash units and heat exchangers) was modeled using phase equilibrium equations and energy balances, allowing the electrolyte to be recovered and recirculated, which improves the overall efficiency of the process.

## 2.4 Sensitivity Analysis

A sensitivity analysis was performed using Monte

**Table 1**. Variables and ranges explored in the sensitivity analysis.

| Variable | Lower Limit | Upper Limit | Units |
|---|---|---|---|
| Split | 0 | 100 | % |
| Distilled water recovery fraction | 35 | 55 | % |
| Temperature step size for flash stages | 5.0 | 30.0 | °C |
| AEL recirculation ratio | 20.0 | 60.0 | - |
| Electrolyte fraction in AEL cathode | 40 | 60 | % |
| AEL operating temperature | 35 | 95 | °C |
| AEL operating pressure | 1 | 40 | Bar |
| AEL current density | 1000 | 6000 | $A/m^2$ |
| Electrolyte concentration | 20 | 30 | wt% |
| Cathode-membrane gap | 0.0002 | 0.006 | m |
| Anode-membrane gap | 0.0002 | 0.006 | m |
| AEL cathode thickness | 0.0005 | 0.003 | m |
| AEL anode thickness | 0.0005 | 0.003 | m |
| SOEC water consumption fraction | 60 | 85 | % |
| SOEC operating temperature | 700 | 900 | °C |
| SOEC condenser temperature | 25 | 60 | °C |
| SOEC flash operating pressure | 1 | 5 | Bar |
| SOEC current density | 2000 | 10000 | $A/m^2$ |
| SOEC electrolyte thickness | 5e-6 | 50e-6 | m |
| SOEC cathode thickness | 250e-6 | 1000e-6 | m |
| SOEC anode thickness | 20e-6 | 100e-6 | m |

**Table 2**. List of material in the sensitivity analysis.

| Component | Material 1 | Material 2 | Material 3 |
|---|---|---|---|
| AEL cathode material | Ni-Mo alloy | Classic Ni-Al alloy (Ni Raney) | SS 316L |
| AEL anode material | Ni-Fe alloy | Ni-Co spinel | SS 316L |

Carlo simulations complemented by machine learning techniques (Random Forest) to identify the variables with the greatest impact on LCOH and energy efficiency. The variables explored and the evaluated ranges are detailed in Table 1.

### Material Screening

Furthermore, the model's versatility was utilized to screen different electrocatalyst combinations by adjusting the kinetic parameters (e.g., exchange current density). Three materials were compared on each electrode, as shown in Table 2.

## 3. RESULTS AND DISCUSSION

The integrated model was simulated across a wide range of operating conditions, as described in the methodology section, enabling various types of analysis.

### 3.1. Voltage Breakdown Analysis

Understanding the distribution of energy losses is vital for stack design. Figure 2 presents the breakdown of the cell voltage at representative conditions (85°C, 30 bar).

The dominance of ohmic losses at high current densities highlights the necessity of zero-gap configurations.

It is observed that at low current densities, activation losses dominate due to the catalytic barrier. However, as production increases, the ohmic component becomes the governing factor, driven by bubble accumulation and electrolyte resistance. This validates the importance of operating at high pressures to compress gas bubbles and reduce the void fraction effect.

### 3.2. Sensitivity and Operating Maps

Sensitivity analysis allowed for the robust identification of the design and operating variables with the greatest influence on the overall system performance. Specifically, it was observed that operating temperature and current density are the dominant factors in energy consumption due to their direct impact on overpotentials and, consequently, on cell voltage, as shown in Figures 3, 4 and 5.

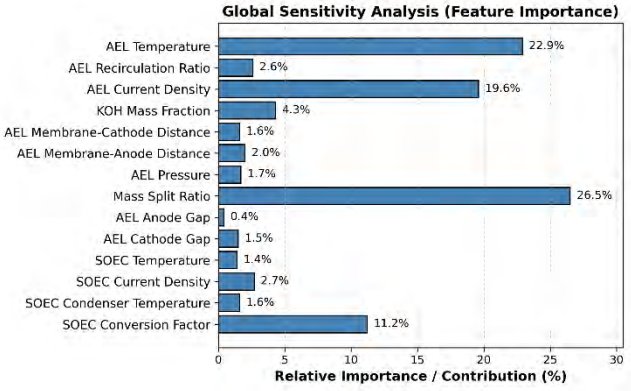

**Figure 3.** Relative importance of each variable on LCOH.

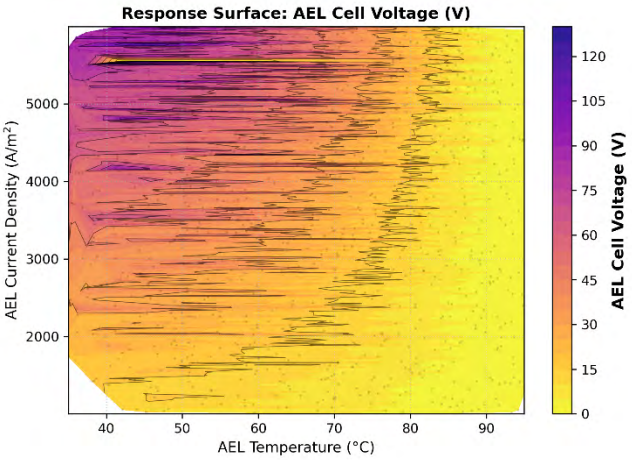

**Figure 4.** Cell voltage response surface.

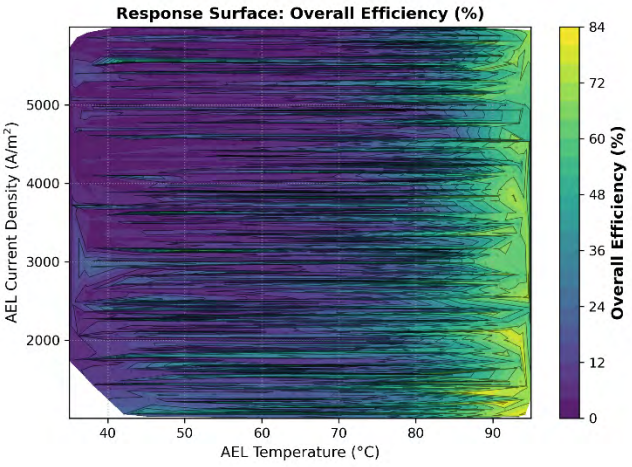

**Figure 5.** Impact of T of AEL and I of AEI on Overall Efficiency.

High-temperature operation minimizes voltage but requires careful thermal management to prevent electrolyte boiling. The results indicate that increasing temperature from 60°C to 90°C results in a voltage reduction of approximately 150-200 mV at high currents, which translates to a significant decrease in energy consumption.

There are zones where the temperature can be lower and maintain good efficiencies at high currents as shown in Figure 5, but in general, the best results are found at high temperatures.

## 3.3. Geometric Optimization

The impact of the geometric variables showed high sensitivity and highly dispersed values even among the most promising simulations, highlighting the need to measure the impact of these variables when there is a trade-off between configurations with lower ohmic resistances and those with lower manufacturing and material costs, when applying a multi-objective optimization approach.

The inter-electrode gap is a critical design parameter. Figure 6 illustrates the sensitivity of the voltage to gap variations.

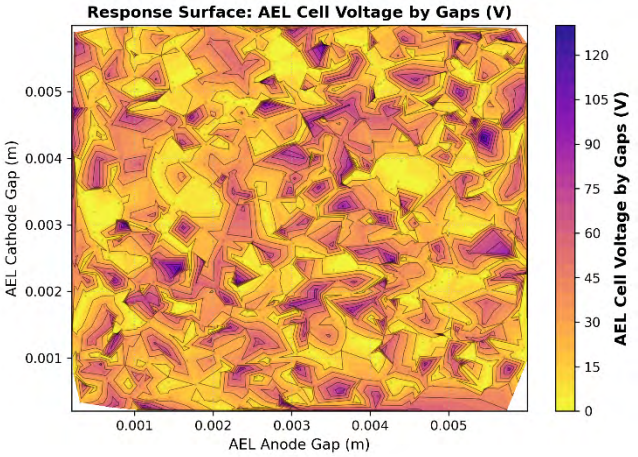

**Figure 6.** Impact of electrode gap distance on cell voltage.

Reducing the gap is the most effective strategy to minimize ohmic resistance in theory but the analysis suggests that there are multiple gap combinations that minimize the cell voltage and is lower when cathode have a greater gap than the anode.

## 3.4. Integrated Process Performance

The three best plants obtained by plotting the Pareto front shown in Figure 7 correspond to designs with a low LCOH (<5 USD/kg) and high overall efficiency (>65%). These points share an operating temperature of the AEL around to 90 °C, although they are quite heterogeneous in the other variables, including the Split system, which has values of 90%, 66%, and 95% at these points.

These results demonstrate that the integration of the desalination and electrolysis system is technically feasible and allow for the delimitation of feasible operating regions as a starting point for more aggressive optimization algorithms that consider environmental indicators.

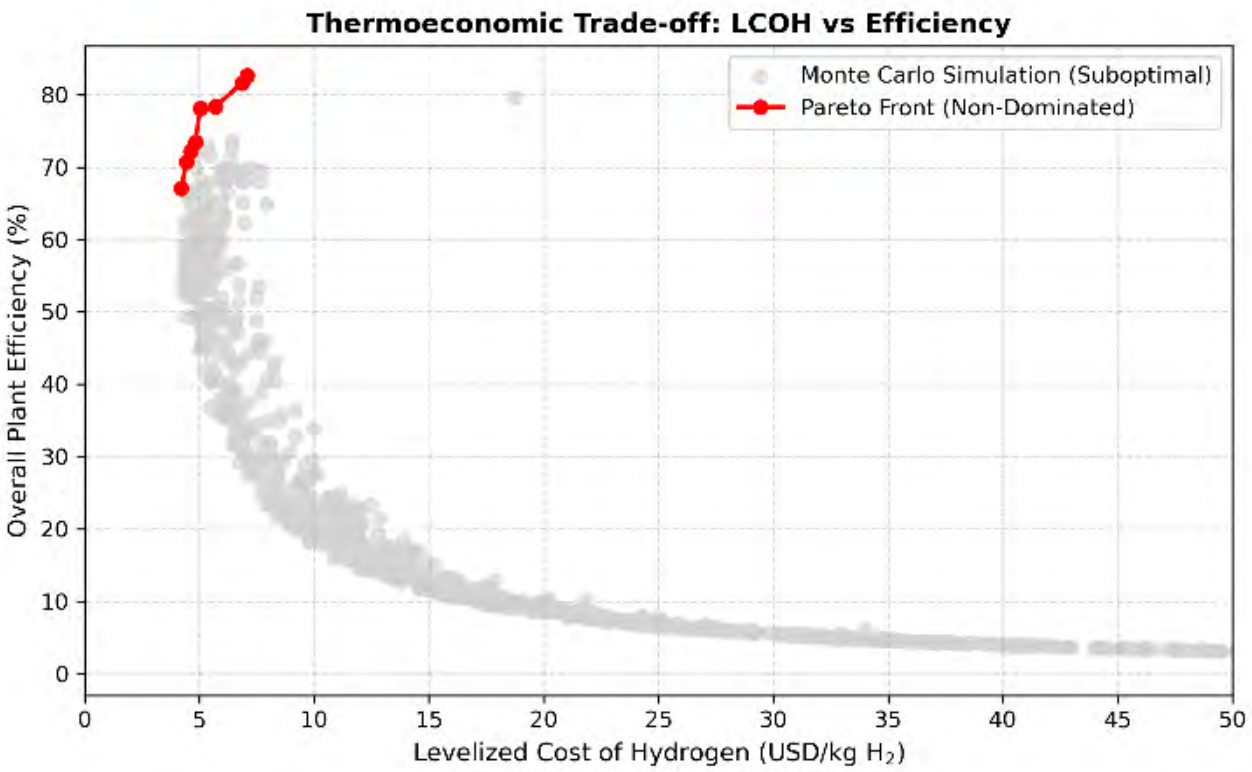

**Figure 7.** LCOH vs Global Energy Efficiency.

From an economic perspective, the results indicate that it is possible to achieve substantial reductions in LCOH through the appropriate selection of operating variables and materials. Operating regions are identified where the trade-off between energy efficiency and investment costs is optimal, validating the importance of sensitivity analysis as a tool for reducing the search space in complex optimization problems.

## 4. CONCLUSIONS

Taken together, the results not only demonstrate the viability of the integrated system but also provide key information on the most promising technological pathways. Furthermore, they highlight the importance of simultaneously considering energy, water, and economic aspects in the design of sustainable processes, aligning with the principles of process intensification and the circular economy.

The integration of desalination technologies with advanced electrolysis systems represents a robust strategy for ensuring the sustainable production of green hydrogen, reducing dependence on freshwater and strengthening the transition to circular models in resource management. This approach allows for the decoupling of hydrogen production from the use of conventional water resources, strengthening the resilience of energy systems and promoting circular water use schemes.

The development and application of rigorous mathematical models accurately capture the complexity of the phenomena involved, providing a solid foundation for decision-making in the early design stages. Through sensitivity analysis, it was possible to identify the variables most influential on system performance, facilitating the implementation of more efficient and targeted optimization strategies.

The results obtained confirm that the appropriate selection of operating conditions, materials, and geometric configurations can lead to significant reductions in the levelized cost of hydrogen and substantial improvements in energy efficiency. In this sense, the work lays the groundwork for the development of multi-objective optimization methodologies that integrate economic, environmental, and safety criteria.

Finally, this study directly contributes to the advancement of technological solutions aligned with the 2030 Agenda by proposing a green hydrogen production scheme with a smaller water footprint, greater efficiency, and high potential for industrial scalability, thus consolidating its role within the global energy transition.

# Net Carbon Balance (NCB): a Better Way to Evaluate and Optimize Carbon Capture Technologies

**André F. Young[a]*, Aline R. Eckstein[b], Leonardo D. Ferreira[b], Vítor M. Sermoud[b], and Ingrid A. de Oliveira[b]**

## ABSTRACT

The objective of this paper is to present a single equation format for quantifying the net carbon balance (NCB) in the evaluation of $CO_2$ capture technologies, and to discuss the benefits of this approach. The equation must take into account indirect emissions, especially the contributions from utility generation systems (heating, cooling and electricity), making use of efficiency values and emission factors. The idea is to synthesize, in a single expression, the quantification of the environmental footprint of a technology, in a practical way so that it could be used as an efficient metric in technical evaluation studies, or as objective function/constraint in optimization problems. It also facilitates demonstrating the relationship between capture efficiency and environmental performance, as well as the contribution of each term to total emissions, and to compare different technologies in terms of time, location and available energy sources. To illustrate the application of the proposed NCB formulation, two processes were compared in two different scenarios: post-combustion and pre-combustion capture with MEA absorption, in a Base Case formulated with literature premises and an NCB Zero Case meaning carbon neutrality. A process simulator – Aspen HYSYS – was used to solve the mass and energy balances associated with each process, providing the necessary information for NCB calculation, whose parameters were obtained from the technical literature and were discussed in relation to their importance to the proposed analysis.

**Keywords**: Carbon Dioxide, Process Design, Modelling and Simulations, Energy Efficiency, Environment, Emissions

## INTRODUCTION

In recent years, studies assessing the technical and economic feasibility of carbon capture technologies have become increasingly common, meeting industrial and government demand for emissions mitigation and energy transition solutions. Among these studies, optimization works can be identified. However, most studies focus solely on maximizing carbon capture efficiency, occasionally taking into account energy consumption, but not the associated emissions. Therefore, the environmental impact reduction associated with these solutions becomes questionable.

For a more realistic technology assessment, it is necessary to consider indirect emissions related to energy generation in the carbon capture technologies (not to mention fugitive emissions), which can be very significant. Therefore, in this work, we propose that technologies should be evaluated and optimized in terms of their Net Carbon Balance (NCB), defined, for example, according to Equation 1:

$$NCB = f_{e,h} \cdot \sum \frac{q_h}{\eta_h} + f_{e,c} \cdot \sum q_c + f_{e,e} \cdot \sum \frac{q_e}{\eta_e} - w_{CO2,cap} \quad (1)$$

where: $q_h$ is the thermal energy consumed for heating, in MJ per year; $q_c$ is the thermal energy removed by cooling, in MJ per year; $q_e$ is the electric energy balance between what is consumed by pumps, blowers and compressors, and what is eventually recovered with turbines, in MJ per year; $\eta_h$ is the efficiency associated with heating utilities generation (e.g, steam generation in a boiler); $\eta_e$ is the efficiency associated with electricity consumption (i.e., conversion between electricity and shaft work); $f_{e,h}$ is an

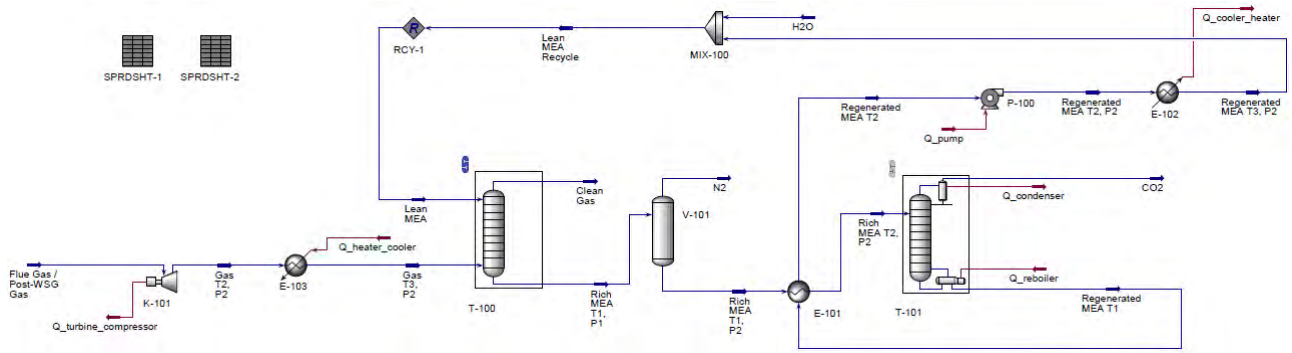

**Figure 1.** Flowsheet of the carbon capture process simulated in this work: MEA absorption.

emission factor relative to heating utilities utilization (e.g., fuel combustion for steam generation in a boiler), in Mtons of $CO_{2e}$ per MJ; $f_{e,\,c}$ is an emission factor relative to cooling utilities pumping and regeneration (e.g, electricity consumption in the fan of a water refrigeration tower), in Mtons of $CO_{2e}$ per MJ; $f_{e,\,e}$ is an emission factor relative to electricity utilization (e.g., a regional emission factor, depending on the energy matrix), in Mtons of $CO_{2e}$ per MJ; and $w_{CO2,\,cap}$ is the amount of $CO_2$ captured, in Mtons per year.

The emission factors, as well as typical efficiency values, can easily be obtained from official technical reports and scientific literature. The amount of heat and electricity consumed in a carbon capture technology can be obtained through process simulation, along with a good estimation of its $CO_2$ capture potential. Defined this way, negative values for NCB indicate a real emissions mitigation scenario, while positive values indicate that emissions are not being effectively reduced, which compromises the environmental meaning of the proposed solution.

In this work, to illustrate the use of NCB in evaluating carbon capture technologies, two processes were compared: carbon capture from a typical post-combustion stream (flue gas); and carbon capture from a typical pre-combustion stream (hydrogen production process by biomass gasification, after water-gas shift), both using MEA absorption. These streams differ in terms of flow rate, temperature, pressure and composition, especially the $CO_2$ content. The processes were simulated in Aspen HYSYS, from where the mass and energy information required for NCB calculation was obtained.

## METHODOLOGY

### Emission Sources

To exemplify the use of the NCB formalism as a metric of evaluation of different carbon capture technologies, we selected two well-established processes: MEA absorption, applied to a post-combustion $CO_2$ emission source and to a pre-combustion $CO_2$ emission source.

As a good representative of a post-combustion source, the flue gas stream from the study by Moghaddam et al. [1] was chosen. The authors performed an optimization study of the MEA (monoethanolamine) absorption process based on process simulation and response surface methodology, and it was also the basis for the simulations performed in this work. This article was selected because it is a recent process simulation study, and the reported flue gas stream has a low $CO_2$ concentration, which is not only typical of post-combustion sources – in contrast to pre-combustion sources –, but also interesting for the analysis proposed in this work, about capture efficiency, energy demand, etc. Also, as a simplification, contaminants were not simulated, which is welcome because they would hinder the simulation and not contribute to the discussions that were intended to be made.

For the selection of a pre-combustion source, we performed a brief literature review on hydrogen production processes from lignocellulosic biomass, a topic of interest for our research group. In these processes, a residual biomass is usually gasified, generating syngas (mainly composed by $H_2$ and CO, but also containing water and contaminants, such as $CH_4$, $CO_2$, $H_2S$ and particulates). The syngas stream then follows though some cleaning stages and undergo water-gas shift (WGS) for the production of more $H_2$ and $CO_2$. The $CO_2$ must be removed, and that is where the carbon capture technologies can be applied. The search was restricted to process simulation studies published in the last five years, and that presented a high level of detail (temperature, pressure, flow rate and composition) on the desired process stream. The thing is that the stream composition, especially the $CO_2$ content, can vary greatly depending on the feedstock processed, the gasification conditions and the subsequent steps, being usually higher, though, than that found in post-combustion sources.

Three articles called our attention: Meramo-Hurtado et al. [2] simulated the gasification of a mixture of rice and cassava waste. The produced syngas followed through the mentioned processing stages up to the $CO_2$

removal step, where a membrane technology was evaluated. Shamsi et al. [3] presented a steam reforming process aimed at removing the tars generated in the gasification of lignocellulosic biomass, increasing $H_2$ production and improving energy efficiency compared to the conventional process. The process was simulated with a pressure swing adsorption (PSA) unit, followed by MEA-PZ (monoethanolamine-piperazine) absorption. Finally, Cook and Hagen [4] simulated hydrogen production from different mixes of woody biomass, in a process fashion that also combined gasification and reforming. The removal of $CO_2$ was done with PSA. Comparing the process streams right after WGS in these three studies, that from Shamsi et al.'s study was the one that we considered the best representative of such streams and was the one selected for this study.

Table 1 presents the two emission sources used as examples in the present work, which can be considered typical post-combustion and pre-combustion sources. As can be seen, the post-combustion source (flue gas) is available at a higher temperature and lower pressure than the pre-combustion source (post-WGS syngas). Considering the conditioning steps required before absorption, these different conditions would typically imply different demands in terms of heating/cooling, and input/output of electric energy for pressurization/depressurization. All of that is accounted for in the NCB equation proposed in this work. In addition, the mole fraction of $CO_2$ is ten times higher in the pre-combustion source, which makes the absorption process easier, consequently demanding less energy and implying lower indirect emissions, as will be shown.

**Table 1:** $CO_2$ emission sources evaluated in this work.

| Stream | Post-Comb. [1] | Pre-Comb. [3] |
|---|---|---|
| Temp. (ºC) | 100.00 | 25.00 |
| Pressure (bar) | 1.00 | 12.00 |
| Flow rate (kg/hr) | 273654.06 | 27411.22 |
| Mole fraction | | |
| $CO_2$ | 0.0232 | 0.2740 |
| $H_2O$ | 0.1019 | 0.0030 |
| $N_2$ | 0.8749 | 0.3130 |
| $H_2$ | 0.0000 | 0.4100 |

An interesting fact – which also helps to justify the choice for the selected references [1, 3] – is that the flow rate of the post-combustion stream is around 10 times higher than the flow rate of the pre-combustion stream, making the flow rates of captured $CO_2$ of the same order.

## Process Simulations

The process simulations were performed in the Aspen HYSYS® software, utilizing the Acid Gas – Chemical Solvents thermodynamic package, which employs the Electrolyte NRTL (Non-Random Two-Liquid) activity coefficient model for the liquid phase and the Peng-Robinson equation of state for the vapor phase. In all the cases, the solvent used for $CO_2$ absorption was an aqueous solution of MEA at 30% by mass.

### Process description

The process flowsheet is illustrated in Figure 1. In the literature, the temperature range in the feed stream of the absorption column is generally cited as being in the range of 40 °C to 60 °C. In this work, the temperature was set at 40 °C. To ensure the gas stream from the emission source met the temperature and pressure conditions of the absorber inlet, a turbine or compressor (K-101) and a heater or cooler (E-103) were positioned upstream of the absorption column. The solvent stream entering at the top of the column contains a small amount of $CO_2$, as it is a recycle stream. The solvent flow rate was adjusted so that the capture ratio, defined as the mass of MEA used per mass of $CO_2$ captured, met the specification (see the definition of the Base Case scenario in the next section).

The absorption column was specified to operate at 3 bar in the post-combustion scenarios and 2 bar in the pre-combustion scenarios, with plastic Mellapak™ 250X packing. The number of stages was determined as the minimum required for the desired robustness (avoiding non-convergence problems), resulting in 80 theoretical stages for the post-combustion scenarios and 30 theoretical stages for the pre-combustion scenarios. The columns were sized by the simulation software, but the size of the columns was not subject of analysis in this work (of course, for a rigorous techno-economic evaluation, alternative designs should be assessed; for example, a very high column could be partitioned in two columns).

After absorption, the $CO_2$-rich solvent exiting the bottom passes through a flash vessel (V-101), used to remove traces of nitrogen present and to adjust the pressure before the regeneration column (T-101). Next, the stream passes through an integration heat exchanger (E-101), which raises its temperature. The inlet temperature to the regeneration column was defined based on the established heat integration, aiming to recover most of the heat available in the bottom product stream.

In the regeneration column, reflux ratio and reboiler duty were adjusted so that the heat ratio, defined as the heat supplied per mole of $CO_2$ captured, met the specification (see the definition of the Base Case scenario in the next section). The column was specified to operate at 1 bar, with total reflux condenser. Once again, the number of stages was determined as the minimum required for the desired robustness, resulting in 75 theoretical stages for the post-combustion scenarios and 40 theoretical stages for the pre-combustion scenarios.

After regeneration, the solvent passes through the

**Table 2:** Stream properties, Base Case, post-combustion process.

heat integration exchanger again, where it is cooled, then follows to a pump (P-100) for pressure adjustment and subsequently to a cooler (E-102) for temperature reduction. The final step to enable solvent recycling is the make-up of water and MEA (MIX-100), compensating for eventual losses. The solvent then returns to the top of the absorption column, closing the cycle.

## Simulated scenarios

Two scenarios were simulated for both the post-combustion and pre-combustion processes: a Base Case scenario and an NCB Zero scenario, which consists in configurations for which NCB equals zero.

The Base Case was defined by establishing three well-accepted procedural premises for carbon capture by MEA absorption: capture efficiency of at least 90% in relation to the amount of $CO_2$ present in the absorption column inlet stream; capture ratio of up to 10 kgMEA/kg$CO_2$; heat ratio of approximately 200 kJ/mol$CO_2$ in the regeneration column. In general, to meet these criteria, the following variables were manipulated: the solvent flow rate at the inlet of the absorption column, the reflux ratio and the reboiler duty of the regeneration column. Although a formal optimization study is not the objective of this work, optimizations performed informally by the authors in terms of NCB demonstrated that the values presented by most of the analyzed parameters were sufficiently close to their optimal values. The stream properties for the Base Case scenarios of the post-combustion and pre-combustion processes can be seen in Tables 2 and 4, respectively.

The NCB Zero scenario was achieved by means of manual modifications of the manipulated variables. The reason for bringing the NCB Zero Case into this analysis was to identify the system's equilibrium point in terms of carbon neutrality, in order to demonstrate the potential of the proposed carbon balance formulation to correlate process performance parameters with the actual carbon footprint of the evaluated technologies. The stream properties for the Base Case scenarios of the post-combustion and pre-combustion processes can be seen in Tables 5 and 6, respectively.

## Carbon Balance Analysis

All the parameter values necessary for solving Equation 1 are presented in Table 3, with the appropriate references. It is worth mentioning that the value adopted for the emission factor related to heating utilities utilization ($f_{e,h}$) is compatible with the use of natural gas as fuel, while the emission factor for electric energy utilization ($f_{e,e}$) corresponds to the value published by the Brazilian Ministry of Science, Technology and Innovation (MCTI) for 2023.

**Table 3:** Parameters for NCB calculation.

| Parameter | Value | Ref. |
|---|---|---|
| Steam boiler efficiency ($\eta_h$) | 0.90 | [5] |
| Pump efficiency ($\eta_{e,pump}$) | 0.75 | [6] |
| Turb./Comp. efficiency ($\eta_{e,t/c}$) | 0.85 | [7] |
| Fan efficiency ($\eta_{e,ref}$) | 0.90 | [8] |
| Heating emission factor ($f_{e,h}$)[a] | $5.59\times10^{-5}$ | [9] |
| Electricity emission factor ($f_{e,e}$)[a] | $1.07\times10^{-5}$ | [10] |
| Water specific heat ($Cp_{H2O}$)[b] | 4.18 | [11] |
| Water density ($\rho_{H2O}$)[c] | 1000 | [11] |
| Water temp. variation ($\Delta T$)[d] | 10 | [12] |

[a] Emission factors given in kg$CO_2$/kJ.
[b] kJ/kg.ºC.
[c] kg/m³.
[d] ºC.

The total thermal energy consumed in the heating stages was calculated as the sum of the duties of the regeneration column's (T-101) reboiler and E-103, when it is a heater. The total thermal energy removed in the cooling stages was calculated as the sum of duties of the regeneration column's condenser, the cooler (E-102) and E-103, when it is a cooler. All these duties can be obtained directly from the process simulator.

The total electric energy consumed or generated in the $CO_2$ absorption process was obtained from the sum

**Table 4:** Stream properties, Base Case, pre-combustion process.

| $H_2O$ | 0.0030 | 0.0334 | 0.8634 | 0.8416 | 0.8630 | 0.0504 |
| $N_2$ | 0.3130 | 0.4120 | 0.0000 | 0.0000 | 0.0000 | 0.0001 |
| $H_2$ | 0.4101 | 0.5397 | 0.0000 | 0.0000 | 0.0000 | 0.0002 |

of the energy contributions of the pump (P-100) and the turbine or compressor (K-101), whose power ratings can be obtained directly from the process simulator. It is important to note that the turbine reduces net electricity consumption, as it generates energy. Therefore, its contribution must be considered with a negative sign in the summation, representing an energy gain rather than a cost. The possibility of harnessing energy from pressurized streams is a characteristic of pre-combustion streams, which can make a difference in certain cases.

The electric energy consumption related to the cooling water plant can be calculated according to Equation 2 [8]:

$$E_{ref} = \frac{F_{tower}.2.432\times10^{-4}}{\eta_{ref}} \quad (2)$$

where: $E_{ref}$ is the heat exchanged in the water refrigeration tower, in GJ/hr; $F_{tower}$ is the flow rate of water in the refrigeration tower, in $m^3$/hr; and $\eta_{ref}$ is the efficiency of the refrigeration tower fan.

The water flow rate in the refrigeration tower, in turn, can be calculated according to Equation 3:

$$F_{tower} = \frac{\sum q_c}{Cp_{H2O}.\Delta T.\rho_{H2O}} \quad (3)$$

where: $Cp_{H2O}$ is the specific heat of water at constant pressure, in kJ/kg.ºC; $\Delta T$ is the temperature variation of the cooling water in the tower, in °C; and $\rho_{H2O}$ is the density of water, in kg/$m^3$.

The cold utility contribution to NCB can then be calculated by multiplying $E_{ref}$ by the electricity emission factor ($f_{e,e}$), subsequently correcting it to kJ/hr as shown in Equation 4:

$$f_{e,c} \cdot \sum q_c = f_{e,e} \cdot E_{ref} \times 10^6 \quad (4)$$

As formulated, NCB should ideally be negative, and the lower its value, the better the environmental performance of the process, in absolute terms of $CO_2$ emission abatement. However, in order to compare different processes, especially $CO_2$ capture technologies applied to emission streams with very different flow rates and compositions, or solutions obtained for the same capture technology that exhibit different capture efficiencies, it is convenient to define a Net Carbon Ratio (NCR):

$$NCR = \frac{NCB}{w_{CO2,cap}} \quad (5)$$

In this work, it allows a fairer comparison of the results for the Base Case scenarios.

## RESULTS AND DISCUSSION

### Base Case

The stream properties for the Base Case scenarios of the post-combustion and pre-combustion processes are presented in Tables 2 and 4, respectively, and the results for the main process parameters can be seen in Table 7. Comparatively, the post-combustion scenario required a higher MEA-to-$CO_2$ capture ratio to achieve an equivalent performance, which is expected due to the much lower $CO_2$ content in the emission source (leading to thermodynamic and mass transfer limitations). Besides that, the need for more solvent has direct impact on the heat ratio in the reboiler of the regeneration column, since more solvent must be evaporated.

This result can be translated in terms of NCB (and NCR): both processes can be considered effective because they contribute to a net abatement of $CO_2$, as indicated by the negative sign of NCB. However, the pre-combustion capture process is more effective than the post-combustion process, since it allows twice the relative abatement (NCR of -0.62) of the post-combustion process (NCR of -0.29). In other words, 71% of the captured $CO_2$ were offset by indirect emissions in the post-combustion process, while only 38% were offset in the pre-combustion process. It is important to emphasize that these processes were not optimized and are being presented in this paper only to illustrate the methodology.

**Table 5:** Stream properties, NCB Zero Case, post-combustion process.

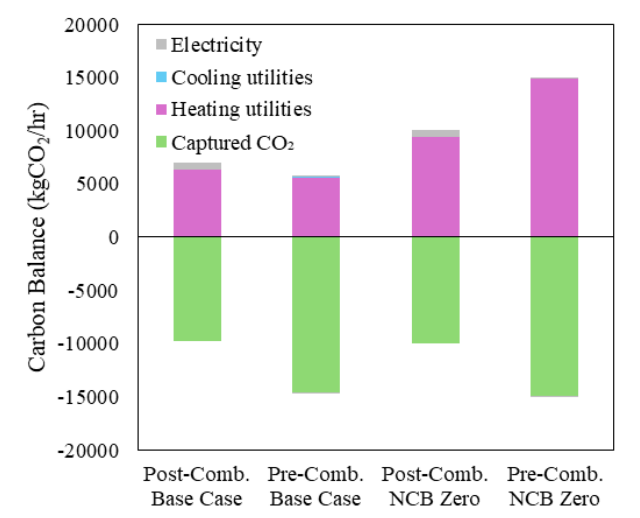

**Figure 2.** NCB breakdown.

It is also interesting to look at the relative contributions of each energy type to the net carbon balance, which can be done with Figure 2. The reboiler duty corresponds to 99% of the energy demand for heating in the post-combustion process, and 95% in the pre-combustion process. As a consequence of the use of natural gas for vapor generation in the boiler, it accounts for around 90% and 95% of the total indirect $CO_2$ emissions, respectively. It means that the environmental effectiveness of these carbon capture processes could be greatly enhanced with the use of lower emission energy sources – eventually renewable energy – for heating, which would reduce the value of $f_{e,h}$. This information is not new, but the advantage of using the proposed NCB formulation in this analysis is that it can be directly inferred from the equation, which synthesizes, in the emission factors, the results of sustainability analyses performed elsewhere.

Electricity consumption accounts for less than 10% of the indirect emissions in the post-combustion MEA absorption process, because the inlet stream must only be pressurized from 1 to 3 bar. In the pre-combustion process, its contribution is even negative, because inlet stream depressurization from 12 to 2 bar can be used to generate electricity (there is an implicit assumption here, that this electricity would be useful elsewhere in the plant, since it is more than what is needed in the carbon capture process itself). In this regard, two comments must be done: first, the relative importance of this term can be higher for technologies that require significant pressure increases, such as membrane separation, for example; second, it strongly depends on the environmental footprint of electricity generation, translated in $f_{e,e}$ (the Brazilian electric energy matrix, used as a basis for

this analysis, is much cleaner than the ones in US or China, for example). It shows that the proposed NCB formulation is an efficient way to compare different locations for carbon capture technologies too. The moment in time can also be evaluated, since national and international agencies are constantly updating these emission factors.

## NCB Zero

The stream properties for the NCB Zero scenarios of the post-combustion and pre-combustion processes are presented in Table 5 and 6, respectively, and the results for the main process parameters can be seen in Table 7. Since the Base Case scenarios for both processes were effective in mitigating net $CO_2$ emissions (negative values of NCB), the equilibrium point would occur under more demanding conditions, for example for obtaining higher $CO_2$ recoveries, as can be seen in the tables. It would be achieved, in MEA absorption systems, with higher heat ratios in the reboiler of the regeneration column.

As a consequence of the increased energy consumption for heating, more fuel must be burned, resulting in higher indirect emissions. In this context, 100% of the $CO_2$ recovered in the capture process is emitted in the same plant, nullifying the environmental benefits of carbon capture. This is an easy way to demonstrate that higher $CO_2$ recovery rates do not necessarily result in lower net emissions, and that indirect emissions must always be taken into account in the evaluation of carbon capture technologies.

The single equation format proposed for NCB, therefore, presents great potential not only for use as an objective function, but also as a constraint in optimization problems, particularly when other environmental or economic aspects are being considered. It is important to point out that this format is not unchangeable: other terms, such as fugitive emissions, could be added, and the emission factors could be recalculated in a dedicated work through the formulation of inventories (life cycle assessment). It is convenient, however, to have a simple

and straightforward way to quantify the net carbon balance. This is the contribution of this paper to the technical and scientific literature.

## CONCLUSION

In this paper, we propose a single equation format for NCB calculation, accounting for direct and indirect $CO_2$ emissions associated with the evaluated technologies. It can be easily adapted, however, to account for fugitive emissions, as well as emissions throughout the entire life cycle of the analyzed processes or products. For example, it is worth noting that the proposed equation only considers operating carbon emissions, but does not consider emissions related to building the capture plant itself. It could be accounted for, if the user wishes.

With this formulation, it was possible to easily demonstrate that higher capture efficiencies do not necessarily correspond to maximum emission mitigation scenarios. Indeed, lower emissions are associated with lower energy consumption, which will depend on the type of stream (composition, condition) being treated, and, in this context, the $CO_2$ content in the emission source is a relevant parameter. However, better than simply accounting for energy consumption is directly assessing the associated emissions, since emission factors are readily available and can be used to evaluate different technologies in terms of time, location and available energy sources.

In next works, we plan to show how the NCB formalism can be applied in optimization studies, serving as a successful, quantitative, non-subjective, objective function and/or constraint.

## ABSTRACT

Flexible, electrified systems for chemical and energy production are promising alternatives to traditional, hydrocarbon-based processes. Flexible systems have the potential to reduce costs and emissions, but the interconnection between design and operation makes these systems challenging to implement. We use an operation-informed design framework to model a flexible, electrified ammonia synthesis system. We examine the levelized cost and carbon intensity of ammonia in response to different grid emissions (0-420 kg/MWh). We find levelized costs from 700-1200 $/ton-$NH_3$ and observe non-monotonicity in carbon-intensity with respect to grid emissions. We rationalize this trend as a design transition from large, grid-reliant systems to smaller, flexible designs that are grid independent. We then study how synergies in demand and unit-operation flexibility can lower both the price and carbon-intensity of ammonia production. We find that for seasonal, or yearly demand (rather than hourly), a fully flexible Haber Bosch process can achieve 20% lower costs and reduce its carbon-intensity by ~70-100%. We highlight major challenge in decarbonization, but also the importance flexibility plays in reducing carbon-intensity. Together, these analyses demonstrate that flexibility helps electrified industrial systems achieve financial and environmental goals.

**Keywords**: Multiscale Modelling, Energy Systems, Process Design

## INTRODUCTION

Global manufacturing relies on chemical and energy systems to interconvert matter and energy. Fundamental production processes for energy, commodity chemicals, and construction material are the basis of the international supply chain. Fossil fuels serve as cheap precursors for these processes, but petroleum resources dwindle as material and energy demand increase. The future security of manufacturing requires a switch to sustainable production.

Flexible, electrified systems are attractive alternatives to traditional processes because they can selectively access intermittent renewable power, avoid operation during energy price spikes, and participate in demand response programs. Despite these benefits, flexible systems struggle to penetrate the chemical sector due to challenges in design and operation. Many unit operations have limited flexibility, requiring mass and energy storage devices to buffer their exposure to variability. The interplay between storage, flexible, and inflexible units creates a challenging problem; the optimal design depends on the holistic operation of the system. Newly developed frameworks for operation-informed design can be implemented to understand how chemical and energy systems respond to multi-scale variability [1]. These frameworks can also be used to identify transitions in design and operation for different conditions such as energy availability, grid renewability, and demand side flexibility.

To identify and address systemic challenges in decarbonization, we implement an operation-informed design framework to perform a case study on electrified ammonia synthesis. Previous studies have examined the levelized cost of ammonia (LCOA) for electrified systems [2, 3, 4]. However, these studies do not fully examine the

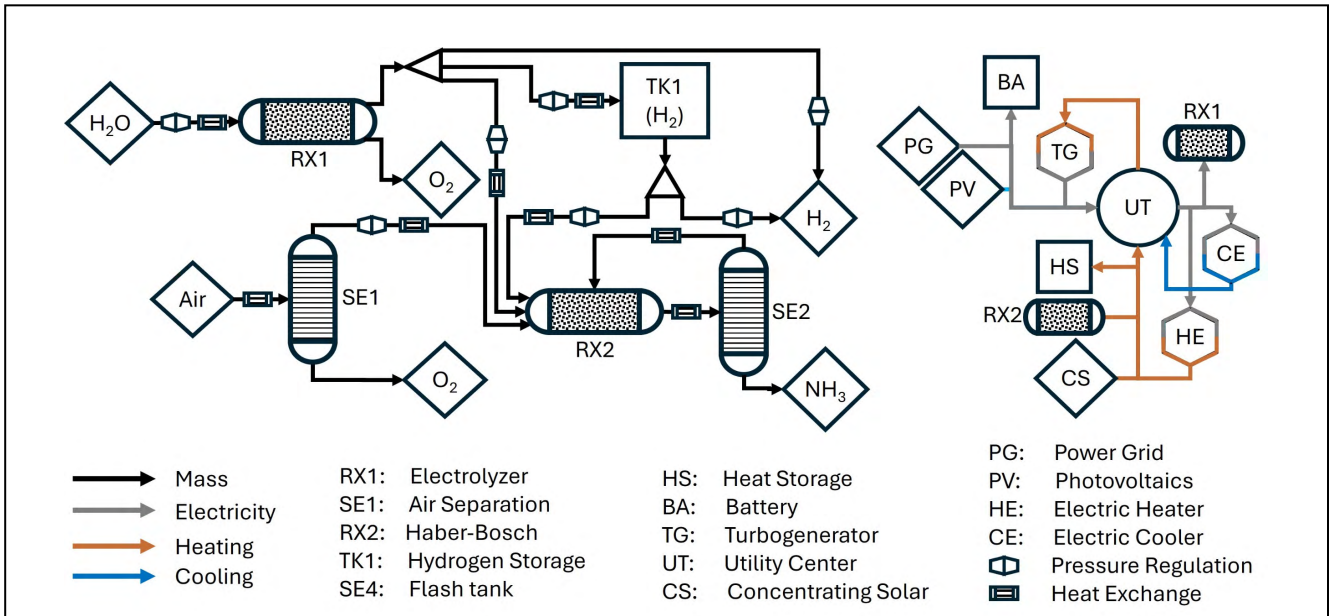

**Figure 1.** Superstructure for flexible, electrifed, ammonia sythesis. The system is connected to the power grid, and can also generate and interconvert power from solar irradiance onsite. Mass and energy storage allow for flexible operation in response to variability in energy price, availability, and associated emissions.

interplay between optimal design and operation. They are either simulation based (and require a pre-supposed design) or focus on operation under uncertainty, and sacrifice detail in terms of the system design and unit models. Recently, studies have suggested that process flexibility can positively impact the environmental and economic outcomes of ammonia synthesis [5, 6]. However, they utilize coarse grain system models and focus broadly on ammonia synthesis across different locations and modes of production. More detailed models exist in the context of process control, but do not optimize design [7].

The operation-informed design framework we use captures non-linearities in design (economies of scale) and operation (thermodynamics) in a single mathematical program. We use this to study the impact of grid emissions on the environmental and economic outcomes of this system. We then understand these outcomes by examining transitions in optimal design and operation. We also analyze the synergy between unit-operation and demand flexibility to identify conditions that can reduce the cost and carbon intensity of electrified ammonia production.

# METHODS

## Superstructure

We consider a system superstructure for flexible, electrified ammonia synthesis (Figure 1). The system can utilize grid electricity ($\leq$ 1 GW) or generate power onsite using photovoltaics and/or concentrating solar units ($\leq$ 10 km$^2$ total panel area). We utilize an emission penalty of 300 \$/ton-$CO_2$ for grid related emissions [8]. Heating, cooling, and electricity can be interconverted using power conversion units (heaters, coolers, turbogenerators). Hydrogen is generated via water electrolysis, and nitrogen is purified using cryogenic distillation of air. Hydrogen and nitrogen are converted to ammonia according to the Haber-Bosch reaction. The system can install hydrogen storage ($\leq$ 1500 m$^3$), as well as electricity and heat storage ($\leq$ 500 MWh each). All units are assumed to be flexible except for the Haber-Bosch reactor, which has limited flexibility.

## Time Structure

The time-structure for the system is a 30-year time horizon with six epochs, each corresponding to five-years. An epoch is represented by a one-year operating period composed of four seasons. Each season contains representative days chosen from 3-years of power-grid data (Figure 2). The representative period accounts for hourly variability in electricity price, grid emissions, and solar irradiance using data from the CAISO grid [9, 10, 11].

Representative days for a season are generated using an IP clustering algorithm which groups individual days around a representative [1]. The algorithm minimizes the distance between all days and their representative at a fixed cost per representative. The time points in a representative day are weighted by the number of days they represent; representatives for larger clusters are weighted more heavily than smaller clusters (which typically represent atypical days). The representative days are hierarchy concatenated to form a season and subsequently a year, which is used as the

operating period for the epoch. We allow for discontinuity in process operation between, but not within, seasons. We do not consider retrofitting in this analysis, and the operation across epochs is repeated.

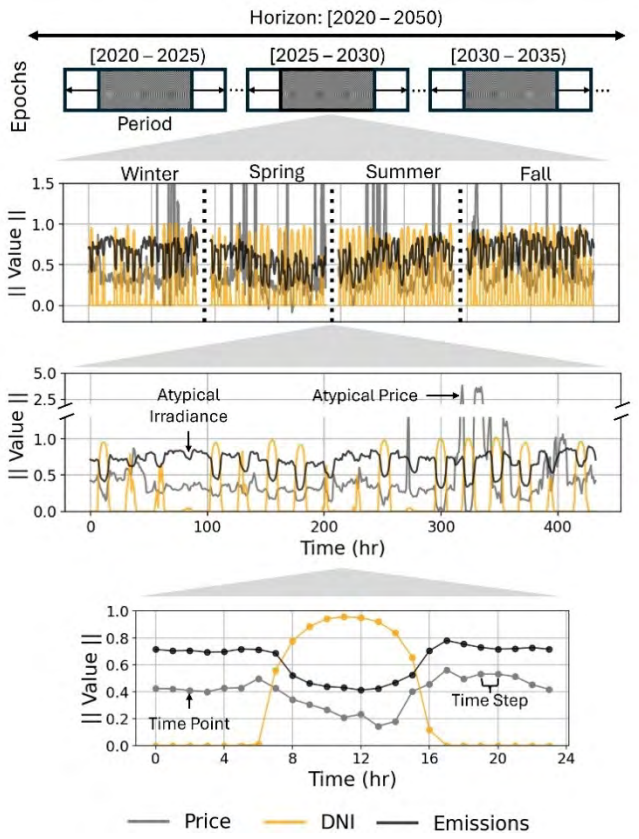

**Figure 2.** A 30 year horizon is partitioned into six epochs of five years. Epochs corresponds to a representative year with four seasons. Seasons are composed of representative days at an hourly resolution.

## Mathematical Program

We utilize an operation-informed design framework to formulate a mathematical program for the system. This framework includes unit models for conversion reactors, separators, heaters, coolers, expanders, compressors, as well as mass and energy storage. Each unit has constraints enforcing mass (eq. 1) and energy (eq. 2) balances, as well as thermodynamic relationships (eq. 3) as described in [1].

$$\begin{aligned} \min \quad & C_{NH3} \\ \text{s.t.} \quad & \mathbf{m}(\mathbf{x}_t, \mathbf{x}_{t-1}) = 0 && \forall\, t \in \mathbf{T}\backslash\mathbf{T^0} && (1) \\ & \mathbf{e}(\mathbf{x}_t, \mathbf{x}_{t-1}) = 0 && \forall\, t \in \mathbf{T}\backslash\mathbf{T^0} && (2) \\ & \mathbf{h}(\mathbf{x}_t) = 0 && \forall\, t \in \mathbf{T} && (3) \\ & \mathbf{l}(\mathbf{y}) \le \mathbf{o}(\mathbf{x}_t) \le \mathbf{u}(\mathbf{y}) && \forall\, t \in \mathbf{T} && (4) \\ & NPV = 0 && && (5) \end{aligned}$$

Here, $\mathbf{x}_t$ are the operating variables at time $t$ and $\mathbf{y}$ are design variables. Limits on operation $\mathbf{o}(\mathbf{x}_t)$ are set relative to functions of the design: $\mathbf{l}(\mathbf{y}), \mathbf{u}(\mathbf{y})$ (eq. 4). $\mathbf{T}$ is the set of time points in the time structure, and $\mathbf{T^0}$ is the first time point in a season. The cost for unit operations is calculated based on their capacity, and the total capital expenditure is amortized over the process horizon. The system generates revenue by selling ammonia, and has operating expenses related to maintenance and labor, electricity purchase, and emissions penalties. There is a 21% corporate tax on profit. We find the system LCOA by minimizing the selling price of ammonia ($C_{NH3}$) subject to a net present value of zero (eq. 5).

First, we demonstrate how the optimal system LCOA, design, and operation change with respect to different levels of grid emissions. We consider representative profiles for the power grid with average emissions from 0-420 kg/MWh. The ammonia production capacity is a design variable between 5 and 100 tons/hr. We assume that there is no demand flexibility, such that the system maintains production at its nominal capacity. For this analysis we use a time structure containing 16 representative days for a period (Figure SI.1a).

Then, to understand how flexibility impacts the LCOA of the system, we fix ammonia production to 45 tons/hr and examine different combinations of demand and process flexibility. We consider systems with hourly demand (eq. 6), seasonal demand (eq. 7), and yearly demand (eq. 8). Average grid emissions are 220 kg/MWh. The sensitivity analysis utilizes 16 representative days for a period. We then analyze design and operation of flexible and inflexible systems using a 77-day time structure (Figure SI.1b).

$$M_{t,NH3} = \delta \;\forall\, t \in \mathbf{T} \tag{6}$$

$$\sum_{t \in \mathbf{T}_s^S} \omega_t M_{t,NH3} = \frac{1}{4}\delta \;\forall\, s \in \mathbf{S} \tag{7}$$

$$\sum_{t \in \mathbf{T}_p^P} \omega_t M_{t,NH3} = \delta \;\forall\, p \in \mathbf{P} \tag{8}$$

$\mathbf{P}$ the set of periods, $\mathbf{S}$ is the set of seasons, $\mathbf{T}_s^S$ is the set of time points for a season, and $\mathbf{T}_p^P$ is the set of time points for a period. $M_{t,NH3}$ is the production of ammonia at time $t$, $\delta$ is the ammonia demand, and $\omega_t$ is the weight for a time point (weights sum to one over $\mathbf{T}_p^P$). For each demand type, we quantify the LCOA for different levels (0-100%) of hourly flexibility from the nominal design of the Haber-Bosch reactor. We then examine how design and operational changes improve the LCOA.

The model is solved using CONOPT. Computations were performed on the Princeton Della computing cluster, using 2.8 GHz Intel Cascade Lake CPUs. Additional details can be found in the supplemental information.

# RESULTS

## Grid Renewability Analysis

We find a range of LCOA from 700-1200 $/ton over a

range of grid emissions from 0-420 kg-$CO_2$/MWh. We identify that the trend in LCOA increases linearly from 0-140 kg-$CO_2$/MWh before exhibiting a non-linear response to changes in grid emissions (figure 3a).

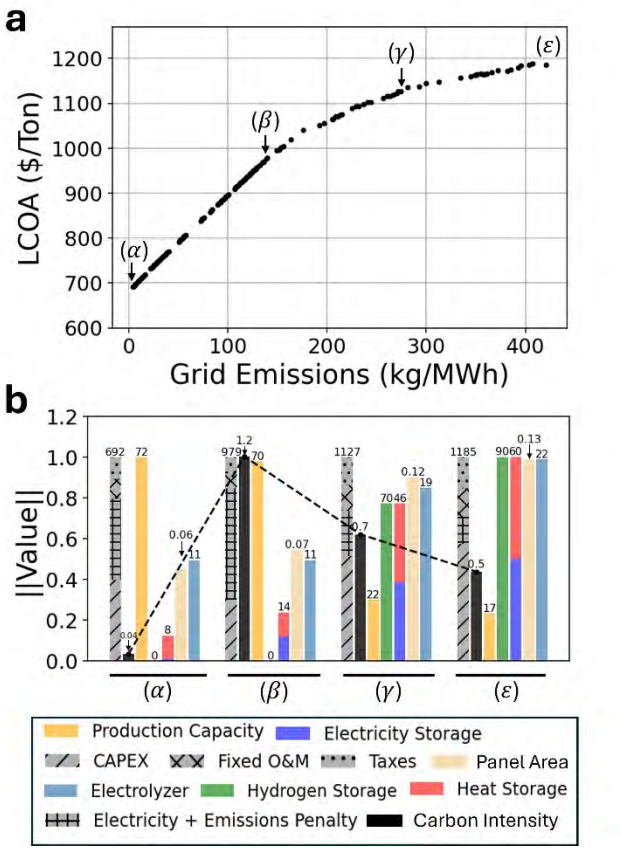

**Figure 3.** The levelized cost of ammonia for different average grid emissions (a). The contributions to the LCOA are shown in grey, along with production capacity in orange (ton-$NH_3$/hr), and carbon intensity in black (ton-$CO_2$/ton-$NH_3$). Relative to production capacity, mass storage ($m^3$), energy storage (MWh), solar facility panel area ($km^2$), and electyrolyzer capacity (MW) are also shown (b). Values have been normalized to lie between zero and one for the purpose of visualization; actual values appear above each bar.

This change is rationalized as a transition point in design and operation when examining instances $\alpha, \beta, \gamma, \varepsilon$. From 0-140 kg-$CO_2$/MWh, the production capacity remains constant, but the fraction of expenses due to emissions rises steadily. In this range, the process has a high production capacity but relies on the grid to provide power during the night, when onsite renewables are inactive. At ~140 kg-$CO_2$/MWh, operating costs dominate capital expenditure, and it becomes optimal to redesign the process: production capacity decreases, and the proportional level of mass and energy storage increase. This allows the process to operate more flexibly. Increased storage reduces power usage from the grid during levels of low solar irradiance. In turn, operating costs drop but capital costs increase disproportionately due to decreased economies of scale and overdesign (Figure 3b). Specifically, as emissions rise from 140 to 420 kg-$CO_2$/MWh, the relative electrolyzer capacity and solar facility size double. Overdesign allows these systems to operate independently from the grid but drastically increases capital costs.

The interplay between capital and operating expenditure causes non-monotonic behavior in the carbon-intensity of the system. Systems operating in low or high emission grids produce ammonia at a lower carbon intensity than grids with intermediate emissions. This presents a major challenge to ammonia decarbonization through electrification. Moderate improvements in grid renewability may not improve system level emissions. Carbon intensive grids must decarbonize significantly for green ammonia production to be competitive. Unfortunately, changes to the grid are often slow and incremental. However, these results suggest that increasing system flexibility is the key to achieving lower emissions and prices.

## System Flexibility Analysis

Storage is not the only sources of flexibility; it can also be achieved by unit operations or the demand side.

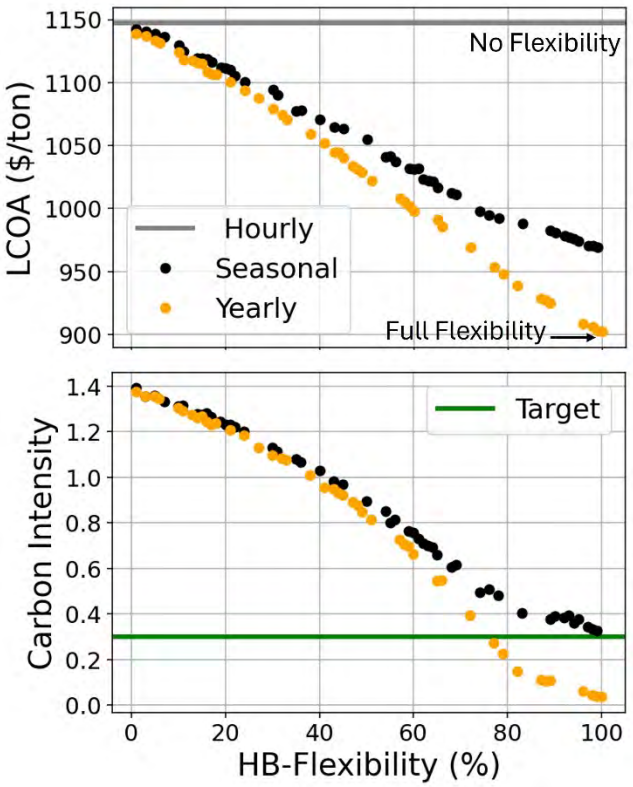

**Figure 4.** Levelized cost of ammonia and carbon intensity (ton-CO2/ton-$NH_3$) for different levels of Haber-Bosch (HB) flexibility with hourly, seasonal or yearly demand.

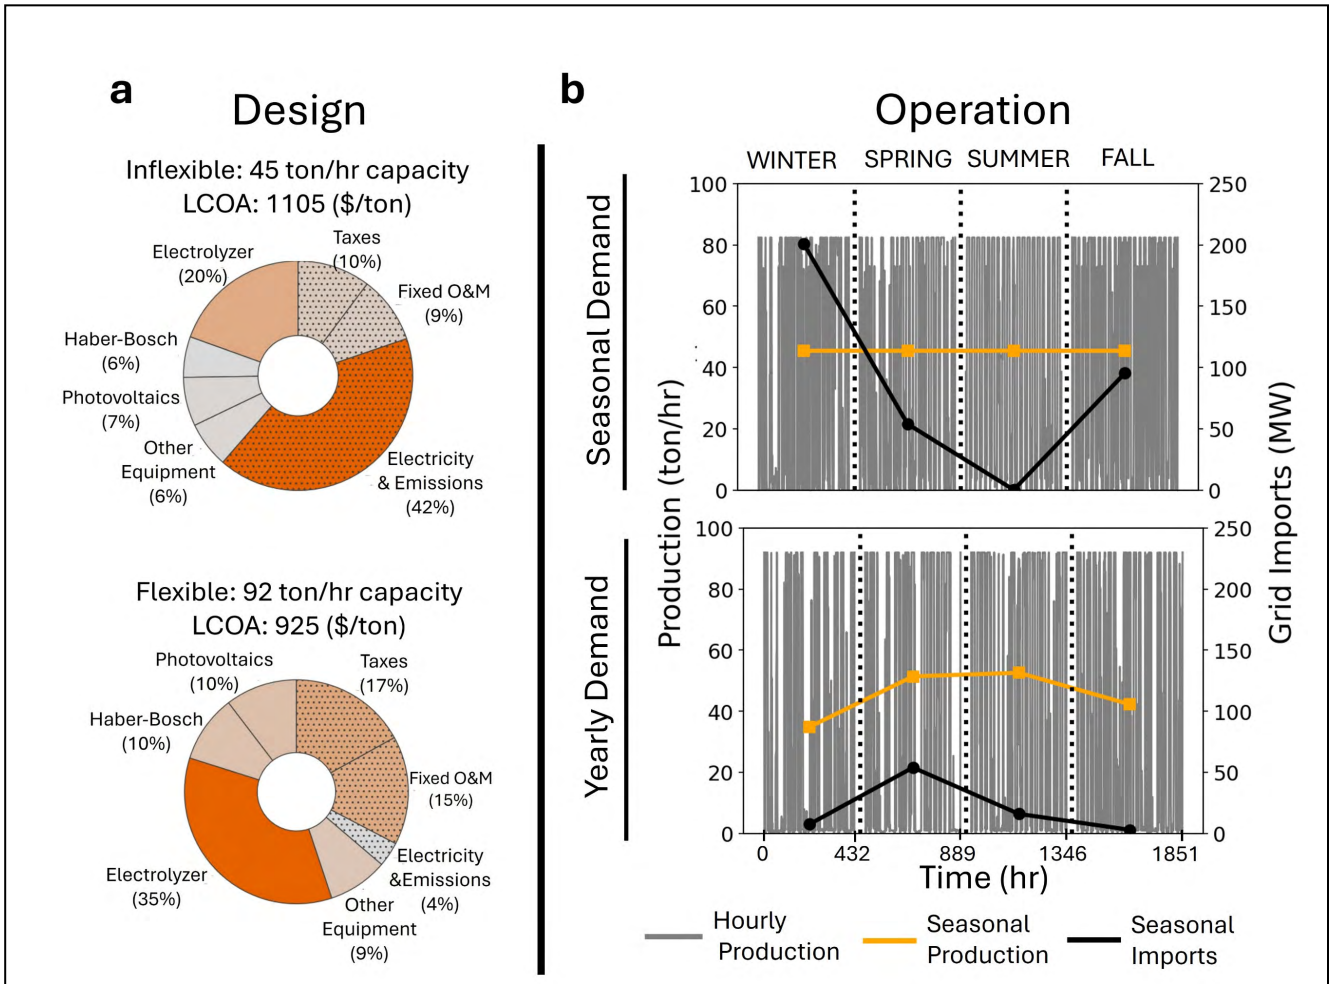

**Figure 5.** Contributions to the LCOA for an inflexible and flexible system (a). Hourly production of ammonia, as well as the seasonal average production and electricity imports from the power grid (b).

We find that synergies between demand and unit operation flexibility drastically reduce ammonia price and emissions. When considering seasonal or yearly demand, Haber-Bosch flexibility can reduce the LCOA by almost 20% (Figure 4a) without requiring inordinate storage capacity. Increased flexibility in the Haber-Bosch process can also move electrified systems towards, and even below, the target carbon intensity for green ammonia (0.3 ton-$CO_2$/ton-$NH_3$); unit flexibility, when coupled with seasonal or yearly demand flexibility, reduces the systems emissions by almost 70% and 100%, respectively.

When examining the LCOA of inflexible and flexible processes, we see that a high level of flexibility results in an islanded process that purchases very little electricity from the power grid. The flexible design is dominated by capital expenditure and is designed at approximately twice the nominal capacity of the inflexible design (Figure 5a). Examining the operation, it is observed that flexible processes produce twice as much material per hour during the day when compared to the inflexible designs but forgo operation during hours of low solar irradiance. Flexible systems benefit from increased economies of scale, and because they do not rely on the grid for power, they also are insensitive to spikes in electricity price and emissions, which often coincide with hour of low solar irradiation.

While the difference in the LCOA and carbon intensity between systems with seasonal and yearly demand is negligible at low to moderate levels of unit flexibility, the difference becomes pronounced at high levels of unit flexibility. Systems with seasonal demand have a different relationship with the power grid than those with yearly demand. Irradiance is low in the winter and fall, so systems with seasonal demand meet the demand requirement by supplementing their onsite power production with grid electricity. For yearly demand, higher production during the spring and summer make up for decreased production during the winter and fall. These seasonal changes in operation allow systems with yearly demand flexibility to achieve almost complete utility independence (Figure 5b); electricity is purchased sparingly from the grid during the spring and summer, and only because very low prices and emissions are achieved during the day.

## CONCLUSIONS

Using a framework for operation-informed design, we have modeled a flexible, electrified ammonia synthesis system. We use this model to quantify how the levelized cost of ammonia changes for different grid emissions and understand the transitions in design and operation associated with these different grids. We also find non-monotonicity in the carbon intensity of this system due to transitions in production capacity. At low grid emissions, large, grid-reliant processes are optimal due to economies of scale. These designs remain optimal even as grid emissions rise, causing a sharp increase in carbon intensity. At emission rates of approximately 140 kg-$CO_2$/MWh, the operating expenditure for electricity and emissions penalties justify a significant downscaling of production capacity. Smaller systems can better leverage onsite energy and mass storage, operating with increased flexibility and reduced grid-reliance. It is important to note that these systems do utilize more land relative to production when compared to grid-reliant systems. Considering the ecological impact of land usage was outside the scope of this work, but in regions with limited land availbility, or sensitive ecosystems, solar power may not be a viable option physically or environmentally. The trends identified in this analysis highlight the importance of operation-informed design, and the role of flexibility in achieving ammonia decarbonization.

We also identify synergies between demand and unit-operation flexibility. We find that improved Haber-Bosch flexibility can lower LCOA by 20% and significantly reduce carbon-intensity for systems with seasonal or yearly demand. Highly flexible systems are designed at much higher capacities than inflexible systems but only operate during hour of peak solar irradiation. Flexible systems are not dependent on the grid, even during hours of low irradiance. Systems with fully flexible unit operations and seasonal demand can achieve a carbon-intensity of approximately 0.3 ton-$CO_2$/ton-$NH_3$ (a target for green ammonia). With yearly demand, these systems can achieve nearly zero emissions by adjusting operation to match seasonal changes in energy availbility.

The results demonstrate the importance of flexibility in achieving economic and environmental targets. They also illustrate synergy between multiple forms of flexibility: unit-level, demand-side, storage. Because optimal flexible systems can have drastically different designs from their inflexible counterparts (and even from one other), it is important to evaluate all contributions to flexibility. Operation-informed design frameworks are particularly powerful for these analyses. While there are many challenges to decarbonization through industrial electrification, studying optimal design and operation together uncovers nuanced trends in these systems, and allows us to make informed and intelligent decision about the transition to sustainability.

## ABSTRACT

Behind-the-meter generation from variable renewable energy is a potential pathway for new data centers to obtain power more quickly and more sustainably than interconnecting to existing electrical grids. Energy storage is needed to accommodate the variability of wind and solar energy across multiple timescales. Hydrogen from electrolysis and ammonia made from this hydrogen can be used as fuel for dispatchable power generation while offering lower $/MWh storage costs than batteries. In this work, we analyze the economics of using hydrogen, and/or ammonia along with batteries in hybrid energy storage systems to enable data centers to be powered by 100% renewables. We perform this analysis using an optimization model for the selection, sizing, and coordinated hourly operation of constituent energy storage technologies toward minimizing the levelized cost of energy (LCOE). The model uses an hourly resolution scheduling horizon of five years to account for hourly, seasonal, and interannual renewable variability. We use this model to specifically analyze the economics of to 5 MW, 50 MW, and 500 MW sustainable data center energy systems in three relevant American locations. We find that including ammonia energy storage in hybrid systems with batteries and hydrogen enables lower LCOE across all scales and locations by reducing energy storage capital investments despite deploying an order-of-magnitude more storage capacity while also enabling less investment in renewable generation. Ammonia is used for seasonal and interannual energy storage and its inclusion in these hybrid storage systems is most advantageous for larger-scale data centers in locations with high wind potential.

## INTRODUCTION

In the United States, the development of renewable generation projects outpaces the addition of the new transmission infrastructure needed to maximize the use of this renewable power within existing electrical grids [1]. In fact, the average wait time for grid interconnection requests for U.S.-based generation projects is five years [2]. The wait time of this interconnection queue is similar for large industrial customers who wish to purchase power from the grid. As a result, new industrial power users who wish to more quickly begin operations prefer “behind-the-meter” power supply wherein they are directly connected to a generation source. Data centers are an increasingly important example of these industrial consumers. At present, they are being rapidly deployed to facilitate the growing adoption of artificial intelligence. By 2030, data centers are projected to be responsible for at least 10% of total U.S. energy consumption [3, 4]. Using behind-the-meter renewables to provide power for data centers provides an opportunity to ensure that this growing customer segment is sustainable from an energy perspective while also lessening the impact of interconnection constraints on the continued development of renewable generation projects.

Energy storage technologies are a necessary aspect of meeting data center power demands, which are generally constant over time, using variable renewable energy. This variability manifests over multiple timescales from within a day to between consecutive years. Batteries are the most well-developed energy storage technology and are well-suited for managing short-term variability, but their deployment is limited by high energy storage costs for long-term supply-demand imbalances. As

such, previous research on energy storage systems for data centers has considered the use of dispatchable fossil-based generation to limit the required size of battery installations [5, 6]. Hydrogen obtained from water via renewable-powered electrolysis can act as dispatchable fuel source without incurring any carbon dioxide emissions upon reconversion to electrical power. The economics of hydrogen energy storage have previously been investigated in the context of data centers [7, 8]. In [7], hydrogen storage was used in a grid-connected data center to facilitate demand response. In [8], hydrogen storage was coupled with bifacial PV in Arctic locations to enable 100% renewable operation. To this end, over 1, 000 metric tons (mt) of hydrogen storage was needed, which may not be suitable for all locations. Furthermore, analysis in [8] did not consider interannual solar generation variability, the management of which could require even more energy storage capacity in a behind-the-meter, 100% renewables system.

Converting hydrogen to ammonia by combining it with nitrogen separated from air can facilitate higher energy storage capacities than hydrogen itself. Ammonia energy storage has been of particular interest over the past decade for high capacity, long duration energy storage due to higher achievable storage volumes as well as lower storage costs [9]. As with hydrogen, ammonia can be used for dispatchable power generation via fuel cells or combustion [10, 11]. To our knowledge, the economics of ammonia energy storage in the context of data centers have not been previously analyzed. We have previously investigated the economics of ammonia energy storage for 100% renewable energy storage in 1 MW residential microgrids U.S. throughout the continental U.S. [12] and combined heat and power systems in remote U.S. locations [13]. Ammonia energy storage economics have also been analyzed in facilitating the energy transition of different provinces in Spain [14], enabling exclusively solar power to meet 4 MW residential power demand in Florence, Italy [15], and using ammonia for both energy storage and export in Can Dao, an archipelago off Vietnam's Southern Coast [16].

These previous efforts employed quantitative modeling approaches to determine the best deployment of ammonia energy storage to manage renewable variability. Specifically, these works used optimization models wherein technology selection, sizing, and operational scheduling decisions are made simultaneously toward lowest cost. This is the state-of-the-art approach for modeling renewables-based chemical production and utilization [17, 18]. In the context of ammonia energy storage, this optimization approach has been implemented using mixed integer linear programming (MILP) models solved via branch-and-cut algorithms [12-14, 16] or using software based on hierarchical operational rules for scheduling [15].

Scheduling decisions in these optimization models are typically made over a yearlong horizon with hourly resolution, including in [12-16]. This allows optimal energy storage system design to account for renewable variability across hourly to seasonal timescales. A representative year which agglomerates multiple years of historical or forecasted weather data is usually selected for this purpose. However, previous work on ammonia energy storage has not considered interannual variability in renewable generation. In general, renewable potential can vary considerably over consecutive years and its consideration in the design of renewable energy systems can increase reliability [19]. Interannual variability has only been previously considered in the economic analysis of renewable ammonia production [20]. We hypothesize that ammonia's low storage cost can facilitate economical interannual energy storage.

In this work, we investigate the economics of using hydrogen and/or ammonia along with batteries in hybrid energy storage systems to facilitate meeting data center power demands using only renewable energy. We specifically formulate a combined design and scheduling model which employs multiple years of historical, hourly resolution time series data to capture interannual renewable variability as well as hourly and seasonal variability which have been considered in previous work. We use this model to analyze the optimal economics of sustainable data center energy systems at 5 MW, 50 MW, and 500 MW power demand scales in three American metropolitan areas: Northern Virginia (NoVa), Dallas-Fort Worth (DFW), and Las Vegas. The goal of this work is to determine the merit of hydrogen and ammonia energy storage toward providing economical and sustainable energy for data centers, the most rapidly growing segment of industrial power consumption.

## CASE STUDY DESCRIPTION

### Battery-$H_2$-$NH_3$ Energy Storage

The energy storage system we analyze in this work must meet data center power demand using energy generated exclusively from wind and solar resources and energy storage (see Figure 1). Energy can be stored directly in its electrical form using battery storage. It can also be used to produce hydrogen via water electrolysis which can be stored as gas at 200 bar and used for dispatchable power generation. Electrical energy can also be used to separate nitrogen from air and combine it with hydrogen to make ammonia, the synthesis of which is also electrically powered. Ammonia can be stored as liquid and used for dispatchable power generation.

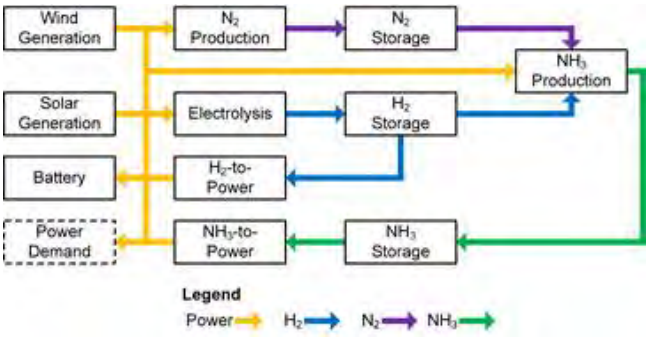

**Figure 1.** Conceptual diagram of 100% renewable energy system with battery, hydrogen, and ammonia energy storage pathways.

## Combined Optimal Sizing & Scheduling Model

The optimization model we use minimizes the levelized cost of energy (LCOE) of meeting data center power demands using behind-the-meter renewables and hybrid energy storage. The LCOE includes capital investments (CapEx) of all technologies in Figure 1, annualized by a capital recovery factor (CRF), as well as annual operating costs (OpEx):

$$LCOE\left(\frac{\$}{MWh}\right) = \frac{CapEx \times CRF + OpEx}{Demand} \quad (1)$$

The model simultaneously optimizes the selection, sizing, and operational scheduling of all constituent technologies in Figure 1. Optimal scheduling decisions for battery state-of-charge and charge/discharge rates, chemical production rates and storage inventories, and dispatchable power generation rates are made across a multi-year horizon of hourly resolution renewable availability time series data.

Hourly power balance constraints ensure that renewable generation plus battery discharge plus dispatchable hydrogen- or ammonia-fueled power generation meet or exceed constant data center power demand plus battery charge plus chemical production power demands. Hourly mass balance equations for hydrogen and ammonia govern the accumulation of their storage inventory between consecutive hours. This storage inventory is constrained to be cyclical between the first and last hour of the multi-year operating horizon. Chemical production and dispatchable power generation technologies are constrained to operating limits defined by their respective operational flexibility. This model is formulated as a MILP and solved using CPLEX in GAMS. Please see our previous work [12] for more technical details, including model equations.

## U.S. Data Centers Case Study Data

We perform a case study considering data centers with power demand scales of 5 MW, 50 MW, and 500 MW in NoVa, Dallas-Fort Worth, and Las Vegas. NoVa has highest current data center capacity in United States. DFW and Las Vegas respectively have high wind and solar potential, and data center capacity is rapidly growing in both metropolitan areas. We optimize the LCOE of meeting data center power demands via (i) battery, (ii) battery-hydrogen, and (iii) battery-hydrogen-ammonia energy storage systems using five years of historical renewable generation data from 2019 to 2024 in each location. The annual average wind and solar capacity factors in NoVa, DFW, and Las Vegas are respectively 39%, 45%, and 27% and 16%, 18%, and 22% [21].

**Table 1:** Capital and operating cost coefficients for renewable generation, battery charge/discharge capacity and electrolysis at different power demand scales. Data for all technologies except for electrolysis are from [22] while electrolysis data are from [23].

| Technology at Demand Scale (MW) | CapEx ($MM/MW) | OpEx (%CapEx) |
|---|---|---|
| Wind (5) | 2.04 | 1.86 |
| Wind (>50) | 1.41 | 2.08 |
| PV (5) | 1.49 | 1.06 |
| PV (>50) | 1.19 | 1.51 |
| Battery - Power (5) | 0.88 | 2.41 |
| Battery - Power (>50) | 0.43 | 2.15 |
| Electrolysis (5) | 1.99 | 2.5 |
| Electrolysis (50) | 1.37 | 2.5 |
| Electrolysis (500) | 0.94 | 2.5 |
| ICE Genset (5) | 1.27 | 2.0 |
| CCGT (>50) | 1.43 | 2.2 |

The capital and operating costs of energy system technologies depend on scale (see Table 1). Battery energy capacity (in MWh) has a capital cost of $0.18/MWh and $0.26/MWh respectively at the 5 MW and >50 MW demand scales [22]. Batteries have a charge efficiency of 90% and a discharge efficiency of 95%. PEM electrolysis is considered in this work for its wide operating range and fast dynamics. Its energy efficiency is assumed to be 51 MWh/mt$H_2$ [23]. High pressure gaseous hydrogen storage has a capital cost of $0.9MM/mt$H_2$. Reconversion of hydrogen and ammonia to electrical power occurs through combustion in internal combustion engine gensets at the 5 MW scale and combined cycle gas turbine (CCGT) plants at 50 MW and 500 MW scales. ICE genset and CCGT efficiencies are respectively 35% and 60% of LHV. ICE gensets have 90% turndown (i.e., can operate between 10% and 100% of installed capacity) while CCGTs have 60% turndown. The capital costs of nitrogen and ammonia production are subject to conventional power law cost scaling (see Table 2). Each technology has an annual operating cost of 2% of capital cost. Nitrogen and ammonia storage have capital costs of $\$5 \times 10^{-2}$MM/mt$N_2$ and $\$1.5 \times 10^{-3}$MM/mt$NH_3$ respectively [24].

Total energy system capital cost is annualized by a

**Table 2:** Capital cost correlations and performance data for nitrogen and ammonia production technologies [24].

| | Capacity (mt/y) | CapEx (MM$) | Scaling Exponent | Efficiency (MWh/mt) | Turndown (%) |
|---|---|---|---|---|---|
| Pressure swing adsorption (PSA) | 10,000 | 6.6 | 0.75 | 0.25 | 90 |
| Cryogenic distillation | 197,500 | 29.5 | 0.55 | 0.18 | 50 |
| Haber-Bosch synthesis | 237,500 | 89 | 0.65 | 0.45 | 90 |

**Table 3:** Optimal LCOE, renewable generation and energy storage capacity, and renewable curtailment for 50 MW data centers in Northern Virginia. Hydrogen and ammonia storage capacities in MWh are based on LHV.

| Storage Pathway | Battery | Battery-$H_2$ | Battery-$H_2$-$NH_3$ |
|---|---|---|---|
| LCOE ($/MWh) | 328 | 185 | 140 |
| Wind (MW) | 192 | 198 | 124 |
| PV (MW) | 556 | 130 | 104 |
| Battery (MWh) | 2,115 | 405 | 441 |
| $H_2$ Storage (MWh) | 0 | 8,382 | 255 |
| $NH_3$ Storage (MWh) | 0 | 0 | 43,340 |
| Wind Curtailment (%) | 62 | 33 | 10 |
| PV Curtailment (%) | 73 | 22 | 17 |

CRF of 0.073 $y^{-1}$. This corresponds to a project lifetime of 30 years with a 6.04% weighted average cost of capital (WACC). This is the average WACC for green and sustainable energy projects in the United States [25].

## RESULTS AND DISCUSSION

Incorporating hydrogen and ammonia as lower cost energy storage media into hybrid renewable energy storage systems for sustainable data centers results in meaningfully lower LCOE than using battery storage alone (see Table 3). Combining hydrogen storage with battery storage results in a 44% LCOE reduction. This is driven by considerably lower solar generation and battery costs. Battery energy storage is too expensive to include enough capacity to store close to all generated MWh of renewable energy specifically due to variability over longer timescales. The battery-only energy storage system thus overbuilds solar generation to enable more demand to be met via direct generation and respectively curtails 62% and 73% of wind and solar over its modeled operational lifetime. Nonetheless, more than 2 GWh of battery storage is still required. In contrast, the battery-hydrogen system installs around 4x more total energy storage capacity despite 5x less battery capacity than the battery system to facilitate more effective renewable utilization. The optimal solar generation capacity for the battery-hydrogen system is 77% less than the battery-only system while optimal wind and solar curtailment are 33% and 22% respectively. Overall, the hybrid battery-hydrogen system still uses batteries for short-term storage and hydrogen for longer-term storage.

Using ammonia in a hybrid battery-hydrogen-ammonia energy system further reduces the LCOE by 24%. The same general trends as described in the previous paragraph are more pronounced. Ammonia's low storage cost results in approximately 20x more total optimal storage capacity than the battery-only system as well as approximately 5x more total storage capacity than the battery-hydrogen system despite 97% less hydrogen storage. Consequently, renewable energy generation capacities and curtailment are both reduced relative to the energy systems where energy storage technologies have higher $/MWh storage costs. Comparing battery-hydrogen and battery-hydrogen-ammonia systems specifically, we note that incorporating ammonia allows for considerably more effective use of wind energy with 37% less wind capacity installed and wind curtailment reduced from 33% to 10%. Wind potential in NoVa exhibits more seasonal and interannual variability than solar potential, and ammonia is more cost effective at balancing supply-demand mismatches that occur over longer timescales.

Interestingly, the optimal hybrid battery-hydrogen-ammonia energy system does not install any hydrogen-to-power capacity. In this system, the installed hydrogen storage only acts as a buffer between electrolysis and the less flexible Haber-Bosch synthesis. This occurs because, for the combustion technologies considered in this work, the roundtrip efficiency of the hydrogen storage pathway is only 39% compared to 32% for the ammonia storage pathway, but hydrogen storage cost is 100x higher on a $/MWh basis. Ultimately, the hybrid battery-hydrogen-ammonia system uses battery storage for short-term cycling and ammonia for longer-duration storage with hydrogen only acting as an intermediate. Specifically, batteries are cycled on short timescales to take advantage of their high roundtrip efficiency. Figure 2

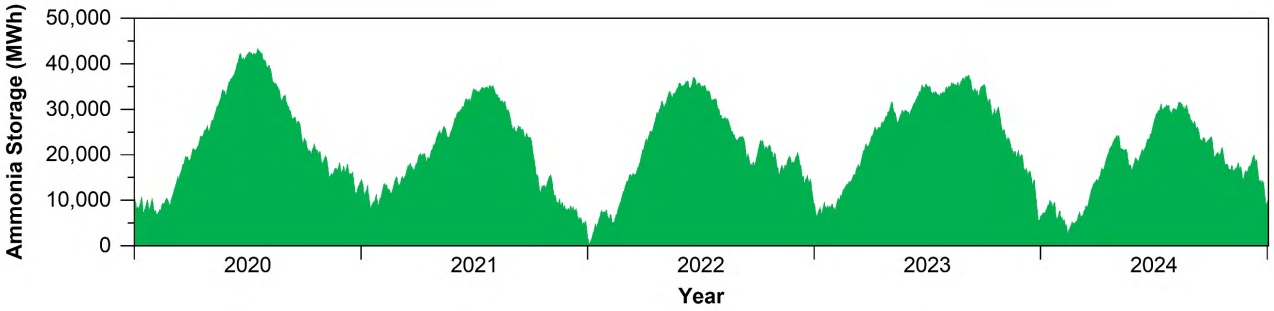

**Figure 2.** Optimal ammonia energy storage schedule for 50 MW data center using battery-hydrogen-ammonia storage pathway in Northern Virginia. Ammonia storage capacity in MWh based on LHV.

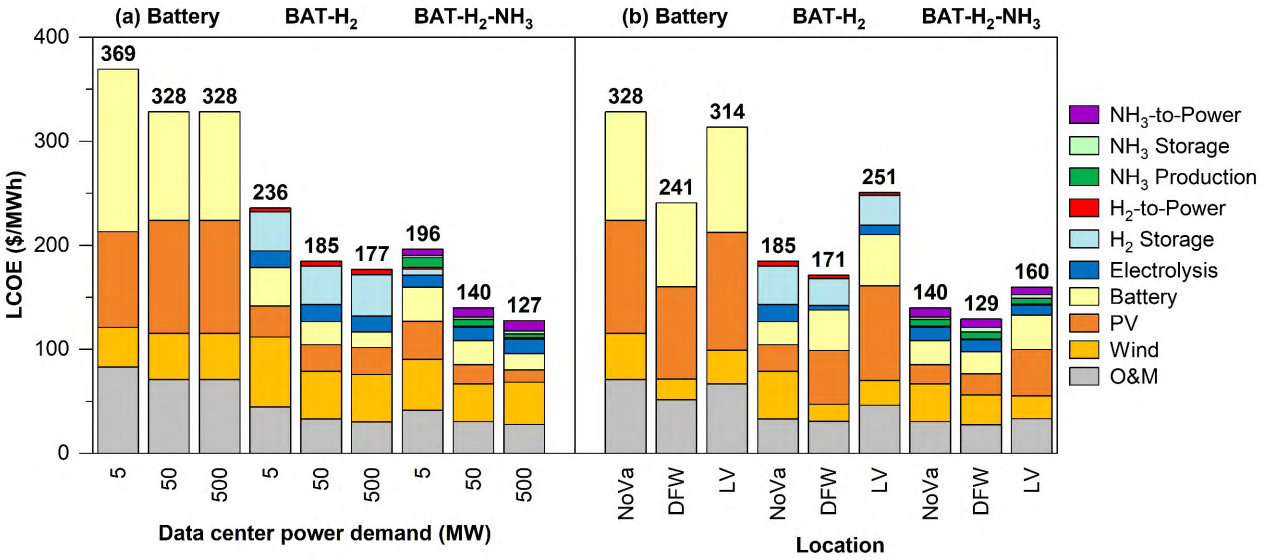

**Figure 3:** Breakdown of optimal LCOE for (a) 5 MW, 50 MW, and 500 MW data centers in Northern Virginia and (b) 50 MW data centers in Northern Virginia, Dallas-Fort Worth, and Las Vegas. Nitrogen production and storage as well as Haber-Bosch synthesis are included in "$NH_3$ Production".

shows the optimal ammonia energy storage schedule over for optimal operation from 2019 to 2024. It is evident that ammonia is accumulated through the first half of each year before being consumed to accommodate for seasonally low wind generation in second half of each year. From an interannual standpoint, the ammonia inventory is depleted by the end of 2021 to account for its lowest wind capacity factor while the highest net ammonia accumulation occurs in 2022 because its capacity factor is the highest.

## Analysis of Power Demand Scale

Sustainable data center using 100% renewables and energy storage exhibit clear economies of scale (see Figure 3a). The LCOE for the 5 MW demand scale is considerably higher than for 50 MW and 500 MW demand scales regardless of the energy storage pathways under consideration. At this small scale, all technologies from wind and solar generation through to ammonia synthesis have higher capital intensity. The loss in economies of scale for nitrogen and ammonia production is particularly impactful. Data center energy systems at the 5 MW demand scale benefit least from the incorporation of ammonia relative to LCOE reductions at 50 MW and 500 MW demand scales. Additionally, the hybrid battery-hydrogen-ammonia storage system at the 5 MW demand scale uses both hydrogen- and ammonia-to-power combustion technologies, unlike the larger systems which only use ammonia for dispatchable power generation. This occurs to reduce the capacity and accompanied higher capital intensity of small-scale ammonia synthesis despite hydrogen having a higher storage cost.

The economic outlook of powering 50 MW and 500 MW data centers with renewables is similar. Renewable generation and batteries exhibit little to no cost savings with this scaleup while electrolysis does exhibit some economies of scale. This is evident in comparing the battery and battery-hydrogen LCOEs which are reduced by

less than $10/MWh with the 10x scaleup from 50 MW to 500 MW. Ammonia energy storage is well-suited for large centers on the order of 500 MW. Incorporating ammonia at this scale results in deeper cost reductions relative to smaller scales. Ammonia is also important for energy storage at hyperscale data centers from an optimal capacity standpoint. The optimal battery and hydrogen storage capacities are 21, 000 MWh and 3, 200 $mtH_2$ respectively when these are the standalone storage pathways for 500 MW NoVa data centers. These capacities are not realistic relative to current deployments, requiring 7x more battery capacity [26] and 10x more hydrogen storage capacity [27] than the largest facilities for each currently operational in the United States. Conversely, the hybrid battery-hydrogen-ammonia data center requires only 2, 800 MWh battery and 100 $mtH_2$ because long-duration, high-capacity storage can be facilitated by 105, 000 $mtNH_3$ ammonia storage.

Large-scale data centers are also best suited to ammonia energy storage from a safety standpoint. The ammonia synthesis and storage capacities these data centers would require are similar to those already used in the ammonia fertilizer supply chain. In contrast, using ammonia for energy storage across many small data centers would increase the number of facilities at which ammonia must be stored and handled and would thus increase the associated risk.

### Analysis of Data Center Location

Hybrid battery-hydrogen and even more so hybrid battery-hydrogen-ammonia storage offers the same qualitative advantages across the three studied locations. Storage pathways with lower storage costs than batteries enable more complete utilization of lower optimal renewable generation capacities, which results in lower generation cost contributions to the LCOE, especially for solar (see Figure 3b). Battery storage cost contributions are also meaningfully less when storage can occur in the form of hydrogen and/or ammonia. When the ammonia storage pathway is considered, the optimal energy storage systems for 50 MW demand data centers in DFW and Las Vegas only use ammonia for dispatchable power generation as was previously discussed for the optimal hybrid battery-hydrogen-ammonia NoVa energy storage system.

The location of data centers does have a quantitative effect of the economics of sustainable data centers for each storage pathway (see Figure 3b). For battery-only storage systems, NoVa has the highest LCOE. Both DFW and Las Vegas have higher solar potential and less seasonal solar variation, making these locations better suited to batteries alone. Hydrogen and even more so ammonia energy storage enables better use of wind generation. This results in Las Vegas having the highest LCOE for these hybrid systems because its wind potential is lower than NoVa or DFW and must install considerably more solar generation as a result. Conversely, DFW has better wind and solar potential than NoVa and considerably better wind potential than Las Vegas. This results in the DFW system having the lowest LCOE regardless of the storage pathways under consideration because these systems have lower total renewable generation and total energy storage costs. Nonetheless, hybrid battery-hydrogen-ammonia energy storage results in a NoVa LCOE only 9% higher than the DFW LCOE. In comparison, the NoVa battery LCOE is 36% higher than the DFW battery LCOE. Overall, ammonia storage makes sustainable data centers more economically competitive in more locations.

## CONCLUSIONS

In this work, we analyze the economics of using hydrogen and/or ammonia along with batteries in hybrid energy storage systems to meet data center power demands using 100% behind-the-meter renewable energy. We perform this analysis through the lens of an economic optimization model which minimizes the levelized cost of energy (LCOE) by simultaneously making technology selection, sizing, and operational scheduling decisions. Optimal scheduling occurs for a five-year operating horizon with hourly resolution based on time series data for historical renewable availability to ensure that optimal selection and sizing decisions account for hourly, seasonal, and interannual variability. We use this model to determine the optimal LCOE of using 100% renewable and hybrid energy storage systems for data centers with 5 MW, 50 MW, and 500 MW power demand in Northern Virginia (NoVa), Dallas-Fort Worth (DFW), and Las Vegas

We find that hybrid battery-hydrogen and battery-hydrogen-ammonia energy systems provide lower LCOE than using batteries alone for all scales and locations. These lower storage cost pathways enable larger storage capacity so that more energy can be economically stored and used rather than curtailed, resulting in less investment in renewable generation. Hybrid battery-hydrogen-ammonia systems provide the lowest LCOE and ammonia provides at least 95% of total energy storage capacity in these hybrid systems due to its low storage cost. Ammonia energy storage is best suited to large-scale data centers due to the economies of scale for nitrogen and ammonia production. It is also best suited to locations with high wind potential, the seasonal and interannual variability of which can be economically balanced with data center power demands via ammonia storage.

Future work will compare the viability of ammonia energy storage with conventional fossil fuel technologies as well as small modular nuclear reactors in the context of data centers across different U.S. locations. This future work will include techno-economic analysis of these

energy storage pathways under a consistent set of assumptions. We will also compare the emissions and water intensity of these different energy storage pathways through a life cycle assessment framework.

## ABSTRACT

Direct Air Capture (DAC) is a negative emissions technology whose performance is inherently linked to ambient conditions, which directly affect its primary feed stream (air). A common simplification in DAC model simulations is the use of fixed weather conditions, which can bias the predicted performance under weather variability. In response, this study quantifies the impact of local meteorological variability and temporal weather aggregation on the performance of DAC units. Building on a previously developed and validated 1D mechanistic model of a fixed-bed Steam-assisted Temperature Vacuum Swing Adsorption (S-TVSA) DAC process, we simulate its operation using weather data from the Met Office station at Buchan (UK), near the Saint Fergus terminal - a strategic hub for Carbon Capture and Storage (CCS) activities in Scotland. A two-branch methodological framework is developed combining optimization and forward simulations. Operating conditions are optimized using a multi-objective genetic algorithm (NSGA-II) to maximize productivity (Pr) and minimize specific equivalent work (Weq) at two temporal resolutions. Furthermore, daily weather inputs are aggregated on a monthly and yearly scale to assess the impact of data resolution on model predictions and real operational gains. Results show that temporal weather aggregation to yearly averages biases DAC key performance indicators, overestimating Pr by up to 5% while underestimating Weq by up to 31%, relative to performance based on daily weather variations. Moreover, optimization strategies that explicitly account for monthly weather variability present monthly gains, by increasing Pr by up to 10%. Yet, these monthly gains do not necessarily translate into significant operational performance benefits at the annual scale when daily weather data is propagated in the process model.

## INTRODUCTION

In light of the ongoing need to pursue mitigation pathways towards climate change, consistent with the Paris Agreement targets, Direct Air Capture (DAC) has emerged as a carbon dioxide ($CO_2$) removal (CDR) option capable of delivering negative emissions by counterbalancing legacy emissions and hard-to-abate residual industrial $CO_2$ that cannot be eliminated through conventional abatement measures [1]. DAC is a novel yet technically complex CDR technology during which atmospheric $CO_2$ is artificially removed through an engineered air contactor [2]. Unlike point-source capture technologies, DAC targets the dilute $CO_2$ in ambient air and is intrinsically sensitive to local weather conditions [3]. Furthermore, although DAC systems are claimed to be location-independent, their operation depends on the availability and integration of utilities, land and energy sources. To avoid the need for building new DAC-specific infrastructure and to reduce their energy consumption, the integration of DAC systems within existing industrial clusters is a beneficial engineering solution. In fact, co-locating DAC units near existing industrial sites can enhance the overall efficiency of the system thanks to the availability of suitable, existing infrastructure, available waste utilities (heat, cooling water) and low likelihood of

environmental constraints [1].

Despite ongoing, promising momentum, the widespread adoption of DAC as a viable CDR at large-scale is currently constrained by several interrelated, unresolved technical complexities that include the integration of resources within existing industrial activity [1], [3], high cost of capture [4], [5], and performance uncertainties due to operational variability under real-world conditions [3], [4], [6].

Dynamic process simulations have highlighted the sensitivity of DAC performance to ambient weather, including spatiotemporal variations in energy demand driven by different temperature (T) and relative humidity (RH) profiles across different locations [4], [7]. To the best of the authors' knowledge, only few studies have quantified the impact of fine weather variability and temporal aggregation on technical key performance indicators (KPIs) [3], [6], [8], employing optimization approaches ranging from mixed-integer linear programming (MILP) to data-driven surrogate-based branch-and-bound (DDSBB) and Bayesian optimization. Most DAC studies report performance under a limited set of representative conditions or rely on temporally averaged weather inputs, without constructing year-long dynamic performance profiles that resolve intra-annual variability. Consequently, the impact of variable ambient conditions on deviations from design-point operation - particularly near constraint limits and along energy-productivity trade-offs - remains insufficiently quantified. In addition, DAC is often assessed in isolation from region-specific deployment constraints such as industrial geography, local climate, and evolving $CO_2$ transport-and-storage (T&S) infrastructure.

To address this gap, we take an initial step toward a decision-support framework for DAC siting using the UK as a case study. We evaluate a Steam-assisted Temperature-Vacuum Swing Adsorption (S-TVSA) fixed-bed process for DAC at an industrial UK location and develop dynamic performance profiles under off-design ambient conditions. We compare predictions obtained using different weather resolutions to quantify temporal aggregation bias, and we optimize operating variables using NSGA-II to maximize productivity (Pr) and minimize specific equivalent work (Weq) under capture-grade specifications. Finally, we quantify the value of higher optimization resolution by comparing a single yearly optimization against twelve month-specific optimizations accounting for intra-annual variability.

# METHODOLOGY

## Temperature-Vacuum-Swing Adsorption Cycle

Previous work focused on the development of a high-fidelity mechanistic model in MATLAB to simulate and optimize the performance of an S-TVSA DAC unit, which constitutes the modeling basis for this work [2]. The system separates $CO_2$ from ambient air containing 400 ppm $CO_2$, nitrogen ($N_2$), and water vapor ($H_2O$) at atmospheric pressure (1 bar) and local ambient temperature, using the benchmark adsorbent APDES-NFC. It comprises five sequential steps: (i) adsorption, (ii) blowdown, (iii) heating, (iv) desorption, and (v) pressurization, as shown in Figure 1. Each step operates under a distinct set of conditions, ranging from low pressure (P) and temperature ($P_L$, $T_L$) to high pressure and temperature ($P_H$, $T_H$). During adsorption, $CO_2$ is selectively captured while $H_2O$ co-adsorbs on the sorbent's surface. During blowdown, pressure is reduced to vacuum to remove residual $N_2$. Steam-assisted heating under vacuum promotes the desorption step, producing a $CO_2/H_2O$ stream which is separated downstream by condensation. At the last step, the bed is then repressurized to initiate the next cycle using air and cooling water.

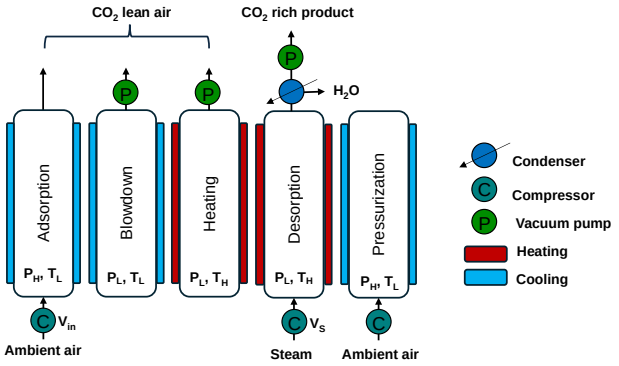

**Figure 1.** Schematic representation of the 5-step S-TVSA cycle considered in this study.

The high-fidelity, one dimensional (1D) fixed bed model describes competitive $CO_2/H_2O$ adsorption equilibria as functions of pressure, temperature, and gas composition using thermodynamically consistent isotherm models (GAB for $H_2O$ and modified Toth for $CO_2$ [9]), assuming negligible $N_2$ adsorption. Adsorption dynamics are captured by coupled partial differential equations for mass, energy, and momentum balances with axial dispersion. Intraparticle mass transfer is captured using a Linear Driving Force (LDF) approximation. The cycle is simulated until cyclic steady state is reached, defined by <0.5% variation in state variables between consecutive cycles at all axial locations.

## Multi-objective optimization

The multi-objective optimization problem to minimize Weq and maximize Pr, subject to a product purity constraint (s.t. Pu ≥ 95%) is formulated as shown below:

$$\min(-Pr + \varphi, W_{eq} + \varphi) \quad (1)$$

$$s.t\ \theta_L \le \theta \le \theta_U$$

$$\varphi = 0.25 \times [\max(0, 95 - Pu)]^2$$

where $\theta$ is the vector of process operating variables, bounded between a lower ($\theta_L$) and upper ($\theta_U$) value as shown in Table 1. The equivalent work term represents the total energy duty of the system, combining the thermal (heating, steam purge) and electrical energy requirements (compressor, vacuum pump, condenser) into a single metric [2].

**Table 1.** Upper and lower bounds applied to the operating variables $\theta$ for optimization of the S-TVSA process.

| | $t_{ads}$ (s) | $t_{heat}$ (s) | $t_{des}$ (s) | $P_L$ (Pa) | $T_H$ (K) | $v_s$ (m/s) | $v_{in}$ (m/s) |
|---|---|---|---|---|---|---|---|
| $\theta_L$ | 1,000 | 500 | 1,000 | 500 | 363 | 0.0015 | 0.005 |
| $\theta_U$ | 15,000 | 1,500 | 40,000 | 5,000 | 373 | 0.005 | 0.01 |

Building on previous work, the purity constraint is represented as a quadratic loss penalty function with a drawdown coefficient c = 0.25 [2]. The decision variables that are optimized include the adsorption time ($t_{ads}$), the heating time ($t_{heat}$), the desorption time ($t_{des}$), the vacuum pressure ($P_L$), the steam temperature ($T_H$), the steam velocity ($v_s$), and the air feed velocity ($v_{in}$). The duration of the blowdown ($t_{bd}$) and the pressurization ($t_{pres}$) steps is 30s [2].

## Industrial Clusters – Location case-study selection

To enable a cluster-specific assessment and the construction of a year-long dynamic performance profile under realistic ambient conditions, a representative site within the Scottish Industrial Cluster was selected. The Scottish Cluster is particularly relevant for large-scale DAC deployment due to its proximity to existing and planned $CO_2$ transport and storage infrastructure [10]. The area of Saint Fergus was chosen as a reference location, serving as a proxy for cluster-level deployment and enabling a detailed, high-resolution assessment of weather-driven performance variability. Year-long ambient meteorological data for 2024 $(T_d, RH_d)$ were obtained on a daily resolution from the Buchan station, the nearest UK Met Office station to the selected reference site [11].

## Effect of weather variability and temporal aggregation

### Dynamic Performance Profiles

Previous DAC process-modelling studies have typically employed constant ambient conditions to evaluate system performance. Although computationally efficient, this assumption neglects the intrinsic temporal variability of atmospheric T and RH that directly define DAC inlet conditions and may therefore bias predicted KPIs. To systematically evaluate the impact of weather resolution on DAC performance, we develop a two-branch methodological framework combining optimization and forward simulations under different temporal representations of ambient conditions. By developing dynamic performance profiles, we can quantify how real operation at a fixed operating set of conditions (fixed operating strategy) responds to different temporal resolutions of weather.

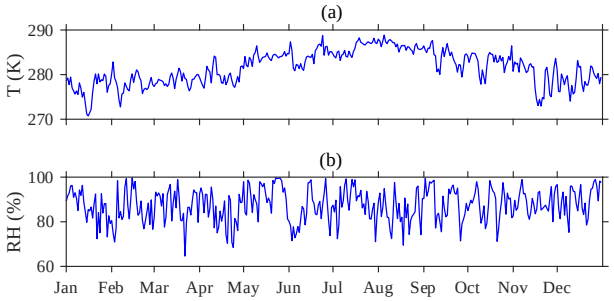

**Figure 2.** Daily ambient conditions at Buchan in 2024: (a) temperature $T_d$ (K) and (b) relative humidity $RH_d$ (%). Over the year, $T_d$ ranged from 270.8-288.9 K and $RH_d$ from 64.6-99.8%. Annual mean values were $\bar{T}_y = 281.6$ K and $\overline{RH}_y = 87.4\%$.

Furthermore, we can evaluate whether temporal aggregation of weather data yields values that are consistent with the fixed monthly and yearly inputs commonly assumed in DAC process simulations, and quantify any discrepancies introduced by this simplification. Daily weather data $(T_d, RH_d)$ for the chosen location, with $d \in \{1, \dots, D\}$ where $D$ are the number of days in 2024 (366), are obtained directly from the data source. The first step of the workflow involves running a multi-objective optimization under yearly averaged $(\bar{T}_y, \overline{RH}_y)$ conditions. From the resulting Pareto set, as shown in Figure 3, the maximum-productivity point $(\mathrm{Pr}^*_{y,max})$ is selected to define the fixed operating strategy for this workflow. Next, this fixed vector of decision variables, $\theta^*_y$, that describe optimal operating conditions at $\mathrm{Pr}^*_{y,max}$ is propagated into forward simulations in the DAC model using the full sequence of daily weather inputs $(T_d, RH_d)$. This procedure yields time-dependent daily trajectories of KPIs, enabling a direct correlation between ambient weather inputs and DAC performance. Daily weather inputs are averaged on a monthly and yearly basis as shown below:

$$\bar{T}_{m,i} = \frac{1}{D_{m,i}} \sum_{d=1}^{D_{m,i}} T_d \qquad (2)$$

$$\overline{\mathrm{RH}}_{m,i} = \frac{1}{D_{m,i}} \sum_{d=1}^{D_{m,i}} RH_d \tag{3}$$

$$\bar{T}_y = \frac{1}{\mathrm{D}} \sum_{d=1}^{\mathrm{D}} T_d \tag{4}$$

$$\overline{\mathrm{RH}}_y = \frac{1}{\mathrm{D}} \sum_{d=1}^{\mathrm{D}} RH_d \tag{5}$$

$D_{m,i}$ denotes the number of days in month $i$.

## Forward Simulations

To assess the impact of weather data temporal resolution on performance predictions, the daily KPI outputs are aggregated into monthly and yearly values.

$$\overline{KPI}_{m,i} = \frac{1}{D_{m,i}} \sum_{d=1}^{D_{m,i}} KPI_d(T_d, RH_d, \theta_y^*) \tag{6}$$

$$\overline{KPI}_y = \frac{1}{\mathrm{D}} \sum_{d=1}^{\mathrm{D}} KPI_d(T_d, RH_d, \theta_y^*) \tag{7}$$

The resulting averaged KPIs are then compared against KPIs obtained from simulations that use fixed monthly $(KPI_{m,i}(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_y^*))$ and fixed yearly $(KPI_y^*(\bar{T}_y, \overline{RH}_y, \theta_y^*))$ ambient conditions by testing the following null hypotheses $H_0$.

$$H_0: \overline{KPI}_{m,i} - KPI_{m,i}(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_y^*) = 0 \tag{8}$$

$$H_0: \overline{KPI}_y - KPI_y^*(\bar{T}_y, \overline{RH}_y, \theta_y^*) = 0 \tag{9}$$

In addition, we can also estimate yearly average KPIs using weighted fixed-month simulations:

$$\bar{\overline{KPI}}_y = \sum_{i=1}^{12} \frac{D_{m,i}}{D} KPI_{m,i}(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_y^*) \tag{10}$$

This methodology allows us to (i) determine whether the temporal averaging implied in fixed-weather modelling is valid and (ii) to quantify the operational penalties that arise when a DAC unit optimized for nominal yearly conditions is exposed to real atmospheric variability.

## Process Optimization

The second branch of the workflow will allow us to quantify the effect of temporal resolution in process improvements of DAC optimal performance. We solve the optimization problem using NSGA-II under two temporal representations of ambient conditions: yearly constant conditions as described above $(\bar{T}_y, \overline{RH}_y)$ and monthly-constant conditions $(\bar{T}_{m,i}, \overline{RH}_{m,i})$, yielding 12 different sets of decision variables $(\theta_{m,i}^*)$. For each optimization scenario, two representative Pareto solutions are extracted: the maximum Pr $(\mathrm{Pr}_{y,max}^*)$ and the minimum Weq points $(\mathrm{Weq}_{y,min}^*)$. For the monthly optimization case, annual mean KPIs are computed by averaging weighted monthly optima:

$$\bar{\overline{\mathrm{KPI}}}_y^* = \sum_{i=1}^{12} \frac{D_{m,i}}{D} KPI_{m,i}^*(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_{m,i}^*) \tag{11}$$

This branch of the workflow tests whether increasing the temporal resolution of the optimization inputs leads to improved predicted annual-mean optimal performance relative to a single yearly-constant optimization. To this end, the following null hypothesis is tested:

$$H_0: KPI_y^*(\bar{T}_y, \overline{RH}_y, \theta_y^*) - \bar{\overline{\mathrm{KPI}}}_y^*(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_{m,i}^*) = 0 \tag{12}$$

Furthermore, to quantify the month-specific value of re-optimization, we compare the performance obtained when operating each month using the annually optimal decision vector $(\theta_y^*)$ against the performance achieved under month-optimal settings $(\theta_{m,i}^*)$, both evaluated under the same month-averaged ambient conditions $(\bar{T}_{m,i}, \overline{RH}_{m,i})$. This test isolates the operational benefit attributable solely to adjusting operating parameters at a monthly timescale, relative to maintaining fixed yearly operation:

$$H_0: KPI_{m,i}(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_y^*) - KPI^*{}_{m,i}(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_{m,i}^*) = 0 \tag{13}$$

Aggregated on an annual scale, we also evaluate:

$$H_0: \bar{\overline{KPI}}_y - \bar{\overline{\mathrm{KPI}}}_y^* = 0 \tag{14}$$

Finally, to evaluate whether gains identified under aggregated ambient conditions translate into improved annual operation under fully time-resolved weather, we test the following null hypothesis:

$$H_0: \overline{KPI}_y - \overline{KPI_y^*} = 0 \tag{15}$$

, where we define:

$$\overline{KPI_y^*} = \frac{1}{\mathrm{D}} \sum_{d=1}^{\mathrm{D}} KPI_d(T_d, RH_d, \theta_{m,i}^*) \tag{16}$$

# RESULTS

## Dynamic Performance Profiles

The DAC unit was optimized at nominal weather conditions that correspond to the yearly average. From the resulting Pareto Front shown in Figure 3, the combination of operating variables corresponding to the maximum productivity was chosen to create our fixed operating strategy.

The simulated DAC productivity exhibits intra-annual variability (Figure 4b), ranging from 5.6 to 6.2 kg/m$^3$/day, with lower values occurring under combinations of high RH and medium-to-high ambient T. Although modest in magnitude, a non-uniform productivity profile can propagate across the $CO_2$ removal value chain. At plant level, it can reduce capacity utilization and

can bias sizing when designs rely on annual-average performance. At cluster scale, time-varying $CO_2$ output may undermine steady-supply assumptions for downstream compression, transport, and storage infrastructure, lowering utilization of shared assets. Even without explicitly modeling the Carbon Capture & Storage (CCS) chain in this study, these results suggest that sustained productivity fluctuations can materially affect integration, cost estimates, and deployment robustness. Energy consumption (Figure 4c) is strongly affected, displaying peak-to-trough variations of up to 76% over the year - an effect that is obscured when steady-state or temporally averaged conditions are assumed. It is interesting to notice that high RH values cause a simultaneous increase in energy consumption and reduction in productivity, consistent with $CO_2$-$H_2O$ co-adsorption: at very humid conditions, $H_2O$ adsorption dominates and water-loaded sorption sites require additional regeneration, increasing energy requirements while reducing effective $CO_2$ throughput. Finally, purity shows a clearer intra-annual trend, decreasing during summer months (Figure 4a). This is consistent with the decreasing adsorption capacity and sorbent's reduced selectivity at higher temperatures, which gives more space for $H_2O$ to compete by occupying and accumulating on the void spaces, yielding a mixture which is less rich in $CO_2$. Although the purity constraint of 95% was met for this combination of ambient conditions and marginal peak-to-through variability (1%) was observed, variable product purity can entail the risk of increasing downstream processing costs to maintain the stream within spec, with significant impacts on the downstream CCS chain.

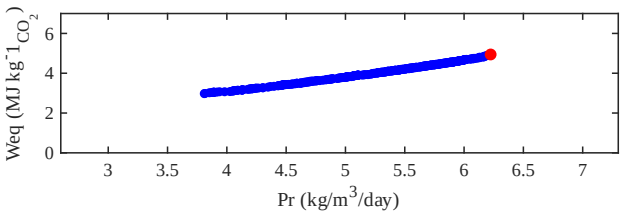

**Figure 3.** Pareto Front resulting from the multi-objective optimization problem of maximizing productivity (Pr) and minimizing equivalent work (Weq) using NSGA-II.

## Temporal Weather Averaging

Figure 5 compares normalized DAC performance indicators obtained using different temporal representations of ambient conditions while maintaining a fixed operating strategy ($\theta_y^*$). KPIs calculated using yearly average conditions are included as a reference (dashed lines) to reflect the common simplifying assumption adopted in much of the existing DAC modeling literature. The results demonstrate that the use of temporally averaged weather inputs leads to systematically biased performance predictions. When monthly- (green bins) or yearly-averaged (dashed line) T and RH values are employed, KPIs can be either over- or under-estimated relative to simulations driven by daily resolved meteorological data (purple bins). System productivity is consistently overestimated, while energy requirements are significantly underestimated when constant yearly ambient conditions are assumed.

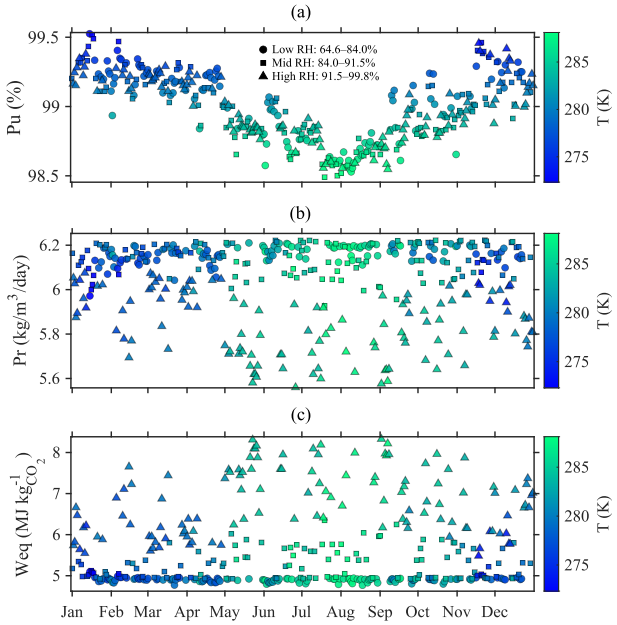

**Figure 4.** Dynamic annual profiles of (a) purity (Pu), (b) productivity (Pr), and (c) equivalent work (Weq) for the optimized DAC unit operating at St. Fergus.

May corresponds to the maximum deviation from the yearly nominal operating conditions, with productivity overpredicted by up to 5% and energy demand underestimated by approximately 31% when compared to the daily-resolved cases. Despite these discrepancies, $CO_2$ purity is shown to be comparatively insensitive to temporal aggregation, with deviations remaining below 1% across all cases. This indicates that purity constraints are robust to weather averaging for the operating regime considered. Other critical KPIs exhibit much stronger nonlinear responses to ambient variability. Electrical energy consumption is underestimated by up to 195% when yearly fixed temporal representations are used underscoring the extent to which averaging suppresses high-energy operating periods. On an annual scale (purple bins), the same trends are observed compared to the yearly-averaged simulations (dashed line). This discrepancy highlights that the annual mean of a nonlinear KPI does not correspond to the indicator evaluated at annual-mean ambient conditions. Hence, we show that:

$$\overline{KPI}_y \neq KPI_y^*(\bar{T}_y, \overline{RH}_y, \theta_y^*)$$

A similar effect is observed at the monthly level. When KPIs obtained from daily-resolved simulations (light purple bins) are averaged over each month and compared to simulations performed using fixed monthly-average ambient conditions (green bins), systematic deviations persist. Specifically, while purity remains largely unaffected, productivity is overestimated by up to 2.5% and energy consumption is underestimated by up to 11% depending on the month. Hence, we conclude that:

$$\overline{KPI}_{m,i} \neq KPI_{m,i}(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_y^*)$$

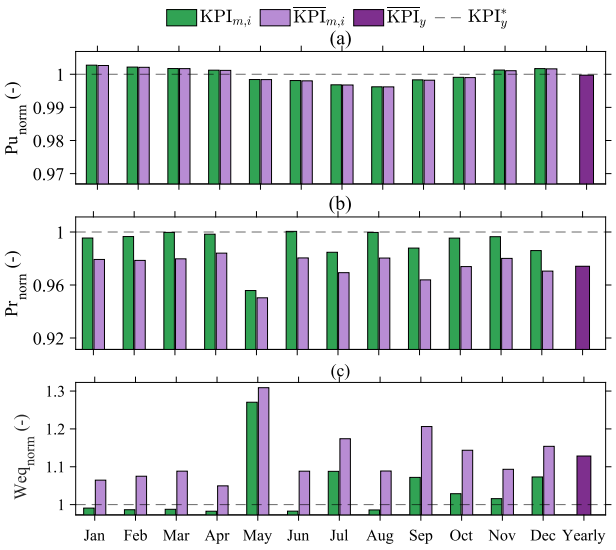

**Figure 5.** Comparison of normalized (a) purity ($Pu_{norm}$), (b) productivity ($Pr_{norm}$), and (c) equivalent work ($Weq_{norm}$) obtained at different temporal resolutions. All results are obtained using the same operating variables $\theta_y^*$ and are normalized by the nominal case that produces $KPI_y^*$.

These deviations arise because short-term excursions to unfavorable temperature and humidity conditions - particularly those associated with high energy penalties - are smoothed out when average inputs are used. These findings demonstrate that temporal aggregation masks the true operational variability of DAC systems by suppressing extreme but impactful weather conditions. While low-resolution weather data may be sufficient for predicting product quality, it fails to accurately capture energy requirements and the system's productivity. This has important implications for techno-economic assessments, utility sizing, and system integration studies, where underestimating peak and cumulative energy demand may lead to overly optimistic cost projections and misinformed process design.

## Optimization at temporal resolutions

Building on the forward-simulation analysis, we move to the optimization framework which enables detangling (i) the benefit of re-optimizing operating conditions at a monthly timescale, (ii) the month- and yearly specific improvement achievable relative to fixed annual operation, and (iii) the extent to which apparent gains under aggregated weather inputs translate into improved performance under fully time-resolved (dynamic) ambient conditions. These hypotheses provide a structured basis to determine whether increasing temporal resolution yields meaningful operational improvements, or whether it primarily increases computational burden without material gains in annual performance. As seen in Table 2, monthly re-optimization ($\overline{\text{KPI}}_y^*$) does not yield consistent annual-mean performance gains relative to a single yearly-constant optimization ($KPI_y^*$). At $Pr_{y,max}^*$, monthly optimization produces negligible change in productivity but increases equivalent work from 4.95 to 5.16 (+4.35%), indicating a deterioration in energy performance. In contrast, at $Weq_{y,min}^*$, monthly optimization substantially increases productivity (+10.13%) but at the expense of increased energy consumption (+15.09%). Overall, these results indicate that increasing temporal resolution in the optimization inputs shifts the optimal trade-off between productivity and energy consumption rather than delivering uniform improvements across the Pareto front. Hence, we conclude that:

$$KPI_y^*(\bar{T}_y, \overline{RH}_y, \theta_y^*) \neq \overline{\text{KPI}}_y^*(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta_{m,i}^*)$$

**Table 2.** Annual-mean KPI comparison for yearly-constant and monthly-constant optimization (max-$Pr$, min-$W_{eq}$). The relative KPI changes are calculated with respect to the yearly optimization strategy that produces $KPI_y^*$ at each operating point. $\Delta\text{KPI} > 0$ signifies an increase in the measured KPI.

| Operating point | Strategy | $Pr$ | $Weq$ | $\Delta\,\text{Pr}\,\%$ | $\Delta Weq\,\%$ |
|---|---|---|---|---|---|
| $Pr_{y,max}^*$ | $KPI_y^*$ | 6.22 | 4.95 | - | - |
| | $\overline{\text{KPI}}_y^*$ | 6.20 | 5.16 | -0.37 | 4.35 |
| $Weq_{y,min}^*$ | $KPI_y^*$ | 3.81 | 2.98 | - | - |
| | $\overline{\text{KPI}}_y^*$ | 4.20 | 3.43 | 10.13 | 15.09 |

Furthermore, as shown in Figure 6, by investigating the month-by-month value of re-optimization at $Pr_{y,max}^*$ we observe that monthly re-optimization yields higher productivity in most months, with $\%\Delta Pr \geq 0$ in 9 out of 12 months. The largest productivity increase occurs in January (+4.75%), while the most pronounced productivity penalty occurs in November (-6.98%), indicating that re-optimization does not consistently preserve the productivity-extreme solution across the full seasonal

envelope of monthly mean conditions. The energy response at $Pr^*_{y,max}$ is mixed and season dependent. The equivalent work decreases (i.e., $\%\Delta W_{eq} \leq 0$) in 8 out of 12 months, reaching a maximum reduction of -11.68% in April and -7.56% in May, but increases in the remaining months, with the largest penalty occurring in October (+7.79%). Consequently, monthly re-optimization at the productivity-driven operating point does not yield uniform co-improvement but instead induces month-specific trade-offs where productivity gains may be accompanied by higher energy consumption (e.g., January, October, December), and energy reductions may coincide with reduced productivity (notably November). At the minimum-energy operating point, monthly re-optimization produces a consistent productivity improvement in every month, with $\%\Delta \mathrm{Pr} > 0$ for 12 out of 12 months. The magnitude of the productivity uplift is substantial, ranging from +1.48% (March) up to +23.02% (November), demonstrating that the fixed yearly operating strategy is systematically conservative in terms of throughput when applied under month-specific ambient conditions.

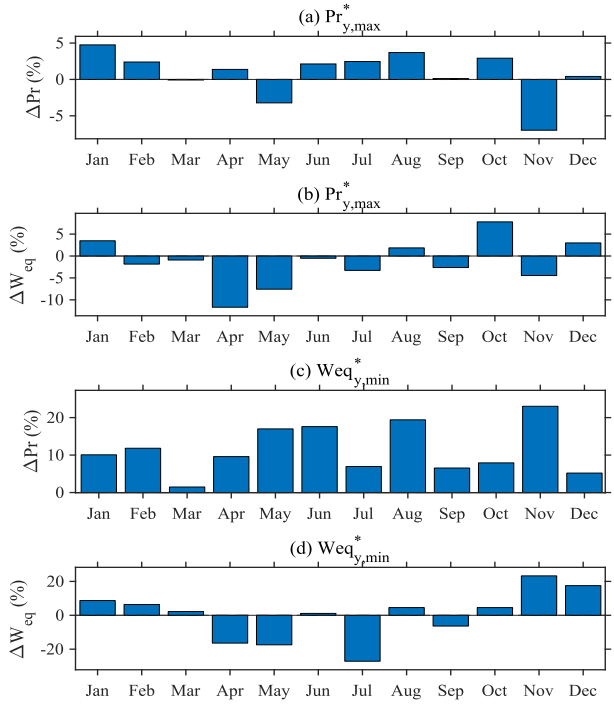

**Figure 6.** Monthly percentage change in productivity and equivalent work when applying monthly re-optimization relative to fixed yearly-optimized operation evaluated at $Pr^*_{y,\max}$ (a/b) and at $W^*_{\mathrm{eq},y,\min}$ (c/d).

In contrast, the energy effect remains highly seasonal. Equivalent work is reduced (i.e., $\%\Delta W_{eq} \leq 0$) in only 4 out of 12 months - specifically April (-16.42%), May (-17.44%), July (-27.12%), and September (-6.35%) - but increases in the remaining months, with pronounced penalties in November (+23.27%) and December (+17.50%). This indicates that month-specific re-optimization does not consistently minimise energy month-by-month but rather relocates the operating point along the Pareto surface in a way that frequently favours productivity increases, occasionally at the expense of higher energy demand. When averaged on an annual scale, at $Weq^*_{y,min}$, montlhy re-optimization provides a clear annual productivity increase (~11%) with a modest reduction in Weq (~2%). A similar decrease in Weq is observed at $Pr^*_{y,max}$ coupled with a marginal increase in Pr (< 1%). Hence, we conclude that:

$$KPI_{m,i}(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta^*_y) \neq KPI^*{}_{m,i}(\bar{T}_{m,i}, \overline{RH}_{m,i}, \theta^*_{m,i})$$

$$\bar{KPI}_y \neq \bar{\mathrm{KPI}}^*_y$$

The above analysis serves as a tool to depict that finer data can improve the predicted KPIs and hence show that literature-assumptions of constant weather prevents the system from reaching its maximum potential. However, these gains are achieved under the assumption of monthly fixed weather inputs. The real operational gains should be evaluated when daily weather data is propagated along with the optimal values of operating variables. Under time-resolved weather propagation, monthly scheduling provides no meaningful benefit at $Pr^*_{y,max}$, yielding negligible productivity change (+0.03%) while increasing equivalent work (+1.72%). In contrast, at $W^*_{\mathrm{eq},y,\min}$, monthly scheduling delivers a substantial productivity gain (+10.24%) but no corresponding energy reduction, with equivalent work remaining effectively unchanged (+0.18%). Overall, the 'real gains' analysis shows that improvements inferred under aggregated ambient conditions do not necessarily translate into energy savings under intra-month variability, while productivity gains persist primarily in the energy-minimization regime. Hence, we conclude that:

$$\overline{KPI}_y \neq \overline{\mathrm{KPI}}^*_y$$

## CONCLUSION

To conclude, this work leverages on a previously developed high-fidelity, mechanistic, model to assess the impact of local weather variability and temporal aggregation on model predictions and real operational gains for an S-TVSA DAC unit. We show that DAC performance responds non-linearly to temperature and relative humidity. Consequently, KPIs evaluated at monthly or yearly average conditions do not reproduce true annual performance under time-resolved operation. Productivity is consistently overestimated, while electrical energy demand and equivalent work are substantially underestimated when yearly average weather inputs are used, with important implications for techno-economic

assessment, plant sizing, and system integration.

The study further shows that increasing the temporal resolution of the optimization inputs from yearly-mean to monthly-mean ambient conditions does not deliver uniform improvements in annual performance but instead repositions the optimal operating strategy along the productivity-energy trade-off surface. Month-specific optimizations can yield localized performance peaks (e.g., productivity uplift in selected months or reduced equivalent work) that can survive aggregation and deliver an improved performance on an annual scale. Importantly, operating at the energy minimization regime can offer substantial productivity gains. However, this work highlights that the value of these strategies must be assessed through dynamic evaluation: when day-to-day weather variability is propagated through the process model, the apparent benefits inferred under aggregated conditions are attenuated, and meaningful operational improvements remain confined to specific operating regimes. Collectively, these findings indicate that weather should be treated as a primary operational input for DAC design and scheduling - rather than a secondary disturbance to be averaged out if robust, region-specific deployment near industrial clusters is to be achieved. Although demonstrated here for the UK, the proposed workflow is directly transferable to other regions through substitution of site-specific meteorological datasets and deployment constraints, enabling consistent cross-regional benchmarking of DAC performance and operating strategies.

## ABSTRACT

This study presents the modeling and operation optimization of an adsorption heat storage to improve the supply of renewable heat to a house. The system configuration is an open system with water being carried by an air flow and adsorbed on zeolite 13X beads in a packed bed. A numerical model is developed based on mass and energy balances, using a Langmuir adsorption isotherm and a Linear Driving Force (LDF) mass transfer equation. The model is implemented in Pyomo and solved with the NLP solver IPOPT. A sensitivity analysis on the discretization parameters is performed to choose a good compromise between accuracy and computational time. The chosen model is then validated against experimental data from the literature, with a mean absolute percentage error less than 5%. The dynamic optimization of the operation of the system to satisfy a heat demand is then performed. The trajectory for the inlet fluid velocity is optimized in several heat demand scenarios. The results show that this numerical framework is able to follow realistic heat demands for a house even in the case of large peaks corresponding to domestic hot water production, with quadratic errors between the demand and supplied power less than 1%.

## INTRODUCTION

Heat production through renewable energy such as solar energy is a key driver of the energy transition. Due to the intermittency of solar irradiation, an energy storage solution is required to achieve a continuous heat delivery. Thermal energy storage technologies are developed based on three different principles: sensible, latent and thermochemical heat storage. The later includes adsorption heat storage based on the exothermic adsorption of a molecule on a porous structure. In this case, the heat is stored as an adsorption potential allowing long storage duration without heat losses. Moreover, this type of storage has a high energy density, up to 10 times larger than a sensible storage and 2 to 3 times larger than a latent storage [1]. Adding salts to the porous structure increases the thermal effects due to the exothermicity of the hydration reaction. However, such thermochemical systems suffer from poor cycling capacity [1] and are thus excluded from this study.

Adsorption heat storage is still under development and research efforts are required in several areas: adsorbent materials, adsorbate choice, storage structure, process optimization [2]. Some prototypes, such as in [3], have been built to assess the adsorption storage feasibility. However, it was not tested in realistic house heating demand scenarios and the operating conditions were not adjusted accordingly. The energy density of experimental prototypes is often much lower than the theoretical energy density of the adsorbent/adsorbate couple [4], highlighting the need for research on system design and operation. In particular, Lefebvre et al. emphasized the need to adjust the operating parameters in order to reach high energy density values [1].

Optimizing a system's design or operation requires a reliable and accurate model that faithfully represents its behavior. Numerous studies have developed a numerical model for an adsorption heat storage from detailed CFD models to simplified 1D models, such as in [5]. However, the models built might not be compatible with optimization studies, where a good trade-off between accuracy and computational time is essential.

Most optimization studies on adsorption heat storage focus on the design of the system ([6], [7]). Zamengo

et al., used a multi-objective methodology to assist the design of a packed bed thermochemical storage [6]. Optimal values for the adsorbent porosity and thickness are determined while maximizing heat storage density, storage rate and exergy efficiency. The conclusion suggests that modular thin beds are more efficient. Anilkumar et al. developed a 3D dynamic mathematical model using analytical equations and applied a multi-objective algorithm to design an efficient adsorption system [7]. Dimensions for the reactor tubes and the fins added to enhance heat transfer are obtained and realistic systems are simulated based on the recommendations. Those studies did not consider the optimization of the operation of the system.

Wang et al. studied the configuration planning of an adsorption heat storage for different applications in a house [8]. Charging and discharging steps are considered and decision variables include the inlet parameters: inlet air temperature, flow rate and humidity. However, constant values are obtained for each heating scenario.

In this study, a physical 1D numerical model for an adsorption heat storage is developed and validated with experimental data from [3]. The dynamic model is implemented in an optimization framework. Trajectories for the inlet conditions (air velocity) are determined in order to satisfy a heating demand from a house. The dynamic behavior of the system is further analyzed.

The remaining parts of the paper are organized as follows: first, the adsorption heat storage is described. Then, the numerical model is presented along with a sensitivity analysis on the discretization parameters and the validation of the model. After that, the optimization problem is formulated and the results from case studies are explained. Finally, a discussion presents the limitations and future work before a conclusion on this study.

## SYSTEM DESCRIPTION

This study considers the supply of renewable heat from solar collectors to a house. An adsorption storage is added to tackle the intermittency of solar energy and reduce the need of a back-up heat production. The storage is the main focus of this work. The system considered is an open system, using air as a carrier and water as the adsorbate. This choice keeps the complexity of the system and the investment cost lower than other configurations. The adsorbent is zeolite 13X in a packed bed.

The two modes of operation are schematized in Figure 1. When excess solar heat is available, it can be used to desorb water from the zeolite, and thus charge the heat storage. This step requires high temperatures, in the range of [120;180]°C which can be achieved with suitable solar collector technologies such as evacuated tube collectors. The choice of the collectors and the detailed analysis of the desorption step is outside the scope of this study. Once the storage is charged, i.e. all the water has been removed, it can be kept in this state for extended periods without any heat losses. When heat is needed in the house but cannot be directly supplied by the solar collectors, humid air is sent to the adsorption storage. This air can be the interior air of the house or the outside air if its humidity and temperature allow for a sufficient temperature lift. The water contained in the air is adsorbed on the zeolite, releasing heat which is collected and carried by the dried air flow. The heat can then be used for space heating or domestic hot water production in the house.

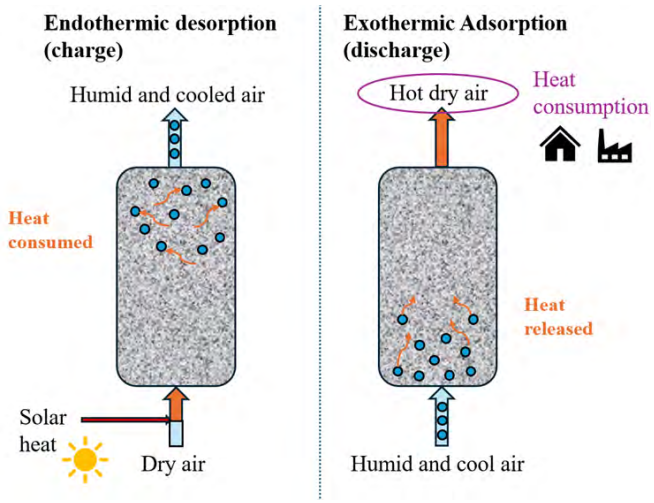

**Figure 1.** Schematic of the adsorption heat storage utilization in a house

## NUMERICAL MODEL

### Model equations

The model of the adsorption heat storage is a 1D model considering only spatial variations along the height of the packed bed. Since the system is open, a constant pressure equal to the atmospheric pressure is considered. There are 7 variables in the model, described in the nomenclature, each depending on the spatial coordinate z and time t, which are omitted for improved readability: $\rho_w, \rho_{da}, \bar{q_w}, q_{eq}, \rho, T, u$.

The model is based on mass and energy balances:

- Mass balance on the dry air, assuming a constant dry air flow

$$\frac{\partial(u\rho_{da})}{\partial z} = 0 \quad (1)$$

- Mass balance on water, neglecting axial dispersion

$$\frac{\partial \rho_w}{\partial t} = -\frac{\partial(u\rho_w)}{\partial z} - \frac{\rho_b}{\varepsilon_b}\frac{\partial \bar{q_w}}{\partial t} \quad (2)$$

- Mixture composition

$$\rho = \rho_w + \rho_{da} \quad (3)$$

- Energy balance on the whole system, assuming a

homogeneous temperature between the solid and the fluid

$$\left[\rho C_{v_f}\frac{\varepsilon_b}{1-\varepsilon_b}+\ \rho_s(1-\varepsilon_s)C_{p_s}+\rho_s(1-\varepsilon_s)\bar{q_w}C_{p_w}\right]\frac{\partial T}{\partial t}= C_{p_f}\frac{\varepsilon_b}{1-\varepsilon_b}\frac{\partial(u\rho T)}{\partial z}-\frac{\Delta H_{ads}\rho_s(1-\varepsilon_s)}{M_w}\frac{\partial\bar{q_w}}{\partial t} \quad (4)$$

- Langmuir isotherm

$$q_{eq}=\frac{Kq_mP_w}{1+KP_w} \quad (5)$$

$$K=K_0\exp\left(-\frac{\Delta H_{ads}}{RT}\right) \quad (6)$$

-Linear Driving Force (LDF)

$$\frac{\partial\bar{q_w}}{\partial t}=K_{LDF}(q_{eq}-\ \bar{q_w}) \quad (7)$$

-Ideal gas law for the fluid phase

$$\rho=\frac{PM}{RT} \quad (8)$$

The model uses a simple adsorption isotherm, Langmuir, with parameters values as follows: $K_0=4.06\text{e}-12\ Pa^{-1}$ and $q_m=0.228\ kg_w/kg_s$. The LDF model is used to describe the mass transfer in the adsorbent. The lumped parameter $K_{LDF}$ takes into account the external diffusion and internal diffusion in the particle and adsorption on the zeolite crystal. A constant $K_{LDF}$ value of $0.0025\ s^{-1}$ was chosen based on the average value computed with the equations detailed in [5].

Initial conditions for the temperature, water concentration in fluid and adsorbed water concentration along the height of the column are required. Inlet conditions for the fluid temperature, water concentration and velocity are also fixed.

## Resolution method

The model was implemented in the Pyomo framework [9]. Pyomo.dae was used to discretize the partial differential equations. The finite difference method was chosen for both time and space discretization, using a fully implicit Backward Euler scheme (first order, constant step). The discretized equations system forms a NonLinear Programming (NLP) problem solved with the IPOPT solver [10]. For a simulation, the number of variables matches the number of constraints, and a dummy objective is added for the resolution.

The model comprises a large number of variables and nonlinear equations and has to represent a steep adsorption front travelling through the storage tank. This makes the problem stiff and difficult to solve. An initialisation strategy was therefore developed as shown in Figure 2. The model was first solved one time step at a time, reducing drastically the complexity of the problem. The results at the end of a time step are used as initial conditions for the next, replacing the implicit scheme for time discretization by an explicit formulation. The results for every time steps are then used together to initialize the simulation over the complete time horizon. The results from the complete simulation are then used to initialize the dynamic optimization, which will be described later in the article.

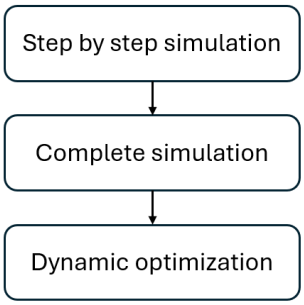

**Figure 2.** Initialisation strategy

## Sensitivity on discretization

A sensitivity analysis on the discretization both in time and space was performed, considering zero degree of freedom, i.e. in a simulation configuration. The inlet conditions are fixed to constant values: $u_{in}=0.3\ m/s, T_{in}=293\ K, \rho_{w_{in}}=0.012\ kg_w/m_f^3$ from [3]. Initially, the storage is at 298K and does not contain water.

Figure 3 presents the temperature profiles obtained at the outlet of the column during adsorption simulations with three different time steps: 50s, 100s and 200s and a fixed spatial discretization of 20 points. The temperature quickly rises due to the exothermic adsorption and stays at a high temperature during several hours. Once the column is saturated and adsorption can no longer take place, the temperature decreases back to the inlet temperature. The profiles obtained with the three discretization time steps are following similar trends, reaching the same adsorption temperature, with only small differences during the transitions. A finer discretization allows to represent steeper transitions at the beginning and at the end of the adsorption phenomenon. Given the small differences between the results, a time step of 100s was chosen, as a good compromise between accuracy and computational time due to the number of variables.

Figure 4 presents the results of adsorption simulations with various numbers of spatial discretization points and a time step of 100s. There are some discrepancies between the profiles. First, the adsorption temperature reached varies by 2°C between 10 and 100 discretization points. Besides, the steepness of the temperature profiles at the beginning and at the end of the adsorption phase is reduced when the number of discretization points is reduced. This can lead to an inaccurate estimation of the adsorption duration. In particular, 10 discretization points does not allow to represent the curvature at the end of the adsorption phase, while all the other plots are superimposed in this zone of the graph.

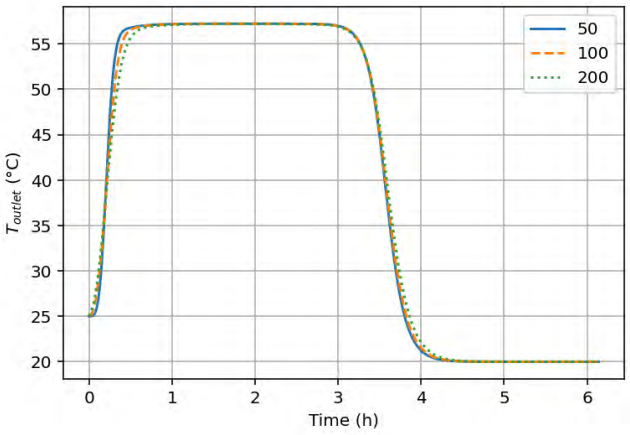

**Figure 3.** Sensitivity analysis on the time step duration

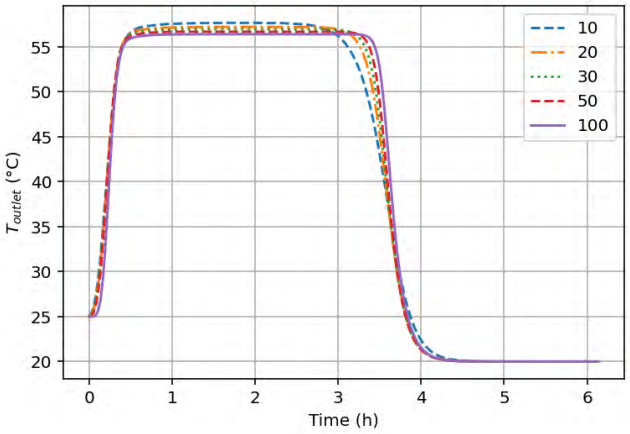

**Figure 4.** Sensitivity analysis on the number of spatial discretization points

Increasing the number of discretization points thus improves the accuracy of the model resolution but at the cost of a larger problem which will be more difficult to use in optimization studies. Table 1 presents the number of variables for each discretization tested. Since most variables depends on the spatial coordinate z, the number of variables increases greatly with the number of discretization points. In order to keep the complexity of the problem as low as possible for optimization while keeping a good accuracy, 20 points were chosen.

**Table 1:** Number of variables in the problem for each spatial discretization

| Number of discretization points | Number of variables |
|---|---|
| 10 | 33267 |
| 20 | 64317 |
| 30 | 95367 |
| 50 | 157467 |
| 100 | 312717 |

## Validation

The model with the chosen discretization of 20 points in the spatial dimension and a time step of 100s was validated against experimental data from the work of Tatsidjodoung et al. [3]. The configuration from their prototype was reproduced in the model for all design and operation parameters, as well as initial and inlet conditions. The cylindrical bed considered has a volume of 144L for a height of 20cm. In the experimental bench, air diffusers ensure a uniform distribution of the flow over the entire section of the bed, justifying the use of a 1D model despite the large diameter of 72cm.

The experiment chosen for the validation is their "test 12" where an adsorption step is performed for two adsorption beds in series. The results at the outlet of the first bed (M1 in [3]) are considered for the validation because of the availability of the corresponding data.

The temperature profiles at the outlet of the bed are plotted in Figure 5. The shapes of the profiles are similar, even in the transition regions when temperature stabilizes at the beginning and the end of the adsorption phase. This ensures that the model predicts an accurate adsorption duration. The region when the temperature starts to decrease, after about 3 hours of heat supply, is not well reproduced by the model. There seems to be a break in the experimental curve at 3.5 hours without physical justification. Therefore, this part of the curve cannot invalidate the numerical model. The overall mean absolute percentage error between the two curves is 4.46% with an adjusted value of $\Delta H_{ads}$ equal to -56398 J/mol in the model, which lies in the range of experimental measurements of [45-75] kJ/mol [11]. The error below 5% ensures the validation of the model.

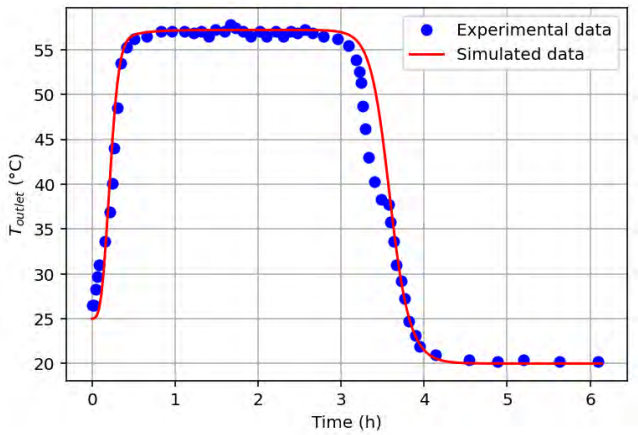

**Figure 5.** Comparison of the experimental [3] and simulated outlet temperature profiles

# OPTIMIZATION

## Formulation of the optimization problem

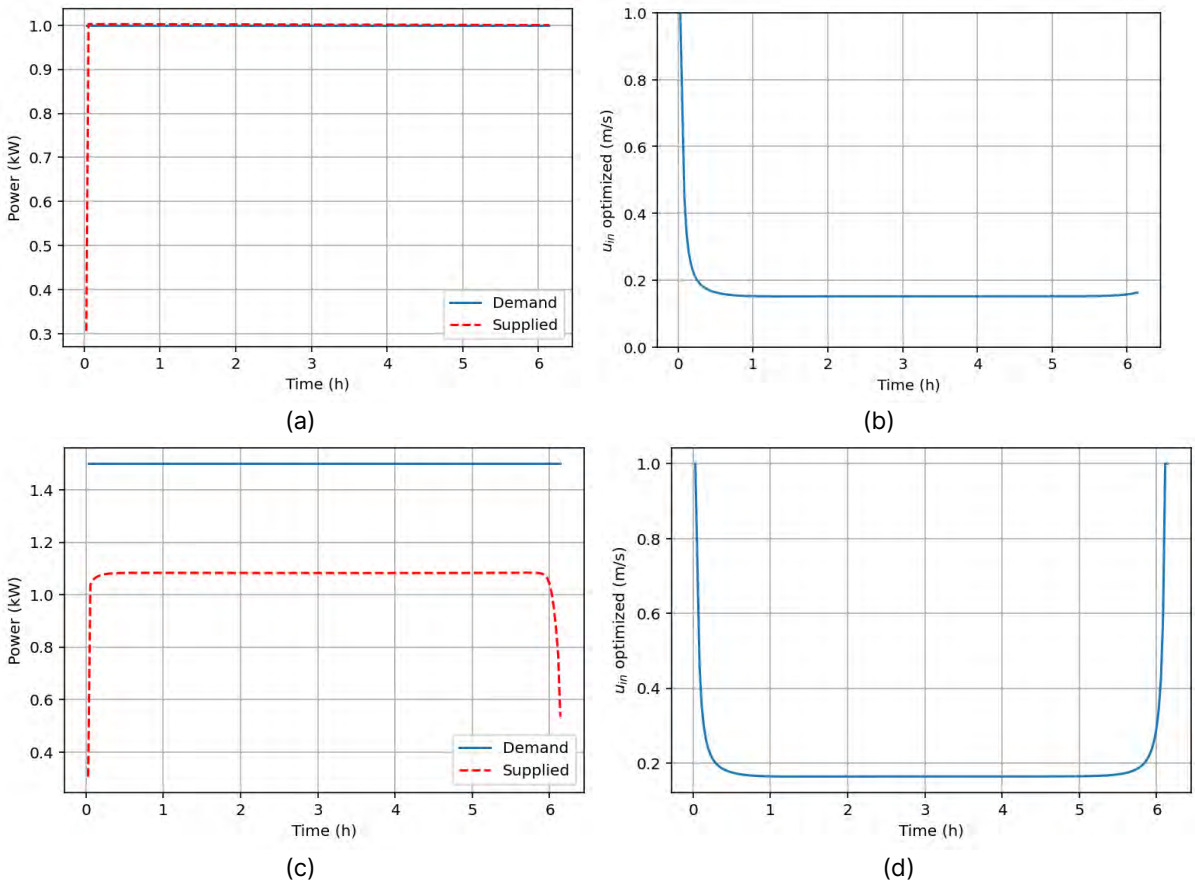

**Figure 6:** Various power demand scenarios and the obtained power supplied and the optimal velocity profiles – constant heat demand

The validated numerical model described previously is then used to perform dynamic optimization of the operation of the heat storage. The design of the system is fixed. The dimensions used are the same as in the validation part, taken from the experimental bench in [3].
The objective function is to minimize the squared difference between the heat power demand and the heat power supplied by the storage at each time step (quadratic error):

$$\min_{u_{in}(t_i)} \sum_{t_0}^{t_f} \left( \dot{Q}_{demand}(t_i) - \dot{Q}_{supplied}(t_i) \right)^2 \qquad (8)$$

The optimization variables are the inlet velocity $u_{in}(t_i)$ at each time step. The velocity is bounded in the interval [0;1] m/s, to ensure that it is lower than the fluidization velocity. The other inlet conditions, namely the temperature and water concentration, remain fixed to the previously mentioned values because in an open system there are generally imposed by the ambient conditions. The only controllable variable is thus the velocity, through the manipulation of the fan.

## Results

To assess the capability of the storage system to satisfy the heat demand of a house, several demand scenarios have been created. These scenarios are realistic heat demands of a room. The heat demand of a whole house is larger and would require several modules of the studied adsorption heat storage. To simplify, only one module is studied here.

Figure 6 shows the results for two distinct scenarios considering a constant heat demand, corresponding to the heating during the night or the middle of the day, when no big change occurs in the demand. Figure 6 (a) shows a heat demand of 1kW, that is almost perfectly matched by the heat supplied, with an objective value (sum of squared errors) of 0.91. The only discrepancy is at the beginning, because the adsorption heat delivery at the outlet of the column is not instantaneous. The corresponding optimal inlet velocity profile is shown in Figure 6 (b). At the initial time, the velocity is as high as possible to start the heat delivery as soon as possible and reduce the difference between the heat demand and the heat supply in the first minutes. Once the heat delivery has started, the velocity goes quickly to its constant value ensuring the required power.

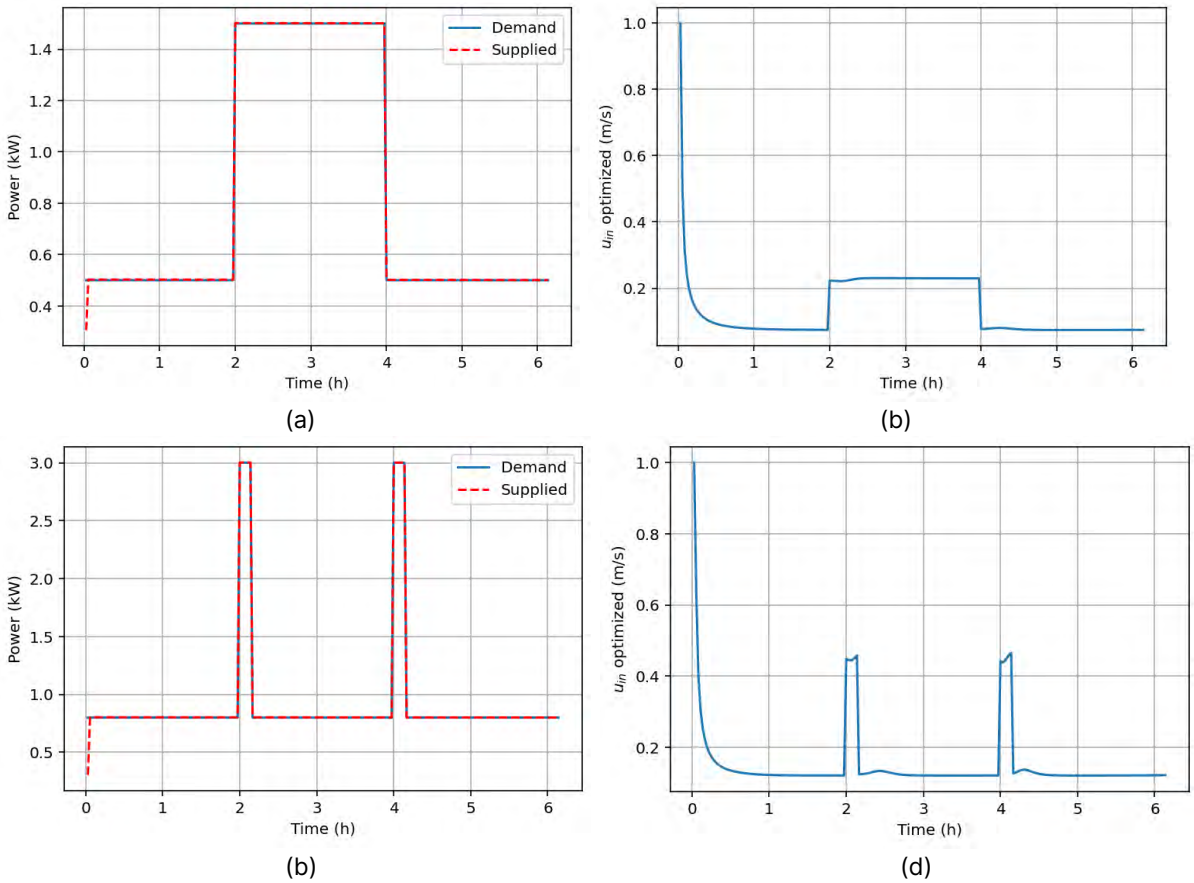

**Figure 7:** Various power demand scenarios and the obtained power supplied and the optimal velocity profiles – variable heat demand

In Figure 6 (c), a similar scenario with a greater heat demand of 1.5kW is shown. In this case, the adsorption storage is not able to satisfy the heat demand, the heat supplied is lower than the demand and the objective is still high with a value of 42.8. Indeed, the capacity of the storage is exceeded, the zeolite cannot adsorb more water and saturates. The optimal solution is here to use the adsorption storage for preheating over the whole time period. A back-up heater will then be necessary to satisfy the heat demand. The optimal inlet velocity for this scenario is shown in Figure 6 (d). As previously, the velocity is high at the very beginning, to start the heat delivery as quickly as possible. It then stabilizes to a value ensuring a stable heat delivery over the whole time horizon. Towards the end of the time period, the storage tank is nearly saturated and not much heat can still be extracted. The velocity increases again to try to match the heat demand, but the supplied power still decreases. This case shows the capacity of the methodology to adjust the inlet velocity to satisfy a heat demand. When the heat demand is too high and the system will not be able to satisfy it over the whole time horizon, the methodology adjusts the inlet velocity to supply the maximum power during the whole time period. In another approach, the volume of the heat storage unit could be optimized to ensure that the heat demand can always be satisfied.

Additional scenarios with variable heat demands were also tested and are shown in Figure 7.

Figure 7 (a) shows a small baseline heat demand of 0.5kW and a larger power of 2 kW for 2 hours. This could be the heat demand of a room with a peak during the hours 6-8pm when people come back home and need more thermal comfort. In this case, the adsorption storage is able to track the heat demand efficiently, with an objective value of 0.06, adjusting the value of the inlet velocity as shown in Figure 7 (b).

Finally, a scenario representing domestic hot water needs has been tested. A baseline heat demand of 0.8kW is chosen and two peaks at 3kW, each lasting 10 minutes, are added. Again, the storage system is able to track the variable heat demand and adjust the fluid velocity, with an objective value of 0.06. Satisfying the real power of domestic hot water production in a house would again require several modules of storage operating in parallel.

## Discussion

The design of the system was fixed in this study, following the prototype dimensions from [3], who tested two adsorption beds in series. Several beds are required to satisfy the heat demand of a whole house. However, this study focused on the dynamic behavior rather than the sizing of the system. Thus, heat demands for a single room were tested according to the size of the adsorption heat storage modelled. Future work should focus on the optimization of the design of the system according to the real heat demand of a house.

This study shows the capability of an adsorption heat storage to follow a heat demand of a house. The dynamic behavior is even able to track fast changes, such as the ones required for domestic hot water production. However, the velocity required to achieve those fast changes is high, leading to high operational costs due to the electricity consumption of the fan. In this study, the water concentration at the inlet is fixed because it is not controllable in most open configuration adsorption systems. Nevertheless, adding a humidifier to increase the inlet humidity of the air flow could help reach higher supplied power values without using as much electricity. Moreover, this added degree of freedom could help achieve a more efficient operation of the storage through dynamic optimization.

Another approach would be to change the system for a closed configuration allowing more control over the inlet variables.

## CONCLUSION

In this work, a numerical model for a packed bed adsorption heat storage was developed. The model is based on mass and energy balances and uses a Langmuir isotherm to describe the adsorption phenomenon and a LDF model for the mass transfer.

A sensitivity analysis was conducted to choose the discretization parameters offering a good compromise between accuracy and model complexity. A time step of 100s and 20 spatial discretization points were chosen. The model was then validated against experimental data from the literature. The value of $\Delta H_{ads}$ in the model was adjusted within the range of experimental data to the value of - 56398 J/mol, in order to reduce the modeling error to less than 5%. Dynamic optimization was then performed on the chosen design. Optimal trajectories for the inlet velocity were computed in order to match a heating demand of part of a house. The methodology was able to track constant and variable heat demands with sums of quadratic errors less than 1%. When the heat demand is too high to be satisfied, the methodology plans the optimal pre-heating.

The results confirmed the potential of the dynamic optimization methodology for the future operation of a real adsorption heat storage unit. Future work will focus on the optimization of added degrees of freedom, such as the inlet humidity, as well as the simultaneous optimization of the design and operation of the system.

## NOMENCLATURE

| Symbol | Description | Unit |
|---|---|---|
| ε | Porosity | [-] |
| $\rho_i$ | Species mass concentration in fluid | $[kg_i/m_f^3]$ |

## ABSTRACT

The present work explores computationally the potential of hybrid operation of a direct reduction shaft furnace with a feed gas mixture of methane and hydrogen, considering the operation of the associated gas handling and conversion units (reformers, condensers, heat exchangers, compressors, heaters, etc.). The state of the system is dependent on both the performance of the shaft furnace, which is sensitive to the feed gas composition and quantity, and the reformer, which converts the methane and the recycled top gas from the shaft furnace into feed gas. This coupling gives rise to nonlinear behavior of the system with respect to changes in the boundary conditions, which justifies a model-based approach for holistic analysis. The system is modelled in Aspen Plus to simulate the operation of an industrial-scale plant using a detailed model of the process units. Three configurations of the system are evaluated: (i) co-feeding of hydrogen with methane, (ii) feeding hydrogen directly to the shaft furnace, and (iii) splitting the hydrogen feed between the two injection points. Further, the effect of $H_2$ share in the feed was evaluated in terms of energy consumption, $CO_2$ emissions and energy cost with low- and relatively high-carbon electricity. The results show that increasing the share of hydrogen in the fresh feed leads to lower $CO_2$ emissions, considering low-carbon electricity.

## INTRODUCTION

The iron- and steelmaking industry is the foremost source of industrial $CO_2$ emissions with a share of 27%, emitting 2.6 Gt/a in 2022 [1], [2]. The sector is particularly energy intensive accounting for 20% of global industrial energy demand, relying mostly on fossil sources. The global production of steel has almost doubled within the last two decades, creating an urgent need to accelerate the decarbonization of this sector [3]. Various pathways have been investigated for a green transition of iron and steel industries, relying on process efficiency and switching to alternative feedstocks and fuels with lower carbon footprints. A strong concept that has been explored is the replacement of blast furnaces, which rely heavily on coke and coal, by direct reduction shaft furnaces (SF) operating on hydrogen-rich gas mixtures. A full transition to hydrogen-based iron ore reduction is a promising pathway to limit the carbon footprint. However, there are still challenges that hinder its adoption by steelmakers, notably the endothermic nature of the reduction reactions, the lower heat capacity of the gas, and, foremost, the high price of green hydrogen. Recent studies have indicated that it may be beneficial to include some carbon monoxide in the feed gas due to its positive impact on the heat supply and less endothermic reduction reactions [4].

The MIDREX process is one primarily gas-based technology for direct reduction of iron ore, representing about 80% of SF-based global steel production [5]. To support the transition toward $H_2$-based reduction, the MIDREX-flex process offers flexible operation using both natural gas (NG) and $H_2$, allowing a smooth and controllable transition for steelmakers [6]. It also enables the retrofitting of existing plants rather than requiring a complete redesign. However, the process behavior during this transition is not clearly known as most of the research works evaluate a complete transition to $H_2$.

The current study evaluates computationally the operation of an iron ore direct reduction process with top gas recycling by gas handling and conversion units

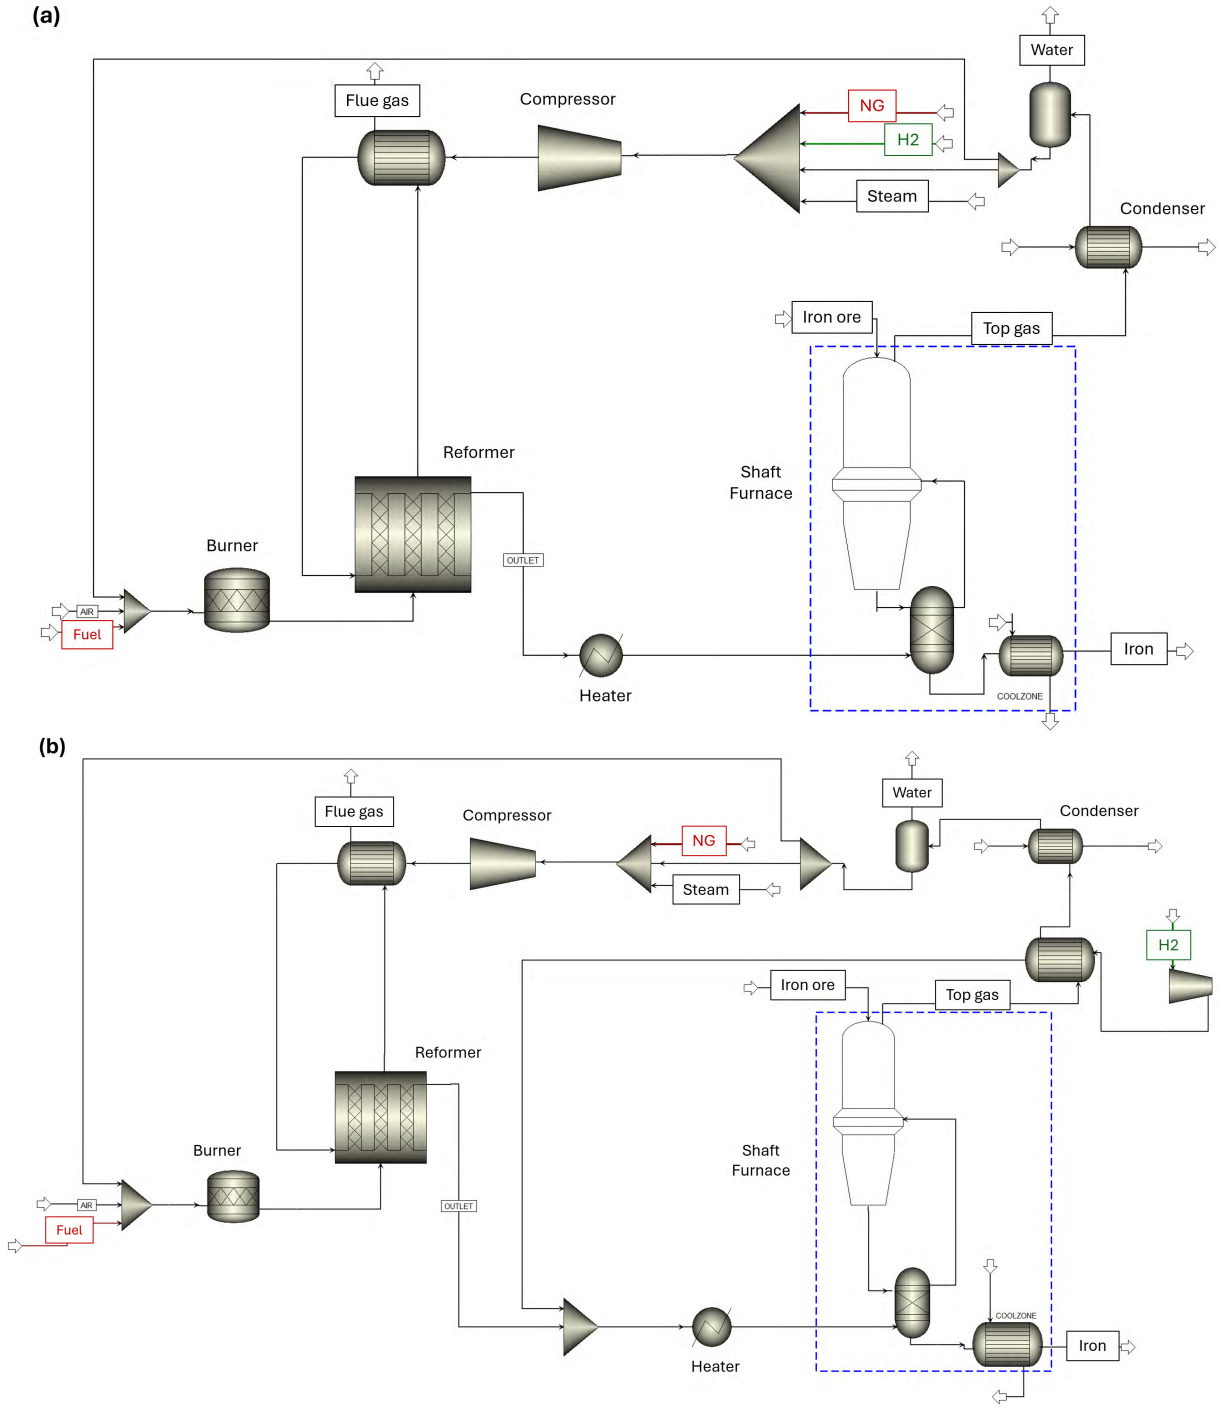

**Figure 1.** Process flowsheet of the direct reduction process.

(reformers, condensers, heat exchangers, compressors, heaters, etc.). The process operation is studied under varied shares of $H_2$ in the feed with different possible injection points in the system. Fresh gas and fuel demands, energy consumption and costs are analysed along with the total $CO_2$ emissions. The study provides guidelines for possible future operation states of iron direct reduction.

## METHODOLOGY

### Process description

The current work considers a shaft furnace

**Table 1:** Process and fuel gas consumption for the evaluated cases.

| Description | **Case 1** $H_2$ injection at reformer upstream | **Case 2** $H_2$ injection at SF level | **Case 3** $H_2$ injection split at reformer upstream and SF inlet | **Case 4** Only $H_2$ based reduction | **Case 5** Only $CH_4$ based reduction |
|---|---|---|---|---|---|
| $H_2$ feed ($kNm^3/h$) | | 27.11 | | 80.69 | — |
| $CH_4$ feed ($kNm^3/h$) | | | 22.09 | | 31.38 |
| Fuel consumption ($kNm^3/h$) | | 56.03 | | — | 56.03 |

employing rich gas mixtures for the iron ore reduction. The process operates with both $H_2$ and NG, where $H_2$ represents 55 mol% of the combined feed. The shaft furnace top gas is recycled back to the system after water removal and mixing with the fresh feed. The process gas is compressed and preheated before entering a steam methane reformer (SMR) for converting $CH_4$ into a rich mixture of $H_2$ and CO, in the presence of recycled top gas. An electric heater is included for further heating of the syngas. It is important to note that 70% of the SF top gas is recycled as process gas, while the other part is fed to the reformer burner along with fuel gas (NG). **Figure 1 (a)** illustrates the process layout of the base case scenario, where both $H_2$ and NG are fed to the reformer.

The paper investigates two other cases with different injection points of $H_2$. The second case assesses the scenario where $H_2$ is supplied directly at the inlet of the SF after being preheated by the top gas, as represented by **Figure 1 (b)**. In the third case, the $H_2$ feed is split so that half of it is fed with the NG and the other half is supplied at the SF inlet. Fully $H_2$-based and $CH_4$-based direct reduction scenarios are considered as reference cases, corresponding to cases 4 and 5, respectively. **Table 1** summarizes the cases with $H_2$, $CH_4$, and fuel consumptions.

It is worth mentioning that the feed of $H_2$ and $CH_4$ is kept constant for the three first cases, while for cases 4 and 5 it is varied to achieve a production of 100 $t_{DRI}/h$ with a metallization rate of 0.93, which is the target production for all the cases.

## Model framework

### Reformer model

The system is modeled using Aspen Plus software (V14). First, the model of the SMR is a plug flow reactor with co-current thermal fluid to simulate an industrial reformer with multi-tubular reactor geometry. The reactor catalytic tubes have a length of 7.9 m, with an internal diameter of 0.2 m [7], and a heat transfer coefficient estimated as 750 $W/m^2$ K [8]. The Peng-Robinson thermodynamic model is used for mass and energy balances of the system, while the pressure drop throughout the reformer is estimated using the Ergun equation.

The main chemical reactions occurring are the steam methane reforming reaction (Eq. (1)) and the water-gas-shift reaction (Eq. (2)):

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2 \; \Delta H_{298\,K} = 206.1\; kJ/mol \quad (1)$$

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \; \Delta H_{298\,K} = -41.15\; kJ/mol \quad (2)$$

The reactions kinetics over nickel-alumina catalysts have been widely investigated in literature [9], [10], [11]. The Langmuir-Hinshelwood-Hougen-Watson (LHHW) model is employed to determine the reaction rates, as an accurate model that considers surface reactions making it suitable for modelling catalyst-based processes [12], such as methane reforming.

### Shaft furnace model

A one-dimensional open source steady-state model, developed by Aspen Technology [13], is used to simulate the SF. The model was implemented in Aspen Custom Modeler (ACM), modeling a counter-current flow of descending iron ore pellets and ascending reducing gases. An RGibbs reactor is integrated to simulate the water-gas-shift and methane reforming reactions over an iron oxide catalyst, and a heat exchange is employed for cooling down the metallized iron to 100 °C. The key reactions for the direct reduction can be expressed as follows:

$$Fe_2O_3 + 3H_2 \longrightarrow 2Fe + 3H_2O \quad (3)$$

$$Fe_2O_3 + 3CO \longrightarrow 2Fe + 3CO_2 \quad (4)$$

The evaluation of energy consumption considers the required compression power, heating duty, and $H_2$ production via electrolysis. Total carbon dioxide emissions are investigated by accounting the emissions linked to process electricity consumption in addition to the

direct emissions with flue gases. Finnish and EU average energy and emissions contexts are used for the analysis.

## SIMULATION RESULTS

### Effect of hydrogen feed point

To find optimal operation points of the direct reduction process, the possible injection points of hydrogen are evaluated as described in **Table 1**. The system behavior is analysed in terms of the metallization rate of direct reduced iron (DRI), energy consumption, and total $CO_2$ emissions.

**Table 2** lists the energy consumption of the process in terms of electricity consumption (EC) and primary energy consumption (PEC). Comparing the three injection points of $H_2$ (Cases 1—3), the first scenario, where hydrogen is co-fed with methane, enables the least energy consumption. This is because less heating is required at the inlet of the SF to maintain syngas temperature at 940 °C. The process gas exits the reformer with relatively high temperature (around 850 °C). Thus, the heater needs to provide a limited temperature increase, whereas the alternative injection options involve cooler gas entering the heater and therefore increasing the heating duty. On the other hand, it is observed that $H_2$-based direct reduction requires higher energy input, most of it in the form of electricity, with a large share for powering the electrolyser (83%).

**Table 2:** Electricity and primary energy consumption of the system in different scenarios.

| | PEC (MW) | EC (MW) |
|---|---|---|
| Case 1 | 549.8 | 160.9 |
| Case 2 | 553.3 | 163.8 |
| Case 3 | 551.6 | 162.4 |
| Case 4 | 647.1 | 471.5 |
| Case 5 | 406.9 | 32.5 |

With regards to the syngas composition, it is found that the injection point of $H_2$ does not have a significant effect on the molar composition. In the current steady-state model, the feed of $H_2$ and $CH_4$ is similar for the three cases, in addition to the fuel consumption that permits a $CH_4$ conversion around 0.9. Thus, the overall mass balance of the system remains nearly unchanged.

**Figure 2** represents the total $CO_2$ emissions of the system considering (a) Finnish and (b) EU average contexts. The grid emission factors used for the study are 29.5 and 187 $gCO_2/kWh$, respectively, based on the statistics of 2024 ([14], [15]). With regards to the different scenarios (cf. **Table 1**), direct emissions are the major contributor to total $CO_2$ emissions, considering the current share of $H_2$ in the system. Further, $H_2$-based direct reduction enables total emissions abatement in the order of 81%, compared with methane-based reduction process, in the Finnish context. However, the emissions of hydrogen-based system rose to surpass the conventional system (case 5) by 12% in the average EU context. Therefore, the hybrid and hydrogen-based processes are environmentally attractive only when electricity has lower carbon footprint and a higher part of renewables.

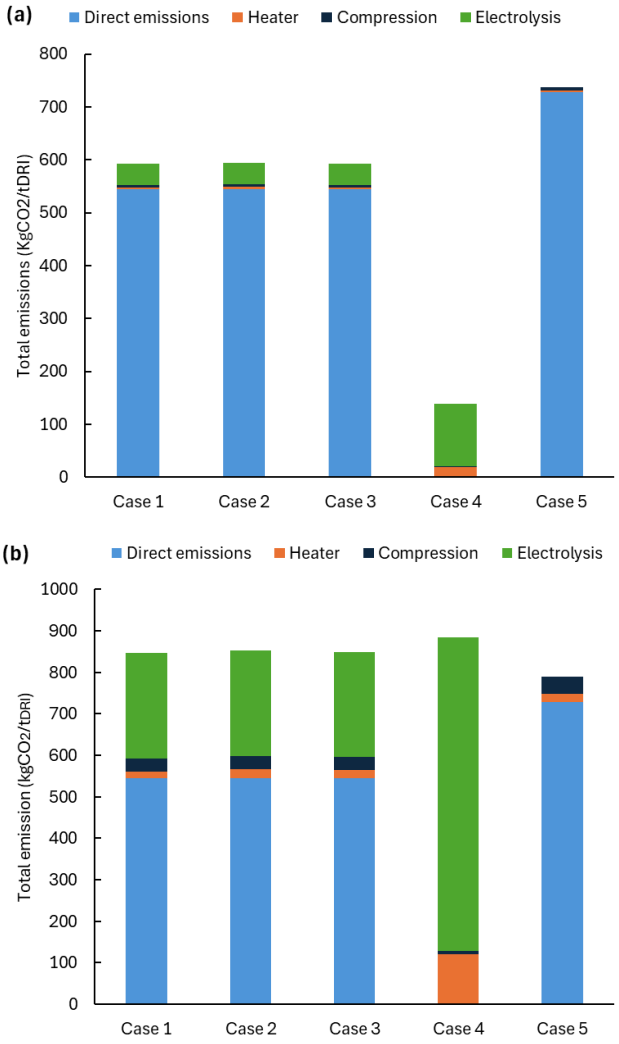

**Figure 2.** Total emissions of the system under different scenarios for (a) Finnish and (b) EU average contexts.

The analysis of energy cost shows that the reduction route combining $H_2$ and $CH_4$ results in a 5% cost reduction, compared with $CH_4$ based DRI process, while the fully hydrogen-based route allows 32% of energy cost reduction, in the Finnish scenario (**Table 3**). In contrast, for the average EU context, the energy cost was increased by 1.6 to 3 folds, comparing with the conventional system, due to higher electricity consumption.

**Table 3:** Energy cost under different scenarios (€/$t_{DRI}$)

| | Finland | EU average |
|---|---|---|
| Case 1 | 300.8 | 348 |
| Case 2 | 302.2 | 352.1 |
| Case 3 | 301.5 | 350.1 |
| Case 4 | 217.4 | 652.2 |
| Case 5 | 317.7 | 212.5 |

## Effect of hydrogen share in the feed

To evaluate the process behavior under different shares of $H_2$, **Figure 3** illustrates the variation of energy consumption and $CO_2$ emissions. It is observed that as hydrogen share increases in the fresh feed, the energy consumption increases as well, because of increased electricity demand. Total emissions of the system decrease with higher shares of hydrogen, caused mainly by lower direct emissions. Note that the Finnish context is considered in this part of the study.

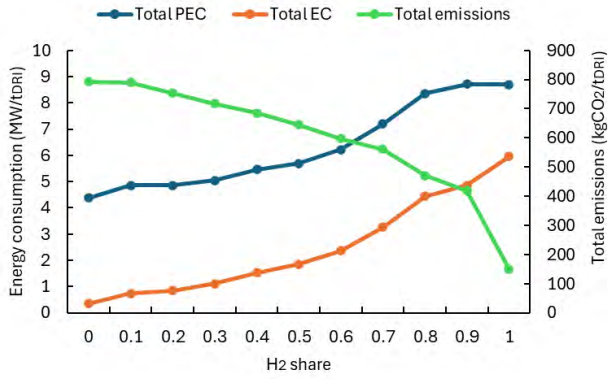

**Figure 3.** Effect of $H_2$ share on energy consumption and $CO_2$ emissions.

**Figure 4** shows the variation of energy cost with the hydrogen share in the feed. Following the increase of electricity consumption, the electricity cost rises linearly with the $H_2$ part. At low to moderate $H_2$ shares (up to 0.7), the cost of NG, used as reducing agent and fuel, is the primary driver for the energy cost. In these cases the process relies significantly on NG to achieve the desired iron ore reduction rate while the cost of NG in Finland is relatively high [16]. Therefore, the transition to hydrogen-based direct reduction is economically wise in regions where electricity is cheaper. Total energy cost remains approximately constant over a wide range of hydrogen shares, as the savings in NG cost are offset by the rising electricity demand.

It is worth mentioning that more in-depth economic analysis is required to assess the feasibility of the green transition, accounting for investment costs in addition to operational costs.

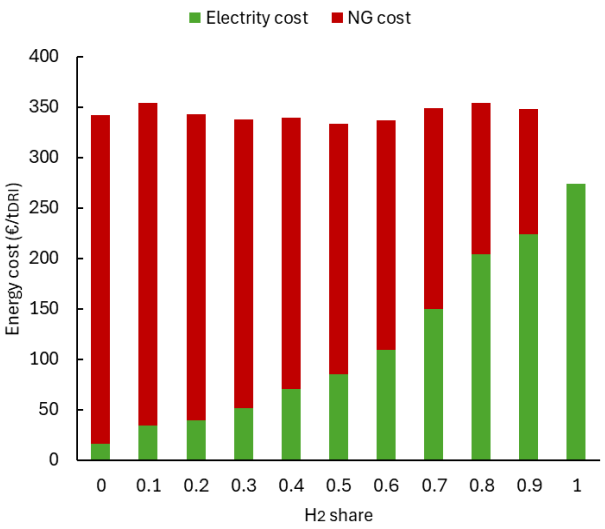

**Figure 4.** Effect of $H_2$ share on energy cost.

## CONCLUSION

The present work investigates a process for direct reduction of iron using a mixture of methane and hydrogen. The system includes steam methane reforming and a direct reduction shaft furnace in addition to heat exchangers, a condenser, and a heater, which are modeled using Aspen Plus software. The effect of having different hydrogen injection points in the process was evaluated, along with the variation of $H_2$ share in the fresh gas feed. Energy consumption, total emissions, and energy cost are the key performance indicators employed to evaluate the process.

The results outline that the feeding point of hydrogen in the system has a negligible impact under steady state mode. However, co-feeding hydrogen with methane is favored for its relatively lower energy consumption. Evaluating the total $CO_2$ emissions shows that a hybrid route for direct reduction can reduce 25% of the emissions compared with fully methane-based reduction. Further, the carbon intensity of electricity is a critical determinant of overall system emissions; up to 97% of $CO_2$ can be avoided when low-carbon electricity is available, whereas a high-carbon electricity supply can limit these benefits and even lead to higher emissions than the conventional reference case. On the other hand, increasing the hydrogen part in the fresh feed leads to lower total emissions when low-carbon electricity is available. From an energy cost perspective, it is found that hydrogen-based direct reduction is economically wise. However, a more in-depth economic study is necessary to identify the cost effectiveness of the system.

## ABSTRACT

The reduction of $CO_2$-emissions in the chemical industry is essential to meet European climate targets. Particularly, the reliance on fossil fuels for process heat supply is a key factor for $CO_2$-emissions. Electrically driven compression heat pumps are a promising option to reduce fossil fuel consumption by upgrading low-temperature waste heat to a higher temperature level, provided that low-carbon electricity is available. However, the integration of heat pumps into chemical utility systems remains a challenge due to economic constraints and the high complexity associated with site-wide heat integration and retrofit of existing structures. This work presents a mixed-integer linear programming (MILP) approach for the optimization of utility systems with integrated heat pumps. To address computational complexity, candidate utility temperature levels are pre-selected, and feasible heat pump coefficients of performance (COP) are precomputed. The framework is applied to both greenfield and retrofit scenarios for a synthetic case study consisting of 400 process streams. In the greenfield scenario, optimal utility temperature levels and heat pump integration configurations are identified. For the retrofit scenario, temperature levels of an existing utility system are modified to reduce total annual costs (TAC). Additionally, sensitivity analysis is conducted to assess the influence of key economic and environmental parameters. The presented case studies demonstrate short solution times, highlighting the suitability of the proposed framework for screening studies and systematic sensitivity analyses in early-stage design and retrofit applications.

## INTRODUCTION

The $CO_2$-emissions of the chemical industry must be reduced significantly to meet Europe's climate goals of zero net-emissions by 2050 [1]. A large proportion of the process heat demand is still met by burning fossil fuels such as natural gas which results in the emission of $CO_2$ [2]. Therefore, an effort should be made to reduce the share of process heat supplied from fossil fuels. This can be achieved by improving the efficiency of chemical processes or using alternative, low-carbon sources of heat supply. Compression heat pumps offer a possibility of providing heat with low $CO_2$-emissions when powered by electricity with a low $CO_2$-emission factor [3]. The use of formerly unused waste heat which is lifted to a higher temperature level by the heat pump can substitute process heat provided by fossil fuels.

Despite the advantages of heat pumps for providing process heat with low $CO_2$-emissions, heat pump integration into chemical processes is still limited by mayor challenges. Among these are economic feasibility and the inherent complexity of the systems involved. [4] In the context of chemical sites, complexity arises, on the one hand, from the large number of potential heat sources and sinks that must be considered for heat integration. On the other hand, both heat integration and the integration of heat pumps increase system complexity by introducing intra- and inter-process dependencies. The integration task then includes the appropriate sizing of heat pumps and identifying optimal integration points that allow independent operation of different considered processes.

In chemical sites, heat is usually provided to the processes via different utility levels such as steam and hot

water at different temperatures. Waste heat from the processes is either used to supply heat to the heating utilities or collected via cooling utilities such as cooling water. The temperature levels of these utilities are often based on historical design decisions. Over time, the design may have become suboptimal due to changes in process conditions or configurations as well as evolving energy trends such as energy price developments and alternative sources of heat supply.

The scope of this contribution is heat pump integration between different temperature levels of the site-wide utility system. This allows the utilization of surplus heat from the lower level and electricity to supply heat to the higher temperature utility level to substitute fossil-based heat. While the integration of heat pumps between different utility levels is limited in efficiency compared to the integration in selected process heat sources and sinks with lower temperature lifts, it offers several advantages. Centralized heat pump integration requires only one power line, it mitigates space limitations associated with integration close to the processes and the utility system may act as a buffer in case of operational fluctuations. Increasing the efficiency of centrally integrated heat pumps may require changing the temperature levels of the existing utility system to optimize waste heat usage and resulting temperature lifts for heat pumps which will be discussed in this work.

## LITERATURE REVIEW

The concept of pinch analysis, introduced by Linnhoff and Hindmarsh in 1983, represents a foundational approach to process heat integration and enables the identification of minimum external energy requirements [5]. Using the problem table algorithm, feasible heat transfer from higher to lower temperature levels is ensured through heat cascading [6]. The methodology was later extended to chemical sites by the concept of total site heat integration which allows targeting and optimization of utility levels as well as cogeneration potentials [7].

Building on these concepts, mathematical optimization approaches have since been developed to address increasingly complex heat integration and utility design problems in process plants and chemical sites. Papoulias and Grossmann proposed MILP optimization based on the transshipment model to minimize utility consumption in a heat recovery network by splitting the temperature range into temperature intervals and solving interval energy balances [8]. Bagajewicz and Barbaro introduced a non-linear targeting approach that optimizes heat pump integration in total sites with continuous decision variables for heat pump temperature levels [9]. Oluleye et al. incorporated heat pump integration in the optimization of existing site cogeneration systems by means of MILP modeling [10]. They focused on different heat upgrading technologies and optimal operational parameters to minimize emissions and total annual costs. Wallerand et al. presented a superstructure-based MINLP optimization of heat pumps into industrial processes [11]. They used a decomposition strategy to solve the complex non-convex optimization task by iteratively solving non-linearities in a master level and technology selection by means of integer variables in a slave level.

The combinatorial complexity of heat transfer between process streams, utility levels and technologies such as cogeneration and heat pumps poses significant challenges for large-scale optimization problems. This may lead to convergence issues for large scale problems which is why many studies employ several simplifications to reduce the solution space. Simplifying utility system optimization is often done by applying simplified equipment models [9, 10, 12], discretizing or using fixed utility candidate temperature levels often from heuristic preselection [13, 14, 15] or linearization of non-linear constraints such as cost functions [16]. While this might exclude the global optimum from the solution space, applying simplified models allow faster solution times which can be valuable for gaining an understanding of the system, optimization under uncertainty or scenario and parameter studies [17].

Heat pump integration into utility systems of chemical sites has been subject to several studies as it provides a valuable option for waste heat utilization and reduction of external heating services [4, 9, 10]. Liew and Walmsley propose a total site targeting method that incorporates open cycle vapor recompression heat pumps with the goal of decreasing boiler energy demand to supply high quality steam [18]. Miah et al. proposed a framework for identifying possible heat integration at different scales incorporating heat pumps to upgrade waste heat and substitute external heating [19].

While previous optimization-based approaches address heat pump integration in utility systems, they often rely on fixed or finely discretized or continuous candidate temperature levels, which can be computationally expensive for large-scale systems. This limits their applicability for extensive parameter studies such as future price scenarios. Based on these limitations, this contribution proposes a mixed-integer linear programming framework for integrating heat pumps into utility systems of chemical plants. Computational complexity is reduced by a structured precomputation of candidate utility temperature levels and corresponding heat pump coefficients of performance, enabling short solution times. The approach is applicable to large-scale systems with several hundred heat sources and sinks and is well suited for screening studies under varying economic and operational conditions.

# METHODOLOGY

## Problem formulation

In chemical sites, heating and cooling services for cold and hot process streams are commonly supplied by site-wide utility systems with different temperature levels, often realized by steam at different pressure levels or water at different temperatures. This allows providing heat to cold streams with a temperature level higher than the cold stream target temperature plus the required minimum temperature difference in heat exchangers. The same principle applies to hot streams which can be cooled down by supplying heat to a utility level with a lower temperature than the process target temperature minus the required minimum temperature difference in heat exchangers. This way, heat surplus from hot process streams can substitute external heat supply to the utility level to supply the cold stream heat demand. The degree of heat integration in existing plants can often be improved by optimizing the utilisation of surplus heat to possibly maintain high quality heat in terms of exergy. While this might increase required heat exchanger area, it may further decrease external heat demand. The same principle applies to heat sinks, where the optimal temperature level for supplying heat to the process stream is not always selected. This aspect becomes particularly relevant when heat pumps are used to supply heat to utility systems. The COP of heat pumps decreases with higher temperature differences between heat source and heat sink and they are limited to sink temperatures of around 200°C [20, 21]. Therefore, process heat sources and heat sinks should be connected to optimal temperature levels to increase the potential for heat pump integration in utility systems of chemical sites.

This can become a challenging task in chemical sites as often several hundred hot and cold streams are connected to the utility system as they cannot be integrated in the processes themselves. The MILP formulation proposed in this work considers the optimization of utility systems. Simple constraint modifications in the MILP allow the analysis of retrofit scenarios as well as the design of new utility systems. The user must supply duties and target temperatures of hot and cold process streams. The approach considers central closed cycle heat pump integration between different temperature levels of the utility system and connections between process streams and utility levels. Optimal utility level temperatures, external heating or cooling requirements for every utility level, optimal connections between streams and utility levels as well as heat pump design and integration are selected during the optimization.

## Candidate temperature level reduction

To enable fast MILP solution times, the number of candidate utility temperature levels must be reduced to reduce combinatorial complexity. In this approach, candidate temperature levels are selected by identifying the highest and lowest feasible temperature levels for hot and cold streams, respectively, that still allow reaching the target temperatures. These levels correspond to the temperatures at which kinks occur in the hot and cold composite curves. While this enables fast calculation, solutions requiring intermediate utility levels for cascaded heat pump configurations are excluded, which is discussed later as a model limitation.

## Heat pump modeling and COP precomputation

As the presented approach should serve as a screening support in decision-making, a simple heat pump model that incorporates thermodynamic principles is applied. The COP is modeled as a function of the Carnot COP by including source ($T_{source}$) and sink ($T_{sink}$) temperatures, required temperature differences in heat exchangers ($\Delta T_{min,source}$ and $\Delta T_{min,sink}$ for source and sink respecively) and compressor efficiency ($\eta_C$) as shown in equation (1).

$$COP = \eta_C \cdot \frac{T_{sink}+\Delta T_{min,sink}}{T_{sink}+\Delta T_{min,sink}-(T_{source}-\Delta T_{min,source})} \quad (1)$$

The maximum temperature lift was assumed to be 60 K for single stage heat pumps with a maximum sink temperature of 200°C [20]. As the candidate temperature levels are predefined, COP values for all feasible combinations of source and sink utility level were also calculated to avoid nonlinearities in the optimization model. The heat pump must further follow the energy balance shown in equation (2) with electricity power demand $P_{el}$, heat demand at the source temperature $\dot{Q}_{source}$ and heat supply at the sink temperature $\dot{Q}_{sink}$ and the COP relation between heat supply and electricity power demand as shown in equation (3).

$$\dot{Q}_{sink} = \dot{Q}_{source} + P_{el} \quad (2)$$

$$COP = \frac{\dot{Q}_{sink}}{P_{el}} \quad (3)$$

Another reduction of model complexity was achieved by eliminating thermodynamically infeasible matches between process streams and utility levels and only keeping feasible matches as sets to be considered during optimization.

## Objective function and constraints

The optimization model is set up as a MILP which minimizes the objective function $c$ subject to sets of linear equality and inequality constraints, represented by $g$ and $f$, respectively. The decision variables include binary variables $x$ and continuous variables $y$.

$$\min_{x,y} c(x,y) \quad (4)$$

$$\text{s.t. } g(x,y) = 0$$
$$f(x,y) \leq 0$$
$$x \in \{0,1\}^m, y \in \mathbb{R}^n$$

The MILP was solved in Python using Gurobi Optimizer [22] on a desktop computer equipped with an Intel® Core™ i7-12700 CPU @ 2.10 GHz (12 cores, 20 threads). The objective function can be chosen to be TAC, operational expenditure (OPEX), capital expenditure (CAPEX) or $CO_2$-emissions. In this work, only heat pump investment costs were considered as we focused on retrofit scenarios. We assume electricity driven heat pump compressors and natural gas boilers as existing external heating equipment. Detailed cost calculations and all assumed cost parameters are given in the supplementary material.

Binary variables control the existence of components such as heat pumps and utility temperature levels and the connection between process streams and utility levels. We further define that every process stream must be connected to exactly one utility level.

To accurately model the utility system, energy balances were set up for every utility level. As depicted in Figure 1 of the supplementary material, each utility level can supply heat to cold process streams and receive heat from hot process streams. If that results in a heat deficit, heat must be supplied to this utility level either by an external heat source (e.g. natural gas boiler), a heat pump or through heat cascading from a higher temperature level. If it results in a heat surplus, the utility level must reject heat either via external cooling, to a heat pump or through heat cascading to a lower utility level.

### Model limitations

As this modeling approach is designed for screening purposes in utility system optimization, it focuses on fast solution times. In the following, we briefly discuss several simplifications that must be considered when interpreting the results. The first simplification arises from the candidate temperature level reduction. By only allowing temperature levels based on process stream data, heat pump integration might be limited e.g. in cases with gaps between candidate utility levels that exceed the maximum allowable temperature lift of a heat pump. Another limitation comes from the shortcut heat pump model which neglects detailed design of heat pump components as well as working fluid selection.

Moreover, no investment cost for new utility levels is considered as this would require tracking the length of required piping which introduces nonlinearities. While this might be sufficient in retrofit scenarios, where only temperature levels of the existing utility system are adjusted slightly, this becomes important in scenarios where new utility levels are added. For screening purposes, fixed investment costs can be assumed for each candidate levels to address this simplification. The same applies to heat exchangers, where no additional costs were considered, as heat exchangers were assumed to exist in retrofit scenarios. It should be checked whether the existing heat exchanger area is sufficient for the proposed utility level and process stream connection. Fixed cost parameters for additional heat exchanger area requirements could be provided as input values for every process stream with predefined utility levels. For heat pumps, fixed specific investment costs were considered (see supplementary material). As effects of scale exist for heat pumps [20], this could be accounted for by including linear estimations of cost correlations from the literature. We further assume no temperature glide in heat exchangers on the utility side. While this Is accurate for utility levels with latent heat supply and demand via condensation and evaporation, it neglects sensible heat transfer e.g. in cooling water. Finally, no stream splitting is allowed, which neglects potentials for higher energy efficiency especially with process streams with a high temperature difference between starting and target temperature.

## CASE STUDY

The synthetic case study discussed in this work consists of 200 hot streams that require cooling and 200 hot streams that require heating. Inlet and outlet temperatures and required heat duties are given as input data, and the respective distributions as well as grand composite curve are presented in the supplementary material. The minimum temperature difference for heat exchangers for every stream of 10 K is provided for every stream. Heat cascading between utility levels is allowed for all scenarios in this work. Sensitivity analysis and parameter studies conducted on the case study are presented in the results and discussion section. The scenarios include analysis of optimal temperature levels for a new utility system as well as retrofit scenarios on an existing utility system.

## RESULTS AND DISCUSSION

In the following, the results for several application scenarios for the proposed utility system optimization approach are presented and discussed.

### Greenfield scenario

The first scenario is the design of a new utility system for the synthetic case study. This includes the selection of optimal temperature levels and the design of heat pumps. The maximum number of utility levels was increased stepwise from 2 to 15, and the resulting impact on TAC and the number of required heat pumps was evaluated for each configuration. All other parameters were

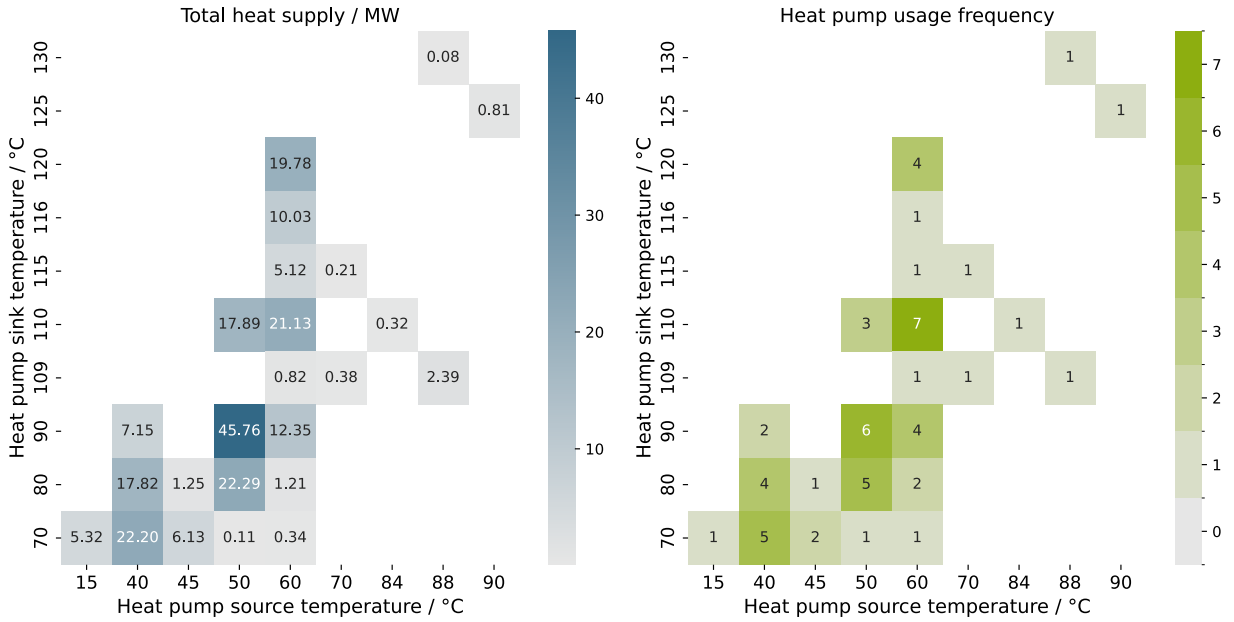

**Figure 2:** Total heat supply of heat pumps and usage frequency for different configurations of maximum number of utility levels.

kept constant. Candidate temperature level reduction resulted in 156 possible utility temperature which results in an average solver time of 8.5 seconds per configuration. As shown in Figure 1, an increasing number of utility levels results in lower TAC as this allows heat integration and heat pump integration becomes more feasible.

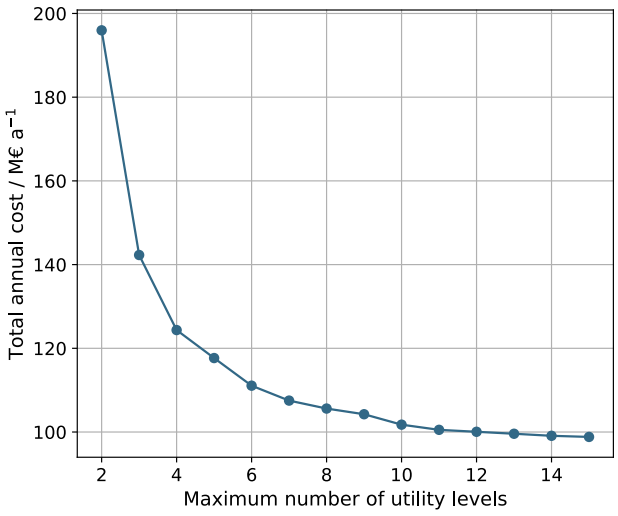

**Figure 1.** Total annual costs for different allowable utility level configurations.

In Figure 2, selected heat pump configurations for different maximum number of utility levels are shown. In the utility level configurations studied, heat pumps with a source and sink temperature of 60 °C and 110 °C were selected most frequently. The analysis further reveals the total heat supply provided by every configuration. Comparison with the selection frequency reveal configurations with a high individual substitution potential. Although the heat pump configuration with a source and sink temperature of 60 °C and 116 °C is only selected in one utility configuration it provides a high substitution potential of over 10 MW. Through this analysis, relevant heat pump configurations can be assessed quickly. It further supports decision-making in selecting an appropriate number of utility levels by clearly illustrating the trade-off between TAC and system complexity.

Moreover, the moderate computation times enable the evaluation of multiple cost assumptions, facilitating informed decisions and serving as a solid basis for subsequent detailed analysis.

## Retrofit scenario 1

In the following, a retrofit scenario for the synthetic case study is discussed. The assumed utility system has temperature levels at 13 °C, 25 °C, 80 °C, 143 °C, 214 °C, 285 °C and 1600 °C. In a first analysis, the potential for changing the temperature of a single utility level is analyzed. The temperature may be adjusted by 10 K. Resulting TAC savings including heat pump investment costs are compared to the existing utility system structure without heat pump integration.

The lowest original temperature level at 13 °C is modified to 15 °C as this is sufficient to supply cooling to the stream with the lowest outlet temperature but it does not affect the potential for heat pump integration. No

modification could be identified for the levels 80 °C, 214 °C, 285 °C and 1600 °C to improve heat pump integration. TAC savings of 0.28 % can be achieved for the levels 13 °C, 80 °C, 214 °C, 285 °C and 1600 °C by integrating the same heat pump between the levels 25 °C and 80 °C. Only the modification of the utility level at 25 °C and 143 °C improve the potential for heat pump integration and therefore results in TAC savings of 0.36 % and 1.08 % respectively. To achieve this reduction in TAC, the level at 25 °C must be increased to 35 °C and the level at 143 °C must be decreased to 136 °C.

## Retrofit scenario 2

In a second retrofit scenario, the same existing utility levels were assumed but two temperature levels could be modified simultaneously. Again, TAC compared to the existing utility system structure without heat pump integration were assessed and included annualized heat pump investment cost and operational cost such as cost for natural gas, electricity and emission certificates as described in the supplementary material. The TAC savings achieved by integrating heat pumps and modifying combinations of utility levels are shown in Figure 3.

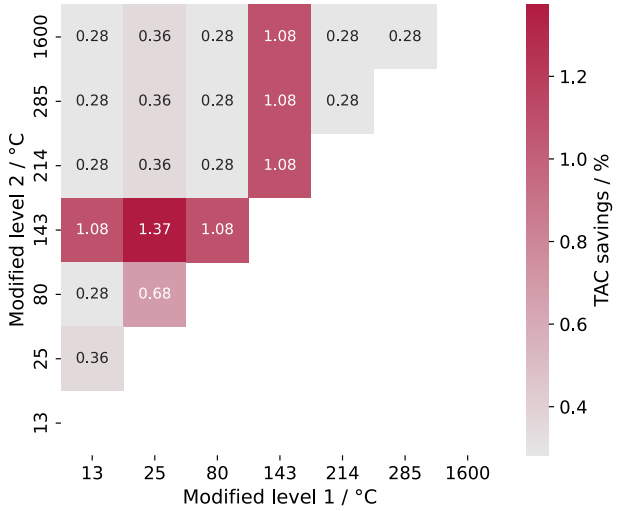

**Figure 3.** Effect of modifying two utility level temperatures on TAC savings.

While for some combinations, the same savings as in the first retrofit scenario can be seen as no additional heat pump integration is feasible, the combined modification of temperature levels 25 °C and 80 °C leads to TAC savings of 0.68 %. For this, the levels must be adjusted to 35 °C and 90 °C. By modifying level temperatures of 25 °C to 35 °C and 143 °C to 134 °C, higher TAC savings compared to the existing utility structure without heat pumps of 1.37 % can be achieved. Notably, when modifying the 25 °C and 143 °C levels simultaneously, the 143 °C level is adjusted to 134 °C instead of 136 °C, as observed in retrofit scenario 1 where only a single level was modified at a time.

As both retrofit scenarios only allow temperature adjustments in a range, the number of integer variables for candidate utility levels decreases significantly, resulting in average solver times of 0.2 seconds per configuration which underlines the potential for heat pump integration screening studies of this approach.

## Retrofit scenario 3

In cases, where temperature levels of the utility system should not be modified, the complexity of the optimization problem is greatly reduced to only integrating and sizing of heat pumps as well as optimizing connections of process streams to the utility system to increase heat integration. One possible application for this is discussed in the last retrofit scenario. In this scenario, the synthetic case study is used with an existing utility system with the modified temperatures that led to the highest TAC savings in the second retrofit scenario (15 °C, 35 °C, 80 °C, 134 °C, 214 °C, 285 °C, 1600 °C). Sensitivity analysis is used to analyze the effect of different parameters on TAC. The results for varying electricity cost, emission certificate cost, specific heat pump investment cost as well as electricity emission factor are shown in Figure 4 where 0 % variation represents the base value.

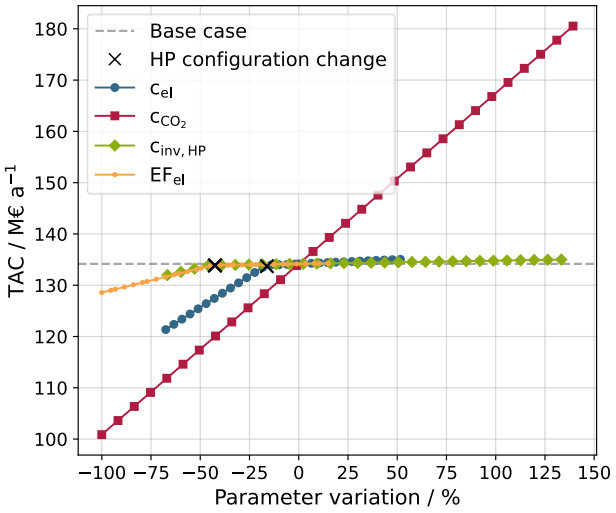

**Figure 4.** Sensitivity of total annual cost (TAC) to selected model parameters.

Due to the significant reduction of model complexity, the required computational time was around 0.1 seconds per parameter variation.

It is evident that $CO_2$ certificate costs for emissions associated with heat supplied by burning natural gas and electricity consumption in heat pumps have the highest impact on TAC. At high temperature levels, technical limitations prevent heat pumps from fully replacing external

heat demand, leading to residual emissions. With increasing emission certificate costs in the future, this underlines the importance of defossilization to stay economically competitive. For increases relative to the base value, the remaining parameters lead to only minor rises in TAC. For negative variations, a tipping point, marked as a change in heat pump configuration in Figure 4, can be observed for electricity cost, specific heat pump investment cost and the electricity emission factor. In the base configuration, a single heat pump is used to upgrade heat from the 35 °C utility level to 80 °C. For all cases located to the left of the markers, a second heat pump becomes feasible, enabling a further upgrade from 80 °C to 134 °C. Compared to the base values, a reduction of approximately 45 % in both the specific heat pump investment cost and the electricity emission factor is required for the second heat pump to become feasible, while a reduction of about 16 % in the electricity price is sufficient. In cases with two heat pumps, the total heat supplied by the heat pumps increases significantly, which explains the steeper gradient observed in the sensitivity analysis compared to cases where only one heat pump is feasible. Conducting sensitivity analysis can thus be an important decision support in combination with the utility system optimization in identifying critical model parameters or evaluating future cost and emission scenarios.

## CONCLUSION AND OUTLOOK

In this work, a MILP framework for utility system optimization including heat pump integration was proposed. Model complexity was reduced by preselecting relevant utility level candidates, precomputation of feasible heat pump COP as well as elimination of thermodynamically infeasible matches between process streams and utility levels. While the proposed simplifications may exclude certain intermediate optima, they lead to a substantial reduction in computational effort. The resulting short solution times, as demonstrated in the presented case studies, make the approach well suited for screening studies and sensitivity analyses. The optimization framework can be applied to various optimization tasks, including greenfield design and the retrofit of existing utility systems. This was demonstrated with a greenfield design of a utility system, analyzing the impact of allowed utility levels on TAC and heat pump integration. Three retrofit scenarios were analyzed in which selected temperature levels of an existing utility system were modified, and promising adjustments were identified. In addition, the effects of different model parameters on TAC and heat pump integration were identified. Overall, the demonstrated computational performance supports the use of the model in early-stage design and retrofit studies, where multiple design alternatives and parameter variations must be evaluated efficiently. Future studies should further address the simplifications discussed in the model limitations section, for example by incorporating utility investment costs or additional heat exchanger costs, particularly for applications requiring a more detailed economic assessment. In addition, the influence of the candidate temperature level reduction on solution quality should be systematically assessed and compared to alternative discretization strategies, to quantify the trade-off between computational efficiency and optimality. Overall, the proposed framework provides a robust and computationally efficient basis for the systematic evaluation of heat pump integration options in complex utility system optimization problems.

## ABSTRACT

Cryogenic fuel tanks used in ships are continuously subjected to heat ingress and motions which affect the thermal behavior of the fluid inside the tanks. In this study, the ullage space of a liquid hydrogen (LH2) tank subjected to heat ingress and periodic rolling motion is analyzed using Computational Fluid Dynamics (CFD). A two-dimensional transient model utilizing the dynamic mesh approach is created to represent the ullage space of a partially filled LH2 tank. Three cases are studied where the properties of the thermal insulation of the tank model are varied, resulting in a different heat ingress for each case. A low-frequency motion is applied to the model domain, which induces mixing of temperature layers and cooling due to vapor contact with wetted walls. After 60 s of tank motion, most mixing is observed in the case with the smallest heat ingress, whereas in the cases with larger heat ingress and, consequently, larger thermal and density gradients, separation into a warmer and colder vapor region can be observed. The model developed in this work can be used to gain insight into how liquid hydrogen tanks used on ships are affected by heat ingress and ship motions.

**Keywords**: Computational Fluid Dynamics, Hydrogen, Heat Ingress, Tank Motion, Cryogenic Fuel Tank

## INTRODUCTION

Hydrogen is considered a potential fuel in the shipping industry to mitigate greenhouse gas emissions from the propulsion system. Like natural gas, hydrogen can be liquefied to increase its energy density and stored in cryogenic tanks; this requires cooling down the hydrogen to temperatures around 20 K. Even with efficient thermal insulation, LH2 tanks are affected by heat ingress leading to boil-off and thermal stratification [1, 2]. Ship motions, on the other hand, can cause mixing and destratification of the fluid, which affects e.g. the tank pressure. Understanding fluid behavior under such conditions is crucial for safe operation and design of the fuel tanks.

Various studies have been conducted on fluid behavior in cryogenic tanks. Kang et al. [3] used Finite Element Analysis to investigate thermal stratification in liquid cryogen tanks and the effects of thermal aspect ratio. S B et al. [4] conducted experiments on thermal stratification and pressurization in a partially filled liquid nitrogen (LN2) tank and developed a CFD model to predict fluid behavior in the tank. Jeon et al. [5] performed experiments on the thermal behavior and generation of boil-off gas in a Type C LN2 tank and conducted numerical simulations using CFD.

Furthermore, Jeon et al. [6] conducted experiments on the Type C LN2 tank subjected to rolling motions and presented a multiphase CFD model using the volume of fluid (VOF) method and a phase change model to predict the effects of liquid sloshing in the tank, while Liu et al. [7] implemented the VOF method to investigate the effects of intermittent external excitations on the thermal performance in a liquid oxygen tank.

Most of these studies implemented two-phase models and either simulated the thermal stratification phenomenon in stationary tanks or the response to motions in tanks with initially uniform fluid temperatures. However, not many studies have been conducted on the effects of tank motions on an initially thermally stratified ullage space of a cryogenic fuel tank through

computational methods.

In this study, CFD modelling with dynamic mesh is used to simulate the fluid behavior in the ullage space of an LH2 tank subjected to external heat input and rolling motion. The vapor phase is modelled exclusively for detailed prediction of thermal behavior in the ullage while limiting the required mesh size and avoiding additional computational costs from including the liquid phase. The resulting model is used to demonstrate how mixing affects the thermal behavior of the vapor phase in an LH2 tank with different heat ingress and temperature gradients. Furthermore, the modelling approach in the present work is validated against experimental cases and datasets sourced from previous studies. Thermal stratification in the ullage is validated against experiments in a stationary LN2 tank [8], while the effect of tank motion is validated against experiments performed in a pressurized hot water-water vapor tank [9].

## METHODOLOGY

### Model LH2 Tank Concept and System Boundary Conditions

A Type C cryogenic storage tank with double-walled vacuum insulation filled with perlite powder is used as the tank concept and visualized in Figure 1. The design choices made here are assumptions and estimates based on literature findings for LH2 tanks [1, 2, 10].

The tank has an inner length and diameter of 1500 mm and 500 mm, respectively. Stainless steel of the grade 316L is used as wall material for both the inner and outer wall, which both have a thickness of 3.5 mm, while the thickness of the annular space between the walls is 100 mm. The liquid filling level of the tank is 50%, with the pressure inside the tank at 4 bar and liquid temperature as well as initial gas temperature at 26 K, while the temperature of the outer wall is set at 288 K. In the CFD simulations, the tank is modelled using a two-dimensional representation.

In total, three cases are considered in this work, where the thermal boundary conditions are varied for each case by adjusting the thermal conductivity of the insulation. Ratnakar et al. [10] investigated the effective thermal conductivity of various insulation materials for cryogenic storage tanks and considered different vacuum levels in their study. The conductivity values used for the tank insulation in this work are taken within the ranges presented in the study for perlite powder vacuum insulation. Here, the thermal conductivity of the insulation is assumed to be varied by adjusting the vacuum level in the annular space.

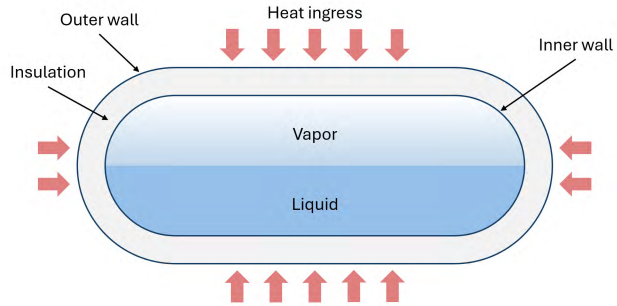

**Figure 1.** Design concept of the model LH2 tank.

The thermal conductivity of the walls and insulation, as well as the total thermal conductivity for the entire wall structure in each case are summarized in Table 1. The heat transfer rates into the liquid zone and the boil-off rates are given in Table 2. These are calculated based on the heat conduction through the walls to the liquid zone with inner wall temperature of 26 K.

**Table 1:** Thermal conductivity of the inner and outer walls ($k_w$), insulation ($k_{ins}$) and the total thermal conductivity ($k_{tot}$).

| | **Case 1** | **Case 2** | **Case 3** |
|---|---|---|---|
| $k_w$ [W/(m²•K)] | 15 | 15 | 15 |
| $k_{ins}$ [W/(m²•K)] | 0.0005 | 0.001 | 0.002 |
| $k_{tot}$ [W/(m²•K)] | 0.000535 | 0.00107 | 0.00214 |

**Table 2:** Heat transfer rate into liquid ($Q_l$) and boil-off rate at the liquid surface ($m_{evap}$).

| | **Case 1** | **Case 2** | **Case 3** |
|---|---|---|---|
| $Q_l$ [W] | 2.3 | 4.7 | 9.4 |
| $m_{evap}$ [kg/s] | $5.2 \cdot 10^{-6}$ | $1.0 \cdot 10^{-5}$ | $2.1 \cdot 10^{-5}$ |

For the tank motion simulations, a periodic rolling motion is applied to the model domain to simulate the motions of a moving ship. In each case, the amplitude is 10° and the period is 12 s. The liquid surface remains flat throughout the motion. This can be seen as an approximate representation of a tank with floating baffles to mitigate sloshing. Furthermore, the tank motion causes wetting of wall surfaces, where wetted surfaces are assumed to have the same temperature as the gas-liquid interface (26 K). Figure 2 shows the ullage at different stages of the tank motion and the direction of gravity perpendicular to the liquid surface. This approach for modelling the ullage and gravity during tank motion allows for simpler implementation of the dynamic mesh while maintaining realistic domain geometry and gravity conditions.

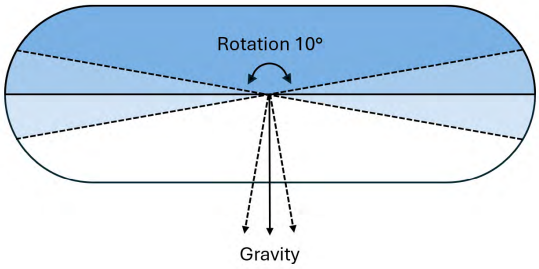

**Figure 2.** Ullage position at different points of the tank motion.

## Numerical Model

CFD analyses of the three cases are conducted using the Ansys Fluent 2024 R1 software. A two-dimensional transient model with dynamic meshing is created to represent the vapor phase inside the tank. The simulations are performed in two parts: Part 1: the formation of the thermal gradient in the ullage due to heat ingress and natural convection, and Part 2: the tank motion and its effect on the thermal gradient is investigated.

### Part 1: Thermal Gradient

The fluid domain consists of hydrogen gas surrounded by the tank walls and the liquid surface at the bottom. For the first part of the simulations, the domain is not moving, and the liquid surface is modelled as a wall with a mass source term to represent boil-off. A pressure outlet of the size 10 mm is set at the middle of the top wall to maintain the tank pressure close to 4 bar. The boundary conditions for the walls and liquid surface for each case are set as described in the previous section for computing the thermal gradient.

In the first part, the thermal gradient in the ullage for the static tank is computed. This is conducted by first calculating the thermal gradients for steady state conditions for a low Rayleigh value by reducing gravity and, subsequently, switching to a transient model and incrementally increasing gravity to normal conditions. This approach is to prevent the solution from diverging. The simulations are run until the temperature gradients become stable, using a time step of 0.01 s.

### Part 2: Tank Motions

Results from the first part of the simulations are then used as the initial conditions for the tank motion simulations. The dynamic mesh method with user-defined functions for the mesh motion is applied to represent the motion and change in shape of the vapor domain over time, see Figure 2. The direction of gravity is also set to follow the motion so that it is always perpendicular to the liquid surface. For the tank motion simulations, the domain is closed. The mass source term for the liquid surface is set to zero, which means that the vapor mass will remain constant. Furthermore, the wetted parts of the walls are set at the same temperature as the liquid surface. The time step used here is 0.005 s.

### Solver Settings

The effects of heat ingress and buoyancy are considered by enabling the energy equation and using the ideal gas law for fluid density to solve the thermal gradients. The governing equations used in the model are continuity, momentum and energy conservation. Species transport is also used to account for the mass source term at the liquid surface, and the fluid flow is modelled using the k-ω SST turbulence model with near-wall treatment. Furthermore, the pressure-based transient solver with PRESTO! pressure discretization scheme and PISO algorithm are used for the solver settings. The convergence conditions for the residuals are set as $10^{-6}$ for energy and $10^{-5}$ for continuity and transport equations.

## METHOD VALIDATION

Before modelling the LH2 cases, the model was validated against experimental data from the literature. Firstly, the model for developing the thermal gradient in the static ullage was validated using experiments reported by Singh et al. [8], where they measured the vertical temperature gradient inside an LN2 tank at atmospheric conditions with liquid filling levels of 57%, 69% and 77%, with heat ingress of 0.27 W, 0.26 W and 0.29 W into the vapor phase, respectively, as well as a heat ingress of 2.03 W into the liquid for all cases. The tank used in the study consisted of an inner and outer vessel made of aluminum sheets with vacuum multi-layer insulation in between. The inner height of the tank was 360 mm, and the diameter was 300 mm [8]. In the present work, two-dimensional meshes with a mesh size of 5 mm were used to model the vapor phase of each validation case. In Figure 3, results from the simulations are compared to the experimental data from the study by Singh et al. [8].

Secondly, the tank motion model was applied to one of the experiments conducted in the study by Grotle and Æsøy [9]. In their study, they measured the thermal response in a pressurized hot water tank subjected to rolling motions using an amplitude of 3° and various frequencies. The tank used in their study was an insulated cylindrical pressure tank with spherical tank heads and supplied with a heating element. The length of the cylindrical part was 0.89 m, the diameter was 0.35 m, and the tank had a liquid filling level of 50%. Before the tank motion tests, the liquid was heated to 393 K, most of the air was removed and the tank pressure was increased to 4.0254 bar [9]. The tank motion model with the dynamic mesh used in the present work was applied to the hot water tank experiment case with a frequency of 0.13 $s^{-1}$, where the liquid surface remains flat [9]. A two-dimensional mesh with a mesh size of 5 mm was used to model

the vapor phase of the hot water tank case. In Figure 4, the simulation results using the tank motion model are compared to the experimental data of the pressure reduction in the hot water tank.

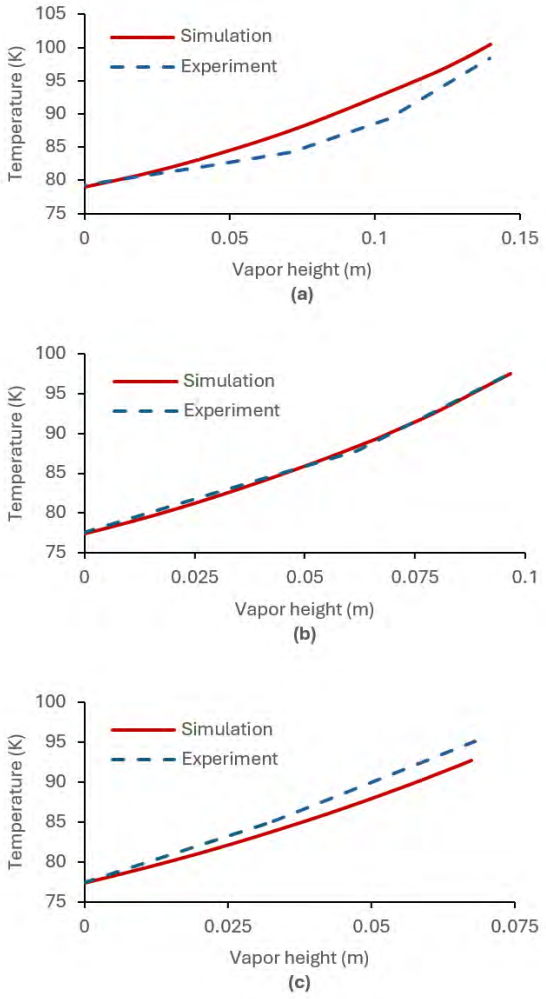

**Figure 3.** Simulation results for the vertical thermal gradient validated against experimental data for liquid filling levels of (a) 57%, (B) 69% and (c) 77% [8].

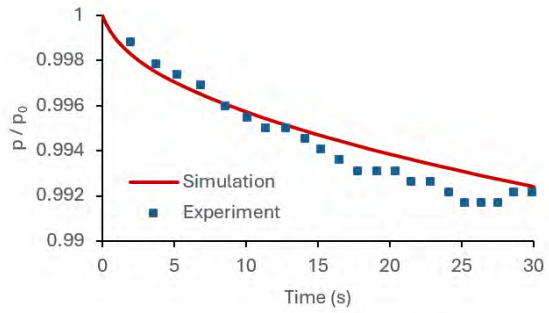

**Figure 4.** Simulation results for the tank motion model validated against experimental data [9]. Results are for tank pressure over time.

# RESULTS FOR LH2 TANK CASES

## Mesh Sensitivity Analysis

A mesh sensitivity analysis was conducted to determine the required mesh size for the LH2 tank ullage model. Three different mesh sizes were compared against each other: cell sizes of 2.5 mm, 5 mm and 10 mm with corresponding minimum cell sizes of 0.5 mm, 1 mm and 2 mm around the pressure outlet. The heat transfer rates at the tank walls and the vertical temperature gradients for the different mesh sizes were investigated for Case 2, see Table 1 and 2. The difference between the heat transfer rates was less than 1% between all cases and Figure 5 reveals that the temperature gradients were almost identical. A mesh size of 5 mm is chosen for this study to balance accuracy and computational costs.

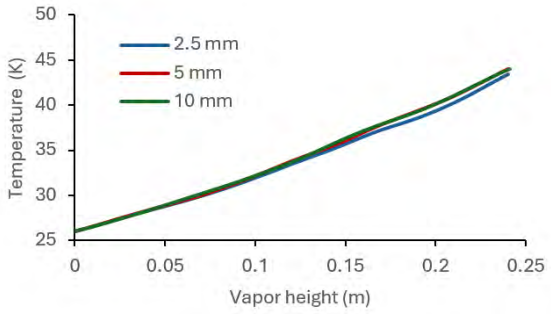

**Figure 5.** Vertical temperature gradient in LH2 tank ullage computed for mesh sizes 2.5 mm, 5 mm and 10 mm.

## LH2 Tank Ullage Simulations

The initial temperature gradients for Case 1, 2 and 3 at stationary conditions were established using the method described earlier. In each case, the transient run was 120 s in total, at which point the gradients had reached a steady state. The temperature contours of the ullage for Case 1, 2 and 3 with the initial thermal gradients are shown in Figure 6(a1), (b1) and (c1), respectively. The time is marked as 0 s to indicate the initial state for the tank motion runs. Furthermore, the corresponding vertical thermal gradients for each case are shown in Figure 7(a). The sizes of the thermal gradients are 10.9 K, 18.7 K and 29.6 K for Case 1, 2 and 3, respectively. These are dependent on the total thermal conductivity values of the tank walls and the associated heat ingress into the tank.

Once the initial thermal gradients were computed, the dynamic mesh method was applied and the tank motion cases were computed for a total run time of 60 s, or five complete oscillations of 12 s periods. The temperature distribution in the ullage for each case at the start and the end of the moving tank runs are shown in Figure 6(a2), (b2) and (c2), and the corresponding vertical temperature gradients are shown in Figure 7(b).

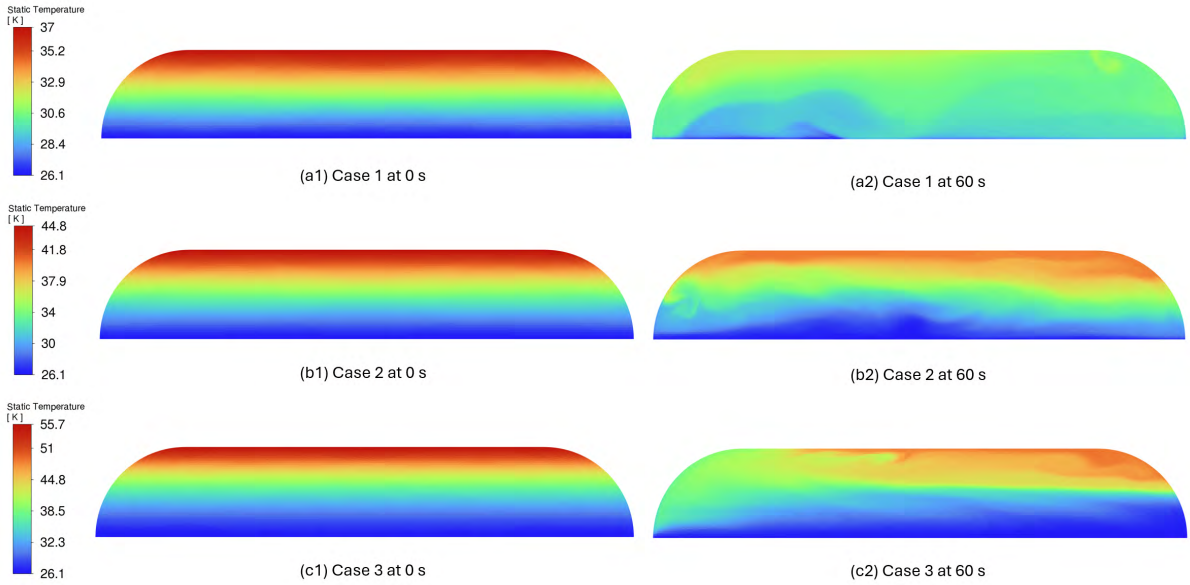

**Figure 6.** Temperature profile of the ullage at stationary conditions ((a1), (b1) and (c1)), and after 60 s of tank motion ((a2), (b2) and (c2)).

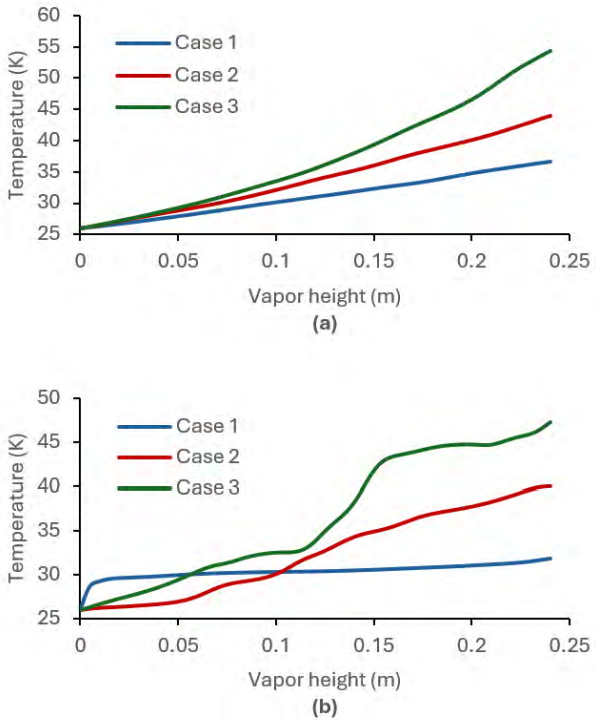

**Figure 7.** Vertical thermal gradient in the ullage for Case 1, 2, and 3 with (a) initial thermal stratification and (b) after 60 s of tank motion.

After 60 s of tank motion, there is a significant reduction in overall temperature and some mixing of temperature layers in all cases. Most mixing can be observed for Case 1, which also has the smallest initial temperature gradient. This is expected behavior, as a smaller temperature difference also means a smaller difference in density between fluid layers, which enhances mixing. For Case 3, on the other hand, the thermal gradient can be seen separating into two fluid layers around the middle of the domain: the denser cold zone at the bottom and the warmer zone with lower density on top. Case 2 also shows separation between fluid layers, although not as clearly as Case 3 and it still has moderate mixing between cold and warm zones.

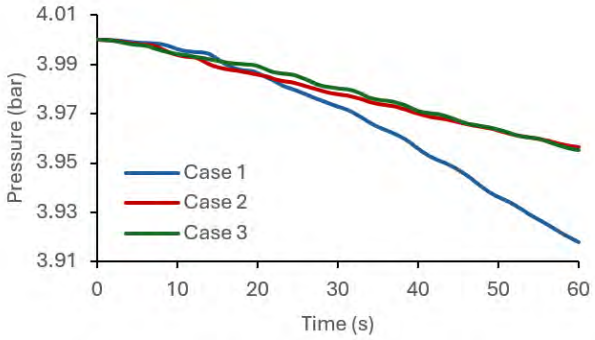

**Figure 8.** Tank pressure over time for Case 1, 2, and 3.

Furthermore, the vapor cooling also causes a reduction in the domain pressure, as shown in Figure 8. Case 1 has a significantly larger pressure reduction compared to Case 2 and 3, which have a similar pressure evolution to each other over time. The mixing and destratification of fluid layers in Case 1 allows warmer fluid to come into

contact with wetted walls and the liquid surface, resulting in more efficient heat transfer from the vapor to the liquid, and consequently, a larger pressure reduction. Both in Case 2 and 3, the fluid separation into two density layers hinders the mixing of the fluid and the subsequent heat transfer from vapor to liquid, slowing down the pressure reduction rate.

## CONCLUSIONS

A numerical investigation on the effects of heat ingress and ship motions on the thermal behavior in the ullage of an LH2 tank was conducted using CFD modelling with dynamic meshing. Three cases were studied, where the thermal conductivity value of the tank insulation was varied and the subsequent response to the thermal gradient and destratification effect due to rolling motion was analyzed. Varying the thermal conductivity value of the insulation affected the size of the temperature gradient. It was observed that for the case with the smallest temperature gradient, the tank motion resulted in destratification and an almost uniform temperature profile in the ullage within five complete oscillations. In the other two cases, the larger difference in density between fluid layers caused separation into cold and warm fluid regions. The results of this work demonstrate the effects of heat ingress and ship motion on the ullage space of an LH2 fuel tank by varying the properties of the thermal insulation. The developed model can be used for further investigations of similar effects in cryogenic tanks.

## ABSTRACT

Heat pumps offer the possibility of reducing $CO_2$-emissions in the chemical industry. However, the integration of heat pumps, especially in non-continuous processes, faces several challenges. Energy storage facilitates a way to enhance heat integration by providing a continuous supply of heat flows. By doing so, the question arises as to whether this implementation should be applied to the process or to the utility level. At the process level, there is usually more freedom, as one is not bound by the existing temperature levels of the utility system, which are mostly difficult to retrofit. Therefore, this study presents an approach that generates heat integration concepts at the process level based on two different criteria. These criteria influence which process streams are grouped for a storage implementation and therefore influence the heat integration. The aim is to maintain the heat flows as continuous as possible by integrated heat storages. Finally, the possible heat integration concept is evaluated in terms of energy efficiency by a know method for continuous process streams, here the pinch analysis.

**Keywords**: Energy Systems, Batch Systems, Energy Storage, Optimization, Energy Efficiency, Heat Integration

## INTRODUCTION

The $CO_2$-emissions of the chemical industry must be reduced significantly to meet Europe's climate goals of zero net-emissions by 2045 [1]. A large proportion of the heat demand in process industry is still met by burning fossil fuels such as natural gas which results in significant amount of $CO_2$-emissions to the atmosphere [2]. Therefore, the supply of process heat from fossil fuels should be reduced. This can be achieved by improving the efficiency of chemical processes or using alternative, low-carbon sources of heat supply. Compression heat pumps offer a possibility of providing heat with low $CO_2$-emissions when powered by electricity with a low $CO_2$-emission factor [3]. The use of formerly unused waste heat which is lifted to a higher temperature level by the heat pump can substitute process heat provided by fossil fuels.

Despite the advantages of heat pumps for providing process heat with low $CO_2$-emissions, heat pump integration into chemical processes is still limited by major challenges. Especially non-continuous processes with fluctuating waste heat supply and process heat demand add an additional challenge for heat pump integration [4]. Furthermore, a heat pump can be integrated at either utility or process level. A heat pump integration at utility level can have a negative effect on the heat pump due to a higher temperature rise, resulting in a lower coefficient of performance (COP). The reason for that is, that the temperature lift depends on the temperatures of the utilities. An adjustment of the temperatures of the utilities is only possible to a limited extend, because in a chemical site other plants would be influenced by this adjustment as well. Therefore, a heat pump integration at process level can be reasonable. Because of the fluctuating nature of the heat flows in non-continuous processes, energy storages offer the possibility of reducing fluctuations and they should be considered as additional possible heat integration concepts. The integration of energy storages would increase the operation time of heat pumps as well [5].

Within the scope of this study, the energetic influence of the number and size of thermal energy storages is analyzed, particularly under the assumption that heat flows are not stored in an ideal manner from an energetic standpoint. Although energetically optimal storage, as

applied in the time average model (TAM), for example, can serve as a reference or benchmark, it may result in heat flows with similar temperature levels being stored in separate energy storages. The question arises to what extent the number of storage units can be reduced and according to which principles heat flows should be aggregated.

To address this issue, the present study provides a concise overview of various methods for heat integration in non-continuous processes with fluctuating waste heat supply at the process level. Furthermore, a systematic procedure is introduced from which different heat integration concepts can be derived based on two distinct criteria that specify which process streams are stored together. The influence of these criteria-particularly with respect to the aggregation and storage of heat flows is analyzed. Finally, one selected variant of these heat integration concepts is evaluated in terms of its energy efficiency.

## LITERATURE REVIEW

Different types of methods were developed to receive heat integration concepts. One the on hand there are graphical methods like the pinch analysis. This is a method, which determines the theoretical maximal internal heat exchange based on the cold and hot process streams [5]. This method assumes that alle streams are continuously available and have a constant start and end temperature. Based on the pinch analysis, the time average model (TAM) was developed for non-continuous processes. The result of the TAM is a maximal threshold of possible internal heat exchange. To use this method, the non-continuous process is overdriven into a continuous representative process, by averaging the duties over the process time. A pinch analysis can now be performed using the average heat flows. The results of the TAM are used to design thermal energy storages conceptually. [6] In addition to TAM, there is also the time slice model (TSM). This is a conceptual method which, in contrast to the TAM approach, attempts to take into account the temporal influence on heat integration. To do this, the batch process is divided into time slices so that continuous behavior occurs in these slices. The external utility demand can now be determined in each interval, by using the pinch analysis for each slice. The sum of the external utility over the entire observation period also represents a minimum threshold value. [6] Other approaches to determining heat integration concepts for batch processes use mathematical optimization. A hybrid approach, which is a combination of a graphical and an optimization part takes time slices into account and also considers the integration of a heat pump. A grand composite curve is generated for each time slice. Based on this, the heat pump is dimensioned once so that surplus heat can be stored on the source or sink side by means of an energy storage and released again in times of deficit. [7] Of course, recurring patterns for the slices must first be found. At the same time, the complexity of possible heat transfer networks increases with an increased number of slices. Walden et al. also consider mathematical optimization as an approach for heat pump integration. The grand composite curve for each hour is used as input and then a heat pump is integrated with the help of a mathematical optimization problem. The integration is carried out for different heat outputs: Either for averaged values (TAM), for each hour an optimization, or an optimization over the entire period under consideration. Using this optimization approach it was possible to reduce the heat pump size and thus the operating costs. Thermal storages were not taken into account in this work. [8] Prendl et al. use a linearization of the operating pattern of the heat pump. At the same time, storage and the heat exchange network are taken into account so that a minimum TAC can be achieved. The linearization of MINLP problems has the advantage that MILP problems are not dependent on start values and still achieve a global optimum; and MILP problems enable lower computing times [9, 11]. Becker et al. also use a mathematical optimization problem, which can be used to optimally integrate a heat pump [10]. In addition to dimensioning the relevant equipment for heat integration, the extent to which the scheduling of non-continuous processes affects heat integration was also investigated. Optimization problems were solved for this purpose [12, 13]. Fluctuating heat supply occurs not only in the process industry, but also in the residential sector. Renaldi et al. develop a mathematical optimization model, which considers the design and the operation für a heating system within a heat pump and a thermal energy storage [14]. Furthermore, cluster algorithms were also used, which, for example, aim to identify recurring operating conditions. Wickramasinghe et al. use the k-means algorithm to group temperature time series for commercial buildings [15]. When using heat pump systems, operating data was also used to determine representative load and temperature profiles. For this purpose, the patterns were extracted using dynamic time warping [16].

## PROBLEM STATEMENT

We consider a case study involving hot and cold process streams for which heat integration is investigated. Heat integration at the utility level is not the first choice due to unfavorable temperature levels, so we have started with heat integration at process level. To this end, a potential study was carried out in advance to identify low-hanging fruits, i.e., the process streams that are interesting for direct heat integration. The influence of simultaneous availability, temperature difference, and

the ratio of heating supply to heating demand were taken into account in the potential study. The process streams identified by the preliminary potential study as suitable for direct heat integration are not considered in the following problem formulation, thereby reducing the number of process streams and slightly simplifying the problem. The remaining process flows are now to be integrated at the process level. Because there are many possible combinations, an optimization problem that considers heat pumps and storage systems simultaneously was ruled out.

## METHODOLOGY

The method aims to determine the impact of the number of storage units on the heat integration concept. The purpose of the storage units is to achieve steady-state conditions, thereby facilitating subsequent, conventional heat integration. For example, heat integration for steady-state conditions can be carried out using well-known analysis methods such as pinch analysis. The question arises which streams should be stored together. To address this question, the method introduces two criteria, each grouping the process streams according to a different objective. These two criteria each have an influence on the grouping of process streams and thus also on the size of the thermal energy storage. The structure of this method is shown in Figure 1. The method starts with a pre-analysis to check the process data for consistency and group them into hot and cold streams. Afterwards it is possible to choose between two different criteria according to which the hot and cold streams are grouped. An energy storage is designed for each of these groups so that stationary conditions are achieved and a following-up pinch analysis is possible. The following section discusses the criteria and storage dimensioning in more detail. The entire methodology is implemented in Python.

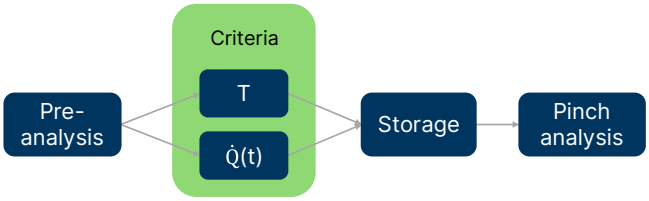

**Figure 1**. Structure of the method.

### Criteria 1: Temperature

This first of the two criteria follows the approach of clustering process streams into groups so that the process streams within a group have similar temperatures. The k-means cluster algorithm is used for grouping [17]. Data points, in our case temperatures, should be grouped so that they are as similar as possible within a cluster and as different as possible between clusters. To use the algorithm, one needs to specify how many clusters the data will be grouped into. The benefit of k-means is that it is easy to implement. This criterion actively influences the temperature prevailing in the energy storage.

### Criteria 2: Temporal heat duty

The second criterion aims to ensure that, if several energy storages are available, the process flows are grouped in such a way that they fluctuate less over the time horizon. This has the advantage that the thermal energy storage can be smaller in size, as it needs to buffer less thermal energy. To determine how the streams are grouped, a small optimization problem is solved. This is a MINLP problem, as the objective function takes variance into account. The objective function minimizes the total variance of all groups over the entire time horizon. At the same time, the constraints must be met, e.g., that each stream may only be assigned to one cluster, and that each cluster should be filled with at least one stream. In the optimization problem, the number of clusters is predefined and varied iteratively within an identical cluster range to maintain comparability with the first criterion. The detailed calculation is provided in the supplementary material. The optimization problem was set up and solved in Gurobi [18].

### Storage

Once the groups have been selected, a storage dimension can be determined based on the selected process streams. A two-layer storage is selected as thermal energy storage, as this allows start and end temperatures to be specified and then used for pinch analysis. The temperature level within the layers are determined in such a way that, for example, in the case of hot streams that need to be cooled, the temperature in the top layer corresponds to the minimum temperature to which it must be cooled minus a temperature difference for heat transfer. Then for the energy storage, a temperature difference of 10 K is assumed for the temperature of the second layer. This value naturally influences the required storage capacity and can of course be adjusted. The output duty of the energy storage is calculated from the sum of the total energy flowing into the storage device. For a specified storage medium, in this case water, the respective heat capacity results in a mass balance that is accumulated over time and then set to a start value so that the storage content is never negative. Figure 2 shows the structure of the storage system. The specific calculation can be found in the supplementary material. The fluctuating process flows are shown on the right-hand side and are grouped together for a storage. In this case, these heat flows are cooled by the storage and the heat flow on the left-hand side remains constant.

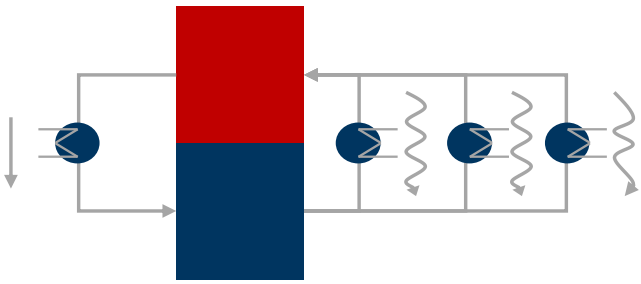

**Figure 2.** Schematic structure of the energy storage.

## Pinch Analysis

The pinch analysis is then performed for a different number of clusters for the hot and cold streams respectively. A minimum temperature difference of 10 K is assumed in each case. The result of the pinch analysis ultimately serves, for example, as the basis for a percentage saving of the total heating requirement. Based on this a final heat integration concept can be derived.

# CASE STUDY

The case study involves a batch process comprising 13 cold streams and 23 hot streams, with a temperature range extending from 5 °C to 144 °C. Due to the absence of a periodic operating pattern, the heat duties do not follow a consistent or recurring behavior, thereby complicating heat integration. The dataset used for analysis is provided at 5-minute intervals over a continuous period of 7 days and captures process- and apparatus-level heat duties for each of the 36 streams. This case study originates from real plant data that was anonymized accordingly.

# RESULTS

The results of the two different criteria are presented below. The subsequent results, such as storage dimensioning and pinch analysis, are only presented for one criterion. All results refer only to the cold process streams.

## Criterion 1:

The first criterion considers the final temperatures to which the streams are heated or cooled. Figure 3 shows the distribution of the different temperatures depending on the number of clusters. The range in which the clusters were varied extends from one cluster to seven different clusters. This is because a maximum of seven different temperatures occur. This does not necessarily mean that there are only seven streams, as streams can also be heated to the same temperature. It is noticeable that the three temperatures around 90 °C are grouped together for most of the clusters tested. The different colors of the temperature data points indicate the cluster and therefore the storage, to which each temperature belongs. The number of clusters corresponds to the number of available storages. For instance, if two clusters are defined, two storages (S1 and S2) are used. In this example, two distinct colors represent the clustering: all streams with temperatures below 100 °C are assigned to one cluster, while those above 100 °C are assigned to another. Consequently, all streams below 100 °C (yellow markers) are grouped together and stored in S2, whereas the remaining streams-requiring temperatures above 100 °C (purple markers)-are grouped into the other cluster and assigned to storage S1. This criterion is used to assign process streams to storage based on the number of available storages, with the objective of minimizing temperature differences among process streams within the same storage. In general, an increasing number of available storages leads to a reduction in temperature variability within each storage.

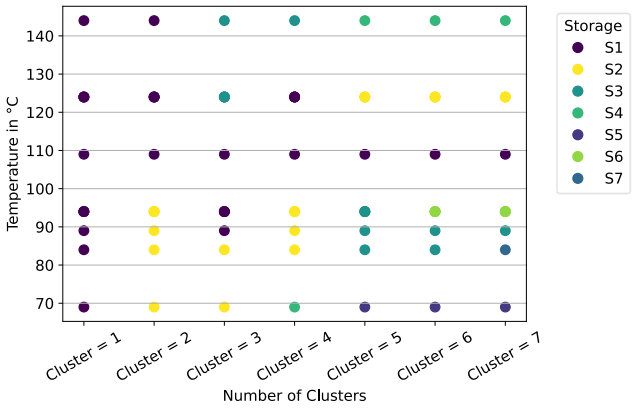

**Figure 3.** Cold Streams Clusterdistribution for criterion 1.

## Criterion 2:

As with criterion 1, the process streams were grouped into a predefined number of clusters. The number of clusters was varied over the same range as for criterion 1. Figure 4 illustrates the composition of a single cluster when the total number of clusters is four. The clusters were chosen such that the variance in the sum of their values was as small as possible. For example, stream W-12 complements the other two streams (W-3 and W-15) very well from approximately hour 80 to hour 130. Nevertheless, there may also be overlaps between the individual streams. The average duty of the streams of this cluster is approximately 380 kW. The presence of overlapping streams arises from the lack of alternative combinations that would result in a lower total variance for the specified number of storages (and corresponding clusters), which is four in this example. The resulting stream distribution is strongly dependent by the individual heat duty profiles.

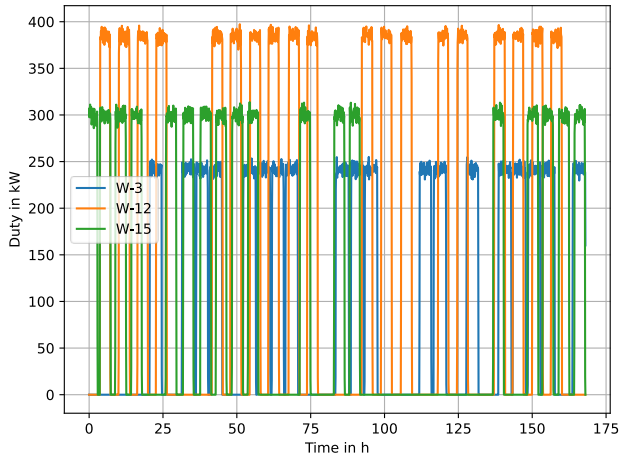

**Figure 4.** Composition of Cluster 1 for criterion 2 for cold streams.

## Comparison of the criteria

As previously mentioned, the cluster criteria have a direct influence on energy storage. Figure 5 shows the influence of the two cluster criteria on the total storage mass and the average maximum temperature difference of the flows belonging to a single thermal storage. It is noticeable that an increase in the number of clusters and therefore also in the number of storages leads to an increase in the total mass of all storages used for both criteria. If only one storage is used, the total storage mass for both criteria is approximately 900 kg. If considering only one cluster, the criterion is irrelevant, as all process flows must be included in one cluster and therefore one storage. If the number of clusters and thus also the number of storage tanks is increased, the total mass of all storages used increases. For criterion 2 (dashed red line), the total mass is always below the solid red line. This is reasonable, as criterion 2 selects the clusters in such a way that the total mass is minimized. The difference between the two red curves also increases with an increase in the number of clusters, as there are now many more possible combinations, meaning that the solutions can deviate more strongly from each other. The average maximum temperature difference of the process flows assigned to each cluster shows a different trend. The temperature difference is determined as follows. For example, for two possible clusters, the maximum temperature difference between the process streams flowing into the storage units is 35 °C and 25 °C. The average of these two temperatures is 30° C. As the number of clusters increases, the maximum temperature difference between the storages decreases. This is reasonable, as more clusters or storage units lead to a finer distribution of the temperature. The solid blue line reaches a temperature difference of zero for seven clusters, as there are seven different temperature levels for the cold process streams, and if the corresponding number of storages are used, only one temperature level flows into each storage. The fact that the two blue curves for one cluster have the same total temperature difference is due to the same reason as for the red curve.

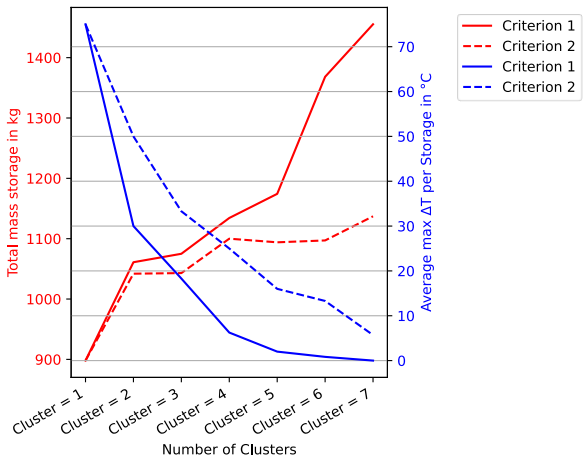

**Figure 5.** Influence of the number of clusters on the total storage mass and on the total deltaT depending on the cluster criterion.

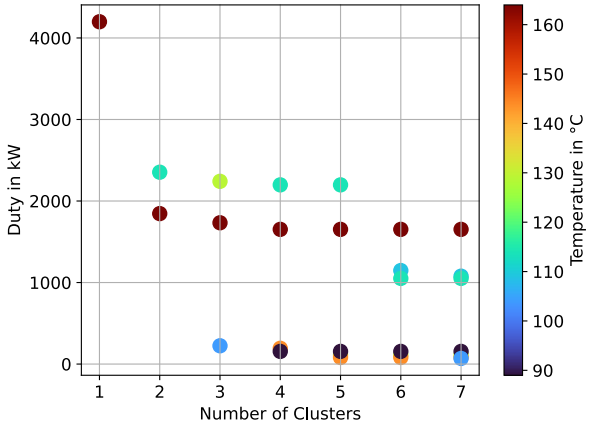

**Figure 6.** Resulting storage temperatures and duties for cold streams exemplified for criterion 1.

## Storage for Criterion 1:

The following section examines the extent to which the number of clusters affects relevant storage sizes and therefore the continuous heat duty. This is illustrated using cluster criterion 1 as an example. Figure 6 shows both the influence on the heat duty, which is then stationary, and on the temperatures inside the energy storage. Since these are storages for heating of cold streams, the temperature of the hotter layer was selected. Basically, the sum of the outgoing duty across the different cluster or storage numbers must be identical. This is because, for all cluster cases, the total energy required to heat the streams over a constant observation period must be

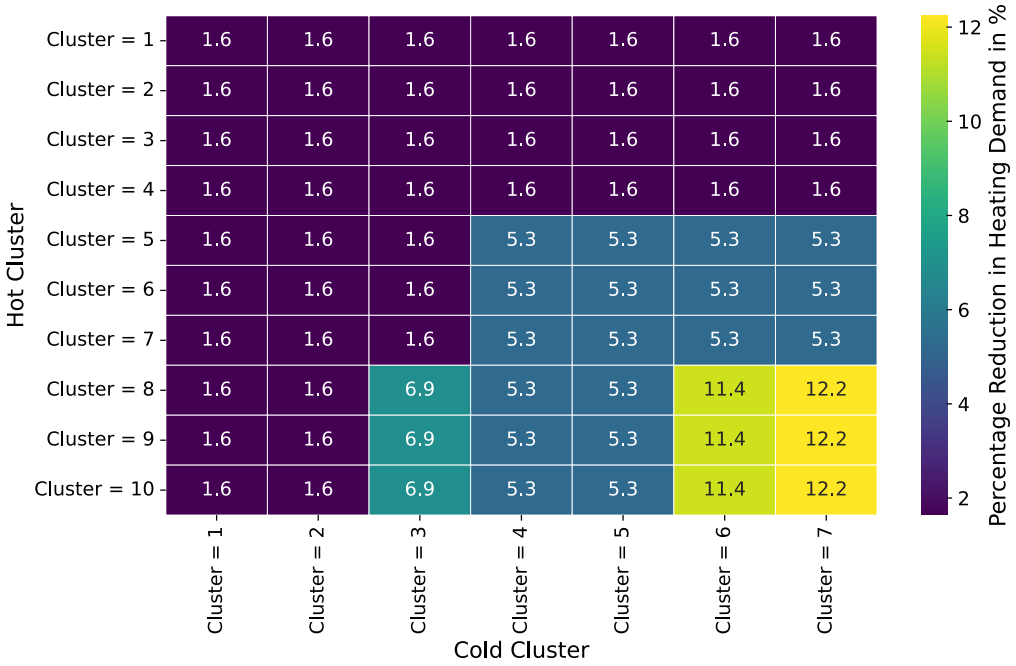

**Figure 7**. Clustermatrix for cold and hot streams.

provided. In addition, it can be seen that the temperature levels used for heating run towards a limit value based on the number of storage. For example, the 169 °C requires a storage with a heating capacity of over 4000 kW. The heating capacity required for this temperature decreases when the number of clusters or storage is increased, as the process streams can now be distributed more finely in terms of temperature distribution (criterion 1), and thus fewer process streams are heated with this temperature level.

## Pinch Analysis for Criterion 1:

Once the relevant storage variables have been determined and the heat flows are in steady-state, a pinch analysis can be performed based on this information. The pinch analysis is performed iteratively for all clusters of hot and cold flows. The results can be seen in Figure 7. This shows the percentage savings in heating duty compared to the case where no heat is integrated. If there are more clusters and thus more storage tanks, greater savings can be achieved. This is because the heating and cooling requirements are at more suitable temperature levels, enabling heat integration without a heat pump. The corresponding grand composite curve for the combination of 9 clusters for the hot process flows and 7 clusters for cold process flows is shown in Figure 8. On the one hand, the pocket shows where heat integration can take place. It is now up to the user to decide whether they also want to integrate storage outside the pocket in order to provide stationary conditions outside of possible heat integration. This can be particularly interesting if, for example, a heat pump can be integrated. In this case, a heat pump could be suitable for the two temperature levels of 40 °C and 120 °C.

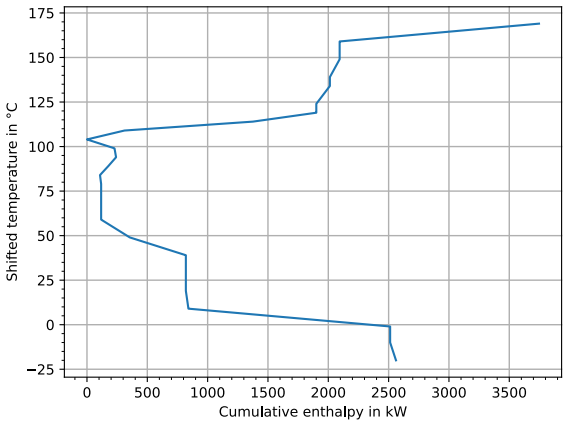

**Figure 8.** Grand Composite Curve for 9 clusters of hot streams and 7 clusters of cold streams.

## CONCLUSION

In this study, we analyzed the influence of the number and size of thermal energy storages, by introducing two different grouping criteria for heat integration of batch process streams at the process level. It was shown that both criteria fulfil the purpose. The first criterion employs k-means clustering to group process streams with

similar temperatures and assign them to the same storage tank. As a result, streams directed to a single storage exhibit comparable temperatures. However, the required storage mass may increase due to mismatches in the heat duty of the grouped process streams. With the second criterion, it was exactly the opposite. To this end, a small optimization problem was solved, which minimizes the variance of the flows belonging to an energy storage. Accordingly, the total mass of all storage tanks was smaller than that of the storage tanks grouped according to temperature. The use of energy storage aimed to compensate for fluctuations in heat flows in batch processes, thereby establishing steady-state conditions that enable the application of established heat integration methods. An energy assessment was carried out using pinch analysis for a storage combination of hot and cold flows. It was shown that internal heat exchange is possible. The remaining heating demand can then be covered by a heat pump. From our point of view, it is important that further possible evaluation criteria are found. Perhaps one that allows a weighting between temperature focus and storage size focus. In addition, it makes sense to identify not just two, but also more layer within an energy storage as integration options. This can be an interesting approach, especially when streams are grouped according to temperature. Finally, it should be added that this is not the optimal heat integration solution. This would involve a larger mathematical optimization problem. Instead, this approach aims to identify promising heat integration concepts at an early stage. These solutions can also be used as starting values for optimization.

## ABSTRACT

Refineries are major sources of direct $CO_2$ emissions, primarily from steam generation, fluid catalytic cracking, and hydrogen production. This study develops a superstructure optimization framework to evaluate the economic and environmental viability of retrofitting existing refineries with small modular nuclear reactors (SMRs) for cogeneration of heat and electricity. A multi-period mixed-integer quadratically constrained program is formulated, simultaneously minimizing the present cost of retrofitting and $CO_2$ emissions over the time horizon. This problem is solved to generate a Pareto frontier via the ε-constraint method. Two cases are analyzed for a medium-scale refinery, considering 1) inflexible operation under average annual electricity prices and 2) flexible operation under hourly prices with the possibility of installation of storage devices. Compared to a benchmark without SMRs in the superstructure, allowing their installation leads to reduced costs at lower or comparable emission levels. The results show that SMRs are primarily used for high-pressure steam generation. Flexible operation and the inclusion of thermal energy storage further reduce costs. Overall, SMRs appear in multiple non-dominated solutions, highlighting their potential as a cost-effective refinery decarbonization strategy.

## INTRODUCTION

Reducing emissions from energy-intensive industries is essential for meeting climate targets. Oil refineries are among the largest industrial sources of direct $CO_2$ emissions, primarily due to fossil-fired steam generation, hydrogen production from steam methane reforming, and large point sources such as fluid catalytic crackers [1]. Electrification and carbon capture can lower emissions, but their effectiveness depends on electricity prices, availability of renewable energy, natural gas prices, and operational flexibility. This has increased interest in exploring other low-carbon sources of heat and power that can be deployed directly at industrial sites.

Small modular nuclear reactors (SMRs) are among the promising options for decarbonizing the chemical industry and refineries. Unlike conventional gigawatt-scale nuclear plants, SMRs typically produce up to about 300 MWe per unit and are designed for modular construction and incremental deployment [2]. Inherent safety features enable simplified plant designs and greater flexibility, particularly for deployment in remote or infrastructure-limited industrial sites. This increased adaptability, along with the ability to cogenerate electricity and steam, makes them especially attractive for chemical plants and refineries, where continuous demand for high-quality utilities exists. Despite these advantages, several challenges remain. High first-of-a-kind capital costs, financing risks, and construction uncertainties pose significant barriers to deployment. Additional challenges include waste-management considerations and other regulatory requirements, which make smaller units expensive to operate. Addressing these issues is essential for realizing the benefits of new technologies [3, 4].

As shown in Fig. 1, the nuclear reactor consists of a reactor vessel, which houses the reactor core, coolant, moderator and control rods. The core contains fuel assemblies where nuclear fission reactions generate heat, surrounded by a moderator (light water or graphite) that slows neutrons to sustain the chain reaction. Control rods regulate the reaction rate by absorbing neutrons. Heat is

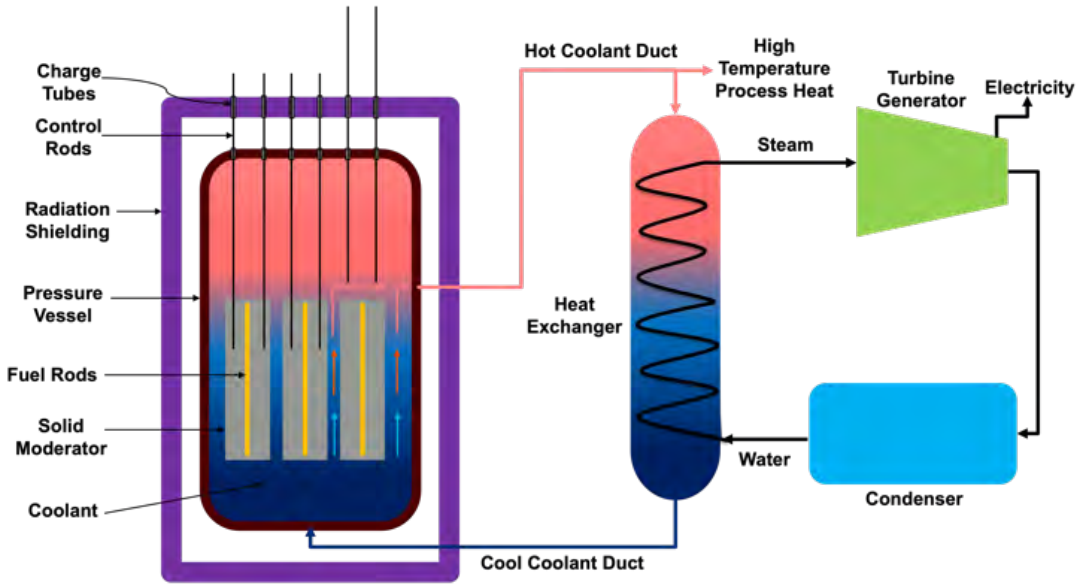

**Fig. 1.** Schematic showing the structure of a nuclear reactor

removed by the coolant and transferred to steam generators or heat exchangers. Nuclear reactors are classified by coolant and moderator type. Table 1 summarizes the types illustrating the trade-offs between maturity and achievable process temperatures.

**Table 1.** Achievable outlet temperatures for different small modular reactor types [11]

| Reactor type | Coolant/moderator | Outlet Temperature (in centigrade) | Maturity |
|---|---|---|---|
| iPWR | Light water/ Light water | 300-330 | High |
| MSR | Molten fluoride or chloride salt/ graphite | 600-750 | Low |
| HTGR | Helium/ Graphite | 750-950 | Low |

Existing techno-economic assessments indicate that construction time, financing conditions, and assumptions regarding modularization dominate the uncertainty in levelized cost of electricity estimates for SMRs [5, 6]. Learning-curve analyses, such as the review by Mignacca et al. [3], suggest that if modularization is achieved at scale, each doubling of installed capacity could lead to cost reductions of approximately 5–10% through "economies of number, " arising from the deployment of many identical units rather than traditional economies of scale. Reactor-level optimization studies investigate design trade-offs related to core configuration and power conversion systems [7, 8]. System-level studies examining SMRs in power system applications and industrial applications highlight the value of cogeneration and flexible operation [9–11].

This paper extends our previous studies [12] by evaluating the potential for deploying small modular reactors to achieve economically viable decarbonization of refineries. The superstructure, shown in Fig. 2, includes both conventional and low-carbon pathways for hydrogen production and steam generation. SMRs enable additional decarbonized pathways for high-pressure steam (HPS) and hydrogen ($H_2$) generation through the co-production of low-carbon electricity and heat. SMR-generated electricity can be used to power proton exchange membrane and alkaline electrolyzers for hydrogen production and electric boilers for steam generation, while reactor heat can be directly utilized to generate HPS. Other pathways for decarbonizing hydrogen production include steam methane reforming with pre- or post-combustion carbon capture and electrolysis using electricity purchased from the grid. Additional pathways for high-pressure steam (HPS) generation include natural gas boilers with post-combustion carbon capture and electric boilers powered by grid electricity. Three storage options are considered: electricity storage in lithium-ion batteries, hydrogen storage in salt caverns, and SMR-generated heat stored in molten nitrate salt, which is referred to as thermal energy storage (TES) in the rest of the paper.

## MATHEMATICAL MODELING

### Small Modular Reactor

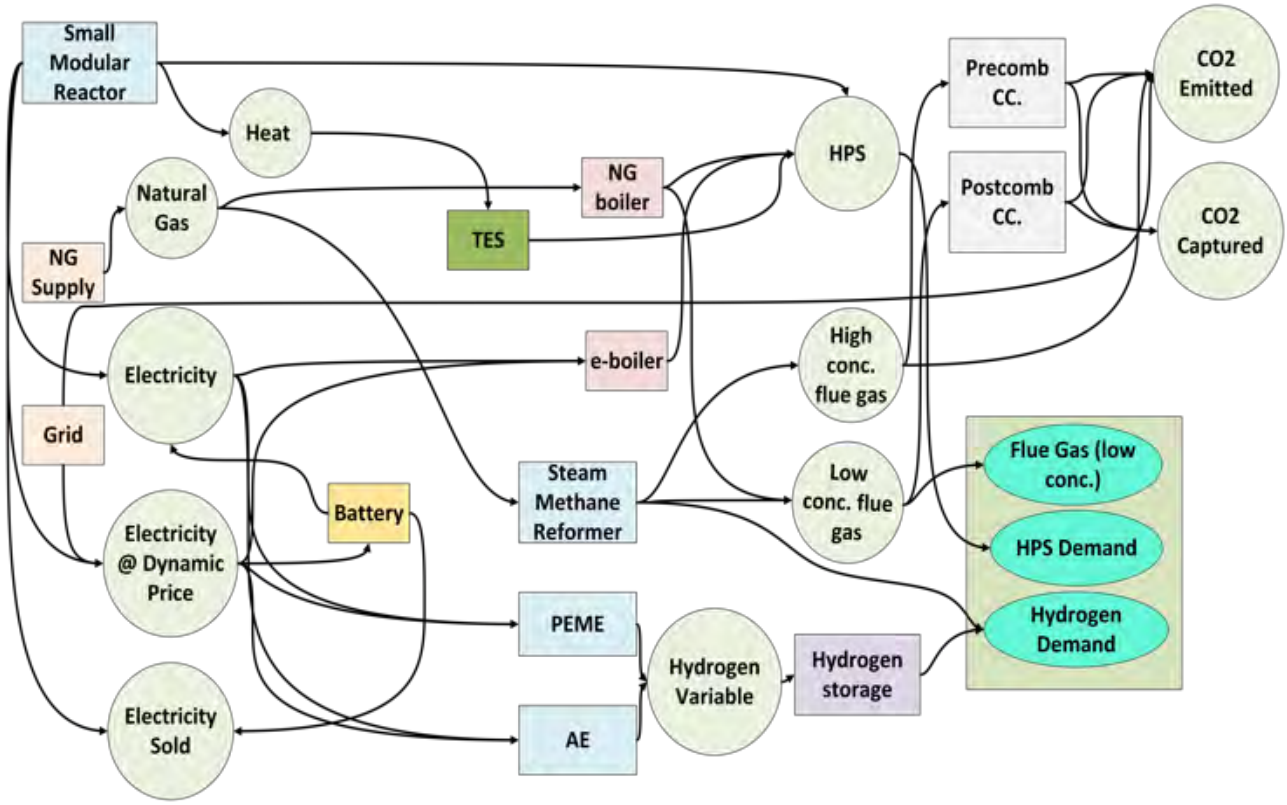

**Fig. 2:** Superstructure considered in this study

We begin by describing the constraints associated with design variables, including decisions on module selection and construction timelines. The stated equations are valid $g \in G, n \in N, yr \in YR$ (where $G$ is the set of SMR reactor technology types considered (e.g., $\mathrm{G} = (\mathrm{iPWR}, \mathrm{HTGR})$, $N$ is the set of candidate module counts (i.e., number of SMR modules that can be installed), $N = \{1, 2, 3, 4, 5, 6\}$, and $YR$ is the set of planning years over the optimization horizon, $YR = \{1, 2, \ldots, 19\}\}$), unless specified otherwise. Equation (1) ensures that no more than one reactor type *g* is installed in any given year, *yr*, as determined by the binary variable $s_{g,yr}$. As shown in equation (2), the module construction decisions $m_{g,n,yr}$ depend on this selection; a module of type $g$ can be constructed in a year $yr$ when the corresponding reactor type is selected. The availability indicator $a_{g,n,yr}$ indicates whether a given module is already constructed, evaluated as a cumulative sum of $m_{g,n,yr}$ over time, as shown in equation (3), each module becomes available in the year it is built and remains available thereafter. According to equation (4), the installed capacity in the year $yr, Q_{g,n,yr}$, is given by the sum of the prior year's capacity $Q_{g,n,yr-1}$and the expansion $QE_{g,n,yr}$undertaken during that year. Annual expansion $QE_{g,yr}$ is bounded between technology-specific lower and upper limits, conditional on the module construction decision binary $m_{g,n,yr}$, as shown in equation (5).

$$\sum_{g \in G} s_{g,yr} \leq 1 \tag{1}$$

$$m_{g,n,yr} \leq s_{g,yr}) \tag{2}$$

$$a_{g,n,yr} = \sum_{tt=1}^{yr} m_{g,n,tt} \tag{3}$$

$$Q_{g,n,yr-1} + QE_{g,n,yr} = Q_{g,n,yr} \tag{4}$$

$$L\, m_{g,n,yr} \leq QE_{g,n,yr} \leq U\, m_{g,n,yr} \tag{5}$$

Now we present the constraints showing operational restrictions. The stated equations are valid $g \in G, n \in N, hr \in HR, d \in D, yr \in YR$(where $HR$ is the set of hourly time steps within a representative day $HR = \{1, 2, \ldots, 24\}$, and $D$ is the set of representative days used to capture intra-year operating variability $D = \{1, 2, 3\}$ for three representative days per year), unless specified otherwise. A module $n$ can be committed in hour $hr$ of representative day $d$ and year $yr$, denoted by binary $o_{g,n,hr,d,yr}$, only if it is already built by that time, denoted by $a_{g,n,yr}$, as shown in equation (6). Electricity production $e_{g,n,hr,d,yr}$ is limited by the installed nameplate capacity $Q_{g,n,yr}$ of each module, equation (7). The reactor's core output $r_{g,n,hr,d,yr}$ scaled by heat-transfer and turbine efficiencies $\eta_{HT_g}$ and $\eta_{TE_g}$, expressed in electrical units, cannot exceed $Q_{g,n,yr}$ when the unit is committed, as enforced in equation (8). Ramp-

rate limits on the core output, bound hour-to-hour variation in $r_{g,n,hr,d,yr}$ by $RR_g/\eta_{TE_g}$, as modeled by equation (9). During implementation this constraint is decomposed into two inequality constraints for each possible value of the absolute function.

$$o_{g,n,hr,d,yr} \le a_{g,n,yr} \quad (6)$$

$$e_{g,n,hr,d,yr} \le Q_{g,n,yr}, \quad (7)$$

$$r_{g,n,hr,d,yr}\,\eta_{HT_g}\,\eta_{TE_g} \le Q_{g,n,yr}\,o_{g,n,hr,d,yr} \quad (8)$$

$$|r_{g,n,hr-1,d,yr} - r_{g,n,hr,d,yr}| \le \frac{RR_g}{\eta_{TE_g}} \quad (9)$$

Startup and shutdown events are tracked by binaries $v_{g,n,hr,d,yr}$ and $w_{g,n,hr,d,yr}$, which relate to changes in commitment status $o_{g,n,hr,d,yr}$ across consecutive hours through equation (10). Equation (11) prevents simultaneous startup and shutdown in the same hour. A module is committed to electricity generation, denoted by binary $oe_{g,n,hr,d,yr}$, only when the module is online, as shown by equation (12). Equation (13) shows that the electricity generated $e_{g,n,hr,d,yr}$ is zero whenever the unit is not committed for generation and is capped by $Q_{g,yr}$ otherwise. Minimum downtime is enforced via Equation (14), which requires the module to remain offline for at least $MDT_g$ hours after a decommitment before a new startup is permitted.

$$v_{g,n,hr,d,yr} = o_{g,n,hr,d,yr} - o_{g,n,hr-1,d,yr} + w_{g,n,hr,d,yr} \quad (10)$$

$$v_{g,n,hr,d,yr} + w_{g,n,hr,d,yr} \le 1 \quad (11)$$

$$oe_{g,n,hr,d,yr} \le o_{g,n,hr,d,yr} \quad (12)$$

$$e_{g,n,hr,d,yr} \le Q_{g,n,yr}\,oe_{g,n,hr}, \quad (13)$$

$$\sum_{i=1}^{MDT_g}(1 - o_{g,n,hr-i,d,yr}) \ge v_{g,n,hr,d,yr}\,MDT_g, \quad (14)$$

Finally, we outline the financial constraints. Operating costs (OPEX) include startup costs, $SC_g\,v_{g,n,hr,d,yr}$, variable costs proportional to overall reactor output ($VC_g\,r_{g,n,hr,d,yr}$), and fixed annual costs, $FC_g\,Q_{g,n,yr}$ as shown by Equation (15). The per unit startup and variable cost components are multiplied by the weights of the representative days, defined as the number of days each representative day denotes, and are then summed to determine the total. Capital expenditure (CAPEX) incurred for building SMR modules each year is a function of the annual capacity expansion and specific capital cost $\delta_{g,yr}$, as shown in Equation (16).

$$OPEX_{SMR,yr} = \sum_{d\in D} w_d \sum_{hr\in HR}\sum_{g\in G}\sum_{n\in N}\left(SC_g\,v_{g,n,hr,d,yr} + VC_g\,r_{g,n,hr,d,yr}\right) + FC_g\,Q_{g,n,yr}$$

$$\forall yr \in YR \quad (15)$$

$$CAPEX_{SMR,yr} = \sum_{g\in G}\sum_{n\in N} QE_{g,n,yr}\;\delta_{g,yr}\;\forall \mathrm{yr} \in \mathrm{YR} \quad (16)$$

## Thermal energy storage (TES)

The TES system is defined for each reactor type $g$ and module $n$. We begin with the equations relating design variables associated with TES. Capacity expansion in TES, $QE_{TES,g,yr}$ is bounded and activated by a binary installation decision $k_{g,n,yr}$, as shown in equation (17). Equation (18) shows that installed TES capacity is calculated as a function of annual capacity expansions analogous to SMR capacity. Equations (19)–(24) define the operational constraints for TES. The state of charge, representing the amount of heat stored $l_{g,n,hr,d,yr}$, is bounded by the installed thermal energy storage capacity $Q_{\mathrm{TES},g,n,yr}$, as specified in equation (19). The maximum charging $c_{g,n,hr,d,yr}$and discharging $d_{g,n,hr,d,yr}$ rates are limited to a fraction of the total installed storage capacity, where the parameter $EP$ represents the minimum charge/discharge time. The evolution of the state of charge is governed by the energy balance in equation (22), which accounts for net heat inflows and charging and discharging efficiencies. Equations (23) and (24) impose cyclic continuity across representative days. These constraints are valid given the use of a chronology-preserving agglomerative hierarchical clustering (AHC) method, following Tso et al. [13], to derive representative days.

$$L\,k_{g,n,yr} \le QE_{TES,g,n,yr} \le U\,k_{g,n,yr} \quad (17)$$

$$Q_{TES,g,n,yr-1} + QE_{TES,g,n,yr} = Q_{TES,g,n,yr} \quad (18)$$

$$l_{g,n,hr,d,yr} \le Q_{\mathrm{TES},g,n,yr} \quad (19)$$

$$c_{g,n,hr,d,yr} \le \frac{Q_{\mathrm{TES},g,yr}}{EP} \quad (20)$$

$$d_{g,n,hr,d,yr} \le \frac{Q_{\mathrm{TES},g,n,yr}}{EP} \quad (21)$$

$$l_{g,n,hr,d,yr} = l_{g,n,hr-1,d,yr} + c_{g,n,hr,d,yr}\,\eta_{\mathrm{Charging}} - \frac{d_{g,n,hr,d,yr}}{\eta_{\mathrm{Discharging}}} \quad (22)$$

$$l_{g,n,1,d,yr} = l_{g,n,24,d,yr} + c_{g,n,24,d,yr}\,\eta_{\mathrm{Charging}} - \frac{d_{g,n,24,d,yr}}{\eta_{\mathrm{Discharging}}} \quad (23)$$

$$l_{g,n,1,d+1,yr} = l_{g,n,24,d,yr} + c_{g,n,24,d,yr}\,\eta_{\mathrm{Charging}} - \frac{d_{g,n,24,d,yr}}{\eta_{\mathrm{Discharging}}} \quad (24)$$

The annual capital expenditure (CAPEX) resulting from the installation of TES is a function of the annual capacity expansion and the capital cost per unit, as shown in Equation (25). For this study, it is assumed that TES incurs no additional operating expenditure.

$$\mathrm{CAPEX}_{\mathrm{TES},yr} = \sum_{g\in G}\sum_{n\in N}\delta_{\mathrm{TES},g,yr}\;QE_{\mathrm{TES},g,n,yr}\;\forall yr \in YR \quad (25)$$

## Constraints modelling the rest of the superstructure

We implement an extension of our previous formulation in Karthikeyan et al. [12], while accounting for flexible operations and the possibility of installation of storage units. The constraints keeping track of the installed capacities of each technology j, in each year, yr ($Q_{j,yr}$), after capacity expansion and decommissioning decisions are included from our previous work (Equations (7) – (10) in [12]). These constraints are now also applicable to the battery and $H_2$ storage units.

The stated operating and physical constraints in the superstructure are applicable to $hr \in HR, d \in D$, and $yr \in YR$, unless otherwise stated. Operating constraints ensure that the hourly mass flow rates of key components ($k'_j$) and power flow rates ($F_{k'_j,j,hr,d,yr}$/ $P_{k,j,hr,d,yr}$) to unit $j$ remains within the installed capacity limits and above a minimum turndown fraction $\chi_j$ of the installed capacity, respectively. We implement an extension to equations (11)-(12) in [12] applicable to mass and power flows at each hour of each representative day.

Constraint (26) ensures that each conversion technology operates above a minimum average annual utilization factor, $\phi_j$, preventing under-use of capital-intensive assets.

$$\phi_j Q_{j,yr} \leq \sum_{d\in D} w_d \sum_{hr\in HR} \sum_{k\in In(j)} P_{k,j,hr,d,yr} \; \forall j \in \{\text{e-boiler, PEME, AE}\} \; \forall yr \in YR \quad (26)$$

For hydrogen storage units, the hourly charging and discharging rates are constrained by equation (27), the installed storage capacity, and the charge/discharge duration $\tau_{j,yr}$, which represents the minimum number of hours required to fully charge or discharge the storage at its rated power.

$$F_{H_2 variable\ or\ H_2\ demand,H_2\ storage,hr,d,yr} \leq \frac{Q_{H_2storage,yr}}{\tau_{H_2storage,yr}} \quad (27)$$

The hydrogen stored in the system, $stor_{H_2,H_2storage,hr,d,yr}$, at any time, is limited by the installed storage capacity, as shown in equation (28).

$$stor_{H_2,H_2storage,hr,d,yr} \leq Q_{H_2storage,yr} \quad (28)$$

Similarly, for battery storage units, the hourly charging and discharging power are constrained symmetrically by the installed battery capacity and the charge/discharge duration $\tau_{j,yr}$, as shown in equations (29) and (30).

$$P_{elec.or\ elec.at\ dynamic\ price,Battery,hr,d,yr} \leq \frac{Q_{Battery,yr}}{\tau_{Battery,yr}} \quad (29)$$

Equation (30) shows that the state of charge of the battery, $stor_{elec.,Battery,hr,d,yr}$, is bounded by its installed energy capacity.

$$stor_{elec.,Battery,hr,d,yr} \leq Q_{Battery,yr} \quad (30)$$

The proposed formulation also specifies physical balances across the task nodes (technology units) and the resource nodes (components) across the superstructure. The task balances are defined by hourly extensions to equations (1)-(2) and (4)-(6) in [12], which relate the inlet and outlet component mass/energy flow rates, ($F_{k,j,hr,d,yr}$/$P_{k,j,hr,d,yr}$) to the flow of a key component $F_{k'_j,j,hr,d,yr}$ using simplified yield-based models for each hour of each representative day.

The total hydrogen and high-pressure steam (HPS) produced across all pathways and aggregated at each hour of each representative day must satisfy the refinery's overall hydrogen and HPS demand. $CO_2$ capture and emissions downstream of carbon capture units are assumed proportional to inlet $CO_2$ flows, governed by the capture efficiency of the respective CC technology.

Hourly mass and energy balances are also imposed across resource nodes at each hour, extending equation (3) in [12].

The mass balance on hydrogen storage, as shown in equation (33) tracks the evolution of stored hydrogen, $stor_{H_2,j,hr,d,yr}$, as a function of the net flow into the storage unit at each hour.

$$stor_{H_2,j,hr+1,d,yr} = stor_{H_2,j,hr,d,yr} + \left( \sum_{k\in In(j)} F_{k,j,hr,d,yr} - \sum_{l\in Out(j)} F_{l,j,hr,d,yr} \right) \cdot \Delta t \quad \forall\, j \in \{H_2\ storage\} \quad (33)$$

Equation (34) enforces continuity between the storage level at the last hour of each day and the first hour of the same representative day, valid due to chronology-preserving AHC.

$$stor_{H_2,j,1,d,yr} = stor_{H_2,j,24,d,yr} + \left( \sum_{k\in In(j)} F_{k,j,24,d,yr} - \sum_{l\in Out(j)} F_{l,j,24,d,yr} \right) \cdot \Delta t \quad \forall\, j \in \{H_2\ storage\} \quad (34)$$

Equation (35) links the storage level at the last hour of each day to that at the first hour of the following representative day, valid due to chronology-preserving AHC.

$$stor_{H_2,j,1,d+1,yr} = stor_{H_2,j,24,d,yr} + \left( \sum_{k\in In(j)} F_{k,j,24,d,yr} - \sum_{l\in Out(j)} F_{l,j,24,d,yr} \right) \cdot \Delta t \quad \forall\, j \in \{H_2\ storage\} \quad (35)$$

The intra-day state-of-charge dynamics of battery energy storage between consecutive hours are modeled in a manner similar to equation (33) in equation (36), accounting for both charging and discharging efficiencies.

$$stor_{elec.,j,hr+1,d,yr} = stor_{elec.,j,hr,d,yr}$$

$$+\Big(\sum_{k\in In(j)} P_{k,j,hr,d,yr}\cdot\eta^{+}-\sum_{l\in Out(j)} P_{l,j,hr,d,yr}\Big)/\eta^{-}\Big]\cdot\Delta t$$

$$\forall\, j\in\{battery\} \tag{36}$$

Equations (37) and (38) establish continuity between the state of charge in batteries on consecutive days, analogous to equations (34) and (35).

$$stor_{elec.,j,1,d,yr} = stor_{elec.,j,24,d,yr}$$

$$+\Big(\sum_{k\in In(j)} P_{k,j,24,d,yr}\cdot\eta^{+}-\sum_{l\in Out(j)} P_{l,j,24,d,yr}\Big)/\eta^{-}\Big]\cdot\Delta t$$

$$\forall\, j\in\{battery\} \tag{37}$$

$$stor_{elec.,j,1,d+1\,yr} = stor_{elec.,j,24,d,yr}$$

$$+\Big(\sum_{k\in In(j)} P_{k,j,24,d,yr}\cdot\eta^{+}-\sum_{l\in Out(j)} P_{l,j,24,d,yr}\Big)/\eta^{-}\Big]\cdot\Delta t$$

$$\forall\, j\in\{battery\} \tag{38}$$

## Equations relating variables from SMR, TES modules and the rest of the superstructure

The electricity balance around the SMR is enforced in equation (39). At each hour and representative day, the total electrical output of all SMR types and modules, $\sum_g\sum_n e_{g,n,hr,d,yr}$, must be fully allocated to: (i) electricity supplied directly to internal equipment, $P_{\text{elec., SMR},hr,d,yr}$; (ii) electricity flow to charge batteries $P_{\text{elec. at dynamic price, SMR},hr,d,yr}$, and (iii) electricity sold to the grid at the dynamic selling price, $P_{elec.sold,SMR,hr,d,yr}$

$$\sum_{g\in G}\sum_{n\in N} e_{g,n,hr,d,yr} = P_{\text{elec., SMR},hr,d,yr} + P_{\text{elec. sold, SMR},hr,d,yr} + P_{\text{elec. at dynamic price, SMR},hr,d,yr} \tag{39}$$

Equation (40) states that for each reactor type and module, the total energy produced at the core of the nuclear reactor discounted by the losses due to heat transfer, $r_{g,n,hr,d,yr}\,\eta_{HT_g}$, is split consistently between three competing uses: direct onsite steam production $h_{g,n,hr,d,yr}$, TES charging $\frac{c_{g,n,hr,d,yr}}{\eta^{+}}$, and electricity generation via the turbine, represented by $e_{g,n,hr,d,yr}/\eta_{TE_g}$.

$$h_{g,n,hr,d,yr} + \frac{c_{g,n,hr,d,yr}}{\eta^{+}} + \frac{e_{g,n,hr,d,yr}}{\eta_{TE_g}} = r_{g,n,hr,d,yr}\,\eta_{HT_g} \tag{40}$$

Finally, equation (41) closes the thermal balance between the SMR–TES system and the refinery steam network. The sum, over all SMR types and modules, of direct reactor heat used for steam production, scaled by the overall heat-transfer efficiency $\eta_{HT}$, $h_{g,n,hr,d,yr}\eta_{HT}$, and the energy generated by discharging the TES, $d_{g,n,hr,d,yr}$, scaled by the discharge efficiency, scaled by the overall heat-transfer efficiency $\eta^{-}$ is equated to the effective high-pressure steam stream $F_{\text{HPS, SMR},hr,d,yr}$ multiplied by the enthalpy of vaporization $\Delta H_{vap}$.

$$\sum_{g\in G}\sum_{n\in N}\left(h_{g,n,hr,d,yr}\eta_{HT} + d_{g,n,hr,d,yr}\eta^{-}\right) = F_{\text{HPS, SMR},hr,d,yr}\,H_{vap} \tag{41}$$

Finally, the annual operational expenditure accounts for costs related to natural gas and electricity procurement, operations of carbon capture equipment, storage system operation, carbon tax incurred on residual $CO_2$ emissions and operations of the SMR, shown in equation (42). The contribution of each representative day is weighted by its occurrence frequency $w_d$.

$$\begin{aligned}\text{OPEX}_{\text{yr}} = \Delta t\cdot\sum_{d\in D} w_d \sum_{hr\in HR}\Big[\sum_{j\in Out(NG)} F_{NG,j,hr,d,yr}\cdot\$_{NG,yr}\\ P_{elec.at\ dynamic\ price,grid,hr,d,yr}\cdot\$_{elec.,hr,d,yr}\\ +\sum_{j\in\{CC\ units\}} F_{CO_2Captured,j,hr,d,yr}\cdot\Big(\frac{\text{NG}_{\text{consumed}}}{\text{unit mass CO}_2}\$_{NG,yr}\\ +\$_{rest\ of\ OPEX,j,yr}\Big)\\ +\sum_{j\in H_2Storage} F_{H_2,j,hr,d,yr}\cdot\$_{H_2\ Storage,yr}\\ +\Big(P_{elec.at\ dynamic\ price,hr,d,yr}+P_{elec,Battery,hr,d,yr}\Big)\cdot\$_{Battery,yr}\\ \sum_{j\in EmissionSources} F_{CO_2Released,j,hr,d,yr}\cdot\$_{CO_2tax,yr}\Big]\\ +OPEX_{SMR,yr}\quad\forall yr\in YR\end{aligned} \tag{42}$$

Annual revenue from SMR's electricity sales is computed as the weighted sum of electricity sold at a fraction of the buying price (discounting for grid congestion effects), as shown in equation (43).

$$\begin{aligned}Revenue_{yr} = \Delta t\cdot\sum_{d\in D} w_d\Big(\sum_{hr\in HR}\big(P_{elec.sold,SMR,hr,d,yr}\\ +P_{elec.sold,battery,hr,d,yr}\big)\\ \cdot\$_{electricity,hr,d,yr}\ f_{selling}\Big)\forall yr\in \text{YR}\end{aligned} \tag{43}$$

Capital expenditure for process capacity expansion are modeled in Equation (44) using a fixed-plus-variable cost formulation. As in [12], the first term, $\alpha_{j,yr}$ denotes the fixed cost incurred for technology j in year yr, while the second term, $\beta_{j,yr}QE_{j,yr}$ accounts for the variable cost. Both components are assumed to be paid throughout the construction period $dur_j$,. The CAPEX associated with the SMR and TES units are added separately.

$$\begin{aligned}CAPEX_{yr} = \sum_{j\in J\setminus\{SMR,TES\}}\Big(\sum_{h=0}^{dur(j)-1}\frac{\alpha_{j,yr+h}y_{yr+h}}{dur(j)}\\ +\sum_{h=0}^{dur(j)-1}\frac{\beta_{j,yr+h}\,QE_{j,yr+h}}{dur(j)}\Big)+CAPEX_{SMR,yr}\\ +CAPEX_{TES,yr}\quad\forall yr\in YR\end{aligned} \tag{44}$$

The first objective minimizes the net present cost as the decarbonization strategy, accounting for annual

capital costs, operating costs, and revenues over the planning horizon and appropriately discounting them, as shown in equation (45).

$$Z_1 = \min \sum_{yr \in YR} \frac{CAPEX_{yr} + OPEX_{yr} - Revenue_{SMR,yr}}{(1+int)^{yr}} \quad (45)$$

The second objective minimizes the overall $CO_2$ equations over the time horizon, as shown in equation (46).

$$Z_2 = \sum_{yr \in YR} \Delta t \cdot \sum_{d \in D} w_d \sum_{hr \in HR} \sum_{j \in In(CO_2)} F_{CO_2,j,hr,d,yr} \quad (46)$$

## RESULTS

The results are presented as Pareto fronts (obtained using ε-constraint method) showing the trade-off between present cost and cumulative $CO_2$ emissions under different policy and market scenarios. Data for the refinery system follows Chattopadhyay et al. [1], and those for the SMR have been obtained from Vanatta et al. [11]. We used five years of hourly price data from the Houston hub of the ERCOT electricity market [14]. Detailed assumptions on battery and hydrogen storage costs will be reported in the full-length paper. Each point on the front represents a non-dominated solution: cost cannot be reduced without increasing emissions, and emissions cannot be reduced without raising costs. Comparing fronts across (i) cases with and without carbon taxes, and (ii) models with and without flexible operation and storage, reveals economically attractive decarbonization pathways. Case (1) considers no operational flexibility and uses average annual prices over a 19-year horizon. This resulted in a MIQCP in Pyomo 6.6.1 comprising 4,674 constraints (1,881 equalities,) and 4,504 variables (1,539 binaries), which was solved with BARON 24.10.10, with a MIP gap tolerance of 0.01%. In contrast, the case considering hourly varying electricity prices and the possibility of installation of storage, modeled using three representative days per year, resulted in a much larger MIQCP with 303,222 constraints (119,833 equalities) and 251,598 variables (66,519 binaries), which was solved with Gurobi 10.0.1 with a MIP gap tolerance of 0.01%. Generation of the Pareto frontier, constructed from 20 discrete points, required 4.5 and 43.6 minutes of CPU time for the inflexible and flexible cases, respectively.

Figure 3 compares case 1 and case 2 scenarios with the benchmark frontiers previously reported in our work [12], in which refinery decarbonization options did not include SMRs. Across the entire emissions range, the inclusion of the possibility of installing SMRs reduces the overall retrofitting costs, pushing the Pareto front downward. The possibility of flexible operations further reduces costs. The leftmost point on the Pareto frontier yielding minimum emissions has also moved leftward, due to a reduced value of minimum attainable feasible scope 1 and 2 emissions. Overall, $CO_2$ taxes raise retrofitting costs across scenarios, and the non-dominated solutions are compressed towards lower emission values. Beyond a certain threshold, increasing the ε value no longer increases $CO_2$ emissions, as the ε-constraint becomes inactive. Staying below the allowed ε limit is financially beneficial due to carbon tax penalties for exceeding it.

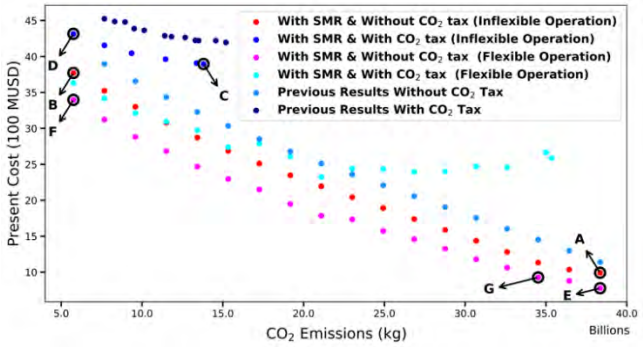

**Fig. 3:** Comparison of Pareto fronts obtained under all cases. Previous results correspond to those reported in [12].

### Case (1): Inflexible operations assuming average annual electricity Prices (No Storage)

Fig. 4 shows the solutions obtained for points (A) and (B) labeled in Fig. 3. When considering average annual electricity prices without $CO_2$ taxes, the lowest-cost solutions on the rightmost part of the frontier rely on conventional operations during the initial years. In this period, hydrogen is supplied entirely by the steam methane reformer; no carbon capture units are installed, and high-pressure steam (HPS) is primarily produced by the natural gas boiler. The SMR mainly functions as a power unit, with electricity sales at 0.8× the purchasing price generating revenue to offset installation costs. In the later years, as natural gas prices are expected to rise, SMRs are partially used for HPS generation. Moving left along the frontier as the ε-constraint is tightened, HPS production increasingly comes from the heat generated by SMRs earlier, while hydrogen continues to be produced via reforming, and electrolyzers remain unused. Both pre-combustion and post-combustion carbon capture units are installed: post-combustion units treat dilute flue gas streams, whereas pre-combustion capture is applied to the higher-concentration reformer gas.

Under carbon taxes implemented at rates, the same as those discussed in Chattopadhyay et al [1], capture is implemented earlier as compared to the high emission solution in the case without taxes, and HPS generation is from SMR-generated heat earlier in the planning horizon

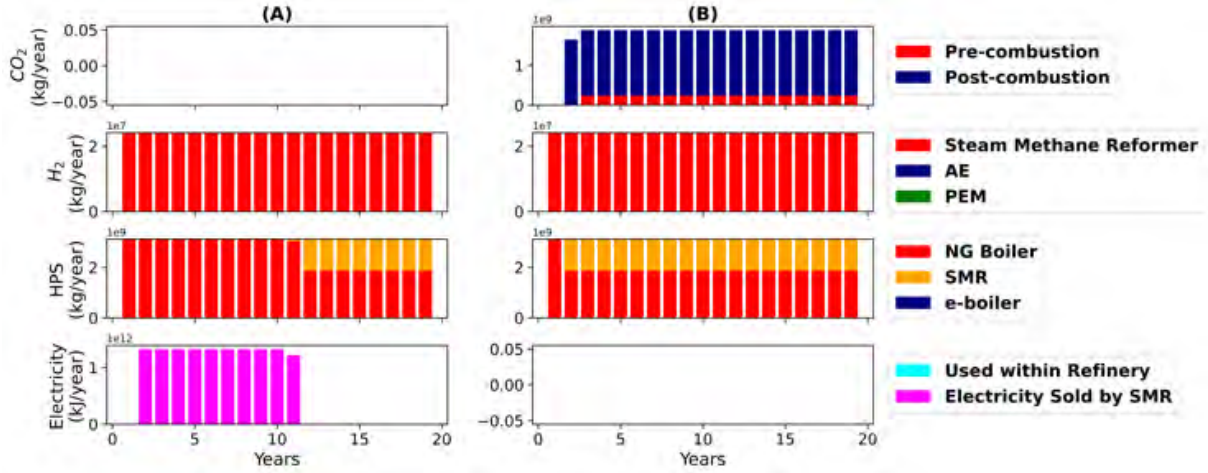

**Fig. 4:** Solutions obtained for case (1) without CO2 taxes

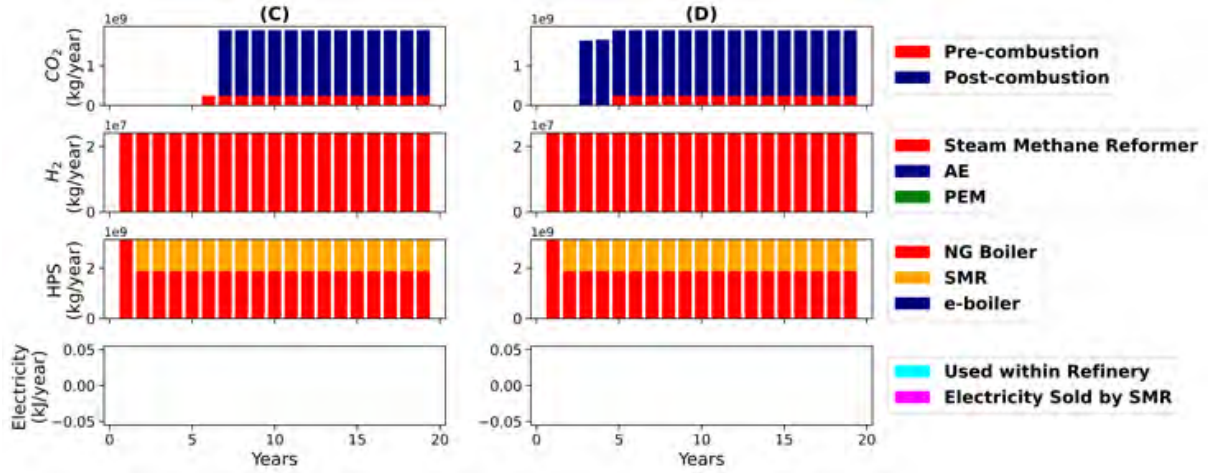

**Fig. 5:** Solutions obtained for case (1) with CO2 taxes

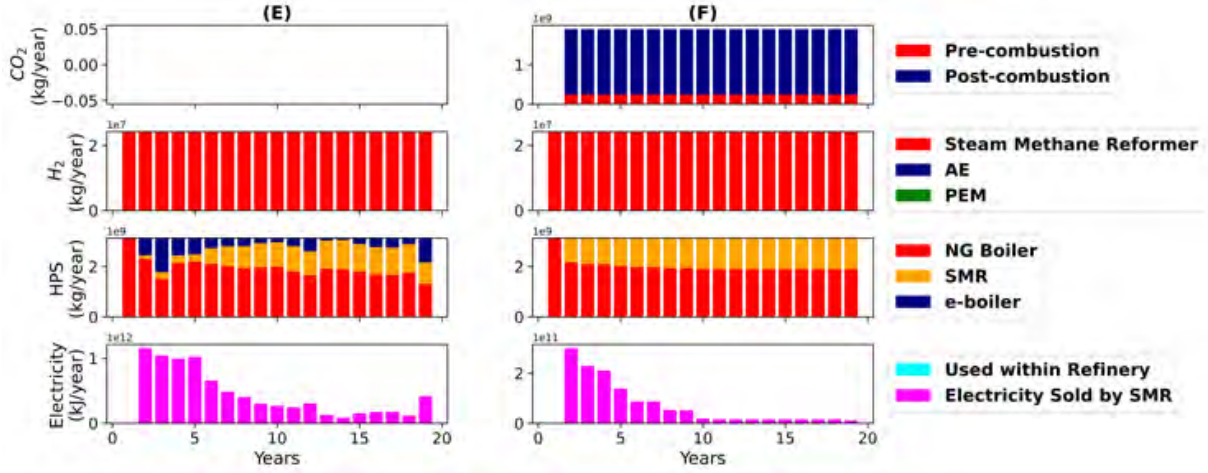

**Fig 6:** Non-dominated solutions under flexible operations; no carbon taxes

even for the rightmost point in the Pareto front (labeled as C in the fig. 3), as shown in Fig. 5. As we move leftward along the Pareto front, solutions involve earlier incorporation of pre and post combustion capture, as shown by the solution at point D in fig. 5.

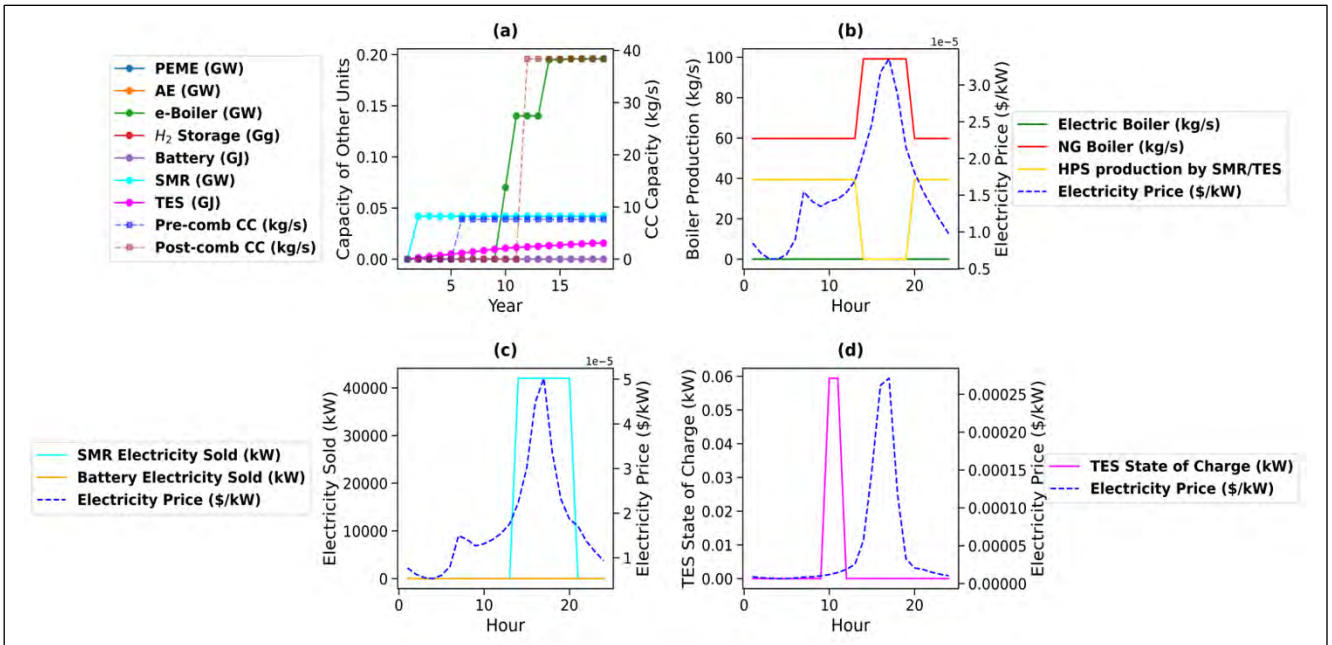

**Fig 7:** (a) Capacity expansion at a representative Pareto optimal solution (b) flexible HPS production over a representative day (c) Electricity sales from Small Modular Reactor across a representative day (d) Evolution of TES State of Charge across a representative day; for point G.

## Case 2: Hourly Prices, Storage, and Flexible Operation

Case 2 considers hourly variations in electricity pricing and the option for enhanced flexibility with the possibility of installation of TES, battery, and hydrogen storage. Figure 6 shows that as the model exploits temporal price variation: hydrogen is still produced mainly by the steam methane reformer, while HPS is supplied by a mix of natural gas boiler, SMR, and e-boiler. E-boiler is chosen in this case, since flexible operation allows electricity to be bought from the grid when cheap for HPS generation. As emissions constraints tighten along the front, e-boiler usage is reduced to limit grid-related emissions, and SMR-generated heat and natural gas boiler in conjunction with capture units, are the main sources for HPS generation.

Figure 7 (a) shows investment decisions for a representative low-cost solution labeled as G in Fig. 3 when considering the possibility of flexible operations in the absence of carbon taxes. The SMR units are built by year 2, iPWR reactors are chosen; e-boiler units are installed from year 10, with expansions until year 13, pre-combustion capture capacity is installed by year 6, and post-combustion capture capacity is installed by year 12. TES capacity is installed starting from year 2, with capacity expansions until year 18. In contrast, no battery or hydrogen storage capacity is installed: under the assumed price profiles, price variations leveraged by these do not add enough value to justify their investment costs. Fig. 7b (hourly profiles, year 3, representative day 3) illustrates how the SMR, NG boiler, and e-boiler contribute towards steam generation. When electricity prices are low, SMR output is allocated more toward steam production; as prices rise, the NG boiler increasingly takes care of the steam load so that the SMR can be used for electricity generation and sales. The electricity-sales profile shown in fig. 7c (hourly profiles, year 3, representative day 1) also follows the price curve while respecting maximum ramp-up/ down rates: more electricity is sold during high-price hours. Finally, Fig. 7d (hourly profiles, year 7, representative day 2) shows the evolving state of charge for the TES unit. The profile roughly follows the electricity price signals, but at a time lead, which enables the TES unit to charge during the low-price durations while allowing the system to use heat generated from the discharge of TES during high price durations.

## CONCLUSIONS

This work developed a multi-period superstructure optimization framework to evaluate the economic and environmental feasibility of integrating SMRs into an existing refinery for cogeneration of heat and electricity. Across all scenarios, the inclusion of SMRs as a decarbonization option lowers costs at comparable emissions or deeper emissions reductions at similar cost. They are predominantly deployed for high-pressure steam generation, reflecting the efficiency of direct nuclear heat utilization. Carbon taxes accelerate the adoption of SMRs and carbon capture units.

Flexible operation consistently reduces system

costs at comparable emissions levels, with TES emerging as a key enabler for leveraging the price variability, whereas battery and hydrogen storage are not selected under the assumed conditions. Despite the significant increase in model size, large-scale MIQCPs were solved to satisfactory convergence, demonstrating the tractability of the proposed approach. Overall, the results suggest that SMRs, particularly when paired with flexible operation and thermal storage, offer a cost-effective pathway for deep refinery decarbonization under a range of policy conditions.

## NOMENCLATURE

## ABSTRACT

The transition toward low-carbon ammonia production increasingly relies on highly efficient routes for renewable hydrogen generation, with Solid Oxide Electrolysis (SOE) representing a particularly promising solution. SOEs, operating with steam at elevated temperatures, offer intrinsic thermodynamic advantages and are attractive when integrated with processes that can effectively utilize or supply high-grade heat. This context opens the possibility for advanced energy coupling between hydrogen production and the exothermic ammonia synthesis process. This work investigates such an energy integration strategy by simulating a small-scale ammonia plant where hydrogen is produced through an SOE system thermally coupled to the ammonia synthesis loop. Specifically, high-grade heat available in the Haber-Bosch (HB) reactor outlet is recovered via a "Heat Recovery Steam Generator" (HRSG) to provide a substantial fraction (55 wt%) of the steam required by the electrolyzer. The assessment demonstrates that the integrated configuration significantly reduces the external electrical demand for steam generation by 84%, achieving a substantial enhancement in system-level electrical efficiency. Total plant energy efficiency increases from 57% to 62%, and the electricity-to-hydrogen ratio decreases from 45.9 to 42.1 kWh/kg. These improvements translate directly into a decrease in the Levelized Cost of Ammonia (LCOA) by 4–5%, underscoring the relevance of high-temperature electrolysis supported by effective plantwide heat recovery.

**Keywords**: Green ammonia, Haber-Bosch process, Hydrogen, Solid Oxide Electrolysis, Energy Integration

## INTRODUCTION

Ammonia is a key industrial commodity, ranking first in global production volume, with an approximate annual yield of 185 Mt/y [1]. Its main synthetic route, the Haber-Bosch process, converts nitrogen and hydrogen into ammonia under severe high-temperature and high-pressure conditions. While nitrogen is readily obtained from air, the hydrogen feedstock is predominantly derived from fossil fuels, primarily via steam methane reforming or coal gasification. This dependence results in substantial greenhouse gas (GHG) emissions. Thus, conventional ammonia synthesis processes are highly $CO_2$-intensive, releasing an estimated 1.65 $kg_{CO_2eq}/kg_{NH_3}$, which accounts for approximately 440 $Mt_{CO2eq}$ annually [2].

Decarbonization efforts for ammonia production inherently necessitate the substitution of fossil-based hydrogen with "green" hydrogen, to be generated via water electrolysis powered by renewable electricity. Electrolysis, an endergonic process, electrochemically dissociates water into hydrogen and oxygen, yielding a carbon-free hydrogen product when the electrical power source is renewable. State-of-the-art commercial technologies include low-temperature systems, such as alkaline (AEL) and proton-exchange-membrane (PEMEL) electrolyzers, which utilize liquid water. In contrast, solid oxide electrolyzers convert high-temperature steam into hydrogen, offering superior thermodynamic efficiency due to the reduced electrical energy demand when operating at elevated temperatures (*i.e.*, 500-900 °C).

The inherent thermal compatibility between the high-temperature heat available in the exothermic ammonia synthesis loop effluents and the high thermal demand of the SOE steam feed is central to this integration, providing a significant opportunity for system-level energy optimization via direct waste heat recovery.

This study investigates a 300 $kg_{NH3}$/h (small-scale) green ammonia plant configuration where the hydrogen feedstock is supplied by an SOE thermally coupled to the synthesis loop. Waste heat recovery from the HB reactor outlet is directly utilized to generate the required superheated steam feed for the electrolyzer. Therefore, the primary objective of this work is to provide a plantwide assessment of the energy integration potential, rigorously evaluating the energetic and techno-economic performance of this integrated configuration compared to a baseline, non-integrated scenario.

## WATER ELECTROLYSIS

Water electrolysis is a key pathway for $CO_2$-free hydrogen production utilizing renewable electricity. Significant thermodynamic distinctions exist between low-temperature liquid-water electrolysis and high-temperature steam electrolysis, the latter being implemented exclusively in solid oxide electrolyzers.

### Thermodynamics of Water Splitting

Water splitting is a non-spontaneous, endergonic reaction requiring an external electrical energy supply. The minimum electrical energy demand is governed by the Gibbs free energy change (ΔG), which decreases inversely with temperature. In the Solid Oxide Electrolyzer Cell (SOEC), supplying superheated steam at 800 °C reduces ΔG from approximately 237 kJ/mol for liquid water (ambient conditions) to about 189 kJ/mol. This corresponds to a drop in the minimum electrical energy requirement by roughly 20%. Crucially, this reduction is cell-specific and does not account for the additional thermal energy required to generate and superheat the steam feed. Consequently, the net energetic advantage of SOE technology is realized only when low-cost or waste heat sources are available for steam generation.

This thermodynamic reduction is also reflected in the cell-level reversible potential (a.k.a. Nernst potential), which defines the minimum theoretical voltage required under equilibrium conditions. The operating cell voltage must exceed the reversible potential to compensate for irreversible losses (*i.e.*, overpotentials), including ohmic resistance, activation barriers, and mass transport limitations. For low-temperature water electrolysis at ambient conditions, the reversible potential is approximately 1.23 V. Supplying superheated steam at 800 °C reduces the reversible potential to approximately 0.83 V, a decrease of nearly 30%. This substantial reduction underscores the potential for decreased electrical energy input per mole of hydrogen in high-temperature steam electrolysis.

Another important reference voltage at the cell level is the thermoneutral potential, which defines the thermoneutral operating condition where the supplied electrical energy exactly balances the total reaction enthalpy. At this potential, the cell operates with zero net heat exchange with the surroundings. Operating below this threshold leads to an endothermic regime, where the heat deficit for the electrolysis reaction is provided by the feed gases. As a result, the outlet gas temperature is lower than the inlet gas temperature. Conversely, operating above this value results in an exothermic regime, where the outlet gas temperature is higher than the inlet gas temperature. Operating near the thermoneutral condition is preferred as it minimizes internal temperature gradients, reducing thermal stress and enhancing long-term stability. Low-temperature electrolyzers (AEL and PEMEL) are generally constrained to the exothermic regime. In contrast, SOEs offer greater operational flexibility by utilizing all three regimes, which is particularly beneficial for process integration and the exploitation of waste heat.

### Solid Oxide Electrolysis Technology: Single Cell Structure and Operation

The solid oxide electrolyzer is a high-temperature electrolysis unit operating at elevated temperatures ranging from 500 to 900 °C. The basic functional unit of this technology is the single Solid Oxide Electrolysis Cell (SOEC), schematically illustrated in **Figure 1**.

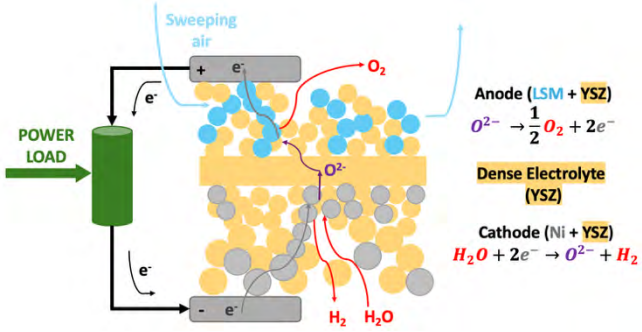

**Figure 1.** Structure of the solid oxide electrolysis cell.

In the SOEC, superheated steam is supplied to the cathode, where the hydrogen evolution reaction (HER) produces hydrogen ($H_2$) and oxide ions ($O^{2-}$). These ions migrate through the solid ceramic electrolyte to the anode, where the oxygen evolution reaction (OER) generates pure oxygen ($O_2$). Due to incomplete steam conversion, a portion of the feed steam exits the cathode along with the produced hydrogen, necessitating downstream separation.

The cell relies on an entirely ceramic composition, ensuring mechanical integrity and thermal stability. Key

materials include the Yttria-Stabilized Zirconia (YSZ) electrolyte, which provides high oxide-ion conductivity. The cathode consists of a Ni-YSZ cermet (ceramic-metal), where nickel acts as a catalyst for the HER and provides electronic conductivity. The anode is often composed of a strontium-doped lanthanum manganite (LSM) perovskite, which is thermally compatible with YSZ.

The defining operational parameter is the high-temperature operation, contrasting with low-temperature technologies (AEL and PEMEL). SOEs typically operate at pressures near atmospheric, as long-term stable performance at significantly higher pressures remains a technological challenge. The wide operating voltage range confirms the theoretical feasibility of operation in all three thermodynamic modes. This high-temperature operation provides a substantial energy advantage, reducing electrical power consumption by approximately 25-28% relative to low-temperature electrolyzers. Crucially, this efficiency gain is maximized when external low-cost or waste heat sources supply the thermal energy for steam generation. **Table 1** summarizes the SOE's key operational parameters.

Challenges associated with high-temperature operation include accelerated material degradation, which reduces cell lifetime and necessitates precise temperature control and smooth transients to maintain structural integrity. Furthermore, from an industrial perspective, current SOE unit capacities (up to 10 MW deployed) are significantly smaller than those of AEL (>1 GW) and PEMEL (>100 MW), indicating that scaling SOE technology for large-scale hydrogen production remains a significant commercial and engineering challenge [3].

**Table 1:** Operating parameters of solid oxide electrolysis technology [4].

| **OPERATING PARAMETER** | Range of values |
|---|---|
| T [°C] | 500-900 |
| P [bara] | 1-3 |
| Cell type [-] | Cathode-supported cell (CSC) |
| Cell voltage [V] | 1.1-1.5 |
| DC electrical power consumption [kWh/kg$_{H_2}$] | 48 (with no steam import)<br>38 (with steam import) |
| Voltage degradation rate [%/1000h] | 0.55-1 |
| Industrial maturity | < 10 MW deployed |

## SOLID OXIDE ELECTROLYZER MODEL

A steady-state, zero-dimensional (0D) model was developed to represent the electrochemical and process behavior of the solid oxide electrolyzer in a simplified yet physically consistent manner. A fully detailed electrochemical-thermo-mechanical model is outside the scope of this work. Instead, the primary objective is to formulate a computationally efficient representation of the SOE suitable for implementation within the plantwide process simulation environment used for the integrated ammonia production system.

The model first describes the operation of the fundamental unit (*i.e.*, the single electrolysis cell) and subsequently extends this description to the stack level, where multiple cells are electrically connected in series to form an electrolyzer module of a defined size.

The core modeling assumption is that both the cell and the stack operate within the linear region of their polarization curves. Under this premise, the irreversible losses are not treated mechanistically but are collectively quantified by a single, comprehensive parameter: the Area Specific Resistance (ASR), in [Ω·cm$^2$]. The ASR term incorporates all irreversible losses arising during cell operation, including ohmic resistance, activation, and concentration overpotentials. The correlation for single cells' ASR is typically obtained by regression of experimental polarization curves, whose value is a function of operating conditions, primarily temperature and pressure. Consequently, the single cell operating voltage, $E_{cell}$ [V], is defined by the following linearized relationship, where $E_N$ [V] corresponds to the Nernst potential and $\hat{\imath}$ [A/cm$^2$] denotes the current density.

$$E_{cell} = E_N + ASR \bullet \hat{\imath} \quad (1)$$

At the stack level, additional irreversible losses arise due to the series electrical connection of multiple cells. To account for these effects, an additional constant resistance contribution of 0.1 Ω·cm$^2$ is incorporated into the cell ASR correlation when evaluating cell performance once integrated in a stack [5]. As a result of this approach, all cells in a stack are assumed to exhibit the same behavior. This methodology preserves computational simplicity while providing a realistic representation of the increased irreversibility observed in stack or short-stack configurations.

### Cell-Level and Stack-Level Formulation

The operating model of the solid oxide electrolyzer is first formulated at the single-cell level and subsequently extended to the stack configuration. The model requires both cell-specific (and, analogously, stack-specific) parameters and the set of operating conditions associated with the selected operational mode.

At the cell level, the model utilizes several inputs:

the active cell area (where electrochemical reactions occur); the inlet hydrogen mole fraction at the cathode; the Faradaic efficiency; the steam-to-hydrogen ratio; and the ASR correlation that characterizes the cell's resistive behavior. The operating state is formally defined by temperature, pressure, and the specified operating regime.

Based on these inputs, the model determines the hydrogen production rate according to Faraday's law for electrolysis, the steam conversion at the cathode outlet, the electrical power required to sustain the imposed operating mode, and the resulting energetic efficiencies. A summary of the input data and the corresponding output variables is reported in **Table 2**.

When the modeling framework is extended to the stack level, the same governing equations are preserved, while specific input parameters are adjusted. Crucially, the ASR correlation is modified to account for the incremental resistive contribution, and the total number of cells connected in electrical series is specified. Under these conditions, the model computes the corresponding performance metrics on a stack basis, accurately capturing the linear voltage scaling imposed by series connectivity and the uniform current density that characterizes all cells within the assembly.

**Table 2:** Input parameters and resulting performance outputs from the cell-level operating model.

| SOEC-Level Operating Model | |
|---|---|
| **INPUT DATA** | **OUTPUT RESULTS** |
| *Cell-specific parameters* | |
| Active cell area [$cm^2$] | $H_2$ production rate [mol/s] |
| Cell Faradaic efficiency [%] | |
| Steam-to-$H_2$ ratio [$kg_{steam}/kg_{H_2}$] | Steam conversion [%] |
| ASR law at the cell-level | Energetic (LHV and HHV) efficiency [%] |
| *Operating conditions* | |
| Temperature [°C] | Electrical power [W] |
| Pressure [bar] | |
| Operating regime | |

## SOE Simulation and Balance of Plant (BOP)

SOEs require several auxiliary process units for proper thermal, fluidic, and operational management. Accordingly, the entire hydrogen production section was modeled in UniSim® Design R500 to evaluate the associated mass and energy balances and overall performance. The resulting process flowsheet, which models all key components of the SOE unit and its Balance of Plant, is shown in **Figure 2**.

Since UniSim does not feature a dedicated solid oxide electrolyzer simulation item or tool, the electrochemical behavior of the SOE stack was integrated into the simulation environment via a spreadsheet interface. The SOE was represented through a Conversion Reactor coupled with the external SOE model described so far. Specifically, the 0D thermoneutral stack model directly supplies the Conversion Reactor with the key operating inputs: namely, the steam conversion and the electrical power required to ensure thermoneutral operation. Downstream of the reactor, a component separator replicates the intrinsic outlet stream partitioning of an SOE, separating the cathode effluent (hydrogen and unconverted steam) from the anode effluent (oxygen and sweeping air).

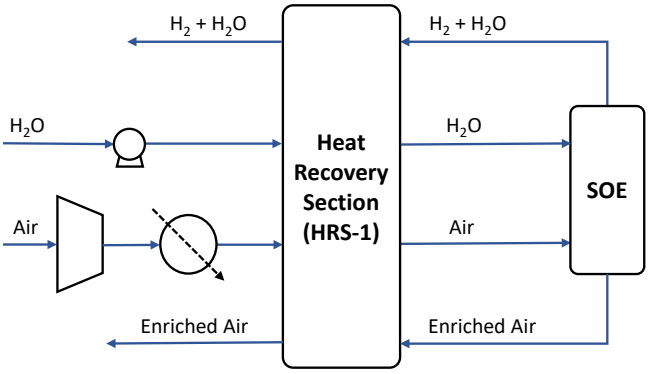

**Figure 2.** Schematic diagram of the hydrogen production section and the 1st heat recovery section (HRS-1).

At the process level, liquid water is fed to the hydrogen production section and must be conditioned to the SOE operating conditions. Preheating and vaporization are primarily achieved in the heat recovery section HRS-1, which recovers thermal energy from the high-temperature SOE exhaust streams. Superheated steam is fed to the electrolyzer, where conversion is deliberately limited (*i.e.*, never exceeding 90%). Unreacted steam leaves the cathode together with the produced hydrogen. Separation is achieved through cooling and condensation, which allows liquid water to be recovered and recycled.

Moreover, a minimum hydrogen fraction (≥10 mol%) was assumed at the cathode inlet to prevent oxidation of the metallic nickel phase in the Ni-YSZ cathode. Furthermore, an air sweep system was assumed at the SOEC anode to mitigate safety risks associated with the presence of pure oxygen at high temperatures. The literature does not always explicitly address these requirements [6]: in the present work, the necessary hydrogen fraction is provided by recycling a defined portion of the hydrogen-rich stream; simultaneously, hot air is supplied to the anode to dilute the produced oxygen, ensuring that the oxygen concentration in the anode exhaust remains at an acceptable level.

In such a process configuration, the final hydrogen product stream leaving the SOE section is delivered at approximately 40 °C and ambient pressure, containing a residual moisture content of ca. 7 mol%.

## PROCESS SIMULATION OF THE GREEN AMMONIA PRODUCTION PLANT

In green ammonia configurations, the Haber-Bosch synthesis loop remains the central component of the plant; yet, the conventional grey-hydrogen production train is entirely replaced by the SOE section for renewable hydrogen sourcing. The hydrogen produced from the SOE is inherently carbon-free; however, it contains residual water, shifting the process focus from carbon removal to effective dehydration, as water is a strong poison for the ammonia synthesis catalyst. Therefore, water is first removed immediately downstream of the SOE through cooling to ambient temperature and condensation. Additional moisture is eliminated during interstage cooling of the hydrogen compressor, and final ppm-level purification is achieved with a molecular sieve dryer placed at the compressor outlet. A further distinction from conventional plants is that only hydrogen, nitrogen, and ammonia circulate within the synthesis loop. This feature eliminates the need for a purge stream, which is typically mandatory in grey ammonia plants due to the presence of inert species such as methane or argon, avoiding syngas losses.

The ammonia synthesis loop consists of three main sections: compression, reaction, and separation. In the compression section, hydrogen from the SOE and nitrogen from the Air Separation Unit (ASU) are independently compressed to high pressure (*i.e.*, the operating pressure of the entire loop) and subsequently mixed to form the ammonia syngas. The reaction section is centered on an ammonia converter operating at high temperature (350-550 °C) and high pressure (150-250 bar). Here, ammonia is formed over an iron-based catalyst, following Temkin-Pyzhev kinetics, and exhibits a relatively low per-pass conversion [7]. Finally, in the separation section, the ammonia product is removed from the unconverted gases through a two-step condensation sequence: first using cooling water and then via a mechanical refrigeration cycle that uses ammonia as refrigerant. The unreacted hydrogen and nitrogen are recycled to the reactor inlet.

Finally, the liquid ammonia product is obtained at ca. 8 bar and 15-20 °C, with a purity higher than 96.5 mol%.

### Energy Integration Strategy

An energy integration strategy is proposed to enhance the energy efficiency of the SOE-based hydrogen production section by using steam produced in the ammonia synthesis loop.

The effluent from the ammonia reactor exits at high temperature, providing a substantial thermal source. Although a portion of this heat is inherently used to preheat the incoming ammonia syngas, the present work aims to recover as much of the remaining thermal potential as possible. To this end, a Heat Recovery section (HRS-2) is installed downstream of the reactor, as shown in **Figure 3**.

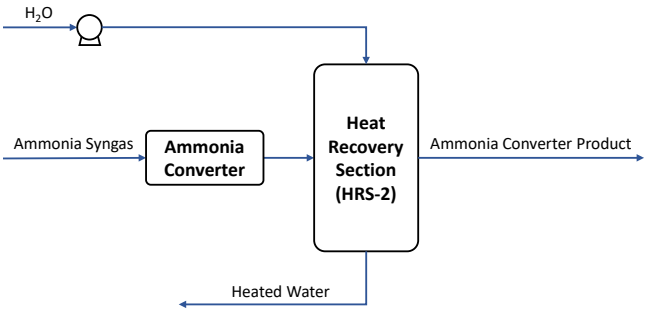

**Figure 3.** Schematic diagram of the ammonia synthesis section and the 2nd heat recovery section (HRS-2).

The introduction of the HRS-2 results in a significantly lower temperature of the product stream leaving the reaction section (*i.e.*, a drop of around 260 °C), which in turn decreases the thermal duty satisfied by the cooling water in the first ammonia condensation stage.

### Integration Mechanism in the SOE BOP

Heat recovered in the first recovery section of the SOE unit (HRS-1) and in the second recovery section (HRS-2) downstream of the $NH_3$ converter are combined to generate all superheated steam requirements of the SOE section. Although the total steam demand of the SOE remains unchanged, a fraction is now provided by the ammonia synthesis loop. On the other hand, the remaining portion is still produced internally within the SOE Balance of Plant from liquid water under ambient conditions.

This modification substantially decreases the electric heating duty, otherwise required to raise the steam to the SOE operating temperature, thereby reducing the total energy consumption of the section and improving the overall energy efficiency of the hydrogen production system.

## PERFORMANCE ANALYSIS OF SOE TECHNOLOGY AND ENERGY INTEGRATION

The performance of the SOE system was evaluated using the developed 0D electrochemical model and process simulations, examining operational behavior at the cell, stack, and system levels, as well as energy efficiency enhancements resulting from thermal integration with the ammonia synthesis loop.

### Operational Modelling of SOE Technologies

Three literature-reported SOEC architectures (*i.e.*, Anghilante [5], Wendel-Braun [8], and Becker [9]) were simulated using the developed electrochemical model. Their geometric characteristics, operating specifications,

and permissible operating ranges are those reported in the aforementioned literature sources.

The behavior of a single cell is evaluated with the first model, with comparisons across the three models carried out under identical operating conditions: atmospheric pressure, 800 °C, and thermoneutral operation. This ensures that differences in operational outputs reflect intrinsic cell properties. At the cell level, results indicate that hydrogen productivity, steam conversion, and power demand strongly depend on intrinsic cell features, including the required inlet hydrogen molar fraction and the magnitude of internal irreversibility (described by the ASR). Conversely, energy efficiency is identical at 96% for all three cathode-supported cell types, as it is determined by imposing the thermoneutral operating regime.

The analysis is then extended to the stack level, following two approaches. In the first approach, each stack consists of 75 cells electrically connected in series. This approach quantifies the reduction in per-cell hydrogen productivity when cells operate as part of a stack. The additional irreversibility arising at the stack scale reduces individual cell productivity from 21% (*Anghilante SOEC*) to 29% (*Becker SOEC*). In the second approach, the electrolyzer's hydrogen production rate is fixed at 55 kg/h. This target value was selected to maintain the required electrical power within the limits reported in scientific literature for each SOE technology and to comply with industrial-scale applications below 10 MW. Under equal hydrogen output, the total electrical demand of the three electrolyzers is nearly identical (within 2% discrepancy) and slightly above 2.1 MW, resulting in comparable performance of the three SOE technologies under thermoneutral operation conditions.

Lastly, the analysis is extended to the system level, combining each SOE with its corresponding Balance of Plant through steady-state UniSim simulations, referring to hydrogen production at 55 kg/h. Since the electrolyzer power demand is almost the same across the three technologies, the focus shifts to the BOP power requirements. Overall, the BOP accounts for between 17% (*Anghilante SOE BOP*) and 20% (*Wendel-Braun SOE BOP*) of the total electrical consumption of the hydrogen production section. The dominant BOP contributor is the electric heater for steam superheating, representing 57% (*Becker SOE*) to 70% (*Wendel-Braun SOE*) of the BOP demand, making it the primary target for process energy integration. Considering both SOE and BOP contributions, the hydrogen production section exhibits a total electrical demand ranging from 2.5 MW (*Anghilante SOE system*) to 2.7 MW (*Wendel-Braun SOE system*). This corresponds to energy efficiency ranging from 68% (*Wendel-Braun SOE system*) to 73% (*Anghilante SOE system*). The resulting specific energy consumption of the electrolysis unit (defined as the total electrical energy required to produce one kilogram of hydrogen) ranges from 45.9 kWh/kg (*Anghilante SOE system*) to 49 kWh/kg (*Wendel-Braun SOE system*).

In this work, the SOEC model reported in Anghilante [5] was selected for subsequent integration with the ammonia production section.

## Impact of Energy Integration on Plant-Level Performance

As mentioned earlier, the proposed energy integration strategy is based on two Heat Recovery Sections (HRS), the first in the SOE unit (HRS-1) and the second downstream of the ammonia reactor (HRS-2). This process integration leads to an 84% reduction in the electrical power required for steam superheating. This results in a substantial energy benefit for the renewable hydrogen production section, reducing its total energy demand by 8%. Correspondingly, the section's energy efficiency increases from 73% to 80%, and the specific energy consumption of the electrolysis unit ratio decreases by 8%, from 45.9 to 42.1 kWh/kg.

**Table 3:** Comparative Plant Performance Metrics (Integrated vs. Non-Integrated Scenarios) at a production capacity of 55 kg/h of hydrogen and 300 kg/h of ammonia.

| Performance Metric | Case 1: Non Integrated | Case 2: Energy Integrated | $\Delta_{(2)-(1)}$% |
|---|---|---|---|
| SOE section: Electrical demand of ELH [kW] | 259 | 42 | -84% |
| SOE section: Energy efficiency [%] | 73 | 80 | +7% |
| Overall plant: Energy efficiency [%] | 57 | 62 | +5% |
| Specific energy consumption of electrolysis unit [kWh/kg$_{H_2}$] | 45.9 | 42.1 | -8% |
| Specific energy consumption of the plant [kWh/kg$_{NH_3}$] | 9.13 | 8.32 | -9% |

The reduced energy demand in the SOE section also positively impacts the overall plant performance. The energy efficiency of the entire green ammonia plant rises from 57% to 62%; thus, the specific energy consumption of the power-to-$NH_3$ plant decreases by 9%, from 9.13 to 8.32 kWh/kg, confirming the effectiveness of the proposed integration strategy. A summary of the key performance enhancements achieved through the thermal integration is provided in **Table 3**.

## TECHNO-ECONOMIC IMPACT OF THE ENERGY INTEGRATION

The techno-economic assessment provides a preliminary cost evaluation (AACE Class 4: Feasibility Estimate) aimed at quantifying the economic impact of the proposed energy integration strategy on the green ammonia production plant. This analysis, based on the UniSim-simulated process configurations, focuses on the estimation of capital and operating expenditures, acknowledging the inherent uncertainty (-30% to +50%) associated with Class 4 evaluations [10].

### Capital Expenditure (CapEx) Analysis

Capital expenditure was estimated using the Module Costing Technique, with equipment costs updated to 2023 using the Chemical Engineering Plant Cost Index (CEPCI). The solid oxide electrolyzer is the dominant cost component, representing approximately 58% of the total plant CapEx with a specific investment of 2, 268 USD/kW [6]. Since the integration strategy does not modify the SOE operation or size, its cost remains unchanged across the two plant configurations.

The primary CapEx effect of the integration arises from the electric heater used for steam superheating. Because its capital cost scales directly with the electrical duty, the 84% reduction in power requirement results in a proportional decrease in heater cost, lowering the hydrogen section BOP capital cost by 52%.

Conversely, in the ammonia synthesis section, the required addition of HRS-2 increases the CapEx of the reaction section by approximately 13%. Considering both sections, the opposing contributions nearly compensate: the total plant CapEx varies only slightly (+0.4%), indicating that the proposed energy integration strategy has no significant impact on the overall investment cost.

### Operating Expenditure (OpEx) Analysis

The operational expenditure assessment includes maintenance, raw materials, utilities, and electricity costs. Annual maintenance is assumed to be 2% of the corresponding CapEx, including a stack replacement cost set at 18.5% of the SOE CapEx with a five-year interval [6]. With the proposed energy integration strategy, raw material (demineralized water) consumption remains essentially unchanged. Utility costs are impacted: the lower reaction section effluent temperature in the integrated configuration reduces the cooling water demand of the first ammonia condenser by 81%, substantially lowering this cost component.

Electricity constitutes the dominant contribution to overall OpEx, accounting for approximately 77% of total operating costs. A continuous supply of renewable power is assumed through a Power Purchase Agreement (PPA), and electricity prices are represented by the Value Adjusted Levelized Cost of Electricity (VALCOE), which we evaluated for four countries (the United States, the European Union, China, and India) to capture geographical variability [11]. The energy integration strategy enables a decrease in electricity-related operating costs of approximately 7% across all countries considered, corresponding to an overall reduction of about 8% in total plant OpEx.

### Levelized Cost Assessment

As a final step, we evaluated the Levelized Cost of green Hydrogen (LCOH) and the Levelized Cost of green Ammonia (LCOA). In the base configuration (without energy integration), the average LCOH is 4.55 USD/kg, decreasing to 4.31 USD/kg in the integrated configuration (*i.e.*, a reduction of approximately 5-6%). A similar trend is observed for LCOA, which decreases from an average value of 1, 024 USD/t to 979 USD/t (*i.e.*, a reduction of about 4-5%).

The strong dominance of renewable electricity cost, which alone accounts for more than half of the total ammonia production cost, ensures that the improvements achieved through energy integration directly translate into lower levelized costs.

The cost variability across regions is significant, mainly driven by the VALCOE. For the LCOH, China (reporting the highest VALCOE at 70 USD/MWh) yields a cost 9% higher than the calculated average value, while India (having the lowest VALCOE, at 50 USD/MWh) yields an LCOH 11% lower. An analogue geographical impact is observed for the LCOA: costs in China are approximately 8% higher than the average value, whereas costs in India are nearly 10% lower.

Overall, these results confirm that the proposed energy integration strategy not only enhances process efficiency but also yields non-negligible economic benefits across diverse geographic markets by mitigating the cost volatility associated with the primary operational expenditure driver (*i.e.*, the electric energy input).

## CONCLUSIONS

We proposed and techno-economically assessed an energy integration strategy between a solid oxide electrolyzer for green hydrogen production and an ammonia synthesis loop. Our approach, which consisted of improving the heat integration of the plant with two heat recovery sections, one in the SOE unit and one downstream of the ammonia converter, proved highly effective. It resulted in a significant reduction (*i.e.*, 84%) in electric-heater duty. This modification successfully shifts the SOE system thermal load, resulting in a 7% increase in the SOE section's energy efficiency (from 73% to 80%) and a corresponding enhancement in the overall plant efficiency (from 57% to 62%).

At the economic level, the integration yields non-negligible economic benefits. The reduction in electrical demand translates directly into a decrease in the LCOH and LCOA, with average savings of 5-6% for LCOH and 4-5% for LCOA.

Lastly, this study is currently subject to several limitations, notably the assumption of steady-state operation (*i.e.*, continuous renewable electrical power input was considered) and the inherent uncertainty associated with a Class 4 cost assessment. However, despite these limitations, the results clearly indicate that solid oxide electrolysis, when appropriately integrated with high-temperature chemical processes, such as the Haber-Bosch loop, offers a highly promising route for efficient green ammonia production.

## ABSTRACT

This study aims to compare different pathways for achieving $CO_2$ emission reductions during the production of methanol and, subsequently, formaldehyde, i.e., its major derivative. An equation-oriented model of the formaldehyde sector is developed, incorporating a superstructure of various transition pathways including feedstock switching (biomass, biogas, waste), process electrification (Power-to-X), and $CO_2$ capture. The OSMOSE tool is used to evaluate the superstructure and compare the alternative production pathways on the basis of thermodynamic, environmental, and economic key performance indicators for future scenarios (2025 and 2050). Furthermore, to cope with the limitations of predefined pricing scenarios, a parameter sweep is performed, exploring a broader set of economic conditions and seeking to identify the zones of economic optimality associated with each configuration through the solving of a Mixed-Integer Linear Programming cost minimization problem, while generalizing the analysis results beyond a specific year or geographic context. Finally, the potential of industrial symbiosis implementation, between clinker and formaldehyde production facilities, as a cost-reduction measure for Power-to-X processes is assessed.

**Keywords**: Formaldehyde, Methanol, Energy Transition, Technoeconomic Analysis, Superstructure Optimization, Industrial Symbiosis

## INTRODUCTION

The chemical industry is an energy-intensive and highly-emitting sector, representing 6.5% of the global greenhouse gases emissions [1]. Methanol (MeOH) is a key building block for solvents, plastics, and fuels. Its major application is its conversion to formaldehyde which accounted for 23% of global MeOH demand in 2023 [2]. Formaldehyde, of chemical composition $CH_2O$, is an organic chemical used as a raw material for the production of resins, polyurethanes, paints and coatings, pharmaceuticals, food intermediates, and chelating agents. It is produced from MeOH via two main routes: the silver process and the metal oxide process [3]. In the silver process, operated at high temperature (580–680°C) and under air deficiency, MeOH is converted into formaldehyde through catalytic dehydration ($CH_3OH \rightleftharpoons CH_2O + H_2$) using a silver-based catalyst. On the other hand, the metal oxide process consists of a direct catalytic MeOH oxidation ($CH_3OH + 0.5\,O_2 \rightarrow CH_2O + H_2O$), performed over a metal oxide catalyst (e.g. iron, molybdenum, or vanadium oxide). The reaction is implemented at medium temperatures (270–430°C) and in the presence of excess air, enabling very high MeOH conversion around 99%. Although European formaldehyde production in 2017 was almost evenly split between the silver and metal oxide processes, this study focuses on the latter given that recent investments tend to favor the metal oxide route [3].

Direct process emissions during formaldehyde production, stemming from MeOH or formaldehyde over-oxidation, are negligeable [3]. The environmental impact of formaldehyde is thus closely linked to the carbon footprint of MeOH feedstock. However, current methanol production is almost entirely fossil-based. Indeed, MeOH is predominately produced from natural gas with steam methane reforming (SMR, ~65%) or coal gasification (~35%, mainly in China), while biomass and other renewable feedstocks account for less than 1% of global production [4]. This results in a high carbon footprint ranging from 0.8 up to more than 4 t $CO_2$/t MeOH produced [5].

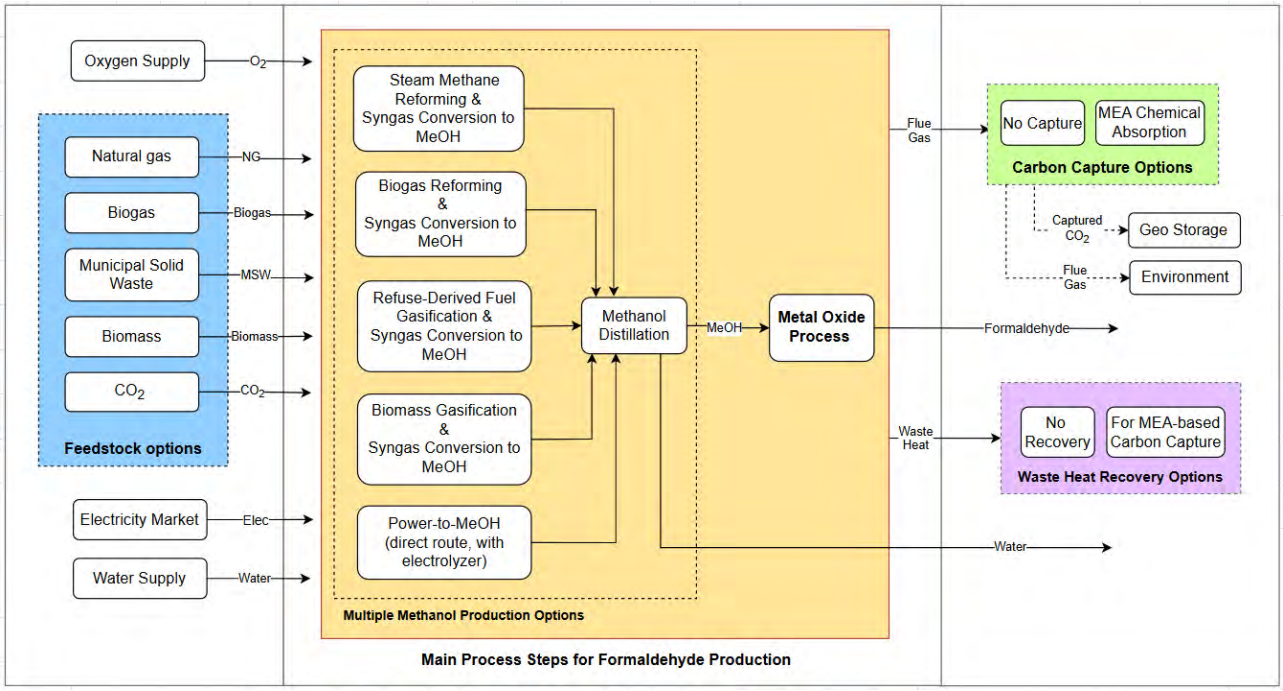

**Figure 1.** Superstructure for formaldehyde industry.

Hence, decarbonizing MeOH production through biomass use, $CO_2$ capture (CC), and process electrification [6] is essential for reducing the environmental impact of the European chemical sector.

## METHODOLOGY

This study aims to compare various pathways for achieving $CO_2$ emission reduction during the production of methanol and, subsequently, formaldehyde, i.e. its major derivative. The methodological framework is adopted from our previous study [7]. Thorough literature review and data collection, from academic papers, institutional reports, and Best Available Techniques reference document [3], are first carried out, aiming at gathering information on the production process under study and applicable emission mitigation pathways. These pathways include energy efficiency improvement, feedstock switching, process electrification, and $CO_2$ capture and storage.

The collected data are used to develop an equation-oriented model of the formaldehyde sector, written in Lua language, consisting of mass and energy balances, as well as economic considerations such as annualized investment (CAPEX) and operating (OPEX) costs. This model incorporates a superstructure (depicted in **Figure 1**) of various MeOH production routes, including synthesis from syngas generated via (1) conventional Steam Methane Reforming (base case, *NG*), (2) biomass gasification (*BM*), (3) biogas tri-reforming (*BG*), (4) refuse-derived fuel (RDF, from municipal solid waste (*MSW*)) gasification, as well as (5) power-to-MeOH (*P2X*) process converting $CO_2$ and hydrogen ($H_2$, produced by alkaline electrolysis) into e-methanol. $CO_2$ in flue gases, from MeOH or formaldehyde production, may be emitted to the environment or captured through monoethanolamine (MEA)-based chemical absorption, using waste heat from the metal oxide process. Configurations abbreviations, process descriptions, and modeling details can be found in the Supplementary Sections **S1** and **S2**.

The production routes previously mentioned are compared based on different key performance indicators (KPIs) including specific energy demand (GJ/t $CH_2O$), $CO_2$ emissions (t $CO_2$/t $CH_2O$), and total cost (€/t $CH_2O$). Specific energy demand encompasses fuel and electricity requirements for an easier comparison across configurations. Specific total emissions include direct and indirect emissions. Direct, or scope 1, $CO_2$ emissions stem from product/feedstock over-oxidation or fuel combustion during formaldehyde or MeOH production. Biogenic $CO_2$ does not contribute to scope 1 emissions, while captured biogenic $CO_2$ is accounted as negative emission. Indirect emissions arise from feedstock supply and electricity production. $CO_2$ emission factors are listed in the Supplementary Section **S3**. Finally, the specific total cost (STC) encompasses both annualized CAPEX (for a greenfield scenario) and OPEX considerations including feedstock, fuel, electricity, $CO_2$ emission (no free allowances or revenues for negative emissions), as well as transport and storage (T&S) of captured $CO_2$.

The OSMOSE tool, developed by the IPESE group of EPFL [8], is used to evaluate the superstructure and a Mixed-Integer Linear Programming (MILP) problem is

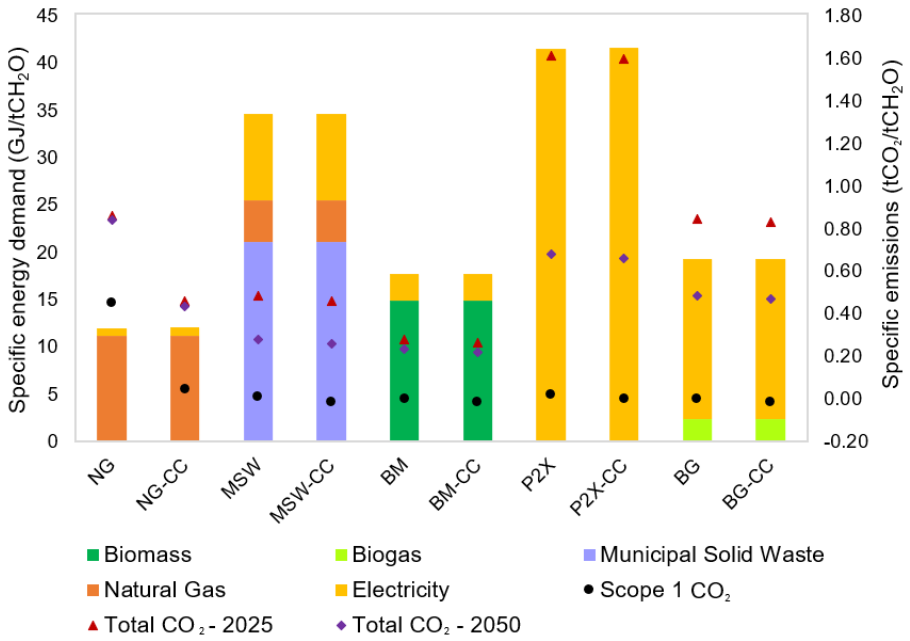

**Figure 2.** Specific energy demand (left axis) and scope 1 and total $CO_2$ emissions (right axis) in 2025 (electricity is sourced from the current Belgian grid) and 2050 (electricity is supplied by the 2050 European electricity mix) scenarios for different production routes.

solved to identify the optimal decarbonization configurations for two different energy and emissions scenarios: (1) the 2025 scenario, considering current energy and $CO_2$ prices in Belgium, and (2) the 2050 scenario, based on estimated future marginal production costs, considering higher ETS and lower energy prices [9-13]. Economic data for both scenarios are listed in **Table 1**.

**Table 1:** Economic parameters considered for 2025 and 2050 scenarios.

| Scenario | 2025 | 2050 |
|---|---|---|
| Electricity (€/MWh) | 78 | 58 |
| Natural gas (€/MWh) | 36 | 40 |
| Biomass (€/MWh) | 17 | 18 |
| Biogas (€/MWh) | 40 | 30 |
| MSW (€/MWh) | 9 | 9 |
| ETS (€/t$CO_2$) | 80 | 200 |
| $CO_2$ T&S (€/t$CO_2$) | 50 | 50 |
| $CO_2$ supply (€/t$CO_2$) | 80 | 80 |

The high volatility of energy prices—stemming from changing global political landscape, availability limitations, and regulatory shifts—prevents the accurate identification of future optimal production routes. To cope with the limitations of predefined pricing scenarios, a parameter sweep is performed, exploring a broader set of economic conditions and seeking to identify the zones of economic optimality associated with each configuration, while generalizing the analysis results beyond a specific year or geographic context. The price of natural gas ($p_{NG}$), electricity ($p_E$), municipal solid waste ($p_{MSW}$), biomass ($p_{BM}$), biogas ($p_{BG}$), and $CO_2$ supply ($p_{CO2}$), as well as the ETS price ($p_{ETS}$) are varied within the pricing sets specified in **Table 2**. For each of the 30, 000 resulting combinations, MILP optimization is performed, seeking total cost minimization. The results are analyzed to identify robust decarbonization pathways.

**Table 2:** Pricing sets considered for the parameter sweep.

| Parameter | Set of values |
|---|---|
| $p_{NG}$ | [10, 25, 50, 75, 100] €/MWh |
| $p_E$ | [10, 25, 50, 75, 100] €/MWh |
| $p_{MSW}$ | [-5, 0, 5] €/MWh |
| $p_{BM}$ | [10, 25, 50, 75, 100] €/MWh |
| $p_{BG}$ | [10, 25, 50, 75, 100] €/MWh |
| $p_{CO2}$ | [0, 25, 75, 100] €/t |
| $p_{ETS}$ | [75, 100, 200, 300] €/t |

## RESULTS

### Energy demand and $CO_2$ emissions reduction

From **Figure 2**, total energy requirement (including fuel and electricity, and excluding feedstock) of conventional formaldehyde production (NG) amounts to 11.96 GJ/t $CH_2O$. Feedstock switching options result in higher total energy requirements: +61% for BG and +248% for

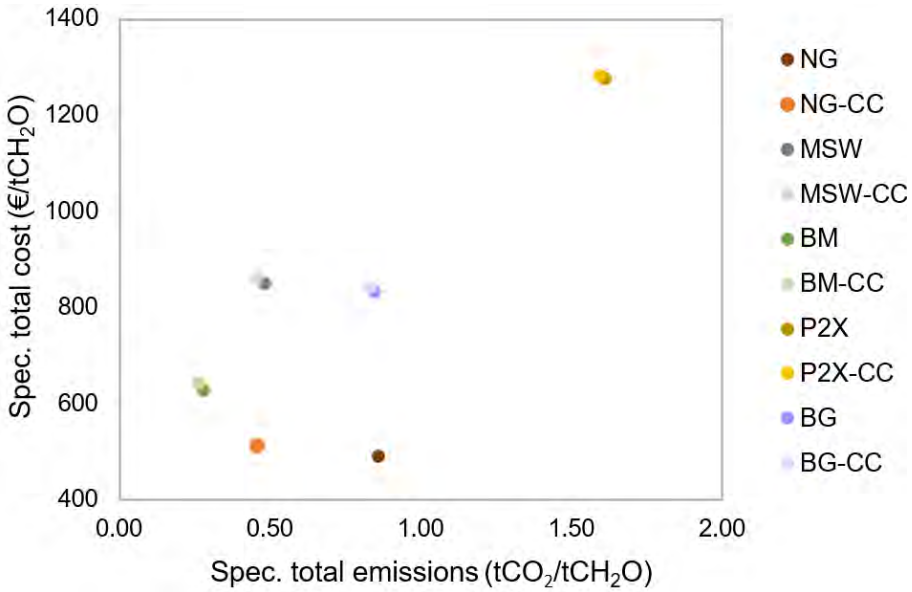

**Figure 3.** Specific total cost (€/t $CH_2O$) vs. total $CO_2$ emissions (t $CO_2$/t $CH_2O$) – 2025 scenario.

P2X due to $H_2$ production via alkaline electrolysis; +48% for BM and +189% for MSW due to lower process efficiency (e.g., drying requirements, lower carbon conversion) and additional energy requirements during MSW pre-treatment. Direct $CO_2$ emissions from formaldehyde production (i.e., 0.018 t $CO_2$/t $CH_2O$ generated by over-oxidation) or fossil $CO_2$ emitted by MeOH production can be captured through chemical absorption with MEA. Heat integration between formaldehyde production and CC unit completely covers the additional heat demand and reduces the energy penalty of $CO_2$ capture to 0.01–1.1% compared to counterparts without CC.

While feedstock switching decreases drastically scope 1 $CO_2$ emissions (96–100%) compared to NG (0.452 t $CO_2$/t $CH_2O$), the contribution of indirect emissions, stemming from upstream material extraction and electricity production, results in a shift in trends as can be seen in **Figure 2**. Total $CO_2$ emissions breakdown can be found in Supplementary Material (Figure **S3**).

Based on current emission factors in Belgium (2025 scenario), BG and P2X routes are associated with total emissions, respectively, only 1% lower and 88% higher than NG due to large electric demand. The least emitting options are BM-CC (-69%) and BM (-68%), followed by NG-CC and MSW-CC (-47%). On the other hand, clear environmental advantage appears for feedstock switching options when low-carbon electricity (e.g., from the projected 2050 European electricity grid) is considered. Carbon footprint reduction between 45% and 77% can be achieved with alternative feedstocks, making NG-CC less environmentally competitive (-49% compared to base case), while P2X corresponds to a modest emission mitigation of 23%. While a 47–49% reduction in $CO_2$ emissions can be achieved by implementing CC in natural gas-based facilities, capturing $CO_2$ from electrified, bio-, and waste-based processes represents little interest in terms of carbon footprint (1–3% additional reduction) since only a limited amount of $CO_2$, stemming from formaldehyde production, is treated.

## Scenario-based economic assessment

Economics being an important decision variable for industrial energy transition, scenario-based economic assessments are depicted in **Figure 3** and **Figure 5**. Despite the environmental benefit of alternative feedstocks, the economically optimal configuration in the 2025 scenario is NG (€489/t $CH_2O$), closely followed by NG-CC, reducing total $CO_2$ emissions by 47% and increasing STC only by 5%. High specific CAPEX (204–399% increase compared to NG for P2X and BM-CC respectively, as can be seen in **Figure 4**), low $CO_2$ ETS price, and expensive electricity (€78/$MWh_e$ vs. €36/$MWh_{NG}$) result in alternative production pathways being economically uncompetitive compared to fossil-based chemicals. Indeed, configurations relying on MSW achieve similar environmental performance as NG-CC with a 67% higher cost. The current Belgian electricity mix results in P2X configurations being the least attractive, both from an economic and environmental perspective. On the other hand, BM and BM-CC achieve drastic emission mitigation (68–69%) at a reasonable cost (+28–32% compared to NG).

In the 2050 scenario, relying on lower energy costs and higher ETS price, NG-CC reduces the STC by 9% compared to the base case (€553/t $CH_2O$). Access to decarbonized electricity improves the environmental ranking of electricity-intensive configurations such as MSW,

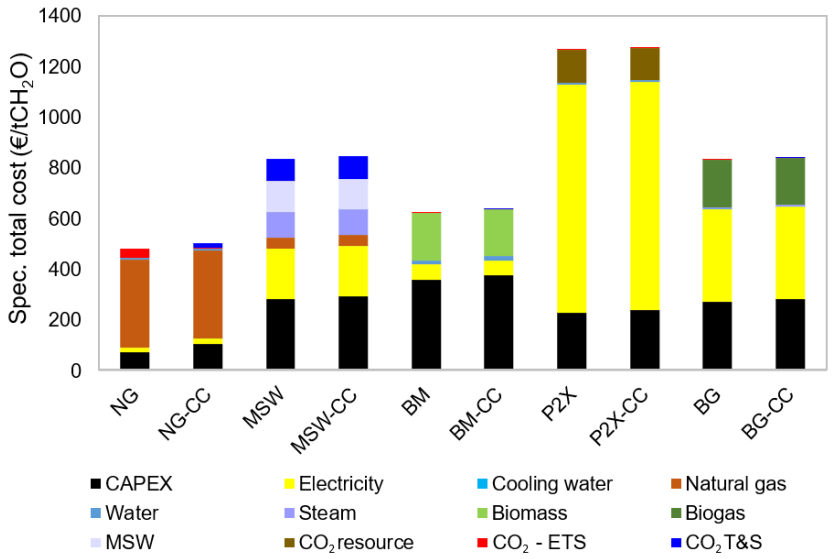

**Figure 4. :** Specific total cost breakdown – 2025 scenario.

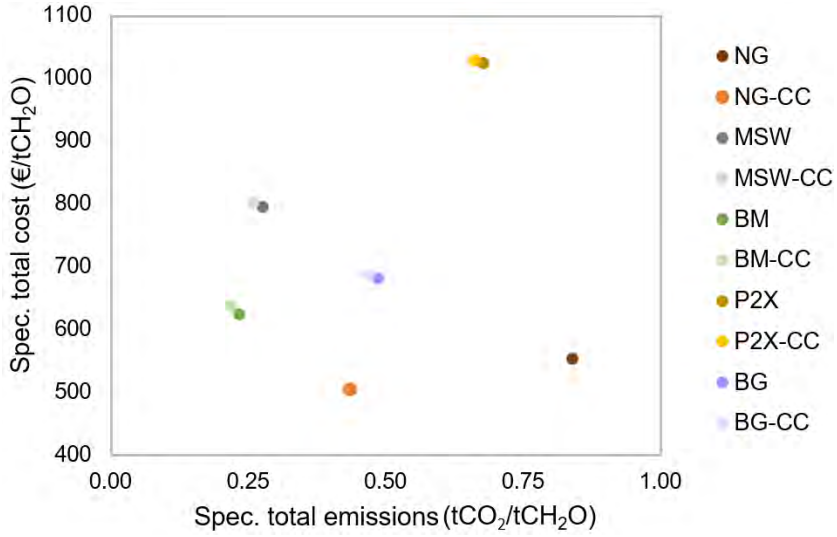

**Figure 5.** Specific total cost (€/t $CH_2O$) vs. total $CO_2$ emissions (t $CO_2$/t $CH_2O$) – 2050 scenario.

BG, and P2X. Biogas-based options benefit from cheaper electricity, reducing the cost gap with the base case down to only 23%, while production pathways relying on MSW are still 44% more expensive than NG. Despite lower emissions, formaldehyde produced from e-methanol feedstock remains the most expensive option with STC exceeding €1, 000/t$CH_2O$. Formaldehyde production from biomass represents the most promising non-fossil-based route, with a 13–15% increase in STC and 73–75% of emission reduction compared to NG.

## Parameter sweep

The ranking of production pathways previously presented is valid solely for the commodities prices considered for the analysis. To cope with the high uncertainty of future energy and feedstock prices, a parameter sweep is performed, exploring a broad set of economic conditions. For each price combination, the configuration achieving the lowest production cost is identified. The results of the parameter sweep are represented in parallel coordinates plots (see **Figure 6** and Supplementary Section **S5**), enabling the identification of robust and flexible solutions for decarbonized formaldehyde production. As a general comment, CC implementation is favored over counterparts without CC for high ETS prices (≥€200/t $CO_2$). Moreover, as can be seen in **Figure 6**, natural gas price is a key parameter driving technology selection.

According to the performed analysis, SMR is the technology with the highest number of occurrences (14, 744), followed by biogas reforming (4, 884), MSW gasification (4, 837), and power-to-X (4, 071), while biomass gasification was found to be optimal only in 1, 464 times

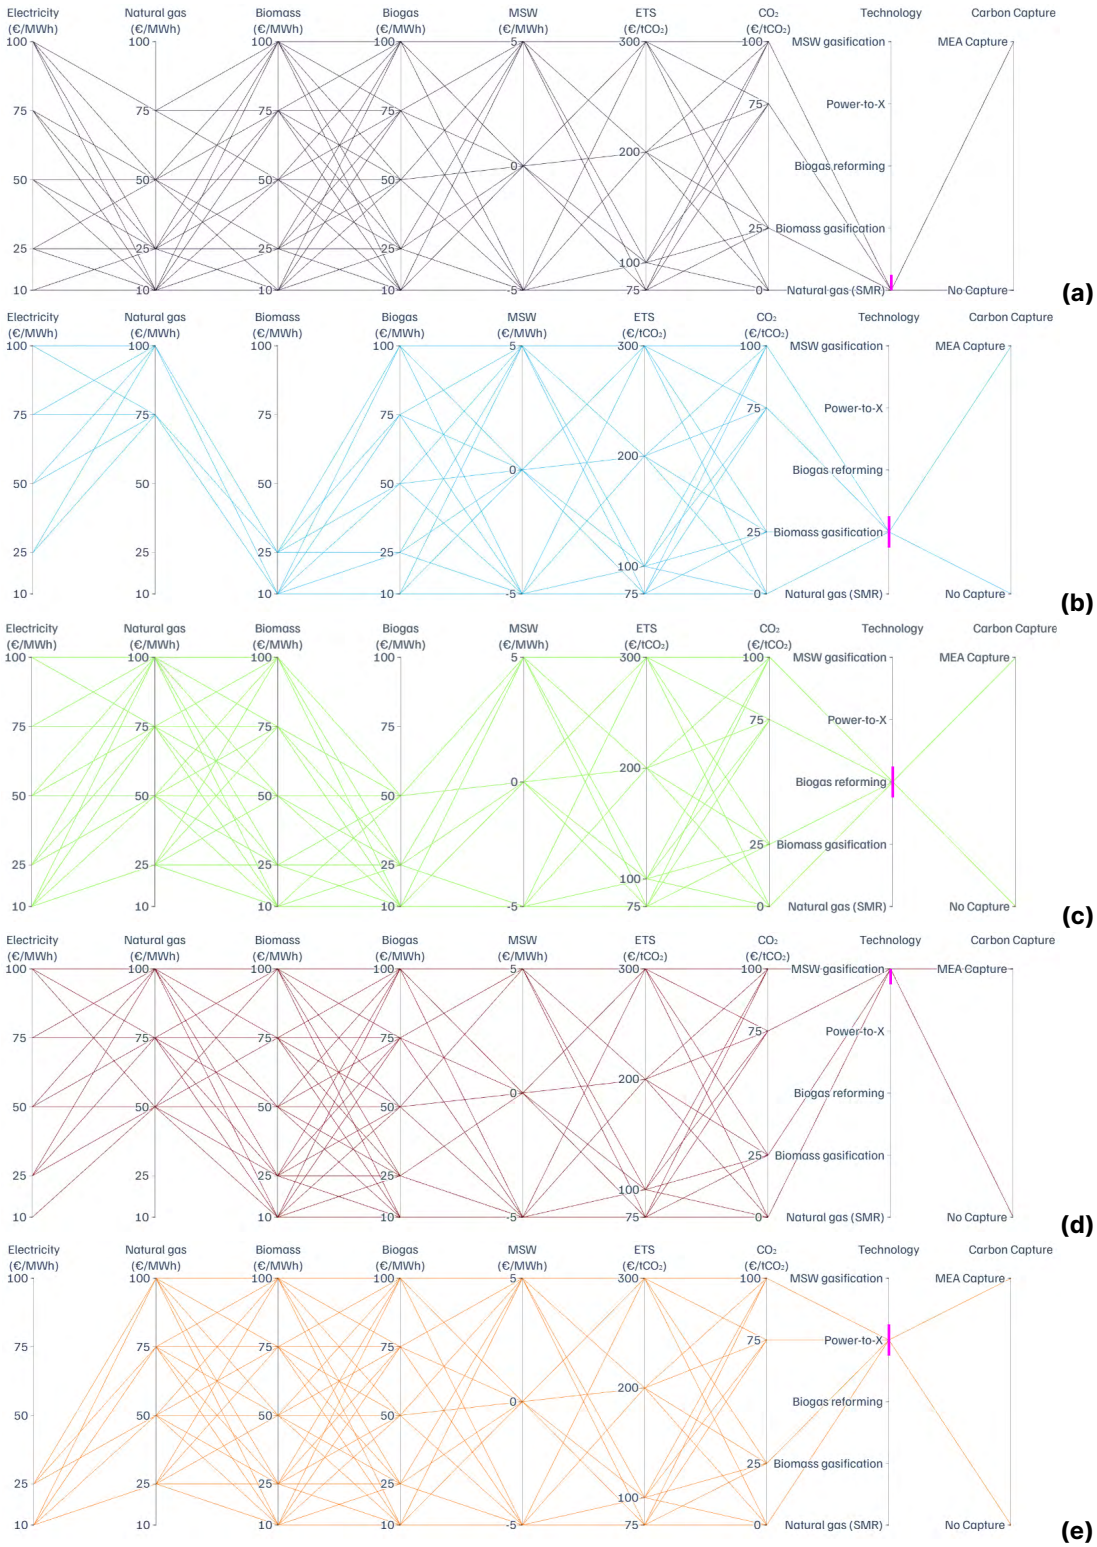

**Figure 6:** Solution space of economic optimality for (a) natural gas-, (b) biomass-, (c) biogas-, (d) MSW-based, and (e) electrified formaldehyde production routes.

out of 30, 000 scenarios tested.

Natural gas-based (**Figure 6**a) routes are identified as optimal for a wide range of economic conditions, making it a flexible and robust solution from an economic point of view. On the other hand, for BM and BM-CC (**Figure 6**b) to appear as economically optimal solutions,

market conditions must combine cheap biomass (≤€25/MWh) and expensive natural gas (≥€75/MWh). Moreover, electricity price should not be in the lower bracket (≥€25/MWh for a biomass price of €10/MWh; ≥€75/MWh when biomass is available at €25/MWh) to avoid favoring electricity-intensive configurations.

Biogas-based options (**Figure 6**c), which offer greater flexibility than biomass-dependent alternatives, become economically viable when natural gas prices exceed €25/MWh and €50/MWh for, respectively, BG-CC and BG. These options may remain optimal even at higher biogas prices (€50/MWh), provided that electricity prices are low to moderate (€25–50/MWh).

Economic optimality for P2X and P2XCC (**Figure 6**e) requires extremely cheap electricity (≤€25/MWh) combined with natural gas and biogas available at a higher price. Moreover, the lower the MSW price, the lower the $CO_2$ supply price should be to remain competitive with MSW-based options. On the contrary of other technologies, P2X-CC is always favored over P2X except when low ETS price (€75/t$CO_2$) is combined with free $CO_2$ feedstock.

Finally, a negative MSW price alone is not sufficient to ensure the economic optimality of MSW and MSW-CC configurations (**Figure 6**d). The availability of natural gas at a sufficiently high price (≥€50/MWh) is required.

As a conclusion, the parameter sweep revealed that NG and NG-CC are the most flexible and robust production pathways. This highlights the challenge of transitioning the chemical sector away from fossil feedstocks. However, biogas and waste-based technologies arise as interesting candidates for non-fossil MeOH and formaldehyde production.

## Potential of industrial symbiosis for the production of e-chemicals

As previously mentioned, bio-based options arise as interesting candidates from an environmental and economic perspective for the energy transition in the chemical sector. However, availability issues are to be expected due to heavy reliance on biomass for industrial decarbonization [14]. Hence, to completely phase out chemicals production from fossil fuels, power-to-X processes should be included to some extent in the production mix. Nonetheless, the economic assessment reveals that e-MeOH feedstock represents the least cost-effective decarbonization pathway for formaldehyde production in a wide range of scenarios.

To address elevated costs, the potential of industrial symbiosis (IS) as a cost-reduction measure is investigated. IS [15] is a systemic approach that promotes collaboration among industries by resources exchanges, such as energy, water, and by-products, enhancing collective sustainability of industrial processes. In the present study, synergies between a formaldehyde production plant (0.1 Mt $CH_2O$/y) and nearby cement industry (0.9 Mt clinker/y) are considered. Commodities prices assumed for this analysis are listed in **Table 3**.

**Table 3 :** Economic parameters for IS implementation.

| Commodities | Cost | |
|---|---|---|
| Coal | 11.5 | €/MWh |
| Municipal Solid Waste | 3 | €/MWh |
| Electricity | 58 | €/MWh |
| $CO_2$ ETS | 200 | €/t$CO_2$ |
| $CO_2$ T&S | 50 | €/t$CO_2$ |

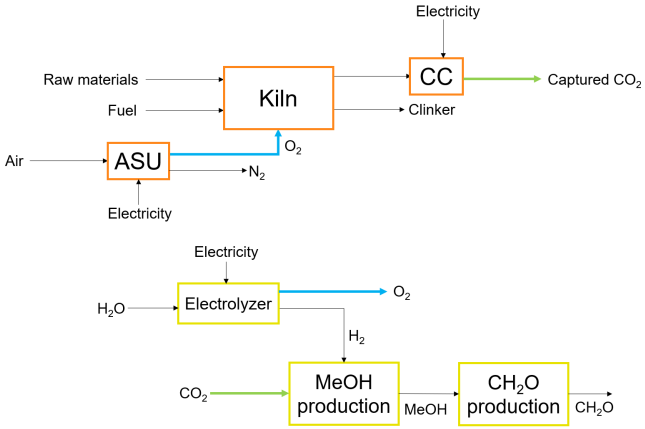

**Figure 7.** Case study for IS implementation between cement and formaldehyde industries.

The base case configuration of the system is depicted in **Figure 7**. In our previous study [16], oxy-fired kiln with cryogenic $CO_2$ capture arises as one of the most promising decarbonization options for the cement industry and hence is chosen as the production route for the IS case. In this configuration, heat is provided by burning a mixture of MSW and coal in oxygen produced by an Air Separation Unit (ASU). The generated $CO_2$ is subsequently captured via a cryogenic capture unit, before being transported and stored. On the other hand, the formaldehyde facility generates oxygen as a by-product of water electrolysis, which is necessary for hydrogen production. Meanwhile, $CO_2$ is required as a feedstock for MeOH production.

Competitiveness of clinker production and power-to-X process can be improved by mutualizing $CO_2$ capture unit and electrolyzer costs through $CO_2$ and oxygen exchanges, as highlighted in **Figure 7**. Such synergies result in an ASU that is no longer necessary, as the oxygen generated by the electrolyzer (0.17 Mt $O_2$/y) entirely covers the oxygen demand of the cement kiln (0.12 Mt $O_2$/y). Furthermore, the cement plant provides the entire $CO_2$ feedstock for methanol production (0.16 Mt $CO_2$/y), reducing the amount of $CO_2$ that needs to be transported and stored (0.59 Mt $CO_2$/y vs. 0.75 Mt $CO_2$/y without IS).

Removing the ASU from the system reduces total

electricity demand by 2% (-28 $GWh_e$/y), which represents 4.2 kt $CO_2$/y considering the current carbon intensity of Belgian electricity. Regarding the economics of the system, instead of buying $CO_2$ from the market at the ETS price (€200/t $CO_2$, representing the maximum marginal abatement cost industries are willing to bear, as well as the long-term target cost of $CO_2$ supplied by Direct Air Capture (DAC)), the formaldehyde facility is supplied by the cement plant at a much lower cost (i.e., capture cost of €27/t $CO_2$). Moreover, oxygen sales to the cement plant result in annual economies of about €11.5M. Despite the use of expensive oxygen (€91/t $O_2$ when produced via electrolysis vs. €30/t $O_2$ when produced with ASU), the cement plant benefits from $CO_2$ sales (€4.3M/y). Moreover, the reduced amount of $CO_2$ to be transported and stored represents additional economies of €8M/y. The implemented synergies and corresponding economies achieved are schematically represented in **Figure 8**.

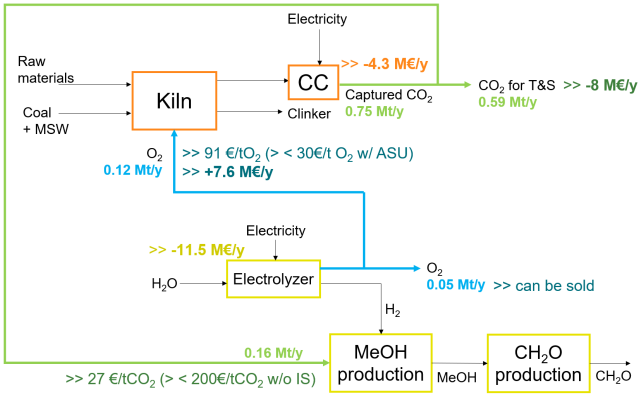

**Figure 8.** Synergies and corresponding economies achieved by IS implementation.

Hence, the implementation of synergies between these industries reduces the total production cost by 3% and by 32% for clinker and formaldehyde, respectively, compared to estimations without IS. Despite the decreased production cost in the IS case, P2X formaldehyde remains more expensive than other decarbonization options such as NG-CC and bio-based routes. Therefore, this option only makes economic sense when there is a scarcity of biomass, high natural gas prices, or low electricity prices. These conditions make P2X options difficult to appear as competitive decarbonization pathways for formaldehyde production.

**Table 4:** Specific total cost of clinker and formaldehyde with and without implementation of IS.

| | No symbiosis | With symbiosis | |
|---|---|---|---|
| Clinker (€/$t_{clinker}$) | 121 | 118 | **-3%** |
| Formaldehyde (€/$t_{CH2O}$) | 1207 | 815 | **-32%** |
| Total (M€/y) | 229.8 | 187.5 | **-18%** |

## CONCLUSION

This study provides a foundation for decision-making regarding $CO_2$ emission mitigation for formaldehyde production based on thermodynamic, environmental, and economic KPIs for future scenarios. For this purpose, an equation-oriented superstructure of formaldehyde industry was developed, encompassing various energy transition pathways including feedstock switching (biomass, biogas, waste), process electrification (Power-to-X), and $CO_2$ capture.

Despite requiring more energy (+ 48–247%) than the base case (11.96 GJ/t$CH_2O$), alternative feedstocks result in reductions of total $CO_2$ emissions up to 77% when low-carbon electricity is used, while emissions are cut by almost half when CC is implemented at NG-based facilities.

The economic assessment in the 2025 scenario identified NG as the most interesting configuration from an economic perspective, closely followed by NG-CC (5% cost increase, 47% emissions reduction compared to base case). Conversely, expensive and fossil-based electricity results in P2X being both the most expensive and most emitting configuration. The most promising bio-based options are BM and BM-CC: 28–32% cost increase, 65–67% emissions reduction compared to NG. If lower energy prices and higher ETS price are assumed (2050 scenario), NG-CC becomes the most cost-effective option, followed by biomass-based configurations, while electrification (P2X) remains the most expensive production route.

A parameter sweep, exploring a broad set of energy pricing scenarios, was also performed. An MILP problem was solved with the OSMOSE tool for each price combination to identify the solution space in which each configuration is associated with the lowest specific total cost. From the 30, 000 pricing scenarios tested, NG-based options (NG and NG-CC) were found to be the most flexible and robust production pathways, representing 49% of the optimal solutions identified. NG-CC exhibits reasonably good environmental performance, with emissions cuts reaching nearly half of current levels, despite its continued reliance on fossil fuels. The most interesting bio-based route is biogas reforming, appearing as optimal as long as moderate-to-high natural gas prices are combined with low-to-moderate electricity prices. On the contrary, stringent conditions for economic optimality arise for BM and P2X configurations requiring extremely low biomass and electricity prices respectively (≤25€/MWh).

Finally, the potential of industrial symbiosis as a cost-reduction measure for power-to-X process was assessed. Synergies between oxy-fired clinker production (requiring oxygen and capturing $CO_2$) and formaldehyde

production from e-MeOH (generating oxygen by electrolysis and requiring $CO_2$ as feedstock) result in reduced electricity demand (-2%) and reduced production costs (-3% for clinker and -32% for formaldehyde). However, P2X formaldehyde remains more expensive than other emission mitigation options, only making economic sense when biomass scarcity, high natural gas prices, and low electricity prices are observed.

These observations highlight the difficulty for the chemical sector to decarbonize and the importance of process efficiency improvements as well as policy frameworks and governmental funding to ensure competitiveness of low-carbon formaldehyde production routes.

## ABSTRACT

"Green" hydrogen production via polymer electrolyte membrane (PEM) electrolyzers must overcome significant energy penalties and high costs to become competitive in renewables-based energy systems. Adaptive operating strategies for PEM electrolyzers—by dynamically adjusting current density, pressure, and temperature—have demonstrated efficiency improvements in simple energy systems. However, their effectiveness in the context of complex power-to-X energy systems featuring variable downstream synthesis processes remains unclear. This work shows that integrated optimization of PEM electrolyzer operating parameters in conjunction with downstream methanation processes (MP) delivers substantial system-wide efficiency and cost benefits under dynamic hydrogen demand and pressure conditions. To demonstrate this, an equation-oriented process model of a PEM electrolysis system is embedded within a higher-level energy system model to compare sequential optimization (where the electrolyzer adapts to predetermined MP operating decisions) against integrated optimization (where electrolyzer and MP operating decisions are determined simultaneously). Sequential optimization delivers 7.3% operating cost savings compared to conventional fixed-parameter operation. In comparison, integrated optimization achieves 9.9% cost reductions and 7.8% decreases in electrolysis system electricity consumption. Operating pressure emerges as the most critical parameter, with electrolyzer electricity consumption exhibiting markedly higher sensitivity than MP electricity consumption. The analysis reveals fundamental trade-offs between component-level and system-level efficiency, demonstrating that prioritizing electrolyzer efficiency optimization yields superior system-wide performance. These findings establish that system-wide coordination through integrated optimization approaches substantially enhances the economic viability of "green" hydrogen supply in complex power-to-X energy systems.

**Keywords**: Scheduling, Energy Efficiency, Energy Systems, Hydrogen, Optimization

## INTRODUCTION

Polymer electrolyte membrane (PEM) electrolyzers enable dynamic integration of hydrogen production into renewables-based energy systems [1]. However, energy-intensive operation and high production costs continue to impede the competitiveness and large-scale deployment of "green" hydrogen technologies [2].

Intelligent operating strategies offer substantial potential to improve both energy and cost efficiency of PEM electrolyzers [3]. Two key mechanisms enable these improvements: (1) dynamic adjustment of operating parameters (i.e., current density, pressure, temperature) to select the most energy-efficient operating point for each load, and (2) information exchange between the electrolyzer and downstream hydrogen applications (e.g., end-use pressure requirements), allowing the electrolyzer to adapt its operation accordingly. While these strategies may temporarily reduce electrolyzer stack efficiency, they yield net system-level gains by reducing hydrogen compression energy demand and lowering operating cost.

These benefits have been demonstrated primarily in relatively simple energy systems comprising photovoltaic units, a PEM electrolyzer, and hydrogen storage to meet a constant hydrogen demand [3]. In contrast, in broader power-to-X applications, PEM electrolyzers are coupled with various downstream synthesis processes (e.g., methanation, Fischer-Tropsch synthesis, Haber-Bosch synthesis), which impose time-varying hydrogen demands and variable pressure requirements [4]. Whether adaptive operating strategies can deliver comparable system-wide efficiency and cost benefits under these complex, dynamic conditions remains unclear.

This work addresses this research gap by extending a previously developed electrolyzer process model to account for downstream methanation process (MP) requirements with variable hydrogen demand and adjustable operating pressures. Two optimization approaches are applied: sequential optimization (where the electrolyzer adapts to predetermined methanation process operating decisions) and integrated optimization (where electrolyzer and methanation process operating decisions are determined simultaneously). The analysis investigates how flexible management of electrolyzer current density, pressure, and storage utilization affects hydrogen production, electricity consumption, and overall system operating costs. The specific contributions are threefold: (1) characterization of optimal electrolyzer operating strategies in integrated power-to-X energy systems with dynamic synthesis requirements, (2) quantitative comparison of sequential versus integrated optimization approaches, and (3) identification of trade-offs between component-level efficiency and system-level performance, providing insights into the practical potential of adaptive operating strategies in complex renewable hydrogen-based energy systems.

## METHODOLOGICAL APPROACH

The optimal operating strategy of a PEM electrolyzer is determined through integrated energy system and process optimization. An equation-oriented process model of a PEM electrolysis system forms the methodological core, quantifying the effects of operating parameter selection (i.e., current density, temperature, pressure) on electricity consumption. This process model is embedded within a higher-level energy system model to derive an operational strategy that satisfies hydrogen demand from methanation processes, which impose both pressure and quantity requirements. The electrolyzer operating strategy encompasses time-variable hydrogen production and dynamic operating pressure adjustment.

Two optimization approaches are analyzed: sequential optimization, in which the electrolyzer adapts to predetermined methanation requirements, and integrated optimization, in which electrolyzer and methanation pressures are determined simultaneously to achieve system-level coordination.

### Electrolysis system

A process model of a PEM electrolysis system [3] forms the methodological foundation. The system comprises the PEM electrolyzer itself and a multi-stage compressor. Throughout this work, 'electrolyzer' denotes the standalone electrolyzer unit, whereas 'electrolysis system' encompasses both the electrolyzer and the associated compressor.

The operational sequence begins with preheating of process water to the target stack operating temperature $T_{stack}$, followed by the electrolysis reaction within the cell. Hydrogen and oxygen, the reaction products, are separated through the membrane and subsequently directed to the positioned flash units. The separated hydrogen stream can be delivered through two outlets. The low-pressure (LP) outlet supplies hydrogen directly at the operating pressure $p_{cat}$ for immediate use, while the high-pressure (HP) outlet enables compression to elevated pressure levels for storage and later use. Both outlets can operate simultaneously, allowing flexible allocation between direct supply and storage.

Electrical energy input occurs via the applied cell voltage $U_{cell}$ and current $I$ to the electrolyzer, as well as through compression work $P_{comp}$ to the compressor. The electrolysis reaction generates waste heat $\dot{Q}_{waste}$, which can be recovered for preheating process water and external heat-integration applications. When the available waste heat proves insufficient for preheating requirements, supplementary heating $P_{heat}$ must be provided by an electric heating element.

Cell voltage $U_{cell}$ consists of three components: the open-circuit voltage $U_{ocv}$, activation overvoltage $U_{act}$, and ohmic overvoltage $U_{res}$. Reduced current densities $j$, decreased operating pressures $p_{cat}$, and increased temperatures $T_{stack}$ contribute to lower cell voltage (Eq. (1) [3]).

$$U_{cell}(j, T_{stack}, p_{cat}) = U_{ocv}(T_{stack}, p_{cat}) + U_{act}(j, T_{stack}) + U_{res}(j, T_{stack}) \quad (1)$$

Aggregating all electrical input components yields the total electrical energy input to the electrolysis system (Eq. (2) [3]).

$$\dot{E}_{el}^{in} = U_{cell} I + P_{heat}(j, T_{stack}, p_{cat}) + P_{comp}(p_{cat}) \quad (2)$$

The electrolysis system efficiency $\eta_{EL}$ (Eq. (3) [3]) quantifies the ratio of usable hydrogen energy to total electrical energy input. Hydrogen energy content is evaluated based on the lower heating value $LHV_{H_2}$. Diffusion and recombination losses $\dot{n}_{H_2}^{loss}$ reduce the total hydrogen production $\dot{n}_{H_2}^{tot}$. Beyond the previously discussed influences, the electrolysis system efficiency exhibits

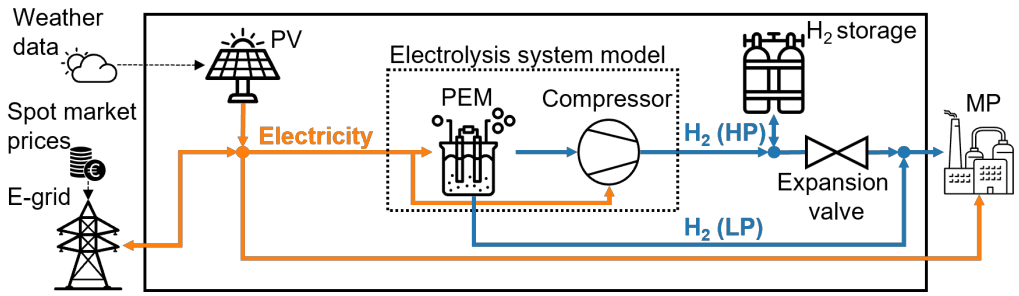

**Figure 1.** Energy system structure (E: Electricity, LP: Low-pressure, HP: High-pressure, MP: Methanation processes, PEM: Polymer electrolyte membrane electrolyzer, PV: Photovoltaic unit).

conflicting parameter dependencies: elevated pressures decrease compression work $P_{comp}$, whereas decreased pressures and elevated current densities minimize hydrogen losses $\dot{n}_{H_2}^{loss}$.

$$\eta_{EL} = \frac{LHV_{H_2}\left(\dot{n}_{H_2}^{tot}(j) - \dot{n}_{H_2}^{loss}(j, p_{cat})\right)}{\dot{E}_{el}^{in}} \tag{3}$$

## Power-to-X energy system

The optimal electrolyzer operating strategy is analyzed within a higher-level energy system configuration (Figure 1). This energy system comprises a photovoltaic (PV) unit and a grid connection, enabling bidirectional electricity exchange (i.e., grid withdrawal during shortages and feed-in during PV surplus conditions), the electrolysis system and a hydrogen storage.

The primary objective of this energy system is to satisfy the electricity and hydrogen demands of two methanation processes. Hydrogen must be delivered at pressure levels between 1 and 20 bar (cf. Scenario definition). Direct supply via the low-pressure (LP) outlet without additional compression can be achieved by maintaining an electrolyzer operating pressure sufficiently elevated. Alternatively, hydrogen can be pressurized to 200 bar via the high-pressure (HP) outlet for temporary storage and subsequent withdrawal. This storage pathway provides operational flexibility to respond to time-variable electricity prices and fluctuating PV generation patterns. Depending on the optimization mode (cf. Scenario definition), direct hydrogen supply via the HP outlet is also possible.

## Optimization problem

Determination of the electrolyzer operating strategy requires solving an energy system optimization problem (Eqs. (4) [3]). The objective function minimizes total operating costs $C$, representing the balance between electricity procurement expenditures and feed-in revenues (Eq. (4a)). Cost calculation incorporates electricity purchase prices $c_{el,t}^{buy}$, feed-in tariffs $c_{el,t}^{sell}$, and corresponding energy quantities $\dot{E}_{el,t}^{buy/sell}$, scaled by the time step duration $\Delta t$ and the number of aggregated period occurrences $n_t^p$ (i.e., scaling aggregated time series costs to annual values).

$$\min_{\mathbf{d},\dot{\mathbf{E}}} C = \Delta t \sum_{t\in\mathcal{T}} n_t^p \left(c_{el,t}^{buy}\dot{E}_{el,t}^{buy} - c_{el,t}^{sell}\dot{E}_{el,t}^{sell}\right) \tag{4a}$$

s.t.

$$\sum_{k\in\mathcal{K}}\left(\dot{E}_{k,e,t}^{out} - \dot{E}_{k,e,t}^{in}\right) + \dot{E}_{e,t}^{buy} - \dot{E}_{e,t}^{sell} = \dot{E}_{e,t}^{D}, \quad \forall e \in \mathcal{E}, \forall t \in \mathcal{T} \tag{4b}$$

$$\dot{E}_{PEM,\mathrm{H}_2,t}^{out} = \dot{n}_{\mathrm{H}_2,t} LHV_{\mathrm{H}_2}, \quad \forall t \in \mathcal{T} \tag{4c}$$

$$\dot{E}_{PEM,el,t}^{in} = U_{cell,t} I_t + P_{heat,t} + P_{comp,t}, \forall t \in \mathcal{T} \tag{4d}$$

$$\dot{E}_{MP,el,t}^{in} = \dot{E}_{MP,el,t}^{in,ref} + \frac{\Delta \dot{E}_{MP,el}^{in}\left(\dot{E}_{MP,\mathrm{H}_2,t}^{in}\right)}{\Delta p_{MP}}\left(p_{MP,t} - p_{MP,t}^{ref}\right), \quad \forall t \in \mathcal{T} \tag{4e}$$

$$p_{cat,t} \geq p_{MP,t}, \quad \forall t \in \mathcal{T} \tag{4f}$$

$$\mathbf{g}(\mathbf{d}, \dot{\mathbf{E}}) \leq \mathbf{0}, \tag{4g}$$

$$\mathbf{d} \in \mathcal{D} = \{T_{stack,t}, p_{cat,t}, j_t, p_{MP,t}\}, \ \forall t \in \mathcal{T} \tag{4h}$$

$$\dot{\mathbf{E}} \in \left\{\dot{E}_{k,e,t}^{out}, \dot{E}_{k,e,t}^{in}, \dot{E}_{el}^{buy}, \dot{E}_{el}^{sell}\right\}. \quad \forall k \in \mathcal{K}, \forall e \in \mathcal{E}, \forall t \in \mathcal{T} \tag{4g}$$

Energy balance constraints must be satisfied for all energy system components ($\forall k \in K$), energy carriers ($\forall e \in E$), and time steps ($\forall t \in T$) through input/output power flows $\dot{E}_{k,e,t}^{in/out}$, ensuring demand requirements $\dot{E}_{e,t}^{D}$ are met (Eq. (4b)).

Integration of the PEM electrolysis system into the energy system model occurs through its input/output power flows $\dot{E}_{PEM,H_2,t}^{in/out}$ (Eqs. (4c) and (4d)).

Methanation pressure variation (i.e., hydrogen demand pressure; hereafter termed methanation pressure for brevity) is governed by Eq. (4e). The methanation process operates at a characteristic curve, which is obtained through a pre-processing step (cf. System assumptions). This characteristic curve provides electricity demand changes $\Delta \dot{E}_{MP,el}^{in}$ in relation to methanation pressure changes $\Delta p_{MP}$ for each hydrogen demand level. Within the optimization, time-dependent hydrogen demand $\dot{E}_{MP,H_2,t}^{in}$ serves as an exogenous input parameter, associated with the corresponding reference electricity

**Table 2:** Optimization modes (LP: Low-pressure, MP: Methanation process, EL: Electrolyzer).

| Mode | EL LP outlet | MP pressure | EL temperature | EL pressure |
|---|---|---|---|---|
| Ref-seq | | Fixed | 80 °C | 30 bar |
| Ref-int | ✓ | 1 to 20 bar | 80 °C | 30 bar |
| pT-opt-seq | ✓ | Fixed | 20 to 80 °C | 1 to 30 bar |
| pT-opt-int | ✓ | 1 to 20 bar | 20 to 80 °C | 1 to 30 bar |

demand $\dot{E}^{in,ref}_{MP,el,t}$ and reference methanation pressure $p^{ref}_{MP,t}$. By applying linear interpolation, Eq. (4e) determines actual electricity demand through the adjustment of methanation pressure $p_{MP,t}$ relative to the reference pressure $p^{ref}_{MP,t}$.

Eq. (4f) ensures that electrolyzer pressure $p_{cat,t}$ is at least equal to the methanation pressure at the low-pressure outlet.

The constraint vector $\mathbf{g}$ encompasses all additional restrictions (e.g., energy storage capacities, load limitations, material balances). Decision variables include electrolyzer operating parameters (i.e., temperature $T_{stack,t}$, pressure $p_{cat,t}$, current density $j_t$), methanation pressure $p_{MP,t}$, and input/output power flows $\dot{\mathbf{E}}$ of all system components.

Solution of the resulting nonlinear programming optimization problem employs the open-source solver IPOPT, obtaining a local optimum. Identical initialization values are applied across all optimizations to ensure reliable, reproducible results and maintain consistency between different operating modes (cf. Scenario definition).

## SYSTEM ASSUMPTIONS AND SCENARIO DEFINITION

### System assumptions

Weather data from Hamburg, Germany, serves as time-dependent input for calculating PV system power availability [5]. Additionally, day-ahead electricity market prices are utilized, with both data sets based on the year 2023. Electricity prices comprise purchase prices and feed-in tariffs, with feed-in tariffs corresponding directly to day-ahead market prices [6]. Purchase prices include additional charges for non-household customers (i.e., grid fees and taxes) [7]. Hourly year-round data are aggregated into seven representative typical days (24 h each) using a hierarchical clustering method [8], yielding 168 time steps. To account for long-term storage, the storage formulation from [9] is applied.

Based on these temporal input data, pre-processing employs the energy system model and optimization approach from [4] to derive the methanation process operating strategy and generate an operating characteristic curve. The operating strategy provides time-dependent hydrogen $\dot{E}^{in}_{MP,H_2,t}$ and electricity demands $\dot{E}^{in,ref}_{MP,el,t}$, along with corresponding methanation pressures $p^{ref}_{MP,t}$, as exogenous input time series. The operating characteristic curve relates methanation pressure variations to electricity consumption across different load levels, enabling pressure adjustment according to Eq. (4e).

Table 1 presents the nominal capacities of all energy system components. The sizing of the PEM electrolysis system, PV unit and hydrogen storage reflect a cost-optimal hydrogen supply configuration [3], while methanation process capacities are derived from [4] with adjustments to match the electrolyzer capacity. The electrolyzer is assumed to operate at a maximum current density of 2 A/cm² at its nominal capacity of 1 MW [3].

**Table 1:** Nominal capacity of energy system components based on [3, 4].

| Component | Nominal capacity |
|---|---|
| PEM electrolysis system | 1 $\mathrm{MW_{H_2}}$ |
| PV unit | 2.5 MW |
| Hydrogen storage | 49.3 MWh |
| Methanation processes | 2x 0.45 $\mathrm{MW_{CH_4}}$ |

### Scenario definition

Four optimization modes are defined to investigate the influence of integrated operating strategies (Table 2). These modes distinguish between the electrolyzer's intrinsic operational flexibility and its coordination with downstream methanation processes.

Regarding the electrolyzer, a distinction is made between fixed state-of-the-art operating parameters (i.e., 80 °C, 30 bar [3]; 'Ref' cases) and dynamically adjustable temperature and pressure within specified limits ('pT-opt' cases). The electrolyzer operating range spans 20 to 80 °C and 1 to 30 bar.

The optimization modes further differentiate the coordination approach. In the sequential approach ('seq'), the methanation process operating strategy (i.e., electricity demand, methanation pressure) is predetermined ($\dot{E}^{in}_{MP,el,t} = \dot{E}^{in,ref}_{MP,el,t}$; $p_{MP,t} = p^{ref}_{MP,t}$), and the electrolyzer subsequently determines its operating strategy accordingly. In the integrated approach ('int'), the electrolyzer operating strategy and methanation pressure (and consequently electricity demand) are determined

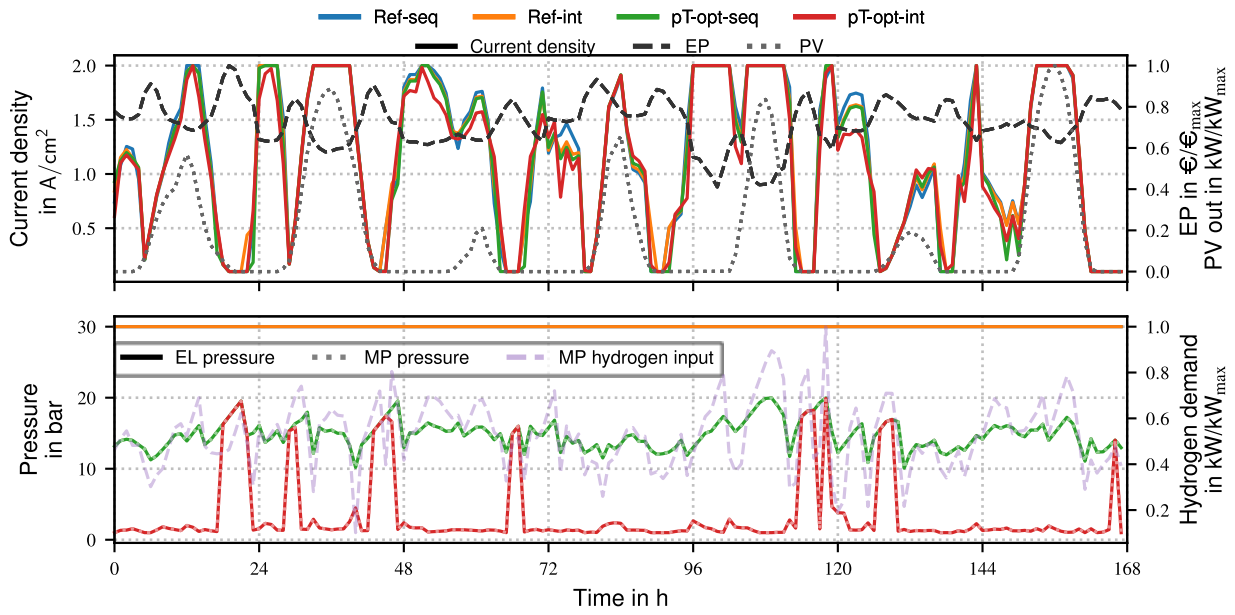

**Figure 2:** Temporal progression of current density, electrolyzer (EL) pressure, and methanation (MP) pressure across the four optimization modes. Electricity price (EP), photovoltaic (PV) output, and methanation hydrogen input are shown for reference, normalized to their respective maximum values. The blue, orange, and green MP pressure curves overlap.

simultaneously, enabling coordinated system-level optimization. Methanation pressure can be adjusted between 1 and 20 bar [4]. Lower pressure selection necessitates additional hydrogen compression within the methanation process to achieve the desired reaction pressure. These effects are captured in the operating characteristic curve derived from the methanation process model [4]. The time-dependent hydrogen demand of the methanation processes remains fixed across all optimization modes.

## RESULTS AND DISCUSSION

### Operational planning

Figure 2 illustrates the electrolyzer operating strategies across the four optimization modes, based on current density (i.e., load indicator) and operating pressure.

**Current density.** The current density of all modes is presented as solid lines in the upper part in Figure 2. Current density profiles—and thus hydrogen production timing and quantities—remain largely consistent across all optimization modes. High current densities (i.e., high operating loads) predominantly occur during periods of low electricity prices (e.g., at 32 h, 100 h) and/or high PV generation (e.g., at 84 h, 156 h).

The 'pT-opt-int' (cf. red line) mode exhibits minor deviations compared to other modes, with slightly lower current densities at certain times (e.g., at 50 h, 124 h) and higher values at others (e.g., at 134 h). This reduction stems from the electrolyzer's higher electrical efficiency at lower loads. Unlike other operating modes, operation at these lower loads is enabled by reducing diffusion losses through lower pressure, allowing the same usable hydrogen production to be maintained despite a lower current density.

**Pressure.** The lower part in Figure 2 illustrates electrolyzer and methanation pressure as solid and dotted lines, respectively.

The electrolyzer operates at a constant pressure of 30 bar in both 'Ref-seq' and 'Ref-int' modes by definition (cf. blue and orange lines, respectively). In the 'pT-opt-seq' mode (cf. green lines), pressure is reduced to match the methanation pressure within a variable range of ca. 10 to 20 bar. In all three modes, methanation pressure is prescribed exogenously and not optimized. In the 'Ref-seq' and 'pT-opt-seq' modes, this constraint results from the sequential optimization approach, whereas in the 'Ref-int' mode, the electrolyzer pressure necessarily exceeds the methanation pressure. Adjusting the electrolyzer pressure would not yield efficiency gains in this configuration (i.e., the methanation pressure already corresponds to the energetically optimal operating point from a methanation perspective).

Pressure optimization behavior differs in the 'pT-opt-int' mode (cf. red lines). Here, the electrolyzer operates predominantly at substantially lower pressures between 1 and 2 bar, with the methanation pressure adjusted accordingly. The reduced electrolyzer pressure

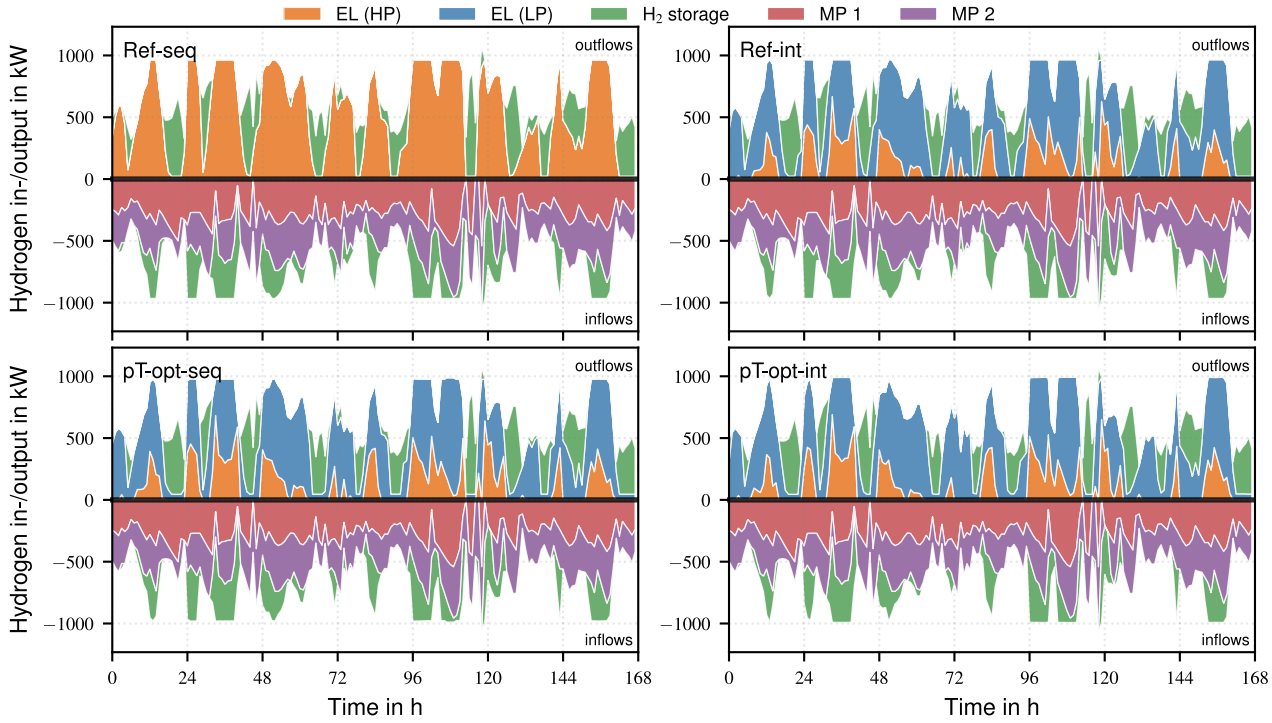

**Figure 3:** Temporal profiles of hydrogen inflows and outflows for production and utilization across all four optimization modes (EL: Electrolyzer, LP: Low-pressure outlet, HP: High-pressure outlet, MP: Methanation process).

increases electrolyzer efficiency, while the lower methanation pressure leads to higher electricity consumption in the methanation process. Overall, the absolute electricity savings of the electrolyzer outweigh the additional electricity demand of methanation during these periods. However, this trade-off is not universally beneficial. At isolated times when the electrolyzer operates at minimum load (e.g., at 20 h, 44 h), no pressure reduction is applied. Under these conditions, the absolute electricity savings of the electrolyzer are insufficient to compensate for the potential increase in methanation electricity consumption, particularly when methanation operates at elevated load.

**Hydrogen production and storage.** Figure 3 illustrates the temporal profiles of hydrogen inflows and outflows for production and utilization across all four optimization modes. Consistent with the current density profiles, electrolyzer hydrogen production remains nearly identical across all optimization modes (cf. orange and blue). As hydrogen demand from the methanation processes is additionally inflexible (cf. red and violet), hydrogen storage utilization exhibits very similar patterns across all modes (cf. green).

Consistent with current density patterns, the electrolyzer operates highly dynamically, switching between full load under favorable conditions (e.g., high PV output or low electricity prices) and minimum load under less favorable conditions. Full-load periods serve both direct methanation supply and hydrogen storage, whereas minimum-load periods rely primarily on storage discharge to meet methanation demand. This strategy ensures a stable and continuous hydrogen supply to the methanation processes over the entire time horizon.

All optimization modes except 'Ref-seq' allow the electrolyzer to supply hydrogen via both the low-pressure (LP) and high-pressure (HP) outlets. Hydrogen is either provided exclusively via the LP outlet (i.e., for direct methanation supply) or simultaneously via both outlets (i.e., for methanation supply and storage). At no point is hydrogen supplied solely via the HP outlet. This indicates that compression to 200 bar for storage is energetically unfavorable compared to direct supply at lower pressure levels, leading to a clear preference for maximizing direct hydrogen utilization.

Nevertheless, hydrogen storage remains economically attractive during periods of high PV availability and/or low electricity prices. The additional energy demand for compression is accepted during these periods, even though the electrolyzer capacity would, in principle, be sufficient to supply the methanation processes continuously without storage reliance.

The 'pT-opt-int' mode exhibits minor storage differences compared to other modes. At isolated time steps, less hydrogen is supplied via the HP outlet and thus

stored (e.g., at 60 h, 74 h). Over the entire period, only 21.3% of the produced hydrogen is provided via the HP outlet in the 'pT-opt-int' mode, compared to 23.3% in the 'Ref-int' mode and 24.2% in the 'pT-opt-seq' mode. As the 'pT-opt-int' mode operates the electrolyzer at significantly lower pressures, the subsequent compression effort is correspondingly higher. For specific time steps, the benefits of storage don't outweigh this increased compression energy demand, rendering high-pressure operation economically unattractive more frequently compared to the other modes.

**Discussion.** The optimization mode does not fundamentally influence the electrolyzer operating strategy with respect to current density. Instead, electrolyzer operation is primarily driven by cost-optimal production conditions, such as low electricity prices or high PV availability, rather than by temporal hydrogen demand. As a result, hydrogen production profiles and storage utilization remain largely consistent across all optimization modes, ensuring a stable hydrogen supply to the methanation processes despite highly dynamic electrolyzer operation.

Regarding pressure, the results indicate that the electrolyzer tends toward the lowest feasible operating pressure when sufficient flexibility is available. When integrated optimization is applied, information exchange between the electrolyzer and the methanation processes enables the determination of an energy- and cost-efficient hydrogen pressure at the overall system level. This leads not only to increased electrolyzer efficiency but also to changes in hydrogen routing, with a clear preference for direct low-pressure supply and a reduced reliance on energy-intensive high-pressure storage.

Consequently, integrated optimization approaches can yield substantial deviations from sequential approaches in optimal operating parameters, including pressure levels and storage usage. Although such approaches require increased planning effort and information exchange, they can enhance system-wide efficiency and contribute to a more cost-effective hydrogen supply and overall energy provision from an integrated energy system perspective.

## Costs and electricity consumption

The economic and energetic implications of these operational strategies are quantified through operating cost and electricity consumption. Figure 4 presents the operating cost of the overall energy system as well as the electricity consumption of the electrolysis system and the methanation processes for all modes.

Compared to the reference case 'Ref-seq', the 'Ref-int' mode achieves operating cost savings of 2%. These savings are primarily attributable to the availability of the low-pressure outlet, which eliminates the need to compress the entire hydrogen output. As a result, the electricity consumption of the electrolysis system is reduced by 2.7%, while the electricity demand of the methanation processes remains unchanged.

The 'pT-opt-seq' mode enables 7.3% savings in total operating cost. These savings mainly result from reducing the electrolyzer operating pressure to the methanation pressure and optimizing the operating temperature. Both adaptions increase electrolyzer efficiency and reduce the electrolysis system's electricity consumption by 5.3%. As in the previous case, no impact on the electricity consumption of the methanation processes is observed.

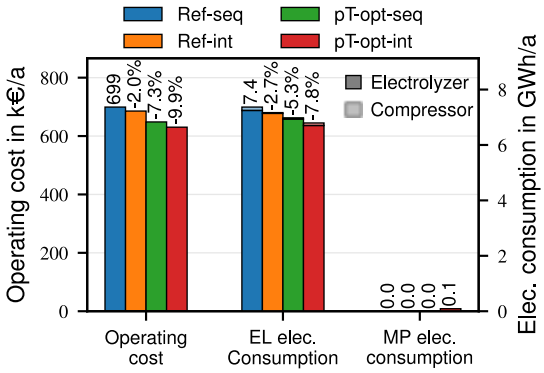

**Figure 4.** Operating cost and electricity consumption of the electrolysis system (EL) and methanation processes (MP) across all optimization modes.

The 'pT-opt-int' mode yields the highest operating cost savings, amounting to 9.9%. A further decrease in operating pressure drives the additional reduction compared to the 'pT-opt-seq' mode, as the methanation pressure is also adjusted under integrated optimization. While this results in a 7.8% reduction in the electricity consumption of the electrolysis system, the lower methanation pressure leads to an increase in the electricity demand of the methanation processes. In absolute terms, however, the electricity savings achieved by the electrolyzer outweigh the additional electricity consumption of the methanation processes.

**Discussion.** No single operating strategy is uniformly optimal for all energy system components within the analyzed energy system configuration. Instead, achieving a system-wide optimum requires balancing the differing sensitivities of the involved processes. In the considered optimization modes, electrolyzer electricity consumption is markedly more sensitive to operating pressure than methanation process electricity consumption. Consequently, operating strategies that prioritize electrolyzer performance—while accepting minor efficiency losses in methanation processes—prove advantageous from a system perspective. While sequential optimization approaches already enable noticeable cost and energy savings, the results demonstrate that additional

benefits can be realized through integrated planning by explicitly accounting for interactions between electrolyzer and methanation operation.

## CONCLUSIONS

"Green" hydrogen production via PEM electrolyzers remains energy- and cost-intensive, limiting the competitiveness of renewable hydrogen-based energy systems. While adaptive operating strategies have demonstrated efficiency improvements in simple systems with constant hydrogen demand, their effectiveness in complex power-to-X configurations with dynamic downstream synthesis processes and variable pressure requirements has remained unclear. This study addresses this research gap by analyzing integrated optimization of PEM electrolyzer parameters in conjunction with downstream methanation processes, demonstrating that operating cost reductions of up to 9.9% are achievable compared to conventional fixed-parameter operation, with electrolysis system electricity consumption reduced by 7.8%.

Sequential optimization approaches, which adjust electrolyzer parameters independently based on predetermined downstream requirements, achieve 7.3% operating cost savings. In contrast, integrated optimization approaches that simultaneously coordinate electrolyzer and methanation operating conditions achieve an additional 2.6%-point reduction. This superior performance stems from the bidirectional information exchange between system components, enabling the determination of system-wide optimal operating pressures rather than component-specific set points. The operating pressure emerges as the most critical parameter, with electrolyzer electricity consumption exhibiting markedly greater sensitivity to pressure variation than methanation process electricity consumption. This results indicates that system-level optimization should prioritize electrolyzer efficiency, even at the cost of minor electricity consumption penalties in downstream synthesis processes.

These findings demonstrate the significant potential of system-wide optimization approaches for enhancing the cost-competitiveness of "green" hydrogen supply. Implementing control architectures that enable real-time coordination between electrolyzers and downstream synthesis units offers substantial economic benefits, particularly when electrolysis systems are designed for wide operating pressure ranges to fully exploit efficiency optimization potential. Future research should extend this analysis to additional synthesis pathways (e.g., Fischer-Tropsch synthesis and Haber-Bosch synthesis) to further enhance the system-level efficiency and economic viability of renewable hydrogen-based energy systems.

## DIGITAL SUPPLEMENTARY MATERIAL

The model code and input data will be made available later in an online repository.

## ABSTRACT

The aviation sector represents one of the most pressing challenges in the energy transition due to its strong reliance on energy-dense liquid fuels and established fuel infrastructure. Sustainable Aviation Fuel (SAF), particularly from agricultural residues, offers a near-term mitigation pathway; however, large-scale adoption is shaped by policy mandates, infrastructure expansion, market price formation, and passenger demand responses. These coupled dynamics are difficult to capture using aggregate or equilibrium-based models. This study develops an agent-based model to analyze SAF transition pathways and applies it to India's civil aviation system. Results show that SAF adoption emerges from the coordination between infrastructure entry, cost learning, and market responses rather than mandate ambition alone. Even moderate mandates fall short of intended adoption levels without timely infrastructure expansion, while aggressive mandates become infeasible under binding supply and price constraints. Passenger demand feedbacks further influence outcomes by linking fuel cost increases to airline operations and route-level allocation decisions. The findings highlight infrastructure coordination and price formation as critical leverage points for aviation decarbonization and demonstrate the value of agent-based models for evaluating realistic SAF transition strategies under policy and market uncertainty.

**Keywords**: Energy Systems, Agent-Based Modeling, Energy Transition, Sustainable Aviation Fuel, Aviation Decarbonization

## INTRODUCTION

Decarbonization of the global energy system has become a central objective of climate mitigation efforts, with particular attention directed toward hard-to-abate sectors. The transport sector contributes nearly 28% of global $CO_2$ emissions, of which aviation accounts for approximately 2–3%, a share that is expected to increase due to sustained growth in air travel demand. Global aviation demand is projected to double relative to 2024 levels by the early 2040s, with annual growth rates in the range of 3.6–4.2% [1]. Unlike road transport, where electrification and efficiency improvements have already delivered substantial emissions reductions, aviation faces fundamental constraints related to energy density requirements, safety certification, long asset lifetimes, and fleet turnover [2, 3]. These constraints severely limit the near- to medium-term feasibility of alternative propulsion systems, positioning aviation as one of the most challenging sectors to decarbonize. A range of mitigation options is being pursued within aviation, including operational efficiency improvements, demand management, carbon offsetting mechanisms, and the development of hydrogen- and electric-powered aircraft. However, these pathways remain either incremental in their emissions impact or constrained by low technology readiness and infrastructure limitations at scale. Within this landscape, Sustainable Aviation Fuel (SAF) has emerged as the most

viable near-term pathway for reducing aviation emissions while maintaining compatibility with existing aircraft fleets and fuel infrastructure. As a drop-in fuel, SAF can be blended with conventional aviation turbine fuel at levels of up to 50% and used in current aircraft without modifications, enabling near-term emissions reductions without disruptive changes to aircraft or airport infrastructure. When produced from renewable and waste-based feedstocks, SAF can reduce life-cycle greenhouse gas emissions by up to 60–80% relative to fossil jet fuel [4].

## LITERATURE REVIEW

SAF can be produced through multiple technological pathways, including Hydroprocessed Esters and Fatty Acids (HEFA) from waste oils and fats, Fischer–Tropsch synthesis via biomass or waste gasification, Alcohol-to-Jet (ATJ) conversion of bio- or waste-derived alcohols, and power-to-liquid routes based on renewable electricity and captured carbon. These pathways differ substantially in technology maturity, capital intensity, and cost trajectories, indicating that large-scale SAF deployment extends beyond a purely technological challenge. Techno-economic analyses consistently identify a substantial cost gap between SAF and conventional aviation turbine fuel. Across production pathways and regional contexts, SAF minimum selling prices are typically estimated to be 3 to 5 times higher than fossil jet fuel, with reported values in the range of USD 1.8–3.5 per kg at industrial scales of 400–600 million liters per year, compared to jet fuel prices of approximately USD 0.4–0.7 per kg [5, 6]. Capital investment dominates costs in gasification-based pathways, while feedstock costs account for more than 50% of operating expenditures in HEFA and ATJ routes. Although learning-by-doing, economies of scale, by-product valorization, and targeted policy support can reduce production costs over time, the magnitude and timing of such reductions remain uncertain. As a result, SAF deployment has been closely tied to policy intervention through blending mandates, tax credits, carbon pricing, and penalties for non-compliance.

Existing studies analyze the impacts of SAF mandates on airline behavior, airline adoption decisions shaped by interactions with airports and fuel suppliers, certification and chain-of-custody requirements for SAF producers, and the role of feed-in tariffs and capital subsidies in enabling biojet fuel supply chains [7, 8, 10]. Scenario-based modeling studies indicate that global SAF deployment faces persistent challenges related to high production costs, feedstock availability, and spatial concentration of supply. Co-benefit analyses further suggest that airlines adopt SAF primarily when SAF price premiums are comparable to carbon prices, while benefit–cost ratios decline when SAF availability is limited to a small number of airports, highlighting the importance of spatial scale and infrastructure coverage [9-11].

Despite these insights, much of the existing literature examines SAF adoption by focusing on individual actors or isolated system components, limiting its ability to capture emergent system behavior. Critical dynamics remain insufficiently explored, including passenger responses to SAF-induced ticket price changes, SAF market behavior under supply–demand imbalances, airline strategies for allocating SAF across airport networks, and the effectiveness of penalties under constrained supply conditions. Moreover, the interaction between short-term operational decisions and long-term strategic investments, which is central to understanding infrastructure lock-in and transition pathways, remains underdeveloped. These limitations point to the need to conceptualize SAF deployment as a socio-technical system in which outcomes emerge from interactions among heterogeneous actors operating under distinct objectives and constraints. The aviation fuel value chain comprises airlines, fuel producers, feedstock suppliers, airports, passengers, markets, and regulators whose decisions interact through non-linear economic, spatial, and temporal feedbacks. Fuel procurement choices influence market prices and investment incentives, infrastructure availability constrains feasible adoption pathways, and early policy signals shape long-term transition trajectories. Such adaptive and path-dependent dynamics are difficult to capture using aggregate, equilibrium-based, or centrally optimized modeling approaches. Agent-based modeling offers a suitable alternative by explicitly representing decentralized decision-making, heterogeneous behavior, and emergent system outcomes [13]. ABMs have been successfully applied in energy and transport systems to study technology diffusion, infrastructure evolution, and policy experimentation under uncertainty [14, 15].

Motivated by these gaps, this study develops Greening Aviation's Energy Requirements through Optimal SAF Supply (Green-AEROS), an agent-based model designed to analyze SAF adoption in aviation as an integrated, multi-actor transition process. Green-AEROS explicitly represents interacting agents across the aviation fuel value chain and links short-term operational behavior, such as route-level fuel blending and passenger demand responses, with long-term strategic decisions, including capacity expansion and infrastructure emergence. The model is applied to India's civil aviation sector, a rapidly growing aviation market with increasing policy interest in SAF deployment, to examine how regulatory ambition, market dynamics, and infrastructure evolution jointly shape SAF adoption pathways and long-term aviation decarbonization outcomes.

## AGENT-BASED IMPLEMENTATION OF GREEN-AEROS

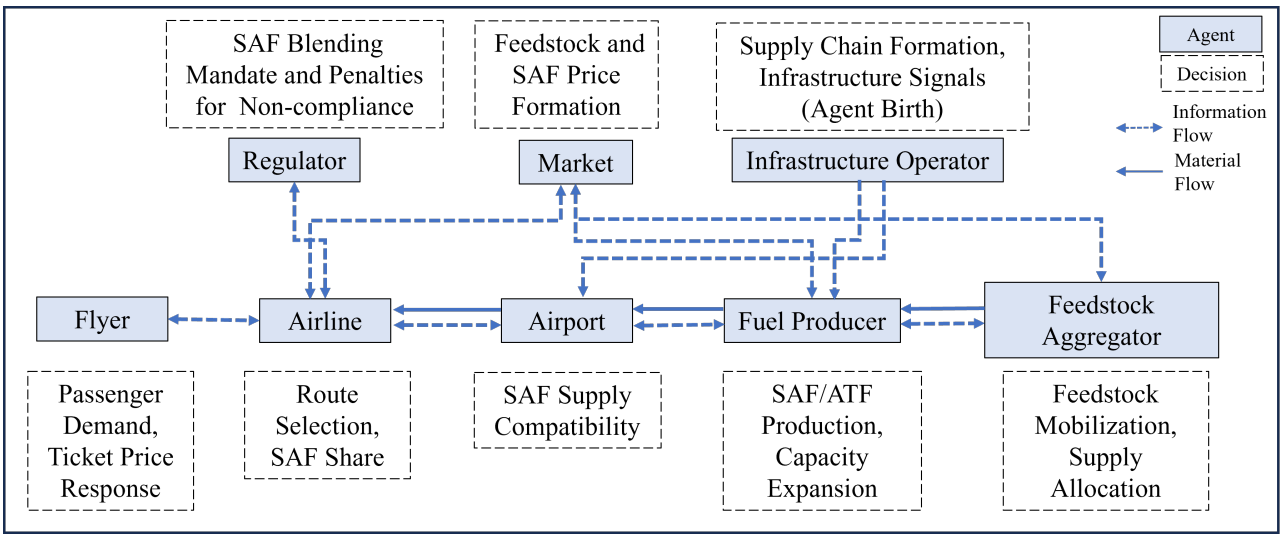

**Figure 1.** Conceptual architecture of Green-AEROS highlighting major agent decision interactions. Solid arrows denote physical flows such as, fuel use, and SAF supply across routes and airports. Dashed arrows indicate information, policy, price, and coordination signals governing market responses, regulatory enforcement, and infrastructure emergence.

Green-AEROS is an agent-based model developed to explore transition pathways for the aviation sector toward SAF. The model represents decentralized decision-making across the aviation fuel value chain by explicitly modeling 8 interacting agent types: flyers, airlines, airports, fuel producers, feedstock aggregators, infrastructure operator, market, and regulator **Figure 1**. Airline agents represent commercial carriers operating across multiple airports. To capture spatially localized behavior, each airline agent comprises airport-specific subagents that make route-level decisions, including passenger demand forecasting and ticket price formation. The allocation of SAF and ATF shares on routes originating from each airport is determined through a linear programming formulation that minimizes penalties, subject to a maximum SAF blending limit of 50% and airport-level SAF availability constraints. Baseline passenger demand is driven by exogenous socio-economic factors such as population growth and GDP per capita, which evolve over time. Flyer agents respond endogenously to ticket price changes, with price sensitivity expressed through the effective fuel cost resulting from SAF–ATF blending. Airport agents decide on SAF infrastructure activation based on airline demand for SAF and local availability from fuel producers. Fuel producer agent consists of two sub-agents: conventional refinery agents supplying ATF and SAF producer agents supplying SAF. SAF producer agents make decisions regarding production volumes, capacity expansion, technology deployment, and feedstock procurement. Production decisions are primarily driven by feedstock availability and learning effects associated with cumulative production. SAF is assumed to be transferred to existing refinery infrastructure for blending with ATF and subsequently transported to connected airports. This assumption reflects the utilization of existing fuel infrastructure and supports early-stage SAF deployment without requiring immediate system-wide retrofitting. Feedstock aggregator agents are spatially distributed according to regional agricultural residue availability and make decisions related to feedstock mobilization and supply network formation with SAF producers. The infrastructure operator agent governs the endogenous emergence of SAF supply chains by signaling the entry of new SAF production facilities and airport-level SAF infrastructure. This agent coordinates linkages between feedstock aggregators, SAF producers, and airports by optimizing the use of existing fuel infrastructure and minimizing system-level bottlenecks. The infrastructure operator signals the need for new SAF production capacity based on airline demand and the capacity expansion decisions of existing SAF producers. Regulator and market agents provide the policy and price-formation environment. The regulator sets national SAF blending mandates for airlines and enforces penalties for non-compliance, with penalties anchored to SAF prices discovered by the market agent. The market agent receives SAF demand from airlines and supply from SAF producers, as well as feedstock supply from feedstock aggregators and feedstock demand from SAF producers, and discovers SAF and feedstock prices in response to supply–demand imbalances. The resulting SAF prices evolve over time with changes in production scale, feedstock availability, and learning effects. To ensure numerical stability and avoid unrealistic price volatility, a min–max capping mechanism is applied to bound SAF price variations. Given the early stage of SAF deployment, the model assumes a uniform

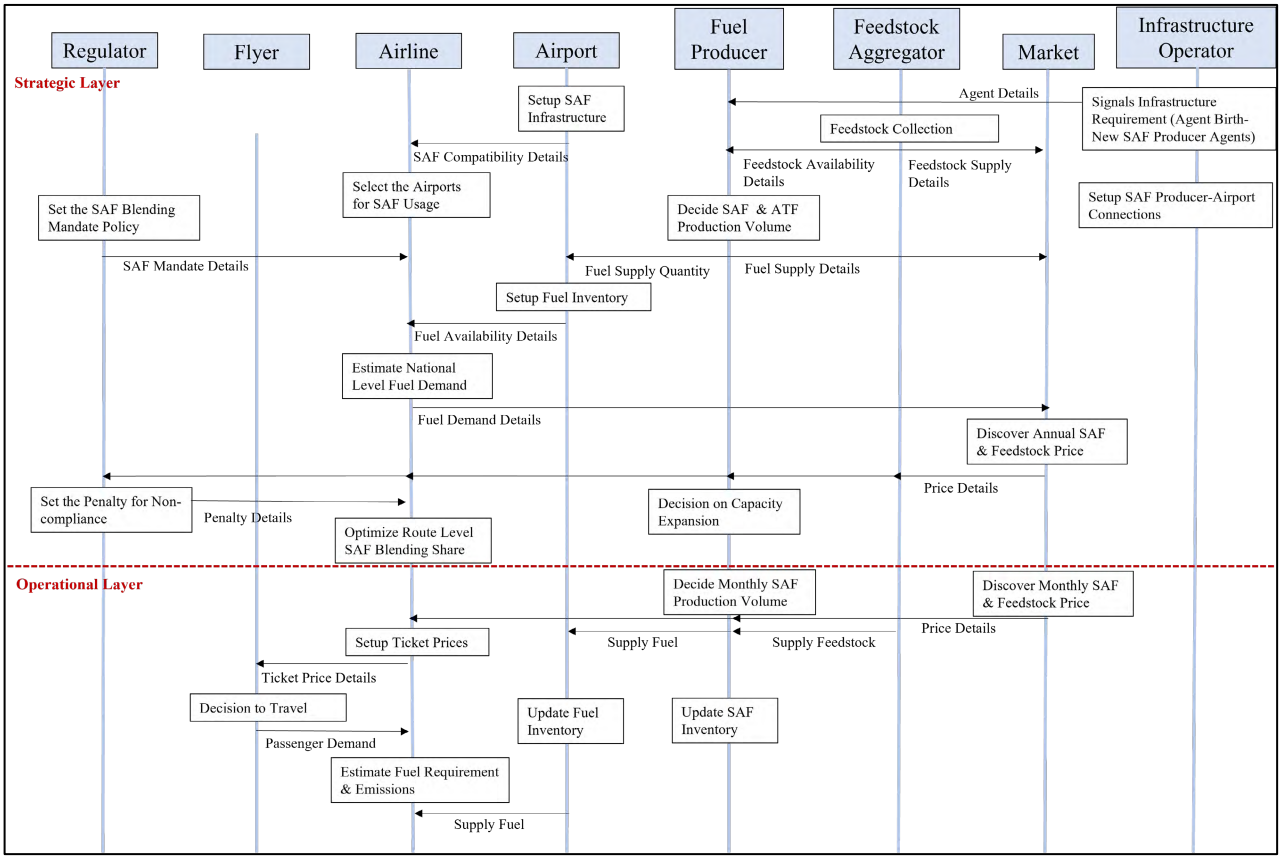

**Figure 2.** Agent-interaction and decision sequence in the Green-AEROS model.

national SAF price, while feedstock prices vary spatially to reflect regional availability. All agents are equipped with forecasting and optimization modules that enable forward-looking decision-making under uncertainty, incorporating costs, risks, incentives, and learning over time. Agent decisions in Green-AEROS occur at two levels, operational and strategic, and evolve over different time scales that jointly shape the transition dynamics. **Figure 2** presents the sequence of agent-level decisions and their interactions within each time step. It highlights the predefined order of decision updates and the exchange of information through shared system variables such as prices, demand, and capacity, thereby representing coordination across agents within a decentralized framework. For instance, at the strategic level, the infrastructure operator signals the birth of new SAF producer agents and determines SAF compatibility at connected airports, which is used by airline agents to optimize SAF blending shares at the route level. These decisions propagate to the operational level, where airlines set ticket prices that are communicated to flyer agents, whose responses capture passenger demand sensitivity to SAF adoption.

## CASE STUDY: INDIA'S CIVIL AVIATION SECTOR

The performance of Green-AEROS is evaluated using a case study of India's Civil Aviation Sector (ICAS), the third-largest domestic aviation market globally, with more than 7, 100 daily aircraft movements and annual carbon dioxide emissions of approximately 30–35 million tonnes [16, 17]. Green-AEROS is implemented in Repast4Py and instantiated to represent 11 major airports (DEL, BOM, BLR, CCU, MAA, HYD, GOI, COK, LKO, AMD, and IDR) and 110 domestic routes, together capturing approximately 69% of domestic air traffic. A single representative airline agent is modeled to capture aggregate airline behavior, incorporating system-level risk preferences and strategic decision-making. Route-level passenger demand is forecast by the airline agent using exogenous socio-economic drivers, including gross domestic product, fuel prices, population, and per capita income. Conventional refineries are assumed to supply the required quantities of ATF, while SAF is produced from agricultural residues through the Alcohol-to-Jet pathway. Blending of SAF and ATF is assumed to occur at refineries located nearest to airports. Feedstock

aggregator agents are distributed across 14 states and 374 districts and supply agricultural residues derived from rice, maize, and sugarcane.

The number and capacity of SAF production sites evolve endogenously over time, driven by airlines' willingness to adopt SAF in order to reduce penalties for non-compliance and by feedstock availability within a procurement distance ($P_d$) from production sites which. Strategic decisions are modeled at an annual resolution, while operational decisions occur monthly over a 20-year simulation horizon spanning 2024–2044. In line with current policy timelines in India, SAF blending mandates are applied from 2027 onward, starting at 1% in 2027, increasing to 2% in 2028, and reaching 5% by 2030. The model is initialized with a single SAF production site with a capacity of 43.75 million liters, supplying SAF to one airport (DEL) at an initial SAF price ($Price_{SAF}$) of 275.23 INR per liter, with a lead time of two years before the facility becomes operational. SAF blending mandates are imposed exogenously as policy requirements; however, realized SAF adoption emerges endogenously from agent interactions and may fall short of mandated levels when supply-side, infrastructure, feedstock availability, or cost constraints become binding.

To examine the implications of increasing policy ambition, three policy configurations are evaluated. All policies follow an identical SAF blending trajectory until 2030, reflecting the current national mandate pathway. **Policy 1** represents a low-ambition pathway, in which the SAF blending requirement increases to a maximum of 5% by 2030 and remains constant thereafter. **Policy 2** reflects a moderate ambition pathway, in which the blending requirement continues to increase beyond 2030, reaching a maximum of 15% over the 20-year horizon. **Policy 3** represents a high-ambition pathway, in which the blending requirement rises further to a maximum of 30% over the same period. These policy configurations are used to assess how infrastructure emergence, market dynamics, and airline decision-making jointly shape feasible SAF adoption trajectories under progressively stronger regulatory targets.

## RESULTS AND DISCUSSION

The evolution of SAF adoption under Policies 1, 2, and 3 by comparing imposed blending requirements with realized SAF shares emerging from agent interactions is illustrated in **Figure 3(a)**. For ICAS, passenger demand across 110 domestic routes increases from 100.4 million passengers in 2024 to 182 million by 2044, with total aviation fuel demand rising from 2.6 billion liters to 4.8 billion liters. Over the same period, ATF prices increase by 8.1%. Against this growth trajectory, early SAF uptake across all policies remains highly localized. In 2027, a national SAF blending level of 1% is achieved with a total SAF requirement of approximately 30 million liters, accomplished by deploying SAF on a single high-volume route (DEL–BLR), where SAF accounts for 24% of the fuel used on that route.

By 2030, the mandated blending level increases to 5%, yet realized SAF adoption remains limited to approximately 1.4% across all three policies. This divergence indicates that mandate escalation alone is insufficient in the absence of supporting infrastructure. From 2031 onward, realized adoption trajectories begin to diverge as infrastructure expansion is triggered endogenously by airlines' incentives to reduce penalties for non-compliance. Policies 2 and 3 achieve the 5% blending target by 2032, requiring approximately 206 million liters of SAF, while Policy 1 reaches the same level by 2033. This earlier achievement under Policies 2 and 3 reflects accelerated entry of SAF production sites and expansion of airport-level SAF compatibility driven by higher post-2030 policy ambition.

**Table 1:** Number of airports supplying SAF and SAF producers operating by 2044.

| | Airports | SAF Producers |
|---|---|---|
| Policy 1 | 3 | 3 |
| Policy 2 | 7 | 5 |
| Policy 3 | 10 | 8 |

Under Policy 2, SAF adoption continues to increase steadily, reaching 15% blending by 2040 with a corresponding SAF requirement of 682 million liters. In contrast, under Policy 3, realized SAF adoption plateaus at a maximum of 25.15% by 2044 despite stronger policy signals. This saturation occurs even though additional SAF production capacity is available, indicating that airport-level blending constraints and limited route coverage restrict further demand growth. **Table 1** shows that achieving a 5% blending level by 2044 requires 3 SAF production sites supplying DEL, BLR, and BOM, whereas higher blending levels depend more strongly on expanding SAF compatibility across additional airports rather than increasing the number of producers alone. Under Policy 2, the addition of 2 SAF producers supplying HYD and MAA, along with SAF availability at LKO and GOI from existing SAF producers, enables higher system-wide adoption. Under Policy 3, even with 8 SAF production sites supplying 10 airports, a 16% SAF shortfall is observed by 2044.

These first-order insights indicate that mandate ambition alone does not determine realized SAF adoption. Instead, adoption is constrained by the timing and spatial alignment of SAF production sites, airport-level blending compatibility, and airline route-level allocation decisions. **Figure 3(b)** shows the regional distribution of India's SAF

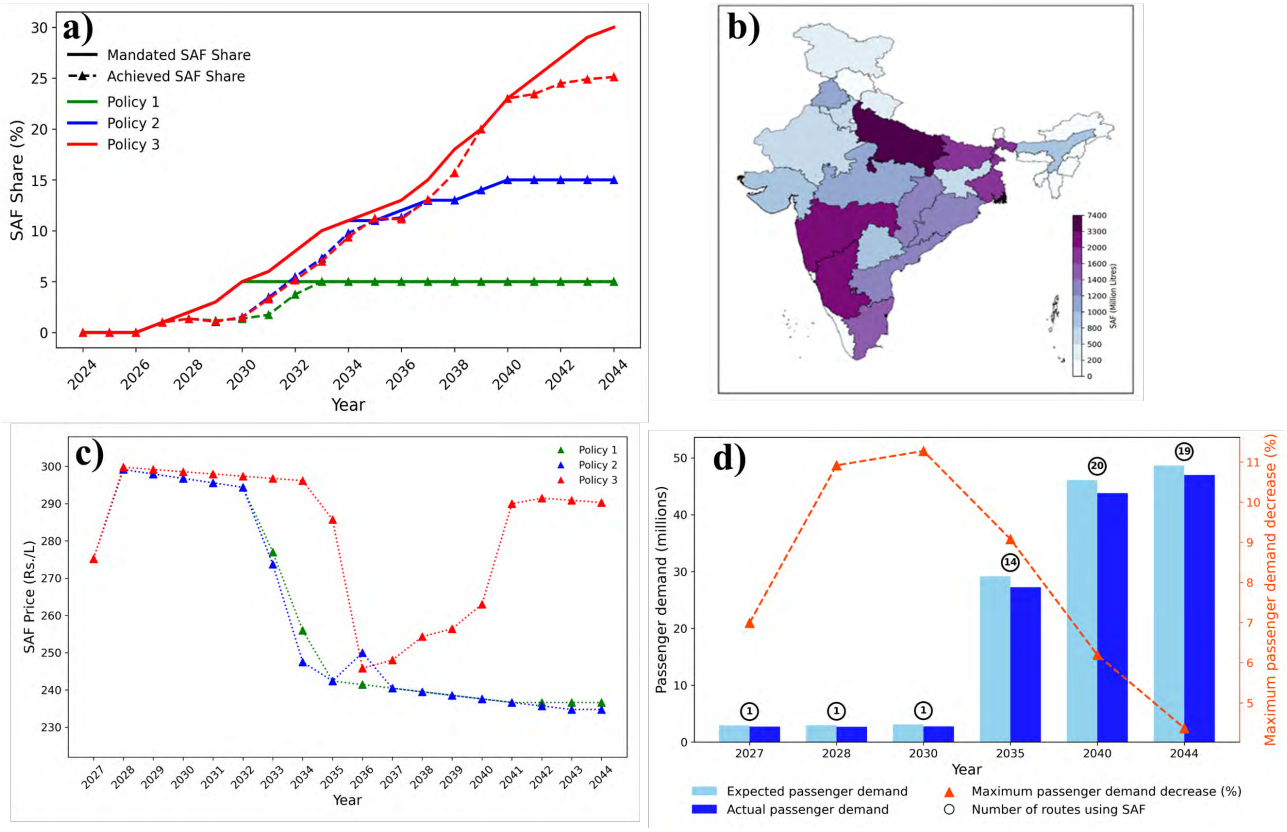

**Figure 3.** (a) SAF uptake under different policies. (b) Spatial distribution of potential SAF production from agricultural residues across India. (c) SAF market price evolution across policy pathways. (d) Passenger response to SAF adoption under Policy 2(only for routes using SAF).

production potential derived from agricultural residues of rice, maize, and sugarcane, which together amount to an estimated 7, 600 million liters annually. While this potential substantially exceeds the SAF requirement even under higher blending policies, it is unevenly distributed across regions and does not automatically translate into effective supply at demand centers. As a result, SAF adoption concentrates at airports with high route volumes and favorable blending conditions, even under a nationally uniform SAF price. This spatial mismatch between feedstock availability, production capacity, and airport demand explains why higher blending levels remain unattainable despite sufficient aggregate resource potential, highlighting the need for coordinated infrastructure expansion alongside policy mandates.

**Figures 3(c) and 3(d)** together reveal how SAF price dynamics translate into uneven passenger demand responses across spatial and temporal scales. In the early phase of Policy 2, limited SAF availability results in high blended fuel costs. In 2027, with a SAF price of 275.23 INR/L, airlines achieve the mandated 1% blending by concentrating SAF usage on a single high-volume route (DEL–BLR), where a 24% SAF share leads to a route-level passenger demand reduction of 6.8%. As SAF prices increase further by 8.2% in 2028 due to continued supply constraints, the maximum route-level demand reduction deepens to nearly 10%, despite SAF still being used on only one route. This illustrates how early SAF adoption manifests as localized demand shocks driven by price pressure rather than system-wide contraction.

As SAF supply expands and prices moderate, these dynamics evolve. By 2035, increased SAF availability lowers prices sufficiently to enable airlines to distribute SAF usage across 14 routes. While the maximum route-level demand reduction remains noticeable at 8.9%, the aggregate passenger demand reduction across all SAF-using routes is limited to 6.6%, indicating a diffusion of impacts rather than intensification. By 2042, SAF prices stabilize under Policy 2 as supply better aligns with demand, allowing SAF usage to expand to 19 routes. At this stage, both maximum and aggregate demand impacts decline further, with a maximum route-level reduction of 4.2% and an overall reduction of 3.4%. These results highlight a key emergent insight: passenger responses to SAF adoption are highly non-linear and scale-dependent. Localized impacts at the route level do not translate proportionally to system-wide outcomes, underscoring the importance of bottom-up modeling approaches in

capturing how micro-level airline allocation strategies shape macro-level demand trajectories during the SAF transition.

## CONCLUSION

In the present study, Green-AEROS is developed as an agent-based model to examine Sustainable Aviation Fuel transition dynamics as an emergent outcome of decentralized decision-making across the aviation fuel value chain. Applied to India's civil aviation sector, this work constitutes one of the first agent-based, system-level representations of the SAF socio-technical system, explicitly integrating airlines, passengers, fuel producers, infrastructure evolution, markets, and regulation within a unified framework. The results show that realized SAF adoption is governed less by mandate ambition in isolation and more by the alignment of infrastructure emergence, supply-side learning, and market-mediated price signals. Moderate mandates fall short of intended adoption levels when SAF infrastructure does not emerge in a timely manner, while highly ambitious mandates become infeasible under binding supply, blending, and price constraints. By jointly representing passenger demand responses, airline operational choices, SAF production expansion, infrastructure birth, and endogenous price discovery, the study reveals tightly coupled policy–infrastructure–market feedbacks that shape realistic SAF transition pathways.

Future work will extend Green-AEROS along several dimensions to strengthen its applicability and policy relevance. Planned developments include representing multiple airline agents with heterogeneous route-selection strategies and incorporating evolving technology maturity to capture strategic diversity in SAF deployment decisions. The model will also be expanded to account for regional feedstock constraints arising from competing uses, which may significantly influence the spatial feasibility of SAF production. In addition, integrating detailed techno-economic assessments at the SAF production site level will enable explicit evaluation of long-term economic viability under alternative policy and market conditions. Given its modular structure, Green-AEROS is readily extendable to other national and regional aviation systems, providing a transferable modeling framework for analyzing SAF transitions across diverse geographies and policy contexts.

## ABSTRACT

Recent geopolitical disruptions and extreme weather events have underscored the importance of resilience in global energy supply chains, particularly for import-dependent economies pursuing ambitious energy transition targets. These events have exposed the limitations of supply chain designs focused solely on cost minimization that lack the flexibility and redundancy required for secure operation under stress. As energy systems evolve toward higher shares of variable renewable energy and increased demand uncertainty, episodic manual re-planning becomes inadequate, highlighting the need for modeling frameworks that integrate predictive modeling, optimization, and control to enable intelligent and adaptive supply-chain design and operations under uncertainty. This work presents a comprehensive data-driven modeling and optimization framework for adaptive energy supply-chain networks under evolving demand. The framework integrates three layers: (i) a machine-learning model for demand forecasting and scenario generation; (ii) a multi-period stochastic optimization model for strategic network design and operations; and a (iii) learning layer that monitors performance metrics and triggers strategic recourse when demand patterns shift significantly. The operational stage, which acts as a learning layer, is posed as a rolling horizon control problem determining necessary recourse decisions to adapt to changes in demand patterns. An illustrative case study, encompassing multiple energy generation hubs, energy carriers and transportation modes is shown to demonstrate the applicability of the framework.

**Keywords**: energy supply chain, intelligent systems, multi-scale modeling, hydrogen, ammonia, resilience

## INTRODUCTION

Recent years have highlighted the critical importance of resilience in global energy supply chains, as geopolitical conflicts and natural disasters have exposed structural vulnerabilities, particularly in import-dependent economies pursuing ambitious energy-transition targets. These disruptions have revealed the risks of supply concentration and supply-chain network designs focused primarily on cost minimization, which often lack the flexibility and redundancy required to ensure secure and reliable operation under stress. As energy systems evolve toward higher shares of variable renewable energy and increased demand uncertainty, the intermittency of renewable generation and emerging electrification trends exacerbate spatio-temporal supply–demand mismatches, motivating energy supply-chain networks with seasonal storage as a multi-scale systems integration solution connecting resource-abundant regions to industrial demand centers [1, 9]. Moreover, the rising frequency of disruptions and changing demand patterns render episodic, manual re-planning inadequate, motivating the need for continuous, data-informed, and adaptive decision-making frameworks.

The process systems engineering community has developed a broad range of methodologies for planning

and operating energy and process systems under uncertainty. Foundational work established stochastic optimization frameworks for process synthesis and multi-period supply chain planning under uncertainty [2, 3], including applications to hydrogen and energy carrier supply chains [4]. At the operational level, model predictive control (MPC) has been widely adopted for real-time energy system scheduling using receding-horizon formulations [5]. More recently, data-driven approaches have emerged that integrate machine learning with mathematical programming, enabling forecasting-informed optimization and scenario-based planning under deep uncertainty [6–8]. Despite these efforts, the disruptions faced in the recent decade have revealed the risks of supply concentration and supply-chain network designs focused solely on cost minimization, lacking flexibility and redundancy. As the power grid has been expanding with intermittent renewable energy sources and the pace and frequency of disruptions rise in supply-chain networks and demand patterns change, episodic manual re-planning proves increasingly insufficient, motivating the need for systems that anticipate short-horizon changes and continuously update operating decisions. Addressing these challenges calls for a shift from static planning to continuous, data-informed, proactive operations capable of adapting as conditions evolve. Therefore, there is a clear need for modeling frameworks that integrate predictive modeling, optimization, and control to design and operate intelligent supply-chain networks.

In this research, we present a data-driven modeling and optimization framework for the design and operation of adaptive energy supply-chain networks under uncertainty. The framework integrates rolling demand forecasting and scenario generation, multi-period stochastic optimization, and a learning-based recourse mechanism to enable proactive adaptation of supply-chain structure and operations. An illustrative case study with multiple energy hubs, energy carriers, and transportation modes is used to demonstrate the applicability of the proposed approach.

## METHODOLOGY

The framework features: (i) a machine-learning model that provides rolling demand forecasts and scenarios for stochastic optimization; (ii) a multi-period stochastic optimization framework for planning and operations; and (iii) a learning layer that tracks changes in demand patterns and informs strategic recourse decisions. The machine-learning layer supplies rolling-horizon predictions at each time step, and the stochasticity of demand is captured through representative scenarios. These scenarios are then utilized in the multi-period, multi-stage stochastic optimization step considering multiple production locations and transportation modes for planning the optimal supply chain network. The operational stage, which acts as a learning layer, is modeled as a rolling horizon control problem that determines the necessary recourse decisions to adapt to changes in short-term demand patterns and long-term forecasts. Figure 1 illustrates the overall structure of the framework and the superstructure of possible energy transmission solutions. The methodology follows a closed-loop architecture in which forecasting, optimization, control, and learning layers interact iteratively. At each reassessment epoch, updated demand information and operational decisions are revised over a receding horizon, and system performance indicators are evaluated to determine whether the existing strategic design remains adequate or whether strategic recourse actions are required.

In the proposed framework, strategic redesign decisions are not triggered by instantaneous forecast–realization discrepancies or ad hoc threshold rules, but rather by a structured interactions between rolling-horizon operational control and a learning-based policy layer enabling an “intelligent” network. At predefined reassessment epochs, the operational layer provides two complementary signals: (i) a backward-looking measure of persistent service stress; and (ii) a forward-looking adequacy indicator reflecting the predicted inability to meet future demand under the existing infrastructure. Only when both conditions indicate sustained capacity inadequacy is a strategic reassessment activated. While this adequacy gate determines *when* redesign is admissible, the selection of *how* to adapt the network structure is delegated to a learning-based recourse mechanism described in Section 2.5. Unlike rule-based triggering schemes, in which both the redesign trigger and the corrective action are fixed ex ante, the proposed framework decouples the admissibility of strategic redesign from the selection of recourse actions, enabling adaptive responses learned from operational experience, thus enabling data-driven and adaptive infrastructure evolution under uncertainty.

### 2.1 Mathematical Notation

The renewable energy supply chain is modeled through a superstructure, as shown in Figure 1(ii), that captures multiple production locations, energy carriers, conversion processes, transportation modes, and temporal scales. Renewable electricity generation, energy carrier production, storage, and transportation are explicitly represented to satisfy energy demand at designated sink locations. The renewable energy supply chain planning problem is modeled as a MILP problem and solved by the Gurobi optimizer. All processes and transportation modes are assumed to be powered by renewable electricity and the energy carriers produced in the

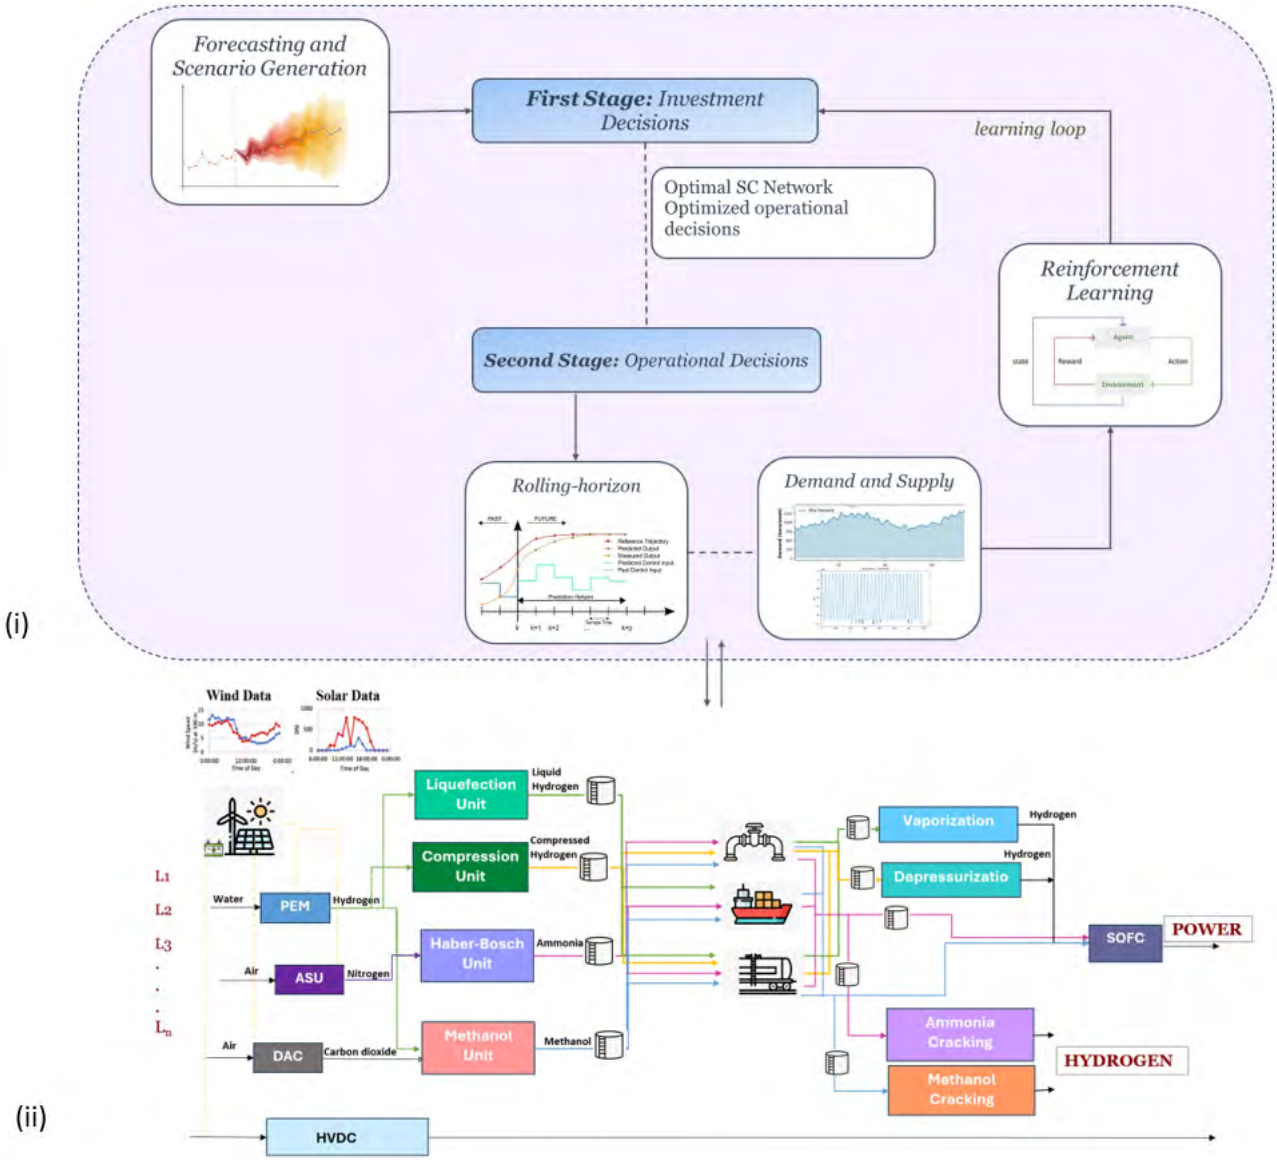

**Figure 1.** (i)Methodology and (ii) Superstructure of Energy Transmission Solutions

installed process plants.

The employed nomenclature is provided in Table 1. $\mathcal{L}$ represents the set production locations, $\mathcal{C}$ represents the set of energy carriers such as liquid hydrogen, methanol, ammonia and compressed hydrogen. $\mathcal{P}$ represents the set of processes to produce these energy carriers such as liquefaction, compression plants and air separation, direct air capture, methanol and Haber-Bosch units that are necessary in producing these energy carriers. The process superstructure is modelled through the parameters of production processes and utilization of mass and energy balance, capacity, transportation, demand and contingency constraints. $\mathcal{M}$ represents the set of transportation modes, either ship or pipe-line transport. $\mathcal{R}$ represents the set of renewable sources, solar, wind, etc.

**Table 1** Notation Table for Sets

| Symbol | Description |
|---|---|
| $l \in \mathcal{L}$ | All locations |
| $c \in \mathcal{C}$ | Energy carriers |
| $p \in \mathcal{P}$ | Conversion processes |
| $r \in \mathcal{R}$ | Renewable resources |
| $m \in \mathcal{M}$ | Transport modes |
| $t \in \mathcal{T}$; $\tau \in \mathcal{T}^h$ | Planning/Operational time steps |
| $k \in \mathcal{K} \subseteq \mathcal{T}$ | Reassessment epochs |
| $\omega \in \Omega_k$ | Scenarios at epoch $k$ |
| $a \in \mathcal{A}$ | Strategic action space |

## 2.2 Demand Forecasting and Scenario Generation

Uncertainty in demand is represented through a machine learning based forecasting model. Using historical data, the forecasting layer generates demand trajectories by sampling quantile levels and mapping them through the cumulative distribution function (CDF) for each period. Then, scenarios corresponding to 25$^{th}$, 50$^{th}$ and 75$^{th}$ percentiles aligned with low, medium and high demand levels are extracted. These scenarios are then embedded into the multi-period stochastic optimization framework to guide investment and operational decisions under demand uncertainty [6].

These probabilistic demand scenarios serve as the primary input to the strategic and operational optimization layers. By continuously updating scenario information as new observations become available, the framework maintains consistency between realized system behavior and future planning assumptions. In the operational layer, the forecasting model processes historical demand observations and generates regime-aware monthly energy demand forecasts on a rolling horizon. The model dynamically updates its feature set with each realized month's demand enabling adaptive learning.

## 2.3 Two-Stage Stochastic Optimization

Strategic investment decisions are determined using a two-stage stochastic optimization framework. First-stage decisions correspond to long-term infrastructure investments, including the portfolio of renewable power plants, production, transportation infrastructure, and storage capacities at each energy hub to generate power, produce energy carriers and to transport them to the demand center. Second-stage decisions represent operational responses to scenario-specific demand realizations, such as production and transportation dispatch.

The objective function minimizes the sum of investment costs and the expected operational cost across demand scenarios. Mass and energy balance, production and transportation capacity, contingency, and demand satisfaction constraints ensure physical and operational feasibility. Moreover, resilience constraints ensure decentralization of multiple energy hubs, oversizing of capacity and redundancy in transportation infrastructure. Investment lead-time constraints are explicitly enforced so that newly installed capacities become available only after realistic construction delays, preventing non-possible recourse actions in the operational layer. The resulting solution defines a robust baseline network design that balances cost efficiency and flexibility under demand uncertainty.

Objective function:

$$\min_{\Delta X_k,\{Y_\omega\}} \; C^{inv}(\Delta X_k) + \sum_{\omega\in\Omega_k} \pi_{\omega k}\left[C^{op}(Y_\omega) + \rho \sum_{\tau\in\mathcal{T}_k^h}\sum_{l\in\mathcal{L}^{dem}} u_{l\tau\omega k}\right]$$

where u is the unmet demand characterized by the Value of Lost Load (VoLL).

Investment Cost (First-stage):

$$C^{inv}(\Delta X_k) = \sum_{l,r} c_r^{RE}\,\Delta K_{lrk}^{RE} + \sum_{l,p} c_p^{P}\,\Delta K_{lpk}^{P} + \sum_{l,c} c_c^{S}\,\Delta S_{lck} + \sum_{l} c_l^{hub}\left(z_{lk} - z_{l,k^-(k)}\right) + \sum_{i,j,c,m} c_{ijcm}^{Q}\,\Delta Q_{ijcmk}$$

Operating Cost (Second-stage):

$$C^{op}(Y_\omega) = \sum_{\tau\in\mathcal{T}_k^h}\left[\sum_{l,p} c_p^{op}\,y_{lp\tau\omega k} + \sum_{i,j,c,m} c_{ijcm}^{tr}\,q_{ijcm\tau\omega k} + \sum_{l,c} c_c^{h}\,I_{lc\tau\omega k}\right]$$

In addition to the aforementioned constraints, an improved resilience footprint is enforced at the strategic design stage through constraints promoting decentralization, oversizing, and redundancy, applied across all demand scenarios $\omega$.

*Decentralization* is imposed by limiting supply concentration from each hub and geographic dispersion is further encouraged using a distance-weighted diversification constraint inspired by electric charge repulsion:

$$\sum_{(i,j)} w_{ij}\left(D_i^{\omega}+D_j^{\omega}\right) \le \gamma\, D_{\text{tot}}^{\omega}\forall\omega.$$

*Oversizing* is enforced by requiring aggregate production and transportation capacity to exceed delivered demand:

$$\sum_i C_i \ge (1+\beta^{\text{sys}})\,D_{\text{tot}}^{\omega}\forall\omega.$$

A *composite* resilience *constraint* combines structural diversity and capacity headroom:

$$\frac{\alpha_K}{|\mathcal{L}|-1}(K-1) + \frac{\alpha_H}{D^{\text{target}}}\left(\sum_i C_i - D_{\text{tot}}^{\omega}\right) \ge R_{\min}\forall\omega.$$

The composite resilience threshold is set to $R_{\min} = 0.5$, for the case study, which aims to provide a balanced contribution of hub diversification and capacity headroom. Higher values would enforce more conservative designs with additional hubs or excess capacity at increased system cost.

## 2.4 Rolling-Horizon Operational Control

The operational stage is posed as a rolling horizon control problem that determines the necessary recourse decisions to adapt to changes in short-term demand patterns and long-term forecasts. At each control step, the current system state, including installed capacities, inventories, and realized demand, is observed, and an optimization problem is solved over a finite prediction

horizon using the latest demand forecasts. Only decisions within the control horizon are implemented, after which the horizon is shifted forward and the procedure is repeated. This rolling-horizon structure enables the system to respond dynamically to short-term demand fluctuations and operational disruptions, while remaining consistent with long-term strategic investment decisions made in the first stage. Importantly, the rolling-horizon layer does not modify infrastructure decisions directly but operates within the feasible region defined by the strategic design layer, exploiting available production and transport capacity across energy hubs as imposed by resilience constraints. Operational disruptions are modeled as time-dependent availability multipliers that erode the effective capacity of affected assets during disruption windows, scaling renewable availability, process throughput capacity, and/or transport capacity at the corresponding hub. At time $\tau_0$, given measured inventory and installed capacities, the optimization problem is solved over the prediction horizon, and the resulting decisions within the control horizon are implemented. For the case study, the prediction horizon is selected to be 24h while the control horizon is 6h.

## 2.5 Learning Layer and Strategic Recourse

The learning layer is the component that enables the system to learn from shifting demand patterns and disruptions to adaptively reconfigure its structure accordingly to ensure future feasibility. A bandit-based learning and monitoring component tracks system-level indicators derived from the rolling-horizon operational layer and evaluates whether observed deviations represent transient fluctuations or sustained structural inadequacy. Rather than directly controlling operations, the learning layer determines when strategic recourse action is warranted over predefined reassessment intervals (six months in the present study).

At each reassessment epoch $k$, the learning layer constructs a compact state vector,

$$\mathbf{s}_k = [\,\bar{u}_k,\, \sigma_{u,k},\, \xi_k,\, \phi_k,\, \Psi_k\,],$$

which summarizes backward-looking service stress and forward-looking adequacy risk based on realized demand, forecast accuracy, and projected demand trends.

When sustained threshold violations are observed across reassessment periods, the learning layer activates a strategic recourse decision. In response, the two-stage stochastic design problem is re-solved using updated demand forecasts and newly generated demand scenarios, while respecting previously installed capacities and construction lead-time constraints. Recourse actions constrain the feasible investment set and include holding the current design, expanding capacity at existing hubs, or enabling new hub investments..

**Table 2** State Vector Components

| | |
|---|---|
| $\bar{u}_k = \frac{1}{W}\sum_{t=k-W+1}^{k}\sum_{l} u_{l,t}$ | average unmet demand over window W |
| $\sigma_{u,k} = \mathrm{std}(u_{k-W+1}, \ldots, u_k)$ | Volatility of unmet demand |
| $\xi_k = \frac{\sum_l K_l^{\mathrm{used}}}{\sum_l K_l^{\mathrm{installed}}}$ | capacity utilization |
| $\phi_k = \mathrm{MAPE}(\hat{D}_{k-W}, \ldots, \hat{D}_k; D_{k-W}, \ldots, D_k)$ *Mean Absolute Percentage Error | forecast accuracy |
| $\Psi_k = \frac{\hat{D}_k - D_{k-W}}{D_{k-W}}$ | demand trend estimate |

**Table 3** Strategic Recourse Actions. The lite RL action $a_k \in \mathcal{A}$ recourse actions:

| Action | Effect on Planning |
|---|---|
| HOLD | $\Delta X_k = 0, z_{lk} = z_{l,k^-(k)}$ |
| EXPAND | $\Delta X_k \geq 0, z_{lk} = z_{l,k^-(k)}$ |
| NEW Hub | $\Delta X_k \geq 0, z_{lk} \in \{0,1\}$ with $z_{l,k^-(k)} \leq z_{lk}$ |

The recourse decision is determined by using a contextual bandit formulation. Given the state vector $\mathbf{s}_k$, the selected action maximizes an upper confidence bound on the expected reward:

$$a_k = \arg\max_{a\in\mathcal{A}} \left(\hat{\theta}_a^{\top}\mathbf{s}_k + \alpha\sqrt{\mathbf{s}_k^{\top}A_a^{-1}\mathbf{s}_k}\right),$$

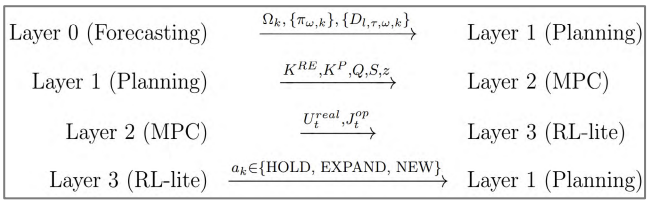
where the action-specific parameters $\hat{\theta}_a$ are updated online based on system performance following previous recourse decisions. The reward associated with action $a_k$is observed after investment effects become operational and is defined as follows at epoch $k+W$ (after investments from $k$ are operational):

$$r_k = -\left(C^{inv}(\Delta X_k) + \sum_{t=k+L}^{k+L+W-1}\left[J_t^{op} + \rho\, U_t^{real}\right] + \lambda_{sw} \cdot 1\left[a_k \neq a_{k^-(k)}\right]\right)$$

The reward signal combines improvements in service adequacy with investment cost penalties, encouraging actions that reduce persistent unmet demand while avoiding unnecessary or overly aggressive investments. Through repeated interaction, the learning layer adapts the mapping between observed stress patterns and preferred strategic responses.

The overall information flow and interaction

between the forecasting, planning, operational control, and learning layers are summarized in the schematic shown below:



## ILLUSTRATIVE CASE STUDY

An illustrative renewable energy supply chain case study motivated by the increasing energy demand of highly industrialized European economies is considered. Germany is selected as the demand region due to its ambitious decarbonization targets, limited domestic variable renewable energy potential, and projected reliance on imported renewable energy. The supply chain planner aims to meet the monthly power demand discrepancies with respect to renewable energy generation and demand through a dedicated energy supply chain network considering candidate hub locations of Spain, Norway, Morocco, Egypt, and Saudi Arabia. The hourly renewable energy profiles of these locations are utilized in the multi-scale model to design and operate an energy supply chain network consisting of multiple energy generation hubs with optimal renewable portfolios, process facilities to produce dense energy carriers, and transportation infrastructure to meet the monthly energy demand.

The framework is evaluated through a series of instances that focus on the role of individual modeling components. First, a baseline case without resilience constraints is solved to find the lowest-cost transmission strategy for a known demand of 10 TWh per month. Second, resilience constraints that promote geographic diversification and capacity spread, as discussed in Section 2.3, are introduced to create a resilient design for the same demand. This instance aims to show the cost differential of the resilient network design vis-à-vis the minimum cost design. Third, demand uncertainty is incorporated using a two-stage stochastic optimization framework, in which demand forecasts and scenarios are generated from historical energy demand data (2019–2021) of Germany to inform strategic planning for system operation commencing in 2024. Finally, the complete intelligent and adaptive framework is evaluated by activating all modeling layers in the integrated closed loop setting. Building on the resilient network design under uncertainty obtained using demand scenarios generated from historical energy demand data, for system deployment starting in 2024, the framework jointly executes rolling-horizon forecasting, stochastic planning, operational control, and learning-based strategic recourse. Following commissioning, the system operation is simulated under a synthetic demand pattern that shows a steady increase trend, from 10 to 12 TWh/month over a six-month period with superimposed Gaussian noise to test the recourse decisions. This setup allows for demonstrating learning-triggered strategic actions in response to ongoing capacity shortfalls. In summary, four increasingly complex configurations are analyzed: (1) a deterministic cost-minimizing design; (2) a resilient deterministic design; (3) a stochastic resilient design that accounts for demand uncertainty; and (4) an intelligent and adaptive design and operation with learning-based reconfiguration. This progressive structure helps to capture the added value of resilience, stochastic planning, and adaptive responses.

## RESULTS AND DISCUSSION

We provide the results of the four progressive cases to illustrate the value of resilience and adaptive operation.

Deterministic Demand Minimum Cost Design: The baseline energy transmission solution represents the minimum-cost network design obtained under the assumption of perfect information on renewable energy demand of 10 TWh/month. Under these conditions, the model invests in electrolyzer and hydrogen liquefaction facilities in Spain powered by solar photovoltaics and battery storage and 11 ships to transport liquid hydrogen to meet the monthly demand. However, the simulation of a random disruption lasting 72 hours in energy hub shows that the system experiences a severe shortfall with nearly 75% of demand left unmet and a substantial value of lost load.

Deterministic Resilient Network Design: In the second case of supply chain design under known demand, we utilize only the two-stage stochastic program component with the composite resilience requirement of $R_{min}$ = 0.5 as explained in Section 2.3 with multiple and geographic diversified energy hubs. The optimal resilient supply chain for the known demand consists of two energy hubs located in Spain and Egypt, with Spain producing and exporting liquid hydrogen and Egypt supplying ammonia as depicted in Figure 2. The network operates 10 vessels from Spain and 2 from Egypt to meet the monthly demand. Despite the added diversification, the total system cost is observed to increase by only about 2% relative to the minimum-cost deterministic solution.

Moreover, when the same disruption is simulated at the Egypt hub as in the non-resilient design to observe if the operational recourse actions suffice to meet demand, the network ramps up production and transportation from Spain within capacity limits, compensating for the temporary loss of supply as demonstrated in Figure 3. As

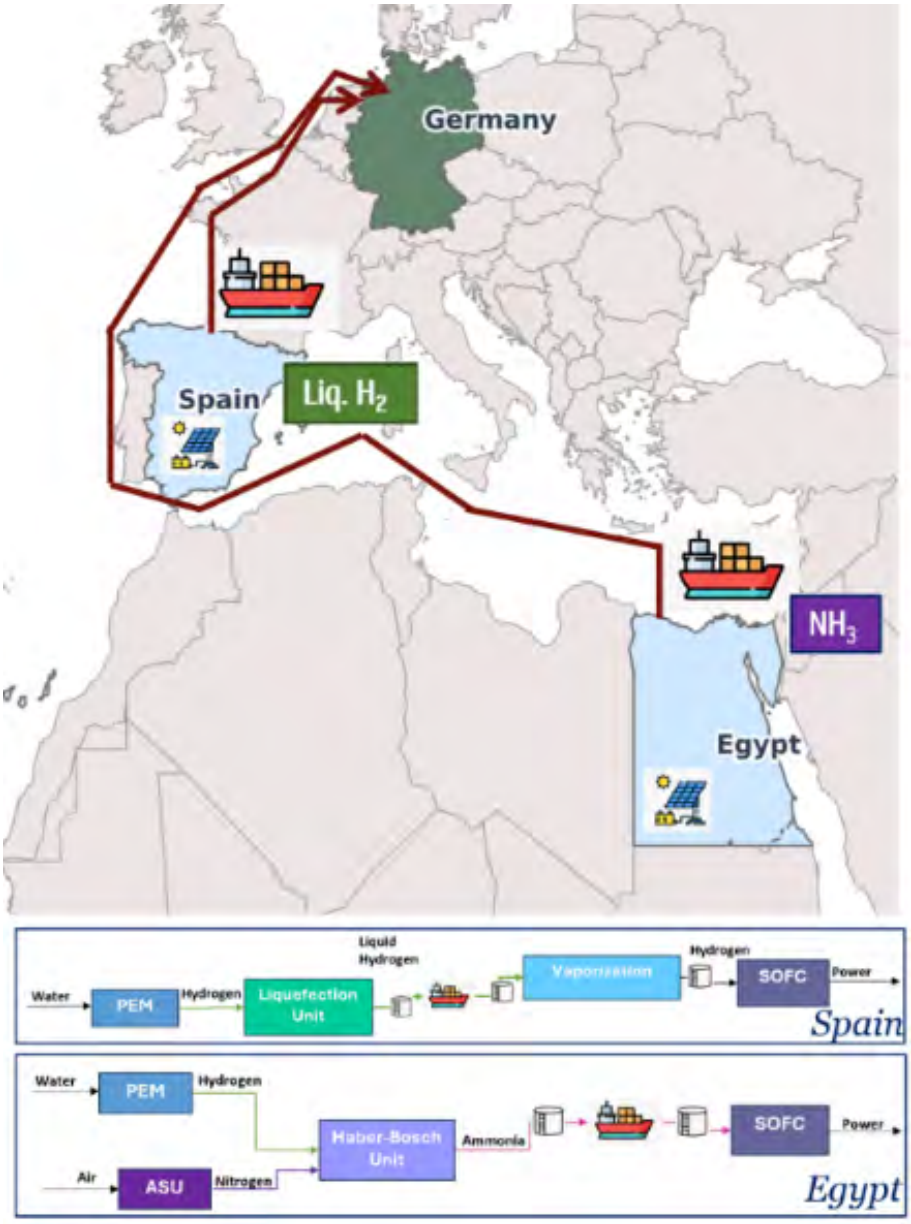


**Figure 2.** Resilient SC Network Configuration

operations at the Egypt hub recover, production gradually rebalances across both locations, and monthly demand is fully satisfied throughout the disruption period. This response confirms that a diversified and flexible network can absorb shocks to a certain extent and recover smoothly, reinforcing the idea that resilience through redundancy and geographic diversification is achievable at relatively low cost.

Stochastic Resilient Design: When demand uncertainty is introduced, the forecasting layer generates probabilistic demand scenarios that are embedded in the stochastic optimization model. The resulting network retains two production hubs in Spain and Egypt, consistent with the resilient design under known demand, but with moderately increased installed capacities to hedge against uncertainty. In this configuration, approximately 89% of demand is supplied from Spain and 11% from Egypt, reflecting the increased capacity at the Egyptian hub. Relative to the resilient deterministic design, accounting for demand uncertainty leads to an approximate 10% increase in total system cost. The cost comparisons of deterministic, deterministic resilient and stochastic resilient cases are depicted in Figure 4 with the selected energy carriers and locations.

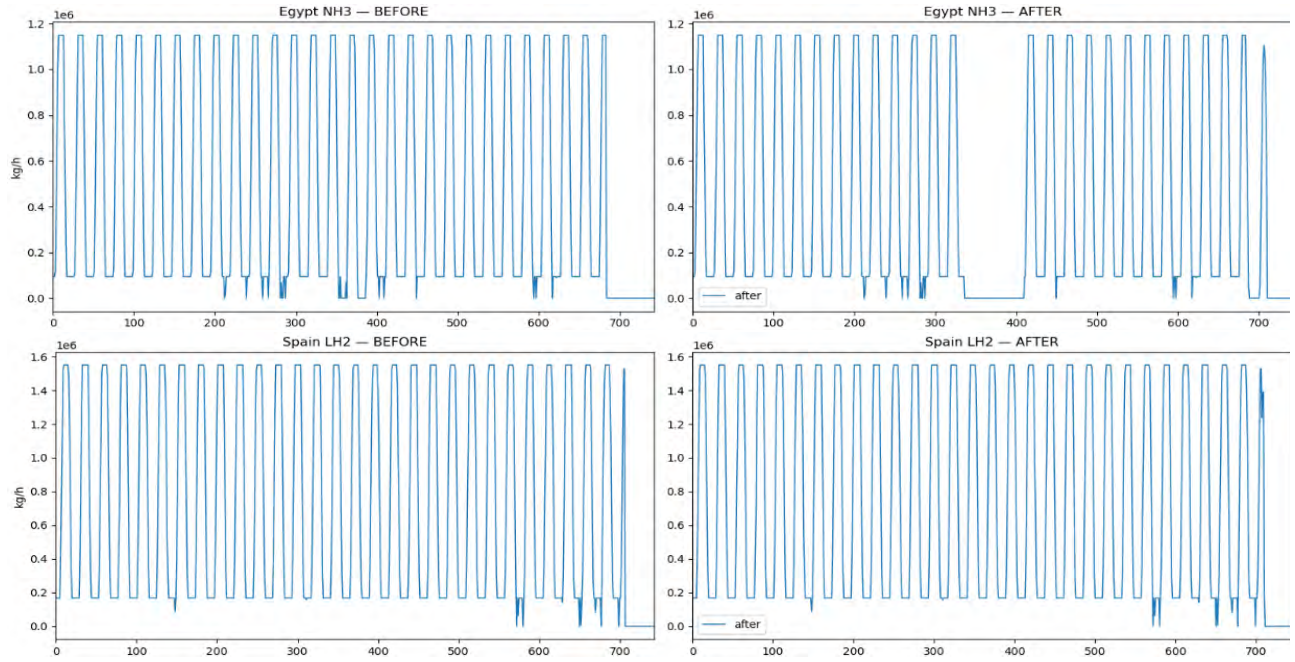

**Figure 3.** Recourse action to a hub disruption

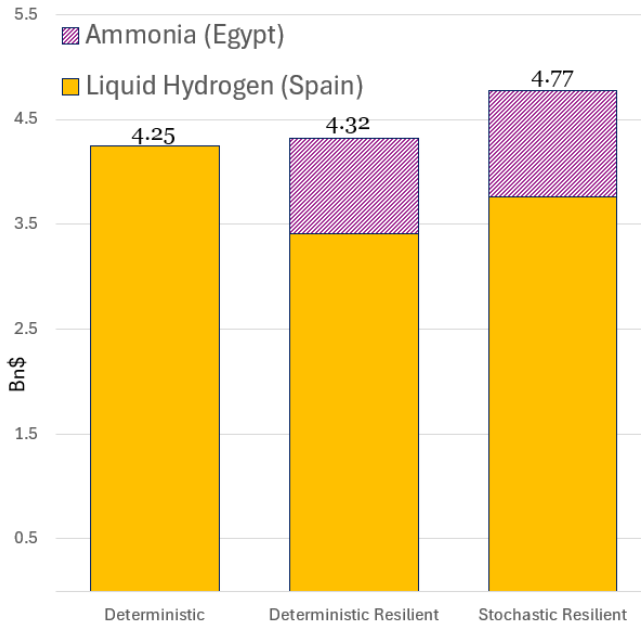

**Figure 4.** Design cost comparison

Intelligent and Adaptive Network Operation: Finally, the complete intelligent and adaptive framework is evaluated under evolving demand conditions to observe investment recourse decisions. First, probabilistic demand scenarios are generated using historical energy demand data (2019–2021) and provided as inputs to the two-stage stochastic optimization model described in Section 2.3. Solving this model yields an initial resilient network design comprising liquid hydrogen production in Spain supported by 10 ships and ammonia production in Egypt supported by 2 ships, corresponding to a mean projected monthly demand of approximately 10 TWh, which is consistent with the results of the resilient design under demand uncertainty. Once the strategic design is fixed, system operation is then simulated using the rolling-horizon control formulation described in Section 2.4. As the supply chain network becomes operational, a random demand data set is introduced. The simulated demand data set exhibits a persistent increasing trend from 10 to 12 TWh/month over a six-month period with superimposed Gaussian noise as depicted in Figure 5.

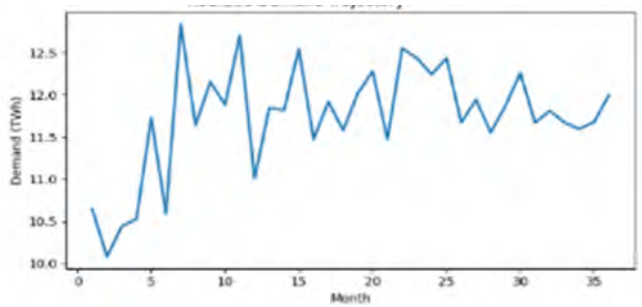

**Figure 5.** Simulated demand profile

At each operational step, the current system state including inventories, energy storage levels, and committed transportation flows, is observed, and short-term demand forecasts are incorporated to optimize production, storage, and transportation decisions over a finite prediction horizon. Only decisions within the control horizon are implemented before the horizon is advanced,

ensuring operational adaptability, while strictly respecting the production and transportation capacities dictated by the strategic design. At the sixth month of operation, corresponding to the predefined reassessment interval, system-level performance indicators obtained from the operational layer are evaluated. These include both backward-looking measures of persistent service stress, such as rolling unmet demand ratios, and forward-looking adequacy indicators reflecting the rolling-horizon controller's predicted inability to meet future demand under the installed infrastructure. After six months, the rolling unmet demand ratio approaches 25%, while both realized and forecasted future inadequacy indicators exceed approximately 6.7%, indicating that no feasible operational policy can satisfy projected demand within the existing network configuration. This persistent and forecast-consistent capacity inadequacy activates the learning-based recourse layer described in Section 2.5. The learning layer, implemented as a multi-armed bandit algorithm, evaluates admissible strategic actions, including maintaining the current design, expanding capacity at existing hubs, or enabling new hub investments, and triggers a re-solution of the two-stage stochastic design problem using updated demand scenarios. Re-solving the design problem under revised scenarios with a mean monthly demand of 11.5 TWh results in the activation of a new liquid hydrogen production hub in Morocco, along with an additional transportation asset. The redistribution of demand shares across energy hubs before and after the recourse action is shown in Figure 6. The introduction of the Moroccan hub improves both capacity adequacy and the geographic diversification of the supply chain, demonstrating the framework's ability to adapt strategic investment decisions over time by learning from realized demand patterns and proactively maintaining long-term energy security.

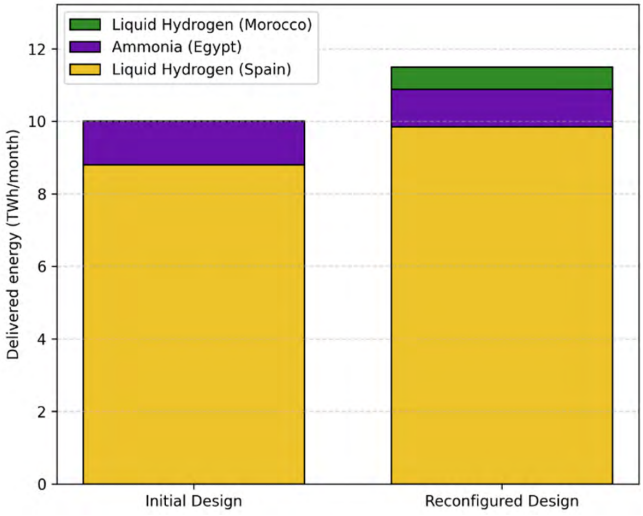

**Figure 6.** The final demand share of energy hubs

## CONCLUSION

This work presents an initial attempt towards the design and operation of intelligent and adaptive energy networks capable of responding to the increasing volatility and uncertainty characteristic of modern energy systems. By integrating hybrid machine-learning forecasting, multi-period stochastic optimization, and rolling-horizon operational control with adaptive recourse mechanisms, the framework addresses critical gaps in existing approaches that rely on static planning paradigms. The proposed methodology enables energy supply chains to function as intelligent systems that continuously predict, optimize, learn from demand patterns, potentially anticipate disruptions, and adapt their configuration and operations as conditions evolve. Through its multi-layered architecture, the framework balances cost efficiency with resilience and security of supply, a balance increasingly vital for modern energy systems operating with increased variable renewable energy share and geopolitical uncertainties. The illustrative case study demonstrates the framework's applicability to a multi-carrier energy supply chain network, showing how the integration of predictive modeling, stochastic optimization, and adaptive control can transform energy supply chains from reactive networks requiring episodic manual intervention into proactive, data-informed systems capable of maintaining reliable operations in the face of sustained uncertainty and disruption. Future work will focus on enriching the learning layer with causal and context-aware signals to distinguish between transient operational shocks and persistent structural mismatches requiring new investments. While demonstrated here for renewable energy supply chains, the proposed closed-loop forecast, optimize, learn and adapt paradigm naturally extends to other large-scale systems with evolving uncertainty, including financial portfolios, critical material supply chains, and infrastructure planning.

## ACKNOWLEDGEMENTS

The authors express their gratitude for the financial support from Texas A&M University and Texas A&M Energy Institute, United States. This work was partially supported by the National Science Foundation Convergence Accelerator Program under the Grant titled "Securing Critical Material Supply Chains by Enabling Photovoltaic Circularity (SOLAR)" with Grant No. 49100423C0005.

## ABSTRACT

The rapid expansion of AI data centers is straining electricity grids alarmingly, forcing data center planners to navigate two-pronged challenges: (1) lengthy interconnection queue delays undermining immediate grid access, and (2) volatile electricity prices that spike dramatically during high demand events. This convergence forces planners to reconsider traditional grid-only strategies. While behind-the-meter (BTM) generation offers a solution, existing research lacks comprehensive frameworks for identifying technology portfolios under combined uncertainties of grid access delays and market volatility. This study develops a two-stage stochastic optimization framework with binary capacity constraints co-optimizing data center location and BTM energy portfolios under these challenges. The model evaluates conventional (gas turbines), renewable (solar, wind, batteries), and emerging technologies (hydrogen fuel cells, small modular reactors) across four progressive scenarios spanning emission targets, demand flexibility, grid curtailment, land constraints, and queue delays, contrasting stochastic and deterministic solutions. Applied to a 5 GW data center expansion in ERCOT, three insights emerge: First, queue delays drive 2.7 GW bridging investments that transition to 92% grid reliance once interconnection is available, while stochastic optimization maintains higher BTM utilization against price volatility. Second, demand flexibility reduces required BTM capacity through load shifting during grid curtailment events, decreasing gas deployment from 2.1 to 1.7 GW. Third, land-constrained decarbonization shifts from wind-dominated portfolios to capital-intensive solar-hydrogen-SMR solutions, with stochastic optimization tripling SMR deployment to prioritize reliability under uncertainty.

## INTRODUCTION

Artificial intelligence is driving unprecedented electricity demand, with data centers projected to double energy consumption by 2026 [1]. In the Electric Reliability Council of Texas (ERCOT), interconnection requests surged from 2.6 GW (2022) to more than 200 GW (2030), extending grid connection congestion and challenges to connect on time [2]. Compounding this crisis, new regulations mandate load curtailment during grid stress events (Texas SB6 [3]), while electricity prices in energy-only markets fluctuate from $20/MWh to $5, 000/MWh [4]. These converging pressures—interconnection delays, mandatory curtailment risk, and price volatility—are forcing data center planners to fundamentally rethink their energy strategies [5]. In response, planners are exploring spatial diversification across regions combined with behind-the-meter generation portfolios to mitigate grid dependency and manage operational risks [6].

Behind-the-meter (BTM) generation offers a pathway to overcome grid constraints, but introduces complex multi-dimensional planning challenges. Planners must simultaneously decide: (1) where to locate facilities across regions with heterogeneous characteristics—zones differ in renewable resource quality, land availability, grid queue lengths, and regulatory requirements; (2) which technologies to deploy, portfolios may include solar, wind, gas turbines, small modular reactors (SMRs),

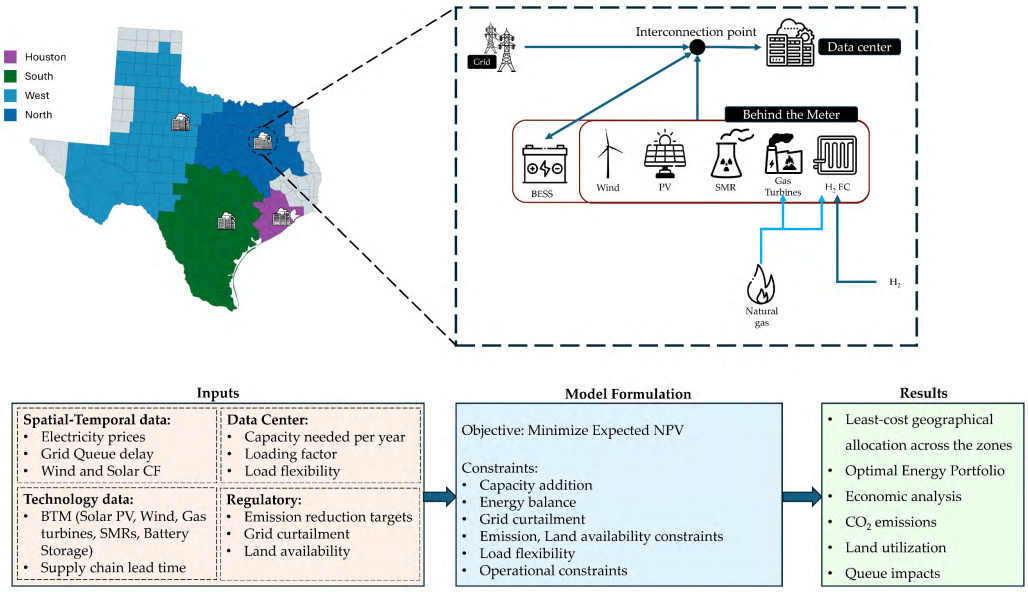

**Figure 1.** Methodological Framework.

fuel cells, and battery storage, each with distinct capital costs, lead times, and operational characteristics; and (3) how to operate under uncertainty, both grid interconnection delays and electricity prices are inherently stochastic, with queue timelines varying from months to years and market prices exhibiting extreme volatility. Additionally, facilities can leverage load flexibility to shift demand temporally, adding another operational dimension. Traditional deterministic planning frameworks fail to capture these interdependencies and uncertainties, potentially leading to suboptimal investments that either oversize capacity or underestimate exposure to regulatory and market risks.

This paper develops a two-stage stochastic optimization framework for multi-zone data center energy planning under uncertainty. Our model integrates spatial facility allocation, technology portfolio selection, and operational planning while explicitly accounting for: (1) stochastic grid interconnection queue delays across zones and time periods; (2) electricity price uncertainty stemming from historical market volatility; (3) zone-specific constraints including renewable capacity factors, land availability, and emission reduction targets; (4) technology-specific lead times affecting investment feasibility; and (5) load flexibility enabling temporal demand shifting. Contributions: We provide (1) a computationally tractable stochastic programming formulation for multi-zone energy infrastructure planning; (2) extensive case study analyses demonstrating how optimal portfolios shift under varying interconnection delays, emission policies, and grid curtailment policies; and (3) managerial insights on technology selection, spatial allocation, and operational flexibility for data facility planners.

# METHODOLOGY

## Problem Definition and System Architecture

We consider a multi-zone capacity expansion and operational planning problem for large-scale data centers subject to grid interconnection constraints, electricity price uncertainty, and emission reduction mandates. The system comprises $|Z|$ zones, each with distinct electricity price profiles, renewable resource availability (solar irradiance and wind patterns), land constraints, and time-varying grid interconnection queue delays. The planning objective is to determine: (1) optimal spatial allocation of facility capacity across zones; (2) behind-the-meter (BTM) generation portfolio composition; (3) energy storage deployment; and (4) grid interconnection capacity requests.

The BTM technology portfolio includes dispatchable sources (natural gas turbines, fuel cells with natural gas or hydrogen, small modular reactors) with high availability factors (90-95%), and variable renewable energy (solar PV, wind) with time-varying capacity factors. Battery energy storage systems provide operational flexibility. Critically, investment decisions must account for technology-specific lead times—the lag between capital commitment and operational availability—ranging from one to several years. Data center load comprises baseload (fixed continuous draw) and flexible load (temporally shiftable within daily windows), enabling demand-side response without compromising service levels.

Figure 1 illustrates the methodological framework. We develop a two-stage stochastic program that determines first-stage capacity investments under

uncertainty, with second-stage operational recourse as conditions realize. The deterministic case (single scenario) serves as a comparison benchmark.

## Mathematical Formulation

Key Notation

| | |
|---|---|
| **Sets** | |
| $Z$ | Set of geographic zones |
| $G$ | Set of BTM generation technologies |
| $T$ | Hourly time periods |
| $Y$ | Planning years |
| **Parameters** | |
| $C_g^{\{capex\}}, C_g^{\{FOM\}}, C_g^{\{VOM\}}, C_g^{\{fuel\}}$ | Capital, fixed O&M, variable O&M, fuel costs |
| $P_{\{z,t\}}^{\{grid\}}(\omega), Q_{\{z,y\}}(\omega)$ | Electricity price (scenario), queue delay (scenario) |
| $\lambda^{\{base\}}, \lambda^{\{flex\}}, \rho^{\{emis\}}, L_z^{\text{avail}}, \delta_{z,t}^{curtail}$ | Load factor, flexibility fraction, Emission reduction target, Land availability, Grid curtailment |
| $\Delta^{DC}$ | Data center module size [MW] |
| $MinCap_g$ | Minimum capacity addition per technology [MW] |
| **Decision Variables:** | |
| $\text{Cap}_{z,g,y}, CapTotal_{z,g,y}$ | Capacity additions [MW], cumulative capacity [MW] |
| $StorCap_{z,y}$ | Storage capacity [MWh] |
| $DCCap_{z,y}$ | Facility capacity [MW] |
| $\text{Gen}_{z,g,t}(\omega)$ | Electricity generation [MW] |
| $\text{Ch}_{z,t}(\omega), \text{Dis}_{z,t}(\omega)$ | Battery charge and discharge in zone $z$ at hour $t$ [MW] |
| $\text{Flexload}_{z,t,y}(\omega)$ | Flexible load [MW] |
| $Unserved_{z,t,y}(\omega)$ | unserved energy [MW] |
| $y_{z,g,y}$ | Binary variable for technology selection decisions |
| $n_{z,y} \in \mathbb{Z}_+$ | Number of data center modules in zone z during year y |

*Objective Function*. The objective minimizes total net present value (NPV) of system costs:

$$\min \sum_{y\in Y^{inv}}(1+r)^{-(y-y^{base})}\left[C^{inv}\cdot \Delta x_y + C^{FOM}\cdot x_y\right] + \sum_{\omega\in\Omega}\pi_\omega \sum_{y\in Y^{op}}(1+r)^{-(y-y^{base})}\left[C^{var}\cdot\left(g_y(\omega)+p_y(\omega)\right)\right] + UnservedPenalty(\omega) \quad (1)$$

Subject to:

$$CapTotal_{z,g,y} = InitCap_{z,g} + \sum_{y'\in Y^{inv}: y'+\tau_g\le y} Cap_{z,g,y'} \ \forall z,g,y \quad (2)$$

$$\sum_{z\in Z} DCCap_{z,y} \ge D_y^{req} \ \forall z,y \quad (3)$$

$$\sum_{g\in G} Gen_{z,g,t,y}(\omega) + GridPurch_{z,t,y}(\omega) + Dis_{z,t,y}(\omega) - Ch_{z,t,y}(\omega) = Load_{z,t,y}^{base} + FlexLoad_{z,t,y}(\omega) - Unserved_{z,t,y}(\omega) \ \forall z,t,y,\omega \quad (4)$$

$$Gen_{z,g,t,y}(\omega) \le CapTotal_{z,g,y}\cdot CF_{z,g,t} \ \forall z,g,t,y,\omega \quad (5)$$

$$GridPurch_{z,t,y}(\omega) \le \left(1-\delta_{z,t}^{curtail}(\omega)\right)\cdot GridCapAvail_{z,t,y}(\omega) \ \forall z,t,y,\omega \quad (6)$$

$$SOC_{z,t,y}(\omega) = SOC_{z,t-1,y}(\omega) + Ch_{z,t,y}(\omega)\sqrt{\eta^{stor}} - \frac{Dis_{z,t,y}(\omega)}{\sqrt{\eta^{stor}}} \ \forall z,t,y,\omega \quad (7)$$

$$SOC_{(z,t,y)(\omega)} \le StorTotal_{z,y} \quad (8)$$

$$Ch_{(z,t,y)(\omega)} \le \frac{StorTotal_{z,y}}{d^{stor}} \ \forall z,t,y,\omega \quad (9a)$$

$$Dis_{(z,t,y)(\omega)} \le \frac{StorTotal_{z,y}}{d^{stor}} \ \forall z,t,y,\omega \quad (9b)$$

$$MinCap_g \cdot y_{z,g,y} \le Cap_{z,g,y} \ \forall z,t,y \quad (10)$$

$$Cap_{z,g,y} \le M\cdot y_{z,g,y} \ \forall z,t,y \quad (11)$$

$$DCCap_{z,y} = \Delta^{DC}\cdot n_{z,y} \ \forall z,y \quad (12)$$

$$y_{z,g,y} \in \{0,1\} \ \forall z,g,y \quad (13)$$

$$n_{z,y} \in \mathbb{Z}_+ \ \forall z,y \in Y^{inv} \quad (14)$$

$$All\ capacity\ and\ operational\ variables \ge 0 \quad (15)$$

The objective function (1) minimizes the expected net present value (NPV) of system costs across all scenarios, where $r$ denotes the discount rate, $\Delta x_y$ represents capacity additions in year $y$ (aggregated across zones and technologies), and $x_y$ is cumulative installed capacity. The terms $g_y(\omega)$ and $p_y(\omega)$ denote BTM generation and grid purchases under scenario $\omega$, with $\pi_\omega$ representing scenario probabilities. The formulation captures annualized capital expenditures ($C^{inv}$, fixed O&M $C^{FOM}$, and variable operating costs including fuel and grid electricity procurement at scenario-specific prices ($C^{var}$).

Constraints (2) track capacity evolution with technology-specific lead times $\tau_g$, ensuring capacity invested in year $y'$ only becomes operational after the lead time elapses. Constraints (3) require total installed facility capacity to satisfy demand targets across all zones.

Equations (4) maintain hourly supply-demand equilibrium in each zone under each scenario, where $Load_{\{z,t,y\}}^{base}$ represents the fixed baseload component and

$FlexLoad_{(z,t,y)}(\omega)$ is the flexible load. Constraint (5) limits technology output by installed capacity and resource availability through the capacity factor $CF_{z,g,t}$.

Constraints (6) govern grid purchases, which are prohibited during curtailment events and constrained by time-varying interconnection capacity. The curtailment indicator $\delta_{z,t}^{curtail}(\omega)$ equals unity when electricity prices exceed zone-specific high percentile thresholds (e.g., 98th-99th percentile). Grid interconnection capacity $GridCapAvail_{(z,t,y)}(\omega)$ evolves based on queue delay schedules $Q_{(z,y)}(\omega)$ during the delay period in year $y$, only previously committed capacity is available; after the delay expires, newly requested capacity becomes accessible.

Equations (7)-(9) govern battery storage dynamics. Equation (7) tracks state-of-charge evolution with round-trip efficiency $\sqrt{\eta^{stor}}$, while constraints (8) and (9) enforce energy and power capacity limits respectively. The parameter $d^{stor}$ denotes the power-to-energy duration (e.g., 4 hours for typical BESS).

Constraints (10) enforce minimum capacity requirements for selected technologies (gas turbines and SMRs), the capacity addition must be at least $MinCap_g$ (e.g., 100 MW). If no capacity is added ($y_{z,g,y} = 0$), then $Cap_{z,g,y} = 0$. While constraints (11) enforce the upper bound for capacity additions.

Constraints (12) enforce modular data center capacity: facility capacity must be integer multiples of a standard module $\Delta^{DC}$ (e.g., 200 MW), reflecting the discrete nature of data center construction. This forces data center capacity to take values of 0, 200, 400, 600, ... MW. The integer variable $n_{z,y}$ represents the number of modules deployed.

The model also includes constraints for load flexibility (daily energy budgets ensuring $\sum_{t\in T_d} FlexLoad_{z,t,y}(\omega)$ meets required daily flexible consumption with instantaneous capacity limits), emission reduction targets (expected value across scenarios constraining total annual emissions to $\rho^{emis} \cdot E_y^{baseline}$), land availability (zone-specific footprint limits), and storage cycling (end-of-year SOC matching initial conditions).

The formulation represents a two-stage stochastic program where each scenario $\omega \in \Omega$ specifies realizations of: (1) hourly electricity prices $P_{z,t}^{grid}(\omega)$ derived from historical years representing diverse market conditions (e.g., extreme weather events, high renewable penetration, volatile fuel prices), and (2) grid interconnection queue delays $Q_{z,y}(\omega)$ representing optimistic (short delays) versus pessimistic (extended delays) timelines. First-stage decisions (capacity investments $Cap_{z,g,y}, StorCap_{z,y}, DCCap_{z,y}, GridCap_{z,y}$, and discrete decisions $y_{z,g,y}, n_{z,y}$) are made before uncertainty realization; second-stage decisions (operational dispatch $Gen_{(z,g,t,y)}(\omega), GridPurch_{z,t,y}(\omega)$, storage operations, flexible load scheduling) adapt to realized conditions with scenario-specific recourse.

## CASE STUDY

We apply the proposed framework to ERCOT, a deregulated energy-only market serving approximately 90% of Texas electricity demand. ERCOT presents an ideal testbed due to: (1) Electricity price volatility; (2) rapid data center load growth; (3) substantial renewable penetration exceeding 35% of generation capacity [2]; and (4) significant spatial heterogeneity in resource availability and grid constraints. The analysis considers four ERCOT load zones, HOUSTON, WEST, NORTH, and SOUTH, as shown in Figure 1.

The BTM technology portfolio encompasses solar PV, wind turbines, natural gas turbines (GT), fuel cells (natural gas and hydrogen-powered), small modular reactors (SMR), and battery energy storage (4-hour lithium-ion). Technology specifications follow NREL Annual Technology Baseline (ATB) 2023 [7], including capital costs, fixed and variable O&M, fuel costs, conversion efficiencies, and land footprint requirements. We model data center deployment planning with phased capacity expansion targeting 2.0 GW (2028), 4.0 GW (2029), and 5.0 GW (2030). Data center load comprises baseload (determined by load factor $\lambda^{base}$) and flexible load (flexibility ratio $\lambda^{flex}$), where $\lambda^{flex} = 0$ represents pure baseload demand.

Historical hourly day-ahead LMP data for each zone spanning are obtained from ERCOT market archives [8]. For stochastic optimization, scenarios combine historical price years with queue delay realizations. Grid curtailment periods are defined as hours exceeding zone-specific percentile thresholds ($\delta_{z,t}^{curtail}$), where grid purchases are prohibited.

We evaluate four progressive scenarios to isolate the impacts of key operational and regulatory constraints on technology selection and spatial deployment. All scenarios include grid interconnection queue delays (ranging from 0-9 months across zones), which represent the baseline infrastructure constraint. The scenarios progressively layer additional constraints:

**Table 1:** Scenario Definitions.

| Parameter | S1 | S2 | S3 | S4 |
|---|---|---|---|---|
| Grid Queue | ✓ | ✓ | ✓ | ✓ |
| Curtailment | - | 2% | 2% | 2% |
| Emission Reduction | - | - | 70% | 70% |
| Land Constraint | - | - | - | Limited |
| Demand Type | Base | Flex | Flex | Flex |

All scenarios include grid interconnection queue

delays as a baseline infrastructure constraint. S1 (Baseline) isolates the impact of interconnection delays alone under pure baseload operation. S2 introduces grid curtailment (2% of hours at 98th percentile prices) and demand flexibility (80% load factor, 30% shiftable). S3 adds a 70% emission reduction target. S4 represents the most constrained case with limited land availability.

The stochastic optimization framework accounts for two primary sources of uncertainty: electricity price volatility and grid interconnection queue delays. These uncertainties are modeled independently from the sensitivity scenarios (S1-S4) described above, each sensitivity scenario is solved under both deterministic and stochastic frameworks.

Price Uncertainty: We construct price scenarios from three representative historical years of ERCOT day-ahead LMP data: 2021 (extreme prices including Winter Storm Uri), 2022 (volatile market conditions), and 2024 (normal operations). Each price scenario represents 8, 760 hourly prices across all four zones, capturing diverse market regimes including extreme weather events, high renewable curtailment periods, and fuel price volatility.

Queue Delay Uncertainty: Grid interconnection timelines are modeled with two realizations reflecting observed processing variability in ERCOT. The low queue (optimistic) scenario features delays decreasing from 9 months (2028) to 0 months (2030) as backlogs clear, while the extreme queue (pessimistic) scenario exhibits persistent delays from 15 months (2028) to 6 months (2030), representing prolonged interconnection congestion.

Scenario Set Construction: The complete stochastic scenario set $\Omega$ combines the three price years with two queue delay realizations, yielding six scenarios. Probability weights reflect the relative likelihood of market conditions: 2024 normal operations receive 60% weight (30% per queue scenario), 2022 volatile conditions receive 30% weight (15% per queue scenario), and 2021 extreme events receive 10% weight (5% per queue scenario). Within each price regime, queue delays are equally likely, capturing the inherent uncertainty in interconnection processing timelines.

Deterministic Baseline: For comparison, the deterministic model uses 2024 prices (normal operations) with the low queue scenario (9→0 months), representing a median planning assumption without explicit hedging against uncertainty.

To maintain computational tractability while preserving seasonal and operational variability, both deterministic and stochastic models employ temporal decomposition with representative days. We select 4 representative days per month using scenario-weighted K-means clustering on daily price profiles, wind capacity factors, and solar capacity factors. Representative days are weighted to preserve annual energy balances, with weights determined by cluster membership (number of days each representative day represents).

Both the deterministic and stochastic models are implemented in Python using Pyomo and solved with Gurobi.

## RESULTS AND DISCUSSION

This section presents the optimization results in two parts: first, we establish deterministic baseline outcomes and sensitivity analysis across the four scenarios; second, we examine stochastic optimization results that account for price and queue delay uncertainty.

### Deterministic Baseline Results

Figure 2 presents the deterministic optimization results across the four sensitivity scenarios, showing BTM technology capacity (2a), energy generation mix (2b), spatial distribution (2c), and battery storage deployment (2d). All deterministic cases use 2024 electricity prices and the low queue delay scenario (9→0 months) as the baseline planning assumption.

HOUSTON is excluded across all scenarios due to prohibitively high electricity prices. In the unconstrained baseline (S1), Figure 2c shows capacity concentrating in SOUTH (64%) and NORTH (20%), with WEST capturing 16%. The system deploys 2.1 GW of gas turbines and 0.5 GW of wind (Figure 2a) as interim capacity during queue delays. Once grid interconnection becomes available by 2030, grid purchases dominate at 92.2% of energy (Figure 2b), with gas declining to 3.0%. This "bridging" strategy invests in BTM capacity primarily for 2028-2029 queue periods, then transitions to grid-dominated operations. Storage remains minimal at 0.3 GWh (Figure 2d).

S2's demand flexibility enables complete spatial consolidation—100% of capacity in SOUTH (Figure 2c). The portfolio simplifies to 1.8 GW of gas turbines with zero renewables or storage (Figures 2a, 2d). Despite facing grid curtailment, load shifting enables 97.7% grid reliance (Figure 2b), demonstrating that operational flexibility substitutes for infrastructure diversification.

Emission constraints (S3) trigger spatial redistribution across WEST (52%), SOUTH (40%), and NORTH (8%) to access diverse wind resources. Figure 2a shows deployment of 6.8 GW wind, 1.5 GW solar, and 0.4 GW hydrogen fuel cells. Wind dominates energy supply at 47.5%, with solar contributing 9.3% and hydrogen fuel cells 8.5% (Figure 2b). Grid purchases persist at 35.1%, filling renewable generation gaps while maintaining the 70% emission reduction target. Storage increases to 0.9 GWh for renewable integration.

Land constrained (S4) force concentration in WEST (64%) and a technology shift to high-density solutions. Solar dominates with 4.7 GW due to superior power density (35 MW/km²) versus wind (0.4 GW, 5 MW/km²).

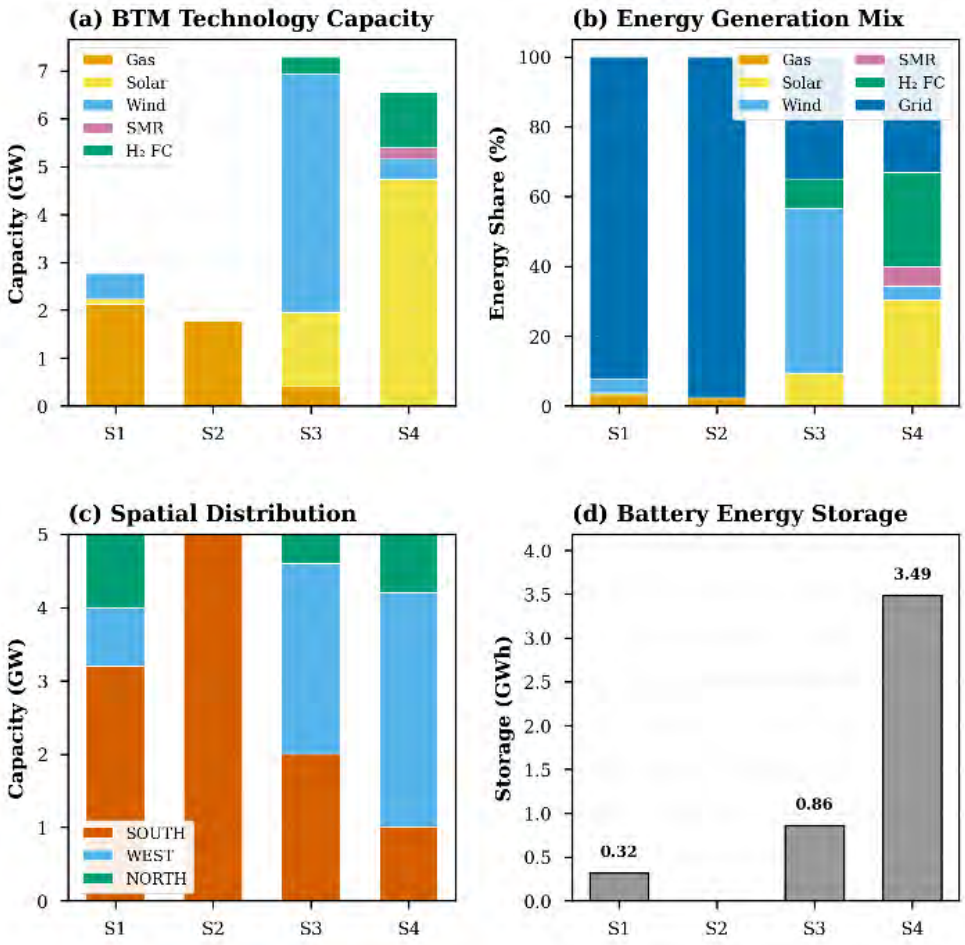

**Figure 2.** Deterministic optimization results.

Capital-intensive technologies emerge: hydrogen fuel cells (1.2 GW, 27.3% of energy) and SMRs (0.2 GW, 5.7%). Storage quadruples to 3.5 GWh—essential for managing diurnal solar patterns. This demonstrates deep decarbonization feasibility under severe land constraints, albeit requiring substantial storage and capital-intensive generation.

## Stochastic Results

Figure 3 presents stochastic optimization results, accounting for price uncertainty (2021, 2022, 2024) and queue delay uncertainty (low vs. extreme scenarios). The stochastic framework fundamentally reshapes spatial allocation and technology selection compared to deterministic baselines.

Uncertainty triggers notable spatial redistribution. In S1, stochastic optimization shifts from deterministic SOUTH-NORTH concentration (64%-20%) to SOUTH-WEST distribution (76%-24%, Figure 3c), eliminating NORTH entirely. This reflects hedging against combined price and queue uncertainty—WEST's wind resources and moderate prices provide superior risk-adjusted returns compared to NORTH's reliance on delayed grid access.

S2 exhibits the most dramatic spatial reversal. Deterministic optimization placed 100% capacity in SOUTH; stochastic optimization distributes across SOUTH (68%) and WEST (32%). This geographic diversification hedges against curtailment events and queue delays by accessing WEST's renewable resources, even in a flexibility-enabled scenario. The stochastic portfolio adds 0.5 GW of wind (Figure 3a) absent in the deterministic case, demonstrating that uncertainty justifies renewable investment despite available flexibility.

Emission-constrained scenarios maintain similar spatial patterns but with subtle shifts. S3 stochastic allocation (WEST 56%, SOUTH 32%, NORTH 8%, HOUSTON 4%) closely mirrors deterministic distribution, confirming that emission constraints dominate spatial decisions regardless of uncertainty. However, S4 under land constraints exhibits a complete geographic flip: deterministic optimization favored WEST (64%), while stochastic optimization concentrates in SOUTH (56%), with WEST reduced to 24%. This reversal reflects uncertainty's

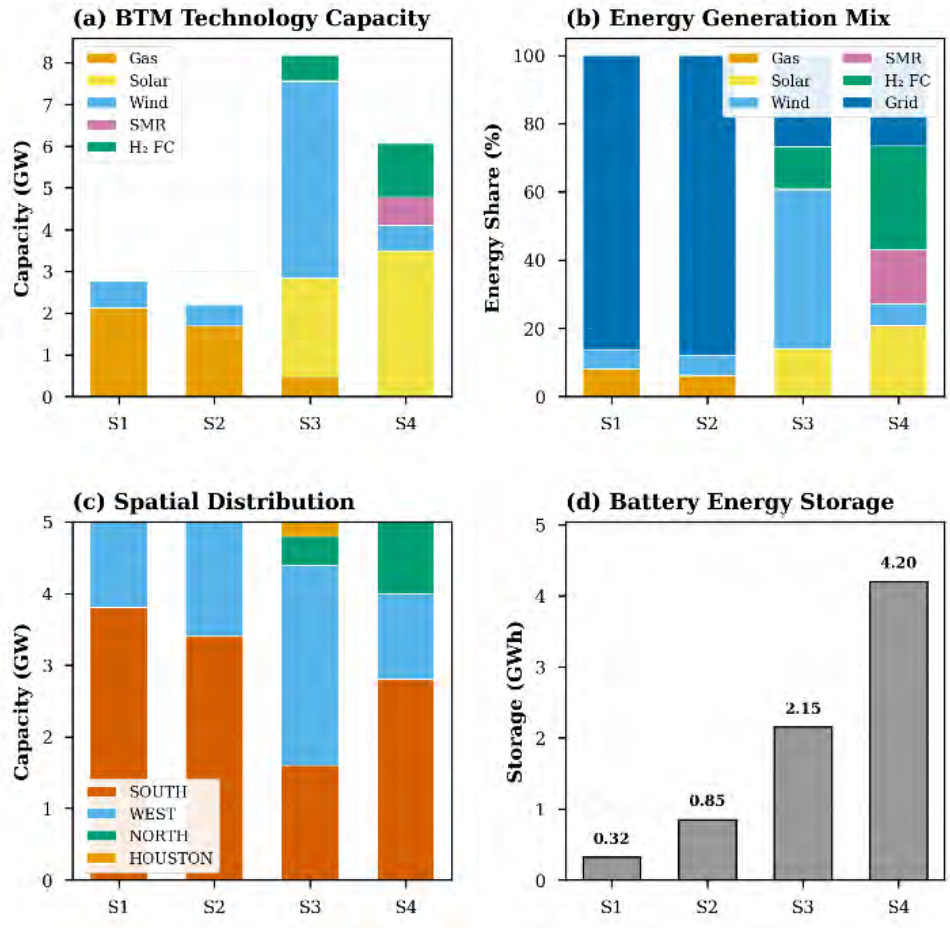

**Figure 3.** Stochastic optimization results.

interaction with land scarcity, SOUTH's operational characteristics provide superior resilience when both land and grid access are uncertain.

Stochastic optimization reveals distinct technology preferences. In S1, both deterministic and stochastic deploy 2.1 GW of gas and 0.6 GW of wind, but the stochastic energy mix shows gas maintaining 8.0% of generation through 2030 versus the potential for higher grid reliance under perfect foresight. This hedging premium protects against extreme price scenarios.

S2's technology portfolio remains stable: 1.7 GW gas and 0.5 GW wind in both frameworks. Generation shares (gas 5.9%, wind 6.0%, grid 88.1%) demonstrate that flexibility combined with moderate BTM investment provides robust performance across uncertainty scenarios.

S3's technology mix shifts notably under uncertainty. While total wind capacity (5.0 GW) remains comparable, solar increases to 2.4 GW (from 1.5 GW deterministic), and hydrogen fuel cells expand to 0.6 GW (from 0.4 GW). The stochastic energy mix (Figure 3b) shows wind at 46.7%, solar at 13.9%, and hydrogen fuel cells at 12.4%, a more diversified portfolio than wind-dominated deterministic alternatives, reflecting technology balancing to hedge resource variability.

The most significant shift occurs in S4. Stochastic optimization triples SMR deployment to 0.7 GW, with SMR energy share reaching 15.8% (Figure 3b). Solar decreases to 3.5 GW while hydrogen fuel cells increase to 1.3 GW (30.4% of energy). This substitution toward high-capacity-factor technologies (SMRs: 95% availability, hydrogen fuel cells: dispatchable) reflects uncertainty's premium on reliability under tight land constraints. SMRs provide consistent generation regardless of weather or price scenarios, justifying higher capital costs.

## CONCLUSIONS AND MANAGERIAL INSIGHTS

This paper developed a two-stage stochastic optimization framework integrating binary capacity constraints, spatial facility allocation, and behind-the-meter energy portfolio selection under electricity price volatility and grid interconnection queue uncertainty. Applied to ERCOT data center planning, the framework reveals how progressive operational and regulatory constraints

reshape technology and spatial strategies.

The results demonstrate that optimal portfolios evolve systematically with constraint tightening. Under queue delays alone (S1), gas turbines serve as bridging capacity during 2028-2029 interconnection periods, with operations transitioning to 92% grid reliance by 2030. Demand flexibility (S2) simplifies portfolios but does not eliminate BTM investment needs, the system maintains 1.7 GW of gas and 0.5 GW of wind to hedge curtailment risk. Emission constraints (S3) trigger fundamental shifts toward spatially distributed wind portfolios (5.0 GW) supplemented by solar and hydrogen fuel cells, achieving 70% reduction while maintaining 27% grid purchases. Land constraints (S4) force capital-intensive, high-density solutions: solar-hydrogen-SMR portfolios with storage quadrupling to 3.5 GWh.

Stochastic optimization reveals that uncertainty drives technology diversification and dispatchable capacity preferences. While spatial patterns remain relatively robust across frameworks, technology selection exhibits significant sensitivity. Under land-constrained decarbonization (S4), stochastic optimization triples SMR deployment (0.2 to 0.7 GW) and increases hydrogen fuel cell energy share to 30.4%, reflecting uncertainty's premium on high-capacity-factor technologies. This substitution toward firm generation quantifies the hedging premium—investments justified by resilience across scenario distributions rather than expected-case optimization.

Among operational strategies, demand flexibility delivers consistent value across scenarios, enabling higher grid reliance and simplified portfolios. However, flexibility alone cannot eliminate infrastructure investment under curtailment and emission constraints. Storage emerges as scenario-specific: negligible in grid-dominated cases, moderate for wind integration, and essential (3.5 GWh) for high-solar land-constrained scenarios, scaling with renewable penetration rather than serving primarily as uncertainty hedge.

Spatial analysis confirms tight coupling between zone selection and technology choice. Emission constraints distribute capacity across zones (WEST 56%, SOUTH 32%, NORTH 8%) to access diverse wind resources, while land constraints concentrate deployment (SOUTH 56%) while forcing technology shifts toward high-density solutions. Binary capacity constraints (100 MW minimums for gas and SMRs, 200 MW data center modules) enforce realistic deployment patterns, ensuring solutions represent implementable strategies.

Future research should model the interaction between behind-the-meter investments and grid expansion planning, capturing how large-scale data center deployment decisions influence grid infrastructure development. Additionally, incorporating renewable energy credit markets and exploring multi-stakeholder coordination between data center operators and utilities would provide comprehensive policy insights for sustainable data center growth.

## ABSTRACT

Heavy-duty road transport remains a challenging sector to decarbonize, as full electrification of long-distance trucking is currently constrained by limitations in energy density and charging infrastructure. Alternative fuels such as hydrogen, biodiesel, and e-fuels are thus gaining increasing attention. In parallel, the cement industry is a major source of unavoidable, process-related $CO_2$ emissions, offering an opportunity to use captured industrial $CO_2$ as a feedstock for e-fuel production. This study evaluates the production of e-methanol and Fischer-Tropsch (FT) diesel from captured $CO_2$ at an Austrian cement plant as a base case. Several system configurations are analyzed, including different electricity supply options across Europe and the use of biogenic versus fossil $CO_2$. An integrated framework combining process simulation, techno-economic analysis, and life-cycle assessment is applied to compare both fuel pathways. Results show that the climate impact of e-fuels is highly dependent on the electricity mix. When non-renewable electricity is used, climate impacts are 100-440% higher than those of fossil diesel. In contrast, a wind-based Austrian scenario achieves the lowest impact, corresponding to a 44-50% reduction compared to fossil diesel. Overall, cement-plant-based power-to-liquid concepts offer limited near- to mid-term mitigation potential under current European energy conditions and deliver climate benefits primarily when based on biogenic $CO_2$, high process efficiencies, and low-carbon electricity. The study further highlights key differences between the fuels, with FT-diesel being a certified drop-in fuel, while e-methanol still requires technical and regulatory validation, underscoring the need for technology-specific and system-level assessments.

## INTRODUCTION

The transport sector contributes approximately 30% to the EU's $CO_2$ emissions, with 72% attributable to road transport [1, 2]. While the decarbonization of domestic transport is progressing with an increasing deployment of electric vehicles, the electrification of long-distance freight transport poses several challenges due to limitations in energy density, vehicle payload, and charging times [3]. Therefore, alternative low-carbon fuels such as hydrogen ($H_2$), biodiesel, and alcohols are increasingly discussed as complementary solutions for heavy-duty transport applications [4, 5]. Among these options, e-fuels (also known as synthetic fuels produced from captured carbon dioxide ($CO_2$) and renewable $H_2$) are widely discussed as promising alternatives to fossil fuels. In this context, Fischer-Tropsch (FT) diesel represents a well-established e-fuel pathway, producing paraffinic diesel-range fuel that is fully compatible with existing engines and infrastructure. In contrast, alcohol-based e-fuels, particularly e-methanol, offer an alternative pathway characterized by comparatively simpler process steps and high system flexibility, as methanol is a well-established platform chemical that can be used both as an energy carrier and as a versatile chemical feedstock. While FT-diesel is functionally seen as a drop-in fuel for heavy-

duty diesel engines and is certified under EN 15940 [6], the large-scale deployment of e-methanol in road transport requires adapted engine concepts and further regulatory validation [7, 8].

Despite their potential, e-fuel production is highly energy-intensive, mainly attributable to the substantial $H_2$ demand [9]. As $H_2$ production via electrolysis dominates the energy consumption of the Power-to-Liquid (PtL) pathways, the environmental performance of e-fuels is strongly dependent on the carbon intensity of the electricity supply [10]. In addition to $H_2$ as key reactant, large quantities of $CO_2$ are required as a carbon source, shifting attention toward industrial point sources. In this context, the cement industry represents one of the largest sources of unavoidable, process-related $CO_2$ emissions, accounting for almost 4% of the European $CO_2$ emissions in 2022 [11]. These emissions originate mainly from the energy intensive calcination of limestone ($CaCO_3 \rightarrow CaO + CO_2$). Captured $CO_2$ from cement plants can theoretically serve as a potential carbon feedstock for e-fuel production, conceptually linking the decarbonization of both industry and transport sectors.

However, the utilization of fossil-derived industrial $CO_2$ for e-fuel production is subject to regulatory restrictions. Under the Renewable Energy Directive (RED) restrict, the eligibility of such pathways for renewable fuels of non-biological origin (RFNBOs) is limited to the period up to 2040, after which permanent $CO_2$ storage through carbon capture and storage (CCS) is required [12]. These regulatory conditions add a system-level constraint that must be considered when assessing cement-based power-to-liquid concepts. Thus, e-fuels represent a promising pathway for the decarbonization of heavy-duty road transport and cement industry, but imply distinct economic and ecological trade-offs, making a comparative assessment essential.

Against this background, the present study investigates whether e-methanol and FT-diesel produced from captured $CO_2$ at a cement plant can deliver economic and environmental benefits compared to fossil diesel. The assessment is conducted under realistic European electricity supply scenarios and the prevailing regulatory framework, enabling a comparative evaluation of both e-fuel pathways with respect to their potential role in a future low-carbon transport system.

# METHODS

## System scope and reference case

This study investigates industrial-scale power-to-liquid fuel production integrated into a cement plant. All assessments are based on a hypothetical, steady-state plant configuration representing a commercial-scale installation. The reference system is anchored to a cement plant located in Austria with annual $CO_2$ emissions of 750 $ktCO_2$/year [13]. Unless stated otherwise, plant scale, capture technology, electrolysis concept, and process design assumptions are kept constant across all cases to enable a consistent comparison.

## Process routes considered

The investigated system includes $CO_2$ capture from cement plant flue gas using a monoethanolamine (MEA)-based solvent scrubbing unit and $H_2$ production via alkaline electrolysis (AEL), which are applied uniformly across all cases. MEA-based $CO_2$ capture is used as the reference technology. Alternative capture concepts may affect absolute results but are not expected to alter the relative comparison between the assessed fuel pathways.

Downstream of $CO_2$ capture and $H_2$ production, two alternative $CO_2$ conversion routes are examined: (i) direct hydrogenation of $CO_2$ to methanol, and (ii) conversion of $CO_2$ via the reverse water-gas shift reaction followed by FT-synthesis to diesel-range hydrocarbons. These two routes define the technological scope of the study and are assessed across all scenarios. Detailed process descriptions are provided in the following section.

## Methodological approach

The methodological framework employed for the assessment of the economic and environmental performance of the evaluated fuel pathways is presented in the *Supplementary Material* (Figure S1), whereas the scope of the study is depicted in **Figure 1.** The integrated approach comprises three principal stages: (1) process design and simulation, (2) subsequent economic process evaluation within a techno-economic assessment (TEA), and (3) life cycle assessment (LCA). According to this framework, the investigated process routes are modelled in Aspen Plus® (V14) to generate mass and energy balances, which serve as the basis for plant design, equipment sizing, and the identification of potential energy savings through heat integration by applying a thorough pinch analysis. Equipment costs were estimated using the Aspen Process Economic Analyzer® (APEA). The resulting simulation data are subsequently used as input for the TEA, in which the process is evaluated based on the efficiency, stream data and economic indicators, while a custom-built Excel-based TEA tool integrates unit cost data with mass and energy balances to calculate capital (CAPEX), operating expenditures (OPEX), and net production costs (NPC). In parallel, the same data are transferred to the LCA to quantify environmental impacts (focusing on climate change) using the SimaPro software and ecoinvent database. This integrated approach is applied to both e-methanol (i) and FT-diesel (ii) pathways, enabling a transparent comparison with conventional diesel under identical system boundaries.

## Scenario definition

Scenarios are defined as variations of external

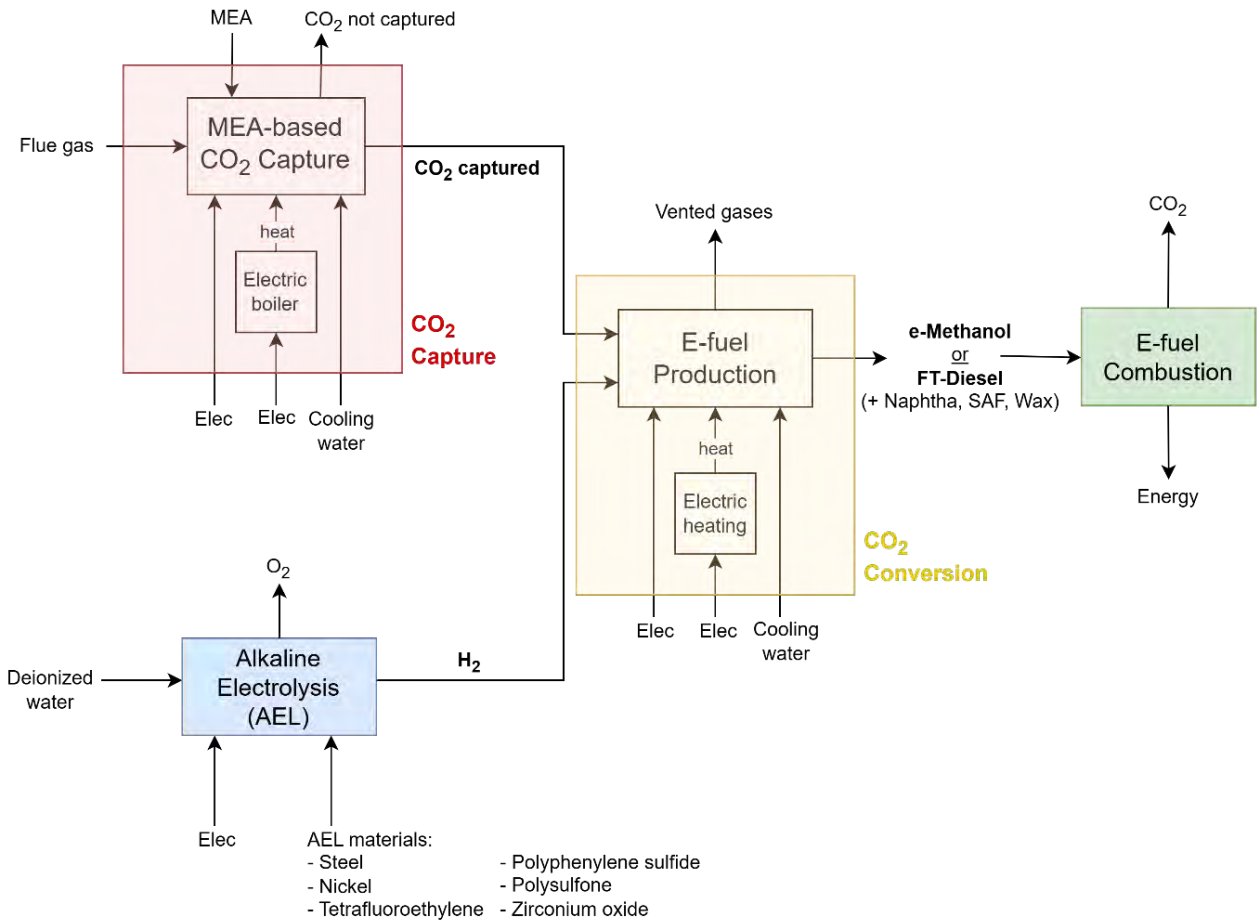

**Figure 1.** Scope of the study, consisting of four main blocks: (1) $CO_2$ capture from a cement plant; (2) $H_2$ production with alkaline electrolysis; (3) e-fuel production from $CO_2$ and $H_2$; and (4) e-fuel combustion.

boundary conditions applied to the reference system, while the plant configuration and process design remain unchanged. The comparison is carried out for Austria (base case) and other European countries, listed in the *Digital Supplementary Material* section S3, to assess the influence of the electricity grid mix on the climate change (CC) damage category (computed according to the GWP100 of the IPCC AR6 method). Grid-based electricity scenarios are evaluated to reflect current system conditions and constraints, rather than to imply compliance with additionality requirements under RFNBO regulation.

The scenarios differ with respect to (i) the carbon origin (fossil vs. biogenic $CO_2$) and (ii) the electricity supply for electrolysis and auxiliary processes. Hence, the following scenarios to mitigate CC of e-fuels in Austria are explored: (1) AT, fossil $CO_2$ from the cement plant is combined with $H_2$ produced using the electricity grid; (2) AT_BIO, biogenic $CO_2$ is combined with $H_2$ produced using the electricity grid; (3) AT_PV, fossil $CO_2$ is used as feedstock while the entire process (electrolysis, $CO_2$ capture, and $CO_2$ conversion) is powered by electricity from solar panels (PV); (4) AT_PV+BIO, biogenic $CO_2$ is used as feedstock for a process entirely powered by electricity from PVs; (5) AT_BIO+RENH2, biogenic $CO_2$ is used as feedstock and PV panels are powering the electrolyzer only, while remaining electricity demand is supplied by the grid; (6) AT_WIND, fossil $CO_2$ is used as feedstock while the entire process is powered by electricity from wind turbines.

## Process simulation

The simulations are performed as steady-state flowsheet models, covering the whole process starting from $CO_2$ and $H_2$ to the final products. The methanol route was modeled as a three-stage fixed-bed reactor system with direct $CO_2$-to-methanol conversion (ratio of $CO_2$:$H_2$=1:3.08), following the configuration and operating conditions developed by [11] and [12]. Reaction kinetics for $CO_2$ hydrogenation were described using a Langmuir-Hinshelwood-Hougen-Watson (LHHW) model taken from [13]. Intermediate condensation between reactor stages was implemented to deduct $H_2O$ and methanol, which enhances overall $CO_2$ conversion. Downstream of

the synthesis step, the water-methanol mixture is upgraded via a two-stage distillation, including one high- and one low-pressure distillation column.

The FT-diesel route consists of a high-temperature rWGS reactor operating at T = 950 °C and p = 11 bar(g) followed by low-temperature FT synthesis, adopting the process concept and product distribution models by [14]. Catalyst specific data for the rWGS reaction were derived from [15]. An elevated system pressure in the rWGS step was selected to avoid intermediate recompression prior to FTS. The FT reactor itself operates at a $CO:H_2$ ratio of 1:2.08, which is maintained by adjusting the $H_2$ feed. Unreacted gaseous components ($CO_2$, CO, $H_2$, $CH_4$, and light hydrocarbons) are recycled to the rWGS inlet, increasing carbon efficiency. Downstream of the FT reactor, a separation unit based on three distillation columns was implemented to obtain naphtha, kerosene, diesel, and wax fractions. Most of the wax is recycled in a hydrocracking unit to increase the diesel yield, while 10 wt% is withdrawn and sold as a by-product.

## Techno-economic assessment

The techno-economic evaluation was based on the calculation of the NPC, expressed on both an energy ($NPC_e$ in EUR/MWh) and mass basis ($NPC_m$ in EUR/kg), which represents the product price required to achieve the economic break-even point. This approach is widely applied in the assessment of Power-to-X and $CO_2$ conversion processes and enables a consistent comparison of alternative process routes and plant configurations [14, 16]. Additionally, different energy pricing scenarios were considered to reflect different energy markets and price variability across Europe, which can be found in the Digital S*upplementary Material* (Table S1).

The NPC were determined by dividing the plant's total annualized cost by its annual product output. CAPEX values were derived from the major equipment costs obtained from process simulations, including reactors, heat exchangers, compressors, separation units, and utilities. These basic equipment costs were converted into total installed costs using standard installation and indirect cost factors according to the methodology originally proposed by Peters M. et al. [16].

## Life cycle assessment

The impact assessment of e-methanol (i) and FT-diesel (ii) compared to fossil diesel is carried out according to a cradle-to-wheel approach using the Environmental Footprint (EF) 3.1 method [17] and the Ecoinvent 3.11 cut-off database [18] in Simapro v10.3. The combustion of 1 MJ of fuel, including emissions, is chosen as the functional unit (FU). The modeled production processes consist of four main blocks depicted in **Figure 1**. While the environmental impact assessment of $H_2$ production considers both energy consumption for operation and materials required for the electrolyzer, construction stages (i.e., facility and machinery) for MEA-based capture and e-fuel production units are excluded from the scope of the analysis due to lack of reliable data. Moreover, allocation methods are applied where co-products are produced: economic allocation for electrolysis ($H_2/O_2$) and energy-based allocation for the FTS to distribute the impact between FT-diesel and co-products (naphtha, kerosene, and wax). The modeling details can be found in the *Supplementary Materials* section S4.

Environmental impacts are evaluated using the climate change category (CC, kg $CO_2$-eq/FU), expressed relative to fossil diesel (=100%), and a single-score indicator (µPt/FU), representing the weighted aggregation of all impact categories (e.g., acidification, eutrophication, ecotoxicity, or water use).

# RESULTS

The results of the process simulation, TEA, and LCA for the investigated e-methanol and FT-diesel pathways are presented in the following sections. Detailed results of the mass and energy balances, the calculation of the CAPEX and NPC, as well as the calculation of the climate change damage category from the LCA are provided in the *Supplementary Materials*.

## Economic study

The following section summarizes the TEA results for the two investigated scenarios: e-methanol (i) and FT-diesel (ii). **Table 1** presents a breakdown of the main cost structure split into CAPEX and OPEX, and the resulting total and relative NPC values. Further details are available in the *supplementary material* (section S4).

From a techno-economic perspective, results indicate a clear differentiation between the two pathways. The FT-diesel route is characterized by substantially higher capital requirements. Total equipment costs amount to 1, 154 MEUR, compared to 343 MEUR for the e-methanol route. This reflects the additional synthesis, upgrading and separation units required along the FT pathway (pre-rWGS, hydrocracker, distillation). Investment in electrolysis is likewise higher for the FT route (717 MEUR vs. 631 MEUR), driven by increased demand for hydrogen. Although both pathways are based on an overall stoichiometric requirement of approximately 3 moles of $H_2$ per mole of $CO_2$, the FT diesel route exhibits electrolysis costs that are around 13% higher compared to scenario (i). This is mainly due to light hydrocarbons that are formed in the FT reactor and are recycled back to the rWGS unit, where they are partially converted into CO. This additional loop requires the addition of hydrogen for maintaining the targeted $CO/H_2$ ratio upstream of the FT reactor. This is further amplified by $H_2$ consumption in the downstream hydrocracker and slight losses in

the FT recycle loop. Consequently, the annualized capital cost (ACC) is almost twice as high for FT-diesel as for e-methanol (142 MEUR/a vs. 74 MEUR/a).

OPEX in both pathways are dominated by electrolysis-related costs. The annual replacement costs (ARC) of the electrolysis stack are 29 MEUR/a for the e-methanol route and 33 MEUR/a for the FT-diesel route, accounting for around 6.4% and 9.8% of total operating expenses (OPEX), respectively. Despite having a higher hydrogen demand and a higher share of electrolysis-related OPEX, the total OPEX of the FT-diesel route are lower than that of the e-methanol route (338 MEUR/a vs. 453 MEUR/a). This is primarily due to revenues from FT co-products (e.g. gasoline, naphtha, kerosene, wax and light gases), which are credited as sales and reduce the net OPEX of the FT pathway by around 7.7% compared to the single-product e-methanol route.

The interaction between higher CAPEX and lower OPEX results in slightly lower annual total net production costs ($NPC_t$) for the FT-diesel route than for e-methanol (513 vs. 556 MEUR/a). However, this apparent advantage is reversed when costs are normalized to the main product output. The $NPC_m$ for FT-diesel is 7.16 EUR/kg, compared to 1.40 EUR/kg for e-methanol. The energy-specific NPC is 590 EUR/MWh for FT-diesel and 250 EUR/MWh for e-methanol.

**Table 1:** CAPEX and OPEX for e-methanol (i) and FT-diesel (ii) based on boundary conditions of the cement plant in Austria.

| | Units | Process Route (i) | (ii) |
|---|---|---|---|
| **CAPEX** | | | |
| Total electrolysis costs | MEUR | 631 | 717 |
| Total equipment costs | MEUR | 343 | 1, 154 |
| Annualized capital cost [ACC] | MEUR/a | 74 | 142 |
| **OPEX** | | | |
| Annual replacement costs of electrolysis stack [ARC] | MEUR/a | 29 | 33 |
| Total OPEX | MEUR/a | 453 | 338 |
| **NPC** | | | |
| Total net-production costs [$NPC_{total}$] | MEUR/a | 556 | 513 |
| Mass specific [$NPC_m$] | EUR/kg | 1.40 | 7.16 |
| Energy specific [$NPC_e$] | EUR/MWh | 250 | 590 |

To account for regional differences within Europe, country-specific electricity prices for 2025 were used to calculate the $NPC_e$, while all other techno-economic parameters and the process configuration remained constant. The resulting NPC spans a range of approximately 300-700 €/MWh for the e-methanol route and 700-1, 000 €/MWh for the FT-diesel route (**Figure 2** and **Figure 3**). Lower energy-specific production costs were observed in the Nordic countries (SE, FI, DK, EE, LV) as well as in south-western Europe (PT, ES).

## Environmental study

The impacts in the CC damage category (kg $CO_2$ eq/FU), relative to fossil diesel (=100%), of e-fuels produced using electricity from different grid mixes (residual mixes with 2023 as reference year, except for Austria, market mix (2021) since residual mix is not available for this country) is depicted in **Figure 4**. Moreover, the overall environmental impact of e-fuels represented by the single score (µPt/FU), is depicted in **Figure 5**.

As expected, using non-renewable-sourced electricity to produce e-fuels results in a CC impact which is higher than the one of fossil diesel for the same energetic work. While CC of e-fuels are usually 100-300% higher than the fossil option, carbon-intensive mixes lead to even higher CC increases as can be observed for Germany (DE), Greece (GR), and Poland (PL). Indeed, the medium voltage electricity grid mix in Germany and Poland is dominated by hard coal (55% and 73%, respectively), while Greek electricity mix relies heavily on natural gas (52%). On the other hand, the lowest CC is achieved in France (FR) and Sweden (SE), respectively +34% and +35% compared to fossil diesel, attributable to two low-carbon grid mix profiles: Swedish electricity is heavily decarbonized through renewables (hydropower, wind turbines, and bioenergy, representing >50%) and nuclear energy (42%), whereas electricity is almost entirely produced from nuclear energy (88%) in France.

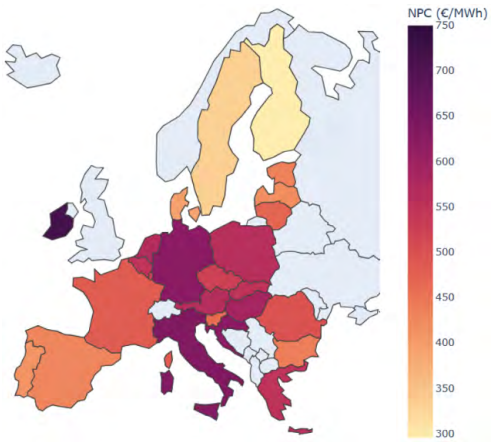

**Figure 2.** Influence on the $NPC_e$ (€/MWh) for the e-methanol route (i) of regional electricity prices. The reference year for the economic assessment is 2025.

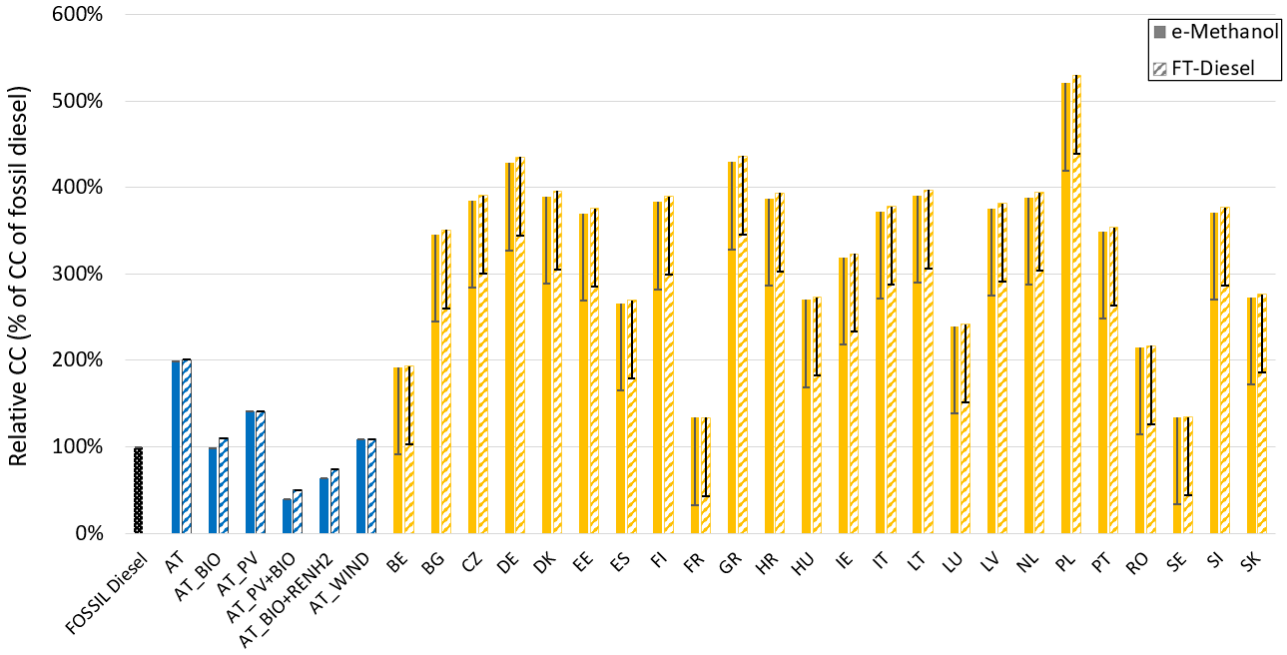

**Figure 4.** Damage assessment of CC for e-methanol (solid bars) and synthetic diesel (hatched bars) across Europe (fossil diesel = 100%), assessed using Environmental Footprint 3.1 method (v1.04).

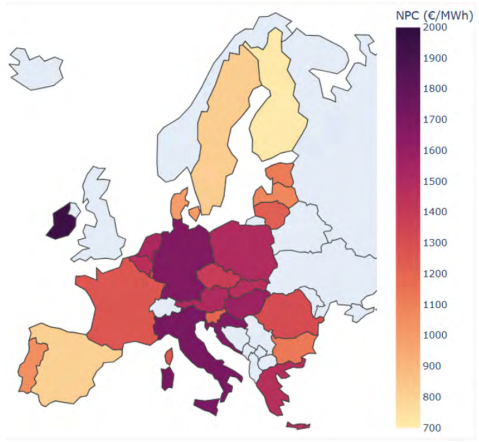

**Figure 3.** Influence on the $NPC_e$ (€/MWh) for the FTS-diesel route (ii) of regional electricity prices. The reference year for the economic assessment is 2025.

When using the Austrian electricity grid mix, e-methanol combustion is associated with a CC of 0.178 kg $CO_2$ eq/FU, i.e., almost twice the one of fossil diesel. Nearly 40% of the CC is attributable to the combustion of the e-methanol, as $CO_2$ captured from the cement plant and used as feedstock is considered fossil (Figure S4).

If biogenic $CO_2$ is used instead, e.g., from a biogas production plant, the emissions during e-fuel combustion would not contribute to CC anymore since the characterization factor for biogenic carbon in EF 3.1. method is 0. Moreover, approximately 30% of the CC is linked to the AEL while electricity demand for $CO_2$ capture and e-methanol production further contribute 20%. These contributions could be reduced by using low-carbon electricity, e.g., PVs or wind turbines.

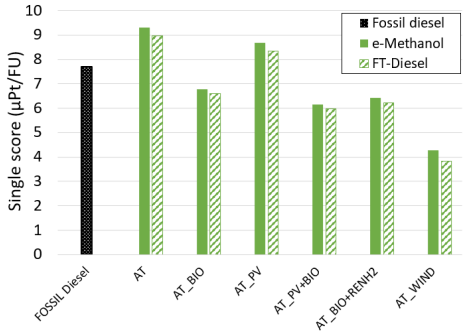

**Figure 5.** Single score of e-methanol (solid bars) and FT-diesel (hatched bars) for different Austrian scenarios, assessed using EF 3.1 method (v1.04).

The benefit of using biogenic $CO_2$ can be observed in **Figure 4**, represented by error bars for different European countries, excluding Austria where the AT_BIO scenario is used instead. Despite reducing the CC by 19-75% and 17-68% for, respectively, e-methanol and FT-diesel compared to initial estimations, switching towards biogenic carbon-rich feedstock alone is not sufficient in most cases to achieve a lower CC than fossil diesel. Only the French and Swedish electricity mixes enable net reductions of the CC for both e-fuels (56-67%) compared to the fossil alternative.

Utilizing PV-based electricity (AT_PV) decreases CC

by 29-30% compared to AT, but remains 41% more impacting than fossil diesel combustion. Moreover, as can be seen on **Figure 5**, AT and AT_PV scenarios are also associated with the highest single scores, indicating the worst environmental impact among all Austrian options. On the contrary, combining biogenic $CO_2$ and solar energy reduces CC by 25-36% when solar energy powers $H_2$ production only (AT_BIO+RENH2) and by 50-60%, compared to fossil diesel, when PVs cover process electricity demand entirely (AT_PV+BIO). Despite clear reduction in the CC damage category, the overall environmental burden mitigation compared to the fossil alternative is limited (17-23% lower single score) due to materials requirements for PVs.

Finally, the CC of e-fuels in AT_WIND scenario is only 9% higher than the one of fossil diesel. Such a small gap could be reduced by improving the energy efficiency of electrolysis or $CO_2$ capture and conversion processes, reducing the flow rate of vented flue gas, or increasing the capture efficiency to above 90%. However, AT_WIND scenario presents the lowest environmental impact (44-50% reduction compared to fossil diesel), suggesting this is the most sustainable Austrian configuration.

## CONCLUSIONS

The limited electrification potential of long-distance heavy-duty transport underlines the need for low-carbon fuels with high energy density. While the utilization of captured $CO_2$ from cement plants is often discussed as a promising mitigation pathway, this study demonstrates that cement-based PtL concepts are fundamentally constrained by high energy demand, limited renewable electricity availability, large electrolyzer scale requirements, and regulatory uncertainty, particularly under RFNBO requirements restricting fossil $CO_2$ utilization beyond 2040. While both e-fuel pathways are technically feasible at process level, their system-level feasibility is constrained by low-carbon electricity availability, grid integration, and electrolyzer scale requirements, reaching hundreds of megawatts in the investigated configurations. Such capacities exceed current installation levels and raise practical challenges related to grid integration, investment risk, and operational flexibility [7, 12].

The techno-economic assessment of e-methanol and FT-diesel production from captured $CO_2$ at an Austrian cement plant highlights a clear differentiation between the two e-fuels, while both remain significantly more expensive than their fossil counterparts. For the Austrian base case, the $NPC_e$ (dominated by electrolysis-related operating costs) amount to 565€/MWh for e-methanol and 1, 498€/MWh for FT-diesel, compared to approximately 81€/MWh for fossil methanol [19] and 155€/MWh for fossil diesel [20], with similar cost relationships observed across other European countries. Under current European market conditions, the production of e-fuels remains economically uncompetitive, even before considering additional limitations such as renewable electricity availability and infrastructure requirements, highlighting the continued need for funding mechanisms and process improvements to close the cost gap.[19, 20]

From an environmental perspective, the LCA highlights the dominant influence of the electricity supply on environmental impacts. When e-fuels are produced using residual or market-based grid electricity mixes, the CC impacts exceed that of fossil diesel in most investigated regions, with CC values 100% to more than 400% higher than fossil diesel for carbon-intensive grid mixes, consistent with previous findings on electricity mix sensitivity in PtL pathways [8, 21, 22]. Substitution from fossil to biogenic $CO_2$ feedstock alone is insufficient to achieve lower CC than fossil diesel in most cases. This is reflected in Austrian scenarios where using biogenic $CO_2$ with grid electricity improves environmental outcomes but remains above fossil diesel. However, the lower energy penalty associated with $CO_2$ capture from biogas streams, due to higher $CO_2$ concentration than in cement flue gases, suggests overestimated CC impacts of biogenic-$CO_2$-based e-fuels when uniform capture assumptions are applied [23]. Meaningful greenhouse gas emission reductions are achievable only when biogenic $CO_2$ is coupled with low-carbon electricity systems (e.g., AT_PV+BIO reducing CC impacts by 60% and 50% for e-methanol and FT-diesel, respectively, compared to fossil diesel). Consequently, the environmental viability of these process routes is strongly dependent on the availability and large-scale deployment of renewable electricity. However, other environmental impact categories should be considered to avoid burden displacement and make a sound decision about renewables deployment. Moreover, the present assessment evaluates absolute environmental impacts relative to fossil diesel and does not explicitly account for substitution effects. Although e-fuels are intended to replace fossil fuels and enable a secondary use of industrial $CO_2$, such system-level effects are not fully reflected in the current LCA. Thus, a comprehensive evaluation of substitution effects and their implications for fossil fuel replacement is therefore identified as an important subject for future studies.

Overall, the findings highlight that PtL assessments are highly sensitive to boundary-condition assumptions. Optimistic conclusions regarding climate benefits of e-fuels often rely on implicit assumptions of abundant low-cost, low-carbon electricity and large-scale electrolysis deployment, which are not yet realized within the European energy system. Consequently, meaningful evaluation of industrial $CO_2$-based e-fuel pathways requires realistic, system-consistent boundary conditions to ensure robust and policy-relevant conclusions [23, 24]. Results indicate that cement-plant-based PtL concepts offer

limited near- to mid-term mitigation potential under current European energy system conditions. Future PtL concepts should therefore prioritize biogenic $CO_2$ sources, efficiency improvements, and access to additional low-carbon electricity, while ensuring that synthetic fuels are deployed where they complement direct electrification and deliver the highest climate benefit. The fundamentally different characteristics of FT-diesel, a certified drop-in fuel for existing engines and infrastructure, and e-methanol, which is still undergoing technical and regulatory validation, highlight the necessity of technology-specific and system-level evaluation when defining their roles in a future low-carbon transport system. In this context, the study emphasizes that e-fuel pathways based on industrial $CO_2$ utilization can only be meaningfully assessed when grounded in realistic assumptions regarding renewable electricity availability and electrolyzer scale-up.

## ABSTRACT

Early-stage system-level assessment of emerging technologies is essential for achieving climate neutrality and a circular economy; however, such assessments are often constrained by the lack of representative life cycle inventory data. In thermal energy systems, performance strongly depends on scale, making direct application of laboratory- or bench-scale experimental data potentially misleading in life cycle assessment (LCA). This study investigates the influence of experimental scale on system-level evaluation using a zeolite-based thermal energy storage (TES) system as a case study.LCAs were conducted using performance data from laboratory-, bench-, and pilot-scale experiments and compared with predicted commercial-scale performance derived from numerical simulations. The TES system stores waste heat via water vapor desorption from zeolite and generates pressurized steam using a moving-bed with indirect heat exchanging system. Heat recovery ratios of 36%, 50%, and 61% were obtained at laboratory, bench, and pilot scales, respectively, while commercial-scale performance was predicted to reach approximately 80% due to reduced heat losses. Accordingly, LCAs based on small-scale data indicated higher greenhouse gas (GHG) emissions than conventional technologies, whereas assessments using commercial-scale data demonstrated clear GHG reduction potential.The results highlight the risk of erroneous conclusions when small-scale data are directly used for system evaluation. By integrating experimentally validated numerical modeling with computer-aided process engineering, scale-dependent data can be transformed into system-representative inputs, enabling fair and consistent assessment of emerging technologies.

## INTRODUCTION

Achieving global visions such as climate neutrality and a circular economy requires the early adoption of emerging technologies and their system-level assessment using tools such as life cycle assessment (LCA) and techno-economic analysis (TEA) to quantify environmental and economic performance. In particular, LCA has been increasingly applied as a decision-support tool in the emerging technology development to guide research priorities [1, 2]. However, conducting LCA for emerging technologies is inherently challenging, as detailed life cycle inventory (LCI) data are often unavailable in existing databases, which predominantly represent mature, commercial-scale processes. For chemical and thermal processes, missing inventory data are frequently generated using process engineering approaches, including mass and energy conservation calculations, numerical modeling, and computer-aided process engineering (CAPE) tools [3, 4]. While such approaches enable the estimation of prospective system performance, a critical methodological challenge remains: determining which scale of

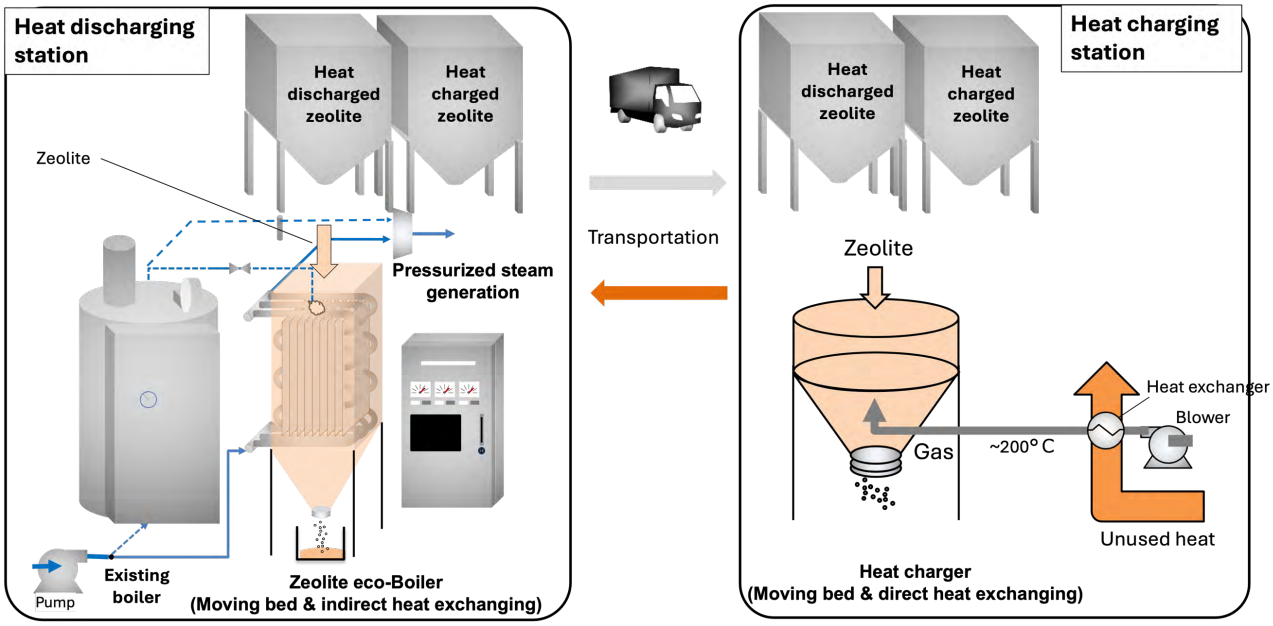

**Figure 1.** Schematic of thermal energy storage and transport system

experimental or modeled data—ranging from laboratory and bench scale to pilot and commercial scale—should be incorporated into system-level assessments. This choice is nontrivial, as key performance indicators such as efficiency, heat loss, and conversion yield often exhibit strong scale dependency [5].

For thermal energy systems in particular, efficiency generally improves with increasing scale due to reduced relative heat leakage and more favorable surface-to-volume ratios. As a result, system evaluations based only on laboratory- or bench-scale experimental data tend to underestimate achievable performance at commercial scale, potentially leading to overly conservative or even misleading conclusions regarding environmental benefits. In contrast, assessments based on full-scale demonstration or operational data provide higher accuracy but are typically time-consuming, capital-intensive, and impractical during the early research and development phases when key design decisions must be made.

To address this methodological gap, the present study employs a thermal energy storage system as a case study to systematically investigate how the scale of experimental data influences system-level evaluation outcomes. By explicitly examining the role of scale in LCA-relevant performance parameters and integrating experimental results with process-based modeling, this work aims to clarify the conditions under which small-scale data can be reliably transformed into system-representative inputs for fair and consistent decision-making in the development of emerging thermal energy technologies.

## MATERIAL AND METHODOLOGY

LCAs using data from laboratory-, bench-, and pilot-scale demonstration tests were conducted and compared with predicted commercial-scale performance derived from numerical simulations in a case study of thermal energy storage technology. The objective was to quantify the uncertainty arising from scale differences and to explore methods to mitigate such uncertainty in the evaluation of emerging technologies.

Thermal energy storage technology enables the recovery and regeneration of waste heat across temporal and spatial gaps through the use of thermal energy storage materials[6]. Fig. 1 shows the schematic of thermal energy storage system using zeolite water vapor adsorption and desorption process[7]. Thermal energy is stored by desorbing water previously adsorbed in zeolite using waste heat. The water-desorbed zeolite is packaged and stored in sealed containers to prevent adsorption of ambient humid and is transported to the heat demand site when required. On the demand side, a heat discharged equipment named "zeolite eco-boiler" capable of continuous generation of pressurized steam is being developed by adopting a moving-bed reactor combined with an

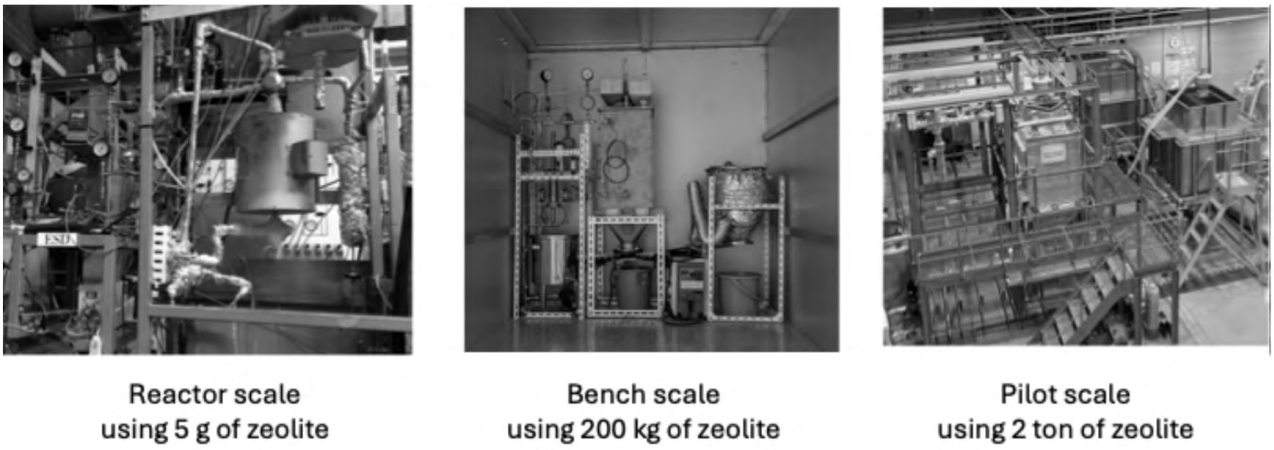

**Figure 2.** Demonstration tests at various scales for zeolite-based thermal energy storage technology

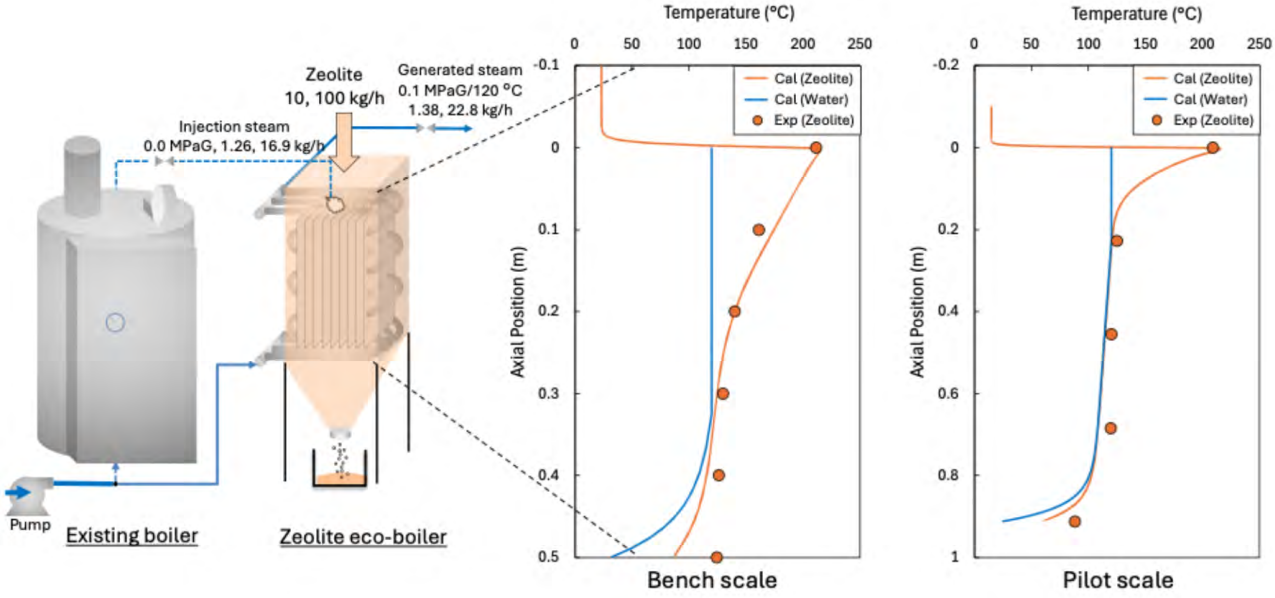

**Figure 3.** Experimental and numerical analysis results for bench- and pilot- scale zeolite eco-boiler demonstration test

indirect heat exchange system[8].

In the proposed system, dried zeolite particles are continuously supplied from the top of the chamber and discharged at a constant flow rate from the bottom, thereby forming a moving bed. Cooperative operation with an existing boiler is assumed. Steam generated from the existing boiler is injected into the chamber, where it is adsorbed by the zeolite, resulting in the release of adsorption heat. A plate-finned-tube heat exchanger is integrated within the chamber, and the released adsorption heat is transferred to feedwater flowing inside the heat exchanger to generate pressurized steam. As a result, the amount of steam generated exceeds the injected steam by approximately 20–30%, enabling a reduction in the fuel consumption of the existing boiler.

A series of experiments for zeolite eco-boiler across multiple scales: laboratory-scale tests using around 5 grams of storage material, bench-scale tests using around 200 kg[8, 9], and pilot-scale tests using around 2 tons[10] were conducted as shown in Fig .2. ) Inventory data for LCA were generated from these experiments, as well as from performance data predicted for commercial-scale systems using numerical modeling that combines energy conservation (for zeolite, gas, and water), mass conservation (for zeolite, gas, and steam), and momentum conservation[11].

The life cycle boundary was kept consistent across all scales to ensure comparability of results. Additionally, the same numerical modeling framework was applied to predict large-scale system performance without any

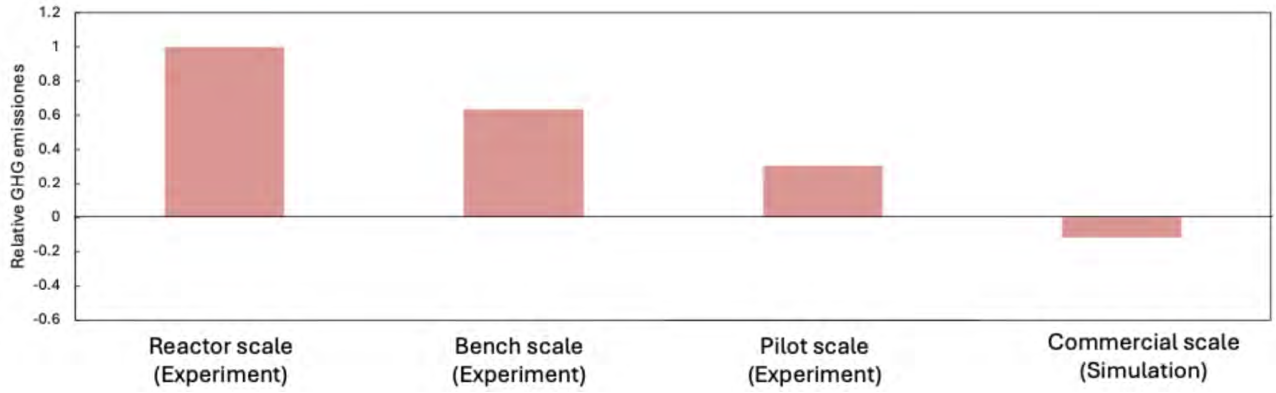

**Figure 4.** Results of lifecycle GHG emissions

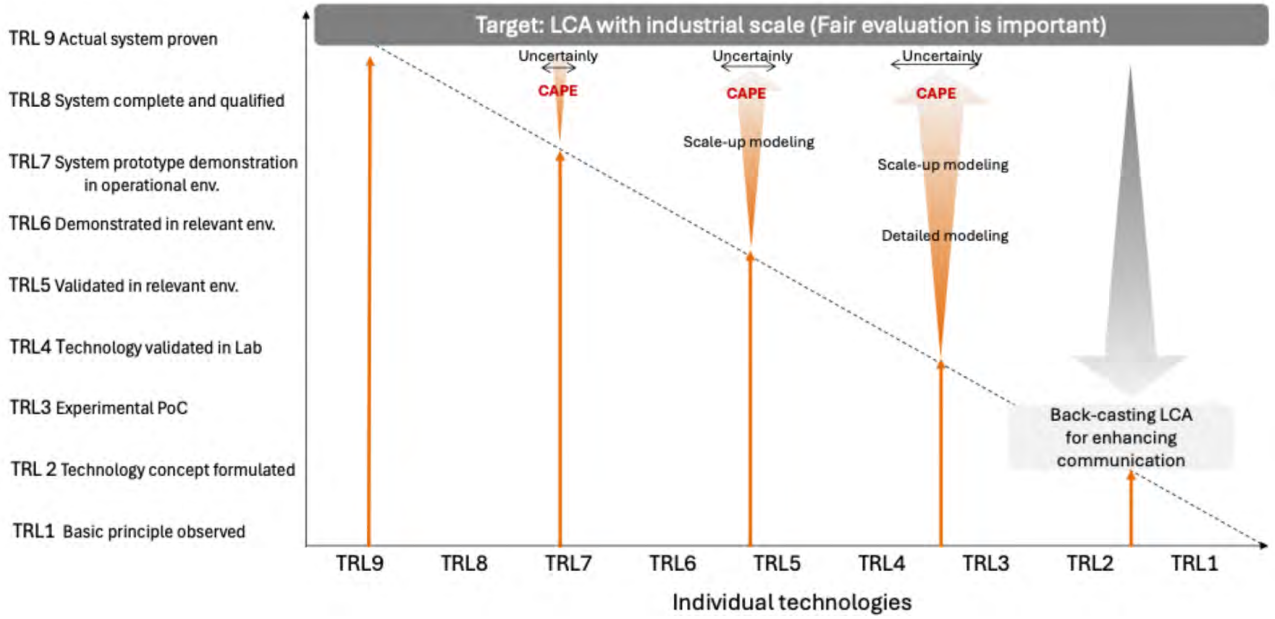

**Figure 5.** Relationship between experimental works, CAPE, and system-level assessment

fitting, by separately modeling heat and mass transfer phenomena. The life cycle boundary was defined to cover the entire system from equipment manufacturing to end-of-life disposal, and the operational lifetime of the equipment was assumed to be 15 years. The size of each component was set to that of a commercially scaled system designed through numerical simulations. Among the performance parameters, only the heat recovery rate—defined as the recovery rate of generated steam relative to the heat storage capacity and relevant to fuel reduction rate–was derived from experimental data obtained at different scales. The functional unit of LCA was defined as the annual steam supply delivered through boiler operation.

## RESULT AND DISCUSSION

Fig. 3 shows the axial temperature distribution during steady-state operation for the bench scale and pilot scale of zeolite-eco Boiler, alongside the results predicted by numerical analysis. In both cases, continuous superheated steam generation and fuel reduction effects were demonstrated. Furthermore, it can be seen that the numerical analysis model incorporating heat and mass transfer simulates the experimental results for both scales.The results clearly demonstrated the scale dependency of TES system performance. The thermal recovery ratio was found to be 36% at the laboratory scale, 50% at the bench scale and 61% at the pilot scale. In contrast, for commercial-scale systems, the predicted thermal recovery ratio reached approximately 80%, indicating a substantial improvement with increasing scale due to reduced heat leakgae. These findings underscore the substantial discrepancy between small-scale exper–

imental data and real-world large-scale performance. Importantly, the numerical model developed in this study, which separately models heat and mass transfer phenomena without introducing scale-up correction factors, successfully reproduced the performance trends observed in scaled-up systems, thereby confirming the validity of the modeling approach.

The implications of these results were further examined through life cycle assessment. Fig. 4 shows the results of relative lifecycle GHG emissions compared to existing boilers. LCAs conducted using laboratory-, bench- and pilot- scale data indicated higher greenhouse gas (GHG) emissions compared to conventional technologies, primarily due to the lower heat recovery ratio at smaller scales. However, when performance data from commercial-scale systems were used, the results showed a clear reduction in GHG emissions, demonstrating the potential environmental benefits of thermal energy storage technology. This contrast reveals a critical methodological issue: using laboratory-, bench-, and pilot- scale data directly for system evaluation of developing technologies can lead to incorrect conclusions and misguided policy or investment decisions.

Furthermore, this study highlights the potential of combining numerical modeling and process engineering methods to bridge scale gaps in system evaluation. When only small-scale experimental data are available, validated numerical models that explicitly account for heat and mass transport phenomena can be used to extrapolate reliable large-scale performance estimates as shown in Fig. 3, thereby reducing uncertainty in environmental and techno-economic assessments. Such hybrid approaches enable more accurate and timely evaluations of emerging technologies without the need for time-intensive full-scale demonstrations.

Fig. 5 illustrates the relationship between experimental works, computer-aided process engineering (CAPE), and system-level assessment as a function of technology maturity. The vertical axis indicates the level of data used for system assessment, while the horizontal axis represents the technology readiness level (TRL) of the evaluated technology. For technologies with high TRLs (TRL 8–9), operational data from real-world systems are already available and major uncertainties have been eliminated; therefore, additional support from CAPE is generally unnecessary. In contrast, for technologies with intermediate TRLs (approximately TRL 3–7), direct use of experimental data to system assessment, as demonstrated in the thermal energy storage case study, may lead to erroneous decision-making, including reversals in the sign of greenhouse gas (GHG) impacts relative to existing technologies. Accordingly, CAPE that integrates modeling and process simulation is required to transform experimental data into system-representative data at a level suitable for fair and consistent system assessment. For technologies at very low TRLs (TRL 1–2), however, the uncertainty associated with scale-up predictions using CAPE becomes excessively large. In such cases, CAPE should instead be used to support goal setting by applying backcasting approaches, such as break-even analysis, to delineate the feasible performance range of the technology.

## CONCLUSION

This study provides a framework that integrates experimentation, numerical modelling, process engineering, and life cycle assessment, thereby enhancing the reliability of system evaluations for emerging technologies. By demonstrating the impact of scale on both performance and environmental effects, it emphasises the importance of scale-aware methodologies in achieving climate neutrality and circular economy objectives. The approach presented here is extendable beyond thermal energy storage to diverse emerging technologies, providing a practical pathway to accelerate sustainable technology development while ensuring robust, information-based decision-making in the early stages of emerging technology development.

## ABSTRACT

European industry accounts for approximately 20% of total European $CO_2$ emissions, with heat demand representing one of the largest energy consumers. Solar thermal collectors offer an efficient renewable alternative to fossil fuels to cover the heat demand. However, due to the temporal mismatch between the solar thermal generation and process heat generation a thermal storage is needed to maximize the renewable utilization. This article presents a novel optimization framework for integrating an ideal heat storage with solar thermal systems in multiperiod heat exchanger network synthesis. We derive an analytical approach to optimize the heat storage by using physical insights from Pinch Analysis: heat can only charge the storage below the lowest pinch point in a given period and discharge above the highest pinch point. We show both how to do it for a storage of infinite size and of finite size, and that the infinite size storage is much more efficient to solve. The approach is validated using real industrial data from a lubricant plant and optimizing the implementation of solar thermal at the plant. By increasing the size of the storage more of the solar thermal heat is utilized, however, the increase in utilization becomes smaller as the storage becomes larger. While 100% solar thermal heat utilisation requires a storage size of 1040 kWh, 90% utilisation can be reached with a storage of 250 kWh, compared to only 70% without a storage.

**Keywords**: Heat Exchanger Network, Energy Storage, Renewable and Sustainable Energy, Solar Thermal

## INTRODUCTION

European industry accounts for approximately 20% of total European $CO_2$ emissions, with heat demand representing one of the largest energy consumers. Currently, this demand is predominantly met through fossil fuel combustion [1]. Decarbonising industrial heat production is therefore critical to achieving European climate targets, and increasing the penetration of renewable heat sources offers a promising pathway forward.

Solar thermal (ST) collectors can efficiently convert solar radiation into low- to medium-temperature heat suitable for many industrial applications [2]. However, a fundamental challenge arises from the temporal mismatch between the availability of solar thermal energy and industrial heat demand. Solar radiation follows predictable daily and seasonal patterns, whereas industrial processes often exhibit different temporal profiles or require heat during periods of low solar availability. This mismatch can significantly limit the fraction of renewable heat that can be directly utilised, potentially undermining the economic viability of solar thermal installations.

Beyond solar thermal integration, industrial processes themselves exhibit fluctuations in heat demand and in the availability of hot process streams over time. These variations create opportunities to capture and store surplus process heat during periods of excess and to recover it during periods of heat deficit. Thermal energy storage systems can address both challenges simultaneously: storing excess solar thermal energy when production exceeds demand and capturing surplus process heat for later use when additional heat is needed.

Efficiently integrating heat sources, storage systems, and process demands in an industrial site requires sophisticated process integration methods. Heat exchanger network synthesis (HENS) provides a systematic framework for designing optimal heat exchanger layouts that minimise utility consumption while meeting all

process heating and cooling requirements. When dealing with time-varying conditions—whether from fluctuating solar production, variable process schedules, or both—multiperiod HENS becomes necessary to capture the full complexity of the system and optimise across all operational scenarios.

Previous work has explored the integration of thermal energy storage into HENS problems. Walmsley et al. [3] investigated the integration of industrial solar and gaseous waste heat into heat recovery loops using both constant and variable temperature storage. Oliveira et al. [4] addressed process integration in a multiperiod sugarcane biorefinery, demonstrating the importance of capturing temporal variations in process conditions. Olsen et al. [5] developed a methodology for thermal energy storage integration based on pinch analysis principles. However, efficient optimisation methods that can simultaneously determine optimal storage parameters—temperature, size, and initial charge—within multiperiod HENS frameworks remain an active area of research.

This work presents a novel analytical optimisation framework for integrating ideal heat storage systems within multiperiod HENS. By using physical insights from pinch analysis principles, we derive closed-form expressions and efficient solution procedures for determining optimal storage temperature and initial charge. We distinguish between infinite-size and finite-size storage cases, showing that the infinite-size formulation offers significant computational advantages and can serve as a screening tool before considering size constraints. The methodology is implemented within COMPHENS [5], an open-source HENS optimisation framework, enabling its application to industrial-scale problems.

We validate the approach using real operational data from a lubricant manufacturing plant in the Mediterranean region, considering solar thermal collector integration. The results quantify the relationship between storage size and solar thermal utilisation, revealing diminishing returns as storage capacity increases and identifying the minimum storage size required for complete renewable heat utilisation.

# MODELLING

## Heat exchanger network synthesis

The HENS modelling framework utilised in this work is the COMPHENS framework [6], which builds upon the seqHENS framework [7], [8]. This splits the problem into four subproblems: first, the minimum utilities required are determined; second, the minimum number of heat exchangers is determined; third, the optimal heat-load distributions are determined; and finally, the network generation and optimisation are performed. In this work, we focus primarily on the first subproblem, implementing heat storage as a preprocessing step to minimise utility costs. To be able to store and use the heat this also means that we will consider multiperiod HENS problems, where the heat storage links these periods together.

## Heat storage

To derive an analytical approach to the heat storage implementation we consider an ideal heat storage, i.e. no losses and constant temperature. In addition, we assume that we have a cyclic process so the heat storage needs to start and end with the same charge level. In practice this means that there is no accumulation or depletion of heat over the cycle and that the heat storage is sized perfectly. It also means that the plant operates at consistent repeating cycles, e.g. over a day or a week.

### Storage temperature

To determine the optimal temperature of the heat storage we use Pinch Analysis. A priori we know that it is only useful to charge the storage below the lowest pinch in each period and it is only useful to discharge it above the largest pinch in each period, otherwise we would need to increase the usage of hot or cold utilities in the period, either to directly charge the storage or to cover the extra heat or cold not available at the correct temperature somewhere else in the process. This already limits the storage temperature to be below the maximum pinch and above the minimum pinch of the overall problem. Furthermore, the optimal use of the heat storage is to charge and discharge it as much as possible over the periods to minimize the utility consumption. To determine the maximum chargeable or dischargeable heat in a single period at a given temperature, we use the Grand Composite Curve (GCC). The maximum chargeable heat is the heat that can be consumed to heat an extra cold stream at that temperature and create an extra pinch point at or below the given temperature (shifted up by $\Delta T_{min}/2$). Similarly, the maximum heat that can be discharged would be the maximum heat that could be delivered from an extra hot stream and create a single pinch point at or above the given temperature (shifted down by $\Delta T_{min}/2$).

By evaluating the maximum chargeable and dischargeable heat as functions of temperature for each period, we can identify the temperature at which these quantities are balanced across all periods. This balance point minimises utility consumption by maximising storage utilisation. For an infinite-size storage, this optimal temperature, $T_{storage}$, is found by solving:

$$T_{storage} = \operatorname*{root}_{T} \sum_{p} Q_p(T), \tag{1}$$

where $T$ is the storage temperature, $p$ denotes the period and $Q_p$ the heat transferred to or from the storage in period $p$ subject to the constraints outlined above, with charging of the storage having a positive sign and discharging having a negative sign. This equation finds the temperature where the net heat transferred to/from

storage over all periods equals zero, ensuring cyclic operation while maximizing the absolute heat transfer.

To derive Equation (1) we have assumed that the heat storage has infinite size and heat capacity, so it is always able to store the heat provided and deliver the heat requested in each period. The infinite storage assumption simplifies the problem significantly, as we only need to find where net heat transfer equals zero. However, for a finite storage, the optimization becomes more complex. In each period, charging is limited by the available capacity (maximum charge minus current charge), and discharging is limited by the current stored energy. This transforms the problem from finding a root to maximizing the total heat transferred subject to the cyclic constraint:

$$T_{storage} = \underset{T}{\operatorname{argmax}} \sum_p |Q_p(T)| \;\; s.t. \sum_p Q_p(T) = 0. \tag{2}$$

### Initial storage charge and storage size

Similarly to the storage temperature the optimal initial charge is the one which maximizes the amount of heat that is transferred between the different periods, and therefore that is charged and discharged from the storage, while making sure that the start and end charge of the storage are the same and no extra utilities are used in any period. If the storage starts at a charge that is large enough such that it never reaches 0,

$$\min_p Q_p > 0, \tag{3}$$

then increasing the initial storage charge by $a$ would just lift the charge in all periods by $a$. Doing this for a second initial charge $b$ which also respects Equation (3) one can easily to find the initial charge, $Q_i$, where the storage just reaches 0 charge once at the end of a single period by linear extrapolation. Ensuring Equation (3) is respected can also easily be done by making sure $a$ and $b$ are larger than the maximum of the total cold and hot utilities when no heat storage is present. Equivalently, one could find the minimum initial charge where the storage is never fully emptied, but has an infinitesimal charge left at the minimum:

$$Q_i = \min_{q_i} q_i \;\; s.t. \min_p Q_p(q_i) > 0. \tag{4}$$

This represents the critical initial charge: any lower and the storage becomes fully depleted in at least one period (limiting heat transfer), any higher and the storage simply operates at an elevated baseline without transferring additional heat, essentially moving away from optimum. From the optimal initial charge, we can also find the optimal size of the storage, $Q_{storage}$, which just equals the maximum stored after any period:

$$Q_{storage} = \max_p Q_p. \tag{5}$$

If we again limit the storage to a finite size we end up with an optimization problem, this time finding the initial charge, $Q_i$, that maximizes the heat transferred:

$$Q_i = \underset{q_i}{\operatorname{argmax}} \sum_p |Q_p(\mathrm{q}_i)| \;\; s.t. \sum_p Q_p(q_i) = 0. \tag{6}$$

However, if the size of the storage is greater than the optimal size from Equation (5) we can instead use Equation (4) to find the initial charge. As these two equations can be solved simultaneously with only two evaluations, they are much faster than the optimization problem in Equation (6) and it will typically be worth checking them first even for a finite storage. In addition, if the storage temperature is not specified Equation (1) must be solved together with Equation (4) for an infinite storage, which is much faster than solving Equation (2) together with Equation (6) for a finite storage, increasing the speed advantage of checking the infinite storage first.

### HENS integration

To add the heat storage to the HENS framework, we need to find both the storage temperature and the initial charge, given either an infinite or a finite storage. These depend on one another and can be solved simultaneously or sequentially. As finding the initial storage charge is very easy for the infinite-size storage, we do not want to redo this, so the storage temperature is solved each time for a given initial storage charge, both for the infinite and finite storage size.

With the heat storage temperature and initial charge we can find the heat transferred in each period. Based on the heat transferred we add a stream to each period of the HENS problem, with a hot stream being added when the storage is discharging heat and a cold stream being added when the storage is charging, with their heat capacity flow rate being dependent on the heat and duration of the period.

## CASE

The case considers a chemical plant producing lubricants, located in the mediterranean region. The plant operates for 16 hours, five days a week. The heat demand consists of heating base oils and additives before they are pumped from storage tanks to mixing tanks, heating the mixing tanks, heating for an intermediate drum storage, and space heating. These heat demands are all relatively low temperature, and with little cooling demand, no internal heat exchange is currently in place. Currently, the heat demand of the plant is covered by a hot oil loop which is heated centrally by a gas boiler and then delivers the heat through several separate loops. The plant is looking into building solar thermal collectors to cover some of the heat demand and reduce the usage of the natural gas boiler.

To get an accurate picture of the time dependency of the heat demand a month-long measurement

campaign was performed and combined with operational data from the plant. The heat produced from the solar thermal collectors were modelled on an hourly basis and averaged into a morning, midday and afternoon production giving three periods of different heat production which was assumed to be the same each day. As the plant is not operational on weekends the solar thermal collectors were assumed to be defocused at this time and the heat storage could therefore not be charged on the weekends. This lead to a total heat production of 18.9 MWh from the solar thermal collectors over the period investigated.

The heat demand of the site and the heat production of the solar thermal collectors were used to optimize the solar thermal heat usage, and due to the large numbers of consumers with intermittent heat demand it was decided that the solar thermal heat would be connected to the existing hot oil loop alongside the gas boiler. To best utilise the solar thermal energy a heat storage is also required with the required heat storage capacity for this plant being investigated.

## RESULTS

To investigate the impact of the heat storage on the amount of solar thermal energy used, the heat storage was optimised for varying sizes using the method described in the Methodology section. The resulting fraction of solar thermal heat utilised is shown in Figure 1. As expected, we see that by introducing the storage, we increase the fraction of the solar thermal heat that can be utilised. This increase is also nonlinear, with the gain in heat usage largest for small storages and flattening out for larger storages. For instance, the increase is greater from no storage to 50 kWh than from 50 kWh to 100 kWh, and this increase is again larger than the increase from 500 kWh to 750 kWh. This is because, for a small storage, increasing the size slightly allows it to store and discharge additional heat over multiple periods, whereas increasing the size of an already large storage only allows some additional heat to be transferred between a few periods. At the extreme is when all the solar thermal is utilised, as we see for a storage size of 1040 kWh, where increasing the size further would not increase the heat utilisation since there is no more heat to transfer between periods.

While a storage size of 1040 kWh achieves 100% solar thermal utilisation, the economic optimum may lie at a smaller capacity. The relationship between storage size and utilisation suggests strong diminishing returns: a 250 kWh storage (24% of the maximum size) captures over 90% of available solar thermal energy, whereas a 500 kWh storage (48% of the maximum size) captures approximately 95%. From a techno-economic perspective, the marginal benefit of the last 10% of utilisation must be weighed against the capital and operating costs of doubling storage capacity from 500 to 1000+ kWh. Additionally, the ratio of storage capacity to total heat production (1040 kWh / 18, 900 kWh ≈ 5.5%) indicates relatively efficient storage sizing, though this ratio would vary with different operational patterns and solar resource availability.

However, determining the optimal plant size would require a techno-economic analysis to evaluate the trade-off between increased heat utilisation and increased storage costs as size increases, which is outside the scope of this study.

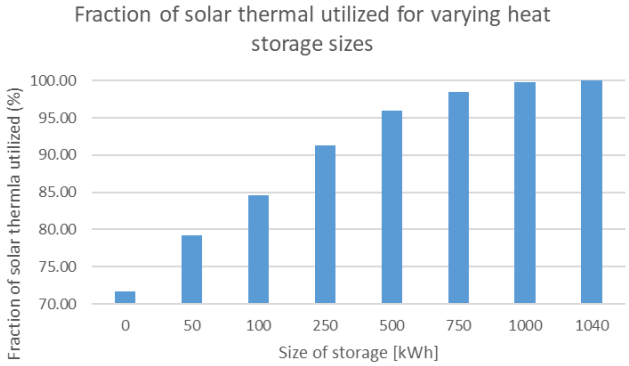

**Figure** 1. Fraction of solar thermal heat utilized as a function of the size of the heat storage.

## CONCLUSION

A model for an ideal heat storage suitable for implementation in multiperiod HENS frameworks has been developed in this work. Based on pinch analysis principles, we have shown efficient methods for optimising both the temperature and initial charge of the storage, with particular emphasis on the infinite-size case, which requires only solving a root-finding problem and performing linear extrapolation, compared to two optimisation problems for finite-size storage. This computational advantage makes the infinite-size approach valuable as a screening tool to establish upper bounds on storage benefits.

Applying this methodology to optimise solar thermal integration at a lubricant manufacturing plant demonstrates that heat storage significantly enhances renewable energy utilisation, with diminishing returns as storage size increases. A relatively modest storage of 250 kWh achieves over 90% solar thermal utilisation, while complete utilisation requires 1040 kWh—representing only 5.5% of the total heat production over the analysed period. This efficient storage-to-production ratio suggests that well-designed thermal storage can enable high solar thermal penetration in industrial applications with manageable storage requirements.

Future work should extend this methodology to non-ideal storage systems that account for heat losses and

temperature variations, and conduct comprehensive techno-economic analyses to identify the economically optimal storage sizing, considering both capital costs and renewable energy benefits.

## ABSTRACT

Human activities have already transgressed several planetary boundaries, yet energy system models remain largely focused on greenhouse gas mitigation, reflecting their original purpose of addressing climate change. Recent integrations of Planetary boundary-based Life Cycle Assessment into Energy System Optimisation Models show that even cost-optimal low-carbon pathways systematically violate multiple planetary boundaries, indicating that supply-side decarbonisation alone is insufficient for absolute environmental sustainability. At a 2050 horizon, where energy supply is largely decarbonised and technologies are assumed mature, further impact reductions through techno-economic optimisation become limited, positioning final energy demand as a key remaining lever for restoring feasibility under planetary constraints. To address this gap, we extend an Energy System Optimisation framework coupled with a Planetary Boundary framework by explicitly treating final energy demand as a decision variable and exploring energy sufficiency configurations within a multi-objective formulation minimising system cost and environmental pressures. The national-scale EnergyScopeTD model is coupled with the RHEIA uncertainty analysis framework to propagate uncertainty in final energy demands and to identify demand-side drivers through global sensitivity analysis. Applied to Belgium, the results show that individual mobility demand is the dominant driver of environmental pressures across multiple planetary boundaries, with consistently higher influence than other end-use demands. While large-scale vehicle fleet electrification substantially reduces climate impacts, it simultaneously shifts pressures toward other environmental dimensions, indicating that technological substitution alone, even combined with moderate sufficiency, is insufficient to achieve absolute sustainability. Overall, the results confirm that energy sufficiency, particularly in mobility, is necessary for operating energy systems within planetary limits, and that anchoring system design in absolute sustainability thresholds provides a robust basis for prioritising demand-side mitigation strategies.

## INTRODUCTION

### Background

With seven out of nine planetary boundaries already transgressed, ensuring that human activities remain within the Earth's safe operating space has become a central challenge for sustainability science [1, 2]. Although climate change has historically dominated environmental policy and energy planning, it is now well established that a narrow focus on greenhouse gas mitigation risks shifting environmental pressures toward other critical Earth system processes, including biodiversity

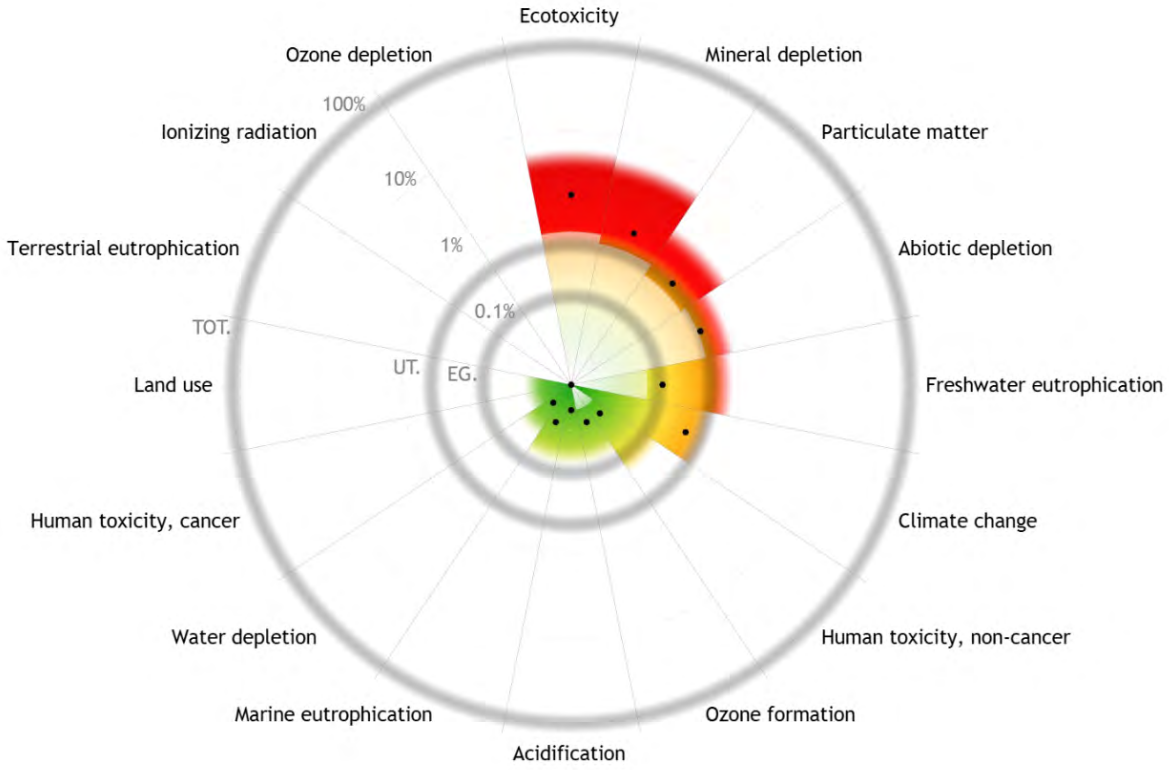

**Figure 1.** Each LCA indicator obtained from the belgian energy system designs satisfying the constraint of 20 Mt CO2,eq emissions in 2045, aligned with the work of Van den Oever [19], and a total system cost below 130% of the optimal-cost solution can vary within a solution space represented by the strongly colored areas. The indicator values corresponding to the optimal-cost solution are shown as black dots. Three boundaries are displayed to facilitate interpretation: moving from the center outward, the first corresponds to the egalitarian sharing principle (EG.), the second to the utilitarian sharing principle (UT.), and the outermost boundary represents the total PB (at 100%), as reported in Table 1. Because the PBs and the associated risk of exceeding them are uncertain, the boundaries are deliberately represented as blurred rather than as sharp, well-defined lines.

loss, freshwater degradation, and material depletion [3, 4]. Achieving climate neutrality alone is therefore insufficient to guarantee a long-term viable Earth system capable of sustaining ecosystems, essential resources, and human well-being [5].

Energy systems are central to this challenge. As energy transitions progress toward low carbon configurations dominated by renewable resources, electrification, and synthetic fuels, the importance of construction phase relative to the full life cycle impacts increases [6, 7]. In such systems, a growing share of environmental pressures originates from material extraction, infrastructure deployment, and upstream supply chains rather than from direct operational emissions [8]. This shift implies that future energy system designs must be assessed not only against climate targets but also against a broader set of environmental constraints reflecting absolute ecological limits.

In response, recent research has proposed integrating life cycle assessment and the planetary boundaries framework into energy system optimisation models, enabling the evaluation of energy transitions against absolute environmental thresholds rather than relative impact reductions [9, 10]. Building on this approach, a methodological framework was recently developed to embed prospective life cycle assessment and planetary boundary-based normalisation directly into national scale energy system optimisation. Applied to a Belgian case study, this framework showed that even under stringent carbon constraints, energy system configurations systematically violate several planetary boundaries [9] (shown in Figure 1).

These results point to a fundamental limitation of supply focused energy system optimisation and raise a critical question for energy system planning. If advanced, cost efficient, and climate compatible energy systems remain environmentally unsustainable when assessed against planetary boundaries, where does the remaining leverage for action lie?

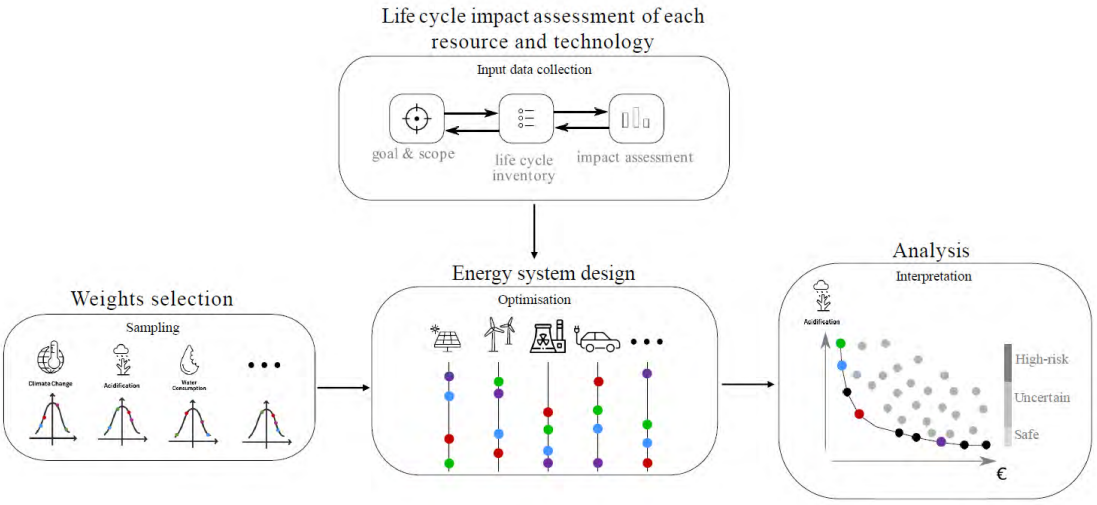

**Figure 2.** Schematic overview of the integrated modeling framework combining life cycle assessment and planetary boundary analysis with energy system optimisation. The process begins with comprehensive input data collection for the energy system, including technology performance, resource availability, and a prospective life cycle inventory (LCI) for all technologies and fuels. These data feed into the energy system design optimisation model (EnergyScopeTD), which has been augmented with life cycle impact assessment capabilities. Within the model, the LCI data are converted into environmental impacts across multiple planetary boundary (PB) indicators (e.g. climate change, land use, water use) and embedded into the optimisation structure. The model then performs a multi-criteria optimisation that jointly minimises the total system cost and a portfolio of environmental impact indicators, with each impact normalised by its PB threshold to ensure comparability. To explore trade-offs between cost and environmental objectives, a sampling of weight combinations is used, generating a broad Pareto front of optimised solutions rather than a single optimum.

## Literature review

Energy system optimisation models have long been used to support strategic energy planning by identifying cost optimal pathways to reduce greenhouse gas emissions and meet climate targets [11, 12]. These models have traditionally emphasised supply side transformations, such as fuel switching, electrification, and the deployment of low carbon technologies, while treating final energy demand as an exogenous and fixed input. Within this paradigm, environmental performance is most often assessed through operational carbon emissions, reinforcing a narrow focus on climate mitigation that has been described as carbon tunnel vision [3, 4].

In parallel, life cycle assessment has been widely applied to quantify environmental impacts across multiple categories and life cycle stages, highlighting the risk of burden shifting when focusing on a single indicator. The integration of life cycle assessment into energy system models has substantially improved the environmental realism of scenario analysis by accounting for upstream supply chains and infrastructure related impacts [13]. However, conventional life cycle assessment remains a relative assessment tool and does not indicate whether a system is environmentally sustainable in absolute terms. The planetary boundaries framework addresses this limitation by defining scientifically grounded thresholds for key Earth system processes, providing an absolute reference against which environmental pressures can be evaluated [14, 15]. Recent studies coupling planetary boundaries with life cycle assessment have shown that many energy pathways compatible with climate targets still exceed planetary boundaries for indicators such as freshwater eutrophication, particulate matter formation, or material use [9]. Yet, the explicit integration of planetary boundaries into large scale energy system optimisation remains methodologically challenging due to issues related to indicator heterogeneity, normalisation, and burden sharing.

To address these challenges, recent methodological advances have introduced multi objective optimisation and goal programming formulations to jointly consider system cost and multiple environmental objectives, combined with systematic exploration of near optimal solution spaces [9, 10] (shown in Figure 2). Existing analyses of optimised energy systems provide valuable insights into technology trade-offs and system designs. However, these analyses almost systematically assume fixed final energy demand, thereby restricting the exploration of mitigation pathways to supply-side resources and technologies.

## Research gap and contribution

Planetary boundary informed energy system optimisation consistently reveals a structural limitation. When multiple planetary boundaries are considered alongside climate targets, cost optimal designs systematically violate several boundaries, and reformulating optimisation objectives does not resolve this issue due to persistent antagonisms between impact categories [9]. Under such conditions, no feasible solution satisfies cost constraints, climate targets, and planetary boundaries within existing optimisation formulations.

Despite these findings, most energy system optimisation studies continue to treat final energy demand as fixed, focusing mitigation efforts almost exclusively on supply side technologies and resources. As a result, the potential of demand-side changes to alleviate environmental pressures under absolute sustainability constraints remains largely unexplored within quantitative energy system optimisation.

This paper addresses this gap by explicitly integrating demand side sufficiency into planetary boundary constrained energy system optimisation. By coupling energy system optimisation with uncertainty propagation and sensitivity analysis, the approach quantifies the relative influence of different demand reduction strategies on environmental pressures, enabling the identification of priority demand side levers without making normative assumptions on social acceptability.

# METHODOLOGY

## Overview of the ESOM–LCA–PB framework

This work builds upon the ESTD-PB modelling framework, which integrates a national-scale bottom-up energy system optimisation model (ESOM) with prospective life cycle assessment (LCA) and the planetary boundaries (PB) framework. The full mathematical formulation and data assumptions are documented in previous publications [9, 12]; the present section recalls only the elements required to understand the analysis introduced in this paper.

The model determines the optimal investment and operation of energy conversion, storage, and supply technologies required to satisfy exogenously defined final energy service demands at minimum total annualised system cost. The optimisation problem is formulated as a linear program with the following objective function:

$$\min \; C_{tot} = \sum_{j \in TECH} \left( \tau_j \, C_j^{inv} + C_j^{maint} \right) + \sum_{i \in RES} C_i^{op}$$

where $C_j^{inv}, C_j^{maint}$, and $C_i^{op}$ denote investment, maintenance, and operational costs, respectively, and $\tau_j$ is the annualisation factor associated with technology lifetime and discount rate. The optimisation is subject to energy balance, capacity, operational, resource availability, and policy constraints, including a climate constraint.

Environmental impacts are assessed using a cradle-to-grave life cycle assessment consistent with prospective background assumptions. For a given environmental impact category $k$, total system impacts are computed as the sum of impacts associated with resource extraction/prodution, technology construction, and system operation:

$$LCA_{tot}^{k} = \sum_{i \in RES} LC\,A_{res}^{k}(i) + \sum_{j \in TECH} \frac{LCA_{constr}^{k}(j)}{L_j} + \sum_{j \in TECH} LC\,A_{op}^{k}(j)$$

To enable an absolute interpretation of environmental performance, life-cycle impacts are normalised using the planetary boundaries framework:

$$f_{PB}^{k} = \frac{LCA_{tot}^{k}}{PB^{k}}$$

where $PB^{k}$ denotes the global safe operating limit associated with Earth-system process $k$.

## Uncertainty propagation and sensitivity analysis

To propagate uncertainty in final energy service demands through the integrated ESOM–LCA–PB framework, this study applies the open-source Python framework RHEIA for uncertainty propagation and global sensitivity analysis [18]. The methodology is used here without modification and is coupled to the energy system model to analyse the effects of demand variability on environmental indicators.

Selected final energy service demands are treated as uncertain input parameters, define as uniform distribution ranging between 70% and 100% of the nominal demand value, while all other model inputs are kept deterministic. These demands are characterised by prescribed probability distributions around a reference level and define a random input vector $\boldsymbol{\xi} = (\xi_1, \ldots, \xi_d)$. For each realisation of $\boldsymbol{\xi}$, sampled via quasi-random Sobol sampling, the energy system optimisation problem is solved, and the resulting life-cycle impacts are computed and normalised using the planetary boundaries framework.

Given the computational cost of repeatedly solving a national-scale energy system optimisation model, uncertainty propagation is performed using Polynomial Chaos Expansion (PCE) surrogate modelling, as implemented in RHEIA. For each environmental indicator of interest, the model response is approximated by a truncated polynomial expansion:

$$\hat{Y}(\boldsymbol{\xi}) = \sum_{\alpha \in \mathcal{A}_{d,p}} u_\alpha \, \Psi_\alpha(\boldsymbol{\xi})$$

where $\Psi_\alpha$ are multivariate orthogonal polynomials consistent with the input distributions, $u_\alpha$are regression coefficients, and $\mathcal{A}_{d,p}$ denotes the set of multi-indices with total degree $|\alpha| \leq p$.

The coefficients $u_\alpha$ are estimated by regression using a limited number of model evaluations generated through space-filling sampling. The polynomial degree is increased until a predefined accuracy criterion is met, as assessed through leave-one-out cross-validation.

Once constructed, the PCE surrogate enables efficient evaluation of output statistics and supports variance-based global sensitivity analysis. For a given output $Y$, the total variance $\mathrm{Var}(Y)$ is decomposed into contributions associated with individual uncertain demands and their interactions. The first-order Sobol sensitivity index associated with demand $i$is defined as:

$$S_i = \frac{\mathrm{Var}_{\xi_i}(\mathbb{E}[Y \mid \xi_i])}{\mathrm{Var}(Y)}$$

and quantifies the contribution of variations in $\xi_i$ to the total output variance. Total Sobol indices are also computed to capture higher-order interaction effects. All sensitivity indices are derived analytically from the PCE coefficients.

## RESULTS AND DISCUSSION

### Case study description

Based on the results presented in Figure 1, the analysis focuses on three environmental indicators identified as the most critical in the reference system: ecotoxicity, particulate matter formation, and freshwater eutrophication. Indicators related to mineral and abiotic depletion are not considered in this case study, as they reflect constraints on resource availability and long-term human activity sustainability rather than direct pressures on environmental systems, which constitute the core focus of this work. The analysis is conducted in two successive stages. First, a global sensitivity analysis is performed to rank final energy service demands according to their influence on each selected environmental indicator. To this end, a second-order Polynomial Chaos Expansion is constructed over the full set of final energy service demands, enabling the computation of Sobol sensitivity indices.

For presentation and synthesis purposes, Sobol indices are aggregated across the selected environmental indicators and across individual energy service categories. The results are reported as box plots, where each box represents the distribution of Sobol indices obtained for a given demand type, pooling the indices computed for all considered environmental indicators and corresponding demand components. In a second step, targeted demand reduction scenarios are defined based on the outcomes of the sensitivity analysis.

### Demand Sobol's indices

The sensitivity analysis shows that variations in mobility demand are the dominant driver of environmental impacts in the energy system.

Across all considered environmental indicators, mobility demand consistently exhibits the highest influence, independent of the specific critical planetary boundary considered. This dominance is reflected in the limited dispersion of Sobol index values associated with mobility demand compared to other final energy service categories, indicating a systematic effect.

These results are consistent with previous findings by Gauthier Limpens [12], who identified individual mobility, particularly through the renewal of the Belgian vehicle fleet, as the largest cost component of the energy transition. Together, these findings suggest a potential alignment between economic and environmental objectives when defining transition pathways toward a more sustainable mobility system. This conclusion is further supported by previous work, who reported a strong covariance between electric vehicle deployment and critical environmental indicators [9]. The present analysis extends this evidence by demonstrating that such relationships are embedded in the global sensitivity structure of the model, with mobility demand emerging as the primary demand-side lever affecting both environmental pressures and total system cost.

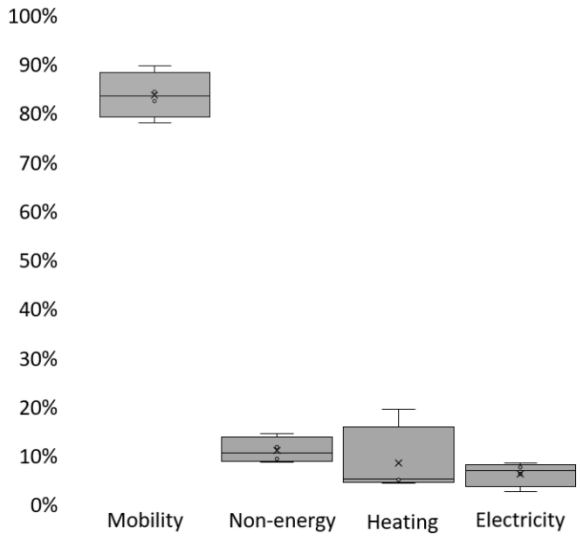

**Figure 3.** Distribution of total Sobol sensitivity indices associated with final energy demand categories across all environmental indicators.

### Impact of end-use demand reduction

Building on the Sobol-based sensitivity analysis, mobility demand reduction emerges as the most impactful lever among the considered demand-side mitigation options. To explore this result further, the environmental

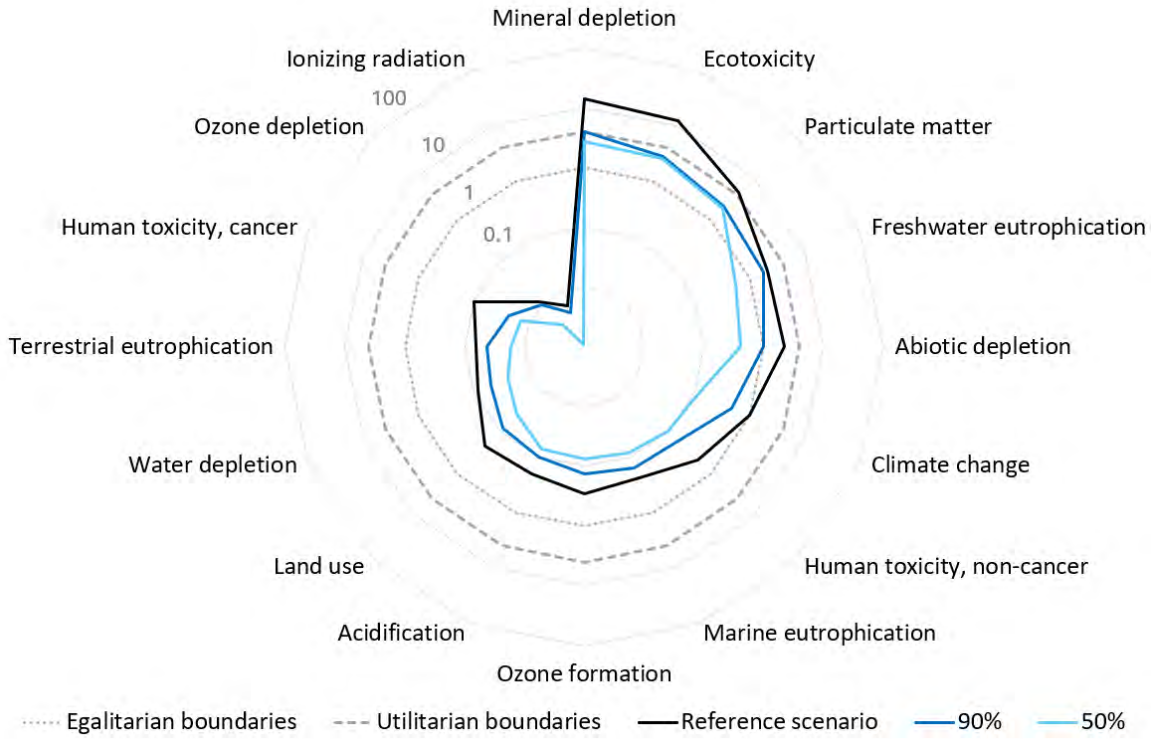

**Figure 4.** Each Life Cycle Assessment (LCA) indicator is shown for Belgian energy system configurations satisfying a constraint of 20 Mt $CO_2$-eq emissions in 2045, consistent with previous work [19], and a total system cost below 130% of the cost-optimal solution. The cost-optimal solution is indicated by the black line, while the 10% and 50% mobility demand reduction scenarios are shown in dark blue and light blue, respectively. Three planetary boundary thresholds are displayed to facilitate interpretation: from the center outward, the innermost boundary corresponds to the egalitarian sharing principle (EG., dotted), the intermediate boundary to the utilitarian sharing principle (UT., dashed), and the outermost boundary represents the full planetary boundary (100%).

implications of stepwise mobility demand reductions are assessed, considering two reduction levels (−10% and −50%) within the studied energy system. At this stage, neither the social acceptability nor the economic feasibility of such reductions is assessed. The analysis exclusively focuses on their effect on absolute environmental sustainability, with the objective of providing a quantified and robust benchmark against planetary boundaries that can later inform socially grounded sufficiency scenarios.

At the first reduction level (−10%), a system configuration complying with all planetary boundaries is achieved under the most permissive sharing principle, the utilitarian allocation, which is based on gross domestic product, favors the Belgian energy system in a global context by allowing differentiated environmental space across countries [9]. When sustainability is instead evaluated using a more constraining population-based sharing principle, the egalitarian sharing principle, three planetary boundaries remain exceeded: ecotoxicity, particulate matter formation and freshwater eutrophication. As noted previously, mineral and abiotic depletion indicators are excluded from the planetary boundary assessment, as they reflect constraints on the continuity of human activities rather than environmental system thresholds. At the second reduction level (-50%), two planetary boundaries remain exceeded under the population-based sharing principle, with only marginal improvements compared to the first reduction level.

## DISCUSSION

The sensitivity analysis shows that mobility demand is the main driver of environmental impacts in the energy system across all planetary boundaries at risk. Its Sobol indices are consistently higher than those of other end-use demands and exhibit limited dispersion, indicating a dominant and systematic influence that is observed across the different critical environmental pressures considered. These findings are consistent with previous studies highlighting individual mobility as a key challenge of the energy transition, both economically and environmentally. While earlier work emphasized cost dominance

and correlations with environmental indicators, the present analysis shows that mobility demand structurally drives environmental pressures at the system level, suggesting an alignment between environmental sustainability and economic efficiency in mobility-oriented strategies. The demand reduction analysis shows that moderate mobility reductions substantially lower environmental pressures and enable planetary-boundary compliance under permissive allocation rules. However, under stricter population-based principles, several boundaries remain exceeded, indicating that technological substitution alone, even with modest sufficiency, is insufficient. Larger reductions further reduce impacts but show diminishing returns for the most constraining boundaries. Overall, mobility demand reduction emerges as a necessary but not sufficient condition for achieving absolute sustainability, requiring complementary demand-side measures in other sectors alongside targeted technological and structural interventions.

## ABSTRACT

The increasing deployment of variable renewable energy (VRE) is essential for achieving a sustainable society; however, its inherent variability poses challenges for maintaining a stable electricity supply. Vehicle-to-grid (V2G) technology enables bidirectional electricity exchange between electric vehicles (EVs) and the power grid and can enhance the utilization of renewable electricity by charging EVs during periods of VRE output curtailment. This study developed a regional V2G system model and evaluated its potential through energy flow simulations and life cycle assessment (LCA). The model explicitly considered hourly operation schedules of individual EVs, the spatial distribution of V2G infrastructure, and minimum output constraints of thermal power generation. The number of EVs is assumed to increase to up to 10, 000 units. In the energy flow simulations, EV charging and discharging were calculated on an hourly basis over one year. LCA was conducted to assess greenhouse gas (GHG) emissions of regional V2G system. Fuel consumption, VRE utilization, and GHG emissions were quantitatively evaluated. The results demonstrated that regional V2G systems could reduce VRE output curtailment and GHG emissions and, under certain conditions, could also reduce thermal power generation. The developed model enabled a quantitative evaluation of the potential of regional V2G systems. For practical deployment, integrated regional platforms would be required to coordinate electricity flows and to manage financial transactions. By assessing the potential of regional V2G systems, this study would provide valuable insights to support the design and implementation of environmentally sustainable V2G systems.

**Keywords**: Electric vehicle, Variable renewable energy, Output curtailment, Energy flow simulation

## INTRODUCTION

To achieve a sustainable society, variable renewable energy (VRE) is being increasingly installed. However, the inherent variability of VRE makes it challenging to maintain a stable electricity supply. In some regions, VRE generation is curtailed when electricity generation exceeds demand. Electric vehicles (EVs), which are equipped with batteries, offer an opportunity to address this issue: charging EVs during periods of VRE output curtailment can enhance the effective utilization of renewable electricity. Furthermore, vehicle-to-grid (V2G) technology enables bidirectional electricity exchange between EVs and the power grid. Previous studies have shown that the deployment of V2G can reduce greenhouse gas (GHG) emissions, energy consumption and cost at national level [1].

However, the environmental impacts of introducing new energy supply technologies depend on the regional conditions, even for the same technology. Thus, energy systems should be designed considering the regional characteristics [2]. Tanegashima, an island in southern Japan, was the first region in Japan to experience VRE output curtailment. A previous study suggests that V2G deployment in Tanegashima has the potential to reduce GHG emissions [3]. However, that study does not consider the locations of V2G installation or the operational schedules of individual EVs.

In this study, we develop a regional V2G system model and evaluate its potential using energy flow simulations and life cycle assessment (LCA). A regional V2G system is defined as an energy system that integrates EVs and V2G technology within a target region. To evaluate the potential of the system, fuel consumption, VRE utilization, and GHG emissions are quantitatively evaluated under cases with and without EVs and V2G. The proposed model is applied to Tanegashima in Japan.

The model explicitly considers (i) hourly operation schedules of individual EVs, (ii) the spatial distribution of V2H/V2B infrastructure, and (iii) minimum output constraints of thermal power generation. By integrating dynamic energy flow simulation with LCA, the proposed approach enables a quantitative evaluation of the environmental performance of regional V2G systems.

## MATERIALS AND METHODS

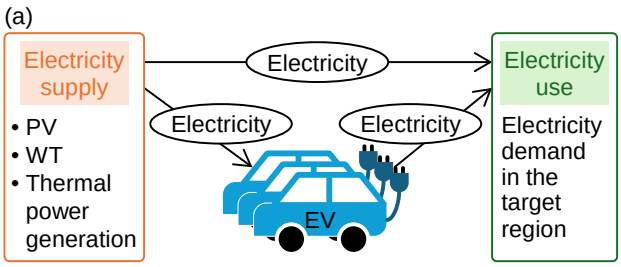
### Model of Regional V2G system

This study constructed a model of a regional V2G system in which EVs and V2G technologies are deployed within a target region. To evaluate the potential of V2G, a large number of vehicle-to-home (V2H) and vehicle-to-building (V2B) systems were assumed to be installed. **Figure 1** (a) shows the concept of the regional V2G system constructed in this study. EVs were assumed to replace internal combustion engine vehicles (ICEVs) and to utilize electricity derived from VRE as much as possible.

Electricity supply in the model consisted of photovoltaic (PV) and wind turbine (WT) as VRE sources and thermal power generation as shown in **Figure 1** (a). Thermal power generation was used to balance electricity demand and supply. Total electricity consumption was estimated based on electricity demand in the target region. The minimum output of thermal power generation is assumed to be unchanged before and after EV deployment. EVs were assumed to charge proactively during periods of VRE output curtailment and to discharge electricity to the power grid via V2H/V2B systems when VRE generation was insufficient.

The model is based on several simplifying assumptions. All EVs are assumed to be use for commuter and to return home every night and to be connected to V2H/V2B systems whenever available. Electricity prices and user-driven charging behavior are not explicitly considered.

Individual vehicle operation schedules and the commuting distances between homes and workplaces were defined. The operation schedules were assumed to be identical for EVs and ICEVs. **Figure 1** (b) shows the vehicle operation schedule and the list of installed equipment. On workdays, individuals were assumed to work from 9:00 to 17:00, with typical driving time at 8:00 and at 18:00. Some individuals randomly worked earlier or later than these hours and may stop at other locations, such as shops, on their way home. Each individual was assumed to have 20 days of paid leave per year, with the dates assigned randomly. On weekends and paid leaves, individuals were assumed either to stay at home (i.e., not drive) or to visit one or two shops. Destinations, departure times, and return times on these days were determined randomly.



Installed equipment

| Home | Office | Shop |
|---|---|---|
| Standard charger | Standard charger | Fast charger |
| V2H | V2B | Nothing |

**Figure 1**. (a) Concept of regional V2G system. (b) EV drive schedule and installed equipment list.

If an individual owned an EV, their home was assumed to be equipped with either standard EV charger or V2H system. The offices were similarly assumed to have either standard EV charger or V2B system, as shown in **Figure 1** (b). At shops visited after work or on holidays, the presence of EV fast chargers was assigned randomly. When EVs were parked at locations equipped with V2H or V2B systems, they were always assumed to be connected to those systems.

### Energy Flow Simulation

In the energy flow simulation, the amounts of EV charging and discharging were calculated on an hourly basis for one year. Based on these results, annual VRE output curtailment, EV electricity discharge to the power grid, electricity demand and thermal power generation were analyzed. Simulation cases were examined both with and without EVs and the V2G systems.

Electricity demand and supply must be balanced at all times to ensure stable grid operation; otherwise, disturbances in system frequency could compromise electricity supply. Before the introduction of EVs, the regional electricity demand at time $t$, $P^{\mathrm{use}}(t)$, was supplied by VRE-

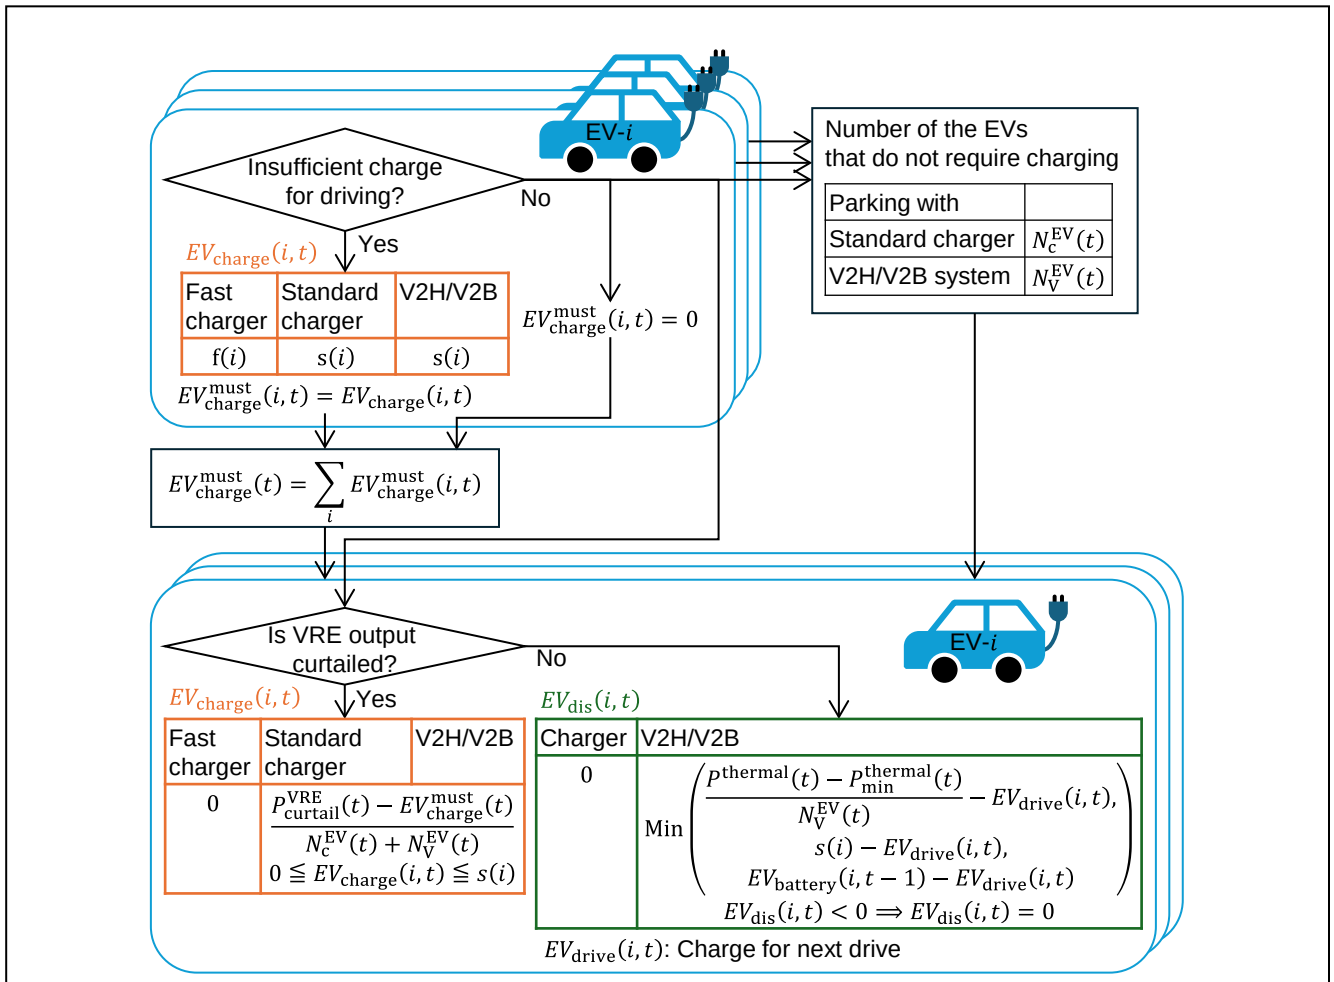


**Figure 2.** Procedure for determining the charge/discharge amount of EVs parked at the locations with chargers or V2H/V2B at time $t$. $f(i)$ and $s(i)$ represents charging speed of fast charger and standard charger, respectively.

based electricity, $P^{\mathrm{VRE}}(t)$, and thermal power generation, $P^{\mathrm{thermal}}(t)$ as expressed in Equation (1).

$$P^{\mathrm{use}}(t) \leqq P^{\mathrm{VRE}}(t) + P^{\mathrm{thermal}}(t) \quad (1)$$

In practice, left-hand and right-hand sides of Equation (1) are balanced. When VRE-based electricity generation was high, a portion of VRE electricity was curtailed because the output of thermal power plants could be reduced below a certain minimum level. The amount of VRE output curtailment, $P^{VRE}_{\mathrm{curtail}}(t)$, was calculated using Equation (2).

$$P^{VRE}_{\mathrm{curtail}}(t) = P^{\mathrm{VRE}}(t) + P^{\mathrm{thermal}}_{\mathrm{min}}(t) - P^{\mathrm{use}}(t) \quad (2)$$

Here, $P^{\mathrm{thermal}}_{\mathrm{min}}(t)$ represented the minimum output of thermal power generation. The minimum output was determined by various factors such as VRE electricity generation and electricity demand. In this study, $P^{\mathrm{thermal}}_{\mathrm{min}}(t)$ was assumed to remain before and after the installation of EVs. Similarly, baseline electricity demand excluding EV charging, $P^{\mathrm{use}}(t)$ was assumed to be the same regardless of EVs deployment.

Thermal power generation, $P^{\mathrm{thermal}}(t)$, was determined by the difference between the electricity demand and VRE electricity generation as shown in Equation (3). However, if this difference was smaller than minimum thermal output, thermal power generation was set equal to the minimum output:

$$P^{\mathrm{thermal}}(t) = \mathrm{Max}\left(P^{\mathrm{use}}(t) - P^{\mathrm{VRE}}(t), P^{\mathrm{thermal}}_{\mathrm{min}}(t)\right) \quad (3)$$

## Simulation for EV charging and discharging

EV charging and discharging behavior was mathematically expressed as follows. While driving, an EV discharges electricity in proportion to travel distance. When parked, an EV may charge or discharge depending on whether the parking location was equipped with a charger (including V2H/V2B systems) whether VRE electricity generation was being curtailed. The battery state of EV-$i$ at time $t$ was calculated using Equation (4).

$$EV_{\mathrm{battery}}(i,t) = EV_{\mathrm{battery}}(i,t-1) + EV_{\mathrm{charge}}(i,t) - EV_{\mathrm{dis}}(i,t) \quad (4)$$

Here, $EV_{\text{battery}}(i,t)$ represented the amount of electricity stored in the battery of EV-$i$ at time $t$, while $EV_{\text{charge}}(i,t)$ and $EV_{\text{dis}}(i,t)$ denoted the amount of charging and discharging at time $t$, respectively.

During driving, EV discharges according to the travel distance. When parked, the charging or discharging behavior was determined by whether the EV was parked at a location equipped with a charger or V2H/V2B system, and whether VRE output curtailment occurred at that time. If an EV was parked at a location without a charger or V2H/V2B, no charging and discharging occurs. When an EV was parked at a location equipped with a charger or V2H/V2B, the calculation procedure for $EV_{\text{charge}}(i,t)$ and $EV_{\text{dis}}(i,t)$ followed the process shown in **Figure 2**.

Before driving, EVs were charged based on the distance between the current parking location at time $t$ and the next destination that had a charger or V2H/V2B. The charging start time and required charging amount were determined by the travel distance. The total amount of electricity that all EVs must charge before driving is defined as $EV^{\text{must}}_{\text{charge}}(t)$ (see **Figure 2**). EVs that did not need to charge at time $t$ were available to function as distributed batteries for the power grid. The numbers of such EVs were counted as $N^{\text{EV}}_{\text{c}}(t)$ and $N^{\text{EV}}_{\text{V}}(t)$, depending on the parking location.

When VRE output was curtailed, EVs parked at the location equipped with standard chargers or V2H/V2B systems were charged. EVs were always connected to V2H or V2B when parked at homes or offices that had such equipment. When EVs were parked at homes or offices with standard chargers, they were charged at a high rate if the battery state of charge was below 50% or if VRE output curtailment occurred. When EVs were parked at locations with fast charger, which meant the EVs were parked at the shops, charging occurred only when the battery state of charge was low.

The amount of EV charging, $EV_{\text{charge}}(i,t)$ was adjusted according to VRE output curtailment, $P^{VRE}_{\text{curtail}}(t)$, and the numbers of EVs available as grid batteries, $N^{\text{EV}}_{\text{c}}(t)$ and $N^{\text{EV}}_{\text{V}}(t)$. The upper limit of $EV_{\text{charge}}(i,t)$ was set to $s(i)$, which represented the charging speed of the standard charger determined by charger performance.

EVs discharged electricity when VRE output was not curtailed and when they were connected to V2H or V2B systems. The discharge amount was calculated based on the controllable output of thermal power generation, $P^{\text{thermal}}(t) - P^{\text{thermal}}_{\text{min}}(t)$, the charging/discharging capacity of the charger, $s(i)$, and the amount of electricity stored in the EV battery, as shown in **Figure 2**. In addition, $EV_{\text{dis}}(i,t)$ was constrained to ensure that sufficient battery charge, $EV_{\text{drive}}(i,t)$, remained for the next driving event, thereby preventing situations in which the EV would need to be recharged immediately before driving due to insufficient remaining battery capacity.

The calculations were repeated on an hourly basis from 0:00 on January 1 to 24:00 on December 31. In cases with EV deployment, hourly values of VRE output curtailment, electricity discharged from EVs to the power grid, and total electricity demand (including EV charging) were calculated. Subsequently, thermal power generation output was determined to balance electricity demand and supply. Annual results were then compared between cases with and without the V2G system.

## LCA for the V2G system evaluation

LCA was conducted to evaluate GHG emissions before and after the installation of EVs. This study targeted electricity supply for the target region as well as vehicle production and operation. The functional unit was set as the annual electricity demand of the region together with the production and operation of vehicles. Vehicle operation schedules were assumed to be identical for EVs and ICEVs. The VRE capacity was assumed to be the same before and after EV deployment.

Foreground data, such as the amount of thermal power generation, were obtained from the energy flow simulations. Data related to vehicle production were derived from a previous study [4]. Background data, including thermal power generation and fuel consumption of ICEVs, were sourced from the Japanese LCA Inventory Database for Environmental Analysis (IDEA) Version 3.5.1 [5] and ecoinvent v.3.11 [6].

## Analysis Settings

This study focused on Tanegashima island, where VRE output was curtailed for the first time in Japan and where VRE output curtailment frequently occurs at present. Tanegashima has a population of approximately 27, 000. Several cases were defined to compare the potential of the regional V2G system. **Table 1** presents five cases representing different configurations of EV deployment and charging infrastructure.

**Table 1:** Case settings.

| Case | EV | Home | Office |
|---|---|---|---|
| 0 | No | - | - |
| 1 | Yes | Standard charger | Standard charger |
| 2 | Yes | Standard charger | V2B |
| 3 | Yes | V2H | Standard charger |
| 4 | Yes | V2H | V2B |

The installed capacities of VRE were set to be PV 13, 000 kW and WT 700 kW, reflecting the local conditions of Tanegashima [7]. Hourly electricity outputs from PV and WT were estimated using solar radiation and wind speed data. Electricity demand in Tanegashima was estimated by allocating the total electricity demand of Kyushu region [8] in proportion to population. The minimum output of thermal power generation, $P^{\text{thermal}}_{\text{min}}(t)$, was estimated

using a regression equation based on VRE output, $P^{\mathrm{VRE}}(t)$, electricity demand, $P^{\mathrm{use}}(t)$, and reported data on the minimum thermal power output released by electric power company [9].

The target vehicle type was the Japanese Kei car, which is the most commonly used vehicle in Tanegashima [3]. The number of EVs was assumed to increase to up to 10, 000 units. EV battery capacities and EV efficiencies were set based on an industrial data source [10].

## RESULTS AND DISCUSSION

### Overview of energy flow simulation with V2G

Energy demand and supply were calculated on an hourly basis using the energy flow simulation model. Under current conditions without EV deployment, VRE output curtailment occurred on 128 days per year. In comparison, 118 days of VRE output curtailment were reported in 2023 [9]. This close agreement suggests that the model developed in this study reasonably represents the actual electricity system of the region.

**Figure 3** shows the temporal dynamics of electricity generation and demand on April 27 with 1, 000 EVs in case 4. The difference in electricity demand between cases with and without EVs is attributable to EV charging. On this day, VRE output was curtailed during the middle of the day. The installation of EVs reduced VRE output curtailment by EV charging. At that time, electricity demand increased in the morning due to EV charging before commuting to work, which led to increase in thermal power generation to meet this additional demand. In the evening, after returning home, EVs discharged electricity to the power grid.

### Annual changes in electricity generation

The simulation shown in **Figure 3** was conducted for one year. Figure 4 shows the annual amounts of electricity demand, thermal power generation, VRE output curtailment, and EV discharge to the power grid. The number of installed EVs was varied from 0 to 10, 000 units.

EV deployment reduced VRE output curtailment (**Figure 4 (a)**). In case 4 with 10, 000-EVs, VRE output curtailment was reduced to 0.26%. The installation of V2H and V2B further decreased VRE output curtailment. EVs were able to charge electricity derived from VRE that would otherwise have been curtailed in case 0, because EV batteries had available capacity created by discharging electricity to the power grid on the previous day.

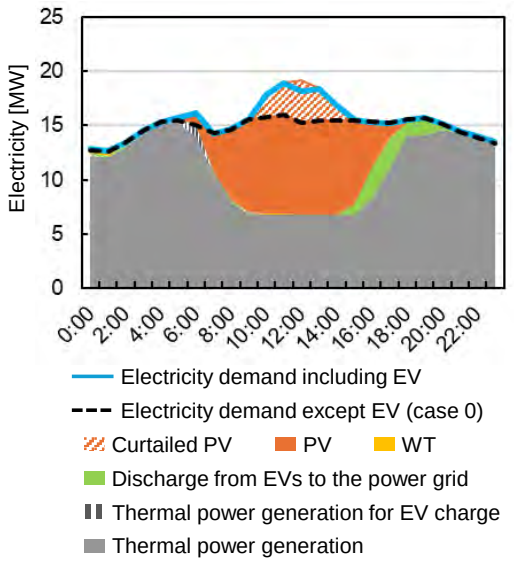

**Figure 3**. Temporal dynamics of electricity generation and demand on April 27th with 1, 000 EVs in case 4.

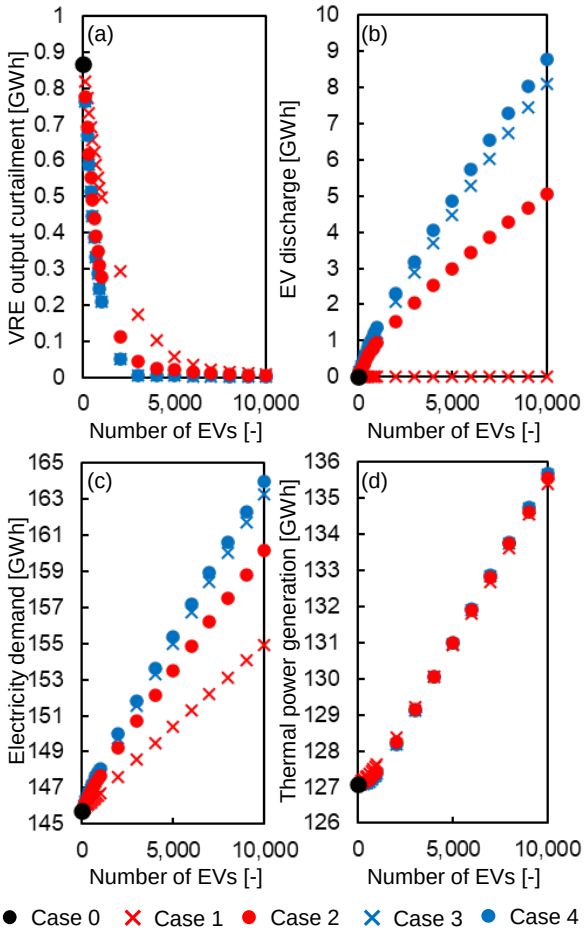

**Figure 4.** Effects of the regional V2G system. Note that the vertical axis scales differ. (a) VRE output curtailment. (b) EV discharge to the power grid. (c) Electricity demand. (d) Thermal power generation.

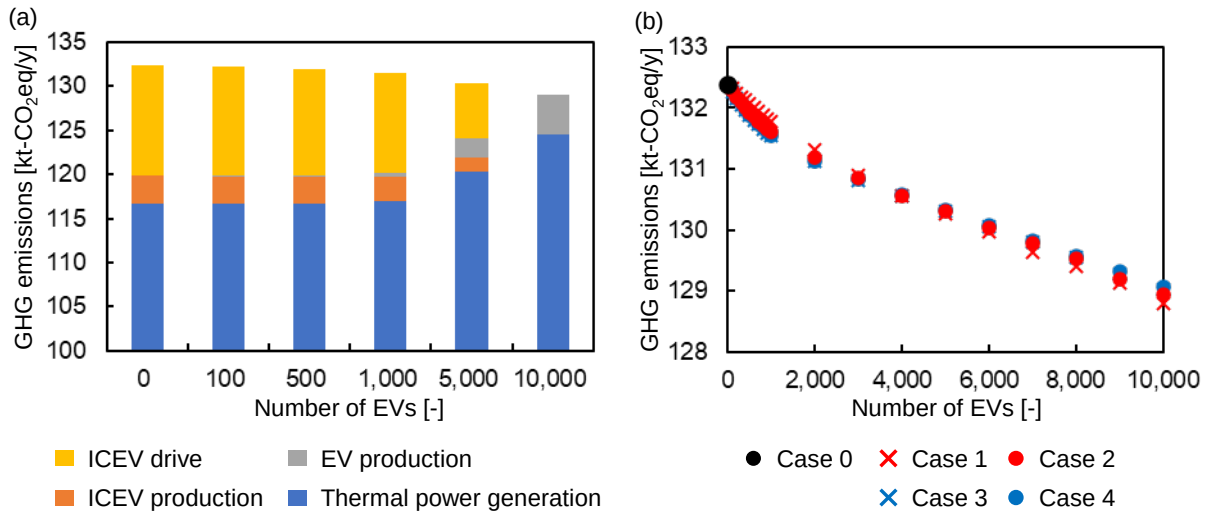

**Figure 5.** GHG emissions from the regional V2G system. Note that the vertical axis scales differ between (a) and (b). (a) GHG emissions from the regional V2G system in case 4. (b) GHG emissions from the regional V2G system among all cases.

By installing V2H and V2B, electricity stored in EV battery could be utilized at homes and offices (**Figure 4 (b)**). VRE output curtailment typically occurred during midday, so EVs mainly charged during this period and discharged in the evening. A comparison between cases 2 and 3 showed that EV discharge to the power grid was smaller in case 2. If EVs were parked at offices overnight, such as company owned vehicles, EV discharge to the power grid would be expected to increase.

The annual electricity demand in Tanegashima is shown in **Figure 4 (c)**. When EVs were deployed, total electricity demand increased due to electricity consumption for EV driving. In cases 2-4, electricity demand increased more than in case 1. This additional increase was caused by EV discharging to the power grid, which in turn created additional opportunities for EV charging.

**Figure 4 (d)** presents the annual amount of thermal power generation. In general, thermal power generation increased with EV deployment because EVs required electricity for driving and charging. However, when fewer than 200 EVs were installed in Cases 3 and 4, thermal power generation decreased compared with Case 0. This reduction occurred because EVs charged electricity that would otherwise have been curtailed and discharged electricity to the power grid during evening hours, thereby reducing the need for thermal power generation.

When fewer than 200 EVs were installed, thermal power generation in case 4 was the lowest among all cases (**Figure 4 (d)**). However, when a large number of EVs were deployed, thermal power generation in case 4 became the highest. This inversion phenomenon was observed at approximately 4, 000-EVs. As shown in **Figure 4 (a)**, VRE output curtailment in cases 2-4 was almost zero at this level of EV penetration. Therefore, when the number of EVs exceeds 4, 000, thermal power generation must increase to meet the electricity demand, because the surplus electricity that was curtailed in Case 0 had already been fully absorbed by EV charging. These results indicate that the environmental effectiveness of regional V2G systems strongly depends on the balance between available surplus VRE and additional electricity demand induced by EV deployment. Beyond a certain penetration level, further EV deployment no longer contributes to GHG reduction unless additional renewable capacity or system-level control is introduced.

These results suggested that the regional V2G system could reduce VRE output curtailment and had the potential to decrease thermal power generation by enabling electricity discharge from EVs to the power grid. However, it should be noted that EV operation also tended to increase thermal power generation due to EV driving.

## GHG emissions of regional V2G system

GHG emissions from the regional V2G system were evaluated using LCA. **Figure 5 (a)** shows the GHG emissions for case 4. As the number of EVs increased, GHG emissions from thermal power generation and EV production also increased. However, total GHG emissions decreased because GHG emissions from ICEV operation were substantially reduced.

**Figure 5 (b)** compares GHG emissions all cases. When a small number of EVs were installed, case 4 exhibited the lowest GHG emissions among all cases. However, as the number of installed EVs increased, case 1 resulted in the lowest GHG emissions. This inversion phenomenon was observed at approximately 4, 000-EVs,

which is consistent with the trend observed for thermal power generation. At low EV penetration levels, GHG emissions could be reduced effectively because EVs were able to utilize surplus VRE that was curtailed in case 0. In contrast, at high EV penetration levels, electricity demand from EVs exceeded the amount of surplus VRE available, leading to increased reliance on thermal power generation.

GHG emissions associated with EV production were higher than those from ICEV production. Although this study did not include vehicles disposal, recycling could further reduce overall GHG emissions. In particular, recycling batteries used in EVs could reduce the environmental impact through appropriate recycling [11].

## Possible role of regional V2G system

In regions distant from major urban centers, particularly remote islands, fuel for ICEV operation must be transformed from remote production facilities, resulting in relatively high fuel costs. If EVs and V2G systems were deployed and locally available VRE was utilized for EV operation, both regional GHG emissions and fuel cost could be reduced. In addition, increased utilization of locally generated energy had the potential to stimulate the local economy.

Furthermore, the installation of regional V2G systems was expected to promote local economic activity and contribute to regional revitalization. The local socio-economic impacts of adopting new technologies can be evaluated using Input-Output (IO) models [12]. The results of this study provided quantitative parameters that can be used to assess these local socio-economic effects.

Beyond reducing life cycle environmental impacts, V2G systems could also enhance energy resilience by mitigating the risk of electricity supply disruptions during natural disasters. In regions equipped with V2G systems, residents could continue to access electricity even in the event of blackouts caused by natural disasters such as typhoons. Therefore, regional V2G systems would be well suited for the development of resilient local energy systems.

Regional V2G systems could reduce VRE output curtailment and GHG emissions and, depending on the number of deployed EVs, may also decrease thermal power generation. In addition, such systems had the potential to stimulate the local economic activity and contributed to the development of resilient local energy systems.

## Limitations of this study

The deployment of V2G system at the regional level was examined in this study. It assumed that a regional V2G system centrally controlled the charging and discharging of individual EVs by comprehensively considering the amount of regional VRE output curtailment, the number of EVs connected chargers and V2H/V2B systems in real time. Without such coordinated control, EVs may demand electricity beyond the available surplus VRE, potentially leading to unnecessary increases in thermal power generation. Under current conditions, individual V2H/V2B systems cannot access regional electricity system information in real time. Therefore, an advanced control system would be required to utilize regional V2G systems effectively.

Even though the model incorporated real-time information on regional electricity system, some EVs discharge electricity to the power grid that had been charged into their batteries during periods without VRE output curtailment. This behavior increased the load on thermal power generation.

The regional V2G system model developed in this study focused exclusively on Japanese Kei cars used for commuting purposes and did not account for differences in vehicle types or usage patterns. All EV owners and their workplaces were assumed to install identical charging equipment, such as standard chargers and V2H systems. Furthermore, the model could be enhanced by incorporating material flow analysis (MFA) to account for the timing of EV deployment, vehicle lifetimes including battery degradation, as well as variations in vehicle types, charging infrastructure, and usage patterns.

To enable the practical deployment of regional V2G systems, an economic framework must also be established. If EVs were allowed to charge and discharge freely at any location, individual EV owners could buy and sell electricity anywhere, leading to complex financial transactions. The development of a dedicated financial system, such as applications or platforms for V2G users, would help facilitate and accelerate the deployment of V2G systems.

For these reasons, regional V2G systems should manage regional electricity demand and supply by accounting for real-time system conditions, while coordinating the individual operation of V2H and V2B systems. Furthermore, the load of thermal power generation could be reduced by distinguishing whether the electricity stored in EV batteries was derived from VRE or from thermal power generation. Such an approach would promote more effective utilization of VRE. Therefore, integrated regional systems capable of controlling electricity flows and managing financial transactions were essential for the successful implementation of regional V2G systems.

# CONCLUSIONS

This study developed a regional V2G system model and evaluated the potential of EVs and V2G systems using energy flow simulations and LCA. Fuel consumption, VRE utilization, and GHG emissions were quantitatively assessed to examine the potential of regional V2G

system.

The results revealed that the deployment of EVs and V2G systems could effectively reduce VRE output curtailment and GHG emissions. In the case of 10, 000-EVs equipped with V2H and V2B systems, VRE output curtailment was reduced to 0.26%. Moreover, when fewer than 200 EVs were installed with V2H, thermal power generation decreased compared with the case without EVs. These findings indicated that regional V2G systems had the potential to reduce VRE output curtailment, GHG emissions, and, under certain conditions, thermal power generation.

The model developed in this study enabled a quantitative evaluation of the potential of regional V2G systems. For the practical deployment of such systems, integrated regional platforms were required to coordinate electricity flows and manage financial transactions. By evaluating the environmental performance of regional V2G systems, this study provided valuable insights to support the design and the implementation of environmentally sustainable V2G systems.

## ABSTRACT

Cost reduction of green ammonia production is critical to advancing the hydrogen-ammonia economy, as ammonia capable of cost-effective storage and transportation is a promising hydrogen carrier and energy carrier to alleviate the intermittency and geographical limitations of renewables. Optimisation and techno-economic assessment based on rigorous model are essential to accurately investigate techno-economic feasibility and fully explore optimisation potential. This work estimates the levelized cost of ammonia (LCOA) of an integrated system including a hydrogen generation process employing Proton Exchange Membrane (PEM) water electrolysis, a nitrogen generation process from flue gas recovery, and an ammonia synthesis process based on Haber-Bosch Process. To enhance the reliability of LCOA, detailed equipment sizing and costing is conducted according to stream data from rigorous modelling in Aspen Plus. A novel optimisation strategy is proposed to enhance the computational robustness by sequentially largening the group of optimised variables and improving the quality of initial points. Homotopy-continuation (HC) method is employed to ease the convergence difficulties for solving the flowsheet with multiple recycle streams and scaling up the plant capacities between 100 $tNH_3\ d^{-1}$ and 600 $tNH_3\ d^{-1}$ from an initially feasible point. Heat integration is also considered to realise the combined supply of heat and power by introducing a steam turbine power cycle and utilising the waste heat from exothermic ammonia synthesis.

**Keywords**: Green ammonia, Rigorous modelling, Process optimisation, Plant scale up

## INTRODUCTION

Cost reduction of green ammonia production is critical to advancing the hydrogen-ammonia economy, as ammonia capable of cost-effective storage and transportation is a promising hydrogen carrier and energy carrier to alleviate the intermittency and geographical limitations of renewables. Currently, most current studies estimate the levelized cost of ammonia (LCOA) using oversimplified assumptions [1 – 3] or shortcut models [4, 5], which is inaccurate and unrealistic. In details, linear correlation is inappropriately used to estimate the LCOA in green ammonia systems with all plant scales, as it is derived in a basis of 300 $tNH_3\ d^{-1}$ using 70 USD $MWh^{-1}$ of electricity [5]. Despite shortcut models could provide feasible initialisation for process simulation and optimisation, a technically feasible solution cannot be guaranteed when it is solely based on shortcut modelling, not to mention a reliable cost estimation. Moreover, optimisation scope is restricted to general terms such as equipment capacity and wind-solar mix ratio [1]. Therefore, optimisation and techno-economic assessment based on rigorous model are essential to accurately investigate techno-economic feasibility and fully explore optimisation potential.

Rigorous model of ammonia synthesis employing Neilsen's expression [6] is widely regarded to have the most accurate prediction of ammonia synthesis performance [7], whilst the application of it always focuses on single equipment simulation and cost assessment [8]. Exothermic nature in ammonia synthesis can be well captured by rigorous modelling, and utilisation of this waste heat can further reduce the LCOA to enhance the economic competitiveness.

In this work, detailed equipment sizing and costing are conducted according to stream data from rigorous modelling and in Aspen Plus. A novel optimisation

strategy sequentially largening the group of optimised variables and improving the quality of initial points will be employed to optimise the LCOA for plants between 100 $tNH_3\ d^{-1}$ and 600 $tNH_3\ d^{-1}$ from an initially feasible point.

# METHODOLOGY

## System description

An integrated system utilising off gas as the nitrogen source for green ammonia production was proposed, as depicted in **Figure 1** [10]. It encompasses an ammonia production system based on the Haber-Bosch process applying an industrial ammonia synthesis convertor (i.e., Topsoe S-200), an electrolysis-based hydrogen production process, and a stepwise nitrogen production technology where a pressure swing adsorption unit is facilitated by an amine-based carbon capture process for nitrogen enrichment. Apart from electric power driven by renewables such as solar and wind, this system also explores heat integration opportunities in ammonia purification process for further energy efficiency improvement and carbon mitigation.

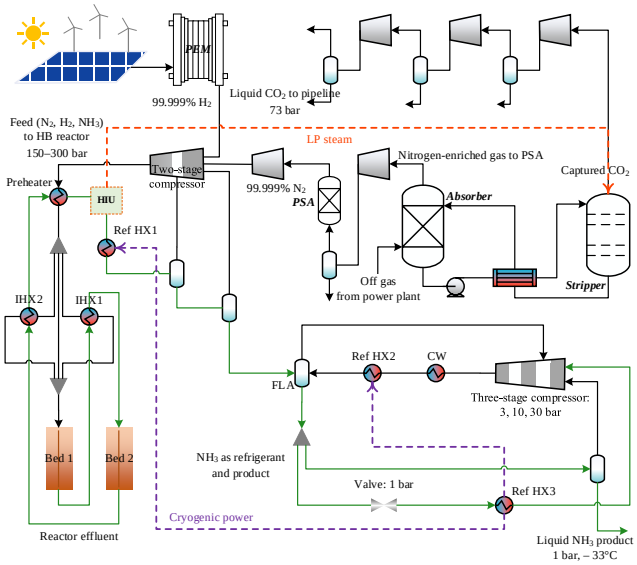

**Figure 1.** Flowsheet of the green ammonia production system.

## Optimisation models

### Modelling of ammonia synthesis

The modelling is conducted in Aspen Plus V12.1. The ammonia synthesis convertor (e.g., Topsoe S-200) is modelled by the combination of two internal heat exchangers (modelled by HEATX) and two plug flow reactors (PFR) as the catalytic beds.

The kinetic model of ammonia synthesis employs widely validated Neilsen's expression [6] throughout all sections (e.g. process simulation, optimisation and techno-economic analysis) as follows:

$$r_{NH_3} = \frac{\eta \cdot \kappa_2 \cdot \left(\alpha_{N_2} \cdot K_{eq}^2 - \alpha_{NH_3}^2 \cdot \alpha_{H_2}^{-3}\right)}{0.654 \cdot \left(1 + K_{a,eq} \cdot \alpha_{NH_3} \cdot \alpha_{H_2}^{-1.523}\right)^{1.308}} \cdot V \quad (1)$$

$$\kappa_2 = 7.89 \cdot 10^{10} \cdot e^{-\frac{11171}{RT}} \quad (2)$$

$$K_{a,eq} = -2.94 \cdot 10^{-4} \cdot e^{-\frac{24052}{RT}} \quad (3)$$

$$\log_{10} K_{eq} = 2.69 \cdot (1 - \log_{10} T) - 10^{-7} \cdot (552 \cdot T - 1.85 \cdot T^2) + \frac{2001.6}{T} \quad (4)$$

### Objective function

The primary objective of this study is to evaluate and minimise the LCOA, defined in Eq. 5, which represents the average production cost per unit of ammonia (USD $tNH_3^{-1}$). The LCOA framework integrates both capital and operating expenditures over the lifetime of the plant, thereby providing a consistent economic metric for comparing alternative design (e.g., various plant scales and heat-integration strategies) and operating strategies (electricity prices and optimised operating conditions).

$$LCOA = \frac{ACCR \cdot CAPEX + OPEX}{m_{NH3}} \quad (5)$$

$$C_{TPI} = 1.18 \cdot \left(C_{TBM} + C_{site} + C_{buildings} + C_{offsite}\right) \quad (6)$$

$$C_{BM} = \frac{I}{I_0} \cdot C_{P0} \cdot \left[F_{BM} + \left(F_d \cdot F_p \cdot F_m - 1\right)\right] \quad (7)$$

$$C_{P0} = F \cdot exp\{A_0 + A_1 \cdot (ln\, S) + A_2 \cdot (ln\, S)^2\} \quad (8)$$

The capital component of the LCOA consists of the annualised investment cost associated with major process equipment. Equipment capital costs (Eq. 6–8) are derived from detailed sizing calculations based on rigorous process simulation. Specifically, heat-exchanger costs are correlated to the required heat-transfer area, vessel costs are evaluated as a function of material of construction and shell weight, and compression or expansion equipment costs are determined from shaft power requirements. All equipment sizes are obtained case-by-case from steady-state stream data generated under each candidate design or operating condition. More detailed sizing and costing equations and associated coefficients can be found in the Supplementary Materials.

Operating expenditure includes the cost of raw materials, utilities, and ancillary services necessary for plant operation as shown in Eq. 9. Key contributors are electricity consumption for compression and refrigeration, hydrogen and nitrogen feedstock costs, cooling-water demand, raw materials (e.g., MEA and water) and carbon tax. Variable operating costs are calculated based on process simulation outputs and unit prices, while fixed operating costs such as labour, insurance, and maintenance are incorporated as a fraction of the installed capital cost following standard chemical-engineering

economic practice. Necessary equations and cost assumptions can be found in the Supplementary Materials.

$$OPEX = C_{RM} + C_{utility} + C_{operation} + C_{maintenance} + C_{overhead} + C_{depreciation} + C_{carbon} \quad (9)$$

The optimisation problem is expressed as:

$Min\ LCOA$

$s.t.$

Mass and energy balance

Thermodynamic constraints: RKS-BM

Chemical equilibrium: Correlation of Gillespie and Beattie (Eq. 4)

Reaction kinetics: Neilson's expression (Eq. 1)

Unit models: PFR, Compressor, Heat exchanger, etc.

Boundary conditions: See **Table 1**

**Table 1:** Boundary conditions of decision variables for the optimisation problem.

| Variables | Unit | Lower bound | Upper bound |
|---|---|---|---|
| PCOMP1 | Bar | 31 | 149 |
| PCOMP2 | Bar | 150 | 300 |
| PFLA | Bar | 3 | 10 |
| TPREHEAT | °C | 140 | 220 |
| TREFRIG-ERATION | °C | –25 | 0 |
| TBED1OUT | °C | 400 | 600 |
| TBED2IN | °C | 350 | 500 |

## Solution strategy

Once a feasible scaled-up flowsheet is established, optimisation is performed using the Large-Scale Sparse Successive Quadratic Programming (LSSQP) algorithm. LSSQP is a gradient-based method widely adopted in the chemical process industry, noted for its fast convergence and robustness in solving large-scale nonlinear programming problems [11]. In this study, the derivative information automatically generated in EO mode is incorporated into the optimisation routine, enhancing computational efficiency and solution reliability.

To outlines the transition from an initial feasible point obtained in SM to the EO-based optimisation workflow, the overall procedure is illustrated in **Figure 2** and explained in the following:

**Step 1:** Generate an initial feasible solution in SM and synchronise the model in EO mode. In this step, all equations from unit models and thermodynamic property models are assembled, and the associated free variables are initialised.

**Step 2:** Scale up the plant by fixing the required product rate, freeing feed flowrates, scaling up the reactor volume, and initially fixing reactor outlet/inlet temperatures while freeing the internal heat exchanger areas. This ensures that the overall degrees of freedom are balanced (DOF = 0).

**Step 3:** Perform EO simulation using the LSSQP solver, with the Homotopy-Continuation (HC) method enabled to enhance convergence. If convergence fails, the HC step size is reduced and the simulation is repeated.

**Step 4:** Switch the selected constant variables to optimisation variables.

**Step 5:** Apply LSSQP optimisation. If convergence is successful, the optimised variable selections and flowsheet solutions are restored before expanding the set of optimised variables. If convergence fails, the optimisation set is reformulated based on the last feasible selection. After all possible combinations of a given number of optimisation variables have been tested unsuccessfully, the number of active optimisation variables is reduced.

**Step 6:** Repeat the optimisation–reset cycle until convergence is achieved across the full set of optimisation variables.

**Step 7:** Once convergence is achieved for all optimisation variables, the global optimal solution is obtained.

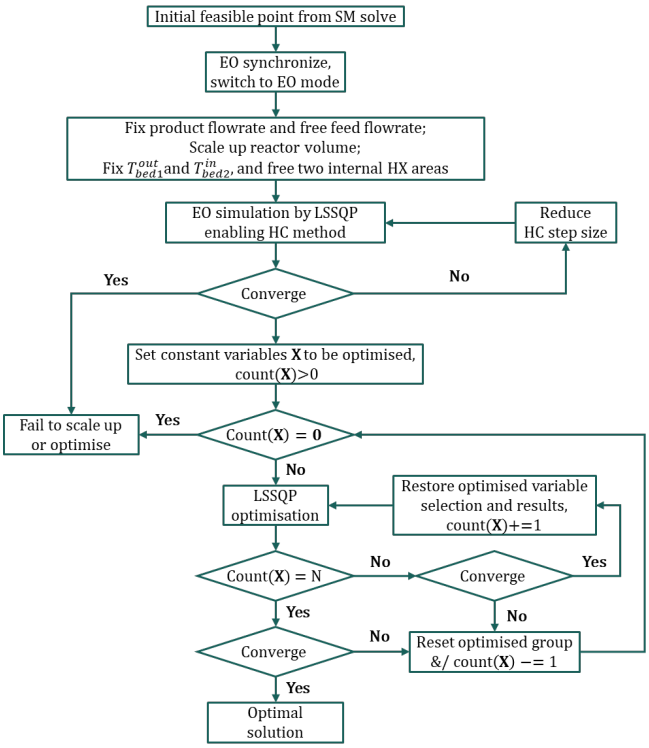

**Figure 2.** Solution strategy of the optimisation in Aspen Plus Equation-Oriented mode.

# RESULTS

## Distribution of optimized variables

As the cost of green ammonia production is highly dependent on hydrogen, which in turn originates from green electricity, the assumption regarding electricity price is critical. The International Renewable Energy Agency (IRENA) estimates that the cost of electrolysis-based hydrogen corresponds to electricity prices ranging from 20 USD $MWh^{-1}$ to 65 USD $MWh^{-1}$ over the period 2020–2050. For the optimisation of the base case, an electricity price of 20 USD $MWh^{-1}$ is assumed.

**Figure 3** presents the distribution of optimised decision variables for plant capacities of 100–600 $tNH_3\ d^{-1}$. The box plots indicate the 30–70% percentile range, median, and full spread of solutions, revealing which variables consistently converge to well-defined optima and which remain flexible.

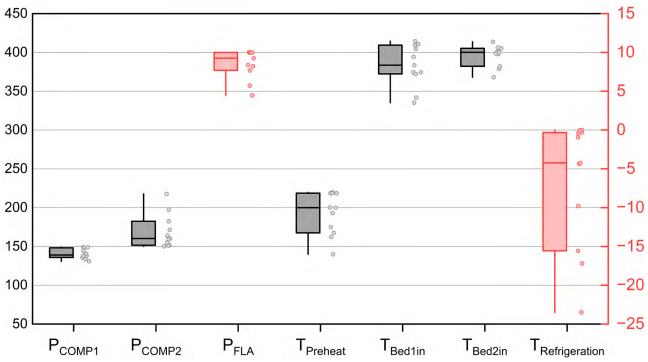

**Figure 3.** Distribution results of optimised variables

The discharge pressure of the high-pressure compressor (PCOMP2), corresponding to the ammonia synthesis loop pressure, consistently converges to 160–225 bar. This narrow range reflects the core economic trade-off in the Haber–Bosch process: although higher pressure enhances equilibrium conversion, the benefit is offset by higher compression energy demand and increased equipment cost. The medium-pressure compressor (PCOMP1) discharge pressure similarly clusters near its upper bound (ca. 150 bar), indicating a clearly defined optimal compression level to meet synthesis loop requirements.

The inlet temperatures of the catalyst beds (Tbed1 and Tbed2) also show tight distributions around 400 °C. This demonstrates that reactor thermodynamics dominate the optimal solution. The selected temperatures represent the classical compromise between improved reaction kinetics at high temperature and reduced equilibrium conversion.

In contrast, variables associated with downstream separation exhibit wide distributions. The flash pressure (PFLA) spans almost its full allowable range, and the refrigeration temperature varies broadly, including sub-zero conditions. These variables have only a minor impact on LCOA, leading to a relatively flat objective landscape and multiple economically equivalent operating points. The preheat temperature also shows moderate flexibility, as its effect can be compensated by internal heat exchange before the reactor.

## Optimized LCOA in various plant scales

**Figure 4** shows the dependence of LCOA on plant scale (100–600 $tNH_3\ d^{-1}$) and electricity price (0–120 USD $MWh^{-1}$). The levelized cost of hydrogen (LCOH) is used as the hydrogen feedstock cost in the LCOA calculation. Plant scale affects both capital-related costs and raw material consumption, while electricity price directly influences electrolysis, compression energy demand, and indirectly the hydrogen production cost.

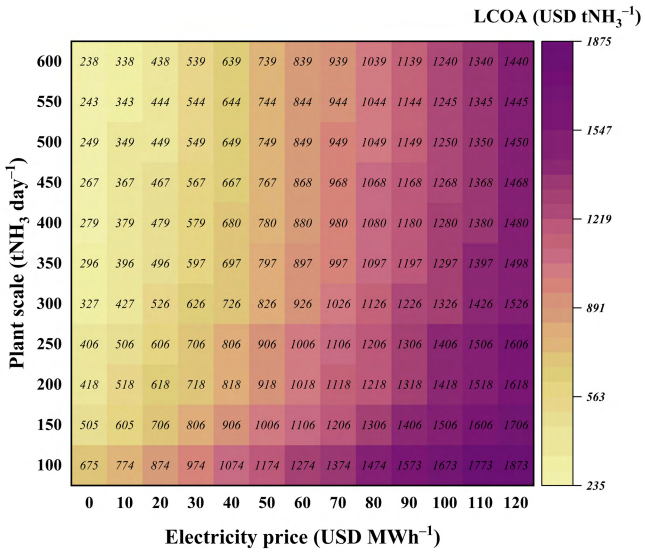

**Figure 4.** Optimised results, scale-up curve of the ammonia synthesis loop.

Electricity price is the dominant factor controlling LCOA across all plant sizes. Under zero-cost electricity, LCOA ranges from approximately 238 to 675 USD $tNH_3^{-1}$ depending on scale. When electricity price increases to 120 USD $MWh^{-1}$, LCOA rises sharply to about 1440–1873 USD $tNH_3^{-1}$.

Plant scale has a secondary but still noticeable effect. Larger plants consistently achieve lower LCOA because capital-intensive equipment, such as reactors and compressors, is amortised over higher annual ammonia output. For instance, at 20 USD $MWh^{-1}$ electricity, increasing capacity from 100 to 600 $tNH_3\ d^{-1}$ reduces LCOA from about 874 to 438 USD $tNH_3^{-1}$. At this electricity price, the corresponding LCOH is comparable to conventional hydrogen costs, and 600 $tNH_3\ d^{-1}$ represents a typical industrial ammonia plant scale. The resulting LCOA (ca. USD $tNH_3^{-1}$) is close to the current market price of ammonia (ca. 410 USD $tNH_3^{-1}$), supporting the credibility

of the economic model.

However, even at the largest scale, electricity prices above 40 USD $MWh^{-1}$ drive LCOA well beyond commonly cited competitiveness ranges for green ammonia (400–600 USD $tNH_3^{-1}$). This indicates that economies of scale alone cannot compensate for high electricity costs, and that access to inexpensive renewable electricity remains the key requirement for economically viable green ammonia production.

To clarify how plant scale influences both the magnitude and structure of ammonia production cost, **Figure 5** and **Figure 6** decompose the LCOA into annualised capital cost (ACC), cost of manufacturing (COM), raw material, and utility costs. An electricity price of 20 USD $MWh^{-1}$ is assumed for all plant capacities.

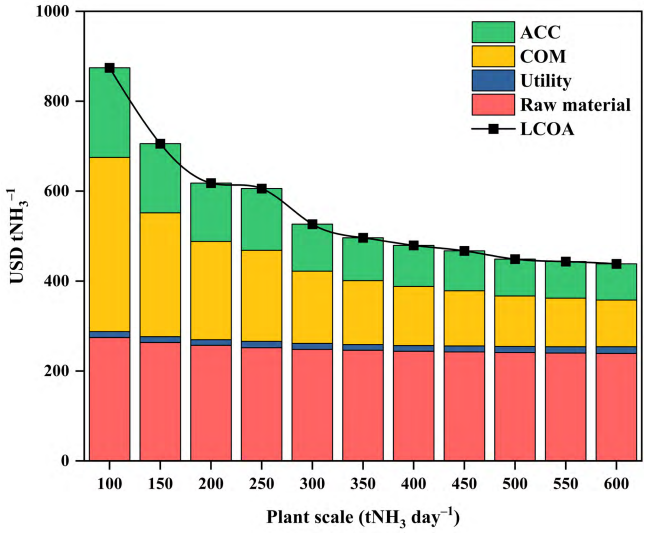

**Figure 5.** Optimised results, scale-up curve of the ammonia synthesis loop.

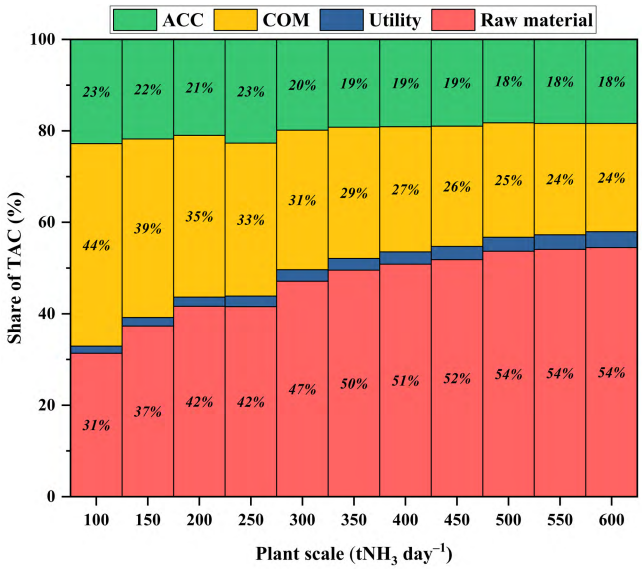

**Figure 6.** Breakdown of TAC.

Figure 5 shows a pronounced economy-of-scale effect, with total LCOA decreasing significantly as plant capacity increases from 100 to 600 $tNH_3\ d^{-1}$. At the smallest scale (100 $tNH_3\ d^{-1}$), LCOA is close to 900 USD $tNH_3^{-1}$, while at 600 $tNH_3\ d^{-1}$ it drops to about 440 USD $tNH_3^{-1}$. The reduction is steep between 100 and 300 $tNH_3\ d^{-1}$ and becomes more gradual beyond 400 $tNH_3\ d^{-1}$, indicating diminishing marginal benefits from further scale-up.

The stacked cost breakdown indicates that the decline in LCOA is mainly driven by reductions in ACC and COM. Both components decrease with scale because capital-intensive equipment is utilised more effectively and fixed costs are distributed over higher production rates. In particular, depreciation, maintenance, and equipment-related operating expenses are key contributors to COM. In contrast, raw material cost changes only slightly in absolute terms, and utility cost remains relatively small and nearly constant across plant sizes. Consequently, small-scale plants are dominated by capital and manufacturing burdens, whereas at large scale the cost structure becomes increasingly governed by raw material inputs.

Figure 6 presents the cost structure in percentage terms, showing the contribution of each component to the total annualised cost (TAC). A clear structural transition occurs as plant scale increases. At 100 $tNH_3\ d^{-1}$, COM is the largest contributor (44%), followed by raw materials (31%) and ACC (23%). With increasing capacity, the COM share steadily declines to about 24% at 600 $tNH_3\ d^{-1}$, while the ACC fraction decreases more moderately from about 23% to 18%.

In contrast, the raw material share increases significantly, rising from roughly 31% at small scale to more than 50% at large scale, eventually becoming the dominant cost component. The utility share remains small across all scales and increases only slightly. This behaviour is consistent with the optimisation results, where operating conditions tend to minimise compression work while maintaining relatively high ammonia synthesis conversion, thereby limiting additional utility penalties at larger scales.

## CONCLUSION

This work estimates the levelized cost of ammonia (LCOA) of an integrated system including a hydrogen generation process employing Proton Exchange Membrane (PEM) water electrolysis, a nitrogen generation process from flue gas recovery, and an ammonia synthesis process based on Haber-Bosch Process. In particular, CO2 in flue gas is removed by Monoethanolamine (MEA)-based carbon capture process and nitrogen is enriched to 90%, contributing to a higher efficiency and cost reduction of nitrogen purification, compared with considering air as the nitrogen source with 79% of nitrogen. An

industrial ammonia synthesis convertor (e.g., Topsoe S-200), consisting of two reactor beds and two internal heat exchangers, is employed to make our work closer to a real-life project. To enhance the reliability of LCOA, detailed equipment sizing and costing is conducted according to stream data from rigorous modelling in Aspen Plus. A novel optimisation strategy is proposed to enhance the computational robustness by sequentially largening the group of optimised variables and improving the quality of initial points. Homotopy-continuation (HC) method is employed to ease the convergence difficulties for solving the flowsheet with multiple recycle streams and scaling up the plant capacities between 100 $tNH_3\ d^{-1}$ and 600 $tNH_3\ d^{-1}$ from an initially feasible point.

Overall, the optimisation results reveal a clear hierarchy in the factors governing the techno-economic performance of green ammonia production. Reactor operating conditions, particularly synthesis pressure and catalyst bed inlet temperature, consistently converge to narrow ranges, demonstrating that reactor thermodynamics and compression trade-offs dominate the optimal process configuration. In contrast, separation and auxiliary thermal variables show wide feasible ranges, indicating a relatively weak influence on the LCOA. From an economic perspective, electricity price is the most critical external parameter, exerting a nearly linear and dominant impact on LCOA across all plant scales due to the electricity-intensive nature of hydrogen production and compression. Plant scale introduces a strong but secondary economy-of-scale effect, substantially reducing LCOA by diluting capital and manufacturing costs, especially between 100 and 300 $tNH_3\ d^{-1}$. However, as capacity increases, the capital- and manufacturing-related expenses become less dominant, while raw material costs (primarily linked to electricity for hydrogen production) emerge as the controlling factor. These results indicate that, beyond industrial-scale capacities, further cost reductions depend more on access to low-cost renewable electricity and improvements in process efficiency than on additional scale-up, while fixing strongly converged reactor operating conditions can enhance optimisation robustness with minimal economic penalty.

# Terawatts for Petabytes: Exploring the impact of AI data centres on Europe's net zero goals

**Mohammad Hemmati, Vassilis M. Charitopoulos***

## ABSTRACT

The unprecedented expansion of Artificial Intelligence is adding increasing electricity demand to Europe's power system. While incumbent plans pursue a net-zero future by 2050, they fail to consider the implications of large-scale AI-based data centres. In this study, a spatially explicit optimisation model is developed to assess how hyperscale data centres may reshape energy infrastructure investment, and emissions trajectories, across different AI demand growth scenarios. The results indicate that, after 2030, AI capacity deployment increasingly shifts toward regions with the ability to expand nuclear and gas-based generation, as firm and flexible power sources are essential for supporting the deployment of high-capacity AI data centres. By 2050, AI-driven electricity demand under high growth scenarios may reach up to 450 TWh, corresponding to 7% of total Europe's demand, with installed AI capacity reaching approximately 85 GW. This additional load leads to an increase of nearly 25 $MtCO_2$ in cumulative emissions between 2030 and 2050. Our analysis indicates that, depending on the AI growth scenario, meeting AI-related electricity demand by 2050 requires between 37 and 323 GW of additional capacity across Europe, ranging from the pessimistic to the lift-off scenario, including investments in nuclear (2-12 GW), gas (2-7 GW), wind (13-100 GW), solar (20-134 GW), and battery storage (0-70 GW).

## INTRODUCTION

Growing interest in generative artificial intelligence (GenAI) has triggered intense competition to advance the technology, driving the need for numerous high-intensity data centres, as well as greater electricity consumption [1]. To better understand the energy consumption of AI-based data centres, it is essential to consider the wide variation in electricity usage across different AI workloads. For example, a 100-word ChatGPT-4 response consumes approximately 0.14 kWh of electricity [2]. Based on OpenAI's reported figure of roughly 285 million daily ChatGPT users, the platform's energy consumption can be estimated at about 0.39 TWh per day, or roughly 14.4 TWh per year [3]. In addition to inference-related demand, model training represents a non-negligible source of electricity consumption. For example, the training of ChatGPT's 4 model is estimated to have required 50 GWh of electricity, equivalent to the output of a French nuclear reactor operating at full capacity for about two days, with further retraining cycles implying recurring energy requirements [4].

By end of 2024, data centres account for approximately 1.5% of global annual electricity consumption [5]. Looking at the Europe, the International Energy Agency (IEA) estimates that the current energy use of data centres, at around 70 TWh in 2024, will increase to approximately 115 TWh by 2030 [6]. McKinsey indicates that data centre electricity demand in Europe is expected to reach 150 TWh by 2030 [7], while the Independent Commodity Intelligence Services (ICIS) forecasts it will rise to 168 TWh by 2030 and further increase to 236 TWh by 2035 [8]. Although more precise forecasts for data centre demand are rare and prediction rates vary widely across the literature, nevertheless even under conservative scenario, the resulting demand could absorb as much as 20% of newly added renewable energy resource (RES) capacity in Europe and lead to emissions of

approximately 39 million tons of $CO_2$ annually, equivalent to nearly one-third of Italy's emissions in 2024 [9]. Consequently, the increasing demand of these infrastructures raises significant concerns regarding power system reliability and the Europe's Net Zero 2050 objectives.

Although only a limited number of studies have forecasted future data centre energy consumption and capacity in Europe up to 2030 [10, 11], no comprehensive approach has yet examined the impact of data centres on the future European energy system and national or continental development plans. Spatially explicit planning models such as PyPSA [12], and the ENTSO-E Ten-Year Network Development Plan (TYNDP) [13] do not incorporate emerging forms of geographically concentrated, high-density demand, such as AI data centres. To date, no planning-oriented framework has quantitatively evaluated how AI-driven electricity demand may influence Europe's grid expansion, infrastructure needs, or energy transition. Given high uncertainty in future AI trends, beyond even IEA forecasts, assessing Europe's current position, identifying regions suitable for hyperscale data centres, and understanding their potential impact on net-zero 2050 goals is essential [14, 15].

Motivated by the gaps identified above, this study develops a long-term expansion planning model to systematically evaluate how growing demand from AI may reshape Europe's power system development. A spatially explicit optimisation model is proposed, covering 33 countries and formulated as a Mixed-Integer Linear Program (MILP). The model incorporates current infrastructure plans, including 177 cross-border transmission projects, operational constraints, land-use restrictions for renewables, and climate targets, with an hourly temporal resolution. To reflect incumbent "myopic" planning under high uncertainty from data centres, a rolling-horizon solution approach is employed.

The main contributions of this work are as follows:

- Developing a European-scale modelling framework to evaluate whether existing power-sector development plans can accommodate AI-driven electricity demand growth.
- Investigating the effects of AI-driven demand on the spatial evolution of generation, transmission, and cross-border electricity flows across Europe.
- Identifying the optimal capacity of hyperscale data centres and the country's most suitable for their deployment under AI growth scenarios.
- Identifying the main trends in data centre-driven electricity demand and energy system development under various scenarios.

The remainder of this paper is organized as follows. First, we present the research methodology and problem description and discusses the main assumptions. Then we report and analyse the main results for the benchmark case and the alternative AI-driven demand scenarios on various elements of the future European energy system. Finally, concluding remarks are drawn.

# METHODOLOGY

## Problem Description

Europe's long-term energy strategy focuses on establishing a net-zero system through a deep transformation of the energy sector, driven by large-scale deployment of renewable, low-carbon, and storage technologies. Analyzing such a complex integrated system to obtain optimal decisions across the planning horizon requires a comprehensive spatial and temporal optimisation framework [16-18]. We employ a MILP model to formulate the capacity and transmission expansion planning problem for integrated European power system from 2025 to 2050. Subject to operational, technical, and climate policy restrictions [19], the model minimises the total system cost, our model includes investment in generation and transmission infrastructure, fixed and variable operating costs [20], emissions costs [21], value of loss of load (VOLL) costs, as ell as renewable curtailment costs. The overall form of the objective function is provided in Eq. (1).

$$TSC = \sum_t FCC_t + FOC_t + FFC_t + CC_t + VOLL_t + Curt_t + TIC \quad (1)$$

Where $TSC$ is the total system cost over the planning horizon, $FCC_t$ denotes facility investment cost, $FOC_t$ denotes variable operating cost, $FFC_t$ is fixed operating cost, $CC_t$ is emissions cost, $VOLL_t$ is load shedding cost, $Curt_t$ is cost related to renewable curtailment, and finally $TIC$ is the transmission investment cost.

An hourly resolution is adopted to accurately capture operational constraints, system flexibility requirements, and the temporal interaction between variable renewable generation and electricity demand, while maintaining computational tractability for the 33-country European power system. To this end, the planning horizon from 2025 to 2050 is discretized into five-year investment periods. Within each representative year, a time-reduction technique based on k-medoids clustering is applied to select 12 representative days, with three typical days assigned to each season, ensuring adequate coverage of seasonal variability [22, 23]. Operational variables, including generation dispatch, storage operation, and cross-border exchanges, are then resolved on an hourly basis for these representative days, with appropriate weighting factors used to approximate full-year system behavior. To provide a planning-consistent baseline, we model the evolution of the European electrical system

using the ENTSO-E TYNDP Global Ambition scenario [13]. To ensure a more realistic system representation, the model includes reliability (LOLE, loss of load expectation) constraints, must-run for thermal units, renewable curtailment costs, and land availability limits for renewable expansion [24]. It is worth noting that, in addition to conventional generation technologies, carbon capture and storage (CCS) options, including Combined-cycle gas turbine with CCS (CCGT-CCS) and bioenergy with CCS (BECSS), are considered as candidate technologies to facilitate compliance with decarbonization targets [25].

## Regional Data Centre Capacity

Although obtaining precise current and future capacity data at the country level is highly challenging and no standardized forecasting methodology exists for installed data centre capacity, the EUDCA provides current capacity estimates and annual projections for hyperscale and colocation data centres across Europe according to Colocation and hyperscale data centre database, Pb7 Research [26]. The database is compiled and maintained by Pb7 Research using a combination of publicly available sources, targeted online searches, and validation checks. Where direct data are unavailable, values are estimated based on complementary sources (e.g., the number of racks or building layout). The estimates were obtained through data gathering and interviews with owners and operators of data centres throughout Europe. Overall, the reported capacities show reasonable consistency with the figures presented in the IEA report.

It should be noted that all reported values refer to IT capacity. These values are converted into total allocated capacity using the projected PUE values provided by the IEA (1.45 in 2024 and 1.29 in 2030) [27]. The 2024 capacity for each country is therefore used as the initial condition and baseline input for optimisation model.

## Data Centre Load Profile

In addition to installed data centre capacity, both the associated energy consumption and the contribution of data centres to each country's total electricity demand must be considered. To this end, we incorporate realistic data centre load profiles into the model. Based on the dataset reported in, half-hourly percentage utilisation data for 87 data centres in the UK are available for the period 2023– July 2025 [28]. By clustering these load profiles, all data centres are classified into three voltage levels: low, medium, and high voltage. The reported utilisation percentage represents the ratio of the actual kVA import of each data centre to its contracted (maximum) kVA capacity from the perspective of the regional electricity network operator. Since hyperscale data centres with capacities exceeding 10 MW (at minimum) require high-voltage connections (110, 230, or 400 kV) and are typically connected to the transmission or sub-transmission network [29, 30], we derive a representative load profile from 57 data centres connected at high-voltage levels using K-medoids clustering. Fig. 1 illustrates the representative load profile of a high-voltage-connected data centre employed in the model.

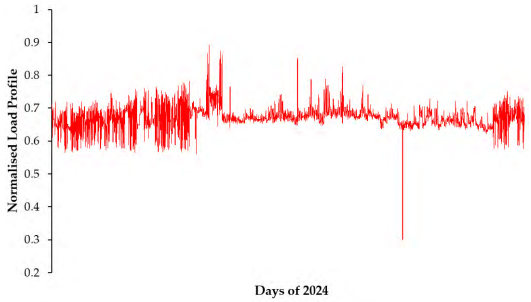

**Figure 1.** Historical hourly load profile of hyperscale data centre [28].

Hence, the energy consumption by AI is calculated as follows:

$$DemandAI_{t,c,h} = DCProfile_h \times CapAI_{t,c} \quad (2)$$

where $DemandAI_{t,c,h}$ is a variable representing AI electricity demand in year $t$, country $c$, and hour $h$, $CapAI_{t,c}$ denotes the optimal AI capacity in year $t$ and country $c$, and $DCProfile_h$ is the normalized hourly demand profile used as model input.

# RESULTS & DISCUSSION

In this section, we present the results of the proposed optimisation framework across all scenarios. First, a benchmark analysis for the base case validates the model by comparing its outputs with TYNDP projections. Next, AI-based data centres are incorporated to assess the impacts of AI-driven demand on capacity investment, generation mix, and emissions trajectories.

## Base Case Analysis (Without AI)

The results of this scenario closely match the TYNDP Global Ambition trajectory [13]. Fig. 2-(a) illustrates the evolution of total installed capacity from 2025 to 2050, closely following the stated decarbonisation pathway. The model projects total installed capacity to reach approximately 4, 700 GW by 2050, which is about 3.3% higher than the TYNDP projection of 4, 548 GW. The resulting energy mix reproduces the main structural transitions of the TYNDP scenario, including the complete phase-out of coal and oil-fired generation by 2035 and the subsequent dominance of renewable energy sources. By 2050, the combined installed capacity of solar and wind reaches around 3, 300 GW, representing a 3.0% increase relative to the TYNDP estimate of 3, 205 GW. Regarding nuclear capacity, the model projects 141 GW by 2050, approximately 15% higher than the TYNDP forecast. This deviation is primarily driven by adequacy and

spinning reserve constraints, which increase the value of firm, low-carbon generation in maintaining system reliability. In term of spatial distribution of installed capacity, Fig. 2-(b), Germany will have the largest total capacity in Europe, at around 11, 000 GW, more than 50% of which is solar. Following Germany, Italy (490 GW), France (377 GW), the UK (333 GW), and Spain (286 GW) are next.

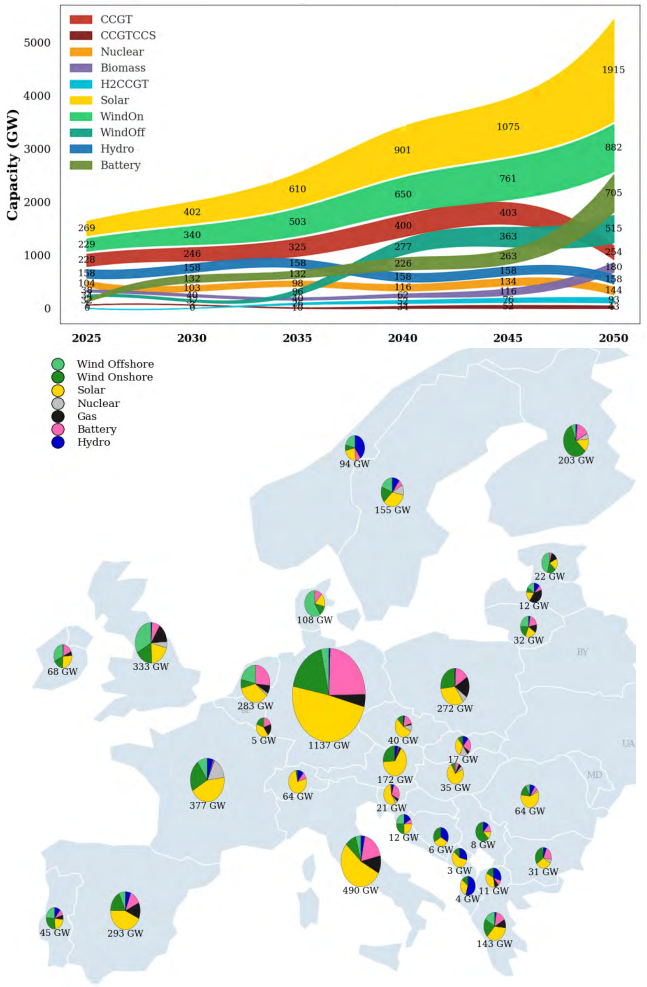

**Figure 2.** Base case analysis: **(a)** Installed capacity trajectories, **(b)** Country-level installed capacity.

The need for flexibility and firm capacity is clearly visible in countries such as the UK (50 GW CCGT, 10 GW CCGT-CCS), Italy (42 GW CCGT, 9 GW CCGT-CCs), Poland (40 GW CCGT), Spain (25 GW CCGT, 16 GW CCGT-CCS) where the model requires significant gas-based generation to meet reliability and reserve requirements. However, the gas installed in Germany and the Netherlands is mainly based on H2-CCGT technology (close to 60 GW in both countries) by 2050. Overall, Europe will have about 140 GW of nuclear capacity, with France leading at 62 GW, followed by the UK (18 GW), Sweden (17 GW), and Finland and Poland (10 GW each). In terms of wind capacity, the UK leads with 170 GW, Finland (130GW), followed by Denmark and the Netherlands (each 78 GW). High solar capacity in Southern Europe is also evident due to higher solar resource potential.

## Impact of different Data Centres growth on the evolution of the power system

In this section, the impact of AI-driven electricity demand on Europe energy system are analysed under one lift-off scenario and two collapse scenarios (pessimistic–med and pessimistic–deflation). The lift-off scenario represents an optimistic pathway, characterized by sustained and rapid growth in AI deployment through 2050. In contrast, the deflation collapse scenario assumes that a contraction of data centre activity begins in 2035 and persists until 2045, while in the medium collapse scenario, the contraction starts in 2035, but AI demand partially recovers after 2040, albeit at a lower growth rate than in the lift-off scenario (cf. Fig. 4 red, dashed line).

Fig. 3 illustrates changes in the installed capacity under the three AI scenarios relative to the base case for the milestone years 2030, 2040, and 2050. Under the lift-off scenario, the system experiences a significant demand shock as early as 2030, requiring approximately 60 GW of additional onshore wind capacity, primarily in Germany, Spain, and Portugal. At the same time, around 10 GW of offshore wind and 35 GW of additional solar capacity are required compared to the base case. To accommodate the increased variability associated with higher renewable penetration, the system also requires approximately +37 GW battery by 2030.

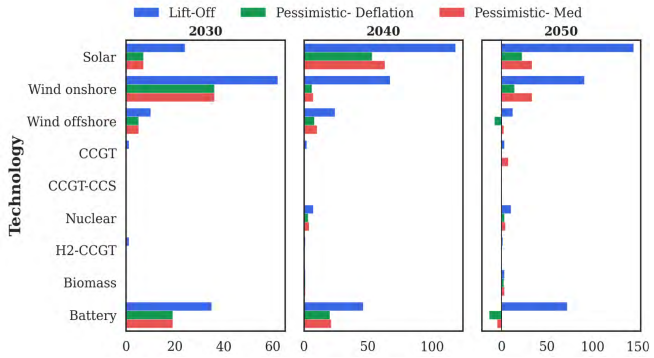

**Figure 3.** Change in Installed capacity under AI scenarios.

By 2040, the lift-off scenario requires approximately +130 GW of solar, +60 GW of onshore wind, and +10 GW of offshore wind compared to the base case. High AI-driven load also necessitates +3 GW of nuclear, primarily in France, to maintain system adequacy. By 2050, additional nuclear requirements range from 1 GW in the deflation scenario to 10 GW in the lift-off scenario, while lift-off and medium scenarios need 5 GW and 3 GW of CCGT, respectively. The growing reliance on gas generation under tighter emissions constraints may challenge long-term decarbonisation goals.

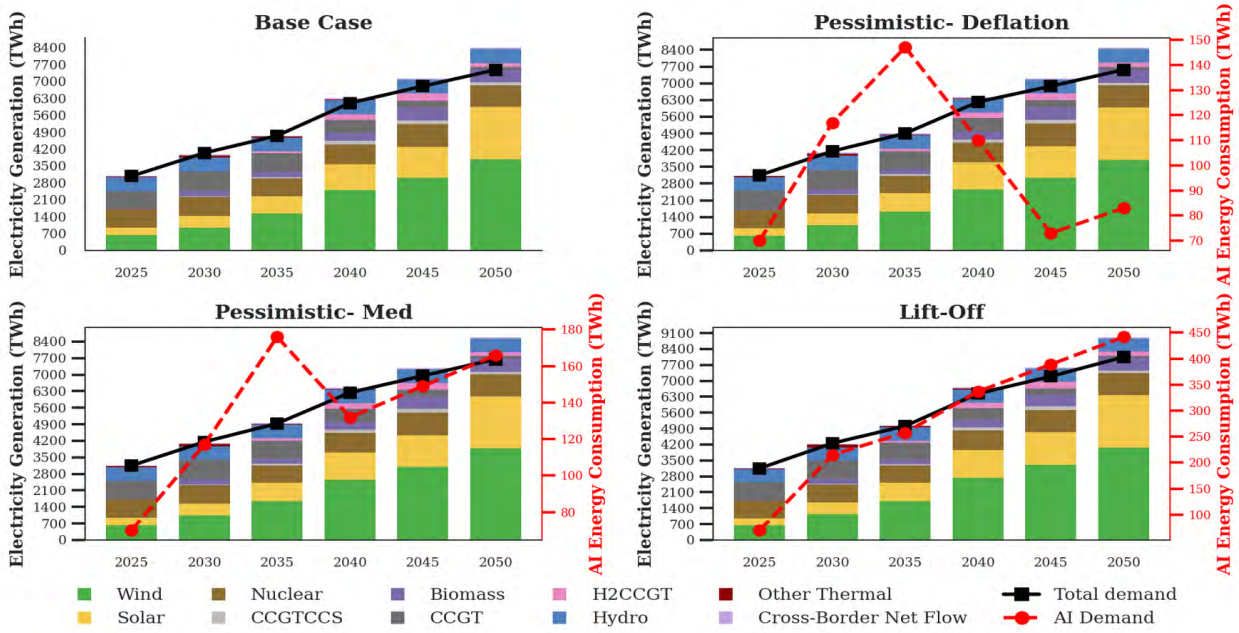

**Figure 4:** Energy mix trajectory under different scenarios, as well as AI energy consumption (red, dashed line)

Under the collapse scenarios, the system exhibits similar behavior until 2035. By 2040, in the deflation scenario, declining AI demand is primarily accommodated through additional renewable and storage capacity (+50 GW solar, +9 GW wind, and +15 GW battery). In contrast, the pessimistic-medium scenario requires not only renewables but also firm capacity additions (+2 GW nuclear and +3 GW CCGT). By 2050, the deflation scenario leads to partial retirement of offshore wind and battery capacity, with offshore wind reduced by about 7 GW in Finland and Denmark due to sustained AI contraction, although nuclear capacity remains 2 GW above the base case and gas capacity is unchanged. Under the pessimistic-medium scenario, renewed AI growth in the final decade drives additional investments of approximately +25 GW solar, +25 GW wind, +3 GW nuclear, and +4 GW CCGT relative to the base case.

## Impact on power generation and interconnection

Fig. 4 compares the evolution of the European energy mix under different AI demand scenarios relative to the base case. The AI-driven electricity demand profile is highlighted in red for all three scenarios. Comparing this profile with total system load shows that, by 2050, AI demand accounts for approximately 450 TWh of total electricity consumption in the lift-off scenario, around nine times higher than in the deflation scenario and three times higher than in the medium scenario. As AI penetration increases, the capacity factors of nuclear and gas technologies rise by up to 15%, and 10 % respectively. As shown, unlike the base case, where coal and nuclear generation are almost entirely phased out after 2040, approximately 8 TWh of electricity between 2040 and 2045 is supplied by these technologies under the lift-off scenario. Cumulatively over the period 2030–2050, the system requires around +150 TWh of nuclear and +97 TWh of additional gas generation compared to the base case in lift-off scenario. In the final decade, tighter emissions constraints increase reliance on $H_2$-CCGT for flexibility, adding 26 TWh more while Wind captures the largest share of energy mix growth and emerges as the most dominant option for supplying AI-related demand, contributing more than +650 TWh over the same period. Overall, these results indicate that the highly concentrated electricity demand associated with hyperscale data centres can significantly alter the energy mix at critical planning milestones.

## Optimal allocation of data centres

From a spatial optimisation perspective, AI-related electricity demand is primarily deployed in countries with sufficient potential to expand nuclear and thermal generation capacity. This pattern is consistent across all scenarios. In the lift-off scenario, Poland (14 GW), France (13 GW), and the UK (11 GW), experience high growth data centre deployment during the 2040–2050 period, driven by their ability to expand firm nuclear and gas capacity (Fig. 5-a). Under lift-off scenario, Portugal emerges as a favorable location for data centre development (3.4 GW), alongside Spain (6 GW), where a combination of low-cost solar electricity and available gas capacity exists.

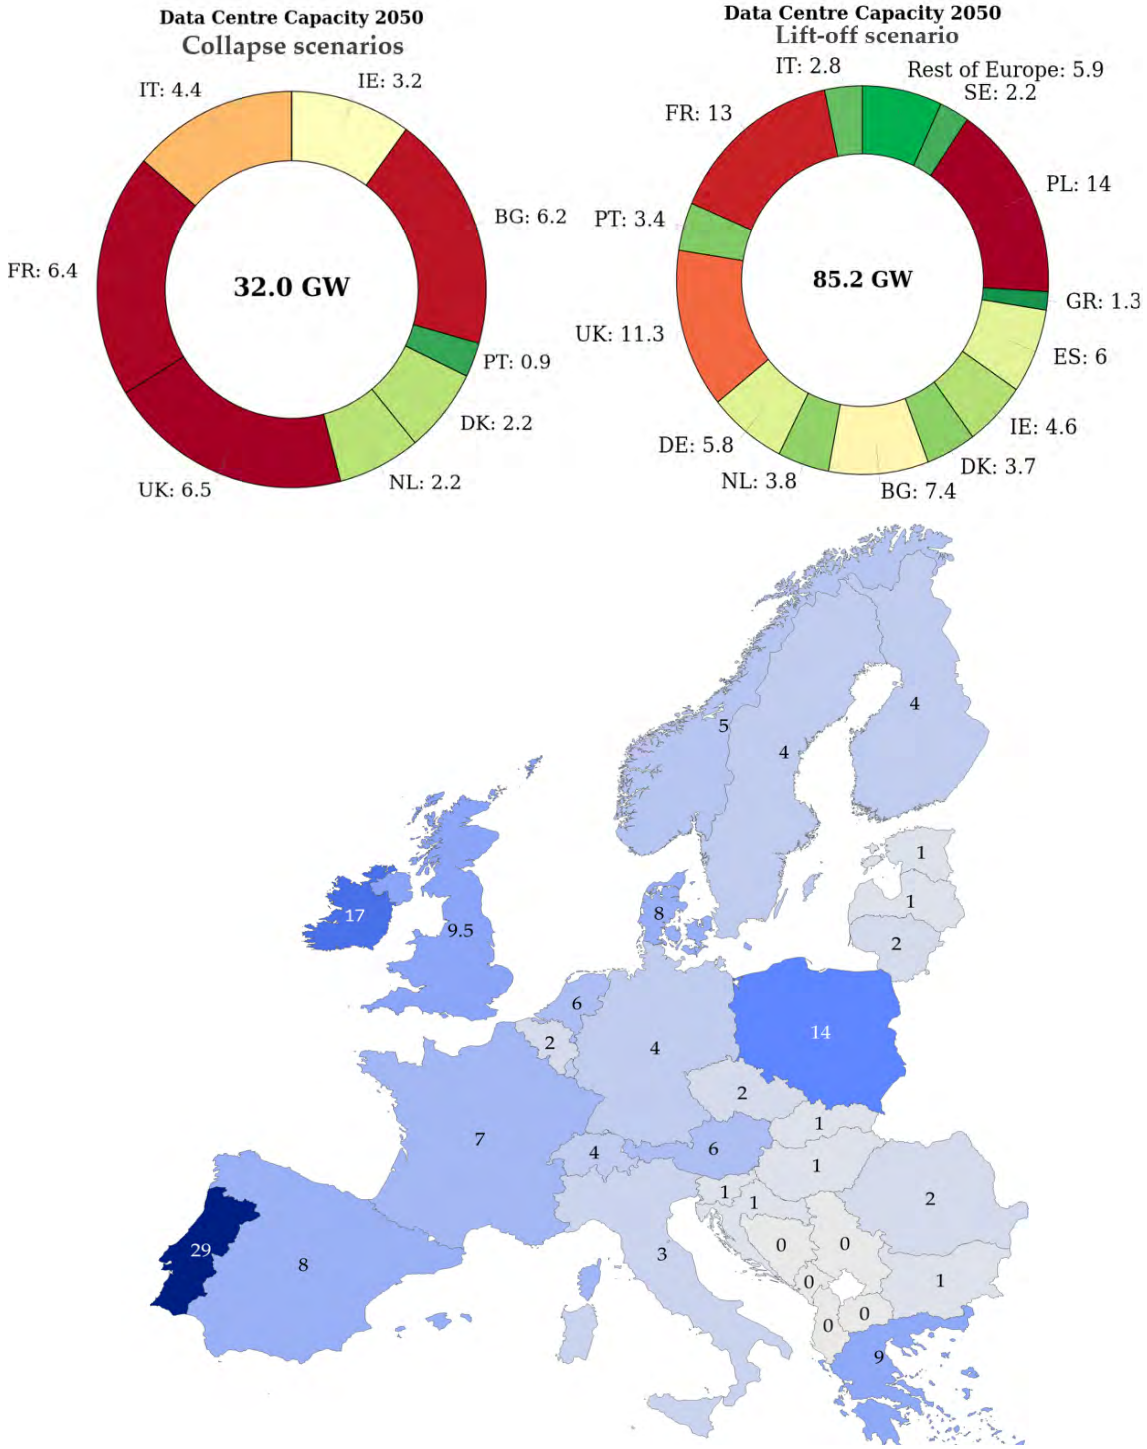

**Figure 5**: (a) Optimal data centre capacity, (b) Share of AI as a percentage of total demand per country (lift-off).

Between 2030 and 2040, Bulgaria and Greece also exhibit notable growth potential, reaching 7.5, and 1.5 GW in lift off scenarios. In contrast, Ireland, Germany, and the Netherlands face binding constraints from 2030 onward, or experience capacity reductions under collapse scenarios, due to stringent carbon limits, rapid growth in base electricity demand, and the absence of nuclear power options.

Under the pessimistic-medium collapse scenario, total AI-based data centre capacity reaches approximately 32 GW by 2050. Owing to the decline in AI demand prior to 2045, baseload nuclear generation is

largely sufficient to accommodate the additional load. As a result, France, the UK, and Bulgaria, benefiting from adequate nuclear expansion potential, together host nearly 20 GW of AI capacity. Italy, enabled by the deployment of CCGT-CCS in the final five years, accommodates around 4.4 GW. Furthermore, driven by the development of $H_2$-CCGT alongside wind capacity between 2035 and 2045, Ireland and the Netherlands recover from the post-2030 collapse and expand their AI capacity to approximately 3.2 GW and 2.2 GW, respectively. These results indicate that even under a market collapse scenario, Europe's power system continues to rely on nuclear and gas-based technologies, particularly CCGT-CCS alongside renewables to ensure system adequacy.

### Spatial AI Demand Shares and Associated Emissions Trajectories

By 2050, AI-based data centres may account for approximately 3–7% of Europe's total electricity consumption, ranging from the pessimistic to the lift-off scenario. The share of AI-driven electricity demand in total national consumption varies widely: 23% in Portugal, 14% in Poland, 9.5% in the UK and Greece, and 7% in France (Fig. 5-b, lift-off scenario). Even at these levels, AI-driven demand has a significant impact on emissions. Across Europe, it contributes approximately 25 $MtCO_2$ cumulatively between 2030 and 2050, driven by an additional 10 TWh of oil- and coal-fired generation and 97 TWh of gas-fired generation. Country-specific impacts vary: Portugal sees only 0.02 $MtCO_2$, the UK ~4 $MtCO_2$, Germany and the Netherlands ~8 $MtCO_2$ combined due to higher gas and coal use, France ~0.2 $MtCO_2$, and Poland nearly 5 $MtCO_2$. These differences reflect each country's mix of AI load, existing capacity, and reliance on flexible fossil generation.

## CONCLUSION

This paper investigates the effects of AI-driven demand growth on Europe's power system development toward 2050 using a comprehensive optimisation framework. Rapid AI expansion substantially increases generation capacity needs, placing high pressure on long-term complemented by flexible gas generation. Across all scenarios, only countries able to simultaneously expand renewable energy while retaining nuclear and gas options infrastructure planning can accommodate sustained AI growth. Between 2030 and 2050, AI demand contributes an additional 323 GW additional capacity from different generation technologies, as well as ~25 $MtCO_2$, posing a challenge to Europe's climate targets under the lift-off scenarios. While Poland, UK and France see significant capacity growth, Southern European countries (Spain, Portugal, Greece) also emerge as key locations for AI deployment under both lift-off and collapse scenarios.

These findings underscore that successfully integrating AI at scale will require the coordinated expansion of flexible, low-carbon generation and infrastructure across Europe. Ongoing work in our group focuses on systematic representations of growth uncertainty [31, 32] via means of multi-stage stochastic programming to elucidate further aspects of optionality.

## ABSTRACT

Biogas offers a promising biogenic carbon source for renewable methanol, but differences in $CH_4/CO_2$ ratio across feedstocks and possible upstream $CO_2$ handling can shift syngas stoichiometry away from the methanol synthesis target range. This work quantifies how biogas composition and reformer operation influence the stoichiometric number (SN) and the associated conditioning requirement needed to meet methanol synthesis targets. A steady-state Aspen Plus® model of an integrated biogas-to-methanol process is used as the analysis framework. A base-case operating point is defined, followed by parametric evaluation of biogas $CH_4/CO_2$ ratio, reformer temperature, reformer pressure and steam-to-methane (S/C) ratio. The studied $CH_4/CO_2$ ratio range covers $CO_2$-rich to $CH_4$-rich cases that may occur across sites and upgrading levels. The resulting SN shifts are tracked and converted into a quantitative correction requirement to maintain the methanol design target (SN = 2.01). Temperature determines the upper limits of conversion and SN, while pressure and S/C ratio have secondary effects once high-temperature operation is reached. By comparison, the $CH_4/CO_2$ ratio has the strongest influence on syngas composition, defining $H_2$-deficiency and $H_2$-excess regimes. Methanol production increases as SN approaches the required target range but shows diminishing gains beyond it, indicating limited benefit from excess hydrogen under fixed synthesis conditions.

## INTRODUCTION

International shipping is entering a transition period driven by tightening greenhouse-gas regulations and the need to reduce transport emissions. The International Maritime Organization (IMO) reports that international shipping emitted close to one billion tonnes of $CO_2$ in 2018 and that emissions are expected to grow with the continued rise of maritime trade [1]. To counter this, the IMO and the European Union (EU), among other stakeholders, have implemented measures to support the decarbonisation of marine transport, thus increasing the push for sustainable alternative fuels [2, 3].

Among the available alternatives, methanol has attracted strong interest as a practical short-term option for maritime decarbonisation. Methanol is in liquid form at ambient conditions, it can be stored and handled using established infrastructure, and it is already being used in dual-fuel marine engines [4]. The key point, however, is that methanol's decarbonisation benefit depends on how it is produced. When synthesised from renewable or biogenic carbon sources (biomethanol), methanol can offer substantially lower life-cycle emissions compared to conventional marine fuels [5]. Despite this potential, large-scale renewable methanol production remains limited and requires process configurations that combine robust syngas generation with efficient synthesis and purification.

Biogas-based methanol production is particularly attractive because it relies on biogenic carbon, but it also introduces an important process challenge: biogas composition varies widely with feedstock and digester

operation. Biogas typically contains a significant amount of both $CH_4$ and $CO_2$. In steam methane reforming (SMR) of biogas, the inlet carbon balance directly shapes the outlet $H_2$, CO, and $CO_2$ levels. Hence, changes in feed $CH_4/CO_2$ ratio strongly influences the resulting syngas composition and its suitability for downstream methanol synthesis [6]. In practice, this means that plants for biogas-based methanol production should be designed to handle varying feed conditions.

A lower direct-emissions route to generate syngas is electrified steam methane reforming (eSMR). In eSMR, high-temperature reforming heat is supplied electrically rather than by fuel combustion, which can reduce direct $CO_2$ emissions from syngas generation when the electricity is renewable or from other low-carbon sources [6]. However, electrifying the heat supply does not by itself guarantee a syngas composition suitable for methanol synthesis. The syngas composition at the reformer outlet remains sensitive to reformer temperature, pressure, and steam-to-carbon ratio and, critically, the $CH_4/CO_2$ ratio of the biogas feed, so syngas stoichiometry must be adjusted to meet methanol synthesis requirements.

Syngas quality for methanol synthesis is commonly assessed using the stoichiometric number (SN), $(H_2-CO_2)/(CO+CO_2)$, which reflects the balance between $H_2$ and carbon oxides ($CO_x$) in the synthesis gas. Stoichiometric methanol synthesis is equivalent to SN = 2, since this corresponds to the hydrogen-to-$CO_x$ balance required by the overall methanol synthesis stoichiometry. Hence, values close to 2 are typically preferred for methanol production. When SN > 2, the syngas is hydrogen-rich, whereas SN < 2 indicates a carbon-rich mixture with insufficient hydrogen for the synthesis stoichiometry. For biogas reforming, external adjustment through the addition of $H_2$ or $CO_2$ (or, alternatively removal of $CO_2$ or $H_2$) may be necessary to meet the SN required for methanol synthesis.

The objective of this work is to quantify how biogas composition and reforming conditions influence synthesis gas stoichiometry and the downstream adjustment required to meet methanol design targets. The analysis is focused on steady-state behavior to give clear insight into the relationship between $CH_4/CO_2$ variability, reformer operation, and stoichiometric control. Specifically, an integrated Aspen Plus® model of a biogas-to-methanol process (eSMR → syngas conditioning → methanol synthesis loop → purification) is used to map how changes in $CH_4/CO_2$ ratio shift SN and to determine the magnitude and direction of the required conditioning action needed to reach the target SN used for methanol synthesis.

A $CH_4/CO_2$ ratio range of 1-5 is used as a bounding design range to cover differences across biogas sources and the effect of upstream $CO_2$ handling, rather than day-to-day variability for a single digester. Hence, the main focus is the syngas production. Process design, optimization, energy use, and cost are not covered in this study.

# METHODS

## Process Modeling and Simulation

Initially, a steady-state Aspen Plus® base-case model was developed to represent the integrated biogas-to-methanol pathway. The flowsheet comprises biogas compression and preheating, mixing with steam, syngas generation in the eSMR reactor, SN adjustment through addition of $H_2$ or $CO_2$, a methanol synthesis loop with recycle/purge, and downstream purification. To calculate thermodynamic properties, Peng–Robinson (PR) was used for the reforming section, Redlich-Kwong-Soave with modified Huron-Vidal mixing rules (RKSMHV2) for the high-pressure methanol synthesis loop, and the non-random two-liquid model (NRTL) for the low-pressure separation section. The main assumptions and key model parameters for the reformer and methanol reactor are listed in Table 1, while Figure 1 illustrates the overall biogas-to-methanol model in more detail.

**Table 1:** Reformer and methanol reactor key parameters and assumptions.

| Block name | Block type | Parameter | Value |
|---|---|---|---|
| ESMR | RGibbs | Calculation mode: chemical equilibrium | |
| | | Operating temperature | 950 °C |
| | | Operating pressure | 25 bar |
| | | Pressure drop | 1 bar |
| BWR | RPlug | Reactor temperature | 230 °C |
| | | Reactor Pressure | 75 bar |
| | | Number of tubes | 1100 |
| | | Length | 7 m |
| | | Diameter | 0.04m |
| | | Pressure drop | Ergun eq. |
| | | Particle density | 1775 kg/m$^3$ |
| | | Particle diameter | 5.5 mm |

A simplified biogas composition of 60 % $CH_4$ and 40 % $CO_2$ (60/40 biogas) was chosen for the base case, with a feed rate of 145 tonne/day. The biogas is compressed to the reformer pressure in a three-stage compressor with intercooling. The compressed biogas is then mixed with 172.7 tonnes/day steam to reach an $H_2O/CH_4$ (S/C) ratio of 3, selected to suppress carbon formation and ensure stable reforming. In the base case, the eSMR was operated at 950 °C and 25 bar. A target of SN = 2.01 was chosen for the methanol synthesis, potentially adding $H_2$ or $CO_2$ downstream to meet this requirement. A value

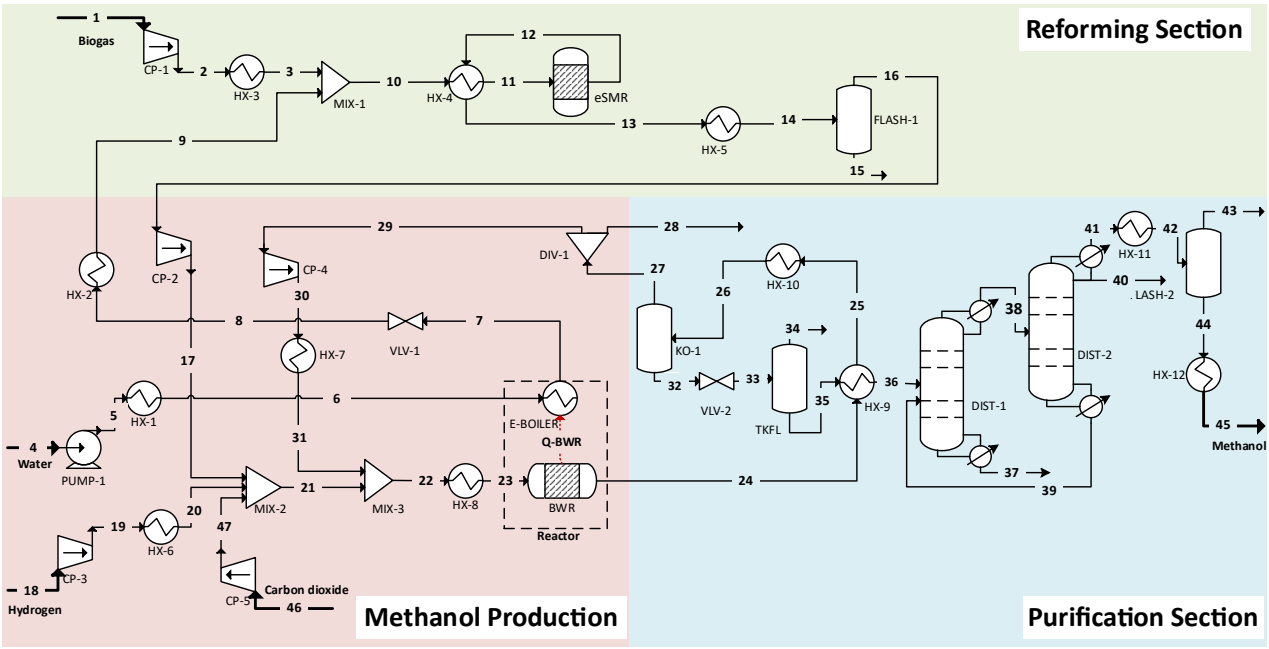

**Figure 1:** Detailed flowsheet for the biogas-to-methanol production base case

slightly above 2 was chosen as the reaction kinetics benefit from high $H_2$ partial pressure, and the catalyst benefits from a reducing atmosphere.

The eSMR operating temperature and pressure were selected based on the parametric sensitivity results, while the methanol reactor temperature and pressure were chosen to reflect industrial operating ranges reported by Nyári et al. [7]. The methanol synthesis catalyst and kinetic data were taken from Van-Dal et al. [8].

## Reforming Section

The eSMR reactor was modelled in Aspen Plus® using an RGibbs equilibrium block. This choice is consistent with electrically heated reforming concepts, where heat is supplied rapidly and uniformly, minimizing thermal gradients and enabling operation close to thermodynamic equilibrium, as reported by Wismann et al. [9]. The following reforming reactions were modeled:

$$CH_4 + H_2O \leftrightarrow CO + 3H_2 \quad (1)$$

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad (2)$$

In conventional reforming processes aimed at $H_2$ production, a water–gas shift (WGS) unit is often added to increase $H_2$ yield. However, when producing methanol, SN plays the key role. Since the WGS reaction generates 1 mol $CO_2$ for every 1 mol $H_2$ produced, it has no net effect on SN and mainly adds extra equipment and utility demand. Therefore, a WGS unit was not included in the model.

## Methanol Synthesis and Purification

The methanol reactor was modelled in Aspen Plus® using an RPlug reactor to represent a fixed-bed boiling water reactor (BWR). This reactor concept was selected because the exothermic reaction heat can be recovered as steam, which can be integrated to support the upstream steam demand in the reforming section. In addition, the BWR configuration provides effective temperature control, enabling operation close to the optimal reaction temperature.

The reactor kinetics were implemented using the Vanden Bussche-Froment model due to its validity at high-pressure [7], making it suitable for commercial operating conditions. The following reactions were modeled:

$$CO_2 + 3H_2 \leftrightarrow CH_3OH + H_2O \quad (3)$$

$$CO + 2H_2 \leftrightarrow CH_3OH \quad (4)$$

$$CO_2 + H_2 \leftrightarrow CO + H_2O \quad (5)$$

A recycle-to-fresh ratio of 4 was chosen, balancing conversion gains against increased compression duty. The reactor geometry was tuned to achieve a superficial gas velocity near 0.4 m/s, supporting hotspot mitigation while maintaining reasonable residence time and heat transfer performance in the catalyst bed.

Downstream purification was represented by a flash

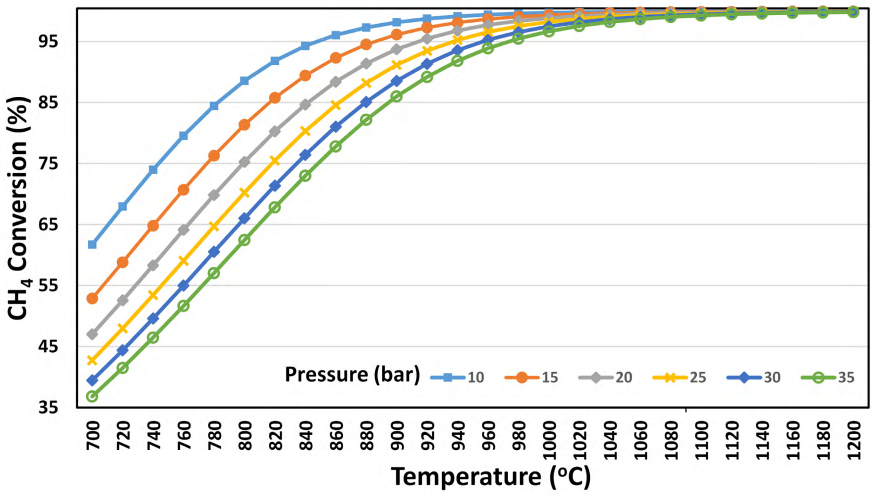

**Figure 2.** $CH_4$ conversion as function of reformer temperature for different reformer pressures (60/40 biogas, S/C = 3).

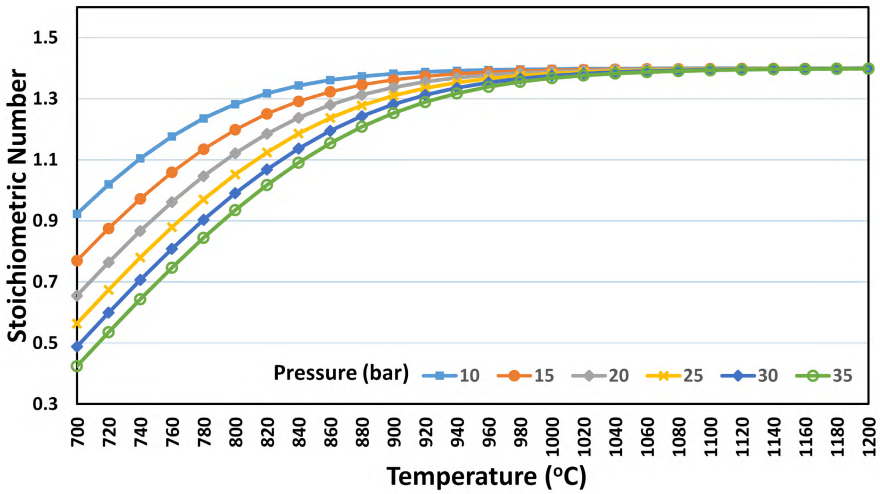

**Figure 3.** Reformer-outlet SN as a function of reformer temperature for different reformer pressures (60/40 biogas, S/C = 3).

separation (for non-condensable removal) followed by two distillation columns to obtain fuel-grade methanol (99.85 wt%) [10]. The purification section is included to close the overall process and verify the reported fuel-grade methanol purity, but it is not the main focus of this work.

## Parametric Analyses

Parametric analyses were performed on a molar basis using the base-case model to examine how changes in feed composition, S/C ratio, reformer temperature and reformer pressure influence reformer-outlet syngas composition and downstream methanol production. Differences between the reformer outlet SN and the methanol design target were assessed to indicate the extent of composition adjustment required to reach the target stoichiometry, i.e., the amount of $H_2$ or $CO_2$ added (or removed, depending on the availability of the corresponding resources) to reach the target SN.

# RESULTS AND DISCUSSION

## Base Case Model

In the base case, the $CH_4$ conversion in the eSMR reactor was 96.2%, resulting in syngas with SN = 1.36. In order to reach SN = 2.01, 6.8 tonne/day green $H_2$ was added downstream. The final methanol production in the base case was 151 tonne/day. Table 2 summarises key overall conversion metrics for the base case model.

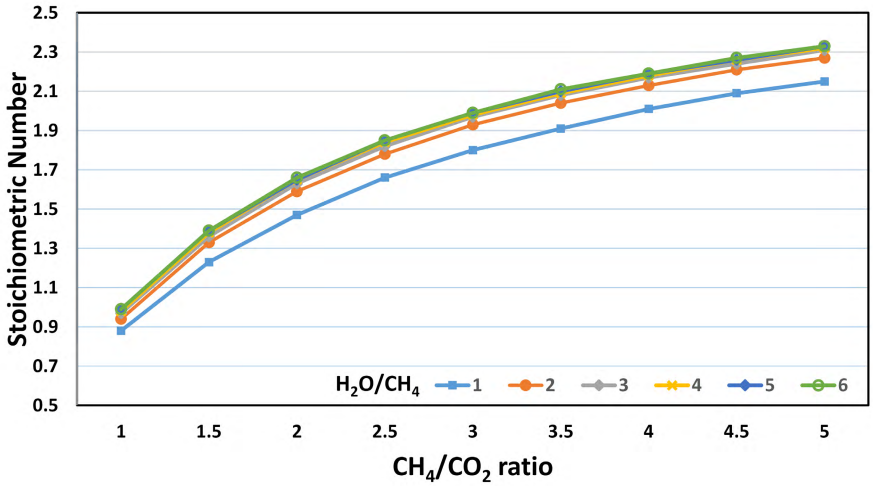

**Figure 4.** SN as function of biogas $CH_4/CO_2$ ratio for different S/C ratios (950 °C, 25 bar).

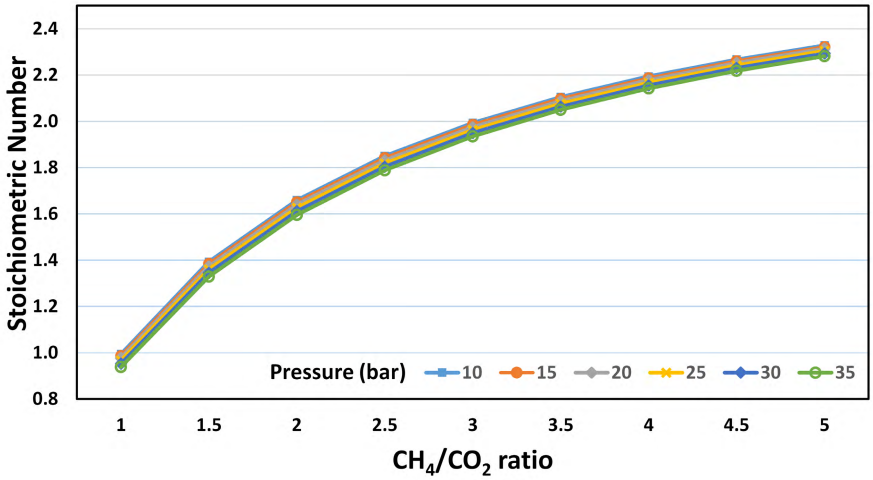

**Figure 5.** SN as function of biogas $CH_4/CO_2$ ratio for different reformer pressures (950 °C and S/C = 3).

**Table 2:** Base case conversion for the methanol section.

| Parameter | Value |
|---|---|
| CO conversion (%) | 98.8 |
| $CO_2$ conversion (%) | 87.9 |
| $H_2$ conversion (%) | 93.6 |
| Biogas to methanol conversion (%) | 92.9 |

## Parametric Analysis

Figures 2 and 3 first establish the combined influence of temperature and pressure on reformer performance for the 60/40 biogas feed at S/C = 3. As expected for an equilibrium-limited endothermic reformer, increasing temperature increases $CH_4$ conversion and shifts the outlet composition towards higher $H_2$ production, which is directly reflected in a higher SN.

Pressure acts in the opposite direction, suppressing conversion and lowering SN, with the effect most evident at the lower end of the temperature range. At sufficiently high temperatures, the conversion and SN curves converge across pressures, indicating that moderate pressure changes have a diminishing influence. This behaviour motivates the selection of 950 °C as a reference operating point for the remaining parametric analysis, where conversion and SN are close to their upper-limit values, and pressure sensitivity is limited. This does, however, come at the cost of high energy input to the reformer.

With the reformer temperature fixed at 950 °C, Figures 4 and 5 highlight the role of feed composition through the biogas $CH_4/CO_2$ ratio. Figure 4 shows SN as a function of the $CH_4/CO_2$ ratio at constant reformer temperature (950 °C ) and pressure (25 bar) while varying the

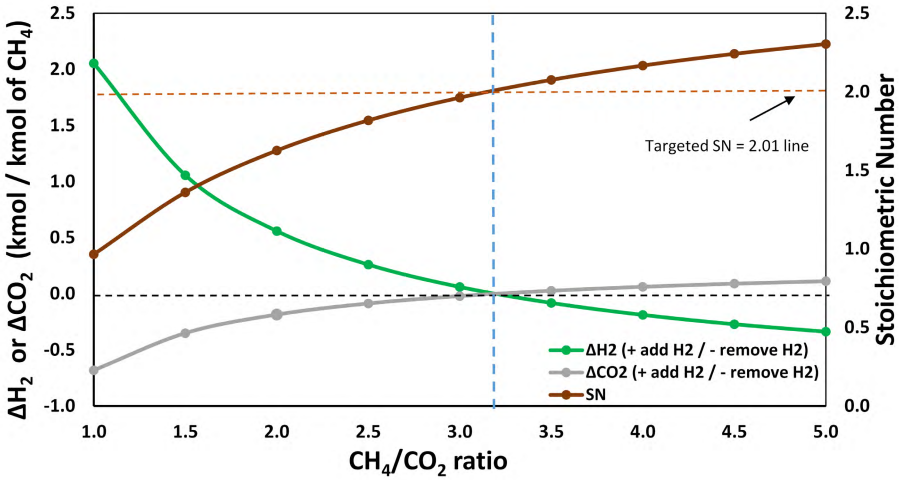

**Figure 6.** $H_2$ and $CO_2$ adjustment required to reach SN = 2.01 as a function of biogas $CH_4/CO_2$ ratio (950 °C, 25 bar, S/C = 3).

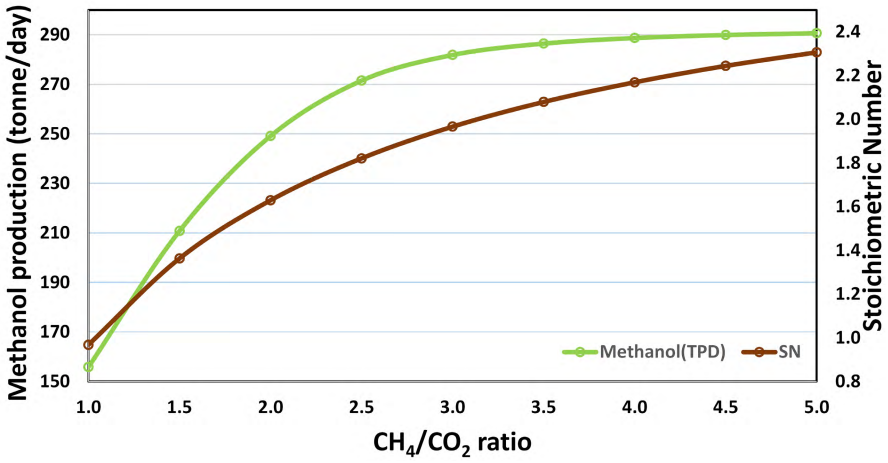

**Figure 7.** Methanol production rate and SN as functions of biogas $CH_4/CO_2$ ratio.

S/C ratio. SN increases steadily with increasing $CH_4/CO_2$ ratio for all S/C values, reflecting improved hydrogen availability as the methane fraction increases. Increasing S/C shifts SN upward across the studied composition range, but the effect reduces at higher S/C, indicating limited additional stoichiometric leverage once sufficient steam is supplied. Importantly, $CO_2$-rich feeds remain $H_2$-deficient (SN < 2.01) even at elevated S/C, demonstrating that steam adjustment alone cannot ensure methanol-grade stoichiometry over the full range of biogas compositions studied.

Figure 5 further illustrates this behaviour by showing the pressure sensitivity at constant temperature (950 °C) for S/C = 3. Across the 10-35 bar range studied, pressure has very little effect on SN compared to $CH_4/CO_2$ ratio. Together, the results in Figures 4 and 5 indicate that while S/C and pressure shift the absolute SN level, the dominant factor governing the transition between $H_2$-deficiency and $H_2$-excess regimes is the feed $CH_4/CO_2$ ratio. This observation motivates the introduction of an explicit stoichiometric correction step when feed composition varies, rather than relying solely on reformer operating adjustments.

In Figure 6, the required stoichiometric correction to reach SN = 2.01 is expressed as a function of the biogas $CH_4/CO_2$ ratio for a fixed reformer operating point (950 °C, 25 bar, S/C = 3). The maroon curve represents the reformer-outlet SN before any adjustment. The green

curve gives the hydrogen adjustment, $\Delta H_2$ (kmol $H_2$ per kmol $CH_4$ in the feed) required to reach SN = 2.01, and the grey curve gives the corresponding required $CO_2$ adjustment, $\Delta CO_2$(kmol $CO_2$ per kmol $CH_4$ in the feed). Positive values indicate addition of the respective component, while negative values indicate removal. The blue dashed vertical line marks the feed composition at which the reformer outlet already meets SN = 2.01, so no correction is required. For $CO_2$-rich feeds (left of the blue dashed line), the syngas is hydrogen-deficient, and the target can be reached by adding $H_2$ (or alternatively removing $CO_2$). For $CH_4$-rich feeds (right of the blue dashed line), the syngas becomes hydrogen-rich, and the correction reverses, requiring $CO_2$ addition (or alternatively $H_2$ removal). Overall, the figure links feed composition directly to the magnitude and direction of the adjustment required, while leaving the practical choice of correction route open, without prescribing a specific implementation route.

Finally, Figure 7 shows how changes in the $CH_4/CO_2$ ratio affect methanol production when the eSMR is operated at 950 °C, 25 bar, and S/C = 3, and no SN adjustment is applied upstream of the methanol reactor. Biogas flow was fixed at 500 kmol/h (to isolate the composition effect) while varying only the $CH_4/CO_2$ ratio. As the SN value increases with increasing $CH_4/CO_2$ ratio, the methanol production also increases quickly until the SN reaches the target for methanol production.

Once SN exceeds the target, the increase in methanol production becomes progressively smaller and eventually levels off. This indicates that further increase in SN provide limited additional benefit and can be interpreted as excess hydrogen relative to methanol demand. Together with Figure 6, this result highlights why maintaining SN close to the design value is important: it maximises methanol production while avoiding regimes where additional high-cost $H_2$ delivers diminishing returns.

## CONCLUSION

This work quantified how biogas composition and reformer operating parameters can influence synthesis-gas stoichiometry and methanol production in an integrated biogas-to-methanol process under steady-state conditions. The results show that biogas composition, expressed through the $CH_4/CO_2$ ratio, is the dominant factor controlling the reformer-outlet stoichiometric number (SN).

Reformer temperature and pressure influence methane conversion and shift SN, but their impact on stoichiometry remains moderate compared with $CH_4/CO_2$ and becomes less significant as operation approaches high-temperature, equilibrium-limited conditions. When assessed over a bounding design range intended to bracket $CO_2$-rich to $CH_4$-rich cases across different sources and possible $CO_2$ upgrading levels, the process transitions between $H_2$-deficiency and $H_2$-excess regimes. Expressing the resulting SN deviation as a correction requirement provides a practical basis for design screening and reveals a crossover near $CH_4/CO_2$ ≈ 3.21, where the reformer outlet meets the required SN without adjustment.

Propagating the same composition into the methanol section shows that methanol output improves as SN increases, but the gains diminish once SN exceeds the target value required for methanol production. This indicates that very high SN values mainly create surplus $H_2$ that is not converted to methanol, rather than delivering proportional increases in methanol production. Overall, the findings emphasise that robust biogas-to-methanol design should be centred on maintaining SN near the synthesis target and sizing conditioning capacity to accommodate plausible feed-composition differences, rather than relying on reformer operating adjustments alone.

Control, energy efficiency, heat integration, hydrogen supply cost, or economic trade-offs were not part of this work. These aspects depend strongly on feed composition and reformer conditions and should be addressed in future work.

## ABSTRACT

The aviation sector is difficult to decarbonize due to limits on aircraft electrification, making sustainable aviation fuel (SAF) a critical near-term solution. This study integrates Aspen-based process modeling with game-theoretic optimization to design a multi-agent SAF production network comprising coal gasification and $CO_2$-assisted natural gas reforming for syngas production, and Fischer–Tropsch (FT) synthesis for SAF production. Techno-economic parameters from Aspen simulations inform an agent-based model in which agents maximize their net present value subject to capacity and demand constraints. Three decision-making frameworks are compared: (i) social welfare optimization, (ii) cooperative bargaining - symmetric (equal bargaining power) and asymmetric (bargaining power weighted by agents' competitiveness outside cooperation), and (iii) competitive equilibria modeled as generalized Nash equilibrium. The results show that social welfare maximization excludes coal and yields the highest total profit, strongly favoring the FT agent's pay-off. Cooperative bargaining includes all agents in the system and promotes $CO_2$ and water recycling with only a 3.5% profit reduction; symmetric bargaining shifts profit toward coal, while asymmetric bargaining partially restores FT agents' share. Under bargaining, complete $CO_2$ recycling is achieved, integrating coal without direct emissions. Under strict competition, upstream syngas producers do not participate in the network, and reliance on external syngas reduces overall profit by 12.4%. These results show that game-theoretic modeling for process synthesis reveals strategic incentives for process design that are typically obscured in more traditional superstructure-based optimization frameworks.

## INTRODUCTION

Aviation is a major contributor to global greenhouse gas (GHG) emissions due to its intensive fuel use. Future demand for air travel is expected to rise [1], and alternatives such as electrification and sustainable aviation fuel (SAF) have been proposed to mitigate this impact. However, aircraft electrification faces significant challenges due to battery weight and volume constraints. Consequently, developing lower-carbon fuel pathways and efficient SAF production systems is critical.

There are multiple pathways to produce SAFs, all of them involving several processing steps. Optimization has been widely applied to find the best processing sequences under different objective functions (i.e. economic and/or environmental) [2, 3]. While these methods effectively identify optimal configurations, they assume centralized decision-making, overlooking the possibility of splitting the process across multiple industrial actors and the strategic interactions among them. Real-world processing networks involve multiple industries that buy and sell products to one another; these industries often have conflicting objectives, making cooperative and competitive behaviors essential to consider in optimal process and network design.

In this study, we analyze the design of sustainable aviation fuel (SAF) production networks under different decision-making paradigms. We integrate Aspen-based

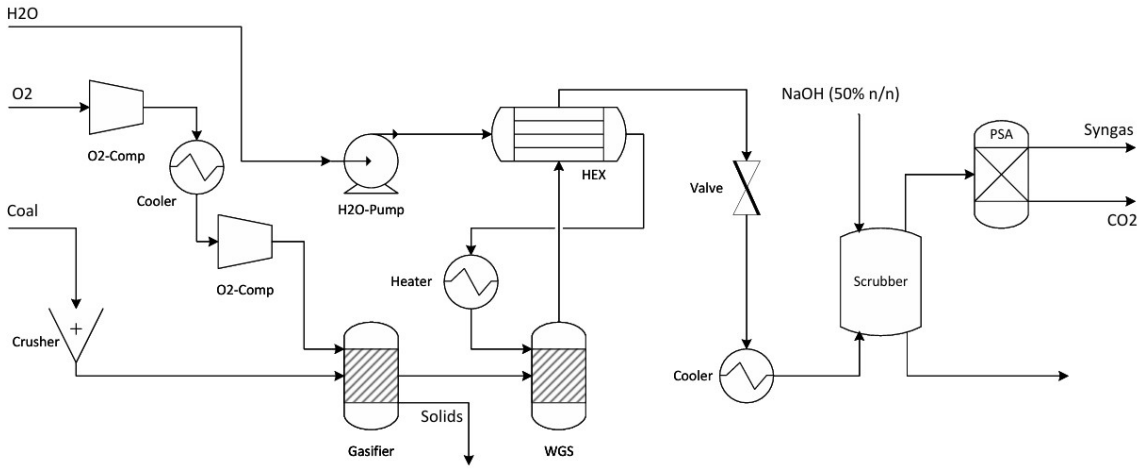

**Figure 1:** Coal gasification and syngas cleanup process flowsheet.

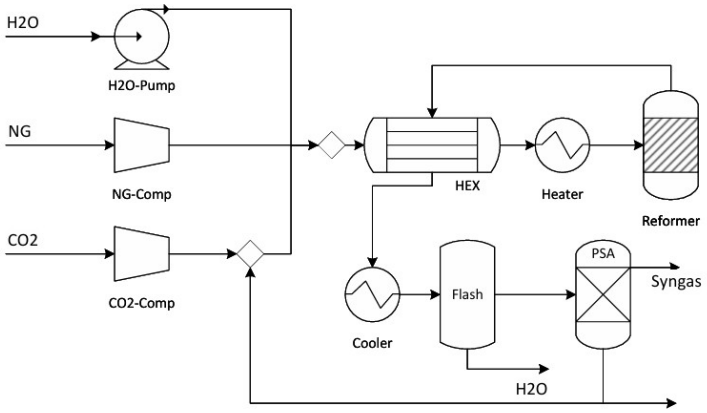

**Figure 2:** $CO_2$-assisted natural gas reforming process flowsheet

process simulations with game-theoretic frameworks to capture multi-agent interactions in a system comprising coal gasification, $CO_2$-assisted natural gas reforming, and Fischer–Tropsch aviation fuel synthesis. By comparing centralized social-welfare optimization, cooperative bargaining, and competitive equilibria, we reveal how these approaches influence system structure, profit allocation, and resource recycling.

This work shows how considering strategic behaviors of agents through game-theoretical models has implications on a SAF network optimal design and resource allocation, managing to find profitable and environmentally preferable solutions through cooperation rather than competition or centralized social-welfare optimization.

## ASPEN-BASED PROCESS MODELS FOR SAF PRODUCTION

Three process flowsheets were designed and implemented in Aspen Plus to represent the agents in the SAF network: coal gasification, $CO_2$-assisted natural gas reforming, and Fischer–Tropsch synthesis of fuels. The process diagrams for each agent are provided in Fig. 1.

### Coal gasification

The coal-based syngas route includes crushing, oxygen-blown gasification, $H_2$/CO ratio adjustment via water-gas-shift (WGS), and contaminant removal. Gasification was modeled using a Gibbs reactor, while WGS was implemented in an equilibrium reactor (REQUIL block) to maintain a $H_2$/CO ratio of approximately 2 for downstream synthesis. Heat integration between reactor effluents and water feeds improves energy efficiency. Syngas cleanup was modeled using a flash unit with the ELECNRTL property package to capture ionic interactions during NaOH absorption.

### Natural gas and CO2 reforming

Reforming was modeled with $CO_2$ addition to control

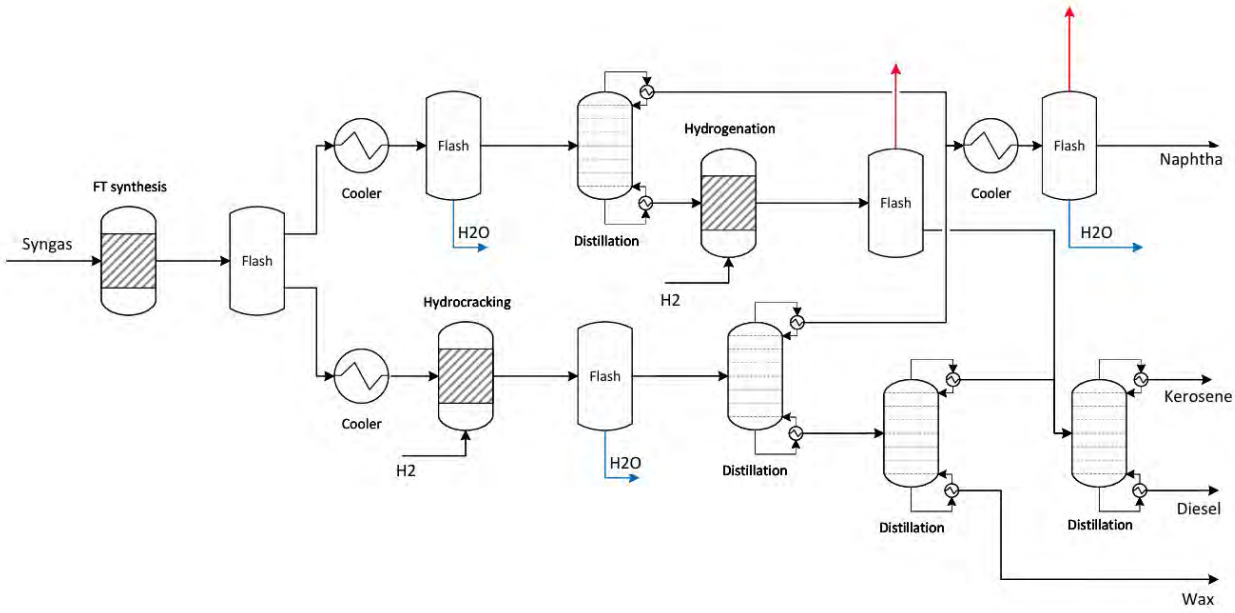

**Figure 3:** FT route of aviation fuel production process flowsheet. Red flows are light compounds to be burnt for energy recovery.

the $H_2$/CO ratio [4]. The flowsheet incorporates steam-methane reforming, autothermal reforming, and WGS reactions, with $CO_2$ recycling from the process to enhance carbon utilization. Natural gas composition includes methane ($CH_4$), ethane ($C_2H_6$), and propane ($C_3H_8$).

## Aviation fuel (Fischer-Tropsch synthesis)

Aviation fuel production was modeled using the Anderson–Schulz–Flory (ASF) distribution to predict hydrocarbon chain growth according to Eq. (1) [5].

$$W_n = n(1-\alpha)^2\alpha^{n-1} \qquad (1)$$

Here, $n$ is the carbon chain length, $\alpha$ is the chain growth factor and $W_n$ is the mass fraction of the carbon chain of length $n$.

The model accounts for paraffin and olefin formation and water generation, ensuring realistic product distribution for jet fuel and co-products. Chain growth and olefin/paraffin ratios are extracted from literature [6].

## Process Costing

Equipment and utility costs for each process were estimated using the Aspen Process Economic Analyzer (APEA). Major units such as reactors, heat exchangers, compressors, and separation systems were sized and costed directly from Aspen outputs. Additional data for reformers and gasifiers were taken from relevant literature [7].

# MODELS FORMULATION

## Agents' objectives and constraints

The payoff of each agent is determined as the Net Present Value (NPV) over a 15-year time horizon at a 15% discount rate. NPV accounts for equipment investment, utilities, feedstock purchases, and product revenues as shown in Eq. (2). Agents invest in capacity at the start of the horizon, with no expansion allowed thereafter.

$$NPV_i = \sum_{t=1}^{15}\left(DF_t \cdot (R_i - U_i - F_i) - C_i^{Cap} \cdot \left(\frac{Cap_i}{Cap_i^0}\right)^{0.6}\right) \qquad (2)$$

Here, $DF = \left(\frac{1}{(1+r)^t}\right)$ is the discount factor for the year $t, R_i$ is the revenue from product sales, $U_i$ is the utility cost, $F_i$ is the feedstock cost, $C_i^{Cap}$ is the cost for a given processing capacity of an agent; we use the 6/10 rule for economies of scale.

Material balances link feed and product flows using conversion factors ($\xi_{a,b}$) where $b$ is the product and $a$ a reference component in the feed; $\xi_{a,b}$ is obtained from ASPEN simulations as shown in Eq. (3). The set $E$ contains all the chemicals that are consumed, produced and traded (coal, natural gas, water, syngas and $CO_2$).

$$F_{i,b}^{out} = \xi_{a,b} F_{i,a}^{in} \quad a,b \in E, \forall i \in Agents \qquad (3)$$

Each agent's feedstock usage is limited by their installed capacity (Eq.(4)).

$$F_{i,feedstock}^{in} \leq Cap_i \quad \forall i \in Agents \qquad (4)$$

Further, yearly aviation fuel demand must be met (Eq.(5)).

$$F^{out}_{AF,AF} = \text{DEMAND} \tag{5}$$

Finally, agents will not participate in a system that yields them negative profit (Eq. (6)).

$$NPV_i \geq 0 \; \forall i \in Agents \tag{6}$$

## DECISION-MAKING FRAMEWORKS

To capture strategic interactions among agents, three decision-making paradigms are implemented, each reflecting a different degree of autonomy and conflict among decision-makers.

### Centralized - Social welfare

This framework assumes that each agent takes actions that maximize the conglomerate's overall well-being (profit), even if those actions are detrimental to the individual's objectives. The system-level objective is defined as:

$$f^{SW} = \sum_{i \in agents} NPV_i \tag{7}$$

### Cooperation - Nash bargain problem

Under this framework, agents remain autonomous but agree to collaborate through negotiation. This cooperation introduces strategic interdependence, as each agent's pay-off depends on the collective agreement. According to Nash's axiomatic framework, the bargaining solution is attained by maximizing the Nash product [8].

$$f^{NB} = \prod_{i \in agents} (NPV_i - d_i) \tag{8}$$

Here, the pay-off of each agent is their NPV, and $d_i$ corresponds to the defection point for that agent. The defection point represents the pay-off an agent would receive by not being part of the bargain and can be interpreted as the bargaining power an agent possesses during the negotiation process.

For this study, two cases are considered: first, defection points are set to zero for all agents, assuming equal footing in the bargain, and that failure to reach an agreement results in no investment in the conglomerate. Secondly, the defection point for each agent is the payoff they receive if the competitive solution is implemented. We will refer to these models as the symmetric and asymmetric bargain problems, respectively.

Both scenarios provide insight into how forced agreements (no cooperation means no investment) and organic cooperation (cooperation occurs only if it is beneficial) shape the structure of the network.

### Competition - Generalized Nash Equilibria

Under strict competition, agents act non-cooperatively, optimizing their own objectives while anticipating others' decisions. This creates strategic conflict, as each agent seeks their self-interest within shared constraints.

Since each agent has its own optimization goal, an integrated formulation of the multiple problems can be obtained by reformulating the optimization problems into their respective KKT conditions, yielding a Mathematical Program with Equilibrium Constraints (MPEC). Solving this model yields a Generalized Nash Equilibria (GNE), which is the point where no agent can improve their outcome by unilateral decisions [9].

The multiple optimization problems to be solved share the form presented in Eq. (9). Here $-i$ signifies all agents except $i$.

$$\left.\begin{aligned} minimize_{x_i} \quad & f_i(x_i, x_{-i}) \\ s.t. \quad & g_i(x_i, x_{-i}) \leq 0 \\ & h_i(x_i, x_{-i}) = 0 \\ & G(x_i, x_{-i}) \leq 0 \\ & H(x_i, x_{-i}) = 0 \\ & (x_i, x_{-i}) \in \mathbb{R}^n \end{aligned}\right\} \forall i \in Agents \tag{9}$$

Here, constraints that belong exclusively to agent $i$ $(g_i, h_i)$ and those shared across agents $(G, H)$ must be clearly distinguished. When reformulating KKT conditions, it is essential to track which constraints are included in each agent's Lagrangian and to correctly associate the corresponding multipliers.

The KKT reformulation for each agent consists of the following components:

**First-Order Conditions (FOCs):**

$$\nabla_{x_i} f_i(x_i, x_{-i}) + \left\langle \begin{bmatrix} \rho_i^T \\ \nu_i^T \\ \lambda^T \\ \eta^T \end{bmatrix} \cdot \begin{bmatrix} \nabla_{x_i} g_i(x_i, x_{-i}) \\ \nabla_{x_i} h_i(x_i, x_{-i}) \\ \nabla_{x_i} G(x_i, x_{-i}) \\ \nabla_{x_i} H(x_i, x_{-i}) \end{bmatrix} \right\rangle = 0$$

**Complementarity Conditions** (ensuring only active inequalities contribute to the Lagrangian):

$$\rho_i^T \cdot g_i(x_i, x_{-i}) = 0, \lambda^T \cdot G(x_i, x_{-i}) = 0$$

**Primal Feasibility:**

$$g_i(x_i, x_{-i}) \leq 0, h_i(x_i, x_{-i}) = 0$$
$$G(x_i, x_{-i}) \leq 0, H(x_i, x_{-i}) = 0$$
$$(x_i, x_{-i}) \in \mathbb{R}^n$$

**Dual Feasibility:**

$$\rho_i, \lambda \geq 0, \nu_i \in \mathbb{R}^{|\nu_i|}, \eta \in \mathbb{R}^{|\eta|}$$

MPECs are particularly hard to solve since complementarities may not respect constraint qualifications [10]. To overcome this, the problem is relaxed into a feasibility program by defining slacks on the First Order Conditions ($\varepsilon_{FOC}$) and in the complementarity constraints ($\varepsilon_{Comp}$), while smoothing the complementarity with a Fischer-Burmeister approximation ($\phi_{FB}$) [10]. The objective function of this program is to minimize said slacks, approximating

the fulfillment of the equilibrium conditions. The complete relaxed problem is shown in equation (9).

$$\left.\begin{array}{c} \min \varepsilon_F + \varepsilon_C \\ s.t: \\ FOC_i(x) \in [-\varepsilon_F, \varepsilon_F] \\ g_i(x) \leq 0, h_i(x) = 0 \\ G(x) \leq 0, H(x) = 0 \\ \phi_{FB}(\rho_i^T \cdot g_i) \in [-\varepsilon_C, \varepsilon_C] \\ \phi_{FB}(\lambda^T \cdot G) \in [-\varepsilon_C, \varepsilon_C] \\ x \in \mathbb{R}^n; \varepsilon_F, \varepsilon_C \geq 0 \\ \rho_i, \lambda \geq 0;\ \nu_i \in \mathbb{R}^{|\nu_i|};\ \eta \in \mathbb{R}^{|\eta|} \end{array}\right\} \forall i \in Agents \quad (10)$$

The Fischer-Burmeister approximation is shown in Eq. (11)

$$\phi_{FB}(a \cdot b) \stackrel{\text{def}}{=} \sqrt{a^2 + b^2 + \delta} - (a + b) \quad (11)$$

Here, $\delta$ is a small positive constant to ensure that the derivative of the square root does not get undefined at the origin. The variables $\rho_i^T, \lambda, \nu_i$ and $\eta$ are the dual multipliers of $g_i, G, h_i$ and $H$ respectively.

## APPLICATION TO SAF PRODUCTION PROBLEM

To illustrate the proposed frameworks, an existing decarbonization initiative at Pittsburgh International Airport (PIT) is used as a case study. PIT aims to incorporate locally synthesized sustainable aviation fuel (SAF) into its operations. In alignment with this goal, the case study evaluates the production of syngas from coal and natural gas, readily available resources in Pennsylvania, as feedstock for SAF synthesis.

The system design includes cross-agent resource exchanges, such as the reuse of $CO_2$ generated during fuel synthesis in the natural gas reforming process, and the integration of water usage between agents. These interactions are modeled under the three frameworks discussed in the previous section.

## RESULTS

The previous optimization problems correspond to Non-Linear Programs (NLPs). They are coded in Python using PYOMO [11] as the modelling tool and IPOPT [12] as the solver.

### System structure

Figures 4, 5, and 6 illustrate the optimal system configurations under the three decision-making frameworks. The social welfare model favors complete syngas production from natural gas, entirely excluding its production from coal.

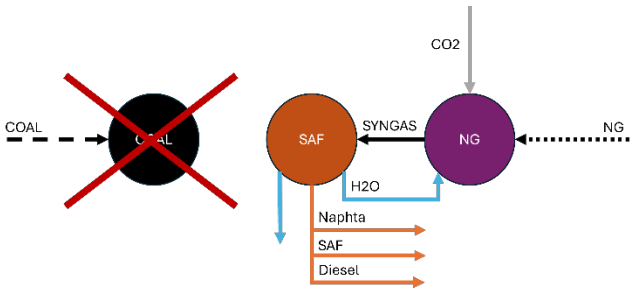

**Figure 4.** Social welfare system design.

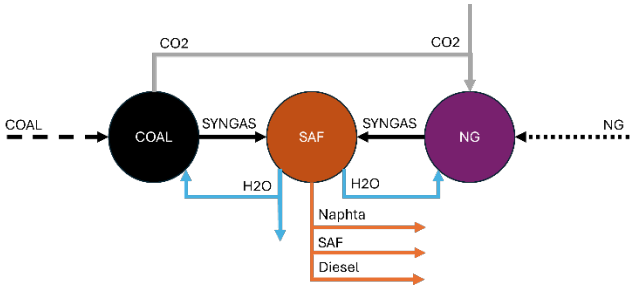

**Figure 5.** Cooperative system design.

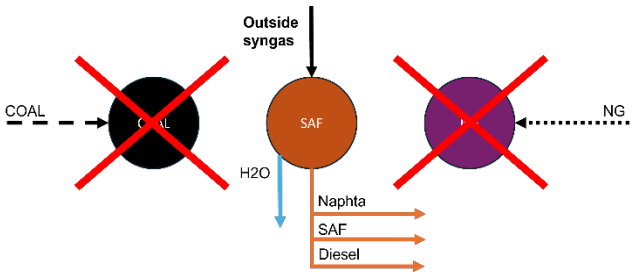

**Figure 6.** Competitive system design.

Under cooperative bargaining, either symmetric or asymmetric, coal is incorporated into the system. This inclusion reflects the bargaining dynamics: agents seek to maximize their individual payoffs while ensuring mutual benefit, which allows coal to enter the system, as it improves the payoff distribution among agents. Resource integration is also increased in this case, with the agents maximizing the reuse of $CO_2$ and water. This behavior arises because resource sharing enhances collective gains without compromising individual objectives under the Nash product formulation.

Under the strict-competition assumption, the system consisting only of coal, natural gas, and the SAF agent fails to admit a generalized Nash equilibrium. This indicates that SAF production cannot be sustained using solely these local resources when all agents behave competitively. An equilibrium emerges only when an external syngas supplier is introduced. In this case, the competitive formulation satisfies first-order optimality conditions within acceptable tolerances, and the complementarity conditions exhibit negligible residuals. The additional degree of freedom provided by the external supplier

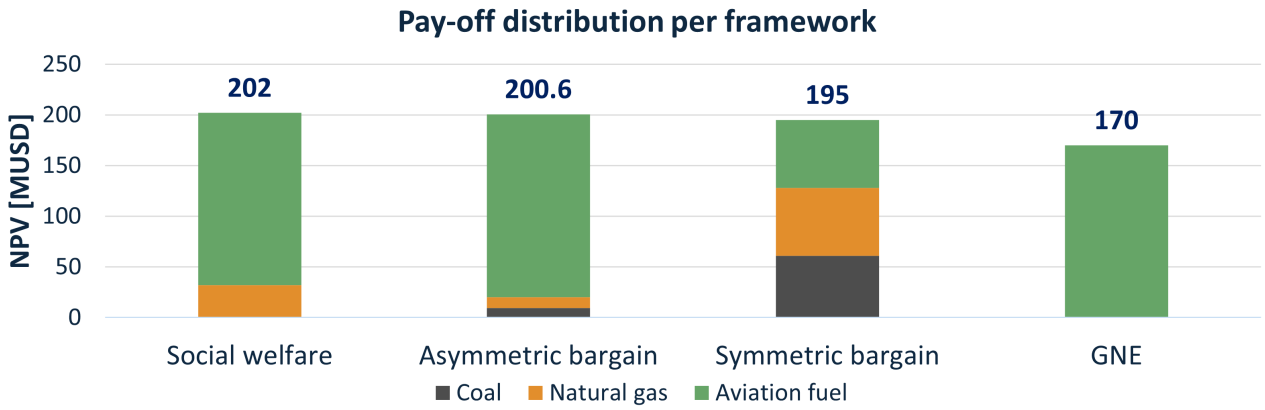

**Figure 7.** Profit distribution among agents under different frameworks. Social welfare maximizes total system profit and strongly favors the SAF agent. Cooperation (bargaining) redistributes profits, while competition (GNE) reduces overall profit and excludes upstream agents.

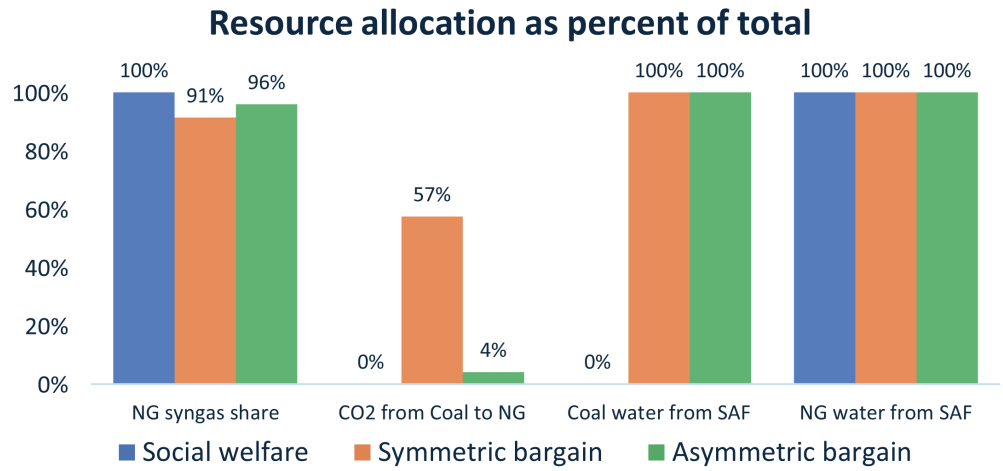

**Figure 8.** Resource distribution under different frameworks. Bairganing corresponds to the maximum reuse of resources ($CO_2$ and water) between the agents. Competition eliminates internal exchanges, favoring external sourcing and hence is excluded from the chart.

enables the SAF agent to meet its demand without full dependence on upstream agents. Consequently, the coal and natural gas agents are excluded from the equilibrium solution.

## Profit and resource allocation

Figures 7 and 8 present the distribution of profits and resource use among agents under the three modelling frameworks.

The social welfare model achieves the highest overall profit, as expected, since its objective is to maximize the sum of all agents' NPVs, allowing for unfair distributions in which one agent receives most of the profit.

In contrast, the Nash bargaining solution redistributes profits across agents. Symmetrical bargaining reflects equal bargaining power for the agents, achieving an equal split of the profit share. An asymmetric bargain, on the other hand, distributes resources based on how competitive each agent is if no agreement is reached. It is important to note that, even though bargaining reduces the total profit of the system, it does so slightly: 99.3% and 96.5% of the maximum attainable system profit is achieved for asymmetric and symmetric bargains, respectively.

In the competitive solution, at the Nash equilibrium, the SAF agent attains a positive NPV, while coal and natural gas agents are excluded, with syngas sourced entirely from the external supplier. This outcome indicates that, in a fully competitive setting, local coal and natural gas agents lack sufficient competitiveness, suggesting that cooperative or centralized schemes may be required if these local feedstock sources are to be used. It is worth noting that the lowest overall NPV for the system and for the SAF agent is achieved in this competitive setting,

resulting in a 12.4% loss in overall system NPV relative to the social welfare maximum. A SAF agent aware of this outcome would then prefer a social welfare approach (i.e. to integrate the syngas production process within the same firm) or an asymmetric bargain where their competitive status is maintained. The SAF agent will discourage symmetric bargaining, since the cooperative solution provides the lowest payoff.

Resource exchanges also differ significantly across frameworks. $CO_2$ trading between agents occurs considerably only under symmetric bargaining, while water integration is maximized under social welfare and both symmetric and asymmetric bargaining compared to competition. This behavior aligns with theoretical expectations: competitive agents tend to minimize reliance on internal resource sharing and instead favor external procurement. These findings suggest that bargaining not only redistributes profit but also promotes resource reuse within the system, enhancing overall integration.

An important result is that bargaining enables a full recycle of $CO_2$ from the coal agent to the natural-gas agent, producing a configuration with no direct $CO_2$ emissions. In this setting, bargaining not only improves the distribution of profits with negligible loss in total system profit, but also leads to a more environmentally favorable configuration of the whole SAF network.

## CONCLUSIONS

This study evaluates three decision-making paradigms, social welfare maximization, cooperative bargaining (with symmetric and asymmetric bargaining power), and strict competition to understand how strategic interactions influence network configuration, profit distribution, and resource sharing in a SAF production system.

Optimization of the social welfare achieves the highest total profit but excludes coal from the system, prioritizing the use of natural gas. Cooperative bargaining enables coal's inclusion and promotes internal resource sharing, generating positive NPVs for all agents with a minor decrease in the system's total profit of the system. However, the SAF agent benefits most from social welfare maximization and asymmetric bargaining. Hence, the SAF agent perceives no incentive to enter an equal-footing bargaining arrangement, whereas upstream agents favor some specific bargains to secure participation and positive payoffs. Coal benefits from any sort of arrangement, while natural gas will only be benefited by a symmetric bargain compared to the centralized social welfare solution.

The competitive solution requires the presence of an external syngas supplier, allowing the convergence to a Generalized Nash Equilibria. However, it excludes the coal and natural gas agents from the system, which is not desirable if the promotion of local resource usage is sought after.

Future work will extend this analysis to consider information asymmetry and coalition formation, offering a deeper understanding of strategic behavior in multi-agent systems.

## ABSTRACT

The development of energy technologies with low $CO_2$ emissions is increasingly important for achieving the United Nations Sustainable Development Goals. In this context, power plants based on the Allam-Fetvedt Cycle appear promising because this cycle (introduced in 2012) features inherent $CO_2$ capture. In this context, its association with biogas as fuel enables its application as a Bioenergy with Carbon Capture and Storage (BECCS) system. This study evaluates the technical, energetic, and economic feasibility of an Allam-Fetvedt Cycle power plant fueled by biogas. The methodology is based on detailed process simulations performed using Aspen Plus® v14. Two biogas production scenarios were assessed: Case 1 and Case 2, corresponding to the processing of 8 and 24 million tons of sugarcane per year, respectively. The economic analysis indicated a high capital investment, primarily in the Air Separation Unit (ASU) and the Balance of Plant (BOP). Nevertheless, a significant reduction in the Levelized Cost of Energy (LCOE) was observed, decreasing from 1443 R$/MWh (€0.227/kWh) in Case 1 to 848 R$/MWh (€0.134/kWh) in Case 2. Overall, the results suggest that integrating biogas into the Allam-Fetvedt Cycle represents a promising technological pathway for power generation with negative carbon emissions. Further research and optimization are required to improve economic viability and strengthen the role of this technology as a strategic option for decarbonizing the energy sector.

## INTRODUCTION

Electricity generation is a fundamental basis for the economic and social development of modern society. Conventional Thermal Power Plants (TPP), primarily fueled by coal, account for a significant share of the global energy mix and operate predominantly according to the Rankine cycle. In contrast, natural gas-fired thermal power plants, particularly combined-cycle gas turbines (CCGT), have demonstrated substantial improvements in energy efficiency and environmental performance when compared to coal-fired power plants. Natural gas power plants are relatively more efficient and emit approximately 450 $gCO_2e\ kWh^{-1}$, about half the greenhouse gas (GHG) emissions of coal-fired power plants [1].

Despite this considerable reduction, the challenge of further decreasing power plant GHG emissions remains. In this sense, the next frontier for reducing $CO_2$ emissions in TPP is its integration with Carbon Capture and Storage (CCS) [2]. Capturing $CO_2$ from flue gases is challenging because of the abundance of $N_2$ that comes from the combustion air. Alternatively, oxy-combustion technology in power plants relies on combustion in an oxygen-rich environment, producing a flue gas composed of $CO_2$ and $H_2O$, thereby avoiding dilution with $N_2$. Due to the relatively high $CO_2$ purity after water is condensed, this CCS technology produces a stream ready for long-term $CO_2$ sequestration in underground formations, such as saline aquifers and depleted oil and gas reservoirs.

One of the technologies considered for oxy-combustion is the Allam-Fetvedt cycle. This cycle is based on a recuperated Brayton cycle operating at high pressure and uses supercritical $CO_2$ ($sCO_2$) as the working fluid under an oxy-combustion regime [2]. Its key distinguishing feature is the recirculation of $sCO_2$ to the combustion chamber. This recycled $sCO_2$ plays a dual role: it reduces the combustion flame temperature to a manageable level and dilutes the combustion products [2]. Furthermore,

$sCO_2$ is non-flammable and non-toxic, low cost, has a density approximately twice that of water vapor, and high volumetric heat capacity [2]. These properties allow a greater amount of energy to be transported per unit volume than water vapor. This allows the use of smaller equipment for the same function, reducing the overall installation footprint and cost while improving cycle efficiency [2]. Modeling studies using natural gas as fuel have indicated that the cycle can achieve efficiencies of up to 60% (LHV – lower heating value – basis), even when accounting for the energy consumption of the Air Separation Unit (ASU) [3].

Biogas, a mixture of about 60% $CH_4$ and 40% $CO_2$ produced via anaerobic fermentation of organic residue, emerges as a more sustainable alternative to natural gas. The Brazilian sugarcane industry generates large amounts of vinasse (stillage) as a byproduct of ethanol production from sugarcane. Vinasse has a high organic load and nutrient content, making it a favorable feedstock for biogas production [4]. Given the amount of vinasse currently produced by existing sugarcane mills in Brazil, the sugarcane sector alone has the potential to produce 15 billion $Nm^3$ of biomethane per year, enough to cover about two-thirds of the domestic natural gas demand [5]. This biogas could be used to increase the presence of the sugarcane sector in the electricity market, which is already significant since sugarcane mills sell surplus electricity produced from bagasse to the national grid. Moreover, biogas utilization in oxy-combustion systems with integral $CO_2$ capture is fully aligned with the Bioenergy with Carbon Capture and Storage (BECCS) concept. This integration offers a promising pathway to achieve negative emissions in electricity generation by combining sustainable bioenergy sources with CCS technology.

This work investigates the potential of the Allam-Fetvedt cycle using biogas in sugarcane biorefineries to produce renewable electricity. This combination allows biogas to be used without separating $CH_4$ and $CO_2$, thereby reducing the cost of biogas upgrading to biomethane. Moreover, it creates the opportunity to store both the $CO_2$ available in biogas and the $CO_2$ produced during the combustion of biomethane. To evaluate the potential of this technology, an integrated process was simulated to use the biogas produced as a co-product of ethanol production in sugarcane mills. Based on this simulation, a techno-economic analysis was conducted that considered both the levelized cost of electricity (LCOE) and the Carbon Abatement Cost (CAC).

# METHODOLOGY

## Allam–Fetvedt Cycle Model for Biogas

The evaluation of energy efficiency and the $CO_2$ capture in the Allam-Fetvedt cycle fueled by biogas followed a structured methodology, ranging from feedstock characterization to the integrated cycle performance analysis. The biogas yield and composition derived from vinasse were investigated. This analysis enabled defining the fuel flow rate required to supply a power plant operating at a thermal power load of around 200 $MW_{th}$. This value was established based on metrics from sugarcane processing plants in the State of São Paulo and served as a key assumption for subsequent steps of the study.

Two scenarios were considered for simulation. Scenario 1 (S1) represents a mill with a sugarcane processing capacity of 8 million tons per year, producing biogas for the TPP that uses the Allam-Fetvedt cycle. Scenario 2 (S2) is a hypothetical scenario that integrates three sugarcane mills supplying a single TPP, totaling 24 million tons of processed sugarcane per year. Table 1 presents the production parameters for both scenarios, and Table 2 summarizes biogas properties considered in this work

**Table 1:** Biogas Production Parameters (1G).

| Parameters | Unit | S1 | S2 |
|---|---|---|---|
| *Harvest and operation* | | | |
| Harvest | $t_{cane}\ y^{-1}$ | 8, 0 x $10^6$ | 2, 7 x $10^7$ |
| Operation | $d\ y^{-1}$ | 225 | 225 |
| Mass flow rate [6] | $t_{cane}\ h^{-1}$ | 1, 481 | 4, 444 |
| *Conventional ethanol process yields* | | | |
| Bagasse | $kg\ t_{cane}^{-1}$ | 252 | 252 |
| Ethanol | $L\ t_{cane}^{-1}$ | 85 | 85 |
| Vinasse | $L\ t_{cane}^{-1}$ | 1, 040 | 1, 040 |
| Biogas | $Nm^3\ t_{cane}^{-1}$ | 22.4 | 22.4 |
| *Biogas flow rate* | | | |
| Volume | $Nm^3\ h^{-1}$ | 33, 185 | 99.556 |
| Mass | $t\ h^{-1}$ | 35.8 | 107.5 |
| *Thermal Power* | | | |
| Available | $MW_{th}$ | 204.7 | 614.2 |

**Table 2:** Biogas properties.

| Properties | Unit | Value |
|---|---|---|
| *Biogas Composition* [6] | | |
| $CH_4$ | % mol | 65, 2 |
| $CO_2$ | % mol | 32, 6 |
| $H_2S$ | ppm | 60, 2 |
| Density | $Kg\ Nm^{-3}$ | 1.08 |
| LHV | $MJ\ kg^{-1}$ | 20.57 |
| Desulfurization efficiency | % | 99 |

Process modeling followed an iterative approach.

The simulations were carried out using Aspen Plus V14, and model validation was performed by comparing them with simulations using natural gas as fuel. The simulation was developed based on the patents reported in [9] and [10], as well as on previous studies [3, 4, 10]. After the validation step, the model parameters were adjusted to represent biogas as fuel. Given the supercritical operating condition and the mixture composition, the Peng-Robinson Equation of State (EoS) was employed. Previous studies indicate that this EoS provides slightly better performance compared to others, particularly for the calculation of volumetric properties of oxygen-rich mixtures [7]. The $CO_2$ Purification Unit (CPU) was also modeled using the Peng-Robinson EoS [8]. The main assumptions used in the simulation of the Allam-Fetvedt cycle and its auxiliary units are summarized in Table 3, while the performance indicators are presented in Table 4.

**Table 3:** Summary of the process assumptions

| Assumptions | Unit | Value |
|---|---|---|
| Maximum Allowable Turbine Outlet Temperature | ºC | 740 |
| Turbine Inlet Pressure | bar | 300 |
| Turbine Outlet Pressure | bar | 34 |
| $O_2$ Molar Fraction in the Oxidant | % | 13.3 |
| $O_2$ Excess in Combustion | % | 3 |
| Combustion Chamber Inlet Pressure | bar | 305 |
| Pressure Drop in the Combustion Chamber | % | 1.6 |

**Table 4:** Performance Assumptions

| Assumptions | Unit | Value |
|---|---|---|
| Gas Turbine Isentropic Efficiency | % | 90 |
| Compressors Isentropic Efficiency | % | 90 |
| Pumps Hydraulic Efficiency | % | 85 |
| Mechanical Efficiency of All Turbomachinery | % | 98 |

It is important to note that, in this work, specific operating conditions were defined for two key auxiliary facilities. The $CO_2$ Purification Unit (CPU) adopted in the model corresponds to systems previously studied and patented in references [11] and [12]. This configuration was selected due to its high $CO_2$ recovery rate, which can reach approximately 99%. Furthermore, to simplify the analysis, the Air Separation Unit (ASU) was not explicitly modeled. Instead, operating data were obtained from the literature [13] and are presented in Table 5.

For the simulation of the Allam-Fetvedt cycle in Aspen Plus, the use of Design Specifications (Design Specs) and customized nesting settings was required, along with a robust convergence method to handle the high complexity of the system. The Design Specs were applied to control the critical operating parameters of the cycle simulation, namely: 13.3% $O_2$ concentration, 3% excess $O_2$ in combustion, turbine outlet temperature of 740ºC, and a $CO_2$ recovery rate of 99.8%. Design Specs were nested outside, giving priority to stabilization of the mass and energy balance of all recycling loops before solving them [15]. The Broyden method was selected as the convergence algorithm to solve the nonlinear systems of equations associated with multiple Design Specs and recycling loops.

**Table 5:** Parameters and assumptions of the ASU.

| Purity at 120 bar | **99, 5%*** | **97%*** | **95%*** |
|---|---|---|---|
| Electricity demand ($kJ_{el}/kgO_2$) [13] | 1.390 | 1.320 | 1.310 |
| Heat recovery from the aftercooler air compressor ($kJ_{th}/kgO_2$) [14] | 1.015 | 1.015 | 1.015 |

## Economic Analysis

The economic analysis of the project estimated the Capital Expenditures (CAPEX) and Operating Expenditures (OPEX) using an adapted methodology based on Amec Foster Wheeler guidelines [2], combined with specific studies on biogas production [16]. In both scenarios, the CAPEX for biogas production followed a methodology based on capital cost studies of biogas plants. The cost adjustment was performed using the six-tenths rule, as expressed by Equation (1):

$$CAPEX_{Proposed} = CAPEX_{Base} \times \left(\frac{Q_{Proposed}}{Q_{Base}}\right)^{R} \quad (1)$$

where, $CAPEX_{Base}$ corresponds to the CAPEX at the reference capacity, and $Q_{Base}$ e $Q_{Proposed}$ represent the reference and proposed plant sizes, respectively. The scaling exponent "R" was assumed to be 0, 6, according to [17].

The calculations were structured around three main indicators: Total Equipment Cost (TEC), Total Plant Cost (TPC) and Total Capital Requirement (TCR) [2]. The calculations already include cost updates based on plant cost indices and the necessary currency conversions [2]. The reference cost is presented in Table 6.

**Table 6:** Cost references for the main equipment of the Allam-Fetvedt Cycle.

| Components | Reference Cost [8] |
|---|---|
| ASU | 120.37 |
| CPU | 35.20 |
| Turbine | 32.55 |
| Heat Exchangers and chillers | 0.4 |
| Compressors | 21.50 |
| Balance of plant (BOP) | 125.82 |

The Total Plant Cost (TPC) comprises TEC plus additional installation cost and contingency, as defined by [2]. The F factor adopted in this study was 2, as in [2]. The TPC was calculated by Equation (2).

$$TPC = F \times TEC \quad (2)$$

The Lang Fang factor adopted was 4.73, and the location factor was 1.3. The TCR was calculated using Equation (3).

$$TCR = F_{Lang} \times F_{Locality} \times TEC \quad (3)$$

OPEX was classified into fixed and variable costs, based to the established assumptions. The fixed operational and maintenance costs, which do not vary with the production level, include: labor costs, estimated using the with the method presented by Turton et al. 2018 [17], in which the number of operators per shift was calculated by Equation 4; maintenance costs, assumed as 2.5% per year of the TPC for innovative technologies and 1.5% per year of TPC for conventional technologies (BOP) [2]; overhead costs, corresponding to 30% of labor costs, in addition to maintenance costs [2]; and insurance and local taxes, representing 0.5% of TPC [2].

$$N_{OL} = \sqrt{6.29 + 31.7P^2 + 0.23N_{np}} \quad (4)$$

where P is the number of process steps that involve solids and $N_{np}$ is the number of non-particulate steps.

The variable costs depend directly on the production level, as detailed in Table 7. Indices used to update costs and exchange rates are presented in Table 8.

**Table 7:** Variable costs [2].

| Item | Value |
|---|---|
| Operation at full power | 7.884 h $y^{-1}$ |
| Chemical product costs | 0.06 € $MW_{th}^{-1}$ |
| $CO_2$ transport and storage | 20 € $t^{-1}$ |
| Makeup water | 0.38 US$ $GJ^{-1}$ |

**Table 8:** Indices and exchange rates.

| Indicators | Value | Reference |
|---|---|---|
| Dollar (USD) | R$ 5.60 | [18] |
| Euro (EUR) | R$ 6.35 | |
| CEPCI 2015 | 556.8 | |
| CEPCI 2022 | 816 | [19] |
| CEPCI 2024 | 799 | |

To evaluate the performance of the Allam-Fetvedt cycle using biogas as fuel, environmental and economic indicators were applied. The net electrical efficiency (%) was determined considering that the net power output accounts for all auxiliary power consumptions. The calculation was performed using Equation (5).

$$\eta_{net} = \frac{Net\ Electrical\ Power\ Output}{Fuel\ Energy\ (LHV)} \times 100\% \quad (5)$$

The $CO_2$ capture rate (%) quantifies how much of the $CO_2$ generated during combustion is effectively captured by the system. It is calculated using Equation (6).

$$TC_{CO_2} = \frac{Massa\ de\ CO_2\ Capturada}{Massa\ Total\ de\ CO_2\ Produzida} \times 100\% \quad (6)$$

The $CO_2$ emissions indicator quantifies the mass of $CO_2$ released to the atmosphere per unit of electrical energy generated. The calculation was performed using Equation (7) and expressed as $tCO_2\ MWh^{-1}$.

$$E_{CO_2} = \frac{Uncaptured\ CO_2\ Mass}{Net\ Electrical\ Power\ Generated} \quad (7)$$

The assessment of the amount of $CO_2$ captured relative to the electrical energy generated was performed using the calculation defined in Equation (8). The result is expressed in $tCO_2\ kWh^{-1}$.

$$CO_{2\ captured} = \frac{Mass\ of\ CO_2\ Captured}{Net\ Electrical\ Power\ Generated} \quad (8)$$

The Carbon Abatement Cost (CAC) represents the additional cost required to reduce one tonne of $CO_2$ emissions when comparing a capture scenario with a non-capture reference scenario [2]. The calculation was performed using Equation (9), with the final unit expressed as $R\$\ tCO_2^{-1}$.

$$CAC = \frac{LCOE_{with\ CCS} - LCOE_{without\ CCS}}{Emissions_{without\ CCS} - Emissions_{with\ CCS}} \quad (9)$$

The LCOE represents the average cost of electricity production over the project's lifespan. It integrates CAPEX and OPEX, both discounted to present value, and divides them by the total electricity generated over the project's lifespan [2]. The calculation is carried out using Equation (10), with the result expressed in $R\$\ MWh^{-1}$.

$$LCOE = \frac{\sum_{t=1}^{n} \frac{CAPEX_t + OPEXt}{(1+r)^t}}{\sum_{t=1}^{n} \frac{Energia_Gerada_t}{(1+r)^t}} \quad (10)$$

Other financial parameters are detailed in Table 9, and they are based on [2] and other parameters relevant to the Brazilian sugarcane industry.

**Table 9:** Other financial parameters.

| Economic Parameters | Value |
|---|---|
| Depreciation | 12 y |
| Discount rate | 8% |
| Inflation rate | Constant |
| Plant lifetime | 25 y |
| Construction time | 3 y |
| Capacity factor | 90% |
| Years 1 and 2 | 65% e 85% |
| Start-up cost | 2% TPC + 3 OPEX mo |
| Decommissioning cost | Zero |

## RESULTS AND DISCUSSION

To evaluate the influence of different operating conditions and flow rate on cycle performance, scenarios S1 and S2 were simulated. The process simulation flowsheet of the Allam-Fetvedt cycle in Aspen Plus is illustrated in Figure 1, and the CPU process flowsheet is shown in Figure 2. The operating parameters of the various key streams are shown in Table 10. The plant's net energy efficiency is presented in Table 11.

**Table 10:** Key process results for scenarios S1 and S2.

| Parameters | S1 | S2 |
|---|---|---|
| Recycle flow rate (kg/s) | 158.6 | 479.7 |
| Combustion outlet temp. (°C) | 1, 152 | 1, 149 |
| Turbine flow rate (kg/s) | 337.1 | 1, 019 |
| Turbine cooling flow (kg/s) | 26.89 | 81.36 |
| Turbine outlet temperature (°C) | 734.43 | 731.99 |
| Turbine outlet pressure (bar) | 34.00 | 34.00 |
| Captured $CO_2$ flow rate (kg/s) | 17.23 | 51.70 |
| Oxygen flow rate (kg/s) | 16.87 | 50.60 |

**Table 11:** Power Block Summary for Cases 1 and 2.

| Parameters | S1 | S2 |
|---|---|---|
| Available thermal power ($MW_{th}$) | 184.3 | 555.8 |
| Turbine gross electric power ($MW_{el}$) | 157.6 | 475.2 |
| Total compression power ($MW_{el}$) | 27.83 | 84.15 |
| ASU power ($MW_{el}$) | 23.44 | 70.33 |
| CPU power ($MW_{el}$) | 2.29 | 6.86 |
| Net electric power ($MW_{el}$) | 104.0 | 313.8 |
| Net plant electrical efficiency (%) | 56.43 | 56.47 |

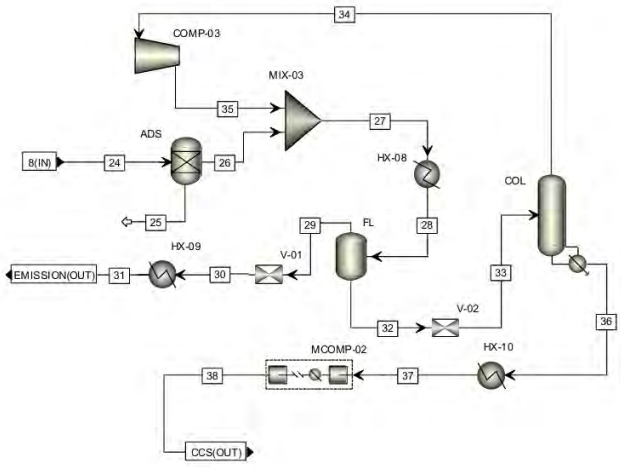

**Figure 2.** Process flowsheet diagram of the CPU in Aspen Plus.

### Economic Analysis

According to [16], the base CAPEX considered was R$ 96.32 million for a biogas production capacity of 3.2 million $Nm^3\ y^{-1}$. Therefore, the calculated capital costs for the different study cases are presented in Table 12. The total CAPEX indicators for the Allam-Fetvedt cycle, including TEC, TPC, and TCR, are summarized in Table 13.

**Table 12**: Estimated CAPEX and OPEX for biogas production (million R$).

| Item | Case 1 | Case 2 |
|---|---|---|
| CAPEX (M R$) | 338, 97 | 655, 30 |
| OPEX (M R$/year) | 51, 66 | 99, 86 |

**Table 13:** Summary of CAPEX Indicators for the Allam-Fetvedt Cycle (Million R$).

| Components | S1 | S2 |
|---|---|---|
| *Estimated TEC for the Allam Cycle (Million R$)* | | |
| ASU | 447 | 865 |
| CPU | 106 | 206 |
| Turbine | 178 | 345 |
| Heat Exchangers | 38, 4 | 72, 0 |
| Recycle and $O_2$ Compressor | 175 | 366 |
| Balance of Plant (BOP) | 535 | 745 |
| *Summary* | | |
| TEC | 1.480 | 2.599 |
| TPC | 2.959 | 5.197 |
| TCR | 9.117 | 16.013 |

Based on the TEC breakdown, the ASU and BOP represent the largest portions of equipment cost in both cases. This reflects the complexity and scale of these units. Furthermore, in scenario S2, all values are higher for all components, which is expected due to the increased production capacity.

In Table 14, the OPEX analysis indicates that costs associated with innovative technologies (such as maintenance of the cooled turbine and recuperator heat exchangers) and the BOP are the highest contributors to operational costs in both cases. Also, for both scenarios, the labor costs remain the same. This occurs because Equation (4) considers only the number of equipment units. Finally, the total OPEX for S2 (R$ 442.82 million per year) is almost twice that of S1 (R$ 238.70 million per year), which is attributed to a production capacity three times larger.

**Table 14:** Results of OPEX (Million R$ $y^{-1}$).

| Item | S1 | S2 |
|---|---|---|
| Labor | 1.14 | 1.14 |
| Technologies | 74.0 | 129 |
| Balance of plant (BOP) | 44.4 | 77.8 |
| Insurance and local taxes | 14.8 | 25.9 |
| CCS | 8.83 | 26.5 |
| Makeup water | 3.64 | 0.91 |

Table 15 presents the cost metrics and $CO_2$ emissions in comparison with a reference Natural Gas Combined Cycle Gas Turbine (CCGT) power plant. It is also shown that, for both cases, the LCOE values are higher than those of the reference CCGT. This difference is mainly attributed to the high CAPEX inherent to the implementation of the Allam-Fetvedt cycle and carbon capture systems. On the other hand, a notable reduction in LCOE is observed when moving from S1 to S2, which is a direct result of economies of scale.

**Table 15:** Economic and environmental metrics.

| Parameters | S1 | S2 |
|---|---|---|
| LCOE Biogas (R$ $MWh^{-1}$) | 1, 443 | 848 |
| Specific Cost, TCP/kW (R$ $kW^{-1}$) | 28, 453 | 16, 560 |
| Specific Cost, TCR/kW (R$ $kW^{-1}$) | 87, 662 | 51, 020 |
| $CO_2$ Emission ($kgCO_2$ $MWh^{-1}$) | 1.2 | 1.2 |
| CAC (R$ $tCO_2^{-1}$) | 2, 980 | 1, 271 |
| **Reference (CCGT) [2]** | | |
| LCOE Reference (R$ $MWh^{-1}$) | 406 | |
| $CO_2$ Emission ($kgCO_2$ $MWh^{-1}$) | 348 | |

For comparison purposes, Table 16 presents the LCOE and CAC data for other advanced natural gas-based technologies with carbon capture. Regarding LCOE, although the Allam-Fetvedt cycle benefits from scalability, using biogas as fuel introduces additional complexities and costs that outweigh those of other natural gas-based carbon capture routes. Consequently, this explains the significantly higher LCOE of the Allam cycle when compared to the other technologies. A similar pattern is observed for the CAC values, with abatement costs in both scenarios S1 and S2 higher than those of the other carbon capture routes. Nevertheless, an improvement is again observed with increasing scale, highlighting the impact of economies of scale.

**Table 16:** Comparison of levelized cost of energy (LCOE) and carbon abatement cost (CAC)

| Cycle/Case | LCOE (R$ $MWh^{-1}$) | CAC (R$ $t^{-1}$) |
|---|---|---|
| CCGT [2] | 397 | - |
| NET Power [2] | 531 | 429 |
| SCOC-CC [2] | 589 | 622 |
| Modified S-Graz [2] | 595 | 644 |
| CES [2] | 604 | 673 |
| Biogas/S1 – this work | 1.443 | 2.980 |
| Biogas/S1 – this work | 848 | 1.271 |

## CONCLUSION

The evaluation of energy efficiency and $CO_2$ sequestration in a thermal power plant operating with the Allam-Fetvedt cycle using biogas as fuel was conducted for two biogas production scenarios of different capacities: S1 (~104 $MW_{el}$) and S2 (~304 $MW_{el}$). The economic analysis revealed that the CAPEX of the Allam cycle in both cases is strongly influenced by the complexity and scale of the plants, particularly due to the ASU and BOP. OPEX was also significantly affected by the maintenance requirements of innovative technologies, while labor cost remained constant between the two cases. The comparison of the LCOE of the Allam-Fetvedt cycle using biogas with other advanced technologies also fueled by biogas indicates higher values. Similarly, the CAC analysis shows a high additional cost per tonne of $CO_2$ avoided, and although a considerable reduction is observed in S2, the CAC remains higher than that of other carbon capture routes. The main distinctive feature of this work lies in the use of a renewable energy source, which positions this technology within the BECCS concept and enables the achievement of net negative emissions, an outcome that fossil fuel-based technologies cannot attain. In summary, although economic viability still requires further optimization and demonstration at a large scale, this work consolidates the technology as a promising, technically validated pathway.

## ABSTRACT

Trinidad and Tobago emits 11.3 metric tonnes of $CO_{2\text{-eq}}$ per capita per year, making it one of the highest per capita per year greenhouse gas (GHG) emitters globally. An estimated 87% of these emissions are linked to the industrial sector, including power generation. This study aims to reduce the national environmental impact of the power generation and waste disposal sectors, with the goal of reducing the country's reliance on natural gas and promoting sustainable power generation via waste-to-energy (WTE) pathways. This work seeks to implement a mixed-integer linear programming (MILP) framework, along with techno-economic analysis (TEA) and life-cycle assessment (LCA) to determine potential sustainable objectives with respect to T&T's power system. The study implements supply chain optimisation considering single objective optimisation (SOO) with life-cycle (LC) endpoint externalities included. The key constraint of the system was the production of sufficient electricity to sustain the national power grid. A WTE model was proposed in which incineration, gasification and anaerobic digestion (AD) were implemented to supplement the country's natural gas based power generation system. When considering LC endpoint externalities, inclusion of WTE along with improved natural gas power generation efficiency resulted in a maximum reduction of 31% in total annualised life-cycle cost (TALC) and 38% in total annualised GHG emissions (TAGE). Thus, indicating the potential of WTE as a key factor in achieving sustainable development goals in SIDS. This work provides a roadmap for the implementation of sustainable power generation practices for policymakers.

## INTRODUCTION

The Caribbean comprises of 13 island nations- most of which are classed as developing states. Across the Caribbean archipelago, energy is an expensive necessity as most of the region is heavily reliant on fossil fuels in meeting its energy needs. The deployment of clean affordable energy (SDG-7) is integral in combatting the effects of climate change and promoting climate action (SDG-13). A holistic approach is required to aid in this transition, considering all aspects of a robust and sustainable energy system supporting the development of sustainable communities (SDG-11). This transition, however, remains a challenging task as both economic and environmental constraints need to be optimised to guarantee SDGs are met across the wider global population.

Waste-to-energy (WTE) technology provides a potential solution to problems related to fossil fuel power generation in Trinidad and Tobago (T&T). At present, like most developing nations and small island developing states (SIDS), waste disposal in T&T is not considered to be sustainable due to an over-reliance on landfilling and open dumping. This over-reliance on landfilling has resulted in overcrowded landfill sites and is also a source of significant greenhouse gas (GHG) emissions along

with other environmental impacts such as toxic gases, toxins in soils and waterways.

Thus, the introduction of WTE technology can provide a potential solution to two problems evident in T&T and other developing nations. WTE technology can lower both environmental impacts of fossil fuel power generation and disposal of municipal solid waste (MSW).

By utilising a supply chain optimisation framework, guidance on achieving clean and affordable energy through whole systems thinking can be fostered and implemented locally and within the Caribbean region, and among SIDS globally. Hence our work aims to utilise mixed-integer linear programming (MILP) to minimise total annualised costs (TALC) via the use of single objective optimisation (SOO). Environmental indicators are considered in this study via the use of life-cycle externality costs related to endpoint indicator categories. One of the key novelties of the presented work is our MILP framework is tailored to resource availability, local infrastructure, energy system capabilities and waste disposal systems within the Caribbean. This is of critical importance as previous works in this field generally focus on larger and more developed nations.

# METHODOLOGY

The model represented in this study focuses on SOO, with monetised impacts for endpoint indicators aligned to human health (HH), eco-system quality (EQ) and resource depletion (RD) being considered in addition to total annualised costs for both power generation and waste disposal. The general superstructure used in this model, which highlights the inputs and outputs of the system along with the technologies utilised, is shown in Figure 1. The scenarios represented in this study generally focus on altering the objective function between minimisation of TALC, minimisation of total annualised GHG emissions (TAGE) and maximisation of power generated from WTE sources.

The model involves the use of binary variables to represent each power plant and WTE technology, thus allowing the model the opportunity to select which power plants and WTE technology can be used. Each plant was constrained to a minimum capacity factor of 0.3. Key variables included the energy required by each plant for both peak and normal times (assumed to be 12 hours each), along with natural gas utilised. The system was constrained to meet the national electricity demand of 8.87 TWh, with a daily peak load of 1350 MW. There are four major classifications of waste considered in the model: organic, paper, plastic and textiles.

## Scenario Description

### Scenario 1

The Business-as-usual (BAU) case combines the present cases for both power generation and waste disposal in T&T. The model minimises TALC for the present power generation case (two single-cycle (SC) natural gas power plants and two combined cycle (CC) natural gas power plants). There is a total power capacity of 1950MW, 990MW and 960MW for SC and CC, respectively.

The waste collection system involves the movement of MSW from fourteen municipalities to any of three landfill sites. This case only considers landfilling as that is the only major waste disposal platform in the country at present.

### Scenario 2

Scenario 2 is split into three subsections (Scenario 2A, 2B and 2C). The general layout and constraints of the model remain constant across all subsections, but the objective function differs. Scenario 2A minimises TALC, Scenario 2B minimises TAGE and Scenario 2C maximises the power generation attributed to WTE technology.

This Scenario considers an upgraded SC plant, resulting in an increased total of 1725MW CC grid power available. The power generated per $tonne_{MSW}$ for each WTE technology is defined in Table 1, and these values are utilised in Scenarios 2 and 3. Additionally, incineration, gasification and anaerobic digestion (AD) are implemented in this case. Scenario 2 also considers the recycling of all rigid plastics.

### Scenario 3

Scenario 3 follows a similar formulation to Scenario 2; however, the system is constrained to ensure all organic waste is directed to AD. Scenario 3 considers a total of 1725 MW of CC grid (same as Scenario 2). TALC is minimised in this scenario as was done in Scenario 2A.

**Table 1:** Power generation for each WTE technology ($MWh/tonne_{MSW}$) (values used for both Scenario 2 and 3).

| Waste Type | Incineration | Gasification | AD |
|---|---|---|---|
| Plastic | 1.87 | 0.96 | - |
| Paper | 1.69 | 1.07 | - |
| Textile | 1.87 | 1.27 | - |
| Organic | 2.00 | 1.04 | 0.08 |

## Model Formulation

### Environmental Assessment

A life cycle assessment (LCA) was carried out to primarily examine environmental impacts related to endpoint indicators of human health (HH), ecosystem quality (EQ) and resource depletion (RD). However, GHG is also calculated via the midpoint impact category for global warming potential (GWP). This was done in alignment with T&T's policy focus on decarbonisation. A cradle-to-power generation gate approach was followed using the

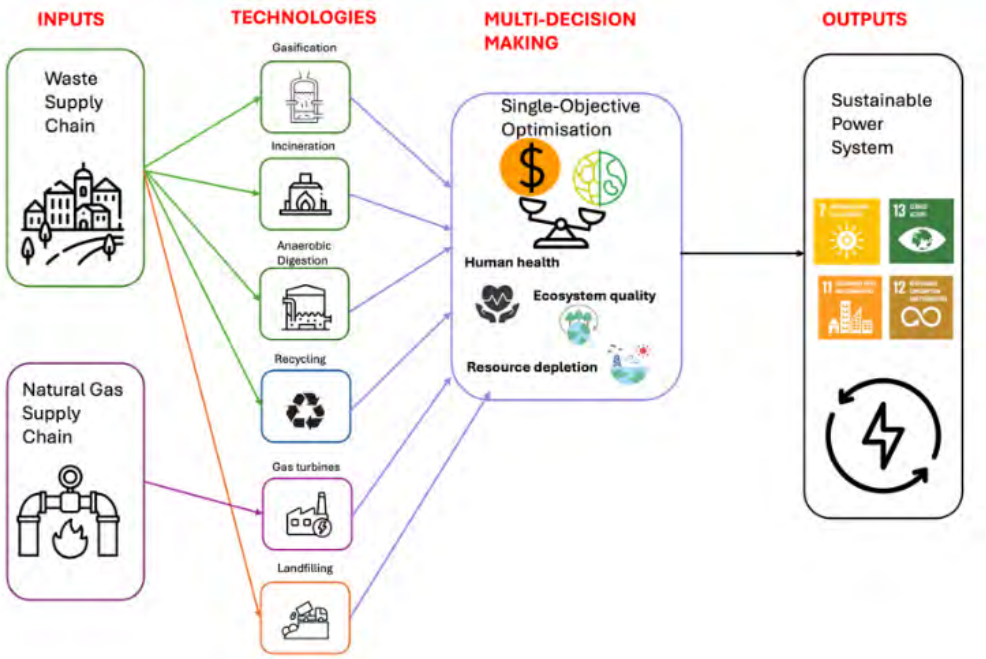

**Figure 1.** Superstructure highlighting waste disposal and power generation pathways and relevant SDGs impacted.

ISO 14040:2006 methodology [1]. When examining the life cycle impact assessment (LCIA), the ReCiPe 2016 Hierarchist (H) (endpoint) method within SimaPRo software was utilised.

The LCI steps compiled the inputs and outputs for each waste fraction (organic, plastic, paper, textiles) for incineration, gasification, recycling, AD and landfilling. Background inventories were derived from the EcoInvent v3.7.1 database using the Attributional Partly Optimised System (APOS) model. Foreground inventories for gasification were derived from Aspen Plus process models, which provide mass and energy balances for gasification. Inputs to the gasification models include MSW, process water and electricity for operations. This model includes emissions related to transport of MSW to waste technology sites, derived from EcoInvent v3.7.1. Total Annualised GHG Emissions (TAGE) is calculated by:

$$TAGE = \sum(F_{i,k}.e_{F,i,k}) + \sum(W_{i,k}.e_{W,i,k}) + \sum(\omega_{i,k}.e_{\omega,i,k}) + \sum(T_{i,k}.e_{T,i,k}) \quad (1)$$

$F_{i,k}$, $W_{i,k}$ and $\omega_{i,k}$ represent the feedstock, waste and residual flows in the system, with i representing inputs into the system, and k, the waste disposal technologies. The inputs, waste and residual system for transportation is denoted by $T_{i,k}$. The environmental impact of each input, output and residual flow is represented by $e_{F,i,k}$, $e_{W,i,k}$, $e_{\omega,i,k}$ and $e_{T,i,k}$, respectively.

## Economic Assessment

The economic assessment is based on the Total Annualised Life-Cycle Cost (TALC), computed by estimating CAPEX and OPEX expenditure based on literature sources. This is inclusive of landfilling, sorting[2], incineration (with energy recovery) [3], gasification[4], plastic recycling [5], anaerobic digestion[6, 7], alongside natural gas power generation[8, 9]. Incineration, AD and recycling costs are estimated based on MSW throughput of the plant (in tonnes), but gasification is estimated based on the cost to run a 10 MW plant. The total costs for power generation via natural gas, waste disposal and transport, and WTE are combined with the externalities attributed to the environmental endpoint impact categories (HH, EQ, RD).

$TAC_{Elec}$ is given by the following equation, accounting for each plant, *j*, and its relevant CAPEX and OPEX, along with the cost, C, of inputs, *i*, into the process:

$$TAC_{Elec} = CAPEX_j + OPEX_j + C_i \quad (2)$$

$TAC_{WD}$ is given by the following equation, accounting for each waste technology, *k*, and its relevant CAPEX and OPEX, along with the cost, C, of inputs, *i*, into the process and the cost of transport in the system ($C_{Transport}$):

$$TAC_{WD} = CAPEX_k + OPEX_k + C_i + C_{Transport} \quad (3)$$

Monetised values for endpoint impact categories, *IC*, are calculated based on each waste fraction, *s*, at each WTE tech, *k*, and for the inputs and production attributed to natural gas power production. The variable $v_{s,k}$ represented the total waste of each type (organic, paper, plastic and textiles) treated by each given technology (incineration, recycling, gasification and AD). $Y_{i,j}$ defines the amount of power produced by each natural gas power

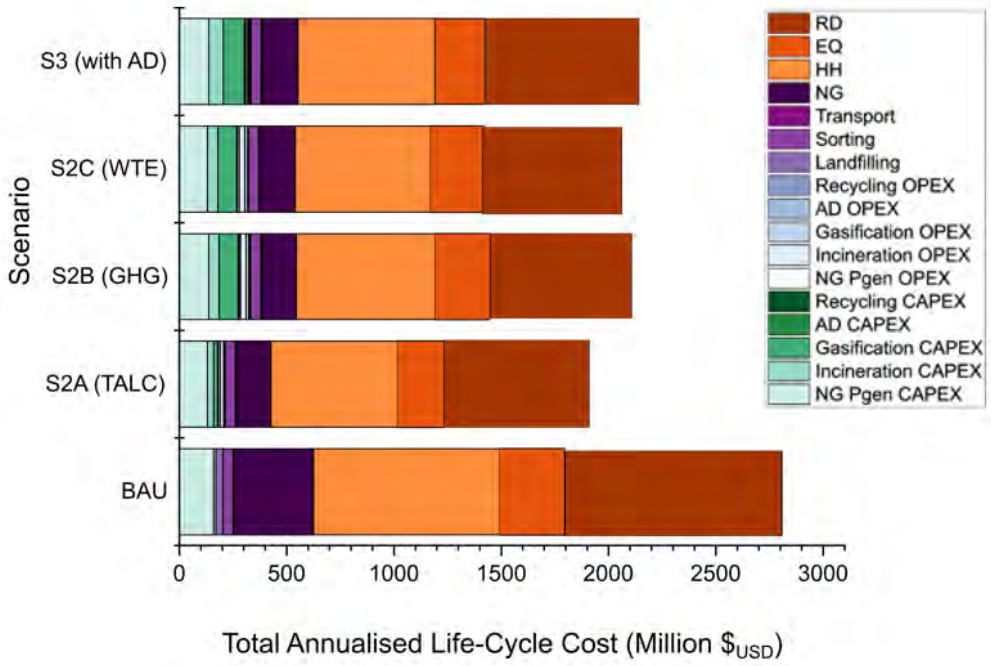

**Figure 2.** Total Annualised Life-Cycle Costs (TALC) for each Scenario, highlighting effects of varied objective funcitons on overall costs, inclusive of life-cycle externality costs.

plant. Endpoint indicators are related to the three categories, HH, EQ and RD, with $EP_{s,k}$ representing the impact for each waste disposal technology (including WTE) for every characterised waste fraction and $EP_{i,j}$ denoting the impact for natural gas combustion for both SC and CC plants. This is then multiplied by the monetisation factors for each category, Mon $_{IC}$, and the following equation is given:

$$LC_{IC} = \left[\sum_{s,k}(EP_{s,k} \,.\, \upsilon_{s,k}) + \sum_{j}(EP_{i,j} \,.\, Y_{i,j})\right].Mon_{IC} \quad (4)$$

The summation of TAC for both waste disposal and WTE technology ($TAC_{WD}$), natural gas power generation ($TAC_{Elec}$) and monetised life-cycle costs, $LC_{IC}$, is given in Equation 4:

$$TALC = TAC_{WD} + TAC_{Elec} + LC_{IC} \quad (5)$$

## Constraints

The following equations, 6, 7 and 8, ensure the HH, EQ and RD values cannot surpass the BAU levels. This ensures no burden shifting occurs to artificially decrease TALC, by trading off performance in one endpoint indicator for another.

$$HH_{Scenario} \leq HH_{BAU} \quad (6)$$

$$EQ_{Scenario} \leq EQ_{BAU} \quad (7)$$

$$RD_{Scenario} \leq RD_{BAU} \quad (8)$$

## Objective Function

The SOO model minimises TALC (Equation 2) for Scenario 2A, minimises TAGE for Scenario 2B (Equation 1) and maximises WTE for Scenario 2C.

## Model Environment

The MILP model was simulated using the General Algebraic Modeling System (GAMS) version 34.3 on an Intel Core i7, 8$^{th}$ Gen. Processor (16 GB RAM).

# RESULTS

The model primarily examined Total Annualised Life-cycle Costs (TALC), which combined overall costs related to the system and life-cycle externality costs related to HH, EQ and RD. Figure 2 highlights the TALC values across 3 scenarios. Scenario 1 represented the BAU case, whilst Scenario 2 highlighted an upgraded efficiency in natural gas power generation combined with WTE in the form of gasification, incineration and AD. Scenario 3 constrained all organic waste to be dispatched to AD. Scenarios 2 and 3 also included recycling of rigid plastics as part of the waste disposal system.

The TALC for the BAU case was found to be $2.74 billion, which included 31.3% for HH, 11% for EQ and 36.7% for RD indicators, respectively. Production of power from natural gas plants accounted for approximately 19% of the TALC and waste disposal via landfilling (including transport) accounted for the remainder.

In comparison to the BAU case, the optimised

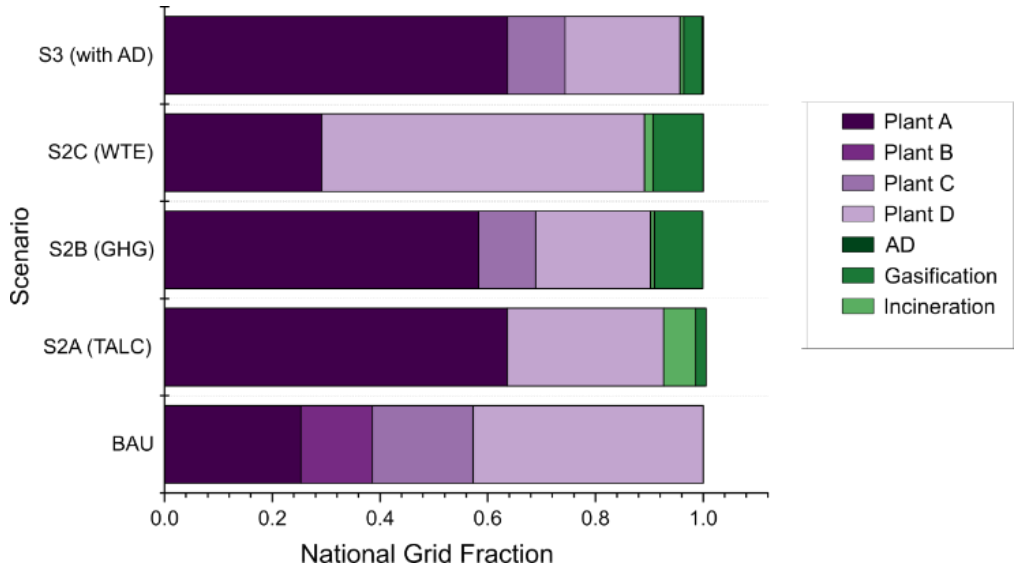

**Figure 3.** Power grid breakdown for each scenario exhibiting fossil-fuel and WTE sources.

(minimised TALC) values for Scenario 2A highlighted a reduction of 31.1% ($1.93 billion TALC). Externality costs attributed to HH, EQ and RD reduced by 31.6%, 29.9% and 33% compared the BAU values, respectively. Costs related to power generation accounted for approximately 16% of the TALC, with recycling, sorting, incineration and gasification representing the remaining 6% of TALC. The WTE from incineration and gasification represents 7.4% of the national grid presently. Due to the increase in power to supply the grid from WTE, only Plant A (765MW – CC) and Plant D (720MW – CC) were required and accounted for 8.2 TWh a year.

When the TAGE of the system was minimised for Scenario 2B, it was noted that TALC increased by 10% to $2.10 billion. This trade-off can be attributed to a 9.4% increase for the HH indicator and an 18.7% increase for EQ whilst there was subsequent decrease in RD of 2.5%, from Scenario 2A to 2B. The model reduced TAGE by increasing the proportion of waste allocated to gasification, thus avoiding potential TAGE emissions by increasing the WTE value to 9.7% of the national grid. Since GHG is prioritised, gasification is preferred to incineration. Production of electricity from gasification results in a reduced GHG emission value for each characterised waste fraction type (organic, paper, plastic and textiles). This increased use of gasification enhanced WTE output to the national grid as it yields approximately double the electricity per $tonne_{MSW}$ compared to incineration.

Scenario 2C explores the maximisation of WTE as the objective function of the model. This gives a TALC of $2.07 billion and a WTE accounting for 10.9% of the national grid. When compared to Scenario 2A, there is a 6.5% increase for the HH indicator and a 16% increase for EQ. There was a subsequent 3.14% decrease in RD. Across Scenarios 2A, 2B and 2C, it can be noted that as WTE increases RD decreases, which can be attributed to the reduced fossil fuel requirement to supply the national grid.

Scenario 3, which constrains all organic waste to be sent to AD, presents a TALC of $2.15 billion which represents a 10% increase when compared to Scenario 2A. The HH indicator only improves upon Scenario 2B and is the worst performing optimised scenario in terms of RD, recording a 5.5% increase compared to Scenario 2B. The increased HH and RD indicators can be attributed to the reduced WTE value of 4.3%. The outcome reflects the reduced power generation potential of AD in comparison to incineration and gasification. The use of AD and thus reduced gasification capacity in this scenario results in a reduction in EQ of (5.5 – 7.5) %. Despite being the worst performing of the optimised scenario with respect to TALC, the introduction of AD still exhibits a 22.4% reduction in comparison to the present BAU case and proves an improvement in terms of EQ when compared to scenarios 2B and 2C. This indicates that AD can be included as a potential WTE option in T&T, alongside gasification and incineration.

Minimisation of TAGE results in 38% $GHG_{LC}$ reduction compared to the BAU case, with a reduction from 6.26 million tonne-$CO_{2\text{-eq}}$ to 3.86 million tonne-$CO_{2\text{-eq}}$. The model achieves this by significantly increasing the waste sent to gasification, from 94, 000 tonnes (S2A – min. TALC) to 426, 000 tonnes and reducing incineration, from 445, 000 tonnes to 47, 000 tonnes. This trade-off is due to gasification's higher electricity production potential compared to incineration. Natural gas power

generation is reduced by 2.5% with 3 combined-cycle power plants online, Plant A, Plant B and Plant C, and sharing the national grid load 58%, 11% and 21% respectively (Figure 3). Power produced from WTE sources accounts for 9.7% of the national grid. Overall, natural gas power generation accounts for 92% of the GHG emissions in the scenario, with incineration and gasification making up 7.5% and transport resulting in a negligible value.

The TAGE for this Scenario 2A (min. TALC) was found to be 4.05 million tonne-$CO2_{eq}$, signifying a reduction of approximately 35% compared to the BAU case and a 5% increase compared to Scenario 2B (min. TAGE). WTE sources account for approximately 9.8% of TAGE, with gasification making up 8.3% and incineration 1.5% of TAGE. Plant A, Plant D, incineration and gasification make up over 99% of TAGE for optimised cases.

## CONCLUSIONS

We present the use of MILP framework tailored to Trinidad and Tobago to promote the sustainable energy transition within SIDS. This work demonstrates the potential of WTE as a cleaner power generation source within the Caribbean. Additionally, upgraded efficiency within the country's natural gas power generation sector can play a significant role in reducing environmental emissions.

The integration of waste-to-energy (WTE) in the form of gasification, incineration and anaerobic digestion (AD) proves to have a beneficial effect in terms of total annualised life-cycle costs (TALC) with reductions of 22 – 31 % for optimised scenarios, when compared to BAU. Similar effects are observed for total annualised GHG emissions (TAGE), with decreases in the range of 34 – 38 % in comparison to the BAU scenario. The scenarios are optimised using SOO, accounting for environmental emissions related to endpoint indicators which are monetised. Drastic reductions were recorded for all optimal scenarios due to the diminished use of natural gas to provide power. This reduction is attributed to increased resource efficiency from the SC to CC upgrade, coupled with 4 – 11 % of the grid being supplied by WTE.

These results validate the use of supply chain optimisation to guide decision making with respect to SDGs for the Caribbean and SIDS globally.

## ABSTRACT

Power-to-X (PtX) technologies play a central role in renewables-based energy systems by enabling the conversion of renewable electricity into multiple energy carriers. However, due to the multiple energy conversion stages inherent to such energy systems, they often suffer low system efficiencies and high operational costs. In this context, waste product utilization offers significant potential for improving system performance. Directly integrating waste product utilization into energy system operational problems, however, is computationally challenging, as it requires high model granularity to capture waste product characteristics and introduces additional complex constraints.This work proposes a method to integrate waste heat utilization into operational optimization problems, aiming to improve the overall performance of PtX energy systems. Detailed process models, together with pinch analysis, are used to generate surrogate models for the thermal (by-)products and their associated temperature levels. The resulting optimization problem is decomposed into multiple subproblems. To balance problem complexity and solution optimality, two alternative approaches, “ex-post” and “co-optimized” are developed, differing in whether waste heat utilization is addressed ex post or jointly optimized with the energy system operation.The proposed method is applied to optimize the daily operation of a PtX energy system. Compared with a reference case without waste heat utilization, the ex-post approach achieves a cost reduction of 7% within identical computational time (0.6h). The co-optimized approach yields cost savings of up to 22% with a computational time of 3.4h. These results demonstrate the effectiveness of the proposed method for integrating waste heat utilization into energy system operational optimization.

## 1. INTRODUCTION

Global efforts to mitigate the impacts of the climate crisis and to reduce dependence on fossil resources are driving the development of innovative and sustainable energy systems. Among various alternatives, power-to-X (PtX) technologies have emerged as a promising solution, enabling the conversion of renewable electricity into alternative energy carriers and chemical products. When considered in a broader context, energy systems with integrated PtX technologies (PtX energy systems) offer significant advantages in terms of operational flexibility, decarbonization, and the provision of seasonal energy storage and supply.

However, as various process technologies and multiple energy conversion steps are integrated, the operation of PtX energy systems face significant challenges, namely low overall energy conversion efficiency and the resulting high operational costs. To improve the overall system efficiency, waste product utilization poses a promising solution [1, 2].

Nevertheless, integrating waste product utilization into the operational optimization problems for highly integrated energy system is a complex task. Generally, these optimization problems involve temporal coupling constraints across the entire operational time horizon

and are therefore usually computational intense. Moreover, the inclusion of complex process technologies often necessitates a high level of model granularity to ensure their operational feasibility, thereby introducing nonlinearities, nonconvexities, and, in some cases, dynamic algebraic equations into the optimization problem (challenge a). In addition, incorporating waste product utilization further increases problem complexity by introducing additional constraints that couple different product balances, rendering the resulting optimization problem highly nested and computationally intractable (challenge b).

Wang et al. [3, 4] developed a decomposition-based optimization method and successfully addressed the first complexity (challenge a). By incorporating detailed process models into energy system operational problems, the decomposition method successfully harmonizes the dynamic operation of a diverse set of process technologies within a PtX energy system. While high-fidelity process models ensure the feasibility of the resulting operational strategies, computational tractability is maintained.

Nevertheless, despite the optimized feasibility and flexibility, previous works have not fully exploited the potential of integrating detailed process models into energy system optimization. Specifically, auxiliary thermal (by-)products of different process technologies remain largely decoupled, often necessitating simultaneous and unnecessary external hot and cold streams purchases.

### 1.1 Contribution of this work

This work further advances the decomposition method to enable waste heat utilization in energy system operational optimization (challenge b). Built on prior work, we incorporate pinch analysis into the decomposition method. Correspondingly, the waste heat can be decomposed into thermal products with different temperature levels. As additional complicating constraints are introduced into the optimization problem, which could increase computational burden, we also develop two alternative solution approaches to balance the computational efficiency and optimality. In these approaches, waste heat utilization is either addressed ex post or jointly optimized with the energy system operation.

This work is structured as follows: The operational problem for a PtX energy system is stated in Section 2. Section 3 details the modeling of the optimization problem, while Section 4 describes the proposed solution approaches. The computational results are discussed in Section 5. Section 6 concludes the work.

## 2. PROBLEM STATEMENT

We adopt the PtX energy system from literature [4] to state our problem, as illustrated in **Figure 1.**

The energy system aims to fulfill electricity (el-) and heating (th-) demands of an office building via energy conversion or direct purchase from the grids (cf. the blue background in **Figure 1**). The th-demand for the office building typically requires a supply temperature at a medium temperature level (MT). A total of twelve energy system components are included: seven conversion components—photovoltaic panels (PVs), a proton exchange membrane (PEM) electrolyzer, a direct air capture (DAC) plant, two identical methanation processes (MPes), a boiler and a combined heat and power (CHP) engine—and five storage components for the products electricity, $H_2$, $CO_2$, $CH_4$ and heat, respectively.

The PtX technologies introduce diverse process characteristics into energy system operation (cf. the green background in **Figure 1**). The DAC plant operates as an adsorption-desorption batch process and requires an external hot stream at high temperature level (HT) after adsorption to raise the column temperature for the subsequent desorption step. The PEM electrolyzer is governed by electrochemical reaction, with conversion efficiency strongly influenced by operating temperature and pressure. The MPes involve strongly exothermic reactions, for which the catalyst performance is constrained by reaction temperature. Consequently, an external cold stream at low temperature (LT) level is required for the PEM electrolyzer and MPes to maintain their respective operating temperatures.

In summary, three thermal products at different temperature levels, HT, MT and LT, are involved in the studied PtX energy system. To date, these thermal products are treated independently during operation, which prevents the exploitation of thermal integration potential and leads to inefficient operational decisions. Therefore, the goal of this work is to develop modeling and solution approaches that enable the integration of waste heat utilization into the operational optimization for the PtX energy system (cf. the red background in **Figure 1**).

## 3. POWER-TO-X ENERGY SYSTEM MODELING

The modeling of the PtX energy and process systems (cf. the blue and green background colors in **Figure 1**) are adopted from our previous work [3–5]. For completeness, an overview of these models is provided in Section 3.1. This work further extends the modeling to address the heating circuit, as detailed in Section 3.2.

### 3.1 Energy and process systems modeling

We collect all twelve energy system components in the set $\mathcal{K}$ and model each component $k\,(k \in \mathcal{K})$ with its input-output relationship(s):

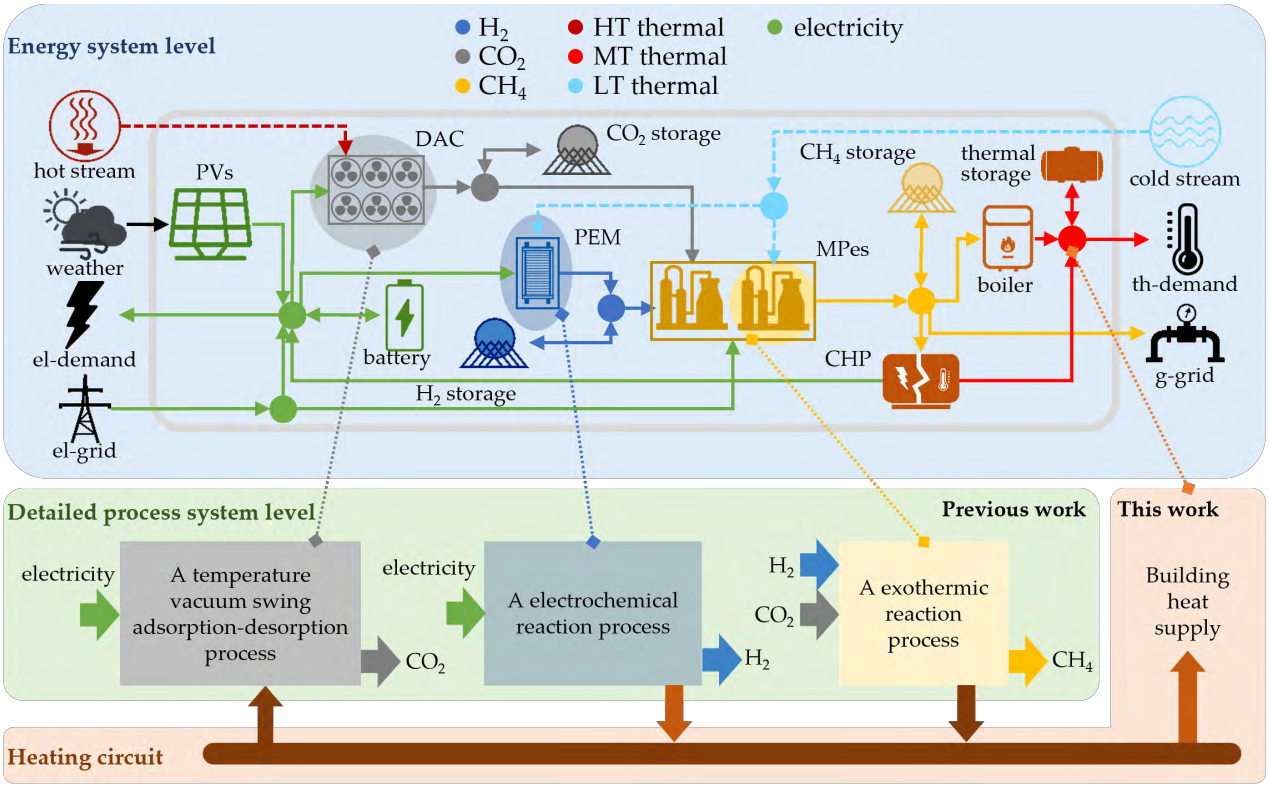

**Figure 1.** Structure of a power-to-X energy system, adapted from [4]. The complete energy system is indicated by a blue bacground, while the components that are modeled using detailed process models are highlighted with a green background. The red background represents the heating circuit for potential waste heat utilization proposed in this work. PVs: photovoltaic panels; DAC: direct air capture plant; PEM: proton exchange membrane electrolyzer; MPes: two identical methanation processes; CHP: a combined heat and power engine; HT, MT and LT: high, medium and low temperature levels, respectively; th: heating; el: electricity.

$$\dot{E}^{\text{out}}_{k,\tilde{e},t} = f(\dot{E}^{\text{in}}_{k,e,t}, \boldsymbol{x}^{\text{ES}}_{k}, \boldsymbol{y}^{\text{PS}}_{k}), \tag{1}$$

where $\dot{E}^{\text{out}}_{k,\tilde{e},t}$ and $\dot{E}^{\text{in}}_{k,e,t}$ denote the input and output product flows of component $k$ at time step $t$ ($t \in \mathcal{T}$), respectively. The subscripts $e$ and $\tilde{e}$ indicate the product types ($e, \tilde{e} \in \mathcal{E} = \{\text{el}, \text{H}_2, \text{CO}_2, \text{CH}_4, \text{th}_{\text{LT}}, \text{th}_{\text{MT}}, \text{th}_{\text{HT}}\}$). $\tilde{e}$ and $e$ are different if $k$ is a conversion component and are identical if $k$ is a storage component.

The surrogate vector $\boldsymbol{x}^{\text{ES}}_{k}$ collectively represents other decision variables of component $k$ at the energy system level, such as on/off status of conversion components, charge/discharge decisions and the state of charge of storage components. These decision variables generally have a direct impact on the operational decisions of other energy system components. The surrogate vector $\boldsymbol{y}^{\text{PS}}_{k}$ denotes other decision variables of component $k$ at the detailed process system level, such as the operating temperature and pressure of a reactor or the outlet temperature of a heat exchanger within the process of $k$. These decision variables ensure the feasibility of $k$ and usually do not have a direct impact on other energy system components ($\mathcal{K}\backslash\{k\}$).

Note that, for notational convenience, this work adopts the following convention: Given a decision variable indexed over multiple sets, say $x_{k,e,t}$ with $k \in \mathcal{K}, e \in \mathcal{E}, t \in \mathcal{T}$, the bold notation $\boldsymbol{x}_k$ or $\boldsymbol{x}$ represents the vector containing all $x_{k,e,t}$ over subsets or the entire index set. For example, $\dot{\boldsymbol{E}}^{\text{in}}_{k,e}$ denotes $\dot{E}^{\text{in}}_{k,e,t}, \forall t \in \mathcal{T}$; $\dot{\boldsymbol{E}}^{\text{in}}$ indicates $\dot{E}^{\text{in}}_{k,e,t}, \forall k \in \mathcal{K}, e \in \mathcal{E}, t \in \mathcal{T}$.

Depending on the inherent operational complexity of component $k$, a detailed process model might be unnecessary. We collect components that require a detailed process model in the set $\mathcal{K}^{\text{PS}} \subseteq \mathcal{K}$. This work considers four key PtX technologies with detailed process models, i.e., $\mathcal{K}^{\text{PS}} = \{\text{PEM}, \text{DAC}, \text{MPes}\}$, where MPes collectively represents the two identical methanation processes. For all other components ($k \in \mathcal{K}\backslash\mathcal{K}^{\text{PS}}$), Eq. (1) generally takes a linear or quadratic form, with or without binary variables, and the vector $\boldsymbol{y}^{\text{PS}}_{k}$ is empty.

**PEM electrolyzer.** The detailed process model of the PEM electrolyzer is adopted from [5]. It comprises heat exchangers, electrolysis cells, flash units, a multistage compressor, all described by detailed electrochemical, heat and mass transfer models. Accordingly,

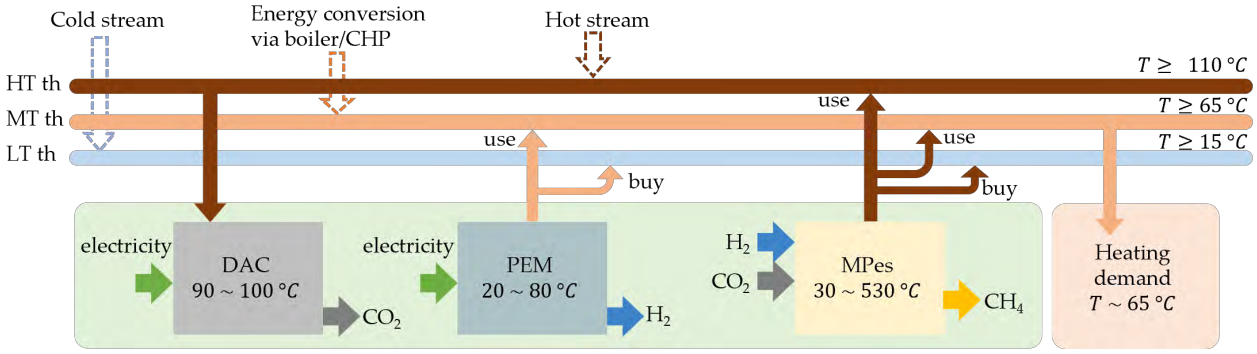

**Figure 2**. Heating circuit for waste heat utilization in power-to-X energy systems. A minimum allowable temperature difference ($\Delta T^{\min}$) of 10 K is assumed for all heat exchangers in the PtX energy system.

the following decision variables are included in Eq. (1):

$$\boldsymbol{y}_{\text{PEM}}^{\text{PS}} = \{\boldsymbol{U}^{\text{cell}}, \boldsymbol{U}^{\text{tn}}, \boldsymbol{I}, \boldsymbol{T}^{\text{stack}}, \boldsymbol{p}^{\text{cat}}, \cdots\}. \tag{2}$$

The waste heat $\dot{Q}_{\text{PEM}}^{\text{waste}}$ is decided by the cell voltage $U^{\text{cell}}$, the thermoneutral voltage $U^{\text{tn}}$ and current $I$, which are related to other operating variables, such as the stack temperature $T^{\text{stack}}$ and cathode pressure $p^{\text{cat}}$. As electrochemical reaction and physical properties are involved, Eq. (1) for the PEM electrolyzer includes multiple nonlinear formulations.

**DAC plant.** The detailed process model of the DAC plant is originally from [6]. It comprises a fan, an adsorption/desorption column, a vacuum pump and heat exchangers. The DAC plant operates through a steam-assisted temperature vacuum swing adsorption (S-TVSA) cycle, and progresses through five phases (adsorption, blowdown, heating, desorption, and cooling). The following decision variables are included in its detailed process model:

$$\boldsymbol{y}_{\text{DAC}}^{\text{PS}} = \{\boldsymbol{T}^{\text{des}}, \dot{\boldsymbol{m}}^{\text{ads}}, \boldsymbol{p}^{\text{des}}, \cdots\}. \tag{3}$$

The external heat supply $\dot{Q}_{\text{DAC}}^{\text{supply}}$ for the DAC plant is required during the heating and desorption phases to ensure that the column reaches and maintains the desorption temperature $T^{\text{des}}$. Other relevant operating variables include, for example, the inlet air mass flow $\dot{m}^{\text{ads}}$ and column pressure $p^{\text{des}}$. The original process model of the DAC plant incorporates detailed mass and heat transfer models, adsorption equilibrium models and is formulated as a system of differential-algebraic equations. To reduce computational burden, a shortcut search path is used, as applied in the literature [4].

**Methanation processes.** The PtX energy system includes two identical MPes. For each MP, the TREMP™ methanation process model from [3] is applied. The process model describes a four-stage Sabatier reaction, consisting of four adiabatic reactors (R1-R4) connected in series, seven adiabatic heat exchangers (HEX1-HEX7), two adiabatic compressors, and three isobaric, isothermal flash units. Accordingly, the following decision variables are included in Eq. (1):

$$\boldsymbol{y}_{\text{MP}}^{\text{PS}} = \{\boldsymbol{T}^{\text{R1-R4}}, \boldsymbol{T}^{\text{HEX1-HEX7}}, \cdots\}. \tag{4}$$

The waste heat of each MP $\dot{Q}_{\text{MP}}^{\text{waste}}$ is determined by the operating temperature of the reactors $T^{\text{R1-R4}}$, which are primarily controlled by the inlet and outlet temperatures of the heat exchangers $T^{\text{HEX1-HEX7}}$. Note that five h eat exchangers operate as cooling units and require external cold streams, while the remaining two operate as heating units and require external hot streams. Together, these seven heat exchangers enable internal heat integration within the MP and release only the residual waste heat (i.e., require only a cold stream supply). Because the detailed process model accounts for physical properties and catalytic chemical reactions, it introduces strong nonlinearities and nonconvexities into Eq. (1).

## 3.2 Waste heat utilization

To enable waste heat utilization, all thermal product flows must be considered along with their corresponding temperature levels. Therefore, we first extend the modeling. The proposed heating circuit for waste heat utilization in the PtX energy system is illustrated in **Figure 2**. We assume a minimum allowable temperature difference ($\Delta T^{\min}$) of 10 K for all heat exchangers in the studied PtX energy system.

According to the process characteristics, the operating temperature for the PEM electrolyzer ranges from 20 to 80 °C [5]. Under optimized operational conditions, with current densities ranging from 0.1 to 2 A/cm$^2$ (corresponding to 50–1000 kW $H_2$ at lower heating value), no waste heat is generated when the current density is below 0.98 A/cm$^2$ (480 kW $H_2$), and the stack temperature remains at 80 °C when the current density is above 0.88 A/cm$^2$ (433 kW $H_2$). The desorption temperature for the DAC plant is between 90 to 100 °C [6]. In MPes, the adiabatic reactors operate between 250 and 530 °C. Accordingly, the outlet temperature of the downstream cooling heat exchangers varies from 30 to 270 °C [3]. Additionally, the supply temperature for domestic heating

demand is typically around 65 °C [7].

Therefore, the HT waste heat of the MPes can be utilized to operate the DAC plant. Any surplus waste heat from the MPes can be further integrated into the thermal product balance at the MT level. At the same temperature level, the waste heat from the PEM electrolyzer can also be used for supplying the th-demand. As a result, the models for the thermal products are updated from:

$$\dot{Q}^{\text{waste}}_{\text{PEM}} = \dot{E}^{\text{out}}_{\text{PEM, th}_{\text{LT}}}, \tag{5a}$$

$$\dot{Q}^{\text{waste}}_{\text{MP}} = \dot{E}^{\text{out}}_{\text{MP, th}_{\text{LT}}}, \tag{5b}$$

to:

$$\dot{Q}^{\text{waste}}_{\text{PEM}} = \dot{E}^{\text{out}}_{\text{PEM, th}_{\text{LT}}} + \dot{E}^{\text{out}}_{\text{PEM, th}_{\text{MT}}} + \dot{E}^{\text{out}}_{\text{PEM, th}_{\text{HT}}}, \tag{6a}$$

$$\dot{Q}^{\text{waste}}_{\text{MP}} = \dot{E}^{\text{out}}_{\text{MP, th}_{\text{LT}}} + \dot{E}^{\text{out}}_{\text{MP, th}_{\text{MT}}} + \dot{E}^{\text{out}}_{\text{MP, th}_{\text{HT}}}. \tag{6b}$$

The bounds of the newly introduced decision variables are decided by the detailed process models:

$$\dot{E}^{\text{out}}_{\text{PEM, th}_{\text{HT}}} = 0, \tag{7a}$$

$$0 \le \dot{E}^{\text{out}}_{\text{PEM, th}_{\text{MT}}} \le \dot{E}^{\text{out, max}}_{\text{PEM, th}_{\text{MT}}}, \tag{7b}$$

$$0 \le \dot{E}^{\text{out}}_{\text{MP, th}_{\text{HT}}} \le \dot{E}^{\text{out, max}}_{\text{MP, th}_{\text{HT}}}, \tag{7c}$$

$$0 \le \dot{E}^{\text{out}}_{\text{MP, th}_{\text{MT}}} \le \dot{E}^{\text{out, max}}_{\text{MP, th}_{\text{MT}}} + \dot{E}^{\text{out, max}}_{\text{MP, th}_{\text{HT}}}, \tag{7d}$$

where

$$\dot{Q}^{\text{waste}}_{\text{PEM}}, \dot{E}^{\text{out, max}}_{\text{PEM, th}_{\text{MT}}} = g_{\text{PEM}}(\dot{E}^{\text{in}}_{\text{PEM}}, \dot{E}^{\text{out}}_{\text{PEM}}, \boldsymbol{y}^{\text{PS}}_{\text{PEM}}), \tag{8a}$$

$$\dot{Q}^{\text{waste}}_{\text{MP}}, \dot{E}^{\text{out, max}}_{\text{MP, th}_{\text{MT}}}, \dot{E}^{\text{out, max}}_{\text{MP, th}_{\text{HT}}} = g_{\text{MP}}(\dot{E}^{\text{in}}_{\text{MP}}, \dot{E}^{\text{out}}_{\text{MP}}, \boldsymbol{y}^{\text{PS}}_{\text{MP}}). \tag{8b}$$

Here, the decision variable $\dot{E}^{\text{out, max}}_{k,e}$ represents the maximum available amount of waste heat for utilization at different temperature levels.

## 4. OPERATIONAL OPTIMIZATION

The operational optimization problem is formulated by minimizing the operational cost, subject to Eqs. (1)–(4) and Eqs. (6)–(8), as well as product balance constraints. The resulting operational optimization is computational very challenging. Therefore, we apply the decomposition method proposed in [3, 4] and further develop it solve the operational problem with integrated waste heat utilization.

The decomposition method reformulates the original optimization problem into a set of subproblems by constructing surrogate models for the detailed process models, which are then solved iteratively. The surrogate models have either a linear or quadratic formulation. For brevity, the following description focuses on the newly developed part of the method. A comprehensive description of the complete method is provided in the previous work [3, 4].

Optimization problem at the energy system level:

$$\min_{\dot{E}^{\text{buy,ES}}, \dot{E}^{\text{sell,ES}}, \dot{E}^{\text{in,ES}}, \dot{E}^{\text{out,ES}}, \boldsymbol{x}^{\text{ES}}} C^{\text{ES}} = \sum_{t\in\mathcal{T}} \Delta t_t \sum_{\tilde{e}\in\mathcal{E}^{\text{ext}}} \left( c^{\text{buy}}_{\tilde{e},t} \dot{E}^{\text{buy,ES}}_{\tilde{e},t} - c^{\text{sell}}_{\tilde{e},t} \dot{E}^{\text{sell,ES}}_{\tilde{e},t} \right) \tag{9a}$$

s.t.

$$\sum_{k\in\mathcal{K}} \left( \dot{E}^{\text{out,ES}}_{k,e,t} - \dot{E}^{\text{in,ES}}_{k,e,t} \right) + \dot{E}^{\text{buy,ES}}_{e,t} - \dot{E}^{\text{sell,ES}}_{e,t} = \dot{E}^{\text{D}}_{e,t} \qquad \forall e \in \mathcal{E}, t \in \mathcal{T}, \tag{9b}$$

$$\boldsymbol{g}^{\text{ES}}\left( \dot{E}^{\text{in,ES}}_{k,e,t}, \dot{E}^{\text{out,ES}}_{k,e,t}, \boldsymbol{x}^{\text{ES}} \right) \le 0 \qquad \forall k \in \mathcal{K}, e \in \mathcal{E}, t \in \mathcal{T}, \tag{9c}$$

Eqs. (6)–(7), (9d)

$$\dot{E}^{\text{buy,ES}}_{e,t}, \dot{E}^{\text{sell,ES}}_{e,t}, \dot{E}^{\text{in,ES}}_{k,e,t}, \dot{E}^{\text{out,ES}}_{k,e,t} \in \mathbb{R}^{+} \qquad \forall k \in \mathcal{K}, e \in \mathcal{E}, t \in \mathcal{T}, \tag{9e}$$

$$\boldsymbol{x}^{\text{ES}} \in \mathbb{R}^{N_x}. \tag{9f}$$

Problem (9)

Optimization problem at the process system level:

$$\min_{\dot{E}^{\text{buy,PS}}_{k}, \dot{E}^{\text{in,PS}}_{k}, \dot{E}^{\text{out,PS}}_{k}, \boldsymbol{y}^{\text{PS}}} C^{\text{PS}}_{k} = \sum_{t\in\mathcal{T}} \Delta t_t \sum_{\tilde{e}\in\mathcal{E}^{\text{ext}}} \left( c^{\text{buy}}_{\tilde{e},t} \dot{E}^{\text{buy,PS}}_{k,\tilde{e},t} \right) \tag{10a}$$

s.t.

$$\boldsymbol{g}^{\text{PS}}_{k,t}\left( \dot{E}^{\text{buy,PS}}_{\text{k},e,t}, \dot{E}^{\text{in,PS}}_{k,e,t}, \dot{E}^{\text{out,PS}}_{k,e,t}, \boldsymbol{y}^{\text{PS}}_{k,t} \right) \le 0 \qquad \forall e \in \mathcal{E}, t \in \mathcal{T}, \tag{10b}$$

$$\dot{E}^{\text{buy,PS}}_{k,e,t}, \dot{E}^{\text{in,PS}}_{k,e,t}, \dot{E}^{\text{out,PS}}_{k,e,t} \in \mathbb{R}^{+} \qquad \forall e \in \mathcal{E}, t \in \mathcal{T}, \tag{10c}$$

$$\boldsymbol{y}^{\text{PS}}_{k} \in \mathbb{R}^{N_y}. \tag{10d}$$

Problem (10)

Pinch analysis at the process system level:

$$\dot{E}^{\text{out,PS}}_{k,\text{th}_{\text{LT}}}, \dot{E}^{\text{out,PS}}_{k,\text{th}_{\text{MT}}}, \dot{E}^{\text{out,PS}}_{k,\text{th}_{\text{HT}}} = \text{pinchAnalysis}(\dot{E}^{\text{in,PS}}_{e,t}, \dot{E}^{\text{out,PS}}_{e,t}, \boldsymbol{y}^{\text{PS}}) \qquad \forall k \in \mathcal{K}. \tag{11}$$

**Table 1:** Bounds on decision variables related to waste heat utilization in the operational optimization problem.

| Ex-post approach | | Co-optimized approach | |
|---|---|---|---|
| $s = 1$ | | | |

After decomposition, the operational problem consists of one optimization problem at the energy system level (Problem (9)), and multiple optimization problems focusing on the process system level (Problem (10)), one for each energy system component $k$ ($k \in \mathcal{K}^{\text{PS}}$).

In Problem (9), the objective function minimizes the purchase of external energy consumption ($\dot{E}^{\text{buy, ES}}_{\tilde{e},t}$) and maximizes the feed-in revenues ($\dot{E}^{\text{sell, ES}}_{\tilde{e},t}$), weighted by their respective cost parameter, $c^{\text{buy}}_{\tilde{e},t}$, and $c^{\text{sell}}_{\tilde{e},t}$, and multiplied by the time-step length $\Delta t_t$ (Eq. (9a)). Equation (9b) represents product balance constraints, while Eq. (9c) summaries the input-output relationships of each $k$. They correspond to Eq. (1) for $k \in \mathcal{K} \backslash \mathcal{K}^{\text{PS}}$ and to surrogate models for $k \in \mathcal{K}^{\text{PS}}$. For energy system component $k \in \mathcal{K}^{\text{PS}}$, the detailed process models are solved separately at the process system level in Problem (10) (cf. Eq. (10b)). The superscripts ES and PS indicate whether a decision variable or a constraint belongs to Problem (9) or (10), respectively.

Due to the inclusion of waste heat utilization, Eqs. (6)–(8) must be incorporated into the operational problem. Equations (6)–(7) can be directly integrated into the optimization problem at the energy system level (Problem (9)) as complicating constraints (cf. Eq. (9d)). Since Eqs. (8) involve detailed process models and cannot be directly integrated into Problem (9), we replace them by incorporating pinch analysis into the decomposition method, as shown in Eq. (11).

The semi-sequential approach introduced in the literature [4] is applied to solve the decomposed optimization problems. The main steps of the approach are presented in **Algorithm 1**.

The energy system components using detailed process models are addressed with a pre-defined sequence (lines 1 to 2). We first determine the operational decisions for MPes by iteratively solving Problems (9) and (10) until their solutions converge to identical operational decisions (lines 3 to 10). Subsequently, pinch analysis is performed for each MP to identify the bounds for waste heat utilization (line 11). We then fix these bounds, along with all decision variables related to MPes, in Problem (9) (lines 12 to 14) and proceed to the DAC plant in the next sequence (cf. line 2). These sequential steps are repeated until all $k \in \mathcal{K}^{\text{PS}}$ are addressed (lines 2 to 14). Consequently, we find an optimal operational strategy for the PtX energy system (line 15).

12: Fix bounds via Eqs. (12) or (13)
13: Fix decision variables of all con-
verged components in Problem (9)
14: s = s+1 and Goto Next k
15: Find an optimal operational strategy
```

As mentioned earlier, incorporating waste heat utilization introduces additional complicating constraints into the optimization problem at the energy system level (cf. Eqs. (6)). These complicating constraints can significantly increase the computational effort required to solve Problem (9). To address this issue, we propose two solution approaches for handling these complicating constraints.

As shown in **Table 1**, the bounds, i.e., the maximum available waste heat at different temperature levels, are integrated into Problem (9) either "ex-post" or "co-optimized", depending on whether waste heat utilization is considered ex post or jointly with operational optimization.

In the ex-post approach, waste heat utilization is initially deactivated (cf. Eqs. (12a)–(12c)). After the operational decisions for MPes are determined, the bounds on the available thermal products that can be reused at HT and MT levels are identified via pinch analysis. These bounds are then passed to Problem (9) for the subsequent sequence (cf. Eqs. (12d)–(12f)). After the operational decisions for the DAC plant are determined, the bounds in Problem (9) are updated for the final component, PEM (cf. Eqs. (12g)–(12i)). In this approach, the complicating constraints, i.e., Eqs. (6), are inactive during $s = 1$, which reduces the complexity of Problem (9).

In the co-optimized approach, the complicating constraints are active throughout all sequences. Instead of fixing the maximum bounds to zero, feasible bounds are specified for the decision variables associated with waste heat utilization. This difference is illustrated by comparing Eqs. (12a)–(12d) with Eqs. (13a)–(13d). Moreover, because pinch analysis is performed at the end of each sequence, the feasible bounds for the first sequence are obtained from the surrogate model of component $k$ ($k \in \{\mathrm{PEM}, \mathrm{MPes}\}$) (cf. Eqs. (13a)–(13c)).

Note that **Algorithm 1** can also handle non-convergence situations. As the focus of this work is the integration of waste heat utilization, a detailed description is omitted. Further information on handling non-convergence can be found in the literature [3, 4].

# 5. NUMERIC STUDY

## 5.1 Implementation and specification

We apply the proposed method to optimize the daily operation of the aforementioned PtX energy system. The resulting operational problem is solved via ex-post and co-optimized approaches, respectively. In addition, a reference case using the original decomposition method is included as a benchmark to evaluate the impact of waste heat utilization.

## 5.2 Results and discussion

We discuss the results of the numerical study from two aspects: computational performance and the resulting optimal operational strategy.

### 5.2.1 Computational performance

The computational effort of all three cases is given in **Table 2**.

In the reference and ex-post cases, the computational performance is very similar, with the operational optimization problem being solved within 40 min in both cases. This is reasonable, as the complexity of the optimization problems addressed in the two cases is nearly identical, with the ex-post case featuring slightly relaxed bounds on decision variables since the second sequence (cf. Eqs. (12e)–(12i) in **Table 1**).

**Table 2:** Comparison of computational performance. HU: heat utilization.

| | w/o HU | w/ HU | |
|---|---|---|---|
| | **Ref.** | **Ex-post** | **Co-optimized** |
| Time [s] | 2133 (~36 min) | 2281 (~38 min) | 12063 (~3.4 h) |
| Nr. of iteration (MPes + DAC + PEM): | | | |
| | 6+2+1=9 | 6+4+1=11 | 11+2+1=14 |
| Average computing time for solving Problem (9) [s]: | | | |
| $s = 1$ | 256 | 259 | 1011 |

**Table 3:** Overview of the system efficiency and operational costs. HU: heat utilization.

| | w/o HU | w/ HU | |
|---|---|---|---|
| | **Ref.** | **Ex-post** | **Co-optimized** |
| Efficiency | 41 % | 48 % | 61% |
| Operational costs [€/d]: | | | |
| Total | 5672 | 5266 | 4431 |
| el-grid | 4855 | 4545 | 3983 |
| hot stream | 793 | 747 | 448 |
| cold stream | 25 | 1 | 1 |
| g-grid | 0 | -27 | 0 |

The co-optimized case requires significantly more computational time, approximately 3.4 hours. In particular, the operational decisions of MPes converge more slowly, necessitating twice as many iterations compared with the other two cases. Moreover, the inclusion of additional complicating constraints at the energy system level further increases the average solution time of Problem (9). Especially, in the first sequence ($s = 1$), the average solution time is about four times as long as in other cases. The average computing times in the subsequent sequences are comparable across the three cases and are therefore not presented here.

### 5.2.2 Optimal operational strategy

The overall operational performance of the PtX energy system is summarized in **Table 3**, where the system efficiency is defined as the ratio of useful output energy to total input energy.

The results indicate that waste heat utilization significantly improves the operational performance of the PtX energy system: The overall system efficiency

increases by up to 48.8 % and the total operational cost decreases by up to 21.9 % (cf. the co-optimized case).

In all three cases, electricity consumption accounts for over 85% of the total operational cost, while the purchase of the hot stream contributes more than 10%. When waste heat utilization is applied, additional savings are achieved not only through reduced reliance on external thermal supplies but also through lower electricity consumption.

To better understand the operational decisions on energy consumption, we examine the resulting operating strategy of selected energy system components. The total amounts of $CH_4$, $CO_2$, and $H_2$ produced for three cases are shown in **Figure 3**.

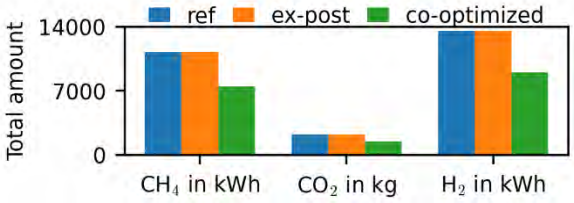

**Figure 3.** Total amounts of $CH_4$, $CO_2$, and $H_2$ produced.

Compared with the reference case, the amounts of $CH_4$, $CO_2$ and $H_2$ produced in the ex-post case remain unchanged. This is because the operational decisions of the MPes are determined before waste heat utilization is applied. As a result, the $CH_4$ output, $H_2$ and $CO_2$ inputs are identical in both cases. However, because less $CH_4$ is required for supplying th-demand, the surplus $CH_4$ is fed into the g-grid. In addition, the CHP engine operates and converts 6614 kWh redundant $CH_4$ into 2554 kWh electricity, leading to cost savings in electricity consumption. In contrast, in the reference case, the CHP engine remains inactive over the entire input time series.

In the co-optimized case, a significant decrease in the production of all three products is observed. To better understand this decrease, we further examine operational decisions related to waste heat utilization. **Figure 4** illustrates the distribution of waste heat from the MPes in both the ex-post and co-optimized cases. The lines indicate the available waste heat, while the bars show the integrated amounts at HT, MT and LT temperature levels.

In the ex-post case, 4257 kWh waste heat is generated from the MPes: 89.5 % at HT level, 5.4 % at MT level, and 5.1 % at the LT level, while the LT waste heat cannot be reused within the PtX energy system. About 52.2 % of the HT waste heat is integrated into the thermal product balance at the HT level to support the operation of the DAC plant. The remaining 47.8 % HT waste heat, together with the 5.4 % MT waste heat is supplied into thermal product balance at the MT level.

In the co-optimized case, although 89.4 % of the total 2805 kWh waste heat is available at the HT level, all of it is integrated into the MT level to support heating demand. As a result, less $CH_4$ is required, which in turn reduces the demand for $H_2$ and $CO_2$ within the energy system (cf. **Figure 3**), thereby significantly reducing the overall operational costs (cf. **Table 3**).

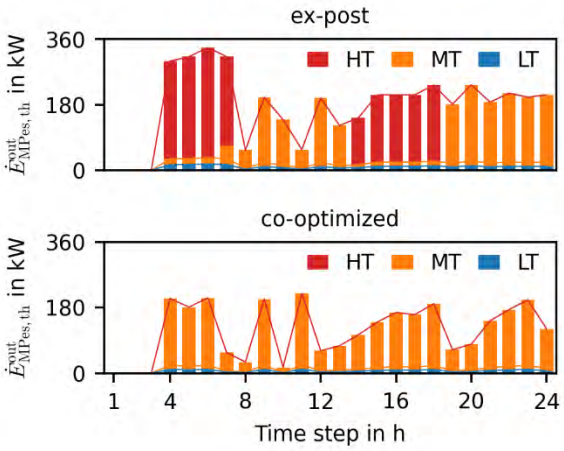

**Figure 4.** Waste heat generated by the MPes and its distribution among reuse options at each time step. Lines: available waste heat; bars: integrated waste heat.

## 6. CONCLUSION

This work presents an optimization method for integrating waste heat utilization into operational problems of PtX energy systems. Using detailed process models and pinch analysis, waste heat at multiple temperature levels is incorporated into the operational optimization problems. The proposed method includes two different solution approaches, namely ex-post and co-optimized, to handle the problem complexity and offer a trade-off between computational effort and solution optimality.

The proposed method is applied to optimize the daily operation of a PtX energy system adopted from literature. Compared with a reference case computed with literature setting (without waste heat utilization), the two proposed solution approaches improve operational performance to different extents while requiring different levels of computational effort. The ex-post case achieves an efficiency improvement of 7 p.p. and cost savings of 7.2 %, while requiring the same computational time as the reference case. When a higher computation effort is acceptable, the co-optimized approach yields significantly larger improvements, with an increase in system efficiency of 20 p.p. and cost savings of 21.9 %.

Overall, the proposed method successfully addresses waste heat utilization within the operational optimization problem and is generally applicable to renewables-based energy systems, especially those with PtX technologies integrated. Future research could focus on reducing the computational effort of the co-optimized

approach. Moreover, control strategies could be integrated into the proposed method to assess their applicability under real-world operating conditions.

## ABSTRACT

Achieving net climate neutrality will likely require negative-emission technologies such as Direct Air Capture (DAC). Potassium hydroxide (KOH) absorption is one of the most mature DAC approaches, but it can cause significant emissions due to natural-gas-based thermal regeneration. Electrochemical regeneration methods, such as electrolysis and electrodialysis, have recently been proposed as alternatives, yet their relative performance and environmental impacts remain unclear. We present a comparative cradle-to-gate life cycle assessment (LCA) of three KOH-based DAC configurations: (i) the established Ca-looping thermal regeneration, (ii) the electrolysis regeneration (DAC-ELY), which co-produces hydrogen, and (iii) the electrodialysis regeneration (DAC-ED). The results show that, expectedly, electricity demand dominates life cycle impacts across all configurations. With the current German electricity mix, the established DAC has the lowest overall impacts, while DAC-ELY and DAC-ED exhibit higher global warming impacts due to the high electricity requirements of electrochemical regeneration. Infrastructure impacts are more noticeable for DAC-ED due to its low current density and large membrane areas. This study highlights that electrification alone does not guarantee lower life cycle impacts and that the sustainability of electrochemical DAC depends on process efficiency, material use, and the expected use of renewable electricity.

**Keywords**: Lifecycle Assessment, Direct Air Capture, Electrolysis, Electrodialysis, Electrochemical Regeneration

## INTRODUCTION

Limiting global warming to 1.5 °C above pre-industrial levels requires reductions in greenhouse gas emissions [1]. Nevertheless, carbon-based resources are expected to remain in use in hard-to-abate sectors such as cement, steel, and aviation, where complete electrification is technically or economically challenging. As a result, residual $CO_2$ emissions are likely to persist, creating a challenge in achieving net-zero emission targets [2]. In this context, direct air capture (DAC) technologies, which remove $CO_2$ directly from the ambient air, have gained increased attention [2].

Several DAC technologies are currently under development in the market. The most mature approach is the absorption of $CO_2$ in a KOH solution with Ca-looping regeneration, which relies on high-temperature thermal regeneration. At the same time, novel electrochemical DAC concepts have recently emerged that replace thermal regeneration with electrically-driven processes, such as electrolysis-based regeneration and electrodialysis-based regeneration. These technologies offer potential advantages in terms of electrification and integration with renewable energy but are currently at lower

technology readiness levels [4].

Techno-economic assessments (TEAs) are widely used to evaluate emerging DAC technologies [5]. However, TEA alone does not capture the environmental implications of these systems. DAC technologies are both energy- and material-intensive, and their environmental performance is strongly influenced by factors such as the electricity supply and infrastructure requirements. A life cycle assessment (LCA) is therefore needed to identify potential environmental trade-offs.

Several studies have investigated the techno-economic and environmental performance of DAC technologies [5]-[8]. However, a comprehensive comparative LCA of the established KOH-based DAC with Ca-looping regeneration and the emerging KOH-based DAC technologies with electrochemical regeneration is still lacking in the literature.

To fill in this gap, we perform a comparative LCA of three KOH-based DAC technologies: DAC with Ca-looping regeneration, DAC with electrolysis-based regeneration, and DAC with electrodialysis-based regeneration. We thus aim to provide insights into their current environmental performance, identify key drivers of impacts, and highlight ways for improving the sustainability of electrochemical DAC systems.

## SYSTEM DESCRIPTION

As mentioned earlier, three KOH-based DAC technologies are studied in the present work, which differ in the sorbent regeneration method: (i) the established Ca-looping regeneration (DAC-Established), (ii) the electrolysis regeneration (DAC-ELY), and (iii) the electrodialysis regeneration (DAC-ED). A schematic representation of the studied technologiesis given in Figure 1.

### Direct Air Capture with Ca-looping Regeneration

This technology is commercialized by Carbon Engineering [3], exhibits a high TRL of 7-8 [9], and will be considered as the benchmark for the comparison of the other technologies. It consists of two connected chemical steps. In the first step, $CO_2$ from the atmosphere is brought in contact with a KOH solution in an air contactor unit, producing an aqueous solution of $K_2CO_3$. In the second step, the solution enters a pellet reactor in which it reacts with $Ca(OH)_2$, producing $CaCO_3$ and KOH. Then the $CaCO_3$ enters a calciner and is decomposed to CaO at high temperatures of 900 °C, while releasing $CO_2$. The heat needed for the release of $CO_2$ is provided by burning natural gas [10]. Finally, the CaO is hydrated in a slaker unit to regenerate the $Ca(OH)_2$ that is fed back to the pellet reactor. If the additional $CO_2$ released from the natural gas burning is not captured, then the process could potentially lead to positive direct $CO_2$ emissions.

### Direct Air Capture with Electrolysis Regeneration

DAC with electrolysis regeneration is a technology at a low TRL but has been proposed as a promising alternative to the established thermal process [11], as it is powered by electricity and can integrate renewable energy [4].

The process consists of two coupled chemical steps, with the first being the same as in the DAC-Established. In the second step, KOH regeneration and $CO_2$ release are achieved in an electrochemical reactor. This reactor comprises an anode, an anolyte compartment, a cation exchange membrane (CEM), a catholyte compartment, and a cathode [11]. The $CaCO_3$ solution produced from the first step is fed to the anodic side of the electrochemical reactor. By applying current, the water oxidation reaction (WOR) occurs at the anode, where gaseous oxygen and protons are produced according to Reaction (1), while the water reduction reaction occurs at the cathode, producing gaseous hydrogen and hydroxide anions according to Reaction (2):

$$H_2O \rightarrow 2H^+ + 2e^- + 0.5O_2 \quad (1)$$

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (2)$$

Simultaneously, mainly $K^+$ migrate through the CEM from the anolyte to the catholyte. This results in an acidic environment in the anolyte and in an alkaline environment at the catholyte. The acidic environment in the anolyte drives the conversion of carbonate species into gaseous $CO_2$, which is released in the form of bubbles, while the alkaline environment in the catholyte enables the regeneration of the KOH [11]. Due to the production of $O_2$ and the release of $CO_2$ in the anolyte, an additional pressure swing adsorption unit (PSA) is required after the electrochemical reactor to separate the two gases [4].

### Direct Air Capture with Electrodialysis Regeneration

Electrodialysis regeneration is another electrochemical approach that has been investigated for DAC. It exhibits a TRL of approximately 4 [5], and similarly to the electrolysis regeneration, the operating principle is based on the pH gradient across ion-exchange membranes.

As in the electrolysis regeneration, the process consists of two main steps, with the initial $CO_2$ capture step being identical to that of the DAC-Established process. In the second step, the $CaCO_3$ solution is fed into an electrodialysis regeneration unit, which exhibits some differences compared to the electrolysis regeneration. The electrodialysis reactor consists of a single anode and cathode, while in between multiple Bipolar Membranes (BPM) and CEM pairs are arranged in series [4].

By applying current, the reactions (1) and (2) occur at the anode and cathode, respectively. In addition, the

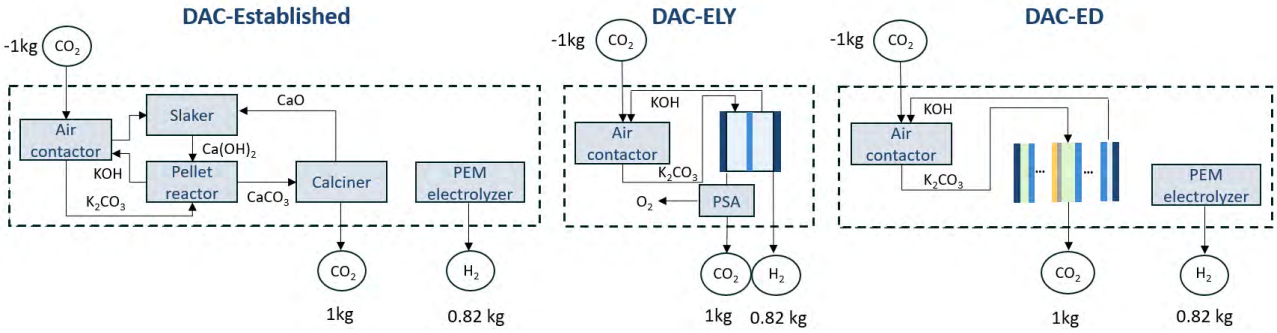

**Figure 1.** Schematic representation of the cradle-to-gate system boundaries for the DAC with Ca-looping regeneration (DAC-Established), the DAC with electrolysis regeneration (DAC-ELY), and the DAC with electrodialysis regeneration (DAC-ED).

BPMs, which consist of an anion exchange layer and a cation exchange layer, result in water dissociation into $OH^-$ and $H^+$. This generates acidic and alkaline environments on opposite sides of the membrane, establishing a pH gradient across the CEM [4]. Similarly to the electrolysis regeneration, in the acidic compartments, $CO_2$ is released in the form of bubbles. In contrast to the electrolysis regeneration, $CO_2$ is released in chambers that are physically separated from the anode, where oxygen is generated. As a result, no additional PSA unit is required for gas separation. Moreover, the large number of BPM-CEM pairs between the two electrodes allows operation at a lower current density compared to the electrolysis unit. Consequently, the production rate of hydrogen is considered negligible compared to the release of $CO_2$ [4].

## MATERIALS AND METHODS

The LCA was conducted in accordance with the ISO 14040/14044 framework, incorporating the main phases of goal and scope definition, life cycle inventory analysis, life cycle impact assessment, and interpretation [12].

### Goal and Scope Definition

The goal of the present study is the comparative LCA of the three DAC technologies. We assess the environmental impacts by performing a cradle-to-gate analysis, including the infrastructure and air capture processes, while excluding end-of-life treatment due to the unknown fate of the final products, as they are similar among the technologies.

The DAC-ELY co-produces hydrogen as a valuable product during electrochemical regeneration. Under the operating current density of 0.14 A $cm^{-2}$, the hydrogen co-production is 0.82 kg $H_2$ per kg $CO_2$ captured [4]. To ensure functional equivalence among the compared systems, multifunctionality is addressed by expanding the system boundaries [13]. In this context, a PEM water electrolyzer is included within the system boundaries for the DAC-Established and the DAC-ED cases to generate 0.82 kg of $H_2$. Thus, the functional unit is 1 kg of $CO_2$ and 0.82 kg of $H_2$.

### Life Cycle Inventory Analysis

The life cycle inventory analysis was performed using literature process modeling and experimental data for the different DAC technologies. GaBi [14] was employed as LCA software to calculate the environmental impacts. Background data for material and energy flows associated with process infrastructure were obtained from the Ecoinvent database [15]. For all the assessed technologies, the electricity supply for the operation was assumed to be provided by the German electricity grid (unless otherwise stated), and the lifetime of the equipment and the plant is assumed to be 20 years. In the following, the assumptions of the inventory modeling and the data used for the different DAC technologies are discussed in detail.

#### PEM Electrolyzer

A PEM electrolyzer operating at a current density of 1.5 A $cm^{-2}$ is assumed to produce $H_2$ in the DAC-Established and the DAC-ED, according to Zachert et al. [16]. Infrastructure data for the PEM electrolyzer stack and balance of plant (BoP) are taken from Bareiß et al. [17]. Due to the lack of inventory data for iridium at the anode, platinum was assumed as a proxy based on available data from the Ecoinvent database [15]. Moreover, the Nafion membrane material was approximated as tetrafluoroethylene (TFE) [18].

#### Direct Air Capture with Ca-looping Regeneration

Operational data for the DAC-Established process are taken from Keith et al. [10]. The thermal energy required for sorbent regeneration is assumed to be supplied by natural gas combustion. The oxygen required for combustion is assumed to be provided by the PEM electrolyzer; therefore, no additional air separation unit was

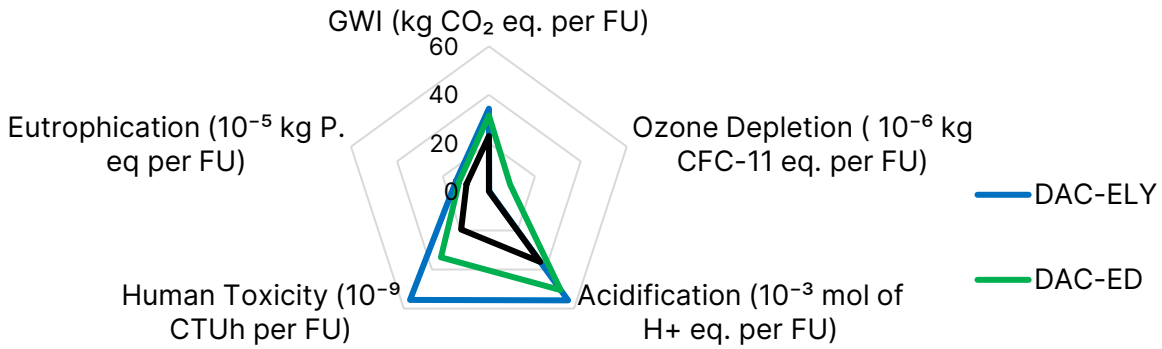

**Figure 2:** Comparative life cycle environmental impacts of the DAC with Ca-looping regeneration (DAC-Established), DAC with electrolysis regeneration (DAC-ELY), and DAC with electrodialysis regeneration (DAC-ED), assuming the German electricity grid. The DAC-Established exhibits the lowest life cycle impacts in all assessed categories, while the DAC-ELY shows the highest scores in all categories except ozone depletion. The functional unit (FU) is 1 kg $CO_2$ captured and 0.82 kg $H_2$ produced. GWI refers to the global warming impact.

included in the system boundaries [19]. Emissions from natural gas combustion were excluded from the inventory, as the $CO_2$ produced during sorbent regeneration was assumed to be fully captured. Only emissions associated with natural gas production and transportation were considered [19]. Infrastructure data for the air contactor and the regeneration units are taken from Madhu et al. [20]. The pellet reactor, slaker, and calciner were approximated as steel tanks for the purpose of infrastructure modeling [20].

### Direct Air Capture with Electrolysis Regeneration

An electrolysis regeneration unit operating at a current density of 0.14 A $cm^{-2}$ is assumed according to the operational data from Liu et al. [4]. A PSA unit for the separation of $CO_2$ and $O_2$ is included [4], with infrastructure data for the PSA taken from Burgers et al. [21]. Infrastructure data for the electrolysis regeneration unit stack and the BoP are obtained from Bareiß et al. [17], with modifications to reflect the specific operating conditions of the DAC system. In contrast to the PEM electrolyzer, a nickel catalyst is used at the cathode instead of platinum due to the alkaline operating environment [11]. Similarly to the PEM electrolyzer case, platinum is used as a proxy for iridium at the anode and TFE for the Nafion membrane.

### Direct Air Capture with Electrodialysis Regeneration

An electrodialysis regeneration unit operating at a current density of 0.012 A $cm^{-2}$ is assumed according to the operational data from Liu et al. [4]. Each regeneration unit is assumed to consist of 20 $CO_2$ recovery-alkali regeneration pairs [4]. Infrastructure data for the electrodialysis regeneration unit stack and the BoP are obtained from Bareiß et al. [17]. Similarly to the electrolysis regeneration case, a nickel catalyst is assumed at the cathode, while platinum was used as a proxy material at the anode. TFE is used as a proxy for the CEM, and the BPM is assumed to consist of two Nafion membranes [22].

### Life Cycle Impact Assessment

We investigated five typical impact categories: global warming impact (GWI), ozone depletion, acidification, human toxicity, and eutrophication. The environmental impacts were quantified using the Environmental Footprint (EF) 2.0 impact assessment method [23]. The results are normalized to the functional unit of 1 kg $CO_2$ captured and 0.82 kg $H_2$ produced.

## RESULTS AND DISCUSSION

### Environmental Performance across Impact Categories

Figure 2 presents the comparative results for the different impact categories of the three DAC technologies assuming the German electricity grid. Overall, the DAC-Established technology exhibits the lowest life cycle impacts in all assessed categories. This can be attributed to its higher technological maturity and optimization level compared to the more novel electrochemical DAC processes. In contrast, the DAC-ELY shows the highest life cycle impacts in all categories except for ozone depletion. For ozone depletion, the DAC-ED has the highest impact, which can be attributed to the larger number of membranes in the electrodialysis configuration, leading to increased material-related ozone depletion contributions.

Since the global warming impact is one of the most important categories, we focus in the following subsections on its detailed analysis, including process- and infrastructure-level contributions, to explain the observed differences among the assessed technologies.

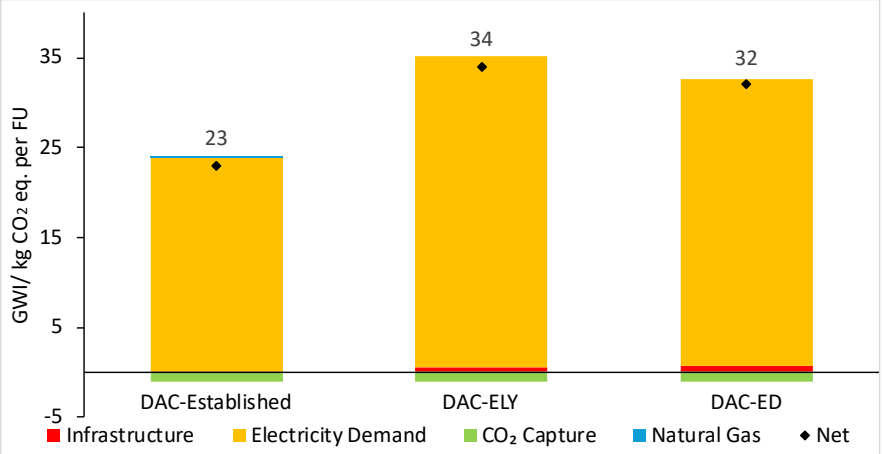

**Figure 3:** Cradle-to-gate global warming impact (GWI) distribution for the DAC with Ca-looping (DAC-Established), the DAC with electrolysis regeneration (DAC-ELY), and the DAC with electrodialysis regeneration (DAC-ED), assuming the German electricity grid. The main GWI contributor is the electricity demand in all three technologies. The DAC-ELY exhibits higher electricity demand compared to the DAC-Established and DAC-ED. The negative GWI is attributed to the direct removal of $CO_2$ from the atmosphere through the DAC process. The infrastructure contribution is approximately 2% of the total GWI in the DAC-ED. The functional unit (FU) is 1 kg $CO_2$ captured and 0.82 kg $H_2$ produced.

## Contribution Analysis of the Global Warming Impact

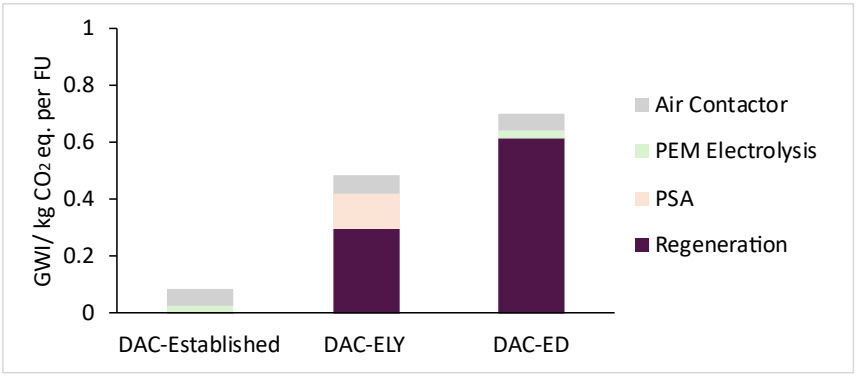
Figure 3 presents the global warming impact distribution for the three DAC technologies. Overall, in all three technologies, the electricity demand dominates the GWI. There is a 47% and 38% increase in the net GWI of the DAC-ELY and the DAC-ED, respectively, compared to the DAC-Established. It should be noted that the high electricity demand in the DAC-Established and the DAC-ED is mainly due to the additional PEM-electrolyzer included to ensure a fair comparison of the three technologies via the system expansion approach.

It can also be seen that there are negative GWI corresponding to 1 kg of $CO_2$ eq. per kg of FU, reflecting the direct removal of $CO_2$ from the atmosphere through the DAC process. Moreover, the highest infrastructure GWI is observed for DAC-ED of about 2% of the total impact. Overall, the contribution of the infrastructure is negligible compared to the electricity demand. However, in case there is a larger penetration of renewable energy resources (as analyzed below), the relative contribution of the infrastructure may become more significant. Therefore, it is still of interest to examine the differences in the infrastructure contributions, as follows.

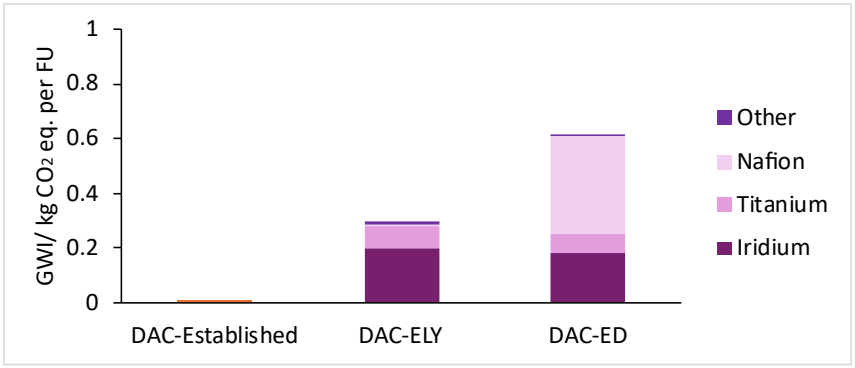
## Contribution of Infrastructure to Global Warming Impact

Figure 4a) presents the distribution of infrastructure-related contributions to the global warming impact of the three DAC technologies. The regeneration unit is the main contributor to the infrastructure impact in the case of DAC-ELY and DAC-ED, while DAC-Established has a negligible infrastructure impact. The contribution of the air contactor is identical across all three technologies, reflecting the use of the same design assumptions. At the same time, the PEM-electrolyzer exhibits considerably lower infrastructure GWI compared to the electrochemical regeneration units in the DAC-ELY and DAC-ED systems. This is primarily due to the higher operating current density (1.5 A $cm^{-2}$ compared to 0.14 A $cm^{-2}$ vs 0.012 A $cm^{-2}$, respectively), which translates into a lower amount of material requirement per functional unit.

Figure 4b) presents the distribution of infrastructure-related contributions from the regeneration units to the global warming impact of the three DAC technologies. For both DAC-ELY and DAC-ED, the main contributors within the regeneration units are the iridium, titanium, and Nafion-based membrane materials. In the case of DAC-ED, the contribution associated with the Nafion membranes is higher than in the case of DAC-ELY. This can be attributed to two factors. First, the DAC-ED regeneration unit operates at a current density approximately eleven times lower than that of the DAC-ELY, resulting in higher material requirements per functional unit. Second, the DAC-ED requires 3 additional membranes per $CO_2$ recovery-alkali regeneration pair. Therefore, the influence of Nafion membranes on the overall infrastructure-related global warming impact is more pronounced in the DAC-ED system.



a)



b)

**Figure 4:** (a) Distribution of infrastructure-related global warming impact (GWI) and (b) distribution of infrastructure-related contributions from the regeneration units to the GWI for the DAC with Ca-looping (DAC-Established), the DAC with electrolysis regeneration (DAC-ELY), and the DAC with electrodialysis regeneration (DAC-ED). The regeneration unit has the highest contribution to the infrastructure of DAC-ED, with Nafion-based membranes being the dominant contributing material. The functional unit (FU) is 1 kg $CO_2$ captured and 0.82 kg $H_2$ produced.

## Influence of the Carbon Footprint of Electricity on the Global Warming Impact

To assess the potential of the novel electrochemical DAC technologies, in Figure 5, we present the influence of the carbon footprint of electricity across different countries on the GW [24]. A lower electricity carbon footprint corresponds to a higher penetration of low-carbon energy sources in the respective electricity mix. The DAC-Established exhibits the lowest GWI across all electricity scenarios. Moreover, the DAC-ELY approaches the GWI of the DAC-ED at lower carbon footprints of electricity, since the electricity demand contribution becomes lower.

The results suggest that, in addition to the larger penetration of renewable electricity, further performance improvements are needed for DAC-ELY and DAC-ED to compete with the DAC-Established technology. Reductions in materials use and infrastructure-related impacts or operation at higher current densities will be necessary to realize the potential of electrochemical DAC technologies.

## CONCLUSION AND OUTLOOK

We performed a comparative LCA of three DAC technologies: the established DAC technology with Ca-looping regeneration; the novel technology of DAC with electrolysis regeneration; and the DAC with electrodialysis regeneration. The results have shown that the DAC-Established outperforms the other technologies in all impact categories, when assuming the German electricity grid. DAC-ELY shows the highest GWI due to the higher electricity demand associated with the electrochemical sorbent regeneration. The infrastructure impact is higher in the case of DAC-ED due to both the use of additional membranes and the low operating current densities. Finally, it is concluded that DAC-ELY and DAC-ED need further performance improvement and a larger share of renewable energy to compete with the DAC-Established.

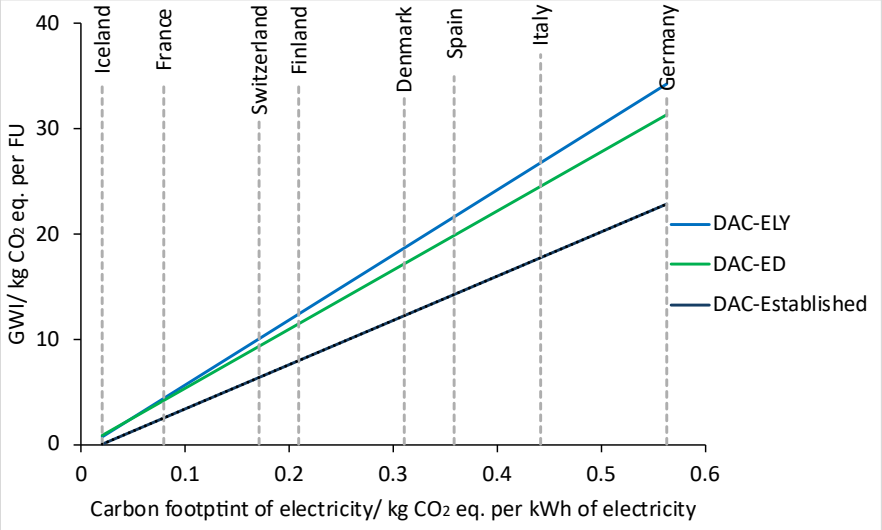


**Figure 5:** Global warming impact (GWI) with respect to the carbon footprint of electricity for the DAC with Ca-looping (DAC-Established), the DAC with electrolysis regeneration (DAC-ELY), and the DAC with electrodialysis regeneration (DAC-ED). DAC-Established exhibits the lowest GWI across all electricity mix scenarios. DAC-ELY approaches the GWI of DAC-ED in cases of larger penetration of alternative energy resources. The functional unit (FU) is 1 kg $CO_2$ captured and 0.82 kg $H_2$ produced.

However, several limitations of this study should be acknowledged. In cases where no dataset was available, proxies were used for the infrastructure, which may not fully capture the specific impacts of the actual materials. Moreover, upstream processes (e.g., metal extraction, refining) were modeled with the average European electricity mix, which may lead to changes if region-specific grids were applied.

Future work should extend the comparison of these DAC technologies beyond environmental performance to include TEA. This will allow for a more holistic evaluation of the three alternatives. Moreover, system optimization with respect to both environmental impacts and costs may help identify trade-offs and pathways for improving the overall performance of electrochemical DAC technologies.

## AKNOWLEGMENTS

This work was funded by the German Federal Ministry for Education and Research (BMBF) within the project HyInnoHECC of SupplHyInno Rhineland (grant number 03ZU1115I). We are grateful to Lara Meuleneers for valuable discussions.

## ABSTRACT

$CO_2$-to-methanol process is an attractive option to simultaneously reducing the anthropogenic $CO_2$ while producing value-added chemicals. In this work, two distinct $CO_2$-to-methanol process routes specifically, single step and dual step are evaluated based on their economic and environmental performance. First, a multiobjective optimization (MOO) framework is formulated to develop the optimal process configurations. Three conflicting objectives including methanol production rate, total annual cost (TAC) and carbon intensity of methanol are considered. For this MOO, the elitist non-dominated sorting genetic algorithm (NSGA-II) is employed to get the Pareto front. From the Pareto front, a balanced compromise solution is identified by the technique for order of preference by similarity to ideal solution (TOPSIS) with entropy information as weighting criteria. Then, the comparative performance analysis is conducted across the Pareto front. At the TOPSIS-selected configuration, the single step process offers economic advantages (1.97% lower levelised cost of methanol (LCoM)), but performs poorly on environmental perspective (3.03% higher carbon intensity of methanol). In contrast, at the cost-optimal point the dual step process is marginally favourable in both aspects (0.55% less LCoM and 1.26% reduction in carbon intensity of methanol). Overall, both processes exhibit comparable economic and environmental outcomes, with the dual step showing better environmental performance and reduced variability across the Pareto space.

## INTRODUCTION

Methanol has an extensive industrial demand, reaching around 112 million metric tons per year in 2024, owing to its versatile applications [1]. It serves as a building block for the production of numerous chemicals, such as formaldehyde, acetic acid, methyl tert-butyl ether (MTBE), and dimethyl ether (DME), among others. In addition, it exhibits favorable combustion properties, which make it a potential alternative fuel and energy carrier. Traditionally, methanol is produced from synthesis gas ($CO/H_2/CO_2$) using heterogeneous $Cu/ZnO/Al_2O_3$ catalyst. The synthesis gas is typically derived from fossil resources, with around 80% obtained through natural gas reforming and the remainder from coal gasification [2]. However, in recent time significant interests are being concentrated on 'green' methanol processes by replacing fossil resources with renewables. In this regard, $CO_2$ hydrogenation through the Power-to-Methanol concept emerges as an attractive option due to its dual benefit. It mitigates global warming by lowering or even reversing the $CO_2$ emission while simultaneously producing value added products. The $CO_2$ is obtained from industrial flue gases or, direct air capture and the green $H_2$ from electrolysis of water using renewable energy (e.g. solar, wind etc.

Main reactions, which are involved in the heterogeneously catalyzed synthesis of methanol are:

Hydrogenation of $CO_2$:

$$CO_2 + 3H_2 \overset{\Delta H = -49.4\ kJ.mol^{-1}}{\Longleftrightarrow} CH_3OH + H_2O \qquad (1)$$

Hydrogenation of CO:

$$CO + 2H_2 \xleftrightarrows{\Delta H = -90.6\ kJ.mol^{-1}} CH_3OH \quad (2)$$

Reverse water gas shift (RWGS):

$$CO_2 + H_2 \xleftrightarrows{\Delta H = 41.2\ kJ.mol^{-1}} CO + H_2O \quad (3)$$

Typically, hydrogenation of $CO_2$ is much faster than hydrogenation of CO [3]. Nevertheless, a CO rich feed is favorable because it consumes water during water gas shift, which limits the conversion of the resulting $CO_2$ hydrogenation to methanol. In contrast, from a chemical perspective, a $CO_2$ rich feed is not so favorable because it produces water during the reverse water gas shift.

In the standard process, a CO rich feed (i.e., synthesis gas) is used. Accordingly, two options are available for the new $CO_2$-to-methanol process, i.e., a single-step process converting the $CO_2$ rich feed directly to methanol or, a dual-step process, where $CO_2$ is first converted to CO in a separate reverse water gas shift reactor. Afterwards, the CO rich feed is converted in a second reactor to methanol following the standard process. The dual step process offers additional potential for improvement by using different catalysts and operating conditions in the different reactors [4]. In this context, a comparative techno-economic analysis is required to find out which process option is the best for $CO_2$-to-methnol production. To the best of our knowledge, limited investigations are available in this direction. Previous studies mainly compared both processes using relatively simple reaction kinetics and basic process analyses, often based on sensitivity studies [5-7]. Optimization is not applied for the rigorous evaluation of single and dual step processes. Therefore, in this contribution, a techno-economic analysis is performed using optimization and a rigorous kinetic model for both processes.

First, fixed bed reactor based single step and dual step processes are developed. Commercial $Cu/ZnO/Al_2O_3$ and $Ni/Al_{12}O_{19}$ catalysts are employed for the methanol synthesis and RWGS reactions, respectively. This study considers the mechanistic model of the methanol synthesis reaction based on the Langmuir-Hinshelwood kinetic model [8], with the corresponding model parameters adopted from Seidel et al., 2021 [9]. The kinetics of RWGS reaction are taken from literature [10]. Subsequently, the economic and environmental performance of the processes are assessed by total annual cost and carbon intensity of methanol. The economic analysis accounts for capital cost, operating cost, labour cost and raw material cost. Carbon intensity of methanol is defined as the total $CO_2$ emissions associated with the process per unit of methanol produced. Finally, the optimal process configuration, including design and operating parameters, is determined through a multiobjective optimization (MOO) technique using the elitist non-dominated sorting genetic algorithm-II (NSGA-II). The MOO problem is formulated with three conflicting objectives: maximizing methanol production rate, minimizing total annual cost and minimizing carbon intensity of methanol. To identify the final optimal point, the technique for order of preference by similarity to ideal solution (TOPSIS) with entropy information as a weighting criterion is implemented. Subsequently, both processes are evaluated based on their optimal configurations.

## PROCESS DESCRIPTION

In this study, two process routes are analyzed/considered for the production of methanol from $CO_2$ namely, single step and dual step process. In both processes, pure $CO_2$ and $H_2$ are mixed and introduced into the reactor following a multistage compressor coupled with intermediate heat exchangers. This multistage compressor and intermediate heat exchanger arrangement are designed such that the desired operating pressure and temperature can be achieved. For the large scale production the feed flow rate is assumed to be fixed at 1000 mol/sec for both the processes.

Figure 1 demonstrates the single step process configuration. The compressed feed is combined with the recycle stream and preheated in a heat exchanger to attain the desired reaction temperature. Such heat integration provides a clear advantage, as reported in the literature [11].The mixed stream is introduced to an isothermal fixed bed type reactor. The reactor is packed with $Cu/ZnO/Al_2O_3$ catalyst and the specified temperature of the reactor is maintained by a water-cooled arrangement. The density of the catalyst is 770 kg/m$^3$ with the bed void fraction of 0.4. The outlet from the reactor is cooled down in a heat exchanger and introduced in a flash separator. The flash separator is operated at high pressure and low temperature at isothermal and isobaric condition. In the separator the gases are separated from liquid products. The gas stream mainly consists unreacted $CO_2$, CO and $H_2$; whereas liquid stream consists of methanol and water. A part of the gas stream is purged (1%) and the remaining is recycled (99%) back to the reactor. On the other hand, the liquid stream is then directed to a distillation column to get the pure methanol.

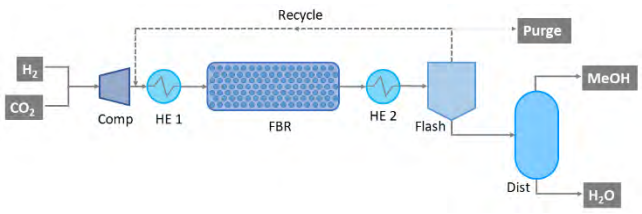

**Figure 1.** Schematic of the single step $CO_2$-to-methanol process route.

The dual step process configuration is shown in Figure 2, where the compressed feed is partially converted to CO in a RWGS reactor. The outlet stream of the RWGS reactor is then cooled down and introduced into a flash separator to separate the water. The remaining vapor stream, composed of $CO_2$, CO and $H_2$ is then compressed and subsequently mixed with the recycle stream. This steam is fed into the methanol synthesis reactor through a heat exchanger, where it is attained the desired temperature. The output of the second reactor is then cooled using a heat exchanger and directed into a flash separator. The vapor stream from the flash separator, mainly contains $CO_2$, CO and $H_2$ is recycled back after a small purge, similar to the single step process. The liquid stream of the flash separator contains methanol and water, which are separated from each other in a distillation column.

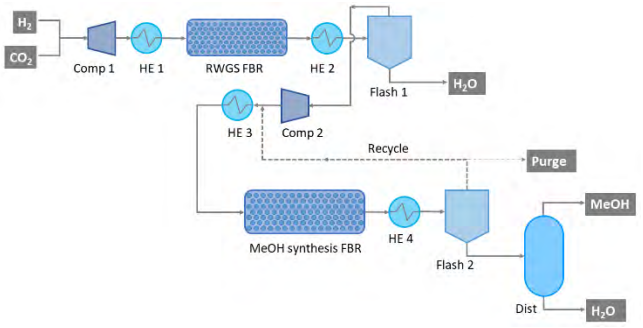

**Figure 2.** Schematic of the dual step $CO_2$-to-methanol process route.

## MATHEMATICAL MODELING

This section highlights the mathematical model formulation of single and dual step process configurations. It consists modeling of reaction kinetics, fixed bed reactor and flash separator.

### Reaction Kinetics

The kinetic model proposed by Seidel et al. [8], with reported parameters [9], is adopted here for the methanol synthesis reactor over $Cu/ZnO/Al_2O_3$ catalyst. Three reactions occurred simultaneously in the second reactor, as mentioned in Section 1. The corresponding rate expressions are described as follows,

$$r_{CO} = (1-\varnothing)k_1\left(p_{CO}p_{H_2}^2 - \frac{p_{CH_3OH}}{K_{P_1}}\right)\Theta_{CO}\Theta_{H_2}^4 \quad (4)$$

$$r_{CO_2} = \varnothing^2 k_2\left(p_{CO_2}p_{H_2}^2 - \frac{p_{CH_3OH}p_{H_2O}}{K_{P_2}p_{H_2}}\right)\Theta_{CO_2}^2\Theta_{H_2}^4 \quad (5)$$

$$r_{rwgs} = \frac{\varnothing}{1-\varnothing}k_3\left(p_{CO_2} - \frac{p_{CO}p_{H_2O}}{K_{P_3}p_{H_2}}\right)\Theta_{CO_2}\Theta_{CO} \quad (6)$$

The reaction constants are calculated from the extended Arrhenius equation, where *j* represents the reactions (1, 2 or 3).

$$k_j = exp\left(\beta_{2j-1} - \beta_{2j}\left(\frac{T_{ref}}{T} - 1\right)\right) \quad (7)$$

On the other hand, synthesis gas is produced in the RWGS reactor over the commercial Ni-catalyst ($Ni/Al_2O_3$). The reaction kinetics is given by:

$$r_{syn} = k_0 e^{\left(-\frac{E}{RT}\right)}\left(C_{CO_2} - \frac{C_{CO}C_{H_2O}}{K_c C_{H_2}}\right) \quad (8)$$

The model parameters are adopted from the work of [10].

### Process Modeling

In this study, both RWGS and methanol synthesis reaction takes place in an isothermal fixed bed reactor (FBR). The reactor is operated at a constant pressure and considered no axial mixing and ideal gas phase. The FBR model is developed considering a cascade of CSTRs, where the number of stages correlates with the degree of back-mixing [12]. The corresponding material balance for each component in the gas phase is expressed as,

$$n^G\frac{dy_i}{dt} = \dot{n}_{feed}y_{i,0} - \dot{n}_{out}y_i + m_{cat}\sum_{j=1}^{NR}\nu_{i,j}r_j \quad (9)$$

Where, $n^G$ denotes total mole present in the gas phase of the reactor. $\dot{n}_{feed}$ and $\dot{n}_{out}$ are molar flow rates of the feed and outlet of the reactor (mol/sec). $y_i$ represents the gas phase mole fraction of component *i*. $\nu_{i,j}$ is the stoichiometric coefficient of component *i* in reaction *j*, $r_j$ is the rate of reaction *j* (mol/sec/$kg_{cat}$) among the total number of reaction *NR*.

The summation of the component material balances over all species (*NC*) yields the total material balance, which is used to compute the outlet molar flow rate ($\dot{n}_{out}$).

$$0 = \dot{n}_{feed} - \dot{n}_{out} + m_{cat}\sum_{i=1}^{NC}\sum_{j=1}^{NR}\nu_{i,j}r_j \quad (10)$$

The outlet stream from the reactor is fed into an ideal flash separator, which is operated at a fixed temperature and pressure. The flash process is computed by the Rachford-Rice method, which is mathematically described by component material balance and total material balance.

$$Fz_i = Vy_i + Lx_i \quad (11)$$

$$F = V + L \quad (12)$$

$$y_i = K_i x_i = \frac{p_i^{sat}}{P}x_i \quad (13)$$

Here, the input flow rate to the flash separator is *F* (mol/sec), with composition *z*. *V* and *L* are the outlet flow rate of the vapor and liquid stream, respectively (mol/sec) with corresponding composition *y* and *x*. *K* is the vapor-liquid equilibrium coefficient of the ideal solution, which is the ratio of saturation pressure and total pressure. The saturation pressure is calculated using Antoine equation.

By substituting equation 13, into the material balance equations, we get the Rachford-Rice equation for the vapor fraction $\delta = V/F$,

**Table 1:** Singificant decision variables with their ranges

| Single step process | | Dual step process | |
|---|---|---|---|
| **Decision variables** | **Range** | **Decision variables** | **Range** |
| Pressure of methanol synthesis reactor (bar) | 25 – 85 | Pressure of RWGS reactor (bar) | 5 – 25 |
| Temperature of methanol synthesis reactor (K) | 450 – 650 | Temperature of RWGS reactor (K) | 900 – 1500 |
| $CO_2$ mole fraction in feed | 0.15 – 0.55 | $CO_2$ mole fraction in feed | 0.15 – 0.55 |
| Catalyst amount methanol synthesis reactor (kg) | 30000 – 150000 | Catalyst amount of RWGS (kg) | 100 – 5000 |
| | | Pressure of methanol synthesis reactor (bar) | 35 – 85 |
| | | Temperature of methanol synthesis reactor (K) | 450 – 650 |
| | | Catalyst amount of methanol synthesis Reactor (kg) | 10000 – 150000 |

**Table 2:** TOPSIS-selected optimal process configurations

| Single step process | | Dual step process | |
|---|---|---|---|
| **Decision variables** | **Values** | **Decision variables** | **Values** |
| Pressure of methanol synthesis reactor (bar) | 76.1 | Pressure of RWGS reactor (bar) | 18.07 |
| Temperature of methanol synthesis reactor (K) | 519.82 | Temperature of RWGS reactor (K) | 1418.82 |
| $CO_2$ mole fraction in feed | 0.2486 | $CO_2$ mole fraction in feed | 0.2496 |
| Catalyst amount methanol synthesis reactor (kg) | 150000 | Catalyst amount of RWGS (kg) | 1507.26 |
| | | Pressure of methanol synthesis reactor (bar) | 69.2 |
| | | Temperature of methanol synthesis reactor (K) | 483.35 |
| | | Catalyst amount of methanol synthesis reactor (kg) | 108201 |

$$F(\delta) = \sum_{i=1}^{NC} \frac{z_i}{[1-\delta(1-K_i)]} - 1 \quad (14)$$

The Newton Raphson method is employed to find out the root of the above equation and correspondingly solve the flash calculations. The ODEs involved in the reactor analysis are solved by the ODE15s solver, and all simulation are conducted in the MATLAB R2022b environment.

## PERFORMANCE ASSESSMENT

The processes are evaluated based on an economic and environmental perspective. For this, three primary performance indicators are used namely, methanol production rate (kg/hr), total annual cost (TAC) and carbon intensity of methanol (kg-eq $CO_2$/kg MeOH).

Total annual cost is expressed as:

$$TAC\ (€/yr) = (ACCR \times CAPEX) + OPEX \quad (15)$$

Where, CAPEX and OPEX represents capital and operating expenditures respectively. The annual capital charge ratio (ACCR) for this study is assumed 10%. The CAPEX includes direct process equipment cost (e.g., reactor, flash separator, distillation column, compressor and heat exchanger), indirect or, auxiliary unit cost, engineering, contingency and working capital. On the other hand, OPEX corresponding to fixed operating cost and variable operating cost. Fixed operating includes salary, supervision, salary overhead, maintenance, land, taxes and insurance and general overhead cost, whereas variable operating considers feed, catalyst and utility costs. The feed $CO_2$ and $H_2$ cost is 0.045 and 3.15 €/kg, respectively. Catalyst cost is 8.7 €/kg with 4 years of lifetime. The utilities includes electricity 78.51 €/MWh and cooling

water 0.03 €/ton. Steam methane reforming is considered as the $H_2$ source due to its lower cost and stable supply. The details of the cost functions can be found elsewhere [13] and the calculations are done based on the year 2024.

The carbon intensity is amount equivalent $CO_2$ emission to produce unit amount of methanol. This accounts the $CO_2$ emission due to the production of $H_2$, electricity and $CO_2$ present in the purge gas. Additionally, a secondary economic metric is computed from the first two i.e., methanol production rate and TAC, which is levelised cost of methanol (LCoM), expressed as,

$$LCoM\ (€/kg) = \frac{TAC}{Annual\ MeOH\ production} \tag{16}$$

## MULTIOBJECTIVE OPTIMIZATION

The efficient design of the process and its performance rely on identifying the optimal design and operating parameters. In order to achieve this a multiobjective optimization strategy is incorporated based on non-dominated sorting genetic algorithm (NSGA-II). The primary performance indicators mentioned in the previous section are chosen as objectives, to take into account the economic and environmental aspects. Thus, the optimization problem is framed with the three conflicting objectives, including maximizing methanol production rate, minimizing TAC and minimizing carbon intensity of methanol.

## RESULTS AND DISCUSSION

In this section, the optimization results and based on this the performance of both the processes are analyzed. The optimization is performed based on the stated objectives and a nonlinear constraint of LCoM < 2 €/kg. The significant decision variables and their feasible regions are primarily determined by sensitivity analysis to avoid the occurrence of infeasible solutions during the optimization. Accordingly, the lower and upper bounds are identified and listed in Table 1. Notably, the total feed flow rate is same for both the processes, while $CO_2$:$H_2$ molar ratio is varying as a decision variables. It ensures identical plant capacity for the fair comparison.

The optimization is carried out over the mentioned decision variable bounds with a population size and number of generations of 30. The NSGA-II parameters are adopted from the literature [14]. The stochastic variability of the algorithm is reduced by performing two independent runs. Then the non-dominated solutions from both runs are combined, and non-dominated sorting (NDS) is performed to find the 'true' Pareto optimal front. Here, the 'true' Pareto front consists of total of 53 and 51 non-dominated solutions for the single step and dual step processes, respectively. These solutions represent trade-offs among the competing objectives, such that improvement in one objective can only be achieved at the expense of deterioration in at least one other objective. However, the TOPSIS method with entropy weighting is employed to identify the decision-preferred compromise solution that reflects the balanced trade-off among all objectives. Accordingly, the design and operating parameters of the optimal process configurations are summarized in Table 2.

The Pareto front for the single step process is provided in Figure 3 (A), which demonstrates the trade-off among the three objectives. It can be noticed that all optimal solutions are in the range of 18171.3 to 27821.1 (kg/hr) for methanol production rate, 177.25 to 171.7 (million €) for TAC and 2.579 to 4.713 (kg-eq $CO_2$/kg MeOH) for carbon intensity of methanol. Correspondingly, the secondary economic metric, i.e., LCoM, varies from 0.7964 to 1.1811 €/kg within the Pareto space. These values represent percent variations of around 37% for methanol production, 3% for TAC and 45% for carbon intensity. Notably, methanol production and carbon intensity show a wide range of variation, because no greenness constraint is imposed apart from the economic constraint (LCoM < 2 €/kg), which preserves the natural trade-off among the objectives. The TOPSIS selected optimum point corresponds to methanol production rate of 27821.1 kg/hr, TAC of 177.25 €/yr and carbon intensity of methanol is 2.579 kg-eq $CO_2$/kg MeOH, that yields LCoM of 0.7964 €/kg.

On the other hand, Figure 3 (B) illustrates the Pareto front of the dual step process in a three dimensional space. The methanol production rate, TAC and carbon intensity of methanol are varied from 18916.4 to 28322.2 (kg/hr), 173.36 to 184.01 (million €) and 2.5 to 4.23 (kg-eq $CO_2$/kg MeOH), correspondingly, LCoM changes from 0.792 to 1.1456 €/kg across the Pareto space. For this case, the recommended optimum point yields objective values of 28322.2 kg/hr, 184.01 million €/yr and 2.501 kg-eq $CO_2$/kg MeOH. The corresponding LCoM is 0.8121 €/kg. An interesting trend can be observed in the Pareto front (Figure 3), where higher methanol production leads to lower carbon intensity. This trend is due to the trade-off between the three objectives and differences in operating conditions. Pareto points with lower TAC produce less methanol, resulting in higher $CO_2$ emission intensity, as it is the ratio of $CO_2$ emission to methanol production rate.

Now, a comparative performance analysis between the two processes based on the TOPSIS-selected optimal configuration are conducted. It is evident from the Pareto-curve trend that higher methanol production demands higher TAC but lower carbon intensity. The dual process achieves 1.80% higher methanol production rate than single step at the expense of 3.81% higher TAC. Consequently, LCoM from single step is 1.97% lower than

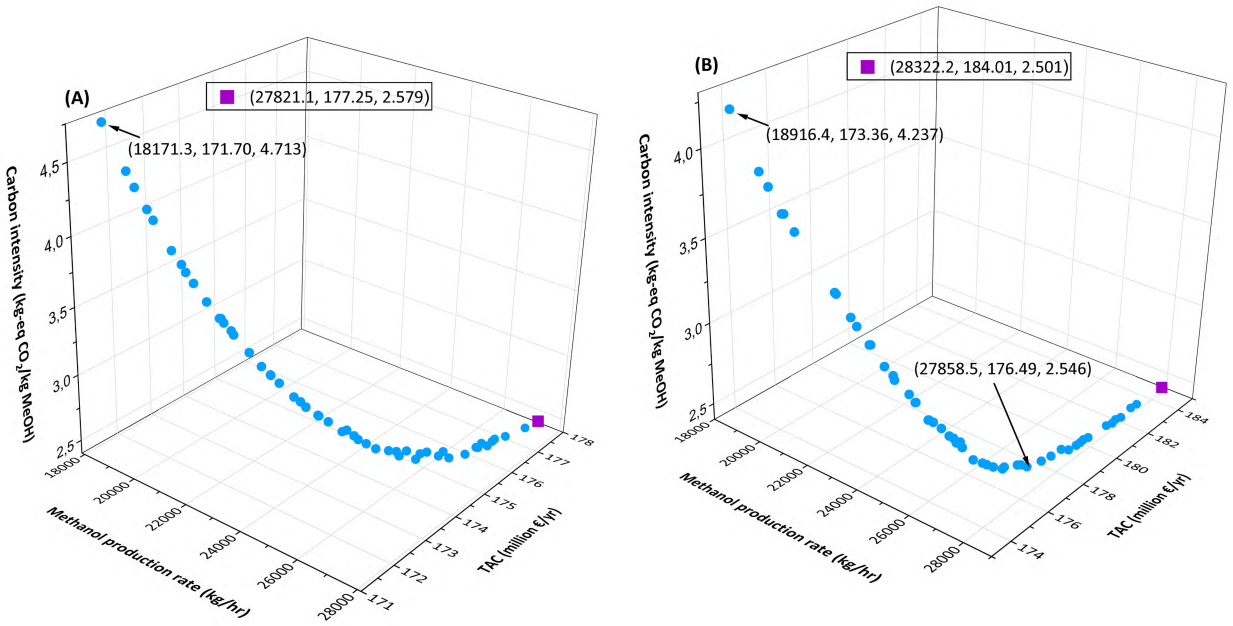

**Figure 3:** Pareto optimal front of the three objectives for the single step (A) and dual step (B) processes; violet squares in these plots corresond to the chosen optimal solution by TOPSIS

dual step process. However, from the environmental perspective dual step outperforms single step by 3.03% lower carbon intensity of methanol.

It is interesting to note that the TOPSIS-selected optimal point and cost-optimal point are the same for the single step process but not for the dual step process. Therefore, at the cost-optimal point (lowest methanol price), the dual-step process attains 0.55% lower LCoM and 1.26% lower carbon intensity than the single-step process. This indicates that, under strict cost-minimization objectives, the dual-step process offers a more favorable economic and environmental performance.

Further, we evaluated the impact of green $H_2$ on the TOPSIS selected optimal configurations. For the single-step process, TAC increases to 322.08 million €/yr, methanol production remains the same, carbon intensity reduces to 0.2861 kg-eq $CO_2$/kg MeOH and LCoM rises to 1.4471 €/kg. For the dual-step process, TAC is 328.65 million €/yr, methanol production rate remains unchanged, carbon intensity 0.2511 kg-eq $CO_2$/kg MeOH and LCoM 1.4505 €/kg. Results indicate that using green $H_2$ produced by electrolysis significantly reduces carbon intensity of methanol while increasing cost. However, the relative performance of both the processes will remain unchanged.

## CONCLUSION

In this study, a comparative assessment of single step and dual step process is performed for the production of methanol from $CO_2$. The optimal process configurations are determined using the NSGA-II coupled with TOPSIS entropy method. This multiobjective optimization problem is formulated considering economic and environmental objectives namely, methanol production rate, TAC and carbon intensity of methanol. Based on TOPSIS-selected optimal configuration, single step process offers better economic performance of 1.97% lower LCoM than dual step process. However, the environmental performance is degraded significantly, accounting 3.03% more carbon intensity. Notably, at the cost-optimal configuration dual step process shows better performance in all the aspects, yielding 0.55% and 1.26% less LCoM and carbon intensity, respectively.

Overall, both processes exhibit comparable economic and environmental performance; however the dual step process demonstrates a narrower Pareto space, indicating slightly less variability in the trade-offs. In fact, for any economic trade-off across the Pareto front, including TOPSIS-selected, cost-optimal and highest price solutions the dual step consistently attains lower carbon intensity than the single step. This clearly suggests that the dual step is environmentally superior under equivalent economic criteria.

Here, the same catalyst is used for methanol synthesis reaction in both processes; however, recent advancements in catalyst research indicate the possibility of further improvement by employing more advanced catalysts for the single-step process. In this direction, it is crucial to investigate the impact of different catalysts,

additional process configurations and variable cost parameters for more comprehensive system-level insight.

## ABSTRACT

Decarbonization of hydrogen-intensive industrial clusters is essential to meet the European Union's net-zero targets. Although hydrogen can replace fossil-based feedstocks and fuels in refineries and chemical industries, its production remains largely dependent on natural gas. Therefore, cost-effective and low-emission supply routes require a system-level approach that integrates regional resources, technologies, and industrial demand. This study applies a multi-objective optimization framework to design a low-carbon hydrogen supply system for Galicia (northwestern Spain), addressing two gaps in regional energy system modeling: model transferability across regions and integration of social criteria beyond techno-economic assessment. The model quantifies trade-offs between total system cost and greenhouse gas emissions, and an employment indicator is integrated via post-processing using TOPSIS. The results show that meeting 100% of the projected 2030 demand (105 kt $H_2$/a) yields a single feasibility-limited solution dominated by biomass gasification (69% of hydrogen production). When the demand was reduced to 60% coverage (63 kt $H_2$/a), 28 non-dominated solutions were obtained. The top-ranked compromise combines 55% PEM electrolysis and 45% biomass gasification, supported by a wind-dominated electricity mix, under equal weighting of economic, environmental, and social criteria. When either emissions or employment is prioritized, this compromise remains top-ranked, while the cost prioritization shifts preference to a solution with hydrogen production from PEM (51%) and alkaline (3%) electrolysis and biomass gasification (46%).

## INTRODUCTION

The deep decarbonization of hydrogen-intensive industrial clusters is required to align European industry with the legally binding climate objectives of the European Union for 2030 and climate neutrality by 2050 [1]. Hydrogen plays a structural role in refineries and chemical value chains, and near-term decarbonization options frequently rely on replacing fossil-derived hydrogen with low-carbon supply routes [2, 3]. Nonetheless, on a global scale, hydrogen production remains predominantly fossil-based, with natural gas still providing the largest share of dedicated hydrogen output [4]. This creates a dual challenge, i.e., low-carbon hydrogen must be implemented on a large scale, keeping costs under control, and avoiding the shift of carbon emissions throughout the life cycle [5].

A regional perspective is critical for this transition. The feasibility and performance of hydrogen pathways depend on location-specific factors such as renewable resource profiles, biomass availability, industrial demand, and infrastructure constraints [6, 7]. These drivers are

particularly relevant for regions with strong renewable and bio-based resources, where integrated local production of both hydrogen and electricity can reduce reliance on grid imports and improve system resilience. In Galicia (a region of $3.0 \cdot 10^4$ km2 and $2.7 \cdot 10^6$ inhabitants located in northwest Spain), hydrogen decarbonization has been actively discussed in relation to industrial needs and local resource potential, but economic, environmental performance and implementation barriers have constrained the pathway portfolio [8, 9].

Decision support for such systems requires methods that can capture discrete technological choices and competing system objectives. Optimization-based hydrogen supply chain (HSC) models, including multi-objective formulations that quantify trade-offs between cost and environmental indicators, have been widely used to support strategic planning [10–12]. Nevertheless, two practical gaps remain for regional deployment studies. Firstly, given the central role of spatial and temporal representation in energy system models, the practical applicability of optimization frameworks across regions with different resource portfolios and seasonal profiles remains an open question. Secondly, social aspects are frequently neglected or discussed qualitatively but are less often integrated in a transparent way that supports the selection of a balanced solution from a Pareto set [13–15].

This study addresses these gaps by applying a previously developed superstructure-based optimization model [16] to a new regional case study in Spain. The analysis assesses the model's applicability under region-specific resource and demand conditions, and its ability to generate feasible and interpretable cost-emission trade-offs for regional planning. As a novel contribution of this work, a quantitative social dimension is incorporated to enable the identification and ranking of preferred Pareto-optimal solutions, complementing the economic and environmental perspectives.

## METHODOLOGY

This work applies a previously developed multi-objective optimization model to the region of Galicia to identify pathways for low-carbon hydrogen production based on renewable and biogenic resources. The methodological framework consists of four main steps: i) collection of regional resource availability data, ii) definition of techno-economic and environmental parameters for the technologies considered, iii) application of a cost-emissions multi-objective optimization model using the augmented e-constraint method, and iv) ex post evaluation of a social indicator to support the selection among Pareto-optimal solutions.

### Regional data

The region of the case study (Galicia) is characterized by a high availability of renewable electricity resources and significant biogenic feedstock potential. Regional data on renewable energy potential, biogenic resource availability, and industrial water use were compiled from regional and national public reports [17, 18]. These data define upper bounds on resource exploitation and constrain the feasible technology deployment within the optimization model.

Renewable electricity and biogenic resource availability are modelled with monthly resolution to capture seasonal variability in generation and feedstock supply. Water availability for hydrogen production is constrained at the regional level based on official annual industrial water demand estimates [19]. The annual water availability is distributed evenly throughout the year to ensure consistency with the model's temporal structure.

A regional spatial representation is adopted. Transport is explicitly accounted for biomass-based resources. A representative transport distance is defined as the distance from the sub-region with the highest resource availability to the hydrogen production plant for each resource.

The hydrogen demand has been defined based on regional estimates for 2030 [8]. The monthly demand of hydrogen is assumed to be constant throughout the year to meet the time resolution of the model.

### Techno-economic and environmental characterization of technologies

A superstructure of alternative technologies, including renewable-based and biogenic pathways, represents hydrogen production pathways. Each technology is characterized by a consistent set of technical, economic, and environmental parameters, including capital expenditure, operational costs, conversion efficiencies, and specific greenhouse gas emissions, which are expressed as $CO_2$-equivalent. All parameters are treated as deterministic and are kept consistent with those used in previous applications of the model in other European regions, allowing direct comparison.

### Multi-objective optimization model

The optimization model adopted in this work was developed and documented in a previous study [16]. It determines the optimal configuration of hydrogen production pathways that satisfy hydrogen demand at minimum cost and minimum greenhouse gas emissions. The model is formulated as a mixed-integer linear programming problem and solved using Python-based optimization tools. Two objective functions are considered: i) minimization of total system cost, and ii) minimization of total greenhouse gas emissions. The Pareto frontier is generated using the augmented $\varepsilon$-constraint method, which ensures a well-distributed set of efficient solutions and

avoids weakly Pareto-optimal points [20]. The optimization model does not include social criteria, which are only introduced in a post-processing step.

## Social indicator definition

A social indicator based on employment creation is introduced to differentiate among Pareto-optimal solutions. Employment creation is used as a proxy for social sustainability, as it is one of the most adopted metrics in the literature to represent the social dimension in hydrogen production assessments [21] and is relatively straightforward to quantify while remaining highly relevant for regional development.

For each Pareto-optimal solution $i$, the total employment is calculated a posteriori as the sum of the total number of jobs generated in the technologies active in that solution. The specific employment factors for each technology, expressed in jobs per unit of hydrogen produced or installed capacity, are assigned based on the values reported in the literature.

The total employment for solution i is calculated as follows:

$$S_i = \sum_k f_k \cdot H_{i,k} + \sum_r e_r \cdot P_{i,r} \quad (1)$$

where $f_k$ is the employment factor for hydrogen production technologies (jobs/t $H_2$/a); $H_{i,k}$ is the annual hydrogen production from technology $k$ (t $H_2$/a) in solution $i$; $e_r$ is the employment factor for electricity generation technologies (jobs/$MW_e$); and $P_{i,r}$ is the installed capacity ($MW_e$) of electricity generation technology $k$ in solution $i$. Technology-specific employment factors $f_k$ and $e_k$ and their literature sources are provided in the Supplementary Material (Table S3).

The social indicator is evaluated ex post and does not constrain the optimization problem. This choice avoids the introduction of highly uncertain social parameters into the feasible region and allows the economic-environmental trade-offs to be explored independently of social preferences.

## Ranking of Pareto-optimal solutions (TOPSIS)

Subsequently, the set of Pareto-optimal solutions is ranked using the Technique for Order Preference by Similarity to the Ideal Solution (TOPSIS), considering the total cost, greenhouse gas emissions, and employment creation [22–24]. Cost and emissions are treated as criteria to be minimized, while employment is treated as a criterion to be maximized.

Let $m$ be the number of Pareto-optimal solutions and $n$ the number of indicators. The decision matrix is $X_{mxn} = [x_{ij}]$, where each row $i$ corresponds to a solution and each column $j$ to a criterion (e.g., cost, emission, employment). The criteria are first normalized using vector normalization as follows:

$$r_{ij} = \frac{x_{ij}}{\sqrt{\sum_{i=1}^{m} x_{ij}^2}} \quad (2)$$

Normalized values are then weighted using a weight vector $w_j$ with $\sum_{j=1}^{n} w_j = 1$:

$$v_{ij} = w_j r_{ij} \quad (3)$$

The positive ideal solution $A^+$ and negative ideal solution $A^-$ are defined as follows:

$$v_j^+ = \begin{cases} max_i v_{ij}, j \in B \\ min_i v_{ij}, j \in C \end{cases} \quad (4)$$

$$v_j^- = \begin{cases} min_i v_{ij}, j \in B \\ max_i v_{ij}, j \in C \end{cases} \quad (5)$$

where $B$ denotes the benefit criteria (employment) and $C$ cost criteria (economic cost and emissions). The distances to the ideal and anti-ideal are computed using the following Euclidean metrics:

$$D_i^+ = \sqrt{\sum_{j=1}^{n} (v_{ij} - v_j^+)^2} \quad (6)$$

$$D_i^- = \sqrt{\sum_{j=1}^{n} (v_{ij} - v_j^-)^2} \quad (7)$$

Finally, the TOPSIS closeness coefficient is given as follows:

$$CC_i = \frac{D_i^-}{D_i^+ + D_i^-} \quad (8)$$

Solutions are ranked in descending order of $CC_i$, with higher values indicating closer proximity to the ideal compromise across economic, environmental, and social dimensions.

## Sensitivity analysis

A sensitivity analysis was conducted to test the robustness of the TOPSIS ranking to changes in the preference structure. The weight vector was modified to prioritize, the economic, environmental, or social criterion while the weights were kept normalized. Table 1 shows the different weights for each indicator in the different scenarios analyzed.

**Table 1:** Weights used for each indicator under different scenarios.

| Scenario | Cost weight | Emission weight | Employment weight |
|---|---|---|---|
| Equal | 0.33 | 0.33 | 0.33 |
| Cost priority | 0.80 | 0.10 | 0.10 |
| Emission priority | 0.10 | 0.80 | 0.10 |
| Employment priority | 0.10 | 0.10 | 0.80 |

# RESULTS

## Multi-objective optimization model

The projected 2030 hydrogen demand for Galicia (105 kt $H_2$/a) was initially imposed as an exogenous requirement. The model returns a single non-dominated solution at this demand level under the considered regional constraints, indicating a feasibility-limited regime. This solution has been reported for completeness in the Supplementary Material. To enable a comparative multi-objective assessment and apply the social dimension, additional runs were performed by scaling the demand to feasible regional supply levels. Accordingly, results are reported for a demand coverage level of 60% of the projected 2030 demand (i.e., 63 kt $H_2$/a), as higher coverage levels collapse the Pareto set to a single solution. The remaining demand could be met outside the modeled region by increasing the number of resources considered or using other conventional carbon capture technologies to reduce emissions. At this coverage level, the model yields a Pareto set with multiple non-dominated solutions (cf. figure 1), allowing the analysis of trade-offs including social performance.

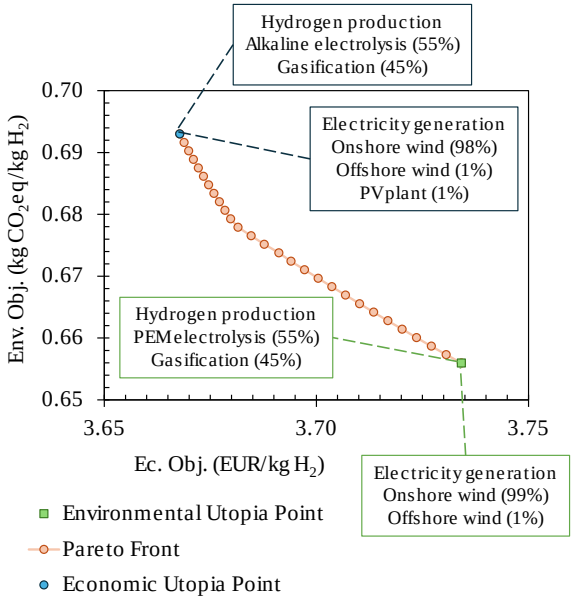

**Figure 1.** Pareto-optimal solutions obtained for a demand coverage level of 60% of the projected 2030 hydrogen demand (63 kt $H_2$/a) in Galicia. The percentages of technologies selected by the model for these solutions have been included in the economic and environmental utopia points.

## Ranking of Pareto-optimal solutions (TOPSIS)

TOPSIS was applied to rank the 28 Pareto-optimal solutions (with a demand coverage level of 60%) using functional-unit indicators expressed per kg $H_2$ under equal weights for cost, emissions, and employment. The highest closeness coefficient was obtained from solution 0, which corresponds to the environmental optimum (3.73 €/kg $H_2$, 0.66 kg $CO_2$eq/kg $H_2$, $6.48 \cdot 10^{-6}$ jobs-year/kg $H_2$), followed by solutions 1 (3.66 €/kg $H_2$, 0.69 kg $CO_2$eq/kg $H_2$, $6.47 \cdot 10^{-6}$ jobs-year/kg $H_2$) and 2 (3.66 €/kg $H_2$, 0.69 kg $CO_2$eq/kg $H_2$, $6.46 \cdot 10^{-6}$ jobs-year/kg $H_2$). Solution 27, which coincides with the economic optimum, is the lowest-ranked solution. Overall, the TOPSIS order selects an interior compromise within the Pareto set. Solutions with lower costs tend to exhibit higher emissions and lower employment, whereas solutions with lower emissions tend to incur higher costs and higher employment. Under equal weights, the environmental optimum provides the closest balance to the ideal point across the three dimensions. Table 2 shows the top three solutions for the equal scenario's hydrogen production and electricity generation technologies.

**Table 2:** Share of hydrogen production and electricity generation technologies for the top three solutions in the ranking, assuming equal weighting for the three criteria considered.

| Rank-Solution | $H_2$ production technologies | Electricity generation technologies |
|---|---|---|
| 1º-0 | PEM electrolysis 55%<br>Gasification 45% | Onshore wind 99%<br>Offshore wind 1% |
| 2º-1 | PEM electrolysis 51%<br>Gasification 46%<br>Alk. electrolysis 3% | Onshore wind 99%<br>Offshore wind 1% |
| 3º-2 | PEM electrolysis 48%<br>Gasification 45%<br>Alk. electrolysis 7% | Onshore wind 99%<br>Offshore wind 1% |

Alk.: Alkaline
PEM: Proton exchange membrane

## Sensitivity analysis

When the economic criterion is prioritized, solutions 1-3 become the top-ranked options, with solution 1 ranked first (3.66 EUR/kg $H_2$, 0.69 kg $CO_2$eq/kg $H_2$, $6.47 \cdot 10^{-6}$ jobs-year/kg $H_2$), followed closely by solutions 2 (3.66 EUR/kg $H_2$, 0.69 kg $CO_2$eq/kg $H_2$, $6.46 \cdot 10^{-6}$ jobs-year/kg $H_2$) and 3 (3.67 EUR/kg $H_2$, 0.69 kg $CO_2$eq/kg $H_2$, $6.46 \cdot 10^{-6}$ jobs-year/kg $H_2$). In this scenario, the lowest-ranked option shifts to the environmental optimum (solution 0) due to the strong emphasis on cost. When the environmental criterion is prioritized, the rankings shift toward low-emission solutions and solution 0 becomes the best-ranked option (3.73 EUR/kg $H_2$, 0.66 kg $CO_2$eq/kg $H_2$, $6.48 \cdot 10^{-6}$ jobs-year/kg $H_2$), while the economic optimum (solution 27) remains the worst-ranked option. When the social criterion is prioritized, the ordering becomes closer to the equal scenario, again selecting solution 0 as the top-ranked option, followed by solutions 1

and 3. Notably, solution 0 is the best-ranked option under both environmental and social priority scenarios, indicating that these two prioritizations converge on the same preferred configuration. Across scenarios, the worst-ranked solution is the economic optimum in all cases except under economic prioritization, where the environmental optimum becomes the lowest-ranked outcome as a direct consequence of assigning a dominant weight to cost.

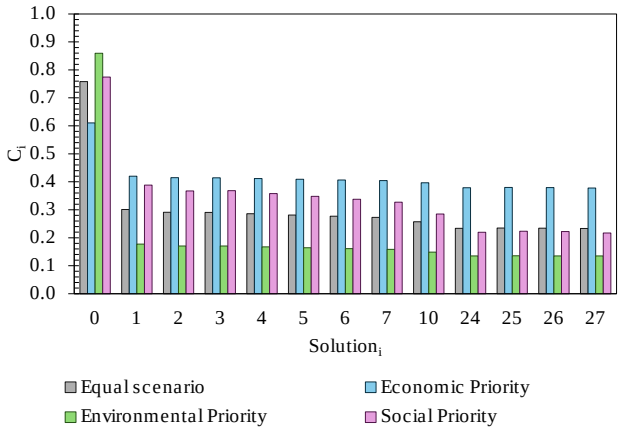

**Figure 2.** TOPSIS proximity coefficients for the best and worst ranked solutions in the equal scenario and sensitivity analysis cases.

Tables 3 and 4 show the contributions of each hydrogen production and electricity generation technology for the economic and the environmental priority scenario, respectively. The environmental priority case is closely aligned with the equal scenario; the corresponding solutions are shown in Table 2.

**Table 3:** Share of hydrogen production and electricity generation technologies for the top three economic priority scenario.

| Rank-Solution | $H_2$ production technologies | Electricity generation technologies |
|---|---|---|
| 1º-1 | PEM electrolysis 51%<br>Gasification 46%<br>Alk. electrolysis 3% | Onshore wind 99%<br>Offshore wind 1% |
| 2º-2 | PEM electrolysis 48%<br>Gasification 45%<br>Alk. electrolysis 7% | Onshore wind 99%<br>Offshore wind 1% |
| 3º-3 | Gasification 46%<br>PEM electrolysis 44%<br>Alk. electrolysis 10% | Onshore wind 99%<br>Offshore wind 1% |

**Table 4:** Share of hydrogen production and electricity generation technologies for the top three social priority scenario.

| Rank-Solution | $H_2$ production technologies | Electricity generation technologies |
|---|---|---|
| 1º-0 | PEM electrolysis 55%<br>Gasification 45% | Onshore wind 99%<br>Offshore wind 1% |
| 2º-1 | PEM electrolysis 51%<br>Gasification 46%<br>Alk. electrolysis 3% | Onshore wind 99%<br>Offshore wind 1% |
| 3º-3 | Gasification 46%<br>PEM electrolysis 44%<br>Alk. electrolysis 10% | Onshore wind 99%<br>Offshore wind 1% |

## CONCLUSIONS

This work applied a multi-objective optimization framework to design a low-carbon hydrogen supply system for Galicia. Quantified trade-offs between cost, emissions, and employment across optimal solutions. The model showed that meeting 100% of the projected 2030 demand (105 kt $H_2$/a) with the regional resources considered is feasible but yields a single solution. Under this full-coverage constraint, the system configuration is dominated by biomass gasification (69% of hydrogen production) and onshore wind power generation.

To enable a multi-criteria comparison and the integration of a social dimension through TOPSIS, the demand coverage was reduced to 60%, for which multiple efficient solutions exist. At 60% demand coverage (63 kt $H_2$/a), the model generated 28 non-dominated solutions. This Pareto set enabled a structured evaluation of competing objectives. The TOPSIS analysis with equal weights identified a stable compromise (solution 0), corresponding to the environmental optimum within the Pareto set. This solution combines 55% alkaline electrolysis with 45% biomass gasification. Its electricity supply is entirely wind-based (99% onshore wind and 1% offshore wind). This solution remained top-ranked when prioritizing either emissions or employment. This indicated robustness to stakeholder preferences. When prioritizing economic performance, the preferred option shifted to solution 1. This solution introduces electrolysis diversity, with 51% PEM electrolysis, 46% gasification, and 3% alkaline electrolysis. In all scenarios, the economic optimum was consistently the lowest-ranked option, except under economic prioritization where the environmental optimum became the worst-ranked outcome due to the dominant weight assigned to cost.

Overall, the framework proved transferable by producing an interpretable Pareto front and revealing binding regional constraints. The post-processing integration of employment via TOPSIS provided a transparent and repeatable basis for compromise selection. These results

provide a concrete evidence base for designing regional hydrogen strategies under resource constraints.
