Alinia Kashan and Molaei [5] confirmed through research that there is a direct correlation between carbon emissions and operating costs. Based on this, they incorporated carbon tax costs into the core composition of operating costs, achieving significant reductions in carbon emissions from pipeline network systems. Deng et al. [6], in their research on risk constraints in coupled power-gas networks, introduced a carbon tracking analysis algorithm that efficiently quantifies the carbon emission intensity at each node and the carbon flow in pipeline segments, achieving minimization of the total system emissions. Cheng et al. [7] proposed an intelligent method for intelligent low-carbon operation and maintenance of integrated energy systems. This method can accurately and in real-time perceive the system's operational status, optimization potential, and abnormal conditions, providing an effective technical pathway for natural gas pipeline networks to dynamically adjust operation and maintenance strategies based on supply and demand conditions. Based on this, the study further introduced intelligent algorithms such as the BP neural network, simultaneously achieving functions such as system energy output prediction, load forecasting, scheduling plan generation, and carbon emission optimization. Zhou et al. [8] proposed a hybrid-driven automatic response framework. When coupled with an optimization model, the resulting solution can reduce compressor energy consumption by 4.6% to 10.8% compared to actual operational schemes. Wen et al. [9], by formulating peak-shaving and flow distribution strategies, constructed a multi-objective optimization model to achieve collaborative scheduling optimization for multiple gas sources. The model considers both economic and environmental benefits, and its feasibility was verified through three case studies.

From the current research progress, the methods for low-carbon optimization of natural gas pipeline network operations can be mainly categorized into two types: one is to incorporate carbon emissions into the objective function for optimization, and the other is to treat carbon emissions as constraints for solving. Current related research mostly focuses on analyzing scenarios with certain user demands, while research on low-carbon optimization for large-scale uncertain demand scenarios is still insufficient. Existing multi-objective optimization studies often set carbon emissions as the objective function or simplified constraints, lacking a methodological system that can efficiently solve the Pareto optimal solutions for energy consumption and cost under different scales of carbon emission constraints, making it difficult to meet the low-carbon operation requirements in dynamic demand scenarios. In studies where carbon emissions are treated as the objective function, this method can only characterize the direct correlation between carbon emissions and operating costs, but lacks a detailed analysis of the dynamic coupling relationship between energy consumption and costs under different carbon emission constraints. Meanwhile, research on the coupled impact of compressor configuration and start-stop strategies on energy consumption and carbon emissions is relatively scarce. Additionally, there is a significant research gap in solving the problems of energy consumption optimization and carbon emission control under uncertain demand in large-scale natural gas pipeline network systems, and a unified methodology that can bridge the optimization research between certain and uncertain demand pipeline networks has not yet been formed.

This paper further constructs an optimization model for natural gas pipeline networks under uncertain demand scenarios. Given that the research object has characteristics such as a large number of stations, long pipeline segments, and complex topological structures, leading to optimization variables in the model that are diverse in type, numerous in nodes, and large in scale, this paper adopts a two-stage stochastic optimization model to quantitatively characterize the demand uncertainty in the pipeline network system. This model sets carbon emission indicators as rigid constraints and establishes multi-step gradient carbon emission constraint conditions. By solving the cost-minimizing optimization model constructed under different demand scenarios through optimization algorithms, it outputs the algorithm iteration processes and detailed optimization schemes corresponding to each scenario. Subsequently, combined with the pipeline flow distribution results under each scenario, the dynamic changes in pressure and flow along the pipeline network in the optimization scheme are verified to meet the system operation constraint requirements. By separately calculating the quantitative values of pipeline network energy consumption and carbon emissions for actual operational schemes and optimization schemes under different carbon emission constraint levels, the carbon emission-cost Pareto frontier curve corresponding to the optimization scheme is finally determined. Meanwhile, the formulation logic and core basis for compressor configuration and start-stop strategies under different demand scenarios, with energy consumption optimization as the core orientation and carbon emissions as the constraint boundary, are deeply analyzed. The optimization deduction process of the model

and implementable detailed implementation plans are fully presented.

## MATHEMATICAL MODEL

### Objective Function

The objective function of the two-stage stochastic programming consists of two parts: the first stage involves fixed costs related to decision variables, and the second stage involves the expected variable costs realized in response to different scenarios.

(1) First stage

Before uncertainty emerges, initial decisions (such as facility location and resource allocation) are formulated prior to the manifestation of uncertainty, requiring consideration of adaptability to multiple possible future scenarios.

$$C_{\text{first}} = \sum_{(i,j)\in \text{A}^{\text{C}}} Y_{i,j} * C_{\text{comp}} \tag{1}$$

where,

$C_{\text{first}}$—the fixed cost in the first stage, yuan;

$Y_{i,j}$—whether the compressor is on or off; when $Y_{i,j} = 1$, it indicates that the compressor remains on; when $Y_{i,j} = 0$, it indicates that the compressor remains off;

$C_{\text{comp}}$—the fixed cost per compressor, yuan.

(2) Second stage

The cost in the second stage mainly includes: the cost of multi-source gas supply calculated based on the actual demand at user nodes, and the energy consumption cost of electric-driven compressors calculated based on real-time electricity prices.

$$C_{\text{second}} = C_{\text{gas}} + C_{\text{com}} \tag{2}$$

$$C_{\text{gas}} = \sum_{(i,j)\epsilon \text{A}^{\text{P}}} Q_{i,j} * c_{\text{g}} \tag{3}$$

$$C_{\text{com}} = \sum_{(i,j)\epsilon \text{A}^{\text{C}}} {N^{C}}_{i,j} * c_{\text{c}} \tag{4}$$

where, $C_{\text{second}}$—the cost of the second stage, yuan.

The objective function of two-stage stochastic programming is the sum of the two-stage costs is Eq. (5).

$$\min f_2 = C_{\text{first}} + C_{\text{second}} \tag{5}$$

### Constraints

The operational constraints include pipeline flow constraints, pipeline pressure constraints, compression ratio constraints, and compressor operation constraints. Due to the division of three representative scenarios during uncertainty modeling, stochastic variables are introduced in the modeling process.

#### Pipeline flow constraints

The flow on pipeline ($i$, $j$) must have upper and lower bounds:

$$Q_{i,j}^{\max} \le Q_{i,j,s} \le Q_{i,j}^{\max} \tag{6}$$

where, $Q_{i,j,s}$—pipeline flow from $i$ to $j$ under scenario $s$, m³/h.

Since supply and demand vary across scenarios, flow balance constraints must be set per scenario as follows:

$$\sum_{i|(i,j)\in \text{N}} Q_{j,i,s} + q_{i,s}^{\text{s}} = \sum_{j|(i,j)\in \text{N}} Q_{i,j,s}, i \in \text{N}_{\text{s}} \tag{7}$$

$$\sum_{i|(i,j)\in \text{N}} Q_{j,i,s} = \sum_{j|(i,j)\in \text{N}} Q_{i,j,s} + q_{i,s}^{\text{d}}, i \in \text{N}_{\text{d}} \tag{8}$$

$$\sum_{i|(i,j)\in \text{N}} Q_{j,i,s} = \sum_{j|(i,j)\in \text{N}} Q_{i,j,s}, i \in \text{N}_{\text{n}} \tag{9}$$

where, $q_{i,s}^{\text{s}}$—supply flow at node $i$ under scenario $s$, m³/h;

$q_{i,s}^{\text{d}}$—demand flow at node $i$ under scenario $s$, m³/h.

#### Node pressure constraints

$$p_i^{\min} \le p_{i,s} \le p_i^{\max} \tag{10}$$

where, $p_{i,s}$—pressure at node $i$ under scenario $s$, MPa.

#### Compression ratio constraints

$$z_{\min} \le z_{i,s} \le z_{\max} \tag{11}$$

where, $z_{i,s}$—compressor pressure ratio at node $i$ under scenario $s$.

#### Power constraints

$${N^{C}}_{\min} \le {N^{C}}_{i,j,s} \le {N^{C}}_{\max} \tag{12}$$

where, ${N^{C}}_{i,j,s}$—power increment from node $i$ to $j$ under scenario $s$, kW.

#### Pipeline pressure drop constraints

$$p_{i,s}^2 - p_{j,s}^2 - \frac{\lambda \text{Z}_{\text{avg}} \rho \text{T}}{\text{C}_0^2 D_{i,j}^5} L_{i,j} Q_{i,j,s}^2 = 0 \tag{13}$$

#### Power calculation

$${N^{C}}_{i,j,s} = \frac{\text{RTZ}_{\text{avg}}}{\eta} Q_{i,j,s} \frac{\upsilon}{\upsilon - 1} \left( z^{\frac{\upsilon}{\upsilon-1}} - 1 \right) \tag{14}$$

$${N^{C}}_{i,j,s} = C_1 \text{Q}_{i,j,s} w \tag{15}$$

Specific constraints and linearization processes can be found in reference [1].

### Solver Configuration

The two-stage stochastic optimization model is implemented using Python programming and solved with the Gurobi solver in a Python environment. Key solution parameters are configured as follows: numerical precision focus mode is set to 2, thread count is 20, and node file initial memory is 0.5 GB.

### Value for ε-Constraints

Based on the model optimization results, the ε-constraint method is further applied to impose carbon emission restrictions of varying intensities. Using the gradient

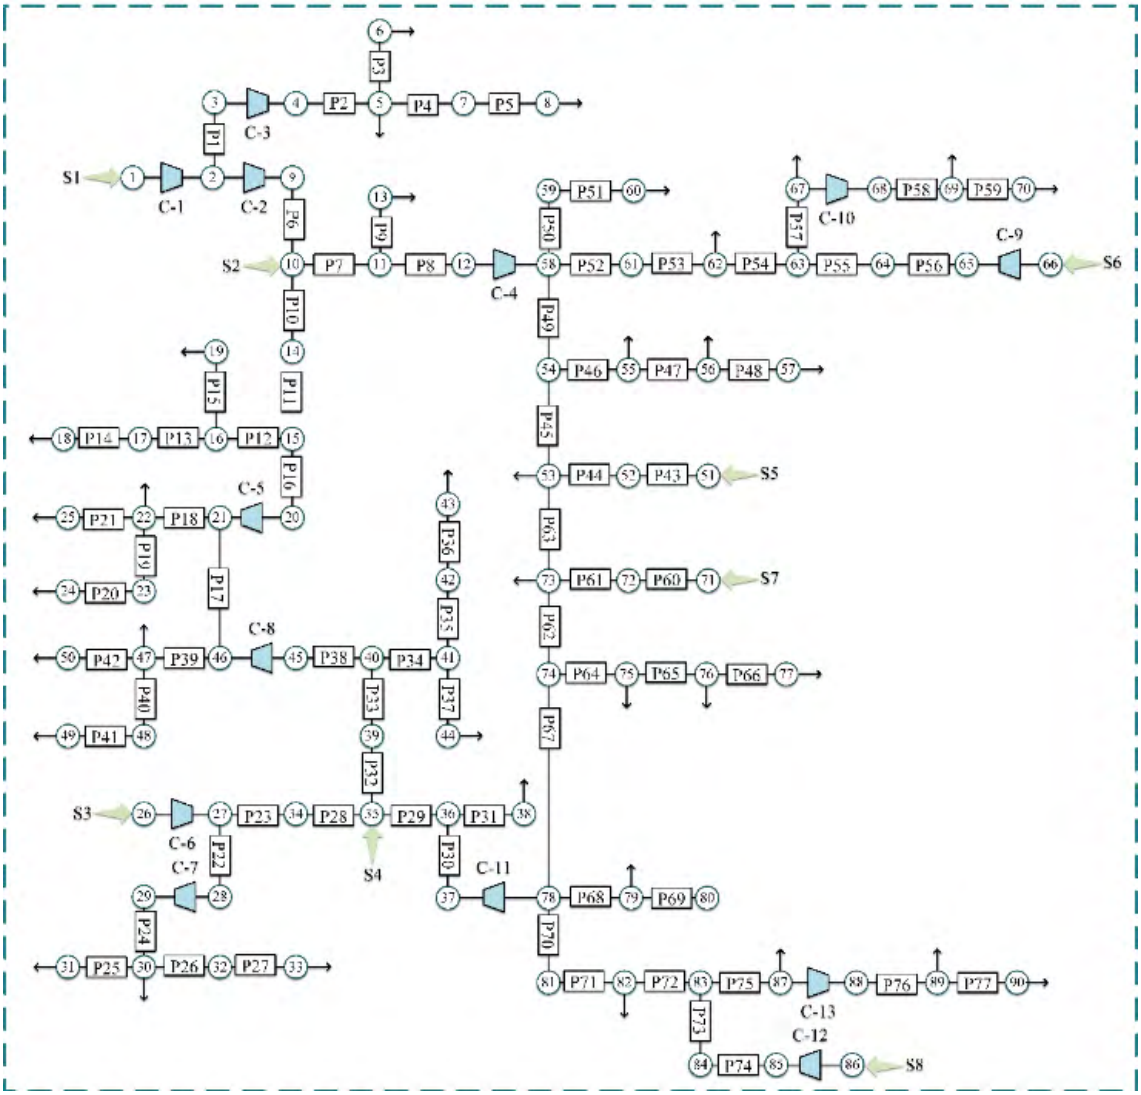

**Figure 1.** Natural gas pipeline network topology

method, ε values are divided into four constraint levels, covering a spectrum from loose to strict carbon emission constraint ranges. Combined with case study solution analysis, on the basis of obtaining the actual optimal energy consumption values, for different scenarios, upper and lower constraint intervals with an interval of approximately 2000 kg are set around the optimal carbon emission values to systematically investigate the impact of carbon constraints on operational strategies.

## CASE STUDY

The case study involves a natural gas pipeline network comprising 8 gas sources (S1–S8), 90 nodes, 77 pipelines, and 13 compressors, as shown in Figure 1. The upper limit of node pressure is set at 2.9 MPa, and the lower limit at 0.8 MPa; the maximum transmission capacity for both pipelines and compressors is 566, 340 $m^3/h$. Based on natural gas production and consumption coefficients in northern China, the gas supply capacity of each source and the flow distribution in the pipeline network were calculated.

Based on the processing of one-year data, probability distribution fitting was performed to analyze its statistical characteristics. As shown in Figure 2, the annual natural gas demand distribution indicates that the actual demand distribution does not fully conform to a normal distribution but exhibits a certain degree of right-skew, meaning the frequency of higher demand days is higher than theoretical expectations. This distribution characteristic suggests the following: (1) During winter or extreme weather conditions, natural gas consumption significantly increases due to heightened heating demand; (2) Holidays, seasonal changes, or specific events may

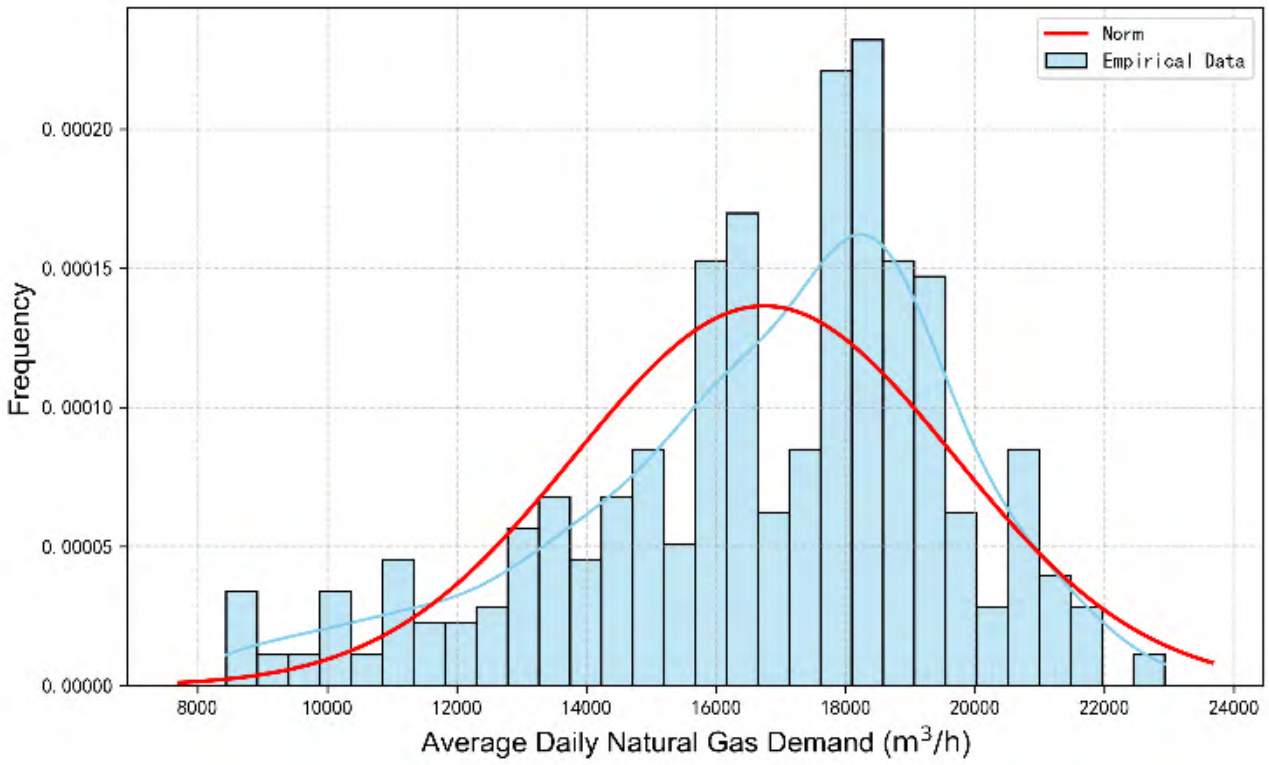

**Figure 2.** Natural gas demand distribution throughout the year.

lead to periodic fluctuations in demand; (3) In energy system planning, full consideration must be given to "tail risks" in such distributions to ensure supply security and system stability.

## RESULTS AND DISCUSSION

All obtained results meet the requirement of an optimality gap of 0. The three scenarios were solved within 30 seconds, with the longest single-solution time being 26.74 seconds.

### Cost-Carbon Emission Analysis

When determining the carbon emission factor values, this paper analyzes regional disparities based on the provincial grid emission factor data released by the Ministry of Ecology and Environment and the National Bureau of Statistics. Significant differences exist among provinces, with higher emission factors in North China and relatively lower ones in South China. To ensure consistency and comparability of the model, this paper ultimately adopts the national average electricity emission factor, i.e., 0.608 kg$CO_2$/kWh, as a unified calculation parameter.

Through analysis and testing of multiple sets of experimental data, the optimization algorithm obtained a series of optimal solutions. To evaluate the trade-off between economic and environmental objectives, this study employs the Pareto frontier analysis method and utilizes the ε-constraint method to transform the multi-objective optimization problem of carbon emissions and costs into a single-objective optimization problem with cost as the primary objective. Ultimately, Pareto frontier curves under different demand scenarios, as shown in Figure 3, were plotted.

The results indicate that the system exhibits a set of optimal Pareto solutions, including the carbon emission minimization solution. The Pareto frontier curve generally shows a downward trend from left to right, indicating a negative correlation between cost and carbon emissions. This relationship is primarily driven by compressor start-stop strategies: as carbon emission constraints tighten, the cost of adjusting compressor operating states and flow distribution to reduce emissions gradually increases, leading to a rising marginal cost of carbon reduction. The environmental optimal solution shows that to achieve emission reduction targets, the system needs to increase the utilization ratio of compressors in the natural gas pipeline network, resulting in higher operating costs. The rings in Figure 3 illustrate the relative proportion of optimal cost values under different scenarios. It is clearly observable that higher user demand corresponds to higher associated costs.

### Analysis of Optimization Strategies under Different Carbon Emission Constraints

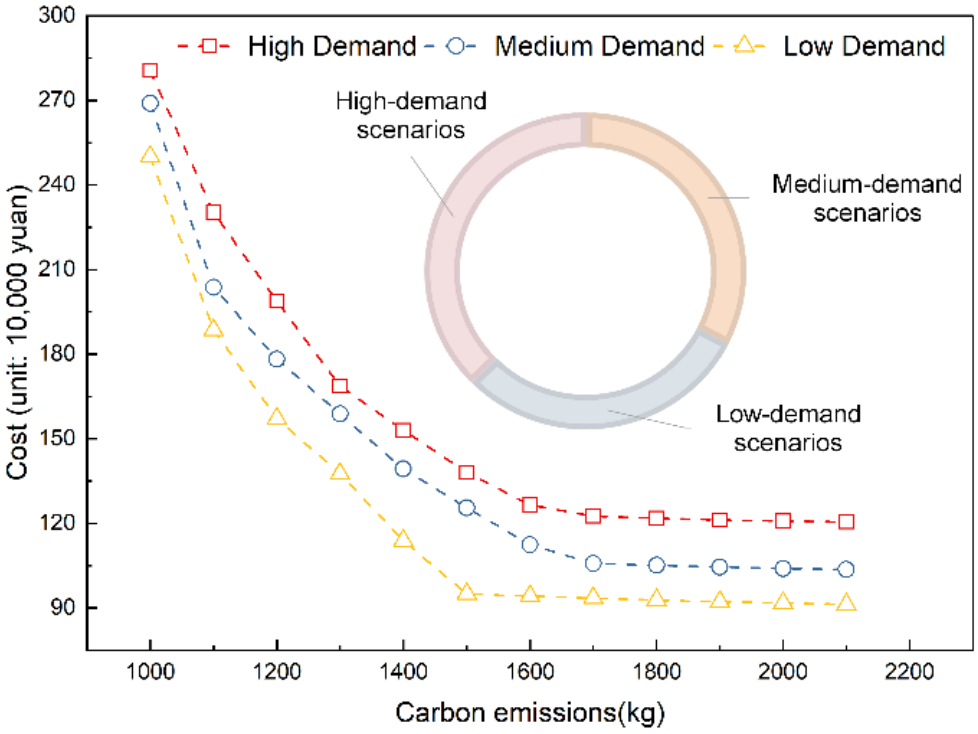

**Figure 3.** Pareto optimal curves for different scenarios.

Under different scenario conditions, by setting differentiated carbon emission constraint levels, the natural gas pipeline transmission system exhibits distinct compressor scheduling strategies and carbon emission constraint response characteristics during optimized operation when coordinating transmission load and multi-objective trade-offs as user demand varies from high to low. Details are as follows:

(1) Scenario 0: In high-demand scenarios, the natural gas transmission system faces high load and flow requirements. Here, the optimization model must balance large-flow transmission tasks, economic cost minimization objectives, and carbon emission constraints. It optimizes compressor start-stop strategies based on multi-unit collaborative operation. When carbon emission constraints are loose, the model prioritizes transmission capacity assurance, activating a sufficient number of compressors (including some inefficient units) to maintain system supply-demand balance, prioritizing flow supply in multi-objective conflicts while striving for economic cost minimization. Under moderate carbon emission constraints, the number of activated compressors is maintained at the minimum level required for flow balance. The system reduces excess carbon emissions and costs from inefficient operation by excluding inefficient and redundant units while ensuring transmission capacity. When constraints are strict, compressors are precisely matched to actual demand, avoiding redundant unit activation to reduce operational energy consumption. This satisfies carbon emission targets and node flow balance while lowering long-term system energy costs.

(2) Scenario 1: In medium-demand scenarios, system transmission loads are relatively moderate with smoother flow fluctuations. Compressor start-stop strategies here emphasize real-time optimization and dynamic adjustment to achieve dual objectives of economic cost minimization and carbon emission control. When constraints are loose (large ε values), compressors typically maintain basic flow balance and steady operation without activating reserve units. Only during significant load fluctuations are partial compressors fine-tuned for start-stop, ensuring stable pipeline operation at lower costs with naturally met carbon emission levels. Under moderate constraint strength, the system dynamically adjusts compressor operating states according to load fluctuations, achieving synergy between economy and carbon reduction while avoiding unnecessary energy consumption and maintenance costs. When constraints are strict (small ε values), compressors activate only high-efficiency units with strong power regulation capabilities, prioritizing minimum carbon emissions to achieve comprehensive optimization of system energy consumption and economic costs under flow balance and constraint conditions.

(3) Scenario 2: In low-demand scenarios, pipeline system transmission loads are small, and the core

challenge is avoiding excess energy consumption. Compressor start-stop decisions focus on streamlining operating units and reducing invalid start-stop to lower energy consumption and operating costs. When carbon emission constraints are loose, the system activates only efficient compressors to meet basic transmission needs under the goal of minimizing operating costs, indirectly reducing emissions through lower energy consumption. Under moderate carbon emission constraints, the system further controls emissions based on energy conservation, achieving cost-carbon emission dual-objective synergy through optimized unit start-stop strategies. When constraints are strict, the system adopts a mode combining high-efficiency compressors with intermittent operation, avoiding invalid emissions under low loads and continuously reducing energy consumption and related costs through precise compressor state regulation.

### Analysis of Optimization Strategies under Different Carbon Emission Constraints

Finally, during the model solving process for each scenario, Pareto optimal solutions are screened from the solution set through non-dominated analysis. The following table summarizes the Pareto solution sets composed of system operation target costs and corresponding carbon emissions under each scenario based on the ε-constraint method and the two-stage stochastic programming approach, corresponding to high-demand, medium-demand, and low-demand scenarios, shown in Table 1. It reflects the actual carbon emissions, energy consumption, and total cost results under different constraint intensities.

**Table 1:** Impact of carbon emission constraints on cost in high-demand scenarios

| Scenario | Total Cost (kCNY) | Carbon Emissions (kg) | Energy Consumption (MW) | Carbon Emission Reduction (%) |
|---|---|---|---|---|
| High Demand | 1232.8 | 1640.91 | 112.4 | -34.96% |
| Medium Demand | 1066.5 | 1419.49 | 97.3 | -42.35% |
| Low Demand | 979.2 | 1303.29 | 89.3 | -36.84% |

Under high, medium, and low demand scenarios, compared to the unconstrained baseline scenario, the model optimization achieves carbon emission reduction rates of 34.96%, 42.35%, and 36.84% respectively. The results demonstrate that this optimization model is significantly effective in coordinating carbon emission control and economic cost optimization for large-scale natural gas pipeline networks, providing feasible scheduling strategies for low-carbon operation under varying demand intensities.

## CONCLUSIONS

Addressing the uncertainty characteristics of user demand, this paper completes typical scenario division based on the probability distribution characteristics of annual demand data. Focusing on the operational optimization of natural gas pipeline systems, this study first constructs an optimization model minimizing energy consumption, then builds a two-stage stochastic programming model to solve for stochastic variables under different demand scenarios. The model selects pipeline flow and compressor station start-up quantity as core decision variables, incorporating multiple constraints including pipeline strength, pressure, flow balance, and compressor power/speed. During model solving, the ε-constraint method is employed to convert carbon emission indicators into constraints, achieving synergistic optimization of energy consumption and carbon emissions. The solution results show significant heterogeneity in the reduction of optimal system energy consumption under differentiated demand scenarios and low-carbon constraints. Pareto frontier analysis reveals that carbon emissions in high, medium, and low demand scenarios are reduced by 34.96%, 42.35%, and 36.84% respectively compared to actual levels.

## ABSTRACT

To improve the energy efficiency of distillation processes, various process intensification concepts have been proposed, including direct heat integration and thermal coupling. Identifying the most suitable alternative for a given separation task requires a rigorous and consistent techno-economic optimization. Superstructure models typically rely on isobaric operation and fixed HETP values, in order to avoid treating column hydraulics when solving the already challenging mixed-integer nonlinear optimization problems. In order to overcome this limitation and evaluate the effect of the simplification, the current work extends a rigorous equilibrium-stage superstructure model to account for tray-specific pressure drop and HETP values. A polylithic solution approach is implemented to improve the convergence for the resulting optimization problems. The proposed approach is demonstrated for the optimization of heat-integrated distillation sequences operated at close to atmospheric and vacuum conditions, enabling a closer investigation of the impact of the classically applied simplifications. As the results illustrate that the overall energy demand and total annualized costs are only marginally affected for the considered wide-boiling mixtures the evaluation of competing process configurations will not be affected by the simplifications. However, considerable changes in column height and heat exchanger areas are observed, particularly under vacuum operation, such that column hydraulics should be considered in design optimization, in case column size restrictions or other considerations require a more accurate equipment sizing.

**Keywords**: Distillation, Energy integration, Superstructure, Optimization, Pressure drop

## INTRODUCTION

Distillation remains the most widely applied separation technology in the chemical and process industries, accounting for approximately 90-95% of all fluid separations tasks [1] and a substantial share of the overall industrial energy demand. Despite its high energy consumption, direct substitution of distillation by alternative separation technologies is largely impractical due to its broad applicability, wide throughput range and capability to produce multiple high-purity products within a single unit [2]. In the context of rising energy prices and increasingly stringent environmental regulations, the development of energy-efficient distillation processes is therefore of central importance.

Numerous energy integration concepts have been proposed and demonstrated as effective means to reduce energy demand [3]. One prominent approach is direct heat integration between columns, in which the heat of condensation of the top vapor from one column is used to supply the heat for evaporating part of the bottoms stream of another column. This is achieved by adjusting the operating pressure of at least one column such that the top temperature of the heat-supplying column exceeds the bottom temperature of the heat-receiving column [4]. For two columns with comparable heat duties, direct heat integration has the potential to reduce energy consumption by up to 50% [4].

Another option to reduce the energy requirement of distillation processes is thermal coupling in which heat exchangers and liquid streams between adjacent distillation columns are replaced by bidirectional liquid and vapor transfer. Equipment-integrated dividing wall column (DWC) implement thermally coupled columns in a single shell and have been shown to reduce capital cost by approximately 30% compared to conventional, non-

integrated distillation sequences [5].

The identification of the best performing concept requires a systematic evaluation of all available process configurations. However, performing a detailed and rigorous analysis of all alternatives with rigorous models is usually intractable, such that shortcut models are the preferred choice for an initial screening [6]. Even the separation of nonideal mixtures can be addressed effectively when making use of thermodynamically sound pinch-based methods [7]. Yet this screening provides only an estimate of the performance, mandating that the most promising alternatives are further evaluated by more rigorous models and a techno-economic assessment.

The optimal design of distillation processes can be determined either through simulation-based approaches or via rigorous numerical optimization [8]. Simulation-based approaches can readily account for column hydraulics, as the column design, especially the number of stages in each section, are fixed prior to simulation. However, typically applied sequential optimization methods are rather cumbersome [5, 9], while gradient-free optimization using surrogate models with response surface methodologies [10] become computationally expensive when design spaces are large.

Mathematical programming applied to superstructure models posed as mixed-integer nonlinear programming (MINLP) problems enable a simultaneous design of the column structure and operating conditions building on gradient-based optimization [5, 8, 11]. While this approach allows for proven (local) optimality, the reported models usually build on isobaric conditions and constant height equivalent of a theoretical plate (HETP) values. Incorporating column hydraulics for pressure drop is a challenge as the actual number of stages and column dimensions are decision variables. Pressure variations resulting from friction losses along the column height affect the boiling temperature, relative volatilities, and ultimately separation performance [12]. Additionally, the pressure drop can increase the heating and cooling demands, and influence the relationship between the number of stages and energy demand, which may become nonlinear at higher stage numbers [13]. In direct heat-integrated distillation sequences, changes in pressure directly impact the reboiler temperature and, consequently, the available temperature driving force in the integrated heat exchanger, thereby significantly influencing feasibility and efficiency. For DWCs, the pressure drop in the parallel sections impacts the vapor split below the dividing wall and thus potentially impairs operation at minimum energy demand.

Although the common simplifications improve the numerical solution of the resulting MINLP problems, they may impair the identification of feasible/optimal designs and may bias the comparison of different process alternatives. While some recent studies have incorporated pressure drop correlations into rigorous distillation models [14] or superstructure optimization of retrofit problems with fixed column dimensions [15], the direct consideration of pressure drop and HETP correlations in superstructure-based design optimization with unknown column dimensions has not been addressed.

Therefore, the current work presents a proof of concept by extending an existing superstructure-based design optimization [16-19] by incorporating correlations for pressure drop and HETP as functions of the vapor load, expressed via the F-factor. By accounting for these effects at the conceptual design stage, a more realistic evaluation of energy-integrated distillation processes is enabled. Furthermore, an investigation of the impact of these correlations on the optimal design is investigated for representative case studies on the design of a heat integrated direct sequence for the separation of two wide boiling mixtures at vacuum and close to atmospheric conditions.

## METHODOLOGY

In this work, a rigorous techno-economic optimization is preformed using an equilibrium-stage superstructure model based on the MESH equations and implemented in the General Algebraic Modeling System (GAMS). The resulting MINLP problem is solved as a series of successively relaxed NLP problems [16]. The following subsections describe the superstructure model for individual distillation columns, its extension to directly heat-integrated sequences, as well as the modifications for the implementation of pressure drop and HETP correlations.

### Superstructure model for individual distillation columns

The superstructure model for an individual distillation column and its implementation is illustrated in **Figure 1.** It builds on the initial work of Kraemer et al. [16] and Skiborowski et al. [17], which was inspired by the work of Bartttfeld et al. [11]. The sizing of the stripping and rectifying sections is enabled by variable locations for the feed, reflux and boil-up streams. Stages above the reflux and below the boil-up tray are effectively bypassed and do not contribute to the separation. They are consequently not considered for equipment sizing and cost calculations.

Each equilibrium stage is described by the MESH equations, comprising mass balances, vapor-liquid equilibrium relations, summation constraints, and enthalpy balances. The thermodynamic properties and vapor-liquid equilibrium calculations are modeled via external equations implemented via a dynamic link library (DLL), enabling a reduced-space formulation that significantly decreases the number of variables and equations

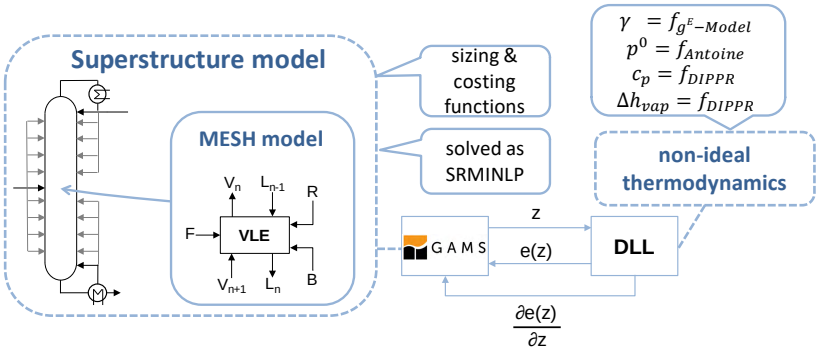

**Figure 1.** Superstructure model of an individual distillation column and implementation in GAMS with external equations for VLE computations.

managed by GAMS [17].

The optimization objective is to minimize the total annualized cost (TAC). Utility prices are derived from Turton et al. [20], while equipment costs are estimated using Guthrie's method, as outlined by Biegler et al. [21].

## Modeling of direct heat-integrated sequences

The model of the heat-integrated direct sequence is based on the work of Waltermann and Skiborowski [18] with the adaptions described by Adami et al. [19]. The operating pressure of the second column is determined from a pre-defined approach temperature and flash calculations for the bottom stream of the first column and top vapor of the second column. Depending on the individual heat requirements either an additional condenser for the second column or an additional reboiler for the first column is implemented to compensate for a mismatch, while an intermediate heat exchanger provides the necessary heat to reach saturation conditions for the connecting stream at the increased pressure.

## Pressure drop and HETP correlations

While the columns were considered isobaric in all preceding work on optimization-based design, the current work employs pressure drop and HETP correlations as functions of the vapor load, represented by the F-factor

$$FF_n = u_n^{superficial} \cdot \sqrt{\rho_n^{vapor}} = \frac{4 \cdot \dot{V}_n}{\pi \cdot D_{Col}^2} \cdot \sqrt{\frac{R \cdot T_n \cdot \sum_i y_{i,n} \cdot M_i}{p_n}}, \quad (1)$$

following the retrofit design approach described by Horsch et al. [15]. The column diameter is determined by the maximum vapor load across all active stages, excluding condenser and reboiler stages, following Douglas correlation [22]

$$D_{Col} \geq \sqrt{\frac{4 \cdot \dot{V}_n}{\pi \cdot FF_n}} \cdot \sqrt{\frac{R \cdot T_n \cdot \sum_i y_{i,n} \cdot M_i}{p_n}}, n = 2, \dots, n_{max} - 1. \quad (2)$$

The actual column diameter is considered to be the largest required stage diameter, ensuring that the maximum allowable F-factor is not exceeded

$$FF_n \leq FF_{max}, n = 2, \dots, n_{max} - 1. \quad (3)$$

The pressure drop per height and the HETP of the individual stages are estimated using polynomial correlations, which are fitted to vendor data for Sulzer BX structured packing derived at 960 mbar [23]:

$$\left(\frac{\Delta p}{h}\right)_n = \left(1 + b_{R,n} - \sum_{m=n+1}^{n_{max}} b_{R,m} + \sum_{m=1}^{n-1} b_{B,m}\right) \cdot (0.3617 \cdot FF_n^3 - 0.6838 \cdot FF_n^2 + 0.7572 \cdot FF_n) \quad (4)$$

$$HETP_n = \left(1 - \sum_{m=n+1}^{n_{max}} b_{R,m} + \sum_{m=1}^{n-1} b_{B,m}\right) \cdot (0.0120 \cdot FF_n^3 - 0.0666 \cdot FF_n^2 + 0.1657 \cdot FF_n + 0.0872) \quad (5)$$

Stages that are effectively bypassed by either the reflux or the boil-up stream do not contribute to the separation performance, as either the liquid or vapor stream is zero, such that the mass- and energy balance enforce the same for the liquid or vapor stream leaving the stage [16]. In order to maintain this property and implement the stage-specific pressure drop and HETP, the values of the bypassed stages are also set to zero, by accounting for the binary decision variables of the reflux ($b_{R,n}$) and boil-up ($b_{B,n}$) location as listed in eq. (4) and (5).

In context of the condenser stage ($b_{R,n} = 1$) and the reboiler stage ($n_{max}$), a doubled pressure drop is assumed to account for the effects of additional friction and phase change in the heat exchangers

$$p_{n_{max}} = p_{n_{max}-1} + 2 \cdot \left(\sum_{m=1}^{n_{max}} b_{B,m} \cdot \frac{\Delta p}{h}_m\right) \cdot \left(\sum_{m=1}^{n_{max}} b_{B,m} \cdot HETP_m\right). \quad (6)$$

The resulting pressure profile along the column is computed recursively as

$$p_n = p_{n-1} + \left(\frac{\Delta p}{h}\right)_n \bullet HETP_n, n = 2, \ldots, n_{max} - 1. \quad (7)$$

In the current work the pressure at the condenser is fixed at the operating pressure, which is determined by means of a preceding shortcut calculation. However, this constraint could also be relaxed to allow for further improvements.

## Initialization and solution procedure

The resulting MINLP problem is solved using a successively relaxed continuous reformulation approach, as outlined by Kraemer et al. [16]. The binary decision variables are relaxed and discrete values are successively enforced through penalty terms based on the Fischer-Burmeister functions. To enhance numerical robustness, a polylithic solution strategy (cf. **Figure 2**) is employed following the concept described by Waltermann and Skiborowski [18].

After a first initialization of the individual column models using all available stages (with fixed reflux and boil-up stages), the columns are connected to a direct sequence without the additional heat integration. This is further optimized for minimum external heat demand. In subsequent steps, the superstructure model is refined to the direct sequence with heat integration. Afterwards an initial estimation of the pressure profile is performed using fixed F-factor values to ensure the numerical robustness of the model, after which the HETP and pressure drop correlations, as well as sizing and cost correlations are introduced to the model. After solving the extended model for minimum heat demand and total annualized cost, resulting in a fully initialized model with reasonable values for all variables, the binary decision variables are relaxed, and a minimization of the TAC is performed with successively increasing penalties until a MINLP solution is obtained. The sequence of model refinement and NLP solutions is performed automatically, such that the overall MINLP problem is started from an initial problem definition up to the final design, representing a proven (local) minimum of the cost objective, which satisfies the predefined product purities.

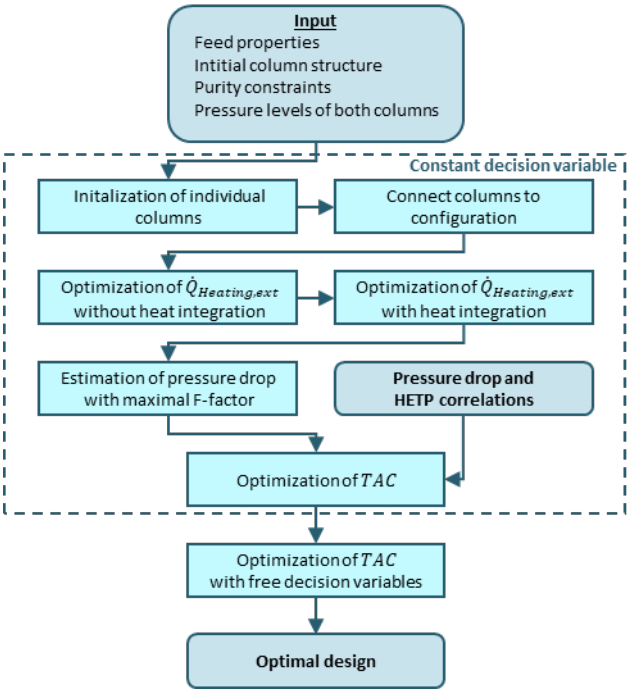

**Figure 2.** Initialization and solution procedure for direct heat integrated distillation sequence.

## CASE STUDY AND RESULTS

To investigate the influence of stage-dependent pressure drop and HETP on the techno-economic design of heat-integrated direct distillation sequences, the separation of a saturated liquid feed into three product

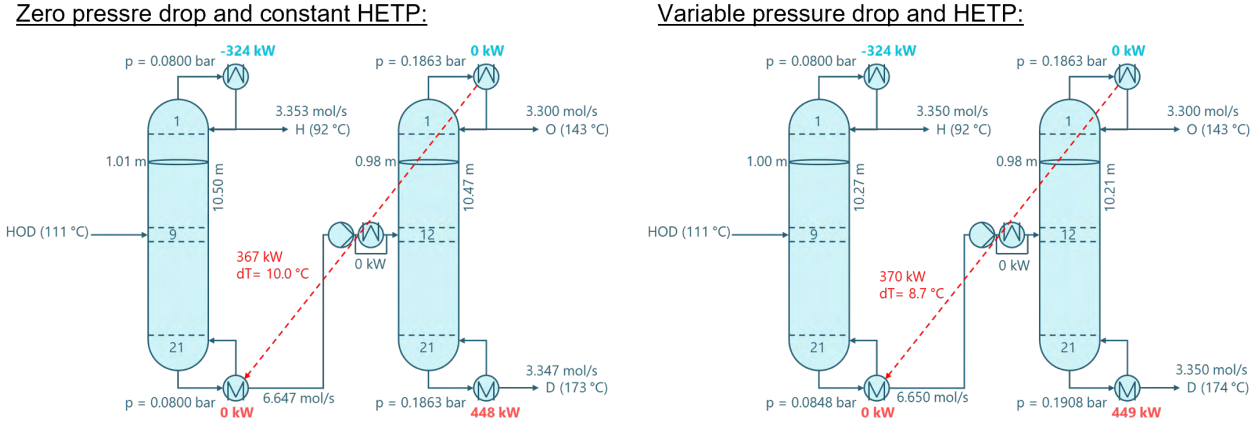

**Figure 3.** Optimalized heat-integrated direct distillation sequences for vacuum separation with isobaric (left) and pressure-drop-aware (right) superstructure.

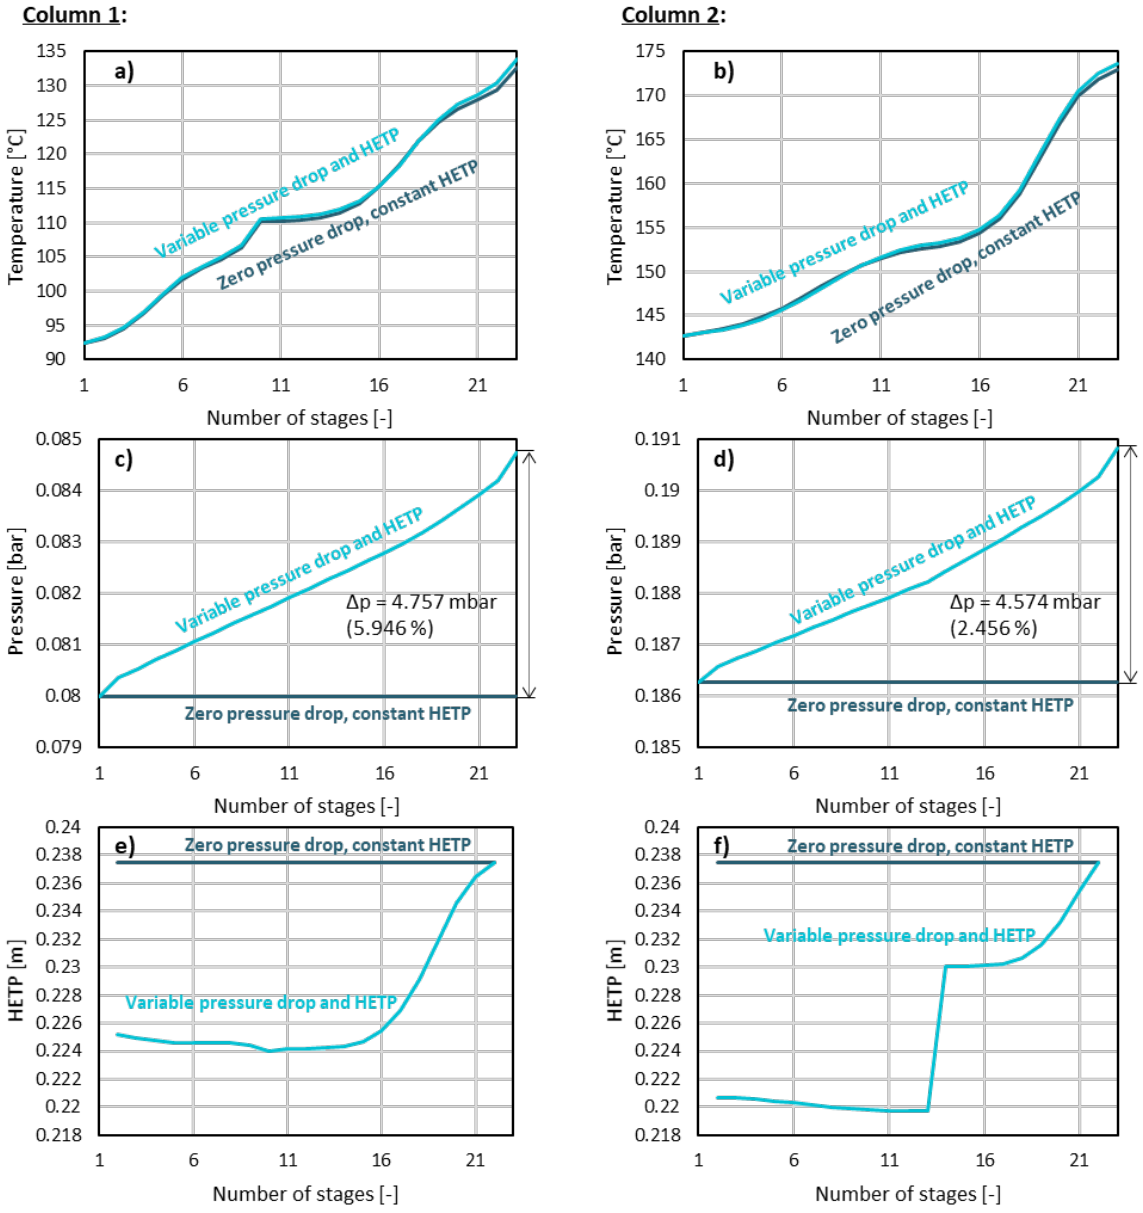

**Figure 4.** Temperature (a,b), pressure (c,d) and HETP (e,f) profiles inside of heat-integrated direct distillation sequence for vacuum separation with isobaric and pressure-drop aware superstructures.

streams with 99 mol% purity is considered.

The separation of hexanol, octanol, and decanol is investigated under vacuum conditions at 80 mbar [24], while the well-studied separation of benzene, toluene, and p-xylene is examined under atmospheric conditions [7, 19]. For both case studies, an equimolar feed and a feed flow rate of 10 mol/s are assumed. In the reference approach assuming isobaric columns with a constant HETP, the HETP is estimated for a maximum allowable F-factor of 1.75 $\sqrt{Pa}$ with the correlation stated in equation (5), resulting in a value of 0.238 m.

Cost data and economic assumptions are adopted from Adami et al. [19], while the VLE is modeled with the NRTL activity coefficient model and the Redlich-Kwong equation of state for the vapor phase fugacity. Pure component vapor pressure, heat capacities and heats of vaporization, are calculated with the extended Antoine equations and DIPPR correlations. All calculations are performed on an Intel i7-14700 CPU with GAMS 49.6.0 using SNOPT as NLP solver.

## Influence on vacuum separation

The optimized flowsheets obtained from the

optimization assuming isobaric operation and constant HETP and variable pressure drop and HETP are shown in **Figure 3**. Both approaches result in the same number of equilibrium stages in the optimal design. However, slight differences in the column height can be noticed. The variations are elucidated in **Figure 4**, which compares the resulting temperature profiles and highlights the variation in stage-specific pressure and HETP values for the resulting designs for both columns. While the temperature profiles are nearly identical, a slight increase in temperature toward the column bottom reduces the temperature difference for heat integration. Consequently, a considerable increase in the reboiler heat exchanger area is observed when pressure drop and HETP are included. Although the pressures increase almost linearly along the column height, which may also be reflected quite well with a constant stage specific pressure drop, the total pressure drop has no significant influence on the reboiler duty, which remains nearly unchanged between both approaches, indicating that isobaric operation and constant HETP can be appropriate approximations.

As the maximum F-factor, which determines the column diameter, occurs at the stage where the boil-up enters in both designs (cf **Figure 4**) the column diameter is basically equal for the two approaches. It is apparent that the HETP varies significantly between the rectifying and stripping sections, reflecting changes in vapor load along the column height and highlighting the importance for the resulting column sizing. This is also apparent in the key quantitative differences between the two designs, which are summarized in **Table 1**. Overall, it can be concluded that the consideration of column hydraulics does not show a significant effect on the energy demand and TAC, but has a noticeable effect on the HETP and the approach temperature in the heat exchanger. The latter might become more pronounced in case of a close boiling system, with higher stage requirements.

## Influence on atmospheric separation

For the atmospheric separation, the qualitative trends observed in the vacuum case persist, but the impact of pressure drop is further reduced. As shown in **Table 1**, the relative pressure increase at the column bottom is below 1%, resulting in negligible effects on temperature profile, energy demand, and TAC.

However, analogous to the vacuum separation, the final column sizing is slightly influenced by the consideration of the stage-specific pressure drop and HETP values. In the context of the current investigation, the variations in investment cost exhibit no substantial influence on the overall TAC, as the operating costs are the prevailing factor in the objective function. In any case it is important to have a proper estimate of the pressure drop and HETP per tray to obtain a reliable estimate of the

column sizing and cost estimation.

### Discussion and limitations

The current results indicate that the consideration of pressure drop and variable HETP can have a noticeable effect on the actual sizing of the column. However, the effect on the overall performance, in terms of heat duties and TAC, was limited for the wide boiling mixtures considered in the case studies. This indicates that assuming isobaric operation with constant HETP values is not expected to have a significant effect on the evaluation of competing configurations. While the overall economic impact is modest for the investigated wide-boiling mixtures, the effect may become larger for close-boiling or azeotropic mixtures and decreasing temperature differences for heat exchangers may become more decisive for thermally-coupled heat pump assisted distillation.

It also needs to be considered that the current proof-of-principle study applied simplified pressure drop and HETP correlations based on vendor data, which solely correlate with the F-factor. Consequently, variations in transport properties like liquid viscosity, surface tensions, as well as liquid load are not explicitly considered. Such effects may alter mass transfer efficiency and friction losses leading to a change in the correlation.

Nevertheless, the present implementation represents a first step towards incorporating pressure drop and variable HETP into an equation-oriented superstructure-optimization. It enables a more realistic assessment of structural design decisions at an early stage and provides valuable insights into the necessity of accounting for pressure-dependent effects in techno-economic optimization of energy-integrated distillation processes.

## CONCLUSION

The presented extension of a superstructure-based optimization model for distillation processes by explicitly incorporating pressure drop and variable HETP values enables a systematic assessment of the influence of these effects on the techno-economically optimized grassroot design.

For the wide-boiling mixtures investigated, the inclusion of pressure drop and HETP correlations has only a minor impact on the overall energy demand and total annualized cost of heat-integrated direct distillation sequences. However, the results clearly indicate the effects on the specific sizing in terms of column height and heat exchanger areas. These effects become more pronounced under vacuum operation, where relative pressure changes along the column are significantly higher.

The presented case studies highlight that the relevance of pressure drop and stage-specific HETP strongly depends on the specific separation task and the chosen optimization objective. Consequently, these effects should be considered when evaluating alternative process configurations, especially in scenarios involving vacuum operation, close-boiling mixtures, or capital-intensive designs.

Future work will investigate the effect of the extension in the proposed approach for dividing wall columns, where vapor splits are inherently linked to pressure drop and column dimensions and heat pump assisted distillation. In addition, the robustness of different process alternatives with respect to multiple operating points and feed variation can be investigated. In order to account for changing properties, like viscosity and surface tension, and the liquid load over the column, generalized approaches, such as those proposed by Stichlmair et al. [25], will be incorporated and compared to the simplified, vendor-based correlations employed in the present study.

## ABSTRACT

Aluminium cold rolling is an energy-intensive process that has a substantial impact on $CO_2$ emissions and production cost, yet plant-level optimization remains challenging due to strong process nonlinearities and various operational constraints. This study develops a physics-consistent hybrid model that combines a Stone–Hitchcock–Ludwik analytical rolling-energy formulation with a residual deep neural network to predict the daily electricity consumption of three single-stand cold rolling mills. Using plant raw data, the hybrid model achieves lower prediction errors than conventional data driven model and yields line-specific physical parameters that agree well with the observed behaviour of each mill. On this basis, an NSGA-II-based tri-objective optimization is carried out to minimise daily energy use, $CO_2$ emissions, and specific production cost (SPC) by adjusting pass-wise reduction and tension schedules and line-wise production allocation. Case studies on a representative operating day and additional plant data show that the optimised operating strategy shifts production load from less efficient to more efficient lines and smooths pass-wise operating conditions, thereby consistently reducing daily energy consumption and unit cost while moderately decreasing $CO_2$ emissions without any hardware modifications. The proposed hybrid prediction–optimization framework thus provides a practical decision-support tool for integrated energy–environment–economic optimization in multi-line aluminium cold rolling operations.

**Keywords**: Aluminium cold rolling, Physics-consistent hybrid modelling, Rolling energy consumption, Multi-objective optimization, NSGA-II (Non-dominated Sorting Genetic Algorithm II)

## INTRODUCTION

Global efforts to mitigate climate change have tightened greenhouse gas (GHG) reduction requirements toward carbon neutrality by 2050 across the manufacturing sector [1]. The aluminium industry, responsible for about 2% of global industrial emissions (≈1.1 $GtCO_2$-eq/year), is a representative carbon- and energy-intensive sector in which process electricity use is a major driver of emissions [2, 3]. In power systems still dominated by fossil fuels, electricity consumption translates directly into GHG emissions, making renewable penetration and fuel switching key mitigation options. In the Republic of Korea, however, a high fossil share in the generation mix and strong industrial dependence on electricity [4] limit the pace of power-sector decarbonisation, so process-level energy efficiency improvement and operational optimization emerge as particularly effective short- to mid-term options.

Cold rolling of aluminium is a power-intensive process that determines final strip thickness (tens of micrometres), flatness, and mechanical properties, and therefore requires high-speed, high-tension operation with precise control [5]. In single-stand foil mills operated under multi-pass schedules, the combination of reduction, entry/exit tension, and rolling speed at each pass jointly determines rolling load, torque, and thus electrical power

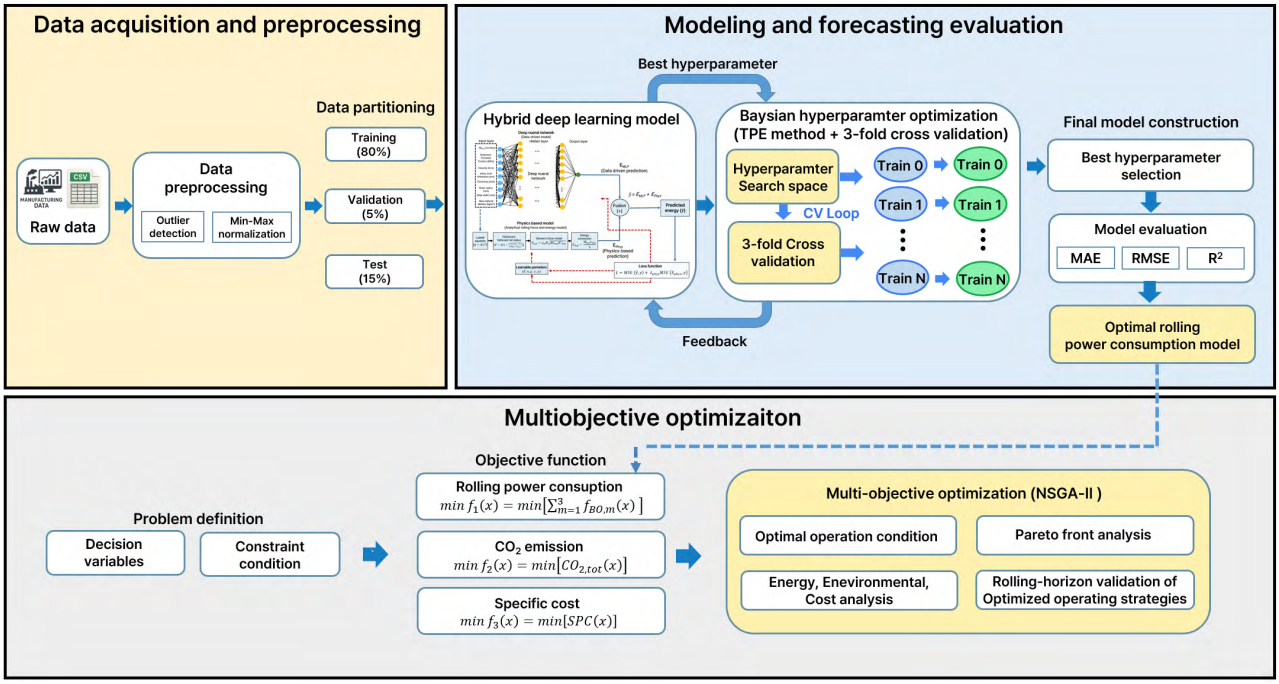

**Figure 1.** Overall framework of data-driven rolling power prediction and multi-objective optimization for aluminum rolling.

demand, under equipment constraints such as motor rating, drivetrain and inverter capacity, and available power supply. Designing pass schedules and allocating production among parallel lines is therefore a constrained decision problem, in which energy performance must be optimised concurrently with process stability and product requirements. Predictive models that reliably quantify the impact of process variables and production allocation on power demand and daily energy use are a key enabler for such optimization.

Modelling approaches for rolling load and power have evolved from analytical formulations and finite element method (FEM) simulations to artificial intelligence (AI)-based methods. Analytical models are computationally efficient and interpretable, but they require calibration for friction, work hardening, and drive efficiency, and their simplifying assumptions can limit accuracy and general applicability. FEM can represent roll–strip contact and deformation in detail, but it is too computationally expensive for repeated evaluation in plant-wide optimization. Data-driven AI models, including artificial neural networks (ANNs), have been applied to rolling load, power, and process monitoring tasks [6–9]; however, their black-box nature can limit interpretability and reduce reliability under extrapolative conditions. To address these limitations, hybrid modelling approaches that embed data-driven correction layers within physics-based structures have been proposed to balance computational efficiency, physical consistency, and predictive accuracy. In particular, previous studies have reported FEM–ANN hybrid models, genetic algorithm–backpropagation neural network (GA–BP) models, and stacking ensemble models combining extreme random tree (ET), AdaBoost regression tree (AdaBoost-RT), linear regression (LR), and backpropagation neural network (BPN) base learners with an LR meta-learner for load and flatness prediction [10–13].

As predictive models have improved, multi-objective optimization studies that embed such models into decision-making frameworks have become more common. In rolling applications, differential evolution (DE)- and Non-dominated Sorting Genetic Algorithm II (NSGA-II)-based methods have been used to derive Pareto-optimal solutions considering energy reduction, strip quality, slip prevention, and motor load balancing, while more recent studies have explored reinforcement learning-based pass schedule design and energy-oriented scheduling under time-of-use (TOU) tariffs and peak-demand constraints [14–16]. However, process-condition scheduling, such as pass-wise load and tension control, and TOU-based operating-time scheduling have mostly been treated separately. Consequently, integrated frameworks that link a physics-informed daily energy model with plant-level energy, environmental, and economic indicators for single-stand, multi-pass, high-speed, high-tension aluminium cold rolling mills remain very limited. To address this gap, this study develops an integrated framework that combines actual plant operating data, including pass-wise reduction, tension, speed, and thickness, with manufacturing execution system (MES)-based

production data, including daily throughput and line-wise allocation, to predict mill-wise daily electricity consumption and to use these predictions in NSGA-II-based tri-objective optimization of energy consumption, carbon dioxide ($CO_2$) emissions, and specific production cost (SPC) across operating conditions and inter-line production allocation. The overall workflow is summarised in Figure 1.

# METHODOLOGY

## Overview of the target process

The case study considers an industrial aluminium sheet cold rolling plant with a nominal capacity of approximately 500 ton/day. The plant consists of three single-stand cold rolling mills (RM4, RM5, and RM6). In each line, intermediate sheet stock supplied from upstream processes is reduced to the target thickness over multiple passes. The layout of the three mills, coil transfer routes, and pass directions are illustrated in Figure 2.

## Problem definition

The plant energy management system (EMS) and process databases provide operating and production data, including alloy grade, strip geometry, pass schedule, key operating variables such as reduction, tension, and speed, and line-wise daily electricity consumption. Among the frequently used production routes, this study focuses on AA8075-series sheets operated under a six-pass cold rolling schedule.

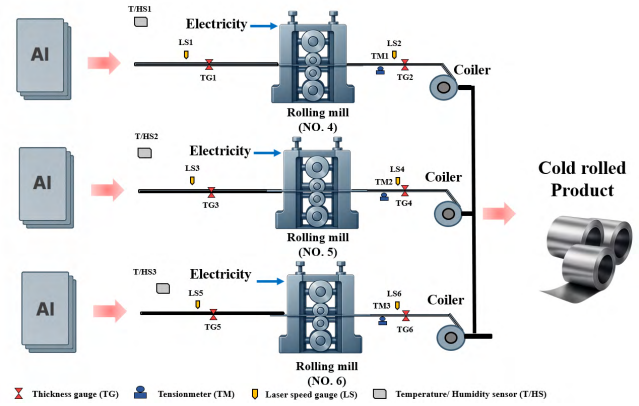

**Figure 2.** Schematic of three parallel aluminum rolling mills (No. 4–6) and product material flow.

The statistical characteristics of the full raw dataset are summarised in Supplementary Material S1. The process variables exhibit typical multi-pass cold rolling behaviour: the reduction ratio is highest in the initial passes and decreases with pass number; tension starts at an intermediate level in pass 1, increases up to pass 5, and slightly decreases in pass 6; and roll speed increases gradually with pass number. The exit thickness for all three lines is tightly distributed around the target value, indicating stable thickness control.

**Table 1:** Detailed values of the model parameters

| Parameter | Description | Unit | Value |
|---|---|---|---|
| $\rho$ | Density of strip (A8075) | kg/m$^3$ | 2710 |
| $N_m$ | Number of rolling mills | - | 3 |
| $N_p$ | Number of passes | - | 6 |
| $h_0$ | Initial thickness of foil | mm | 0.3 |
| $h_{aim}$ | Target thickness of foil of final production | mm | 0.03 |
| $R$ | Work roll radius | m | 0.375 |
| $B$ | Width of strip | mm | 1690 |
| $\psi$ | Force arm coefficient | - | 0.45 |
| $\eta_m$ | Mechanical efficiency | - | 0.85-0.995 |
| $\mu$ | Friction coefficient | - | 0.05-0.08 |
| $K$ | Strength coefficient | MPa | 110-200 |
| $n$ | Strain hardening exponent | - | 0.2-0.25 |

A representative operating condition is defined such that the total daily throughput of the three mills is 219.3 ton/day, with the incoming strip thickness $h_0$=*0.3 mm* and target final thickness $h_{aim}$=*0.03 mm* over six passes. The material, geometric, and operating parameters used in the analytical cold rolling model for this base case are summarised in Table 1, including strip density $\rho$, number of passes $N_p$, number of mills $N_m$, initial and target thickness $h_0$, $h_{aim}$, roll radius $R_w$, strip width $B$, arm coefficient $\psi$, mechanical efficiency $\eta_m$, friction coefficient $\mu$, strength coefficient $K$, and strain-hardening exponent $n$. These parameters, summarised in Table 1, constitute the nominal parameter set and are applied to both the analytical cold rolling model and the hybrid energy prediction model, except where indicated otherwise.

## Data preprocessing

Process raw data can contain noise, input errors, and missing values, which may deteriorate the stability and reproducibility of model training. To address this, pass-wise reduction, tension, speed, thickness, daily throughput, and electricity consumption are preprocessed by removing physically unrealistic outliers and imputing missing values with the variable-wise median, followed by min–max normalisation of all input variables.

Normalisation is defined as

$$X' = \frac{X - X_{min}}{X_{max} - X_{min}}, \quad (1)$$

$X'$ is the normalised value, $X$ is the original value, and $X_{\max}, X_{\min}$ are the maximum and minimum of each variable. The preprocessed data are split into 80% for training, 5% for validation, and 15% for testing.

## Model development

The model architecture used to predict the daily electricity consumption of the cold rolling mills is illustrated in Figure 3. Normalised process inputs x (Production, pass-wise reduction, speed, tension, exit thickness, etc.) are fed in parallel to a data-driven deep neural network $f_{DL}(x, \theta)$ and to an analytical rolling-energy model $E_{phys}(x, \phi)$ based on the Stone–Hitchcock–Ludwik formulation. The network is a fully connected deep neural network (DNN) with rectified linear unit (ReLU) activation and a linear output layer for regression, trained using mean squared error (MSE) and the Adam optimiser with early stopping. The analytical module computes per-pass rolling force, torque, power, and energy for each mill and aggregates them to daily energy using mill-specific physical parameters ϕ=(K, n, μ, η).

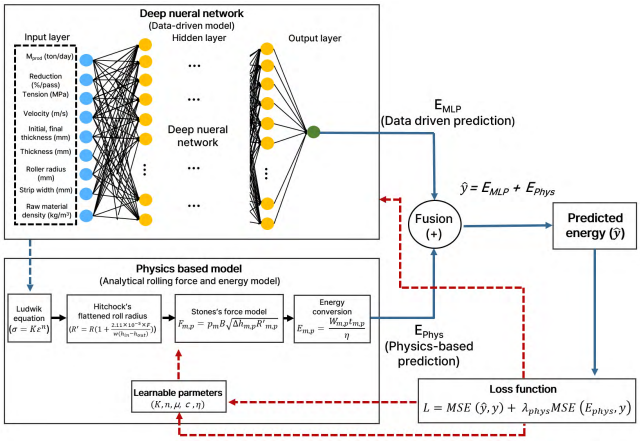

**Figure 3.** Physics-consistent hybrid model for rolling-energy prediction

The detailed equations and formulation of the analytical rolling-energy model are summarised in Supplementary Material S2. The hybrid predictor is formulated in residual form and trained with the composite loss.

$$\hat{y}(x; \theta, \phi) = f_{DL}(x, \theta) + E_{phys}(x, \phi) \quad (2)$$

$$L = MSE\ (\hat{y}, y) + \lambda_{phys} MSE\ (E_{phys}, y) \quad (3)$$

where $\lambda_{phys} > 0$ controls the weight on physics consistency. The physical parameters ϕ are treated as learnable and updated jointly with $\theta$, so that the DNN mainly captures residual patterns while the analytical model provides the physical baseline and global energy scale.

## Bayesian optimization

Bayesian hyperparameter optimization was employed to enhance the predictive performance of the physics-consistent hybrid model. A Tree-structured Parzen Estimator (TPE)–based algorithm, implemented via the Optuna library, was used to efficiently explore a mixed continuous–discrete search space, tuning key hyperparameters such as the number of hidden units, learning rate, weight decay, physics-loss weight ($\lambda_{phys}$), and batch size. Each trial was evaluated using the hybrid loss $L(\theta, \phi)$ on the validation set, and the hyperparameter configuration yielding the minimum validation loss over all trials was selected.

## Model evaluation

The dataset was randomly shuffled and split into 80% for training, 5% for validation (Bayesian hyperparameter optimization), and 15% for testing. Test-set performance was evaluated using mean absolute error (MAE), root mean squared error (RMSE), and the coefficient of determination ($R^2$), defined for $N$ test samples as

$$MAE = \frac{1}{N} \sum_{i=1}^{N} |\hat{y}_i - y_i| \quad (4)$$

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^{N} (\hat{y}_i - y_i)^2} \quad (5)$$

$$R^2 = 1 - \frac{\sum_{i=1}^{N} (\hat{y}_i - y_i)^2}{\sum_{i=1}^{N} (y_i - \bar{y}_i)^2}, \bar{y} = \frac{1}{N} \sum_{i=1}^{N} y_i \quad (6)$$

# MULTI-OBJECTIVE OPTIMIZATION

## Objective function

The multi-objective optimization problem is solved using the NSGA-II evolutionary algorithm. The previously developed physics-informed hybrid surrogate model is used as the evaluator: for each candidate operating condition (pass-wise reduction, tension, and production allocation), it predicts the daily electrical energy use of each mill. NSGA-II then searches for a set of Pareto-optimal solutions that simultaneously minimise energy consumption, $CO_2$ emissions, and economic cost.

$$\min f_1(x) = \min \sum_{m=1}^{3} f_{BO,m}(x) \quad (7)$$

$$\min f_2(x) = \min \alpha_{elec.} E_{total,day}(x) + \alpha_{raw} M_{raw,day}(x) + \alpha_{lub} M_{lub}(x) + \alpha_{add} M_{add}(x)\ [ton/day] \quad (8)$$

$$\min f_3(x) = \frac{C_{elec.}(x) + C_{ETS}(x) + C_{raw}(x) + C_{O\&M}}{M_{prod,day}(x)} \quad (9)$$

The objective functions in this study are defined at the plant level as follows: (i) total daily electricity consumption, evaluated as the sum of the hybrid-model-predicted daily electricity use of the three mills; (ii) total daily

$CO_2$ emissions arising from electricity consumption as well as raw material, lubricant, and additive use; and (iii) the specific production cost (SPC), defined as the ratio of total daily operating cost to daily production. The coefficients required for evaluating the $CO_2$ and SPC objective functions are compiled and derived in Supplementary Tables S3 and S4, respectively.

**Table 2:** Prediction accuracy of energy consumption by different machine learning models

| Sheet | Model | MAE | RMSE | $R^2$ |
|---|---|---|---|---|
| Rolling Mill 4 | SVR | 0.357 | 0.653 | 0.964 |
| | RFR | 0.349 | 0.660 | 0.964 |
| | XGB | 0.314 | 0.637 | 0.966 |
| | DNN | 0.434 | 0.684 | 0.961 |
| | Hybrid DNN | 0.202 | 0.400 | 0.987 |
| Rolling Mill 5 | SVR | 0.284 | 0.366 | 0.983 |
| | RFR | 0.307 | 0.406 | 0.980 |
| | XGB | 0.285 | 0.376 | 0.982 |
| | DNN | 0.302 | 0.402 | 0.980 |
| | Hybrid DNN | 0.258 | 0.357 | 0.988 |
| Rolling Mill 6 | SVR | 0.153 | 0.274 | 0.963 |
| | RFR | 0.178 | 0.294 | 0.957 |
| | XGB | 0.154 | 0.254 | 0.968 |
| | DNN | 0.136 | 0.216 | 0.967 |
| | Hybrid DNN | 0.115 | 0.169 | 0.986 |

## Decision variables and industrial constraints

The decision vector comprises (i) daily production allocated to each mill, $M_{m,\,day}$(m=1, 2, 3) (ii) pass-wise reduction ratios $R_i$ (i=1, ..., 6), and (iii) pass-wise tensions $T_i$ (i=1, ..., 6), and can be written for each mill as

$$x = [\, M_{i,day},\ R_1, R_2R_3R_4R_5R_6, T_1, T_2, T_3, T_4, T_5, T_6] \qquad (10)$$

Search bounds are chosen to reflect the feasible operating window of the actual equipment: lower and upper limits for $M_{m,\,day}$ $R_i$, and $T_i$ are set to the minimum–maximum values observed in plant data, thereby preventing unrealistic operating combinations. In addition, the total daily production is constrained to remain close to the reference target to avoid trivial improvements obtained by artificially changing throughput.

# RESULTS AND DISCUSSION

## Performance comparison of hybrid model

Table 2 compares the daily energy prediction performance of support vector regression (SVR), random forest regression(RFR), extreme gradient boosting (XGB), pure DNN, and the proposed Bayesian optimization (BO)-hybrid DNN for the three foil rolling lines (RM4–RM6) using identical inputs. The BO-hybrid DNN yields the lowest MAE/RMSE and highest $R^2$ across all lines, indicating that incorporating physical load–torque–power–energy relations improves both accuracy and robustness at the daily energy scale.

Figure 4 shows the BO-hybrid DNN predictions of

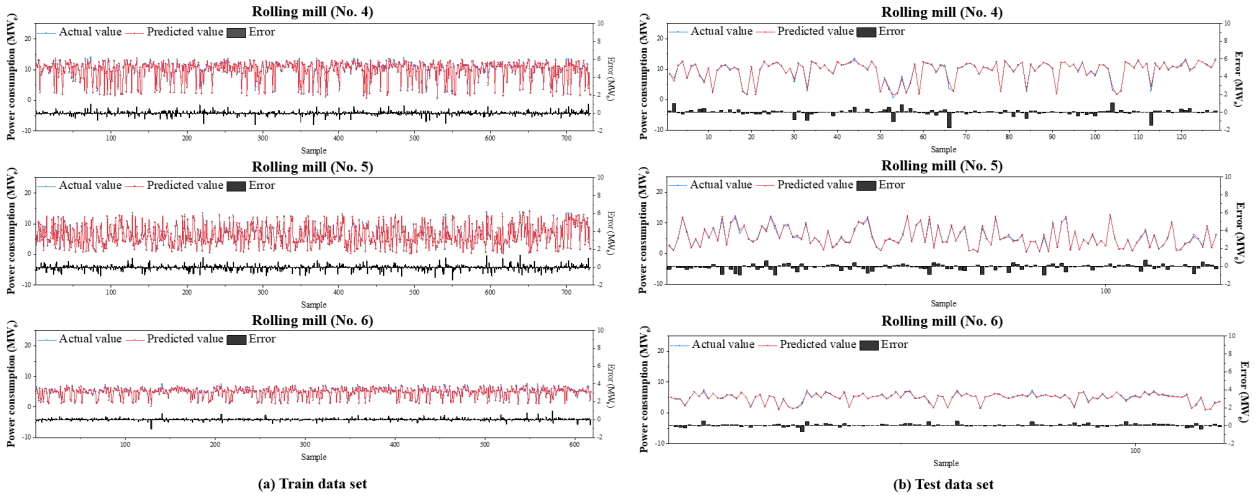

**Figure 4.** Actual and predictive value calculated by BO-Hybrid model.

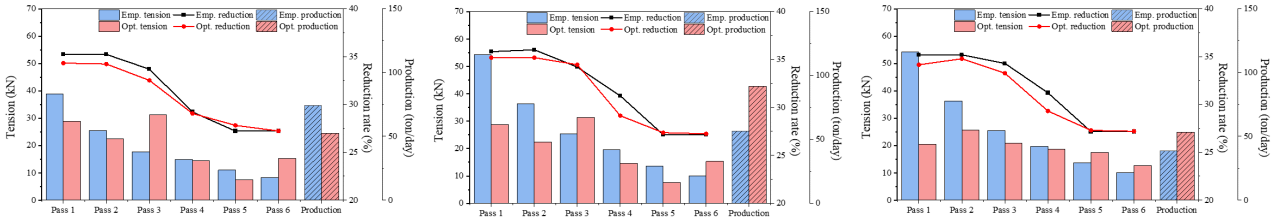

(a) Rolling mill (No. 4) (b) Rolling mill (No. 5) (c) Rolling mill (No. 6)

**Figure 5.** Optimization results of tension, reduction, and daily production for rolling mills No. 4–6 (empirical vs. optimized).

daily energy consumption for each line, with training results on the left and test results on the right. In each subplot, red markers denote measured values, black markers denote model predictions, and blue bars indicate the absolute error per sample. For all three lines, the predicted curves closely follow the measured trends, with most absolute errors remaining within a narrow range and only limited deviations at a few peak-load or non-standard operating points.

**Table 3:** Inferred physical parameters of the rolling process for the three mills

| Parameter | Unit | Description | RM4 | RM5 | RM6 |
|---|---|---|---|---|---|
| $K_{MPa}$ | MPa | Strength coefficient | 180 | 178 | 181 |
| $n$ | - | Strain-hardening exponent | 0.24 | 0.25 | 0.24 |
| $\mu$ | | Friction coefficient | 0.05 | 0.05 | 0.03 |
| $\eta$ | % | Mechanical efficiency | 90.8 | 93.1 | 92.2 |

***RM : Rolling mill**

In addition to predicting energy, the BO-hybrid DNN simultaneously back-estimates the physical parameters ($K$, $n$, $\mu$, $\eta$) for each mill, as summarised in Table 3. The inferred values fall within similar ranges but exhibit mill-specific variations, indicating that the model not only improves daily energy prediction but also yields interpretable, line-dependent physical parameters rather than purely statistical correlations.

## Multi-objective optimization results

### Case study of a representative operating day

Energy consumption and $CO_2$ emissions are strongly positively correlated, because $CO_2$ is computed directly from the predicted daily electricity use via a fixed grid emission factor; thus, reducing energy immediately reduces $CO_2$. In contrast, energy (or $CO_2$) and SPC exhibit an overall inverse relationship, since SPC is defined as total daily operating cost per unit throughput and includes fixed capital/ operations and maintenance (O&M) components as well as energy-dependent costs.

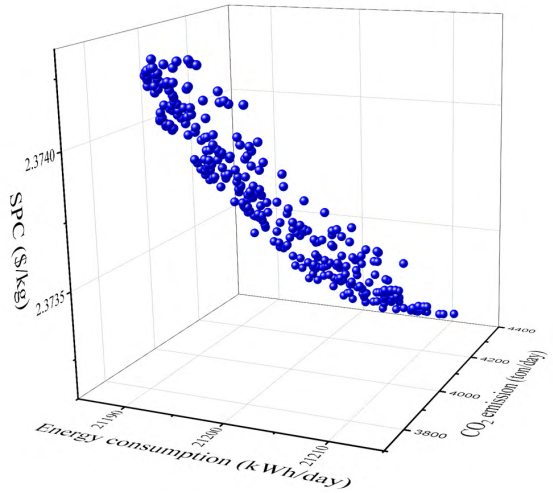

**Figure 6.** Pareto solution set in objective space for (a) 3D of energy consumption, $CO_2$ emission, and SPC

Along the Pareto front, some operating conditions slightly increase energy use but allow higher daily production and more favourable load sharing among mills, thereby diluting fixed costs per ton and yielding lower SPC despite higher energy and $CO_2$.

Figure 7 compares the three objective values—daily energy consumption, daily $CO_2$ emissions, and SPC—between the empirical operating condition and the optimized condition, shown in normalized form with absolute values annotated on each bar. Daily energy consumption decreases from 25.91 to 21.19 MWh/day (≈18.22%), and SPC from 2.51 to 2.502 USD/kg (≈0.32%), indicating a simultaneous reduction in unit production cost, including electricity and emissions trading system (ETS)-related charges. $CO_2$ emissions change only marginally, from 4158.5 to 4156.4 kg/day (≈0.05%), as a substantial fraction of total emissions arises from non-electricity contributions such as materials and process auxiliaries. Overall, these results summarise that appropriate adjustment of line-wise production allocation and pass-wise operating

conditions can improve energy, environmental, and economic performance simultaneously even under unchanged equipment and system configurations.

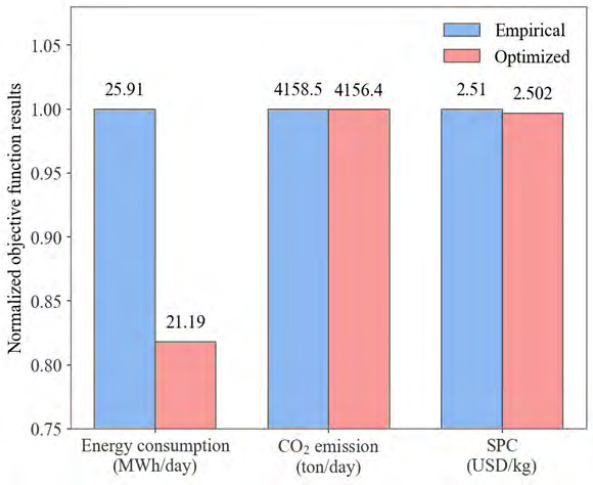

**Figure 7.** Relative comparison of normalized objective functions (Energy, $CO_2$, SPC)

## Case study with additional operating data

In this section, the proposed hybrid prediction–optimization framework is validated on 40 additional operating days that were not used for training, under the actual plant constraints of each day (target throughput, mill capacities, speed/tension limits, etc.). For each day, NSGA-II is applied with pass-wise reduction, tension, speed, and line-wise production allocation as decision variables. As shown in Figure 8(a), although the total daily production varies between approximately 288 and 489 ton/day, the optimised solutions consistently redistribute load away from Mill 4 and toward the more energy-efficient Mills 5 and 6. Consequently, Figure 8(b) indicates that empirical daily electricity use, which ranges from 20.9 to 33.1 MWh, is reduced and flattened to about 20.3–21.9 MWh under the optimised operation, corresponding to an average energy reduction of roughly 21.12%. Figures 8(c) and (d) show that, despite relatively small percentage reductions in $CO_2$ (0.01–0.068%, but on 2.56 ton/day in absolute terms) and SPC also decreased, with the relative reduction ranging from 0.21 to 0.283% and averaging approximately 0.24%. Despite the dominance of raw material cost in the total cost structure, the optimization consistently improves energy, environmental, and economic performance across all 40 days while satisfying the production constraints.

## CONCLUSION

This study developed a physics-consistent hybrid energy surrogate for daily electricity prediction in aluminium cold rolling by coupling a Stone–Hitchcock–Ludwik analytical rolling-energy model with a residual deep neural network. The hybrid model improved predictive capability while preserving physically interpretable mill-specific parameters consistent with actual plant behaviour. On this basis, an NSGA-II-based tri-objective optimization framework was formulated to minimise energy consumption, $CO_2$ emissions, and SPC through the adjustment of pass-wise operating conditions and line-wise production allocation. The results showed that the proposed framework can systematically improve plant operation by shifting production toward more energy-efficient mills and by smoothing pass-wise schedules under practical process constraints. Furthermore, out-of-sample validation confirmed that the framework remains effective under varying operating conditions. These findings demonstrate that the proposed approach offers a practical and scalable tool for integrated energy–environment–economic optimization of industrial aluminium cold rolling plants without additional hardware modification.

## ABSTRACT

Anaerobic digestion (AD) across Europe and the UK faces increasing economic and operational pressure from volatile feedstock supply under climate extremes. Existing stochastic programming (SP) approaches for feedstock planning often rely on limited historical observations and/or simplify yield uncertainty in ways that miss the joint, non-linear response of crops to weather variability, thereby understating downside supply risk. We develop an integrated decision-support framework that links climate uncertainty to AD procurement planning by coupling mechanistic crop simulation, generative surrogate modelling, and stochastic optimization. First, APSIM is used offline to generate a mechanistic yield knowledge base across weather trajectories and discrete planting-density choices. Then, a conditional GAN (CGAN) is trained to produce non-parametric joint yield samples for multi crops conditioned on scenario features and management, enabling fast Monte Carlo evaluation. At last, these samples are embedded in a two-stage SP that optimizes first-stage land allocation and planting densities, with second-stage recourse represented by spot-market purchases to cover shortfall. The architecture is designed for stage-based rolling updates as forecasts are progressively replaced by observations. We demonstrate the framework on a 15-ha unit under different contracts of biogas-equivalent output. Results reveal a target-induced regime shift in optimal procurement. Under moderate production targets, monocropping solutions minimize cost with negligible loss in reliability, reflecting broad operational indifference across several land allocation patterns. As contract levels approach the biophysical limits of a 15-ha system (~$110\times10^3$ $m^3$), the optimizer transitions into a risk-reducing regime where maize–rye double cropping becomes increasingly necessary. At high targets, the feasible set collapses toward near-complete double cropping. At a representative contract of $140\times10^3$ $m^3$, the least-cost rye-only plan achieves 34.3% supply confidence, while full double cropping increases confidence to 85.7% but with higher cultivation cost. Even under full intensification, an irreducible tail risk remains (14.3% shortfall frequency), implying unavoidable reliance on spot-market procurement under extreme seasons. The APSIM–CGAN–SP integration translates climate-driven biophysical uncertainty into actionable procurement strategies. It reveals threshold behavior, tail-risk exposure, and the limits of intensification under fixed land constraints. The framework supports both pre-seasons planning and rolling in-season updates, providing a quantitative basis for contract feasibility assessment, hedging design, and resilient feedstock procurement.

## INTRODUCTION

Anaerobic digestion (AD) is a mature bioenergy technology that converts organic matter into biogas [1]. Unlike intermittent renewable sources such as solar or wind power, AD facilities often operate as baseload units, which means they rely on a steady and predictable feedstock supply. In practice, even short-term feedstock

shortages can trigger substantial economic losses or force unplanned shutdowns [2]. This dependence turns feedstock availability into a planning problem, operators must decide how much to grow, how much to contract, and how much risk to leave to the spot market.

Energy crops such as maize and rye are widely used as high-energy feedstock in AD systems [3]. Beyond providing high-energy biomass, these crops support greenhouse gas mitigation, energy security, and rural development [3]. However, climate-driven yield variability and extreme events increasingly translate agricultural uncertainty into operational risk for AD sites [4], [5]. Yield forecasting serves not as a standalone objective but as a foundational input for the generation of supply chain scenarios. These scenarios are subsequently embedded in procurement and production-planning frameworks to enable hedging strategies that account for operational variability and upstream supply uncertainty [6].

Process-based crop models (e.g., Agricultural Production Systems sIMulator (APSIM) [7]) can provide realistic yield responses but are computationally too expensive for real-time stochastic optimization. Purely data-driven machine learning (ML) models are faster, yet often lack physical consistency and can be unreliable under extremes such as heatwaves or floods [8]. This limits their usefulness for decision support, especially when yield uncertainty and needs to be propagated into procurement and production planning. This creates a need for surrogate-based modeling strategies, balancing physical rigor with mathematical tractability in process systems engineering [9].

Existing AD supply-chain studies have largely focused on logistics or facility siting under deterministic assumptions, overlooking the stochastic nature of biophysical production [10]. While integrated crop–operations frameworks have appeared in the ethanol sector [11], such crop-to-decision integration remains limited in AD. Mechanistic models like APSIM remain accurate but infeasible for real-time optimization, and no operational framework currently connects biophysical yield uncertainty to tactical procurement decisions [12].

In mature electricity markets, stochastic programming (SP) is routinely used to hedge fuel contract risks under price volatility [13], [14]. AD procurement faces a similar make-or-buy challenge, but the dominant uncertainty arises not from market prices but from biophysical variation in crop yields. Yield variability translates into supply shortfalls and, consequently, greater pressure from volatile spot-market purchases. SP is therefore a natural framework for trading off upfront commitments (planting density and contracts) against scenario-dependent recourse actions and supply-gap penalties. If future yields can be predicted with adequate physical realism, managers can jointly optimize planting densities and purchase contracts to reduce exposure to costly spot-market feedstock.

To address the trade-off between biophysical realism in crop modeling and the computational demands of large-scale system decision-making, this paper proposes an integrated framework to support feedstock procurement decisions for ADs. This method utilizes the APSIM simulator to generate a high-fidelity dataset that captures the nonlinear response of crop yields to extreme weather events (such as heat waves). Based on this data, we train a physically-aware Conditional Generative Adversarial Network (CGAN) as a surrogate model, that simulates the complex mechanistic relationships between crops and conditions such as soil and weather. Finally, we embed this surrogate model generating probabilistic crop yield scenarios into a two-stage SP framework to evaluate land use and cultivation decisions under climate-driven uncertainty. By incorporating ensemble weather forecasts into the scenario generation process, this framework enables AD operators to optimize land allocation and planting density based on production objectives. The resulting decision-making tools reduce the risks associated with adverse yield outcomes and recourse costs related to volatile spot market feedstock procurement.

## METHODOLOGY

The proposed framework (Figure 1) optimizes AD feedstock procurement by coupling biophysical process simulation, deep learning surrogates, and two-stage stochastic programming SP.

### Problem Definition

A standard feedstock procurement agreement (FPA) for an AD site has been formalized, which specifies a contracted cultivation capacity $A_{tot}$ (ha) and an annual baseload production target expressed as a feedstock requirement $Q_{target}$ ($m^3$ biogas or $t$ DM-equivalent). Internal supply is secured via fixed cultivation fees (covering seeds, management and land use). To ensure baseload operation, a minimum supply guarantee is effectively enforced by shortfall recourse.

The decision process is a two-stage stochastic problem. The first stage is here-and-now decision. Prior to the growing season, the manager determines the area allocation $\boldsymbol{A} = \{A_M, A_R, A_{DR}\}$ and planting densities $\boldsymbol{D} = \{D_m, D_r\}$ for maize (M), rye (R), and double-cropping (DR). It denotes sequential maize–rye double cropping within the same year, where rye and maize occupy less overlapping growing seasons on the same land base. DR is approximated in this prototype by combining monocrop yields with an annual reduction factor $\eta_{DR} \in (0, 1]$ that reflects a possible reduction in crop yield due to a shortened growing season or insufficient nutrients.

And the second stage is wait-and-see decision.

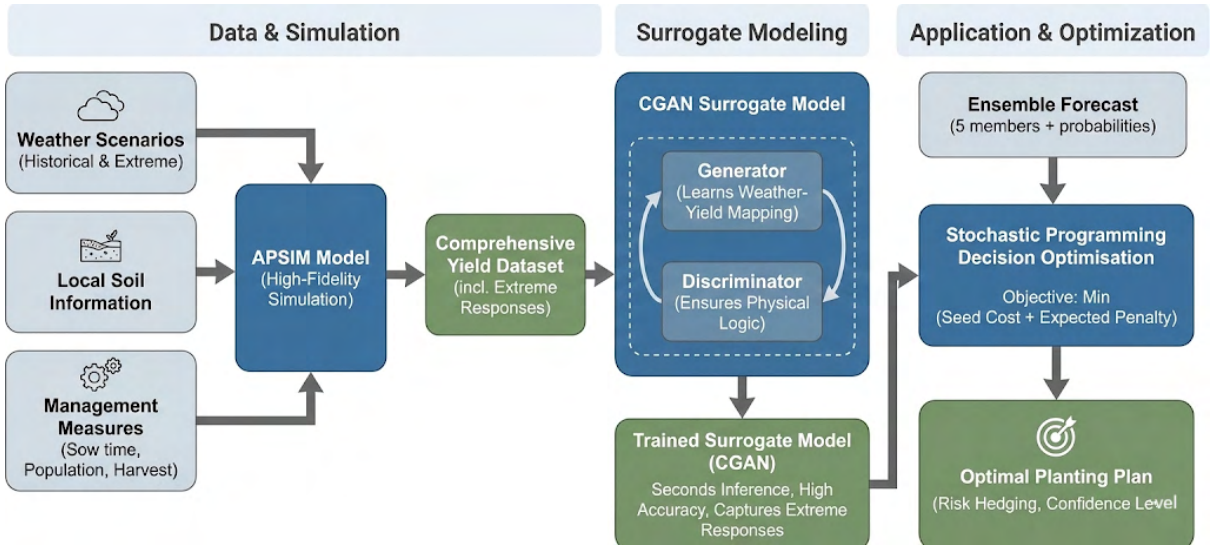

**Figure 1.** Integrated decision-support framework for AD feedstock procurement optimization under climate uncertainty, coupling biophysical simulation (APSIM), surrogate modelling (CGAN), and two-stage SP.

After weather scenarios $s$ are realized, the yield $Q_s$ is observed. If realized yields are insufficient to meet $Q_{target}$ due to adverse weather, shortfalls are mitigated via spot-market purchases at a premium price $P_{buy}$, while surpluses are stored or sold at a credit price $P_{sell}$.

To address data scarcity under extreme climates, the APSIM is used to generate a mechanistic knowledge base. We incorporate a pre-simulation spin-up using historical weather data to initialize the earlier soil environment (e.g., plant-available water capacity). This captures the biophysical memory, where residual moisture conditions from previous years interact with current climate anomalies to produce non-linear yield responses

DR yields are represented by $\hat{Y}_{DR,s} = \eta_{DR}(\hat{Y}_{M,s} + \hat{Y}_{R,s})$, where $\eta_{DR} \in (0,1]$ is an operational efficiency factor capturing inter-crop competition and harvesting windows.

## Surrogate Modelling via CGAN

To bypass the computational cost of APSIM, a CGAN is employed as a surrogate. Unlike standard regressions, the CGAN maps the conditional inputs (weather $W_s$ and density $D$) to a probabilistic yield manifold. The Generator $G$ takes a latent noise vector $z^{(j)} \sim \mathcal{N}(0, I)$ as an additional input. By drawing $N$ independent samples of $z$ for each weather scenario $s$, the model generates a yield cloud:

$$\left[\hat{Y}_{M,s}^{(j)}, \hat{Y}_{R,s}^{(j)}\right] = G\left(W_s, D, z^{(j)}\right), j = 1, \ldots, N \quad (1)$$

where $W_s \in R^{12}$ represents standardized weather anomalies (temperature and precipitation deviations) across key growth stages. Here $s$indexes the five climate regimes and $j$indexes CGAN samples within each regime. Only the weather space is reduced by clustering historical meteorology into five climate regimes (empirical probabilities $\{\pi_s\}$). No post-CGAN reduction is applied. For regime $s$, the CGAN generates $N_s$ joint samples $\left[\hat{Y}_{M,s}^{(j)}, \hat{Y}_{R,s}^{(j)}\right]$, all retained; hence $S = \sum_s N_s$. Scenario weights are $p_{s,j} = \pi_s / N_s$. The CGAN internalises physiological overturn points where high density exacerbates water stress, ensuring the surrogate is physics aware.

This $N$-fold sampling is critical as it captures the inherent stochasticity of the biological system (e.g., non-linear interactions between soil moisture and micro-climates) that weather anomalies alone cannot fully explain. It transforms the surrogate from a point-estimator into a stochastic generator, providing the density information required for risk-aware optimization.

The optimization employs a sample average approximation approach to reconcile weather uncertainty. Climate uncertainty is represented by $s \in S$ representative ensemble members (e.g., $S = 5$), capturing large-scale climatic shifts. These encompass worst-case (dry/hot), best-case (wet/cool), and median trajectories. We apply a scenario reduction logic where the probability $P_s$ of discarded ensemble members is redistributed to the closest representative member.

To bridge the gap between high-fidelity mechanistic simulation and stochastic optimization, we apply an impact-based scenario discretization approach. The initial APSIM simulations, which represent the full population of potential biophysical outcomes, are partitioned into five representative climate regimes based on their total annual biomass.

Specifically, we utilize a quantile-based binning method to ensure that the entire variance of climate-driven risks, from extreme failures to optimal harvests, is captured. Each bin represents 20% of the probability

space ( $P_s = 0.20$), effectively discretizing the continuous yield distribution into five distinct states: Worst-case, Lower-Mid, Median, Upper-Mid, and Best-case.

The mean feature vector (weather anomalies) and mean biomass of each quintile serve as the representative scenarios for the CGAN surrogate and the subsequent two-stage stochastic model. This discretization ensures that the hedging decisions are grounded in the actual statistical density of the 30-year climatological baseline, rather than arbitrary weather samples.

## Two-stage stochastic programming formulation

The objective is to minimize the expected total cost (ETC), reconciling deterministic investments with probabilistic recourse impacts:

$$minC_{cultivation}(x) + \sum_s \sum_{j=1}^{N_s} p_{s,j}\ C_{\text{recourse}}(x, s, j), \text{with} \sum_s \sum_j p_{s,j} = 1 \quad (2)$$

Subject to:

$$A_M + A_R + A_{DR} \le A_{tot}, A_k \ge 0 \quad (3)$$

The recourse cost $\mathcal{L}_s^{(j)}$ captures the make-or-buy logic:

$$\mathcal{L}_s^{(j)} = P_{buy} \cdot max\left(0, Q_{target} - \hat{Q}_s^{(j)}\right) - P_{sell} \bullet max\left(0, \hat{Q}_s^{(j)} - Q_{target}\right) \quad (4)$$

where $\hat{Q}_s^{(j)}$ is the total simulated yield for scenario $s$ and Monte Carlo draw $j$, $p_{s,j} = \pi_s/N$. The first term represents the shortfall penalty, and the second term is the credit from surplus sales or recovery. All results and comparisons refer to this total expected cost. Hence, plans with very low cultivation expenditures may still be suboptimal if they induce higher expected shortage or imbalance penalties in the recourse stage.

$$\hat{Q}_s^{(j)} = \sum_{c\in\{m,r\}} A_c \hat{Y}_{c,s}^{(j)} \eta_c\,, \quad (5)$$

where $Y_{c,s}$denotes the realised dry-matter yield ($t/ha$) under scenario $s$, and $\eta_c$is the crop-specific conversion to methane (e.g., $\eta_c = VS_c \times BMP_c, Nm^3\,CH_4/t$). This maps biomass outputs to the contractual unit consistently across monocrop and double-crop cases.

To ensure resilience against tail-risks, we evaluate the Cost Value-at-Risk ( $VaR_{0.95}$). Let $TC_s^{(j)}$ be the realised total cost sample:

$$TC_s^{(j)} = Cost_{seed} + \mathcal{L}_s^{(j)} \quad (6)$$

where $VaR_{0.95}(TC)$ is defined as the 95th percentile of the scenario-weighted cost distribution. This metric allows the operator to quantify the financial exposure during synchronized biophysical failures, beyond simple expected values.

The framework supports rolling updates at crop growth-stage decision epochs $\tau$ (e.g., sowing, early growth, flowering, pre-harvest). At each $\tau$, forecast components in $W_{s,\tau}$ are updated by replacing them with realised observations and refreshed ensemble information, yielding updated scenario inputs and (if required) updated spot price $P_{buy,\tau}$ from latest market quotes. The two-stage problem is resolved with updated inputs. After sowing, $A$ and $D$ remain fixed, while the rolling update refines the procurement hedge under increasingly accurate yield outlooks.

# RESULTS AND DISCUSSION

## Biophysical Yield Response and Sensitivity Analysis

Before optimising the procurement strategy, we first quantify the biophysical response of crop yield to planting density under climatic stress. Figure 2 shows APSIM-simulated dry matter yields of maize and rye as functions of planting density for five representative scenarios selected by ranking all ensemble members by APSIM-implied total annual biomass and taking predefined yield quantiles. In the upper-quantile (favourable) case, maize averages $17.5\ t\ DM \cdot ha^{-1}$and rye $11.0\ t\ DM \cdot ha^{-1}$. In contrast, in the lower-quantile (adverse) case the combined biomass availability declines markedly, with total dry matter reduced to approximately $20.6\ t\ DM \cdot ha^{-1}$. This quantile-based spread provides the empirical basis for the subsequent hedging optimisation, which trades off deterministic cultivation costs against the expected cost of shortfall procurement under low-yield realisations.

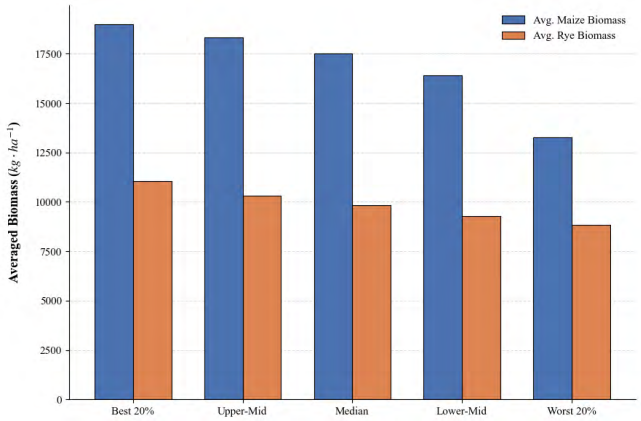

**Figure 2.** Mean crop biomass (dry matter) response for maize and rye under 5 climate ensemble scenarios, categorised by total yield performance quantiles ( $kg \cdot ha^{-1}$ ).

The yield–density relationship is inherently non-linear and strongly regulated by inter-annual climate variability, where increased density does not monotonically

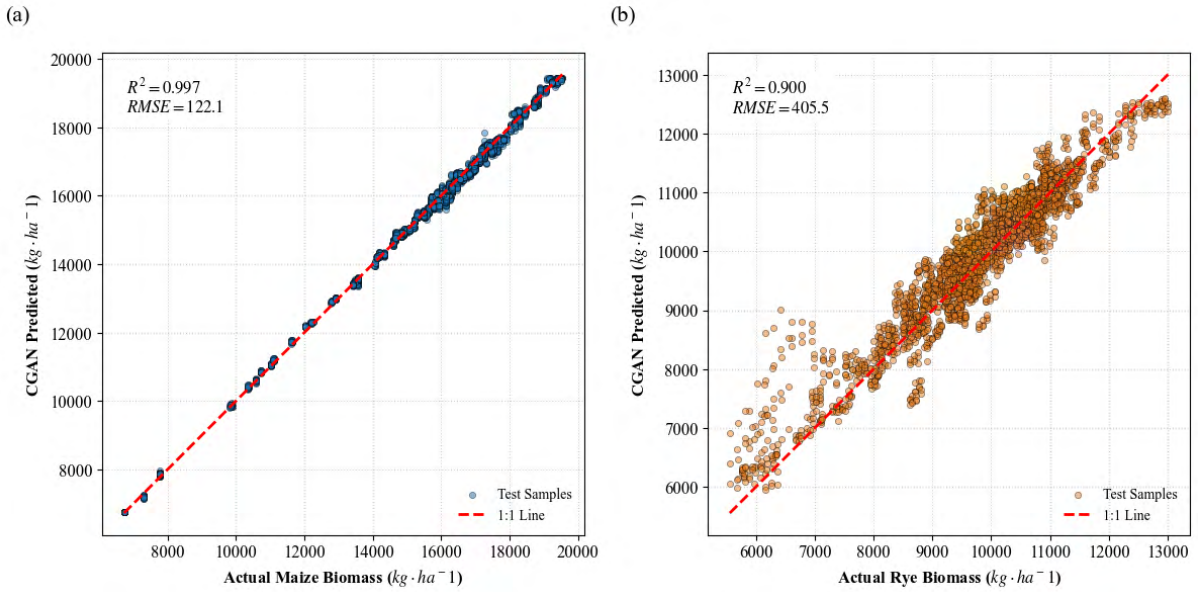

**Figure 3.** Validation of the CGAN surrogate model on the independent test dataset ( $n = 3024$ ). (a) Maize biomass yield. (b) Rye biomass yield.

translate into higher productivity under water-limited conditions [15]. Increasing planting density generally accelerates canopy closure and increases leaf area index (LAI), thereby enhancing the potential for radiation interception. However, LAI is only a proxy for light capture and is not sufficient to determine final biomass or economic yield. Our mechanistic simulations confirm that while higher densities expand radiation interception capacity, they simultaneously exacerbate transpiration demand, potentially triggering yield collapse during synchronized heat-water stress. This non-linear coupling necessitates the use of a mechanistic solver like APSIM to capture the stochastic tipping points that purely statistical models often overlook. Empirically, this often results in a plateauing (or even declining) yield response beyond an intermediate density, with the optimal density shifting across weather scenarios, consistent with our motivation to treat density and area allocation as hedging decisions under uncertainty.

The non-linear yield response and the pronounced quantile gap indicate that a deterministic, average-year calibration is insufficient for procurement planning. Instead, the decision must account explicitly for the distributional tail where shortfall costs concentrate. This motivates the stochastic optimisation model, which hedges the plant's operational costs against low-probability, high-impact adverse seasons. Implementing this framework with APSIM directly is infeasible because the optimisation requires repeated evaluation of yield distributions under many scenarios and decision candidates. To enable fast probabilistic sampling while retaining biophysical realism, we train a CGAN as a surrogate of APSIM.

The predictive performance of the CGAN surrogate model was evaluated using an independent test dataset ( $n = 3024$ scenarios). The parity plots in Figure 3 illustrate the model's ability to replicate the complex biophysical outputs of the APSIM platform across diverse climatic conditions and management intensities.

As shown in Figure 3a, the CGAN achieved superior predictive fidelity for maize biomass ( $R^2 = 0.997$). The data points are tightly clustered along the parity line across the entire productivity spectrum. This indicates that the generative network successfully captures the primary physiological drivers of maize growth under summer conditions. In contrast, the prediction for rye biomass (Figure 3b) exhibited higher variance ( $R^2 = 0.90$). While the general trend remains robust, the increased dispersion suggests that the secondary crop in the system is subject to more complex stochastic influences that are harder for the model to generalize.

Beyond parity and RMSE/$R^2$, we compared the marginal density of maize and rye yields (empirical vs CGAN) and observed close alignment overall; modest overestimation of rye in the lowest decile may slightly favor double-crop hedging under severe-drought scenarios, a point considered in the sensitivity discussion.

A critical observation in the rye validation is the systematic over-estimation in low-productivity regimes. This phenomenon is driven by two main factors. First, unlike maize, which grows during the relatively stable summer window, rye's phenology spans the winter-spring transition. It is highly sensitive to events such as late-spring frosts or erratic rainfall distributions. While APSIM's

mechanistic equations may trigger near-zero yields once stress thresholds are exceeded. As a function approximator, the CGAN tends to soften such hard threshold behavior, producing a less discontinuous lower tail (regression-to-the-mean). The smaller absolute magnitude of rye yields further reduces the signal-to-noise ratio in the joint-output model, potentially biasing learning toward the dominant maize gradients. Importantly, the surrogate shows no drift and preserves the directional response to planting density, supporting its use as a computationally efficient generator of yield samples for Monte Carlo-based stochastic optimization.

We conducted a sensitivity analysis by sweeping the contracted annual production target from $80$ to $200 \times 10^3\ m^3$, spanning regimes from readily achievable to practically infeasible for a 15-ha farm system. For each target level, we solved the land-allocation problem over three cropping options: maize monocropping, rye monocropping, and maize–rye double cropping. Visualised the resulting optimal area shares in Figure 4. Each point on the curve corresponds to the minimum-cost solution (under the defined reliability metric) obtained by enumerating feasible density pairs and searching over land allocations with 1 ha resolution.

Figure 4 reveals a clear regime shift in the optimal allocation as the production target increases. At low targets $(\approx 80 - 110 \times 10^3\ m^3)$, the optimiser predominantly allocates land to maize and rye monocropping, indicating that under moderate contractual requirements, a single-crop strategy provides sufficient biomass supply without relying on intensification. An additional feature in Figure. 4 is the intermittent appearance of a small DR share within the low-target regime, embedded in an otherwise single crop dominated allocation. This should be interpreted as a near-indifference band rather than a qualitative regime change. Under the objective of minimizing expected total cost (seed expenditure plus expected shortfall purchasing), several allocation patterns can become quasi-equivalent in this range. Introducing a marginal area of the DR system may slightly reduce tail shortfall exposure under adverse realizations, which can offset its yield-penalty factor and additional seed inputs. Because the objective differences are small and land is discretized at 1-ha resolution, the optimizer may switch between near-tied allocations across adjacent targets, producing the visually inserted sliver. Importantly, this indicates operational robustness in the low-target regime, that small changes in allocation do not materially affect expected cost or reliability.

Around $110 \times 10^3\ m^3$, the allocation begins to transition. This marks a threshold for operational sustainability, as further increases in target yields bring mono-crop strategies close to their biophysical limits, posing significant risks under unfavourable yield expectations. Beyond this threshold, the optimiser progressively reallocates area away from monocropping and toward intensification via double cropping, which becomes the dominant strategy as targets approach $135 - 140 \times 10^3\ m^3$.

For higher targets ( $> 140 \times 10^3\ m^3$ ), the solution space collapses toward an all-out intensification regime in which almost all land is assigned to double cropping. This indicates that, for a fixed land base, meeting high contractual requirements relies primarily on stacking production within the year rather than marginal tuning of a single crop. Overall, Figure 4 summarises how increasing contractual pressure drives a qualitative change in the optimal procurement strategy, from simple monocropping to increasingly intensive multi-crop deployment. This marks a clear shift in land-allocation behaviour and reveals distinct planning regimes.

To illustrate the decision complexity at a risk-sensitive contract level, we fix the production target at $Q_{tar} = 140 \times 10^3 m^3$ for the 15-ha system and evaluate the cost–reliability trade-off over the feasible land-allocation and density options. We define supply confidence as the probability that internal production meets the contractual target:

$$Confidence = Pr(\hat{\mathrm{Q}} \geq Q_{\mathrm{tar}}) \tag{7}$$

It is estimated via CGAN-based Monte Carlo sampling (scenario-weighted) as the fraction of simulated realizations in which annual supply exceeds the target.

Table 1 summarises three representative strategies spanning the economic-to-reliability spectrum. Land is reported as D/M/R ha, where D denotes maize–rye double cropping, M maize monocropping, and R rye monocropping. Pop denotes planting densities for maize/rye. At the low-input extreme (0/0/15), allocating all land to rye minimises cultivation cost (£5, 536) but achieves only 34.3% confidence, implying frequent reliance on external procurement under adverse yield realizations. A balanced strategy (7/1/7) increases confidence to 59.4% at a moderate cost (£7, 009), reflecting that reallocating hectares toward intensification and diversification can materially reduce downside exposure. The high-reliability extreme (15/0/0) assigns all land to double cropping, achieving the highest confidence observed in this set (85.7%) at the highest cost (£8, 364). Notably, even the most intensive plan does not reach 100% confidence, indicating residual exposure to extreme climate realizations under a fixed 15-ha land constraint. In those cases, recourse actions (spot-market purchases) remain necessary. Practically, these strategies correspond to different managerial priorities. If the operator is cost-constrained and can tolerate frequent recourse purchases, the low-input rye plan is preferred. If a balanced hedge is required, the mixed allocation offers a mid-cost improvement in reliability. If the minimum supply guarantee compliance is the dominant objective, the solution shifts toward full intensification via double cropping.

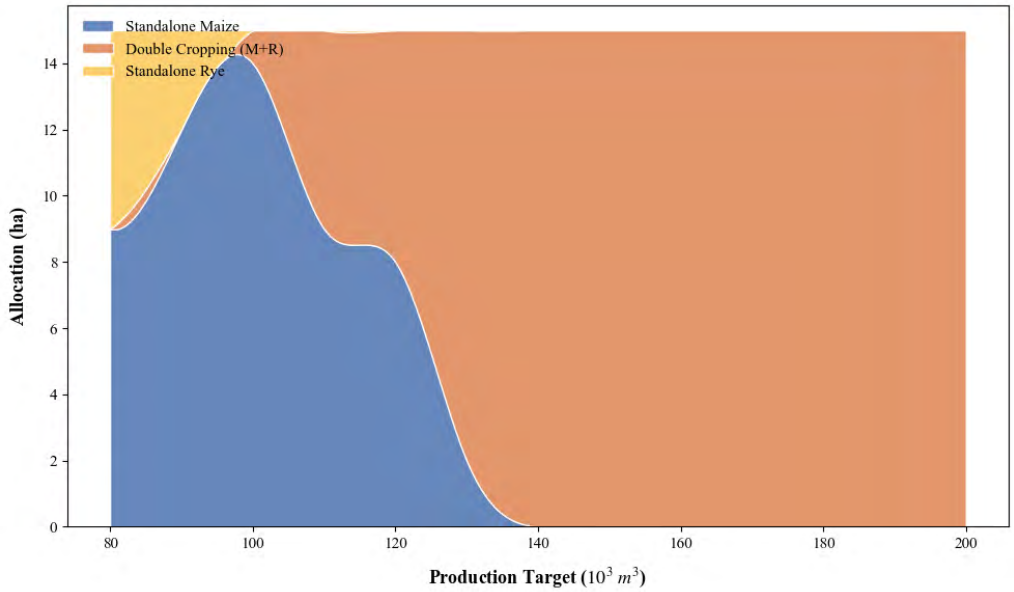

**Figure 4.** Optimal land allocation across production targets for a 15-ha system. For each annual production target ( $80 - 200 \times 10^3$ $m^3$ ), the optimization selects the area (ha) allocated to maize monocropping (blue), rye monocropping (yellow), and maize–rye double cropping (orange). The stacked areas visualise the evolution of the optimal strategy as contractual requirements increase, revealing a threshold-like transition from monocropping-dominated solutions to intensification via double cropping.

Overall, the $140 \times 10^3 m^3$ target represents a regime where the system transitions from cost-first planning to explicit risk mitigation. Hectare-level allocation choices produce large changes in confidence, while marginal cost increases eventually yield decreasing reliability gains. This provides a quantitative basis for contract feasibility discussions, either accepting a target with residual procurement exposure, or complementing agronomic optimisation with target flexibility and/or external buffering arrangements.

**Table 1:** Strategic decision matrix for optimal land allocation under a high production target ( $140 \times 10^3$ $m^3$). The table compares the performance of three Pareto-optimal regimes: Economic, Balanced, and Reliable, extracted from the climate-resilience simulations. Allocations are presented as hectares of double-cropping (D), standalone maize (M), and standalone rye (R).

| Land (D/M/R ha) | Pop (M/R) | Total Cost (£) | Confidence (%) |
|---|---|---|---|
| 0.0/0.0/15.0 | 8/250 | 5, 535.71 | 34.30 |
| 7.0/1.0/7.0 | 8/250 | 7, 008.57 | 59.40 |
| 15.0/0.0/0.0 | 8/250 | 8, 364.29 | 85.70 |

Although the numerical experiments in this paper focus on pre-season planning, the proposed architecture is explicitly designed for stage-based rolling updates. As the season progresses, forecast components in the scenario feature vector $W_{s,\tau}$ can be progressively replaced by realized observations, and procurement price inputs ($P_{spot,\tau}$) can be refreshed from market quotes. This update decreases predictive uncertainty in the CGAN-generated yield distribution and enables rapid re-evaluation of shortfall exposure under the same committed planting plan. Each solve is a two-stage SP with first-stage cropping/procurement decisions and second-stage recourse. Designing explicit mid-season controls is left for the journal version. The surrogate's low evaluation cost is precisely what makes such sequential re-optimisation operationally feasible.

## CONCLUSION

This study addresses the robustness of AD feedstock procurement under extreme climate uncertainty by developing a closed-loop decision support system encompassing weather scenario synthesis, mechanistic yield generation and stochastic planting decision optimization with rolling updates. Through typical case study, the study concludes that:

- The CGAN surrogate trained on APSIM simulations reproduces non-linear yield responses to climate variability and management intensity with strong out-of-sample agreement. This provides realistic, distributional yield inputs for downstream

stochastic optimization, enabling planners to hedge against downside under-yield tail events rather than relying on mean-year assumptions.

- The optimal planting structure (land allocation across monocropping vs double cropping, and discrete planting densities) is highly target dependent. As the contracted gas target increases, the decision space compresses and the optimal policy exhibits regime shifts. Low targets admit multiple low-cost feasible allocations, whereas high targets push the system toward intensification and diversification, which reveals threshold-like behavior consistent with biophysical and land constraints.
- A cost–reliability trade-off evaluation at the intensified target level ($140 \times 10^3 m^3$) shows residual exposure even under maximal intensification. In our case study, the most reliable strategy still requires recourse procurement in approximately 14.3% of realizations. It quantifies the remaining vulnerability to extreme climate outcomes under a fixed land base and highlights a practical carrying-capacity ceiling for contract design.
- In practice, the framework yields three actionable strategy classes: economical, balanced, and reliability oriented. Multiple strategies allow decision-makers to select policies aligned with budget and risk preferences. The rolling (stage-based) update capability allows the procurement hedge to be revised as forecast uncertainty collapses through the season, improving decision timeliness without changing already-committed sowing decisions.

## ABSTRACT

In this study, we propose a method to uniquely determine robust operating conditions for simulated moving bed (SMB) chromatography, an essential continuous liquid-phase separation technique in the pharmaceutical industry, in the form of explicit algebraic equations. The proposed method incorporates process robustness—defined as the probability of meeting the target purities under flow-rate uncertainty due to pump errors—without requiring computationally expensive dynamic simulations. In a computational demonstration, the method achieved a joint probability of 0.960 for simultaneously attaining 99.9% purity in both extract and raffinate products.

**Keywords**: Adsorption, Process Design, Process Operations, Optimization, Design Under Uncertainty

## INTRODUCTION

Simulated moving bed (SMB) chromatography is a continuous liquid-phase separation technique widely used in the pharmaceutical and petrochemical industries. SMB is based on the concept of true moving bed (TMB) chromatography (Fig. 1a), in which continuous separation is achieved by countercurrent contact between a liquid phase and a solid adsorbent. In SMB, the countercurrent separation in TMB is mimicked by connecting multiple chromatographic columns in a semi-closed loop and periodically switching the inlet/outlet ports (Fig. 1b). These ports serve to supply the feed and desorbent and to withdraw the two product fractions, extract and raffinate. The port roles are switched simultaneously in the direction of the internal fluid flow at fixed time intervals, referred to as the step time.

This dynamic port switching adds substantial operational complexity to SMB; consequently, it is highly challenging to determine robust operating conditions—four zone flow rates and the step time—that simultaneously enhance productivity and guarantee high purity as required in pharmaceutical applications, under unavoidable uncertainties such as pump errors. Mazzotti et al. proposed the well-known triangle theory [1], which enables

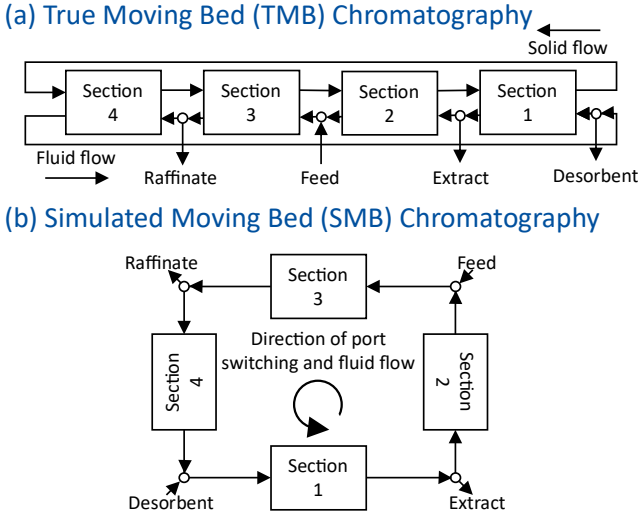

**Figure 1.** Schematic diagram of (a) true moving bed chromatography process and (b) simulated moving bed chromatography process.

SMB operating conditions to be determined solely from algebraic equations based on a TMB process model. Although Triangle Theory remains the most widely used method for selecting SMB operating conditions, it does not provide a systematic way to identify robust

conditions in the presence of flow-rate uncertainties caused by pump errors. Note that they pointed out that the triangle theory can account for robust operation in a trial-and-error manner. Recently, sampling-based uncertainty quantification for SMB has been explored [2]; however, uncertainty quantification alone may require a large number of dynamic simulations, making the computational cost prohibitive for robust operating-condition determination.

In this study, we propose a method to uniquely determine robust SMB operating conditions under flow-rate uncertainty, without requiring any dynamic simulations. Specifically, the robust operating conditions under flow-rate uncertainty are derived analytically as explicit algebraic equations. This formulation enables a substantial reduction in computational cost for operating-condition selection. The robustness of the derived conditions is quantified by probability of achieving the target purities for the extract and raffinate products [3] and is validated computationally using dynamic simulations. In our case study, the probability that a purity of 99.9% is simultaneously achieved in both products was 0.960.

# METHODS

## Derivation of Unique Operating Condition

In this section, we present a method for uniquely determining robust SMB operating conditions in the presence of flow-rate uncertainty. Building on the triangle theory [1] as the theoretical foundation, we derive explicit algebraic equations for the robust operating conditions, expressed as dimensionless flow rates of the four zones (Fig. 1a, b), which are normalized by step time. According to the triangle theory, the dimensionless flow rate in $j$th zone, $m_j$, is defined as:

$$m_j = \left(Q_j t^{\mathrm{step}} - V_{\mathrm{zone}}\epsilon\right)\!/V_{\mathrm{zone}}(1-\epsilon), j = 1,2,3,4, \quad (1)$$

where $Q_j, t^{\mathrm{step}}, V_{\mathrm{zone}}$, and $\epsilon$ are the volumetric flow rate in $j$th zone, step time, total zone volume, and the total porosity, respectively. In this study, the adsorption equilibrium of the two components is described by the following competitive Langmuir isotherm:

$$q_i^j = H_i C_i^j \!/\left(1 + b_1 C_1^j + b_2 C_2^j\right), i = 1,2, \quad (2)$$

where $q_i^j$ and $C_i^j$ represent the solid-phase and the liquid-phase concentrations for $i$th component in $j$th zone, respectively; $H_i$ and $b_i$ refer to the Henry's constant and the affinity coefficient for $i$th component. Under Eq. (2), the triangle theory provides the conditions on $m_j$ required to achieve complete separation—i.e., 100% purity for both extract and raffinate—through the following three inequalities:

$$H_2 < m_1 < \infty, \quad (3)$$

$$m_{2,\min}(m_2, m_3) < m_2 < m_3 < m_{3,\max}(m_2, m_3), \quad (4)$$

$$-\epsilon\!/(1-\epsilon) < m_4 < m_{4,\max}(m_2, m_3), \quad (5)$$

where $m_{2,\min}(\bullet), m_{3,\max}(\bullet)$, and $m_{4,\max}(\bullet)$ stand for algebraic functions defined by the triangle theory [1].

In this study, the uncertainty in the dimensionless flow rates of the four zones arising from pump errors is modeled by a four-dimensional multivariate normal distribution:

$$\tilde{\boldsymbol{m}} \sim \mathrm{p}(\boldsymbol{m}) = N(\boldsymbol{m}, \boldsymbol{\Sigma}), \boldsymbol{m} = [m_1, m_2, m_3, m_4]^T \quad (6)$$

where $\tilde{\boldsymbol{m}}$ denotes the uncertain (random) vector of dimensionless flow rates, and $\boldsymbol{m}$ is its mean vector. The matrix $\boldsymbol{\Sigma}$ is the covariance matrix; its entries $\Sigma_{k,l}$ are not necessarily zero. Derivation of $\boldsymbol{\Sigma}$ can be found in the literature [4].

The robust operating condition $\boldsymbol{m}^*$—i.e., the set-point flow-rate vector to be specified for the pumps while accounting for pump errors—is determined by the following multiobjective optimization problem:

$$m_1^* = \arg\min_{\boldsymbol{m}} m_1 - H_2 \quad (7)$$

$$(m_2^*, m_3^*) = \arg\max_{\boldsymbol{m}} m_3 - m_2 \quad (8)$$

$$m_4^* = \arg\min_{\boldsymbol{m}} m_{4,\max}(m_2^*, m_3^*) - m_4 \quad (9)$$

*s.t.* all set of $\boldsymbol{m}$ in the following Eq. (10) satisfy Eqs. (3)-(5) simultaneously:

$$(\tilde{\boldsymbol{m}} - \boldsymbol{m})^T \boldsymbol{\Sigma}^{-1} (\tilde{\boldsymbol{m}} - \boldsymbol{m}) \le \chi^2_{n=4}(\mu). \quad (10)$$

Here, the three objective functions in Eqs. (7)–(9) represent desorbent consumption, productivity, and enrichment, respectively. In Eq. (10), $\chi^2_{n=4}(\mu)$ is the $\mu$-quantile of the chi-square distribution and $n$ refers to the degrees of freedom. Because $\mu \in [0,1)$, the conservativeness can be arbitrarily adjusted by controlling how much flow-rate uncertainty is considered. Note that this optimization problem cannot be solved analytically and therefore requires a numerical solution. In this study, we derive an analytical solution by reformulating it as a two-stage optimization [4]: Eq. (8) is treated as the primary objective function, while Eqs. (7) and (9) are considered as subsequent objectives.

Consequently, we derive a closed-form expression for the robust operating condition $\boldsymbol{m}^*$, given by the following explicit algebraic equations:

$$\begin{bmatrix} m_2^* \\ m_3^* \end{bmatrix} = -\boldsymbol{A}^{-1}\left(\boldsymbol{\Gamma}_{23} + \boldsymbol{n}_{23}\sqrt{\chi^2_{n=2}(\mu)}\right), \quad (11)$$

$$\begin{bmatrix} m_1^* \\ m_4^* \end{bmatrix} = \boldsymbol{\Gamma}_{14} + \boldsymbol{n}_{14}\sqrt{\chi^2_{n=2}(\mu)}, \quad (12)$$

$$\boldsymbol{A} = \begin{bmatrix} H_2 - H_1\left(1 + b_2 C_2^F\right) & b_2 C_2^F H_1 \\ H_2 - \omega_G\left(1 + b_2 C_2^F\right) & b_2 C_2^F \omega_G \end{bmatrix}, \quad (13)$$

$$\boldsymbol{\Gamma}_{23} = \begin{bmatrix} -H_1(H_2 - H_1) \\ -\omega_G(H_2 - \omega_G) \end{bmatrix}, \tag{14}$$

$$\boldsymbol{n}_{23} = \begin{bmatrix} \sqrt{[A_{11}, A_{12}] \begin{bmatrix} \Sigma_{22} & \Sigma_{23} \\ \Sigma_{32} & \Sigma_{33} \end{bmatrix} [A_{11}, A_{12}]^T} \\ \sqrt{[A_{21}, A_{22}] \begin{bmatrix} \Sigma_{22} & \Sigma_{23} \\ \Sigma_{32} & \Sigma_{33} \end{bmatrix} [A_{21}, A_{22}]^T} \end{bmatrix}, \tag{15}$$

$$\boldsymbol{\Gamma}_{14} = \begin{bmatrix} H_2 \\ m_{4,\max}(m_2^*, m_3^*) \end{bmatrix}, \tag{16}$$

$$\boldsymbol{n}_{14} = \begin{bmatrix} \sqrt{\Sigma_{11}} \\ \sqrt{\Sigma_{44}} \end{bmatrix}, \tag{17}$$

where $C_i^F$ represents feed concentration for $i$th component and $\omega_G$ is a solution of quadratic equation given by the triangle theory [1]. Thus, without performing computationally expensive SMB dynamic simulations, the robust operating condition $\boldsymbol{m}^*$ can be determined simply by substituting the a priori identifiable parameters $C_i^F, H_i, b_i, \Sigma$, and $\mu$ into Eqs. (11) and (12).

## Process Robustness Quantification

In this study, SMB process robustness is defined as the probability of achieving purities at or above the specified target purity, and this metric is used to evaluate the robust operating conditions $\boldsymbol{m}^*$ determined by Eqs. (11) and (12). This quantified process robustness is computed from the joint predictive distribution of the extract and raffinate purities, $\mathrm{p}(P_E, P_R)$, obtained under the flow-rate uncertainty $\mathrm{p}(\boldsymbol{m})$, as follows:

$$\mathrm{p}(P_E, P_R) = \int_{\mathcal{M}} \mathrm{p}(P_E, P_R|\boldsymbol{m})\mathrm{p}(\boldsymbol{m})d\boldsymbol{m} \tag{18}$$

where $P_E$ and $P_R$ refer to extract and raffinate purities, respectively; $\mathcal{M}$ denotes the uncertainty region defined by $\mathrm{p}(\boldsymbol{m})$; $\mathrm{p}(P_E, P_R|\boldsymbol{m})$ is a probabilistic model based on the SMB process model, which is formulated as a system of coupled partial differential–algebraic equations [3]. Additionally, the predictive distribution of the purity for a single product can be obtained by marginalizing the joint distribution $p(P_E, P_R)$, i.e., by integrating out the other purity variable, as follows:

$$\mathrm{p}(P_s) = \int_0^{100} \mathrm{p}(P_E, P_R)dp_{\hat{s}}, (s, \hat{s}) = (E, R), (R, E). \tag{19}$$

The process robustness is computed by integrating the joint predictive distribution $\mathrm{p}(P_E, P_R)$ from the specified target purities $r_E$ and $r_R$ up to 100 as follows:

$$\mathrm{P}(P_E \geq r_E, P_R \geq r_R) = \int_{r_E}^{100} \int_{r_R}^{100} \mathrm{p}(P_E, P_R)dP_E dP_R, \tag{20}$$

where $\mathrm{P}(P_E \geq r_E,\ P_R \geq r_R)$ is the joint probability that the purities of extract and raffinate simultaneously meet or exceed the target values $r_E$ and $r_R$, respectively. Similarly to Eq. (19), the probability for a single product purity (i.e., the marginal probability) is obtained as follows:

$$\mathrm{P}(P_s \geq r_s) = \int_{r_s}^{100} \mathrm{p}(P_s)dP_s, s = R, E. \tag{21}$$

# RESULTS

We determined the robust operating conditions $\boldsymbol{m}^*$ using Eqs. (11) and (12), and quantified the process robustness of $\boldsymbol{m}^*$ by the marginal probability (Eq. (21)) or the joint probability (Eq. (20)). The SMB scale and model parameters were taken from the study by Grosfils *et al.* [5], as shown in Table 1. Here, $\sigma_{\mathrm{pump}}$ denotes the standard deviation of the pump error used to construct the covariance matrix $\boldsymbol{\Sigma}$ in Eq. (6). Details of the derivation of $\boldsymbol{\Sigma}$ from $\sigma_{\mathrm{pump}}$ are available in the literature [4].

**Table 1:** Parameters used in this study [5].

| parameter | value | parameter | value |
|---|---|---|---|
| $C_1^F$ [g/L] | 1.20 | $C_2^F$ [g/L] | 1.20 |
| $H_1$ [ - ] | 3.23 | $H_2$ [ - ] | 6.50 |
| $b_1$ [L/g] | 0.210 | $b_2$ [L/g] | 0.422 |
| $\epsilon$ [ - ] | 0.620 | $V_{\mathrm{zone}}$ [mL] | 141 |
| $t^{step}$ [s] | 300 | $\sigma_{\mathrm{pump}}$ [mL/s] | 0.124 |

When the conservativeness parameter $\mu$ is varied over $[0, 1)$, Eqs. (11) and (12) determine the four dimensionless flow rates $\boldsymbol{m}^*$ by reconciling the three objective functions in Eqs. (7)–(9), in particular at the expense of the primary objective, productivity (Eq. (8)). In this study, $\mu$ was set to six values: 0, 0.05, 0.25, 0.5, 0.75, and 0.99. Note that at $\mu = 0$, Eqs. (11) and (12) reduce exactly to the theoretical optimum in the triangle theory. As can be seen from Table 2, increasing $\mu$ leads to a simultaneous increase in $m_1^*, m_2^*$, and $m_4^*$, and a decrease in $m_3^*$; i.e. increasing $\mu$ results in higher desorbent consumption, lower productivity, and lower enrichment.

**Table 2:** Determined robust operating conditions $\boldsymbol{m}^*$ by the proposed method (Eqs. (11) and (12)). Note that $\boldsymbol{m}^*$ are shown to three decimal places for comparison across different $\mu$ values.

| $\mu$ | $m_1^*$ | $m_2^*$ | $m_3^*$ | $m_4^*$ |
|---|---|---|---|---|
| 0 | 6.500 | 2.491 | 3.968 | 2.556 |
| 0.05 | 6.547 | 2.609 | 3.970 | 2.555 |
| 0.25 | 6.611 | 2.771 | 3.972 | 2.556 |
| 0.50 | 6.672 | 2.925 | 3.974 | 2.560 |
| 0.75 | 6.744 | 3.105 | 3.977 | 2.570 |
| 0.99 | 6.944 | 3.609 | 3.984 | 2.644 |

For the target purities $r_E = r_R = 99.9$, the proposed method (Eqs. (11) and (12)) enabled the determination of robust operating conditions $\boldsymbol{m}^*$ with an arbitrary level of conservativeness by varying $\mu$. Using dynamic simulations of the SMB process model [3], we estimated Eqs. (18) and (19) and quantified the process robustness of each of the six $\boldsymbol{m}^*$ in Table 2 using Eqs. (20) and (21). As shown in Table 3, $\mathrm{P}(P_E \geq r_E), \mathrm{P}(P_R \geq r_R)$, and $\mathrm{P}(P_E \geq r_E,\ P_R \geq$

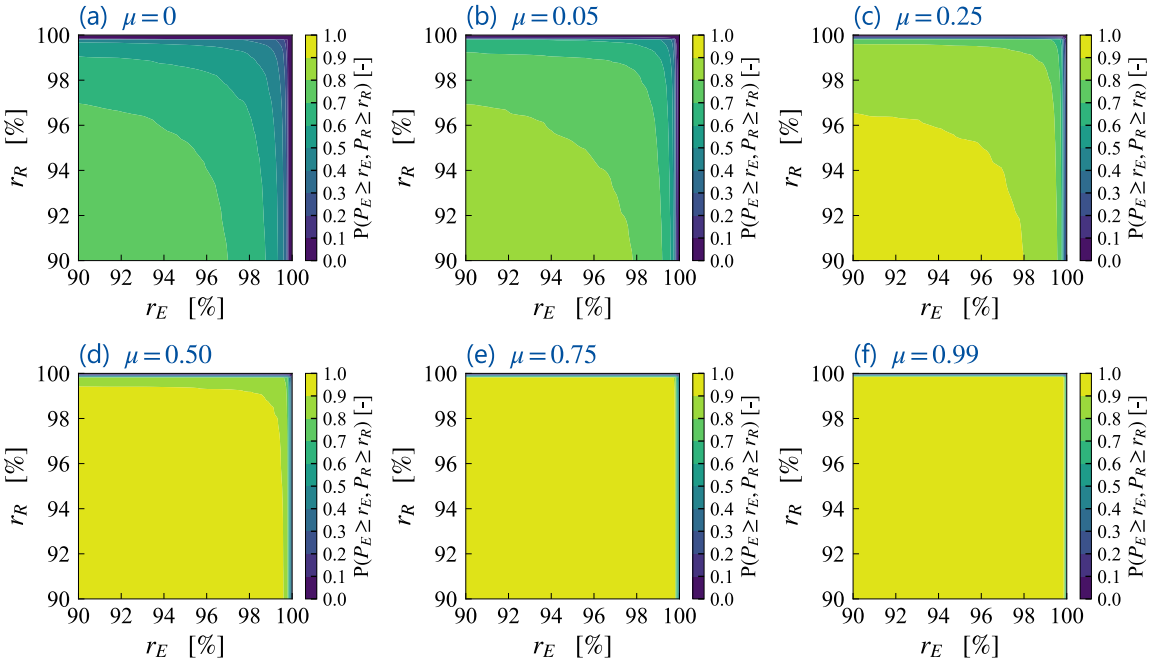

**Figure 3:** Comparison of six robust operating conditions by a contour plot of $\mathrm{P}(P_E \geq r_E, P_R \geq r_R)$: (a) $\mu = 0$. (b) $\mu = 0.05$. (c) $\mu = 0.25$. (d) $\mu = 0.50$. (e) $\mu = 0.75$. (f) $\mu = 0.99$. The color bar on the right side of each contour plot refers to the value of $\mathrm{P}(P_E \geq r_E, P_R \geq r_R)$.

$r_R$) all increase with $\mu$. Particularly, at $\mu = 0.99$, all values exceed 0.950. Thus, $\mu = 0.99$ yields a robust operating condition $\boldsymbol{m}^*$ for $r_E = r_R = 99.9$.

**Table 3:** Values of process robustness at $\mu$ quantified by Eqs. (20) and (21) at the target purity as $r_E = r_R = 99.9$.

| $\mu$ | $\mathrm{P}(P_E \geq 99.9)$ | $\mathrm{P}(P_R \geq 99.9)$ | $\mathrm{P}\left(\begin{matrix}P_R \geq 99.9,\\ P_E \geq 99.9\end{matrix}\right)$ |
|---|---|---|---|
| 0 | 0.113 | 0.133 | 0.0104 |
| 0.05 | 0.268 | 0.239 | 0.0646 |
| 0.25 | 0.485 | 0.436 | 0.245 |
| 0.50 | 0.651 | 0.617 | 0.462 |
| 0.75 | 0.802 | 0.789 | 0.689 |
| 0.99 | 0.973 | 0.978 | 0.960 |

When examining the response of the process robustness with the target purity treated as a variable, the trend of robustness of extract purity, $\mathrm{P}(P_E \geq r_E)$, with respect to the target value $r_E$ changes markedly depending on $\mu$. As observed in Fig. 2a, increasing $\mu$ transforms $\mathrm{P}(P_E \geq r_E)$ from a gently varying curve into a more sharply curved profile that remains close to $\mathrm{P}(P_E \geq r_E) = 1.0$ over a wide range of $r_E$. This change in curvature indicates that the robustness of the extract purity is strongly influenced by $\mu$.

In contrast, the robustness of the raffinate purity, $\mathrm{P}(P_R \geq r_R)$, with respect to its target value $r_R$ is less sensitive to $\mu$ than $\mathrm{P}(P_E \geq r_E)$. As shown in Fig. 2b, even as $\mu$ is varied from 0 to 0.99, the overall profile remains similar: $\mathrm{P}(P_R \geq r_R)$ decreases linearly for $r_R < 98.0$ and then exhibits a sharp drop at $r_R \approx 99.0$. The difference between the shapes of the $\mathrm{P}(P_E \geq r_E)$and $\mathrm{P}(P_R \geq r_R)$ curves in Figs. 2a and 2b arises from the shape of the shock fronts in the internal concentration profiles of the SMB process, as discussed in detail in the literature [3].

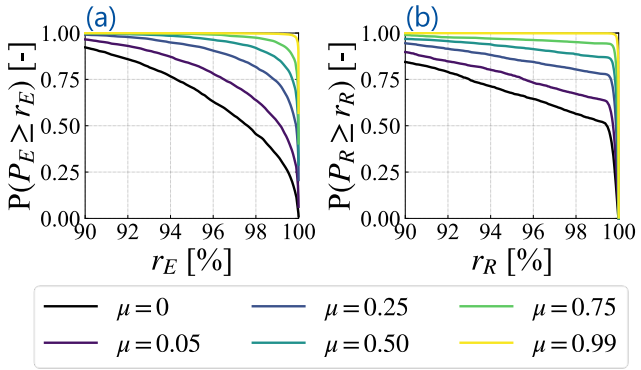

**Figure 2.** Comparison of process robustness with $\mu$. (a) Change of robustness $\mathrm{P}(P_E \geq r_E)$ through the target extract purity $r_E$. (b) Change of robustness $\mathrm{P}(P_R \geq r_R)$ through the target raffinate purity $r_R$.

By comparing the joint probability $\mathrm{P}(P_E \geq r_E, P_R \geq r_R)$ across the six $\mu$ values, we found that an appropriate choice of $\mu$ for efficient SMB operation under the flow-

rate uncertainty depends on the target purities $r_E$ and $r_R$. As shown in Fig. 3, an area where $\mathrm{P}(P_E \geq r_E,\, P_R \geq r_R) \geq 0.90$ first appear at $\mu = 0.25$ (Fig. 3c). With further increases in $\mu$, the area expands; however, at $\mu = 0.75$ (Fig. 3e) most of the domain already attains $\mathrm{P}(P_E \geq r_E,\, P_R \geq r_R) \geq 0.90$, and little additional expansion is observed when increasing $\mu$ to 0.99 (Fig. 3f). Although, as shown in Table 2, the difference between $\mu = 0.75$ and $\mu = 0.99$ is pronounced for stringent targets of 99.9%, this difference becomes negligible for moderate targets such as 95.0 or 99.0. These results indicate that $\mu$ should be selected by simultaneously considering the desired process robustness at the specified target purities and the other performance metrics in Eqs. (7)–(9).

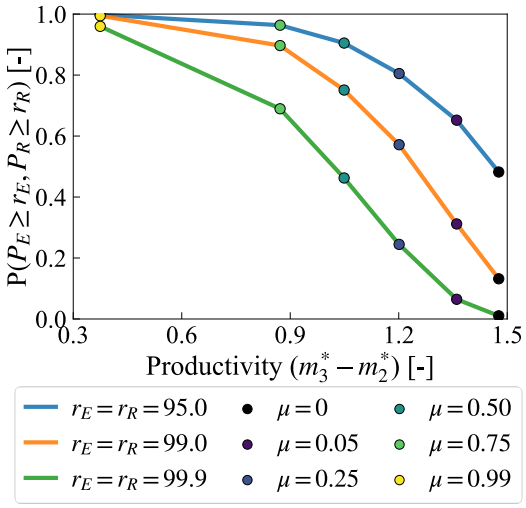

**Figure 4.** Trade-off relationship between productivity and robustness $\mathrm{P}(P_E \geq r_E, P_R \geq r_R)$ at three target purities.

The choice of an appropriate $\mu$ should be guided by the trade-off between process robustness (Eq. (20)) and productivity, which is treated as the primary objective function (Eq. (8)). As shown in Fig. 4, the trade-off curve for $r_E = r_R = 99.9$ is nearly linear, indicating that robustness can be increased at the expense of productivity in an approximately proportional manner. In contrast, the trade-off curves for targets of 95.0 and 99.0 are convex toward the upper right, implying diminishing returns: increasing $\mu$ beyond 0.75 yields little improvement in robustness. In particular, for the 95.0 target, the joint probability already satisfies $\mathrm{P}(P_E \geq 95.0,\, P_R \geq 95.0) \geq 0.90$ at $\mu = 0.50$. These results highlight that, within the proposed framework, selecting $\mu$ appropriately under the robustness–productivity trade-off is essential and should be tailored to the desired target purities.

## CONCLUSION

We proposed a methodology to determine robust SMB operating conditions under flow-rate uncertainty in the form of explicit algebraic equations. We further evaluated the robustness and discussed an appropriate conservativeness parameter. Experimental validation of the method constitutes an important direction for future work.

## ABSTRACT

A topology optimization approach is applied to the design of a compact fluid distribution device that achieves uniform flow distribution among parallel channels while minimizing the mean residence time under a pressure loss constraint. Such devices are widely used in applications including parallel microreactors, thermal management systems, and energy devices, where both compactness and precise flow control are required. The design problem is formulated using a density-based method in which the design variable represents the local void fraction of a fictitious porous medium. The governing equations are based on the incompressible Navier–Stokes equations with an additional Darcy-type resistance term. The objective function is defined as the spatially averaged design variable, corresponding to the minimization of the effective flow passage volume and thus the mean residence time. Constraints are imposed on both flow rate uniformity among parallel channels and the total pressure loss. A two-stage topology optimization strategy is proposed to obtain physically realizable geometries. The results show that the proposed strategy effectively removes non-functional regions while preserving flow uniformity, leading to compact designs. Furthermore, numerical investigations reveal that designs with fewer early-stage bifurcations tend to achieve smaller flow passage areas under identical pressure loss conditions. These findings demonstrate that topology optimization provides a rational and flexible framework for the systematic design of compact fluid distribution devices.

## INTRODUCTION

The performance of many engineering systems strongly depends on their geometrical configuration, yet the optimal shape is rarely obvious. In such cases, systematic design methods based on mathematical optimization provide a powerful alternative to conventional trial-and-error approaches. Among various structural optimization techniques, topology optimization has attracted increasing attention because it allows the material distribution within a prescribed design domain to be optimized, enabling the generation of novel and non-intuitive structures.

In recent years, topology optimization has been successfully extended from structural mechanics to fluid mechanics. Several studies have demonstrated the potential of topology optimization for fluid flow problems, including flow channel design, heat transfer enhancement, and microfluidic devices. Comprehensive reviews of topology optimization methods for fluid-based systems can be found in recent literature [1, 2]. Since the pioneering work on topology optimization for Stokes flow [3], the method has been successfully applied to a wide range of fluid-related problems, including channel flow optimization [4] and catalytic microreactors [5]. These studies have shown that topology optimization can significantly enhance performance compared with conventional heuristic designs.

Fluid distribution devices, which distribute an inlet flow into multiple parallel channels, are widely used in various applications such as parallel microreactors, fuel cell stacks, heat exchangers, and thermal management systems [6, 7]. In such systems, uniform flow distribution among channels is crucial for achieving high performance and operational safety. Uneven flow distribution can lead to issues such as local overheating, reduced efficiency,

and degradation of device lifetime [6, 7].

Although various design strategies for fluid distribution devices have been proposed, including geometrical optimization based on CFD simulations [8], biomimetic or fractal-inspired designs [9], and empirically optimized manifold structures [10], most conventional approaches rely on predefined geometrical configurations and parametric tuning. As a result, the design freedom is inherently limited, and the obtained solutions may not be globally optimal.

To overcome these limitations, topology optimization offers a promising framework for the rational design of fluid distribution devices. A previous study demonstrated the feasibility of achieving target flow distributions using topology optimization [11]. However, this study primarily focused on objectives such as energy dissipation minimization, while the compactness of the device, which is closely related to the mean residence time, has received less attention. In practical applications, the mean residence time is a key performance indicator because it directly affects reactor productivity, system responsiveness, and overall device size. Therefore, designing a compact fluid distribution device while maintaining uniform flow distribution is of great practical importance.

In the present study, topology optimization is applied to the design of a fluid distribution device that achieves uniform flow distribution among parallel channels while minimizing the mean residence time under a pressure loss constraint. The optimization problem is formulated using a density-based method, and a two-stage optimization strategy is introduced to obtain physically realizable geometries. Furthermore, the effects of pressure loss constraints, initial design variables, and the number of parallel channels on the optimized designs are systematically investigated.

## PROBLEM FORMULATION AND METHODOLOGY

### Design problem

In this study, the topology optimization of a fluid distribution device is conducted using the same two-dimensional geometry as that employed in [11], in order to enable a direct comparison with the previous study.

A schematic of the computational domain is shown in Fig. 1. The design domain is defined between a single inlet and multiple outlet channels, and topology optimization is performed only within this region. The inlet velocity is specified as a uniform profile, and pressure boundary conditions are imposed at the outlets. No-slip boundary conditions are applied on all solid walls.

The optimization problem is formulated such that the objective function corresponds to the minimization of the spatially averaged design variable over the design domain. Since the design variable represents the local void fraction of the porous medium, minimizing its average value leads to a reduction in the effective flow passage volume, which is equivalent to minimizing the mean residence time of the fluid. Two constraints are imposed in the optimization problem. The first constraint ensures uniformity of flow rates among all outlet channels, which is evaluated by the normalized deviation of individual outlet flow rates from the target value. The second constraint is imposed on the total pressure loss between the inlet and the outlets to ensure practical operating conditions. Accordingly, the design problem is formulated as a constrained optimization problem with the objective of minimizing the mean residence time while satisfying the constraints on flow rate uniformity and pressure loss.

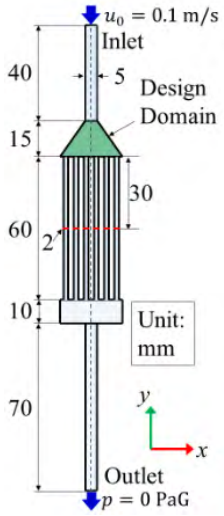

**Figure 1.** Computational domain and design domain [11].

### Topology optimization method

In this study, a density-based topology optimization method is employed to determine the optimal material distribution within the design domain. The design variable is defined as a continuous scalar field that represents the local void fraction of a fictitious porous medium, taking values between 0 (solid region) and 1 (fluid region).

To model the presence of the porous medium, a Darcy-type resistance term is introduced into the momentum equations. The inverse permeability is interpolated as a function of the design variable, such that high resistance is imposed in solid-like regions and negligible resistance is applied in fluid-like regions. This approach enables a smooth transition between solid and fluid regions during the optimization process.

To avoid numerical instabilities such as checkerboard patterns and mesh dependency, a PDE-based filtering technique is applied to the design variable. Furthermore, a smoothed Heaviside projection is employed to promote clear separation between solid and fluid regions and to reduce gray-scale regions in the optimized designs.

The optimization problem is solved using a gradient-based algorithm. Sensitivities of the objective function and constraints with respect to the design variables are evaluated using the adjoint method. The design variables are then updated iteratively until convergence is achieved.

## Governing equations

The fluid flow in the design domain is modeled as a steady, incompressible laminar flow. The governing equations are the incompressible Navier–Stokes equations with an additional Darcy-type resistance term to represent the effect of the fictitious porous medium.

The continuity equation is given by

$$\nabla \cdot \boldsymbol{u} = 0 \tag{1}$$

where $\boldsymbol{u}$ denotes the velocity vector. The momentum equation is expressed as

$$\rho(\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = -\nabla p + \mu \nabla^2 \boldsymbol{u} - \alpha(\gamma)\boldsymbol{u} \tag{2}$$

where $p$ is the pressure, $\rho$ is the fluid density, and $\mu$ is the dynamic viscosity. The last term represents the Darcy-type resistance introduced to model the porous medium. The inverse permeability $\alpha(\gamma)$ is defined as a function of the design variable $\gamma$, such that high resistance is imposed in solid-like regions and low resistance is imposed in fluid-like regions.

Specifically, the inverse permeability is interpolated using a convex function of the design variable, which allows a smooth transition between solid and fluid phases during the optimization process. This formulation enables the flow field to be continuously modified as the design variable evolves.

These governing equations are solved numerically using the finite element method at each optimization iteration to evaluate the objective function and constraints.

## Objective function and constraints

The optimization problem is formulated to minimize the mean residence time of the fluid while satisfying constraints on flow rate uniformity and pressure loss.

As described in the previous section, the design variable $\gamma$ represents the local void fraction of the fictitious porous medium. Therefore, the mean residence time is proportional to the effective flow passage volume in the design domain. In this study, the objective function is defined as the spatially averaged design variable over the design domain $\Omega_d$, given by

$$J(\gamma) = \frac{1}{\Omega_d} \int_{\Omega_d} \gamma \, d\Omega \tag{3}$$

where $|\Omega_d|$ denotes the area of the design domain. Minimizing this objective function corresponds to minimizing the effective flow volume and thus the mean residence time.

To ensure uniform flow distribution among the outlet channels, a constraint on the outlet flow rates is imposed. The flow rate through the $i$-th outlet, $Q_i$, is evaluated by integrating the normal velocity over the outlet boundary. The flow uniformity constraint is defined based on the normalized deviation of each outlet flow rate from the target value $Q_{\text{target}}$, expressed as

$$g_1 = \frac{1}{N} \sum_{i=1}^{N} \left| \frac{Q_i - Q_{\text{target}}}{Q_{\text{target}}} \right| \leq \varepsilon \tag{4}$$

where $N$ is the number of outlet channels and $\varepsilon$ is a prescribed tolerance.

In addition, a constraint is imposed on the total pressure loss between the inlet and the outlets to ensure practical operating conditions. The pressure loss $\Delta p$ is defined as the difference between the spatially averaged inlet pressure and the averaged outlet pressure, and the constraint is expressed as

$$g_2 = \Delta p \leq \Delta p_{\max} = \beta \Delta p_0 \tag{5}$$

where $\Delta p_{\max}$ denotes the allowable maximum pressure loss, $\Delta p_0$ is the pressure loss that would be obtained if the entire design domain is completely open to flow, and $\beta$ is the design parameter.

Accordingly, the optimization problem is formulated as a constrained minimization problem with the objective of minimizing the mean residence time subject to the constraints on flow rate uniformity and pressure loss.

## Optimization procedure

The optimization problem is solved using a gradient-based optimization algorithm. At each iteration, the governing equations described in the previous section are solved to obtain the velocity and pressure fields, from which the objective function and constraint values are evaluated. All simulations were performed using COMSOL Multiphysics® 6.0, which provides a finite element framework for solving the governing equations and implementing topology optimization.

The sensitivities of the objective function and constraints with respect to the design variables are computed using the adjoint method. Gradient-based optimization methods are widely used in topology optimization because they efficiently handle large numbers of design variables through adjoint sensitivity analysis, making them computationally more efficient than population-based optimization methods for high-dimensional design problems. This approach enables efficient sensitivity evaluation with a computational cost that is independent of the number of design variables, making it suitable for large-scale topology optimization problems.

The design variables are updated iteratively using the Method of Moving Asymptotes (MMA), which is widely used in topology optimization due to its robustness and numerical stability. During the optimization process, the filtering and projection techniques described in

the previous section are applied at each iteration to ensure mesh-independent solutions and to promote clear separation between fluid and solid regions.

The optimization is terminated when the relative change in the objective function over successive iterations becomes sufficiently small, indicating convergence of the solution. The resulting optimized distribution of the design variable is then interpreted to obtain the final geometry of the fluid distribution device.

## RESULTS AND DISCUSSION

This section presents the results of the topology optimization of the fluid distribution device. First, the effectiveness of the proposed two-stage optimization strategy is demonstrated. Subsequently, the effects of pressure loss constraints, initial design variables, and the number of parallel channels on the optimized designs are systematically investigated.

### Two-stage topology optimization

In this study, water (298K) was used as the working fluid. The values $N, \varepsilon$, and $\beta$ were set to 6, 0.001, and 1.25, respectively. The initial value of the design variable, $\gamma_0$, was set to 0.5. The topology optimization problem was solved using COMSOL Multiphysics® 6.0. The resulting solution is referred to as the first-stage optimization result. The obtained distribution of the design variable is shown in Fig. 2 (left), where red and blue regions correspond to fluid and solid phases, respectively. The black lines indicate streamlines.

In the region from the inlet to just upstream of the first bifurcation point, the streamlines are nearly parallel to the $y$-axis and the velocity component in the $x$-direction is negligible. This indicates that the flow in this region can be regarded as fully developed and that the region does not contribute to the flow distribution process. From the viewpoint of reducing the mean residence time, such a region should therefore be eliminated.

Based on the first-stage optimization result, a clear channel geometry without gray-scale regions was extracted following the procedure proposed in Ref. [9]. In addition, the region identified as unnecessary from the viewpoint of mean residence time reduction was removed, and the geometry shown in Fig. 2 (right) was generated. However, subsequent CFD analysis confirmed that this geometry no longer satisfied the flow uniformity constraint that was achieved in the first-stage result.

Therefore, the geometry shown in Fig. 2 (right) was adopted as a new design domain, and the second-stage topology optimization was performed. The optimized result obtained after the second stage is shown in Fig. 3. CFD analysis confirmed that the final design satisfied the flow uniformity constraint. As a result, a fluid distribution device was designed with a reduction of 76.3% in the design domain area compared with the initial configuration.

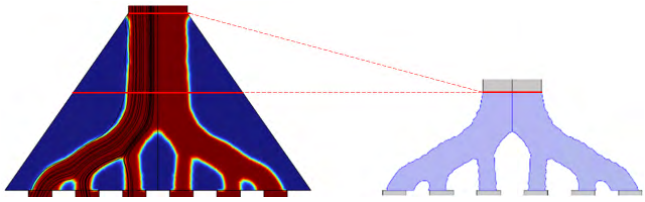

**Figure 2.** First-stage optimization result (left) and the design space generated for second-stage optimization (right).

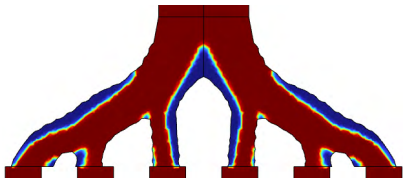

**Figure 3.** Second-stage optimization result.

These results demonstrate that the proposed two-stage topology optimization strategy is effective for obtaining physically realizable and compact fluid distribution device designs.

A comparison with the results reported in Ref. [11] provides further insight into the characteristics of the optimized designs. In Ref. [11], the optimization was performed using the dissipation function as the objective function, whereas the present study employs the mean residence time as the objective. Although both studies yield designs that initially bifurcate into two branches, noticeable differences can be observed in the resulting geometries. The design reported in Ref. [11] exhibits wider channel widths and a shorter distance from the inlet to the first bifurcation. Moreover, the flow is gradually redirected, resulting in a smooth branching into six channels. These features can be considered advantageous from the viewpoint of minimizing the dissipation function, as they contribute to reducing flow resistance and energy loss. In contrast, the present study aims to reduce the effective flow passage volume by minimizing the mean residence time. This objective promotes the formation of narrower channels and longer straight sections prior to branching, leading to a more compact distribution region. These differences highlight that the resulting topology is strongly influenced by the choice of the objective function, and demonstrate the flexibility of topology optimization in tailoring designs to specific performance requirements.

### Effects of initial design variables and pressure loss constraint

In topology optimization problems, the obtained solution often depends on the initial values of the design variables, and the optimization process may converge to

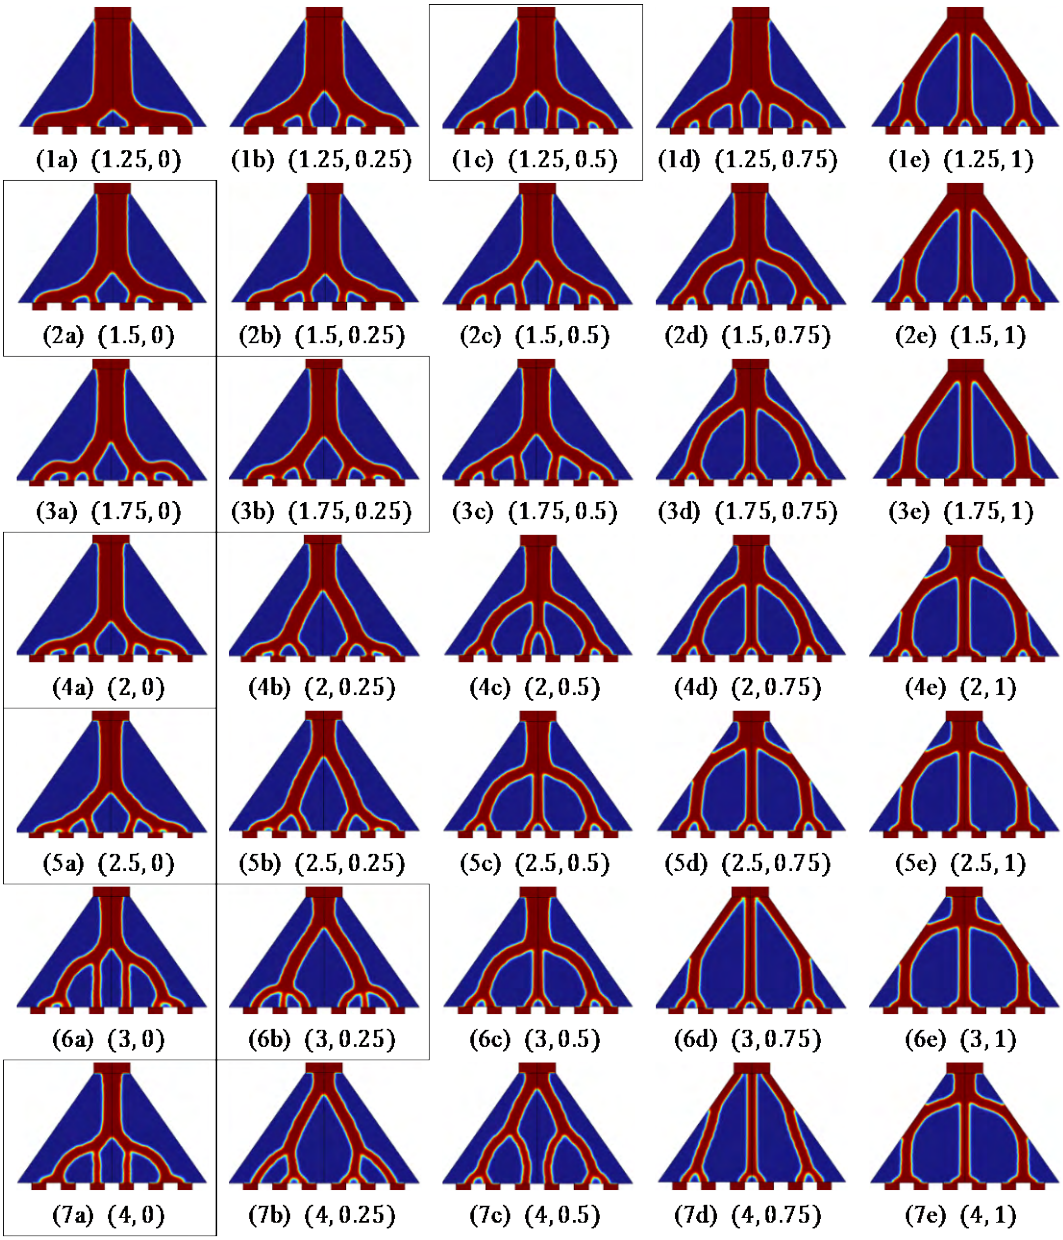

**Figure 4.** Optimization results for all combinations of seven values of $\beta$ (= 1.25, 1.5, 1.75, 2, 2.5, 3, 4) and five values of $\gamma_0$ (= 0, 0.25, 0.5, 0.75, 1). The red regions represent the fluid, and the blue regions represent the solid. The designs highlighted with black frames correspond to the cases that achieved the minimum objective value for each $\beta$. The legend indicates ($\beta$, $\gamma_0$).

local optima. In addition, the flow channel structures obtained under different pressure loss constraints may exhibit characteristics different from those of the design derived in the previous section.

In this section, the first-stage optimization described in the previous section was performed for a total of 35 cases, consisting of five different initial values of the design variable $\gamma_0$and seven different values of $\beta$.

The resulting optimized channel structures are summarized in Fig. 4. As shown in the figure, the obtained flow channel structures can be classified into two groups based on their topological features: those that first bifurcate into two branches (e.g., Fig. 4(1d), hereafter referred to as Group A) and those that first bifurcate into three branches (e.g., Fig. 4(1e), hereafter referred to as Group B). It is found that the designs belonging to Group A tend to exhibit smaller objective function values than those belonging to Group B. Moreover, for each value of $\beta$, the design with the minimum objective function value always belongs to Group A. These results indicate that, under

identical pressure loss conditions, the channel geometries in Group A tend to have smaller flow passage areas in the branching region compared with those in Group B.

Subsequently, for all 35 first-stage optimization results, channel geometries were generated by eliminating gray-scale regions and removing flow-irrelevant regions using the same procedure as described in the previous section. Among these cases, the geometry generated from the result shown in Fig. 4(4a) exhibited the smallest flow passage area. A second-stage topology optimization was then performed using this geometry as the new design domain. As a result, a fluid distribution device with a reduction of 79.6% in the initial design domain area was obtained.

## Effect of the number of parallel channels

In this section, the effect of the number of parallel channels on the optimized flow channel topology was investigated. Topology optimization calculations were performed for cases with $N = 4$ and $N = 8$ in order to examine how the flow channel configurations in the fluid distribution design domain change with the number of outlets. The governing equations, objective function, and constraints were identical to those used in the design problem with $N = 6$. However, the inlet flow rate was adjusted such that the flow rate per outlet channel was the same as that in the $N = 6$ case.

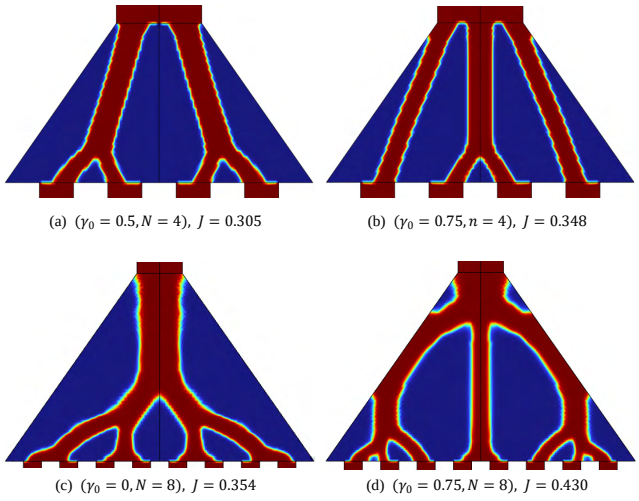

**Figure 5.** First-stage topology optimization results for different numbers of parallel channels.

For each value of $N$, first-stage topology optimization was performed for five different initial values of the design variable, $\gamma_0 = 0, 0.25, 0.5, 0.75$, and $1$. For the case of $N = 4$, the distributions of the design variable corresponding to the minimum and maximum objective function values are shown in Fig. 5(a) and Fig. 5(b), respectively. The corresponding results for $N = 8$ are shown in Fig. 5(c) and Fig. 5(d).

It is observed that the designs with the minimum objective function value initially bifurcate into two branches, whereas those with the maximum objective function value initially bifurcate into three branches. This tendency is consistent with the results obtained for the $N = 6$ case, indicating that the relationship between the initial branching structure and the objective function value is preserved even when the number of parallel channels is changed.

## CONCLUSIONS

In this study, a topology optimization approach was applied to the design of a compact fluid distribution device that achieves uniform flow distribution among parallel channels while minimizing the mean residence time under a pressure loss constraint. The optimization problem was formulated using a density-based method combined with incompressible Navier–Stokes equations including a Darcy-type resistance term.

A two-stage topology optimization strategy was proposed to obtain physically realizable geometries. In the first stage, an optimized material distribution was obtained, while gray-scale regions and flow-irrelevant areas were identified. In the second stage, these regions were removed and the optimization was repeated using the reduced design domain. The results demonstrated that the proposed strategy effectively eliminates nonfunctional regions while maintaining flow uniformity, leading to highly compact fluid distribution devices.

The effects of pressure loss constraints and initial design variables were systematically investigated through multiple optimization runs. The optimized flow channel topologies were classified into two characteristic groups based on their initial branching structures. Designs that initially bifurcate into two branches were found to yield smaller objective function values than those that initially bifurcate into three branches. This tendency was consistently observed under identical pressure loss conditions.

Furthermore, the effect of the number of parallel channels was examined by performing topology optimization for cases with four and eight outlets. The same relationship between the initial branching structure and the objective function value was observed, indicating that the identified design tendency is robust with respect to the number of parallel channels.

A comparison with a previous study using dissipation minimization as the objective function highlighted that the resulting topology strongly depends on the choice of the objective function. While dissipation minimization favors wider and smoother channels, minimizing the mean residence time promotes narrower flow passages and a more compact distribution region. These results demonstrate the flexibility of topology optimization

in tailoring fluid distribution devices to specific performance requirements.

Overall, the present study provides a systematic framework for designing compact and high-performance fluid distribution devices and offers insights into the relationship between objective functions and resulting flow channel topologies.

## ABSTRACT

Flowsheet synthesis is an integral step in process design, entailing the selection of a set of unit operations and their connectivity to convert raw materials to products. Superstructure optimisation represents a promising class of synthesis approaches, allowing for the systematic exploration of the flowsheet design space. Despite this, many superstructure formulations suffer from numerical instabilities, combinatorial explosion, and/or rely on restrictive assumptions on the types of flowsheet alternatives that can be considered. The modified state-operator network (MSON) formalism has recently been proposed to address some of these issues for isobaric flowsheets. The constant-pressure assumption restricts the applicability of the MSON to real process applications as pressure is a key process variable in many unit operations, such as distillation, reaction, and extrusion, and is necessary to elicit flow. In this work, we present the extended MSON (E-MSON) which inherits the numerical stability of MSON, whilst removing the isobaric assumption. This is achieved through the introduction of new constraints that further improve the numerical behaviour of the MSON. The E-MSON is then applied to a simple non-isobaric superstructure optimisation problem, the results of which demonstrate that the E-MSON can serve as a framework for non-isobaric flowsheet synthesis, enabling a broader range of flowsheet alternatives to be considered.

## INTRODUCTION

Flowsheet synthesis is a key step in the broader problem of chemical process design, involving the selection of a feasible or even optimal configuration of unit operations to convert raw materials into valuable products. Traditional approaches to flowsheet synthesis and design are hierarchical and heuristic-based [1]. In these methods, the design procedure is decomposed into increasingly detailed stages that progress from high-level structural decisions to detailed unit design. These stages rely on ad hoc rules-of-thumb to eliminate potential configurations without performing detailed design calculations [2]. Although it is relatively straightforward to apply such an approach, decomposing the design problem makes accounting for the interdependence of decisions made at different stages largely intractable [1].

With the advancement of nonlinear and mixed-integer programming, superstructure optimisation has become an increasingly promising alternative to hierarchical process synthesis techniques [3]. Superstructure optimisation first involves the representation of all candidate flowsheet topologies in a superstructure. This superstructure is then translated into a mathematical programming problem which can then be solved to yield the optimal flowsheet configuration [4], allowing for a systematic exploration of the process design space.

In general, due to the binary decision variables representing unit selection or deselection in flowsheet alternatives, and nonlinearities in the models that describe process phenomena, superstructure optimisation problems can be represented as mixed-integer nonlinear programming (MINLP) problems. How to represent the superstructure is, however, non-trivial, having a significant

influence on the solvability of the subsequent problem, and on the quality of the result obtained [1]. For instance, one commonly encountered issue which depends on the formulation of choice is combinatorial complexity.

Among superstructure representations, there exist several graph-theoretic approaches, including the State Task Network [5], State Equipment Network [6], and the State Operator Network [7]. More recent approaches instead involve abstraction of the flowsheet into building blocks, such as the phenomena building block approach of Lutze et al. [8] or the building-block superstructure presented by Demirel et al. [9]. These abstract representations facilitate intensified or novel unit operations to be yielded as a solution of the optimisation problem, but this generality comes at the expense of the solvability of the subsequent mathematical programming problem [1].

In the State Operator Network (SON) [7], which is the subject of this work, nodes of the graph represent process units, this may include unit operations, e.g., a distillation column, discrete subsets of a unit operation, e.g., a stage of a distillation column, or an intensified unit operation, e.g., a vapour compression distillation which includes the distillation column and heat pump. The edges of the graph are streams, representing material flows from unit operation to the other. To allow for material to flow between units, conceptual mixers and splitters are introduced. Each inlet of each process unit is associated with a conceptual mixer that combines the properties of connected streams (edges) into the input to the units' model. Similarly, a splitter that splits material flows across streams is defined at each outlet.

To ensure that meaningful results are obtained upon the solution of superstructure optimisation problems, rigorous and high-fidelity models must be utilised [7]. In the SON, each process unit is described by a detailed process model that not only includes mass, energy, summation of composition, and heat balance equations, detailed thermodynamic models, and kinetic models when applicable, but also costing and sizing correlations. The model equations that represent each unit are therefore coupled, nonlinear, and high-dimensional, making the solution of superstructure optimisation problems challenging.

Superstructure optimisation problems may be solved in equation-oriented optimisation paradigms, e.g., Pyomo, or by using simulation-based optimisation. Simulation-based optimisation offers the advantages of in-built-process models and thermodynamic routines, as well as initialisation strategies which can be crucial to obtaining high-quality solutions. On the other hand, equation-oriented optimisation paradigms offer great flexibility in formulating the problem and a greater choice of numerical solvers. They also provide complete access to functional forms, allowing the construction of convex relations for global optimisation. Despite this, due to the sheer number of variables and constraints in these problems, global optimisation is typically intractable, meaning superstructure optimisation problems are generally only solved to local optimality.

Another complication associated with superstructure optimisation is numerical failure. When sections of the superstructure are deselected, whether that be building blocks or entire units, mass flows into these units must be set to zero. Thus, even the seemingly simple calculation of a mole fraction can lead to a numerical singularity and hence the failure of the optimisation solver. Several examples of numerically undefined behaviour or singularity arise when process units are deselected [10].

Several approximate methods to avoid numerical issues have been presented, including the relaxation of problematic equations to continuous and differentiable approximations [11], and the introduction of small non-zero flows into deselected units [12]. Exact, systematic formulations that are guaranteed to avoid numerical issues due to unit deselection have also been proposed. Yeomans and Grossmann [13] suggested to formulate the optimisation problem using generalised disjunctive programming (GDP), representing the binary decisions of unit selection and deselection as logical disjunctions. Using the logic-based outer approximation (LBOA) algorithm, the primal problem constructed at each iteration only includes the model equations pertaining to selected units with non-zero inlet flowrates. This avoids numerical failure entirely, however, the automatic generation of the primal problem in process simulation software can be challenging, as noted by Navarro-Amorós et al. [14]. Further issues pertaining to initialisation of the master problem of the LBOA algorithm may also occur [15].

Another promising solution to the problem of numerical failure arising from unit deselection is to modify the superstructure representation itself, as performed in the modified SON (MSON), presented by Gopinath and Adjiman [15, 16]. In the MSON, mixers are modified in the to have a fictitious stream. Fictitious stream flowrates are non-zero when unit operation is deselected and zero otherwise; splitters are similarly modified, ensuring that the solution (optimal point, objective function value) is unaffected by these fictitious flows.

The MSON formulation leads to improved numerical stability, eliminating the possibility of singularities in deselected units. Applied to the design of a counter-current carbon capture column, the optimisation of an MSON superstructure yielded a high-performance solution, indicating its applicability to complex synthesis problems. The MSON may be used in both equation-oriented and simulation-based optimization paradigms. Being based on the SON [7], the MSON also inherits an implicit reduction of combinatorial complexity, as compared to task-based representations such as the State Task Network.

In the definition of both the SON [7] and MSON [15], the pressure is assumed to be constant throughout the

flowsheet. Although an extension to treat pressure as an optimisation variable has been presented for the specific case of the synthesis of counter-current columns only [16], the MSON cannot directly be applied generally to non-isobaric flowsheet synthesis without modification.

Pressure is a key operating variable in many unit operations, due to its influence on chemical and phase equilibria [17], and being essential to elicit flow. Many unit operations, such as pressure-swing distillation, membrane-based processes, and high-pressure synthesis also cannot be modelled without allowing pressure to vary across the flowsheet [18-20]. Furthermore, compression and expansion can represent significant proportions of process costs, e.g., up to 75% of the capital expenditure for refrigeration systems [21]. Rigorous flowsheet modelling also requires accurately accounting for pressure drops.

Therefore, a superstructure formulation that inherits the mathematical tractability of the MSON, whilst relaxing its isobaric assumption, is highly desirable. It would broaden the scope of flowsheet alternatives and objectives that can be considered in a superstructure optimisation problem. Thus, in this work, we present the extended MSON (E-MSON), establishing a framework which facilitates the systematic and rigorous synthesis of non-isobaric flowsheets. We demonstrate the application of E-MSON on a test problem, successfully allowing the process units to operate at different pressures. In the next section, we present the superstructure representation of the E-MSON, highlighting the variables and sets of relevance, before giving its full derivation.

## E-MSON: SUPERSTRUCTURE REPRESENTATION

The E-MSON formulation avoids numerical singularities through the introduction of strictly positive fictitious streams into deselected units [15]. Each stream has a mass flowrate, $f \in \mathbb{R}^+$, composition, $\boldsymbol{q} \in [0,1]^K$, where $K$ is the number of components considered in the problem, and is at temperature, $T \in \mathbb{R}^+$, and pressure, $P \in \mathbb{R}^+$.

Let the set of all process units in the superstructure be represented by $\boldsymbol{\mathcal{L}}$, with each unit $u \in \boldsymbol{\mathcal{L}}$ being described by rigorous model equations (mass and energy balances, sizing, costing, etc.). We represent the set of conditional units, referring to units that can be deselected in a particular alternative, as $\boldsymbol{\mathcal{T}} \subseteq \boldsymbol{\mathcal{L}}$, such that the set of permanent units that must be included in all alternatives is given by $\boldsymbol{\mathcal{L}} \backslash \boldsymbol{\mathcal{T}}$. The set of units include all unit operations, including pressure-change equipment such as pumps, valves, and compressors, which we represent as $\boldsymbol{\mathcal{PC}} \subset \boldsymbol{\mathcal{L}}$. The set of all nodes of the graph can then be defined as $\boldsymbol{\mathcal{U}} = \boldsymbol{\mathcal{L}} \cup \boldsymbol{\mathcal{F}} \cup \boldsymbol{\mathcal{P}}$, where $\boldsymbol{\mathcal{F}}$ and $\boldsymbol{\mathcal{P}}$ refer to the sets of feeds and products containing the material sources and sinks to and from the superstructure respectively.

Each unit $u \in \boldsymbol{\mathcal{U}}$ is also associated with inlet and outlet indices corresponding to the sets $\boldsymbol{\mathcal{IN}_u}$ and $\boldsymbol{\mathcal{OUT}_u}$, the union of which give, for all $u \in \boldsymbol{\mathcal{U}}$, the sets of all mass inlet and outlet indices $\boldsymbol{\mathcal{I}}$ and $\boldsymbol{\mathcal{O}}$. At each inlet and outlet, we additionally specify an isenthalpic mixer and splitter, respectively, to facilitate connectivity between units. Permanent units $u \in \boldsymbol{\mathcal{L}} \backslash \boldsymbol{\mathcal{T}}$ are associated with standard mixers and splitters, denoted by $m_i$ and $s_o$ at inlet $i \in \boldsymbol{\mathcal{I}}$ and outlet $o \in \boldsymbol{\mathcal{O}}$ respectively. The inlet flowrate, composition, temperature, and pressure to a unit from a mixer at inlet $i$ are labelled as $f_i^{in}, \boldsymbol{q_i^{in}}, T_i^{in}$, and $P_i^{in}$, and the outlet flowrate, composition, temperature and pressure from a unit to a splitter at outlet $o$ as $f_o^{out}, \boldsymbol{q_o^{out}}, T_o^{out}, P_o^{out}$.

As in the MSON [15, 16], conditional units are connected to modified isenthalpic mixers and splitters, labelled as $\widetilde{m}_i$ and $\tilde{s}_o$. At modified mixer $\widetilde{m}_i$, the flowrate of the fictitious stream, $f_i^M$, takes the auxiliary value, $f_i^A$, when the unit is deselected. Additionally, when $f_i^M > 0$, the corresponding unit's inlet composition, temperature, and pressure are constrained to take the auxiliary values, $\boldsymbol{q_i^A}, T_i^A$, and $P_i^A$, defined *a priori* for the fictitious stream. Analogously, at the modified splitter, $\tilde{s}_o$, the variables $f_o^S, \boldsymbol{q_o^S}, T_o^S$, and $P_o^S$ define the fictitious stream. An example of a completely labelled conditional unit following the E-MSON formalism can be seen in Figure 1.

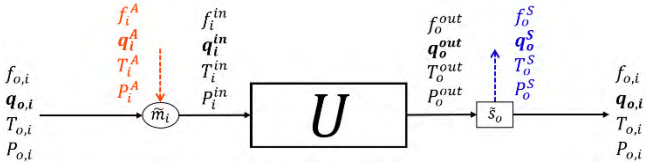

**Figure 1.** Example representation of a conditional unit $\underline{U}$ in the E-MSON formulation, including all variables of relevance. The fictitious streams of the modified mixer and splitter are coloured and marked by dashed lines.

The connectivity between mixers and splitters is captured in the sets $\boldsymbol{\mathcal{M}_i}$ and $\boldsymbol{\mathcal{S}_o}$, where $\boldsymbol{\mathcal{M}_i} \subseteq \boldsymbol{\mathcal{O}}$ represents the set of outlet indices connected to mixer $m_i$ or $\widetilde{m}_i$ and $\boldsymbol{\mathcal{S}_o} \subseteq \boldsymbol{\mathcal{I}}$ represents the set of inlet indices connected to splitter $s_o$ or $\tilde{s}_o$. As with all other streams, the connections between mixers and splitters are parameterised in terms of flowrate, composition, temperature, and pressure, denoted as $f_{o,i}, \boldsymbol{q_{o,i}}, T_{o,i}$, and $P_{o,i}$, respectively.

To enable the selection and deselection of conditional units in the superstructure, each conditional unit $u \in \boldsymbol{\mathcal{T}}$ is also associated with a binary variable $z_u$ that describes whether it is selected in ($z_u = 1$) or deselected from ($z_u = 0$) a particular flowsheet configuration. It is important to also define $\boldsymbol{\mathcal{C}_u}$, representing the set of "output" variables, that is, those variables corresponding to conditional unit $u \in \boldsymbol{\mathcal{T}}$ that are included in flowsheet-level constraints or the objective function.

In the case where continuous or discrete *design*

variables are present in the model of a conditional unit (such as a reboiler duty or the number of stages in a column), additional auxiliary variables must be defined to ensure model convergence. We represent these continuous and discrete design variables in the vectors $\boldsymbol{x}_{\mathcal{A}_u}$ and $\boldsymbol{y}_{\mathcal{A}_u}, \forall\, u \in \mathcal{T}$, respectively, and store the auxiliary values similarly in the vectors $\boldsymbol{x}^{\boldsymbol{A}}_{\mathcal{A}_u}$ and $\boldsymbol{y}^{\boldsymbol{A}}_{\mathcal{A}_u}, \forall\, u \in \mathcal{T}$. As with other auxiliary variables in the E-MSON approach, these should be assigned values in advance such that, in combination with $f_i^A, \boldsymbol{q}_{\boldsymbol{i}}^{\boldsymbol{A}}, T_i^A$, and $P_i^A$ for all inlets $i \in \mathcal{IN}_u$, a solution is obtained to the model equations of process unit $u \in \mathcal{T}$.

We also define a binary variable, $z_{o,i}$ for all $o \in \mathcal{M}_i, i \in \mathcal{IN}_u, u \in \mathcal{L} \cup \mathcal{P}$. When outlet $o$ and inlet $i$ are connected, meaning $f_{o,i} > 0$, the binary variable $z_{o,i}$ takes a value of 1 and otherwise the binary variable is zero. Further, when $z_{o,i} = 1$, the pressure at the inlet $i$ must be equal to the pressure $P_{o,i}$ of the stream that exits outlet $o$ (cf. Figure 2b), this ensures the mixing of streams does not result physically in unintended flows, i.e.: from a high-pressure unit into a low-pressure one. When outlet $o$ and inlet $i$ are disconnected, when $z_{o,i} = 0$ and $f_{o,i} = 0$, the downstream pressure, $P_i^{in}$, is allowed to vary independently of $P_{o,i}$ (c.f Figure 2c).

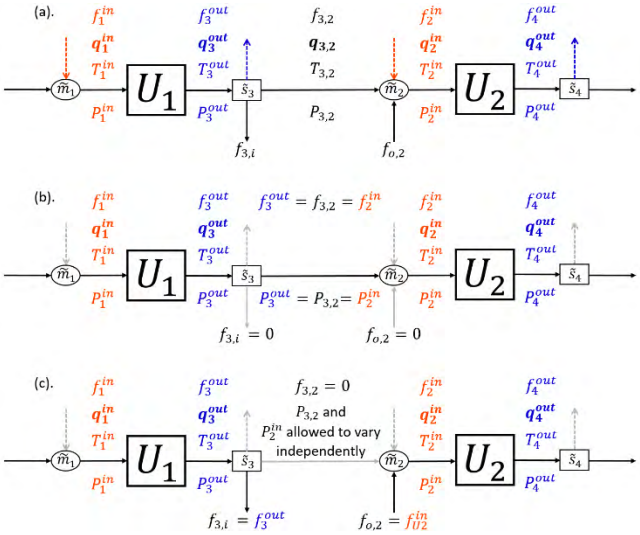

**Figure 2.** Representation of how pressures are connected within the E-MSON approach. (a) denotes the relevant variables of two conditional units, $U_1$, which has a single inlet and two outlets, and $U_2$, which has two inlets and a single outlet. (b) shows the pressure relationship when the two units are connected (when $z_{3,2} = 1$), and (c) illustrates the case when they are not connected (when $z_{3,2} = 0$).

Note that, due to Equations 9b to 9d and 10b to 10g, all streams leaving a splitter are at a composition, temperature, and pressure equal to the splitter's inlet.

Note that meaningful relations between the pressures of two units cannot be derived solely based on their selection in a flowsheet (as denoted by $z_u$). Inlet and outlet pressures should only be equal when two units are directly connected via flow, as indicated by $z_{o,i}$. In addition to enforcing correct pressure relationships, the introduction $z_{o,i}$ allows for the consideration of flowsheet alternatives where the same units are selected but different streams are active. For instance, the comparative performance of two flowsheet alternatives including the same set of conditional units, but with or without a recycle stream, can now directly be compared using the E-MSON formalism. Lastly, we mention the following assumptions made in the derivation of the MSON, which carry across to the E-MSON: all flows are assumed isenthalpic and frictionless, implying no pressure losses are incurred between units; all units are at steady state; no reaction occurs in mixers and splitters; and all mixers and splitters are isenthalpic and the work of mixing is zero.

## E-MSON: FORMULATION

What follows is a complete definition of the E-MSON model equations; although many of these constraints are in common with the MSON approach [15, 16], they are included here for completeness. The MINLP reformulation of the E-MSON is given in Big-M form in this work, but alternative reformulations, such as those using convex hulls [22], could also be utilised. To constrain that the flowrate $f_{o,i}$ between outlet $o$ and inlet $i$ must be non-zero when $z_{o,i} = 1$, and zero when $z_{o,i} = 0$, the following constraints are defined, $\forall\, o \in \mathcal{M}_i, \forall\, i \in \mathcal{IN}_u, \forall\, u \in \mathcal{L} \cup \mathcal{P}$:

$$f_{o,i} \leq \bar{f} z_{o,i} \tag{1a}$$

$$\varepsilon_f z_{o,i} \leq f_{o,i} \tag{1b}$$

where $\bar{f}$ and $\varepsilon_f$ are upper and lower bounds on flowrate respectively. Additionally, as in the MSON derivation, we constrain that all inter-unit flowrates directed to a deselected unit are zero, as follows:

$$f_{o,i} \leq \bar{f} z_u, \forall\, o \in \mathcal{M}_i, \forall\, i \in \mathcal{IN}_u, \forall\, u \in \mathcal{T} \tag{2}$$

and that all flowrates into process units are positive:

$$\varepsilon_f \leq f_i^{in}, \forall\, i \in \mathcal{IN}_u, \forall\, u \in \mathcal{L} \tag{3}$$

Further to this, we can impose the following linear relations between unit and stream binary variables, such that the number of feasible combinations of binary variables is reduced significantly. If a unit is deselected, the connected flows should accordingly be inactive:

$$z_{o,i} \leq z_u, \forall\, o \in \mathcal{M}_i, \forall\, i \in \mathcal{IN}_u, \forall\, u \in \mathcal{T} \tag{4a}$$

$$z_{o,i} \leq z_u, \forall\, i \in \mathcal{S}_o, \forall\, o \in \mathcal{OUT}_u, \forall\, u \in \mathcal{T} \tag{4b}$$

and, if a unit is selected, it should have at least one active inlet and one active outlet stream:

$$z_u \leq \sum_{i \in \mathcal{IN}_u} \sum_{o \in \mathcal{M}_i} z_{o,i}, \forall\, u \in \mathcal{T} \quad (5a)$$

$$z_u \leq \sum_{o \in \mathcal{OUT}_u} \sum_{i \in \mathcal{S}_o} z_{o,i}, \forall\, u \in \mathcal{T} \quad (5b)$$

The mass, component, and enthalpy balances around standard mixers are defined as follows, $\forall\, i \in \mathcal{IN}_u, u \in (\mathcal{L} \backslash \mathcal{T}) \cup \mathcal{P}$:

$$f_i^{in} = \sum_{o \in \mathcal{M}_i} f_{o,i} \quad (6a)$$

$$f_i^{in} q_{i,c}^{in} = \sum_{o \in \mathcal{M}_i} f_{o,i}\, q_{o,i,c}, \forall\, c \in \{1, \dots, K\} \quad (6b)$$

$$f_i^{in} h(T_i^{in}, \boldsymbol{q_i^{in}}, P_i^{in}) = \sum_{o \in \mathcal{M}_i} f_{o,i}\, h(T_{o,i}, \boldsymbol{q_{o,i}}, P_{o,i}) \quad (6c)$$

where $h(T, \boldsymbol{q}, P)$ is the enthalpy per unit mass of a stream at temperature $T$, pressure $P$, and composition $\boldsymbol{q}$. Note the sum of all component fractions need not be constrained to one at mixers and splitters, given that it is satisfied by the input specifications at sources.

To ensure the desired behaviour of fictitious streams at modified mixers is enforced, at all inlets $i \in \mathcal{IN}_u, \forall\, u \in \mathcal{T}$, modified mixer constraints are defined. The mass, component, and enthalpy balances are given by:

$$f_i^{in} = \sum_{o \in \mathcal{M}_i} f_{o,i} + f_i^M \quad (7a)$$

$$f_i^{in} q_{i,c}^{in} = \sum_{o \in \mathcal{M}_i} f_{o,i}\, q_{o,i,c} + f_i^M q_{i,c}^A, \forall\, c \in \{1, \dots, K\} \quad (7b)$$

$$f_i^{in} h(T_i^{in}, \boldsymbol{q_i^{in}}, P_i^{in}) = \sum_{o \in \mathcal{M}_i} f_{o,i}\, h(T_{o,i}, \boldsymbol{q_{o,i}}, P_{o,i}) + f_i^M h(T_i^A, \boldsymbol{q_i^A}, P_i^A) \quad (7c)$$

To ensure that the fictitious flowrate and inlet pressure are only equal to the auxiliary value when the unit is deselected, and that when the unit is selected, the fictitious flowrate is zero, the following constraints are also necessary, where $M$ is a suitably large positive constant:

$$f_i^M = f_i^A (1 - z_u) \quad (7d)$$

$$-M z_u \leq P_i^A - P_i^{in} \leq M z_u \quad (7e)$$

Additionally, across *all* mixers, the inlet and outlet pressures should only be equal when the corresponding flowrate is non-zero (i.e.: $z_{o,i} = 1$), therefore, $\forall\, o \in \mathcal{M}_i, \forall\, i \in \mathcal{IN}_u, u \in \mathcal{L} \cup \mathcal{P}$:

$$-M(1 - z_{o,i}) \leq P_i^{in} - P_{o,i} \leq M(1 - z_{o,i}) \quad (8)$$

Equation 8 implies that if there are multiple non-zero flows from different outlets connected to an inlet, each of those outlets are at the same pressure. At each standard splitter, we require mass balance constraints and enforce the equality of compositions, temperatures, and pressures across the splitter, $s_o$. Hence, $\forall\, o \in \mathcal{OUT}_u, \forall\, u \in (\mathcal{L} \backslash \mathcal{T}) \cup \mathcal{F}$, we define:

$$f_o^{out} = \sum_{i \in \mathcal{S}_o} f_{o,i} \quad (9a)$$

$$q_{o,c}^{out} = q_{o,i,c}, \forall\, c \in \{1, \dots, K\}, \forall\, i \in \mathcal{S_o} \quad (9b)$$

$$T_o^{out} = T_{o,i}, \forall\, i \in \mathcal{S_o} \quad (9c)$$

$$P_o^{out} = P_{o,i}, \forall\, i \in \mathcal{S_o} \quad (9d)$$

At modified splitters, we define the following, including the fictitious stream, $\forall\, o \in \mathcal{OUT}_u, \forall\, u \in \mathcal{T}$:

$$f_o^{out} = \sum_{i \in \mathcal{S}_o} f_{o,i} + f_o^S \quad (10a)$$

$$q_{o,c}^{out} = q_{o,i,c}, \forall\, c \in \{1, \dots, K\}, \forall\, i \in \mathcal{S_o} \quad (10b)$$

$$T_o^{out} = T_{o,i}, \forall\, i \in \mathcal{S_o} \quad (10c)$$

$$P_o^{out} = P_{o,i}, \forall\, i \in \mathcal{S_o} \quad (10d)$$

$$q_{o,c}^{out} = q_{o,c}^S, \forall\, c \in \{1, \dots, K\} \quad (10e)$$

$$T_o^{out} = T_o^S \quad (10f)$$

$$P_o^{out} = P_o^S \quad (10g)$$

As fictitious mass flow is added to the unit upon its deselection, to ensure that exact results are obtained from the remainder of the flowsheet, we must also enforce that when $z_u = 0, f_o^S = f_o^{out}$, by:

$$f_o^{out} - f_o^S \leq \bar{f} z_u \quad (11)$$

Furthermore, we must also ensure that no mass leaves in the fictitious stream when the unit is selected, restricting $f_o^S$ to zero as follows:

$$0 \leq f_o^S \leq \bar{f}(1 - z_u) \quad (12)$$

To ensure the design variables of conditional units ($\boldsymbol{x}_{\mathcal{A}_u}$ and $\boldsymbol{y}_{\mathcal{A}_u}$) take the required auxiliary values upon deselection ($\boldsymbol{x}^{\boldsymbol{A}}_{\mathcal{A}_u}$ and $\boldsymbol{y}^{\boldsymbol{A}}_{\mathcal{A}_U}$), we introduce, $\forall\, u \in \mathcal{T}$:

$$-M z_u \leq x_{\mathcal{A}_u} - x^A_{\mathcal{A}_u} \leq M z_u \quad (13a)$$

$$-M z_u \leq y_{\mathcal{A}_u} - y^A_{\mathcal{A}_u} \leq M z_u \quad (13b)$$

As well as this, the "output" variables of a conditional unit, $x_i, i \in \mathcal{C}_u$, should only impact flowsheet-wide constraints if the unit is active. This is achieved by introducing an auxiliary vector of continuous variables, $\boldsymbol{x_i^S}$, and the following constraints, $\forall\, i \in \mathcal{C}_u, \forall\, u \in \mathcal{T}$:

$$-M(1 - z_u) \leq x_i - x_i^S \leq M(1 - z_u) \quad (14a)$$

$$-M z_u \leq x_i^S - c_{u,i} \leq M z_u \quad (14a)$$

where, $c_{u,i}$ is the relevant member of a vector of values $\boldsymbol{c_u}$, often of zeroes, which "output" variables should take upon unit deselection. Further, the flowsheet wide constraints and objective are expressed in term of auxiliary variables $x_i^S$ instead of $x_i\, \forall\, i \in \mathcal{C}_u, \forall\, u \in \mathcal{T}$.

In addition to enforcing that physically meaningful values of pressure are obtained from the E-MSON, it is also of interest to include constraints related to the pressure-change units, $u \in \mathcal{PC}$. If $\mathcal{PC}$ is partitioned into a set $\mathcal{COM}$ of compressing units that lead to a positive pressure difference across them, and analogously a set $\mathcal{EXP}$

of expanding units that lower pressure, such that $\mathcal{PC} = \mathcal{EXP} \cup \mathcal{COM}$, it is possible to enforce that only the correct pressure-change occurs across them. Although the detailed models of such units should ensure that only the correct pressure difference can occur in compressors and expanders at feasible solutions (i.e. an increase across compressors, and a decrease across expanders), numerical difficulties and thus solver failure can still be encountered. For instance, if poor initialisation leads to a negative $\Delta P$ across a compressor or an NLP solver progresses in this direction, this can result in a negative value for power, which in many cost correlations would then be raised to a non-integer exponent [21] and thus cause a numerical singularity. To avoid this, we define the following for compressing units, $\forall\, i \in \mathcal{IN}_u, \forall\, o \in \mathcal{OUT}_u, \forall\, u \in \mathcal{COM}$:

$$\varepsilon_P \leq P_o^{out} - P_i^{in} \tag{15a}$$

where $\varepsilon_P$ is a small positive constant to ensure a positive $\Delta P$ is obtained. Analogously for expanding units, $\forall\, i \in \mathcal{IN}_u, \forall\, o \in \mathcal{OUT}_u, \forall\, u \in \mathcal{EXP}$:

$$\varepsilon_P \leq P_i^{in} - P_o^{out} \tag{15b}$$

## AN APPLICATION OF E-MSON

We now illustrate the use of the E-MSON formalism for variable pressure flowsheet synthesis on a simple test problem. The E-MSON representation of the problem is given in Figure 3.

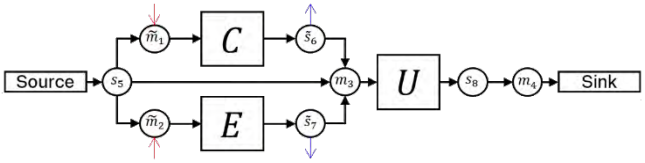

**Figure 3.** E-MSON representation of the test problem, where units $C$ and $E$ are a conditional compressor and expander, respectively, and $U$ is an arbitrary permanent unit. Splitter $s_8$ and mixer $m_4$ are shown for completeness and may be eliminated in practice.

Three feasible flowsheet alternatives can be obtained from the superstructure, where exactly one of the compressor, $C$, the expander, $E$, or a bypass stream is active. Within the problem, the key decision variables are the two unit selection binary variables, $z_C$ and $z_E$, the three flow activity binaries to indicate whether compression, expansion, or neither occurs ($z_{6,3}, z_{7,3}, z_{5,3}$), as well as the inlet pressure to the permanent unit, $P_U^{in}$.

For simplicity, streams in this problem are described only in terms of mass flowrate and pressure, implying any constraints involving composition and temperature from the full E-MSON derivation are not included. Simplified models are also used for each unit operation. The purpose of this problem is to provide initial evidence of the applicability of the E-MSON to non-isobaric superstructure optimisation problems. Indeed, as the pressure across the compressor and expander must vary from the source pressure, the MSON and SON formulations are inapplicable to even this rudimentary case.

The compressor and expander are assigned a fixed cost, and no mass loss is assumed across them. Notably, as the pressure difference across pressure-change units is constrained to be in the correct direction for each unit, neither the inlet pressure nor the outlet pressure is involved in the toy compressor and expander models. These models are given by, $\forall\, u \in \{C, E\} = \mathcal{PC} = \mathcal{T}$:

$$f_i^{in} = f_o^{out}, \forall\, i \in \mathcal{IN}_u, \forall o \in \mathcal{OUT}_u \tag{20a}$$

$$c_u = \mu_u \tag{20b}$$

where $\mu_u$ is a unit-specific constant.

The permanent unit is modelled as following, based on modification of the toy unit models in the case studies on which the MSON was first tested [15], $\forall\, u = U = \mathcal{L} \backslash \mathcal{T}$:

$$x_u f_i^{in} = f_o^{out}, \forall\, i \in \mathcal{IN}_u, \forall\, o \in \mathcal{OUT}_u \tag{21a}$$

$$x_u = \frac{P_i^{in}}{P_{UB}}, \forall\, i \in \mathcal{IN}_u \tag{21b}$$

$$c_u = \mu_u \left(f_i^{in} P_i^{in}\right)^{\upsilon_u}, \forall\, i \in \mathcal{IN}_u \tag{21c}$$

$$P_i^{in} = P_o^{out}, \forall\, i \in \mathcal{IN}_u, \forall\, o \in \mathcal{OUT}_u \tag{21d}$$

where $\upsilon_u$ is a unit-specific constant, $x_u$ is a scaled pressure, and $P_{UB}$ is an upper bound on pressure.

The objective is to maximise "profit", modelled as the revenue (the value of the stream being processed, given by the inlet flowrate into the sink and corresponding price $c_f$) minus the cost of each unit included in the selected configuration. It is given as:

$$\max\left(c_f f_{sink}^{in} - c_U - c_E^S - c_C^S\right) \tag{22}$$

where $c_f$ is set to 1 without loss of generality, and $c_E^S$ and $c_C^S$ are auxiliary variables representing the cost of the expander and compressor, respectively, taking a value of zero when the unit is deselected. To complete the definition of the model, the unit-specific parameters are given in Table 1, and the additional E-MSON specific parameters are given in Table 2.

**Table 1.** Unit-specific parameters of the E-MSON test problem, where $f_i^A, P_i^A, \mu_u$, and $\upsilon_u$ are the fictitious flowrate, fictitious pressure, and unit-specific parameters of the compressor, $C$, expander, $E$, and unit, $U$.

| Unit | $f_i^A$ | $P_i^A$ | $\mu_u$ | $\upsilon_u$ |
|---|---|---|---|---|
| $C$ | 25.0 | 1.1 | 20.0 | - |
| $E$ | 25.0 | 9.9 | 5.0 | - |
| $U$ | - | - | 0.3 | 0.7 |

**Table 2.** Additional constants necessary to define the E-MSON test problem. Where $f_{source}$ and $P_{source}$ are the source flowrate and pressure, respectively, $\bar{f}$ and $P_{UB}$ are the flowsheet-wide upper bounds on flow rate and pressure, $P_{LB}$ is the lower bound, and $\varepsilon_F$ and $\varepsilon_P$ are small constants to ensure positive flowrates and pressure differences.

| Parameter | Value |
|---|---|
| $f_{source}$ | 50.0 |
| $P_{source}$ | 5.0 |
| $\bar{f}$ | 50.0 |
| $P_{UB}$ | 10.0 |
| $P_{LB}$ | 1.0 |
| $\varepsilon_F$ | $1/\bar{f}$ |
| $\varepsilon_P$ | 0.1 |

**Table 3.** Results from the E-MSON test problem, where $P_U^{in}$ is the inlet pressure to the unit $U$ in the superstructure.

| Primal Iteration # | Selected Configuration | Objective Value | $P_U^{in}$ |
|---|---|---|---|
| 1 | Bypass active | 10.689 | 5 |
| 2 | Expander active | 5.390 | 1 |
| 3 | Compressor active | 6.751 | 10 |

The test problem was implemented in gPROMS Process 2025.2.0, utilising MINLPOA, a proprietary implementation of OAERAP [23], as the MINLP solver, NLPSQP as the primal NLP subproblem solver, and LPSOLVE as the master MILP problem solver. All the solvers utilised were run with standard settings, except for the convexity-based termination criterion of MINLPOA, which was disabled. The problem involved 72 variables, 8 of which were binary. The solver ran for 4 master problem iterations, obtaining solutions for each feasible combination of unit selection and flow activity binaries (3 combinations out of a possible 32), also indicating that the master problem at the final (fourth) iteration becomes infeasible. Convergence was achieved in less than 1 second. Further detail on the three primal problems that were solved is provided in Table 3, with the alternative in which no pressure-change unit was selected being found as optimal.

The results reported in Table 3 were obtained independently of which of the three configurations was selected as the initial guess to the problem. This was also found to be the case upon initialisation from an infeasible point, where all binary variables were set to zero.

## CONCLUSION

In this work, we have presented E-MSON, a framework for the superstructure optimisation of non-isobaric flowsheets. It is a generalisation of the MSON approach in which modified isenthalpic splitters and mixers are introduced to avoid numerical difficulties, with the addition of pressure-change units and new constraints that ensure physically meaningful solutions. The extended MSON has then been tested on a toy superstructure containing an expander and a compressor, yielding promising results. Although this illustrative problem is small, it represents a non-isobaric flowsheet synthesis problem and is thus, to the authors' knowledge, beyond the scope of other exact and rigorous graph-theoretic superstructure formulations such as the SON, or MSON.

In future work the E-MSON will be applied to a broader range of problems, including more realistic process applications in which pressure represents a key operating variable. Beyond this, integrating such rigorous and exact superstructure formulations into molecular design problems is of interest, facilitating simultaneous molecular and process design. Additionally, constraints to further improve numerical convergence for units which require a particular inlet phase will be considered.

Furthermore, given the time-consuming nature of implementing such optimisation problems, automating the writing and execution of E-MSON superstructure optimisation problems is also of value. A Python library to do so within gPROMS Process is currently in development, permitting the user to visually represent the superstructure and generate the corresponding E-MSON problem formulation quickly.

## DIGITAL SUPPLEMENTARY MATERIAL

Digital supplementary material, including the gPROMS Process 2025.2.0 file used in the solution of the test problem, and relevant case files, is available here: https://psecommunity.org/LAPSE:2026.0034

## ABSTRACT

Sohar Port and Freezone is well-positioned to drive Oman`s economic future through continued expansion, increased reliance on sustainable energy, and the integration of advanced digital tools. Sohar contributes 25% of the current GHG emissions in Oman. Decarbonizing Sohar industrial clusters is a strategic challenge for emerging economies striving to attain net-zero objectives. This research develops a superstructure optimization framework for designing an integrated Carbon Capture, Utilization and Storage (CCUS) value chain, specifically applied to the Sohar Port and Freezone in Oman. A mixed-integer linear programming (MILP) formulation that simultaneously selects capture technologies, identifies optimal transport modes (pipeline, trucking, and shipping), and allocates $CO_2$ flows among utilization and geological storage alternatives. The novelty of this work lies in the multi-scale integration of techno-economic, spatial, and policy dimensions, coupled with GIS-based route generation into the optimization model. Currently, the total $CO_2$ emission from Sohar Freezone is around 20.3 $MtCO_2$/yr, after applying the CCUS value chain optimization, 7 – 14 $MtCO_2$ annual net reduction could be achieved, corresponding to 30-70% cluster-level decarbonization at 50 – 85 USD/$tCO_2$ levelized cost of $CO_2$ capture, transport, and storage. Sensitivity analysis reveals that port-based $CO_2$ hubs, combined with short-haul shipping to offshore storage, reduce the system cost by 23–31% compared to single-mode configurations. The framework offers decision–support tools for policymakers and industrial stakeholders, integrating techno-economic optimization with regional carbon control policies. The Sohar case study demonstrates the capabilities of computational superstructure design to expedite CCUS implementation in the industrial clusters in the Gulf region.

**Keywords**: CCUS, Superstructure Optimization, MILP, Sohar Freezone

## INTRODUCTION

The reduction of carbon dioxide emissions became a major international concern, considering that in 2024 emissions were 53.2 Gt $CO_2$eq, a 1.3% rise from 2023 levels. Globally, fossil fuel $CO_2$ emissions, the primary contributors to the global green house gases (GHG) emissions, continue to rise despite international climate change mitigation agreements [1]. Achieving the Paris Agreement's goal of limiting the rise in temperature of earth to 1.5 °C, GHG emissions must decline to net zero by mid of this century. To achieve targeted GHG reduction, International Energy Agency (IEA) has outlined a range of technological alternatives, such as, carbon capture, utilization and storage (CCUS), switching to low-carbon fuel, process efficiency improvements, and renewable energy with CCUS accounting for 14% of the overall GHG reduction potential [2]. As per the Global CCS Institute, as of mid-2025, CCUS projects captured 64 million tons of $CO_2$ globally in 2025, 25.5% increase in capturing capacity compared to 2024 (51 Mtpa) [3].

Industrial clusters with emissions that are hard-to-abate are progressively prioritized for carbon capture, utilization, and storage (CCUS) deployment. This is due to their substantial $CO_2$ concentrations and continuous $CO_2$ point sources, which facilitates the economic viability of shared transport and storage infrastructure. According to IEA, the pipeline for CCUS projects have significantly increased in recent years, and policy and business model support is essential for achieving bankability

**Nomenclature**

| | | | |
|---|---|---|---|
| $i$ | $CO_2$ source | $F^{SH}_{i,j,tt}$ | Continuous, $CO_2$ flow from source i to hub j using transport technology tt ($tCO_2$/yr) |
| $j$ | Hub location | $F^{HS}_{j,k,tt}$ | $CO_2$ flow from hub j to storage k using transport technology tt ($tCO_2$/yr) |
| $k$ | Storage site | $F^{HU}_{j,m,tt}$ | $CO_2$ flow from hub j to utilization m using transport technology tt ($tCO_2$/yr) |
| $m$ | Utilization option | $F^{H}_{j}$ | total $CO_2$ flow at hub j ($tCO_2$/yr) |
| $ct$ | Capture Technology | $\mathrm{Cap}^{SH}_{i,j,tt}$ | Installed pipeline capacity from source i to hub j using transport tt ($tCO_2$/yr) |
| $tt$ | Transport technology | $\mathrm{Cap}^{HS}_{j,k,tt}$ | Installed pipeline capacity from hub j to storage k using transport tt ($tCO_2$/yr) |
| $x_{i,ct}$ | Binary,1 if capture technology $ct$ is installed at source $i$, otherwise, 0 | $\mathrm{Cap}^{HU}_{j,m,tt}$ | Installed pipeline capacity from hub j to utilization m using transport tt ($tCO_2$/yr) |
| $x^{hub}_{j}$ | Binary,1 if hub j is developed, otherwise, 0 | $E_i$ | Annual $CO_2$ emissions at source i ($tCO_2$/yr) |
| $x^{stor}_{k}$ | Binary, 1 if storage k is developed, otherwise, 0 | $\varepsilon_{ct}$ | Capture efficiency of technology ct |
| $x^{util}_{m}$ | Binary,1 if utilization m is developed, otherwise, 0 | $\mathrm{tech_applicable}_{i,ct}$ | Binary, returns to 1 if capture technology ct is applicable to source I based on $CO_2$ concentration constraints, otherwise 0. |
| $x^{SH}_{i,j,tt}$ | Binary, 1 if a pipeline of type tt is built from source i to hub j, otherwise 0 | $\underline{C}_{tt}$ | Minimum feasible $CO_2$ capacity of pipeline type tt per year |
| $x^{HS}_{j,k,tt}$ | Binary, 1 if a pipeline of type tt is built from hub j to storage k, otherwise 0 | $\bar{C}_{tt}$ | Maximum annual $CO_2$ injection rate |
| $x^{HU}_{j,m,tt}$ | Binary, 1 if a pipeline of type tt is built from hub j to utilization m, otherwise 0 | $I^{max}_{k}$ | Maximum annual injection rate of storage k ($tCO_2$/yr) |
| $x^{S\to H}_{i,j}$ | Binary, 1 if source i is connected to hub j, otherwise 0 | $U^{cap}_{m}$ | Maximum annual $CO_2$ utilization capacity by utilization m ($tCO_2$/yr) |
| $f_{i,ct}$ | Continuous, $CO_2$ captured at source i using technology ct ($tCO_2$/yr) | M | Big -M constant used to activate or deactivate the flow |

at commercial scale [4]. Concurrently, hub and cluster strategies are being actively evaluated, wherein shared pipelines, compression, and injection infrastructure minimize redundancy and decrease unit transportation and storage expenses.

Oman has established a national strategy for achieving net-zero emissions by 2050, which is backed by policy frameworks and other supporting initiatives [5]. Sohar Freezone and industrial area are ideal location for a "clustered" decarbonization approach due to the concentration of emissions-producing industries there, including refinery, metals, cement, and petrochemicals. Initiatives for industrial decarbonization in Sohar are receiving more attention as it emits more than 20.3 $MtCO_2$/yr which accounts for 20% of total Oman's $CO_2$ emissions in 2024 (98.51 $MtCO_2$/yr) [6], [1]. CCUS system-level optimization is required to determine (i) what technologies should be put in place at each source to capture $CO_2$, (ii) which hubs should be turned on, and (iii) how $CO_2$ should be routed to utilization and/or stored while keeping capacity constraints into consideration and lowering the total annualized cost.

The optimization in literature on optimization offers a robust basis for CCUS network planning, employing mixed-integer linear programming (MILP) and superstructure formulations. These applications encompass CCUS supply chain optimization under uncertainty, rollout planning, and source-sink matching with capacity constraints [7]. Recent research highlights the need for strong decision-support systems for actual industrial clusters by reviewing the state of source-sink matching techniques and problems and further developing spatial

and cluster-based optimization [8].

The main purpose of this study is to develop a superstructure optimization model that aims for the design and planning of a CCUS supply chain network featuring the minimum annualized net cost for Scope 1 emissions in the Sohar Freezone industrial area in Oman. The model is implemented in GAMS using Mixed Linear Integer Programming (MILP) for different scenarios.

## METHODOLOGY

In this study, to achieve $CO_2$ reduction target aligning with Oman's Pathway to Net-Zero 2050 report and make use of captured $CO_2$ to produce value-added products, and optimization based CCUS supply chain model for major $CO_2$ emitters in Oman's industrial sector is developed using GAMS program. The methodology consists of five major steps.

Step 1: Identify the major industries (sources) that emits $CO_2$ in a large quantity, possible capture technologies, $CO_2$ hubs, storage and utilization nodes.

Step 2: Create a superstructure of CCUS network by connecting the identified $CO_2$ emission sources, hubs, storage sites and utilization routes.

Step 3: Construct CCUS supply chain optimization model in GAMS using mixed-integer linear programming (MILP) formulation for three scenarios to achieve 7% reduction level in $CO_2$ emission by 2030, 54% reduction by 2040 and 94% reduction in $CO_2$ emissions by 2050 aligning with Oman's net zero pathways' targets.

Step 4: Optimize and identify the best CCUS network configuration for relevant scenarios with various targeted criteria and conduct techno-economic analysis.

### Data Collection

$CO_2$ sources data related to emission, concentration of $CO_2$ and factories' geological location, storage and utilization nodes in the Sohar Freezone are collected in Tables 1, 2, and 3 and analyzed. The study focuses on SFZ industrial area due to it considers as the largest $CO_2$ emitters in Oman, as described in Table 1. Geographic locations of these factories, hubs, utilization and storage sites are also collected and used in the optimization model. The potential $CO_2$ sinks for Sohar Freezone, including those long-term $CO_2$ storage and utilization routes are identified and provided in Tables 2 and 3. An offshore deep saline aquifer is being considered as a potential long-term sink due to its high injection capacity of up to 20 $MtCO_2$/yr, while an onshore geological storage site is being considered as secondary alternative with 10 $MtCO_2$/yr capacity.

Moreover, three utilization paths are evaluated and studies: Enhanced oil recovery (EOR), chemical production, and concrete manufacturing, with capacities ranging from 0.8 to 5 $MtCO_2$/yr as shown in Table 3.

**Table 2:** Possible $CO_2$ Storage Sites at Sohar Freezone

| Storage options | Type | Max. Injection rate $MtCO_2$/yr | Longitude | Latitude |
|---|---|---|---|---|
| Storage 1 | Offshore deep saline aquifer | 20 | 56.70 | 24.52 |
| Storage 2 | Geological storage | 10 | 56.45 | 24.30 |

**Table 3:** Possible $CO_2$ Utilization Route at SFZ

| Utilization Options | Type | Capacity $MtCO_2$ | Longitude | Latitude |
|---|---|---|---|---|
| Utilization 1 | EOR Field | 5.0 | 56.969 | 23.619 |
| Utilization 2 | Chemical Plant | 2.0 | 56.631 | 24.475 |
| Utilization 3 | Concrete Facility | 0.8 | 56.579 | 24.429 |

## OPTIMIZATION MODEL AND ASSUMPTIONS

### Model Assumptions

Figure 1 represents the full supply chain of CCUS for this case study. The superstructure CCUS supply chain model is developed in GAMS under the following assumptions and basis:

- Capture plants are located near the emissions source to prevent accounting transportation cost of fuel gas.
- Each industrial source is connected to at most one capture technology, which is installed directly at source location the capture technology is selected based on the $CO_2$ concentration at feed stream, energy consumption, CAPEX and OPEX and technology efficiency.
- All capture technologies alternatives have the same availability.
- The targeted emissions reduction is 7% as an early phase decarbonization by 2030, and 50% as a realistic carbon reduction through CCUS that shall be attained by 2040, and 94% as an ambitious target to decarbonize emissions from scope 1 industries by 2050. These reduction level % is aligned with Oman Pathway towards net-zero objectives [5].
- Onshore and offshore pipelines are the transport mode that is considered for Sohar Freezone and for each transport link (source to hub, hub to utilization

**Table 1:** $CO_2$ Emissions Data for 17 Major Emitters from Sohar Freezone

| Factory No. | Industry Type | $CO_2$ Emissions $tCO_2$/yr | Plant Capacity tone/yr | $CO_2$ Conc. (mol%) in Flue Gas | Capture Priority Score | Emissions Intensity $tCO_2$/tone of Product | Longitude | Latitude |

or storage), one transport type shall be selected.

- One emission source node can only be connected to one hub. However, a hub node can get $CO_2$ from more than one emission source node.
- Energy consumption is modelled using technology-specific energy intensities and a uniform energy price, with transport and storage implicitly included in OPEX terms to ensure parsimonious system-level optimization.
- The basis of energy price is 70% energy come from natural gas as heat and 30% from electricity, the cost of electricity in Oman for non-residential tariff is around 18.1 USD/GJ, while the cost of heat from natural gas 3.5 USD/GJ, hence, the energy price is considered as 7.88 USD/GJ [9].
- Based on various techno-economic studies in CCUS value chain, the discount rate for standard commercial projects is between 7% – 8% and for this study, 8% is considered [10], [11].
- The carbon capture cost is 50 USD/$tCO_2$ as a baseline as an exogenous policy parameter in the optimization to represent the economic value of permanent $CO_2$ storage; this reflects mid-range prices used in global net-zero and CCUS techno-economic studies [12].
- The hub cost is defined as including compression/liquefaction, intermediate buffer storage, on/off – loading facilities, mode switching (rail – ship – pipeline) and export terminals. Capture plant CAPEX / OPEX, injection wells and subsurface monitoring, and utilization plant costs are excluded from the hub cost.
- The overall CCUS network is economically optimized for 20 years' life span to provide the geographic distribution and scale of capture, transportation, utilization and sequestration sites.

## Overall Optimization Model and Model Constraints

The purpose of optimization model is to minimize the total cost of CCUS value chain that is associated with cost of $CO_2$ capture, transportation, $CO_2$ hub, storage, utilization and energy consumption., as described in equation 1.

$$\min. obj = Total\ Annualized\ net\ cost = CCUS\ cost - CCUS\ revenue = Capture\ cost + Tansport\ cost + Hub\ Cost + Storage\ Cost + Utlization\ Cost + Energy\ Cost - Revenue\ Carbon\ Credit - Revenue\ Utilization \quad (1)$$

In addition, the MILP superstructure model includes four main constraints to guarantee the precision and viability of the results, i.e., capture allocation, mass balance, network connectivity / capacity and sink capacity. $CO_2$ capture at each source is bounded by emission capacity and limited to at most one technology, as described in equation 2.

**Figure 1.** Superstructure for Sohar Freezone CCUS Supply Chain Network

$$\sum_{ct} f_{i,ct} \le E_i, \sum_{ct} x_{i,ct} \le 1, f_{i,ct} \le E_i \times \varepsilon_{ct} \times x_{i,ct} \times tech_applicable_{i,ct} \quad (2)$$

Second constraint is the mass conservation, where the captured $CO_2$ is routed through hubs and then either to utilization or storage,

$$\sum_{j,tt} F^{SH}_{i,j,tt} = \sum_{ct} f_{i,ct},\ F^{H}_{j} = \sum_{i,tt} F^{SH}_{i,j,tt}, \sum_{k,tt} F^{HS}_{j,k,tt} + \sum_{m,tt} F^{HU}_{j,m,tt} = F^{H}_{j} \quad (3)$$

Third, connectivity and activation link flows to discrete pipeline choices (no free transport is considered) using big-M logic, which is a constant used to activate / deactivate the flow when transport type from source to hub, hub to storage, and hub to utilization is selected. The hub will open if any $CO_2$ flow from any source is connected ($x^{S\to H}_{i,j} \le x^{hub}_{j}$).

$$\sum_{tt} F^{SH}_{i,j,tt} \le M \sum_{tt} x^{SH}_{i,j,tt},\ F^{SH}_{i,j,tt} \le M\, x^{SH}_{i,j,tt} \quad (4)$$

The last constraint is pipeline sizing and sink limits enforce capacity feasibility, and the utilization and storage locations are bounded by maximum injection rate and utilization capacities refer to equations (5, 6).

**Table 4:** CCUS value chain optimal network and $CO_2$ flow in pipelines for different $CO_2$ reduction level scenarios

| Scenarios | Source | Capture Technology | Connection | Amount of $CO_2$ Captured $tCO_2/yr$ | Transport Type | End User |
|---|---|---|---|---|---|---|
| Scenario A: 7% Emissions Reduction by 2030 | F6 | Advanced Solvent-based Absorption Technology | F6 to Hub 2 | 1422696 | Onshore pipeline | Hub 2 to Utilization 2 and 3 |
| Scenario B: 54% Emissions Reduction by 2040 | F1 | Advanced Solvent-based Absorption Technology | F1 to Hub 1 | 3748480 | Offshore pipeline | Hub 1 to Storage 2, Utilization 2 and 3 |
| | F2 | | F2 to Hub 1 | 2658186 | Offshore pipeline | |
| | F3 | | F3 to Hub 1 | 1457340 | Onshore pipeline | |
| | F7 | | F7 to Hub 1 | 1741718 | Onshore pipeline | |
| | F8 | | F8 to Hub 1 | 1167075 | Onshore pipeline | |
| | F10 | | F10 to Hub 1 | 202284 | Onshore pipeline | |
| Scenario C: 94% Emissions Reduction by 2050 | F1 | Advanced Solvent-based Absorption Technology | F1 to Hub 1 | 3748480 | Onshore Pipeline | Hub 1 to Storage 1, Storage 2, and Utilization 3 |
| | F2 | | F2 to Hub 1 | 2658186 | Onshore Pipeline | |
| | F3 | | F3 to Hub 1 | 2394000 | Onshore Pipeline | |
| | F4 | | F4 to Hub 1 | 2288550 | Onshore Pipeline | |
| | F5 | | F5 to Hub 1 | 2008318 | Onshore Pipeline | |
| | F6 | | F6 to Hub 1 | 1775550 | Onshore Pipeline | |
| | F7 | | F7 to Hub 1 | 1741718 | Onshore Pipeline | |
| | F8 | | F8 to Hub 1 | 1167075 | Onshore Pipeline | |
| | F9 | | F9 to Hub 1 | 1003489 | Onshore Pipeline | |
| | F10 | | F10 to Hub 1 | 202284 | Offshore Pipeline | |
| | F11 | | F11 to Hub 1 | 107730 | Onshore Pipeline | |
| | F13 | | F13 to Hub 1 | 9393 | Onshore Pipeline | |

$$\underline{C}_{tt} x^{SH}_{i,j,tt} \le Cap^{SH}_{i,j,tt} \le \overline{C}_{tt} x^{SH}_{i,j,tt}, F^{SH}_{i,j,tt} \le Cap^{SH}_{i,j,tt} \quad (5)$$

$$\sum_{j,tt} F^{HS}_{j,k,tt} \le I^{max}_{k} x^{store}_{k}, \sum_{j,tt} F^{HU}_{j,m,tt} \le U^{cap}_{m} x^{util}_{m} \quad (6)$$

These constraints collectively ensure that the chosen capture technologies, hub locations, pipeline types, and sink options must all be physically consistent in order for CCUS network to achieve the desired capture target.

## RESULTS AND DISCUSSION

The superstructure optimization model findings indicate a distinct cost-effective sequence for CCUS deployment in one major industrial area in Oman, Sohar Freezone, driven mainly by scale, infrastructure availability, and distances. As described in Table 4, in short-term scenario A (7% reduction target), $CO_2$ reduction is predominantly accomplished by localized capture and utilization, hence, reducing the need for transport and storage sites as the utilization is preferred. Table 5 and Figure 2 represent the cost components of CCUS supply chain in the three scenarios. For scenario A, the total cost is 282 million USD/ yr, with capture component account for 70% of total cost. Transport cost is less than 2 MUSD/yr and storage are not preferred as the utilization path is nearby the decarbonized factory.

As the goal for mitigation rises to 54% reduction in $CO_2$ emission, the CCUS system experiences a structural shift towards centralized hubs and permanent geological storage. As depicted from Table 5, in scenario B the cost of capture escalates significantly to 1.56 billion USD annually, although $CO_2$ transport and storage (18 and 125 MUSD/yr, respectively) are identified as economically viable system components. Despite a significant increase in total cost, the $CO_2$ avoidance cost decreases to 134 USD/$tCO_2$ compared to scenario A (224.8 USD/$tCO_2$), this indicates for the importance of economies of scale and efficiency improvements from shared CCUS infrastructure. Moreover, the implementation of carbon credit revenues (500 MUSD/yr) is essential in mitigating rising CAPEX and energy costs, demonstrating that integrated hub-based carbon capture, utilization and storage systems are more effective than disjoined, source-specific solutions after mitigation approaches moderate levels

**Table 5:** Total cost for the optimal CCUS networks for three studied scenarios

| Cost item | Scenario A | Scenario B | Scenario C |
|---|---|---|---|
| Total Cost, MUSD/yr | 281.59 | 2007.42 | 3553.53 |
| Capture, MUSD/yr | 202.01 | 1558.36 | 2712.71 |
| Hub cost, MUSD/yr | 14.85 | 47.18 | 71.57 |
| Transportation, MUSD/yr | 1.97 | 17.95 | 28.53 |
| Utilization, MUSD/yr | 33.61 | 33.61 | 18.33 |
| Storage, MUSD/yr | 0 | 125.46 | 330.97 |
| Energy, MUSD/yr | 29.15 | 224.86 | 391.42 |
| Revenue income, MUSD/yr | 82.68 | 69.25 | 64 |
| Carbon Credit Revenue, MUSD/yr | 0 | 500 | 915.24 |
| $CO_2$ Avoidance cost, USD/t$CO_2$ | 224.87 | 133.69 | 135.03 |

[13].

The model approaches a fully integrated CCUS network with numerous storage sinks and a dominant hub under conditions of deep decarbonization (scenario C, 94% level reduction), with practically all major emissions sources linked to this network, as result indicated in Table 4. Table 5 shows that in scenario C, the capture cost (2.71 billion USD/yr) and storage cost (331 MUSD/yr) constitute the predominant system expenses, although energy consumption emerges as an essential factor (391 MUSD/yr), indicative of the thermodynamic penalty associated with near-complete abatement. In comparison to scenarios A and B, the utilization cost in scenario C (18.33 million USD/yr) is reduced, indicating that the storage option is the most practical choice for large scale CCUS network deployments in the Sohar Freezone industrial area. The $CO_2$ avoidance cost is stabilized at around 135 USD/t$CO_2$, indicating that after infrastructure is constructed, marginal abatement costs remain relatively constant even at high capture levels.

These findings align with Oman's strategies for achieving net zero pathway and global climate emissions reduction objectives. The utilization-driven configuration in the 2030 scenario aligns with Oman's Nationally Determined Contribution (NDC), highlighting cost-efficient industrial mitigation while constraining infrastructure lock-in. The 2040 scenario B depicts a transitional phase consistent with Oman vision 2040, wherein shared $CO_2$ transport and storage infrastructure become economically and strategically viable. The captured $CO_2$ required to be transported to the end-users, either storage sites or utilization plant via pipelines, ships or trucks. The cost of pipeline is highly influenced by the economies of scale, and it varies from country to country. However, shipping can be the best options for very long transport distances, and mid-range $CO_2$ capacities compared to pipelines. In this case study, shipping is not feasible option since the $CO_2$ will be stored and utilized within the same region, hence, onshore and offshore pipelines are considered in this study. As well as, to deploy the CCUS network for large scale, $CO_2$ storage sites must be selected and established. The onshore storage sites are usually less expensive compared to offshore storage sites, due to reuse of depleted oil & gas reservoirs and less data availability for offshore storage sites [14]. The same results are obtained in this case study, geographical storage sites are preferable, compared to onshore sites, Table 4. By 2050, network pipelines and geological storage will be prevailed, aligning with the global net-zero goals established by IEA and IPCC [15]. These pathways emphasise the importance of CCUS for decarbonization hard – to-abate industrial sector.

The results collectively establish the Sohar Freezone as a credible foundation for Oman's long-term decarbonization policy, capable of progressing from initial mitigation to complete net-zero compliance in accordance with international climate commitments.

## CONCLUSION

This study developed a mixed-integer linear programming to evaluate the cost effective of CCUS network for major industrial region in Oman, Sohar Freezone. The study's main objective was to determine the extent to which the CCUS infrastructure, technology selection, and system configuration should evolve under different emissions-reduction targets that are aligned with Oman transition towards net-zero by 2030, 2040 and 2050.

The model results indicate that the implementation of CCUS in Sohar is most economically viable when executed in a phased and system-integrated approach. At low mitigation levels, scenario A, localized capture and utilization, which requires short distance transportation and no geological storage, is the main method of reducing $CO_2$ emissions. Centralized nodes, shared pipeline networks, and permanent storage become economically

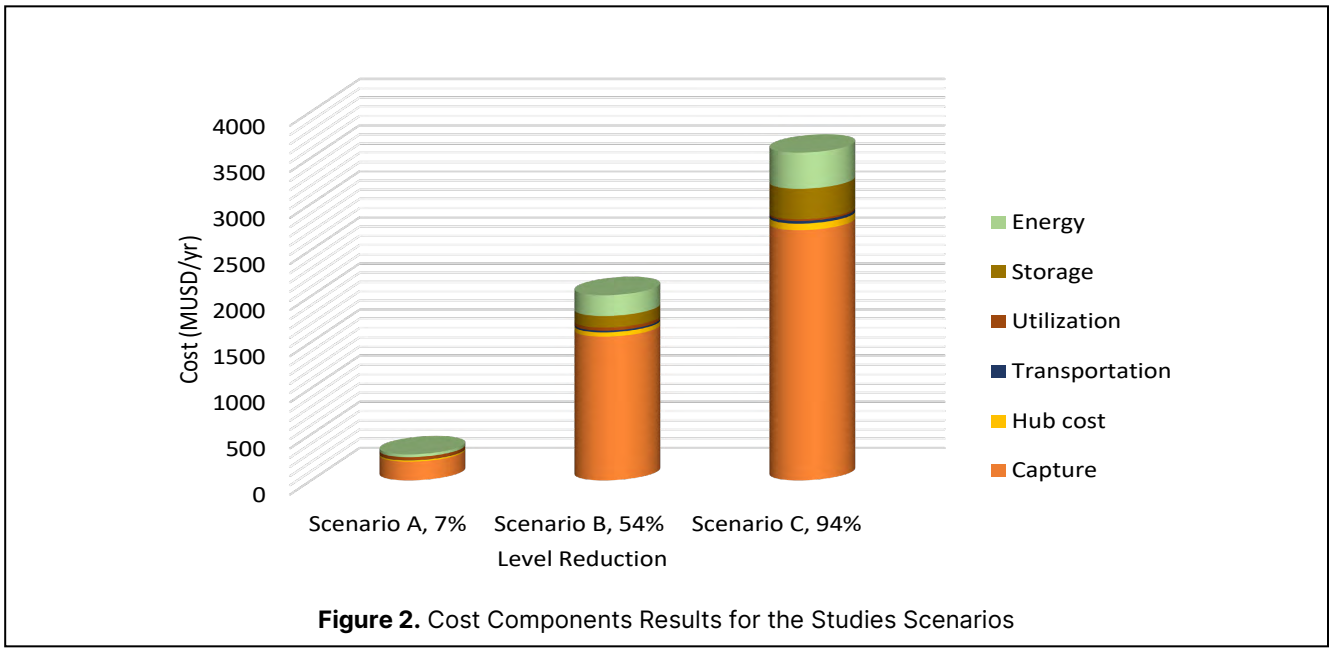

**Figure 2.** Cost Components Results for the Studies Scenarios

viable as ambition increases, scenario B, resulting in substantial reduction in $CO_2$ avoidance costs because of economic of scale. In scenarios of deep decarbonization, scenario C, the system evolves into a sophisticated CCUS network primarily characterized by extensive capture and geological storage, with utilization serving a supplementary component. Moreover, it is important to highlight that, marginal abatement costs remain relatively stable at very high capture rates once the infrastructure is established.

The results emphasise the potential of Sohar Freezone to function as a strategic CCUS anchor for the decarbonization of Oman's industrial sector. The initial deployment of CCUS value chain is driven by industries and availability of utilization paths, however, sustained success relies on the government and supported policies for planning shared transportation, building storage infrastructures and availability of carbon market mechanisms. These findings show how CCUS may move from being a short-term mitigation alternative to being a foundation of Oman's net-zero industrial strategy, in line with global climate goals, and provide practical guidance for policy-makers and business leaders [5].

Although the model offers significant insights regarding to the deployment of CCUS, future research should enhance the framework by integrating the uncertainty in the carbon pricing and technology learning rates, dynamic multi-period investment strategies, and interactions with emerging low carbon alternatives like, green hydrogen and process electrification, to future strengthen long-term planning applicability.

## ABSTRACT

Shell-and-tube heat exchangers are critical assets in the process industries, yet their design optimization typically relies on deterministic formulations that ignore operational variability. This study presents a systematic comparison of four optimization approaches, spanning three paradigms for decision-making under uncertainty, applied to shell-and-tube heat exchanger design. The objective minimizes total annualized cost (comprising capital and pumping costs) subject to thermal duty, pressure drop, velocity, and geometric constraints. Six uncertain parameters are modeled across three categories: mass flowrates (coefficient of variation = 10%), inlet temperatures (coefficient of variation = 2%), and fouling resistances (uniform distribution). Shell-side heat transfer is computed via the Bell–Delaware method, while tube-side correlations follow Sieder–Tate. The four approaches benchmarked are: (1) deterministic optimization as a baseline, (2) sample-average approximation, a classical stochastic programming method, (3) box-constrained robust optimization, which guards against worst-case realizations without probabilistic assumptions, and (4) Wasserstein distributionally robust optimization, which hedges against distributional ambiguity. Results reveal a clear cost–robustness hierarchy: deterministic designs yield the lowest expected cost but lack formal guarantees, sample-average approximation balances cost and reliability with modest computational overhead, the distributionally robust approach achieves the tightest cost dispersion at a moderate premium, and robust optimization delivers the highest feasibility guarantees at the greatest cost. These findings provide practitioners with quantitative guidance for selecting an appropriate optimization paradigm based on reliability requirements, data availability, and computational budget.

**Keywords**: optimization under uncertainty, heat exchanger design, stochastic programming, distributionally robust optimization, robust optimization

## INTRODUCTION

Shell-and-tube heat exchangers (STHEs) are the most widely deployed heat transfer equipment in the chemical and petrochemical industries, representing a significant share of capital investment. Operating costs (dominated by pumping power) contribute substantially to facility-wide energy consumption [1]. Traditional deterministic design assumes fixed operating conditions, yet industrial reality involves persistent parametric uncertainty: upstream disturbances introduce flowrate fluctuations, control systems exhibit finite bandwidth, and fouling evolves stochastically. Designs optimized under nominal conditions often violate pressure-drop or thermal-duty constraints when conditions deviate, whereas conservative designs with arbitrary safety factors incur unnecessary capital costs [2].

Recent advances in STHE optimization have ex-

plored metaheuristic algorithms[3], data-driven surrogates [4], and multi-objective frameworks [5]. However, these efforts largely employ deterministic formulations or ad-hoc robustness strategies without rigorous uncertainty quantification. Optimization under uncertainty encompasses three principal paradigms [6]: stochastic programming, which optimizes over a known probability distribution, robust optimization, which hedges against worst-case realizations within a deterministic uncertainty set, and distributionally robust optimization, which guards against the worst-case distribution within an ambiguity set [7]. Although each paradigm has been applied individually to process design problems, systematic comparative studies evaluating multiple paradigms on identical case studies remain scarce [8].

Despite theoretical progress, systematic comparative studies evaluating multiple methodologies on identical problems under consistent uncertainty specifications remain limited. Existing literature presents individual methods in isolation, with incomparable assumptions about uncertainty, constraint formulations, and evaluation protocols, hindering practical adoption. Engineers lack actionable guidance on method selection that accounts for application requirements, data availability, and computational resources.

This work addresses these gaps through a systematic benchmarking of four optimization strategies spanning the three main paradigms for decision-making under uncertainty, applied to STHE design under realistic operational variability. The objectives are: (i) to provide the first consistent comparison of deterministic, sample-average approximation (SAA), box-constrained robust optimization (RO), and Wasserstein distributionally robust optimization (WDRO) approaches for STHE design under identical uncertainty specifications; (ii) to quantify cost–robustness trade-offs across paradigms; (iii) to assess computational scalability of each approach; (iv) to identify failure modes and practical limitations; and (v) to develop actionable method selection guidelines for industrial practitioners.

# PROBLEM FORMULATION AND METHODS

## Deterministic Design Model

The STHE design problem minimizes total annualized cost (TAC) comprising annualized capital expenditure (via a capital recovery factor accounting for interest rate and plant lifetime) plus annual operating expenditure. The capital recovery factor is $CRF = \frac{i(1+i)^n}{(1+i)^n-1}$, with interest rate i = 5% and lifetime n = 20 years. TAC is calculated with equation (1).

$$\mathrm{TAC} = \frac{\mathrm{CAPEX}}{\tau} + 8760 C_{\mathrm{elec}} \frac{P_s + P_t}{\eta} \tag{1}$$

where $C_{\mathrm{elec}}$ is electricity cost ($/kWh), $P_s$ and $P_t$ are shell/tube-side pumping power (kW), $\eta$ is pump-motor efficiency, and 8, 760 represents annual operating hours.

The design vector $x$ comprises 11 variables: shell diameter $D_s$, tube length $L$, baffle spacing $L_{bc}$, tube-side passes $N_p$, plus some discrete selections. Thermal-hydraulic performance employs the Bell-Delaware method for shell-side, accounting for flow bypassing, baffle leakage, and adverse gradients through correction factors $J_c, J_l, J_b, J_s, J_r$ typically ranging 0.6-0.9. This can be observed in equation (2).

$$h_s = h_{\mathrm{ideal}} \cdot J_c \cdot J_l \cdot J_b \cdot J_s \cdot J_r \tag{2}$$

Tube-side forced convection employs Sieder-Tate for turbulent flow ($\boldsymbol{Re > 10,000}$), shown in equation (3).

$$\mathrm{Nu}_t = 0.027 \mathrm{Re}^{0.8} \mathrm{Pr}^{1/3} \left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{3}$$

Operational constraints enforce: (i) pressure drop $\Delta P_s, \Delta P_t \leq 75$ kPa (typical available head); (ii) velocity $0.8 \leq v_t \leq 3.0$ m/s (fouling mitigation and erosion prevention); (iii) length-to-diameter $L/D_s \leq 15$; (iv) heat duty $Q \geq Q_{\mathrm{req}}$.

## Uncertainty Quantification

We model six uncertain parameters across three physical categories using physically-motivated probability distributions. Shell-side and tube-side mass flowrates exhibit the largest variability (10% CV) due to upstream disturbances and control limitations. Shell-side and tube-side inlet temperatures are regulated more tightly (2% CV). Shell-side and tube-side fouling resistances follow uniform distributions reflecting epistemic uncertainty about the fouling state within cleaning cycles. Training data comprises 30 scenarios sampled via Latin hypercube sampling (LHS) to ensure coverage of the uncertainty space. Testing employs 100 independent scenarios for out-of-sample validation. Stress scenarios (N=10) represent extreme combinations to assess robustness under tail events, shown in equation (4).

$$F_{m,s} \sim \mathrm{TN}\left(27.8\ \mathrm{kg/s}, (2.78\ \mathrm{kg/s})^2, 19.46, 36.14\right) \tag{4}$$

The $\pm 30\%$ truncation bounds capture process transients while preventing physically unrealistic scenarios. Flowrate affects both thermal (heat transfer $\propto Re^{0.6}$) and hydraulic ($\Delta P \propto Re^{1.8}$) performance simultaneously.

Shell-side inlet temperature is modeled with the same distribution structure (2% CV), as shown in equation (5). Tube-side inlet temperature follows equation (6).

$$F_{m,s} \sim \mathrm{TN}\left(27.8\ \mathrm{kg/s}, (2.78\ \mathrm{kg/s})^2, 19.46, 36.14\right) \tag{5}$$

$$T_{t,\text{in}} \sim \text{TN}\left(298.15\ \text{K}, (5.96\ \text{K})^2, 286.19, 310.11\right) \quad (6)$$

Fouling resistance accumulates monotonically from clean to heavily fouled state. We employ a uniform distribution reflecting epistemic uncertainty about the actual fouling state within cleaning cycles, as shown in equation (7).

$$R_s \sim \text{Uniform}\left(0.00033\ \text{m}^{2\cdot\text{K/W}}, 0.00050\ \text{m}^{2\cdot\text{K/W}}\right) \quad (7)$$

These bounds correspond to moderate fouling service (treated cooling water, light oils) per TEMA standards.

LHS generates scenarios with improved convergence relative to crude Monte Carlo. A three-tier evaluation protocol is employed: (i) training ($N = 30$) drives optimization following guidelines for 4-6 uncertain parameters; (ii) test ($N = 100$) assesses out-of-sample performance; (iii) stress ($N = 10$) probes extreme events (deterministic worst-cases plus tail samples beyond 95$^{\text{th}}$ percentile).

## OPTIMIZATION APPROACHES UNDER UNCERTAINTY

### Deterministic Optimization

As a reference baseline, deterministic optimization solves the design problem at nominal (expected-value) parameters $\xi_0$, as in equation (8).

$$\min_x \text{TAC}\,(x, \xi_0) \quad \text{s.t.} \quad g(x, \xi_0) \le 0,\ x \in \mathcal{X} \quad (8)$$

Where $g$ represents constraints. Differential evolution with adaptive penalty functions, shown in equation (9).

$$\Phi(x, \xi_0) = \text{TAC}(x, \xi_0) + \rho_k \sum_i \max\left(0, g_i(\boldsymbol{x}, \xi_0)\right)^2 \quad (9)$$

where $\rho_k = \rho_0 \cdot (1.2)^k$ (initialized $\rho_0 = 1000$, capped at 10, 000) encourages exploration then ensures constraint satisfaction. The adaptive penalty mechanism steers the optimizer away from tight constraint boundaries, which may result in incidental margins under perturbations. However, since no uncertainty information enters the formulation, any out-of-sample feasibility is problem-specific rather than guaranteed, and this approach serves strictly as a cost baseline.

### Sample-Average Approximation

Sample-average approximation is a classical stochastic programming method that replaces the true expected value with an empirical average over a finite scenario set drawn from the known distribution. The penalized formulation is given in equation (10).

$$\min_x \text{E}_\xi\,[\text{TAC}(x, \xi)] \quad \text{s.t.} \quad \text{Prob}(g(x, \xi) \le 0) \ge \alpha \quad (10)$$

using sample average over N=30 scenarios:

$$\min_x \frac{1}{N} \sum_{n=1}^{N} \text{TAC}(\boldsymbol{x}, \xi^{\boldsymbol{n}})$$

Penalized objective aggregates across scenarios:

$$\Phi_{\text{SAA}}(x) = \frac{1}{N} \sum_{n=1}^{N} \left[ \text{TAC}(x, \xi^n) + \rho_k \sum_i \max\left(0, g_i(\boldsymbol{x}, \xi^{\boldsymbol{n}})\right)^2 \right]$$

By the law of large numbers, the sample-average objective converges to the true expectation as $N \to \infty$. Computational cost increases 30 times, but parallelizes trivially over scenarios.

### Box-Constrained Robust Optimization

Robust optimization hedges against the worst-case realization within a deterministic uncertainty set, without invoking probability distributions. The formulation seeks a design that minimizes cost under the most adverse conditions within the hyperrectangle defined by physical parameter bounds, as expressed in equation (11).

$$\min_x P_{90}\,[\text{TAC}(x, \xi)] \quad \text{s.t.} \quad P_{90}[g_i(x, \xi)] \le 0 \quad (11)$$

The uncertainty set is defined as the hyperrectangle bounded by physical parameter limits, as expressed in equation (12).

$$\widehat{P_{90}}[\text{TAC}(x, \xi)] = \text{TAC}_{(\lceil 0.9N \rceil)}(x) \quad (12)$$

The inner maximization is solved via vertex enumeration of the $2^6$ = 64 box corners, followed by Nelder–Mead refinement to capture interior worst cases arising from model nonlinearities. By construction, this formulation provides deterministic feasibility guarantees for all realizations within the uncertainty set, without requiring probabilistic assumptions.

### Wasserstein Distributionally Robust Optimization

WDRO hedges against distributional ambiguity [7], this is shown in equation (13).

$$\min_x \sup_{P \in \mathcal{D}} E_P\,[\text{TAC}(x, \xi)] \quad (13)$$

The ambiguity set is defined as a Wasserstein ball centered on the empirical distribution, as given in equation (14).

$$\mathcal{D} = \left\{P : d_W\left(P, \widehat{P_N}\right) \le \varepsilon\right\} \quad (14)$$

The radius is calibrated via a confidence parameter to ensure that the true distribution lies within the ball with high probability:

$$\varepsilon = \sqrt{\frac{2}{N}\ln\left(\frac{1}{\alpha}\right)}\left(1 + \frac{1}{\sqrt{N}}\right)$$

With $\alpha = 0.05$ ensures that the true distribution lies within the Wasserstein ball with at least 95% probability. A tractable mean–variance approximation yields the surrogate objective in equation (15).

$$\Phi_{\mathrm{WDRO}}(x) = \frac{1}{N}\sum_{n=1}^{N} \mathrm{TAC}(x, \xi^n) + \lambda\sqrt{\frac{1}{N}\sum_{n=1}^{N}[\mathrm{TAC}(x, \xi^n) - \mu]^2} \quad (15)$$

Where $\lambda = \varepsilon/\sqrt{N}$ acts as a variance penalty, promoting cost consistency across distributional perturbations.

## RESULTS AND DISCUSSION

### Comparative Performance Analysis

Table 1 summarizes the out-of-sample performance of each method, evaluated on 2, 000 independent test scenarios. Cost statistics are reported without outlier filtering, preserving the tail behavior that uncertainty-aware methods are designed to address.

**Table 1:** Comparative Performance Metrics

| Method | Avg Cost ($) | CV (%) | Test Feas (%) | Time (s) |
|---|---|---|---|---|
| Deterministic | 10, 518 | 0.84 | 76.5 | 0.1 |
| SAA | 10, 553 | 0.91 | 76.7 | 3.8 |
| WDRO | 10, 833 | 0.49 | 77.4 | 3, 737 |
| RO | 28, 359 | 0.57 | 78.8 | 16.0 |

Deterministic optimization yields the lowest expected cost, as anticipated from a formulation that ignores uncertainty. When the resulting design is evaluated a posteriori under stochastic scenarios, it achieves 76.5% feasibility, a consequence of the penalty-based solver steering designs away from constraint boundaries, rather than an inherent robustness property. The cost variability is moderate (CV = 0.84%), and sub-second runtime enables rapid design-space exploration. However, this approach provides no formal guarantees on out-of-sample performance.

SAA delivers balanced performance at a negligible cost premium (+0.3%) over the deterministic baseline. Test feasibility (76.7%) is comparable to the deterministic result, suggesting that for this case study, SAA drives the optimizer toward a similar region of the design space while incorporating scenario-based penalty information. The modest computational overhead (3.8 s) remains practical for iterative design workflows.

WDRO achieves the tightest cost dispersion (CV = 0.49%) at a 3.0% cost premium, validating the variance-penalizing effect of the distributional robustness formulation. Feasibility improves to 77.4%, and the 95$^{th}$-percentile cost is notably compressed relative to the mean. The distributional guarantee ensures reliable performance even when the true distribution deviates from the empirical estimate, a property particularly valuable for processes subject to seasonal or operational drift. The computational cost (~62 min) is substantially higher than SAA, reflecting the inner Nelder–Mead optimization required at each candidate evaluation.

Box-constrained RO yields the highest-cost design (US$28, 359, a 169% premium), reflecting the well-known conservatism of worst-case optimization. The optimizer selects a substantially larger shell diameter (D_s ≈ 0.96 m vs. 0.49–0.52 m for other methods) to guarantee feasibility across the entire uncertainty set. This conservatism produces the highest out-of-sample feasibility (78.8%) and the best performance under distributional drift (51.1% feasibility at κ = 1.0 vs. 45–46% for other methods). While the cost premium is prohibitive for routine applications, the RO paradigm is appropriate for safety-critical equipment where constraint violations carry severe consequences.

Table 2 compares the key geometric and thermal–hydraulic parameters of the optimal designs obtained by each method. Although the deterministic, SAA, and WDRO formulations all converge to compact geometries with similar heat transfer areas (131–145 m²), they differ in the balance between shell diameter and tube length. The deterministic design favors a short, wide configuration (D_s = 0.49 m, L = 2.5 m), while SAA opts for a narrower but longer exchanger (D_s = 0.45 m, L = 6.3 m) approaching the L/D limit. WDRO selects an intermediate geometry (D_s = 0.52 m, L = 5.4 m). In contrast, the RO design is fundamentally different: a shell diameter nearly twice as large (D_s = 0.96 m) with 596 m² of transfer area—roughly four times the other designs. This oversizing is the mechanism by which RO guarantees feasibility under worst-case conditions but at a substantial cost penalty. All designs operate within the velocity and pressure-drop constraints, with RO exhibiting the lowest tube-side velocity (0.86 m/s), close to the minimum bound.

### Cost-Robustness Trade-offs

Figure 1 illustrates the cost–robustness trade-off. Deterministic and SAA cluster near US$10, 500 with CV around 0.84–0.91%, while WDRO achieves the lowest dispersion (CV = 0.49%) at a modest 3% cost premium. RO, at US$28, 359, lies far outside the cluster (indicated by arrow), reflecting the substantial cost of worst-case pro-

tection. The plot confirms that WDRO offers the most favorable cost–dispersion balance among uncertainty-aware methods.

**Table 2:** Optimal design parameters by optimization method

| Parameter | Units | DET | SAA | RO | WDRO |
|---|---|---|---|---|---|
| Shell diameter | m | 0.491 | 0.450 | 0.964 | 0.518 |
| Tube length | m | 2.54 | 6.33 | 10.41 | 5.44 |
| Number of tubes | – | 2583 | 518 | 1436 | 668 |
| Heat transfer area | $m^2$ | 130.7 | 130.8 | 596.5 | 145.0 |
| Tube velocity | m/s | 1.12 | 1.20 | 0.86 | 0.93 |
| Overall U | $W/m^2K$ | 1185 | 1185 | 260 | 1069 |
| L/D ratio | – | 5.2 | 14.1 | 10.8 | 10.5 |
| TAC | US$/yr | 10, 506 | 10, 548 | 28, 367 | 10, 830 |

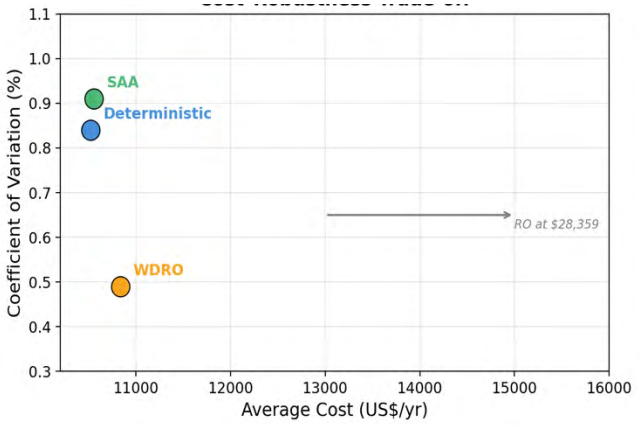

**Figure 1.** Cost–robustness trade-off across the four optimization approaches.

The observed CV range (0.49–0.91% for SP and DRO methods) indicates that cost variability is well controlled under the specified uncertainty levels. The 3.0% WDRO premium is modest relative to typical 10–20% industrial contingency factors, suggesting that formal distributional guarantees offer superior risk mitigation compared to ad-hoc safety margins.

Figure 2 compares feasibility across methods. Under nominal conditions (κ = 0), all methods achieve 76–79% feasibility, with RO performing marginally better due to its worst-case design margins. As distributional drift increases (κ → 1), feasibility degrades for all methods, but RO retains a consistent advantage (51% vs. 45–46%), confirming that worst-case guarantees translate into superior drift resilience.

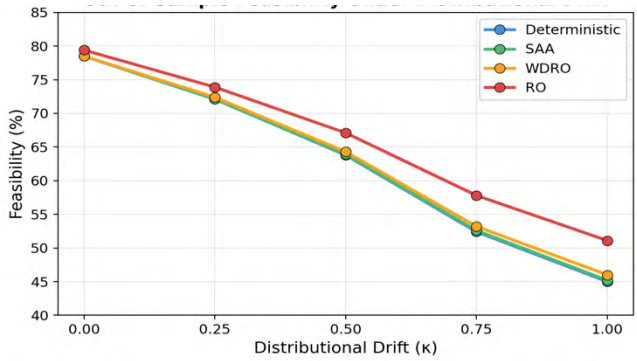

**Figure 2.** Out-of-sample feasibility as a function of distributional drift.

## Method Selection Guidelines

Based on the comparative analysis, the following guidelines are proposed for practitioners. Deterministic optimization is suited to preliminary design and rapid prototyping where sub-second runtime enables extensive sensitivity analysis. It is acceptable when operational variability is low (CV < 5%) and equipment operates well within constraint boundaries, but should not be relied upon for safety-critical applications.

SAA is recommended as the default method for general industrial practice. It provides a principled framework for incorporating uncertainty with modest computational overhead (~4 s) and negligible cost premium. It is particularly effective when reliable historical data is available to characterize the uncertainty distribution and the process exhibits approximately stationary behavior.

WDRO is recommended for applications that demand cost predictability and robustness to distributional uncertainty. It is especially justified when training data is limited, the true distribution is imperfectly known or non-stationary, or regulatory requirements mandate high reliability. The 3% premium purchases formal distributional guarantees and the tightest cost dispersion among all methods tested.

RO is reserved for safety-critical applications where constraint satisfaction must be guaranteed across all foreseeable operating conditions. The worst-case focus provides deterministic feasibility guarantees but at a substantial cost premium (169% in this case study), making it impractical for routine design. RO is most appropriate when probability distributions are unavailable or unreliable and when the consequences of constraint violation are severe.

## CONCLUSION

This study benchmarks four optimization approaches (spanning three paradigms for decision-making under uncertainty) on the same STHE design problem. The principal findings are: (1) deterministic optimization provides the lowest-cost baseline but offers no formal robustness guarantees; (2) SAA delivers comparable cost at negligible premium while incorporating scenario-based uncertainty information; (3) WDRO achieves the tightest cost dispersion (CV = 0.49%) at a modest 3% premium, confirming the practical value of distributional robustness when uncertainty characterization is imperfect; and (4) box-constrained RO guarantees feasibility across the entire uncertainty set but at prohibitive cost (169% premium), illustrating the conservatism inherent to worst-case formulations. Across all methods, the cost premium for uncertainty awareness is modest relative to typical industrial contingency factors, while providing formal guarantees that ad-hoc safety margins cannot.

## ABSTRACT

While classical heuristics can be applied to decide on the preferred reactor concept for simple reaction schemes, more complex reaction networks require more sophisticated methods, such as the multilevel reactor design approach or superstructure optimization. Based on an analysis of the existing methods a nonlinear programming framework for a superstructure-based reactor network synthesis is presented, emphasizing numerical robustness and flexible network representation without relying on integer decisions. The approach, which is implemented in GAMS, allows for the combination of continuous stirred-tank and cross-flow reactor models. An exemplary application for the classical Van de Vusse reaction is first shown for validation, prior to the application to an enzymatic cascade based on the Weimberg pathway. Assuming fast co-factor regeneration, the performance of the resulting PFR cascade, which can also be interpreted as a sequence of batch reactions, is compared with a commonly applied single batch reactor. The results show that the two-reactor configuration consistently achieves higher product formation by mitigating inhibition effects, demonstrating the potential of reactor network synthesis for complex reaction systems like enzymatic cascades.

**Keywords**: reactor network, NLP, GAMS, enzymatic cascades, reaction engineering

## INTRODUCTION

The systematic design of reactor networks is a central and enduring challenge in chemical reaction engineering because the selection and interconnection of reactors fundamentally determines achievable yields, selectivities, and overall performance for complex reaction systems. Even when the problem is restricted to kinetics-based descriptions, the number of feasible reactor configurations grows rapidly with increasing system complexity, rendering the use of heuristics or intuitive or case-specific design approaches insufficient and highlighting the need for systematic, theoretically grounded methodologies for reactor network synthesis.

A unifying framework for assessing the limits of reactor performance is provided by the concept of the attainable region (AR), first introduced by Horn [1] as the “totality of physically possible reactors.” The AR represents the complete set of achievable outlet states for a given reaction system under admissible operating conditions, enabling the identification of optimal reactor configurations through geometric arguments. Building on this concept, Feinberg and Hildebrandt [2, 3] demonstrated that the complete attainable region can be constructed from a finite set of elementary reactor building blocks—namely the continuously stirred tank reactor (CSTR), the plug-flow reactor (PFR), and the differential side stream reactor (DSR)—in combination with ideal mixers and splitters. A key implication of this result is that any optimal reactor performance can, in principle, be realized by a reactor network composed exclusively of these elementary units [4].

Despite its conceptual power, the explicit construction of the full attainable region is computationally demanding and becomes impractical for systems of realistic dimensionality. Consequently, over the past four decades, numerous optimization-based targeting methods have been developed to identify optimal or near-optimal reactor configurations without explicitly constructing the entire AR. These approaches follow two different lines,

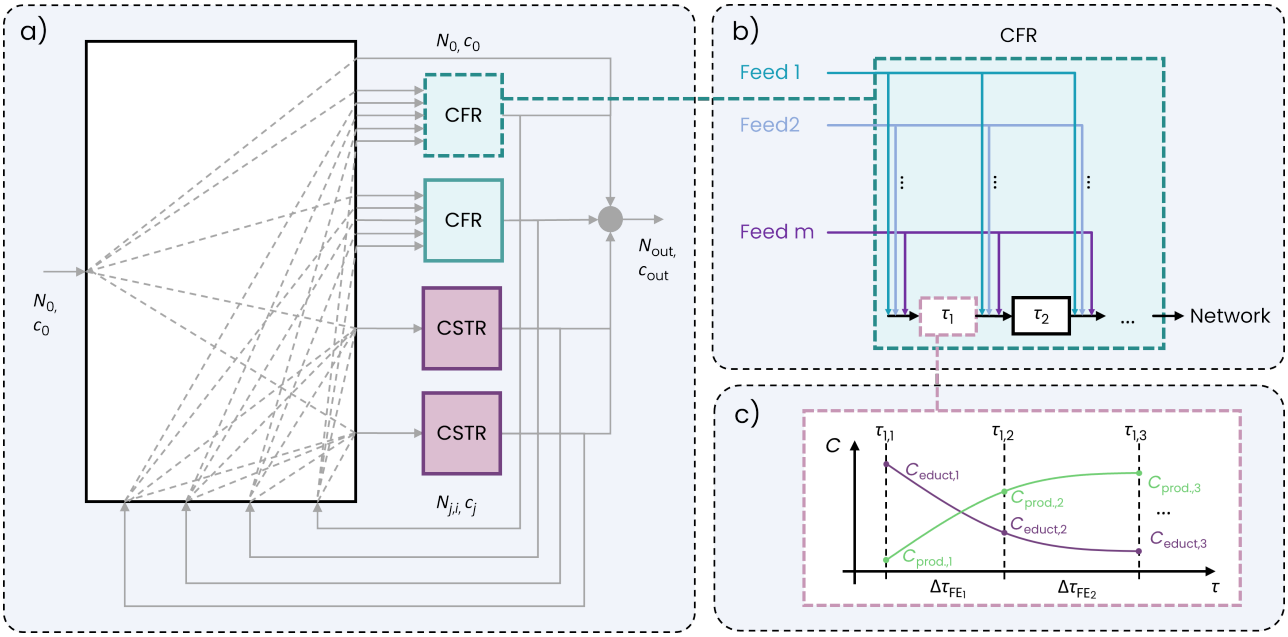

**Figure 1.** a) An example of the superstructure network for a network with 2 CFRs and 2 CSTRs. b) The connections of the multiple inlet streams inside the CFRs. c) The collocation method for each segment of the CFR (FE stands for finite element).

either pursuing a dynamic optimization of e.g. elementary process functions (EPF) [5], subsequently analyzing the result in a multilevel reactor design approach [6], or pursuing a superstructure-based optimization to determine the optimal reactor network. The latter typically formulate the reactor network synthesis problem as a nonlinear (NLP) or mixed-integer nonlinear programming (MINLP) problem. Examples include discretized recycle reactor modules that interpolate between PFR and CSTR behavior [7], combinations of CSTRs and PFRs [8, 9], networks of just CSTRs [10] and networks composed of CSTRs and DSRs with optional side streams [4, 11]. To render these models tractable, governing differential equations are transformed into algebraic equation systems, either by discretizing PFRs and DSRs as series of CSTRs [8, 12] or by employing direct transcription techniques such as orthogonal collocation on finite elements [4]. The resulting nonlinear and mixed-integer optimization problems are typically solved using local deterministic methods or stochastic metaheuristics, such as genetic algorithms, each with their own limitations in reliability and scalability.

The current contribution revisits the reactor network synthesis problem from both a modeling and numerical robustness perspective and proposes a refined superstructure model that:

- avoids unnecessary integer decisions while retaining the generality needed to capture arbitrary network connectivity,
- relies on continuous stirred tank and cross-flow reactors, and
- is solved by means of a polylithic solution approach in GAMS.

A key novelty of our work is that we demonstrate how many numerical difficulties traditionally associated with reactor network synthesis are not inherent to the problem itself but are instead induced by specific modeling choices**.**

To validate the proposed methodology and benchmark its performance against established approaches, we first illustrate the application to the classical Van de Vusse reaction network [14] that has been extensively investigated for reactor network synthesis and attainable region analyses.

As a second innovative application, we consider the design of an optimal reactor network for an enzymatic cascade**.** Such cascades involve a sequence of biocatalytic transformations catalyzed by multiple enzymes. They are of growing interest in biocatalysis and process intensification due to their potential for high selectivity and environmentally friendly operation. One example that is considered in the current study, such as the oxidative Weimberg pathway for pentose conversion to α-ketoglutarate [14], which builds on recent advances in in-vitro enzyme cascade design for metabolic pathways. Up to today, model-based optimization methods for enzymatic cascade reaction systems focus on optimizing the single pot approach [15-18]. Even though, these multi-step reactions can often be carried out in a single pot, this is not

necessarily optimal under all conditions. Inhibition or allosteric effects are only two possible reasons a more complex reactor network can be a beneficial choice. These systems provide an excellent application for reactor network synthesis methods because they combine strongly nonlinear kinetics with interlinked reaction steps.

## METHODOLOGY

### Model formulation

Figure 1 provides an illustration of the superstructure model used in this work. A generic reactor network superstructure following the state-space approach is formulated to allow arbitrary interconnections between feed streams, reactors, bypasses, and outlet streams via a distribution network. The individual reactors in the network are assumed to operate at steady state. An overall molar balance is imposed over the complete reactor network, ensuring consistency between all feed, reactor, bypass, and outlet flows. Unlike the work of Recker et al. [10], which considers solely ideal CSTRs, also tubular cross flow reactors (CFRs), which can implement a PFR or DSR [11] are considered as building blocks. The system of differential equations for the CFRs is modeled via a direct transcription using orthogonal collocation on finite elements, resulting in a NLP formulation. Intermediate feeding is feasible in between the finite elements, while a Radau IIA collocation captures axial variations in composition along the length of each finite element. For CSTR-only models' large cascades of CSTRs are required to accurately approximate the PFR performance. For kinetically sensitive systems, minor changes in residence time distribution and mixing assumptions can induce disproportionate deviations in the state trajectory, while networks with a large number of CSTRs pose combinatorial challenges for optimization. With the combination of CSTRs and CFRs a superstructure with two of these reactors is rich enough for most applications.

Unlike the EPF-approach that requires an interpretation of internal fluxes to identify CSTRs [19], the superstructure implements CSTRs as perfectly mixed reactors, with outlet compositions determined by the steady-state reaction rates and an explicit residence time. The superstructure formulation allows flexible stream splitting, mixing, and recycling, enabling the optimization of network topology, reactor selection, and sizing, while ensuring that material balances and component mole fractions are satisfied throughout the network.

### Model implementation

The superstructure model is implemented in GAMS. A polylithic modeling and solution strategy is employed, which starts with the definition of the reaction kinetics that are included for each reactor type, with the flexibility to incorporate multiple reaction mechanisms. On this basis each individual reactor is initialized based on the overall feed and a small residence time. After the definition of potential additional constraints, e.g. for the definition of a minimum conversion or an upper bound for some intermediate composition, an initial solution for the full superstructure model is determined for a distribution network with a fixed structure that distributes the feed to all available reactors and does the same for the reactor products. After this initialization, the fixed split factors in the distribution network are relaxed and the reactor network optimization is performed.

Optimization of the superstructure is performed using nonlinear programming solvers (e.g., CONOPT), maximizing a specified performance objective, while satisfying all reactor and network constraints. Note that solver options, scaling factors, and finite-element discretization have to be selected to ensure numerical stability depending on the specific application. The respective model implementations for the subsequent case studies are provided via Gitlab (link in the appendix).

## CASE STUDIES

### Van de Vusse reaction

A commonly studied example for reactor network optimization is the so-called Van de Vusse reaction shown in Figure 2:

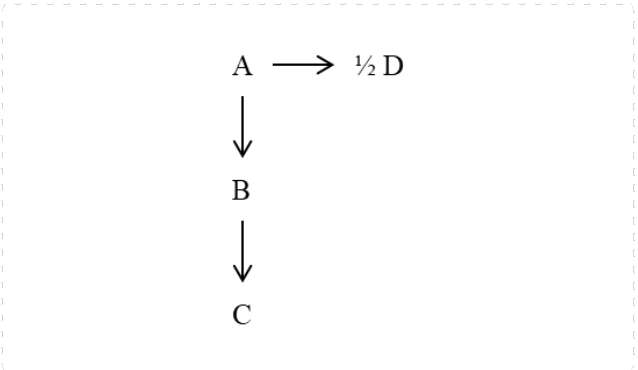

**Figure 2.** The chemical reaction network of the widely studied Van de Vusse reaction.

All reactions are catalyzed by the same catalyst. The kinetic and feed-related parameters are reflecting the case study 1 considered in the work of [19]. The Yield of B is selected as an objective to be maximized by selecting the specific reactor network structure and the residence time and temperature of the isothermal reactors.

### Weimberg pathway

Reactor network synthesis is particularly interesting for applications to enzymatic cascades, as they involve multiple enzymes whose concentrations must be carefully balanced to achieve optimal performance. The

reaction network of the Weimberg pathway is shown in Figure 3. This cascade is well characterized kinetically, with each step catalyzed by a distinct enzyme. Two reactions in the pathway are cofactor dependent.

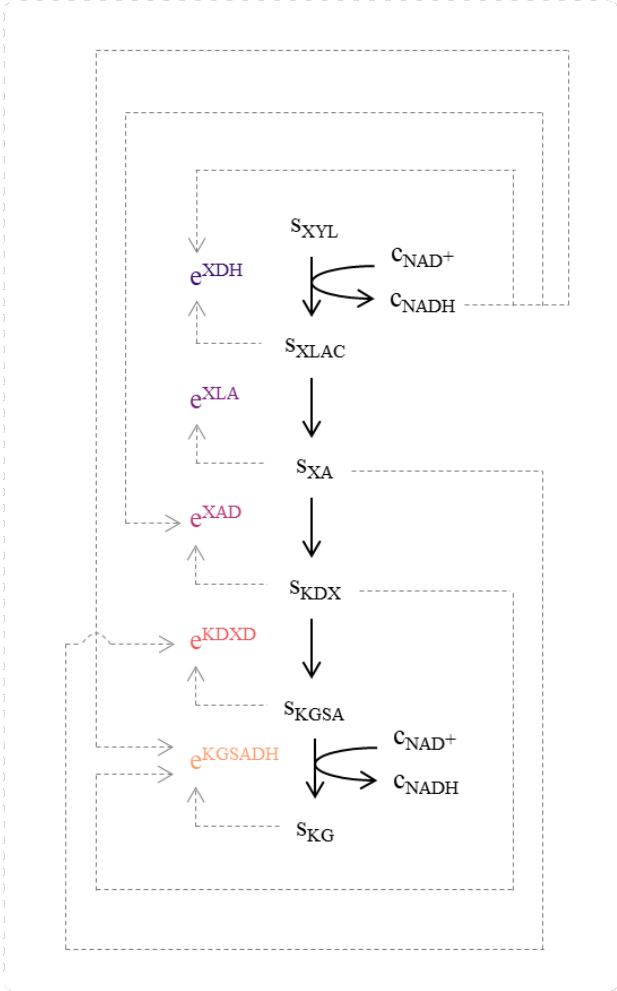

**Figure 3:** The chemical reaction network of the enzymatic cascade reaction of the Weimberg pathway. The black arrors show the reaction steps, while the grey, dashed arrows show inhibition effects.

**Figure 3.** also presents the substrate (s) and enzyme (e) abbreviations, together with the chemical reaction network and known inhibitory interactions between substrates and enzymes (dashed lines). A detailed kinetic model of the Weimberg pathway was developed by Shen et al. [14]. In their study, cofactor regeneration was implemented via a secondary reaction converting pyruvate to L-lactate catalyzed by L-lactate dehydrogenase. Under the assumption that this regeneration step proceeds rapidly—corresponding to the use of sufficiently high L-lactate dehydrogenase levels—we apply the proposed methodology to evaluate the performance gains achievable by employing multiple batch reactors instead of a single batch reactor for the Weimberg pathway. The well-known analogy between batch reactors and plug-flow reactors was used to apply our steady-state centric methodology to this dynamic problem.

The objective of the optimization problem is to maximize product formation ($s_{KG}$). CONOPT3 is employed as NLP solver in GAMS analyzing two scenarios: (i) a single-reactor configuration, in which the optimizer determines the optimal enzyme titers, and (ii) a two-reactor configuration in series, in which the optimizer determines the optimal allocation of a fixed enzyme budget between the reactors. The GAMS models are available in a GitLab repository (link provided in the appendix).

## RESULTS AND DISCUSSION

### Van de Vusse reaction

To validate the reactor network synthesis approach, the case study with parameters considered by Xie et al. [19] was solved. The resulting optimal reactor network matched the previously reported configuration, consisting of a CSTR followed by a PFR in series (cf. Figure 4), which also reflects the objective function and design variables reported by Xie et al [19] (objective function value: $Y_{A\rightarrow B} = 63.5\ \%$).

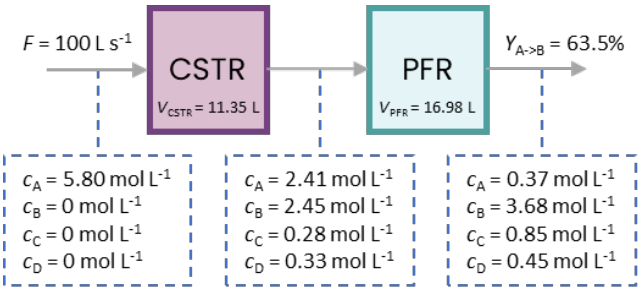

**Figure 4.** The results of the Van de Vusse case study.

Optimization of the Van de Vusse case study also allows for the identification of some hidden pitfalls for the flexible CFR model. If side-feeding and side-draws locations are feasible and the residence time in each finite element is treated as decision variable the solver exploits this by activating feed injections and effluent withdrawal at intermediate locations, effectively bypassing finite elements and reducing the numerical accuracy of the integration of the differential equation system. This concentrates residence time only in the most sensitive segments, resulting in a degenerate optimum: comparable objectives obtained with different apparent reactor sizes and partial volume utilization, which is not a faithful realization of the intended CFR behavior. Consequently, the different degrees of freedom in the CFR model should be used with care, to avoid such compromising bypass streams.

## Weimberg pathway

The results of the comparison between the single batch reactor and the superstructure with two PFR (batch reactors) are summarized in Figure 5. The x-axis represents the total enzyme loading, while the y-axis denotes the total substrate concentration, for which each 3 distinct values have been evaluated. The percentage improvement in product formation achieved by the resulting two-reactor configuration is shown for each combination as a third dimension in the heat-map representation.

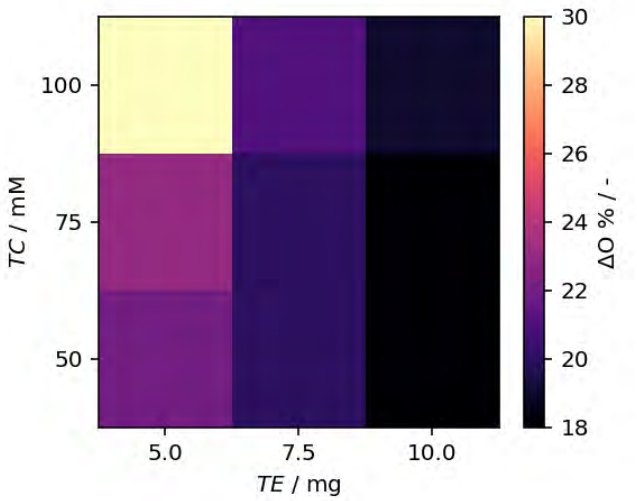

**Figure 5.** Comparison of the produced product with two batch reactors against the produced product with one reactor for different substrate and enzyme amounts in a raster-type contour plot.

For all conditions, the resulting two-reactor network consistently outperforms the single-reactor configuration, with up to 30% more product with the same enzyme budget. The performance advantage becomes increasingly pronounced at higher substrate loadings and lower total enzyme amounts.

Further insight is provided by examining the enzyme allocation strategy identified by the optimizer. Figure 6 illustrates the optimal enzyme distributions for the case of 75 mM substrate and 7.5 mg total enzyme. In addition to determining the optimal relative enzyme ratios, the optimizer also identifies the optimal partitioning of enzymes between the reactors when the two-reactor network is considered.

The optimizer preferentially distributes enzymes between the two reactors to mitigate inhibitory effects, particularly those affecting the final two enzymes in the cascade. This result is noteworthy, as it challenges the prevailing assumption in enzymatic cascade design that co-localizing all enzymes within a single reactor is invariably optimal.

## CONCLUSIONS

A continuous NLP-based framework for reactor network synthesis was presented and demonstrated on both classical and biocatalytic reaction systems. By avoiding integer decisions and relying on carefully formulated CSTR and CFR models, the approach enables the systematic identification of optimal reactor configurations while maintaining numerical robustness.

Application to the Weimberg enzymatic cascade showed that splitting the reaction across two batch reactors can provide substantial kinetic advantages over conventional single-pot operation. The optimized solutions consistently favored enzyme distributions that alleviate inhibition effects, particularly in the downstream cascade steps, resulting in higher product formation under constrained enzyme budgets. This behavior challenges the commonly held assumption that enzymatic cascades should always be operated in a single reactor and highlights the importance of considering reactor network structure as an additional design degree of freedom.

Overall, the results demonstrate that reactor network synthesis can provide valuable insights into both achievable performance limits and optimal process configurations for complex reaction systems. When combined with careful modeling choices, the proposed framework offers a reliable and flexible tool for the design of advanced reactor networks in both chemical and biochemical applications.

## ABSTRACT

Pharmaceutical supply chains face increasing pressure to deliver high service levels while meeting environmental and social expectations. Vaccine supply chains amplify these challenges due to strict cold-chain requirements, demand uncertainty driven by acceptance and preferences, and the urgency of public-health objectives. This paper develops a multi-objective mixed-integer linear programming (MILP) framework for national-scale vaccine distribution that explicitly integrates economic cost, service level, greenhouse-gas emissions, and population-level vaccine effectiveness. Behavioral realism is incorporated by modeling vaccine acceptance and brand preferences as operational constraints rather than ex-post indicators. Trade-offs are explored using an ε-constraint method that preserves the MILP structure and enables systematic recovery of Pareto-optimal solutions. The framework is applied to a 52-week national case study for metropolitan France during the 2021 COVID-19 vaccination campaign, focusing on Pfizer-BioNTech and Moderna mRNA vaccines. Results show that population-level effectiveness saturates early once acceptance-driven coverage is achieved, making cost and emissions the primary decision levers under service guarantees. Balanced solutions maintain near-maximal protection while achieving substantial emission reductions at moderate additional cost, whereas deeper decarbonization requires explicit service concessions. The proposed framework provides transparent, policy-relevant insights and supports informed decision-making in large-scale vaccine logistics.

**Keywords**: Vaccine supply chain, Multi-objective optimization, MILP, Sustainability, ε-constraint

## INTRODUCTION

Pharmaceutical supply chains (PSCs) are a cornerstone of global healthcare systems, ensuring the timely delivery of essential medicines, vaccines, and other healthcare products. Their performance directly conditions public health outcomes, particularly under conditions of uncertainty and time pressure. Over recent decades, PSCs have become increasingly complex due to stringent quality requirements, strict regulatory oversight, and the perishable nature of many pharmaceutical products [1–3]. Additional challenges arise from demand variability, emergency preparedness, and growing expectations regarding sustainability and equity [4].

Within this broad pharmaceutical context, vaccine supply chains (VSCs) constitute a particularly critical and challenging subset. Vaccines are highly perishable and often require strict cold-chain management, sometimes at ultra-low temperatures (e.g., mRNA vaccines). Distribution performance is tightly linked to public acceptance and preferences, which directly affect uptake and, ultimately, immunization. At the same time, energy-intensive storage and transport generate non-negligible environmental impacts that are rarely considered explicitly in distribution planning. Unlike other pharmaceuticals, vaccines are often deployed at national or global scale during public health emergencies, where both operational efficiency and social equity are paramount.

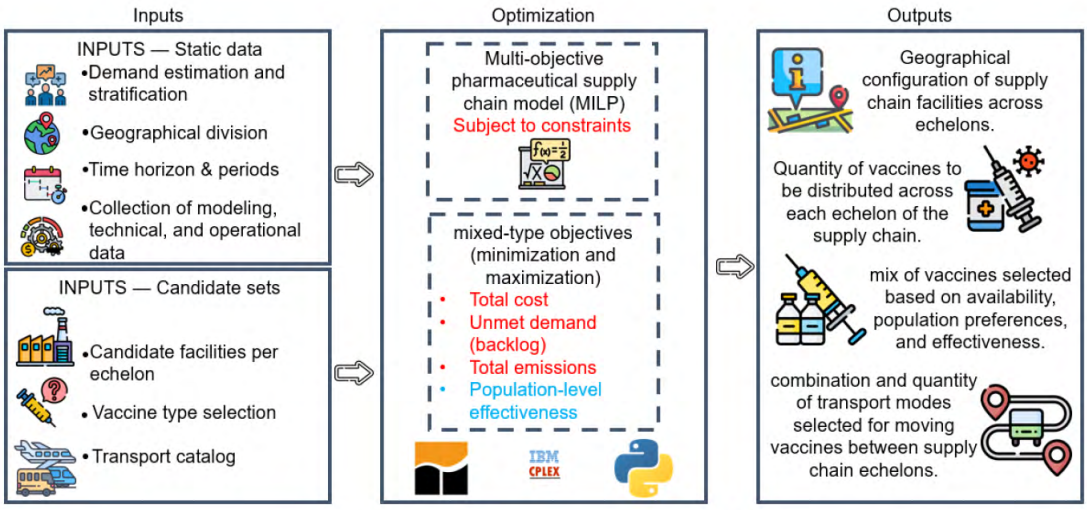

**Figure 1.** General framework of the proposed optimization model: inputs (static data and candidate sets) feed the MILP, which produces outputs.

The COVID-19 pandemic highlighted these challenges at an unprecedented scale. Beyond the health crisis, it exposed structural weaknesses in vaccine logistics when systems are stressed by uncertainty, compressed timelines, and capacity constraints. The emergency deployment of mRNA vaccines at the end of 2020 introduced ultra-low temperature requirements that amplified bottlenecks in cold-chain infrastructure, staffing, testing and release, and transportation. As a result, vaccine distribution emerged not only as a medical issue, but as a large-scale operation and decision-support problem, where trade-offs between speed, coverage, cost, and environmental performance became explicit.

Despite significant advances in pharmaceutical and vaccine supply chain modeling, several limitations remain:

- Limited integration of social and behavioral factors, such as public acceptance and preference heterogeneity, in optimization-based approaches;
- Partial treatment of sustainability, with greenhouse gas emissions rarely assessed alongside economic and operational objectives;
- Scarcity of empirically grounded, national-scale models combining demographic data, logistics constraints, and cold-chain requirements.

This work addresses these gaps by proposing a national-scale, multi-echelon, multi-objective optimization framework for vaccine distribution. The model explicitly integrates cold-chain and capacity constraints, behavioral features related to vaccine acceptance and preferences, and multiple performance indicators, including cost, backlog, emissions, and vaccination effectiveness. The framework is designed as a decision-support tool, enabling the exploration of trade-offs rather than the identification of a single optimal solution.

A key insight emerging from the analysis is that vaccination effectiveness saturates early, making cost and emissions the primary decision levers for large-scale deployment strategies. This result highlights the importance of combining epidemiological effectiveness with economic and environmental criteria when designing resilient and sustainable vaccine distribution policies.

The remainder of this paper is organized as follows. Section 2 presents the proposed multi-echelon MILP framework, including the network structure, operational constraints, objective functions, and the ε-constraint solution strategy used to explore trade-offs among cost, service, emissions, and effectiveness. Section 3 describes the national-scale case study for metropolitan France during the 2021 COVID-19 vaccination campaign, detailing data sources, assumptions, and calibration choices. Section 4 reports and discusses the main results, with a focus on Pareto-optimal trade-offs and their implications for large-scale vaccine deployment strategies. Finally, Section 5 concludes with key insights for decision-makers and outlines perspectives for extending the framework.

## METHODOLOGICAL FRAMEWORK

The proposed optimization framework models a pharmaceutical supply chain (PSC) in a structured, multi-echelon, multi-period setting. The chain is represented as a sequence of operational stages, capturing flows from origin to end users under capacity, inventory, and routing

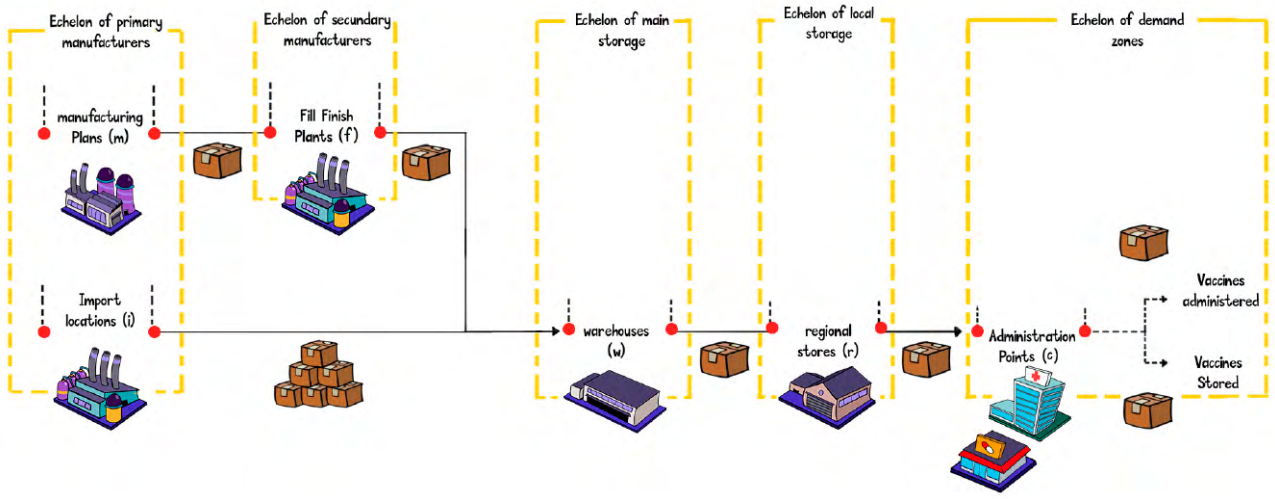

**Figure 2:** Schematic representation of the five-echelon pharmaceutical supply chain network (nodes and arcs) used in the MILP formulation.

constraints. Figure 1 illustrates the modeling pipeline, linking input data, the MILP optimization core, and resulting outputs. Inputs include static data (e.g., demand, geographical information, time horizon, costs, emission factors) and candidate sets (e.g., facility options, vaccine types, transport modes) from which the model selects. The optimization core is formulated as a Mixed-Integer Linear Program (MILP) with binary, integer, and continuous decision variables, solved using GAMS/CPLEX. Outputs comprise facility locations, vaccine allocation over time, selected vaccine mix, and transport configuration.

## Network structure and flows

The network comprises five echelons: primary manufacturers, secondary manufacturers (fill–finish), main storage, regional storage, and demand zones (administration points). Vaccines flow along the sequences *(manufacturer → fill–finish → warehouse)*, *(import → warehouse)*, and *(warehouse → regional → administration)*, ensuring consistent representation of sourcing, processing, storage, and last-mile distribution over multiple periods (Figure 2).

## MILP formulation and operational constraints

Key decisions include facility activation, vaccine flows, transport logistics, and inventory management. Binary variables indicate active facilities and routes, integer variables capture shipment counts and number of facilities. Continuous variables describe vaccine flows, inventory, and administered doses. Slack variables allow minor deviations to preserve feasibility.

Core assumptions include deterministic data (demand, travel times, costs, capacities), discrete planning periods, strict cold-chain compliance, and stable inventory without spoilage beyond standard holding costs. Operational constraints ensure feasibility:

- **Routing and transport:** shipments occur only if facilities and routes are active; shipment sizes respect predefined bounds.
- **Inventory:** standard stock–flow identity with min/max bounds enforced at operational facilities.
- **Processing:** production, fill–finish, and imports respect throughput limits; transport trips are derived from shipment quantities relative to maximum capacity.

## Objective functions

The model considers four main objectives to capture vaccination campaign priorities:

1. **Economic efficiency (cost minimization):** Includes production/procurement, facility activation, transport, cold-chain, inventory, administration, and unmet demand penalties. Fixed and variable costs across all echelons are aggregated into a single additive objective [1].
2. **Service-level compliance (backlog minimization):** Defined as the total number of doses not administered despite demand. Backlog is computed across all vaccine types, locations, and periods. Minimizing backlog serves as a proxy for service reliability and ensures high-risk populations are protected [5].
3. **Environmental sustainability (GHG minimization):** Accounts for emissions from transport (van, trailer, airplane), refrigeration, dry ice, and packaging materials. Fuel consumption and emissions depend on distance, vehicle load, and speed, justifying a dedicated environmental objective [6].
4. **Population-level vaccine effectiveness** $(VE)$ **(maximization):** Consistent with overall (population)

effectiveness measures used in vaccine study design, weighting administered doses by product-specific efficacy provides a tractable proxy for population protection—even when indirect (herd) effects are not explicitly modeled [7].

$$VE(\%) = 100 \times \frac{\sum_{v \in V, c \in C, t \in T} q_{v,c,t} \cdot ef_v}{tpd} \quad (1)$$

where:

$V$ = set of vaccine types

$C$ = set of vaccination centers (demand zones)

$T$ = set of planning periods

$q_{v,c,t}$ = number of doses of vaccine v administered at center c during period t

$ef_v$ = clinical efficacy of vaccine v

$tpd$ = total planned doses for the campaign

This metric integrates coverage and per-dose effectiveness into a single, linear indicator that can be incorporated alongside cost, backlog, and emissions in a multi-objective optimization framework.

## Multi-objective solution approach: the ε-constraint method

The vaccine supply chain model involves multiple, often conflicting objectives: Cost (min), Backlog (min), Emissions (min), and Effectiveness (max). Using a single weighted sum may miss relevant trade-offs, especially in mixed-integer problems. We employ the ε-constraint method, which: (i) optimizes one objective (primary) while converting the others into constraints; (ii) preserves the MILP structure and ensures extreme Pareto points can be recovered; (iii) avoids heuristic weight tuning. The implementation follows best-practice recommendations from [8].

The solution procedure follows four main steps:

1. **Payoff table (ideal and nadir anchors)**
   - Optimize each objective individually and record all objective values.
   - Compute lower/upper anchors for each objective to define ε bounds.
2. **Grid of ε values**
   - Generate a uniform grid of ε points between the anchors.
   - Provides a transparent schedule of target levels for the constrained objectives.
3. **ε-constrained solves**
   - At each grid point, optimize the primary objective while enforcing ε constraints for the others.
   - Retain solutions only if the MILP reaches optimality (integer-optimal).
4. **Rotate the primary objective**
   - Cycle the primary objective across runs to explore the Pareto frontier evenly.
   - Reduces bias and avoids gaps in the recovered solutions.

In the national-scale application, 50 grid points ($g_o$ = 1, …, 50) were generated using the ε-constraint method. Only solutions that achieved full optimality—i.e., feasible and meeting the solver's convergence criteria—were retained for analysis, ensuring that all reported trade-off points are valid and reliable.

Trade-offs were quantified by identifying non-dominated (Pareto) solutions. Dominance was assessed in the full four-dimensional space of Cost (min), Backlog (min), Emissions (min), and Effectiveness (max) [13]. A solution A dominates B if it is no worse in every objective and strictly better in at least one. Conversely, a solution is non-dominated if no other solution dominates it. When applying an ε-constraint grid, weakly efficient points were filtered out to ensure that the retained set represents true Pareto candidates [8].

This approach highlights configurations that are not strictly inferior to any others across all objectives and focuses the analysis on a compact set of meaningful alternatives.

# CASE STUDY: FRANCE (2021)

France was selected for this study due to its extensive availability of detailed public vaccination data, mature logistics infrastructure, and clearly defined administrative regions. During the COVID-19 pandemic, collaboration among public health institutions, statistical offices, and other agencies ensured high-quality, timely, and comprehensive open datasets, enabling accurate data-driven analysis [10].

Within the European context, France faced complex logistical and public health requirements, including cross-border vaccine imports, coordination with EU procurement initiatives, and compliance with stringent cold-chain conditions for large-scale distribution [11]. The combination of detailed open data, multi-tiered administrative structures, and a robust logistics system makes France a suitable case for modeling vaccine distribution, capturing interactions across import flows, warehouses, regional hubs, and local administration points.

## Geographic Scope and Spatial Representation

This study considers metropolitan France only: 13 regions, 96 departments, and approximately 34, 945 communes. Administrative divisions allow efficient mapping and resource allocation, enabling accurate distance calculations and detailed logistical planning [12]. Spatial

fragmentation was applied across echelons:

- National/port nodes for imports (i),
- Plant locations (f),
- Regional hubs (w),
- Department-level stores (r),
- Commune-level administration points (c).

Clusters of communes follow official geographical breakdowns to consolidate nearby localities while maintaining reporting consistency. The analysis focuses on the population aged 15 years and older.

## Vaccine selection

This study focuses on two widely deployed mRNA vaccines, Pfizer-BioNTech (BNT162b2) and Moderna (mRNA-1273), selected for their central role in the French vaccination campaign, the availability of detailed logistical data, and contrasting cold-chain requirements. Pfizer-BioNTech requires ultra-cold storage and specialized transport, while Moderna can be stored at less stringent temperatures, allowing for the evaluation of different logistical strategies. National delivery records corroborate this choice. Excluding Pfizer's paediatric presentation, Pfizer and Moderna together account for >96% of cumulative doses delivered in metropolitan France up to 2024 and approximately 98% during 2021, the core year modelled. The predominance of mRNA products thus makes the focus on BNT162b2 and mRNA-1273 representative for modelling the French campaign [14].

## Supply chain nodes

Nodes represent specific points in the vaccine supply chain, organized into five echelons in the generic model:

1. Primary manufacturers,
2. Secondary manufacturers (fill–finish),
3. Main storage (warehouses),
4. Local storage (regional stores),
5. Demand zones (administration points).

For France, manufacturing and fill–finish are inactive (no domestic facilities), so all inbound supply enters via import locations: Puurs (Belgium, Pfizer) and Visp (Switzerland, Moderna). The operational chain reduces to i → w → r → c. Warehouse candidates were selected among departments exceeding a 3 M-dose cumulative delivery threshold. Regional stores correspond to the 13 administrative regions, and administration centers to the 22 former regional capitals. Figure 3 illustrates the spatial organization of the national vaccine supply chain, highlighting the geographical alignment between echelons and the main logistic flows across the French territory.

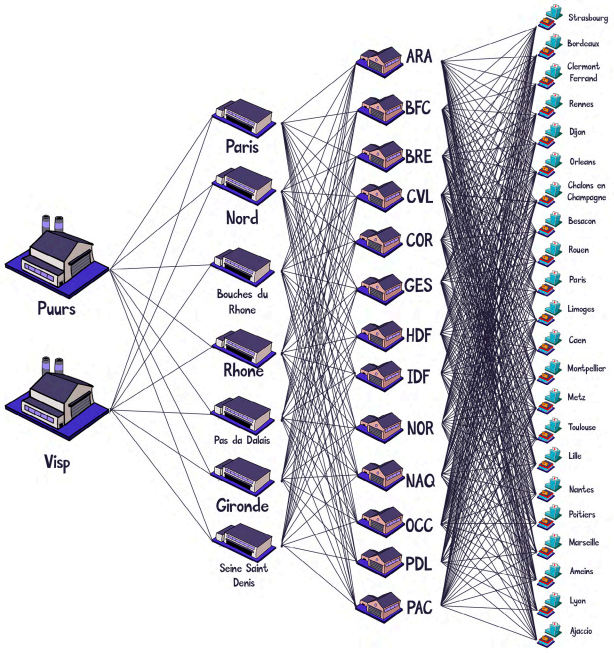

**Figure 3.** National supply chain structure and geographical alignment across echelons.

## Demand Parameters

The demand parameter for the vaccine supply chain model was based on demographic data for individuals aged 15 years and older. The year 2021 was chosen to align with the vaccine shipment timeline, with the first shipment arriving on 27 December 2020 and the initial vaccination recorded on 5 January 2021. The model simulates a 52-week period corresponding to this timeframe, ensuring temporal consistency.

Demographic data were extracted from the INSEE database and aggregated according to the department codes comprising the 22 former administrative regions. Several departments were grouped within a former region and labeled using the name of the main city in the cluster. The selected labels were: Strasbourg, Bordeaux, Clermont-Ferrand, Rennes, Dijon, Orléans, Châlons-en-Champagne, Besançon, Rouen, Paris, Limoges, Caen, Montpellier, Metz, Toulouse, Lille, Nantes, Poitiers, Marseille, Amiens, Lyon, and Ajaccio.

## Population Acceptance and Hesitancy

Vaccine acceptance and hesitancy rates were derived from representative international surveys [9], with global averages of approximately 79% acceptance and 21% hesitancy. Booster acceptance among already vaccinated individuals averaged 88%, with a hesitancy rate of 12%.

For the French case study, these values were adapted to the two main mRNA vaccines, Pfizer-

BioNTech and Moderna, based on their relative usage. (Pfizer = 85.3%, Moderna = 14.7%). To avoid over-constraining the model, these normalized values are then implemented as upper bounds (preference caps) with a small modeling slack: 80% for Pfizer and 10% for Moderna. This preserves empirical guidance while allowing flexibility in the optimization.

# RESULTS AND DISCUSSION

## ε-constraint exploration and anchor solution

The multi-objective problem was explored using an ε-constraint grid composed of 50 feasible configurations. For each grid point, one objective was optimized while the remaining ones were enforced through ε-bounds. Only solutions reaching proven integer optimality were retained, ensuring that all reported configurations correspond to valid and comparable trade-offs.

For the national-scale French instance (5.088M equations and 1.941M variables, solved with 2 threads), the four single-objective baseline runs required 0.01–5.82 h and closed with MIP gaps between 0.00% and 0.153%; the representative balanced Pareto point $g_o = 50$ required 7.43 h and closed with a 0.14% MIP gap.

As a preliminary step, each objective was optimized independently to compute the corresponding single-objective optima. These solutions, referred to as *anchor solutions*, delineate the extreme boundaries of the attainable performance space—namely the minimum cost, minimum backlog, minimum emissions, and maximum effectiveness configurations (Table 1).

**Table 1:** Single-objective optima (SO) used as anchor points for ε-grid construction

| Objective function | Cost (USD) | Backlog (doses) | Emissions (kgCO2e) | Effectiveness (%) |
|---|---|---|---|---|
| Cost | 2.339B | 120.149K | 7.540M | 71.39 |
| Backlog | 2.427B | 118.847K | 8.113M | 71.38 |
| Emissions | 2.707B | 8.349M | 7.095M | 63.92 |
| Effectiveness | 3.040B | 118.847K | 8.457M | 71.3 |

Beyond defining the ε-grid bounds, they provide natural reference policies against which multi-objective compromises can be interpreted. Recovering these extremes within the constrained runs also validates the correctness of the ε-constraint implementation.

These anchor solutions clearly illustrate the inherent trade-offs: minimizing cost, for instance, does not guarantee low emissions or maximal effectiveness, highlighting the need for a multi-objective perspective.

## Structure of the trade-off space

The global structure of the trade-offs is illustrated in Figure 4, which shows all feasible grid points across the four objectives. A parallel coordinates plot is used to visualize the multi-dimensional performance, highlighting patterns across cost, backlog, emissions, and effectiveness. Two consistent trends emerge.

First, within the retained feasible ε-grid, population-level effectiveness exhibits very limited variability, ranging from approximately 70.5% to 71.4%. This indicates that, once acceptance-driven coverage and the induced vaccine mix are satisfied, the system enters a high-protection plateau in which additional logistical effort yields negligible incremental protection. Effectiveness is therefore retained not because it strongly shapes the local Pareto geometry, but because it acts as a public-health safeguard: it certifies that candidate policies remain in the high-protection regime while cost and emissions are traded off. This distinction matters because the single-objective anchors used to define the ε-bounds span a wider effectiveness interval, and the emissions-optimal anchor drops to 63.92%, showing that stronger environmental pursuit can indeed decrease protection when service is relaxed.

Second, most variation occurs along the economic and environmental dimensions. Cost and emissions become the dominant levers shaping the frontier, revealing that post-coverage decisions are primarily logistical rather than epidemiological. This shift indicates that improving sustainability or reducing expenditure involves reallocating storage, routing, and transport choices rather than increasing administered doses.

## Non dominated solutions

Table 2 reports the non-dominated configurations extracted from the feasible ε-grid. Among the 50 evaluated points, only three solutions remain Pareto-efficient, indicating that most intermediate configurations are dominated. This small set substantially simplifies interpretation and provides decision-makers with a concise portfolio of representative policies, ranging from cost-oriented to environmentally efficient strategies.

**Table 2:** Four-dimensional non-dominated solutions extracted from the feasible ε-grid.

| $g_o$ | Cost (USD) | Backlog (doses) | Emissions (kg $CO_2e$) | Effectiveness (%) |
|---|---|---|---|---|
| 38 | 2.367B | 118.847K | 7.943M | 71.31 |
| 44 | 2.365B | 162.653K | 7.872M | 71.35 |
| 50 | 2.369B | 118.847K | 7.858M | 71.39 |

Among these, $g_o = 50$ clearly stands out as the most policy-relevant “clean-and-served” solution. It achieves the lowest carbon footprint (7.858M kg $CO_2e$), meets the

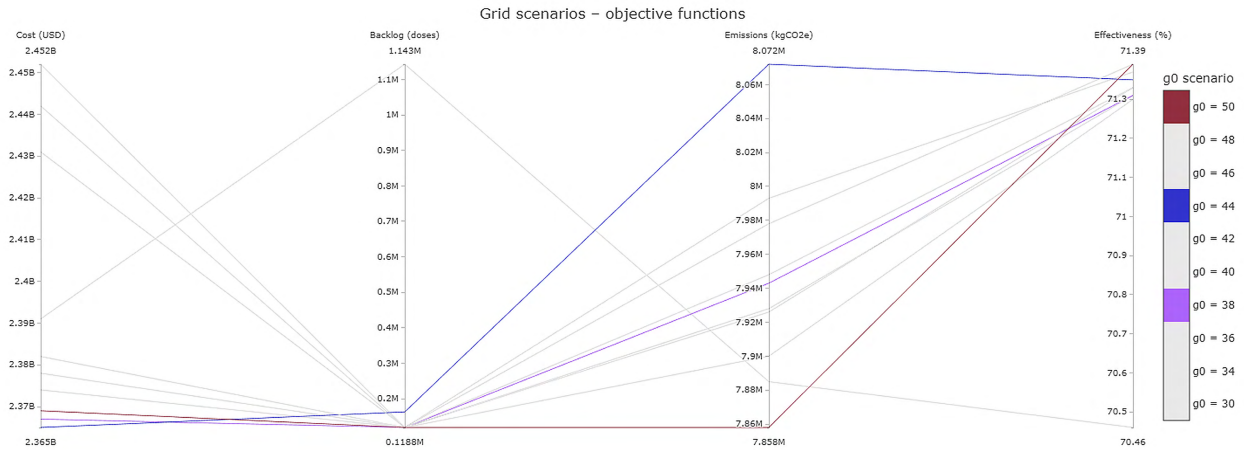

**Figure 4.** Trade-offs across the four objectives (cost, backlog, emissions, effectiveness).

backlog floor (118.847K doses), and attains the highest effectiveness (71.39%), all while maintaining total cost near the lower bound (2.369B USD). This configuration illustrates how tight ε-constraints on backlog and cost, combined with emissions as the primary objective, can produce a solution that simultaneously balances service quality, cost efficiency, effectiveness, and environmental performance.

The other non-dominated solutions highlight the trade-offs involved in prioritizing a single objective. $g_0$ = 38 also respects the backlog floor but exhibits slightly higher emissions (7.943M kg $CO_2$e) and marginally lower effectiveness (71.31%). By contrast, $g_0$ = 44 achieves the absolute minimum cost (2.365B USD) but at the expense of a higher backlog (162.653K doses) and increased emissions (7.872M kg $CO_2$e). Compared to these alternatives, $g_0$ = 50 occupies the most balanced region of the multi-objective frontier, providing the best combination of cost, service, effectiveness, and environmental impact.

## CONCLUSIONS AND PERSPECTIVES

This study developed a multi-objective optimization framework for national-scale vaccine supply chains, explicitly integrating economic, environmental, and public-health objectives while capturing real operational constraints. By combining a multi-period, multi-echelon MILP with cold-chain realism and behavior-aware elements reflecting vaccine acceptance and preferences, the framework provides a practical tool to explore trade-offs in large-scale vaccination campaigns. The ε-constraint method enabled systematic recovery of Pareto-optimal solutions without altering the linear structure of the problem, ensuring methodological rigor and operational relevance.

Application to the French national case study yields several key insights. Population-level vaccine effectiveness saturates early once acceptance-driven coverage is achieved, making cost and emissions the main levers for decision-making under service guarantees. Among Pareto-efficient solutions, certain configurations achieve minimal carbon footprint, high coverage, and controlled costs simultaneously, illustrating that well-designed strategies can balance economic, environmental, and public-health objectives. Solutions focusing solely on cost or another single objective either increase emissions or backlog, highlighting the trade-offs inherent in multi-objective planning.

Strategies with lighter cold-chain requirements can substantially reduce emissions without compromising protection, helping identify where genuine trade-offs begin. Procurement remains the primary cost driver, while behavior-aware constraints ensure realistic vaccine mixes and stable flows across the supply network.

Beyond these case-specific insights, the contribution is methodological and transferable. The framework combines a solver-neutral formulation, a reproducible data pipeline, and a rigorous ε-constraint protocol, enabling transparent, policy-relevant decisions. Decision-makers can compare cost, carbon, and coverage on the same scale, making trade-offs explicit and defensible. Future research could enhance realism and impact by :

- Integrating bilevel optimization to explicitly model policy interventions.
- Modeling vaccine loss and perishability along the supply chain.

- Incorporating finer-grained emission accounting across transport, storage, and packaging.
- Applying geospatial optimization for facility siting to improve distribution efficiency.

Overall, this framework provides a robust, adaptable decision-support tool, capable of guiding vaccine supply strategies today and evolving with new data and public-health priorities. Importantly, it demonstrates that multi-objective planning can identify strategies that achieve high coverage, reduce environmental impact, and control costs simultaneously, offering actionable insights for large-scale vaccine logistics.

## ABSTRACT

This paper presents a Europe-wide optimisation framework for designing and operating a multi-period Carbon Capture and Storage (CCS) supply chain across Europe. A MATLAB preprocessing pipeline constructs an auditable techno-economic dataset (emission nodes, ports, aquifers, candidate pipeline/shipping arcs and costs) and exports it to a GAMS optimisation model. The planning problem is formulated as a two-stage stochastic MILP, where scenario-independent first-stage decisions select discrete pipeline and shipping capacity bands and port operating modes, while scenario-dependent second-stage decisions allocate capture, transport and sequestration flows. Uncertainty is represented through correlated scenarios of capture unit costs for four capture technologies ($CV = 0.35, \rho = 0.8, N_s = 20$). To address the computational burden induced by inter-temporal binary investments and scenario replication, we apply a two-phase arc-screening heuristic: an LP relaxation on the full network identifies promising corridors, and a reduced MILP is solved on the resulting candidate arc sets. The resulting stochastic model contains 1, 278, 661 continuous variables and 48, 860 binaries and is solved in 1, 347.9 s with a 4.85% optimality gap.

## 1. INTRODUCTION

As a consequence of the Paris Agreement reached at the 2015 United Nations Climate Change Conference, 196 Parties pledged to reduce their emissions and to collaborate to limit global temperature rise well below 2 °C above pre-industrial levels, aiming to stay below 1.5 °C [1]. Nonetheless, the climate-change mitigation scenarios presented by the Intergovernmental Panel on Climate Change suggest that even rapid decarbonisation may not be enough to achieve this stringent target [2]. A promising strategy to address both climate and economic challeng-es is the implementation of Carbon Capture and Storage (CCS) [3–5]. CCS is widely recognised as an indispensa-ble technology for limiting global warming below 1.5 °C [6, 7]. Consequently, a significant body of research has focused on designing CCS supply chains in recent years. For instance, [8] proposes a temporal decomposition scheme for CCS supply-chain design.

In this work, a multi-period mixed-integer linear programming (MILP) model for a CCS supply chain across Europe is formulated and solved in full space (i.e., without decomposition) to minimise overall cost under uncertainty. The model is grid-based and spatially explicit, simultaneously optimising capture, multi-mode transport, and geological sequestration nodes over a planning horizon. Transport technologies include onshore pipelines, offshore pipelines, and maritime shipping. Emissions from power, iron and steel and cement industries are projected from the EDGAR database [9]; potential storage comes from JRC/CO2Stop [10]. In the figures 1-4 are shown the regional discretisation used for Europe (Figure 1), the location of the European ports (Figure 2), the place of the aquifers (Figure 3) and the large stationary emission sources considered (Figure 4).

Uncertainty is introduced explicitly in unit capture costs for four technologies—post-combustion (coal), post-combustion (gas), oxy-combustion (coal), and pre-combustion. These four uncertain parameters are correlated, reflecting shared cost drivers; for example, a decrease in coal post-combustion cost is expected to co-move with a decrease in gas post-combustion cost.

Compared with Álvarez-Menchero et al. [8], this study (i) expands the spatial scope to continental Europe,

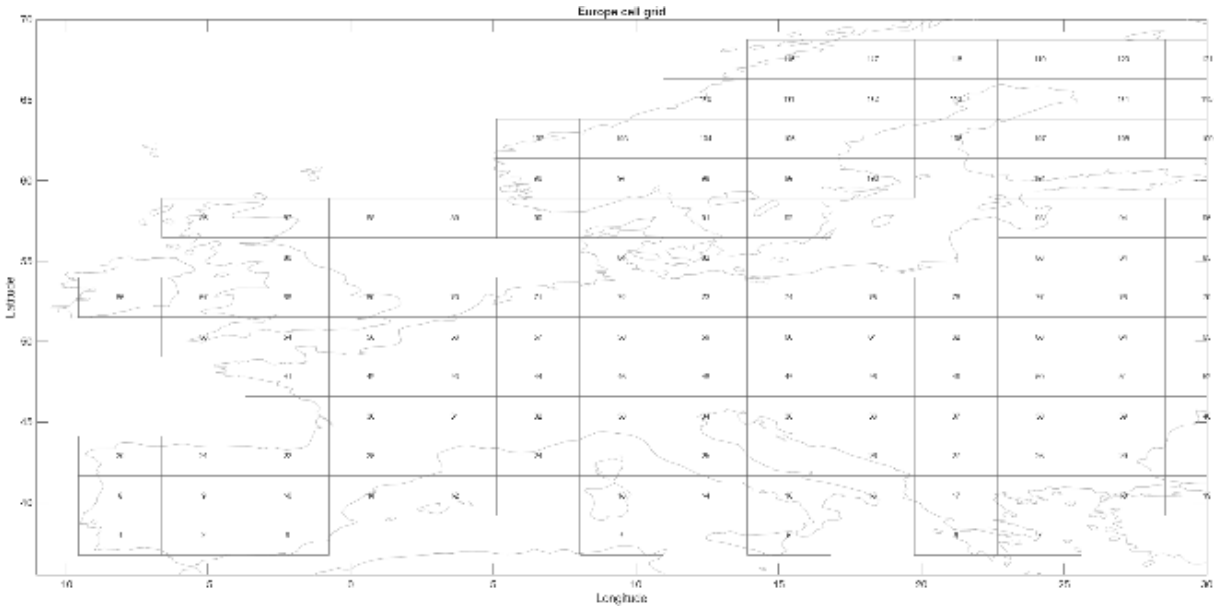

**Figure 1.**Regional discretization

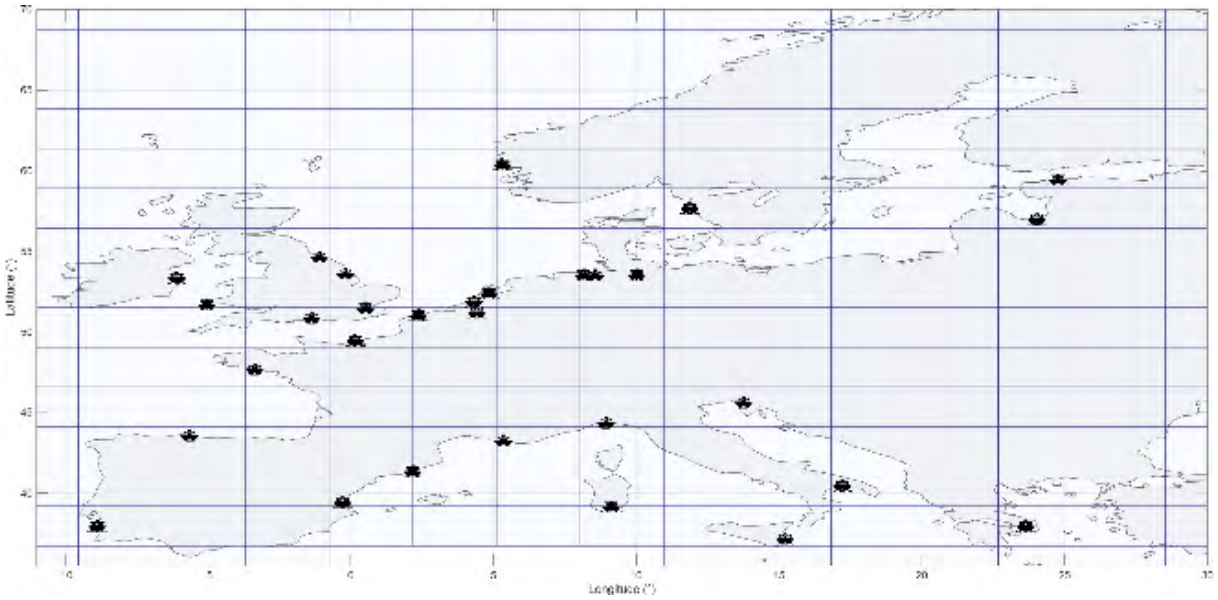

**Figure 2.**Port locations.

(ii) adds ship transport alongside onshore/offshore pipelines, and (iii) considers correlated uncertainty in the costs of the capture technologies.

## 2. PROBLEM STATEMENT

### 2.1 Model formulation

The proposed optimisation model can be interpreted as the interaction of three tightly coupled subproblems:

- a **capture subproblem**, which allocates emissions to capture technologies and enforces a time-dependent capture target;
- a **transport subproblem**, which designs a discrete infrastructure (pipelines and shipping arcs) and routes captured $CO_2$;
- a **sequestration subproblem**, which injects $CO_2$ into aquifers under rate and capacity limits.

The overall model is formulated as a two-stage stochastic MILP. The first-stage variables represent *strategic* infrastructure decisions—pipeline and shipping capacity band activations and port operating modes—and are therefore shared across all scenarios. The second-

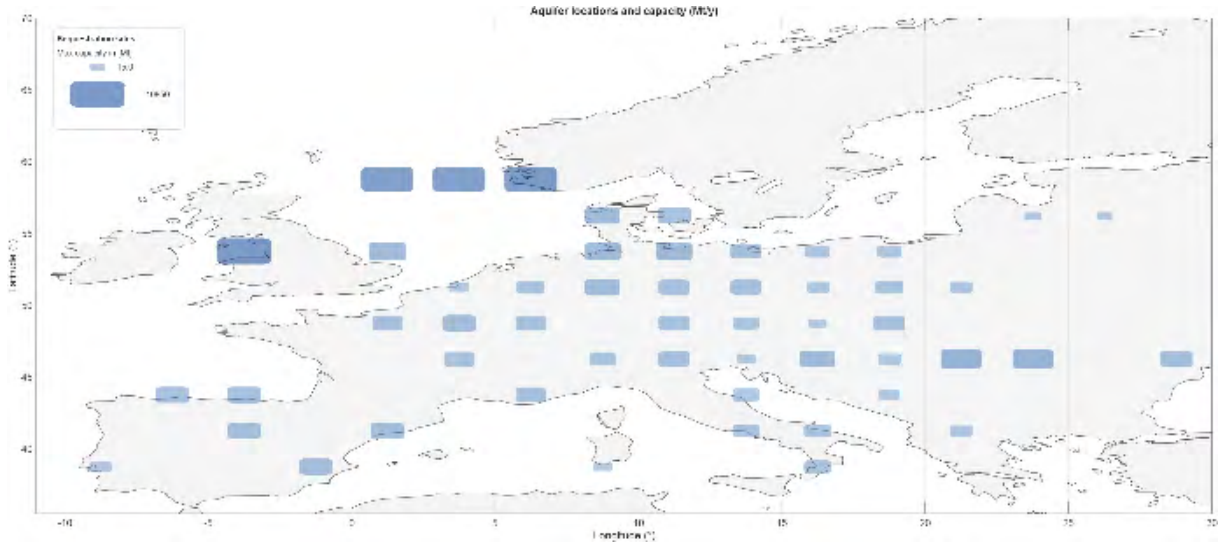

**Figure 3.** Aquifer locations.

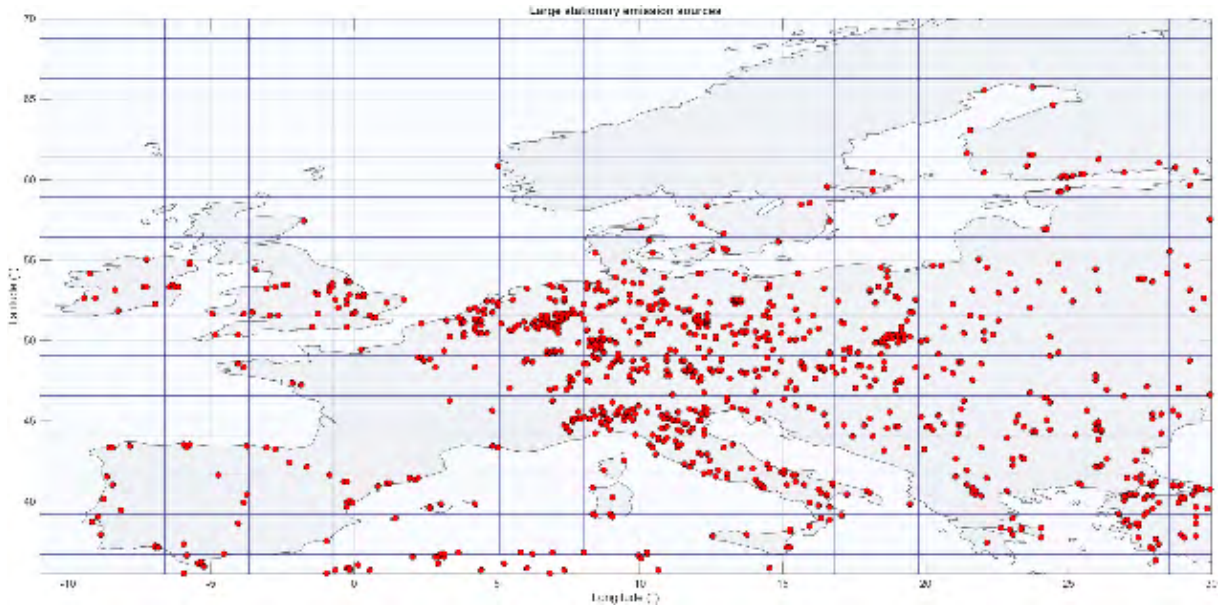

**Figure 4.** Large stationary emission sources.

stage variables are *operational* and scenario-dependent—capture levels, transported flows, and sequestration—so that the system can adapt to each realisation of uncertain capture costs. The three subproblems are coupled through a node-wise mass balance and an expected-cost objective.

Because the formulation combines (i) large-scale discrete network design and (ii) scenario replication of operational decisions, the full stochastic MILP can become computationally demanding. This motivates the two-phase solution approach presented later (LP screening followed by a reduced MILP).

### 2.2.1 Capture subproblem

At each emitting node $n$ and year $t$, the model decides how much $CO_2$ is processed by each capture technology $c$, denoted $pCO2_{c,n,t,s}$, and the corresponding captured amount $cCO2_{c,n,t,s}$. Processing is limited by the local emission availability, and by technology-specific feasibility rules (e.g., fuel-share-based envelopes for the power sector).

First, processed $CO_2$ cannot exceed total emissions:

$$\sum_{c} pCO2_{c,n,t,s} \leq E_{n,t}^{total} \quad \forall n, t, \mathrm{s} \tag{1}$$

Second, technology eligibility is enforced through an admissible envelope $E_{c,n,t}^{allow}$:

$$pCO2_{c,n,t,s} \le E^{allow}_{c,n,t} \ \forall c,n,t,\mathrm{s} \tag{2}$$

Captured $CO_2$ is obtained from processed $CO_2$ via the technology efficiency $ce_c$:

$$cCO2_{c,n,t,s} = ce_c pCO2_{c,n,t,s} \ \forall c,n,t,\mathrm{s} \tag{3}$$

Finally, a year-dependent capture target $\alpha(t)$ imposes a minimum captured fraction of total emissions:

$$\sum_n \sum_c cCO2_{c,n,t,s} \ge \alpha_t \sum_n E^{total}_{n,t} \ \forall t,s \tag{4}$$

In addition to these core constraints, pre-combustion capture is modelled as a niche option through deployment caps. A node-level cap limits the local pre-combustion contribution relative to power emissions:

$$cCO2_{pre^{comb},n,t,s} \le preCapFrac^{node} E^{power}_{n,t} : \forall n,t,s \tag{5}$$

and an EU-wide cap limits aggregate pre-combustion deployment:

$$\sum_n cCO2_{pre^{comb},n,t,s} \le PreCapTotal_t \ \forall t,s \tag{6}$$

### 2.2.2 Transport subproblem

Captured $CO_2$ can be transported through (i) pipelines on candidate arcs $A_{n,nn}$ and (ii) maritime shipping on candidate port-to-port arcs $SArc_{n,nn}$. Transport capacity is discretised into throughput bands $q$ with bounds $\left[Q^{min}_q, Q^{max}_q\right]$. The activation of a band is controlled by binary variables $y^{pipe}_{q,n,nn,t}$ and $y^{ship}_{q,n,nn,t}$, which are first-stage (scenario-independent) decisions. Operational flows—$qCO2^{pipe}_{q,n,nn,t,s}$ and $qCO2^{ship}_{q,n,nn,t,s}$—are second-stage (scenario-dependent).

#### Pipeline capacity selection and linking

If a pipeline band is activated, the corresponding flow must remain within the band bounds:

$$qCO2^{pipe}_{q,n,nn,t,s} \ge Q^{min}_q y^{pipe}_{q,n,nn,t} \ \forall q,(n,nn) \in Aout, \forall t,\mathrm{s} \tag{7}$$

$$qCO2^{pipe}_{q,n,nn,t,s} \le Q^{max}_q y^{pipe}_{q,n,nn,t} \ \forall q,(n,nn) \in Aout, \forall t,\mathrm{s} \tag{8}$$

where $Aout \subseteq A$ excludes arcs whose origin is an aquifer node (aquifers are sinks in the network).

At most one capacity band can be chosen per arc-year:

$$\sum_q y^{pipe}_{q,n,nn,t} \le 1 \ \ \forall (n,nn) \in Aout, t \tag{9}$$

To avoid redundant designs, anti-parallel construction is forbidden:

$$\sum_q y^{pipe}_{q,n,nn,t} + \sum_q y^{pipe}_{q,nn,n,t} \le 1 \ \forall (n,nn) \in A,\ n < nn, \forall t \tag{10}$$

Finally, infrastructure is persistent over time: once activated, it cannot be deactivated in later years:

$$\sum_q y^{pipe}_{q,n,nn,t} \ge \sum_q y^{pipe}_{q,n,nn,t-1} \ \forall (n,nn) \in Aout, \forall t > 1 \tag{11}$$

#### Shipping capacity selection and linking

Shipping arcs follow the same band-activation logic:

$$qCO2^{ship}_{q,n,nn,t,s} \ge Q^{min}_q y^{ship}_{q,n,nn,t} \ \forall q,(n,nn) \in SArc, \forall t,\mathrm{s} \tag{12}$$

$$qCO2^{ship}_{q,n,nn,t,s} \le Q^{max}_q y^{ship}_{q,n,nn,t} \ \forall q,(n,nn) \in SArc, \forall t,\mathrm{s} \tag{13}$$

with one band per arc-year,

$$\sum_q y^{ship}_{q,n,nn,t} \le 1 \ \forall (n,nn) \in SArc, \forall t \tag{14}$$

anti-parallel exclusion,

$$\sum_q y^{ship}_{q,n,nn,t} + \sum_q y^{ship}_{q,nn,n,t} \le 1 \ \forall (n,nn) \in SArc,\ n < nn, \forall t \tag{15}$$

and persistence,

$$\sum_q y^{ship}_{q,n,nn,t} \ge \sum_q y^{ship}_{q,n,nn,t-1} \ \forall (n,nn) \in SArc, \forall t > 1 \tag{16}$$

### 2.2.3 Sequestration subproblem, coupling constraints, and objective function

Sequestration takes place at aquifer nodes. The key coupling between capture, transport and sequestration is the node-wise mass balance, enforced for every node, year, and scenario.

$$\begin{aligned} &\sum_{q,nn:(nn,n)\in A} qCO2^{pipe}_{q,nn,n,t,s} + \sum_{q,nn:(nn,n)\in SArc} qCO2^{ship}_{q,nn,n,t,s} \\ &\qquad + \sum_c cCO2_{c,n,t,s} \\ &= \sum_{q,nn:(n,nn)\in A} qCO2^{pipe}_{q,n,nn,t,s} \\ &\qquad + \sum_{q,nn:(n,nn)\in SArc} qCO2^{ship}_{q,n,nn,t,s} \\ &\qquad + Seq_{n,t,s} \ \forall n,t,\mathrm{s} \end{aligned} \tag{17}$$

Sequestration is further limited by an annual injection cap:

$$Seq_{n,t,s} \le SeqRate \ \forall n,t,s \tag{18}$$

and by finite site capacity over the full horizon:

$$\sum_t Seq_{n,t,s} \le S_n \ \forall n, \forall s \tag{19}$$

Total cost in each year and scenario is the sum of capture, transport, and storage costs. Capture costs are scenario-dependent via $UCC_{c,s}$:

$$TCC(t,s) = \sum_{n,c} UCC_{c,s} \ cCO2_{c,n,t,s} \ \forall t,\mathrm{s} \tag{20}$$

Pipeline transport costs are proportional to distance and include an offshore multiplier $aco_{n,nn}$:

$$TTC^{pipe}_{t,s} = \sum_{q} \sum_{(n,nn)\in Aout} qCO2^{pipe}_{q,n,nn,t,s}\ d_{n,nn}\, UTC_q\, aco_{n,nn}\ \forall t, s \tag{21}$$

Shipping costs are calculated in the following way:

$$TTC^{ship}_{t,s} = \sum_{q} \sum_{(n,nn)\in SArc} qCO2^{ship}_{q,n,nn,t,s}\ (UTC^{ship,slope} d_{n,nn} + UTC^{ship,int}_{q})\ \forall t, s \tag{22}$$

Storage costs are linear in injected $CO_2$, scaled by an offshore storage multiplier:

$$TSC_{t,s} = \sum_{n} Seq_{n,t,s}\, USC\, USC^{off}_{n}\ \forall t, s \tag{23}$$

Let $TC_{t,s} = TCC_{t,s} + TTC^{pipe}_{t,s} + TTC^{ship}_{t,s} + TSC_{t,s}$. The objective minimises the expected total cost across the planning horizon using scenario probabilities $\pi_s$:

$$\min\ Z = \sum_{s} \pi_s \sum_{t} TC_{t,s} \tag{24}$$

## NOMENCLATURE

### Sets

$t$: years {1, 2, …, 10}

$n$: nodes {1, 2, …, 203}

$c$: capture technology $\{post^{comb}_{coal},\ post^{comb}_{coal},\ pre^{comb}, oxy^{fuel}\}$

$\mathcal{Q} = \{q1, q2, q3, q4\}$:set of discrete throughput bands, $|\mathcal{Q}| = 4$
$q$: throughput bands $\{q_1, q_2, q_3, q_4\}$

$\mathcal{S}$:set of scenarios, $|\mathcal{S}| = 20$

$s$: scenarios $\{s_1, s_2, \ldots, s_{20}\}$

$A$: set of feasible pipeline arcs

$SArc$: set of feasible shipping arcs (port-to-port)

$pred$: predecessor relation ($(t, tt) \in pred \Rightarrow tt$ precedes $t$)

## PARAMETERS

$coord_{n,p}$:coordinates of node $n$ (degrees)

$d_{n,nn}$:distance between nodes $n$ and $nn$ (km)
$aco_{n,nn}$:offshore pipeline cost multiplier on arc $(n, nn)$ (dimensionless)

$E^{total}_{n,t}$:total emissions [Mt/y]

$E^{power}_{n,t}$:power-sector emissions [Mt/y]

$E^{cement}_{n,t}$:cement-sector emissions [Mt/y]

$E^{steel}_{n,t}$:iron&steel emissions [Mt/y]

$\alpha_t$:required capture fraction in year $t$ (target on captured CO2

$ce_c$:capture efficiency of technology $c$

$S_n$:total storage capacity at aquifer node $n$ over the horizon [Mt

$SeqRate$:maximum annual injection rate (scalar) [Mt/y]
$USC$:unit storage (sequestration) cost [€/Mt]

$USC^{off}_{n}$:offshore storage cost multiplier at aquifer $n$ (dimensionless
$Q^{min}_{q}$:minimum throughput in band $q$ [Mt/y]

$Q^{max}_{q}$:maximum throughput in band $q$ [Mt/y]

$UTC_q$:pipeline unit transport cost in band $q$ [€/Mt·km]
$UTC^{ship,slope}$:shipping distance slope [€/Mt·km]

$UTC^{ship,int}_{q}$:shipping intercept in band $q$ [€/Mt]

$UCC_{c,s}$:scenario capture unit cost [€/Mt]

$\pi_s$: scenario probability, $\sum_{s\in\mathcal{S}} \pi_s = 1$

$sh^{coal}_{n}$:coal share of power emissions at node $n$ (dimensionless $sh^{gas}_{n}$:gas share of power emissions at node $n$ (dimensionless
$E^{allow}_{c,n,t}$:eligible-emissions envelope for tech $c$ [Mt/y]

$preCapFrac^{node}$:node-level cap fraction for pre-combustion (dimensionless
$preCapFrac^{EU}$:EU-wide cap fraction for pre-combustion (dimensionless)

$PreCapTotal_t$:EU-wide pre-combustion cap in year $t$ [Mt/y]

### Continuous decision variables (scenario - dependent)

$pCO2_{c,n,t,s}$: processed CO2 [Mt/y]

$cCO2_{c,n,t,s}$: captured CO2 [Mt/y]

$qCO2^{pipe}_{q,n,nn,t,s}$: pipeline flow on arc $(n \to nn)$ [Mt/y]

$qCO2^{ship}_{q,n,nn,t,s}$: shipping flow on arc $(n \to nn)$ [Mt/y]

$Seq_{n,t,s}$: sequestered CO2 at aquifer node $n$ [Mt/y]

$TCC_{t,s}$: total capture cost [€/y]

$TTC^{pipe}_{t,s}$: pipeline transport cost [€/y]

$TTC^{ship}_{t,s}$: shipping transport cost [€/y]

$TTC_{t,s}$: total transport cost (=pipeline+ship) [€/y]

$TSC_{t,s}$: total storage cost [€/y]

$TC_{t,s}$: total system cost [€/y]

$Z$: expected objective value [€], $Z = \sum_{s\in\mathcal{S}} \pi_s \sum_{t\in\mathcal{T}} TC_{t,s}$

### Binary decision variables (scenario - independent)

$y^{pipe}_{q,n,nn,t} \in \{0,1\}$:1 if pipeline band $q$ is activated on arc $(n \rightarrow nn)$ in year $t$

$y^{ship}_{q,n,nn,t} \in \{0,1\}$:1 if shipping band $q$ is activated on arc $(n \rightarrow nn)$ in year $t$

$z^{out}_{n,t} \in \{0,1\}$:port mode (1=ship-export, 0=ship-import)

## 3. UNCERTAINTY MODELLING.

Uncertainty is introduced in the capture unit costs through a scenario-based representation. Let $UCC^{mean}_{c}$ denote the nominal capture cost for technology $c$. We generate a set of scenarios $scen$in MATLAB by sampling correlated cost multipliers with coefficient of variation $CV = 0.35$ and common correlation $\rho = 0.8$ across the four capture technologies (post-combustion coal, post-combustion gas, oxy-combustion coal, and pre-combustion), reflecting shared cost drivers (e.g., energy penalty, solvent/oxygen supply costs, and scale effects). Scenario-specific capture costs are then computed as

$$UCC_{c,s} = UCC^{mean}_{c}\xi_{c,s} \quad (25)$$

where $\xi_{c,s}$ is the sampled multiplier, and scenario probabilities are taken as uniform. The stochastic MILP minimises the expected total cost, with first-stage infrastructure decisions shared across all scenarios and second-stage operational decisions adapting to each scenario realisation.

## 4. SOLUTION APPROACH.

As has been mentioned previously, the stochastic CCS network design problem introduced in Section 2 results in a large-scale mixed-integer linear programme (MILP). To keep the model tractable, we adopt a two-phase solution heuristic.

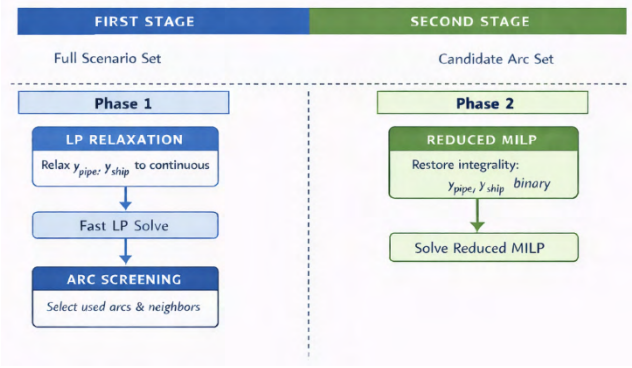

**Figure 5.** Two-phase heuristic diagram

### 4.1 Phase 1: LP relaxation on the full scenario set + arc screening

In Phase 1, we solve a *relaxation* of the full stochastic MILP in binaries $y^{pipe}_{q,n,nn,t}$ and $y^{ship}_{q,n,nn,t}$ are relaxed. This converts the original MILP into a large but comparatively fast linear programme (LP) over the full scenario set and the complete set of candidate arcs.

The objective of Phase 1 is to get structural information about where the optimal solution tends to route $CO_2$. The LP solution provides two key outputs:

- Arcs that carry non-negligible $CO_2$ flow in at least one time period and scenario are flagged as *used*.
- A conservative candidate set construction. To avoid overly aggressive pruning, we expand the used-arc set by adding a controlled neighbourhood around the endpoints of used arcs (i.e., we keep used arcs and arcs departing from nodes that appear as endpoints of used arcs). This step is critical in practice: it preserves alternative routings that the LP may not select strongly, but that can become essential once integrality is enforced.

The output of Phase 1 is therefore a Candidate Arc Set (for pipelines and for shipping), together with the Phase-1 operational solution (e.g., captured $CO_2$ levels) that can later be used to stabilise Phase 2.

### 4.2 Phase 2: reduced stochastic MILP on the candidate arc set

In Phase 2, integrality is restored and the model is solved as a reduced stochastic MILP defined on the Candidate Arc Set identified in Phase 1 (Figure 5).

Phase 2 returns a fully implementable solution: discrete infrastructure investments (pipelines, shipping capacity bands, and port mode), and consistent scenario-dependent operational decisions (capture, transport flows, and sequestration) that meet the decarbonisation targets.

### 4.3 Validation of the solution method

The proposed solution method was validated on reduced-size instances for which the integrated full-space stochastic MILP could still be solved directly. These simplified instances retained the main structural features of the original problem, including multi-period decisions, uncertainty in capture costs, and the coupling between capture, transport, and sequestration, while reducing the number of nodes, candidate arcs, time periods, and/or scenarios to keep the integrated formulation computationally manageable.

The comparison focused on the consistency of the objective value and on the main first-stage investment decisions, namely the activation of pipelines, shipping

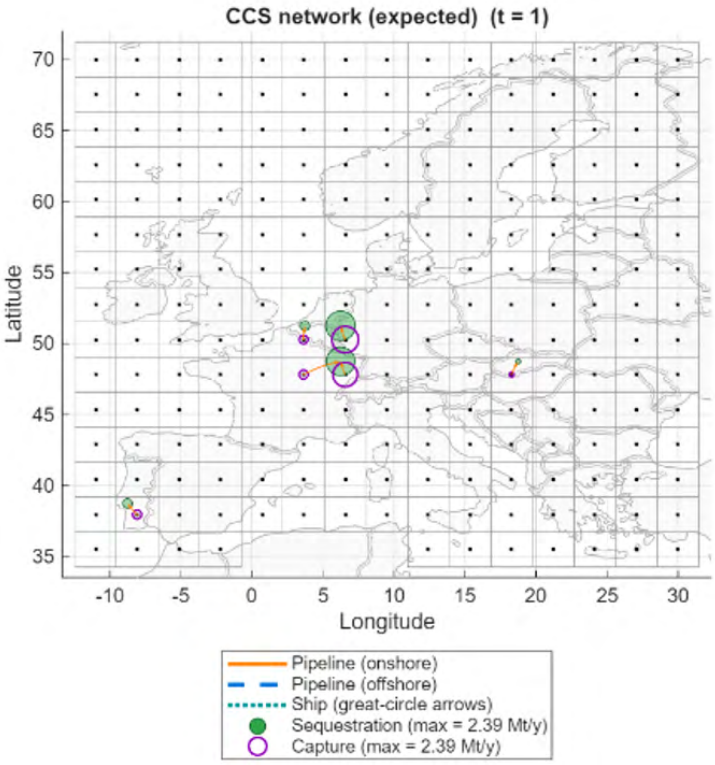

**Figure 6.** CCS network in year 1

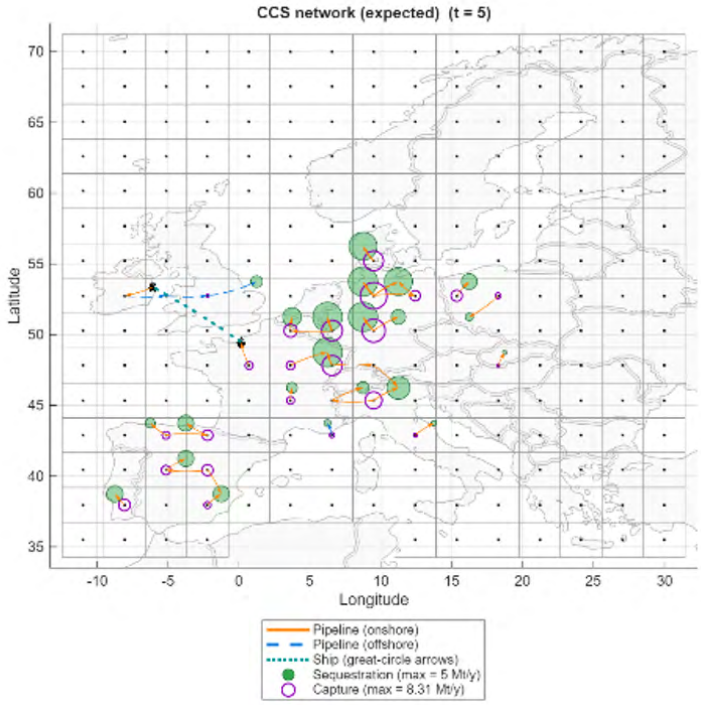

**Figure 7.** CCS network in year 5

arcs, and capacity levels. The reduced-instance tests showed that the proposed two-phase approach reproduced the same qualitative infrastructure patterns as the integrated model and provided solutions of comparable quality. This confirms that the candidate-arc screening step preserves the key design information required by

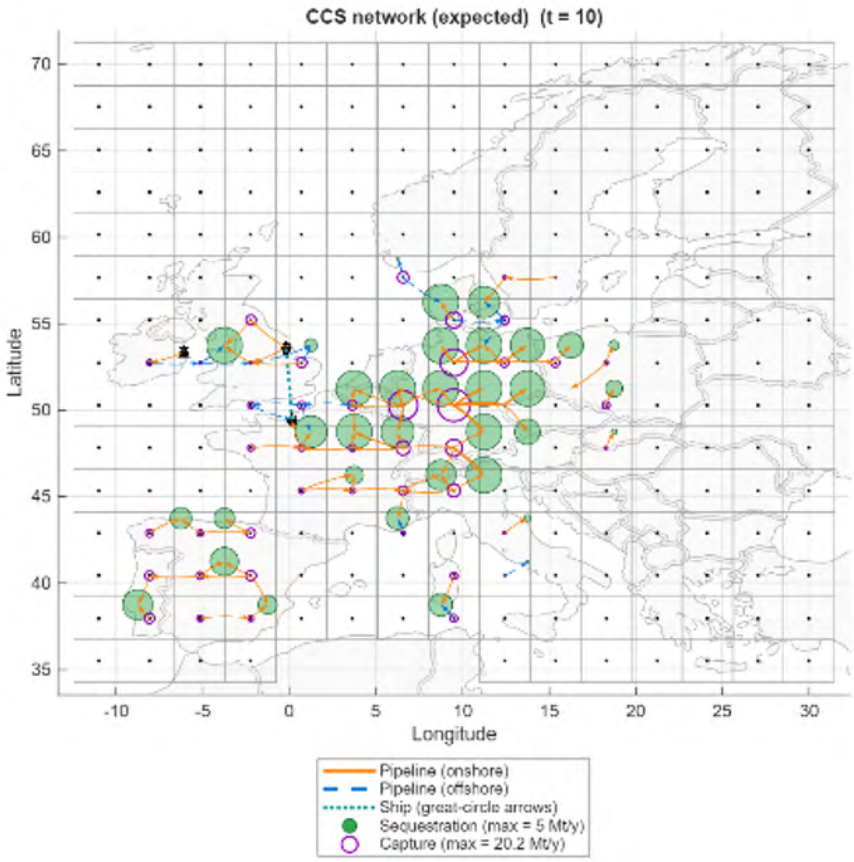

**Figure 8.** CCS network in year 10

the full-space formulation for the instances examined.

These validation runs were used during model development to verify the soundness of the proposed solution strategy before applying it to the large European-scale cases considered in this work. For such large stochastic instances, the direct solution of the integrated model becomes computationally very demanding. Therefore, the proposed method should be understood as a tractable solution strategy that preserves the essential structure and strategic decisions of the integrated formulation while enabling the treatment of realistically sized case studies.

**Table 1**. Model size and computational performance

| No. of continuous variables | No. of binary variables | Solution time (s) | Optimality gap (%) |
|---|---|---|---|
| 1, 278, 661 | 48, 860 | 1, 347.9 | 4.85 |

## 5. RESULTS

This section summarises the key outputs of the optimisation. To visualise the spatial evolution of the infrastructure, Figures 6–8 depict the designed CCS network in years 1, 5, and 10, respectively, highlighting how the selected pipeline/shipping corridors and utilised storage sites develop over time. Figure 9 presents the annual captured $CO_2$ by technology over the 10-year horizon. Figure 10 reports the total annual system cost together with its decomposition into capture, transport, and sequestration contributions. Finally, Table 1 reports the model size and computational performance.

## 6. CONCLUSION

We developed an integrated MATLAB–GAMS framework for Europe-wide CCS network design that combines multi-technology capture, multimodal transport (pipelines and shipping), and geological storage in a multi-period setting. Capture-cost uncertainty is modelled via correlated scenarios and embedded in a two-stage stochastic MILP, enabling here-and-now infrastructure decisions. To make the large stochastic design problem tractable, a two-phase LP-based arc-screening strategy reduces the candidate transport network before solving the reduced MILP. The approach delivers a feasible time-

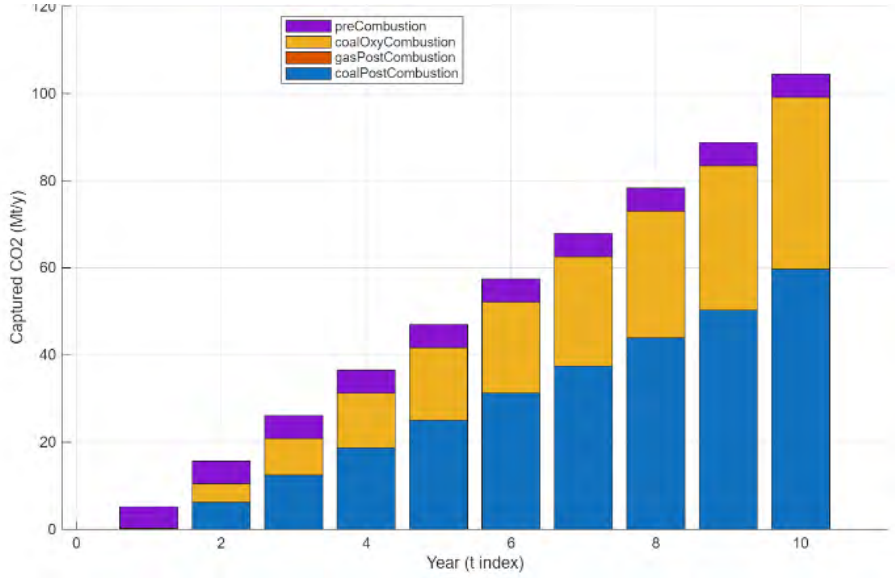

**Figure 9.**Annual captured $CO_2$

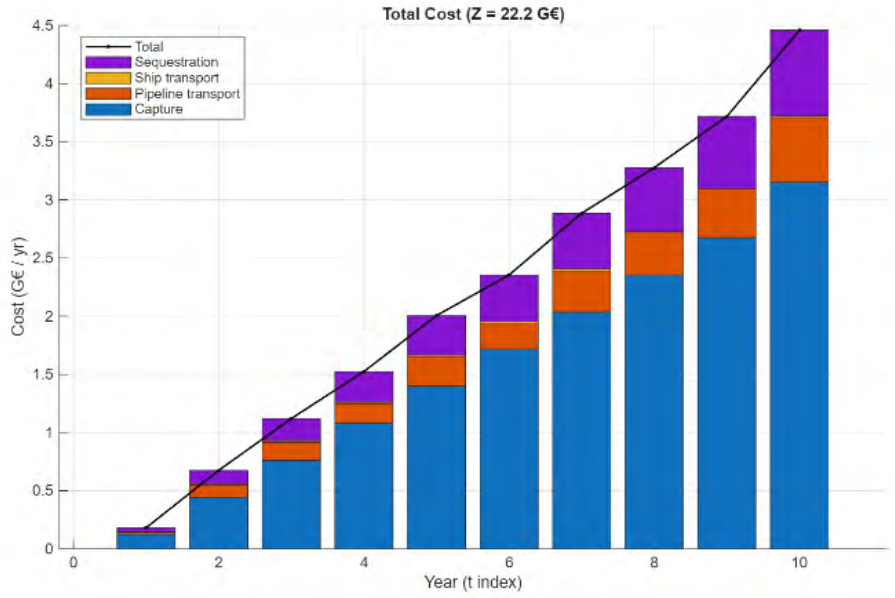

**Figure 10.**Total annual cost.

evolving infrastructure plan together with technology and cost insights, while achieving practical runtimes for a problem of this scale. Future work will focus on tightening optimality guarantees and extending uncertainty to additional parameters (e.g., transport and storage costs, storage capacity).

## ABSTRACT

Renewable powered water electrolysis offers a promising strategy to decarbonize industrial sectors with high demand for hydrogen. Operational optimization of industrial electrolyzer systems is often formulated as mixed-integer linear programming (MILP) problems, where a constant hydrogen production to electrical power consumption ratio is assumed instead of the nonlinear relationship. Incorporating a nonlinear electrolyzer model into a linear optimal hydrogen dispatch framework remains a significant challenge. This study addresses this challenge by formulating the optimization problem in two ways. First, the model is solved as a nonlinear programming (NLP) problem by incorporating a nonlinear model of an alkaline electrolyzer (AEL) into the optimization framework. The binaries and integers are relaxed to continuous variables and associated penalty terms are added to the objective function to enforce integrality. The NLP is solved using the local nonlinear solver Interior Point OPTimizer (IPOPT) using a multi-start approach, where the solver is executed from random initial points and the minimum objective value is taken as the best guess for the global minimum. Second, a linearized model of the AEL is used in an MILP formulation. The univariate nonlinear terms within the model are approximated using three piecewise linearization techniques, i.e., convex combination, convex combination with SOS2 variables and a slope based big-M formulation. The bilinear terms are relaxed using the McCormick envelope. Results show that the MILP formulation achieves faster solution times, with varying accuracy depending on the linearization method, whereas the NLP approach more accurately captures the hydrogen production curve, albeit having longer convergence times.

**Keywords**: Alkaline electrolyzer, Renewable hydrogen system, Piecewise linearization, McCormick relaxation, Operational optimization

## INTRODUCTION

Optimal dispatch problems for electrolysis require robust and quickly solvable process models to enable real-time control decisions. For this reason, mixed-integer linear programming (MILP) models are often employed [1-3]. Among the simplest models are those assuming a constant electrolyzer efficiency or a fixed hydrogen production to electrical power consumption ratio. Baumhof et al. [4] showed that such models exhibit significant deviations in the partial load range of the electrolyzer resulting in sub-optimal solutions. In fact, there exists a nonlinear relationship between power consumption and hydrogen production that can be modeled using detailed physical models or semi-empirical models of the electrolyzer [5]. Baumhof et al. [4] incorporated the widely adopted semi-empirical model of an alkaline electrolyzer (AEL) first proposed by Ulleberg [6] and later extended by Sánchez et al. [7] into their MILP framework by piecewise linearizing the power consumption vs hydrogen production curve obtained from a separate nonlinear AEL model. Furthermore, the study builds the MILP by introducing different operational states, i.e., on, off and stand-by, of the AEL.

Due to the inherent complex nature, incorporating a nonlinear component model into a linear optimization problem remains a challenge. On one hand nonlinear solvers like Interior Point OPTimizer (IPOPT) only works

with continuous variables [8] and thus cannot handle integers and binary variables. On the other hand linear solvers only work with linear objective function and linear constraints [9]. This study incorporates the nonlinear AEL model into a linear operational optimization problem by first solving the problem as a nonlinear program (NLP), where the integer and the binary variables are relaxed to continuous variables and associated penalty terms are added to the objective function to enforce integrality. Second, the problem is reformulated as an MILP by linearizing the univariate nonlinear terms within the AEL model using three different piecewise linearization techniques, and relaxing the multilinear terms using McCormick envelope. Furthermore, this paper extends the work of Baumhof et al. [4] by developing an AEL system model tailored to a multi-stack configuration. This work is part of the development of a digital twin for a renewable powered 40 MW AEL system designed to supply hydrogen to a refinery in Corinth, Greece within the framework of the EU project EPHYRA [10].

The paper has two primary objectives. First, it tries to identify the best linearization method when linearizing the nonlinear semi-empirical AEL model when applied to a hydrogen dispatch problem, evaluating performance in terms of accuracy and computational speed. Second, it compares the results of the MILP with the NLP to assess the merits of each approach and evaluates if the linearized model can accurately reproduce the variable trajectories when compared to the NLP formulation.

## DESCRIPTION OF THE SYSTEM

The industrial system, illustrated in **Figure 1**, has a 40 MW pressurized AEL at its core that produces hydrogen for a refinery. The AEL is primarily powered by a photovoltaic (PV) plant, with supplementary power produced through waste heat recovery from the refinery via an Organic Rankine Cycle (ORC). When required, power can be drawn from the grid for meeting additional hydrogen demand. The AEL system is divided into 8 stacks with each operating at a pressure of 20-25 bar and consuming 5 MW power when operating at full capacity. The produced hydrogen is compressed and routed through a hydrogen storage system operating at 350 bar before being delivered to the refinery. The system operates in such a way that it meets the hydrogen demand of the refinery at each time step.

## MODEL FORMULATION

The optimal hydrogen dispatch problem is first formulated as a mixed-integer nonlinear problem (MINLP) and solved as an NLP by relaxing the binary and integer variables to continuous variables and then introducing penalty terms within the objective function to encourage integrality. Then it is converted to an MILP by linearizing the nonlinear terms within the AEL model. The optimization framework is implemented in the Python based optimization framework Pyomo. The NLP is solved using the local nonlinear solver Interior Point OPTimizer (IPOPT), whereas the MILP formulation is solved using the linear solver Gurobi. The objective function and the constrains within the optimization problem are described in detail in the following paragraphs.

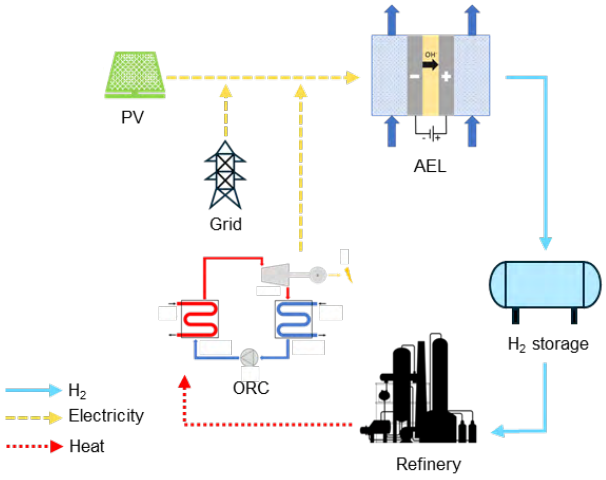

**Figure 1.** Process flow diagram of the industrial setup.

### Objective function

The objective of the optimization problem is to minimize the total operating costs associated with the system over a period of $n$ hours. The objective function is thus formulated as:

$$\min \sum_{t=1}^{n} \left[ P_{\text{grid}}^{t} c_{\text{grid}}^{t} + \sum_{s=1}^{N_{\text{stack}}} z_{\text{su}}^{t,s} c_{\text{su}} \right] \quad (1)$$

where, $P_{\text{grid}}$ is the power drawn from the grid, $c_{\text{grid}}$ the cost to purchase one unit of grid electricity, $z_{\text{su}}$ a binary variable denoting the start-up of one AEL stack, discussed in detail in the following section, $c_{\text{su}}$ the cost associated with the start-up of a stack, $n$ the total number of time steps, and $N_{\text{stack}}$ the total number of stacks. The superscripts $t$ and $s$ are the time step and the AEL stack indices and are used throughout the model. The objective function in the NLP adds further penalty terms for enforcing integrality of the binary and the integer variables.

### Operational States of the AEL Stacks

The operational states of the AEL stacks are modeled in a similar way to Baumhof et al. [4]. However, in this work, the model is further extended to be compatible with a multi-stack AEL system. Each stack has three operational states, i.e., on, off and standby. These operational states are described by the three binary variables $z_{\text{on}}, z_{\text{off}}$, and $z_{\text{sb}}$. At any time step, only one of the states can be active, which can be written as:

$$z_{\text{on}}^{t,s} + z_{\text{off}}^{t,s} + z_{\text{sb}}^{t,s} = 1 \quad (2)$$

The cold start-up of a stack is indicated by the binary variable $z_{\text{su}}$. The variable $z_{\text{su}}$ is 0 at the start and becomes 1 whenever transitioning from off to on state between two consecutive time steps. The constraints are thus written as:

$$z_{\text{su}}^{t=1,s} = 0 \quad (3)$$

$$z_{\text{su}}^{t,s} \geq z_{\text{on}}^{t,s} - z_{\text{on}}^{t-1,s} - z_{\text{sb}}^{t-1,s} \text{ for } t = 2, \dots, n \quad (4)$$

An additional constraint is added to avoid a stack from transitioning from off to standby state:

$$z_{\text{off}}^{t-1,s} + z_{\text{sb}}^{t,s} \leq 1 \text{ for } t = 2, \dots, n \quad (5)$$

## AEL Model

The AEL is modeled using the widely adopted semi-empirical model proposed first by Ulleberg [6] and later extended by Sánchez et al. [7]. For brevity, only the equations that were linearized are mentioned in this paper.

The reversible cell voltage of an AEL cell can be written as:

$$U_{\text{rev}}^{t,s} = U_{\text{rev0}}^{t,s} + \frac{RT_{\text{stack}}^{t,s}}{2F} \ln\left(\frac{(p_{\text{cell}}^{t,s} - p_{\text{H}_2\text{O}})^{1.5}}{\alpha_{\text{H}_2\text{O}}}\right) \quad (6)$$

where, $U_{\text{rev}}$ is the reversible cell voltage, $U_{\text{rev0}}$ the standard reversible cell voltage, $T_{\text{stack}}$ the stack temperature, $F$ the Faraday number, $p_{\text{cell}}$ the cell pressure, $p_{\text{H}_2\text{O}}$ the partial vapor pressure, and $\alpha_{\text{H}_2\text{O}}$ the water activity. The cell voltage $U_{\text{cell}}$ is expressed as:

$$U_{\text{cell}}^{t,s} = U_{\text{rev}}^{t,s} + K_1 \frac{I_{\text{cell}}^{t,s}}{A_{\text{cell}}} + s\log\left(K_2 \frac{I_{\text{cell}}^{t,s}}{A_{\text{cell}}} + 1\right) \quad (7)$$

where, $I_{\text{cell}}$ is the cell current, $A_{\text{cell}}$ the cell area, and $s$ an empirical coefficient. $K_1$ and $K_2$ are two nonlinear terms that are dependent on $T_{\text{stack}}$. The Faraday efficiency $\eta_{\text{Faraday}}$ is calculated as:

$$\eta_{\text{F}}^{t,s} = B_1 + B_2 \exp\left(K_3 \frac{A_{cell}}{I_{cell}^{t,s}}\right) \quad (8)$$

where, $\eta_{\text{F}}$ is the Faraday efficiency, $B_1$ and $B_2$ two empirical coefficients, and $K_3$ a nonlinear term that depends on $T_{\text{stack}}$. At each time step, the total amount of hydrogen produced by an AEL stack $\dot{m}_{\text{prod, st}}$ is described by the Faraday law as:

$$\dot{m}_{\text{prod, st}}^{t,s} = \frac{\eta_{\text{F}}^{t,s} I_{\text{cell}}^{t,s}}{2F} M_{H_2} N_{\text{cell}} z_{\text{on}}^{t,s} \quad (9)$$

where, $N_{\text{cell}}$ is the number of cells in the stack, and $M_{\text{H2}}$ the molar mass of hydrogen. The total amount of hydrogen produced $\dot{m}_{\text{prod}}$ is the summation of the hydrogen produced by each stack:

$$\dot{m}_{\text{prod}}^{t} = \sum_{s=1}^{N_{\text{stack}}} \dot{m}_{\text{prod, st}}^{t,s} \quad (10)$$

The power consumed by an AEL stack $P_{\text{stack}}$ can be written as:

$$P_{\text{stack}}^{t,s} = N_{\text{cell}} U_{\text{cell}}^{t,s} I_{\text{cell}}^{t,s} z_{\text{on}}^{t,s} + P_{\text{sb}} z_{\text{sb}}^{t,s} \quad (11)$$

where, $U_{\text{cell}}$ is the cell voltage that is assumed to be same for all the cells in a stack, and $P_{\text{sb}}$ the power consumed by a stack in its standby state. $P_{\text{stack}}$ has to be between the maximum capacity $P_{\text{cap}}$ and the minimum load $P_{\text{min}}$ of the stack:

$$P_{\text{stack}}^{t,s} \leq P_{\text{cap}} z_{\text{on}}^{t,s} + P_{\text{sb}} z_{\text{sb}}^{t,s} \quad (12)$$

$$P_{\text{stack}}^{t,s} \geq P_{\text{min}} z_{\text{on}}^{t,s} + P_{\text{sb}} z_{\text{sb}}^{t,s} \quad (13)$$

Constraints (6) to (8) were approximated using a composite linearization approach, where piecewise approximation [11] and the McCormick envelope method [12] were used sequentially. Furthermore, the multilinear terms in equations (9) and (11) were relaxed using the same McCormick relaxation. The linearization methods used in this study are discussed in detail in the next section.

## Power Balance

At every time step, the power balance of the whole system can be expressed by:

$$P_{\text{PV}}^{t} + P_{\text{ORC}}^{t} + P_{\text{grid}}^{t} = P_{\text{e}}^{t} + P_{\text{comp}}^{t} \quad (14)$$

where, $P_{\text{PV}}$ is the power produced by the PV plant, $P_{\text{ORC}}$ is the power produced by the ORC, $P_{\text{e}}$ is the total power consumed by the AEL system, and $P_{\text{comp}}$ is the power consumed by the hydrogen storage compressor. $P_{\text{e}}$ is the summation of the power consumption of each stack, expressed as:

$$P_{\text{e}}^{t} = \sum_{s=1}^{N_{\text{stack}}} P_{\text{stack}}^{t,s} \quad (15)$$

$P_{\text{comp}}$ is a function of the specific power consumption of the compressor $w_{\text{comp}}$ and the storage inlet mass flow rate $\dot{m}_{\text{sto, in}}$ [13]. To keep the model simple, $w_{\text{comp}}$ is taken as a constant parameter. Therefore, the constraint is written as:

$$P_{\text{comp}}^{t} = w_{\text{comp}} \dot{m}_{\text{sto, in}}^{t} \quad (16)$$

$P_{\text{PV}}$ is modeled as a function of solar irradiance and module efficiency [14]. The polynomial equation to calculate $P_{\text{ORC}}$, expressed as a function of the temperature of the heat source and the cooling air (ambient) temperature, was obtained from the manufacturer of the ORC unit while the heat source temperature data were provided by the refinery.

## Mass Balance

The mass balance of the system at every time step is written as:

$$\dot{m}^t_{\text{prod}} = \dot{m}^t_{\text{d}} + \dot{m}^t_{\text{sto, in}} - \dot{m}^t_{\text{sto, out}} \quad (17)$$

where, $\dot{m}_{\text{prod}}$ is the total hydrogen produced, $\dot{m}_{\text{d}}$ the hydrogen demand, and $\dot{m}_{\text{sto, out}}$ the mass flow rate of the hydrogen exiting the storage.

## Hydrogen Storage

The operation of the hydrogen storage at each time step can be expressed by the following two constraints:

$$m^t_{\text{sto}} = m^{t-1}_{\text{sto}} + (\dot{m}^t_{\text{sto, in}} - \dot{m}^t_{\text{sto, out}})\Delta t \quad (18)$$

$$m^{t=0}_{\text{sto}} = m_{\text{sto, ini}} \quad (19)$$

where, $m_{\text{sto}}$ is the amount of stored hydrogen at any time step, and $m_{\text{sto, ini}}$ is the amount of hydrogen stored at the start of the operation. Both $\dot{m}_{\text{sto, in}}$ and $\dot{m}_{\text{sto, out}}$ are limited by the maximum inlet and outlet flowrates of the storage, $\dot{m}_{\text{sto, in, max}}$ and $\dot{m}_{\text{sto, out, max}}$, respectively:

$$\dot{m}^t_{\text{sto, in}} \leq \dot{m}_{\text{sto, in, max}} \quad (20)$$

$$\dot{m}^t_{\text{sto, out}} \leq \dot{m}_{\text{sto, out, max}} \quad (21)$$

The maximum amount of stored hydrogen is limited by the volumetric storage capacity $V_{\text{sto, max}}$ and is given by:

$$m^t_{\text{sto}} \leq V_{\text{sto, max}} \rho_{H_2} \quad (22)$$

where, the density of hydrogen, $\rho_{H_2}$, is calculated using the standardized equation for hydrogen gas density, given in [15]. Two further constraints are added to prevent the storage from being charged and discharged at the same time:

$$\dot{m}^t_{\text{sto, in}} \leq z^t_{\text{ch}} \dot{m}_{\text{sto, in, max}} \quad (23)$$

$$\dot{m}^t_{\text{sto, out}} \leq (1 - z^t_{\text{ch}}) \dot{m}_{\text{sto, out, max}} \quad (24)$$

where, $z_{\text{ch}}$ is a binary variable indicating the charging of the storage.

# LINEARIZATION METHODS

The nonlinearities in the optimization problem, described by equation (1) to (24), can be divided into two categories. The first category contains the univariate nonlinear terms that are linearized using piecewise linear approximation methods. Three different piecewise linearization techniques [11] are implemented and are discussed below. The second category consists of the multilinear terms, i.e. the bilinear and trilinear terms, that are approximated by the McCormick relaxation [12].

## Piecewise Linearization Methods

### Convex combination (CC)

A nonlinear function $f(x)$ is approximated by discretizing the domain of $x$ into $k-1$ segments with $k$ being the number of breakpoints. The linear approximations of $x$ and $f(x)$ are weighted sums (convex combination) of their values at the breakpoints, where the weights $\lambda_i$ sum to 1. In (29) to (32), the binary variables $z_i$ ensure that at most two adjacent $\lambda_i$ can be non-zero. The convex combination method can be written as:

$$f = \sum_{i=1}^{k} f(x_i)\lambda_i \quad (25)$$

$$x = \sum_{i=1}^{k} x_i \lambda_i \quad (26)$$

$$\lambda_i \geq 0 \quad (27)$$

$$\sum_{i=1}^{k} \lambda_i = 1 \quad (28)$$

$$\sum_{i=1}^{k-1} z_i = 1 \quad (29)$$

$$\lambda_1 \leq z_1 \quad (30)$$

$$\lambda_i \leq z_{i-1} + z_i \text{ for } i = 2, \dots, k-1 \quad (31)$$

$$\lambda_k \leq z_{k-1} \quad (32)$$

### Convex combination with SOS2 variables (CC-SOS2)

To avoid the use of binary variables $z_i$, as seen in (29) to (32), the set of variables $\{\lambda_1, \lambda_2, \dots, \lambda_n\}$ can be formulated as a Special Ordered Set of type 2 (SOS2), which ensures the adjacency rule of the $\lambda_i$ variables. With $\lambda_i \in$ SOS2, the formulation is then fully described by (24) to (27). It has to be noted that a suitable solver capable of handling SOS2 variables needs to be chosen.

### Slope based Big-M formulation

To avoid the use of continuous variables $\lambda_i$ in (25) to (32), the nonlinear function $f(x)$ can be approximated using a big-M formulation. Constraints (33) and (34) restrict the variable $x$ to lie within the active segment, while (35) and (36) employ a Big-M formulation to define the function value $f$ by the slope and the intercept of the selected segment.

$$x \geq x_i - (1 - z_i)(x_{\max} - x_{\min}) \quad (33)$$

$$x \leq x_{i+1} + (1 - z_i)(x_{\max} - x_{\min}) \quad (34)$$

$$f \geq a_i x + b_i - (1 - z_i)M \quad (35)$$

$$f \leq a_i x + b_i + (1 - z_i)M \quad (36)$$

$$\sum_{i=1}^{k-1} z_i = 1 \quad (37)$$

where, $a_i = \frac{f(x_{i+1}) - f(x_i)}{x_{i+1} - x_i}$, and $b_i = f(x_i) - a_i x_i$. $M$ is a sufficiently large positive constant used to activate or deactivate constraints (35) and (36).

## McCormick Relaxation

The McCormick envelope relaxes the product of two continuous variables, $w = xy$, where $x \in [x_{\text{lb}}, x_{\text{ub}}]$ and $y \in [y_{\text{lb}}, y_{\text{ub}}]$, by defining the convex hull of the feasible set through the following linear inequalities:

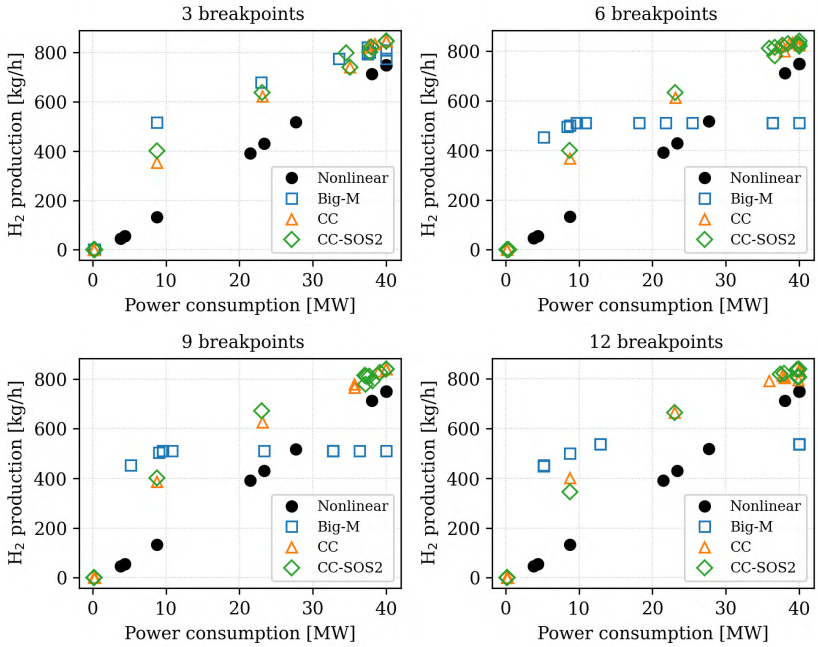

**Figure 2.** Hydrogen production-power consumption curve: NLP vs. MILP formulations using different linear approximation methods with 3 breakpoints (**top left**), 6 breakpoints (**top right**), 9 breakpoints (**bottom left**) and 12 breakpoints (**bottom right**).

$$w \geq x_{\mathrm{lb}} y + y_{\mathrm{lb}} x - x_{\mathrm{lb}} y_{\mathrm{lb}} \tag{38}$$

$$w \geq x_{\mathrm{ub}} y + y_{\mathrm{ub}} x - x_{\mathrm{ub}} y_{\mathrm{ub}} \tag{39}$$

$$w \leq x_{\mathrm{ub}} y + y_{\mathrm{lb}} x - x_{\mathrm{ub}} y_{\mathrm{lb}} \tag{40}$$

$$w \leq x_{\mathrm{lb}} y + y_{\mathrm{ub}} x - x_{\mathrm{lb}} y_{\mathrm{ub}} \tag{41}$$

If the bilinear term consists of a continuous variable $x \in [x_{\mathrm{lb}}, x_{\mathrm{ub}}]$ and a binary variable $z \in \{0,1\}$, the McCormick relaxation reduces to the following inequalities:

$$x_{\mathrm{lb}} z \leq w \leq x_{\mathrm{ub}} z \tag{42}$$

$$x - x_{\mathrm{ub}}(1-z) \leq w \leq x - x_{\mathrm{lb}}(1-z) \tag{43}$$

## RESULTS

The NLP is solved using a multi-start approach using the local nonlinear solver IPOPT, in which the optimization problem is executed 50 times from random initial points and the solution with the minimum objective value is taken as the best guess for the global minimum. The MILP is solved with the linear solver Gurobi using the three piecewise linearization methods, described in the section above, by gradually increasing the number of breakpoints to potentially enhance the accuracy of the decision variables. The optimization was done over a 15-hour period. The dimensions of the different formulations are listed in **Table 1**. All the simulations were run using a computer with a 13th Gen Intel(R) Core(TM) i7-1365U processor.

**Table 1:** Dimensions of the MILP formulations and the NLP

| Method | Variable count | Constraint count |
|---|---|---|
| CC (3 breakpoints) | 8040 | 11257 |
| CC (6 breakpoints) | 12360 | 13417 |
| CC (9 breakpoints) | 16680 | 15577 |
| CC (12 breakpoints) | 21000 | 17737 |
| CC-SOS2 (3 breakpoints) | 6600 | 8377 |
| CC-SOS2 (6 breakpoints) | 8760 | 8377 |
| CC-SOS2 (9 breakpoints) | 10920 | 8377 |
| CC-SOS2 (12 breakpoints) | 13080 | 8377 |
| Big-M (3 breakpoints) | 5880 | 12457 |
| Big-M (6 breakpoints) | 8040 | 21097 |
| Big-M (9 breakpoints) | 10200 | 29737 |
| Big-M (12 breakpoints) | 12360 | 38377 |
| NLP | 2655 | 2287 |

We first assess the accuracy of the linearization methods by comparing the hydrogen production curve (hydrogen production versus power consumption) obtained from the MILP formulations using the three linearization methods with that of the NLP. Given that the NLP formulation retains the original nonlinear model, we take the hydrogen production curve from the NLP as the reference. We see from **Figure 2** that the curves from all of

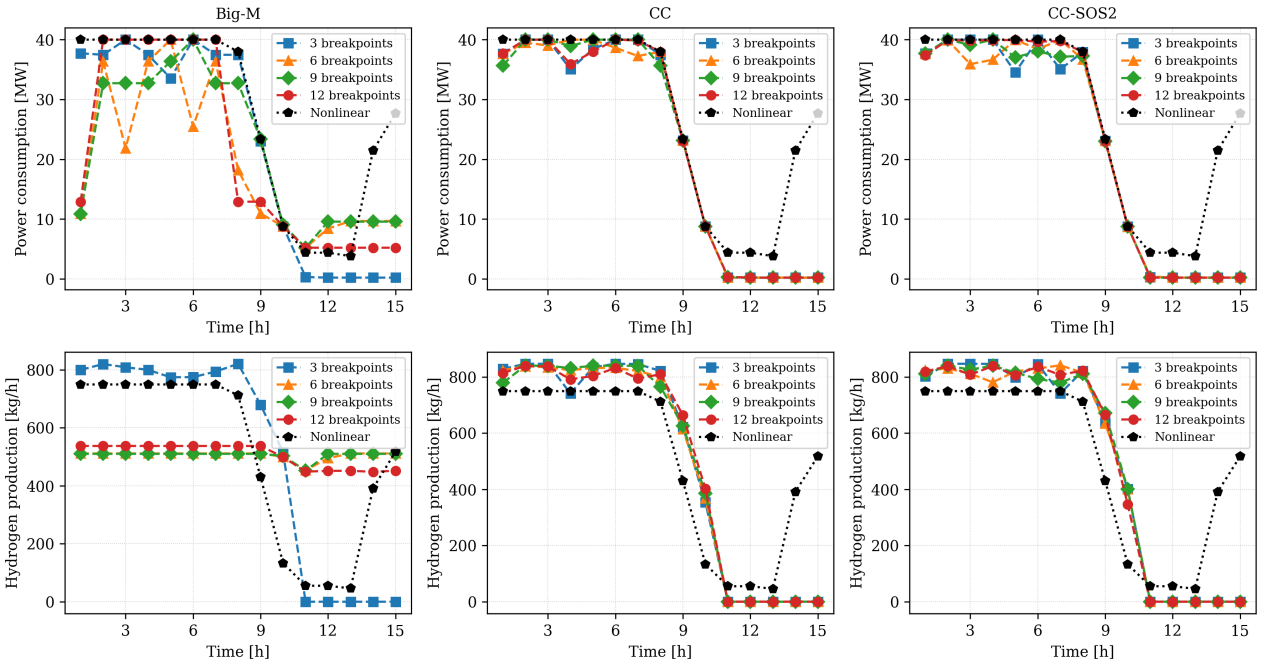

**Figure 3.** Power consumption (**top**) and hydrogen production (**bottom**) profiles: MILP formulations with different linearization methods vs. NLP.

the MILP formulations deviate from that of the NLP, but to varying degree. As expected, the CC and the CC-SOS2 produce very similar results since their underlying principles are the same. The performance of the big-M formulation heavily depends on the choice of the big-M parameter, which is difficult to appropriately determine. As a rule of thumb, the big-M was initially set equal to the difference between the maximum and minimum values of the nonlinear function being linearized. While this was sufficiently large for three breakpoints, the big-M value had to be increased every time the number of breakpoints was increased to prevent infeasibility, causing the feasible region to increase resulting in loose relaxation. Consequently, the big-M linearization method exhibits larger deviation in the hydrogen production curve as the number of breakpoints increases. This is also evident in **Figure 3**, where we see that beyond three breakpoints, the big-M formulation produces unusable results. Due to the difficulty in choosing an adequately large value of big-M, we come to the conclusion that the CC and the CC-SOS2 methods are the better choices for linearizing the nonlinear AEL model.

A further interesting observation is the impact of the number of breakpoints on the accuracy of the hydrogen production curve. As can be seen in **Figure 2**, increasing the number of breakpoints does not noticeably improve the accuracy of the curve, which is somehow unexpected. This behavior can be explained by the fact that the univariate nonlinear terms might exhibit only mild nonlinearities within the specified variable bounds. Future investigations will be carried out to understand this behavior in more detail.

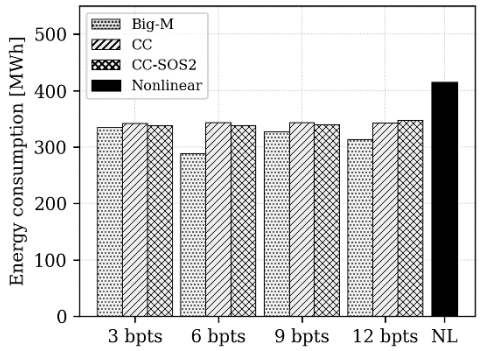

**Figure 4.** Total energy cosumption over a 15-hour period: MILP formulations vs. NLP.

We also see from both **Figure 2** and **Figure 3** that regardless of the linearization method used, compared to the NLP, the MILP formulations always underestimate the power consumption per kilogram of hydrogen produced. The constraints for the hydrogen production (equation 9) and the power consumption (equation 11) contain bilinear and trilinear terms, which were relaxed in the MILP using McCormick envelope. Since the McCormick relaxation provides an outer approximation of a multilinear term, the relaxation can lie below the actual function value causing the underestimation. This is further evident in the total energy consumption of the AEL over the 15-hour

optimization period, shown in **Figure 4**. However, a partitioned McCormick envelope, that will be implemented in the future, could provide a more accurate approximation.

Finally, we examine the total computational time of the different solution approaches. From **Table 2** we see that CC-SOS2 performs the fastest when having three breakpoints. However, as the number of breakpoints increases, the computational time of CC-SOS2 grows more rapidly than that of the standard CC formulation, making CC the more flexible option. As discussed previously, the Big-M method with more than three breakpoints does not produce satisfactory results. Therefore, its computation times are not considered meaningful for comparison. The reported MILP solution times were consistent across multiple runs. In contrast, the time taken for each run of the NLP varies widely with the multi-start strategy taking a total of 257 seconds for 50 runs. This wide spread of the objective values, ranging from 7909.76 to 28620.28, indicates the presence of local optima and makes it difficult to estimate in advance how many runs are required to reliably identify the best solution. Advanced optimization algorithm, such as BO-IPOPT [16, 17], which is a hybrid algorithm based on Bayesian optimization and IPOPT, will be employed in future work to address this issue.

**Table 2:** Solution times of the MILP formulations and the NLP.

| Method | Solution time (seconds) |
|---|---|
| CC (3 breakpoints) | 1.12 |
| CC (6 breakpoints) | 10.08 |
| CC (9 breakpoints) | 54.45 |
| CC (12 breakpoints) | 100.19 |
| CC-SOS2 (3 breakpoints) | 0.92 |
| CC-SOS2 (6 breakpoints) | 33.95 |
| CC-SOS2 (9 breakpoints) | 101.37 |
| CC-SOS2 (12 breakpoints) | 148.47 |
| Big-M (3 breakpoints) | 1.72 |
| Big-M (6 breakpoints) | 7.45 |
| Big-M (9 breakpoints) | 9.96 |
| Big-M (12 breakpoints) | 40.39 |
| NLP | 0.82-61.14 (single run)<br>257.03 (50 runs) |

## CONCLUSION

This study addresses a major challenge of integrating a nonlinear AEL model into a linear optimal dispatch problem of a renewable powered industrial AEL system. Two approaches were taken and compared. The first approach includes solving the operational optimization problem as an NLP by relaxing the binaries and integers within the model to continuous variables and then adding associated penalty terms to promote integrality. The NLP is then run using a multi-start strategy from random initial points. The minimum objective value is taken as the best guess for the global minimum. The second approach formulates the optimal dispatch problem as an MILP by linearizing the univariate nonlinear terms within the AEL model using piecewise approximation and relaxing the multilinear terms using McCormick envelope. The hydrogen production curve of the NLP is taken as reference since the NLP uses the original nonlinear AEL model.

We see that out of the three piecewise linearization methods, namely, CC, CC-SOS2 and big-M formulation, CC and CC-SOS2 perform very similarly in reproducing the hydrogen production curve irrespective of the number of breakpoints. The big-M method performs well only with three breakpoints. Beyond three breakpoints, choosing the big-M value becomes significantly difficult, requiring large values, and producing unusable results.

Another important, albeit surprising, observation is that increasing the number of breakpoints does not have any meaningful impact on the accuracy of the solution, possibly due to the univariate nonlinear terms within the AEL model exhibiting mild nonlinearities within the specified variable bounds.

Furthermore, we see that the MILP always underestimates the power consumption of the AEL when compared to the NLP. The McCormick relaxations of the hydrogen production and power consumption constraints can be attributed to this underestimation.

Finally, when taking a look at the computational times, we observe that the CC method is generally the fastest when working with a varied number of breakpoints. While the CC-SOS2 is marginally faster when having three breakpoints, the computational time increases much faster as the number of breakpoints increases making CC the more flexible option. We consider the big-M method not suitable for this optimization problem as it cannot produce usable results when more than three breakpoints are used and exhibits the longest computation time even in the three-breakpoint case. Comparing the computation time of the MILP with the NLP is difficult as the NLP is modeled with a multi-start approach with the time taking for each run varying widely. The presence of local optima in the NLP means it is hard to estimate how many runs are necessary to reliably obtain the best solution.

Future work includes potentially increasing the accuracy of the linearized AEL model by using the partitioned McCormick envelope that yields a tighter relaxation of multilinear terms by subdividing the variable bounds into smaller intervals. Furthermore, the MILP approach will be compared with global hybrid modeling approaches, e.g., BO-IPOPT [16, 17], and investigated as a potential initialization scheme for these hybrid methods. Additionally, these models will be validated with real data from a real plant before being evaluated for real-time digital twin implementation

## ABSTRACT

The state task network (STN) representation is a widely used modeling approach for optimal multipurpose batch production scheduling. In practice, STNs have been traditionally formulated as mixed-integer programming (MIP) problems and solved using general-purpose MIP solvers relying on branch-and-bound and branch-and-cut. In the meantime, alternative modeling and solution paradigms for optimization have been developed, enabling the incorporation of alternative variable types and optimization algorithms. Specifically, this work relies on the Hexaly software, which introduced set-based models and their solution through general-purpose hybrid algorithms, i.e., methods that combine traditional MIP with constraint programming, local search, large neighborhood search, among other tools. So far, Hexaly has shown promising results when tackling optimal scheduling problems, however, set-based models and solution approaches for STN optimization have not been studied in the literature. Aiming to fill this gap, this work introduces the first set-based models for the STN problem and performs preliminary benchmarking tests with Hexaly's general-purpose hybrid algorithms. Results from two case studies suggest that set-based models may perform better than the traditional MIP STN formulation when dealing with a simple STN with sequential connectivity and a long-term scheduling instance of a STN with fixed integer batching variables. Overall, this work establishes the foundations for advancing research on set-based approaches for network scheduling, opening new directions beyond traditional MIP optimization.

## INTRODUCTION

Scheduling problems represent some of the most prominent applications of mathematical optimization [1]. In particular, the state task network (STN) [2] scheduling model is a seminal mixed-integer programming (MIP) formulation that led to the development of a variety of network scheduling MIP formulations such as the resource task network (RTN) [3] model, among other extensions [4, 5]. The main practical feature of network scheduling models is their flexibility in supporting complex tasks with multiple inputs and outputs, enabling material mixing and splitting, i.e., the STN and RTN models do not require materials to be handled sequentially [6]. This modeling flexibility has led to a variety of real-world applications, e.g., optimal scheduling in a vegetal oil refinery [7], multipurpose batch plant scheduling in the chemical-pharmaceutical industry [8], electricity scheduling for cement plants [9], among others [10, 11]. Despite several extensions and variants are available in the literature, this work concentrates on the standard STN formulation.

Traditional mathematical programming has powered the generation of optimal STN scheduling solutions in chemical engineering. Most works in the literature rely on MIP modeling and algorithms, e.g., branch-and-bound and branch-and-cut [10]. This is because STN scheduling applications are usually linear and only require binary or integer variables combined with continuous variables. Nonetheless, the generalized disjunctive programming (GDP) modeling formalism has also been proposed to derive STN formulations, through the incorporation of Boolean variables, disjuncts and logic relationships [12, 13]. In addition to MIP and GDP, a higher-level modeling formalism available in the literature is set-based modeling, which not only enables all the modeling features from MIP and GDP, but also introduces the idea of using sets as

variables. Set-based optimization has resulted in compact formulations yielding computational advantages compared to MIP in a variety of scheduling applications, e.g., job-shop, open-shop, resource-constrained, among others [14]. However, the field of optimal set-based STN scheduling has not yet been explored.

This work brings novelty by deriving and testing the first set-based formulations for the STN scheduling problem. Set-based models introduce three key variable types, namely set variables, list variables and interval variables. In this work, we aim to contribute novel mixed-interval disjunctive program (MIDP) and mixed-interval-list disjunctive program (MILDP) STN models. Our secondary objective is to evaluate the computational performance of commercial software Hexaly given these set-based formulations. How we choose to model the STN directly contributes to the efficiency with which the optimization problem is solved. However, deriving the best set-based model (e.g., intervals, intervals + sets, intervals + lists) is not straightforward. While Hexaly exploits this type of modeling, the progress made by their proprietary algorithms and heuristics is not directly visible to the practitioner. Thus, observing how different formulations of the STN interact with Hexaly is vital for determining which combinations of set-based modeling paradigms are most efficient.

This study is organized as follows: first we provide modeling background. Then, we describe the proposed MIDP and MILDP STN models. Two case studies are then used to illustrate the performance of the proposed set-based formulations. Concluding remarks and future work are provided at the end.

## BACKGROUND

Background on STN MIP modeling is provided first, followed by background on set-based modeling.

### Mixed-integer program (MIP)

Optimal STN scheduling relies on four key fixed sets that are used to define a problem: tasks $i \in I$ (e.g., $i \in$ {manufacture product A, separate A from B, ...}); units $j \in J$ available to perform these tasks (e.g., $j \in$ {reactor 1, reactor 2, distillation column, ...}); states $k \in K$ that act as initial, intermediate or final storage defining the feasible interconnection between tasks, and a scheduling horizon that is discretized into $n_T + 1$ time points $t \in T = \{0, 1, 2, \dots, n_T\}$. Based on these four sets, additional fixed sets are used to specify the interconnections between tasks, units and states, namely

$$IJ^{\times} = \{(i,j) \in I \times J |\ i \text{ can be performed in } j\}, \quad (1)$$

$$IK^{+} = \{(i,k) \in I \times K |\ i \text{ feeds } k\}, \quad (2)$$

$$IK^{-} = \{(i,k) \in I \times K |\ k \text{ feeds } i\}. \quad (3)$$

Generally, two variable types need to be optimized in a STN problem: discrete timing variables and continuous batch size variables. In a traditional MIP model, timing variables $x_{i,j,t} \in \{0,1\}$ decide if task $i$ is executed in unit $j$ starting at time $t$. Non-overlapping constraints are needed to ensure that a given unit can only perform one task at a time, i.e.,

$$\sum_{i \in I \,:\, (i,j) \in IJ^{\times}} \sum_{t' \in T \,:\, t - \tau_{i,j} + 1 \le t' \le t} x_{i,j,t'} \le 1, \forall j \in J, \forall t \in T, \quad (4)$$

where $\tau_{i,j}$ is the number of discrete time points needed to execute task $i$ in unit $j$, i.e., a discrete processing time.

Batch size variables $b_{i,j,t} \in [0, \beta_j^{max}] \subset \mathbb{R}$ define the amount of material processed in task $i$ by unit $j$ at time $t$, where $\beta_{i,j}^{max}$ and $\beta_{i,j}^{min}$ are the fixed maximum and minimum capacities of unit $j$ when executing task $i$. Variable $b_{i,j,t}$ is bounded by $\beta_{i,j}^{max}$ and $\beta_{i,j}^{min}$ when a task is executed, as defined by the following capacity constraints:

$$\beta_{i,j}^{min} x_{i,j,t} \le b_{i,j,t} \le \beta_{i,j}^{max} x_{i,j,t}, \forall (i,j) \in IJ^{\times}, \forall t \in T. \quad (5)$$

STN problems stand out due to the consideration of states $k$, representing storage facilities in which incoming materials from previous task executions can be stored until they are released to subsequent tasks. This means that there is a mass balance inherently embedded within the scheduling problem. These mass balances are needed to ensure that, at a given time point, enough materials are available for the execution of subsequent tasks and storage facilities do not overflow. Mathematically, storage modeling requires intermediate storage states $s_{k,t} \in \mathbb{R}$ to define the mass balance constraints in (6) and (7), as well as the state tracking constraints in (8).

$$s_{k,0} = \gamma_k^{init} - \sum_{(i,j) \in IJ^{\times} \,:\, (i,k) \in IK^{-}} \rho_{i,k}^{-} b_{i,j,0}, \forall k \in K, \quad (6)$$

$$s_{k,t} = s_{k,t-1} + \sum_{(i,j) \in IJ^{\times} \,:\, (i,k) \in IK^{+}, t - \tau_{i,j} \ge 0} \rho_{i,k}^{+} b_{i,j,t-\tau_{i,j}} - \sum_{(i,j) \in IJ^{\times} \,:\, (i,k) \in IK^{-}} \rho_{i,k}^{-} b_{i,j,t}, \forall k \in K, \forall t \in T \backslash \{0\}, \quad (7)$$

$$\gamma_k^{min} \le s_{k,t} \le \gamma_k^{max}, \forall k \in K, \forall t \in T. \quad (8)$$

These constraints introduce parameter $\gamma_k^{init}$ denoting the initial storage in state $k$; the maximum ($\gamma_k^{max}$) and minimum ($\gamma_k^{min}$) storage capacity of state $k$, and the fraction of material in state $k$ consumed ($\rho_{i,k}^{-}$) or produced ($\rho_{i,k}^{+}$) by task $i$.

A common completion constraint is that all executed tasks must have finished by the end of the scheduling horizon, which can be expressed as

$$x_{i,j,t} = 0, \forall (i,j) \in IJ^{\times}, \forall t \in \{n_T - \tau_{i,j} + 1, \dots, n_T\}. \quad (9)$$

The constraints in (4)-(9) are standardly used to model STN problems, however, additional requirements are often imposed depending on specific application

requirements. Other modeling features considered in the case study section include constraint (10) to ensure that every task is executed at most once, or constraint (11) to ensure that the number of times task $i$ is executed in unit $j$ matches integer batching parameter $\psi_{i,j}$.

$$\sum_{\substack{j\in J\\(i,j)\in IJ^{\times}}}\sum_{t\in T}x_{i,j,t}\leq 1,\forall i\in I,\forall t\in T, \tag{10}$$

$$\sum_{t\in T}x_{i,j,t}=\psi_{i,j},\forall(i,j)\in IJ^{\times}. \tag{11}$$

## Set-based modeling

Set-based modeling relies on three variable types that are not used in MINLP or GDP modeling defined as:

### Interval variables

> Let $n,m\in\mathbb{Z}$ be fixed numbers with $m\geq n$ and $(\!(n,m)\!)=\{(n',m')\in\mathbb{Z}^2|\ n'\geq n,m'\leq m,m'\geq n'\}$. We define an *interval variable* $(x,y)\in(\!(n,m)\!)$, i.e., $(x,y)$ can take tuples in $(\!(n,m)\!)$ as values.

For instance, take $n=0$ and $m=2$. Then, it is possible to define interval variable $(x,y)\in(\!(n,m)\!)$, where $(\!(n,m)\!)$ is equal to $\{(0,1),(0,2),(1,2),(0,0),(1,1),(2,2)\}$. Note that interval variables are herein defined as tuples, but they resemble intervals in the sense that the second entry $y$ (the "end") is always greater than or equal to the first entry $x$ (the "start"). By convention, an interval variable is said to be empty when its start and end points match.

### Set variables

> Consider some fixed set $A$ and take $\mathbb{P}(A)$ as the power set of $A$, i.e., the set of subsets of $A$. We define a *set variable* $X\in\mathbb{P}(A)$, i.e., $X$ can take sets in $\mathbb{P}(A)$ as values.

For example, take $A=\{0,1\}$. Then, it is possible to define set variable $X\in\mathbb{P}(A)$ with $\mathbb{P}(A)=\{\{0\},\{0,1\},\{1\},\{\}\}$. Note that sets $\{0,1\}$ and $\{1,0\}$ are the same, i.e., set variables do not distinguish between different orderings of elements. List variables are similar to set variables, except that these account for permutations.

### List variables

> Consider some fixed set $A$ and its power set $\mathbb{P}(A)$. Also, take $\mathbb{S}(A)=\bigcup_{X\in\mathbb{P}(A)}\mathcal{S}(X)$, where $\mathcal{S}(X)$ is the set of lists obtained by permuting the elements of $X$. We define a *list variable* $y\in\mathbb{S}(A)$, i.e., $y$ can take lists in $\mathbb{S}(A)$ as values.

Again, take $A=\{0,1\}$ as an example. Then, it is possible to define list variable $y\in\mathbb{S}(A)$ with $\mathbb{S}(A)=\{\langle 0\rangle,\langle 0,1\rangle,\langle 1,0\rangle,\langle 1\rangle,\langle\rangle\}$. Note that set and list variables may take the empty set $\{\}$ or empty list $\langle\rangle$ as valid values.

In the previous definitions, $A$ is called a "fixed set" in the sense that it is not a set variable. In fact, Hexaly only supports $A$ being a finite range set of the form $\{0,1,2,\ldots,n-1\}$. However, Hexaly supports establishing one-to-one relationships between $A$ and other sets of the same size, even if they contain variables, e.g., a one-to-one function between $A$ and a set of interval variables that needs to be shuffled through a list variable. For notation simplicity, this work avoids one-to-one functions and allows $A$ being a finite set of variables explicitly.

# MATHEMATICAL MODELS

In this section, we introduce the constraints needed to formulate MIDP and MILDP set-based STN models.

## Mixed-interval disjunctive program (MIDP)

We propose a STN MIDP model that replaces timing variables $x_{i,j,t}\in\{0,1\}$ by timing interval variables. To do that, we define execution subindex $q\in Q_{i,j}$, where $Q_{i,j}$ is the fixed set of all potential executions of task $i$ in unit $j$ defined as

$$Q_{i,j}=\{1,2,\ldots,\lfloor n_T/\tau_{i,j}\rfloor\},\forall(i,j)\in IJ^{\times}, \tag{12}$$

with $\lfloor\bullet\rfloor$ being the floor operator. This allows to define interval variables $(\mathfrak{x}_{i,j,q}^{start},\mathfrak{x}_{i,j,q}^{end})\in(\!(0,n_T)\!),\forall(i,j)\in IJ^{\times},\forall q\in Q_{i,j}$. Interval $(\mathfrak{x}_{i,j,q}^{start},\mathfrak{x}_{i,j,q}^{end})$ represents the potential execution $q$ of task $i$ in unit $j$, starting at time point $\mathfrak{x}_{i,j,q}^{start}$ (inclusive) and finishing at time point $\mathfrak{x}_{i,j,q}^{end}$ (exclusive).

For some $(i,j)\in IJ^{\times}$, not every interval $q\in Q_{i,j}$ is necessarily going to be executed. Therefore, we use the convention that the length of $(\mathfrak{x}_{i,j,q}^{start},\mathfrak{x}_{i,j,q}^{end})$ is 0 (i.e., $\mathfrak{x}_{i,j,q}^{end}-\mathfrak{x}_{i,j,q}^{start}=0$) when interval $q$ is not executed. Otherwise, the interval is executed and its length is equal to the processing time of the task-unit pair $(\mathfrak{x}_{i,j,q}^{end}-\mathfrak{x}_{i,j,q}^{start}=\tau_{i,j})$, i.e., we impose the following interval presence constraints:

$$\left[\mathfrak{x}_{i,j,q}^{end}-\mathfrak{x}_{i,j,q}^{start}=\tau_{i,j}\right]\vee\left[\mathfrak{x}_{i,j,q}^{end}-\mathfrak{x}_{i,j,q}^{start}=0\right],$$
$$\forall(i,j)\in IJ^{\times},\forall q\in Q_{i,j}, \tag{13}$$

where $\vee$ is the or operator. Now, we introduce a new operator defined as $\mathbf{if}(\Omega)=\{1\text{ if }\Omega=\text{True},0\text{ if }\Omega=\text{False}\}$, where $\Omega$ is a logical condition. Hexaly supports this operator for a variety of logical conditions. This operator allows us to define non-overlapping constraints as

$$\sum_{\substack{i\in I\\(i,j)\in IJ^{\times}}}\sum_{q\in Q_{i,j}}\mathbf{if}\left(t\geq\mathfrak{x}_{i,j,q}^{start}\right)-\mathbf{if}\left(t\geq\mathfrak{x}_{i,j,q}^{end}\right)\leq 1,$$
$$\forall j\in J,\forall t\in T. \tag{14}$$

Next, we introduce MIDP capacity constraints as

$$\mathbf{if}\left(\bigvee_{q\in Q_{i,j}}\begin{bmatrix}\mathfrak{x}_{i,j,q}^{start}=t\\ \mathfrak{x}_{i,j,q}^{end}-\mathfrak{x}_{i,j,q}^{start}\neq 0\end{bmatrix}\right)\beta_{i,j}^{min}\leq b_{i,j,t},$$

$$b_{i,j,t} \leq \mathbf{if}\left(\bigvee_{q\in Q_{i,j}}\begin{bmatrix}\mathfrak{x}^{start}_{i,j,q} = t\\ \mathfrak{x}^{end}_{i,j,q} - \mathfrak{x}^{start}_{i,j,q} \neq 0\end{bmatrix}\right)\beta^{max}_{i,j},$$

$$\forall (i,j) \in IJ^{\times}, \forall t \in T, \tag{15}$$

which link timing interval variables with continuous batch size variables that remain unchanged with respect to the traditional MIP STN model. Note that $x_{i,j,t}$ is equivalent to the **if** operator multiplying $\beta^{min}_{i,j}$ and $\beta^{max}_{i,j}$ in (15), i.e., if $x_{i,j,t} = 1$, then there is some interval $q \in Q_{i,j}$ of non-zero length starting at time $t$.

Since batch size variables $b_{i,j,t}$ remain unchanged in this formulation, mass balance and state tracking constraints (6)-(8) remain unchanged with respect to the MIP formulation. Furthermore, MIP completion constraints in (9) are readily enforced by $(\mathfrak{x}^{start}_{i,j,q}, \mathfrak{x}^{end}_{i,j,q}) \in (\!(0, n_T)\!)$, i.e., the end of an interval $\mathfrak{x}^{end}_{i,j,q}$ is bounded above by $n_T$. In summary, MIP constraints (4), (5) and (9) are the counterpart of MIDP constraints (13)-(15), while both MIP and MIDP share constraints (6)-(8).

After defining the main components of the MIDP STN model, we now examine how the additional MIP modeling features in (10) and (11) can be incorporated into the MIDP formulation. An equivalent version of constraint (10) in the MIDP model to ensure that each task is executed at most once is of the form

$$\sum_{\substack{I\in I\\ (i,j)\in IJ^{\times}}} \sum_{q\in Q_{i,j}} \mathbf{if}\left(\mathfrak{x}^{end}_{i,j,q} - \mathfrak{x}^{start}_{i,j,q} > 0\right) \leq 1, \forall i \in I. \tag{16}$$

Regarding constraint (11), major modifications are needed if the number of times task $i$ is executed in unit $j$ is known and equal to $\psi_{i,j}$. Firstly, set $Q_{i,j}$ in (12) must be redefined as

$$Q_{i,j} = \{1, 2, \dots, \psi_{i,j}\}, \forall (i,j) \in IJ^{\times}, \tag{17}$$

So that only $\psi_{i,j}$ intervals are considered in the formulation. Secondly, these intervals must be scheduled, meaning that interval presence constraints in (13) simplify to the following interval length constraints:

$$\mathfrak{x}^{end}_{i,j,q} - \mathfrak{x}^{start}_{i,j,q} = \tau_{i,j}, \forall (i,j) \in IJ^{\times}, \forall q \in Q_{i,j}. \tag{18}$$

Lastly, all intervals have length $\tau_{i,j}$, thus the condition within the **if** operator in (15) simplifies and capacity constraints reduce to

$$\mathbf{if}\left(\bigvee_{q\in Q_{i,j}} \left[\mathfrak{x}^{start}_{i,j,q} = t\right]\right)\beta^{min}_{i,j} \leq b_{i,j,t},$$

$$b_{i,j,t} \leq \mathbf{if}\left(\bigvee_{q\in Q_{i,j}} \left[\mathfrak{x}^{start}_{i,j,q} = t\right]\right)\beta^{max}_{i,j},$$

$$\forall (i,j) \in IJ^{\times}, \forall t \in T. \tag{19}$$

## Mixed-interval-list disjunctive program (MILDP)

The interval variables from the MIDP formulation can be included in sets that define list variables, so that some constraints of the MIDP formulation can be reformulated in terms of list variables in a MILDP model. To do that, we create the following sets with $Q_{i,j}$ defined in (12):

$$A_j = \left\{\left(\mathfrak{x}^{start}_{i,j,q}, \mathfrak{x}^{end}_{i,j,q}\right) \in (\!(0, n_T)\!) \,|(i,j) \in IJ^{\times}, q \in Q_{i,j}\right\},$$

$$\forall j \in J, \tag{20}$$

which for every unit $j$ contain all the intervals (i.e., tasks) that can be potentially performed in that unit. To decide which intervals are going to be scheduled and their order, we define list variables $y_j \in \mathbb{S}(A_j)$. We denote $y_j = \langle y_j(1), y_j(2), \dots, y_j(|y_j|)\rangle$, where the components $y_j(p), \forall p \in \{1, 2, \dots, |y_j|\}$ provide ordered access to the individual intervals in $y_j$. With this new variable, interval presence constraints take the following form:

$$\mathfrak{x}^{end}_{i,j,q} - \mathfrak{x}^{start}_{i,j,q} = \mathbf{if}\left(\left(\mathfrak{x}^{start}_{i,j,q}, \mathfrak{x}^{end}_{i,j,q}\right) \in y_j\right)\tau_{i,j},$$

$$\forall (i,j) \in IJ^{\times}, \forall q \in Q_{i,j}. \tag{21}$$

Also, non-overlapping constraints can now be compactly formulated as

$$y_j(p) < y_j(p-1), \forall p \in \{2, 3, \dots, |y_j|\}, \forall j \in J, \tag{22}$$

where the strict $<$ constraint between two intervals means that the second entry of the right-hand-side interval tuple is less than or equal to first entry of the left-hand-side interval tuple. Note that having $|y_j|$ as variable in (22) is an accepted cardinality expression in Hexaly's set-based modeling platform.

Capacity constraints remain unchanged with respect to those defined for the MIDP model in (15). Also, mass balance and state tracking constraints (6)-(8) remain unchanged in the MILDP formulation. Similarly to the MIDP model, completion constraints of tasks within the scheduling horizon are not needed because these are readily satisfied by interval variables. In summary, MIP constraints (4), (5) and (9) are the counterpart of MILDP constraints (15), (21) and (22), while both MIP and MILDP share constraints (6)-(8).

Now that the main MILDP constraints have been defined, we explain how constraints (10) and (11) are translated from the MIP formulation to the MILDP model. On the one hand, constraint (10) takes the form of constraint (16) from the MIDP model. On the other hand, imposing a constraint equivalent to (11) in the MILDP model requires defining set $Q_{i,j}$ as in (17) instead of (12), imposing interval length constraint (18) instead of (21), imposing capacity constraints (19) instead of (15), and enforcing the following constraint on the size of lists:

$$|y_j| = \sum_{\substack{i\in I\\ (i,j)\in IJ^{\times}}} \psi_{i,j}, \forall j \in J. \tag{23}$$

## CASE STUDY

We assess the performance of the proposed MIDP and MILDP formulations in comparison with the traditional MIP formulation through two case studies. The objective functions and parameters defining these case studies are introduced below.

### Case Study 1

This case study was proposed by Hirn and Grapendal [15], who proposed a STN model for the optimal scheduling of electromagnetic compatibility tests with limited scheduling time and equipment. That is, 15 devices of different sizes are scheduled to be tested in 3 testing chambers with different capacities. For this case study, each task represents a device that needs to be tested once; therefore, special constraint (10) is enforced. Additionally, a profit maximization objective is considered. For the MIP formulation the objective function is defined as

$$\max \sum_{(i,j)\in IJ^{\times}} \sum_{t\in T} \upsilon_i x_{i,j,t}, \tag{24}$$

where $\upsilon_i$ is the fixed profit generated by one execution of task $i$, which readily considers the difference between revenue and task execution costs. Objective function (24) translates into

$$\max \sum_{(i,j)\in IJ^{\times}} \sum_{q\in Q_{i,j}} \upsilon_i \mathbf{if}\left(\mathfrak{t}_{i,j,q}^{end} - \mathfrak{t}_{i,j,q}^{start} > 0\right), \tag{25}$$

for set-based formulations. The resulting optimization problem is shown in Table 1, while all the fixed parameters are available as supplementary material (Appendix A).

**Table 1:** MIP, MIDP and MILDP problem formulations.

| MIP | MIDP | MILDP |
|---|---|---|
| Eq. (24), s.t. Eqs. (4)-(10). | Eq. (25), s.t. Eqs. (6)-(8), (12)-(15), (16). | Eq. (25), s.t. Eqs. (6)-(8), (12), (15), (16), (21), (22). |

### Case Study 2

This case study was adapted from the work by Velez and Maravelias [16], who studied MIP formulations for long-term STN scheduling. It considers the well-studied Kondili et al. [2] STN, which includes one mixing task performed in a separation unit, three reaction tasks scheduled in two reactors and one separation task with its corresponding separation unit. This STN has three inputs for which purchasing costs are considered and two products that generate revenue. For this case study, it is assumed that the number of times each task is executed in each unit is known, thus, special constraint (11) is enforced. In this case, the profit maximization objective takes the following form:

$$\max \sum_{k\in K} \omega_k s_{k,n_T} - \sum_{(i,j)\in IJ^{\times}} \alpha_{i,j} \psi_{i,j}, \tag{26}$$

where $\omega_k$ is the revenue from selling the material in state $k$ and $\alpha_{i,j}$ is the cost of running task $i$ in unit $j$. Altogether, the optimization problem considered is summarized in Table 2, while all the fixed parameters are available in the supplementary material (Appendix B).

**Table 2:** MIP, MIDP and MILDP problem formulations.

| MIP | MIDP | MILDP |

## RESULTS AND DISCUSSION

This section evaluates the performance of the MIP, MIDP, and MILDP models by solving multiple instances of case studies 1 and 2 across varying levels of complexity. All optimization runs were performed in the Python API of Hexaly 14.0 with a time limit of 3600 seconds on a 1.7 GHz, 64 GB, Intel Core® Ultra™ 7 165U, Dell Inc. Latitude 7350 laptop.

### Case Study 1

Different instances of this case study were generated by testing different time horizons $n_T$ from 5 to 17, while keeping the scheduling time step fixed. Since tasks can be executed only once, increasing $n_T$ results in increased flexibility to accommodate more tasks within the scheduling horizon. The performance plots obtained with solution time and objective gap as performance metrics are shown in Figures 1 and 2, respectively.

In the y-axis, Figure 1 shows the fraction of problems solved to global optimality within the solution time shown in the x-axis. Similarly, Figure 2 shows the fraction of problems solved to either feasibility or global optimality within the percentual objective gap in the x-axis. From Figure 1, the MIDP formulation clearly outperforms the MIP and MILDP formulations for this case study. Within the time limit, the MIDP formulation can solve 11 out of the 13 tested instances to global optimality. On the contrary, the MIP and MILDP formulations are unable to close the objective gap to satisfactory levels (see Figure 2).

Figure 2 shows that the MILDP model achieves better effectiveness at closing the optimality gap reported by the solver compared to the standard MIP, despite not performing as well as the MIDP formulation. Furthermore, all formulations reached the same primal objective within the imposed time limit. This outcome suggests that the set-based formulations used enable Hexaly's optimization algorithm to compute tighter objective lower bounds for this test problem. Based on publicly available documentation, the observed increased performance of set-

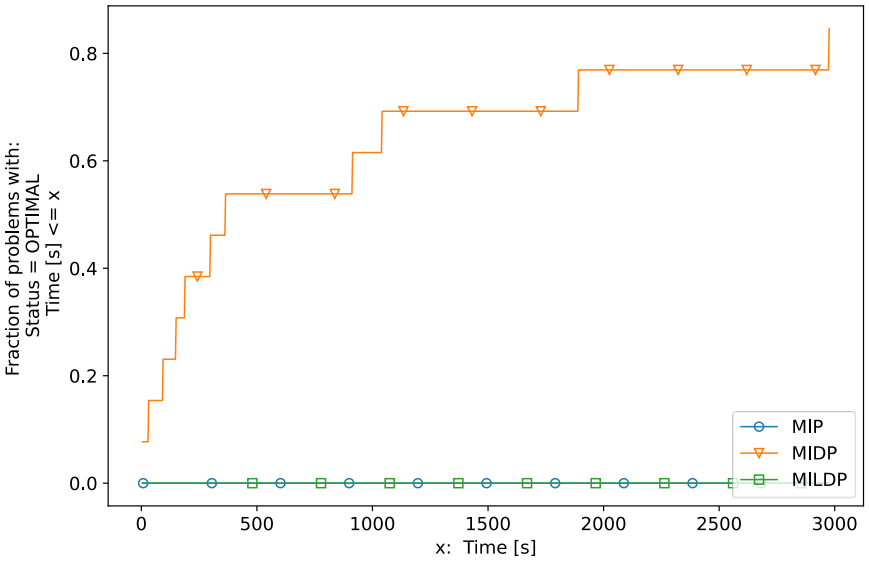

**Figure 1.** Solution time performance profile for case 1.

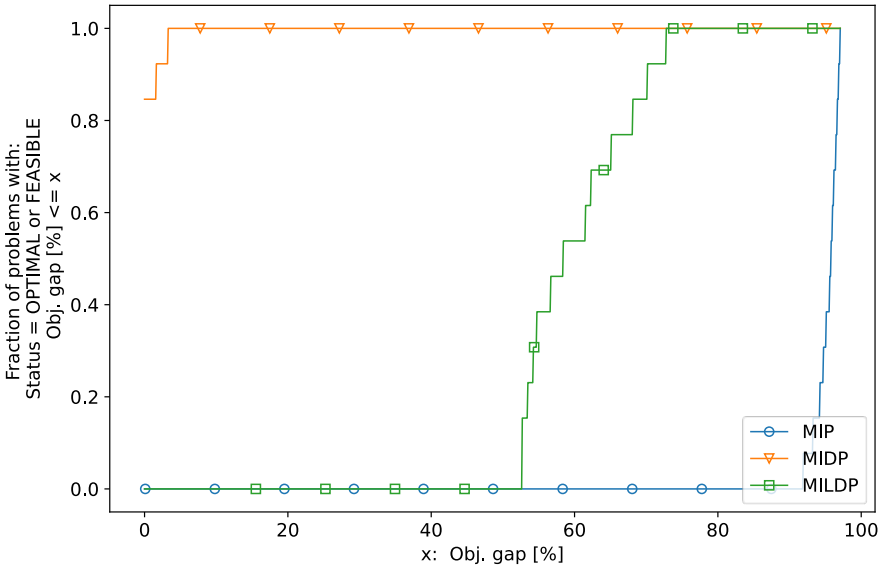

**Figure 2.** Objective gap performance profile for case 1.

based formulations at solving the dual problem and finding better objective bounds is attributed to a combination of column generation, column elimination and/or branch-cut-price strategies tailored to list and interval variables. Particularly, the energetic relaxation implemented in Hexaly has been shown to be effective for deriving lower bounds in scheduling problems [17].

The results obtained in this work align with the previous findings by Hirn and Grapendal [15], who highlighted how increasing the time horizon affects the number of nodes that a standard MIP algorithm (GLPK) must explore to close the optimality gap. As the time horizon $n_T$ increases, more devices can be scheduled, which adds combinatorial complexity and forces GLPK to move from exploring roughly $1$ node to about $1 \times 10^7$ nodes before finding the optimal solution, until all devices can finally be scheduled at $n_T$=16. This is in line with the best-performing set-based model (MIDP), which only struggles to close the optimality gap for the instances with $n_T$=14 and $n_T$=15, reporting gaps of 3.21% and 1.61%, respectively. In contrast, the MIP formulation solved with Hexaly consistently reports optimality gaps larger than 90%, further highlighting the computational benefits of the proposed MIDP model.

## Case Study 2

A total of $20$ different instances of this case study were generated by adjusting the fineness (or accuracy)

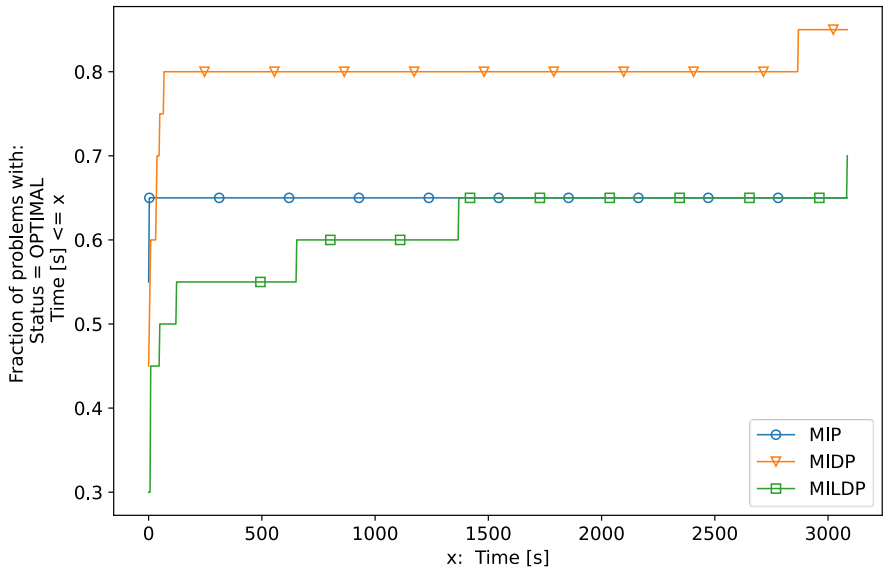

**Figure 3.** Solution time performance profile for case 2.

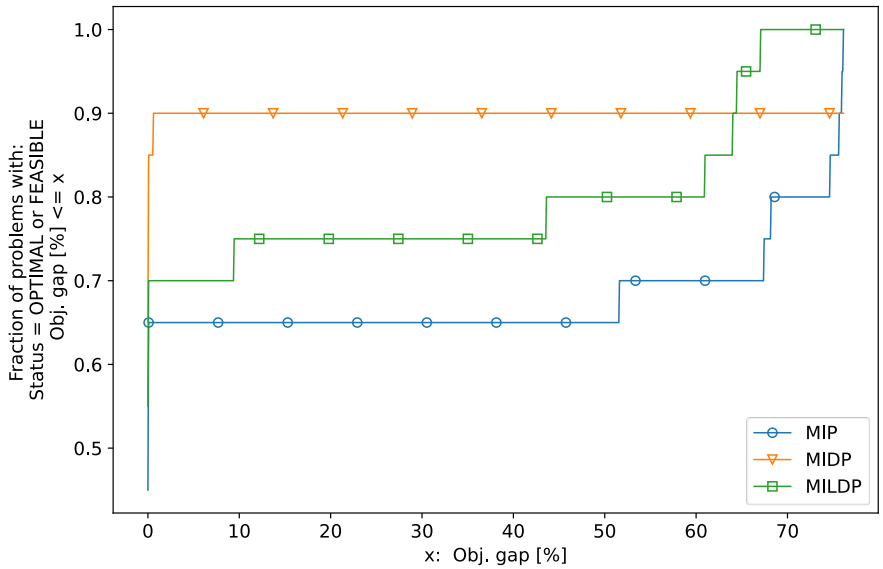

**Figure 4.** Objective gap performance profile for case 2.

for time discretization, ranging from 2 (i.e., $n_T = 1$), to 121 (i.e., $n_T = 120$) discretization points. The remaining parameters of the formulation were adjusted to maintain a physical scheduling horizon of 120 hours. The performance plots obtained with solution time and objective gap as performance metrics are shown in Figures 3 and 4, respectively.

Figure 3 illustrates improvements in the performance of the MIP formulation relative to the previous case study. Specifically, the MIP formulation outperforms the MILDP formulation for solution times below 1500 seconds. However, at higher time limits the MILDP model exhibits a slight increase in performance, solving one additional instance to global optimality within the 3600 seconds limit. In contrast, the MIDP formulation outperforms both the MIP and MILDP models, solving more than 80% of the test problems to global optimality.

Similarly to the previous case study, both the MIDP and MILDP models outperform the original MIP model in closing the objective gap (see Figure 4). However, not all formulations reach the same primal solution in this case study. The MILDP model consistently identified the best-known primal solution across all instances. This indicates that the advantage of set-based formulations arises not only from dual strategies that yield tighter objective lower bounds, but also from primal heuristics that quickly generate high-quality feasible solutions. Specifically, Hexaly leverages local search and large neighborhood search

strategies that operate directly on interval and list variable domains, eliminating the need for binary reformulations. For example, consider a task-unit pair $(i, j)$. The MIDP and MILDP formulations avoid introducing one binary variable $x_{i,j,t}$ for each time point $t \in \{0, 1, 2, \ldots, n_T\}$, and instead replace them with $\psi_{i,j}$ interval variables, where $\psi_{i,j}$ is a fixed integer. In terms of variable reduction, the best-case scenario in the set-based formulations compared to the MIP formulation would occur when $\psi_{i,j} = 1$ and $n_T = 120$. In that case, 121 binary variables in the traditional MIP formulation are replaced by a single interval variable in the MIDP and MILDP formulations. At solving time, Hexaly does not reformulate interval and list variables as binary variables, but applies powerful primal heuristics combined with exact algorithms to the set-based representation directly. Thus, this study shows that exploiting set-based formulations rather than relying on standard binary variable models enables the primal solver within Hexaly to scale better with large scheduling instances and get good quality solutions faster.

The results discussed through this and the previous section highlight instances where at least one of the proposed MIDP and/or MILDP formulations outperform a traditional MIP formulation when using Hexaly. Nevertheless, set-based formulations are not always expected to bring computational improvements. To illustrate this, we have performed a computational experiment that is a modified version of the current case study, with the only difference being that integer batching variables are now left unfixed, i.e., constraint (11) is removed from the MIP. In the MIDP formulation, this translates to using definition (12) instead of (17), constraint (13) instead of (18), and constraint (15) instead of (19). Similarly, the MILDP formulation needs to be modified by using definition (12) instead of (17), constraint (21) instead of (18), constraint (15) instead of (19), and removing constraint (23).

Assuming a 300-second time limit, the solving-time performance profiles of this modified case study are shown in Figure 5. Recall that, within 300 seconds, the MIDP formulation solves 80% of the test problems to optimality, compared to 65% solved by the MIP model in the original version of this case study (see Figure 3). In this modified version, the MIP performance-profile line lies above both the MIDP and MILDP lines in Figure 5, indicating that the MIP formulation is now outperforming the set-based formulations, e.g., the MIP formulation solves 55% of the tested instances to optimality within 40 seconds, compared to 25% solved to optimality by the MIDP formulation. These results highlight that STN optimal scheduling benefits from the proposed MIDP and MILDP formulations when dealing with problems with fixed integer batching variables; however, this outcome does not generalize to problems with unfixed integer batching variables for the case study under consideration.

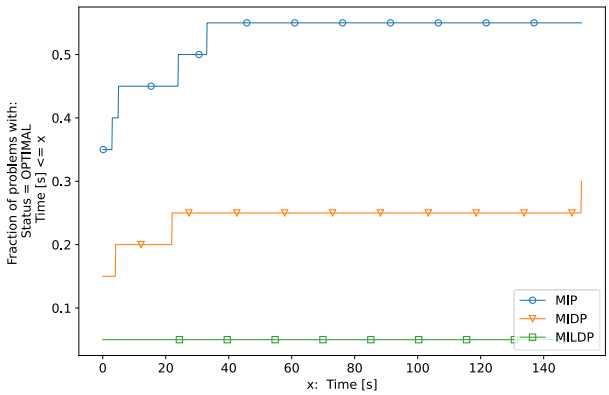

**Figure 5**. Solution time performance profile for the modified version of case 2.

## CONCLUSIONS

The optimal STN scheduling problem has traditionally been addressed through standard MIP formulations and classical solution algorithms. In contrast, this work introduced the first set-based STN models, opening a new avenue for research in optimal network scheduling. Documentation suggests Hexaly performs well for specific classes of industrial-scale problems, such as scheduling and vehicle routing, precisely because it exploits this set-based modeling paradigm effectively. We have shown promising results for determining a strong set-based model for representing and solving STN formulations using Hexaly, namely a mixed-interval disjunctive programming (MIDP) formulation.

As future work, we aim to continue refining and studying the proposed set-based formulations. Also, a systematic comparison of set-based, constraint programming, and MIP optimization beyond Hexaly and across multiple modeling and solution platforms was outside the scope of this work. The solver embedded in Hexaly is known to be competitive with commercial and open-source solvers such as Gurobi, CPLEX, HiGHS, and OR Tools, e.g., in job shop scheduling [18]. Consequently, a broader benchmarking study with a larger set of test instances is necessary to further clarify how STN scheduling benefits from the proposed set-based formulations.

## DIGITAL SUPPLEMENTARY MATERIAL

A file containing the parameters needed to define the case studies and to replicate the sensitivity analyses shown in the result section are available at https://psecommunity.org/LAPSE:2026.0003. All results can be replicated by running the code available at https://psecommunity.org/LAPSE:2026.0002.

## ACKNOWLEDGEMENTS

The authors would like to thank the Hexaly team for

their valuable feedback on the manuscript.

## ABSTRACT

Ammonia has received in recent years significant attention as potential carbon free fuel. However, its combustion properties limit its direct application for both providing heat and in power generation through gas turbines. Ammonia cracking is one potential solution to circumvent the problem by producing hydrogen. When using the ammonia in gas turbines, it is possible to heat integrate the endothermic decomposition reaction with the exhaust gas from the gas turbine. Thermodynamic and kinetic limitations have however a major impact on the achievable ammonia conversion. Based on the consideration of these limitations, this paper presents a detailed investigation of key design parameters affecting the overall process efficiency utilizing both an equilibrium reactor model and a reactor model based on detailed kinetics and heat transfer. Ammonia decomposition should occur at sufficiently high pressure to avoid a) the com-pression energy demand for achieving the pressure of the combustion chamber and b) to reduce equipment size although the increased pressure results in a reduced conversion when considering an equilibrium reactor. It is crucial for the energy efficient integration of ammonia decomposition with gas turbines to avoid a partial combustion of the decomposed ammonia even as an increased temperature of the reactor results in an increased ammonia conversion. Furthermore, it is beneficial to operate the compression stages without intercooling to reduce the required fuel flow to the gas turbine.

**Keywords**: Alternative Fuels, Process Design, Modelling and Simulations, Surrogate Model

## INTRODUCTION

The application of ammonia in the energy sector has received significant attention in recent years [1]. Ammonia can be considered as both a hydrogen carrier and a fuel in itself. The utilization of Ammonia as fuel results in no direct $CO_2$ emissions and has the potential to drastically reduce the emissions associated with energy use when produced from decarbonized hydrogen, *i.e.*, hydrogen produced from natural gas reforming with $CO_2$ capture or electrolysis [2]. In addition, it has in its liquid state the advantage of a relatively high volumetric energy density and established logistics chains. Hence, it can solve the problem of transporting hydrogen from regions with high renewable potential to regions with high energy demand [3]. Ammonia is also seen as direct fuel and not only as hydrogen carrier. It is considered as one alternative for dispatchable power generation [4] with a benefit at low capacity utilizations compared to other fuels when utilized in gas turbines [5]. Its potential application in gas turbines for electricity generation is however hindered by its poor combustion properties [6]. Consequently, decomposition of ammonia into hydrogen and nitrogen is required to maintain a stable flame [5]. Ammonia decomposition, that is the reverse of its synthesis, is an endothermic reaction given by

$$2NH_3 \rightleftharpoons N_2 + 3H_2 \quad (1)$$

High conversions can either be achieved at high temperatures or at a low pressure. Furthermore, the activity of ammonia decomposition catalysts at the low temperatures of gas turbine flue gas is low [7]. As a consequence, analyses normally focus on providing the heat for the decomposition reaction by burning a part of the (partially) decomposed) ammonia as fuel [5]. The decomposition of the ammonia leads however to an efficiency penalty, resulting in calls for the industry to develop novel

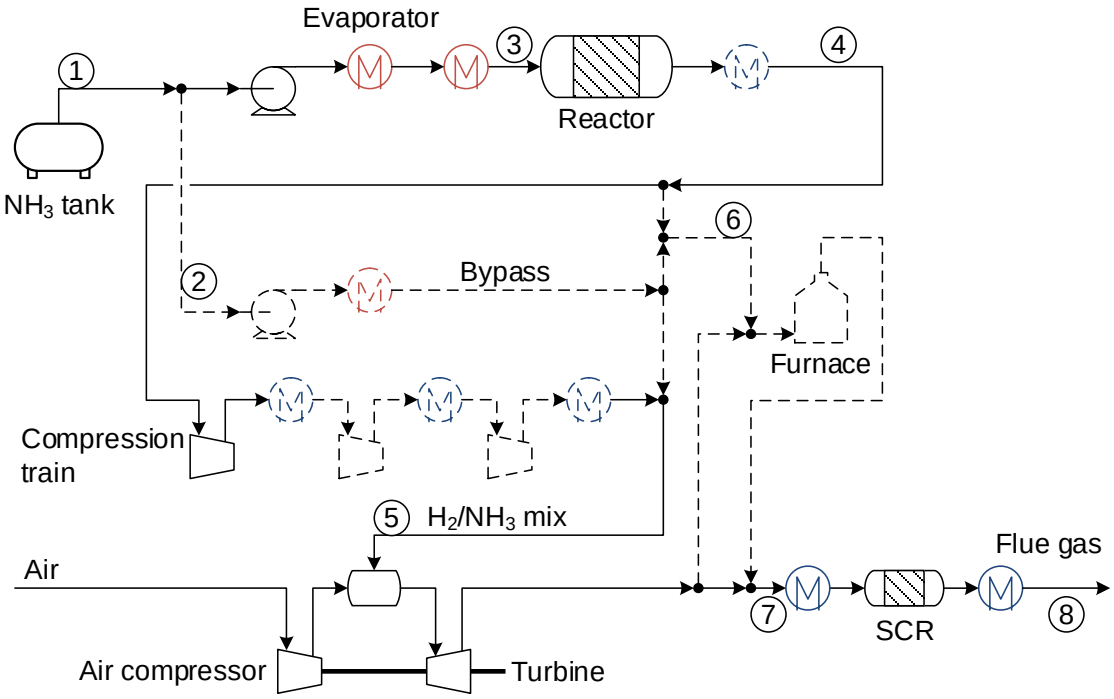

**Figure 1.** Process flow diagram of the proposed process. Blue heat exchangers correspond to coolers while red heat exchangers to heaters or boilers.

gas turbine burner types to be able to utilize pure ammonia. An alternative route for increasing the efficiency is to focus on partial decomposition of ammonia [8]. The partial decomposition has the advantage of a) having a reduced energy demand for the reaction, b) smaller reactor sizes as full conversion is not required, and c) the potential for heat integration with the flue gas of the gas turbine as less energy is required at lower temperatures.

The application of ammonia in gas turbines has however still open questions. While Cesaro et al. investigated as well the efficiency of partially cracked ammonia [5], their investigation did not consider the thermal integration of the gas turbine flue gas with the decomposition reactor. Instead, the decomposed ammonia (in this case a mixture of hydrogen and nitrogen) is used for providing the energy to the endothermic reaction while the flue gas is only utilized for preheating. Similarly, Paschchenko focused extensively on the operation of the gas turbine, but assumed an equilibrium reactor for the conversion of ammonia [8]. The investigation of the partial decomposition of ammonia has, however, still open questions with respect to the optimal process configuration due to the large number of design parameters.

Hence, we present in this study a thorough analysis of a novel integrated process for partial ammonia decomposition coupled with a gas turbine for exhaust heat recuperation. A focus of the work is to understand how the different design choices may affect the process energy efficiency and potential complexity. A detailed model of the decomposition reactor at low temperatures is included in the process flowsheet as surrogate model to account for the catalytic performance and potential limitations in the heat transfer. This allows the analyses of heat transfer limitations, and hence, both direct integration for heat recuperation and indirect through a heating fluid with a high heat capacity are investigated.

## PROCESS DESCRIPTION

### Modelling approach

The overall process is modelled in Aspen HYSYS and illustrated in Figure 1. All dashed components are optional depending on the chosen process configuration. Ammonia is stored (*$NH_3$ tank*) at refrigerated conditions (-33 °C and 1.1 bar pressure) to avoid explosive spillage in the case of a leak [9]. The liquid ammonia (*stream 1*) is first pumped before being evaporated (*Evaporator*) to avoid excessive compression requirements. The gaseous ammonia is then heated to the inlet temperature of the *Reactor*. In this study, two different reactor models are considered; initial analyses focusing on investigating the reactor pressure utilize an equilibrium reactor with an approach to equilibrium of 250 K while in-depth analyses are conducted utilizing a conversion reactor in which the conversion and outlet temperature of the different streams are calculated using a table lookup method given the inlet temperature to the reactor of ammonia and the heating medium (exhaust gas or a heating liquid). The detailed reactor model for creating the table is implemented

in MATLAB and models a shell and tube reactor with experimentally calculated kinetics for low temperature ammonia decomposition using a Co-Ce catalyst. These kinetic values are seen as optimistic as the used weight-hourly space velocity is below the experimental range, but potential trends in the analyses are considered to be independent of the exact kinetic values. After the decomposition reactor, the partially cracked ammonia is cooled (to *stream 4*) and compressed to the combustion chamber pressure at 30 bar (*Compression train*). Both the cooling after the reactor and interstage cooling between the compression stages can be deactivated to analyze their impact. The number of compressor stages is automatically calculated based on a maximum allowed compression ratio of 2.6. The process allows furthermore the inclusion of a bypass of the decomposition reactor (*stream 2*). The bypass corresponds to pumping the liquid ammonia directly to the combustion chamber pressure before evaporating it. The bypass can be seen as an additional degree of freedom for controlling the composition to the gas turbine.

Subsequently, the *Bypass* and the stream from the *Compression train* are mixed and fed to the combustion chamber of the gas turbine (*stream 5*). The mass flow of the *Air* to the combustion chamber is used for adjusting the temperature in the combustion chamber to 1160 °C. Electricity is subsequently generated using an expander model corresponding to a turbine. The exhaust gas contains significant amounts of $NO_x$ which is removed by first adding ammonia (not shown in the Figure but modelled) to the exhaust gas and subsequent selective catalytic reduction (*SCR*) modelled as an equilibrium reactor. Heat recuperation from the exhaust gas is achieved both before and after the *SCR* reactor to allow for the required temperature in the *SCR* reactor.

As the temperature of the exhaust gas of the turbine may be too low to provide heat to the decomposition reaction, a potential *Furnace* is included. The fuel to the furnace (*stream 6*) is partially cracked ammonia at the same composition as the fuel to the combustion chamber while the air is a fraction of the exhaust gas. However, as the furnace is operating at a lower pressure, it utilizes the partially cracked ammonia before the compression to the pressure of the combustion chamber to avoid unnecessary energy demands. The flow to the furnace is controlled by pinch analysis and a specified minimum temperature approach $\Delta T_{min}$ of 25 °C. In the case of the detailed reactor model, we specify the required temperature of *stream 7* as input parameter while the furnace flow is calculated through a piecewise linear surrogate model. If the outlet temperature of the gas turbine exceeds the specified value, we use instead the outlet temperature directly. The hot liquid requires furthermore a $\Delta T_{min}$ of 12.5 °C for the heat transfer between the exhaust gas and the hot liquid. This assures the potential for designing an optimal heat exchanger network. Different approaches are chosen as the minimum temperature approach can occur at the reactor inlet in the case of the equilibrium reactor, while this is already included in the detailed reactor model.

## Design parameters

The complete process has several important design parameters. These design parameters are explained in detail in the following sections.

### Reactor pressure and temperatures

The reactor pressure has an impact on both the potential parasitic electricity requirements for the compression of the partially cracked ammonia and the equilibrium conversion of ammonia. Higher conversions can be achieved at low reactor pressures, but additional electricity for compression is required in this case. In addition, lower pressures result in larger equipment sizes. Similarly, higher reaction temperatures result in higher conversions, while they may require more combustion of partially cracked ammonia to achieve the temperatures as the temperature of the exhaust gas may be too low for providing the heat to the decomposition reaction.

The equilibrium reactor approach utilizes a constant temperature change in the reactor to approximate a counter current reactor while the table look-up method includes the temperature and relative flow of the heating medium as input parameters. The latter is implemented through the temperature of *stream 7* in Figure 1.

### Cooling of the partially cracked ammonia and interstage cooling

The outlet stream from the ammonia decomposition reactor can be cooled to a desired temperature in *stream 4*. In addition, inter-stage cooling in the *compression train* can be applied or not. If the outlet stream is not cooled and no interstage cooling is applied, the efficiency of the compressors is reduced due to the increased temperature. The benefit of this approach is a simplified compressor design (albeit with potentially more expensive materials due to elevated temperatures) and a reduction in required fuel flow to the combustion chamber due to the increased temperature of the fuel.

### Bypass of the decomposition reactor

The bypass of the decomposition reactor (*stream 2*) is an important factor for both the overall cracking ratio and the required compression energy demand. Introducing a bypass reduces the compression demand after the decomposition reactor and increases the conversion in the decomposition reactor due to a longer residence time for a given reactor size. In addition, it reduces the equipment size for compressors and heat exchangers However, care must be taken to avoid a significant reduction in overall cracking ratio to maintain a stable flame in the

combustion chamber. The bypass does not affect the heat required for the cracking ratio for a constant overall cracking ratio.

## Key performance indicators

The overall cracking ratio $X_P$ provides information regarding the conversion of ammonia. It has an impact on the flame in the combustion chamber as well as the potential $NO_x$ formation of the process. It is calculated through the conversion in the decomposition reactor $X_R$ and the bypass ratio, $BR = \dot{m}_2/\dot{m}_1$. $\dot{m}_1$ corresponds here to the complete ammonia feed, including the bypass and the required ammonia for the SCR reaction, while $\dot{m}_2$ represents the flow through the *Bypass*. The stream numbers are also included in Figure 1. It is given by

$$X_P = BR \times X_R \tag{2}$$

The overall lower heating value efficiency $\eta_{LHV}$ can be calculated as

$$\eta_{LHV} = \frac{P_{turb} - P_{para}}{\dot{m}_1 \times LHV_1} \tag{3}$$

where $P_{turb}$ corresponds to the electricity generation in the *Turbine* and $P_{para}$ to parasitic electricity demand for pumping and compression. It is closely related to the energy efficiency of the gas turbine $\eta_{GT}$, calculated as

$$\eta_{GT} = \frac{P_{turb} - P_{comp}}{\dot{m}_5 \times LHV_5} \tag{4}$$

with $P_{comp}$ representing the electricity demand for the *Air compressor* while the denominator is based on the inlet flow to the combustion chamber (*stream 5*). The gas turbine efficiency is higher than the overall efficiency of the process. It can provide an overview of the losses incurred by the partial ammonia decomposition.

The ratio of feed stream to the furnace stream, $FR = \dot{m}_6/\dot{m}_1$, is another important key performance indicator. While it is indirectly included in the overall efficiency $\eta_{LHV}$, it is still important to understand what fraction of ammonia must be combusted to achieve the desired decomposition reactor temperature.

# ANALYSIS

The analysis is split into two distinctive sections, an analysis of the impact of the reactor pressure on the performance of the process through the application of the equilibrium reactor and a subsequent in-depth analysis utilizing the detailed reactor model and a table lookup method for additional parameters. In both cases, one-dimensional sensitivity analyses are conducted. The reference parameters are provided in Table 1**.** Note that the heating fluid temperature is only relevant for the table lookup method.

**Table 1:** Reference parameters for the analysis.

| Parameter | Value | Unit |
|---|---|---|
| Reactor inlet temperature $T_3$ | 400 | °C |
| Reactor inlet pressure $p_3$ | 10 | bar |
| Cooling temperature $T_4$ | 23 | °C |
| Bypass ratio $BP$ | 0 | |
| Heating fluid temperature $T_7$ | 455 | °C |

## Equilibrium reactor

The equilibrium reactor model is first utilized for analyzing the impact of the reactor pressure as the impact of the reactor pressure is significantly affected by the chosen reactor size in the detailed reactor model. Interstage cooling is utilized to avoid high temperatures after the compression train affecting the results significantly. Instead, it is assumed that the compressed gas after the compression section is cooled to 100 °C.

Figure 2 shows the impact of the reactor inlet pressure on the performance of the integrated process. Due to the chemical equilibrium of the decomposition reaction, low pressures are beneficial for achieving a high ammonia conversion; the conversion is reduced from 79.5 % at a reactor pressure of 2 bar to 32.9 % at a reactor pressure of 15 bar. However, due to the increased conversion at lower pressures, it is necessary to have a higher furnace bypass ratio to provide sufficient high temperature heat for the decomposition reaction resulting in a similar behavior of both KPIs as shown in Figure 2 a). In the case of a high conversion, the minimum temperature approach is at the reactor inlet corresponding to an increased $\Delta T$ at the reactor outlet. While the turbine efficiency is largely unaffected by the reactor inlet pressure, we see large increases in the process efficiency from 36.7 % to 43.0 % when increasing the reactor inlet pressure from 2 bar to 15 bar.

The increase is especially pronounced in the range of 2 bar to 10 bar where the latter already results in 42.6 %. The efficiency increase of 17 % can be explained by 1) the reduction in the required furnace bypass ratio due to the reduced head demand in the decomposition reaction and 2) the reduced compression energy demand. The latter is especially important as the compression energy requirement at a reactor pressure of 2 bar corresponds to 7 % of the lower heating value of the partially cracked ammonia. This electricity demand is reduced to 1.9 % at a pressure of 10 bar and 1.2 % at a pressure of 15 bar.

Given these initial analyses utilizing the simplified equilibrium reactor model, detailed analyses are conducted utilizing a reactor pressure of 10 bar. This pressure can be seen as a beneficial compromise between the required conversion of ammonia for the gas turbine and the process efficiency.

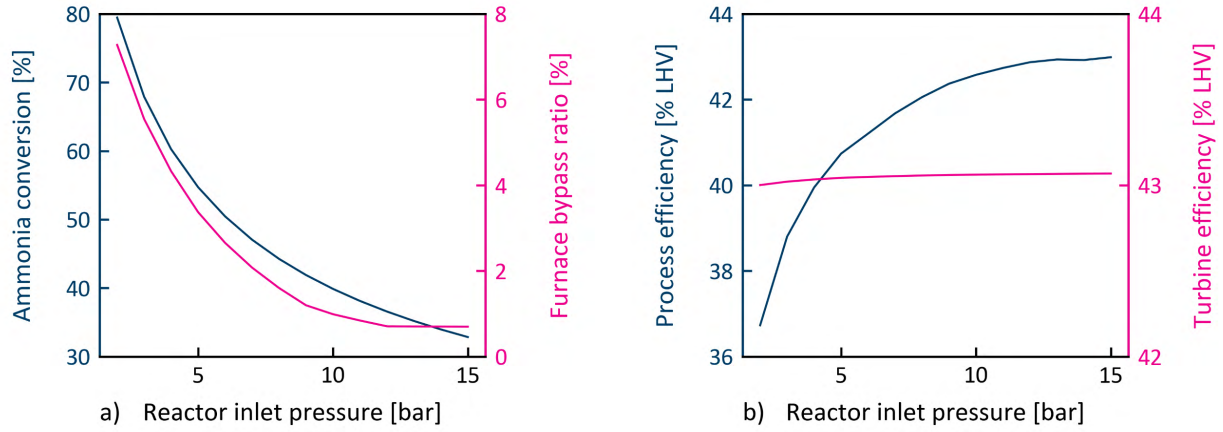

**Figure 2.** Results for the eqilibrium reactor model when varying the reactor inlet pressure. The results show a) (blue) the ammonia conversion, a) (pink) the furnace bypass ratio, b) (blue) the process efficiency, and b) (pink) the gas turbine efficiency.

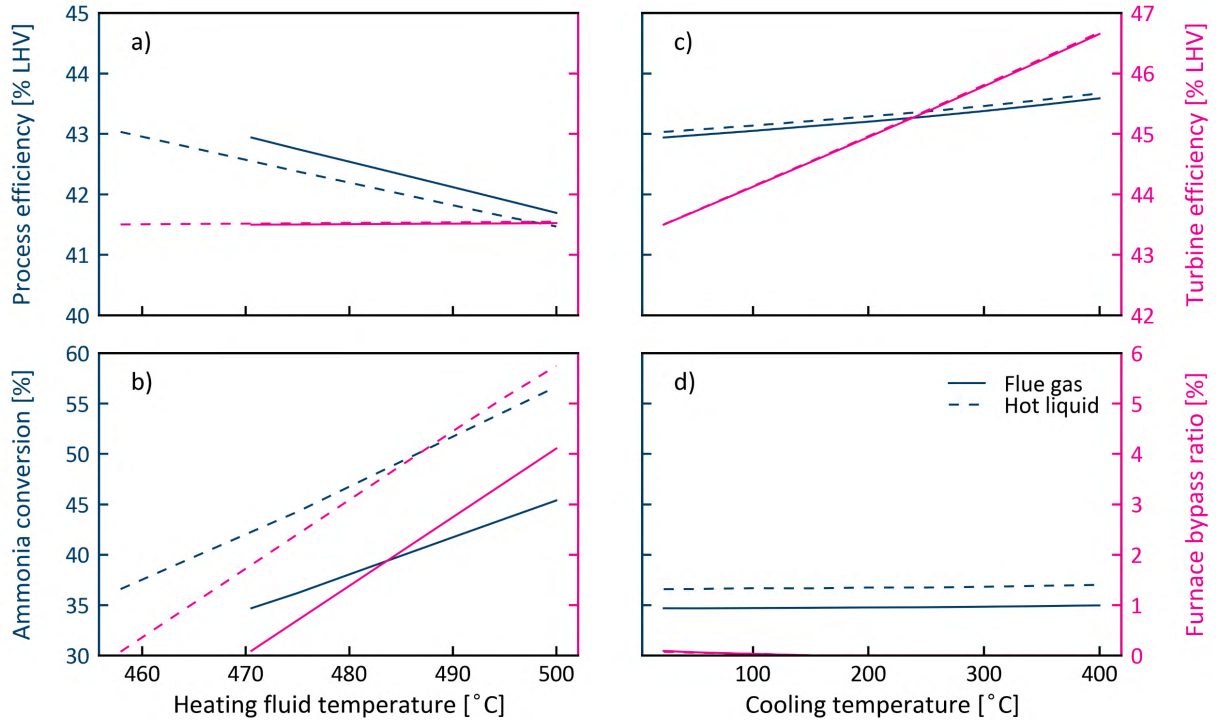

**Figure 3.** Results for the detailed reactor model when varying in a) and b) the heating fluid temperature or in c) and d) the cooling temperature when utilizing the exhaust gas (solid) or a hot liquid (dashed) as heat transfer medium. The results show a) and c) (blue) the process efficiency, a) and c) (pink) the gas turbine efficiency, b) and d) (blue) the ammonia conversion, and b) and d) (pink) the furnace bypass ratio.

## Detailed reactor model

Figure 3 illustrates the results for varying the heating fluid temperature, a) and b), and the cooling temperature, c) and d) for both using the flue gas and the hot liquid for providing heat to the decomposition reactor. When investigating the impact of the heating fluid temperature, shown in Figure 3 a) and b), we see directly the difference of 12.5 °C for the minimum value used for the heating fluid temperature, representing the chosen $\Delta T_{min}$ when using the hot liquid. This difference leads to a shift of the complete analysis. Increasing the heating fluid temperature results in a linear decrease in the process efficiency while the turbine efficiency increases slightly. The linear decrease of the process efficiency is nearly independent of the chose heating fluid when considering

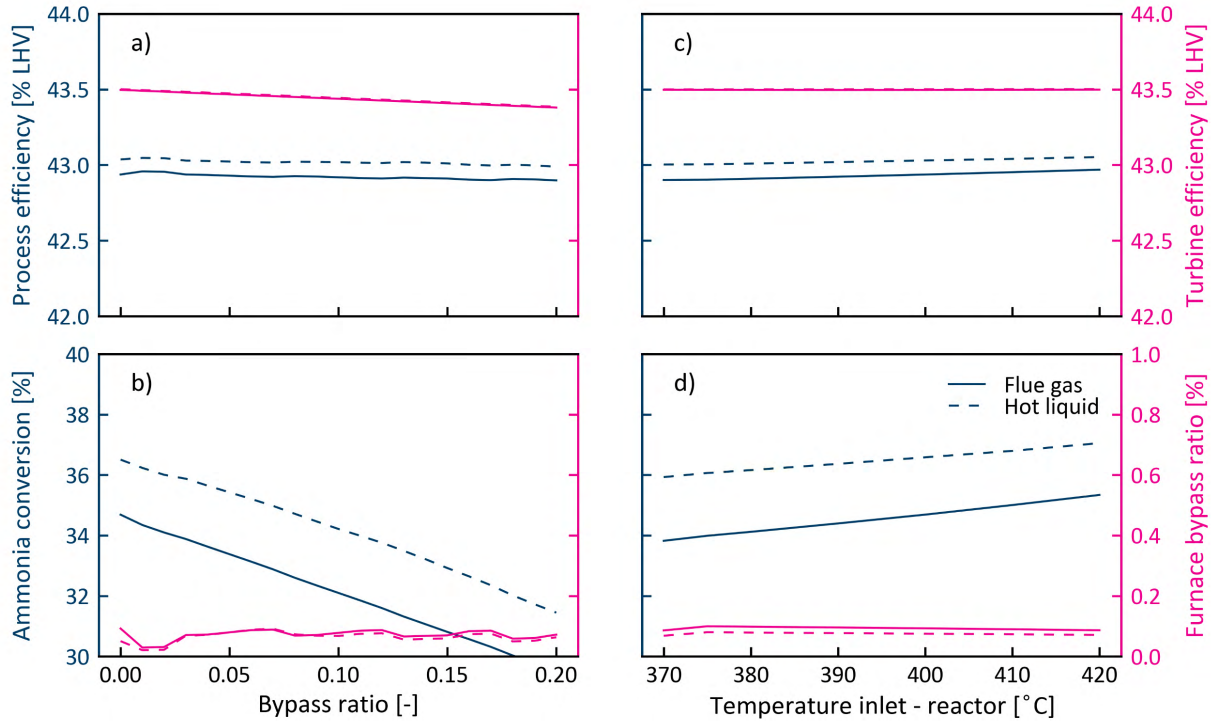

**Figure 4.** Results for the detailed reactor model when varying in a) and b) the heating bypass ratio or in c) and d) the reactor inlet temperature of the $NH_3$ feed when utilizing the exhaust gas (solid) or a hot liquid (dashed) as heat transfer medium. The results show a) and c) (blue) the process efficiency, a) and c) (pink) the gas turbine efficiency, b) and d) (blue) the ammonia conversion, and b) and d) (pink) the furnace bypass ratio.
**Note** the change in y-axis ticks compared to Figure 3.

the 12.5 °C temperature difference. When increasing the heating fluid temperature, the temperature of the exhaust gas from the gas turbine is not sufficient for providing the heat to the decomposition reactor. It is hence necessary to combust part of the partially cracked ammonia to reach the required temperature level. The observed increase in the cracking ratio is furthermore different between utilizing the exhaust gas directly or utilizing a hot liquid due to the differing heat transfer properties with a steeper slope when using the hot liquid.

The impact of the cooling temperature on the efficiencies is more pronounced as shown in Figure 3 c). Increasing the cooling temperature, *i.e.*, cooling less after the reactor, has a profound effect on both the turbine efficiency and the process efficiency, although the effect on the latter is smaller. The increase in the gas turbine efficiency can be explained by the chosen boundary conditions. As the temperature of the feed increases with increasing cooling temperature, less fuel must be provided to the combustion chamber for achieving the desired temperature level after the combustion chamber. The benefit for the process efficiency is, however, reduced as the increased temperature in the compressor results in an increased electricity demand of the compressor by 120 % when increasing the temperature before the compression from 23 °C to 400 °C. There is however still a significant net benefit of not cooling the partially cracked ammonia. On the other hand, the cooling temperature has next to no effect on both the ammonia conversion and the furnace bypass ratio as the reactor conditions remain unchanged, and hence, the conversion and required additional heat through the furnace bypass.

Figure 4 shows the results when varying the bypass ratio, a) and b) and the inlet temperature to the reactor, c) and d). The reactor bypass ratio has only a minor direct impact on both the gas turbine and the process efficiency as shown in Figure 4 a). Increasing the bypass ratio reduces both efficiencies, but the reduction is only 0.04 percentage points for the process efficiency and 0.1 percentage for the gas turbine efficiency. Both numbers are considered to be within the margin of error in the table lookup method. The slight change in the efficiency is on the one hand explainable by the reduced ammonia conversion as shown in Figure 4 b). Due to the bypass, we reduce the overall ammonia conversion. However, the reduction from 34.7% to 29.5 % in the case of using the exhaust gas directly and from 36.5 % to 31.4 % in the case of using an intermediate hot liquid does not reflect the actual loss as the conversion within the reactor is increased. If the conversion in the reactor remains the same, one would expect a conversion of 27.7 and 29.2 %, respectively. Hence, the conversion in the reactor is

increased if the mass flow of the heating medium is increased compared to the mass flow of ammonia. As a consequence, using a bypass would allow for a smaller reactor size at the cost of a slightly reduced process efficiency. The furnace bypass ratio is in practice independent of the chosen bypass of the decomposition reactor. The observed non-linearities can be attributed to steps within the table lookup method resulting in less accurate simulations. The observed value of 0.1 % is also rather small.

Similar to the reactor bypass ratio, we do not observe a significant impact of the reactor inlet temperature on the efficiencies as shown in Figure 4 c). While the process efficiency experiences a small increase with a higher reactor inlet temperature, the turbine efficiency remains unaffected by this change despite the increased ammonia conversion as shown in Figure 4 d). The furnace bypass ratio is again small and unaffected by the changes, similar to the results shown in Figure 4 b) for the cooling temperature. The result can be explained by the chosen size for the reactor model. The reactor outlet temperature of the partially cracked ammonia is for the chosen size nearly independent of the reactor inlet temperature within the given range

# DISCUSSIONS AND LIMITATIONS

## Impact of the reactor model approach

On the one hand, the chosen reactor model and its representation has a significant impact on the identification of key operating parameters in the analysis. Specifically, utilizing an equilibrium reactor requires assumptions regarding the approach to equilibrium and the heat transfer within the reactor to approximate the temperature change $\Delta T$ in the reactor. Neither parameters can be directly deduced from kinetic studies. Especially the assumed $\Delta T$ in combination with the inlet temperature has a major effect as the equilibrium is calculated at the reactor outlet conditions. In addition, when analyzing the reactor bypass, we cannot observe the increased conversion in the reactor when using an equilibrium reactor.

On the other hand, it is not possible to utilize a kinetic reactor when designing a process due to the requirement of specifying a size for the reactor. As can be seen in the results for varying the inlet temperature to the reactor, the assumption of a constant size provides a suboptimal configuration in some of the values for the inlet temperature.

One improvement would hence be to operate iteratively between the detailed reactor model and the process model to adjust the size of the reactor model based on the analyses from the process model or alternatively use a complete surrogate model of the detail reactor model.

## Cooling before compression

As shown in the analyses, with a required combustion chamber pressure of 30 bar, cooling before the compression chamber is disadvantageous. Although compression at high temperatures results in an increased electricity demand, it is compensated by the reduced feed flow rate for a constant electricity generation in the turbine. However, the feed gas to the combustion chamber has without cooling a temperature of 675 °C resulting in potential problems when compressing a mixture consisting of ammonia and hydrogen. When assuming cooling of the partial cracked ammonia post the reactor to 23 °C, the temperature is reduced to 175 °C without interstage cooling. While temperatures of 600 °C are observed for air compression, the corrosive nature of ammonia and potential hydrogen embrittlement can lead to problems. Consequently, it is important to consider the practical limits for the compression section.

## Inclusion of a steam cycle for combined cycle operation

The current model does not include a steam cycle utilizing the still available exhaust heat for increased electricity generation. Due to the utilization of parts of the heat for the decomposition reaction, less heat is available for the steam cycle. Specifically, we observe a reduction in the temperature of the exhaust gas stream available for steam generation. Consequently, electricity generation in a potential steam cycle will be reduced compared to the standard process without ammonia decomposition. When not cooling the reactor before the compression steps, ammonia is heated using the exhaust flue gas from the reactor. This is especially a problem when choosing high reactor inlet temperatures for ammonia as the temperature exceeds in this case the exhaust of the heating medium from the reactor. This implies that the optimal process parameters may differ when including a steam cycle for an increased efficiency.

## Dynamic flexibility of the process and operation at part-load

The overall process requires a constant heat supply to the decomposition reactor for maintaining a constant cracking ratio to the combustion chamber. As this is not necessarily feasible, introducing the bypass will allow a tight control of the composition to the combustion chamber. In this situation, operational flexibility can be achieved through sacrificing efficiency.

Part-load operation of gas turbines is in general achieved through a reduced pressure in the combustion chamber. As a consequence, the temperature of the exhaust gas is reduced. Hence, more partially cracked ammonia must be combusted to compensate for the reduced temperature of the exhaust gas. This implies that the efficiency penalty of the gas turbine at reduced load

is furthermore exacerbated by the need for additional combustion of ammonia for achieving the required temperature in the decomposition reactor.

## CONCLUSION AND FUTURE WORK

In this work, we provide an in-depth analysis of a coupled process for electricity generation from ammonia. The process, in which the ammonia decomposition reactor is heat-integrated with the gas turbine exhaust gas, allows for a high efficiency in the operation of the gas turbine. Lowering the required ammonia conversion results in improved overall performance due to a reduction in the required high temperature heat, and hence, the removal of combusting a fraction of the partially cracked ammonia for providing the heat to the decomposition reactor. Similarly, higher operating pressures for the reaction are beneficial to avoid the compression of the partially decomposed ammonia.

Future work will focus on part-load operation and analyzing the dynamic behavior of the complete process to propose potential control strategies given the increasing share of variable renewable power generation and the demand for adjustable dispatchable generators.

## ABSTRACT

The scheduling of multi-line polyolefin production is a complex decision-making process characterized by sequence-dependent changeovers, strict physicochemical constraints, and dynamic market environments. Traditional optimization methods often suffer from high computational costs and a lack of flexibility in online adjustments. To address these challenges, this paper proposes a Deep Reinforcement Learning (DRL) framework for dynamic scheduling tasks. We first construct a high-fidelity simulation environment that meticulously models realistic industrial constraints, including transition materials, shutdowns, and inventory limits. A Soft Actor-Critic (SAC) agent with a tuple-based action space is employed to mitigate the combinatorial explosion associated with multi-line decisions. Furthermore, a dynamic action masking mechanism embedded with domain knowledge is introduced to strictly enforce hard constraints and significantly improve sample efficiency. Case studies based on real-world industrial data demonstrate that the proposed method can autonomously generate valid schedules that satisfy complex production requirements. Comparative experiments further reveal that the action masking mechanism accelerates training convergence, and the DRL agent exhibits superior adaptability to dynamic price fluctuations.

**Keywords**: Scheduling, Modelling and Simulations, Optimization, Reinforcement learning, Polyolefin production

## 1 INTRODUCTION

Polyolefins are the most widely produced chemical materials globally. Consequently, the efficiency of polyolefin production scheduling directly impacts economic performance and market responsiveness [1]. This process, characterized by continuous operations and frequent grade transitions, faces several challenges, including complex transition processes, sequence-dependent changeover costs, and strict process constraints. Although traditional methods, such as mathematical programming and heuristic algorithms, have achieved some success, they encounter significant limitations in practical applications. The primary issues are high computational costs and a lack of flexibility [2]. Fundamentally, these methods rely on static scheduling, which involves offline optimization based on fixed initial states and demands over a specific time horizon. When production disturbances occur or boundary conditions change, the entire schedule must be recalculated from scratch. This process is computationally expensive and time-consuming, resulting in response delays that fail to meet the requirements of modern chemical manufacturing for efficient and rapid decision-making [3].

Reinforcement Learning (RL) presents a promising approach for solving such complex sequential decision-making problems. Previous studies have demonstrated the potential of RL in industrial scheduling [4, 5]. In this framework, the scheduler is modeled as an agent that learns by observing states from the environment, executing actions, and receiving reward signals that reflect economic benefits or operational efficiency. Unlike traditional static methods that solve specific scenarios independently, RL trains a generalized end-to-end policy by interacting with a simulation environment. This policy maps high-dimensional production states directly to near-optimal scheduling actions. Leveraging the "offline training, online execution" mechanism, the trained agent can generate schedules via simple forward inference when facing different horizons or initial states. This data-

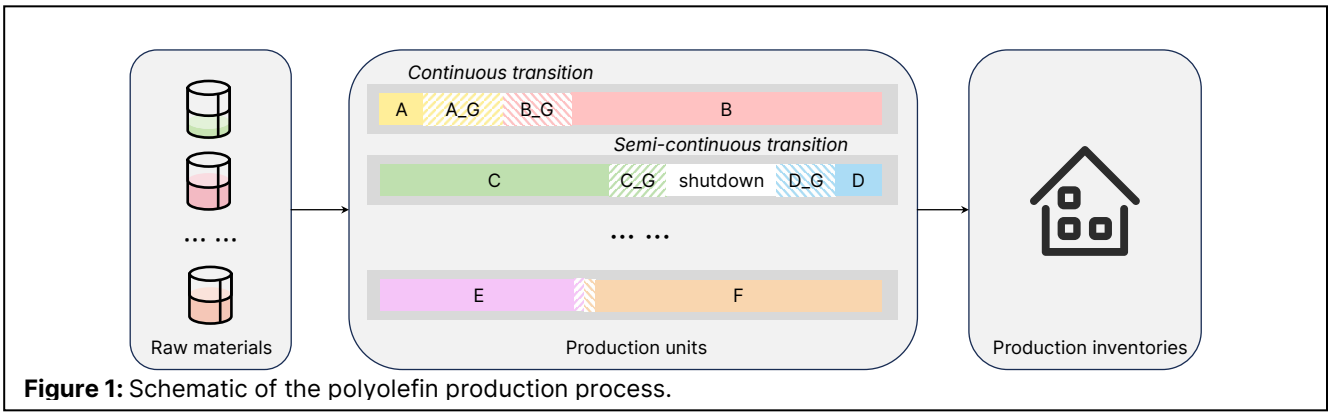

**Figure 1:** Schematic of the polyolefin production process.

driven approach avoids computationally expensive re-optimization for every new scenario, thereby demonstrating a significant advantage in computational efficiency over traditional methods.

Motivated by these advantages, this study constructs a high-fidelity simulation environment and proposes a Deep Reinforcement Learning (DRL) framework for multi-line polyolefin scheduling in real-world industrial scenarios. The main contributions are summarized as follows:

1. Design of a tuple-based action space with a multi-head architecture: To tackle the combinatorial explosion inherent in multi-line scheduling, we design a tuple-based action structure implemented via a multi-head neural network. This approach effectively decomposes high-dimensional decision variables, enabling precise and collaborative control over parallel production units.

2. Implementation of a domain-knowledge-embedded dynamic action masking mechanism: We introduce a real-time masking mechanism that dynamically adjusts the feasible action space based on process states. By rigorously filtering out actions that violate physicochemical constraints, this mechanism ensures operational validity and significantly accelerates training convergence.

3. Introduction of a dual-level stochastic mechanism for robust generalization: We incorporate episode-level domain randomization and step-level market price volatility into the environment. This dual uncertainty prevents overfitting to deterministic conditions and compels the agent to develop "market acumen, " thereby maximizing economic benefits in non-stationary environments.

The remainder of this paper is organized as follows: Section 2 details the methodology, including the mathematical problem description and the construction of the simulation environment. Section 3 presents the case study and analyzes the experimental results. Finally, Section 4 concludes the paper.

# 2 METHOD

## 2.1 Problem Description

The polyolefin production system consists of multiple parallel production units, as illustrated in Figure 1. These units share upstream raw material inventories and produce various downstream polyolefin product grades. This study explicitly models detailed grade transition processes, accounting for both transition material generation and unit shutdowns. As depicted in the first unit of Figure 1, the transition from prime grade A to prime grade B involves producing transition materials for both grades (denoted as $A_G$ and $B_G$) without interrupting production. This mode is defined as a continuous transition. In contrast, the second unit illustrates a transition from grade C to grade D, which requires a shutdown period in addition to generating transition materials. This mode, termed a semi-continuous transition, typically occurs when significant physicochemical differences between products necessitate equipment cleaning to remove catalyst residues.

Consequently, the polyolefin production scheduling problem is characterized as a complex decision-making process involving multi-line, multi-product, and mixed continuous-discrete dynamics. The core objective is to maximize the total economic benefit over a finite horizon by collaboratively optimizing product sequencing, production rates, and transition operations across parallel units, subject to market demands, raw material availability, and strict process constraints.

## 2.2 Mathematical Formulation

To strictly define the scheduling problem, the aforementioned polyolefin production system is mathematically formulated as follows:

Given Parameters:

1. Basic Parameters: Consider a scheduling horizon of $T$ days ($t \in \{1, 2, \dots, T\}$). There are $U$ production units ($u \in \{1, 2, \dots, U\}$) capable of consuming $MR$ types of raw materials ($mr \in \{1, 2, \dots, MR\}$) to produce $MP$ different product grades ($mp \in \{1, 2, \dots, MP\}$). Each prime product grade is associated with a specific transition material ($mp_G \in \{1_G, 2_G, \dots, MP_G\}$). The set of products compatible with unit $u$ is denoted as $linkum_{u,mp}$, and the set of feasible transitions between products is denoted as $linkmm_{mp,mp'}$.

2. let $Recipe_{mp,mr}$ denote the raw material consumption ratio, $Pcost_{mp}$ the processing cost, and $Price_{mp}$ the selling price. The transition material shares the same recipe ($Recipe_{mp,mr}$) and processing cost ($Pcost_{mp_G}$) as its corresponding prime grade, but commands a lower selling price ($Price_{mp_G}$). The unit cost for each raw material is denoted as $Rcost_{mr}$.

3. Production Process Parameters: During a grade changeover, the quantity of transition material and the necessity of a shutdown are determined by both the preceding and succeeding products. For a transition from product $mp$ to $mp'$, the transition attributes $Changeover_{mp,mp'}$ are defined by a 6-tuple $(T_{BG}, Q_{BG}, T_{AG}, Q_{AG}, T_{stop}, Cost_{stop})$. These elements represent the duration and quantity of the preceding transition material, the duration and quantity of the succeeding transition material, the shutdown duration, and the shutdown cost, respectively.

Operating Rules and Constraints:

1. Product Demand Limits: By the end of the scheduling horizon, the accumulated production yield of each product must fall within the specified demand range $[Demand_{mp}^{min}, Demand_{mp}^{max}]$.

2. Production Rate Limits: The production rate for each product must operate within the allowable range $[Rate_{mp}^{min}, Rate_{mp}^{max}]$.

3. Raw Material Inventory Limits: The inventory levels of specific raw materials must remain within the safety limits $[Inv_{mr}^{min}, Inv_{mr}^{max}]$ throughout the entire horizon. The daily external supply of raw material is denoted as $S_{mr,t}$, and the daily external consumption is $EC_{mr,t}$.

4. Workforce and Timing Constraints: Due to maintenance crew limitations, simultaneous changeovers on multiple production units are prohibited. Furthermore, changeovers are restricted to specific time windows on designated working days $Fd_d$.

Decision Variables:

$ch_{mp,mp',u,t}$ : Binary variable indicating whether a changeover from product $mp$ to $mp'$ starts on unit $u$ on day $t$.

$t_{mp,u,t}$: Production duration of product $mp$ on unit $u$ on day $t$.

$r_{mp,u,t}$: Production rate of product $mp$ on unit $u$ on day $t$.

Objective Function:

The objective function is formulated to maximize the total profit, which comprises seven distinct components: sales revenue from prime products, sales revenue from transition materials, raw material costs for prime products, processing costs for prime products, raw material costs for transition materials, processing costs for transition materials, and shutdown costs associated with semi-continuous transitions.

The objective function is expressed as:

$$\max Profit = Revenue_{mp} + Revenue_{mp_G} - Cost_{mp,raw} - Cost_{mp,prod} - Cost_{mp_G,raw} - Cost_{mp_G,prod} - Cost_{trans} \quad (1)$$

These components are calculated using Eqs. (2)–(8) as follows:

$$Revenue_{mp} = \sum_t \sum_u \sum_{mp} r_{mp,u,t} \cdot t_{mp,u,t} \cdot Price_{mp} \quad (2)$$

$$Revenue_{mp_G} = \sum_t \sum_u ch_{mp,mp',u,t}(Q_{BG} \cdot Price_{mp_G} + Q_{AG} \cdot Price_{mp'_G}) \quad (3)$$

$$Cost_{mp,raw} = \sum_t \sum_u \sum_{mp} \sum_{mr} r_{mp,u,t} \cdot t_{mp,u,t} \cdot Recipe_{mp,mr} \cdot Rcost_{mr} \quad (4)$$

$$Cost_{mp,prod} = \sum_t \sum_u \sum_{mp} r_{mp,u,t} \cdot t_{mp,u,t} \cdot Pcost_{mp} \quad (5)$$

$$Cost_{mp_G,raw} = \sum_t \sum_u \sum_{mr} ch_{mp,mp',u,t}(Q_{BG} \cdot Recipe_{mp_G,mr} + Q_{AG} \cdot Recipe_{mp'_G,mr}) \cdot Rcost_{mr} \quad (6)$$

$$Cost_{mp_G,prod} = \sum_t \sum_u ch_{mp,mp',u,t}(Q_{BG} \cdot Pcost_{mp_G} + Q_{AG} \cdot Pcost_{mp'_G}) \quad (7)$$

$$Cost_{trans} = \sum_t \sum_u ch_{mp,mp',u,t} \cdot Cost_{stop} \quad (8)$$

## 2.3 Proposed DRL Framework for Dynamic Scheduling

To address the complexity of multi-line polyolefin scheduling, we formulate the problem as a Markov Decision Process (MDP) [6]. The overall framework of the proposed method is illustrated in Figure 2. This section first details the mathematical fundamentals of the MDP and then introduces three key mechanisms designed to handle combinatorial explosion, strict constraints, and non-stationary processes: a multi-head tuple action space strategy, a domain-knowledge-embedded dynamic masking mechanism, and a dual-level stochastic mechanism for generalization.

### 2.3.1 State Space and Reward Function

The state space $s_t \in \mathcal{S}$ serves as the foundational input for the agent's decision-making, providing a comprehensive snapshot of the production system. To accommodate the multi-line characteristics of polyolefin manufacturing, the state vector is structured hierarchically, comprising global states shared across all units and local states specific to each individual unit, as defined in Eqs. (9)–(11):

$$s_t^{global} = [\tau_t, inv_{mr,t}, \rho_t] \quad (9)$$

$$s_{u,t}^{unit} = [\delta_{u,t}, \nu_{u,t}, \Pi_{u,t}] \quad (10)$$

$$s_t = \left[s_t^{global}, s_{1,t}^{unit}, s_{2,t}^{unit}, \ldots, s_{U,t}^{unit}\right] \quad (11)$$

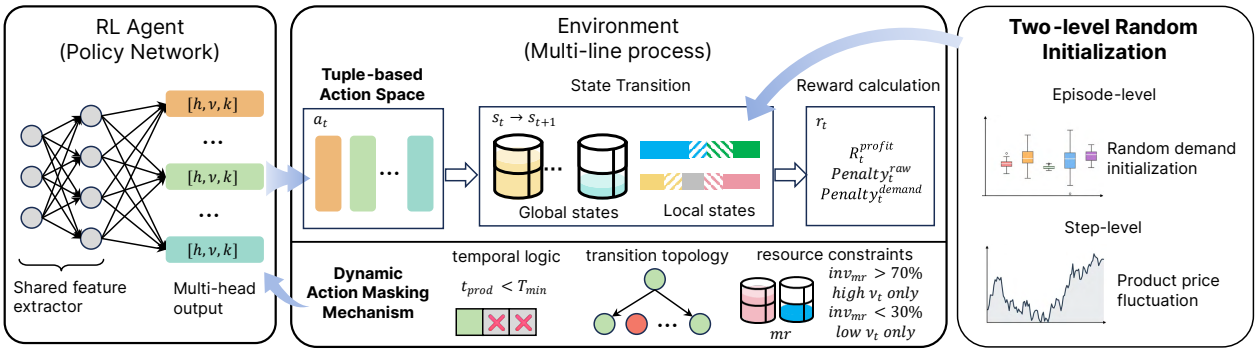

**Figure 2.** Overview of the proposed Deep Reinforcement Learning framework for multi-line polyolefin scheduling.

Specifically, The global state $s_t^{global}$ encompasses the normalized time progress $\tau_t$, the raw material inventory levels $inv_{mr,t}$, and the product market price ratios $\rho_t$. The local state for unit $u$, denoted as $s_{u,t}^{unit}$, captures the detailed production status of the $u$-th unit. This comprises the production duration ratio relative to the minimum requirement $T_{min}$ (denoted as $\delta_{u,t}$), the normalized current production rate $v_{u,t}$, and a binary indicator $\Pi_{u,t}$ signaling whether the unit is currently in a transition state.

To guide the agent towards optimal policies, the reward function $R(s_t, a_t)$ aims to achieve a multi-objective trade-off between economic benefits and the risk of constraint violations. It is defined as follows:

$$R_t = \omega_1 R_t^{profit} - \omega_2 Penalty_t^{raw} - \omega_3 Penalty_t^{demand} \quad (12)$$

where $R_t^{profit}, Penalty_t^{raw}, Penalty_t^{demand}$ represent the daily net profit from production, the penalty for raw material inventory overflow or shortage, and the penalty for violating product demand limits, respectively. $\omega_1, \omega_2$, and $\omega_3$ denote the weight hyperparameters. The calculation of $R_t^{profit}$ follows Eq. (1), while the other two terms are calculated as follows:

$$Penalty_t^{raw} = \sum_{mr}\left(\max(0, inv_{mr,t} - Inv_{mr}^{max})^{1.5} + \max(0, Inv_{mr}^{min} - inv_{mr,t})^{1.5}\right) \quad (13)$$

$$Penalty_t^{demand} = \sum_{mp}\left(\max(0, inv_{mp,t} - Demand_{mp,t}^{max})^{0.5} + \max(0, Demand_{mp,t}^{min} - inv_{mp,t})^{2}\right) \quad (14)$$

Different degrees of non-linear terms are introduced in the above calculations to reflect the varying levels of tolerance for different boundary violations.

### 2.3.2 Tuple-based Action Space

Direct application of DRL to multi-line scheduling faces a critical challenge: the curse of dimensionality. In a system with $U$ parallel units, a naive flattening of decision variables results in an action space size that grows exponentially, rendering exploration inefficient and convergence nearly impossible. To overcome this combinatorial explosion, we propose a decomposed tuple-based action formulation implemented via a multi-head neural network architecture.

Instead of treating the global action as a monolithic high-dimensional vector, we structure the action at time $t$ as a joint tuple containing distinct decision components for each unit, as defined in Eq. (15):

$$a_t = \{[h_{1,t}, v_{1,t}, k_{1,t}], [h_{2,t}, v_{2,t}, k_{2,t}], \ldots, [h_{u,t}, v_{u,t}, k_{u,t}]\} \quad (15)$$

This formulation decomposes the decision process for each unit $u$ into three strategically discretized components (illustrated in Figure 3):

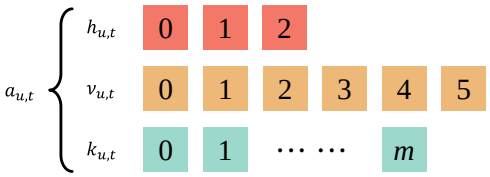

**Figure 3**. Architecture of the tuple-based action space for a single production unit.

Specifically, $h_{u,t}$ determines the transition timing on unit $u$. It takes values from the set $\{0, 1, 2\}$, corresponding to no transition, a transition at 11:00 AM, and a transition at 4:00 PM, respectively. $v_{u,t}$ represents the discretized production rate level for the subsequent product. It comprises six integer values (0-5), mapping to the 0th, 20th, 40th, 60th, 80th, and 100th percentiles of the allowable production rate range. Finally, $k_{u,t}$ identifies the target product grade to be produced following a transition. Its domain consists of feasible options corresponding to the specific products compatible with unit $u$, as defined by the set $linkum_{u,mp}$.

To realize this tuple-based control, we design a specific multi-head neural network. The network utilizes a shared feature extractor to capture global states, which then branches into $U$ independent output heads. Each head autonomously generates the probability

distributions for the sub-actions $\langle h, v, k \rangle$ of a specific unit. This architecture effectively linearizes the decision complexity from exponential to linear relative to the number of units, significantly enhancing the scalability of the algorithm for large-scale industrial scheduling .

### 2.3.3 Dynamic Action Masking Mechanism

To address the hard constraints inherent in industrial production and enhance the sample efficiency of reinforcement learning, this study introduces a dynamic action masking mechanism. Prior to the generation of the action probability distribution, this mechanism evaluates the validity of actions in real-time based on the current state. By zeroing out the probabilities of invalid actions, it dynamically constructs a subspace of feasible actions.

Specifically, the action mask addresses three dimensions: temporal logic, transition topology, and resource constraints.

First is the temporal logic mask, which strictly enforces minimum production duration constraints. If the continuous production time of unit $u$ for the current grade has not reached the minimum requirement, the mask restricts the transition timing action to 0. Simultaneously, the product selection mask permits only the current grade, effectively precluding premature interruptions or transitions, thus ensuring process continuity and stability.

Second is the transition mask based on topology and demand. For product selection, the mask activates only those target grades with direct physical connections to the current product, as defined by the transition set $linkmm_{mp,mp'}$ , thereby preventing illegal cross-series transitions. Furthermore, an inventory-driven intervention logic is introduced: when the global inventory of the current product approaches its maximum limit (e.g., reaching 85%), the mask automatically disables the "maintain current product" option. This compels the agent to execute a transition, fundamentally mitigating the risk of inventory overflow.

Finally, the resource constraint mask governs material balance by mapping raw material inventory states to the feasible space of production rates. By monitoring inventory levels in real-time, this mechanism dynamically truncates the action space when critical thresholds are breached. Specifically, to prevent stockouts, high-production rate actions are masked when raw material inventory is critically low; conversely, to mitigate overflow risks, low-rate options are disabled when inventory approaches its upper limit, thereby compelling the unit to adjust its consumption rate to maintain stability.

Through this multi-dimensional masking mechanism, complex physical and business constraints are internalized as inherent rules of the environment. This eliminates futile exploration of invalid actions during the early stages of training, significantly accelerating policy convergence.

### 2.3.4 Stochastic Dynamics and Generalization

A core challenge in deploying DRL to industrial scheduling is the "reality gap" and the propensity for agents to overfit to fixed training scenarios. To cultivate an agent capable of mastering generalized scheduling logic rather than merely memorizing specific case data, we introduce a dual-level stochastic mechanism comprising episode-level domain randomization and step-level market dynamics.

At the episode level, to prevent reliance on deterministic initial conditions, the environment state is rigorously randomized upon initialization. For each unit, the initial product grade is sampled uniformly from the feasible set, while the initial production rate and raw material inventories are randomly instantiated within the specific operational bounds defined in Section 2.2 . Concurrently, to simulate diverse market pressures, the upper limit of product demand undergoes a random drift around its base value, as formalized in Eqs. (16) and (17) :

$$Demand'_{max} = \max(Demand_{min}, Demand_{max} + \Delta_{demand}) \tag{16}$$

$$\Delta_{demand} \sim U\left(-D_{factor}, +D_{factor} \times (Demand_{max} - Demand_{min})\right) \tag{17}$$

where $D_{factor}$ represents the demand fluctuation factor. This high-variance initial distribution forces the agent to rely on the current state $s_t$ for decision-making rather than memorizing historical trajectories, thereby enhancing the model's generalization capability.

Complementing this initialization strategy, we introduce step-level stochasticity to evaluate and improve the agent's adaptability to non-stationary environments. Unlike traditional scheduling assumptions where prices remain static throughout the horizon, we model the product selling price $Price_{mp,t}$ as a time-variant stochastic process following a Bounded Random Walk, as described in Eqs. (18) and (19):

$$Price_{mp,t+1} = \max(0, Price_{mp,t} + \Delta Price_{mp,t}) \tag{18}$$

$$\Delta Price_{mp,t} = \text{clip}(\epsilon_t, -3\%, 3\%) \times Price_{mp,t} \tag{19}$$

where $\epsilon_t \sim \mathcal{N}(0, \delta^2)$ represents the daily random perturbation term. This dynamic structure introduces strict non-stationarity into the environment, implying that the economic return of a decision is coupled with fluctuating market signals. Consequently, this compels the agent to develop "market acumen"—learning to predictively build up inventory of high-value products during upward price trends or shift to lower-cost grades during downturns. By training under these dual stochastic conditions, the agent learns a robust policy that maximizes total economic benefits even in highly dynamic and uncertain market environments .

## 3 CASE STUDY

**Table 1:** Operational parameters and product specifications for Polyethylene (PE) production units.

| unit code | Num of product | initial product | initial rate | key raw material |
|---|---|---|---|---|
| FDP1-1 | 6 | DG0 | 42.5 | ethylene |
| FDP1-2 | 8 | D8H | 43.0 | limits: |
| LPU1-1 | 1 | TZG | 10.5 | [2000,8000] |
| LPU1-2 | 1 | POE | 4.2 | initial:5250 |
| LPU2-1 | 2 | TUN | 39.3 | |

**Table 2**: Operational parameters and product specifications for Polypropylene (PP) production units.

| unit code | Num of product | initial product | initial rate | key raw material |
|---|---|---|---|---|
| PPU1-1 | 3 | PP3 | 8.5 | propylene |
| PPU1-2 | 4 | K33 | 8.5 | limits: |
| PPU2-1 | 3 | T44 | 28.5 | [1200,4000] |
| PPU2-2 | 7 | TF7 | 27.5 | initial:3550 |

## 3.1 Base Case

To validate the effectiveness of the proposed framework, we conducted a case study utilizing real-world data from a polyolefin production plant. The scheduling horizon was set to $T = 30$ days, covering two distinct production scenarios: Polyethylene (PE) and Polypropylene (PP). The PE scenario comprises 5 production units and 12 product grades, whereas the PP scenario consists of 4 units and 13 grades. These scenarios exhibit distinct operational characteristics: the PE process involves semi-continuous transitions (requiring shutdowns) for specific grade changes, while the PP process is characterized exclusively by continuous transitions. Detailed parameters for these production units are provided in Table 1 and Table 2.

The model was trained using the discrete Soft Actor-Critic (SAC-discrete) algorithm implemented on the Tianshou reinforcement learning platform. For reproducibility, the model was trained for 500 epochs with a batch size of 512, a fixed random seed of 42. Both actor and critic networks utilized a [512, 512] hidden layer architecture with learning rates of $10^{-4}$ and $3 \times 10^{-4}$, respectively, alongside a discount factor $\gamma = 0.99$. The reward function weights were configured as $\omega_1 = 10^{-6}, \omega_2 = 2.0$, and $\omega_3 = 0.5$.

Figure 4 presents the testing results for both scenarios, depicting scheduling Gantt charts, comparisons between realized production yields and market demands, and inventory trajectories for critical raw materials. As evidenced by the visualization, the schedules generated by the trained agent for both PE and PP lines strictly adhere to demand requirements and raw material inventory constraints. These results demonstrate the method's capability to successfully accomplish complex scheduling tasks within industrial specifications.

## 3.2 Comparative Experiments

We designed two sets of comparative experiments to systematically validate the effectiveness of the action masking mechanism and to evaluate the adaptability of the proposed reinforcement learning framework in handling dynamic environments.

### 3.2.1 Effectiveness of Action Masking

To assess the contribution of the action masking mechanism, we conducted an ablation study by training a variant of the model with the masking mechanism disabled on the Polyethylene scenario, while maintaining identical hyperparameters. The comparison of training curves between the unmasked baseline and the proposed masked model is illustrated in Figure 5.

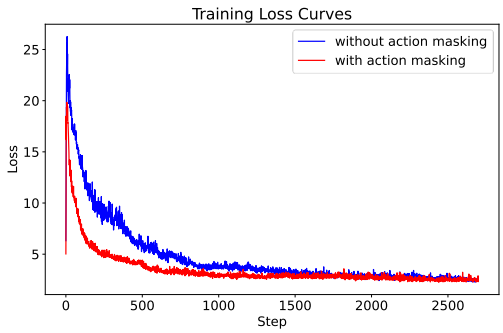

**Figure 5**. Comparison of training loss convergence with and without the action masking mechanism.

As illustrated in the figure, the incorporation of the action masking mechanism yields a significantly more stable loss profile and an accelerated convergence rate during training. This indicates that action masking effectively constrains the decision space, preventing the agent from engaging in futile exploration of invalid states during the early training stages, thereby substantially improving sample efficiency.

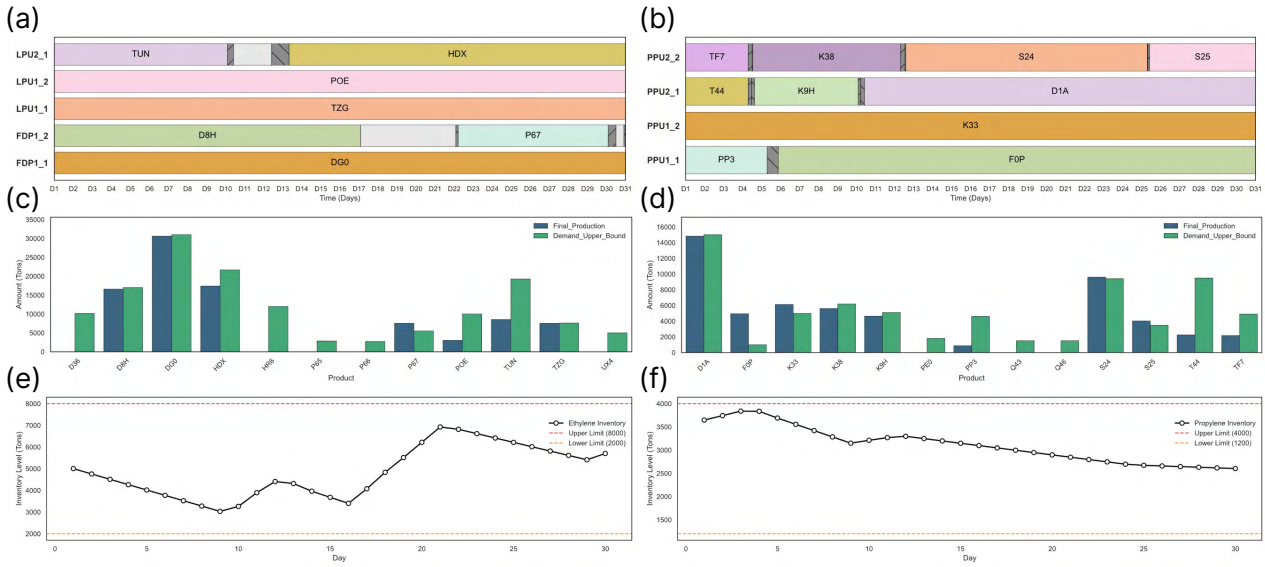

**Figure 4:** Scheduling optimization results for Polyethylene (PE) and Polypropylene (PP) scenarios: (a) Scheduling Gantt chart for PE units; (b) Scheduling Gantt chart for PP units; (c) Comparison of realized production yields vs. market demand for PE units; (d) Comparison of realized production yields vs. market demand for PP units; (e) Inventory trajectory of the key raw material (Ethylene) for PE units; (f) Inventory trajectory of the key raw material (Propylene) for PP units.

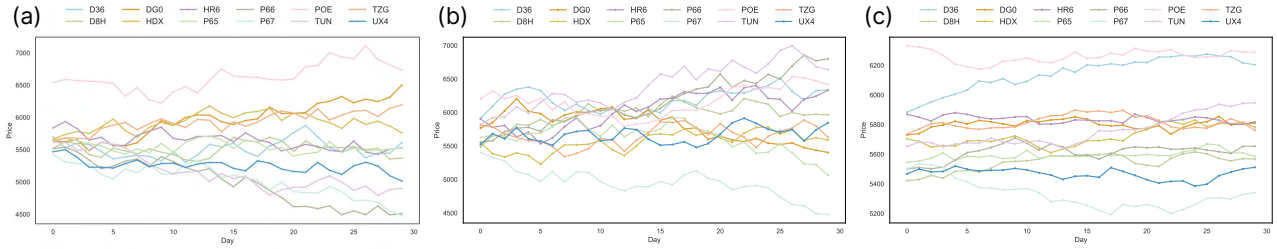

**Figure 6:** Three distinct price fluctuation scenarios generated by the Random Walk model for the Polyethylene line: (a) Scenario 1($(\delta = 0.15)$); (b) Scenario 2($(\delta = 0.1)$); (c) Scenario 3($(\delta = 0.05)$).

### 3.2.2 Adaptability to Dynamic Price Fluctuations

To evaluate the agent's responsiveness to market dynamics, we incorporated the daily random walk for product prices (as defined in Eq. (18)-(19)) into the training environment and trained a specific "Dynamic Agent" . For the testing phase, we generated three distinct test instances characterized by different price fluctuation profiles, as shown in Figure 6.

We compared the performance of the "Dynamic Agent" against a "Static Agent" (trained without price volatility) on these instances. The resulting Gantt charts are compared in Figure 7.

The results reveal a distinct contrast in behavioral patterns. The Static Agent generated rigid schedules that remained nearly invariant across different price scenarios. In contrast, the Dynamic Agent proactively adjusted its production sequence and inventory strategy in response to varying price signals, thereby achieving superior economic returns (higher objective function values). This confirms the model's capability to effectively handle dynamic manufacturing environments.

## 4 CONCLUSION

This study addresses the complex scheduling problem in multi-line polyolefin production by proposing a Deep Reinforcement Learning (DRL) solution grounded in a high-fidelity simulation environment. By integrating a tuple-based action space with a domain-knowledge-embedded dynamic action masking mechanism, the proposed framework effectively overcomes the challenges of combinatorial explosion and strict hard constraint satisfaction inherent in industrial processes. The case study utilizing real-world data verifies that the trained agent can autonomously generate optimal schedules that

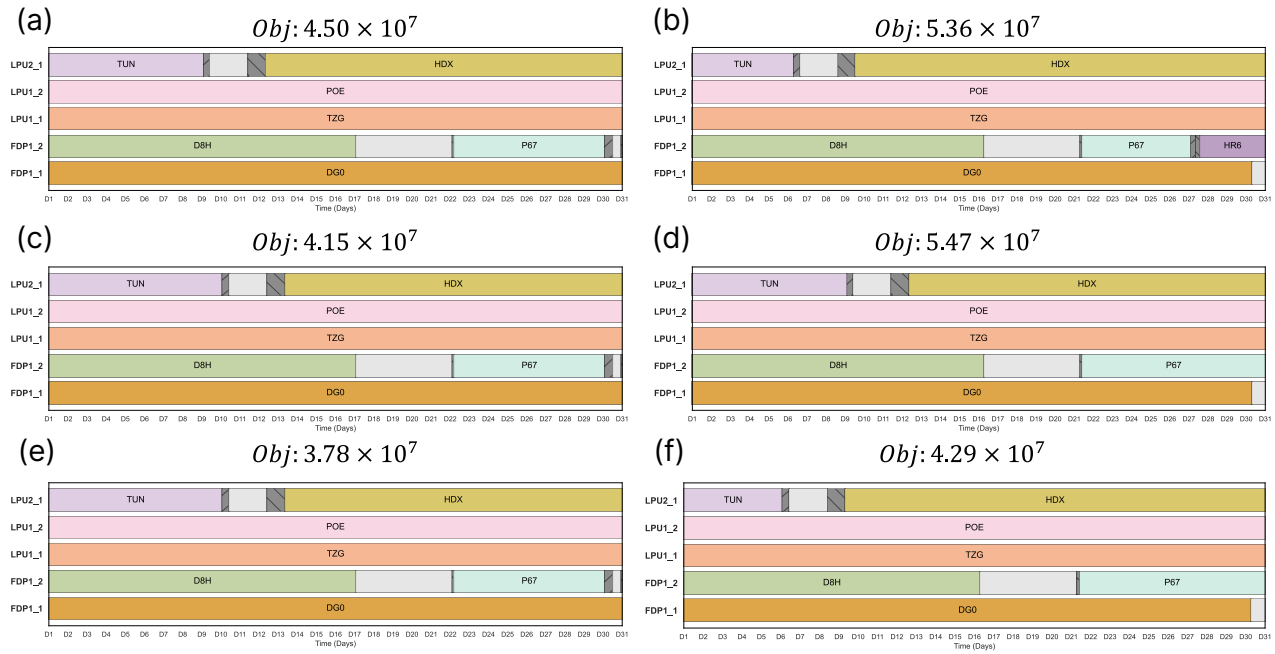

**Figure 7:** Comparison of scheduling strategies under different price fluctuation scenarios: (a, c, e) Schedules generated by the static model (trained without price volatility) under Scenarios 1, 2, and 3, respectively; (b, d, f) Schedules generated by the adaptive model (trained with price volatility) under Scenarios 1, 2, and 3, respectively.

strictly adhere to complex operational rules, such as transition constraints and inventory limits. Furthermore, comparative experiments demonstrate that the action masking mechanism significantly accelerates training convergence by eliminating futile exploration. Crucially, the agent trained under dynamic conditions exhibits robust adaptability to non-stationary market price fluctuations, proactively adjusting production strategies to maximize economic benefits. These findings confirm that the "offline training, online execution" paradigm of DRL offers a highly efficient and flexible alternative to traditional static optimization methods for intelligent industrial decision-making.

## ABSTRACT

This work explores symbolic regression (SR) as an interpretable surrogate modelling approach for the multi-objective optimisation of pressure swing adsorption (PSA) systems for $CO_2$ capture. A first-principle model was used as a virtual plant to generate synthetic datasets covering the operating space defined by cycle step durations. Two surrogate frameworks were developed and compared: SR models derived through evolutionary search and deep neural networks (DNNs) trained via Hyperband-based tuning. Both surrogates were used as simulation models within an optimisation procedure based on a particle swarm optimisation (PSO) algorithm to maximise $CO_2$ purity and recovery. While DNNs achieved the lowest prediction errors (MSE ≈ $10^{-6)}$, the SR surrogates provided compact analytical representations and significantly faster optimisation. The SR framework yielded a denser and more diverse Pareto front (4345 vs 508 points). It was about 34 times faster (38.6 s vs 1331 s), confirming its efficiency for surrogate-based optimisation of cyclic adsorption processes.

**Keywords**: PSA, multi-objective optimisation, surrogate models, optimality, symbolic regression

## INTRODUCTION

Pressure swing adsorption (PSA) systems play a key role in gas separation technologies due to their flexibility, high efficiency, and low maintenance costs (Capra et al., 2018; Habib et al., 2016). They have been extensively employed in processes ranging from air separation (Kamin et al., 2022; Tian et al., 2022) and hydrogen purification (Luberti and Ahn, 2022; Kalman et al., 2022) to carbon dioxide ($CO_2$) capture from flue gases (Nikolaidis et al., 2016, 2015). Despite their industrial maturity, optimisation of PSA units remains challenging due to their inherently cyclic operation, strong multiscale dynamics, and the tight coupling between adsorption, desorption, and switching phases, which lead to highly nonlinear and constrained process behaviour (Khajuria & Pistikopoulos, 2013; Leperi et al., 2019). The coupled mass, heat, and momentum balances that govern adsorption and desorption transitions must be solved repeatedly over multiple cycles until the system reaches a cyclic steady state (CSS), resulting in a computationally expensive optimisation problem governed by large sets of stiff partial differential equations (PDEs) (Ward and Pini, 2022; Rebello & Nogueira, 2024).

Surrogate modelling techniques have emerged as an alternative to accelerate process optimisation while retaining sufficient physical accuracy. Surrogate-based optimisation replaces the high-fidelity first-principles model with an approximate data-driven representation that captures the input-output relationships between decision variables (e.g., step durations, pressures, and reflux ratios) and process performance metrics (e.g., $CO_2$ purity and recovery).

These surrogate models have been successfully applied to PSA, generating Pareto fronts that describe the trade-offs between competing objectives, such as purity, recovery, and energy consumption (De Witte et al., 2021; Panerati et al., 2019; Zhang et al., 2022).

Among the various surrogate modelling strategies, deep neural networks (DNNs) have received particular attention (Costa et al., 2024; Nogueira et al., 2022; Subraveti et al., 2019). As demonstrated by Rebello and

Nogueira (2024), DNN-based surrogate frameworks can reliably approximate the nonlinear behaviour of cyclic adsorption systems, drastically reducing simulation time and enabling systematic multi-objective optimisation. The resulting operating maps help identify optimal process configurations and inform decision-making. Despite their predictive accuracy, these data-driven models remain largely opaque, offering limited interpretability and little insight into the physical or phenomenological mechanisms underlying adsorption dynamics (Rebello et al., 2024).

To overcome these limitations, recent research has begun to explore more transparent machine learning paradigms, in which the emphasis shifts from pure prediction to computational efficiency and analytical tractability. In this context, SR offers a promising approach (Makke & Chawla, 2024; Quade et al., 2016; Angelis et al., 2023). Unlike neural networks, which encode relationships implicitly through parameters distributed in hidden layers, SR explicitly searches for analytical expressions that best fit the available data (Rebello et al., 2024; Hu & Zhang, 2023). By combining evolutionary search and sparse regression principles, symbolic regression identifies compact, readable equations that capture system behaviour while revealing underlying physical trends and nonlinear dependencies.

Symbolic regression has been increasingly adopted across a wide range of engineering applications. In process monitoring and fault detection, SR has been used to derive interpretable diagnostic expressions directly from process data (Hale et al., 2022). In soft sensing, SR has been applied to construct explicit input-output mappings for inferential estimation of difficult-to-measure variables (Kay et al., 2024). In the context of control, SR has been employed to identify compact symbolic controllers and model predictive control surrogates that are both computationally lightweight and physically transparent (Scheffold et al., 2021). For optimisation, SR-derived surrogates have been embedded into mathematical programming frameworks to enable gradient-based search and reduce evaluation cost (Sofronova et al., 2021). More broadly, SR has demonstrated strong potential for scientific discovery, recovering governing equations from data across physics, chemistry, and materials science (Angelis et al., 2023).

Beyond its direct application as a surrogate modelling tool, SR offers several promising extensions, particularly relevant to computationally intensive multi-objective optimisation problems. The analytical nature of SR expressions enables direct embedding into algebraic optimisation solvers, avoiding the matrix operations and numerical differentiation overhead inherent to black-box models such as DNNs, which becomes especially advantageous when objective function evaluations must be performed repeatedly across large swarms or populations (Cozad et al., 2014). Furthermore, SR-derived surrogates naturally produce smooth, differentiable expressions that facilitate gradient-based search and yield denser, more diverse Pareto fronts at a lower computational cost, while also producing a significantly richer set of optimal solutions. These properties suggest that SR could be extended to higher-dimensional multi-objective problems, to online re-optimisation under changing operating conditions, and to real-time decision support in $CO_2$ capture systems, where computational efficiency is a critical practical constraint.

However, symbolic regression models have not yet been investigated for PSA systems. This represents a notable gap in the emerging literature on machine learning applications in chemical process systems, where the potential of faster surrogate models remains largely unexplored. Moreover, given the highly nonlinear nature of PSA dynamics, the behaviour of SR-based surrogates requires careful assessment, as these models may introduce spurious or artificial local minima in the optimisation landscape if not properly regularised and validated.

In this context, the objective of this work is to compare the performance of DNN and SR surrogate models for the optimisation of PSA systems, and to evaluate whether SR-based models can effectively serve as reliable and computationally efficient surrogates, where interpretability is understood as a consequence of the analytical nature of SR expressions rather than a claim of physical correspondence to adsorption dynamics.

## METHODOLOGY

The overall methodology adopted in this study is illustrated in Figure 1. The methodology is structured into four main stages: data curation (Section 2.1), SR model (Section 2.2), DNN model (Section 2.3), and multi-objective optimisation (Section 2.4).

The case study investigated in this work concerns the optimisation of a single-column PSA unit for capturing $CO_2$ from a binary $CO_2/N_2$ mixture. The PSA process operates cyclically, relying on the preferential adsorption of $CO_2$ over $N_2$ onto a solid adsorbent, zeolite 13X, under alternating pressure conditions. Each cycle comprises a sequence of steps (Figure 2): pressurisation (pres), adsorption (ads), heavy reflux (HR), depressurisation (depress) and light reflux (LR). During the pressurisation stage, the column pressure is increased to the adsorption level; in the adsorption step, $CO_2$ is selectively retained by the zeolite, while $N_2$ exits as the light product. The subsequent depressurisation and purge steps promote $CO_2$ desorption and restore the adsorbent's capacity for the next cycle. The process is governed by key decision variables, including the durations of each step ($t_{pres}$, $t_{ads}$, $t_{depres}$, and $t_{purge}$). The leading performance indicators considered are $CO_2$ purity and $CO_2$ recovery, which depend nonlinearly on these operational conditions and on the

thermodynamic and kinetic properties of the zeolite 13X adsorbent.

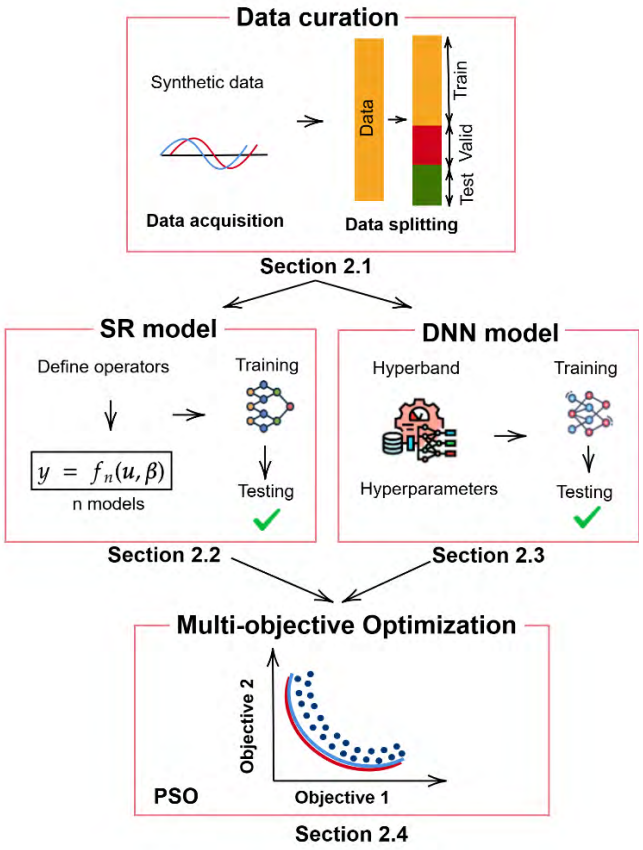

**Figure 1**. Diagram describing the methodology adopted in this work.

The detailed formulation of the mechanistic PSA model used in this work, including the PDE system, modelling assumptions, boundary and initial conditions, and the adopted kinetic and process parameters, is presented in Rebello and Nogueira (2024).

## Data curation

Synthetic data were generated using a mechanistic PSA model implemented as a virtual plant. The sampling of operating conditions was performed using Latin Hypercube Sampling (LHS) to ensure a uniform and statistically independent exploration of the design space. The selected input variables correspond to the step durations of the PSA cycle, pressurisation ($t_{pres}$), adsorption (tads), heavy reflux ($t_{HR}$), depressurisation ($t_{depres}$), and light reflux ($t_{LR}$), which were systematically varied within physically feasible limits. For each LHS sample, the virtual plant was simulated until a cyclic steady state (CSS) was reached, and the corresponding process performance indicators were recorded. The model outputs, or target variables, are $CO_2$ purity and recovery, which quantify the PSA process's separation efficiency and product quality.

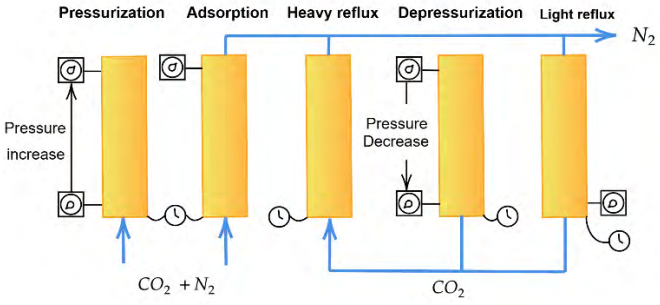

**Figure 2.** Schematic representation of the PSA cycle for $CO_2$ capture from a $CO_2/N_2$ gas mixture, illustrating the successive steps.

The complete dataset was then curated to remove incomplete or non-convergent simulations and subsequently normalised to improve numerical stability during model training. Finally, the curated data were randomly split into training (70 %), validation (15 %), and testing (15 %) subsets. This partition ensures that the surrogate models, both SR and DNN, are trained on representative data while preserving independent sets for unbiased performance evaluation and generalisation assessment.

## SR model

The SR framework was employed to identify analytical surrogate models that capture the nonlinear relationship between the PSA operating variables and the process performance indicators, namely $CO_2$ purity and $CO_2$ recovery. Symbolic regression formulates this task as a nonlinear regression problem of the form:

$$\boldsymbol{y} = \boldsymbol{f}(\boldsymbol{u_n}, \boldsymbol{\beta}) \quad (1)$$

where u denotes the vector of decision variables (step durations), and β represents the fitted parameters. Candidate expressions are iteratively constructed by combining elementary mathematical operators: {+, −, ×, ÷, sin, cos, exp, log} and constants through an evolutionary symbolic search. This process explores a large function space while progressively selecting the most representative equations based on their predictive accuracy and structural simplicity.

Model selection was guided by a multi-objective fitness criterion that balances prediction error, quantified by the mean squared error (MSE) on the validation dataset, with a complexity penalty proportional to expression length.

The evolutionary search was terminated once convergence was achieved, i.e., when no significant improvement in model accuracy or parsimony was observed.

The best-performing symbolic expressions for $CO_2$ purity and recovery were then independently validated using the testing subset. These analytical surrogates

replace the high-fidelity PSA model in the multi-objective optimisation framework.

The SR models were developed in Python using the PySRRegressor package (Tonda, 2025) (see: https://astroautomata.com/PySR/), an open-source library for SR that combines genetic programming with simulated annealing for evolutionary search. The algorithm was run with random initialisation, and multiple repetitions were performed to ensure convergence to consistent solutions.

## DNN model

The same dataset generated by the mechanistic PSA model was also used to identify the DNN models. The network architecture was defined using the HYPERBAND algorithm (Li et al., 2018) (see: https://keras.io/keras_tuner/api/tuners/hyperband/), which efficiently explores the hyperparameter space to identify near-optimal configurations. The DNNs adopted a multiple-input single-output (MISO) structure, where the input layer receives the PSA decision variables $t_{pres}$, $t_{ads}$, $t_{HR}$, $t_{depres}$, and $t_{LR}$, and the output layer provides a single process indicator, either $CO_2$ purity or $CO_2$ recovery.

The search space considered the number of hidden layers (ranging from 1 to 5), the number of neurons per layer (from 50 to 300 in steps of 50), activation functions (ReLU and tanh), and learning rates (0.0001, 0.001, and 0.01). Each candidate model was trained using the MSE as the loss function, with the Adam optimiser configured according to the selected learning rate.

Model training aimed to minimise the MSE between predicted and target values, while the mean absolute error (MAE) was also monitored as an auxiliary metric. Each model was trained for up to 1000 epochs, with early stopping and dropout regularisation applied to prevent overfitting and improve generalisation.

After training, the resulting DNN models were validated on the independent test set to assess predictive accuracy. The best-performing networks were subsequently integrated into the multi-objective optimisation framework.

## Multi-objective optimisation

The optimisation stage aims to identify the operating conditions that maximise $CO_2$ purity and recovery, as predicted by the surrogate models. The problem is formulated as a multi-objective optimisation (MOO) task, in which both objectives are maximised simultaneously subject to operational constraints. Mathematically, it can be expressed as:

$$\begin{cases} \max Pur_{CO_2}(\boldsymbol{u}, \boldsymbol{\beta}) \\ \max Rec_{CO_2}(\boldsymbol{u}, \boldsymbol{\beta}) \end{cases} \tag{2}$$

subject to:

$$\boldsymbol{u} \in [\boldsymbol{u_{min}}, \boldsymbol{u_{max}}] \tag{3}$$

where **u** represents the decision variable vector containing the step durations of the PSA cycle, and β denotes the surrogate model parameters. The objective functions are defined as follows:

$$Pur_{CO_2} = \frac{moles_{CO_2,out}\big|_{depress} + moles_{CO_2,out}\big|_{LR}}{moles_{CO_2,total}\big|_{depress} + moles_{CO_2,total}\big|_{LR}} \tag{4}$$

$$Rec_{CO_2} = 1 - \frac{moles_{CO_2,out}\big|_{ads}}{moles_{CO_2,in}\big|_{press} + moles_{CO_2,in}\big|_{ads}} \tag{5}$$

The multi-objective problem was solved using the particle swarm optimisation (PSO) algorithm, chosen for its efficiency in handling nonlinear and nonconvex search spaces. Each surrogate model, SR, and deep neural network, DNN, was embedded within the optimisation routine to compute the objective functions at each iteration. The algorithm simultaneously explores the trade-off between $CO_2$ purity and recovery, producing a Pareto front that reflects the optimal balance between these competing objectives. This formulation enables a direct comparison of the optimisation performance obtained with SR- and DNN-based surrogates in terms of accuracy, smoothness, and convergence behaviour.

# RESULTS AND DISCUSSIONS

The statistical characteristics of the dataset used for surrogate model identification were first analysed to verify the independence and coverage of the sampled operating variables. The correlation heatmap (Figure 3) indicates weak pairwise correlations among inputs, minimising multicollinearity during training.

Figure 4 displays the LHS generated step durations for $t_{pres}$, $t_{depres}$, $t_{ads}$, $t_{LR}$, and $t_{HR}$. The plots show patterns consistent with stratified, quasi-independent draws. Note that the horizontal axis represents the sample order of LHS points, evidencing broad coverage of the operating domain for each step.

The analytical surrogate expressions obtained using the SR approach for predicting $CO_2$ purity and recovery are presented in Equations 6 and 7. The resulting symbolic forms represent compact yet accurate approximations of the nonlinear mappings between the process decision variables.

$$Pur_{CO_2} = \sin\left(\frac{t_{ads} + 0.058}{sin^3\left(\frac{1}{cos\left(t_{depres}^3\right)}\right) + sin\left(t_{depres} e^{cos(0.609)}\right)}\right) \tag{6}$$

$$Rec_{CO_2} = 0.91\cos^4\left(e^{-4(\sin(t_{depres}/0.94)\sin(t_{ads}))^2} t_{ads}\right) \quad (7)$$

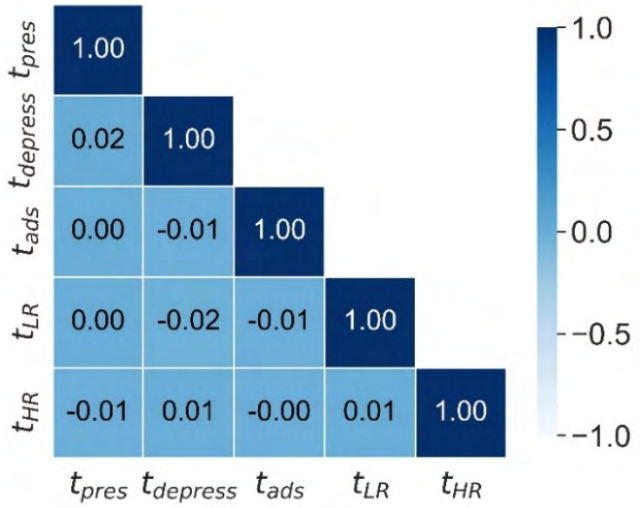

**Figure 3.** Correlation heatmap for the input variables of the surrogate models.

Both SR-derived equations capture the nonlinear dependence of $CO_2$ purity and recovery on the durations of the adsorption ($t_{ads}$) and depressurisation ($t_{depres}$) steps. Their explicit analytical structure facilitates low-complexity surrogate representation suitable for direct embedding into optimisation routines.

The DNN developed for predicting $CO_2$ purity used a fully connected feedforward architecture with five input features and four hidden layers, employing the ReLU activation function. The hidden layers comprised 300, 200, 50, and 200 neurons, respectively, followed by a single linear output neuron. This configuration resulted in 82451 trainable parameters. The model was trained using the Adam optimiser with a learning rate of 0.001 and MSE as the loss function.

Similarly, the DNN model designed for $CO_2$ recovery employed the same input structure and ReLU-activated hidden layers, but with a more compact topology. The network consisted of two hidden layers containing 300 and 100 neurons, respectively, also followed by a single linear output neuron. The total number of trainable parameters in this configuration was 32001. This model was also trained with the Adam optimiser at a learning rate of 0.001, ensuring consistent training dynamics and convergence across both networks.

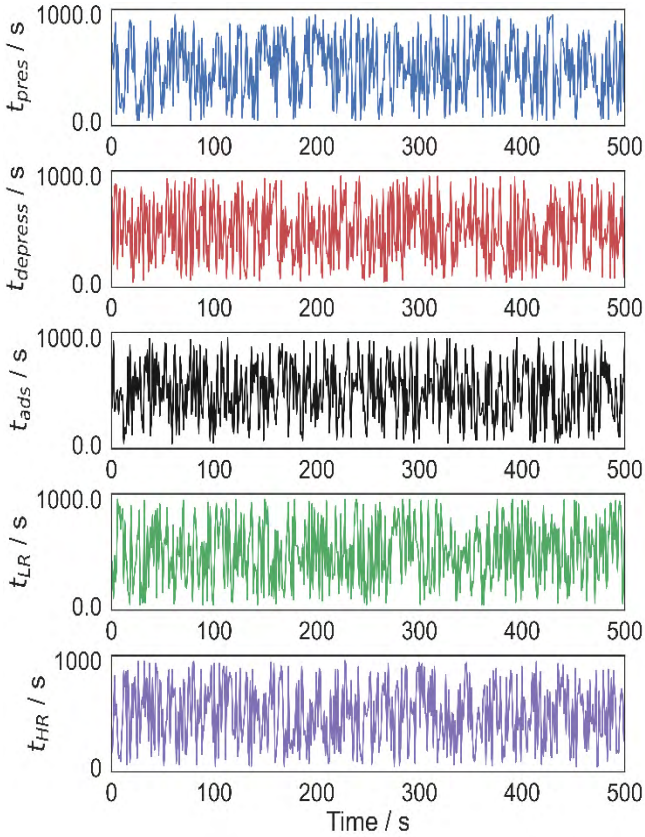

**Figure 4.** Sampled PSA Step Durations Generated by LHS.

Figure 5 compares the parity plots for the two surrogate modelling approaches used to predict $CO_2$ purity and recovery. Subfigures 5a and 5b correspond to the SR-based models, while subfigures 5c and 5d refer to the DNN surrogates. In all cases, the predicted values exhibit a good agreement with the reference data. The mechanistic PSA model has the points tightly distributed along the identity line. A slightly better predictive performance is observed for the DNN models, which exhibit lower dispersion and greater alignment along the diagonal, reflecting their enhanced capacity to capture complex nonlinear relationships.

Table 1 summarises the prediction errors obtained for both surrogate modelling strategies. The metrics considered were the MSE and MAE, both computed in the denormalised domain for direct physical interpretation. The DNN models outperform the SR surrogates in predictive accuracy, with MSE values one to two orders of magnitude lower. Nevertheless, the symbolic regression models also demonstrate satisfactory performance, achieving low error rates and accurately reproducing the PSA system's main nonlinear trends.

The multi-objective optimisation procedure was carried out using the PSO algorithm, configured with a swarm of 100 particles and 100 iterations. Both surrogate-based frameworks (SR and DNN models) were

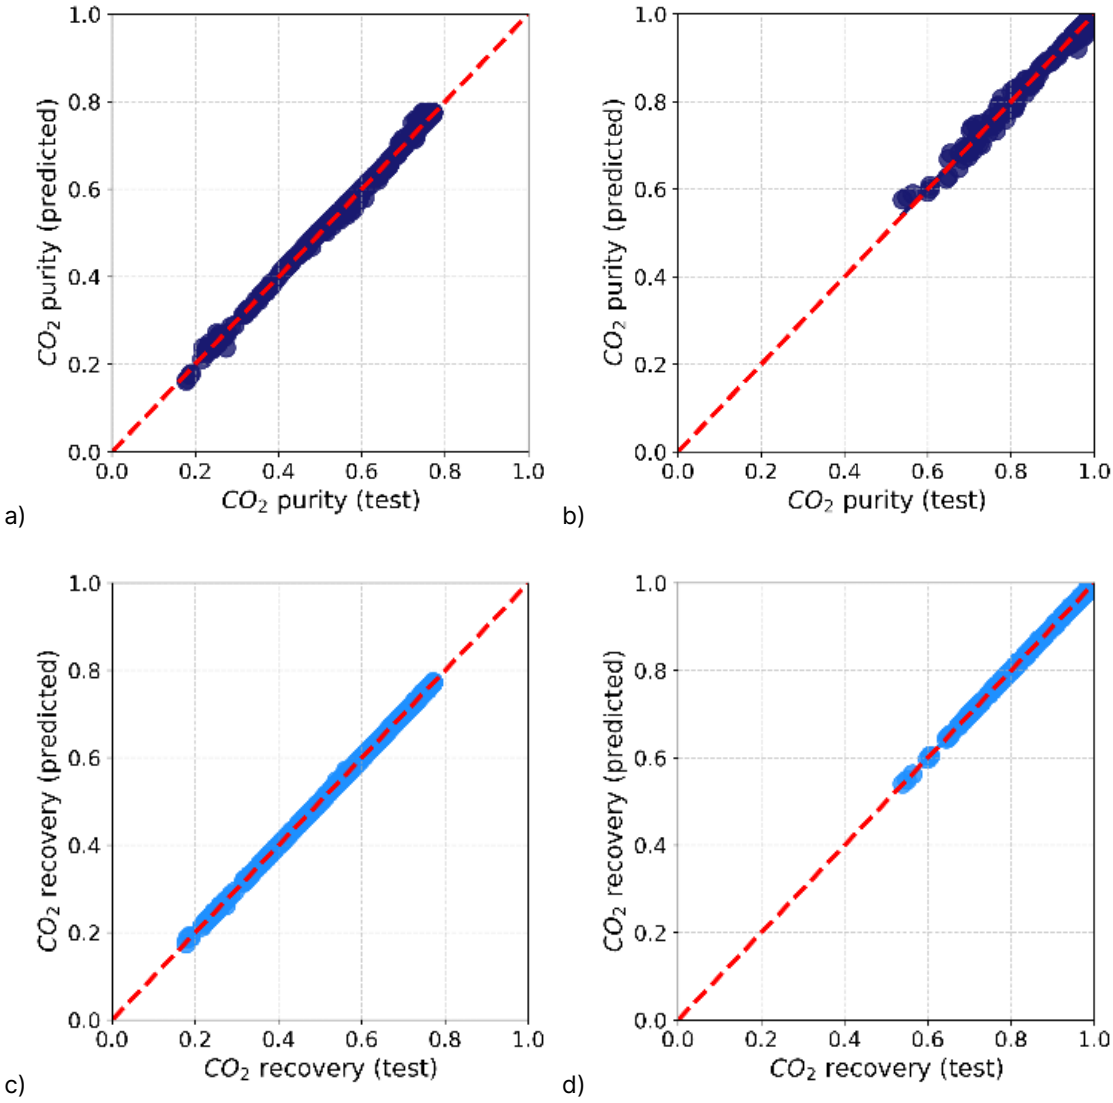

**Figure 5**. Parity plots comparing predicted and reference values for $CO_2$ purity and recovery obtained with SR (a, b) and DNN (c, d) surrogate models.

employed in the optimisation problem defined in Section 2. Additionally, the optimisation results were compared with those obtained using the mechanistic PSA model, which was optimised under the same conditions but with 50 particles and 50 iterations. The decision variable values corresponding to the Pareto-optimal points from each surrogate model were further evaluated in the mechanistic simulator to verify the consistency and physical plausibility of the predicted solutions. The resulting Pareto fronts, illustrated in Figure 6, display the trade-off between $CO_2$ purity and $CO_2$ recovery for each modelling strategy.

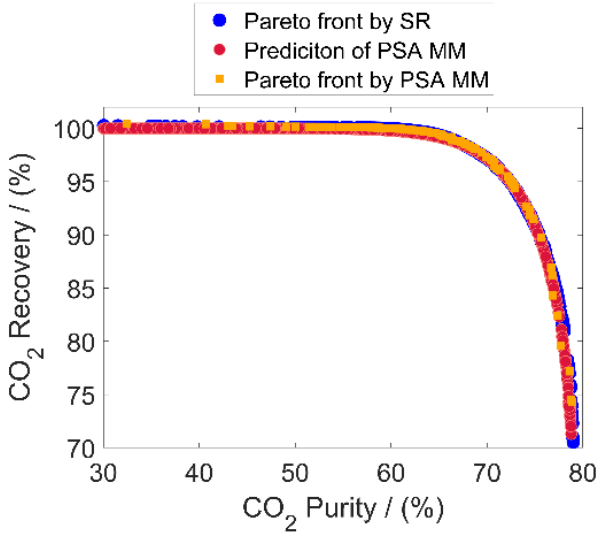
**Table 1:** Final MSE and MAE values for the test dataset obtained with the SR and DNN surrogate models.

| Model | Variable | MSE | MAE |
|---|---|---|---|
| SR | $CO_2$ purity | $5.0 \times 10^{-5}$ | $4.33 \times 10^{-3}$ |
| SR | $CO_2$ recovery | $5.9 \times 10^{-5}$ | $4.03 \times 10^{-3}$ |
| DNN | $CO_2$ purity | $1.24 \times 10^{-6}$ | $5.70 \times 10^{-4}$ |
| DNN | $CO_2$ recovery | $5.22 \times 10^{-7}$ | $5.11 \times 10^{-4}$ |

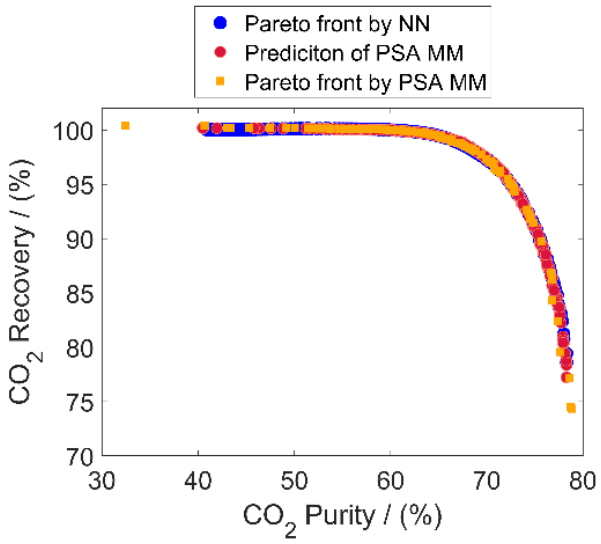
The optimisation using the SR surrogate produced a Pareto front containing 4345 optimal solutions, while the DNN surrogate yielded 508 points. Despite both optimisations using the same number of particles and iterations, the SR-based approach produced a denser, more diverse Pareto front, indicating superior exploration of the solution space compared to the DNN model.

This is attributed to the continuous and differentiable nature of the analytical expressions derived via SR,

which induces a smoother optimisation landscape, facilitating uniform exploration of the trade-off region by the PSO algorithm. In contrast, DNN surrogates may introduce local irregularities and discontinuities due to nonlinear activation functions such as ReLU, causing the swarm to concentrate on fewer regions of the Pareto front and resulting in a sparser front.



a) Pareto front by SR surrogate



b) Pareto front by DNN surrogate.

**Figure 6**. Comparison of Pareto fronts obtained with SR and DNN surrogates against the PSA MM.

Figure 7 presents the cumulative optimisation time per iteration obtained for both surrogate-based optimisation frameworks. Each curve represents the total computation time accumulated across all particles up to a given PSO iteration. The SR-based optimisation required a total of 38.6 s to complete the 100 iterations, whereas the DNN-based framework required 1331.5 s under the same conditions.

These results highlight a substantial difference in computational efficiency: the SR approach was approximately 34.5 times faster than the DNN model. This performance gap arises mainly from the analytical nature of the SR surrogates, which allow direct function evaluations without the matrix operations and backpropagation overhead inherent to neural networks. Consequently, SR models enable a much faster exploration of the search space while maintaining sufficient predictive accuracy for the multiobjective optimisation task.

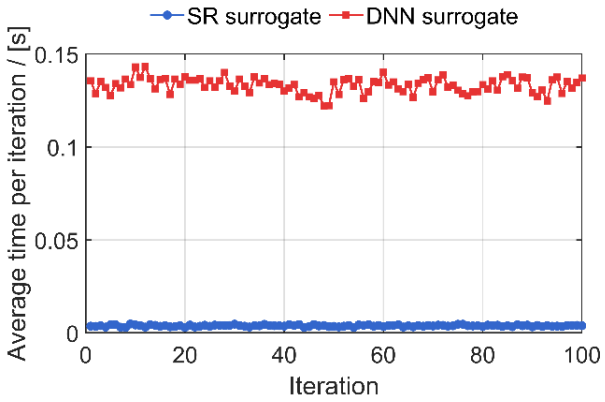


**Figure 7.** Average computational cost per iteration of optimisation using surrogate SR and DNN models.

## CONCLUSION

This study demonstrated that SR can serve as an efficient surrogate modelling strategy for optimising PSA processes. Compared to DNN, the SR-based framework achieved faster convergence and produced a more diverse Pareto front while maintaining good predictive accuracy. These findings highlight the potential of SR as a computationally lightweight alternative for data-driven optimisation of cyclic adsorption systems, offering a balance between robustness, and efficiency.

## ACKNOWLEDGEMENTS

The present work contributes to completion of a sub project at SUBPRO, a research-based innovation center within Subsea Production and Processing at the Norwe gian University of Science and Technology. The authors would like to express their gratitude for the financial support received from SUBPRO, funded by the Research Council of Norway through grant number 237893, major industry partners, and NTNU.

## ABSTRACT

The growing penetration of renewable energy sources and power-to-hydrogen (P2H) systems demands high-fidelity, large-scale optimization frameworks that capture the nonlinear physics of both AC power flow and hydrogen thermodynamics. However, existing approaches rely on DC approximations and simplified electrolyzer models, neglecting critical operational constraints. As a result, accurately modeling such systems leads to large-scale nonlinear programs that are computationally intractable for conventional CPU-based solvers. This motivates the need for scalable optimization frameworks capable of handling both physical fidelity and computational complexity. This paper proposes a fully GPU-native framework for solving large-scale multi-period AC optimal power flow (AC-OPF) problems with integrated power-to-hydrogen systems. High-fidelity thermodynamic models of hydrogen production, compression, cooling, and storage are coupled with AC power flow constraints, resulting in large-scale nonlinear programs (NLPs) with up to 14.4 million variables and 22.4 million constraints in the largest benchmark case (9, 591-bus network with a 168-hour horizon). To enable scalable solutions, condensed-space KKT reformulations and GPU-accelerated sparse Cholesky factorization are employed within an end-to-end GPU optimization pipeline. Numerical results on benchmark networks up to 9, 591 buses demonstrate 10–600× speedups over CPU solvers, whereas CPU-based solvers fail to converge on the largest instances. Operational studies further highlight the importance of thermodynamic constraints in realistic hydrogen system scheduling.

**Keywords**: AC optimal power flow, power-to-hydrogen, integrated energy systems, GPU-accelerated optimization, nonlinear programming

## 1. INTRODUCTION

Global electricity demand is growing rapidly due to the electrification of industrial processes, the expansion of data centers, and the increasing penetration of electric transportation systems [1]. Achieving carbon neutrality under these trends requires a fundamental transformation of power systems toward renewable energy sources (RES). However, the inherent intermittency and uncertainty of RES introduce significant temporal mismatches between electricity supply and demand, posing critical challenges to secure and efficient system operation.

Addressing these challenges necessitates flexible energy storage solutions that enable sector coupling across multiple energy domains. Among the available options, Power-to-Hydrogen (P2H) technology offers a promising solution by converting surplus electricity into hydrogen, enabling long-duration storage and cross-sectoral decarbonization [2].

Despite the potential of integrated systems, existing optimization frameworks often rely on significant simplifications to manage computational complexity. On the grid side, many studies utilize Direct Current (DC) power flow approximations, which ignore voltage limits and reactive power requirements [3]. On the hydrogen side, electrolyzers are frequently represented as idealized, controllable electrical loads [4]. Such formulations neglect critical physical characteristics of hydrogen systems, including the nonlinear auxiliary power

consumption of balance-of-plant components (e.g., compressors and cooling systems) and the thermodynamic dynamics of hydrogen storage vessels, such as pressure and temperature evolution. Ignoring these effects can lead to inaccurate assessments of system flexibility and suboptimal operational decisions.

To address these limitations, this paper proposes a high-fidelity, integrated optimization framework that couples a multi-period Alternating Current Optimal Power Flow (AC-OPF) model with detailed hydrogen production and storage dynamics. The AC-OPF formulation explicitly captures voltage magnitudes, active and reactive power flows, and transmission losses, while the hydrogen subsystem is modeled with rigorous operational and thermodynamic constraints. This integrated formulation enables a physically consistent representation of the coupled power–hydrogen system across multiple time periods.

The resulting optimization problem is a large-scale, nonlinear program (NLP) characterized by strong temporal coupling and complex network constraints. Solving such problems using conventional CPU-based nonlinear solvers becomes computationally prohibitive for realistically sized systems, particularly at the national scale.

To overcome this computational challenge, the proposed framework is implemented using ExaModels.jl, a GPU-based algebraic modeling system, and solved with MadNLP.jl, a GPU-accelerated nonlinear solver [5]. By leveraging the massive parallelism of modern graphics processing units (GPUs), this computational strategy enables the efficient solution of large-scale, high-fidelity integrated energy system models that were previously intractable.

The proposed approach is validated through case studies ranging from regional to national-scale power networks. The results demonstrate both the operational importance of detailed hydrogen process modeling and the substantial computational advantages of GPU-accelerated nonlinear optimization.

The remainder of this paper is organized as follows. Section 2 presents the mathematical formulation of the multi-period AC-OPF and hydrogen system models. Section 3 describes the GPU-accelerated computational framework. Section 4 reports numerical results and performance analyses, and Section 5 concludes the paper.

## 2. MATHEMATICAL MODELING

This section presents the mathematical formulation of the proposed multi-period AC-OPF problem with integrated hydrogen production and storage. Figure 1 illustrates the overall structure of the coupled power-hydrogen system, including the electrical network, electrolyzer, compressor, cooling system, and hydrogen storage tank, as well as their physical and operational interactions.

The proposed formulation extends the conventional AC power flow representation [6] by explicitly incorporating the inter-temporal dynamics and operational constraints of hydrogen subsystems. The model is implemented using ExaModelsPower.jl, an open-source modeling library for creating GPU-compatible nonlinear AC optimal power flow models [7].

The integrated system is formulated as a large-scale NLP problem over a discrete time horizon $t \in \mathcal{T}$. Building upon [8], the proposed formulation augments the basic power-to-hydrogen model with rigorous thermodynamic constraints for compression and cooling. At selected buses $i \in \mathcal{H} \subseteq \mathcal{N}$, hydrogen production and storage facilities are installed and electrically coupled to the power grid. Each hydrogen facility consists of a proton exchange membrane (PEM) electrolyzer, a compressor for pressurized hydrogen storage, and a cooling system to maintain safe operating temperatures. The coupling between the power grid and the hydrogen subsystem is realized through the electrical power consumption of these components, which directly enters the nodal power balance equations of the grid.

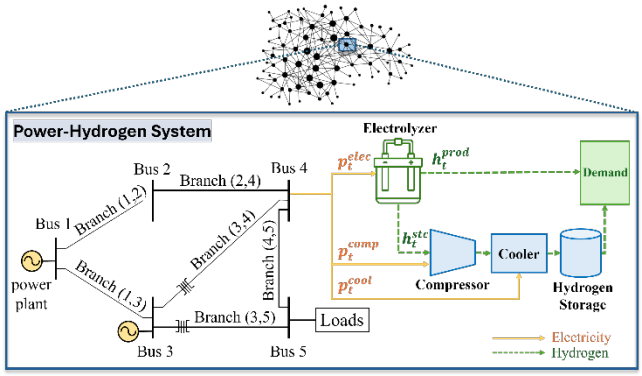

**Figure** 1. Schematic of the integrated power–hydrogen system. Selected buses in the transmission network are equipped with hydrogen production facilities, each comprising a PEM electrolyzer, compressor, and cooler. The electrical power consumption of these components the nodal power balance equations of the grid.

### 2.1 Multi-period AC-OPF with Integrated Hydrogen Loads

The core of the integrated energy system is the nonlinear AC power flow model, which ensures the physical feasibility of power system operation. For each bus $i \in \mathcal{N}$ and time period $t \in \mathcal{T}$, the nodal active and reactive power balance equations are formulated as

$$\sum_{g \in \mathcal{G}_i} p^g_{i,t} - p^d_{i,t} - p^{H2}_{i,t} = \sum_{j \in \mathcal{N}_i} p_{ij,t}, \forall i \in \mathcal{N}, t \in \mathcal{T} \quad (1)$$

$$\sum_{g \in \mathcal{G}_i} q^g_{i,t} - q^d_{i,t} = \sum_{j \in \mathcal{N}_i} q_{ij,t}, \forall i \in \mathcal{N}, t \in \mathcal{T} \quad (2)$$

where $p^g_{i,t}$ and $q^g_{i,t}$ denote the active and reactive power

generation, and $p_{i,t}^{d}$ and $q_{i,t}^{d}$ represent the fixed active and reactive power demands, respectively. The term $p_{i,t}^{H2}$ denotes the total active power consumption of the hydrogen facility. This term is non-zero only for the subset of buses equipped with hydrogen systems, $i \in \mathcal{H} \subseteq \mathcal{N}$, and is decomposed as

$$p_{i,t}^{H2} = p_{i,t}^{elec} + p_{i,t}^{comp} + p_{i,t}^{cool}, \tag{3}$$

where $p_{i,t}^{elec}$, $p_{i,t}^{comp}$, and $p_{i,t}^{cool}$ denote the electrical power consumption of the PEM electrolyzer, hydrogen compressor, and cooling system, respectively.

The branch active and reactive power flows between buses $i$ and $j$ are defined using the standard polar form of the AC power flow equations as

$$p_{ij,t} = G_{ij}V_{i,t}^2 - V_{i,t}V_{j,t}\left(G_{ij}cos\theta_{ij,t} + B_{ij}sin\theta_{ij,t}\right), \tag{4}$$

$$q_{ij,t} = -B_{ij}V_{i,t}^2 - V_{i,t}V_{j,t}\left(B_{ij}cos\theta_{ij,t} + G_{ij}sin\theta_{ij,t}\right), \tag{5}$$

where $V_{i,t}$ and $\theta_{i,t}$ are the voltage magnitude and angle at bus $i$, and $G_{ij}$ and $B_{ij}$ are the elements of the bus admittance matrix. Operational security is ensured by enforcing voltage magnitude limits, generator output limits, and branch flow limits.

## 2.2 Hydrogen Production Model

For notational simplicity, the bus index $i$ is omitted in the hydrogen subsystem equations. All hydrogen-related variables are defined for each hydrogen-equipped bus $i \in \mathcal{H}$ and time period $t \in \mathcal{T}$, unless otherwise stated. The hydrogen production system is based on a PEM electrolyzer, modeled based on electrochemical principles described in [9]. The hydrogen generation rate is modeled as a function of the electrolyzer current. The hydrogen production rate $h_t^{prod}$ is given by

$$h_t^{prod} = \frac{3600 \cdot N_c \cdot A \cdot M_{H2} \cdot i_t \cdot \eta_F(i_t)}{2F}, \tag{6}$$

where $N_c$ is the number of cells, $A$ is the electrode active area, $M_{H_2}$ is the molar mass of hydrogen, $i_t$ is the current density, $F$ is Faraday's constant, and $\eta_F(i_t)$ is the Faradaic efficiency.

The Faradaic efficiency is modeled as a logarithmic function of the current density following,

$$\eta_F(i_t) = 0.98 - 0.02ln(i_t), \tag{7}$$

where the current density $i_t$ is restricted to the practical operating range $0.5 \le i_t \le 2.5\,\mathrm{A/cm^2}$.

The electrical power consumption of the electrolyzer is modeled as

$$p_t^{elec} = V_c(i_t) \cdot i_t \cdot A \cdot N_c, \tag{8}$$

where $V_c(i_t)$ is the voltage of a single cell, which depends nonlinearly on the operating current density. The electrochemical parameters for cell voltage are adopted from [10].

## 2.3 Compressor and Cooling Power Models

Hydrogen produced by the electrolyzer is compressed prior to injection into the storage tank. The compressor power consumption is modeled based on isentropic compression:

$$p_t^{comp} = \frac{\gamma R T_{elec}}{(\gamma - 1)\eta_{comp}} \bullet n_t^{stc} \bullet \left[\left(\frac{P_t^{comp,out}}{P_{H_2}}\right)^{\frac{\gamma-1}{\gamma}} - 1\right], \tag{9}$$

where $\gamma$ is the specific heat ratio, $R$ is the gas constant, $T_{elec}$ is the electrolyzer outlet temperature, $\eta_{comp}$ is the compressor efficiency, $n_t^{stc}$ is the molar flow rate entering the storage tank, and $P_t^{comp,\,out}$ and $P_{H_2}$ denote the compressor outlet and inlet pressures, respectively.

The outlet temperature of the compressor is given by

$$T_t^{comp,out} = T_{elec} + \frac{T_{elec}}{\eta_{comp}}\left[\left(\frac{P_t^{comp,out}}{P_{H_2}}\right)^{\frac{\gamma-1}{\gamma}} - 1\right], \tag{10}$$

The cooling system removes excess thermal energy to maintain safe tank temperatures. The cooling power is derived from a simple energy balance:

$$p_t^{cool} = \frac{Q}{COP} = \frac{h_t^{stc} \bullet c_p \bullet \Delta T}{COP}, \tag{11}$$

where $c_p$ is the specific heat capacity, $\Delta T$ is the required temperature reduction, and $COP$ denotes the coefficient of performance of the cooling system.

## 2.4 Hydrogen Storage Dynamics and Thermodynamic Constraints

The hydrogen storage tank is modeled using dynamic mass and energy balance equations. The hydrogen inventory evolves as

$$h_t^{st} = h_{t-1}^{st} + h_t^{stc} - h_t^{std}, \tag{12}$$

where $h_t^{stc}$ and $h_t^{std}$ denote hydrogen charged into and discharged from the storage tank, respectively. The hydrogen inventory in the storage tank is bounded by its minimum and maximum storage capacities:

$$S^{min} \le h_t^{st} \le S^{max}, \tag{13}$$

The tank temperature dynamics are governed by the internal energy balance:

$$\begin{aligned} c_v \bullet n_t^{st} \bullet T_t^{tank} &= c_v \bullet n_{t-1}^{st} \bullet T_{t-1}^{tank} \\ &+ c_p \bullet n_t^{stc} \bullet T_{tank,in} - c_p \bullet n_t^{std} \bullet T_t^{tank}, \end{aligned} \tag{14}$$

where $c_v$ is the constant-volume specific heat, $n_t^{st}$ is the molar quantity stored in the tank, and $T_{tank,in}$ denotes the inlet temperature after cooling.

The tank pressure is determined by the ideal gas law:

$$P_t^{tank} = \frac{n_t^{st} R T_t^{tank}}{V_{tank}}, \tag{15}$$

where $V_{tank}$ denotes the storage volume.

To ensure operational safety and compatibility with downstream systems, the compressor outlet pressure satisfies

$$P_t^{comp,out} = P_t^{tank} + \Delta P_{margin}, \tag{16}$$

where $\Delta P_{margin}$ represents the pressure margin required for reliable injection into the storage vessel.

## 3. GPU-BASED COMPUTATIONAL FRAMEWORK

This section presents the computational framework developed to solve the proposed large-scale, multi-period nonlinear AC-OPF problem with integrated hydrogen production and storage. The framework adopts a fully GPU-native optimization pipeline based on ExaModels.jl for algebraic modeling, MadNLP.jl for nonlinear programming, and GPU-accelerated sparse linear solvers for Newton step computation. This end-to-end GPU execution enables scalable solution of tightly coupled, high-dimensional energy system optimization problems.

### 3.1 Computational Challenges in Large-Scale Nonlinear Optimal Power–Hydrogen Flow

The integrated power–hydrogen optimization problem formulated in Section 2 can be expressed as a large-scale NLP problem:

$$\begin{aligned} &\min_x f(x) \\ &\text{s.t. } g(x) = 0, \\ &\quad h(x) \le 0 \end{aligned}$$

where $x$ comprises generator outputs, bus voltages, branch flows, and hydrogen system states (e.g., current density, tank pressure, temperature, and stored mass) across all buses and time periods.

Dimensionality and inter-temporal coupling: The problem dimension scales with both network size and time horizon length. The incorporation of hydrogen dynamics introduces additional state variables and constraints with strong inter-temporal coupling, substantially increasing memory requirements and computational complexity. For large-scale instances, this leads to NLPs with tens of millions of variables and constraints.

Nonlinearity and nonconvexity: The AC power flow equations introduce strong nonlinearities and nonconvexity, necessitating the use of Newton-type iterative methods to achieve reliable convergence. Each iteration requires solving a Karush–Kuhn–Tucker (KKT) system:

$$\begin{bmatrix} \nabla^2 L(x,\lambda) & J(x)^T \\ J(x) & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta \lambda \end{bmatrix} = - \begin{bmatrix} \nabla L(x,\lambda) \\ g(x) \end{bmatrix}$$

where $L(x,\lambda)$ is the Lagrangian and $J(x)$ is the Jacobian of constraints.

These systems are typically ill-conditioned due to wide variable scaling, tight operational constraints, and strong coupling between electrical and thermodynamic subsystems.

Large-scale sparse linear algebra: On conventional CPU architectures, sparse factorization of these systems dominates the computational cost, severely limiting scalability. These challenges motivate the development of a GPU-based computational framework capable of efficiently handling large-scale nonlinear optimization problems.

### 3.2 Algebraic Modeling Using ExaModels.jl

The proposed formulation is implemented using ExaModels.jl, which provides a GPU-oriented abstraction for algebraic modeling and parallel automatic differentiation. All nonlinear objective and constraint functions are formulated within this algebraic framework, enabling the automatic generation of first- and second-order derivative information required by Newton-type optimization methods.

ExaModels employs a single-instruction multiple-data (SIMD) parallel abstraction that maps residual evaluation, Jacobian assembly, and Hessian computation directly onto GPU threads. This design enables highly parallel evaluation of derivative information and significantly accelerates the linearization steps performed at each Newton iteration [5].

The hydrogen production and storage models introduced in Section 2 are incorporated into this algebraic framework, enabling a unified representation of the electrical and thermodynamic subsystems within a single optimization model. This unified formulation preserves consistency across coupled physical domains and facilitates efficient execution on GPU architectures.

### 3.3 GPU-Accelerated Nonlinear Optimization with MadNLP.jl

The resulting nonlinear programming problem is solved using MadNLP.jl, a high-performance primal–dual interior-point solver designed for large-scale and GPU-accelerated nonlinear optimization. At each iteration, MadNLP solves a structured Newton system derived from the KKT optimality conditions.

A central challenge in implementing interior-point methods on GPUs lies in solving the associated KKT linear systems. In standard formulations, the KKT matrix is indefinite and requires sparse symmetric factorization with numerical pivoting to ensure numerical stability. However, pivoting introduces data-dependent branching

and irregular memory access patterns, which are poorly suited for massively parallel GPU architectures. Moreover, as the interior-point iterations approach the solution, barrier terms associated with active constraints lead to increasingly ill-conditioned KKT systems, making purely iterative solvers difficult to deploy robustly.

To address these challenges, MadNLP adopts condensed-space KKT reformulation strategies that transform the original indefinite KKT system into symmetric positive definite (SPD) forms, thereby enabling the use of pivoting-free Cholesky factorizations that are well suited for GPU execution. Two complementary strategies are employed.

MadNLP employs condensed-space KKT reformulations — including Lifted KKT and HyKKT strategies — that transform the indefinite KKT system into symmetric positive definite form, enabling pivoting-free Cholesky factorization suitable for GPU execution [11, 12].

These reformulations allow MadNLP to achieve robust and scalable convergence for highly ill-conditioned multi-period optimization problems with substantial performance improvements over conventional CPU-based implementations.

## 3.4 GPU-Based Newton Step Computation and Sparse Linear Solvers

The condensed-space KKT reformulations described in Section 3.3 produce SPD systems, which can be efficiently factorized using Cholesky-based sparse direct solvers such as NVIDIA's cuDSS library [13].

Since the condensed KKT matrices are positive definite, cuDSS performs Cholesky factorization without numerical pivoting, avoiding the data-dependent branching that hinders parallel execution. The factorization consists of a symbolic analysis phase — performed only once since the sparsity structure remains fixed across interior-point iterations — and a numerical factorization phase that is reused at each iteration.

The computational workflow proceeds as follows: sparse Jacobian and Hessian matrices are evaluated in parallel using ExaModels and assembled directly into GPU-resident memory, the KKT matrix is factorized using cuDSS, and the Newton direction is recovered via GPU-accelerated triangular solves. Throughout this process, all data remains GPU-resident, minimizing host–device data transfers.

# 4. CASE STUDY

This section presents numerical experiments to evaluate the computational performance of the GPU-based framework and to analyze the operational characteristics of the integrated power–hydrogen system. The results demonstrate the scalability of the proposed approach and reveal the operational trade-offs arising from rigorous thermodynamic modeling of hydrogen production and storage.

## 4.1 Experimental Setup

This subsection outlines the optimization problem formulation, benchmark networks, hydrogen system modeling assumptions, and computational setup adopted in the case study. These components collectively define the experimental environment for evaluating both computational performance and operational behavior.

### 4.1.1 Optimization Problem

The objective of the case study is to minimize total generation cost over a multi-period planning horizon, subject to electrical and hydrogen operational constraints. The objective function is defined as:

$$\min \sum_{t\in\mathcal{T}} \sum_{i\in\mathcal{N}} \left( a_i (p^g_{i,t})^2 + b_i p^g_{i,t} + c_i \right) \tag{17}$$

where $p^g_{i,t}$ denotes the active power output of generator $i$, and $a_i, b_i, c_i$ are the corresponding cost coefficients. This objective is minimized subject to the AC power flow constraints (Eqs. 1-5) and the hydrogen system constraints (Eqs. 6-16) detailed in Section 2.

Additionally, a fixed hydrogen demand profile is imposed at each hydrogen bus to represent downstream industrial consumption requirements:

$$h^{prod}_t - h^{stc}_t + h^{std}_t \geq D_t \tag{18}$$

where $D_t$ is the hydrogen demand at time $t$.

### 4.1.2 Hydrogen System Specifications

The parameters for the hydrogen subsystems are listed in Table 1. A nominal electrolyzer configuration with a maximum hydrogen production capacity of approximately 1000 kg/h is assumed at each installation site. The storage tank is sized to buffer fluctuations over the planning horizon.

**Table 1.** Hydrogen production and storage system specifications.

| Parameter | | Value |
|---|---|---|
| Number of cells | $N_c$ | 5000 |
| Active cell area | $A$ | 2000 $cm^2$ |
| Hydrogen production capacity | $h^{prod}_{max}$ | 1000 kg/h |
| Operating temperature | $T_{elec}$ | 323 K |
| Hydrogen outlet pressure | $P_{H_2}$ | 30 bar |
| Tank volume | $V_{tank}$ | 25 $m^3$ |
| Operating pressure range | $P^{tank}$ | 0-700 bar |
| Operating temperature range | $T^{tank}$ | 270-375 K |

### 4.1.3 Modeling Configurations

Two modeling configurations are considered to assess the impact of thermodynamic detail on both solution accuracy and computational requirements.

The isothermal model assumes constant temperature and pressure throughout the hydrogen process. Adiabatic compression work is approximated using a simplified linear correlation [14], and storage thermal dynamics are neglected. This simplification reduces problem dimensionality and significantly improves computational efficiency.

The thermodynamic model incorporates the full rigorous formulation presented in Section 2. This includes isentropic compression (Eq. 9-10), cooling power requirements (Eq. 11), storage mass balance (Eq. 12), and temperature dynamics via the energy balance (Eq. 14). Tank pressure is determined by the ideal gas law (Eq. 15). This model captures the operational flexibility limits and auxiliary power consumption of the integrated system.

### 4.1.4 Test Networks and Problem Scale

We evaluate the framework on seven benchmark networks from the PGLib library [15], ranging from the 30-bus IEEE system to a 9591-bus synthetic grid. To simulate a wide deployment of P2H technology, hydrogen production facilities (electrolyzer, compressor, storage) are assumed to be colocated with all active power generators. This placement strategy is motivated by the practical consideration that hydrogen production facilities require access to substantial electrical infrastructure, which is typically available at generation sites.

**Table 2.** Problem dimensions for benchmark cases with integrated hydrogen systems (60-min resolution). k=$10^3$, m=$10^6$

| Case | Periods | Isothermal | | Thermodynamic | |
|---|---|---|---|---|---|
| | | nvars | ncons | nvars | ncons |
| case30 | 24 | 6.0k | 8.9k | 6.3k | 9.1k |
| case118 | 24 | 29.8k | 41.8k | 32.0k | 44.1k |
| case300 | 24 | 68.1k | 96.0k | 75.0k | 102.8k |
| case793 | 24 | 164.0k | 227.3k | 185.0k | 248.3k |
| case2312 | 24 | 490.6k | 701.9k | 540.2k | 751.6k |
| case4020 | 24 | 897.8k | 1.4m | 908.5k | 1.4m |
| case9591 | 24 | 2.0m | 3.2m | 2.1m | 3.2m |
| case4020 | 168 | 6.3m | 9.7m | 6.4m | 9.8m |
| case9591 | 168 | 14.3m | 22.2m | 14.4m | 22.4m |

Table 2 summarizes the problem dimensions for each test case under both modeling configurations. We consider two planning horizons: a standard 24-hour day (24 periods) and a week-long 168-hour horizon (168 periods), both with hourly resolution. The inclusion of thermodynamic variables and constraints significantly increases the problem size. For the largest instance (*case9591*, 168h), the thermodynamic formulation involves over 14.4 million variables and 22.4 million constraints, a scale that poses significant challenges for conventional CPU-based solvers.

### 4.1.5 Computational Platform

All GPU experiments are conducted on an NVIDIA H200 GPU using MadNLP v0.8.6 as the nonlinear programming solver and cuDSS v0.4.0 for sparse Cholesky factorization. For comparison, CPU-based solvers including MadNLP with UMFPACK and Ipopt with MUMPS are evaluated on a dual Intel Xeon 8480C system (112 cores total, 3.8 GHz max turbo).

## 4.2 Computational Performance

We evaluate the computational efficiency and scalability of the proposed GPU-native optimization framework (MadNLP-GPU) against two CPU-based alternatives. Figure 2 reports the wall-clock solution times for all benchmark networks under both the isothermal and thermodynamic formulations.

For the isothermal formulation, both CPU-based solvers exhibit reliable convergence on small- to medium-scale instances (up to *case793*). However, their performance degrades rapidly as network size and planning horizon increase. Ipopt successfully solves the 24-hour *case9591* instance in approximately 4, 200 seconds, while MadNLP-CPU fails on instances larger than *case793*. In contrast, MadNLP-GPU demonstrates consistently strong performance across all test cases, with solution times ranging from less than 1 second for *case30* to approximately 470 seconds for the largest instance (*case9591*, 168-hour), highlighting the excellent scalability of the GPU-based approach.

The thermodynamic formulation introduces tight bounds on temperature and pressure states, as well as strong nonlinear coupling between electrical and thermodynamic variables. These factors, combined with the wide range of variable scales, significantly degrade the numerical conditioning of the KKT system, consistent with the conditioning challenges discussed in Section 3, and pose severe challenges for CPU-based solvers.

Under this formulation, Ipopt fails to converge for all benchmark instances, and MadNLP-CPU solves only up to *case793*, requiring approximately 3 hours. By contrast, MadNLP-GPU maintains robust convergence across the full test set, solving the largest instance (14.4 million variables, 22.4 million constraints) in approximately 6, 650 seconds.

On instances where both GPU and CPU solvers converge, the GPU achieves speedups of 10-600× depending on problem size and model complexity. More importantly, the GPU-based framework extends the tractable problem size: from *case2312* onward, CPU-based solvers fail, whereas MadNLP-GPU scales efficiently to problems with millions of variables. These results confirm that the proposed framework enables high-fidelity modeling of integrated power-hydrogen systems at scales previously inaccessible to conventional approaches.

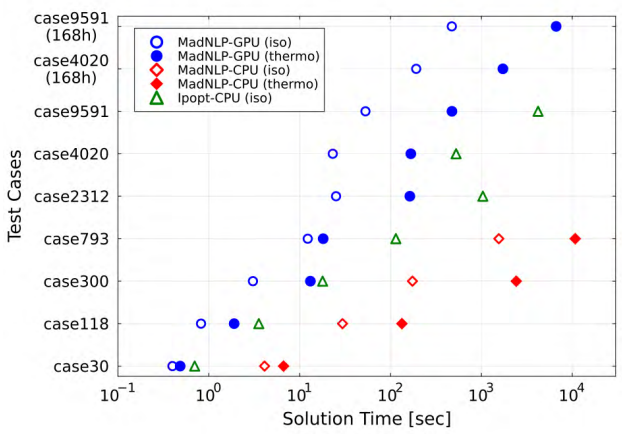

**Figure** 2. Wall-clock solution times for GPU and CPU solver configurations. Hollow and filled markers denote isothermal and thermodynamic formulations, respectively. GPU refers to MadNLP-GPU. Missing data points indicate solver failure.

## 4.3 Hydrogen System Operational Analysis

To illustrate the operational behavior captured by the proposed framework, Figure 3 presents the optimal 24-hour dispatch for a hydrogen production facility at bus 69 of the *case118* network. This bus is connected to a generator and is well-connected to neighboring buses, providing sufficient electrical capacity for hydrogen production. The optimization minimizes total generation cost while satisfying a fixed hydrogen demand of 42 kg/h.

Figure 3(a) shows the hydrogen production rate alongside the baseline electrical load profile. Production varies between 39 and 45 kg/h, exhibiting an inverse correlation with system load. During off-peak hours (hours 1–8), the electrolyzer operates above the required demand at 43–45 kg/h, with the surplus directed to storage. As system load increases (hours 9–10 and 16–23), production decreases to 39–41 kg/h, falling below the fixed demand. This pattern is consistent with both generation cost minimization and network capacity constraints.

Figure 3(b) illustrates the storage dynamics. The tank inventory follows a diurnal cycle, increasing from 50 kg to 60 kg during low-load periods, then decreasing as stored hydrogen compensates for reduced production during high-load periods. The storage thus decouples instantaneous production from the fixed demand.

Figure 3(c) presents the power consumption breakdown. The electrolyzer dominates at 1.86–2.04 MW, exhibiting approximately 9% variation over the horizon. Auxiliary equipment (compressor and intercooler) consumes less than 1 kW under the moderate pressure ratio (30 to 60 bar) considered in this study, representing a

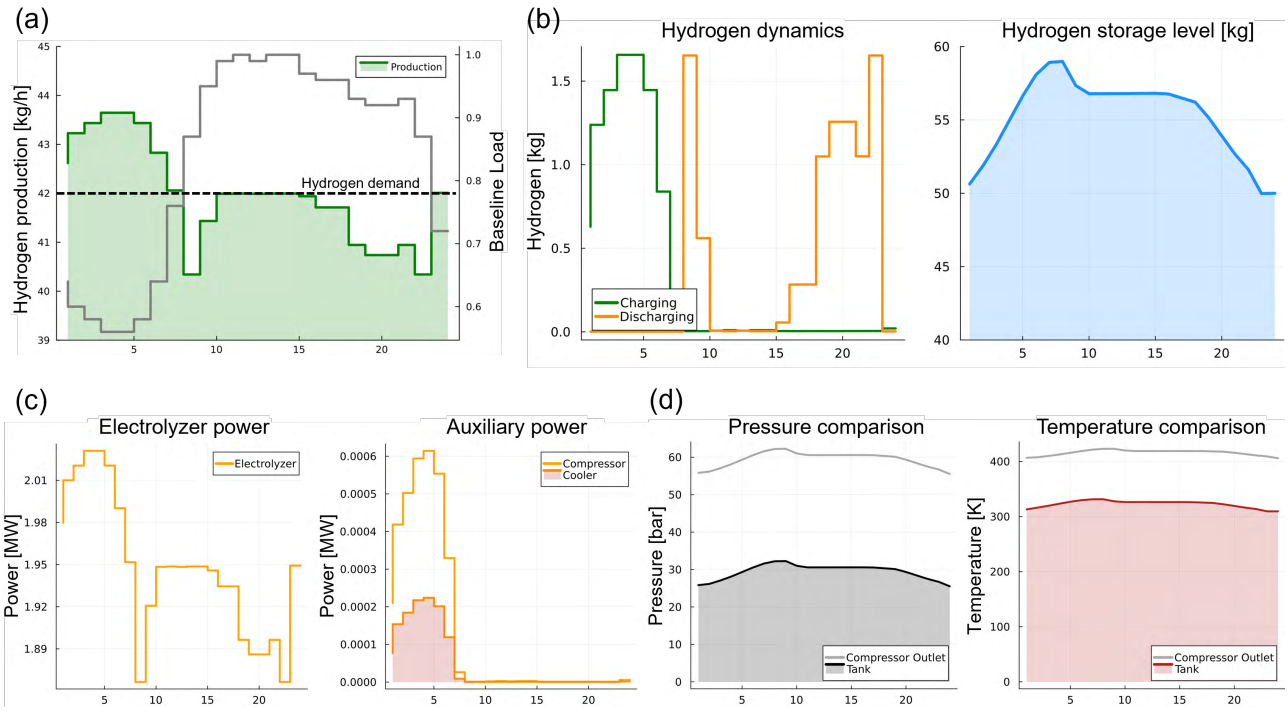

**Figure** 3. 24-hour operational profiles at bus 69 for the IEEE 118-bus system: (a) hydrogen production rate and electrical baseline load with fixed hydrogen demand, (b) storage charging/ discharging dynamics and inventory level, (c) electrolyzer and auxiliary (compressor and cooler) power consumption, and (d) compressor outlet and storage tank pressure/temperature profiles.

negligible fraction of total consumption. For higher storage pressures (350–700 bar), compression power would become significant, and the detailed thermodynamic model would be essential.

Figure 3(d) shows pressure and temperature profiles. The compressor outlet reaches pressures above 60 bar and temperatures exceeding 400 K during active charging. Following intercooling, the storage tank operates at approximately 30 bar and 300–320 K, within the specified limits (0–700 bar, 270–375 K).

The compressor outlet temperature, exceeding 400 K, must be managed through intercooling to maintain safe storage conditions. Isothermal models would not capture these thermal requirements, potentially yielding schedules that violate equipment limits. This justifies the thermodynamically consistent formulation proposed in this work, demonstrating the practical value of high-fidelity modeling for integrated power–hydrogen system operation.

## 5. CONCLUSION

This paper proposed and demonstrated a GPU-accelerated framework for multi-period AC-OPF with integrated hydrogen systems, incorporating high-fidelity thermodynamic constraints for electrolyzer, compressor, cooling, and storage operations. The GPU-based solver achieved 10–600× speedups over CPU alternatives, enabling the solution of problems with over 14 million variables, while CPU-based solvers failed to scale beyond medium-sized instances. Operational analysis on the IEEE 118-bus system demonstrated that hydrogen production is inversely correlated with electrical load, with storage buffering production and demand. The thermodynamic model captured critical constraints—such as compressor outlet temperatures exceeding 400 K—that simplified isothermal formulations fail to capture.

Future work will extend this framework to optimal placement of hydrogen facilities, large-scale integration of renewable energy sources, and $CO_2$ emission mapping for decarbonization-oriented power–hydrogen system planning.

## ABSTRACT

The optimization of chemical reactions requires navigating a high-dimensional design space composed of both discrete and continuous variables. Although one-hot encoding has been widely adopted, it lacks chemically meaningful information and suffers from sparsity and poor generalization. To address these limitations, we explored the use of pretrained molecular foundation models to generate latent representations as input variables for optimization. However, rigorously comparing different combinations of reaction representations and optimization algorithms remains a time- and resource-intensive challenge. In this work, we developed an end-to-end benchmarking platform that systematically evaluates diverse encoding schemes and optimization strategies under identical conditions. The platform automates the entire workflow from data preprocessing to result analysis, supporting fair comparison across multiple representation–optimizer combinations. Furthermore, we designed a custom reaction representation that integrates a 3D equivariant encoder with a bidirectional cross-attention module to explicitly capture interactions between reaction components. The proposed platform provides a scalable foundation for reaction optimization and advances the feasibility of autonomous experimental systems.

## INTRODUCTION

Organic chemical reactions underpin key processes across fine chemicals, pharmaceutical manufacturing, and the synthesis of functional materials. Achieving economic and environmentally responsible production of target molecules under constrained time and resource budgets therefore requires precise optimization of reaction conditions. In strongly condition-dependent, multivariable systems—such as metal-catalyzed cross-coupling and asymmetric catalysis—reaction yield and selectivity can vary dramatically with the choice and combination of substrates, ligands, catalysts, solvents, temperature, and concentration [1]. However, the reaction-condition space comprises mixed discrete and continuous variables, resulting in a highly combinatorial search space. This makes trial-and-error experimentation or limited design-of-experiments protocols insufficient for efficiently identifying globally optimal conditions [2].

Enabled by AI-accelerated experimental planning and high-throughput automation, the paradigm of self-driving laboratories (SDLs) has rapidly emerged [3]. Within SDL frameworks, the mapping from experimental conditions to observed reaction outcomes is typically evaluated in a closed loop of experimentation, and condition selection is guided by optimization strategies. Despite these advances, the effectiveness of these approaches depends critically on how reaction conditions are represented. Widely used one-hot encodings (OHE) induce sparse search spaces that fail to reflect chemical similarity [4], while molecular fingerprints, being hash-based and discrete, can miss three-dimensional geometry and subtle variations of the local chemical environment, and distances in fingerprint space often correlate poorly with chemically meaningful similarity [5]. These limitations motivate the reformulation of the search space through chemically informed representations that enable the extraction of meaningful features.

Recent advances in deep learning have substantially improved data-driven prediction of reaction yield, particularly with graph neural networks and attention-based models [6, 7]. However, comparatively limited attention has been paid to the role of learned latent representations in shaping the optimization landscape and their geometric influence on search efficiency in practical optimization loops . This gap suggests that reaction representation learning and optimization strategy design should not be treated as independent problems, but rather as a coupled, end-to-end design challenge.

Here, we propose an integrated framework that unifies AI-driven reaction representations with optimization for organic synthesis. Using pretrained foundation models, reaction components—substrates, ligands, catalysts, bases, and solvents—are embedded as continuous vectors. A chemically informed cross-attention mechanism is introduced to explicitly model interactions between the reaction center and surrounding reagents, establishing a meaningful continuous alternative to OHE. We couple this latent representation with a range of derivative-free optimizers and benchmark encoder–optimizer combinations on representative cross-coupling reactions. Finally, we investigate the relationship between latent-space structure and optimization performance, deriving practical design principles for representation-centric search spaces.

# METHODOLOGY

## Molecular representation models and embedding extraction

In this study, we benchmarked multiple pretrained molecular foundation models to transform discrete reaction-condition components into continuous vector representations. The following pretrained encoders were considered: MoLFORMER [8], KPGT [9], UMA [10], Frad [11], KERMT [12], and SMI-TED$_{289M}$ [13]. To enable a consistent comparison across encoders, all input molecules were standardized to canonical SMILES or reaction SMILES through a single preprocessing pipeline, and the same set of reaction components was provided to each encoder. All encoders were used in inference mode with frozen weights, and embeddings were extracted without fine-tuning. Each encoder outputs a fixed-length vector representation at the molecular level, and the encoders used along with their output dimensions are summarized in Table 1. Most encoders directly output molecule-level embeddings, which were used without modification. For UMA, which outputs atom/node-level representations, node embeddings were aggregated to yield a single molecular vector.

**Table 1**. Summary of molecular representation models used in this study.

| Model | Core Architecture | Output Dimension |
|---|---|---|
| MoLFormer | Transformer encoder with linear attention | 768 |
| KPGT | Graph Transformer | 2304 |
| UMA | 3D equivariant message passing (eSCN-based) | 256 |
| FRAD | Equivariant Transformer (TorchMD-Net) | 256 |
| KERMT | Graph Transformer | 3200 |
| SMI-TED$_{289M}$ | Encoder-decoder Transformer | 768 |

## Reaction-Level Representation

The reaction vector was constructed by concatenating the component embeddings $\mathbf{e}_{c_i} \in \mathbb{R}^{d_i}$. Continuous process variables were scaled to [0, 1] via min–max normalization and included as additional inputs.

Since each encoder has different output embedding dimensions, we applied a VAE to project all embeddings to a common latent dimension of $d = 256$, preventing performance comparisons from being confounded by differences in dimensionality. The VAE loss function consists of KL divergence loss and component-wise reconstruction loss:

$$L_{\text{total}} = \lambda_{\text{recon}} \cdot L_{\text{recon}} + \lambda_{\text{KL}} \cdot L_{\text{KL}} \tag{1}$$

The reconstruction loss employs cross-entropy loss over the candidate embedding set for each component. For absent components, a learnable "NONE" embedding $\mathbf{n}_i$ was included in the candidate set to represent missing inputs as a meaningful class. The logits are then computed by scaling the Euclidean distance between the reconstructed component vector $\hat{\mathbf{e}}_i$ and the candidate set $\mathcal{C}_i = \left\{\mathbf{c}_i^{(1)}, \ldots, \mathbf{c}_i^{(N_i)}, \mathbf{n}_i\right\}$ by temperature $\tau$:

$$\text{logit}_k = -\frac{\left\|\hat{\boldsymbol{e}}_i - \boldsymbol{c}_i^{(k)}\right\|_2}{\tau} \tag{2}$$

Here, $\hat{\mathbf{e}}_i$ is the embedding vector of the $i$-th component reconstructed by the decoder, $\mathbf{c}_i^{(k)}$ is the embedding of the $k$-th candidate molecule, and $\mathbf{n}_i$is the learnable NONE embedding. The ground truth label $y_i$ is the index of the candidate closest to the original embedding, with the NONE class assigned for missing components:

$$\boldsymbol{L_{recon}} = \frac{\mathbf{1}}{\boldsymbol{K}} \sum_{\boldsymbol{i=1}}^{\boldsymbol{K}} \boldsymbol{CrossEntropy}(\boldsymbol{softmax}(\boldsymbol{logit}_i), \boldsymbol{y}_i) \tag{3}$$

## Designed Reaction Representation

The benchmarked molecular representation models

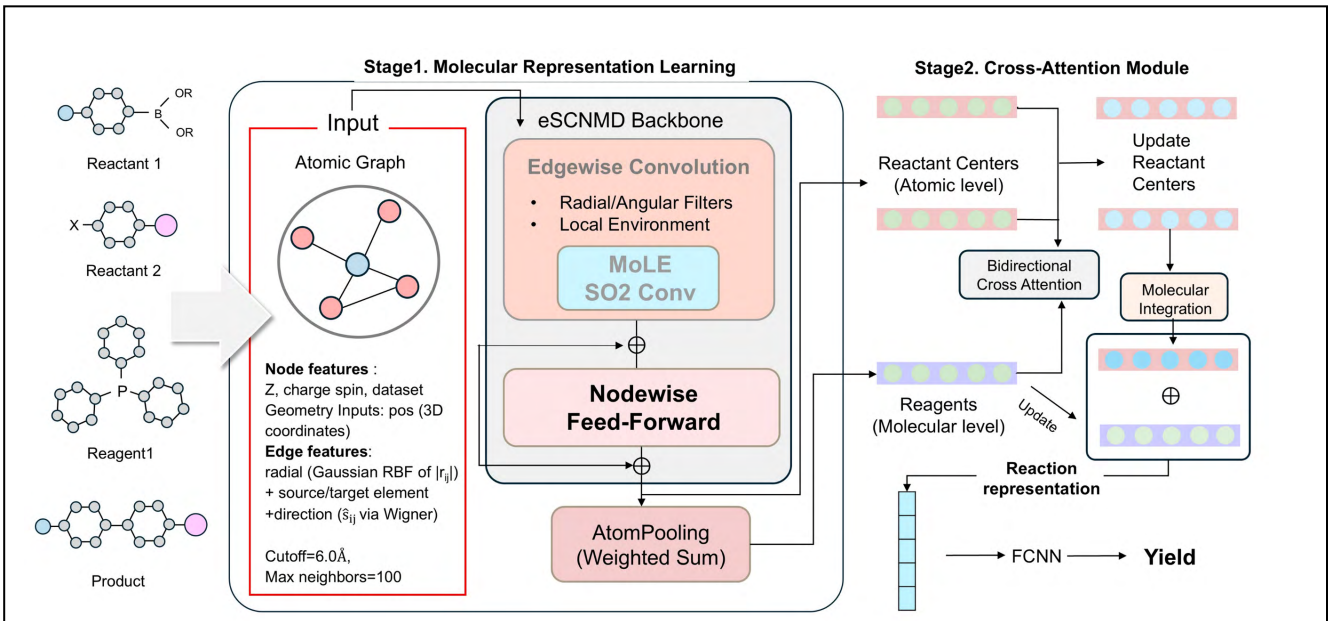

**Figure 1.** Architecture of the custom reaction representation model. (Left) Stage 1 extracts atomic and molecular embeddings using an eSEN backbone with eSCN convolution over 3D geometric features. (Right) Stage 2 employs a bidirectional cross-attention module that enables mutual information exchange between reaction centers and reagents.

encode each molecule independently and represent reactions through simple concatenation, followed by VAE-based dimensionality reduction. However, this approach does not explicitly capture chemical interactions between reaction components. Based on the benchmark results, UMA was selected as the backbone encoder due to its consistently competitive optimization performance. Moreover, its 3D equivariant architecture, which leverages both interatomic distances and directional information, is well suited to capturing the geometric features critical for stereoselectivity and coordination environments in chemical reactions. Building upon UMA, we integrated a bidirectional cross-attention module to explicitly capture inter-component interactions (Figure 1).

## Cross-Attention Module

We employ a parallel bidirectional cross-attention mechanism between reaction centers and reagents. The two attention pathways are computed simultaneously with swapped query and key/value roles:

$$\boldsymbol{Q} = \boldsymbol{W_Q h_q};\ \boldsymbol{K} = \boldsymbol{W_K h_{kv}};\ \boldsymbol{V} = \boldsymbol{W_V h_{kv}} \tag{4}$$

$$\boldsymbol{Attention}(\boldsymbol{Q},\boldsymbol{K},\boldsymbol{V}) = \boldsymbol{softmax}\left(\frac{\mathbf{Q}\bullet\mathbf{K}^{\mathbf{T}}}{\sqrt{\mathbf{d_k}}\bullet\tau}\right)\cdot\boldsymbol{V} \tag{5}$$

$$\begin{aligned}\boldsymbol{h'_{center}} &= \boldsymbol{Attn}\left(\boldsymbol{h_{center}},\boldsymbol{h_{reagent}},\boldsymbol{h_{reagent}}\right)\\ \|\ \boldsymbol{h'_{reagent}} &= \boldsymbol{Attn}\left(\boldsymbol{h_{reagent}},\boldsymbol{h_{center}},\boldsymbol{h_{center}}\right)\end{aligned} \tag{6}$$

where $\mathbf{h}_{\text{center}}$ and $\mathbf{h}_{\text{reagent}}$ denote the embeddings of reaction center atoms and reagent molecules, respectively, and $\|$ denotes parallel computation. This bidirectional design enables mutual information exchange between reaction centers and reagents.

## Problem Formulation

The reaction optimization problem is defined over a latent design space constructed from discrete reaction components. Each reaction condition is represented as a continuous vector $\mathbf{z} \in \mathbb{R}^d$ obtained by encoding the discrete components through a pretrained molecular encoder. The optimization problem is formulated as:

$$\boldsymbol{z}^* = \boldsymbol{arg}\max_{\boldsymbol{z}\in\mathbb{R}^d} \boldsymbol{f}(\boldsymbol{Decode}(\boldsymbol{z})) \tag{7}$$

At each iteration, the optimizer proposes a latent vector $z_t \in \mathbb{R}^d$, which is mapped to the nearest candidate condition via:

$$\mathbf{Decode}(\boldsymbol{z_t}) = \mathbf{arg}\ \min_{\mathbf{z_i}\in\mathcal{Z}}\ \|\ \mathbf{z_t}-\mathbf{z_i}\ \|_2 \tag{8}$$

where $\mathcal{Z} = \{z_i = \text{Encode}(c_i) \mid c_i \in \mathcal{C}\}$ is the set of encoded candidate reaction conditions. The corresponding yield $f(\text{Decode}(z_t))$ is then retrieved from the pre-existing experimental dataset and returned to the optimizer as the observed objective value.

## Black-box Optimization Algorithms

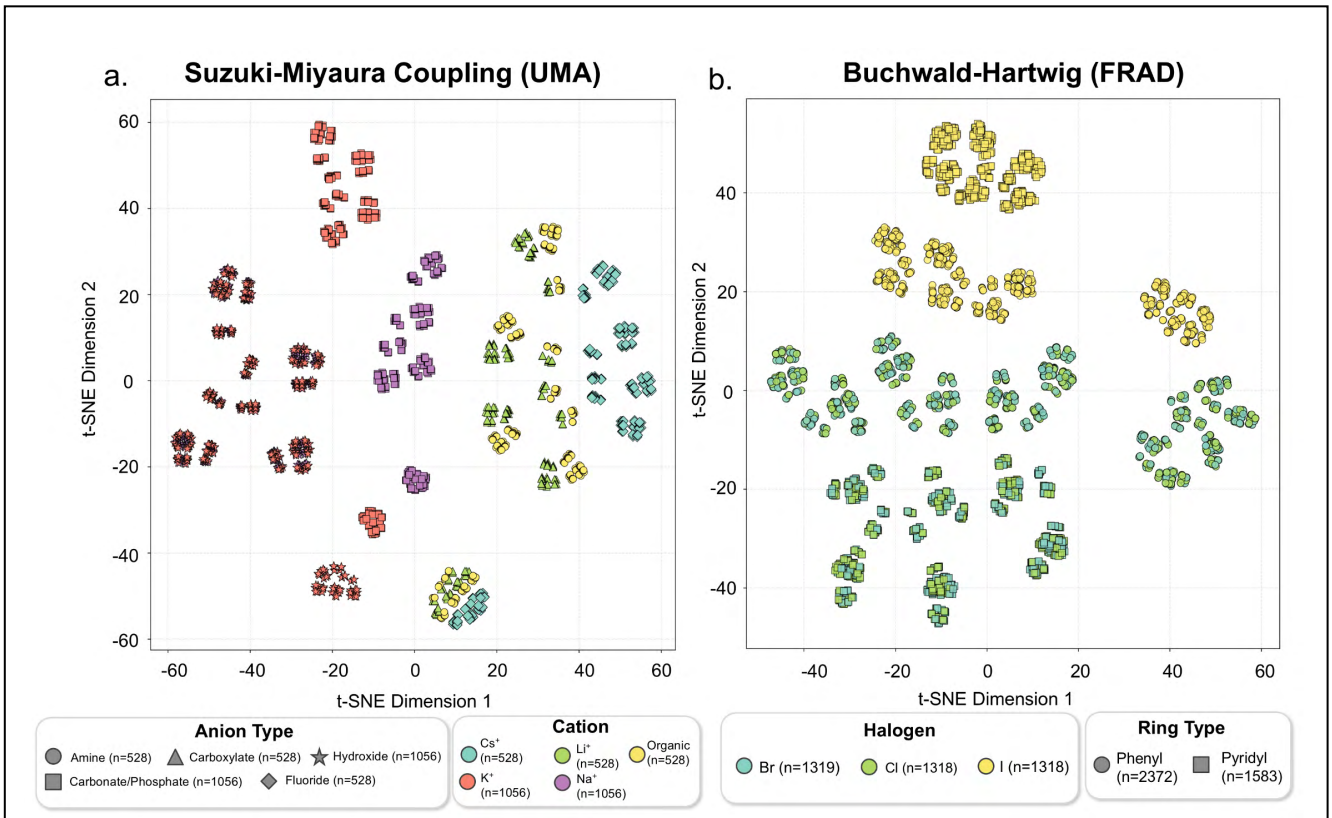

**Figure 2.** t-SNE visualization of reaction vectors for (a) Suzuki–Miyaura coupling encoded by UMA, where colors and marker shapes represent cation and anion types of the base, respectively, and (b) Buchwald–Hartwig amination encoded by FRAD, where colors and marker shapes represent halogen and aromatic ring types of the aryl halide, respectively.

To efficiently explore high-yield conditions within a limited experimental budget, we systematically benchmarked a variety of black-box optimization algorithms. In previous reaction optimization studies, Bayesian optimization (BO), which learns a surrogate model from observed data and proposes the next experimental conditions through an acquisition function, has been widely adopted. However, chemical reaction spaces are characterized by a high proportion of categorical/discrete variables, and the objective function is often non-smooth or multimodal, accompanied by experimental noise and constraints. These characteristics can conflict with the smoothness and stationarity assumptions underlying standard GP-based BO, potentially degrading its performance. Moreover, BO has frequently been reported to encounter challenges with high-dimensional bottlenecks, where exploration becomes more challenging as the number of dimensions increases [14]. Additionally, its computational demands grow with the accumulation of data, which restricts its scalability in closed-loop settings. Therefore, rather than relying on a specific algorithm, this study broadly compared and evaluated algorithms with different search mechanisms from the perspective that optimal strategies may vary depending on the structure of the reaction space and experimental scenarios. The optimization algorithms used in this study, along with their classification, are summarized in Table 2.

**Table 2**. Categories of black-box optimization algorithms benchmarked in this study.

| Category | Algorithms |
|---|---|
| Bayesian Optimization | EDBO [2], Gryffin [15], BoTorch [16], ProcessOptimizer [17], ATLAS [18] |
| Evolutionary Algorithms | DEAP [19], PSO [20], CMA-ES [21], PADDY [22] |
| Direct Search Methods | NOMAD [23], DIRECT [24] |
| Surrogate-assisted DFO | BOBYQA [25], SNOBFIT [26], BAM [27], PWAS [28] |

## Benchmarking Platform

To enable quantitative comparison of reaction representation and optimization algorithm combinations under identical conditions, we developed an end-to-end benchmarking platform that streamlines the entire workflow from reaction data input to result analysis and visualization. Users simply input a reaction dataset and select encoding methods and optimization algorithms; the platform then automatically performs search space

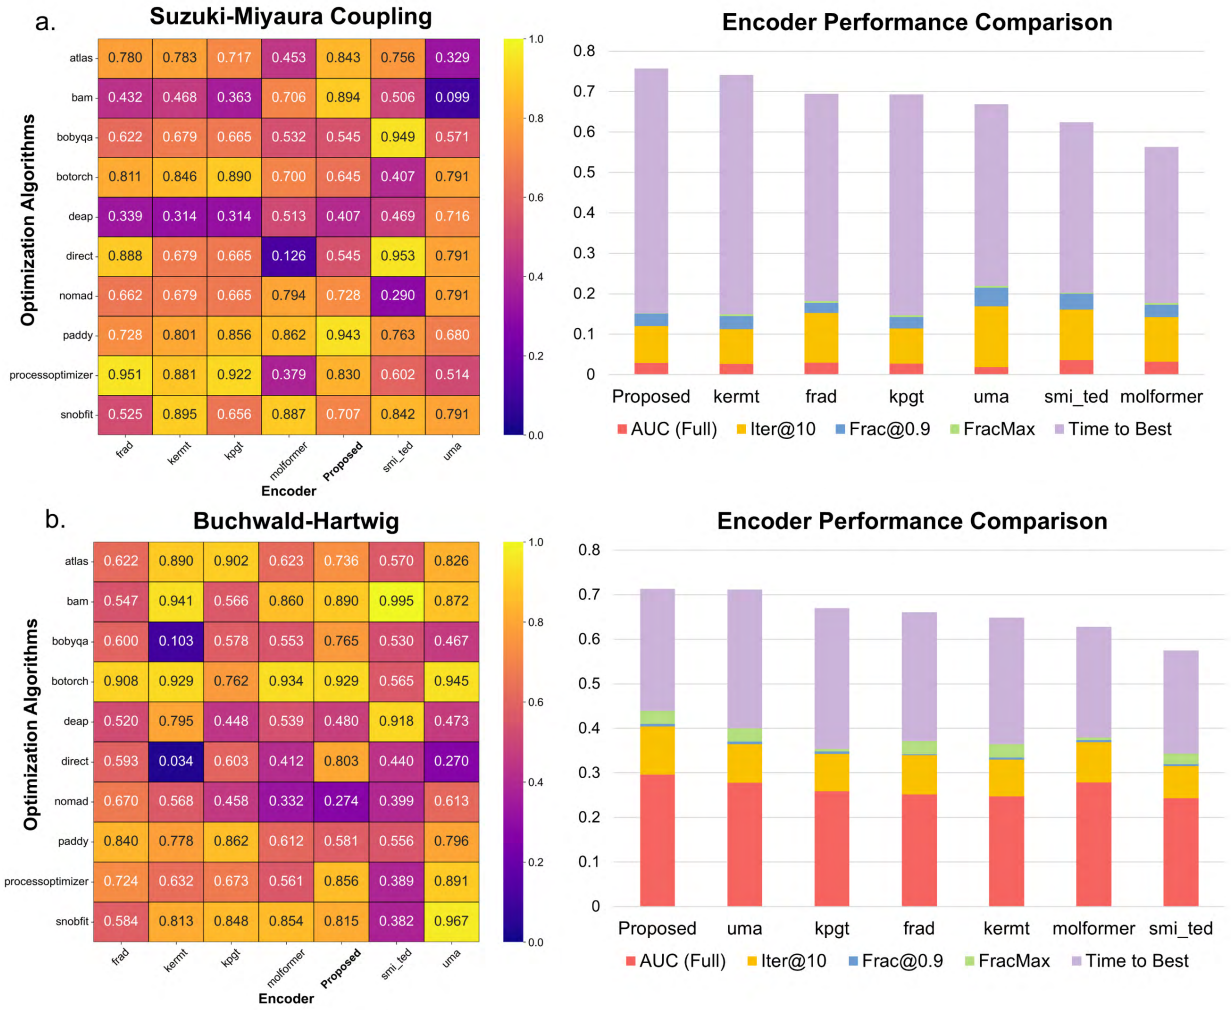

**Figure 3.** Optimization performance benchmarking for (a) Suzuki–Miyaura coupling and (b) Buchwald–Hartwig amination. Left: heatmap of final scores (weighted sum of five evaluation metrics) for each encoder–algorithm combination. Right: aggregated encoder performance across five evaluation metrics.

construction, optimization iterations, performance evaluation, and result reporting. The platform analyzes the input dataset to identify the objective function and decision variables, classifies each variable as categorical/discrete or continuous, and applies appropriate encoding and scaling rules to construct the search space. For reaction representation, the platform employs the pipeline described in the previous sections. To resolve package version compatibility issues between pretrained models, independent Docker-based virtual environments were established for each model.

All algorithms are evaluated under identical budgets and a unified closed-loop protocol. At each iteration, the optimizer proposes the next experimental conditions based on accumulated observations, and the resulting objective values are appended to the history for use in subsequent iterations. To ensure fair comparison and reproducibility, the platform automatically logs all key information generated during optimization, including proposed conditions, observed objective values, and best-so-far trajectories. In addition, visualizations based on t-distributed stochastic neighbor embedding (t-SNE) and Uniform Manifold Approximation and Projection (UMAP) provide qualitative insight into exploration behavior over iterations.

# RESULTS

## Reaction Latent Space Analysis

### Suzuki-Miyaura Cross-Coupling

Suzuki–Miyaura cross-coupling forms C–C bonds between organoboron compounds and organic halides under palladium catalysis [29]. The dataset used in this study was constructed through high-throughput nanomole-scale reaction screening [30]. Reaction vectors

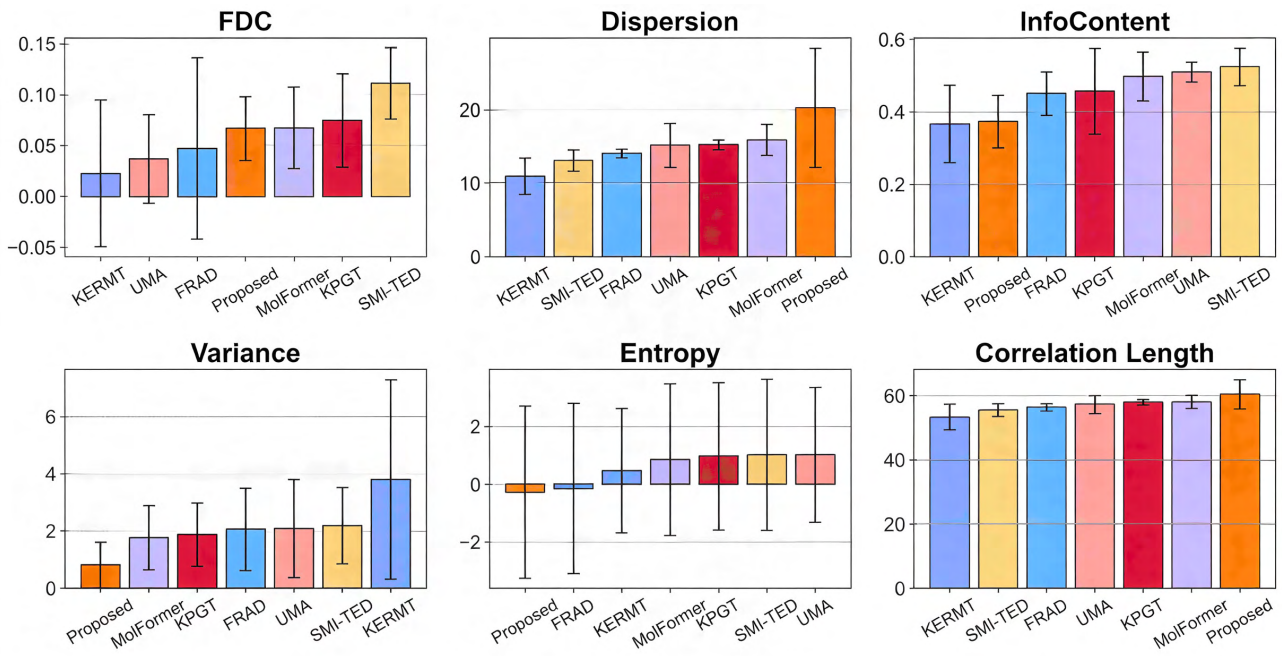

**Figure 4:** Fitness landscape metrics for each encoder, averaged across all reaction datasets. Six metrics are reported: fitness-distance correlation (FDC), dispersion, information content, variance, entropy, and correlation length. Bars indicate the mean value and error bars represent ±1 standard deviation.

were generated using UMA and visualized via t-SNE. The results revealed a hierarchical clustering structure dominated by the cation type of the base ($Cs^+$, $K^+$, $Li^+$, $Na^+$, and organic cations), with secondary sub-clustering by anion type (amine, carbonate/phosphate, carboxylate, fluoride, and hydroxide) within each cation region (Figure 2a).

This hierarchical structure reflects the underlying reaction mechanism. In transmetalation, the cation modulates the reaction rate through complexation with Pd-bound hydroxide [31, 32], while the anion determines the activation pathway [33]. The emergence of this chemically meaningful hierarchy without explicit supervision demonstrates that pretrained molecular encoders can capture mechanistically relevant features of reaction components.

## Buchwald-Hartwig Amination

Buchwald–Hartwig amination is a cross-coupling reaction that forms C–N bonds between aryl halides and amines under palladium catalysis [34]. The dataset was constructed through high-throughput, nanomole-scale reaction screening [35]. Reaction vectors generated by FRAD and visualized via t-SNE revealed that the structural characteristics of aryl halides governed the latent space distribution, with phenyl and pyridyl derivatives occupying distinctly separated regions (Figure 2b).

This separation reflects the underlying reaction mechanism. The nitrogen atom in pyridine induces stereoelectronic stabilization during oxidative addition, leading to a fundamentally different pathway from phenyl halides [36]. Within each ring type, further separation by halogen type was observed—iodine derivatives formed independent clusters, while bromine and chlorine derivatives intermixed, consistent with the reactivity order ArI > ArBr > ArCl. Meanwhile, ligands, bases, and additives exhibited uniform distributions, confirming that aryl halide structure is the dominant factor. These results demonstrate that pretrained encoders can identify the most mechanistically influential components without explicit reaction knowledge.

## Comparative Analysis of Encoder–Optimizer Combinations

For each reaction dataset, combinations of 7 encoders and 10 optimization algorithms were systematically compared under identical evaluation budgets and initial conditions. Performance was assessed using five metrics: AUC Full (area under the best-so-far curve over all iterations), Iter@10 (best-so-far yield at iteration 10), Frac@0.9 (number of iterations required to reach 90% of the maximum yield), FracMax (whether the global maximum yield was achieved), and Time to Best (the iteration at which the best value was first discovered). The final score for each encoder–algorithm combination was computed as a weighted sum of min-max normalized metrics. To verify that results are not sensitive to the weighting scheme, 100 random weight combinations were sampled from a Dirichlet distribution, confirming that the proposed

representation consistently ranked first regardless of weight choice. Figure 3 presents the heatmap of final scores and the aggregated encoder performance for each reaction.

In the Suzuki–Miyaura reaction, the proposed representation achieved the highest aggregated performance across all encoders, while maintaining a relatively stable performance on average across the 10 optimization algorithms. In contrast, other encoders exhibited larger performance fluctuations depending on the algorithm. For instance, MoLFormer scored 0.887 with SNOBFIT but only 0.126 with DIRECT, and UMA achieved 0.680 with PADDY yet dropped to 0.099 with BAM. Notably, the performance range of the proposed representation across algorithms (0.407–0.943) was narrower than those of MoLFormer (0.126–0.887) and UMA (0.099–0.791), indicating that the cross-attention-based reaction representation provides a latent space less sensitive to the choice of optimization algorithm.

In Buchwald–Hartwig reaction, the proposed representation also achieved the highest aggregated performance. It recorded high final scores with BoTorch (0.929), BAM (0.890), ProcessOptimizer (0.856), and SNOBFIT (0.815), indicating that the representation, which explicitly models interactions between reaction components, improves the fitting quality of surrogate models. Meanwhile individual molecular encoders exhibited high sensitivity to algorithm selection. For example, KERMT achieved 0.941 with BAM but dropped to 0.034 with DIRECT, and UMA recorded 0.967 with SNOBFIT but declined to 0.270 with DIRECT.

Overall, the proposed reaction representation demonstrated advantages in both robustness across algorithms and overall performance compared to simple molecular concatenation approaches. This is attributed to the fact that explicitly reflecting inter-component interactions in the latent space provides a structure that enables optimization algorithms to explore high-yield regions more efficiently. However, the proposed representation did not rank first in every reaction scenario, and cases where specific encoder–algorithm combinations were more advantageous depending on reaction characteristics were also observed. This supports the conclusion that no single optimal strategy exists, and the selection of an appropriate representation–algorithm combination tailored to the reaction scenario is important.

### Landscape Characterization of Latent Representations

To understand the structural basis of these performance differences, we analysed the fitness landscape induced by each encoder using six metrics derived from the length scale framework [37]: fitness-distance correlation (FDC), dispersion, information content, variance, entropy, and correlation length. FDC indicates how strongly better fitness values align with proximity to the global optimum. Dispersion describes whether good solutions are clustered or widely scattered in the space. Information content measures how rugged or irregular the landscape is to small perturbations. Variance represents the diversity of local gradients across flat and steep regions. Entropy captures the overall complexity and unpredictability of the landscape structure. Correlation length reflects how smoothly neighboring regions are connected. Figure 4 reports the average and standard deviation of each metric across all reaction datasets.

## CONCLUSION

The proposed representation exhibited the lowest variance, the lowest entropy, and the highest correlation length among all encoders. This combination indicates that the latent space formed yields a smooth, structurally simple landscape where the objective function changes predictably over long distances. Such properties are directly favorable for surrogate-based optimization, as they allow surrogate models to fit the underlying function more accurately with limited observations. The proposed representation also recorded the highest dispersion, suggesting that high-quality solutions are distributed broadly rather than confined to a narrow region, which benefits global search strategies. These landscape characteristics offer a structural explanation for the robust optimization performance observed in Figure 3.

This study proposed an integrated framework that combines foundation molecular representations with black-box optimization for organic reaction optimization problems and systematically analyzed its effectiveness. We demonstrated that the continuous latent representations from foundation models reflect molecular similarities learned from large-scale chemical data, thereby aligning the combinatorial space of reaction conditions into an optimization-friendly continuous representation space and enabling chemically meaningful exploration during the optimization process. In particular, by adopting UMA as the backbone and designing an interaction-aware reaction representation that explicitly models interactions between reaction components through bidirectional cross-attention, we confirmed that this design can address the dimensional increase and lack of interaction modeling in simple concatenation approaches. Furthermore, by utilizing the proposed representation as input design variables for optimization algorithms, we quantitatively demonstrated that various derivative-free optimization methods can effectively explore high-dimensional, mixed-integer reaction conditions under limited budgets, and showed that the advantageous representation–algorithm combinations may vary depending on the structure of the reaction scenario. Moreover, by analyzing the latent space generated by foundation

models, we demonstrated that the characteristics of the representation space can be closely related to optimization efficiency, providing empirical evidence for representation evaluation criteria from an optimization perspective that complements prediction-focused assessments.

In future work, we plan to extend this framework by integrating it with automated experimental equipment and SDLs, developing a closed-loop autonomous optimization system where robots execute the proposed experimental conditions and the results are fed back into learning and exploration. Through this, we aim to enhance the feasibility of autonomous reaction optimization that can identify high-performance conditions with minimal iterations even under limited experimental budgets.

## ABSTRACT

The electrification of regional aviation requires coordinated planning of airport energy systems that integrate renewable generation, energy storage, and hydrogen technologies in a cost-efficient and resilient manner. This paper presents a scalable techno-economic optimization framework that models multiple airports as collaborative energy hubs. An object-oriented mixed-integer linear programming (MILP) formulation is combined with a genetic algorithm (GA) to optimize infrastructure sizing and energy dispatch. The framework is applied to three Swedish regional airports—Västerås, Jönköping, and Visby. A set of scenarios, including parties operating under shared wind-energy contracts using power purchase agreements (PPAs) and dynamic pricing (DP), was studied. Detailed representations of battery energy storage, hydrogen production and storage, and market interactions are included. Results show that coordinated operation and airport collaboration under a smart energy management system can reduce total annual cost by up to 5% while enhancing operational flexibility and resilience to demand peaks and grid disturbances.

## INTRODUCTION

Over the past decade, there has been an increasing effort to reduce greenhouse gas emissions. Under the Paris Agreement and net-zero goals, countries should reduce their carbon emissions by at least 55% relative to 1990 levels by 2030. Transport remains a major source of anthropogenic $CO_2$, and aviation presently accounts for about 2.5 % of total emissions; without effective mitigation, this share could increase to around 22 % by 2025 [1]. Although aviation's footprint is comparatively modest today, expanding demand, further stimulated by new air mobility services, could drive substantial emissions growth.

In response, researchers are developing low-carbon propulsion technologies for aviation. Hydrogen-fueled aircraft, which emit only water vapor, rely on advances in fuel cell technology and cryogenic storage systems, while electric propulsion for short-haul routes requires significant improvements in battery energy density and power-to-weight ratios [2].

Electrified aviation starts with short-haul flights, which show how regional airports can serve as energy hubs and provide an affordable transportation option. However, transitioning to electrified airports requires significant infrastructure investments, including airport energy systems, grid connections, power generation, and storage. This transition will be especially tough for medium-sized and smaller regional airports.

The resilience of the energy system is another challenge in electrification. The term resilience was first introduced by Holling et al. [3] to describe the capacity of ecosystems to absorb change. Molyneaux et al. [4] adopt the concept of resilience in energy systems and review different scenarios to measure the system's resilience. Resilience is the ability to adapt to change and uncertainty while maintaining a consistent performance during the transformation [5].

The integration of hydrogen into the energy system poses challenges, including balancing cost efficiency with infrastructure scalability. These challenges are compounded by the need for flexibility to adapt to dynamic market conditions and by the integration of renewable energy sources. In a study, Almansoori et al. [6-7] propose a mixed-integer linear programming (MILP) framework to optimize hydrogen supply chains by minimizing

sizing and dispatching costs across different demand profiles.

Multiple objectives are often involved in optimizing hybrid energy systems. In a study, Zheng et al. [8] designed a multi-objective framework to assess the potential of photovoltaic (PV) systems and battery energy storage for grid integration and deployment in the charging infrastructure. Yan et al. [9] investigated the combined use of wind and solar energy with hydrogen systems for off-grid applications like airports. Despite the potential benefits of integrating PV panels and wind turbines, some studies [10] highlight conflicts with existing safety regulations.

Xiang et al. [11] employed MILP to model an integrated hydrogen-solar storage microgrid and evaluate scenarios involving combinations of hydrogen production, PV energy, and battery storage systems. Their study highlighted the need for further investigation into effective grid integration strategies.

The resilience of the hybrid energy system was evaluated by Zhao et al. [12], focusing on the airport with the hydrogen-integrated technologies. The study introduces a MILP framework to optimize hydrogen storage and operation under various levels of disruptions in grid capacity and hydrogen permeability. As a result, integrating hydrogen increases the system's resilience but also raises the total annual cost.

A more detailed MILP model for the airport energy network was investigated by Vouros et al. [13] for a regional airport, where the total annual cost was evaluated across different resilience levels.

This paper advances the techno-economic assessment of airport energy systems through a scalable, object-oriented framework combined with a hybrid MILP–genetic algorithm approach. Unlike conventional single-site studies, it captures inter-airport collaboration, renewable energy flexibility markets, and modular system expansion, enabling a more realistic and extensible analysis of coordinated multi-airport energy hubs.

## Electricity Pricing Schemes and Flexibility-Oriented Operation

Modern airport microgrids require the capability to adjust electricity supply and demand in near real time. Europe's electricity-market reform recognizes the role of flexibility markets in ensuring fair compensation for flexible resources such as energy storage, demand response, and dispatchable generation, while providing clear price signals for investment [14].

Long-term power-purchase agreements (PPAs) represent a common mechanism for valuing renewable electricity. Under a PPA, a buyer commits to purchasing a predefined quantity of electricity from a generator at a fixed price for 10–15 years. This agreement hedges against market volatility and allows risk sharing between contracting parties [15]. The contract price is often benchmarked against average wholesale market prices or a long-term forecast, with margins reflecting financing costs and risk preferences. Airports such as JFK [16] and Bristol [17] have adopted long-term renewable energy contracts.

The alternative dynamic pricing (DP) approach links electricity prices to real-time or day-ahead market outcomes. Dynamic tariffs reflect market-clearing prices and convey short-term supply conditions to consumers, incentivizing them to shift loads or operate storage systems [18]. In practice, suppliers often add a margin above the wholesale price to cover project financing and risk, which directly affects the economic attractiveness of storage and demand-response technologies that exploit price variability under dynamic pricing schemes.

While flexibility markets typically involve explicit participation of distributed energy resources through aggregators bidding into local or regional platforms operated by distribution system operators (DSOs), this study does not model such market structures explicitly. Instead, flexibility is represented implicitly through dynamic electricity pricing and coordinated dispatch of storage and conversion technologies at airport energy hubs. Long-term power purchase agreements (PPAs) are considered as bilateral contracts that provide price stability but do not constitute flexibility markets. On the other hand, dynamic pricing reflects changing system conditions over time and can encourage flexible operation of airport assets. This allows for system-level flexibility without the need for direct market involvement.

# METHODS

This section describes the assumptions, algorithms, and model structure. First, the details of the algorithm are presented, followed by the model structure and problem assumptions.

## Algorithm

The algorithm proposed in this work determines the optimal capacity and dispatch of the energy network for a multi-objective problem by combining MILP with the genetic algorithm (GA). The primary objective is to enable scalable modeling of energy networks for multiple airports. To achieve this, an object-oriented framework is implemented that leverages inheritance and encapsulation principles. Each component in the system inherits common base features, such as mass and energy balance constraints, while also retaining its own specific attributes. The overall problem formulation and optimization process are summarized as follows:

1. Airport object:

   An airport object is created and equipped with the required components, including energy storage

units, production technologies, market interfaces, and transportation systems. The capacity of each component can be defined as either a decision variable or a fixed parameter. A single problem instance may include multiple airport objects.

2. System connections:

   System components are interconnected either by user-defined instructions or by automatic configuration. These connections are subsequently used to formulate the mass and energy balance equations.

3. Energy network formulation:

   The energy network model is formulated as an MILP framework. Unit capacities can be optimized either directly within the MILP solver or through an outer-loop GA that explores the design space.

4. Optimization and results:

   The optimizer determines the optimal values of the decision variables according to the defined objective functions. The resulting solution is stored as a problem object for post-processing and analysis. The same object can subsequently be used for dispatch optimization under fixed unit capacities.

The final MILP model is generated based on the added components and their corresponding connections. Therefore, the implemented framework can be used for various applications, such as smart charging stations.

## Problem Definition

We study three potential airport infrastructures to support battery-electric and hydrogen-electric aircraft.

Västerås Airport (VST) is located in an industrial city near major cities such as Stockholm and Uppsala. The airport could use excess energy generated by local power plants and contribute to the network. In addition to handling short-haul training flights, this airport transports approximately 100, 000 passengers per year.

Visby Airport (VBY), located on the island of Gotland, experiences significant seasonal passenger inflow and supports occasional international traffic, particularly during the tourist season. While not a primary international hub, its island location and wind energy potential make it strategically relevant for decentralized electrification planning. According to Swedavia statistics, the airport handled around 300 flights per month in 2025. While recent studies focus on the current status and technical potential, several planning and expansion studies identify significant potential for increasing wind capacity on the island, both offshore and onshore. An offshore floating wind farm is planned for 2032 with a capacity of around 1.75 GW.

The third airport is Jönköping (JKG), which enables short-range flights to southern cities. Recent studies focus on the airport's future role by investigating various charging and battery-swapping scenarios.

**Figure 1.** Three airports in contract with a wind energy supplier collaborated to improve resilience under a smart energy management control system

In addition, all the candidates are based on the SE3 grid region and operate under the same grid company. Therefore, agreements between energy providers and airports that serve as hubs are easier to establish.
This paper examines different scenarios in which a smart energy management system dispatches energy for three airports with a PPA or DP contract with a wind energy supplier. The wind farm can provide up to 2 MW of capacity during peak production hours, as the energy must be shared among all three airports. This limit reflects near-term availability and grid access constraints, rather than the island's full wind potential.

**Table 1:** Number of weekly flights for Västerås, Jönköping, and Visby airports

| Airport | 2025 | 2035* |
|---|---|---|
| Västerås (VST) | 70 | 140 [13] |
| Jönköping (JKG) | 18 | 58 [20] |
| Visby (VBY) | 76 | 224 [21] |

## Flight Schedules

The flight schedule information was obtained from the OpenSkyNetwork [19] API. Figure 2 demonstrates estimated hourly flight schedules for VST, JKG, and VBY airports for a week. The number of flights and the fleet mix in 2035 are estimated based on the Swedavia Net Zero Roadmap and previous studies on Swedish airports, as shown in Table 1.

## Hybrid Airport Energy Network Architecture

The airport's hybrid energy system can be divided into multiple sections. The storage and generation units, hydrogen conversion technologies, demand, and supply. Figure 3 shows the detailed structure of the hybrid airport energy network.

PV cells and wind turbines are the main electricity generation units. The weather data, including solar

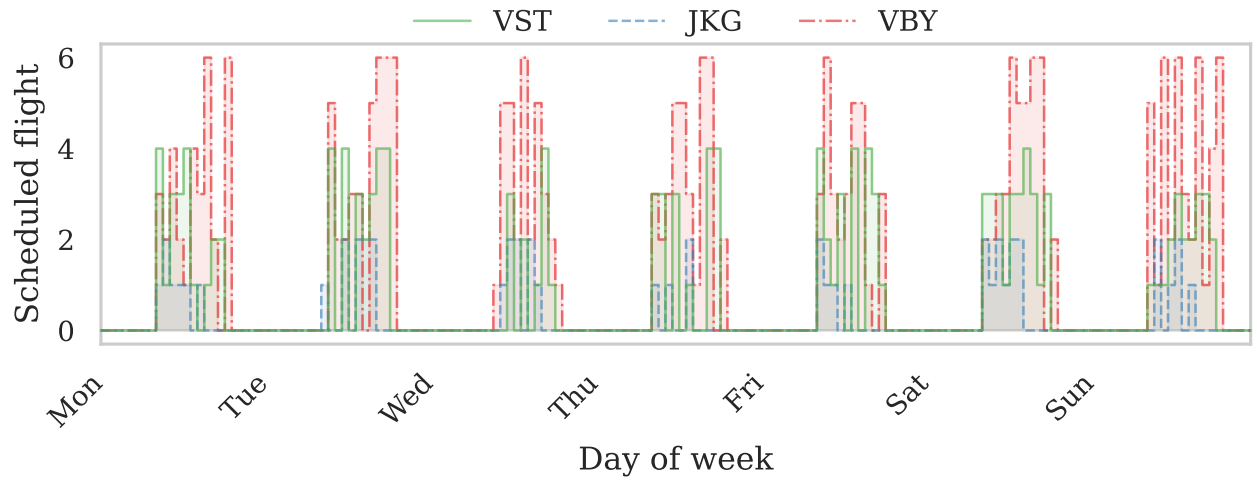

**Figure 2.** A representation of hourly flight schedules during a week

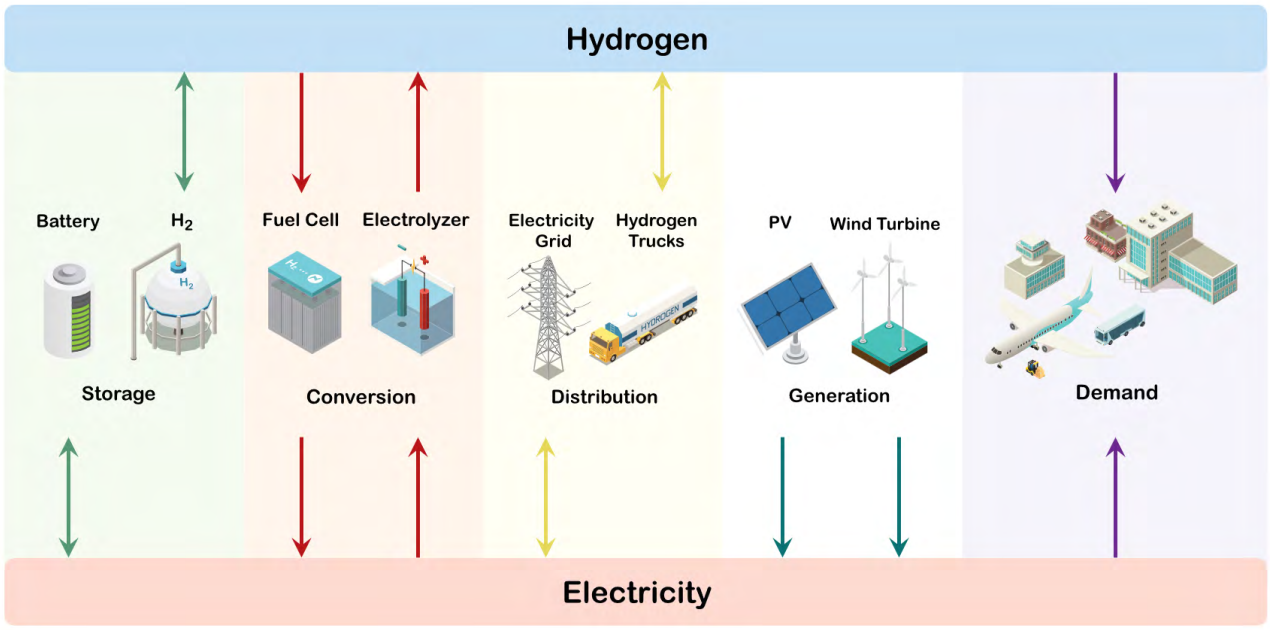

**Figure 3.** A schematic of mass and energy flow within an electrified airport energy network

irradiation and wind speed, are obtained from public databases such as SMHI [22] and PVLib [23]. Cut-in and cut-off wind speeds, as well as power curves, are considered during the data processing. Solar energy generation varies throughout the day based on the irradiation level and PV surface temperature. Equations (1-3) simplified, assuming panel and ambient temperatures are identical. Based on [24, 25], the equations for wind and solar energy are defined as:

$$P_k^{PV} = P_{STP}\frac{G_k}{G_{STP}}\left(1+\alpha_{pv}(T_{PV,k}-T_{STP})\right) \quad (1)$$

$$P_k^{WT} = P_k^{WT}(v_k) \quad (2)$$

The annual average accumulated global solar radiation is aligned with the Swedish records [26, 27].

BESS plays a critical role in peak shaving and providing short-term flexibility and buffering for the energy system. The battery model formulation, derived from [28], is outlined in Equation (3).

$$S_k^{bat} = S_{k-1}^{bat}(1-\beta^{bat}) + \left(\zeta_{ch}^{bat}\eta_{ch}^{bat}P_{ch,k}^{bat} - \zeta_{dch}^{bat}\frac{P_{dch,k}^{bat}}{\eta_{dch}^{bat}}\right)\Delta t \quad (3)$$

Where, the charging ($\eta_{ch}^{bat}$) and discharging efficiencies ($\eta_{dch}^{bat}$) in addition to a self-discharge term ($\beta^{bat}$) considered in the model to represent losses during the battery operation.

In order to isolate charging and discharging states, a pair of binary variables $\zeta_{ch,dch}$ is considered in (3), where:

$$\zeta_{ch} + \zeta_{dch} \leq 1 \tag{4}$$

Hydrogen tanks in both liquid ($H_2^l$) and vapor ($H_2^v$) phases are formulated in Equations (5-6). The term $\beta_{evap}^{H_2^l}$ shows the rate of evaporation for liquid hydrogen in the mass balance equations.

$$S_k^{H_2^l} = S_{k-1}^{H_2^l}\left(1 - \beta_{evap}^{H_2^l}\right) + \left(\zeta_{in}^{H_2^l} F_{in}^{H_2^l} - \zeta_{out}^{H_2^l} F_{out}^{H_2^l}\right)\Delta t \tag{5}$$

$$S_k^{H_2^v} = S_{k-1}^{H_2^v} + \beta_{evap}^{H_2^l} S_{k-1}^{H_2^l} + \left(\zeta_{in}^{H_2^v} F_{in}^{H_2^v} - \zeta_{out}^{H_2^v} F_{out}^{H_2^v}\right)\Delta t \tag{6}$$

The stored energy and hydrogen can be utilized in an electrolyzer and a fuel cell, respectively, to produce hydrogen and generate electricity during peak hours and provide flexibility for the system. The formulation for the fuel cell and electrolyzer is provided in (7-8).

$$F_k^{Elyz} = \frac{\eta^{Elyz}}{\alpha_{LVH}^{H_2}} P_k^{Elyz} \tag{7}$$

$$P_k^{FC} = \eta^{FC} \alpha_{LHV}^{H_2} F_k^{FC} \tag{8}$$

The airport can interact with the electricity and hydrogen market using the electricity grid connection and hydrogen transportation units, such as tube trucks and tank trucks. The hydrogen transportation units are limited and carry discrete amounts of hydrogen, with lower and upper limits. The electricity spot prices were retrieved from the Nord Pool platform. A synthetic DSO price is calculated taking into account the local energy tax and the DSO fee. While power purchases follow DSO prices, the selling value to the market is assumed to equal spot prices. In general form, each energy or mass stream in the system follows the balance equations. Mathematical formulation depends on the structure of hybrid energy networks. Equations (9-10) show the mass and energy balance.

$$P_k^i = \sum_j P_k^{ji} \tag{9}$$

$$F_k^i = \sum_j F_k^{ji} \tag{10}$$

Where $ji$ represents the stream from item $j$ to $i$. A non-negative constraint applied to the streams.

$$D_k^E \leq \sum_i P_k^i \quad \forall\, i \in \{bat, grid, FC, PV, WT\} \tag{11}$$

$$D_k^{H_2^l} \leq \sum_i F_k^i \quad \forall\, i \in \{liquef, H_2^l\} \tag{12}$$

$$D_k^{H_2^v} \leq \sum_i F_k^i \quad \forall\, i \in \{comp, H_2^v\} \tag{13}$$

The energy hub prioritizes airport demand while offering excess energy to the local grid to balance the load. The demand equations are shown in (11, 13).

The optimization includes design variables defined as:

$$N_{min}^i \leq N^i < N_{max}^i \;\; \forall\, i \in \{bat, FC, Elyz, H_2^l, H_2^v, comp, liquef\} \tag{14}$$

The objective of the design and optimization problem is to minimize total annual cost (TAC) while avoiding the power outage in (19).

$$\text{CAPEX} = \sum_i \left(\frac{L_{sys}}{L_{cyc}^i}\right) N^i C_{cap}^i \;\; \forall\, i \in \{bat, FC, Elyz, H_2^l, H_2^v, comp, liquef\} \tag{15}$$

$$\text{OPEX} = \sum_i \left(Q_{buy,k}^i C_{buy,k}^i - Q_{sell,k}^i C_{sell.k}^i\right) \quad \forall\, Q \in \{P^{grid}, F^{tat}, F^{tut}\}, \forall\, i \in \{grid, tat, tut, wt\} \tag{16}$$

$$CRF = \frac{r(1+r)^{L_{sys}}}{(1+r)^{L_{sys}} - 1} \tag{17}$$

$$\text{TAC} = \text{CRF} \times \text{CAPEX} + \left(\frac{\alpha}{\tau_{\text{sim}}}\right) \times OPEX \tag{18}$$

$$\min \;\; TAC + \sum_i \sum_{k=1}^{\tau_{sim}} w^i \delta_k^i \quad \forall\, i \in \left\{D^E, D^{H_2^l}, D^{H_2^v}\right\} \tag{19}$$

## System Parameters

This section covers both technical and economic parameters. Design variable constraints set upper and

lower limits on decision variables. Table 2 presents the limits for the system's decision variables.

**Table 2.** Design variable constraints

| Symbol | Description | Value |
|---|---|---|
| $C_{max}^{bat}$ | Maximum battery capacity | 200 MWh |
| $C_{max}^{H_2^v}$ | Maximum vapor $H_2$ tank capacity | 4000 kg |
| $C_{max}^{H_2^l}$ | Maximum liquid $H_2$ tank capacity | 6000 kg |
| $C_{max}^{FC}$ | Maximum fuel cell capacity | 7 MW |
| $C_{max}^{Elyz}$ | Maximum electrolyzer capacity | 10 MW |
| $C_{max}^{comp}$ | Maximum compressor capacity | 200 kg/h |
| $C_{max}^{liquef}$ | Maximum liquefaction unit capacity | 60 kg/h |

To model airport energy system infrastructures incorporating hydrogen and energy storage technologies, it is essential to adopt up-to-date cost projections for both capital expenditures (CAPEX) and operation and maintenance (O&M) costs. Accordingly, this study synthesizes current and future cost estimates for key components, including green hydrogen production, battery energy storage systems, fuel cells, electrolyzers, hydrogen storage tanks in both compressed gaseous and liquid forms, and hydrogen delivery infrastructure. At present, green hydrogen production remains relatively costly due to its strong dependence on renewable electricity inputs. However, continued technological learning, economies of scale, and declining renewable energy costs are expected to substantially reduce production costs, with several projections indicating that green hydrogen could reach prices below 2 €/$kg_{H_2}$ by 2035.

**Table 3.** Cost estimation per unit for key equipment in the hybrid energy system

| Equipment | Unit | 2025 | 2035 | 2050 | Ref. |
|---|---|---|---|---|---|
| Electrolyzer (Alkaline/PEM ) | €/kW | 270 – 900 [600] | 200 – 700 [450] | 120 – 270 [200] | [29,30] |
| Fuel Cell (PEM, stationary) | €/kW | 600 – 1200 [900] | 250 – 600 [500] | 80 – 300 [180] | [12,29] |
| $H_2^v$ tanks (350-700 bar) | €/$kg_{H_2}$ | 500 – 900 [700] | 400 – 600 [500] | 250 – 450 [350] | [11,13] |
| $H_2^l$ tanks | €/$kg_{H_2}$ | 1150 – 1450 [1350] | 1200 – 1300 [1250] | 900 – 1200 [1000] | [11,13] |
| Battery Storage (Li-ion) | €/kWh | 260 – 350 [300] | 180 – 270 [220] | 95 – 275 [160] | [21,29] |

## Scenarios

This section describes the scenarios studied in this research. Table 4 lists the scenarios analyzed in the following section. The first scenario, which includes design and dispatch optimization, is considered the basis for comparison. Scenarios 2-5 ($S_{2\text{-}5}$) represent base-case sizing as we evaluate various combinations of contract type and involvement.

The term "Collab" indicates the involvement of all three airports in contact with the wind energy supplier. While no collaboration considers only the VBY airport for accessing wind energy. $S_{10}$ and $S_{11}$ use the same design as $S_7$, and $S_6$ to evaluate the effect of switching to PPA while the system is optimized for the DP contract.

**Table 4.** Description of different scenarios

| $S_i$ | Sizing | Wind | Collab | Contract | Margin [%] |
|---|---|---|---|---|---|
| 1 | ✓ | - | - | - | - |
| 2 | - | ✓ | ✓ | PPA | 0, ±5, ±10 |
| 3 | - | ✓ | - | PPA | 0, ±5, ±10 |
| 4 | - | ✓ | ✓ | DP | 0, 5, 10 |
| 5 | - | ✓ | - | DP | 0, 5, 10 |
| 6 | ✓ | ✓ | - | DP | 0, 5, 10 |
| 7 | ✓ | ✓ | ✓ | DP | 0, 5, 10 |
| 8 | ✓ | ✓ | ✓ | PPA | 0, ±5, ±10 |
| 9 | ✓ | ✓ | - | PPA | 0, ±5, ±10 |
| 10 | - | ✓ | ✓ | PPA | 0, ±5, ±10 |
| 11 | - | ✓ | - | PPA | 0, ±5, ±10 |

## Computational Setup

The framework is implemented in Python 3.9 [29] using GEKKO Optimization Suite [30] for MILP formulation within an object-oriented structure, with AMPL [31] and CPLEX [32] as external solvers. Its modular design supports extension to larger airport networks and other multi-energy hub systems. The full GA optimization (40 generations, population 200) requires around 20 hours on an Intel i7-13700HX processor and 32 GB of RAM.

# RESULTS AND DISCUSSION

The selection of the optimization time window can impact the final result. While a larger window yields a more general solution, it also increases computational cost. Therefore, the effect of window size is studied in Figure 4. A one-week window should reflect the system's demand and supply, given that flight schedules follow a weekly pattern at most airports.

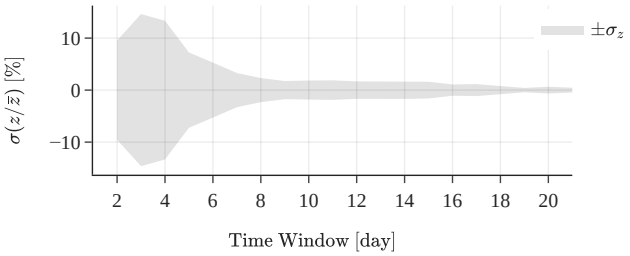

**Figure 4.** Variance of the difference between objective functions against different optimization window sizes for multiple starting dates in a year

Table 5 presents a selection of scenarios observed in this study, assuming a 5% margin for under-contract cases to ensure mutual benefits. The complete results report is available in the supplementary materials section. The MILP models for all scenarios were solved using CPLEX, with an optimality gap of 0.5%.

**Table 5.** CAPEX and OPEX values for selected scenarios

| $S_i$ | CAPEX [MEuro] | OPEX [MEuro] | Δ*OPEX* [%] | TAC [MEuro] | ΔTAC [%] |
|---|---|---|---|---|---|
| 1 | 41.25 | 8.45 | 0.0 | 11.76 | 0 |
| 2 | 41.25 | 8.1 | -4.1 | 11.42 | -2.9 |
| 4 | 41.25 | 8.2 | -2.9 | 11.51 | -2.1 |
| 6 | 42.17 | 8 | -5.4 | 11.38 | -3.2 |
| 7 | 40.9 | 8 | -5.3 | 11.29 | -4 |
| 8 | 39.77 | 8.22 | -2.7 | 11.41 | -3 |
| 9 | 40.73 | 8.26 | -2.3 | 11.53 | -2 |
| 10 | 40.83 | 8.15 | -3.5 | 11.43 | -2.8 |

The base scenario has the highest capital and operating costs and suggests higher storage capacity to meet

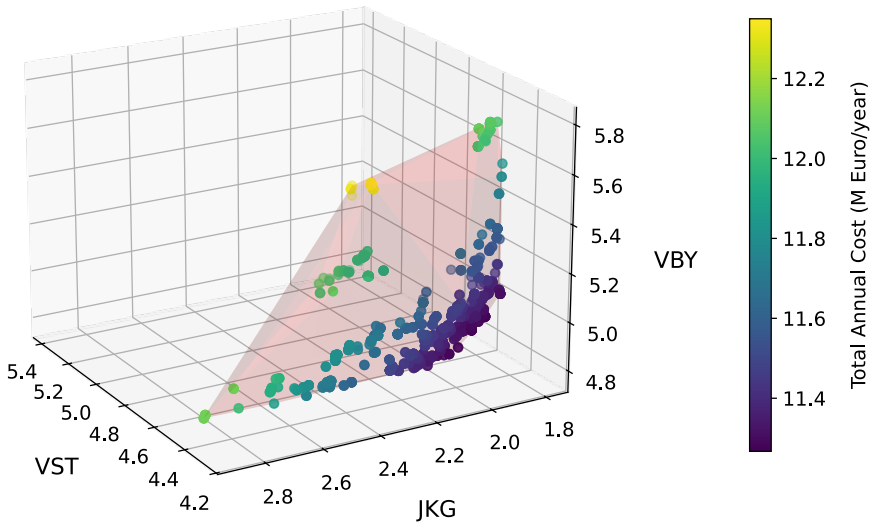

**Figure 5.** The optimal design and dispatch candidates from the last population of GA based on the total annual cost for VST, JKG, and VBY airports

demand during peak hours.

$S_2$ and $S_3$ show the effect of the contract with the wind farm, considering a fixed optimal design from the base scenario. In addition, $S_2$ represents the advantage of airport collaboration, reducing operational costs under normal conditions and providing room for resilience during unforeseen surges.

The scenarios with equipment sizing, while keeping up with demand, eliminate design redundancy and identify an optimal dispatch profile to reduce both OPEX and CAPEX. While the DP contract offers lower OPEX, a market study must still be conducted to reduce planning risk. On the other hand, PPA offers a fixed price for energy over a long period to mitigate spot price volatility. Considering the cost gap between $S_7$ and $S_8$, and the long-term energy price, one of these two scenarios may be the optimal choice. Despite a reduction of up to 5% in TAC, airports can meet demand and remain more flexible with the same base investment in the face of potential system disruptions.

All the case studies so far assume TAC is the sum of TAC across all individual airports. However, when it comes to collaboration and resilience, airports have the right to invest independently to achieve their own goals. To address conflicts among objectives, a three-objective optimization problem was solved using a GA to minimize TAC for the studied airports, under the assumptions in $S_7$. Figure 5 shows the optimal GA population after 50 generations with a population size of 200.

Three samples from the corners of the optimal surface were selected to represent cases in which each airport takes a major part in the investment. Another sample was selected to demonstrate minimal investment across all airports, bringing the total to four. The selected candidates are shown in Figure 6. By moving away from the optimal area, we offset the economic decision by increasing the system's flexibility. However, the pool of optimal candidates provides a guideline for moving toward a more resilient design.

While the TAC is almost identical across these cases, the individual's share of the total investment ranges from 0% to 90%, compared with the minimum-investment case. The TAC for these candidates is shown in Figure 7. An airport network represents a selected candidate and the objective value associated with each airport. The amount of TAC for all three airports aligns with their weekly load.

Figure 8 shows the decision variables for all airports among the selected candidates. One option to increase the VST airport's resilience is to invest in a fuel cell to handle sudden grid interruptions or utilize hydrogen to generate electricity on demand. This results in an 18% increase in TAC, representing the worst optimal point for VST. The same information applies to the VBY airport in describing candidate three.

The second network has the highest investment share for JKG, suggesting that investing in Battery is optimal. Based on the observations, BESS capital cost dominates the problem's objective value. In other words, the cost of battery storage technologies has a high impact on the future of electrification. In this case, increasing battery storage capacity improves disturbance rejection and peak shaving at JKG airport. As a result, BESS is a short-term solution to meet demand and handle grid outages for a couple of hours.

Hydrogen storage, on the other hand, despite its

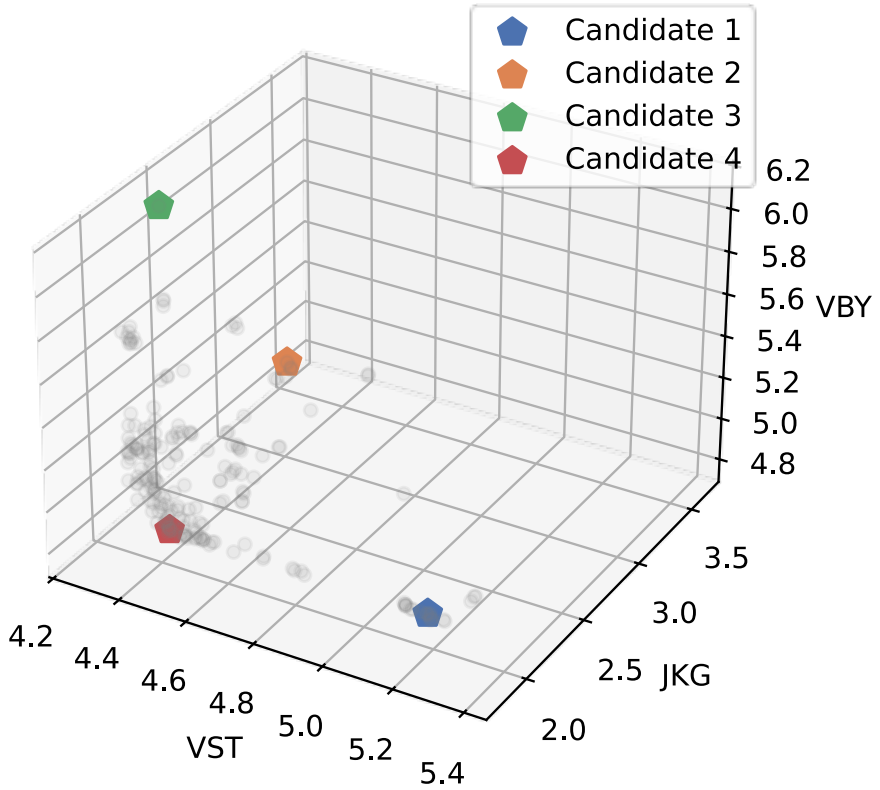

**Figure 6.** Total annual cost of VST, JKG, and VBY airports with respect to optimal candidates from the GA final population

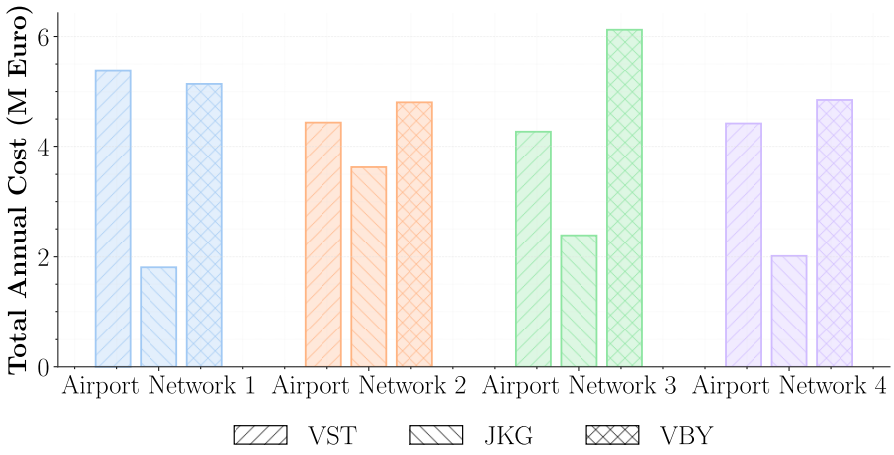

**Figure 7.** Total annual cost of VST, JKG, and VBY airports for the selected optimal candidates

lower efficiency at converting to electricity, is considered better at withstanding higher load spikes and sustaining longer grid outages. Therefore, investing in hydrogen technology is recommended for larger airports such as VST and VBY to increase the system's resilience.

The fourth airport network suggests greater investment in hydrogen storage, a liquefaction unit, and an electrolyzer. The result is promising, as this candidate has the lowest TAC across all airports. In conclusion, airports can take advantage of hydrogen production units rather than relying on the market. A detailed market study that accounts for safety and operating costs is required to reach a final conclusion.

From a system perspective, coordinated airport operation provides implicit benefits to the electricity grid by smoothing demand peaks and absorbing excess renewable generation. Optimized dispatch of battery and hydrogen storage enables load shifting away from high-

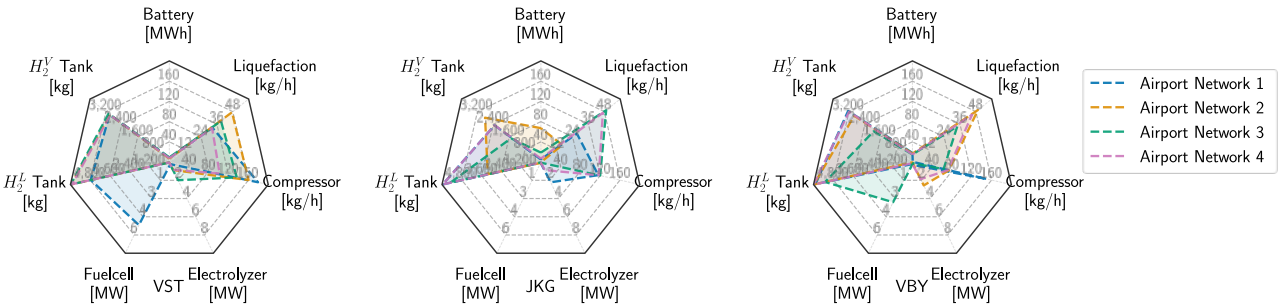

**Figure 8.** A comparison of decision variable values for the selected optimal population

priced periods and reduces reliance on grid imports during peak hours. In addition, the ability to export surplus electricity during periods of high renewable generation helps balance the local grid and mitigate congestion. Although these services are not monetized through an explicit flexibility market in this study, the results demonstrate that airport collaboration can provide flexibility-relevant services that are valuable for distribution system operation.

Beyond airport applications, the proposed framework is transferable to other multi-energy systems with distributed assets and flexible market interactions, such as smart charging networks, industrial energy hubs, and islanded microgrids. Its object-oriented structure enables scalable representation of interconnected nodes and shared resources, making it suitable for analyzing coordinated operation in energy communities and regional energy clusters. This highlights the framework's potential as a scalable decision-support tool for designing and operating complex, multi-vector energy systems under evolving market and regulatory conditions.

## CONCLUSION

This work formulates a mixed-integer linear programming (MILP) model, embedded in an object-oriented framework and combined with a genetic algorithm, to optimize the sizing and operation of electrified airport energy hubs. Applied to a network of three regional airports, the approach demonstrated that coordinated operations and shared renewable contracts can reduce total annual costs by up to 5% while increasing flexibility during demand surges. Battery energy storage emerged as the primary contributor to capital cost and is effective for short-term resilience, whereas on-site hydrogen production and storage provide longer-duration security and can further lower costs for larger facilities. The study also illustrates that contract selection (dynamic pricing versus fixed price) influences the balance between operating costs and market exposure and that coordinated dispatch yields ancillary benefits for the local grid by smoothing peaks and absorbing excess renewable generation. These results suggest that future airport energy systems should prioritize coordinated operation, hybrid storage integration, and market-aware design to achieve cost-effective and resilient electrification.

## ABSTRACT

This study presents different approaches for introducing mixed integer problems into a meta-heuristic algorithm. The algorithms are developed to address the simultaneous design and optimization of a heat pump unit. A distinction is made between integer variables such as nominal tube diameters and the adsorbent employed in the process. The choice of adsorbent is named as a "key variable" due to its high impact on the process. To optimize the selection of these "key variables", a branched version of Particle Swarm Optimization (PSO) is presented and compared with the non-Branched version and a deterministic solver (IPOPT). Advanced Convergence Criterion is also implemented to mitigate the computational effort of these approaches. In the studied cases, Branch_PSO presents a higher degree of consistency and can even outperform the traditional PSO in simultaneous process optimization and material screening. However, its computational effort in cases with a large number of branches might be an obstacle.

**Keywords**: Optimization, Particle Swarm Optimization, Adsorption, Energy Systems, Energy Efficiency, Mixed Integer nonlinear problems, Key Variables, Heat Pumps, Material Screening

## INTRODUCTION

Mixed Integer Nonlinear Programs (MINLP) are complex optimization problems that combine nonlinear objectives or constraints with integer variables. They frequently arise in fields such as engineering, economy, and logistic planning. Classic examples of such problems are the development of superstructures to determine which equipment shall be used in a certain process to maximize profit or operation scheduling to make the most of the resources available according to the requested shipments [1].

A possible approach to MINLP is the adaptation to a Nonlinear Program (NLP) via the relaxation of the integer variables into continuous ones. Another approach relies on the model adaptation by converting the nonlinear equations into linear ones, diminishing the problem's complexity. When no simplification is used, MINLP optimization can be achieved through deterministic methods, such as Branch-and-Bound (BB). A comprehensive review of those methods and commercial solvers applied to MINLPs can be found in Kronqvist et al. [2].

Nonetheless, there are some limitations to the deterministic methods. For example, they are usually unreliable when it comes to nonconvex problems, forcing a conversion into a convex problem, which is not always possible, or they fail to reach the global optimum by getting stuck in local optima or due to the premature cut of the branch that contained it (in the case of branch-based methods) [3].

Therefore, Evolutionary Algorithms have emerged for MINLP to avoid the previously mentioned problems. In the case of genetic algorithms (GA) [4] and Artificial Bee Colony (ABC) [5], the coding and decoding processes can be modified to encompass the existence of discrete variables. For Particle Swarm Optimization (PSO), the methodologies vary. The most common one is considering the discrete variables as continuous in terms of

evolution and rounding them off before the evaluation [6]. The rounding operation can be performed by simply using the round operator in the code language or by vertex approximation, as described further in the work of Chowdhury et al. [7]. An alternative approach uses operators such as sigmoid functions that affect the velocity of binary or discrete variables, ensuring their integer nature [8].

It is also common to encounter cases in the literature where multiple optimization strategies are combined to take advantage of their individual strengths. An example of this can be seen in Nema et al. [9], where a Hybrid PSO-BB is implemented. In that case, branch-and-bound is used to enhance convergence and PSO ensures the exploration of the problem domain to avoid being trapped in local minima.

However, the integer variables are rarely used as a key to altering the properties of the problem. From a process engineering perspective, the integer side of the problem is more commonly associated with variables such as the nominal pipe diameter or number of trays within a distillation column. This means that the variables considered have a sense of continuity despite their discontinuous nature, since the insufficiency of a variable value leads to the evaluation of the next higher value available, much similar to climbing a ladder.

When other types of integer variables such as the type of catalyst, solvent, or adsorbent materials are considered, the evaluation may not have that continuity. The optimal operating conditions for each material are rarely the same due to their different properties. By changing the evaluated material, the optimum for the process operation is likely to change, hampering the process optimization. As such, the sense of continuity is not naturally present in their evaluation. It is easier to think of such variables as keys on a key chain. When looking for the right key, trial-and-error is usually the chosen approach. It is not uncommon for the first try (key B) not leading to an open door, but neighboring keys (A and C) have no correlation with key B and choosing the next key to try is not evident.

Some techniques can be employed to mitigate this problem. One can use logic criteria to order the variables (ex. sort the adsorbents by their maximum capacity of adsorption). In the specific case of evolutionary algorithms that rely on random attributes for determining the values to be used in the next iteration, such as PSO, it is also possible to increase the number of evaluations to ensure proper exploration. That increase comes at the cost of higher computational effort, but can be an advantage for statistical analysis of the results obtained. At last, one can isolate the "key variables" and solve the optimization problem individually for each of the possibilities and then analyze the overall results. This last approach might not be viable if the problem considers multiple "key variables" (e.g. evaluating multiple catalysts for a reactor superstructure)

The present work aims to explore the impact of the "key variables" in MINLP optimization when using PSO algorithms. For that purpose, a base PSO algorithm considering rounding of operations was compared to a Branch_PSO. Additionally, advanced convergence criterion was also considered. A deterministic solver (IPOPT) was also considered in the comparison. The different algorithms were compared based on the performance obtained during the optimization of a material screening with simultaneous process optimization for adsorption heat pumps.

## METHODS

In this work, four different PSO algorithms were compared:

- Base_PSO
- Branch_PSO
- Base_PSO_ACC
- Branch_PSO_ACC

These four algorithms were also compared with the deterministic method known as IPOPT (Interior Point OPTimizer). The case study considered in this study was the simultaneous design and optimization of adsorption heat pumps, as presented by Silva et al. [6].

The algorithms and the case studies are detailed in the following subsections.

### Base_PSO

Amongst the different variations of the PSO algorithms presented in the literature, the one chosen as a comparison base was Constraints-based Sliding Particle Swarm Optimizer (CSPSO). CSPSO was introduced by Nogueira et al. [10] and adapted for later works in the optimization of chemical processes [6, 11-14]. CSPSO will be referred to as Base_PSO for the remainder of this paper.

The Base_PSO evaluates the MINLP by considering the integer variables as continuous ones and then rounding up their value upon the objective function evaluation.

For better understanding of Base_PSO, the corresponding equations and algorithm can be consulted in the referred papers or in the Supporting Information.

### Branch_PSO

To evaluate the impact of the rounding operation on the previous algorithm, the integer variables were updated externally through the logic statements presented in Algorithm 1.

**Algorithm 1.** Branch_PSO operation.

Define $N_d$.
Create $C$.
Define $N_C$.
for i=1:$N_C$:
  Run PSO for $C(i)$, updating only the continuous variables.
  Save $Y_{globest_branch}$ and $X_{globest_branch}$
end
Find $Y_{globest} = \min$ or $\max(Y_{globest_branch})$ and respective $X_{globest}$

In this algorithm, $N_d$ is the number of discrete variables, $C$ is the list of all the possible combinations (branches) of values for the discrete variables, $N_C$ is the number of possible combinations (branches) obtained, $C(i)$ is the branch that is being evaluated in the $i$th run of the PSO algorithm, $Y_{globest_branch}$ is the vector that stores the global optimum found for each branch correspondent with the particle position $X_{globest_branch}$, $Y_{globest}$ is the best optimum amongst all branches in the $X_{globest}$ position. The position of the $N_p$ particles defines the values for the decision variables.

## Advanced Convergence Criterion (ACC)

During a PSO run, the number of iterations required to reach the optimal solution is often overestimated. Due to that, the PSO algorithm keeps on running even after effective convergence has been achieved, merely concentrating the particles around the optimal region without significant improvement in the global best solution. To overcome this limitation, an advanced convergence criterion is proposed.

Instead of relying exclusively on a predefined maximum number of iterations ($N_{it_{max}}$), the proposed criterion monitors the variation of the global best value between successive iterations. Convergence is assumed when the difference between the current and previous best values remains below a predefined threshold ($error_{crit}$) for a given number of consecutive iterations ($c_{it_{min}}$). This approach ensures that the optimization process is terminated only after a consistent solution has been identified, avoiding redundant and unnecessary iterations. This procedure is presented in Algorithm 2.

**Algorithm 2.** Advanced Convergence Criterion.

Set $Y_{globest_{before}} = \infty$
Set $k = 0$
Set $c_{it} = 0$
while $k < N_{it_{max}}$
  Run one PSO iteration.
  $error_k = Y_{globest} - Y_{globest_{before}}$
  if $error_k < error_{crit}$
  then Set $c_{it} = c_{it} + 1$
  else Set $c_{it} = 0$
  end
  if $c_{it} = c_{it_{min}}$
  then break
  end
  Set $Y_{globest_{before}} = Y_{globest}$
  Set $k = k + 1$
end

In this algorithm, $c_{it}$ is the number of consecutive iterations that were assumed converged based on the cut-of criterion.

The application of this criterion to the Base_PSO and Branch_PSO resulted in Base_PSO_ACC and Branch_PSO_ACC algorithm, respectively.

## IPOPT solver

To compare the performance of the developed algorithms, the IPOPT solver was also implemented to the same case study as the PSO.

The IPOPT (Interior Point OPTimizer) is used for large-scale Nonlinear Problems and is available as an open-source software package. The solver was implemented through the `cyipopt` library in Python [15].

The solver is based on barrier methods and therefore requires information about the derivatives of the constraints and objective function, unlike the PSO algorithm [16].

To approximate the Branch_PSO behavior, the solver was used in a similar way as described in Algorithm 1, with the integer ("key") variables being handled externally.

The calculation of the Objective Function derivative was made based on the forward finite-differences method with a step of $10^{-6}$.

## Case study: Design and optimization of adsorption heat pumps

Since the major distinction made between "ladder" and "key" variables lies with the physical and processual meaning the integer variables acquire within a process or operation, the different algorithms were compared within a design and optimization problem of a given processual unit. The comparison of the algorithm's performance under typical benchmark problems could not demonstrate the impact of the "key" variables evaluation methods and is not presented in the present paper.

The processual unit chosen for the case study was

an adsorption heat pump (AHP). Adsorption-based heat pumps offer a sustainable alternative to conventional heating technologies due to their low electricity consumption and ability to operate with renewable or waste heat sources [17, 18]. Their performance strongly depends on the choice of the adsorbent–adsorbate pair, making material screening and optimization essential to identify high-efficiency systems [19-21]. Usually, the operation cycle of AHPs is generically represented as pictured in Figure 1.

Isosteric heating and isobaric desorption are the steps where heat is supplied to the adsobent bed in the amounts $Q_{\text{heat}}$ and $Q_{\text{des}}$, respectively, and $Q_{\text{cond}}$ is produced as the working fluid is condensed. During the isosteric cooling and isobaric adsorption, heat is released to the environment in the amounts $Q_{\text{cool}}$ and $Q_{\text{ads}}$ and the working fluid is once again evaporated with the heat provided $Q_{\text{evap}}$.

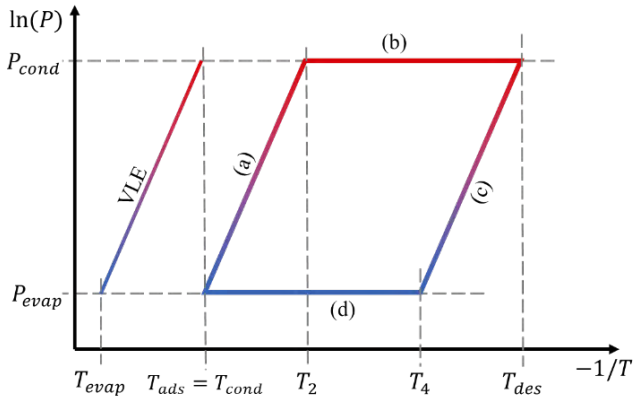

**Figure 1.** Diagram of ln(*P*) vs −1/*T* of an adsorption heat pump's cycle operation [vapor liquid equilibrium, isosteric heating (a), isobaric desorption (b), isosteric cooling (c), and isobaric adsorption (d)].

The performance of the equipment is measured by the coefficient of performance ($\text{COP}_{\text{heat}}$), calculated by Equation 1. This coefficient expresses the amount of heat produced by unit of heat required to operate the unit. $Q_{\text{evap}}$ is considered ambient provided heat and therefore not considered within the required heat.

$$\text{COP}_{\text{heat}} = \frac{Q_{\text{cond}}+Q_{\text{ads}}+Q_{\text{cool}}}{Q_{\text{des}}+Q_{\text{heat}}} \quad (1)$$

In the study of Silva et al. [6], it is possible to encounter more details about the model equations, the adsorbent materials and the parameters considered in the model simulation. These are not included here for the sake of brevity.

The optimization problem is summarized below.

$$\max_{T_{\text{evap}},T_{\text{cond}},T_{\text{des}},\text{Material}} \text{COP}_{\text{heat}} \quad (2)$$

*s.t.*

$$g_1 = q_{\min} - q_{\max} \leq 0 \quad (3)$$

$$g_2 = T_{\text{evap}} - T_{\text{cond}} + 5 \leq 0 \quad (4)$$

$$g_3 = T_{\text{cond}} - T_{\text{des}} \leq 0 \quad (5)$$

$$g_4 = T_4 - T_{des} \leq 0 \quad (6)$$

$$g_5 = T_{cond} - T_4 \leq 0 \quad (7)$$

$$g_6 = T_2 - T_{des} \leq 0 \quad (8)$$

$$g_7 = T_{cond} - T_2 \leq 0 \quad (9)$$

$$T_{evap} \in [280.0, 303.0]\ \text{K} \quad (10)$$

$$T_{cond} \in [309.0, 365.0]\ \text{K} \quad (11)$$

$$T_{des} \in [345.0, 473.0]\ \text{K} \quad (12)$$

$$\text{Material} \in \{1, 2, 3, 4, 5, 6, 7, 8, 9, 10\} \quad (13)$$

In this formulation, $q_{min}$ and $q_{max}$ are the minimum and maximum adsorbed amount (dependent on all the decision variables), $T_2 = T_{cond}^2/T_{evap}$ and $T_4 = T_{evap}T_{des}/T_{cond}$. In the PSO algorithms, the constraints were enforced by assigning the value of 100 (penalization) to the objective function whenever the constraints were not verified. In the IPOPT implementation, the constraints $g_2$-$g_7$ were applied within the solver algorithm. The same did not occur with the constraint $g_1$ because the IPOPT algorithm requires information about the derivatives of the constraints and that handling was not perceived as trivial, given the intricate equations at stake. Therefore, $g_1$ was handled with the penalization system in both PSO and IPOPT.

## Simulation

The material screening with simultaneous process optimization for adsorption heat pumps was implemented in a computer with 32 GB of RAM and an Intel(R) Core(TM) i7-14650HX (2.20 GHz), using Spyder 6.1.0, associated with Python 3.10.13 64-bit.

The parameters used in the four PSO algorithms considered can be found in Table 1.

**Table 1.** Parameters used in the PSO algorithms.

| | $N_p$ | $N_{it_max}$ | $error_{crit}$ | $c_{it_{min}}$ |
|---|---|---|---|---|
| Base_PSO | 3000 | 200 | | |
| Base_PSO_ACC | 3000 | 200 | $10^{-14}$ | 20 |
| Branch_PSO | 300 | 200 | | |
| Branch_PSO_ACC | 300 | 200 | $10^{-14}$ | 20 |

When it comes to the number of particles and iterations in the branched and base operation, the common rule is to maintain the number of iterations constant and then calculate the number of particles by ensuring that $N_{p_branched_PSO}\, N_c = N_{p_Base_PSO}$ for better comparison.

In IPOPT, the convergence criterion was user-

defined to better compare with the PSO algorithms. The absolute tolerance was defined as $10^{-14}$, and the bounds relaxation factor was considered as 0.0. The initial guess for the continuous decision variables was considered as the mid-interval value.

# RESULTS

## Material Screening of Adsorption Heat Pumps

The results for the maximization of the performance coefficient for heating operations ($COP_{heat}$) are presented in Table 2. The optimal values obtained by each optimizer are reported with a high number of significant figures to clearly highlight the differences between them, with the final digits shown in bold for added emphasis.

**Table 2**. Computation time and $\max(COP_{heat})$ obtained for the different algorithms applied.

| | |
|---|---|
| **Base_PSO** | |
| $t$/s | 3870 |
| $\max(COP_{heat})$ | 1.863846575137443118 |
| **Base_PSO_ACC** | |
| $t$/s | 198 |
| $\max(COP_{heat})$ | 1.863846575137442896 |
| **Branch_PSO** | |
| $t$/s | 1650 |
| $\max(COP_{heat})$ | 1.863846575137444228 |
| **Branch_PSO_ACC** | |
| $t$/s | 524 |
| $\max(COP_{heat})$ | 1.863846575137442896 |
| **IPOPT** | |
| $t$/s | 51 |
| $\max(COP_{heat})$ | 1.8638465751374385 |

As can be perceived, Branch_PSO surpasses Base_PSO used in the previous study. The computation time is reduced by 57%. In addition to this, the most probable value (MPV) for the optimum is slightly better in Branch_PSO for the maximization of $COP_{heat}$, although all the differences in results displayed in Table 2 are not significant when one considers a practical application.

In the case of the advanced convergence algorithms, the time reduction in computational time is quite significant when compared to the algorithms where the number of iterations was set from the beginning (95% for Base_PSO and 68% for Branch_PSO). However, the solution in cases that do not consider accelerated convergence is slightly more accurate than the ACC version. Nevertheless, since only one run was performed for each case, the different randomness of the initial particle colocation amongst algorithms can also be a factor in this analysis. It can also be seen that Base_PSO_ACC is 62% faster than Branch_PSO_ACC. This is due to the fact that Branch_PSO_ACC needs to meet the convergence criterion in all the branches and Base_PSO has 10x more particles in the unconstrained search for the global optimum.

Comparing the IPOPT results with the PSO ones, IPOPT is the fastest one (74% faster than Base_PSO_ACC) but is also the one where the optimal value of the objective function found is the lowest.

To better analyze the different methods, the heatmaps of the evaluations made by each algorithm were plotted and are presented in Figure 2.

Several notes can be taken from the data in the heatmaps. The first one is that Base_PSO algorithms did not execute any evaluation in the quadrants where the optimum for materials 1 and 7 were located (signaled with the pink dotted boxes). This highlights the problem of "key" variables because if the algorithm cannot locate the optimum within a given discrete option of adsorbent or configuration of the unit, then the comparison is not being performed fairly. It is important to note that these materials were not the worst two of the ten that were evaluated, as materials 9 and 2 display a lower or equal $\max(COP_{heat})$ value.

The second note worth mentioning is the inability of IPOPT to locate the optimum for material 9. In fact, IPOPT failed to make a single evaluation that is not penalized. The penalization on its own is not an exclusive limitation to the success of the optimization, as material 8 also had some penalized evaluations and the algorithm still got within the optimal quadrant. The fact that the evaluation of material 9 could not produce any non-penalized evaluation is cause for raising doubts on the effectiveness of IPOPT for the evaluation of more complex problems where the equations are not easily differentiated with respect to the decision variables. One can argue that the initial guess of the optimum has an effect, but making a more educated guess also requires more information on the problem, or a trial-and-error approach. With Branch_PSO, all materials were evaluated fairly, with a very similar number of evaluations in the optimal regions of all materials, even with the ACC. It is also interesting that material 9 was the most penalized material for the PSO algorithms as well, but they still converged to the optimal region (including the Base_PSO ones that fail in the other two materials, 1 and 7).

Hence, despite the lower computational time, IPOPT has a worse performance when considering optimum evaluations and the flexibility provided in the problem evaluation stage. Within the PSO methods, Branch_PSO outperformed Base_PSO in terms of balance across the evaluation of the different materials, Base_PSO_ACC can be considered a viable alternative as well for fast evaluation, but the convergence problems due to the "key" variables misevaluation are still a possibility.

# CONCLUSIONS

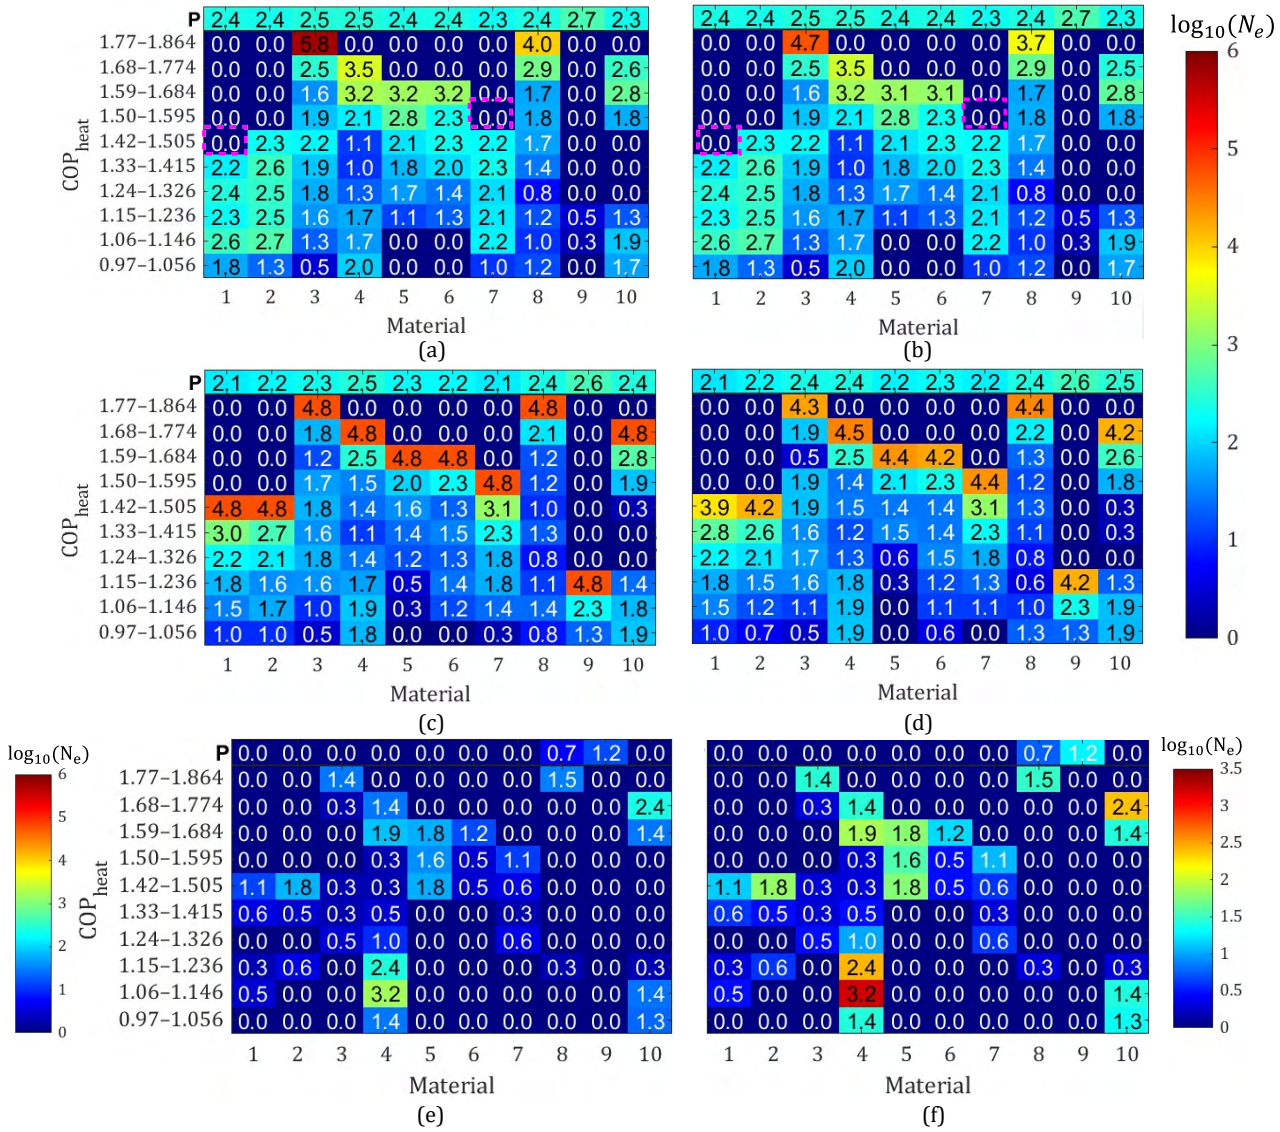

**Figure 2.** Heatmaps for the evaluations performed in Base_PSO (a), Base_PSO_ACC (b), Branch_PSO (c) Branch_PSO_ACC (d), IPOPT with the same scale as the PSO maps (e) and with autoscale (f). The values in the Heatmap are expressed in $\log_{10}$(Number of experiments ($N_e$)). The pink dotted squares represent quadrants that were not evaluated in the Base_PSO algorithms (correspondent with the location of that material optima). P stands for the evaluations that resulted in penalizations due to the non-observation of the constraints (only $g_1$ in the IPOPT cases).

Four different PSO algorithms were presented to solve MINLP. The algorithms were designed to assess the impact of "key variables" on optimization and process design problems. Their performance was compared to a deterministic solver (IPOPT).

For the design and optimization of adsorption heat pumps, Branch_PSO outperformed Base_PSO and highlighted the discontinuous problem of "key variables". Advanced convergence (ACC) had a large advantage in shorter computation time and can be employed in real-life applications if the error values are not prohibitive upon comparison with the remaining approaches.

Although IPOPT was the fastest algorithm, it delivered the lowest optimal value and showed limited robustness in constrained regions. IPOPT failed to produce any non-penalized evaluations for material 9, indicating difficulties in handling complex, non-smooth problems with stringent constraints.

Heatmap analyses showed that Base_PSO failed to explore the optimal regions of materials 1 and 7, which highlights the issue of key-variable misidentification, i.e., the inability of the algorithm to correctly explore variables

such as material selection. In contrast, Branch_PSO ensured a balanced evaluation of all materials, even with ACC enabled.

Overall, Branch_PSO_ACC provides the best compromise between robustness and computational efficiency, while Base_PSO_ACC remains a viable faster alternative with some risk of missing optima due to incomplete exploration of key variables.

As a final note, and despite the better performance of Branch_PSO, the algorithm presents a limitation in the incremental computational effort when a larger number of branches is considered. The breaking point when the computational effort nullifies the other advantages is a parameter that can only be evaluated case by case. However, with the increase in computational power and core-based parallelization, this problem can be surpassed with multiple particles being evaluated simultaneously, reducing computational time.

## DIGITAL SUPPLEMENTARY MATERIAL

Base_PSO algorithm can be found in Supporting Information (LAPSE:2026.0035).

## ABSTRACT

This study presents a techno-economic modeling framework integrating a modular blue $H_2N_2$ production unit with a hydrogen refueling station (HRS) across capacities ranging from 0.1 to 4.0 tpd. A model-based approach is used to size key process and refueling components and to estimate the resulting hydrogen retail cost. The analysis indicates that hydrogen retail costs range from 4.6 to 10.8 USD $kgH_2^{-1}$ over the considered capacity range. Relative to alternative on-site hydrogen production pathways, the proposed system demonstrates better cost-effectiveness while meeting clean hydrogen production standards. The approach is particularly suitable for regions with established natural gas infrastructure, as it leverages existing supply chains. Overall, the results provide actionable insights for policymakers and industry stakeholders in planning future hydrogen refueling infrastructure.

**Keywords**: Hydrogen, Hydrogen Refueling Stations, Distributed Production, Modelling, Technoeconomic Analysis.

## INTRODUCTION

The decarbonization of heavy-duty transportation presents a distinct challenge within the broader energy transition. Unlike passenger vehicles, long-haul freight operations require high energy density, fast refueling, and minimal downtime [1]. These constraints limit the applicability of battery-electric solutions at scale. As a result, hydrogen has emerged as a candidate for deep decarbonization of freight corridors. Even though vehicle technology allows for hydrogen adoption, the heavy transportation sector is increasingly shaped by the feasibility and cost of hydrogen at refueling locations [2].

A central barrier to hydrogen development in freight transportation lies in the reliance on centralized hydrogen production coupled with long-distance delivery [3]. While large-scale hydrogen facilities benefit from economies of scale, they introduce significant logistical complexity, including high-pressure storage, liquefaction or compression, and dedicated transport infrastructure [3-5]. These downstream requirements contribute substantially to delivered hydrogen costs and pose scalability challenges for geographically distributed hydrogen refueling station (HRS), particularly along highway freight corridors where demand is spatially dispersed.

In response to these challenges, onsite and distributed hydrogen production has gained increasing attention as a complementary infrastructure strategy [6]. By producing hydrogen directly at refueling stations, onsite systems can eliminate transportation-related costs and losses, improve supply reliability, and enable incremental deployment aligned with localized demand growth. Such approach is attractive for freight applications, where hydrogen demand is concentrated at specific highway nodes rather than centralized hubs.

Onsite hydrogen production can be realized through both green and blue pathways, depending on regional resource availability and infrastructure constraints. Green hydrogen offers clear long-term decarbonization potential but remains cost-intensive at small scales due to the combined capital requirements of electrolyzers, and renewable electricity. In contrast, blue hydrogen pathways can leverage existing natural gas infrastructure to achieve improved cost competitiveness at distributed

scales, provided that high $CO_2$ capture efficiencies are maintained and methane emissions are effectively controlled [7]. This infrastructure compatibility positions blue hydrogen as a potential transitional solution for accelerating early-stage hydrogen deployment in freight applications [7].

Building on this premise, our previous work developed a modular blue hydrogen production based on a fixed-bed chemical looping process, designed explicitly for small-scale and distributed operation [8]. The system produces high-purity hydrogen while separating $CO_2$ and $N_2$ into concentrated streams, enabling efficient carbon capture without additional separation units [8, 9]. Prior techno-economic analysis demonstrated hydrogen production costs in the range of 2.8 – 3.9 USD $kgH_2^{-1}$ at the plant gate for modular deployments [9, 10]. While these costs remain higher than those of large, centralized facilities, the modular system is well suited for integration with downstream users where hydrogen delivery costs dominate total supply-chain economics.

Despite growing interest in onsite hydrogen production, limited studies have systematically evaluated the integration of modular blue hydrogen systems with hydrogen refueling stations. In particular, the combined effects of production scale, refueling station equipment sizing, operating costs, and carbon intensity on retail hydrogen prices remain insufficiently explored.

We address this gap by developing an integrated techno-economic framework that couples a modular onsite blue $H_2$ and $N_2$ production system with a hydrogen refueling station across a range of distributed production scales. By explicitly modeling equipment sizing, operating requirements, hydrogen retail cost, and lifecycle $CO_2$ emissions, this work provides comprehensive assessment of the role of onsite blue hydrogen production in enabling cost-effective and low-carbon hydrogen refueling infrastructure for long-haul freight transportation.

## SYSTEM DESCRIPTION

### The Blue $H_2$-$N_2$ Production System

Figure 1 presents an overview of the blue $H_2$-$N_2$ production platform investigated in this study. The system is composed of three primary units: (i) a multi-reactor reforming section, (ii) an integrated heat recovery network, and (iii) a downstream gas separation and purification unit. The reforming section uses an intensified fixed-bed reactor previously reported in [8], which operates according to the chemical looping reforming (CLR) concept and cyclically undergoes oxidation (OX), reduction (RED), and reforming (REF) steps.

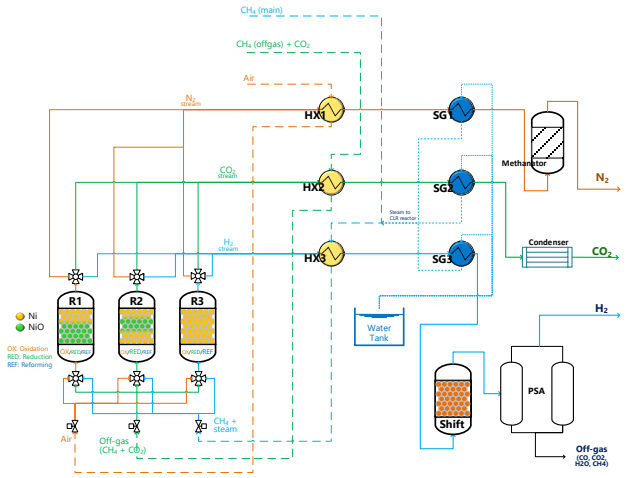

**Figure 1.** Simplified flow diagram of the blue $H_2$-$N_2$ production system considered in this study [9].

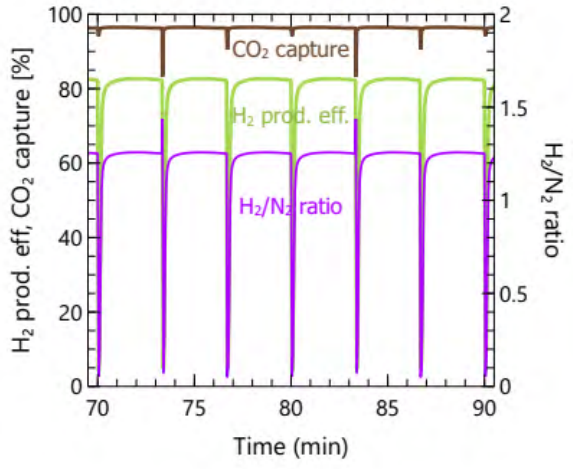

**Figure 2.** Performance metrics of the blue $H_2N_2$ production system discussed in this study [9].

Due to the inherently cyclic nature of CLR operation in fixed-bed configurations, continuous product generation cannot be achieved with a single reactor. To overcome this limitation, at least three reformers are operated in parallel, enabling semi-continuous system operation. This multi-reactor arrangement produces three separated outlet streams: a $N_2$-rich stream, a $CO_2$-rich stream, and a $H_2$-rich stream. Figure 2 presents the performance metrics of the blue $H_2N_2$ production system, where the system can produce $H_2$ with 82% efficiency and potential 98% of $CO_2$ capture [9]. A detailed description of the reactor sequencing, system integration, operating strategy, and system performance is provided in [9].

### Hydrogen Refueling Station (HRS)

The HRS configuration comprises four main components: (i) multi-stage hydrogen compressors; (ii) a three-stage cascade hydrogen storage system; (iii) a hydrogen

dispenser; and (iv) a cooling system, following the configuration reported in [11]. The HRS is designed to accommodate onsite hydrogen production from both blue and green hydrogen pathways.

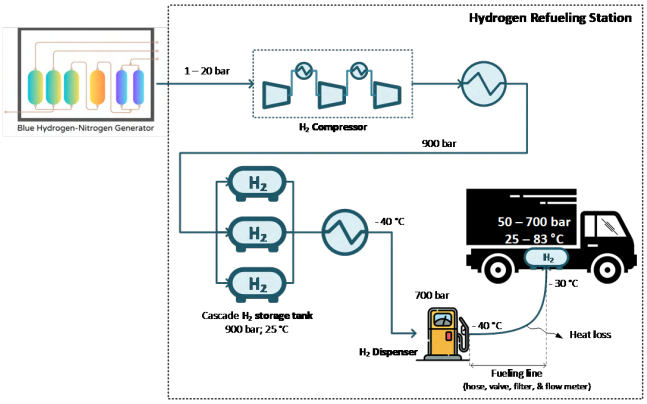

**Figure 3.** Simplified schematic of the integrated blue $H_2$-$N_2$ generator co-located with HRS.

## METHODOLOGY

The techno-economic analysis in this study spans the system boundary, from natural gas supply to downstream treatment of the captured $CO_2$ by-product. Both capital expenditures (CAPEX) and operating expenditures (OPEX) are considered for the integrated blue $H_2$-$N_2$ generator and the hydrogen refueling station (HRS).

The techno-economic analysis of the blue $H_2N_2$ generator has been reported earlier [9, 10], and is summarized in Table 1. The reported hydrogen production cost includes the downstream treatment of the captured $CO_2$.

In the present study, the economic analysis focuses primarily on the hydrogen refueling station, including costs associated with hydrogen compression, storage, and dispensing to fuel electric vehicles (FCEVs). The HRS analysis considers the major system components: hydrogen compressors, hydrogen storage tanks, hydrogen dispensers, and refrigeration systems.

**Table 1:** $H_2$ production costs via the modular blue $H_2N_2$ generator estimated in our previous studies [9, 10].

| Capacities | $H_2$ retail cost [USD $kgH_2^{-1}$] | Daily production [$kgH_2$ $day^{-1}$] |
|---|---|---|
| 0.5 tpd | 3.806 | 570 |
| 2.8 tpd | 3.042 | 2, 882 |
| 7 tpd | 2.882 | 7, 100 |
| 17 tpd | 2.736 | 17, 107 |

### Compressors

Piston and diaphragm compressors are commonly used for high-pressure hydrogen compression. In this work, a piston compressor is considered with an inlet pressure of 0.1 bar and a discharge pressure of 90 bar. This configuration enables hydrogen dispensing at 87.5 MPa, which corresponds to the maximum allowable pressure specified by the SAE J2601 standard for 70 MPa-class HRS [12, 13]. The high overall compression ratio is achieved through a multi-stage compression process, in which hydrogen is compressed sequentially across multiple stages with lower individual pressure ratios.

The compressor power requirement is calculated assuming adiabatic compression, expressed as:

$$\dot{W}_{comp} = c_{H2}\frac{T_{inlet}}{\eta_{comp}}\left(\left(\frac{P_{outlet}}{P_{inlet}}\right)^{\frac{r-1}{r}} - 1\right) \bullet \dot{m}_{H2} \quad (1)$$

where $c_{H2}$ is the specific heat of hydrogen at constant pressure (14.304 kJ $kg^{-1}$ $K^{-1}$), $\eta_{comp}$ is the compressor efficiency (assumed to be 70%), $T_{inlet}$ is the compressor inlet temperature in Kelvin, $P_{inlet}$ and $P_{outlet}$ are the inlet and outlet pressures, respectively, $r$ is the specific heat ratio of hydrogen (1.4), and $\dot{m}_{H2}$ is the hydrogen mass flow rate through the compressor in kg $s^{-1}$.

### Storage tanks

The hydrogen storage system is designed as a cascade configuration with multiple pressure levels. Storage tanks are sequentially filled by the compressor, starting from the low-pressure level and progressing to higher pressure levels, following a conventional with a conventional cascade refueling strategy [11, 12, 13]. The required storage capacity is calculated as:

$$C_{tank} = \dot{m}_{H2} t_{dispensing} \quad (2)$$

where $C_{tank}$ is the total hydrogen storage capacity in kg or metric ton, and $t_{dispensing}$ is the daily refueling duration, assumed to be 18 h. In this study, a two-level pressure storage system is considered, with the total storage capacity evenly distributed between the two pressure levels.

### Refrigeration and dispensing unit

The hydrogen dispenser system is designed to comply with the SAE J2601 fueling protocol, which specifies a hydrogen precooling temperature range of -30 to -40°C. Precooling is required to prevent the onboard hydrogen tank temperature in FCEVs from exceeding 85°C during refueling, a threshold above which tank safety may be compromised. The temperature increase during refueling is primarily attributed to the negative Joule-Thompson effect of hydrogen, which causes gas heating during throttling process. Accordingly, the hydrogen delivery temperature must remain between -40°C and -17.5°C [12, 13].

The main components of the dispenser system include a refrigeration unit for hydrogen precooling and a dispensing nozzle that regulates the hydrogen mass flow rate into the FCEVs storage tank. The cooling load for a single dispenser during vehicle fueling is calculated as:

$$\dot{Q}_{cool} = \dot{m}_{H2,D} \bullet \left(h_{storage} - h_{dispenser}\right) \quad (3)$$

where $\dot{m}_{H2,D}$ is the hydrogen mass flow rate at the dispenser (equal to 16.7 g $s^{-1}$) [11], $h_{storage}$ and $h_{dispenser}$ are the specific enthalpies at the storage (900 bar and 25°C) and at the dispenser exit (900 bar and -40°C), respectively. This calculation is based on following assumptions: (i) a dispensing pressure of 700 bar; (ii) two dispensers are required for station capacities of 100-200 kg $day^{-1}$; (iii) a fueling duration of 5 min per vehicle, and (iv) on board storage capacity of 5 kg.

The electrical power requirement for the refrigeration system is calculated as:

$$\dot{W}_{refrigeration} = \frac{Q_{cool}}{COP} \quad (3)$$

where the coefficient of performance ($COP$) is assumed to be 1.0 based on reference in [12].

**Table 2:** Economic formulations and cost data used in the techno-economic analysis of HRS.

| **Parameter** |
|---|
| Capital cost |
| • Compressor [USD] [12] $Cost_{compressor} = 45,626 \bullet \dot{W}_{comp}^{0.5861}$ |
| • Storage tank [USD] |
| • High pressure [13] $Cost_{storageHP} = 1,001 \bullet \dot{m}_{H2}$ |
| • Low pressure [12] $Cost_{storageLP} = 1,709 \bullet \dot{m}_{H2}$ |

*) $n_{dispenser} = 2$ for each additional 100–200 $kgH_2$ $day^{-1}$ of station capacity [12].

**Table 3:** Framework used to estimate $H_2$ production costs, adapted from the U.S. DOE/NETL [14].

| **Components** | **Formula** |
|---|---|
| Capital Cost | |
| - Bare Erected Cost of j-components ($BECj$) | $\sum BEC_j$ |
| Total $BEC$ | |
| Engineering Procurement and Construction ($EPC$) | $10\%\ (BEC)$ |
| Contingency ($CON$) | $20\%(BEC\ +\ EPC)$ |
| Total Plant Cost ($TPC$) | $BEC + EPC + CON$ |
| Owner Cost & Other Financial Cost ($O\&OFC$) | $20\%\ (BEC)$ |
| Total Overnight Cost ($TOC$) | $TPC + O\&OFC$ |
| Total as spent Cost ($TASC$) | $TOC + 18\%TOC$ |
| Annualized Capital Cost ($TASCpa$) | $TASC\ \times\ f$ |
| Annual Operation and Maintenance Cost ($O\&M$) | $O\&M$ |
| Total Annual Cost ($TAC$) | $TASCpa + O\&M$ |
| $H_2$ retail cost (USD/kg) | $TAC/_{H2prod.}$ |

## Economic and emissions analysis

Capital and operating costs for each major HRS component are estimated using cost correlations and assumptions compiled from the literature [12, 13], as summarized in Table 2. These cost correlations are applied consistently across all HRS capacities considered. The cost of individual HRS components are combined with those of the blue $H_2$ production unit to estimate Bare Erected Cost ($BEC$). Additional costs, including contingency, procurement, overnight cost, owner cost and other financial costs, are subsequently estimated.

The total capital cost is annualized using a capital recovery factor $f$ of 0.159, corresponding to a project lifetime of 20 years and a discount rate of 15%, reflecting the perceived investment risk associated with hydrogen refueling infrastructure. The annualized capital cost is then combined with the operation and maintenance (O&M) costs of both HRS and blue $H_2$ production unit. This overall cost estimation framework is summarized in Table 3.

A sensitivity analysis is conducted on the estimated hydrogen retail cost with respect to key variable operating costs, including natural gas price, $CO_2$ transportation cost, and electricity price. The variability ranges for these operating costs are based on unit cost values reported in the literature [15-17].

Finally, the carbon dioxide equivalent ($CO_2e$) emissions associated with the hydrogen refueling station and onsite blue $H_2$ production are evaluated. The primary sources of $CO_2$ emissions arise from electricity consumption for hydrogen and $CO_2$ compression and refrigeration

**Table 4:** Key parameters used for equipment price estimation, obtained from dynamic simulations of the proposed system at hydrogen production rates of 0.1-, 0.5-, 1.0-, 2.0-, and 4.0-ton $H_2$ per day.

| Equipment | Scaling variable | $H_2$ production rate | | | | |
|---|---|---|---|---|---|---|
| | | 0.1 tpd | 0.5 tpd | 1.0 tpd | 2.0 tpd | 4.0 tpd |
| CL Reformer | Volume [$m^3$] | 0.08 | 0.42 | 1.06 | 1.16 | 3.39 |
| Shift Reactor | Shift gas flow [kg $s^{-1}$] | 0.01 | 0.05 | 0.1 | 0.15 | 0.31 |
| Heat recovery system | Heat duty per temp. [kW $K^{-1}$] | 0.053 | 0.275 | 0.671 | 1.074 | 2.146 |
| PSA | $H_2$ flow [liter $s^{-1}$] | 3.2 | 22.2 | 39.7 | 63.4 | 127.0 |
| $CO_2$ compressors | Power [kW] | 5.4 | 27.4 | 66.9 | 107.1 | 214.2 |
| Heat rejection unit | Amount of heat [kW] | 6.3 | 33.0 | 78.2 | 125.2 | 250.4 |
| HRS compressors | Power [kW] | 47.8 | 236.4 | 594.6 | 955.1 | 1903.1 |
| HRS storage tanks | Capacity [$kgH_2$ $day^{-1}$] | 86.4 | 427.6 | 1075.6 | 1727.6 | 3442.3 |
| HRS refrigeration | Cooling load [kW] | 1.3 | 6.45 | 16.2 | 26.0 | 51.9 |
| HRS dispenser | # of dispenser(s) | 2 | 6 | 10 | 20 | 40 |

system. Electricity is assumed to be supplied by the grid, and emissions are calculated using a grid emission factor of 287 $kgCO_2e$ $MWh^{-1}$ [18].

## RESULTS AND DISCUSSION

The HRS and onsite blue $H_2$ production units were sized to match the onsite hydrogen production capacities of 0.1, 0.5, 1.0, 2.0, and 4.0 $tH_2pd$. Table 4 summarizes the sizing results for the main equipment in both the on-site blue hydrogen production system and the HRS, which are subsequently used to estimate hydrogen retail costs. The resulting retail hydrogen cost estimates are presented in Table 5.

**Table 5:** Estimated hydrogen retail costs for HRS with on-site hydrogen production.

| Capacities | $H_2$ retail cost [USD $kgH_2^{-1}$] | Daily production [$kgH_2$ $day^{-1}$] |
|---|---|---|
| 0.1 tpd | 10.871 | 115 |
| 0.5 tpd | 6.122 | 570 |
| 1.0 tpd | 4.923 | 1, 434 |
| 2.0 tpd | 4.821 | 2, 303 |
| 4.0 tpd | 4.607 | 4, 589 |

The retail costs obtained from the proposed onsite blue hydrogen pathway are compared with alternative onsite hydrogen production technologies reported in the literature, as shown in Figure 4. Overall, the results clearly demonstrate the benefits of economies of scale, with higher production capacities yielding more competitive hydrogen retail costs. Most onsite hydrogen production technologies operate at relatively small scales (0.1 – 0.5 tpd), with corresponding retail hydrogen costs ranging between 8 and 10 USD $kgH_2^{-1}$. In particular, HRS with on-site electrolysis powered by renewable electricity operate at capacities of 0.1 tpd or lower and report retail hydrogen costs exceeding 12 USD $kgH_2^{-1}$.

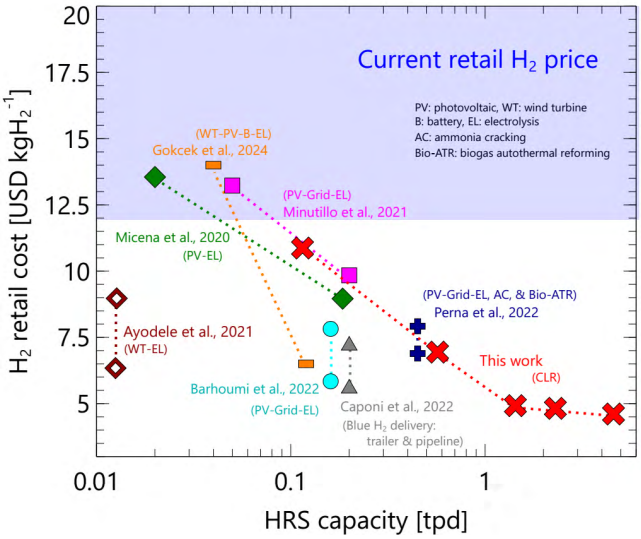

**Figure 4.** Comparison of hydrogen retail costs across different on-site hydrogen production technologies reported in the literature [6, 12, 13, 19-22].

Figure 4 indicates that HRS supplied by onsite blue hydrogen production becomes cost-effective at production rates above 1.0 tpd, achieving hydrogen retail costs of approximately 4.8 USD $kgH_2^{-1}$. To date, limited studies have reported onsite blue or green hydrogen pathways at comparable production scales. At smaller production capacities, the cost advantage of the proposed system reduces. Specifically, at a production scale of 0.5 tpd, the retail hydrogen cost increases to approximately 6.1 USD $kgH_2^{-1}$. As the production scale is further reduced to 0.1 tpd, the retail cost rises to approximately 10 USD $kgH_2^{-1}$, placing the proposed system within similar cost range to onsite green hydrogen production technologies.

Figure 5 shows the sensitivity analysis of the estimated retail price for a 0.5 tpd HRS with respect to key variable operating costs, including natural gas price, $CO_2$ transportation cost, and electricity prices. Overall, the retail hydrogen cost exhibits a linear response to variations in all operating cost components. Among these factors, natural gas is the most influential, followed by electricity price, and $CO_2$ transportation cost. Variations in natural gas price result in changes to the retail hydrogen cost ranging from -9% to 21%, while $CO_2$ transportation cost leads to variations of -1% to 10%. Electricity price fluctuations result in retail cost changes of approximately -13% to 13%.

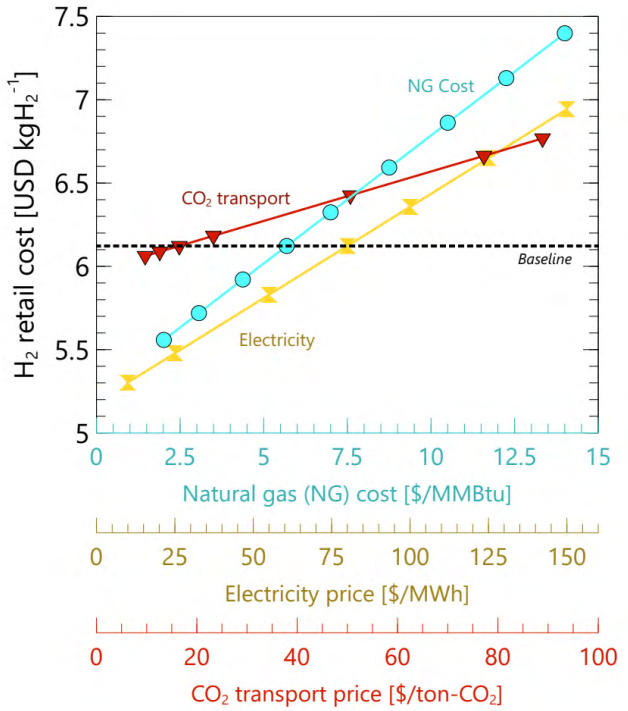

**Figure 5.** Sensitivity analysis of blue $H_2$ retail costs with respect to variations in natural gas price, electricity price, and $CO_2$ transportation cost for a HRS with 0.5 tpd onsite blue hydrogen production.

Figure 6 illustrates the $CO_2e$ intensity associated with the HRS supplied by onsite blue hydrogen production considered in this study. The estimated emissions intensity remains relatively constant across all production scales, at approximately 3.05 $kgCO_2$ $kgH_2^{-1}$. At this level, more than 75% of total emissions originate from the HRS unit, primarily due to the electricity consumption for hydrogen compression and refrigeration. Overall, the resulting $CO_2e$ intensity meets the U.S. Department of Energy (DoE) criteria for clean hydrogen production [23]. However, it should be noted that this value is achieved under the assumptions of a 95% $CO_2$ capture and negligible methane leakage during natural gas transmission.

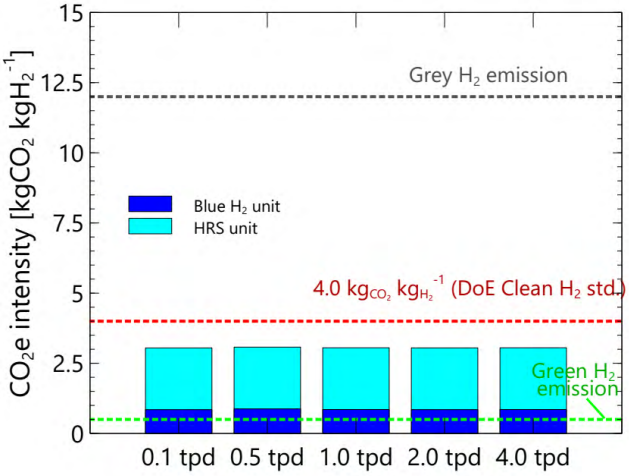

**Figure 6.** $CO_2e$ intensity associated with HRS supplied by onsite blue $H_2$ production discussed in this study.

## CONCLUSIONS

This paper presented a techno-economic analysis model that integrates a modular blue $H_2N_2$ generator with a HRS model across production scales. Dynamic simulations were performed to size the main equipment of the blue $H_{2+}$-$N_2$ generator and its integration with HRS components, enabling estimation of the resulting hydrogen retail cost. The retail cost was estimated to range from 4.6 – 10.8 USD $kgH_2^{-1}$ across capacities of 0.1 – 4.0 tpd. Compared to other on-site production technologies, this process option was shown to be the most cost-effective while meeting clean $H_2$ production standards. The proposed system could be particularly attractive to regions with extensive natural gas infrastructure, like the United States, as it leverages existing supply chains. However, reliance on natural gas raises concerns over fugitive methane emissions, which remain subject to regulatory scrutiny. Despite these considerations, the findings provide valuable insights for policymakers and industry stakeholders in shaping future hydrogen infrastructure.

## ABSTRACT

This work presents an integrated geospatial-technoeconomic optimization framework for siting modular blue and green hydrogen production units co-located with hydrogen refueling stations (HRS) along U.S highways, with a case study focused on New England. The workflow identifies geospatial highway networks and natural gas infrastructure intersections, estimates hydrogen demand based on heavy-duty truck flows from U.S. Freight Analysis Framework, and formulates a mixed-integer linear program (MILP) that selects technology candidates and their capacities to minimize total cost, subject to corridor coverage and supply-demand constraints. Two onsite hydrogen production scenarios are evaluated: a green hydrogen-only production case and a mixed configuration combining modular green and blue hydrogen. Results indicate that, under a 5% hydrogen adoption scenario in truck traffic, 29 HRS with onsite hydrogen production are needed in the New England region. These findings highlight the benefits of integrating local hydrogen production with HRS planning to reduce the reliance on centralized hydrogen delivery and storage infrastructure.

**Keywords**: Low-carbon hydrogen, hydrogen refueling stations, onsite production, highways, geospatial-technoeconomic optimization, MILP.

## INTRODUCTION

Hydrogen is projected to play a significant role in meeting future energy demand, driven by emerging applications across multiple sectors, with approximately 27% of total hydrogen demand attributed to transportation [1]. Among transportation modes, heavy-duty applications, particularly long-haul trucking, are widely regarded as one the most adopters of hydrogen [2]. This sector currently contributes nearly 30% of global transportation-related $CO_2$ emissions [3], making deep decarbonization particularly challenging with conventional electrification approaches alone.

The large-scale deployment of low-carbon hydrogen for transportation must be supported by the development of reliable hydrogen infrastructure capable of delivering fuel at points of use. However, centralized hydrogen production requires hydrogen storage and long-distance transportation, both of which remain technically challenging [4, 5], creating a major bottleneck for hydrogen market penetration. As an alternative, distributed hydrogen production tailored to local demand has been proposed as a viable alternative. This approach is especially well aligned with transportation applications, which require networks of hydrogen refueling stations (HRS) along heavy-duty vehicles corridors.

Onsite hydrogen production can be achieved through either green hydrogen or blue hydrogen, depending on local resource availability and infrastructure characteristics. While green hydrogen offers superior environmental performance, its production cost remains less favorable than that of blue hydrogen [6]. The economic advantage of blue hydrogen, however, depends critically on minimizing methane leakage and achieving high $CO_2$ capture efficiency throughout the production process [7]. Leveraging the existing infrastructure of natural gas pipeline networks can further increase the com-

petitiveness of onsite blue hydrogen production by potentially eliminating the need for hydrogen transportation.

In our previous work, we developed and optimized a fixed-bed chemical looping reactor for hydrogen production that generates high-purity hydrogen while simultaneously producing concentrated $CO_2$ and $N_2$ streams in three separate outlets [8, 9]. The system is designed for small-scale operation to support distributed production scenarios that utilize existing natural gas infrastructure. A techno-economic assessment of this technology estimated hydrogen production costs in the range of 2.8 – 4.0 USD $kgH_2^{-1}$ [9, 10]. Although these costs are higher than those reported for large-scale centralized blue hydrogen plants, it is important to note that onsite production eliminates downstream transportation and distribution costs, resulting in a delivered hydrogen cost that is closer to the price paid by end users.

In this work, we develop an integrated geospatial-technoeconomic optimization framework to site modular blue and green hydrogen units co-located with HRS along U.S. highway corridors. Modular blue hydrogen uses the blue $H_2$-$N_2$ technology developed in prior work [8, 9], while modular green hydrogen is supposed to be supplied via renewable-powered electrolysis. Heavy-duty truck flow and highway networks are extracted from the Freight Analysis Framework (FAF) [11], and the US Energy Information Administration (EIA) natural gas pipeline network [12] is used to assess proximity between highways and existing pipeline infrastructure. A mixed-integer linear programming (MILP) model is formulated to optimally select facility locations and technology capacities that minimize total system cost while satisfying corridor coverage and supply-demand constraints.

This study addresses a key gap in the literature by providing a system-level framework that explicitly integrates existing natural gas infrastructure with onsite hydrogen production to support heavy-duty hydrogen demand along US highway networks.

## SYSTEM DESCRIPTION

### The Blue $H_2$-$N_2$ Production System

Figure 1 illustrates the novel blue $H_2$-$N_2$ production system discussed in this work. The system consists of three major subsystems: (i) multi-reformer system; (ii) a heat recovery system; and (iii) a gas purification system. The multi-reformer system uses the intensified reforming reactor discussed in [8], which operates based on the chemical-looping reforming (CLR) principle and consists of successive oxidation (OX), reduction (RED), and reforming (REF) stages.

To address the intrinsic operational discontinuity of a CLR fixed-bed reactor, a minimum of three reactors is used to achieve a semi-continuous product stream. This multiple-reactor configuration generates three distinct outlet streams: a $N_2$-rich stream, a $CO_2$-rich stream, and a $H_2$-rich stream. Additional details of the system design and operation are provided in [9].

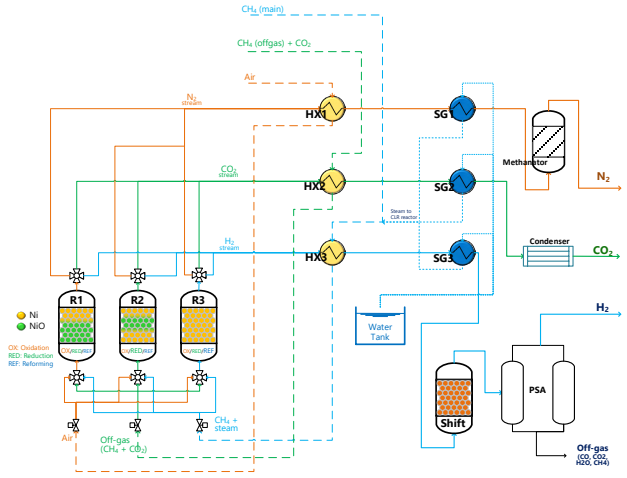

**Figure 1.** Simplified flow diagram of the blue $H_2$-$N_2$ production system considered in this study.

### Hydrogen Refueling Station (HRS)

The HRS configuration comprises four main components: hydrogen compressors, a three-stage cascade hydrogen storage system, a hydrogen dispenser and a cooling system, following configuration reported in [13]. The HRS is designed to accommodate onsite hydrogen production from both blue and green hydrogen pathways.

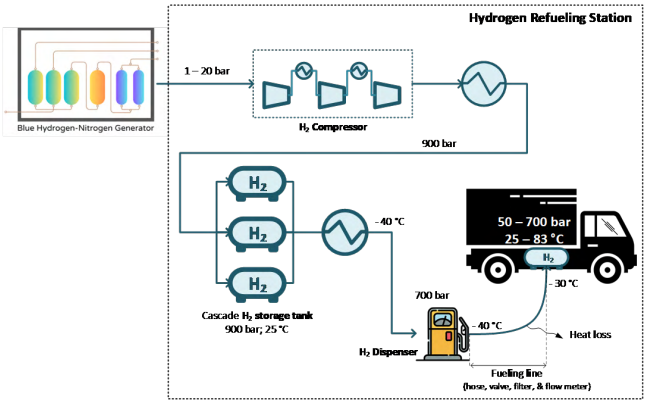

**Figure 2.** Simplified schematic of the integrated blue $H_2$-$N_2$ generator co-located with HRS.

### Supply Chain Schematic

Figure 3 illustrates the overall hydrogen supply chain system considered in this study. The system boundary extends from energy primary resources, including renewable electricity as well as natural gas pipelines, through onsite hydrogen production units, and finally to hydrogen demand centers and $CO_2$ storage sites.

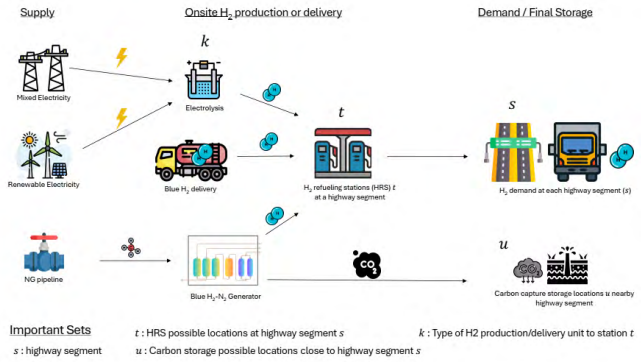

**Figure 3.** Overall hydrogen supply chain schematic discussed in this work.

## METHODOLOGY

**Figure 4.** FAF highway network and source of truck flow data overlaid with natural gas pipeline infrastructure.

This study uses the Freight Analysis Framework (FAF) dataset provided by the U.S. Department of Transportation [11], which contains detailed information on interstate highway networks and heavy-duty truck flow statistics. Natural gas pipeline data are obtained from the U.S. Energy Information Administration (EIA) [12]. All datasets are spatially aligned and integrated within a unified geographic information system (GIS) environment, QGIS [14], as illustrated in Figure 4.

This study focuses on the New England region, comprising Connecticut (CT), Massachusetts (MA), Rhode Islands (RI), New Hampshire (NH), Vermont (VT), and Maine (ME). This region is selected as a representative case without access to large-scale carbon capture, utilization, and storage (CCUS) infrastructure and because it encompasses the northern extent of the major Interstate 95 (I-95) freight corridor along the U.S. East Coast. Figure 5 shows the major interstates highways across New England considered in this study, while Figure 6 depicts annual heavy-duty truck traffic volumes across the region.

The FAF dataset is available at the level of individual interstate segments, including segment identifiers, lengths, route names, truck traffic volumes, etc. Based on these data, a structured data preparation workflow is developed to transform the raw network datasets into a form suitable for optimization. The major steps are summarized below:

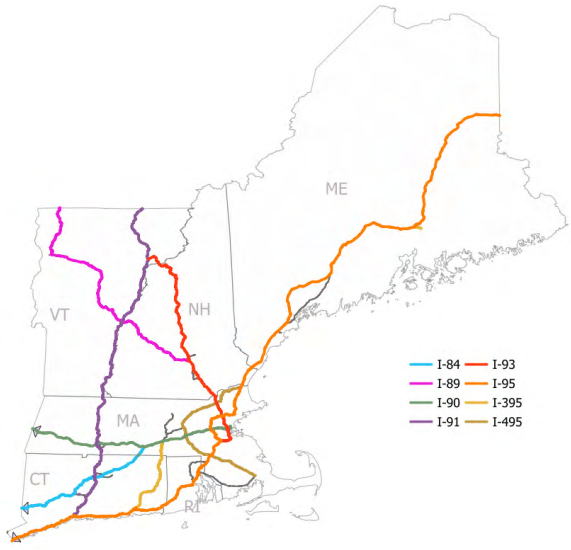

**Figure 5.** Major interstate highway across New England discussed in this study. For reference, segment labels are ordered along each interstate from south to north, and west to east within the map.

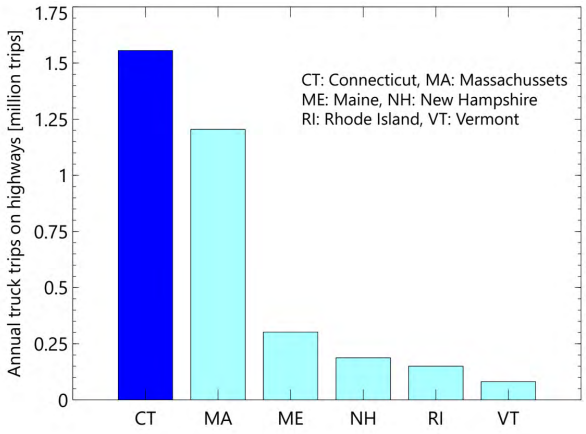

**Figure 6.** Annual heavy-duty truck trips across New England based on FAF data [11].

1. Segment labeling and ordering
   Each interstate is sorted from upstream (starting node) to downstream (terminal node), and every segment is assigned a unique identifier. For example, segments along Interstate 84 (I-84) are labeled as: `I84_s1, I84_s2, …, I84_sN`.
2. Identification of interstate branches
   For interstate that intersect, segment on each route is assigned connectivity information to represent branching and cross-interstate connections.
3. Hydrogen demand estimation

Hydrogen demand for each highway segment is estimated from segment-level truck flow data by accounting for segment length and fuel consumption:

$$demand_s = \alpha \times TruckFlows \times length_s \times FuelConsumption \quad (1)$$

where $\alpha$ represents the hydrogen adoption rate. In this study, a 5% adoption rate is assumed, with a fuel consumption of 15 kg $H_2$ per mile for hydrogen-powered trucks.

4. Selection of HRS candidate locations
   Candidate HRS locations are selected based on proximity to existing natural gas pipelines. Using GIS tools, highway segments whose centroids lie within 0.04° longitude-latitude radius of a natural gas pipeline are identified as candidate sites.
5. Construction of the influence matrix
   An influence matrix is constructed to quantify the ability of a candidate station $t$ to serve hydrogen demand at highway segment $s$. Influence matrix, $\mathrm{infl}_{st}$, ranges from 0 to 1 and is defined based on the distance between segment $s$ and candidate station $t$:
   - Self-influence (same segment):

$$\mathrm{infl}_{st} = 1.0 \quad (2)$$

   - Different segments:

$$\mathrm{infl}_{st} = \left(1 - {}^{d}/_{radius_{max}}\right) \bullet f_{\mathrm{connect}} \quad (3)$$

     where $f_{\mathrm{connect}} = 1.0$ if segment $s$ and candidate station $t$ are on the same interstate, and $f_{\mathrm{connect}} = 0.8$ if they are on different but directly connected interstates.
   - Beyond maximum service radius: $\mathrm{infl}_{st} = 0$ for distance greater than 125 miles.

   To reduce computational complexity, the influence matrix is pruned using the following rules:
   - Remove influence pairs with $\mathrm{infl}_{st} \leq 0.1$;
   - Ensure each segment $s$ retains at least one candidate station $t$;
   - Limit the number of influence pairs to at most 40 per segment $s$;
   - Always retain the top 5% strongest influence values;
   - Enforce a minimum spacing of at least 25 miles between candidate stations.

After dataset processing, the MILP optimization problem is formulated. Tables 1 and 2 summarize the sets, indices, decision variables, and parameters used in the model.

The objective of the optimization model is to determine the optimal configuration of HRS, including their capacity levels, the selection of onsite hydrogen production, and the associated $CO_2$ transport to nearby CCUS locations, while satisfying regional hydrogen demand and infrastructure constraints. The total system cost, $TC$, is defined as:

$$\begin{aligned} TC = \big(&\textstyle\sum_{t\in T}\sum_{c\in C} y_{tc}^{\mathrm{HRS}}\,\mathrm{cap}_c\,\mathrm{Cost}_c^{\mathrm{station}} \\ &+ \textstyle\sum_{t\in T}\sum_{c\in C}\sum_{k\in K} y_{tck}^{\mathrm{H2unit}}\,\mathrm{cap}_c\,\mathrm{Cost}_{ck}^{\mathrm{H2unit}} \\ &+ \textstyle\sum_{t\in T} x_t^{\mathrm{add}}\,\mathrm{Cost}^{\mathrm{add}} \\ &+ \textstyle\sum_{(t,u)\in TU} f_{tu}^{\mathrm{CO2}}\,\mathrm{Cost}^{\mathrm{CO2del}}\big) \\ &\bullet\ 365\ {}^{\mathrm{days}}/_{\mathrm{year}} \end{aligned} \quad (4)$$

$TC$ represents the annualized total cost of the HRS with onsite production, including both capital and operating expenditures, assuming 20-year project lifetime. The total cost accounts for hydrogen production, hydrogen compression, and $CO_2$ transportation to storage.

**Table 1:** Sets and indices used in the MILP formulation for HRS placement with onsite production on the U.S. highways.

| Sets and indices | Description |
|---|---|
| $s \in S$ | Set of all highway segments; index $s$ |
| $t \in T \subseteq S$ | Set of candidate HRS locations; index $t$ |
| $u \in U \subseteq S$ | Set of CCUS locations mapped to highway segments; index $u$ |
| $ST = \{(s,t)\epsilon S \times T\}$ | Set of feasible influence pairs between demand segment $s$ and candidate locations $t$ |
| $TU = \{(s,t)\epsilon S \times T\}$ | Set of feasible transport pairs between candidate locations $t$ and CCUS site $u$ |
| $c \in C = \{0.1, 0.5, 1.0, 2.0, 4.0\}$ | Set of HRS capacity levels [tpd]; index c |
| $k \in K = \{\mathrm{CLR}, \mathrm{ELRE}\}$ | Set of $H_2$ production unit types, CLR-based (blue $H_2$) or ELRE (electrolysis-renewable energy); index $k$ |
| $K_{NG} = \{\mathrm{CLR}\} \subseteq K$ | Subset of natural gas based $H_2$ production technologies |

The optimization minimizes the total system cost by jointly selecting the capacity of HRS installation the station, $y_{tc}^{\mathrm{HRS}}$, and the type of hydrogen production unit, $y_{tck}^{\mathrm{H2unit}}$. Station capacities are discretized at 0.1, 0.5, 1.0, 2.0, and 4.0 t$H_2$pd. A continuous variable, $x_t^{\mathrm{add}}$, is introduced to relax the discrete capacity selection and ensure demand satisfaction for segments with hydrogen demand levels that fall between the predefined capacity options.

The optimization is subject to a set of supply-demand, capacity, infrastructure, and emissions constraints. Hydrogen demand at each highway segment $s \in$

$S$ must be satisfied by nearby candidate locations $t$, as defined by the influence set $ST$:

$$\text{demand}_s = \sum_{t:(s,t)\in ST} \text{supply}_{st}\ ;\ \forall\ s \in S \quad (5)$$

**Table 2:** Variables and parameters used in the MILP formulation for HRS placement.

| Variables/ Parameters | Description |
|---|---|
| Decision Variables | |
| $y_{tc}^{\text{HRS}} \in \{0,1\}$ | 1 if a HRS of capacity c is installed at candidate station $t$ |
| $y_{tck}^{\text{H2unit}} \in \{0,1\}$ | 1 if a $H_2$ unit type k of capacity c is installed at candidate station $t$ |
| $x_t^{\text{add}} \geq 0$ | Additional low-carbon $H_2$ delivered to candidate station $t$ |
| State Variables | |
| $\text{avail}_t$ | Total $H_2$ available at candidate station $t$ |
| $\text{supply}_{st}$ | H2 supplied from candidate station $t$ to segment $s$ |
| $f_{tu}^{CO2}$ | $CO_2$ transported from candidate station t to segment s |
| Parameters | |
| $\text{demand}_s$ | $H_2$ demand at segment $s$ |
| $\text{infl}_{st} \in [0,1]$ | Influence factor of station $t$ on meeting demand at segment $s$ |
| $\text{cap}_c$ | Nominal HRS capacity level $c$ (tpd) |
| $\text{Cost}_c^{\text{station}}$ | Cost associated with a HRS of capacity $c$ |
| $\text{Cost}_{ck}^{\text{H2unit}}$ | Cost of $H_2$ production unit type $k$ for capacity $c$ |
| $\text{Cost}^{\text{add}}$ | Cost of additional delivered low-carbon $H_2$ |
| $\text{Cost}^{\text{CO2del}}$ | Cost per unit of $CO_2$ transported from HRS $t$ to CCUS site $u$ |
| $\text{loc}_t^{\text{HRS}} \in \{0,1\}$ | 1 if segment $t$ is eligible to host a new HRS |
| $M$ | Big-M parameter (sufficiently large constant) |
| $\rho^{\text{NGH2}}$ | Natural gas consumption per unit of $H_2$ produced (CLR technology) |
| $\text{NG}^{\text{extract}}$ | Fractional limit of extractable natural gas from the nearby pipeline |
| $\text{NG}_t^{\text{avail}}$ | Natural gas availability at candidate station $t$ |
| $\text{EF}_{ck}^{\text{H2unit}}$ | Emission factor of $H_2$ production/delivery unit $k$ at capacity $c$ |
| $\text{EF}^{\text{add}}$ | Emission factor associated with additional delivered $H_2$ |
| $\text{Em}^{\text{max}}$ | Maximum allowable emission intensity: 4 $kgCO_2\ kgH_2^{-1}$ |
| $\text{ccusdist}_{tu}$ | Distance between HRS candidate $t$ and CCUS site $u$ |

Hydrogen supply from station $t$ to segment $s$ is permitted only if the station lies within the influence of the segment:

$$\text{supply}_{st} \leq \text{infl}_{st}\text{avail}_t\ ;\ \forall\ s \in S, t \in T \quad (6)$$

The total hydrogen supplied by a station cannot exceed its available hydrogen:

$$\sum_{s:(s,t)\in ST} \text{supply}_{st} \leq \text{avail}_t;\ \forall\ t \in T \quad (7)$$

Hydrogen availability at a station $t$ is defined as the sum of onsite production and externally delivered hydrogen:

$$\text{avail}_t \leq M \sum_{c\in C}\sum_{k\in K} y_{tck}^{\text{H2unit}}\ ;\ \forall\ t \in T \quad (8)$$

Available hydrogen at station t is defined as the sum of onsite production:

$$\text{avail}_t = \sum_{c\in C}\sum_{k\in K} y_{tck}^{\text{H2unit}}\,\text{cap}_c + x_t^{\text{add}};\ \forall\ t \in T \quad (9)$$

Additional hydrogen delivery is permitted only when a production unit exists and is limited by the installed station capacity:

$$x_t^{\text{add}} \leq M \sum_{c\in C}\sum_{k\in K} y_{tck}^{\text{H2unit}}\ ;\ \forall\ t \in T \quad (10)$$

$$x_t^{\text{add}} \leq M \sum_{c\in C}\sum_{k\in K} y_{tc}^{\text{HRS}}\text{cap}_c\ ;\ \forall\ t \in T \quad (11)$$

A station may only be constructed at a valid candidate location:

$$\sum_{k\in K} y_{tck}^{\text{H2unit}} \leq \text{loc}_t^{\text{HRS}};\ \forall\ t \in T \quad (12)$$

Furthermore, a hydrogen production unit of capacity $c$ may be installed only if corresponding station capacity is selected, and at most one production unit can be installed at each station:

$$\sum_{c\in C}\sum_{k\in K} y_{tck}^{\text{H2unit}} \leq y_{tc}^{\text{HRS}};\ \forall\ t \in T \quad (13)$$

$$\sum_{c\in C}\sum_{k\in K} y_{tck}^{\text{H2unit}} \leq 1;\ \forall\ t \in T \quad (14)$$

For blue hydrogen production route $K_{NG}$, natural gas consumption must not exceed the available extraction limit:

$$\sum_{c\in C}\sum_{k\in K_{NG}} y_{tck}^{\text{H2unit}}\text{cap}_c\rho^{\text{NGH2}} \leq \text{NG}^{\text{extract}}\text{NG}_t^{\text{avail}};$$

$$\forall\ t \in T \quad (15)$$

System-level lifecycle emissions from all hydrogen production routes are constrained by a maximum emissions intensity threshold:

$$\sum_{t\in T}\left(\sum_{c\in C}\sum_{k\in K} y_{tck}^{\text{H2unit}}\text{cap}_c\text{EF}_{tck}^{\text{H2unit}} + x_t^{\text{add}}\text{EF}^{\text{add}}\right)$$

$$\leq \sum_{t\in T}\left(\sum_{c\in C}\sum_{k\in K} y_{tck}^{\text{H2unit}}\text{cap}_c + x_t^{\text{add}}\right)\text{Em}^{\text{max}} \quad (16)$$

For stations using blue hydrogen production, all generated $CO_2$ must be transported to feasible CCUS locations:

$$\sum_{u:(t,u)\in TU} f_{tu}^{CO2} = \sum_{c\in C}\sum_{k\in K_{NG}} y_{tck}^{\text{H2unit}}\text{cap}_c\text{EF}_{tck}^{\text{H2unit}}\ ;$$

$$\forall\ t \in T \quad (17)$$

Since no potential CCUS exist within New England, captured $CO_2$ is transported outside the regional boundary

via the first segments of Interstate 84 (I84_s1), Interstate 90 (I90_s1), or I-95 (I95_s1). Tables 3 and 4 summarize the key parameters used in the MILP formulation. Cost and emission factors for the blue $H_2N_2$ generators follows our prior work in [9, 10], while the electrolysis from renewable are adopted from the literature [6, 15].

**Table 3:** Estimated costs and emission factors (EF) for HRS and the onsite hydrogen production unit at different capacities. Reported costs include both capital and operating expenses. Detailed regarding this is provided in [20].

| Capacities | HRS-only | | $H_2$ prod. unit | |
|---|---|---|---|---|
| | CLR | ELRE | CLR | ELRE |
| Cost [USD $kgH_2^{-1}$] | | | | |
| 0.1 tpd | 2.683 | | 8.188 | 8.079 |
| 0.5 tpd | 2.016 | | 4.264 | 8.079 |
| 1.0 tpd | 1.948 | | 3.066 | 8.371 |
| 2.0 tpd | 1.948 | | 2.873 | 8.079 |
| 4.0 tpd | 1.948 | | 2.735 | 8.074 |
| Emission Factor [USD $kgH_2^{-1}$] | | | | |
| 0.1 tpd | 2.2 | -- | 0.84 | -- |
| 0.5 tpd | 2.2 | -- | 0.84 | -- |
| 1.0 tpd | 2.2 | -- | 0.84 | -- |
| 2.0 tpd | 2.2 | -- | 0.84 | -- |
| 4.0 tpd | 2.2 | -- | 0.84 | -- |

**Table 4:** Other important parameters used in the formulation.

| Parameters | Values | Units | Refs |
|---|---|---|---|
| $NG_t^{avail}$ | $4.16x10^3$ | tNGpd | [16] |
| $\rho^{NG\text{-}H2}$ | 1.23 | kgNG $kgH_2^{-1}$ | [9, 10] |
| $NG^{extract}$ | 0.1 | - | assumption |
| $Em^{max}$ | 4.0 | $kgCO_2$ $kgH_2^{-1}$ | [17] |
| $Cost^{CO2del}$ | | | |
| - dist. < 100 mi. | 9.7 | USD $tCO_2^{-1}$ | [18] |
| - dist. 100-200 mi. | 12.6 | USD $tCO_2^{-1}$ | [18] |
| - dist. 200 – 500 mi | 24.1 | USD $tCO_2^{-1}$ | [18] |

To evaluate the impact of different hydrogen pathways, two HRS onsite production scenarios are considered:

1. IDEAL

   This scenario represents a fully renewable, zero-carbon pathway in which only onsite electrolyzers powered by renewable electricity are permitted at all HRS locations.

2. MIXED

   This scenario allows HRS to be supplied with low-carbon hydrogen from either electrolyzers-renewable electricity or blue $H_2$-$N_2$ generators.

The MILP optimization problem is implemented in GAMS (version 52.3.0) [19] and solved using the CPLEX. The optimization results identify the selected highway segments for HRS deployment, along with the corresponding station capacities and hydrogen production unit. These results are subsequently visualized using GIS-based mapping tools.

## RESULTS AND DISCUSSION

Figures 7 and 8 illustrate the optimal placement of HRS including their associated onsite production technologies, for the two evaluated scenarios: IDEAL and MIXED. Despite the different technology assumptions, both scenarios identify the same 29 HRS locations across New England. Of these, 12 stations are located in MA, 6 in CT, 5 in ME, 3 in NH, 2 in VT, and 1 in RI. While the total number and spatial distribution of HRS remain identical, the allocation of station capacities differs between the two scenarios.

HRS deployment is more densely concentrated in CT and MA, driven by high truck traffic volumes along corridors. In contrast, VT and NH host only five stations in total, despite their long interstate corridors (I-89 and I-93), primarily due to limited access to natural gas pipeline infrastructure. Notably, both scenarios consistently identify the largest HRS (4.0 $tH_2pd$) at segment I89_s92 in VT, which serves hydrogen demand associated with truck traffic through the mountainous regions of VT and NH.

Figure 8 further indicates that CLR-based onsite production is favored in high-demand regions of CT and MA in the MIXED scenario, owing to both demand density and access to $CO_2$ transport routes exiting the region via I95_s1 and I84_s1. Conversely, electrolyzer-based hydrogen production is selected in more remote locations, such as along I-89 in northern VT, where access to $CO_2$ transport options is limited.

From a cost perspective, the IDEAL scenario results in an annualized total system cost of 81.19 million USD $year^{-1}$, whereas the MIXED scenario reduces this cost to 53.62 million USD $year^{-1}$. The corresponding levelized cost of hydrogen (LCOH) at the station level is 9.24 USD $kgH_2^{-1}$ for the IDEAL scenario and 5.96 USD $kgH_2^{-1}$ for the MIXED scenario. As illustrated in Figure 9, this cost reduction is accompanied by increased $CO_2$ emissions. The IDEAL scenario achieves lower emissions at higher cost, while the MIXED scenario offers improved economic performance at the expense of higher $CO_2$ intensity, highlighting a clear trade-off between cost and emissions across hydrogen production pathways.

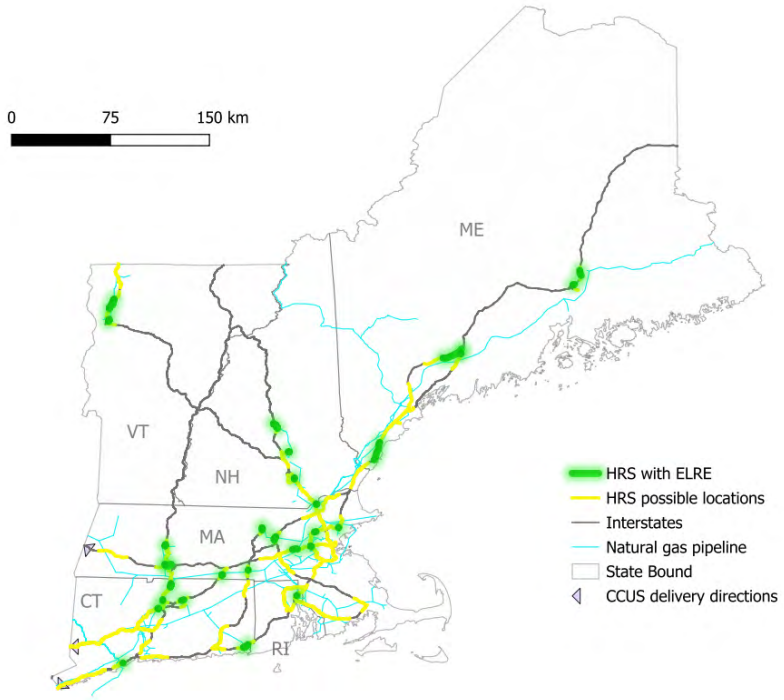

**Figure 7.** Optimal HRS siting with onsite hydrogen production across New England for the IDEAL scenario, which permits only low-carbon $H_2$ via renewable-powered electrolysis.

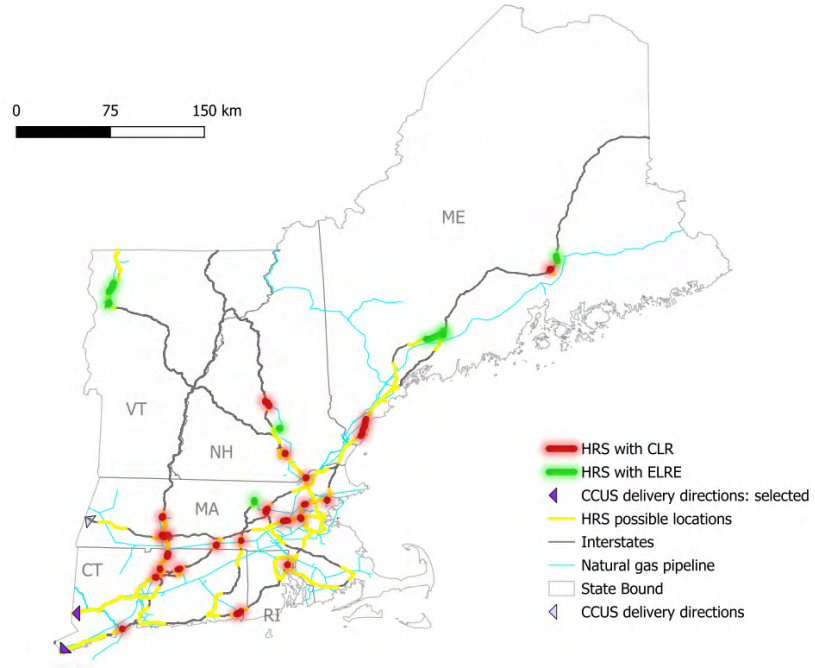

**Figure 8.** Optimal HRS siting with onsite hydrogen production across New England for the MIXED scenario, which allows low-carbon $H_2$ from both renewable-powered electrolysis (green) and blue $H_2$-$N_2$ generators (red).

## CONCLUSIONS

The paper presents the workflow integrating geospatial of highway networks and natural gas intersections, freight activities, and a mixed-integer linear programming (MILP) model that selects sites and sizes HRS

and $H_2$ technologies. By minimizing the total cost, 29 HRS with onsite production were identified in New England to cover $H_2$ demand from 5% of total truck flowing through the region. Most HRS are concentrated in CT and MA due to their high truck flow. The final $H_2$ cost that must be paid by the users varies from 5.96 to 9.24 USD $kgH_2^{-1}$ depending on the onsite $H_2$ production. The IDEAL and MIXED scenarios highlight the trade-offs that must be considered between achieving cost-effectiveness and reducing $CO_2$ emissions.

This study showcases the benefit of onsite production leveraging the existing infrastructure to provide hydrogen at the point of use. Further work should examine additional case studies and regional contexts to evaluate how implementation pathways may vary under different infrastructure and market conditions. Overall, this study provides valuable insights for policymakers in shaping strategies for the decarbonization of long-haul freight transportation.

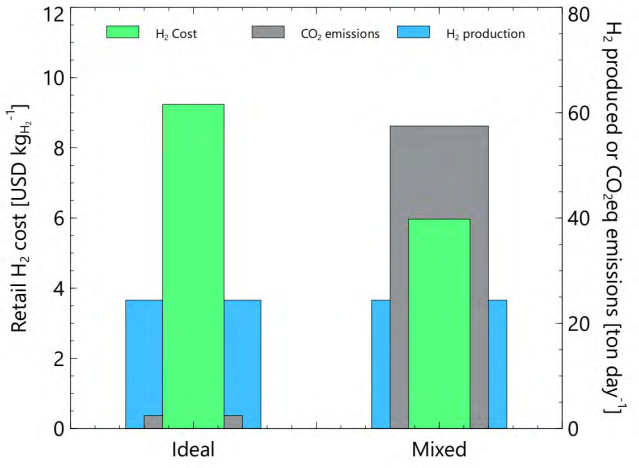

**Figure 9.** $H_2$ retail cost at HRS for the IDEAL and MIXED onsite production scenarios [USD $kgH_2^{-1}$].

## ABSTRACT

Membranes provide an efficient method for treating flue gases to capture $CO_2$ from various point sources, achieving high recovery and purity rates. However, the lack of systematic process-level design tools has limited the translation of advanced membrane materials into large-scale technical and economic metrics. Thus, in this study, we present a superstructure model for the design of membrane-based carbon capture, both from highly energy-intensive industries and from power plants. The superstructure model enables the flexible design and global optimization of multi-stage membrane systems. Multiple membranes are compared under technical performance indicators (specific energy and specific area), while the already commercialized polymeric membranes Polaris and PolyActive are taken into consideration for estimating their economic performance. The presented framework establishes a robust link between material innovation and optimal process design, providing a key tool for the large-scale deployment of membrane-based carbon capture.

**Keywords**: carbon capture, membrane systems, superstructure, optimization

## INTRODUCTION

As 2050 approaches, the efforts to achieve the net-zero transition should be intensified. Under these terms, Carbon Capture, Utilization, and Storage (CCUS) technologies should be strengthened across technical, economic, and environmental dimensions and implemented at an industrial scale. Post-combustion carbon capture can assist energy-intensive industries and existing fossil-fuel power plants in their decarbonization. Various technologies have been proposed and evaluated for this purpose, with membrane process systems constituting a promising option [1].

More specifically, membrane systems are characterized by high energy efficiency, compact and modular design, operational simplicity, and significant environmental benefits relative to other state-of-the-art technologies, without the use of heating utilities, which can be both costly and environmentally impactful. Most recent advances focus on material development, while significant gaps remain in optimizing membrane systems that utilize these materials at process level, and measure their performance under industrial scales [2].

In particular, a comprehensive framework that finally links advanced material properties and large-scale process design is still missing. This work addresses this critical gap by introducing a superstructure modelling framework that systematically optimizes membrane systems for post-combustion carbon capture.

## METHODOLOGY

### Single-stage membrane model

Any membrane network is based on the combination of multiple single stages. To model such a single-stage system, the following assumptions have been made:

- Isothermal conditions along the length of the membrane.
- Negligible pressure drops or concentration polarization phenomena occur on the feed side of the membrane module.

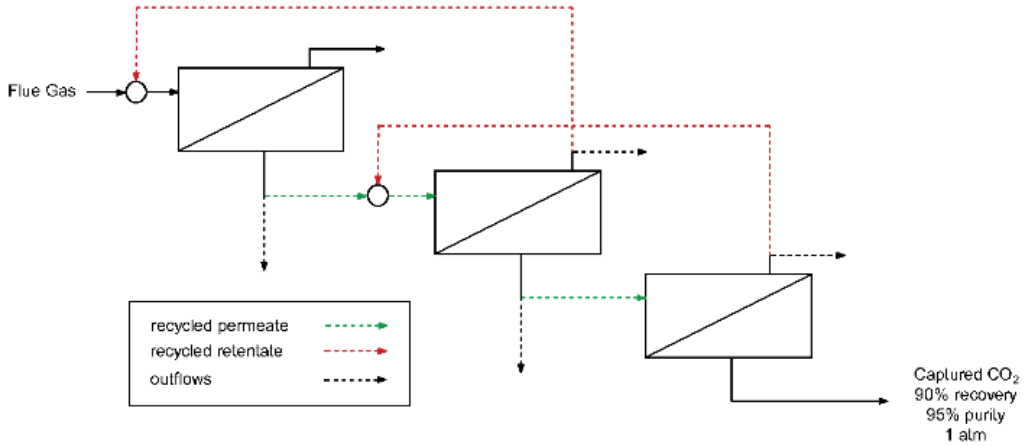

**Figure 1.** Developed membrane module network.

- A cross-current flow pattern is implemented.

In a single-stage membrane process, the membrane sheet is discretized along its length (z-axis) into a specific number of elements of length $dz$ and area $dA$. In each one of them, the transmembrane flux of a component in a flue gas can be estimated using the solution-diffusion model.

$$J_i(z) = P_i(P_{feed}x_{feed,i}(z) - P_{perm}x_{perm,i}(z)) \quad (1)$$

where $P_i$ the permeance of the component $i$, and is a characteristic of the membrane material used, $P_{feed}$ and $P_{perm}$ the pressure applied in the feed and the permeate channel, respectively, $x_{feed,i}$ and $x_{perm,i}$ the molar fractions of the component $i$ in the feed stream and right after crossing the membrane. A multicomponent mixture is considered, so $i$ corresponds to $CO_2$, $N_2$, $O_2$, and $H_2O$.

The total flux can be estimated by the summation of the fluxes of the individual components (Equation (2)). By implementing the total and partial mass balances among the elements, the rest of the flows and compositions can be determined, through Equations (3-6):

$$J_{tot}(z) = \sum_{i=1}^{components} J_i(z) \quad (2)$$

$$Q_{ret}(z) = Q_{feed}(z) - J_{tot}(z)\,dA \quad (3)$$

$$x_{i,ret}(z)\,Q_{ret}(z) = x_{i,feed}(z)\,Q_{feed}(z) - J_i(z)\,dA \quad (4)$$

$$Q_{perm} = \sum_{z=0}^{L} J_{tot}(z)dA \quad (5)$$

$$X_{i,perm} = \frac{\sum_{z=0}^{L} J_i(z)dA}{Q_{perm}} \quad (6)$$

where $Q_{feed}$ and $x_{ifeed}$, $Q_{ret}$ and $x_{i,ret}$ and $Q_{perm}$ and $x_{i,perm}$ the flow rates and the molar fractions comprising the feed the retentate and the permeated side streams [3, 4].

## Membrane module network

The implemented superstructure model is comprised of 3 membrane stages. To model this network, Equations (1)-(6) are developed once for each stage, and additional mass balances are introduced to specify the connections between them. The retentate stream of each stage can either exit the system or be recycled to the feed of the previous stage. The retentate from the 1st-stage has the lowest $CO_2$ content, thus it is assumed to exit the system directly. For the permeate streams concentrated in $CO_2$, the option of feeding them to the next stage or bypassing this route is available for all 3 stages. This feature enables the determination of the presence or the absence of a membrane stage without introducing integer variables, despite the discrete nature of the decision [3, 5].

In Figure 1, a schematic of the developed network is shown, with all allowable connections depicted. Dashed lines correspond to plausible flows, whose presence or absence gives the final configuration of the system, and is a subject of the optimization performed.

To increase the driving force at each stage, compressors and vacuum pumps are installed on the feed and permeate sides, respectively. To determine their energy consumption (kW), Equation (7) is applied to either the compressors (c) or the vacuum pumps (vp), using the corresponding efficiency and flow rate.

$$W_{c/vp} = \frac{10^{-3}}{\eta_{c/vp}} \cdot \frac{\gamma}{\gamma - 1} \cdot RTQ \cdot \left[ \left( \frac{P_{high}}{P_{low}} \right)^{\frac{\gamma-1}{\gamma}} - 1 \right] \quad (7)$$

Turbines are also included in the network at the side

of the retentate streams that either exit the system or being recycled, to recover part of the electricity used for compression. The recovered energy (kW) is calculated through Equation 8.

$$W_{turb} = \frac{\eta_{turb}}{10^3} \cdot \frac{\gamma}{\gamma - 1} \cdot RTQ \cdot \left[1 - \left(\frac{P_{low}}{P_{high}}\right)^{\frac{\gamma-1}{\gamma}}\right] \quad (8)$$

The heat capacity ratio $\gamma$ (-) is determined based on the composition of each gaseous stream, while the efficiency for the compressors, the vacuum pumps and the turbines are equal to 0.85, 0.7 and 0.9 [6].

## Key performance indicators

In this analysis, the developed superstructure membrane module network is used to estimate both the technical and economic performance of different membrane materials. Thus, appropriate key performance indicators are defined. Based on them, the evaluation of the designed systems is determined.

The primary key process performance metrics are specific energy (MJ/kg$_{CO_2}$) and specific area (m$^2$/(kg$_{CO_2}$/s)). These two metrics are strongly influenced by the properties of the membrane material and the composition of the flue gas being treated, and they exhibit a trade-off.

$$sE = \frac{W_{total}}{X_{CO_2,perm}\, Q_{perm} MW_{CO_2}} \quad (9)$$

$$sA = \frac{A_{total} 10^3}{X_{CO_2,perm}\, Q_{perm}\, MW_{CO_2}} \quad (10)$$

Moreover, during the design of a carbon capture system regardless of the technology implemented, specific purity and recovery rates should be achieved. For this reason, the corresponding metrics can be calculated through Equations (11-12), respectively. These two metrics are introduced as constraints during the design of the membrane systems studied here.

$$Pu_{CO2} = \frac{X_{CO_2,perm}}{1 - X_{H_2O,perm}} \quad (11)$$

$$Rec_{CO2} = \frac{X_{CO_2,perm} \cdot Q_{perm}}{X_{CO_2,feed} \cdot Q_{feed}} \quad (12)$$

From literature, the purity of the final stream of captured $CO_2$ should be at least 95% to enable storage or utilization as raw material, while recovery should reach values of 90%.

For cost calculations, the methodology presented in previous works [4, 7] is followed. In the present work, we adopted fixed values for the electricity price and for the membrane material, equal to 0.1$/kWh and 50$/m$^2$ [4, 7].

## Membrane materials and case studies

In Table 1, the material properties of $CO_2$ permeance (GPU) and the selectivity values for $CO_2/N_2$, $CO_2/O_2$, and $CO_2/H_2O$ (-) required by the process model are reported for 5 materials. The selected membranes belong to different material classes, resulting in markedly different combinations of their properties. Two are polymeric and already at commercial scale (Polaris and PolyActive); two are facilitated-transport-based (FSC and FT-PVAm); and one is an inorganic, graphene-based membrane (NSLG, nanoporous single-layer graphene).

**Table 1:** Material properties of membranes tested during the analysis/optimization [4, 8].

| Material | $P_{CO_2}$ (GPU) | $a_{CO_2/N_2}$ | $a_{CO_2/O_2}$ | $a_{CO_2/H_2O}$ |
|---|---|---|---|---|
| Polaris | 2200 | 50 | 10 | 0.1 |
| PolyActive | 1450 | 46 | 17 | 0.1 |
| FSC | 838 | 95 | 21 | 0.1 |
| FT-PVAm | 1456 | 165 | 10 | 0.1 |
| NSLG | 10000 | 30 | 13 | 1.0 |

These materials and their performances are tested for the treatment of a number of flue gases, ranging from highly concentrated point-sources, with $CO_2$ content of 13-24% (coal power plant, cement plant, oil refinery) to more diluted ones with <8% $CO_2$ content (natural gas power plant, aluminium industry).

## Optimization framework

The aforementioned membrane module network is formulated as a nonlinear programming (NLP) problem in the GAMS-Python environment, GamsPy. No integer variables are introduced into the system of equations, and discrete decisions, such as the presence or absence of a membrane module in the final system configuration, are determined entirely by the model's continuous variables. Despite the absence of integer variables, the final problem remains non-convex due to the nature of the equations that comprise the model of the developed superstructure. Such optimization problems can be difficult to solve and to guarantee global optimality. To prevent such issues, the global solver BARON [9] is used.

Two different optimization problems are solved for each material and case study:

- the bi-objective optimization of specific energy and specific area, by implementing the weighting method, and
- the single objective minimization of the capture cost.

In both cases, optimization is performed subject to two constraints: purity (95%) and recovery (90%), which are implemented as inequality constraints.

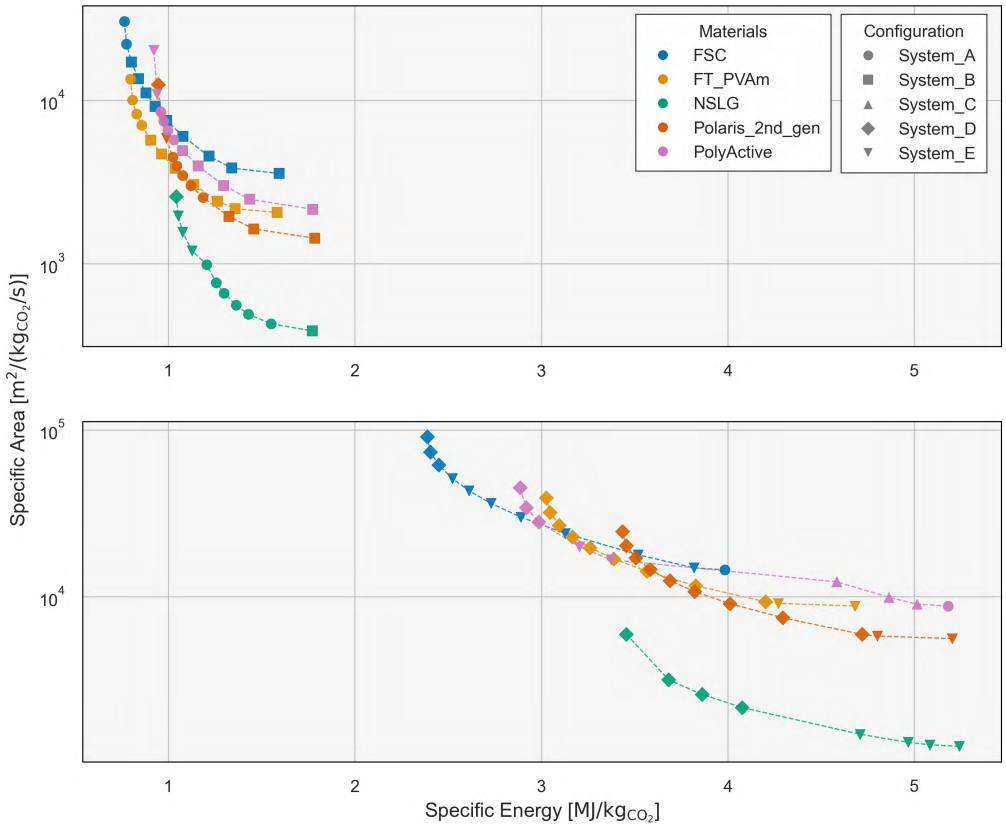

**Figure 2:** Technical Pareto fronts when treating a flue gas from a coal power plant with composition $x_{CO_2}$=13.7%, $x_{N_2}$=72.8%, $x_{O_2}$=3.6% (up) and from a natural gas power plant with composition $x_{CO_2}$=3.9%, $x_{N_2}$=75.2%, $x_{O_2}$=12.3% (below), under purity and recovery constraints of 905 and 90% respectively. Each curve is comprised of points with a variety of system configurations.

## RESULTS AND DISCUSSION

### Technical bi-objective optimization

In this series of optimization problems, the Pareto front curves for the specific energy and specific area of the studied membrane materials are generated for all membrane materials listed in Table 1. We report the results for two case studies with high and low $CO_2$ concentrations (Figure 2). The two objectives are closely correlated with the composition of the treated flue gas and the material properties. By using the superstructure model rather than a fixed-configuration model for membrane process, we produce Pareto fronts along which the points represent optimal configurations with different numbers of membrane stages and connections among them. The exact configurations suggested by the optimization are described in Table 2 and are shown in the Pareto fronts of Figure 2 with different symbols.

This approach finally allows a detailed comparison between materials, and the identification of limiting properties that determine each material's performance depending on the case study.

From this analysis, we observe that the $CO_2/O_2$ selectivity of the membrane material affects the allowable and feasible configurations on the Pareto front, particularly when the $O_2$ content is high. For example, in the Pareto fronts of specific energy-specific area of the FSC and FT-PVAm membranes, for the coal power plant case study, all the points correspond to systems with 2 stages thanks to the high selectivity. At the same time, the lower $CO_2$ permeance of these materials leads to higher specific area values.

For diluted flue gases with $CO_2$ concentrations < 8%, as in a natural gas power plant, the estimated specific energy and specific area values increase significantly. More specifically, the curves of most materials consist of points corresponding to systems with 3 stages, and only the curves for FSC and PolyActive (which have higher $CO_2/O_2$ selectivity) contain points corresponding to systems with 2 stages.

Moreover, we notice that some of the tested membranes achieve similar performances in terms of specific energy and area, by adopting different operating conditions or system configurations depending on the membrane properties. However, with diluted flue gases, the

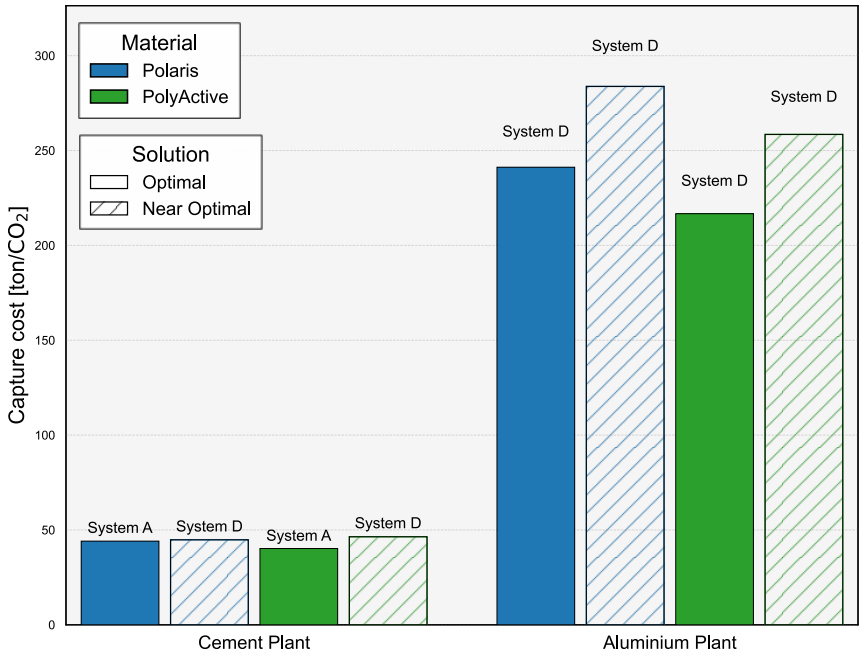

**Figure 3.** Best two minimum capture cost values for Polaris and PolyActive for capturing $CO_2$ from a cement plant, and an aluminium plant.

separation is more challenging, and all membranes require more complex configurations to meet the constraints of recovery and purity.

**Table 2:** Description of the membrane networks suggested after the technical and economic optimization.

| | |
|---|---|
| **Double Stage Systems** | |
| System A | Recycle of the 2nd stage retentate to the 1st stage feed |
| System B | Recycle of the 2nd stage retentate to the 1st stage feed and bypass of the 1st permeate to the final outlet |
| System C | Recycle of the 2nd stage retentate to the 1st stage feed and recycle of the 2nd stage permeate to the 2nd stage feed |
| **Triple Stage Systems** | |
| System D | Recycle of the 2nd and 3rd stages retentates to the feed of the previous stage |
| System E | Recycle of the 2nd and 3rd stages retentates to the feed of the previous stage and bypass of the 2nd stage permeate to the final outlet |

## Cost minimization

The evaluation of economic performance is limited to the commercialised membrane materials, Polaris and PolyActive, for which price data are available. In this analysis, the capture cost is used as the objective function. In Figure 3, we report the results for two case studies: one with high $CO_2$ content (cement plant: $x_{CO_2}$=18%, $x_{N_2}$=63%, $x_{O_2}$=10%) and one with lower $CO_2$ content (aluminium plant: $x_{CO_2}$=4%, $x_{N_2}$=74.6%, $x_{O_2}$=20.5%). In particular, we show the minimum capture cost (optimal), along with the next-best optimal value (near-optimal).

In the case of the Cement plant, with high $CO_2$ content, the minimum capture cost can be secured with a double-stage system. However, for the membrane material Polaris, a slightly higher capture cost (~2%) can be achieved with a triple-stage system. The analysis of near-optimal solutions can be very helpful during decision-making. Indeed, a triple-stage system has typically lower specific energy consumption, thus it can be preferred in cases of an increase in the electricity price, which is always prone to a plethora of uncertainties, to enhance robustness in the economic performance of the system.

For the more dilute flue gas from aluminium plants, the next-best points for both materials have higher specific energy and specific area values, under the same system configuration. This means that, for challenging separations with low $CO_2$ and high $O_2$ concentrations, the points with minimum cost lie at the very end of the Pareto front, in the region of lower specific energy. In this case, achieving a similar capture cost with a different configuration would require adding a 4th stage, which would lower specific energy and increase specific area.

## Robustness of the computational framework

The presented framework constitutes a key tool for

evaluating the performance of both established and emerging membrane materials at the process level. To improve the robustness and the computational efficiency of the model simultaneously, we have built the model as a non-linear program, avoiding discrete variables and defining a maximum number of possible recycle and bypass streams based on preliminary analysis. Also, we use the global solver BARON to ensure global optimality, given the non-convex behaviour of the superstructure that introduces many local minima in the solution domain.

Finally, the framework allows to perform both technical and economic optimization of different material properties under multiple case studies. By determining the optimal membrane network and operating conditions for each available material, we can determine the best option for each case study.

These results may also contribute to identify material properties that are desirable to improve the performance of the membrane process and to drive material enhancements in this direction. Finally, the ability to identify alternative designs with similar performance metrics provides the flexibility to consider both the operability of each design in real-life applications and its robustness under uncertainty.

## CONCLUSION

We present an inclusive and detailed superstructure model capable of addressing multiple case studies across membrane materials and flue gas compositions. The framework enables us to identify optimal process configurations through fast and robust multi-objective technical and economic optimization. A range of membrane materials with varying material properties is tested, and the optimal configuration at both the structural and operational levels is determined. Through technical optimization, material performance targets are established to improve process feasibility. Such a framework constitutes an important advance in bridging the gap between small-scale material development and large-scale implementation of membrane process systems.

## ABSTRACT

Water supply in the countryside of São Paulo state, Brazil, is based on groundwater resources that can be contaminated with substances such as heavy metals or fluoride, requiring the usage of water treatment technologies such as Reverse Osmosis (RO); however, RO systems create a stream of high-salinity brine, with negative environmental consequences. Besides, regulatory constraints demand that well operations must be interrupted for a daily contiguous period. In this work, a Mixed-Integer Linear program (MILP) was implemented to define water network topologies and well exploitation schedules, under these downtime constraints, aiming the minimization of RO plant capacity (and, therefore, of brine discharges). This model was then applied to the water supply of a small city in the São Paulo countryside, with around 8000 inhabitants, where high fluoride concentrations warranted the implementation of an RO system. Demand variations between weekdays and weekends (with demands 52.7% higher) were modeled using a multi-scenario formulation. This model was optimized under different conditions of tank capacity and membrane technologies. Different membrane systems (with salt retention rates varying from 85% to 99.5%) associated with different storage tanks (with volumes between 50 and 1000 $m^3$) led to different system topologies, and a trade-off was observed between plant capacity, tank capacity, and operating pressure: while a low pressure system with a small tank capacity required larger plant capacities (up to 44.02 $m^3/h$), high pressure systems associated with large storage tanks required smaller plants for treatment (with a capacity as small as 11.15 $m^3/h$).

## INTRODUCTION

### Water Production Networks and Reverse Osmosis Plants

In an urban center, the water supply system is comprised of networks of water abstraction, treatment and consumption units. The abstraction units send raw water to the treatment units, where it is converted to drinking water for distribution to the consumers.

The production of drinking water under adequate quality constraints and in sufficient volume to match the demands of the consumers is a key challenge for several urban centers: climate change-fueled water scarcity, growing population, and improvements in living standards increase design and operation requirements of water production and distribution systems. Hence, the enhancement of currently existing systems, the exploration of alternative water resources and the adoption of different water treatment technologies are often needed.

Among these new technologies, the usage of Reverse Osmosis (RO) systems for the treatment of groundwater sources is an attractive possibility. In these membrane-based separation plants, a brackish water stream is split in two: a high-salinity stream (the “reject” or “concentrate”) and a low-salinity stream (the “permeate”). This separation technology is one of the possible

alternatives for the purification of water resources with high concentrations of monovalent ions, such as fluoride, but some disadvantages (such as its high energy needs and the discharge of a considerable volume of brine) warrant careful considerations before implementation [1].

## Optimization of Water Production Networks

Due to the widespread presence of water networks, in the most varied engineering fields, several optimization strategies have been applied to their design and operation. These methods can be categorized in two groups: “pinch” approaches, which require less computational resources but don’t necessarily lead to an optimal solution, and systematic approaches, in which all mass balances of each equipment in the system become constraints in a mathematical program. This approach can yield demonstrably optimal solutions, and makes the selection of generic objective functions straightforward; however, more computational resources are required [2]. For instance, when the concentrations of contaminants are important to the problem (as is the case in urban water production networks), the resulting mathematical program can be classified as a pooling problem, which must either be solved as a non-convex, nonlinear optimization program, or linearized through the usage of integer variables [3].

Classical analyses of water networks usually focused on systems that operate in a steady-state regime, relevant to industrial contexts. However, in an urban water supply context the dynamic operation of the system needs to be taken into account: not only the water demand is variable, the water resources might only be available in selected periods of the day. Hence, a more sophisticated mathematical tooling is required, and these systems must be modeled through an Optimal Control formulation. In this technique, the temporal domain is discretized, and the optimization variables become the state of each equipment in the system in a selected set of time instants [4].

## São Paulo State Legal Requirements

One additional operational requirement, particular to São Paulo state, is the legally-mandated contiguous daily downtime period: every day, pumping from each well operation has to be interrupted for a single period of four hours, to allow the water level in the well to recover. This constraint is absent from previously published models, but is paramount to the water management company, allowing it to replace *ad-hoc* heuristics with results from a deterministic optimization model.

# MATERIALS AND METHODS

## Mathematical Programming

The optimal control problem was initially converted to a Disjunctive Programming formulation: the optimization horizon was divided in $H$ intervals and the water production network was modeled as a set of equipments (nodes) connected between themselves. For every equipment $E$, for every instant $h \in \{1, 2, \ldots, H\}$, were defined flowrates $Q_E^h$ (in m³/h) and contaminant loads $F_E^h$ (in g/h) for each of its inputs and outputs. Each equipment of the system was modeled linearly, as shown below, and the inputs and outputs of connected equipments were subjected to equality constraints. The logical constraints were converted to a Mixed-Integer Linear Programming (MILP) formulation, and the resulting program was solved.

### Equipments and connections

All equipments were modeled in a straightforward fashion; however, a more sophisticated formulation was required for wells (contiguous downtime requirement), splitters (linearization of bilinearities) and tanks (multi-scenario optimization with the usage of design days).

### Wells

For a well $W$, its downtime fraction $D_W$ was known, as well as its contaminant concentration $c_W$ and its maximum water production $Q_{\max,W}$. Initially, were defined output flowrates $Q_W^h$ and contaminant loads $F_W^h$ for each instant $h$, as wells as their limits (1 and 2, respectively).

$$0 \leq Q_W^h \leq Q_{\max,W} \forall h \in \{1, 2, \ldots, H\} \quad (1)$$

$$F_W^h = c_W Q_W^h \quad (2)$$

For the downtime modeling, two boolean variables were defined for each instant $h$: $X_W^h$ was True if and only if the well was inactivated in instant $h$ (3), and $Y_W^h$ was True if and only if $X_W^h$ was True and $X_W^{h-1}$ was False (4).

$$\begin{bmatrix} X_W^h \\ Q_W^h = 0 \end{bmatrix} \vee \begin{bmatrix} \neg X_W^h \\ 0 \leq Q_W^h \leq Q_{\max,W} \end{bmatrix} \quad (3)$$

$$\begin{gathered} X_W^h \wedge \neg X_W^{h-1} \Rightarrow Y_W^h \forall h \in \{2, 3, \ldots, H\} \\ X_W^1 \wedge \neg X_W^H \Rightarrow Y_W^1 \end{gathered} \quad (4)$$

The downtime (5) and its contiguity (6) were constrained through the number of True $X_W^h$ and $Y_W^h$, respectively.

$$\text{card}\{h \in \{1, 2, \ldots, H\} : X_W^h\} \geq H D_W \quad (5)$$

$$\text{card}\{h \in \{1, 2, \ldots, H\} : Y_W^h\} \leq 1 \quad (6)$$

### RO plants and brine discharges

A RO plant $P$ is characterized by its minimum and maximum feed flowrates $Q_{\min,P}$ and $Q_{\max,P}$, its yield $\eta_P$, defined as the ratio between permeate and feed flowrates, and its salt retention $\rho_P$, defined as the rate between brine and feed contaminant loads. For each

instant $h$, were defined feed, permeate and concentrate flowrates ($Q^h_{\text{in},P}, Q^h_{\text{perm},P}$ and $Q^h_{\text{brine},P}$, respectively) and contaminant loads ($F^h_{\text{in},P}, F^h_{\text{perm},P}$ and $F^h_{\text{brine},P}$, respectively). The yield (7), salt retention (8), mass balances (9) and operation limits (10) were modeled.

$$Q^h_{\text{perm},P} = \eta_P Q^h_{\text{in},P} \tag{7}$$

$$F^h_{\text{brine},P} = \rho_P F^h_{\text{in},P} \tag{8}$$

$$\begin{aligned} Q^h_{\text{in},P} &= Q^h_{\text{perm},P} + Q^h_{\text{brine},P} \\ F^h_{\text{in},P} &= F^h_{\text{perm},P} + F^h_{\text{brine},P} \end{aligned} \tag{9}$$

$$Q_{\min,P} \le Q^h_{\text{in},P} \le Q_{\max,P} \tag{10}$$

Each plant requires a brine discharge unit $R$ with input flowrates and contaminant loads (respectively, $Q^h_{\text{in},R}$ and $F^h_{\text{in},R}$) with a maximum contaminant load $c_R$, which limits brine concentration (11).

$$F^h_{\text{in},R} \le c_R Q^h_{\text{in},R} \tag{11}$$

## Mixers, splitters and selectors

A mixer $M$ is associated with mass balances constraints (12), that ensure that its output flowrates and contaminant loads ($Q^h_{\text{out},M}$ and $F^h_{\text{out},M}$, respectively) match the sum of its $n_M$ input flowrates $i_1, i_2, \ldots, i_{n_M}$ and contaminant loads ($Q^h_{\text{in},i_j,M}$ and $F^h_{\text{in},i_j,M}$, respectively, for $j \in \{1, 2, \ldots, n_M\}$).

$$\begin{aligned} \sum_{j=1}^{n_M} Q^h_{\text{in},i_j,M} &= Q^h_{\text{out},M} \\ \sum_{j=1}^{n_M} F^h_{\text{in},i_j,M} &= F^h_{\text{out},M} \end{aligned} \tag{12}$$

Splitters, on the other hand, required a more sophisticated model. For a splitter, $S$, with two output streams ($o_1$ and $o_2$), mass balances were introduced through constraint (13), but the same-concentration constraint (14) had to be replaced by a linear formulation.

$$\begin{aligned} Q^h_{\text{in},S} &= Q^h_{\text{out},o_1,S} + Q^h_{\text{out},o_2,S} \\ F^h_{\text{in},S} &= F^h_{\text{out},o_1,S} + F^h_{\text{out},o_2,S} \end{aligned} \tag{13}$$

$$Q^h_{\text{in},S} F^h_{\text{out},o_1,S} = Q^h_{\text{out},o_1,S} F^h_{\text{in},S} \tag{14}$$

Constraint (14) was linearized with a logarithmic piecewise discretization [5]. Initially, the number $G_S = 2^{N_S}$ of possible split fractions was chosen, with $N_S \in \mathbb{N}$. Then, for each $n \in \{1, 2, \ldots, N_S\}$ two continuous variables were defined ($Q^h_{\text{internal},n,S}$ and $F^h_{\text{internal},n,S}$), as well as a boolean variable $W^h_{n,S}$. These variables were constrained with a Disjunctive Programming formulation (15) and the continuous variables were combined to yield output flowrates and contaminant loads (16).

$$\begin{bmatrix} W^h_{n,S} \\ Q^h_{\text{internal},n,S} = \frac{2^{-n} Q^h_{\text{in},S}}{1 - 2^{-N_S}} \\ F^h_{\text{internal},n,S} = \frac{2^{-n} F^h_{\text{in},S}}{1 - 2^{-N_S}} \end{bmatrix} \vee \begin{bmatrix} \neg W^h_{n,S} \\ Q^h_{\text{internal},n,S} = 0 \\ F^h_{\text{internal},n,S} = 0 \end{bmatrix} \tag{15}$$

$$\begin{aligned} Q^h_{\text{out},o_1,S} &= \sum_{n=1}^{N_S} Q^h_{\text{internal},n,S} \\ F^h_{\text{out},o_1,S} &= \sum_{n=1}^{N_S} F^h_{\text{internal},n,S} \end{aligned} \tag{16}$$

Finally, for topology optimization, a simplified splitter, with integer and constant split fraction, is introduced. This unit defines to which of its two possible outputs all input flowrate and contaminant loads are directed. Constraint (17) makes use of a boolean variable ($V_S$) to model a given selector, $S$.

$$\begin{bmatrix} V_S \\ Q^h_{\text{out},o_1,S} = Q^h_{\text{in},S} \\ Q^h_{\text{out},o_2,S} = 0 \\ F^h_{\text{out},o_1,S} = F^h_{\text{in},S} \\ F^h_{\text{out},o_2,S} = 0 \end{bmatrix} \vee \begin{bmatrix} \neg V_S \\ Q^h_{\text{out},o_1,S} = 0 \\ Q^h_{\text{out},o_2,S} = Q^h_{\text{in},S} \\ F^h_{\text{out},o_1,S} = 0 \\ F^h_{\text{out},o_2,S} = F^h_{\text{in},S} \end{bmatrix} \tag{17}$$

## Consumers and associated tanks

The water supplied to a population center must obey the legal requirements for contaminant load concentration, and the supplied volume must be enough to cover the local water demand. In this model, consumers and storage tanks were modeled as a single unit: while offering less flexibility, by constraining contaminant load requirements in the tank input, and demand in its output, no bilinearity is introduced, reducing the complexity of the mathematical program.

For a consumer $C$, are known the capacity of the associated tank ($V_{\max,C}$) the demand in each instant $h \in \{1, 2, \ldots, H\}$ ($Q^h_{\text{demand},C}$) and the minimum and maximum contaminant concentrations ($c_{\min,C}$ and $c_{\max,C}$, respectively). For each instant $h$ were defined input and output flowrates (respectively, $Q^h_{\text{in},C}$ and $Q^h_{\text{out},C}$), input contaminant load ($F^h_{\text{in},C}$), and volume of water stored ($V^h_C$). Constraints (18) and (19) model the behavior of the tank, constraint (20) ensures that water demand is met, and constraint (21) ensures that input contaminant concentration lies between the legally allowed limits. Constraint (22) ensures that the daily operation of the tank is cyclical, that is, the difference $\Delta V_C$ between the volumes stored in the tank at the start (instant $0$) and end (instant $H$) of the day is equal to $0$.

$$0 \le V^h_C \le V_{\max,C} \tag{18}$$

$$\begin{aligned} &Q^{h-1}_{\text{in},C} - Q^{h-1}_{\text{out},C} + V^{h-1}_C = V^h_C \\ &\qquad \forall h \in \{2, 3, \ldots, H\} \\ &Q^H_{\text{in},C} - Q^H_{\text{out},C} + V^H_C = V^1_C + \Delta V_C \end{aligned} \tag{19}$$

$$Q^h_{\text{out},C} = Q^h_{\text{demand},C} \tag{20}$$

$$F^h_{\text{in},C} \le c_{\max,C} Q^h_{\text{in},C}$$
$$F^h_{\text{in},C} \ge c_{\min,C} Q^h_{\text{in},C} \quad (21)$$

$$\Delta V_C = 0 \quad (22)$$

## Superstructure optimization

To assess the inclusion or exclusion of a given unit $U$, a binary variable $z_U$ is defined, and constraint (23) forces the inactivation of the unit if this binary variable is zero.

$$z_U = 0 \Rightarrow Q^h_{\text{in},U} = 0 \forall h \in \{1, \ldots, H\} \quad (23)$$

## Multi-scenario modeling

Assuming that a given period of time can be split in $D$ sets of $N_d$ days each with similar water supply and demand (for instance, week days and weekends, or days in different months of the year), a multi-scenario approach can be employed, instead of optimizing the system for each time instant [6]. Under this model, $d$ "clones" of the system are optimized simultaneously, with the inclusion of extra constraints to ensure that the optimal design is the same for the entire period: for all pairs $(d, d')$ of sets of days, all selectors $S$ must activate/inactivate the same output (23), all units $U$ which could be included or excluded from the system are included/excluded (24) and the volume of each tank $C$ must be a continuous function of time (25) (constraint (22), defined in the previous section, must be discarded). Finally, the volume stored in the tank must be greater than zero and smaller than its capacity (25).

$$V_{S,d} = V_{S,d'} \quad (24)$$

$$z_{U,d} = z_{U,d'} \quad (25)$$

$$V^H_{C,d} + (N_d - 1)\Delta V_{C,d} + Q^H_{\text{in},C,d} - Q^H_{\text{out},C,d} = V^1_{C,d+1} \quad (26)$$

$$0 \le V^h_{C,d} + (N_d - 1)\Delta V_{C,d} \le V_{\max,C} \quad (27)$$

The contiguity of the downtime periods required a few more constraints, however. As defined in constraint (5), the number of intervals in which some well $W$ had to be inactivated is $A_W = [HD_W]$. If $D = 2$, it can be shown that the contiguity of the downtime periods is assured (even if the downtime is divided between two days) if Constraint (26) applies.

$$Y^{H-A_W+n}_{W,d=1} = Y^{H-A_W+n}_{W,d=2} \forall n \in \{2, \ldots, A_W\} \quad (28)$$

Finally, to avoid global deficit or surplus, $V^1_{C,D+1}$ is defined as $V^1_{C,1}$ in Constraint (26).

## Objective function

Finally, the objective function was defined as the total permeate production in the plant (27), as a proxy for capital and operational costs. However, the model accepts different objective functions, with the possibility of minimizing water usage or other system properties.

$$\begin{aligned} \min \quad & \textstyle\sum_{d=1}^{D} \left( N_d \sum_{h=1}^{H} Q^h_{\text{perm},P} \right) \\ \text{s.t.} \quad & \text{constraints (1-13)} \\ & \text{constraints (15-21)} \\ & \text{constraints (23-28)} \end{aligned} \quad (29)$$

## Case Study

The model defined in the previous sections was applied to the optimization of the design and operation of the water production system in a small city in São Paulo state, Brazil (Figure 1), where the water demands of a population of *c.* 8000 people was supplied by five wells (Table 1) with high fluoride concentrations. The modeling scenarios investigated contemplated fluoride removal by RO (plant $P$, in the figure) and daily contiguous periods of four hours in which water production from each well was interrupted. The permeate produced by this RO plant, with a low concentration of fluoride, was then mixed with the raw well water, to adjust the fluoride concentration in the distributed water to the legally allowed concentraion interval (between 0.6 and 0.8 mg/L). This stream supplied a water storage tank $T$, which supplied the city. In the base case, the storage tank had a capacity of 500 m³, and the plant operated with a recovery of 80% and a salt retention of 95%. Afterwards, sensitivity analyses were performed to assess the impact of tank capacity and salt retention.

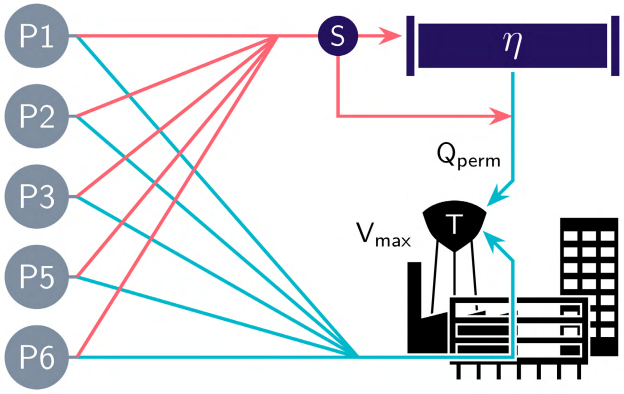

**Figure 1.** Schematic representation of the water production network studied, showing an RO plant with a permeate production $Q_{\text{perm}}$ and a salt retention $\eta$, supplying a tank with capacity $V_{\max}$. Two water pipes must be implemented: one (a subset of the structure shown in pink) feeds the water treatment system and the other (in teal) supplies the storage tank $T$. A splitter $S$ splits the stream that feeds the plant in an excess water stream (which is sent to the storage tank) and a plant feed stream. Mixers, selectors, and the brine discharge are not shown, for clarity.

**Table 1:** Properties of the wells.

| Well | Maximum flowrate ($m^3/h$) | Fluoride concentration (mg/L) |
|---|---|---|
| P1 | 16.0 | 6.15 |
| P2 | 28.0 | 6.03 |
| P3 | 23.0 | 6.62 |
| P5 | 30.0 | 1.09 |
| P6 | 16.0 | 1.04 |

The water demand exhibited hourly and daily variations, with the weekend demand of 1, 608 $m^3$/day being 52.7% higher than demand in weekdays (equal to 1, 056 $m^3$/day). Hence, a multi-scenario approach was adopted, with two sets of days ($N_1$=5 week days and $N_2$=2 weekend days).

The goal of the optimization was to determine the optimal plant capacity and network topology, obeying legal requirements for minimum and maximum fluoride concentrations and producing drinking water, with water quality within the legal drinking water standards, to supply the demand of the city. The water storage tank accumulated excess drinking water produced during the week to cover the needs of the (higher demand) weekends. Finally, plant input and output flowrates were set to be constant, requiring the introduction of a new constraint (30), where $Q_{\text{perm},P}$ was a continuous variable also constrained by (10). As the flowrates were the same in every period, the objective-function was simply the sum of of the permeate output in all instants considered, without need for the weights $N_d$ adopted in (29).

$$Q^H_{\text{perm},P,d}=Q_{\text{perm},P} \quad \forall d \in \{1,2\}, \forall h \in \{1,\ldots,H\} \tag{30}$$

In this model, constraint (27) was adapted, replacing the factor $(N_d-1)$ by the factor $N_d$. This modification, which allowed one extra day of weekend or week day demand, was required to improve the robustness of the model, permitting the operation of the system in "long weekend" conditions.

In this model, a bi-hourly discretization was adopted (that is, $H$=12), and the granularity of the logarithmic approximation of the splitter was set to $G_S$=16=$2^4$. This granularity leads to small (<5%) differences between the optimal split fractions obtained from the linearized model and the results which would be obtained from the nonlinear program.

The model was implemented in the modeling language CasADi [7], in a Python script, and solved with the Mixed-Integer Linear solver CPLEX 22.1.1.0. The Mixed-Integer gap was set to 0.01%. The script was executed in a personal computer running Debian GNU/Linux 12, with an 8-core/16-thread AMD Ryzen 7 2700 CPU and 48 GB of RAM.

# RESULTS AND DISCUSSION

## Base case

Initially, the system was implemented adopting $\rho$=95% and $V_{\max,T}$=500 $m^3$. It was possible to optimize the resulting mathematical program to optimality in a reasonable time frame, obtaining a minimal plant capacity of $Q_{\text{perm},P}$=17.76 $m^3$ (Table 2).

**Table 2:** Properties of the mathematical program and software performance.

| MILP properties (after presolve) | |
|---|---|
| Number of variables | 2077 |
| Continuous variables | 1741 |
| Binary variables | 336 |
| Constraints | 1294 |
| **Software performance** | |
| Feasibility | Feasible |
| Mixed-Integer Gap | 0.00% |
| Execution time (s) | 107.69 |
| Best objective function value | 1065.74 |

In the optimal solution, the storage tank, as expected, accumulated excess drinking water production during the week days and used this water to cover the increased weekend demand (Figure 2a). In the optimal solution, the production of wells 1, 2 and 3 was directed to the RO plant, while the production of wells 5 and 6 was sent directly to the tank (as illustrated in Figure 3, point "e"). The downtimes of each well obeyed the legal requirements (Figure 2b).

## Tank capacity and plant salt retention effects

To assess the impacts on plant capacity requirements of changing tank capacity or the selection of membrane elements (properties that lead to complex financial trade-offs: larger plants require higher volumes of feedwater and lead to higher reject flowrates, membrane elements with higher salt retention rates have higher energy demands, and the CAPEX of a tank grows with its capacity) a sensitivity analysis was performed. 300 pairs $(\eta, V_{\max,T})$ of salt retention and tank capacity values were selected in a centered square lattice with $\eta$ between 85 and 99.5% and $V_{\max,T}$ between 50 and 1000 $m^3$. Then, the resulting mathematical program was optimized, as the base case was in the previous section. Of the initial 300 points, 274 were in the feasible region.

By comparing the optimal plant capacity values and the optimal system topologies in each analyzed point, some global trends could be observed (Figure 3). First, the optimal topology of the network depended on the storage tank capacity and membrane design (both its

capacity and its rejection characteristics). In a scenario with higher plant capacity requirements (Figure 3a) all wells were connected to the plant, but in a scenario where a smaller plant was required (Figure 3f) only the wells with higher contaminant concentrations demanded RO treatment.

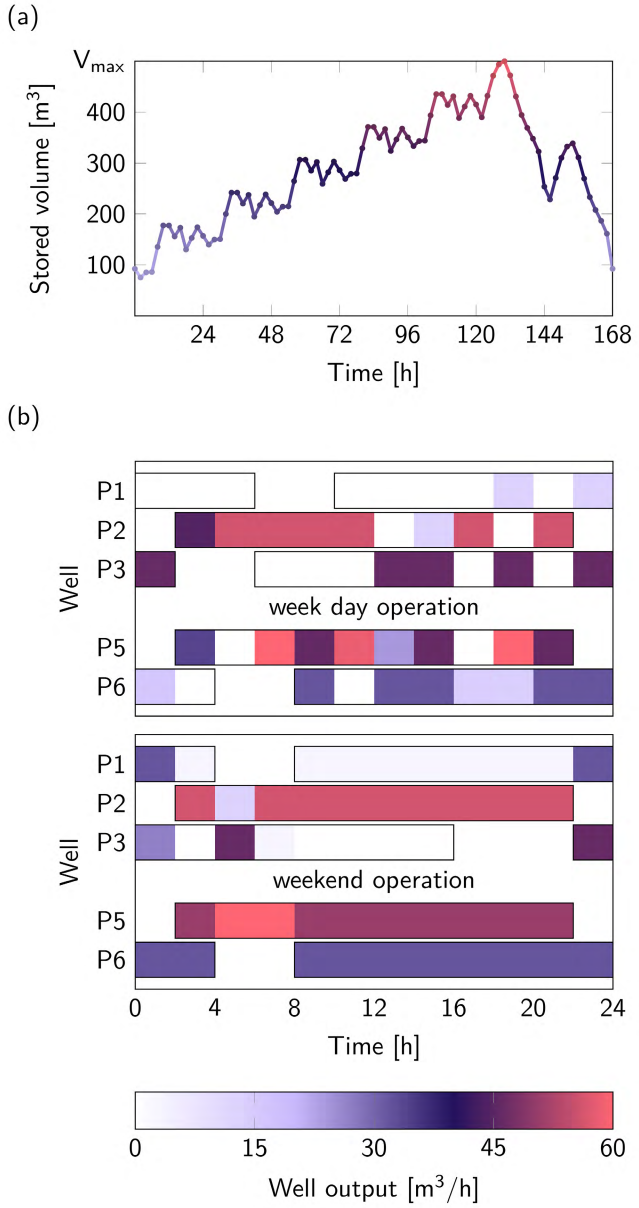

**Figure 2.** Operation of the tank (a) and wells (b) on week days and weekend days.

Second, while $Q_{\text{perm},P}$ changed smoothly with both $\eta$ and $V_{\text{max},T}$ for smaller values of $\eta$, there were some discontinuous regions for $\eta$<90%; besides, as this parameter grows, eventually an unfeasible region was reached, initially for systems with smaller tanks, and then for systems with progressively larger storage capacities. However, no general relations between plant capacity discontinuities and changes in optimal topology were observed.

Finally, the complexity of the mathematical landscape, illustrated in the figure, demonstrated that no global recommendations for the improvement of the system could be made: while increasing salt retention (by selecting different membrane elements) or storage capacity might lead to a significantly smaller plant, there are diminishing returns for these modifications, specially for higher values of $\eta$ and $V_{\text{max},T}$.

## CONCLUSION

A Mixed-Integer approach was developed and implemented for the optimization of water production networks with Reverse Osmosis water treatment units, in which there are legal requirements for daily contiguous downtime periods. This model was then applied to a case study, were large demand variations between weekends and week days required a multi-scenario optimization strategy with the usage of “design days” to model demand in each scenario without needing to optimize the operation of the system over the entire optimization horizon.

The application of the model to the case study demonstrated its reasonable performance (with global optimization achieved in less than two minutes, in the base case), and yielded important results: first, it was shown that the implementation of an RO system is a feasible alternative to lower the high contaminant concentration in the water supply of the city; second, a sensitivity analysis performed by optimizing systems with different membrane technologies and equipped with different storage capacities exhibited pathways for system improvement, defining a landscape of trade-offs between tank CAPEX, energy usage, and water abstraction and waste.

However, further research is warranted: given the random nature of water demand, which is affected by several environmental and social factors, a stochastic optimization approach would increase the robustness of the proposed schedules. This modeling approach would also allow the consideration of contaminant concentration variations, which can be significant.

Finally, while the current mathematical program minimizes plant flowrate, as a proxy for water treatment expenses, a future research avenue lies in minimizing the system costs as a whole, considering CAPEX and OPEX for each equipment (wells, plants, tanks) and minimizing total annualized costs.

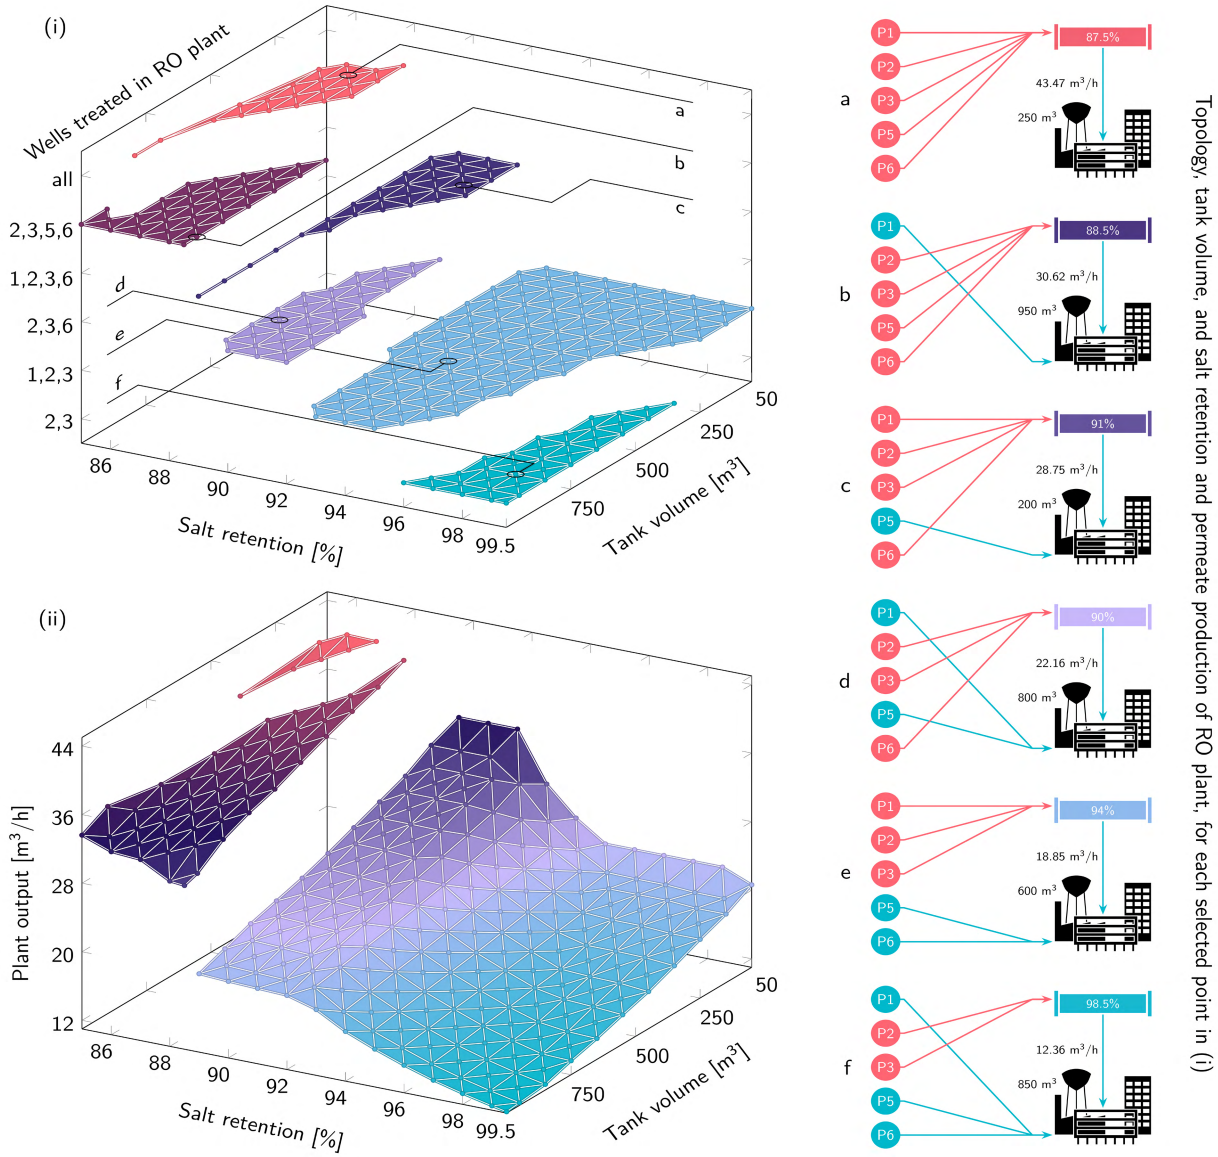

**Figure 3:** Relation between salt retention, tank volume, optimal network topology (i), and plant capacity requirements, with illustrative examples of the different network topology recommendations (a-f).

## ABSTRACT

The design of Power-to-Ammonia systems (P2A) is a challenging task. While the technology for all its components, including renewable energy harnessing, electrolysis, Haber-Bosch synthesis, and auxiliary buffers, is mature, assembling such a system to meet the challenges of varying power profiles is not trivial. To ensure resilient, cost-effective designs, careful selection of unit capacities and coordination of all system operations are required. Specifically, this requires modeling system behaviour and enforcing operational constraints to capture system flexibility over a representative time frame. The first steps towards a novel P2A design framework are presented, with a focus on enhanced process operations and exploring new options for process flexibility. A general methodology is proposed, where the full system can be customized, namely by enabling or disabling: (i) multiple renewable energy harnessing sources, (ii) grid operations, and (iii) buffers, including battery and/or an $H_2$ tank. The model is defined as a linear function of a set of design and operation variables, expressed through a set of matrices and vectors, which are then used to formulate and solve a Linear Programming problem. The design methodology is presented and illustrated via 3 distinct P2A configurations, with key results and analyses of system flexibility and performance. A discussion of future steps towards developing this design framework is also presented.

## INTRODUCTION

Ammonia ($NH_3$) is a key building block in the modern economy, with a global production of 183 million metric tons in 2020. Its relevance stems from its role as a precursor in fertilizer production, supporting an estimated 50% of food chains [1]. Given its potential as an energy vector, demand is forecast to increase and to capture new markets, such as maritime transportation [1].

The Haber-Bosch (HB) process is the industry's standard for ammonia production, accounting for more than 90% of the total output [2]. It reports roughly 63% energy efficiency and 1.5-1.6 ton $CO_2$ / ton $NH_3$ for the Best Available Technology, via the Steam Methane Reforming (SMR) process [3]. While the HB process has long achieved full technological maturity, the industry accounts for an estimated 1-2% of $CO_2$ emissions, making it a primary target for decarbonization and achieving the UN's Sustainable Development Goals [4].

The primary source of carbon dioxide ($CO_2$) emissions in this process is related to the operation of the SMR section, where a 3:1 molar syngas mixture of hydrogen ($H_2$) and nitrogen ($N_2$) is produced. Natural gas (primarily composed of methane – $CH_4$) is used in this section as a feedstock to manufacture $H_2$, and as a fuel to achieve high temperatures in the reforming units [5].

The last section of the process is the HB synthesis, where the syngas from the SMR section is catalytically converted to $NH_3$ in a reaction loop. Direct $CO_2$ emissions are much lower and are mainly due to $CH_4$ purge from the loop, where it remains chemically inert. The synthesis reaction is autothermal, avoiding fuel consumption except during process start-up, but it requires a power supply to achieve the high pressures in the synthesis loop [2].

Water electrolysis is a more sustainable route to hydrogen production, as it avoids the use of fossil fuels.

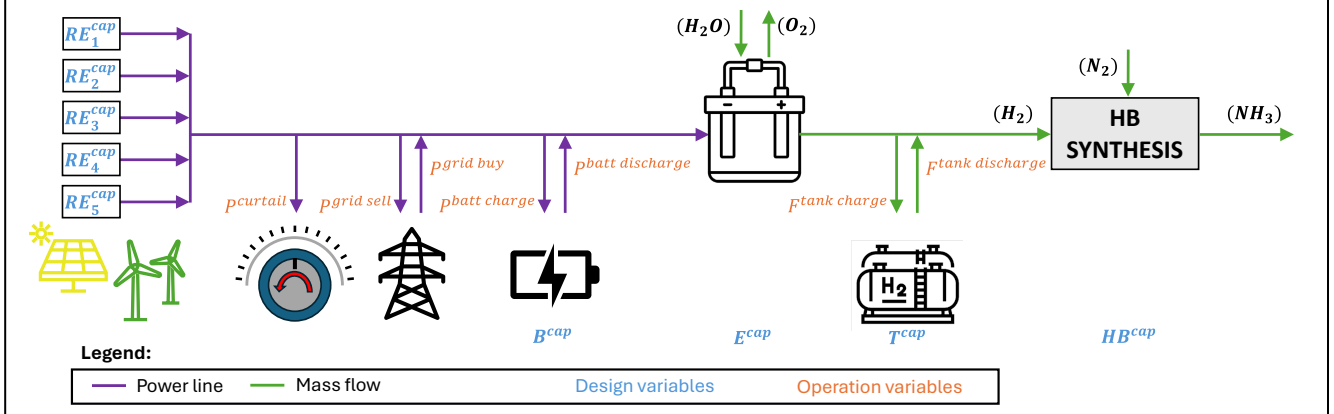

**Figure 1.** P2A system superstructure (adapted from [4]). Multiple renewable sources (e.g., solar and wind) may be enabled to power the system. Their installed capacities are represented as $RE_i^{cap}$ ($i$ = *1, ..., 5*). Power curtailment ($P^{curtail}$) may be activated at periods when a large excess of energy is available from the renewable sources to protect the system from excessive power. Buying ($P^{grid\ buy}$) and selling ($P^{grid\ sell}$) energy to the grid may also be enabled, subject to the local power grid's restrictions. A battery ($B^{cap}$) may be used as a buffer to store energy ($P^{batt\ charge}$) during peak energy availability and supply ($P^{batt\ discharge}$) the system when the harnessed power is low. These 3 auxiliary services may be enabled or disabled in the design framework, though at least one is generally required to stabilise power in the system. The electrolyzer and HB synthesis capacities are denoted as $E^{cap}$ and $HB^{cap}$, respectively. A buffer $H_2$ tank ($T^{cap}$) may also be enabled to stabilise the $H_2$ flowrate to the HB synthesis section, via charge ($F^{tank\ charge}$) or discharge ($F^{tank\ discharge}$) operations. A set of constraints may also be enabled to capture the availability (e.g., grid) or flexibility (e.g., HB synthesis) of all units in managing their loads, in accordance with industrial experience. System design consists of taking all requirements above and the complexity of managing this system over time to achieve the most economical $NH_3$ manufacturing cost.

However, a fully green route can only be achieved when all process equipment is powered by renewable energy sources, thereby minimizing direct and indirect $CO_2$ emissions. These processes, known as Power-to-Ammonia (P2A), are part of the broader Power-to-X class [6] and are schematically depicted in Figure 1.

Renewable sources, electrolysis, and HB synthesis are the core components of P2A systems. Collectively, they provide power for operation and enable a chemical route for producing ammonia from water ($H_2O$) and $N_2$. Multiple auxiliary services, including buffers (battery and $H_2$ storage tank), power curtailment, and grid transactions, may also be considered. Since renewable energy production is not constant, one or more services are generally required to stabilize energy and mass flows, and ensure that the core units operate within their safety specifications.

Moreover, the design of these systems is challenging because the fluctuating power profiles of renewables preclude the use of conventional methods tailored for full-load operation. While this approach would deliver the most cost-effective sizes for electrolysis and HB synthesis, it may require oversizing buffers and/or renewable-harvesting infrastructure (highlighted in blue in Figure 1), thereby increasing the costs of green $NH_3$ manufacturing.

Operating process units at variable loads can be advantageous in this context, provided time-varying operations in auxiliary units (highlighted in orange in Figure 1) are considered to achieve resilient, competitive project designs. Several contributions have been proposed in the last decade on this subject [3, 7, 8]. A review of design strategies for P2A systems is presented in [4].

This work presents the first steps towards a novel design methodology for P2A systems, informed by gaps identified in the scientific literature, as follows:

- Full system customization, including enabling/disabling process units and setting parameters to test and solve a wide range of process configurations, which is the main focus of this paper.
- Robust design by factoring uncertainty on renewable power, process costs, and key model parameters.
- Enhanced chemical process operations (e.g., electrolysis and/or HB synthesis startup/shutdown) for increased accuracy of system behaviour.
- Explore the potential of $H_2$ process loading/unloading for improved process flexibility and project economics.

A strong focus is placed on capturing the system's performance over a representative time interval, while high-

level models are used to capture the behaviour of all the system's units. A design methodology based on Linear Programming (LP) tools is proposed. Its building blocks are presented in the next section, and its application is illustrated in the results section.

# METHODOLOGY

## Design and operation variables

The P2A superstructure used in this work is presented in Figure 1. It includes all the core and auxiliary units presented above, which may be enabled/disabled individually. For each of these units, a design variable representing their capacities is defined in the design problem (highlighted in blue in Figure 1, e.g., $E^{cap}$ for the nominal electrolyzer capacity).

To capture the impact of short-term fluctuations and seasonal patterns in renewable energy harvesting on the operation of these systems, 1 year of operation, discretised in 1h intervals, is considered [4]. This amounts to a total of 8760h in the defined time-horizon, and as many variables in the design problem for each activated system operation (shown in orange in Figure 1, e.g., $P^{curtail}$ for power curtailment); the focus of the design problem is not on delivering the optimal values for this extended set of operation variables, but rather incorporating them on the design problem to more accurately capture the challenges of time-varying operation. This includes the variability of renewables and constraints on unit operations, to achieve a robust and economic system design.

## P2A modelling

### Renewable sources

Up to 5 independent renewable sources may be selectively enabled in the design framework. For all sources, a technical specification is selected, and the corresponding power profiles are obtained from historical data at the selected project location(s) consistently with the time structure presented above (e.g., from [9]. These are obtained and specified in the design problem as fractions of the renewable source capacities, such that, at all times in the time horizon, renewable power is given by the product of the corresponding source capacity and these fractions. For all sources, a constant energy price (€/MWh) is assumed.

Power curtailment is a mechanism by which the power generated from a renewable source may be reduced. Formally, this corresponds to adjusting the power from all sources individually; from a modelling perspective, a single variable per time interval is considered, bounded between 0 and the total renewable power.

### Electrolyzer

Several technologies are available for water electrolysis [9]. Proton Exchange Membrane (PEM) electrolysis is considered, given the very low $O_2$ concentrations achieved in the $H_2$-rich stream, which acts as a catalyst poison in the HB synthesis. A PEM cell includes an anode and a cathode compartment, connected via a proton-exchange membrane and an external electron circuit as depicted in Figure 2.

An oxidation reaction (Equation 1) and a reduction reaction (Equation 2) occur at the electrolyzer's anode and cathode, respectively. This electrochemical reaction is driven by an externally applied voltage, in which $H_2O$ is globally converted to $H_2$ and $O_2$, as shown in Equation 3.

$$H_2O \rightarrow 2H^+ + \frac{1}{2}O_2 + 2e^- \quad (1)$$

$$2H^+ + 2e^- \rightarrow H_2 \quad (2)$$

$$H_2O \rightarrow H_2 + \frac{1}{2}O_2, \Delta H^\circ = 241.93\ kJ/mol \quad (3)$$

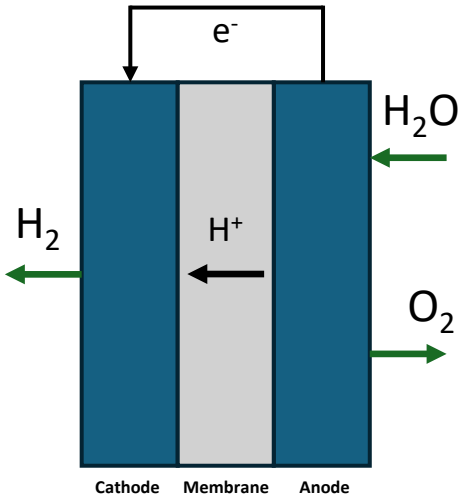

**Figure 2.** Schematic representation of a PEM cell.

A high-level model is used to capture system behaviour rather than to rigorously model all phenomena. The use of renewable energy to drive this reaction is the key focus, via the definition of a specific energy consumption – expressed in MWh / ton $H_2$ – where the reaction enthalpy in Equation 3 defines its lower bound. The output $H_2$ flowrate ($F^{H2\ elect}$) is then calculated as the product of this high-level parameter and the power input to the electrolyzer ($P^{elect}$).

$H_2O$ is assumed to be available on demand, and $O_2$ is released from the P2A system (not sold). None is considered in the total cost of green $NH_3$ production, on the assumption that their prices would represent a small fraction of total manufacturing costs, and particularly the electrolyzer's operating costs.

### HB synthesis

The process enables the conversion of a 3:1 molar mixture of $H_2$ and $N_2$ (syngas) to $NH_3$:

$$3H_2 + N_2 \rightleftarrows NH_3, \Delta H^\circ = -92.28\ kJ/mol \quad (4)$$

A simplified process layout is schematically depicted in Figure 3. The syngas is first compressed and fed to a converter, which typically includes 2 or 3 iron-based catalytic beds. Several designs for this converter have been proposed, in which the feed gas is conveniently distributed and preheated to sustain autothermal operation [2]. Conversions per pass of around 25% are commonly reported, which requires gas recycle to achieve high overall conversions. The mixture is then cooled to promote the condensation and removal of $NH_3$ from the process stream. A purge is commonly employed to remove inert components, such as Argon (Ar); in the SMR-based process, it also includes purging $CH_4$. The unreacted gas is compressed and mixed with the make-up gas, thus completing the synthesis loop. Operating pressures in the range 150-300 bar and temperatures 623-773 K have been reported for this process [10].

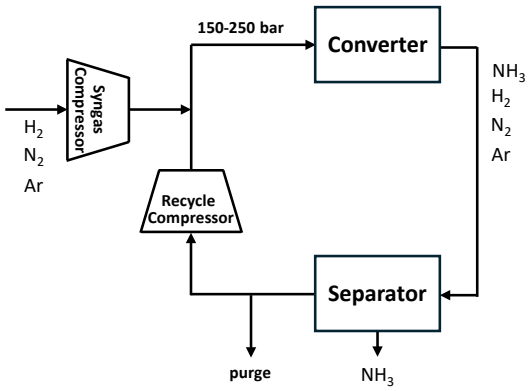

**Figure 3.** Schematic representation of the HB synthesis.

$N_2$ for the HB synthesis is supplied via an Air Separation Unit (ASU) or a Pressure Swing Adsorption (PSA) unit, depending on the scale of $NH_3$ production. It is assumed that the capital costs of the HB synthesis also include the ASU or PSA unit, and that the operational costs and operational constraints of this unit are not significant, in contrast with the operation of the electrolyzer and HB synthesis. Formally, the HB synthesis's compressors also require a power supply; some studies suggest this accounts for a small fraction of the electrolyzer's power demand and is not considered in this study.

The full conversion of the feed syngas is assumed, from which the $NH_3$ flowrate ($F^{NN3\,HB}$) is calculated directly from the stoichiometry in Equation 4.

## Grid

Two 24h price profiles are assumed for: (i) energy bought from the grid, and (ii) energy sold to the grid. These profiles are repeated for the 365 days of the time horizon. The primary modelling consideration concerning grid interaction is setting the upper bounds of $P^{grid\ buy}$ and $P^{grid\ sell}$, which limit the extent of these operations.

## Buffers

Battery and $H_2$ tank, if enabled, are modelled as conventional storage devices according to Equations 5 and 6, respectively:

$$C_{j+1} = C_j + \left(P_j^{batt\ charge} - P_j^{batt\ discharge}\right)\Delta t$$
$$j = 1, \dots, 8760 \quad (5)$$

$$H_{j+1} = H_j + \left(F_j^{tank\ charge} - F_j^{tank\ discharge}\right)\Delta t$$
$$j = 1, \dots, 8760 \quad (6)$$

where $C_j$ and $H_j$ denote the battery's energy charge and $H_2$ tank's holdup, respectively, at time $j$, and $\Delta t$ = 1h. An initial condition for both buffers is also required.

## Energy and mass balances

Energy and mass balances are defined at all nodes of the system, based on the associated power and flowrates in the system's main line. This includes the supply of renewable energy and interaction with auxiliary units. Power and flowrates are calculated for all streams over the 8760 h of the time horizon, assuming no power transmission losses occur.

From a modelling perspective, energy utilization in the electrolyzer to produce $H_2$ is the primary consideration; this is quantified by the electrolyzer's specific energy consumption. This is highlighted in Figure 1, where the modelling focus is on power/flowrate upstream/downstream of the electrolyzer, respectively. In the HB synthesis, $H_2$ is converted to $NH_3$ according to the stoichiometry in Equation 4.

# Design problem via Linear Programming

The design problem must deliver the capacities of all hardware units (design variables) while minimizing ammonia production cost by fully articulating them with all operation variables. This problem is particularly well-suited to optimization, as it involves tens of thousands of process variables and operational constraints. This choice enables a systematic route to finding the best design via formal optimization principles. Since all model equations and inequations are expressed as linear functions of the design and operation variables, Linear Programming is a particularly suitable choice for the design problem.

## Objective function

The objective function for the design problem, assuming all optional units are enabled, is shown below:

$$f = \left(E^{cap}k^E + HB^{cap}k^{HB} + B^{cap}k^B + T^{cap}k^T\right) + \sum_{i=1}^{5} RE_i^{cap}k_i^{RE} + \sum_{j=1}^{8760} P_j^{grid\ buy}k_j^{grid\ buy} - \sum_{j=1}^{8760} P_j^{grid\ buy}k_j^{grid\ buy}$$

(7)

The objective function comprises 3 types of costs. Firstly, the CAPEX and OPEX costs for all units enabled in the P2A design. All are expressed in the objective function as the product of a constant annualised cost factor (e.g., $k^E$ in M€ / per unit of installed capacity – Table 1) with the corresponding design variable (e.g., $E^{cap}$). OPEX costs include maintenance and, in the case of the electrolyzer, exclude the power supply, which is accounted for through renewable power sources.

The second cost type relates to the total energy harnessed in 1 year of operation. For all enabled sources, this is calculated as the product of the selected source capacity ($RE_i^{cap}$, *i = 1, …, 5*) with the sum of all load fractions (full year) and the corresponding energy price ($k^{RE}$).

The last cost component considers grid interaction. If buy from and/or sell to the grid service(s) are enabled, the costs are expressed in the objective for all hours in the time horizon as the product of $P^{grid\ buy}$ or $P^{grid\ sell}$, respectively, and the corresponding price vectors ($k^{grid\ buy}$ and $k^{grid\ sell}$). Note that for consistency, selling energy to the grid represents a monetary income, and the corresponding product in Equation 7 is multiplied by "-1".

## Constraints

The design problem also includes several constraints. These relate mainly to the allowed flexibility in the operation of the core and buffer units as presented earlier. Two types of constraints may be imposed on electrolyzer operation, as follows:

- Power must be within a lower and an upper bound, defined as fractions of the nominal capacity.

$$E^{cap}\phi_{min}^{E} \le P_j^{elect} \le E^{cap}\phi_{max}^{E}, j = 1, \dots, 8760 \quad (8)$$

- Power change between consecutive time intervals must be within a lower and an upper bound, defined as fractions of its nominal capacity.

$$E^{cap}\mu_{min}^{E} \le P_{j+1}^{elect} - P_j^{elect} \le E^{cap}\mu_{max}^{E},$$
$$j = 2, \dots, 8760 \quad (9)$$

where $\phi_{min}^{E}$ and $\phi_{max}^{E}$ denote the minimum and maximum electrolyzer loads, expressed as a fraction of the electrolyzer capacity to enforce a valid power operating range. Equation 9 limits the extent of ramping power in this unit, by imposing a similar type of constraint via the difference of power between consecutive times, and where $\mu_{min}^{E}$ and $\mu_{max}^{E}$ enforce the corresponding limits.

A similar approach is adopted to HB synthesis operation via parameters $\phi_{min}^{HB}$, $\phi_{max}^{HB}$, $\mu_{min}^{HB}$ and $\mu_{max}^{HB}$:

$$HB^{cap}\phi_{min}^{HB} \le F_j^{NH3\ HB} \le HB^{cap}\phi_{max}^{HB},$$
$$j = 1, \dots, 8760 \quad (10)$$
$$HB^{cap}\mu_{min}^{HB} \le F_{j+1}^{NH3\ HB} - F_j^{NH3\ HB} \le HB^{cap}\mu_{max}^{HB},$$
$$j = 2, \dots, 8760 \quad (11)$$

System design also includes a key equality constraint that enforces that the sum of $NH_3$ manufactured across all time intervals matches a predefined target ($M^{NH3}$, in kt $NH_3$):

$$\sum_{j=1}^{8760} F_j^{NH3\ HB} \frac{\Delta t}{1000} = M^{NH3} \quad (12)$$

Global limits on the total energy bought from and sold to the grid annually may also be enabled to further constrain operations in line with local regulations, energy availability, and limits on green $H_2$ production. These are expressed as fractions of the total energy consumed in electrolyzer operation.

Additional constraints are also defined to ensure that the energy charge and $H_2$ mass holdup are within the minimum and maximum limits of the corresponding storage devices' capacities. The maximum discharge and charge rates are specified via the upper bounds on $P^{batt\ charge}$, $P^{batt\ discharge}$, $F^{tank\ charge}$, and $F^{tank\ discharge}$.

## Software/workflow

The design framework is implemented in Python. This includes calculating all matrices and vectors that define the design problem's objective function and constraints and using them to solve the corresponding LP problem. The numpy and scipy libraries [11, 12] deliver this functionality. All P2A plant specifications are imported to Python, and all LP matrices are automatically generated. At the end, the optimizer is returned, from which the design variables can be extracted, and some analyses of the system's performance may be performed.

## Key unit specifications

A summary of the key parameters required for configuring P2A systems is presented in Table 1.

# RESULTS AND DISCUSSION

To illustrate the application of the P2A design framework, 3 examples are configured based on the general superstructure presented in Figure 1 and solved via LP. A small-scale 10 kt $NH_3$/year production target is considered. The electrolyzer has a specific energy consumption of 50 MWh/t$H_2$ and is constrained to operate between 0% and 100% of the nominal load. Wind and solar sources are assumed to be available in Sines (Portugal) as the location for energy generation. Renewable harnessing data was collected for both sources from [9]; the average load factors for the solar and wind series are 0.189 and 0.447, respectively. Grid prices for a representative day of operation on an hourly basis are shown in Figure 4, and the remaining cost factors are estimated as listed in Table 2.

**Table 1:** Key user-defined parameters in the proposed

design framework for P2A systems.

| Description | Units |
|---|---|
| Renewable energy prices (per source). | €/MWh |
| Renewables load fractions (per source, for all 8760 h in a year). | - |
| Grid buy and sell prices (24h series). | €/MWh |

| Electrolyzer min and max loads[1]. | - |
| Electrolyzer min and max load change[2]. | - |
| HB synthesis min and max loads[1]. | - |
| HB synthesis min and max load change[2] | - |
| CAPEX and OPEX cost factors (all units). | [3] |
| $NH_3$ target production. | kt $NH_3$ |

[1] – expressed as a fraction of the unit's capacity ($\phi_{min}^{E}$ and $\phi_{max}^{E}$; $\phi_{min}^{HB}$, $\phi_{max}^{HB}$); [2] – same as [1] and referring to the load increments between consecutive hours ($\mu_{min}^{E}$ and $\mu_{max}^{E}$; $\mu_{min}^{HB}$ and $\mu_{max}^{HB}$); [3] – expressed in M€ per unit of installed capacity (annualised for a 30-year project duration).

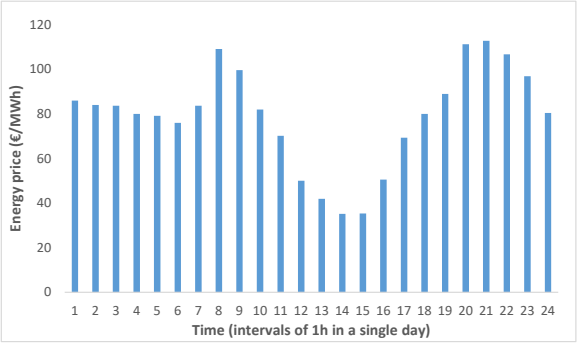

**Figure 4.** Grid prices for a representative day of operation, on an hourly basis.

**Table 2:** Infrastructure cost factors and renewable energy prices used in all scenarios.

| Equipment | Cost factor | Units |
|---|---|---|
| Electrolyzer | 1.33*10$^5$ | €/MW |
| HB synthesis | 1.80*10$^5$ | €/(kt $NH_3$/y) |
| $H_2$ tank | 2.80*10$^4$ | €/t $H_2$ |
| Solar source | 40 | €/MWh |
| Wind source | 45 | €/MWh |

In the 3 illustrative examples presented in sequence, distinct auxiliary units and constraints are enabled. The key results for all scenarios are shown in Table 3.

## Scenario 1: Full load P2A with grid

This design aims to reproduce the full-load operation of the classic HB process via SMR. This is achieved by enforcing the HB synthesis to operate at 100% of its nominal capacity for all hours of the time horizon. This scenario establishes a base case for comparison with the remaining P2A examples. Buying energy from the grid is enabled and subject to a 10% limit on the annual contribution of grid energy for green $H_2$ manufacture.

The design capacities and KPIs for all scenarios are listed in Table 3. The HB synthesis operates, as expected, at an average 100% load (always at full load), and the minimum installed capacity of 10 kt $NH_3$/y is achieved to deliver the target production. Since no buffer is active between the electrolyzer and the HB synthesis, the electrolyzer must also operate at 100%, thereby achieving the minimum costs for the core units. The 10% limit on grid energy utilization is active. The grid acts as an indispensable buffer to ensure full load requirements are met, particularly when renewable generation is low. The burden to deliver an optimal design under these conditions falls on the contracted power from renewables, which largely exceeds the actual system needs, as shown in the energy and cost shares in the second column of Table 3. Grid operation and curtail power for this scenario are illustrated in Figure 5.

A manufacturing cost of 1080 €/t$NH_3$ is achieved. If the 10% limit on grid usage is removed, the price would fall from 1080 to 841 €/tNH3, with 33.7% grid utilization.

## Scenario 2: Flexible P2A with grid

In this and the next scenarios, the full-load requirement is relaxed, and instead, the HB synthesis is required to operate at 70%-100%, with load increments between consecutive hours limited to 10% of its nominal capacity. The same grid utilization conditions as defined in the first scenario are also considered.

From Table 3, the 10% grid utilization limit remains active. However, by adding flexibility to the HB synthesis, the design of the electrolyzer and HB synthesis are now slightly oversized, with an average load of 88.6%. These units contribute more significantly to overall costs but enable a significant reduction in the solar and wind contracted capacities from 17.9 MW to 13.6 MW and from 32.3 MW to 21.0 MW, respectively. Power curtailment is significantly reduced, and a much lower manufacturing cost of 894 €/t$NH_3$ is obtained. By further extending flexibility to 50-100% loads and a maximum of 20% loads' increment, the cost can be further reduced to 861 €/t$NH_3$.

## Scenario 3: Flexible P2A with $H_2$ tank

An islanded system is considered, precluding the utilization of the grid to assist P2A system operation. An $H_2$ tank is considered to provide the necessary flexibility and meet the load requirements of HB synthesis operation as presented in scenario 2.

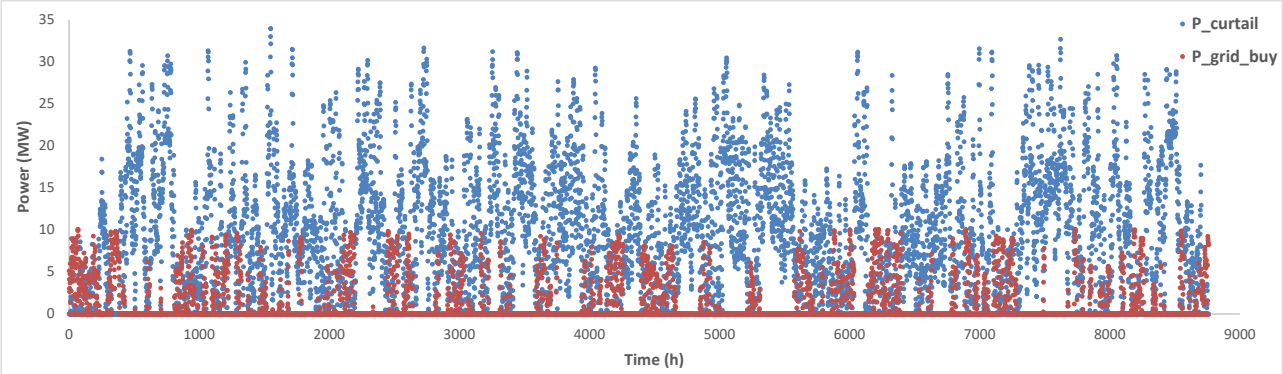

**Figure 5.** Curtailment and grid power bought from the grid over the full time-horizon in scenario 1.

The $H_2$ tank decouples the electrolyzer and HB synthesis operations: in the previous scenarios, there are no buffers between the two units, and their operating loads are always synchronized. Now, they are to some extent independent of one another, as confirmed by their average operating loads in Table 3. This change effectively enables full flexibility for the electrolyzer unit (0-100% load). A new energy mix is obtained, promoting the slightly cheaper solar source as listed in Table 2. Note that despite optimal capacities of 18.7 MW and 17.8 MW for solar and wind, respectively, wind power still dominates energy shares due to the higher load fractions in the corresponding renewables' series.

A 14.0 t $H_2$ tank capacity is delivered from the optimal design. This capacity would be sufficient to continuously supply the HB synthesis for 65 h at the nominal rate, with no $H_2$ supplied from the electrolyzer. The tank holdup is depicted in Figure 6, where several cycles between full charge and no charge are identified.

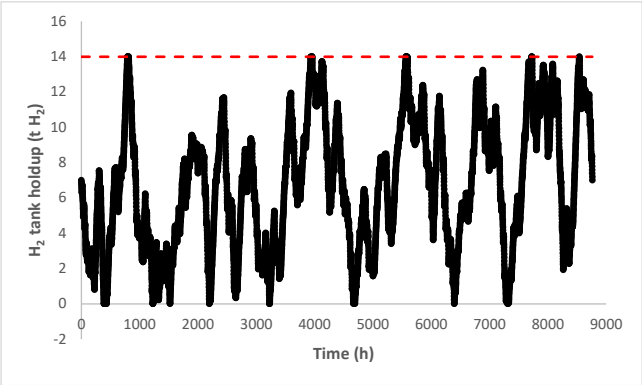

**Figure 6.** $H_2$ holdup over the time horizon for scenario 3.

A cost of 861 €/t$NH_3$ is achieved. While this is a small improvement over scenario 2, a fully green P2A system has been developed.

## Design results

The design results and summary of the Key Performance Indicators (KPIs) in the 3 scenarios presented above are listed in Table 3.

**Table 3:** Summary of design results and KPIs for all scenarios presented earlier.

| | Design variables & KPIs | Scenario 1 | Scenario 2 | Scenario 3 | Units |
|---|---|---|---|---|---|
| Design capacities | $RE_{solar}^{cap}$ | 17.9 | 13.6 | 18.7 | MW |
| | $RE_{wind}^{cap}$ | 32.3 | 21.0 | 17.8 | MW |
| | $E^{cap}$ | 10.1 | 11.4 | 15.0 | MW |
| | $HB^{cap}$ | 10.0 | 11.3 | 10.6 | kt $NH_3$/y |
| | $T^{cap}$ | - | - | 14.0 | t $H_2$ |
| KPIs | $NH_3$ cost | 1080 | 894 | 868 | €/t$NH_3$ |
| | Elect load[1] | 100 | 88.6 | 67.5 | % |
| | HB load[1] | 100 | 88.6 | 94.8 | % |
| Energy shares | Solar | 33.5 | 25.5 | 34.9 | % |
| | Wind | 142.4 | 92.7 | 78.7 | % |
| | Grid | 10 | 10 | 0 | % |
| | Curtail | 85.9 | 28.2 | 13.5 | % |
| Cost shares | Renewables | 63.6 | 51.5 | 50.5 | % |
| | Electrolyzer | 12.5 | 17.1 | 23.1 | % |
| | $H_2$ tank | 0 | 0 | 4.5 | % |
| | Grid | 7.2 | 8.7 | 0 | % |
| | HB synthesis | 16.7 | 22.7 | 21.9 | % |

## CONCLUSION AND FUTURE WORK

This work presents the key principles of a novel and fully customizable methodology for P2A design. It consists of a superstructure of core and auxiliary units, the latter of which may be enabled or disabled to test a multitude of P2A configurations. High-level models are defined for all units, and model complexity arises mainly from considering a full year of operation with hourly resolution. The design problem is formulated as an LP, containing both design and operation variables; while calculating the former is the main goal of the design problem, the full consideration of operation variables, and

particularly their operation in the full time-horizon, is critical to achieve design results considering the full complexity of renewables' variability.

The initial results provide useful insights into how unit flexibility, renewable variability, buffers, and objective function definition affect unit capacities, thereby offering a systematic approach to optimal and robust P2A designs. While the initial results are promising, multiple key developments are desirable to enable a more detailed modelling and optimization of these systems. Several phenomena, including: (i) power transmission, (ii) reaction conversion in electrolyzer and HB synthesis, (iii) $H_2O$ and $N_2$ supply, (iv) powering the HB synthesis' compressors from renewables, (v) neutrality conditions on buffers' operation, and (vi) setting multiple production objectives, will be considered in future work.

Furthermore, this framework enables more advanced utilization modes. For instance, assuming all design variables are set, the framework may be used in P2A systems to facilitate process management and articulation of all units to achieve the most economical manufacturing costs. One of the most critical elements in this framework is setting a priori load fractions for renewable sources based on historical data, as is common practice in the field. Understanding how the design methodology can be improved to deliver robust designs that operate efficiently across a broad range of meteorological conditions remains largely unexplored and may be explored in the future through this design framework.

Given the focus on design modularity presented in this design framework, it readily enables more advanced features than those captured in Figure 1. Work is ongoing to capture the impact of process shutdowns on P2A operation and economics. This is an important consideration because the HB synthesis may require maintenance for 10% of the total operation time [8]. To achieve better process economics and flexibility, buying/selling $H_2$ is also being developed as an optional feature to make the best use of the investments in renewable power and electrolyzer infrastructure.

## ABSTRACT

Self-driving laboratories (SDLs) increasingly use Bayesian optimisation (BO) to navigate expensive design spaces, yet high-fidelity simulations and experiments remain too costly to query at scale. Multi-fidelity Bayesian optimisation (MFBO) alleviates this by combining abundant low-fidelity evaluations with scarce high-fidelity observations. However, Gaussian process (GP) surrogates can become computational bottlenecks as data volume and dimensionality increase, motivating scalable alternatives. Here, we assess transfer learning based deep neural network (DNN) surrogates that pretrain on low-fidelity data and fine-tune on high-fidelity observations. We construct a chemical process benchmark for glacial acetic acid separation and purification with paired low- and high-fidelity flowsheets. The optimisation considers eight decision variables and minimises the minimum selling price (MSP), while enforcing a product purity threshold via a quadratic penalty. To reflect realistic resource constraints, we define seven training scenarios with approximately constant total simulation time, given the large cost gap between fidelities. Across all scenarios, the transfer learning DNN outperforms a GP regression baseline trained only on high-fidelity data. Test-set $R^2$ increases from 0.41 to 0.71 for the DNN, compared with 0.32 to 0.51 for GP, with gains already visible in the most data-scarce setting. These results suggest that transfer learning–enhanced DNN surrogates can offer accurate, scalable multi-fidelity surrogate models for process optimisation, and could be a practical component in BO-based automated discovery settings where low- and high-fidelity data coexist.

**Keywords**: Multi-fidelity Bayesian optimisation, Transfer learning, Deep surrogate models, Process optimisation

## INTRODUCTION

Self-driving laboratories (SDLs) and simulation-driven design workflows increasingly rely on sequential decision-making algorithms to navigate expensive design spaces [1-3]. Bayesian optimisation (BO) has been widely adopted in this context for optimising expensive black-box objectives in chemical process design, as it balances exploration and exploitation through a probabilistic surrogate model and an acquisition function, achieving competitive solutions with relatively few evaluations [4-7]. However, high-fidelity process simulations often involve rigorous thermodynamic models, equilibrium-stage calculations, recycle loops, and strong nonlinearities, making each evaluation computationally expensive and limiting the number of feasible evaluations within a realistic compute budget. Multi-fidelity Bayesian optimisation (MFBO) alleviates this by integrating abundant, inexpensive low-fidelity evaluations with scarce high-fidelity observations within a single optimisation loop [8-10]. The key technical challenge is to learn a surrogate that can exploit large amounts of biased low-fidelity data while achieving high predictive accuracy in the high-fidelity regime.

Gaussian processes (GPs) have been a dominant surrogate choice in BO and MFBO due to their principled uncertainty quantification and strong small-data performance [11-13]. However, standard GP training scales cubically with the number of training points, which becomes increasingly problematic as low-fidelity datasets grow or

as optimisation campaigns accumulate data over time [14]. Deep neural networks offer a scalable alternative: they can leverage large datasets, learn flexible representations, and train efficiently on modern hardware. In multi-fidelity settings, transfer learning is particularly appealing—a model pretrained on abundant low-fidelity data can learn general input–output structure, while fine-tuning on limited high-fidelity observations corrects systematic bias and calibrates the model toward the target objective [15]. However, a careful evaluation is needed to determine whether this strategy provides reliable improvements over GP baselines under realistic multi-fidelity constraints.

In this work, we evaluate transfer learning–enhanced deep surrogate models as scalable alternatives to GP regression for multi-fidelity optimisation in chemical process design. We construct a benchmark for glacial acetic acid separation and purification with paired low- and high-fidelity BioSTEAM flowsheets, considering eight decision variables and minimising a penalised minimum selling price. To enable fair comparison, we define seven budget-matched scenarios in which total simulation time is kept approximately constant while the ratio of high- to low-fidelity data varies. The contributions are threefold: (i) a reproducible multi-fidelity process benchmark with strong cost asymmetry between fidelity levels; (ii) a transfer learning surrogate strategy that leverages low-fidelity pretraining and high-fidelity fine-tuning; and (iii) a controlled comparison against a GP regression baseline across multiple budget-matched scenarios, demonstrating how predictive accuracy scales with increasing data availability.

# METHODS

## Overview of the study design

This work evaluates surrogate modelling strategies for multi-fidelity optimisation under realistic computational constraints. We construct a paired low-fidelity (LoFi) and high-fidelity (HiFi) process simulation benchmark for glacial acetic acid separation and purification, and compare two surrogate training paradigms: (i) Single-fidelity baseline (HiFi-only): a GP surrogate trained only on HiFi samples. (ii) Multi-fidelity transfer learning (LoFi pretraining + HiFi fine-tuning): a DNN surrogate pretrained on abundant LoFi data and subsequently fine-tuned using a smaller set of HiFi samples. To ensure a fair comparison aligned with practical usage, we define seven scenarios in which the total simulation time budget is approximately constant, exploiting the large cost disparity between LoFi and HiFi evaluations (approximately 0.5 s vs 167 s per evaluation).

## Process benchmark: acetic acid separation and purification

We use a BioSTEAM-based flowsheet representing a hybrid liquid-liquid extraction (LLE) and distillation process to produce glacial acetic acid [16, 17]. A dilute aqueous feed (10, 000 kg $h^{-1}$, 10 wt% acetic acid) is contacted with ethyl acetate (solvent-to-feed mass ratio 1.5) to yield an acetic-acid-rich extract and a water-rich raffinate. The extract is processed in an extract-distillation column with phase separation to enable solvent recycle, and subsequently purified in an acetic acid purification column to meet the product specification. In parallel, the raffinate and water-rich streams are distilled to recover ethyl acetate for recycle and discharge a wastewater stream. Unless otherwise specified, pressure is set by BioSTEAM defaults (1 atm), and thermodynamic phase equilibria determine unit temperatures except for a heat-exchanger temperature decision variable. The overall process flowsheet is shown in Figure 1.

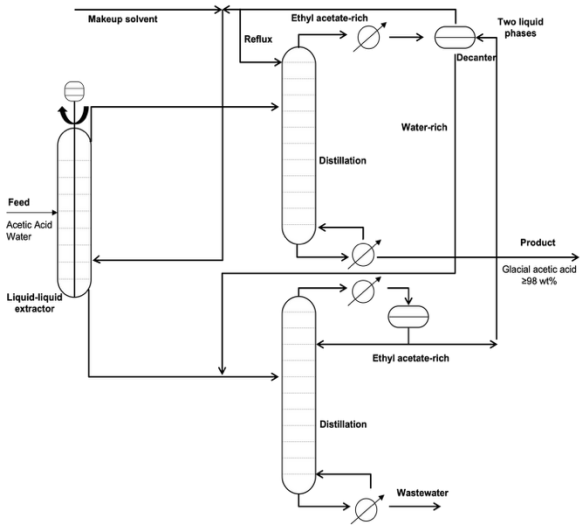

**Figure 1.** Process flow diagram for glacial acetic acid separation and purification. Solid lines denote process streams; dashed lines denote recycle streams.

## Fidelity definitions: LoFi and HiFi models

Two fidelity levels are implemented to reflect computational cost and model fidelity. In the LoFi model, the extractor is represented by a single-stage equilibrium unit (bst.MixerSettler), and key columns are modelled using shortcut distillation (bst.ShortcutColumn, Fenske-Underwood-Gilliland formulation) [18-20]. In the HiFi model, the extractor is modelled as a multi-stage system (bst.MultiStageMixerSettlers, $n_{\text{stages}} \in [10, 50]$ ) and the two main columns are simulated using equilibrium-stage distillation (bst.MESHDistillation) solved via MESH equations, with tightened convergence tolerances (sys.set_tolerance(rmol=1e-3, mol=1e-3, subsystems=True)) [21]. The raffinate distillation column is implemented as a shortcut column in both fidelities. A key implementation detail is that, because the LoFi extractor

is single-stage, the decision variable $n_{\text{stages}}$does not affect LoFi outputs and is only active in the HiFi model.

## Decision variables and optimisation objective

Let $\mathrm{x} \in \mathbb{R}^8$denote the vector of decision variables: the number of extraction stages ($n_{\text{stages}}$, integer 10–50), six recovery ratios for light and heavy keys in three distillation columns (each in $[0, 0.9999]$), and the heat-exchanger temperature $T_{\text{hex}} \in [273, 350]$K. The optimisation objective is to minimise a penalised MSP proxy:

$$f(\mathrm{x}) = \mathrm{MSP}(\mathrm{x}) + \lambda \max\,(0, p_{\min} - p(\mathrm{x}))^2,$$

where $p(\mathrm{x})$is the acetic acid mass fraction in the final product stream and $p_{\min} = 0.98$. We use a quadratic penalty with $\lambda = 10$. The MSP is computed from BioSTEAM cost outputs as:

$$\mathrm{MSP}(\mathrm{x}) = \frac{\mathrm{CAPEX}(\mathrm{x}) + \mathrm{OPEX}(\mathrm{x})}{F_{\text{prod}}(\mathrm{x})},$$

with annual production $F_{\text{prod}}$computed using 7, 920 operating hours per year. Because a full techno-economic analysis model is not invoked, this MSP serves as a consistent cost proxy for comparing surrogate performance across fidelities. Numerical safeguards are applied to handle unstable simulations (e.g., failed simulations return a large objective value, and extreme MSP values are clipped).

## Data generation and budget-matched scenarios

**Table 1.** Scenario-wise training set sizes for surrogate models.

| | GP | DNN | |
|---|---|---|---|
| **Case No.** | HiFi train set size | LoFi train set size | HiFi train set size |
| 1 | 100 | 5000 | 50 |
| 2 | 200 | 10000 | 100 |
| 3 | 400 | 20000 | 200 |
| 4 | 800 | 40000 | 400 |
| 5 | 1600 | 80000 | 800 |
| 6 | 3200 | 160000 | 1600 |
| 7 | 6400 | 320000 | 3200 |

Training datasets are generated by sampling $\mathbf{x}$and running the simulator at the selected fidelity to obtain targets $f(\mathbf{x})$. Initial designs are generated using Latin hypercube sampling (LHS; `scipy.stats.qmc.LatinHypercube`, seed=42) over $[0, 1]^8$, which is then scaled to the variable bounds; the integer variable $n_{\text{stages}}$is obtained by rounding [22]. We define seven scenarios with increasing HiFi data availability. In each scenario, we compare a HiFi-only GP model trained with $N_{\text{HiFi}}$samples to a transfer learning DNN trained with $N_{\text{LoFi}}$LoFi samples for pretraining and $N'_{\text{HiFi}}$HiFi samples for fine-tuning, where $(N_{\text{HiFi}}, N_{\text{LoFi}}, N'_{\text{HiFi}})$ are chosen to keep the total simulation budget approximately constant. The specific dataset sizes are reported in Table 1.

## Surrogate models

We compare two surrogate modelling approaches. As a single-fidelity baseline, we train a GP surrogate using only HiFi data, assuming $\hat{f}_{\text{GP}}(x) \sim \mathcal{GP}(m(x), k(x, x'))$, with kernel hyperparameters learned by maximising the marginal likelihood on the HiFi training set [13]. The GP was implemented using scikit-learn's GaussianProcessRegressor with a radial basis function (RBF) kernel. For the proposed approach, we train a DNN surrogate using two-stage transfer learning: model parameters are first obtained by minimising a regression loss on the LoFi dataset,

$$\theta^{(0)} = \arg\min_{\theta} \sum_{i \in \mathcal{D}_{\text{LoFi}}} \mathcal{L}(g(x_i; \theta), f_{\text{LoFi}}(x_i)),$$

and are then fine-tuned on the HiFi dataset starting from $\theta^{(0)}$,

$$\theta^{*} = \arg\min_{\theta} \sum_{j \in \mathcal{D}_{\text{HiFi}}} \mathcal{L}(g(x_j; \theta), f_{\text{HiFi}}(x_j)).$$

where $g(\cdot; \theta)$is a fully connected network. In our implementation, the DNN was implemented in PyTorch with a 2-layer feature network (64-64 hidden units with ReLU) and is trained using Adam with mean-squared error loss. Input features were normalised to [0, 1] using the physical bounds of each decision variable. Pretraining is performed for 200 epochs (learning rate $10^{-3}$), followed by fine-tuning for 100 epochs (learning rate $10^{-4}$), updating all layers [15].

All surrogate training and optimisation experiments were performed on the King's College London CREATE HPC cluster (SLURM scheduler), with each job allocated a single NVIDIA A40 GPU (48 GB VRAM, CUDA 12.2), 4 CPU cores, and 16 GB of system memory.

## Evaluation protocol and metric

Model performance is evaluated against HiFi ground truth using the coefficient of determination [23]:

$$R^2 = 1 - \frac{\sum_n (y_n - \hat{y}_n)^2}{\sum_n (y_n - \bar{y})^2}.$$

Reporting $R^2$across the seven budget-matched scenarios quantifies how efficiently each approach leverages limited HiFi data and how predictive accuracy scales under fixed total compute.

# RESULTS AND DISCUSSION

## Predictive performance across budget-matched scenarios

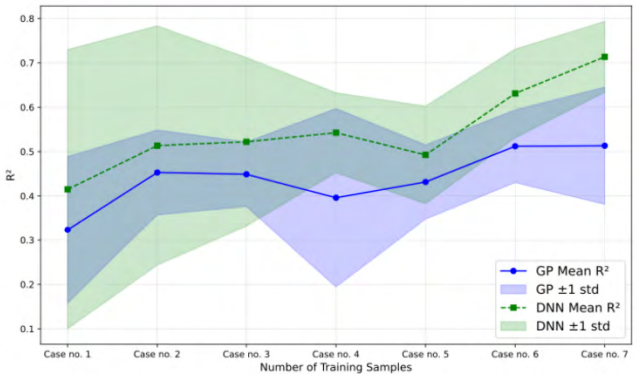

**Figure 2**. HiFi test-set $R^2$ across seven budget-matched scenarios comparing a HiFi-only GP baseline and a transfer-learning DNN (LoFi pretrain + HiFi fine-tune). Error bars denote mean ±one standard deviation over 10 random seeds.

Figure 2 summarises the predictive accuracy of the two surrogate models across seven budget-matched scenarios. Each case corresponds to an increasing training budget (Table 1), where the GP baseline is trained using HiFi evaluations only, while the transfer learning DNN is pretrained on a substantially larger LoFi dataset and then fine-tuned using a smaller HiFi set. Generalisation performance is reported as the coefficient of determination $R^2$ on held-out HiFi data. To quantify robustness, each model was trained with 10 different random seeds, and the figure reports the mean $R^2$ with a $\pm 1$ standard deviation band.

Across all cases, the transfer learning DNN achieves higher mean $R^2$than the GP baseline. In the most data scarce setting (Case 1), the DNN already shows a clear advantage (mean $R^2 \approx 0.41$ vs $0.32$), indicating that LoFi pretraining provides useful inductive bias that improves HiFi generalisation even when only a small number of HiFi samples are available for fine tuning. As the training budget increases, the performance gap persists and becomes more pronounced. For example, in the largest budget setting (Case 7), the DNN reaches a mean $R^2 \approx 0.71$, whereas the GP baseline saturates around $R^2 \approx 0.51$. Overall, the GP shows only modest gains with additional data, while the DNN continues to improve, consistent with better scalability in data rich regimes.

Importantly, this improvement is achieved under matched simulation budgets, where the DNN uses fewer HiFi evaluations than the GP in each case (for example, 50 vs 100 in Case 1, and 3, 200 vs 6, 400 in Case 7) by exploiting inexpensive LoFi data. These results suggest that transfer learning enables more effective utilisation of multi fidelity information, yielding higher HiFi predictive accuracy than a HiFi only GP surrogate across a wide range of training budgets.

## Learning Dynamics in the Low-Data Regime

To explain why the transfer learning DNN outperforms the GP surrogate in the most data-scarce scenario, we analyse the learning dynamics in Case 1 using the training and held-out HiFi validation loss curves shown in Figure 3. In this setting, the proposed model is pretrained on 5, 000 simulations and then fine-tuned using only 50 HiFi simulations, whereas both the GP baseline and the from-scratch DNN are trained using 100 HiFi simulations only. Validation performance is measured on an independent held-out HiFi set, making it a direct indicator of surrogate quality for the rigorous model.

The left panel (training loss) primarily reflects optimisation behaviour rather than generalisation. As expected, the GP baseline exhibits near-zero training loss

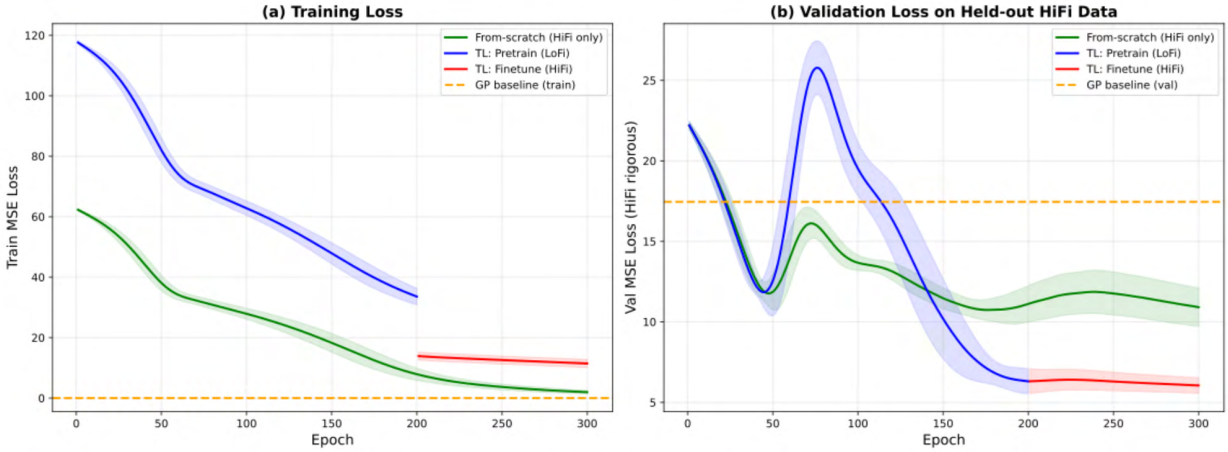

**Figure 3.** Loss curves in Case 1 showing learning dynamics and positive transfer: (a) training MSE and (b) held-out HiFi validation MSE. The TL-DNN is pretrained on 5,000 LoFi samples and fine-tuned on 50 HiFi samples, whereas the GP and from-scratch DNN are trained on 100 HiFi samples.

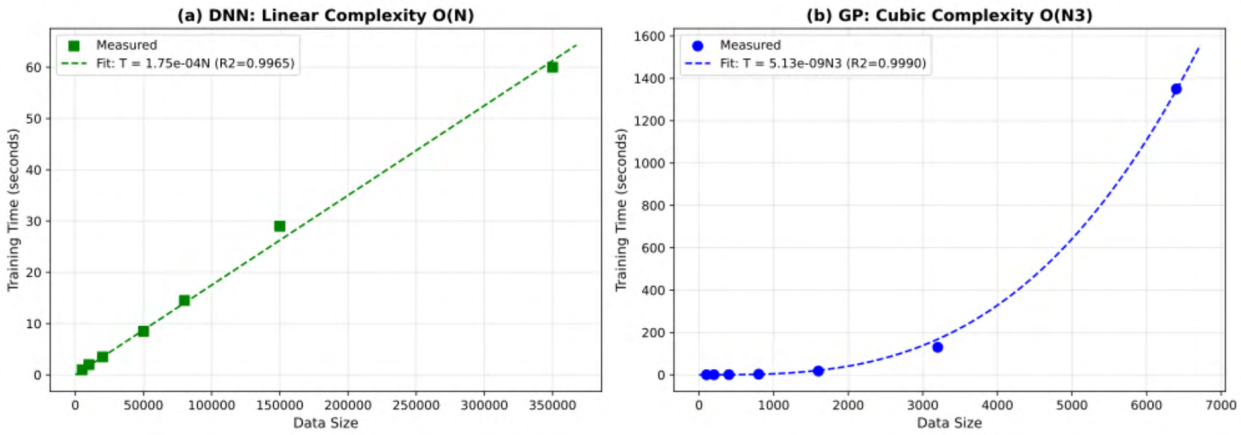

**Figure 4.** Empirical surrogate training time versus dataset size: (a) DNN training shows approximately linear scaling $O(N)$with a linear fit, and (b) GP training exhibits cubic scaling $O(N^3)$with a cubic fit.

because kernel regression can interpolate the training data, which does not imply strong predictive performance away from observed points. The from-scratch DNN steadily drives the training loss down to very small values over epochs, indicating that the network can fit the limited HiFi training set extremely well. However, this apparent advantage is not mirrored in generalisation.

The right panel of Figure 3 provides the key evidence. The from-scratch DNN reduces validation loss initially but then plateaus and remains substantially above the transfer learning model, consistent with limited generalisation under scarce HiFi supervision. In contrast, LoFi pretraining yields a rapid decrease in HiFi validation loss even before any HiFi fine-tuning is applied, suggesting that the low-fidelity data already encode transferable structure of the process response surface. After switching to HiFi fine-tuning, validation loss decreases further and stabilises at the lowest level among all methods. Importantly, this improvement is achieved despite using half as many HiFi samples as the baselines (50 vs 100), indicating genuine positive transfer rather than an advantage from greater access to high-fidelity supervision.

These dynamics support a mechanistic interpretation of the Case 1 results in Figure 2. LoFi pretraining provides a useful representation of the input–output relationship that acts as an implicit regulariser, constraining the model to physically plausible response patterns and reducing overfitting when only a small HiFi dataset is available. Fine-tuning with sparse HiFi samples then serves to calibrate systematic LoFi bias toward the rigorous objective. Together, this two-stage training strategy improves sample efficiency in the HiFi regime, explaining why transfer learning yields superior predictive accuracy compared to both a HiFi-only GP and a from-scratch DNN in low-data multi-fidelity settings.

## Computational scalability with increasing data

Figure 4 compares the empirically measured surrogate training time as the dataset size increases. The DNN surrogate shows approximately **linear** scaling, well described by the fitted relationship $T = 1.75 \times 10^{-4} N$ seconds $(R^2 = 0.9965)$, where $N$ is the number of training samples. This trend indicates that enlarging the LoFi pretraining set remains computationally practical. For example, the fit corresponds to roughly 56 s of training time at $N = 320,000$, which matches the largest LoFi pretraining set used in our scenarios.

In contrast, the GP baseline follows a much steeper **cubic** scaling with dataset size, consistent with the computational cost of exact GP training. The measured times are accurately captured by $T = 5.13 \times 10^{-9} N^3$ seconds $(R^2 = 0.9990)$. Under this scaling, training time increases rapidly even within the sample sizes considered here, reaching approximately 168s at $N = 3,200$ and 1, 345 s at $N = 6,400$.

Together with the accuracy trends in Figure 2, these timing results highlight a key practical advantage of the transfer-learning DNN: it can absorb large LoFi datasets at modest training cost while avoiding the rapidly growing computational burden that limits GP surrogates as datasets expand over iterative optimisation campaigns.

## Scope, limitations, and implications for end-to-end MFBO

The results above demonstrate that transfer learning with a DNN surrogate can deliver consistently higher HiFi predictive accuracy than a HiFi-only GP baseline under approximately matched simulation budgets, while also offering substantially better computational scalability as training datasets grow. However, the conclusions of this study should be interpreted within the scope of

the present evaluation, which focuses on surrogate model quality rather than full closed-loop optimisation performance.

First, our comparisons are based on offline predictive metrics (primarily $R^2$on held-out HiFi data). While improved predictive accuracy is a necessary condition for improved optimisation performance, it is not sufficient by itself. In end-to-end MFBO, overall efficiency depends not only on the surrogate's mean predictions but also on how uncertainty is estimated and utilised by the acquisition function to select the next evaluation. Therefore, a direct next step is to integrate the proposed surrogate into an MFBO loop and quantify optimisation outcomes such as best-so-far objective value, sample efficiency, and HiFi evaluation savings under realistic stopping criteria.

Second, the multi-fidelity pairing in this benchmark is intentionally cost-asymmetric and includes an important modelling detail: the LoFi extractor is represented as a single-stage equilibrium unit, meaning the extraction stage decision variable does not influence LoFi outputs and becomes active only in the HiFi model. This setting reflects a realistic scenario in which low-fidelity approximations omit certain degrees of freedom or physics. Nevertheless, it implies that transfer learning primarily leverages LoFi data to learn shared response structure across the remaining variables, while HiFi fine-tuning is responsible for learning the effect of extraction staging. This reinforces the interpretation of transfer learning as an approach that provides a useful inductive bias and regularisation rather than a complete substitute for HiFi supervision.

Third, the objective function used here is a consistent process-economic proxy with penalty-based feasibility enforcement and numerical safeguards for unstable simulations. Although this formulation is appropriate for controlled benchmarking and surrogate comparison, it does not represent a full techno-economic analysis with annualised CAPEX and explicit financial assumptions. Consequently, the reported values should be interpreted comparatively rather than as absolute economic predictions.

It is worth noting that eight decision variables are well within the capacity of traditional flowsheet optimisation tools such as sequential quadratic programming or evolutionary algorithms. However, these methods typically operate at a single fidelity level, most commonly using shortcut or simplified models, and require numerous function evaluations to converge. When high-fidelity simulations are employed, involving rigorous thermodynamic models and equilibrium-stage calculations, the cost per evaluation becomes a dominant bottleneck. The focus of this work is therefore not on handling dimensionality, but on improving the trade-off between predictive accuracy and computational cost by leveraging abundant low-fidelity data to reduce the number of expensive high-fidelity evaluations required.

Overall, these findings support the use of transfer learning–based deep surrogates as MFBO-ready components for process optimisation workflows where low-fidelity data are abundant and high-fidelity evaluations are costly. Future work should evaluate end-to-end MFBO performance with fidelity selection policies, extend the benchmark to additional flowsheets and fidelity definitions, and further examine uncertainty calibration for acquisition-driven decision making.

## CONCLUSION

This study evaluated transfer learning–enhanced deep surrogate models as scalable alternatives to GP surrogates for multi-fidelity optimisation in a BioSTEAM-based acetic acid separation and purification benchmark. Under budget-matched scenarios that reflect the large cost disparity between shortcut (LoFi) and rigorous (HiFi) process simulations, the proposed approach pretrained a DNN on abundant LoFi data and fine-tuned it using a much smaller HiFi dataset.

Across seven scenarios, the transfer learning DNN consistently achieved higher predictive accuracy on held-out HiFi data than a HiFi-only GP baseline, with the advantage already evident in the most data-scarce setting. Analysis of learning dynamics in the low-data regime provided evidence of positive transfer: LoFi pretraining yielded a representation that improved HiFi generalisation and reduced sensitivity to limited HiFi supervision, while subsequent fine-tuning corrected residual bias toward the rigorous objective. In addition to accuracy gains, empirical timing results showed that DNN training scaled approximately linearly with dataset size, whereas GP training exhibited steep cubic scaling, indicating a practical computational advantage as datasets grow.

Taken together, these findings suggest that transfer learning–based deep surrogates can improve both sample efficiency and scalability in multi-fidelity settings where low-fidelity evaluations are plentiful and high-fidelity evaluations are expensive. While this work focused on surrogate modelling performance, integrating the proposed surrogate into end-to-end MFBO loops with acquisition and fidelity selection policies is a natural next step to quantify downstream optimisation gains in realistic closed-loop workflows.

## ABSTRACT

This work proposes a two-stage optimization framework for the optimal utilization of biogas from pig manure, integrating process-level design with short-term operational planning under dynamic electricity tariff schemes in Mexico. In the first stage, a multi-objective optimization based on 3E (Exergy, Environment, and Energy) analysis was performed. The results demonstrate that increasing the biogas split fraction for upgrading significantly reduces the environmental and exergy indices, enhancing thermodynamic and environmental performance without compromising the energy index. High upgrading flows (split > 0.7) emerged as the most favorable compromise across the evaluated metrics. In the second stage, support vector regression (SVR) surrogate models were developed to approximate nonlinear relationships between the operational split and process outputs. These surrogates were embedded in a Mixed-Integer Linear Programming (MILP) formulation to optimize weekly scheduling under the Mexican Net Billing scheme, incorporating an economic objective (+1E index). The SVR-MILP framework successfully captured market-driven decisions, prioritizing biomethane upgrading during base and intermediate tariff periods and switching to electricity generation during peak hours to maximize economic profit. Biomethane upgrading accounts for approximately 90-100% of the total positive economic benefits, while electricity generation contributes the remaining 10%, depending on the exposure to peak electricity tariffs. Thus, the proposed methodology offers a robust, computationally efficient decision-support tool for flexible biogas systems, bridging the gap between steady-state design and dynamic market responsiveness based on a 4E approach.

**Keywords**: Biogas upgrading , Power generation, Simulation-optimization , 4E analysis, Planning & scheduling.

## INTRODUCTION

Population growth drives a substantial increase in energy demand, directing development plans toward energy security, environmental impact management, and economic growth. Accordingly, international treaties like the 2030 Agenda for Sustainable Development and the Kyoto Protocol emphasize the transition to renewable energy and the reduction of greenhouse gas emissions [1].

Livestock farming represents a key opportunity for waste valorization, particularly manure, which is rich in organic matter and nutrients. However, improper management significantly contributes to the global carbon footprint, water eutrophication, soil acidification, and air pollution [2].

Among livestock residues, pig manure is particularly suitable for on-site energy systems due to its high methane yields, stable biogas production profiles, and organic fertilizer [3]. While currently regarded as a carbon-neutral energy source, its valorization routes vary. Conventional pathways, such as electricity generation using internal combustion engines or combined heat and power (CHP) systems, are mature but often exhibit limited efficiencies. Conversely, upgrading biogas for transportation fuels, grid injection, as well as hybrid configurations, represents a more effective approach to harnessing its potential [4-5].

Although various biogas upgrading techniques exist (e.g., adsorption, membrane separation), absorption remains the most prevalent in the chemical industry due to its high efficiency and low operating pressures. However, absorbent selection is a critical factor directly influencing process performance and operating costs [6]. In addition, process selection depends on methane concentration and plant requirements. For instance, when upgrading is not viable, integrating power generation systems, requiring only the removal of corrosive contaminants such as hydrogen sulfide and siloxanes, is an alternative [7]. However, these valorization processes involve complex trade-offs between technical, economic, and environmental factors. Therefore, a comprehensive evaluation using sustainability metrics, such as 4E analysis (Energy, Exergy, Economy, and Environment) within a dynamic system-level framework, is essential.

Thus, the objective of this work is to design a biogas valorization system using agro-industrial residues, employing a multi-objective optimization framework based on 4E analysis. Additionally, this study integrates optimal planning and scheduling strategies for feedstock utilization to maximize economic performance under dynamic electricity pricing schemes.

## CASE STUDY

The biogas feed stream from anaerobic digestion has a mass composition of methane (0.599), carbon dioxide (0.399), siloxanes (0.001), and others (<0.0001), with a volumetric flow rate of 150 $Nm^3/h$ [8]. The proposed utilization scheme integrates two alternative pathways, as illustrated in Figure 1.

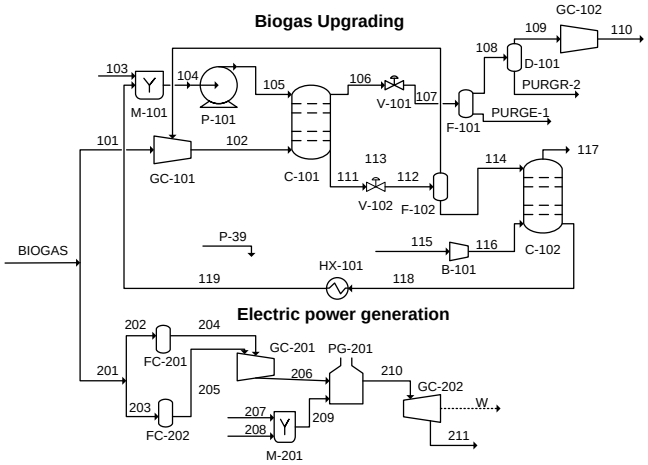

**Figure 1.** Process Flow Diagram for plant biogas utilization.

The first (upper) pathway corresponds to a biogas upgrading process based on high-pressure water scrubbing (HPWS). This process relies on physical absorption and desorption principles to produce biomethane with high purity (P ≥ 97 %) and recovery (R ≥ 95 %). The biogas is compressed using a gas compressor (GC-101), while water is pressurized by a pump (P-101); both streams are fed into an absorption packed column (C-101) at 5 barg and 5 °C. The top stream consists of methane-rich gas, which is first flashed (F-101), subsequently conditioned in a dehydration column (D-101), and further pressurized in a second compressor (GC-102) at 250 barg for final utilization and transport. The bottom stream of C-101, containing water and absorbed gas impurities, is directed to a flash vessel (F-102) at 2 barg to recover residual methane, which is recycled back to the absorption column. The liquid phase from the flash vessel is sent to a desorption packed column (C-102) at atmospheric pressure, where air supplied by a blower (B-101) strips the absorbed gases. The desorbed gases are released to the atmosphere through the top stream, while the regenerated water is recirculated to the absorption system (M-101 to P-101). The second pathway involves power generation through the combustion of cleaned biogas in a gas turbine to produce electricity for on-site consumption and grid injection. In this configuration, the biogas is first purified in activated carbon columns (FC-201/202) and subsequently pressurized by a low-pressure compressor (GC-201). The fuel is then fed into the power generation unit, which comprises an air supply system (M-201), a combustion chamber (PG-201), and a gas turbine (GC-202). The generated electricity is supplied to the national grid, while the flue gases are discharged into the atmosphere.

Both processes were modeled and simulated in Aspen Plus™, employing the NRTL thermodynamic model and the equation of state Redlich-Kwong to describe liquid-vapor equilibria and incorporating Henry's law to accurately predict gas solubility in the absorption and desorption units.

## METHODOLOGY

Two optimization stages were considered in the proposed methodology, which are described as follows:

### First stage: Process optimization

The first stage of this methodology consists of optimizing the process operating conditions, and the multi-objective optimization problem is formulated as follows (Equation 1):

$$\underset{x}{Min}\ \underline{Z} = \left[ Z_i(\underline{x}) \right] i = 1, \dots, j.$$

$$s.t.\ h(\underline{x}) = 0; g(\underline{x}) \leq 0 \qquad (1)$$

where $\underline{Z}$ represents a vector containing $j$ objective functions, and $(\underline{x})$ denotes the vector of decision variables. Furthermore, $\boldsymbol{h}(\underline{x})$ and $\boldsymbol{g}(\underline{x})$ represent the vectors for

equality and inequality constraints associated with the decision variables.

The selected objective functions were energetic, exergetic, and environmental indicators, which are used to identify optimal scenarios for on-site biogas utilization. The decision variables included water feed flow rate ($F_{H2O}$), air feed flow rate ($F_{AIR}$), and combustion air feed flow rate ($F_{AIRC}$). Additionally, inequality constraints were defined for the purity (P) and recovery (R) of biomethane and process water ($P_{CH4} \geq 0.97, P_{H2O} \geq 0.99, R_{CH4} \geq 0.95, R_{H2O} \geq 0.99$), with all values expressed as mass fractions.

## Energy

In this work, the energy intensity (EI) index was used, defined as the ratio of electrical energy consumption to the product mass flow rate, expressed in kWh/kg (Equation 2). This indicator enables the assessment of the energy penalty associated with biogas upgrading and power generation.

$$EI\left[\frac{\text{kWh}}{kg}\right] = \frac{Energy\ consumption}{Product\ mass\ flow} \quad (2)$$

## Exergy

Exergy represents a metric of the quantity and quality of energy. The exergy losses ($\sigma T_0$) were quantified as an indicator of system irreversibility; lower values indicate improved thermodynamic performance and a more efficient plant.

To determine the exergy loss, the difference between the physical exergy of the inlet streams [$\Delta \dot{E}x_{In,j}$] and outlet streams [$\Delta \dot{E}x_{Out,j}$] was considered, in addition to the exergy destroyed by heat generation [$\dot{E}x_{q,j}$] and work [$\dot{W}_j$], where $j$ represents each process equipment within the plant (Equation 3).

$$\sigma T_0[\text{kW}] = \Delta \dot{E}x_{In,j} - \Delta \dot{E}x_{Out,j} + \dot{E}x_{q,j} - \dot{W}_j \quad (3)$$

## Environment

The objective function associated with the environment integrates Life Cycle Assessment (LCA), allowing the calculation of environmental impacts associated with the construction and operation of the biogas utilization plant. LCA is a methodology established in the ISO 14040 standard and is typically applied in four stages:

1. **Goal and scope definition:** Minimization of the environmental impact for biomethane and energy production, where the Eco-indicator 99 (EI-99) methodology was integrated as the appropriate tool for the LCA.
2. **Inventory analysis:** This step considers the inputs and outputs of matter and energy, construction materials, and the consumption of auxiliary services associated with the process, where all loads must be expressed per reference unit (Life Cycle Inventory, LCI).
3. **Environmental impact assessment:** In this step, process data are translated into environmental impact information; Equation 4 represents the Eco-indicator 99 calculation. Where $\beta$ represents the total amount of chemical substance $b$ released per unit of reference flow via direct emissions, $\alpha$ represents the damage caused in each category $k$ per unit of chemical substance $b$ released into the environment, $\omega$ is the weighting factor for damage in category $d$, and $\delta$ is the normalization factor for damage categories.
4. **Interpretation:** The results are analyzed, and conclusions and recommendations for the system are generated.

$$EI\text{-}99\left[\frac{\text{mPt}}{year}\right] = \sum_b \sum_d \sum_k \alpha_{b,k} \beta_b \delta_d \omega_d \quad (4)$$

The Eco-indicator 99 (EI-99) method was selected due to its suitability for comparing environmental trade-offs in energy and process systems at an early design stage [10].

To perform the optimization, a computational interface COM was implemented using Aspen Plus™ and Matlab™, allowing automated simulation-optimization using a multi-objective genetic algorithm based on NSGA-II (gamultiobj). The optimization hyperparameters included 100 generations, 100 individuals, and a crossover fraction of 0.8. Eleven optimization scenarios were evaluated, varying the split fraction (s) of biogas flow rate destined to each process from 0.00 to 1.00 with increments of 0.1.

To identify the best solution within the optimal set, a global criterion decision-making method was employed. This approach identifies the point on the Pareto front that minimizes the sum of the normalized deviations from the ideal point (Equation 5) [11].

$$\min\ [\underline{Y_j}]$$

$$Y_j = \sum_{i=1}^{n} \left\| \frac{\Phi_{i,j} - {\Phi_i}^{min}}{{\Phi_i}^{max} - {\Phi_i}^{min}} \right\| \quad (5)$$

where $Y_j$ represents the normalized $L_1$ distance of solution $j$ to the ideal point, $\Phi_{i,j}$ notes the value of the $i$-th objective function for the $j$-th optimal solution, ${\Phi_i}^{max}$ and ${\Phi_i}^{min}$ correspond to the maximum and minimum values achieved by each objective function within the Pareto set, and $n$ represents the number of objective functions (3).

## Second stage: Optimal biogas planning utilization

The second stage focused on planning and scheduling optimization under economic performance metrics. Using the dataset generated in the first stage, a surrogate model was implemented using support vector regression (SVR), enabling the approximation of the process behavior over the evaluated operating range.

Particularly, SVR was selected due to its robustness under limited training data, its ability to capture nonlinear trends, and its smooth extrapolation behavior within the training domain, making it suitable for embedding within a mixed-integer linear programming (MILP) framework solved using Gurobi™ Optimizer, both implemented in Python™.

The MILP model was formulated to determine the optimal utilization of the biogas flow rate between upgrading and power generation pathways. The objective function aimed to maximize economic profit under time-of-use electricity pricing of Mexico's Net Billing scheme (independent generation and consumption rates). Electricity prices were defined as follows: electricity consumption (base: $ 0.066, intermediate: $ 0.109, and peak: $ 0.130 USD/kWh), electricity generation (base: $ 0.029, intermediate: $ 0.053, and peak: $ 0.101 USD/kWh) [9]. Additionally, a biomethane sales price of $ 1.73 USD/Nm$^3$ was considered.

## Economy

The economic performance of the system was assessed through an economic index defined as the net economic profit [USD], accounting for revenues from biomethane upgrading and electricity export, as well as costs associated with electricity consumption. Equation (6) presents the mathematical formulation of the economic objective function as a function of electricity prices and operational decisions:

$$\underset{x}{Max}\ Z = \sum_{t\in\tau}(P_{CH4}bm_t + p_t{}^{gen}E_t{}^{exp} - p_t{}^{cons}E_t{}^{imp})\Delta t \quad (6)$$

where $bm_t$ denotes the biomethane production rate, $E_t{}^{exp}$ and $E_t{}^{imp}$ represent the exported and imported from the grid, at time interval ($\Delta t$), respectively, and $P_{CH4}$, $p_t{}^{gen}$, and $p_t{}^{cons}$ correspond to the biomethane selling price, electricity generation, and electricity consumption tariffs, respectively.

Table 1 summarizes the applicable electricity tariffs by day of the week and time of operation, which were explicitly integrated into the optimization framework.

# RESULTS

Figure 2 shows the three-dimensional trade-off between energy intensity (EI), Eco-indicator 99 (EI-99), and exergy losses ($\sigma T_0$) for the evaluated scenarios, while Table 2 summarizes the corresponding optimal values for each scenario. Distinct marker shapes were used to differentiate the results of each optimization scenario. The dashed line represents the system trajectory.

As the operational split increases from 0.0 to 1.0, a pronounced and non-linear reduction in EI-99 and $\sigma T_0$ is observed. A higher biogas flow directed to upgrading results in a reduction in overall environmental impacts and a more thermodynamically efficient system without a significant penalty in the energy intensity index, in contrast to the electricity generation process. While the transition from low to intermediate splits (0.0-0.7) shows substantial reductions in EI-99 and $\sigma T_0$, the marginal benefits diminish for higher split values (above 0.7). Consequently, the region corresponding to high operational splits can be identified as the most attractive compromise between the indicators reported for the system studied.

**Table 1:** Electricity rates by day and hour.

| | Day-tariff category | | |
|---|---|---|---|
| | **Base** | **Intermediate** | **Peak** |
| **Consumption** | $ 0.066 USD/kWh | $ 0.109 USD/kWh | $ 0.130 USD/kWh |
| **Generation** | $ 0.029 USD/kWh | $ 0.053 USD/kWh | $ 0.101 USD/kWh |
| | **Day-tariff periods** | | |
| | **Base** | **Intermediate** | **Peak** |
| **Monday to Friday** | 00:00-6:00 | 6:00-19:30, 23:30-00:00 | 19:30-22:30 |
| **Saturday** | 00:00-7:00 | 7:00-00:00 | |
| **Sunday and Holidays** | 00:00-19:00, 23:00-00:00 | 19:00-23:00 | |

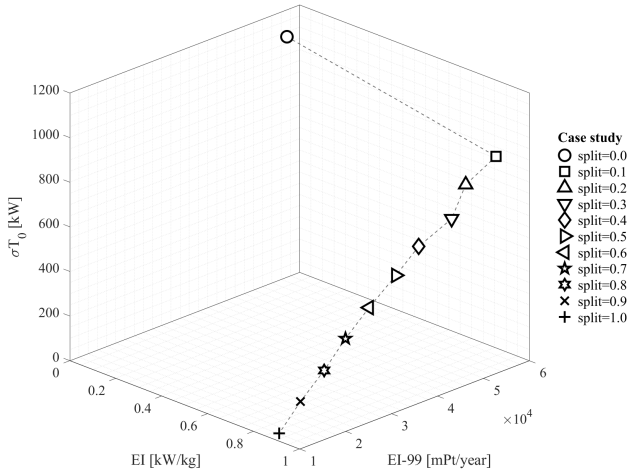

**Figure 2.** First stage optimization results.

$\sigma T_0$ values exhibit a decrease of more than 98% when shifting from full electricity generation to upgrading, while EI-99 shows a similarly strong downward trend, decreasing by approximately 81%. In addition, the energy intensity index remains relatively stable for values above 0.3 within a narrow range between 0.89 and 0.94 kWh/kg.

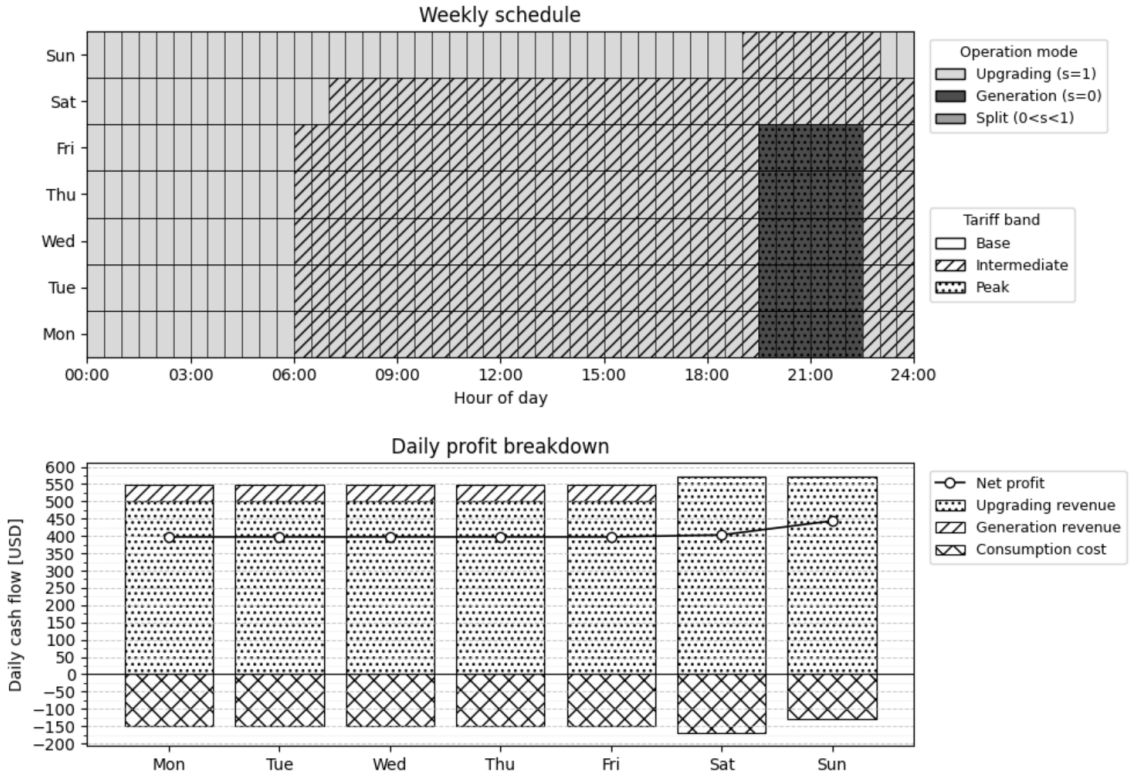

**Figure 3.** Weekly scheduling and daily profitability under time-of-use electricity rates.

**Table 2:** Optimal objective function values.

| Split | $EI\left[\frac{\mathbf{kWh}}{\boldsymbol{kg}}\right]$ | $EI\text{-}99\left[\frac{\mathbf{mP}}{\boldsymbol{year}}\right]$ | $\sigma T_0[\mathbf{kW}]$ |
|---|---|---|---|
| **0.00** | 0.05 | 57, 269.00 | 1, 078.20 |
| **0.10** | 1.00 | 52, 783.00 | 972.98 |
| **0.20** | 0.96 | 48, 188.00 | 867.11 |
| **0.30** | 0.99 | 43, 620.00 | 761.73 |
| **0.40** | 0.94 | 38, 948.00 | 655.13 |
| **0.50** | 0.92 | 34, 990.00 | 548.76 |
| **0.60** | 0.91 | 29, 650.00 | 442.51 |
| **0.70** | 0.90 | 25, 010.00 | 336.24 |
| **0.80** | 0.90 | 20, 370.00 | 230.11 |
| **0.90** | 0.89 | 15, 710.00 | 123.67 |
| **1.00** | 0.89 | 11, 077.00 | 17.60 |

In the second stage of the proposed framework, the SVR allowed capturing nonlinear relationships between the operational decision variables and key process outputs, specifically, electricity generation and electricity consumption. This approach significantly reduces computational effort compared to direct process simulation and optimization. The surrogate models exhibited high predictive performance for operational variables, objective function values, and operating conditions, with coefficients of determination ($R^2$) above 0.99 over the evaluated operating range (0≤Split≤ 1). Thus, the SVR-based surrogate demonstrated stable behavior across the entire operational range, producing smooth and physically consistent values that enabled its direct embedding into the MILP formulation.

Figure 3 illustrates the optimal weekly operational schedule and the corresponding daily economic metrics obtained from the SVR-assisted MILP optimization under time-of-use electricity tariffs in Mexico. The upper panel represents the selected operational mode for each 30-minute interval throughout the week, revealing a consistent operational pattern during low-price periods (base and intermediate tariff), the system operates in upgrading mode (s=1), prioritizing biomethane production. During peak tariff hours, the system consistently switches to power generation mode (s=0). In this time-based context, electricity generation represents revenues that exceed the benefits of upgrading and methane production. This confirms that the optimization framework correctly captures the economic trade-off imposed by the time-varying electricity process and improves operational decisions in the short-term market.

The lower panel of Figure 3 represents the daily cash flow breakdown. Across all days, upgrading revenue represents the dominant contribution to total profit; therefore, biomethane upgrading remains the primary

economic driver of the system. Electricity generation provides an additional revenue income stream, mainly concentrated on days with extended peak tariff exposure; even then, the electricity consumption cost is higher than base and intermediate tariffs. Biomethane upgrading represents the dominant source of profit, accounting for 91 % of the total positive cash flow from Monday to Friday and 100 % during the weekend.

## CONCLUSIONS

This work proposed and validated a two-stage optimization framework for the sustainable valorization of biogas under 4E metrics, integrating process-level optimization with operational planning and scheduling under dynamic electricity pricing schemes.

In the first stage, a multi-objective optimization based on 3E analysis was implemented to evaluate alternative biogas utilization scenarios, revealing a strong trade-off between electricity generation and upgrading pathways. Increasing the split fraction toward upgrading led to a pronounced reduction in EI-99 and $\sigma T_0$ indexes, representing a more thermodynamically efficient and environmentally friendly process. Consequently, a high biogas flow rate to upgrading (split upper to 0.7) was identified as the most attractive compromise region.

In the second stage, a surrogate-based optimization strategy using SVR and a MILP framework demonstrated that the optimal operation presents a clear operational pattern: biomethane upgrading is consistently favored during base and intermediate tariff periods (s=1), where stable biomethane revenues outweigh electricity-rated benefits, whereas power generation becomes economically attractive during peak tariff intervals (s=0), when electricity generation revenues compensate for the lower overall efficiency of this pathway. The resulting weekly schedule confirms that the proposed framework effectively aligns short-term operational decisions with market-driven price signals.

From an economic perspective, biomethane upgrading emerged as the dominant contributor to overall profitability throughout the week, while electricity generation served as a complementary revenue stream during high-price periods. Based on the optimal weekly schedule obtained from the SVR-MILP framework, biomethane upgrading accounts for approximately 90-100 % of the total positive economic benefits, while electricity generation contributes the remaining 10 %, depending on the exposure to peak electricity tariffs. This highlights the importance of hybrid utilization strategies, where flexibility in biogas allocation enables enhanced economic resilience under variable energy markets.

## ABSTRACT

Pyrolysis, a key waste-to-X technology, enables converting a wide portfolio of biomass waste into valuable chemicals and fuels. However, raw pyrolysis oils are chemically and physically unstable. A multi-step stabilisation is necessary to reduce acidity and the content of reactive components, mainly carbonyls and carboxylic acids. During stabilisation, which involves deoxygenation and hydrogenation as the main steps, an aqueous phase is generated as a by-product. This stream contains mainly water, but relevant amounts of methanol and ethanol (2-8 wt%) are also present, together with minor concentrations of higher alcohols, $C_1$-$C_4$ carboxylic acids, and light esters. The aim of this work is to design and optimise a process to isolate the methanol and ethanol embodied in the aqueous phase and exploit them as intermediates to generate biofuels, biochemicals, and pharmaceutical products. The process consists of a train of four distillation columns to maximise the recovery rate and purity of the two targeted products. COCO-COFE, a CAPE-OPEN process simulator, is used for flowsheet development. The optimal number of theoretical stages and the optimal positioning of the feed to each unit have been optimised, considering a trade-off CAPEX-OPEX as the criterion. Results show that up to 95% and 98% yield can be achieved for methanol and ethanol, respectively. Methanol purity is limited to a maximum of 92 wt% due to the presence of volatile impurities, while ethanol contains residual propanol (6 wt%). The overall heat demand is in the order of 1 MJ/kg feed.

## INTRODUCTION

Fast pyrolysis is considered a high-potential route to produce sustainable advanced biofuels. However, Fast Pyrolysis Bio Oil (FPBO) is not suitable for direct use as a transportation fuel, and further chemical upgrading is required to enhance stability. Different approaches can be adopted to reduce the concentration of acidic compounds, including co-processing in Fluid Catalytic Cracking (FCC), and hydrotreating. The Biomass Technology Group (BTG), a private Dutch company specialised in converting biomass into sustainable biofuels, has developed a proprietary stabilisation process using a Ni-Cu-based catalyst called Picula™ [1]. This process, which is shown in Figure 1, includes the following main steps [2]:

1. Selective hydrogenation at mild temperatures (200-250°C). The obtained product is called Stabilised Pyrolysis Oil (SPO);
2. Deoxygenation at high temperature (350°C). The obtained product is called Stabilised Deoxygenated Pyrolysis Oil (SDPO);
3. Final hydrogenation (refinement step at 425°C) to produce Hydrogenated Pyrolysis Oil (HPO).

This FPBO stabilisation process generates a liquid product that comprises both an organic and an aqueous phase. The presence of a water phase is largely determined by the substantial water content present in the biomass feedstock. Aqueous phase from pyrolysis is a complex mixture of water (> 60 wt%) and various dissolved organic compounds, including alcohols (methanol, ethanol, propanol, and butanol), sugars (levoglucosan and others), carboxylic acids (mainly acetic, propionic,

and butyric acid), esters, furfural, guaiacol, and minor quantities of aldehydes and ketones. The aqueous phase is generally disposed of as waste or potentially utilised as co-feed in biogas plants. However, given its composition, it could be considered a valuable resource for producing various bio-based chemicals and fuels, though the chemicals of interest are extremely diluted in water. Therefore, up-concentration and purification are needed, which makes the process economically challenging. The aim of this work, which is carried out within the framework of the FUEL-UP project [3] funded by the European Commission, is to design and optimise a process to isolate the chemicals embodied in the aqueous phase.

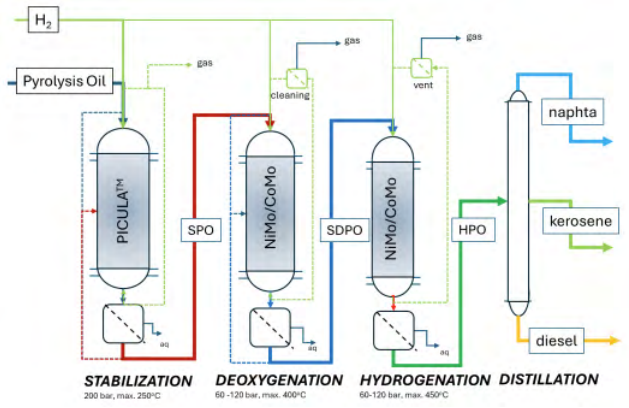

**Figure 1.** The FPBO upgrading process developed by BTG [2].

The idea is to separate aqueous/organic phase and subsequently treat the two phases individually [1]. The water phase can be further processed to separate and recover valuable chemicals. However, water-alcohols-carboxylic acid mixtures have an azeotropic nature, which makes compounds separation challenging.

One viable option is extractive distillation. This approach can effectively isolate polar components, such as alcohol and acetic acid, enabling their direct use as valuable products or in subsequent processes like biofuel upgrading [4]. Alternatively, azeotropic distillation can be used to remove water from the aqueous phase of pyrolysis oil by utilising the formation of azeotropic mixtures [5]. However, these technologies suffer from the introduction of a third component (the entrainer) during the separation process as a major drawback [4]. This can lead to relevant final product purity issues. Besides, the plant layout complexity considerably increases, and there is a need for heat integration to minimise the energy consumption of product recovery and solvent regeneration. Recently, other advanced separation options have also been investigated, including freeze concentration, reverse osmosis, or bioconversion. However, these technologies are all characterised by a much lower Technology Readiness Level (TRL).

For these reasons, in this work, a train of distillation columns in series is identified as the simplest and most robust separation scheme:

- The first distillation column allows a bulk removal of $C_1$-$C_3$ alcohols and eventual other species whose boiling point is lower than water;
- A variable number of downstream columns can be used to refine the separation.

## FEEDSTOCK CHARACTERISATION

The composition of the water phase obtained during Stabilised Pyrolysis Oil (SPO) and Stabilised Deoxygenated Pyrolysis Oil (SDPO) production at BTG has been measured using GC-FID (Gas Chromatography - Flame Ionization Detector) technique in SINTEF, and it is shown in Table 1. 14 different species were identified, and their concentration was quantified through calibration curves. The remaining peaks of unidentified species were combined with the peaks of the nearest species observed in the chromatogram (closest retention time).

**Table 1:** Composition of the aqueous phase samples from SPO ($SPO_{Aq}$) and SDPO ($SDPO_{Aq}$) measured with GC-FID. Acronyms: water (H2O), methanol (MeOH), ethanol (EtOH), 1-propanol (1-PrOH), 1-butanol (BuOH), acetic acid (AcAc), tetrahydrofuran (THF), Methyl acetate (MeA), ethyl acetate 8EtA), acetone (Acet), formic acid (FoAc), isopropanol (2-PrOH), propionic acid (PrAc), butyric acid (BuAc), 1-pentanol (PeOH).

| | GC-FID results | | For simulation | |
|---|---|---|---|---|
| **Component** | **$SPO_{Aq}$** | **$SDPO_{Aq}$** | **$SPO_{Aq}$** | **$SDPO_{Aq}$** |
| H2O | 72.50 | 89.90 | 85.60 | 94.22 |
| MeOH | 4.95 | 0.33 | 5.84 | 0.35 |
| Ethanol | 2.70 | 1.85 | 3.19 | 1.94 |
| 1-Propanol | 0.32 | 0.55 | 0.38 | 0.58 |
| Butanol | 0.13 | 0.03 | 0.15 | 0.03 |
| Acetic Acid | 0.22 | 0.00 | 0.26 | 0.00 |
| THF | 0.23 | 0.19 | 0.27 | 0.20 |
| Methyl Acetate | 0.25 | 0.00 | 0.30 | 0.00 |
| Ethyl Acetate | 0.59 | 0.49 | 0.70 | 0.51 |
| Acetone | 0.05 | 0.08 | 0.06 | 0.08 |
| Formic Acid | 0.05 | 0.05 | 0.06 | 0.05 |
| Isopropanol | 0.20 | 0.10 | 0.24 | 0.10 |
| Propionic Acid | 0.23 | 0.47 | 0.27 | 0.49 |
| Butyric Acid | 0.37 | 0.50 | 0.44 | 0.52 |
| Pentanol | 1.91 | 0.87 | 2.26 | 0.91 |
| SUM | 84.70 | 95.41 | 100.00 | 100.00 |

For simplicity, alcohols heavier than $C_5$

(concentration below 0.1 wt%) were lumped into pentanol, and carboxylic acids higher than $C_4$ were lumped into butyric acid. The concentrations of the compounds detected with the GC cover 85% and 95% of the mass balance for $SPO_{Aq}$ and $SDPO_{Aq}$, respectively. For modelling purposes, the composition has been normalised to 100%, as shown in Table 1.

## PROCESS DESIGN

### Thermodynamic model

In water-alcohols-carboxylic acids systems, strong non-idealities are present due to the azeotropic nature of most of the involved binary interactions. Activity models like Non-Random Two-Liquids (NRTL) and UNIQUAC are the most suitable to describe VLE of this system. However, it has been verified that the existing default NRTL models available in Aspen Plus and COCO-COFE V3.7, a license-free software released by AmsterChem, do not accurately reproduce the equilibrium measurements of most of the binary and ternary mixtures involving the 14 compounds of interest for this application. Therefore, the NRTL model has been re-parametrised to increase predictability. The NIST ThermoData Engine V10.3 was used as the experimental data source. The re-fitted model shows a significantly improved capability to reproduce experimental data, as the Average Relative Deviation (ARD) in the prediction of vapor phase composition at fixed liquid composition and temperature (for isothermal data) or pressure (for isobaric data) drops from 16% and 12.1% of the current COFE and Aspen models, respectively, down to 7%.

Details on the procedure followed for the mode reparametrisation and the outcomes of its performance evaluation are described in a separate contribution.

### Process Flow Diagram

The Block Flow Diagram of the designed process for efficient recovery of methanol and ethanol at the highest possible purity is drawn in Figure 2. It consists of a train of four distillation columns in series:

- The first column (Col. 1) is a bulk water removal;
- The second column (Col. 2) separates methanol from ethanol;
- The third column (Col. 3) is a methanol purification step. The target is to minimise the residual concentration of acetone, acetates, and THF. Given the azeotropic nature of most mixtures including the mentioned compounds, there is a limit in the maximum amount of impurities that can be removed by simple distillation. Two scenarios have been investigated: scenario A has maximum methanol purity as the target, while in scenario B methanol recovery is maximised.
- The last column (Col. 4) is an ethanol purification step. The target is to minimise the residual concentration of water and heavier alcohols, with a special focus on propanol.

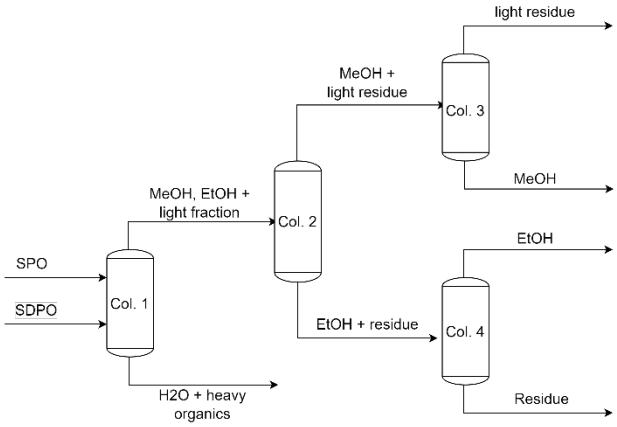

**Figure 2.** BFD of the distillation process designed for methanol and ethanol recovery from pyrolysis oil stabilisation wastewater.

Three case studies are analysed considering three different feedstocks:

- Only $SPO_{Aq}$ stream (CS1);
- Only $SDPO_{Aq}$ stream (CS2);
- Combined $SPO_{Aq}$ + $SDPO_{Aq}$ streams (CS3).

The same process layout and the same specifications are used to run each case study. A small variation is introduced when $SDPO_{Aq}$ only is treated: given its very low methanol content, column 3 is removed in this configuration.

The specifications set to design each distillation column are gathered in Table 2.

**Table 2:** List of the specifications chosen to model each distillation column.

| Column | Top / bottom | Specification | Value |
|---|---|---|---|
| Column 1 | Top | EtOH recovery | 99% |
| | Bottom | H2O recovery | 99% |
| Column 2 | Top | MeOH recovery | 99.99% |
| | Bottom | EtOH recovery | 99.99% |
| Column 3, scenario A | Top | THF recovery | 95% |
| | Bottom | EtA recovery | 20% |
| Column 3, scenario B | Top | THF recovery | 55% |
| | Bottom | MeOH recovery | 95% |
| Column 4 | Top | EtOH recovery | 99% |
| | Bottom | 1-PrOH recovery | 95% |

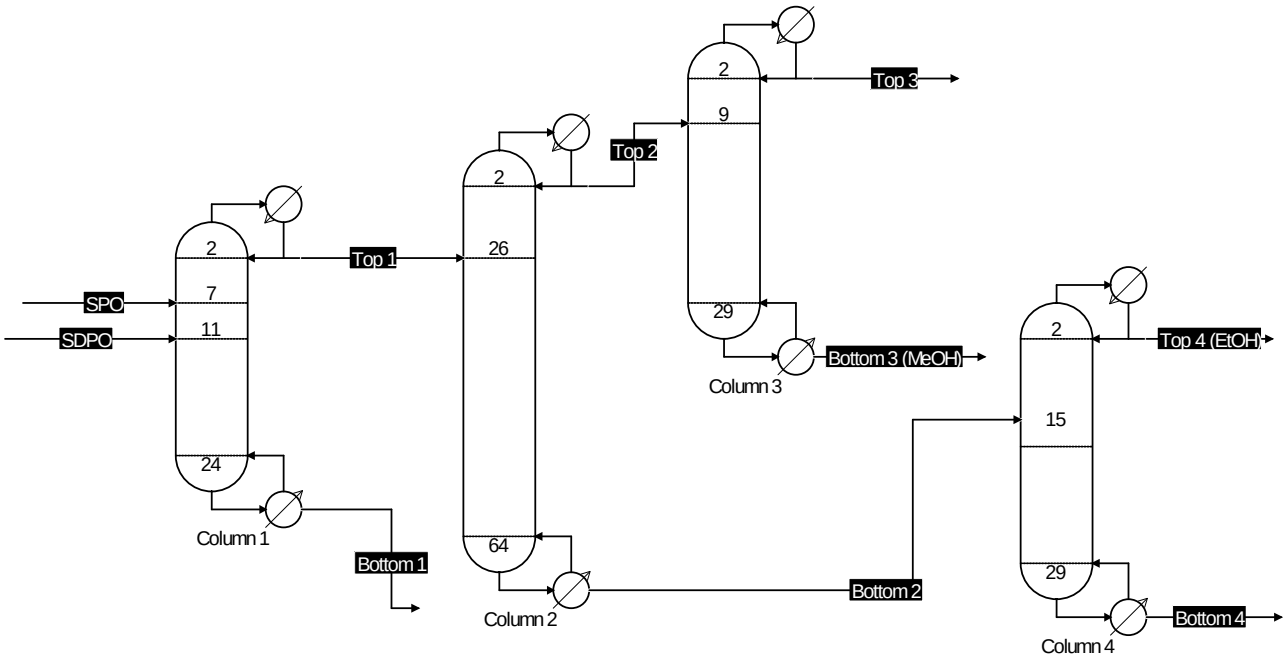

**Figure 2.** Process flowsheet implemented in COCO-COFE process simulator for methanol and ethanol recovery from combined $SPO_{Aq}$ and $SDPO_{Aq}$ streams.

## Process optimisation

The optimal number of theoretical stages and the optimal positioning of the feed to each column are optimised, considering a trade-off CAPEX-OPEX as the criterion. Indeed, increasing the number of theoretical stages results in a decrease in the energy demand for the separation, but it also generates an increase in the investment costs to build the column. More specifically, the minimum number of stages for which an increment lower than 5% is observed in the reboiler duty compared to a configuration with 5 additional stages is selected as the optimum. Noteworthily, only the reboiler duty is considered for the optimisation, while the cooling energy demand for the condenser is neglected. This choice can be justified based on the utilities needed in the reboiler and condenser. Indeed, the operating temperatures in each of the four columns are such that low-pressure steam is required as the utility in the reboiler, while standard cooling water can be used for distillate condensation.

As for the feed positioning, feeding from the top to the bottom of the column is investigated (with a step of two stages), and the feed position associated with the lowest reboiler duty is chosen as the optimum.

## Flowsheet implementation

The Block Flow Diagram (BFD) shown in Figure 2 is used as the basis to develop a process flowsheet. The simulation is implemented in COCO-COFE, a license-free and CAPE-OPEN flowsheet environment released by Amsterchem. A size of 3 ton/h of $SPO_{Aq}$ and 3 ton/h of $SDPO_{Aq}$ feed is assumed as representative of a commercial-scale application of the proposed technology.

A screenshot from the simulation developed for the combined $SPO_{Aq}$ and $SDPO_{Aq}$ feed is drawn in Figure 2.

# RESULTS

## Optimal column sizing

The optimal theoretical stage number and the optimal feed positioning identified for each column are gathered in Table 3. These are the same for all three case studies.

**Table 3:** Results of distillation column layout optimisation.

| Column | Optimal N stages | Optimal feed stage |
|---|---|---|
| Col. 1 | 25 | 7, 11 |
| Col. 2 | 65 | 26 |
| Col. 3, scenario A | 20 | 2 |
| Col. 3 scenario B | 35 | 25 |
| Col. 4 | 35 | 22 |

## Product recovery rate and purity

The yield and purity of methanol and ethanol obtained from the optimised process model are gathered in Table 4.

**Table 4:** Methanol and ethanol yield (%) and purity (wt%) obtained in the different modelled process configurations. Components' acronyms are retrieved from Table 1.

| Comp. | Scen. | KPI | CS1 | CS2 | CS3 |
|---|---|---|---|---|---|
| MeOH | A | Yield | 56.0 | - | 51.0 |
| MeOH | A | Purity | 95.5 | - | 92.2 |
| MeOH | B | Yield | 94.6 | - | 94.9 |
| MeOH | B | Purity | 88.1 | - | 81.1 |
| EtOH | - | Yield | 98.0 | 93.1 | 98.0 |
| EtOH | - | Purity | 85.5 | 85.7 | 86.0 |

Results indicate that there is a trade-off between methanol yield and purity. Indeed, a high recovery rate can be achieved (95%, scenario B), but the corresponding product quality is relatively poor (81-88 wt%). On the other hand, increasing the methanol purity up to 95 wt% is possible (scenario A), but in this case, only 56% of the total methanol content present in the feed is recovered in the final product stream. The reason behind this observation is that the presence of volatile impurities negatively affects the product quality, as these compounds have boiling points close to methanol, and some of them form non-ideal interactions, which makes their separation via distillation more challenging. The detailed composition of the methanol product stream obtained when using $SPO_{Aq}$ only, or combined $SPO_{Aq}$ and $SDPO_{Aq}$ feed, is reported in Table 5.

**Table 5:** Methanol composition (wt%) in the different modelled process configurations. Components' acronyms are retrieved from Table 1.

| Component | CS1 | CS1 | CS3 | CS3 |
|---|---|---|---|---|
| Scenario | A | B | A | B |
| MeOH | 95.50 | 88.14 | 92.20 | 81.06 |
| EtA | 4.08 | 8.94 | 7.11 | 15.88 |
| THF | 0.40 | 2.36 | 0.67 | 2.85 |
| Acet | - | 0.32 | - | 0.17 |

The most abundant impurity is ethyl acetate, which is predicted to reach concentrations above 7 wt% in the combined feed case study. Indeed, the re-parametrised NRTL model used in this work indicates that methanol (MeOH) and ethyl acetate (EtA) form a minimum-boiling azeotrope at a methanol concentration of 70 vol% (see Figure 3), and the bubble and dew curves become flat and close for higher methanol concentrations, which indicates that the mixture is difficult to separate by conventional distillation methods. Notably, MeOH-EtA VLE represents the most constraining azeotropic behaviour on the methanol product purity, and this observation holds for all the analysed case studies.

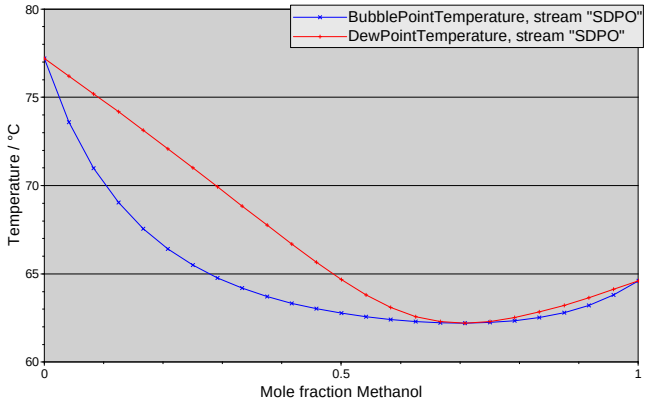

**Figure 3.** Temperature-composition VLE diagram for the binary mixture MeOH-EtA obtained with the re-fitted NRTL model.

Ethanol is obtained at a purity ranging between 85 wt% and 86 wt%. It contains residual water and $C_3$ alcohols, mainly isopropanol. Indeed, isopropanol forms an azeotrope with a comparable composition and boiling point of the water-ethanol one, which hinders their separation. The detailed ethanol product stream composition is gathered in Table 6.

**Table 6:** Ethanol composition (wt%) in the different modelled process configurations. Components' acronyms are retrieved from Table 1.

| Component | CS1 | CS2 | CS3 |
|---|---|---|---|
| EtOH | 85.49 | 85.74 | 85.98 |
| H2O | 7.93 | 7.88 | 7.94 |
| 2-PrOH | 6.28 | 4.90 | 5.68 |
| 1-PrOH | 0.28 | 0.66 | 0.39 |
| MeOH | - | 0.81 | - |

The highest methanol purity is achieved in CS1. Given that a substantial amount of residual volatile organics is present in the final product, maximising yield (scenario B) looks the most promising option. On the other hand, ethanol yield and purity prove to be not affected by the type of feedstock, with comparable results achieved in all the investigated case studies.

## Energy requirements

The total thermal energy demand of the process is calculated as the sum of the reboiler duties of all four columns (three for CS2), and the results are shown in Table 7. As the bottom temperature ranges from 63°C to 99°C in all columns, low-pressure steam is the required utility.

CS2 is the option associated with the lowest energy demand, but in this case only ethanol is recovered as a product. Recovering methanol and ethanol from both SPO and SDPO aqueous streams in the same plant (CS3) is more energy efficient than treating the SPO aqueous stream only. The total duty is around 1 MJ/kg of treated

aqueous stream, resulting in a 16% reduction in the heat demand.

**Table 7:** Specific energy requirement (in MJ/kg feed) of the distillation process for methanol and ethanol recovery.

| Case study | Scenario A | Scenario B |
|---|---|---|
| CS1 | 1.16 | 1.15 |
| CS2 | 0.73 | 0.73 |
| CS3 | 0.95 | 0.97 |

## CONCLUSIONS

A distillation-based process for the recovery of valuable organic compounds, namely alcohols, from pyrolysis oil wastewater stream has been designed, modelled, and optimised. This study shows that there is potential for ethanol and methanol recovery for applications in fuel blending. These alcohols can be effectively separated from water and other heavier compounds: high recovery rates (> 95%) can be achieved by adopting a simple process layout made up of four distillation columns in series, which minimises investment costs. Moreover, no third compound is introduced to avoid contamination effects.

However, the presence of detectable concentrations of esters (i.e., methyl acetate and ethyl acetate), and furans (like tetrahydrofuran) together with alcohols in the SPO and SDPO-derived aqueous mixtures represents a major challenge since all these species have a similar boiling point range as methanol and ethanol. As a result, the obtained alcohol purity is limited.

To target applications requiring a higher degree of purity, such as in the chemical industry, the separation scheme becomes more complex, and an unspecified number of additional purification steps/columns need to be added in a future process layout.

## ACKNOWLEDGEMENTS

The FUEL-UP project has received co-funding from the European Union's Horizon Europe Research and Innovation Programme under Grant Agreement N° 101136123.

The authors express their gratitude to BTG (Netherlands) for their precious contribution concerning feedstock supply and to Avecom (Belgium) for their support and cooperation in sample analysis.

## ABSTRACT

Critical metals are essential for clean energy technologies but, due to being mainly sourced through mining, the critical metal supply chain is susceptible to geopolitical risks. Electronic waste (e-waste), however, can serve as an alternative "urban mine", but the recovery at high purities requires complex and resource-intensive processing. This work explores the modeling and optimization-based design for the intensification of liquid-liquid extraction in small channels as a means to recover critical metals from e-waste. Small channels can achieve high mass transfer rates while mitigating the environmental impact. A superstructure-based approach is employed to represent the alternative system configurations, while a plant propagation algorithm is used to optimize the multi-objective problem to recover Neodymium (Nd) and Samarium (Sm). The multi-objective problem aimed to tackle product quality, process economics, and environmental impact. The results demonstrated that optimally designed extraction can support efficient recovery of critical metals; however, decision making support may be essential for the selection of one process design from those identified as optimal in a multi-objective design approach.

**Keywords**: Superstructure optimization, multi-objective optimization, extraction, critical metals, process intensification

## INTRODUCTION

Critical metals are integral to renewable low carbon and hydrogen technologies and essential for the global energy transition since they are necessary to produce solar panels, batteries, wind turbines, electronics and catalysts (Department for Business & Trade, 2025). These metals are mainly sourced through mining; however, only few countries have access to available ores, with China controlling more than 90% of the global rare earth market and South Africa controlling most of the platinum group metals market (*Recycling Rare Earth Metals - Mathys & Squire LLP*, n.d.). With the global demand in critical metals being higher than ever, their availability has become susceptible to geopolitics, thereby threatening the supply chains. Alternatives to mining include the recovery of critical metals from the increasing volumes of electronic waste (e-waste), which can serve as "urban" mines with critical metal concentrations often higher than in primary ores (Hagelüken, 2012). However, the recovery of metals from e-waste at required purities necessitates multiple processing steps, including solvent extraction and recovery steps.

Metals recovery from waste is traditionally carried out via pyrometallurgical or hydrometallurgical routes. Hydrometallurgical routes are preferred since these do not involve hazardous emissions and offer high recovery and selectivity for a wide range of metals. Hydrometallurgical routes involve the dissolution of the solid waste in acidic solutions followed by a solvent extraction step responsible for selectively separating the metals into solvent phases. Traditionally, dissolution and extraction are carried out in batch systems, and thus are usually characterized by low efficiency, while they are difficult to monitor and digitize due to non-uniformities associated with the batch processing. In lieu of batch dissolution and extraction, intensified flow processing in small channels presents an alternative that can enable the transition to

fully monitored continuous processes, owing to enhanced mass transfer rates that can eliminate flow non-uniformities, increase efficiency, and decrease solvent usage. Throughput in intensified small channel processing can be increased in a modular way by increasing the number of channels and not their volume, thus also facilitating an easier transfer from lab to pilot to industrial settings and ensuring process safety.

In this work, we explore the multi-objective optimal design for the separation of Neodymium (Nd) and Samarium (Sm), primarily used for magnets found in electronics and electric vehicles, using continuous flow liquid-liquid extraction (LLE) in small channels (Garciadiego-Ortega et al., 2020). Mass transfer in the channels is modeled as a set of differential equations. We follow a superstructure-based approach to determine the optimal flowsheet by accounting for multiple extraction steps (Mencarelli et al., 2020). Each step may consist of several stages. The multiple objectives reflect final products quality, process economics and environmental footprint (e.g. solvent usage). The optimization problem is solved employing Fresa, a nature inspired plant propagation optimization algorithm (Fraga, 2021).

This manuscript is structured as follows: first, an overview of the extraction system under consideration is presented. Then, the modeling components, simulation and optimization methods are provided. The proposed system is then used to implement a case study and the results are discussed. Finally, some concluding remarks and future directions are provided.

# METHODOLOGY

## System under consideration

For this work, we considered the continuous flow LLE system in small channels adapted from Pineda et al., (2021). In the channels, high mass transfer rates can be achieved by inducing segmented flow, that is a repeating pattern of two immiscible liquids moving as elongated drops (plugs) separated by continuous phase slugs. The reader is referred to the work of Garciadiego-Ortega et al. (2020) for a detailed presentation of segmented flow in small channels. This extraction system employs two extraction steps and one scrubbing step. A feed of known concentration and a stream of fresh organic solvent enter the first extraction step, E1. For the organic solvent, we assumed a mixture of 2-ethylhexyl diamide amine in n-dodecane. The organic outlet of E1 is introduced into a scrubbing step, SCR, to further purify the organic stream, whilst the aqueous outlet of E1 is introduced into subsequent extraction step, E2. The mixers in the flowsheet of Fig. 1 are used to combine the two distinct organic and aqueous streams, respectively. Note that the mixers used in this work do not appear in the work of Pineda et al. (2021) since the considered system was used to optimally detect trivalent Samarium and Neodymium in nuclear waste, while also considering uncertainty. In the work of Pineda et al. (2021), each extraction step was equivalent to a single stage, and thus a single channel. The current work aims to identify optimal designs for the recovery of the two metals employing multi-stage extraction steps. The number of stages is a design variable as explained in a later section of this paper. Fig. 2 depicts a multi-stage configuration where the flow is introduced co-currently in each stage (channel) but counter-currently overall in a given processing step: the feed is introduced in the first stage of a step whilst the solvent is introduced in the last stage. This pseudo-countercurrent configuration aids in more efficient separations (Bascone et al., 2019) and thus is preferred to co-current configurations.

## Modeling

Modeling solvent extraction in small channels is a problem well addressed in the open literature. Although computational fluid dynamics (CFD) models offer rigor and accuracy (Zhang et al., 2019), they can hinder the solution of the optimization problem due to the computational burden that arises from such models. Instead, we can use a simplified model that consists of two differential mass balances, for the aqueous and organic phases (Pineda et al., 2021). Thus, the differential mass balance for the aqueous phase concentration $C_{a,i,j}$ of the $i$-th component of the $j$-th processing step reads:

$$v_{a,j}\frac{\partial}{\partial x}C_{a,i,j}(x) = -K_j\left[C_{a,i,j}(x) - C^*_{a,i,j}(x)\right] \text{ for } x = 0, \dots, L_j \quad (1)$$

where $C^*_{a,i,j}$ is the equilibrium concentration given by $C^*_{a,i,j} = C_{o,i,j}/a_i$ with $a_i$ being the distribution coefficient of the $i$-th component. We used values of $a_{Nd} = 3.7$ and $a_{Sm} = 0.3$, for the extraction and scrubbing steps described above, that come from the work of Suzuki et al. (2017). The mass balance of the organic phase concentration $C_{a,i,j}$ of the $i$-th component of the $j$-th step reads:

$$\frac{\partial}{\partial x}C_{o,i,j}(x) = -q_j\frac{\partial}{\partial x}C_{a,i,j}(x) \text{ for } x = 0, \dots, L_j \quad (2)$$

where $K_j$ is the mean overall volumetric mass transfer coefficient, $L_j$ is the channel length, $q_j = \frac{\dot{Q}_{a,j}}{\dot{Q}_{o,j}}$ is the ratio between the volumetric flow rate of the aqueous phase, $\dot{Q}_{a,j}$, and the organic phase, $\dot{Q}_{o,j}$, of each step, $v_{a,j} = \frac{\dot{Q}_{a,j}}{A_j}$ is the superficial velocity of the aqueous phase, and $A_j = \pi D_j^2/4$ is the cross sectional area of each channel in a processing step. To estimate the mean overall volumetric mass transfer coefficient, $K_j$, a hydrodynamics correlation is used (Kashid et al., 2010):

$$K_j = \left(\frac{\dot{Q}_{a,j} + \dot{Q}_{o,j}}{A_j}\right)\left(\frac{Ca^{-0.09}Re^{-0.09}}{L_j}\right)\left(\frac{D_j}{L_j}\right)^{-0.1} \quad (3)$$

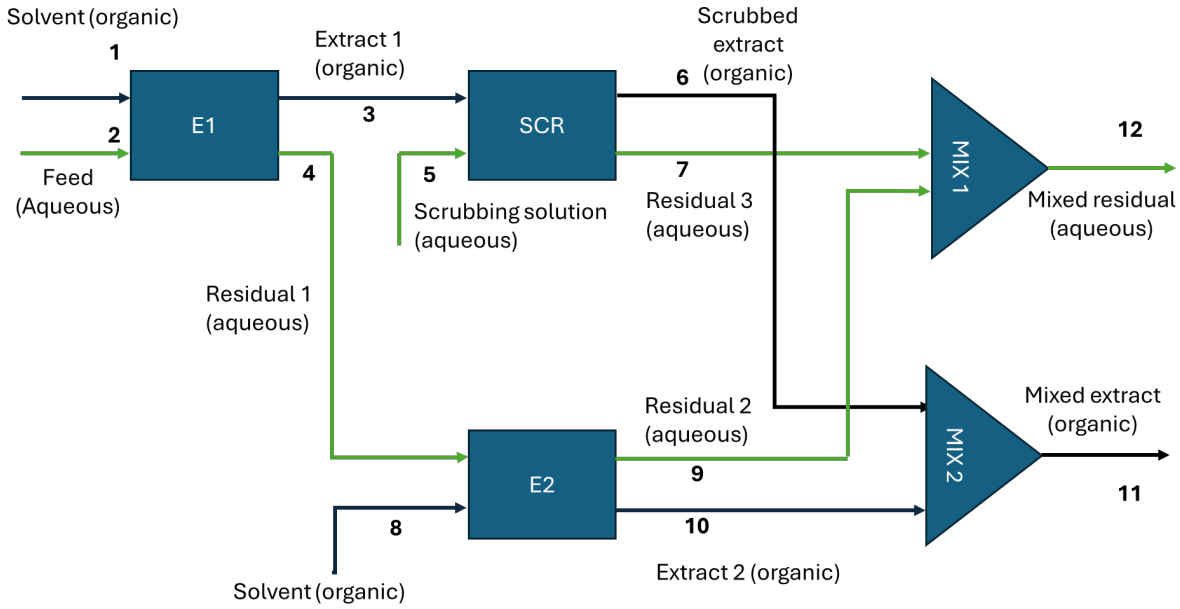

**Figure 1.** Schematic of the continuous flow LLE system considered in this work.

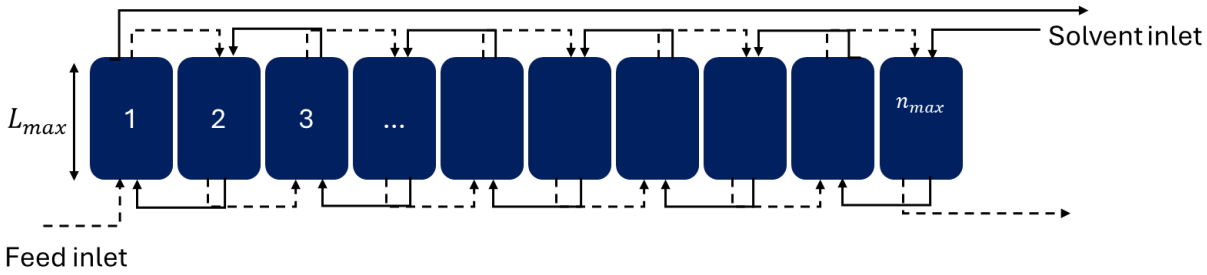

**Figure 2.** Schematic of the pseudo-countercurrent multi-stage configuration within each step of the system considered in this work.

where $Ca$ and $Re$ are the capillary and Reynolds numbers, respectively, and $D_j$ is the diameter of the channels of each step.

## Simulation and optimization

We employ a superstructure-based approach to determine the optimal flowsheet for the separation process (Mencarelli et al., 2020). The process flowsheet involves two distinct extraction steps and a scrubbing step as depicted in Fig. 1. Each extraction step may comprise of several stages (in this work: single-channel stages). The Julia programming language (Bezanson et al., 2017) is used to model the flowsheet as a superstructure of extraction steps (scrubbing included), and in turn, each extraction step as a superstructure of stages. This approach offers good scalability and modularity. The pseudo-countercurrent configuration (see Fig. 2), implemented in Julia, results in multiple recycle streams. The streams have to be torn and converged in order to simulate the superstructure. Therefore, to converge the streams we have implemented Broyden's method in Julia (Broyden, 1965).

Optimal designs are generated by considering a search space defined by the decision variables vector $\mathbf{x} = [q_j, \xi_j, D]$, where $\xi_j$ is a decision variable that defines both the number of stages $n_j$ as well as the length $L_j$ of the $j$-th step (i.e., channel). Note that we assume the length stays uniform within a given step, that is all channels share the length, although it can vary across the different processing steps. This assumption aims to facilitate structural simplicity of the flowsheet in order to maintain low capital cost and promote scalability of the plant. In parallel, a distinct channel length variable for each stage would drastically increase the search space and potential solutions, thus leading to an exponential increase in computational time.

Therefore, given $\xi_j \in [0,1], L_{\max,j}, L_{\min,j}, n_{\max,j}$:

$$n_j \leftarrow \lceil \xi_j n_{\max,j} \rceil \tag{4}$$

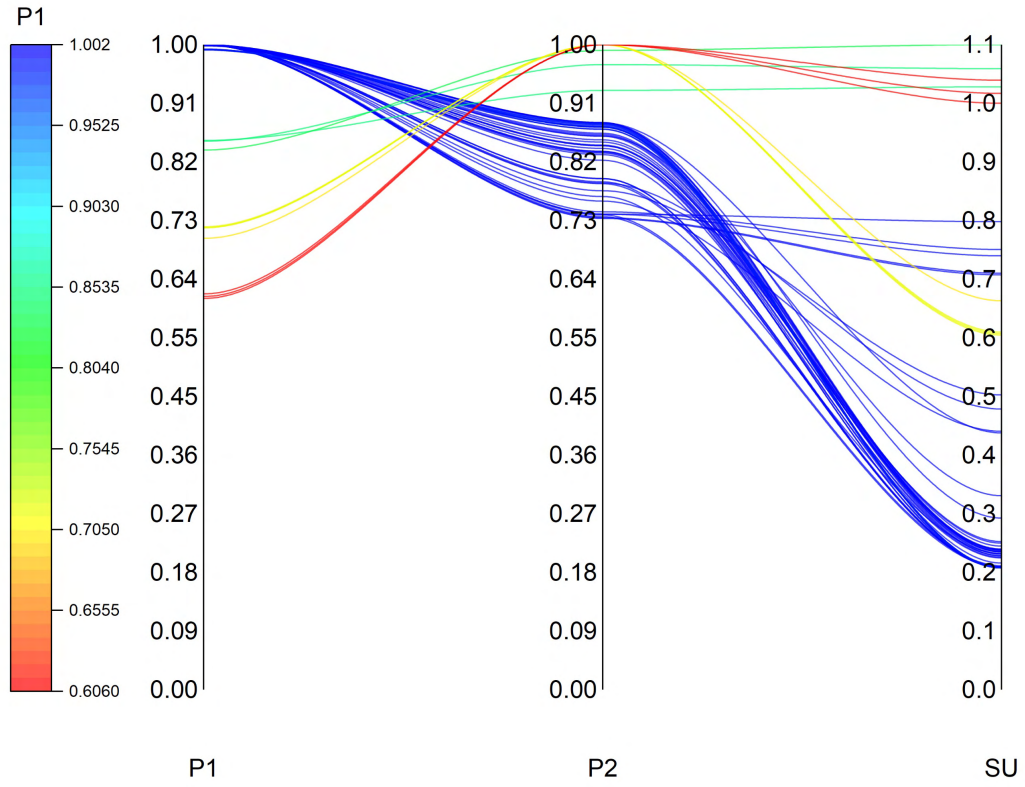

**Figure 3.** Parallel coordinate plot of the non-dominated solutions obtained by Fresa for the settings in Table 4 to solve the three-objective problem defined by Eqs. (6)-(8). P1 and P2 correspond to the purities of Nd and Sm, respectively, while SU is the organic solvent usage in $\mathrm{m}^3/\mathrm{yr}$.

$$L_j \leftarrow \left(\xi_j n_{\max,j} - n_j + 1\right)\left(L_{\max,j} - L_{\min,j}\right) + L_{\min,j} \qquad (5)$$

The formulation described in Eqs. 4 and 5 is useful because a single value for $\xi_j$ (not physically meaningful) is passed down to define two physically meaningful design variables, $n_j$ and $L_j$. This decreases the dimensionality of the problem, thus reducing the potential computational cost. Moreover, the above formulation deals with discrete decisions (e.g., the number of stages per step) by relying solely on continuous variables. This mitigates the combinatorial explosion that would be caused if we employed discrete or binary variables instead. This representation of the design space is effective since it includes all the designs of interest, yet it mitigates any infeasible designs. However, there will be potential designs, that albeit feasible, might be impractical.

We employed Fresa to solve the optimization problem. Fresa is an implementation of a plant propagation algorithm in the Julia programming language (Fraga, 2021). Fresa is a nature-inspired evolutionary algorithm that mimics the propagation of strawberry plants. In fertile soil, strawberry plants send runners to exploit (i.e. refine) the surroundings, while in less fertile soil, fewer but longer runners are sent to explore the *design space* to find more fertile soil. We refer the reader to original paper Salhi & Fraga (2011) for a detailed description of the plant propagation algorithm.

## CASE STUDY AND RESULTS

Neodymium (Nd) and Samarium (Sm) are metals that can be considered as rare earth elements. Applications of these metals include, but are not limited to, magnets for electronic devices, electric vehicles (EVs), and wind turbines. Hence, these metals are pivotal in energy transition. Pineda et al. (2021) have explored optimal design of continuous flow LLE in small channels with the aim to optimally *detect* Nd and Sm radionuclides during the decommissioning of nuclear power plants. In this work, we drew data from the work of Pineda et al. (2021) to develop designs to achieve the best *separation* of Nd and Sm.

As stated above, the main goal of this work is to intensify the separation of critical metals in order to achieve high metals purities and recoveries, while minimizing the environmental impact and operational cost by minimizing the organic solvent usage. The above goals are addressed through the definition of a three-objective

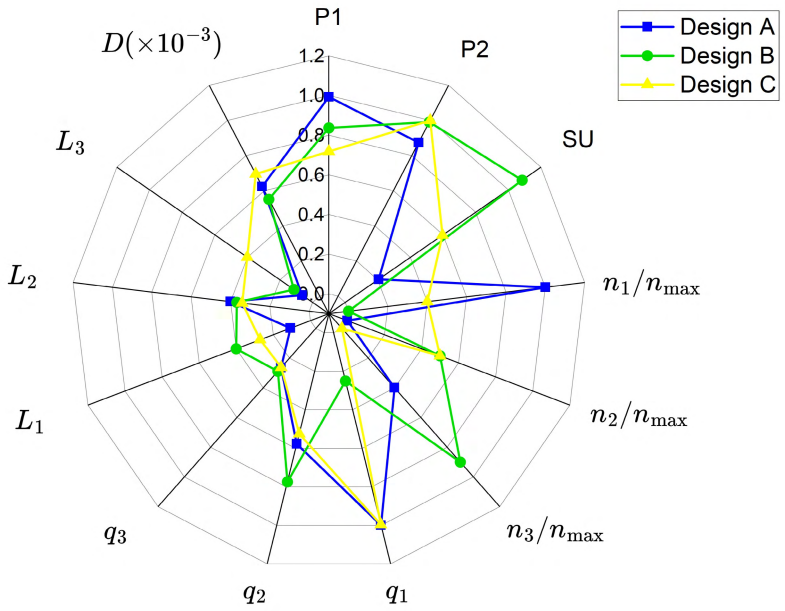

**Figure 4.** Radar chart of representative designs drawn from the set of non-dominated solutions (objectives and design variables) of the three-objective problem defined by Eqs. (6)-(8).

optimization problem:

$$\max_{\mathbf{x}} f_1(\mathbf{x}) = \frac{C_{\text{Nd, 11}}}{C_{\text{Nd, 11}} + C_{\text{Sm, 11}}} \equiv \text{Purity}_{\text{Nd}} \tag{6}$$

$$\max_{\mathbf{x}} f_2(\mathbf{x}) = \frac{C_{\text{Sm, 12}}}{C_{\text{Nd, 12}} + C_{\text{Sm, 12}}} \equiv \text{Purity}_{\text{Sm}} \tag{7}$$

$$\min_{\mathbf{x}} f_3(\mathbf{x}) = (\dot{Q}_1 + \dot{Q}_8)\frac{\text{m}^3}{\text{s}} \times 31,536,000\ \frac{\text{s}}{\text{yr}} \tag{8}$$

Note that while only the purities of the two components are explicitly optimized, the component recoveries are also implicitly optimized, due to the Purity of Nd being associated to the Recovery of Sm and vice versa. To gain better insight into why this happens, the recoveries of the components read:

$$\text{Recovery}_{\text{Nd}} \equiv \frac{C_{\text{Nd,11}}\dot{Q}_{11}}{C_{\text{feed}}\dot{Q}_{\text{feed}}} \tag{9}$$

$$\text{Recovery}_{\text{Sm}} \equiv \frac{C_{\text{Sm,12}}\dot{Q}_{12}}{C_{\text{feed}}\dot{Q}_{\text{feed}}} \tag{10}$$

From Eqs. (6), (7), (9) and (10), we can deduce that to increase the purity of (for instance) Nd the concentration of Sm in Stream 11 must be reduced. Since there are only two final outlet streams as depicted in Fig. 1 (Streams 11 and 12), reducing the concentration of Sm in Stream 11 translates into concentrating Sm in Stream 12, and thus increasing its recovery. The same stands for the Purity of Sm and Recovery of Nd. Note also that Eq. 8 targets only the organic solvent streams (Streams 1 and 8) and accounts for solvent consumption in a yearly basis operation.

The extraction system consists of four streams of known concentration. The feed enters E1 at a given metal concentration and known flow rate. A stream of fresh organic solvent also enters E1 whose flow rate is determined by the design variable, $q_1$., Stream 8 that contains fresh organic solvent enters a subsequent extraction step, E2, at a flowrate determined by $q_2$, whilst the fresh aqueous solvent stream that enters the scrubbing step, Stream 5, enters at a flowrate determined by $q_3$.Table 1 summarizes the streams of known concentrations.

**Table 1:** Streams of known concentrations in the liquid-liquid extraction flowsheet. Flow rate values that depend on the optimal designs are denoted by To Be Defined (TBD).

| Stream | Description | Concentration (M) | | Flow rate ($m^3/s$) |
|---|---|---|---|---|
| | | **Nd** | **Sm** | |
| Feed (2) | Aqueous | 0.001 | 0.001 | $1.3 \times 10^{-8}$ |
| 1 | Organic | 0.0 | 0.0 | TBD |
| 8 | Organic | 0.0 | 0.0 | TBD |
| 5 | Aqueous | 0.0 | 0.0 | TBD |

The mass balance of Eq. 1 features the mean overall volumetric mass transfer coefficient which is calculated based on Eq. 3. The dimensionless numbers featured in Eq. 3 require values for the physical properties of the mixture that flows through the channel. Thus, we used values for the interfacial tension, the viscosity, and density of the mixture that we drew from the work of Pineda et al. (2021). The values for both the organic and the

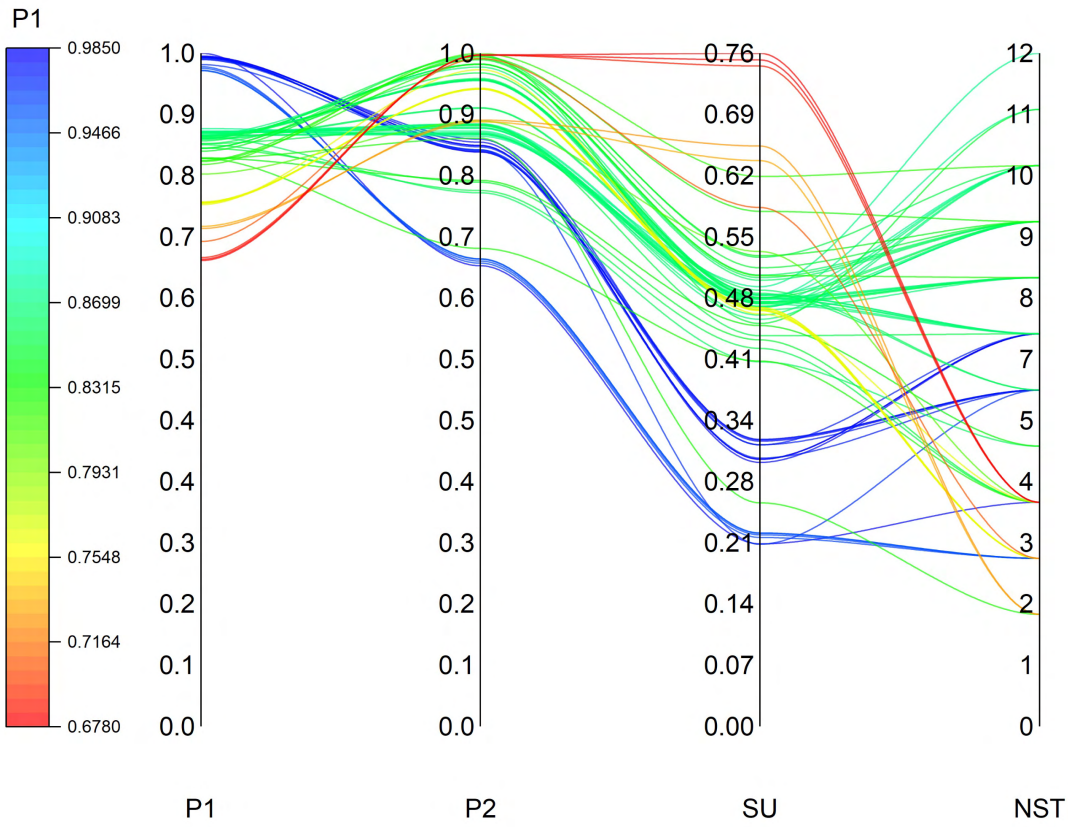

**Figure 5.** Parallel coordinate plot of the non-dominated solutions obtained by Fresa to solve the four-objective problem defined by Eqs. (6)-(9). P1 and P2 correspond to the purities of Nd and Sm, respectively, SU is the organic solvent usage in $\mathrm{m}^3/\mathrm{yr}$, and NST is the number of stages total.

aqueous mixtures are summarized in Table 2.

As discussed previously, a vector of design variables, $\mathbf{x} = [q_j, \xi_j, D]$, is employed to optimize the metal recovery process. These variables are bounded due to operational (e.g., flow rate ratio to maintain segmented flow) or structural (e.g., channel length) constraints. Although, channel length, $L_j$, and number of stages, $n_j$, are not directly leveraged, they are implicitly defined through the $\xi_j$ variable; hence, upper and lower bounds for those design pseudo-variables are also required. Table 3 summarizes the lower and upper bounds for the physical and pseudo- design variables.

**Table 2:** Thermophysical properties of the liquid mixtures in the process flowsheet.

| Property | Value | |
|---|---|---|
| | Organic | Aqueous |
| Interfacial tension, $\gamma$ $(\mathrm{N\ m^{-1}})$ | 0.01 | 0.01 |
| Viscosity, $\mu$ $(\mathrm{kg\ m^{-1}s^{-1}})$ | 0.0023 | 0.001 |
| Density, $\rho$ $(\mathrm{kg\ m^{-3}})$ | 844 | 997 |

**Table 3:** Lower and upper bounds for the design (pseudo-) variables. Regular variables appear in bold while pseudo-variables in plain font.

| Variable | Value | |
|---|---|---|
| | Lower | Upper |

| $\boldsymbol{\xi_j}$ $(-)$ | **0.0** | **1.0** |
| $L_j$ $(\mathrm{m})$ | 0.05 | 0.4 |
| $n_j$ $(-)$ | 0 | 10 |
| $\boldsymbol{D}$ $(\mathbf{m})$ | **0.001** | **0.005** |

Solving the three-objective problem resulted in 57 non-dominated solutions in 10101s (≈ 168 min or ≈ 2.8 hrs) on a 48-core Intel® Xeon® w7-2495X @4800 MHz and 250 GB of memory. The non-dominated solutions are summarized in a parallel coordinate plot of Fig. 3. The solutions in Fig. 3 appear color-coded in a scale from low to high purity of Nd. Fig. 3 shows a clear trade-off between the purity of the two components, demonstrated by the intersection of lines between the purity of Nd, P1, and the

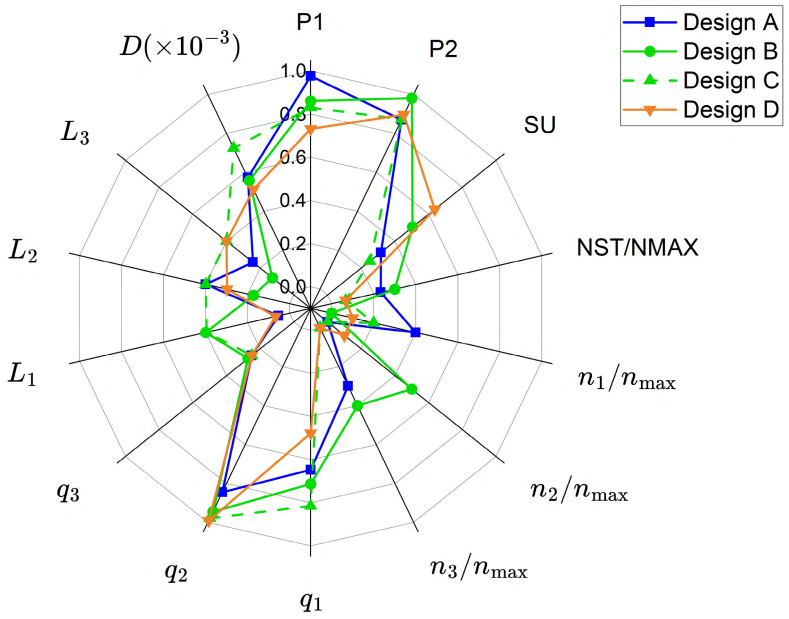

**Figure 6.** Radar chart of representative designs drawn from the set of non-dominated solutions (objectives and design variables) of the four-objective problem defined by Eqs. (6)-(9).

purity of Sm, P2. Therefore, the third objective, solvent usage, SU, is an important deciding factor, assuming that the first two objectives are of equivalent significance.

To gain better insight into the optimal designs, we have selected representative solutions to plot on the radar chart of Fig. 4, which shows the values of the objectives together with the values of the design variables. Design A results in a P1 ≈ 0.99 and P2 ≈ 0.87, whilst keeping SU ≈ 0.20 requiring ten stages for E1 (the reader is referred to Fig. 1), no stages for E2, and four stages for E3. Employing E3, the scrubbing step, as well as not employing the second extraction step, E2, results in a very high purity of Nd at the expense of lowering the purity of Sm. Designs that had non-zero stages for E2 led to potentially lower P1, mainly due to back extraction and higher SU, since an additional stream of fresh organic solvent is employed, and thus were dominated by other solutions. Design B, on the other hand, is characterized by P1 ≈ 0.84, P2 ≈ 0.99, and SU ≈ 1.09. While the trend in purities has reversed, vis-à-vis Design A, SU is significantly higher. Specifically, Design B disabled E1 (no stages), while it required five and nine stages for E2 and E3, respectively. However, enabling step E2 without enabling step E1 is essentially incoherent. If there are no stages for E1, no separation takes place, and the streams entering E3 are empty; hence, E3 stages in this design have no impact whatsoever in the objective values. The reason this design appeared in the set of non-dominated solutions is potentially due to the stochasticity of the optimization method that did not potentially converge to the global Pareto frontier, and although one would not normally consider it, it still presents as a valid design. Another representative solution is that of Design C, which comprises of P1 ≈ 0.72, P2 ≈ 0.99, and SU ≈ 0.6. Although this design achieves lower P1 compared to Design B, it achieves savings in SU by employing four stages for E1 and five stages for E2. To select an optimal design amongst the three representatives, one must weigh in process profitability (e.g., component purity *vs* price) and operational cost/environmental footprint (e.g., solvent cost). However, capital cost may be considered, as well. Although the total number of allowable stages is relatively small (i.e., 30) and might not impact considerably the economics of a pilot plant, the scaling out of the process, that is installing multiple channels in parallel for every stage to increase throughput, can have a big impact on capital cost. Therefore, we must investigate the minimization of total stages in addition to the three objectives we have already considered.

Note that although the superstructure does not consider the scaled-out process, capital cost is reflected through the number of stages per step. Thus, the fourth objective, in addition to the original three of Eqs. (6)-(8) reads:

$$\min_{\mathbf{x}} f_4(\mathbf{x}) \equiv \sum_{j=1}^{3} n_j \tag{11}$$

The four-objective problem was solved using the same feeds, concentrations, and thermophysical properties as before, yielding 75 non-dominated solutions in 7136 s (≈ 118 min or ≈ 2 hrs). The resulting Pareto set, shown in Fig. 5, exhibits the same trade-off between Nd and Sm

purities observed in the three-objective case. Four representative designs are presented in Fig. 6. Design A achieves high purities (P1 ≈ 0.98, P2 ≈ 0.87) with moderate solvent usage (SU≈ 0.32) using seven total stages allocated to E1 and E3. Design B prioritizes Sm purity (P2 ≈ 0.98) but incurs higher solvent usage (SU ≈ 0.5) and exhibits counterintuitive stage allocation, again disabling E1. Designs C and D highlight low-complexity alternatives: Design C achieves balanced purities with minimal solvent usage using only two stages in E1, while Design D trades Nd purity for a small gain in Sm purity at substantially higher solvent consumption.

The results show that no single optimal configuration exists; instead, families of non-dominated optimal designs emerge, reflecting trade-offs between separation performance, solvent usage, and total stages. While near-perfect Nd and Sm purities typically require multiple stages, comparable performance can often be achieved with fewer stages, albeit sometimes at higher solvent consumption. Overall, the multi-objective framework provides clear decision support for balancing performance, operational sustainability, and capital cost.

## CONCLUSIONS

This work focused on modeling and multi-objective optimization to intensify the design of continuous flow LLE in small channels for critical metals recovery from e-waste. A superstructure-based approach was used to represent alternative flowsheet configurations with variable numbers of extraction and scrubbing stages, while mass transfer in segmented flow was described using simple differential balances to balance accuracy and computational efficiency. Discrete design decisions, such as stage allocation, were handled through a continuous pseudo-variable formulation to limit combinatorial complexity. The resulting nonlinear optimization problem was solved using the plant propagation algorithm implemented in Fresa.

The framework reveals key trade-offs between separation performance, solvent usage, and process complexity. Several non-dominated solutions show that high metal purities can be achieved with relatively simple configurations, highlighting opportunities for more compact and scalable designs. Overall, the approach supports informed selection of designs that balance performance with practical implementation constraints. Future work will consider tackling the intensification of metals recovery under feed variability conditions and parametric uncertainty.

## ABSTRACT

The Heterogeneous Capacitated Vehicle Routing Problem (HCVRP) is a fundamental extension of the classical Vehicle Routing Problem in which customer demands must be satisfied using a fleet of vehicles with varying capacities and costs. In this paper, a novel and intuitive decomposition-based formulation for HCVRP is presented that decomposes the problem into two tractable sub-problems: (i) a route generation and an optimal customer sequencing problem and (ii) a vehicle route assignment problem. In the first stage, all feasible customer combinations are constructed as routes, and for each route an optimization problem is solved to identify the optimal customer sequence that results in the minimum distance travelled. In the second stage, the optimal routes are selected, and vehicles are assigned using a mixed integer linear programming (MILP) formulation that minimizes the fixed cost of vehicle utilisation and total transportation costs, ensuring demand satisfaction for all customers while meeting vehicle capacity limitations. Computational results demonstrate that the decomposition strategy preserves optimality while significantly reducing solution time.

**Keywords**: Vehicle Routing, Mixed integer linear programming, Decomposition, Optimization

## INTRODUCTION

Vehicle routing problem (VRP), introduced by Dantzig and Ramser (1959), determines optimal routes for delivering products from a depot to multiple locations with minimum cost [1]. In classical VRP, a set of homogeneous vehicles is supposed to start from the depot, visit the customer nodes once to fulfil their demand and come back to the depot [2]. The total products to be delivered are constrained by the vehicle capacity, generating the capacitated vehicle routing problem (CVRP) [3]. A more practical extension of this problem is where customers are served by a heterogeneous set of vehicles with different capacities and costs. In these heterogeneous capacitated vehicle routing problems (HCVRP), the fleet composition also becomes a decision variable [4]. The schematic for the HCVRP is presented in Figure 1. Since its introduction in Golden et al. (1984) [5], HCVRP is one of the most studied problems in literature, with multiple variants involving different complexities[6], [7], [8], [9], [10].

The contributions on VRP and its variants in the last two decades are surveyed in Golden et al. (2023)[11] and Archetti et al. (2026)[12]. The solution method used to solve VRP can mostly be segregated into three types: 1) Exact, 2) heuristics-assisted, and 3) metaheuristic methods[13]. With the advancements in AI and ML, recently, large-scale VRPs have been solved by incorporating AI and ML techniques into the solution methods[14], [15], [16].

Despite HCVRP being a well-known problem, due to its NP-hard nature, finding an optimal solution remains a challenge, especially with exact methods. Yaman (2006) [17] proposed four formulations for the HCVRP based on the subtour elimination constraints of Miller, Tucker, and Zemlin (1960) [18]. Later, Baldacci et al. (2009) proposed some valid inequalities that strengthen the linear relaxation of the MILP formulation[19]. Pessoa et al. (2008)[20] proposed an improved branch-cut-and-price model (BCP) based on the formulation presented by Fukasawa et al. (2006)[21]. Recently, several improvements on the BCP framework have been proposed that can solve

large-scale HCVRP instances[22], [23], [24], [25]. However, the design and implementation of such a complex and sophisticated algorithm require substantial effort, limiting the application to real-world problems, which sometimes deviate from classical HCVRPs discussed in the literature[22], [26].

To address these problems, this paper presents a novel decomposition-based formulation for the HCVRP. The proposed formulation is inspired by the set-partitioning approach of Balinski and Quandt (1964)[27]. The key contribution of our work is to decompose the HCVRP into two problems: 1) A route generation, invalidation and optimal customer sequencing problem, and 2) Vehicle and route assignment problem. At first, based on the customer locations, all possible route combinations are generated. Each route starts and ends at the same depot. For each customer combination, a mathematical optimization problem is solved to find the minimum distance option and the corresponding customer sequence.

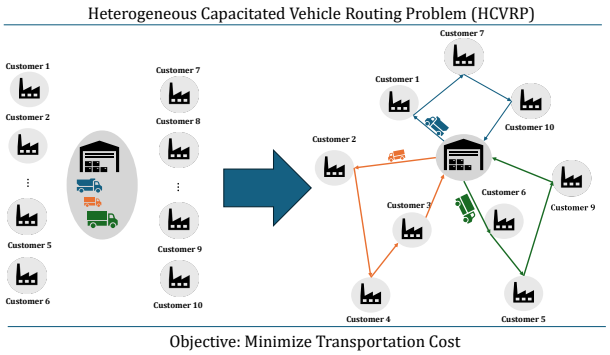

**Figure 1.** General Depiction of HCVRP

Once the optimal customer sequence for each customer combination is found, these routes are sent to the heterogeneous vehicle route assignment MILP problem.

In the vehicle assignment problem, each vehicle is assigned to go only on one route in such a way that all the customer demands on that route can be met. Constrained by the capacity of the vehicle, multiple vehicles might be required to cater to the demands of all customers. The objective function of the assignment MILP problem minimizes the fixed cost of using the vehicles along with the overall transportation cost.

The rest of the paper is organised as follows: in Section 2, the HCVRP problem is described, and a traditional arc-based formulation with MTZ subtour elimination constraints, taken from the literature, is presented. The novel decomposition-based HCVRP model is described in detail in Section 3, followed by the computational results and a discussion about the efficacy of the proposed model in Section 4. Section 5 summarizes the results and key takeaways.

## PROBLEM DESCRIPTION

An HCVRP problem consists of $l \in L$ locations in which location $L^0$ represents the depot and other locations $l \in L^C$ denotes the customer locations. Each customer $l \in L^C$ has a known demand of $De_l$. The demand of depot is considered to be 0. The distance between each pair of locations ($d_{l,l'}$) or the transportation cost ($c_{l,l'}$) are given. Multiple vehicles ($v \in V$) with heterogeneous capacity ($VQ_v^{max}$) are used to travel from the depot to customer locations to cater to the demands. The objective is to find the optimal path to serve the customers with minimal cost.

The traditional mathematical model to solve the abovementioned HCVRP problem is taken from Yaman (2006), which uses Miller-Tucker-Zemlin (MTZ) based sub-tour elimination constraints. We define $yAl_{l,l',v}$ be the binary variable that assumes a value of 1 if the vehicle $v$ has travelled from the location $l$ to $l'$ or 0 otherwise. All vehicles need not be used, and whether a vehicle is used for delivery or not is captured through a binary variable $yS_v$. We define $zP_l$ be the variable for the position or order of the stops in that location.

The objective function minimizes the cost of transportation, along with the fixed cost associated with vehicle use and is presented in Equation 1.

$$\min xTC = \sum_{l\in L}\sum_{l'\in L}\sum_{v\in V} c_{l,l'} * yAl_{l,l',v} + \sum_{v\in V} FC_v * yS_v \quad (1)$$

$$\sum_{l\in L, l\neq l'} yAl_{l,l',v} = \sum_{l\in L, l\neq l'} yAl_{l',l,v} \ \forall l' \in L^C, \forall v \in V \quad (2)$$

$$\sum_{l\in L, v\in V, l\neq l'} yAl_{l,l',v} = 1 \ \forall l' \in L^C \quad (3)$$

$$\sum_{l'\in L^C} yAl_{l,l',v} \leq 1 \ \forall v \in V, l \in L^0 \quad (4)$$

$$\sum_{l'\in L^C} yAl_{l',l,v} \leq 1, \forall v \in V, \forall l' \in L^C \quad (5)$$

$$\sum_{l\in L^C} De_l * \sum_{l\in L^C, l\neq l'} yAl_{l,l',v} \leq VQ_v^{max}, \forall v \in V \quad (6)$$

$$\sum_{l\in L^0}\sum_{l'\in L^C, l\neq l'} yAl_{l',l,v} \leq yS_v, \forall v \in V \quad (7)$$

$$zP_l - zP_{l'} + VQ_v^{max} yAl_{l,l',v} \leq VQ_v^{max} - De_l$$
$$\forall l \in L^C, l' \in L^C l, l \neq l', v \in V \quad (8)$$

The equation (2) is the flow conservation equation, stating if a vehicle enters a node, it must leave, equation (3) guarantees that every customer is visited by only once and by only one vehicle, equation (4) ensures that each vehicle starts at most one route, equation (5) ensures that each vehicle ends at depot, equation (6) links the vehicle to the route stating that vehicle is only used if and only if it is selected, equation (7) defines the vehicle capacity constraint stating total demand served by the

vehicle does not exceeds its capacity and equation (8) eliminates subtours by the use of MTZ subtour elimination constraints.

**Figure 2**. Route Generation, Invalidation and Sequencing Algorithm

## PROPOSED FRAMEWORK

The proposed framework consists of three stages: 1) Route generation and invalidation, 2) optimal customer sequencing stage and 3) optimal route selection and vehicle allocation.

In the first stage, based on the location details of depot($L^0$) and the customers ($l \in L^C$), the pairwise distances ($d_{l,l'}$), all possible combinations of customers are generated. The algorithm for the same is described in Figure 2.

The algorithm creates a list of feasible routes by exploring all possible combinations of the customers with the depot. These combinations are created using nested loops in which the outer loop determines the size of the combination and the inner loop iterates from right to left, checking for an increment in the right-most position. If it is not possible, it moves to the left, resetting the right position in a lexicographical manner. It needs to be noted that at this stage, all possible combinations regarding the sequence of customer locations are explored and stored as routes, with the default starting and ending point for each route being the depot.

It should be noted that till this point, routes are essentially a set of locations (combining the depot and customer locations) without the sequence in which these locations can be travelled. Once the routes are generated, using the customer demands and maximum vehicle capacity, a route invalidation logic can be implemented, which limits the maximum number of customer locations that can be travelled, essentially eliminating the routes in which the sum of customer demands exceeds the maximum vehicle capacity available to the depot.

It should be noted that the route invalidation logic depends on customer demand and vehicle capacity. Consequently, although this logic significantly reduces the computational time and memory requirements of the proposed algorithm, it necessitates solving the algorithm separately for each demand scenario. In contrast, excluding the invalidation logic may increase memory usage or execution time; however, in this case, the algorithm's outcome becomes independent of demand scenarios. As long as the customer set remains unchanged (i.e., no customer is added or removed), the route generation and sequencing algorithm needs to be executed only once.

In the route sequencing stage, an optimisation problem is solved to find the optimum sequence in which the distances travelled to cover all customer locations on that route are minimum. We define $y_{l,l'}$, a binary variable, that assumes the value 1 if the vehicle travels directly from $l$ to $l'$, and to be 0 otherwise, and $zP_l$ be an integer variable that indicates the position of the location $l$ on that route. It should be noted that the following distance minimization optimization problem is solved for each route $r$ and the corresponding optimum distance is stored in the variable $xDist_r$.

$$\min\ xDist_r = \sum_{l=1}^{n_r} \sum_{l'=1:(l\neq l')}^{n_r} D_{ll'} * y_{l,l'} \tag{9}$$

$$\sum_{l'=1:(l\neq l')}^{n_r} y_{l,l'} = 1, \forall l \in \{1, \dots, n_r - 1\} \tag{10}$$

$$\sum_{l'=1}^{n_r-1} y_{n_r,l'} = 0 \tag{11}$$

$$\sum_{l=2}^{n_r} y_{l,1} = 0 \tag{12}$$

$$\sum_{l=1:(l\neq l')}^{n_r} y_{l,l'} = 1, \forall l' \in \{2, \dots, n_r\} \tag{13}$$

$$zP_{n_r} = n_r \tag{14}$$

$$zP_1 = 1 \tag{15}$$

$$zP_{l'} - zP_l - y_{l,l'} - (n_r - 2)(1 - y_{l,l'}) \leq 0 \quad \forall l, l' \in 1, \dots, n_r \text{ and } l \neq l' \tag{16}$$

Where equation (9) is the objective function which minimizes the distance, equation (10) and equation (11) enforces exactly one leaving arc from each node except the terminal node, equation (12) ensures no incoming arc to the depot, whereas equation (13) ensure only one outgoing arc from depot. Equation (14) and (15) calculates the position of the depot as starting node and terminal node in the route. Equation (16) essentially determines the positions of other nodes and eliminates subtours using big-M constraint. The proposed mathematical model provides the optimal sequence of customers for each route and the corresponding minimum distance of the entire route. Customer positions are stored and sent to the third stage, in which an optimal route will be chosen for each assigned vehicle that minimises the overall distribution cost while meeting the demands of all customers.

For finding the optimal route and the corresponding vehicle allocation an efficient mixed integer linear programming (MILP) approach is proposed. Here, we define $yVR_{v,r}$ be a binary variable, and it takes the value of 1 if vehicle $v$ is assigned to route $r$ and assumes 0 otherwise. Another binary variable $yVSl_v$ is defined to denote whether the vehicle $v$ is utilized or not. $xVDL_{v,l}$ captures the amount delivered to the customer($l$) by vehicle $v$ and $xVTS_v$ denotes the total amount supplied by the vehicle $v$, the total route distance as calculated in the route sequencing stage($xDist_r$) are captured as an input parameter $D_r$, and the fixed cost of using a vehicle is denoted as $FC_v$ and the total cost be $xTC$. The objective function to be minimised is as follows:

$$\min xTC = \sum_{r\in R, v\in V} D_r * yVR_{v,r} + \sum_{v\in V} FC_v * yVSl_v \tag{17}$$

Subject to

$$\sum_{r\in R} yVR_{v,r} \leq yVSl_v\ \forall v \in V \tag{18}$$

$$xVTS_v \leq VQ_v^{max} * yVSl_v\ \forall v \in V \tag{19}$$

$$xVTS_v \leq VQ_v^{max} * \sum_{r\in R} y_{v,r}\ \forall v \in V \tag{20}$$

$$xVTS_v = \sum_{l\in L^C} xVDL_{v,l}\ \forall v \in V \tag{21}$$

$$xVDL_{v,l} \leq De_l * \sum_{r\in R_l} y_{v,r}\ \forall v \in V, \forall l \in L^c \tag{22}$$

$$De_l = \sum_{v\in V} xVDL_{v,l}\ \forall l \in L^c \tag{23}$$

Where equation(18) ensures that the vehicle is only assigned to a maximum of one route if it is selected, equation(19) ensures that the vehicle carries a load only if it is selected, and equation(20) defines that the total load carried by the vehicle equals the total demand in that route. Equation(21) equates the total load of a vehicle to the combined demand of customers it caters to. Equation(22) ensures that the vehicle delivers only to the customers belonging to the assigned route, and Equation(23) ensures full demand satisfaction of the customer locations. It should be noted that Equation (23) facilitates that the demand of one customer can be quenched by multiple vehicles.

## RESULT AND DISCUSSIONS

To demonstrate the efficacy of the abovementioned approach, we designed 9 instances of HCVRP problems spanning between 5 and 15 customer nodes with 2-3 heterogeneous vehicles. We also include 3 instances from CVRP library[28] and modify them as HCVRP instances. The computational efficiency of the proposed model is demonstrated by comparing it with the HCVRP model proposed by Yaman (2006), which uses MTZ subtour elimination routines. All instances are solved in Fico Xpress Optimization Suite[29] on an Intel®Core™ i9-14900K (3.7 GHz) machine with 64 GB RAM. The termination criteria were set to either 0% Optimality Gap or 3600 s, whichever is attained early. The problem characteristics and the result comparison are shown in Table 1. In the case of the smaller instances 1-5, each model attains the same solution (Figure 3) with 0% optimality gap, proving that the proposed decomposition strategy does not affect the optimal solution. In the large-scale instances 6-9, a significant reduction in computational time is observed in the proposed model, substantiating the computational efficiency.

**Table 1:** Model Performance and Characteristics

| | | | Yaman (2006) | | | Proposed Model | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| Instance | Customer Nodes | Vehicles | Best Known Solution | Optimality Gap (%) | Time (s) | Best Known Solution | Optimality Gap (%) | Time (s) | | |

**Figure** 2. Impact of Invalidation Logic on Resultant Routes and Computational Time

It should also be noted that Instances 1-9 are solved without using the route invalidation logic mentioned in Figure 2. The majority of the computational time is devoted to the route enumeration algorithm, as can be seen from Table 1. In a real-world situation, this route enumeration algorithm only needs to be solved if a new customer enters the supply chain or leaves the supply chain. Compared to this, the vehicle route assignment problems take minimal time and can be solved daily based on the customer demand.

However, with increasing customer locations (>20), the route generation and sequencing step may require a significant amount of memory and time, which can be reduced by implementing the route invalidation logic. To test the efficacy of the proposed algorithm combined with route invalidation logic, 3 instances from the CVRP

library are taken and suitably modified to create HCVRP instances. Figure 3 demonstrates the efficacy of route invalidation logic on the reduction of route generation and sequencing efforts when applied to Instance 10. The other two instances taken from CVRP Library are also solved using the invalidation logic and are solved to optimality in a reasonable time.

## CONCLUSION

This paper presented a novel decomposition-based formulation for the heterogeneous capacitated vehicle routing problem aimed at improving computational efficiency while preserving optimality. By separating the original NP-hard problem into two intuitive and modular subproblems: 1) route generation and optimal customer sequencing, and 2) optimal route selection and vehicle assignment problem, the proposed approach alleviates the combinatorial burden typically encountered in monolithic MILP formulations. Unlike sophisticated exact methods such as branch-cut-and-price algorithms, the proposed framework is conceptually simple and requires substantially less modelling and implementation effort, making it more suitable for practical decision-support applications.

Furthermore, due to the simplicity of the proposed decomposition-based formulation, it can be easily extended to incorporate the complexities of HCVRP, such as time windows, split deliveries, multiple depots, etc. One major limitation of the proposed algorithm, however, is the memory- and time-intensive route-generation stage, which renders the problem intractable as the number of locations grows (>25), thereby motivating future research to address this challenge.

## ABSTRACT

Production scheduling in the process industry is often treated as a static optimization problem, although real plants require frequent rescheduling due to disturbances such as rush orders, equipment breakdowns, and changes in processing times. This paper compares a simulation-optimization approach that couples a discrete-event simulator with an evolutionary algorithm (EA) with a sequence-based mixed-integer linear programming (MILP) formulation for real-time scheduling of multistage batch systems. Both methods are embedded in an event-driven rolling-horizon framework under strict computation time limits.In static experiments for a 3-stage, 2-machine flow-shop setting (10 products, 20 orders, random processing times), the EA achieved lower makespans across all tested time budgets, improving results by about 7–13% on average compared to the MILP approach. In real-time experiments (40 initial orders, maintenance, three rush orders, 10 s and 60 s periodic updates), the solution quality of the MILP approach was lower after disturbances under restricted computation times. Each experiment was repeated 25 times with identical randomly generated processing times across methods per run; in 4% of all runs no solution was obtained within the available response time. Including explicit allocation decisions for the EA increases flexibility but can reduce short-term responsiveness within the rolling-horizon setting.Overall, the results indicate that MILP can be competitive in stable scenarios when sufficient solver time is available, whereas simulation-optimization is better suited to reactive scheduling in real-time settings where rapid schedule adaptation is critical.

**Keywords**: Simulation, Scheduling, Rolling Horizon Optimization

## INTRODUCTION

Production scheduling is used in the process industry to improve resource utilization and to increase operational efficiency in dynamic situations. In the scientific literature, scheduling problems are often addressed as static optimization problems, where a fixed set of orders, resources, and processing times is assumed, and the problem is solved in advance for a given state of the plant, or for set of predefined scenarios to evaluate the performance of the plant. In these cases MILP is effective in computing high-quality or even optimal schedules if enough time is given or if the problem is decomposed.

In industrial practice, production environments encounter frequent and unforeseen disturbances, such as arrivals of rush orders, machine breakdowns, maintenance activities, and variations in processing times. These events render precomputed schedules suboptimal or even infeasible, and they require adaptations of the schedule of operations, often under strict time constraints, to regain feasibility and to reduce losses in plant efficiency. In reality, production scheduling systems must frequently react to changes in the state of the production system rather than solve a one-time static optimization task [1]. This setting is commonly referred to as real-time or online scheduling.

Some research effort has been devoted to extend MILP formulations to online or rolling-horizon scheduling frameworks [2, 3]. Nevertheless, the performance of MILP in real-time environments is hampered by the need to frequently re-start the optimization with limited computation time in reaction to disturbances and structural

changes, such as new order arrivals or unavailability of resources, modify the objective or the feasible region and preclude a continuation of the branch-and-bound search, ruling out a reuse of the previously explored search tree [4].

Simulation-optimization provides an alternative paradigm for real-time scheduling. By coupling a detailed discrete-event simulation model with a metaheuristic optimization algorithm, it can incorporate complex plant constraints and adapt to changing system states [5]. EAs coupled to schedule builders generate feasible and executable schedules quickly and retain the state of the search across updates, which is advantageous in reactive environments [6] and can be used for high frequency scheduling tasks [7].

In this paper, we compare a standard MILP approach with a simulation-optimization approach based on an EA [6] across problem instances of increasing complexity. The available computation time is varied to reflect the requirement of real-time scheduling that feasible and high-quality solutions must be generated within strict time limits, even for complex problem instances. Static scheduling experiments are used to analyze the performance of both methods in the non-reactive case, while real-time scheduling experiments are used to assess their responsiveness and robustness in the presence of disturbances.

The MILP-based approach uses a sequence-based formulation, because sequence-based models are among the most compact and widely used formulations for scheduling problems. This formulation avoids the use of a discrete time grid and eliminates time discretization errors which facilitates initialization from an existing system state in online or real-time settings. Compared to time-indexed formulations, sequence-based models require fewer decision variables and constraints, which can lead to reduced computational effort and improved scalability.

## SCHEDULING APPROACHES

We consider a multistage batch scheduling problem with a set of orders that have to be processed sequentially through multiple production stages. Each stage consists of one or more parallel units, and each order is assigned to one unit at every stage. Units process at most one order at a time, and preemption is not allowed. Processing times differ between units, and all orders are subject to release-time constraints.

### Sequence-Based MILP Formulation

The MILP scheduling approach is a sequence-based formulation for multistage batch plants as in [8]. We set $M$ to an upper bound on the scheduling horizon, e.g., $M = \sum_i \max_j \tau_{ij}$.

#### Sets and Indices

- $i, i' \in I$: orders
- $k \in K$: processing stages
- $j \in \mathrm{J}$: units

#### Decision Variables

- $x_{ij} \in \{0,1\}$: equals 1 if $i$ is assigned to $j$
- $y_{ii'j} \in \{0,1\}$: equals 1 if $i$ precedes $i'$ on $j$
- $s_{ij} \geq 0$: start time of order $i$ on $j$
- $s_{ik} \geq 0$: start time of $i$ on $k$
- $ms \geq 0$: makespan

#### Parameters

- $\tau_{ij}$: Processing time of order $i$ on unit $j$

#### Objective Function

The objective is to minimize the makespan which is the completion time of the last processed operation across all orders (completion at final stage):

$$MS \geq s_{ik_{last}} + \sum_{j \in J_{ik_{last}}} \tau_{ij} x_{ij} \ \forall i \qquad (1)$$

#### Constraints

##### Assignment constraints

Each order must be assigned to one unit at each stage:

$$\sum_{j \in J_{ik}} x_{ij} = 1 \ \forall \mathrm{i}, \mathrm{k} \qquad (2)$$

**Sequencing consistency constraints**

One order must precede the other on a unit:

$$y_{ii'j} + y_{i'ij} \geq x_{ij} + x_{i'j} - 1 \ \forall i, i', j, k \ with \ i < i' \qquad (3)$$

**Start Time per Stage**

$$s_{ik} = \sum_{j \in J_{ik}} s_{ij} \ \forall i, k \qquad (4)$$

**Activation of start time**

$$s_{ij} \leq M x_{ij} \ \forall i, j \qquad (5)$$

**Disjunctive (non-overlap) constraints**

Orders assigned to the same unit cannot overlap in time.

$$s_{ij} + \tau_{ij} \leq s_{i'j} + M\left(1 - y_{ii'j}\right) \forall i, i', j, k \qquad (6)$$

**Stage precedence constraints**

Each order must complete processing at stage $k$:

$$s_{ik} + \sum_{j \in J_{ik}} \tau_{ij} x_{ij} \leq s_{ik+1} \ \forall i, k \qquad (7)$$

**Release-time constraints**

Orders cannot start before their release times:

$$s_{ik} \geq \rho_i \ \forall i, k \qquad (8)$$

## Real-Time Scheduling Loop for the MILP Approach

The MILP formulation is embedded in an event-driven rolling-horizon framework. Scheduling updates are triggered periodically as well as by disruptive events such as rush orders.

At each update event, the start time of the scheduling horizon is aligned with the current state of the production system. Orders that have completed or are currently being processed are fixed by constraining their assignment $X_{ij}$ and start-times $S_{ij}$. Newly released orders are included by updating the order set and the corresponding constraints. Lower bounds on start times are imposed to ensure consistency with executed operations and release dates.

When a maintenance event occurs on a machine, an additional disjunctive time constraint is introduced dynamically to ensure that no operation is scheduled within the maintenance window. For each operation $o$ that can be assigned to machine $j$, a binary decision variable $z_{oj}(o, j)$ is created together with two bounding equations. The lower and upper constraints are formulated as

$$s_{oj} + \tau_{oj} \leq \mathrm{t}_j^{\mathrm{maint,start}} + M \cdot (z_{oj} + (1 - \mathrm{x_{oj}}))$$
$$s_{oj} \geq \mathrm{t}_j^{\mathrm{maint,end}} - M((1 - z_{oj}) + (1 - x_{oj}))$$

The constraint is conditioned on the assignment variable $x_{oj}(o, j)$ and is therefore enforced only if operation $o$ is scheduled on machine $j$ where $s_{oj}(o, j)$ denotes the start time of operation $o$ on machine $j, \tau_{oj}(o, j)$ represents its processing time, and $M$ is a sufficiently large constant. The interval $[\mathrm{t}_j^{\mathrm{maint,start}}, \mathrm{t}_j^{\mathrm{maint,end}}]$ defines the maintenance period on the respective unit $j$. By incorporating the processing time in the first constraint, the model ensures that an operation assigned before maintenance must also be completed before the maintenance window begins. If the operation is assigned to the affected machine, the binary variable activates a big-M disjunction that forces it to be scheduled either entirely before or entirely after the maintenance period. If $z_{oj}(o, j) = 0$, the completion time is restricted to occur before maintenance starts; if $z_{oj}(o, j) = 1$, the first inequality is relaxed, and the operation is forced to start after the maintenance period.

The MILP model is rebuilt at each update and solved within the available computation time. To improve performance, warm-start information from the previously computed solution is provided to the solver in the form of initial values for assignment variables and, optionally, for start times. However, due to structural changes in the model and the limited ability of MILP solvers to retain internal search state across re-optimizations, the solver effectively restarts after each disturbance.

The real-time MILP scheduling procedure can be summarized as follows:

1. Initialize the scheduling horizon based on the current plant state
2. Generate an event list consisting of periodic and event-driven updates
3. At each update event, fix the completed and the ongoing operations
4. Update orders, resource availability, and constraints
5. Initialize the solver using information from the previous solution
6. Solve the MILP within the available computation time and transfer the best available schedule to the production system
7. Repeat until the end of the simulation horizon.

## Simulation-Optimization Approach

The simulation-optimization–based real-time scheduling approach used in this work is based on a previously published framework [6] that couples a detailed discrete-event simulator with an EA. The method operates as a continuously running optimization process that preserves the search state across updates and incrementally adapts schedules in response to changes in the production system.

This approach is used as a reference method for comparison with the MILP-based approach. The EA design, population management strategies, and simulation integration are described in detail in the original publication and are only briefly explained here.

The EA is embedded in a simulation–optimization real-time scheduling loop: schedules are encoded as genotypes (primarily a global order sequence $\pi_{\mathrm{seq}}$ and, possibly resource-allocation decisions $\pi_{\mathrm{alloc}}$), and each genome is evaluated by executing it in a discrete-event simulator with a detailed model that represents the current state of the production system and acts as a schedule builder, using priority rules and enforcing logic or plant constraints (including repair mechanisms to keep the schedules executable). The EA runs continuously, iterating through selection, recombination, and mutation to gradually improve schedule quality on the current simulation model. At periodic update times and when disruptive events occur (e.g., rush orders, maintenance, delays), the production system feeds new state information to the scheduler, which updates the simulation model and reinitializes the population using strategies such as carrying over the full population, keeping the best individual, or random restart. The best available schedule can already be exported after one iteration and is then further improved as optimization continues.

# CASE STUDY

The experimental study is designed to compare the performance of the sequence-based MILP approach and simulation-optimization based on an EA under strict computation time limits. Two types of experiments are conducted. First, static scheduling experiments are used to analyze the behavior of both approaches independent of the effect of real-time updates due to disturbances. Second, real-time scheduling experiments are performed to evaluate the performance under dynamic operating conditions with disruptive events. In all experiments, the fitness criterion is the minimization of the makespan.

To ensure a fair comparison, both approaches are implemented on a single CPU core, and the schedules generated by the EA are evaluated sequentially. All experiments were performed on a Ryzen 9800X3D CPU with 64GB of RAM. The MILP model was solved using the IBM ILOG CPLEX Optimizer 20.1.0.0 via the GAMS command-line interface.

## Static Scheduling Experiments

The static experiments are performed for a multistage batch scheduling problems as described above. The production system consists of three stages, each equipped with two parallel units of different efficiency. A total of ten product types and twenty orders are considered in each experiment.

The processing times were generated randomly for each order–machine combination, with values uniformly distributed between 0 and 4 time units.

### Objective and Constraints

Both the MILP and EA approaches solve identical scheduling problem All precedence constraints, machine capacity constraints, and order release constraints are enforced in both approaches.

### Computation Time Limits

To reflect the requirements of real-time and near-real-time scheduling, the available computation time is strictly limited. Both methods are executed with computation time limits of 10, 15, 20, and 25 seconds. Each configuration is repeated ten times using different randomly chosen processing times.

The MILP solver runs until the specified time limit is reached or an optimal solution has been found. The EA runs continuously during the available time and improves the candidate schedules incrementally.

### Evolutionary Algorithm Configuration

The EA uses a custom programmed compiled discrete-event simulator for schedule building and evaluation. In the static scheduling experiments, the decision variables of the EA comprise either only the sequencing of orders by a global priority parameter or in addition also the allocation of orders to machines. If the allocation is not controlled by the EA, the schedule builder assigns the machine with the earliest completion time. The EA parameter settings are taken from the prior study reported in [6] and remain fixed across all experiments.

## Real-Time Scheduling Experiments

The real-time scheduling experiments are performed for the same multistage batch plant with three stages and two units per stage. Forty orders are released at the beginning of the simulation. All experiments follow an event-driven rolling-horizon scheme with a periodic update interval of either 10 seconds or 60 seconds. At each update event, rescheduling is performed based on the current state of the production system. The update interval also defines the maximum computation time available for solving the scheduling problem at each event. In addition, rush orders and maintenance occur within the production horizon, these are not known a priori.

For each update interval, three scheduling approaches are evaluated: the MILP formulation, the EA with allocation genome, and the EA without allocation genome. Each experiment is repeated 25 times with randomly generated processing times. The processing times for each order–unit combination are sampled randomly with a uniform distribution in the interval [1, 12] minutes.

The EA is implemented with the same settings as in the static experiments.

### Disruptive Events and Update Policy

During execution in the real-time setting, three rush orders are introduced, representing unplanned disturbances that require immediate rescheduling. Rush orders become known at the 1st, 3rd, and 5th periodic update events.

In addition, a maintenance request is introduced temporarily disabling individual machines. A maintenance downtime of 500 seconds starting at simulation time 2000 seconds is requested for machine M01 at the second update event. At the fourth update event, a maintenance downtime of 500 seconds starting at simulation time 3000 seconds is requested for machine M04. Operations that are still running at the requested maintenance times are completed before the maintenance started but during the full maintenance interval no new operation can be started.

### Experimental Variants

The EA-based simulation-optimization approach is evaluated in two configurations:

1. Using a genome encoding only of the sequence of orders, and
2. Using a genome encoding of both the sequence of orders and the allocation of orders to machines.

In the first configuration, machine allocation is

determined by a First-In-First-Out (FIFO) (earliest completion time) dispatching rule.

The MILP-based approach employs the sequence-based formulation described in Section 2 and is embedded in the same real-time scheduling framework. At each update event, the MILP model is rebuilt so that it reflects the current system state and then is solved within the available computation time.

## RESULTS

In this section we present and discuss the results of the static and real-time scheduling experiments described in Section 3.

**Table 1:** Static scheduling results for a fixed problem structure under varying computation time limits. For each time limit, 10 instances with randomized processing times were solved using the MILP-based approach and the EA. The table reports the average relative difference in solution quality over all instances. The objective was the minimization of the makespan (see eq. 1).

| Time limit (s) | EA better (count) | MILP better (count) | Mean relative difference (%) | Std. dev. of rel. diff. (%) |
|---|---|---|---|---|
| 10 | 9 / 10 | 1 / 10 | 12.49 | 11.30 |
| 15 | 9 / 10 | 1 / 10 | 13.12 | 8.97 |
| 20 | 8 / 10 | 2 / 10 | 7.37 | 12.86 |
| 25 | 10 / 10 | 0 / 10 | 9.79 | 5.18 |

**Table 2:** Real-time scheduling results for update intervals of 10 seconds and 60 seconds. A Each experiment was repeated 25 times. In every run, the processing times were randomly generated but kept identical across the compared methods for the same run.

| Update interval | Method | Mean makespan [h] | Std. dev. | Improvement vs. MILP % |
|---|---|---|---|---|
| 10 s | MILP | 4.72 | 0.57 | - |
| | EA w. alloc. | 2.24 | 0.22 | 52.4 |
| | EA w.o. alloc. | 2.06 | 0.21 | 56.2 |
| 60 s | MILP | 2.94 | 0.50 | - |
| | EA w. alloc. | 2.17 | 0.24 | 26.1 |
| | EA w.o. alloc. | 1.96 | 0.26 | 33.5 |

### Static Scheduling Results

Table 1 summarizes the results of the static scheduling experiments for a fixed problem structure under varying computation time limits for the minimization of the makespan. For each time limit, multiple problem instances were generated, and the table reports the resulting average solution quality obtained by each approach.

For all computation time limits, the EA achieves a better average solution quality than the MILP-based approach. As the available computation time increases, the performance gap between the two approaches does not decrease monotonically.

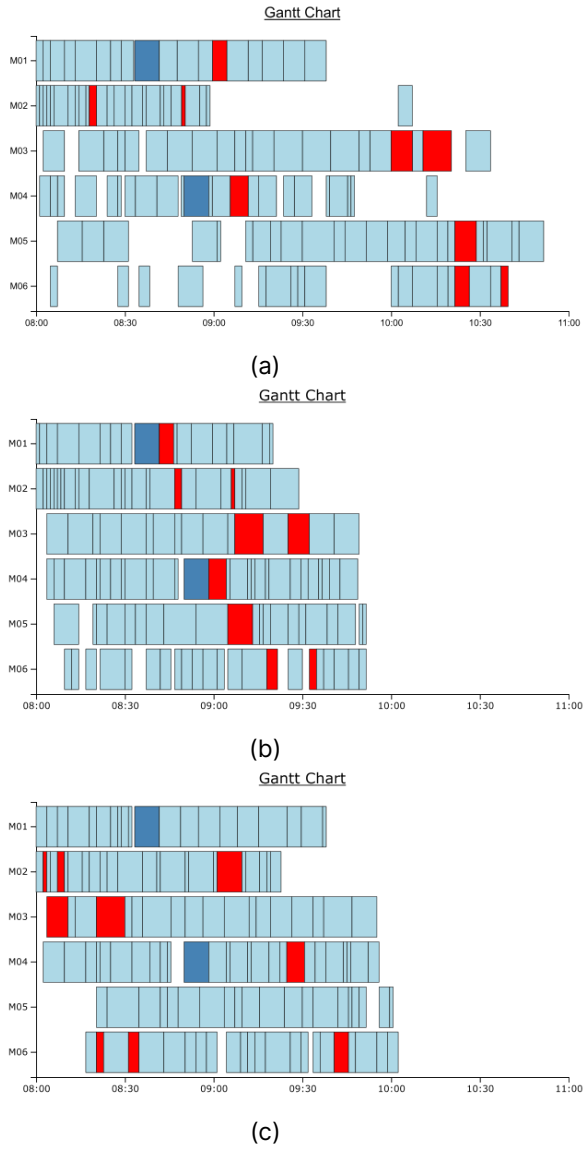

**Figure 1:** Gantt charts of the schedules generated by the MILP approach (a), EA with allocation genome (b), and EA without allocation genome (c) after 10 periodic updates with an update interval of 60 seconds. The rush orders are highlighted in red, and the maintenance downtimes are highlighted in dark blue.

### Real-Time Scheduling Results

Table 2 presents the results of the real-time

scheduling experiments for the two different update intervals. The number of update cycles is fixed at 10 for all experiments. After the tenth update, no further rescheduling is performed, and the last computed schedule is simulated until the end of the production horizon. The table reports the average makespan values for the full simulation horizon. Runs in which the MILP solver did not return a feasible solution within the specified response time were excluded from the averaging procedure, as no valid schedule could be extracted in these cases. Across all experiments, this occurred in 4% of all runs.

The EA-based approaches achieved a better performance under real-time conditions with limited computation time per update.

When the update interval is increased to 60 seconds, the gap between the performance of the EA and of the MILP formulation becomes smaller. In 4% of all runs, the MILP approach did not provide a feasible solution within the available computation time. This occurred equally across both response-time settings.

For both response-times, the inclusion of allocation decisions in the EA genome led to slightly higher makespan values compared to the sequence-only encoding, so the higher flexibility of this formulation is outweighed by the increased size of the search-space.

The results are illustrated by the Gantt charts shown in Figures 1 a-c. All figures show results for the same simulation run, i.e., they are based on identical randomly generated processing times and the same disruptive events, including rush-order arrivals and maintenance downtimes.

The schedule generated by the MILP-based approach (Figure 1a) exhibits an uneven distribution of the workload across parallel units, showing idle periods on some machines. In contrast, the EA-based schedules (Figures 1b and 1c) show a more balanced allocation of processing tasks across the available machines.

## CONCLUSIONS

This paper compared a sequence-based MILP approach with a simulation-optimization approach based on an EA for scheduling of multiproduct batch plants under strict computation time limits. The comparison was performed using static experiments as well as real-time scheduling scenarios with periodic updates and disruptive events.

The static results show that the EA achieves competitive or superior makespan values under tight time budgets.

In real-time scheduling, the MILP-based approach also exhibits a lower solution quality under restricted computation times. Increasing the available solver time improves the performance of the MILP formulation, however, the EA variants show a consistent advantage across both response-time settings. In a small number of cases (4% of all runs across all experiments), no feasible solutions were obtained by the MILP formulation within the available computation time. This is an additional weakness of the MILP approach which is not reflected in the quantitative comparisons where these runs were ignored. These infeasibilities can be related to the limited ability of the MILP solver to retain internal search state information across successive re-optimizations.

In contrast, the EA preserves information on the search state between updates and adapts the schedules incrementally. The EA only handles few degrees of freedom, the remaining ones are handled by a rule-based schedule builder. While theoretically including allocation decisions should provide better solutions than handling the allocations by the rule-based schedule builder, the increase of the size of the search space outweighs this advantage for short computation times. The use of a schedule builder also increases the robustness of the optimization, at the price of a loss of optimality. Overall, the results indicate that simulation-optimization is a competitive approach for real-time scheduling when fast schedule adaptations are required.

Future work will extend the analysis to different problem settings and will investigate hybrid strategies combining MILP-derived baseline schedules with simulation-optimization for real-time adaptation.

## ABSTRACT

Brazil is the world's largest producer of orange juice, generating significant peel residues that are currently underutilized. This study proposes a mixed-integer linear programming (MILP) framework for optimal supply chain design, utilizing Special Ordered Sets of type 2 (SOS2) to accurately represent non-linear investment costs. The model maximizes Net Present Value (NPV) by integrating production costs with multi-echelon logistics, including inland transport, port handling, and international maritime freight. Applied to a case study in São Paulo, the framework evaluates pathways for the co-production of D-limonene, pectin, and bioenergy. Results indicate a positive NPV of BRL 1.27 billion, with pectin contributing over 65% of total revenue. The optimization favors centralized configurations in Araraquara or Matão to exploit economies of scale while minimizing the transport of high-volume, wet biomass. Notably, total transportation costs represent only 1.13% of expenditures, as the high value-density of the bioproducts effectively absorbs global distribution costs. This work demonstrates that in regions with high biomass abundance, strategic success is primarily governed by process efficiency and industrial scale rather than logistical constraints, providing a robust tool for decision-making in the citrus bioeconomy.

**Keywords**: Supply chain optimization, biorefinery, orange peel waste, mathematical programming

## INTRODUCTION

The industrial processing of oranges in São Paulo generates massive volumes of peel residues, which are typically diverted to low-value uses despite their high concentration of pectin and D-limonene. These residues support the evaluation of biorefinery concepts to improve economic performance through high-value product diversification. At a regional scale, the deployment of such systems is governed by complex trade-offs between biomass availability, conversion technologies, and market demand, requiring mathematical programming for integrated assessment.

Mixed-integer linear programming allows the explicit representation of discrete decisions, such as facility siting and technology selection, alongside continuous material flows and economic performance metrics. Such models enable the systematic evaluation of alternative network configurations and support the identification of coordinated and economically consistent solutions for the regional deployment of citrus biorefineries [1, 2].

Recent literature has extensively explored the optimization of biorefinery supply chains within the Brazilian context, primarily focusing on the sugarcane and energy sectors. Bruschi *et al.* (2026) [3] provided a comprehensive review of MILP architectures for biomass supply chains, establishing robust modeling foundations for regional networks. Aba *et al.* (2022) [4] proposed a multi-period MILP model to manage the integrated supply chain of fossil fuels and biofuels, addressing seasonality and demand fluctuations for corn and sugarcane ethanol. Similarly, [5] developed a bi-objective MILP framework to evaluate the trade-offs between financial profit and environmental impact, identifying optimal technology configurations for the transition from sugar-only to mixed-product plants. More recently, [6] utilized robust MILP optimization to assess low-carbon ammonia and hydrogen production from ethanol and biomethane,

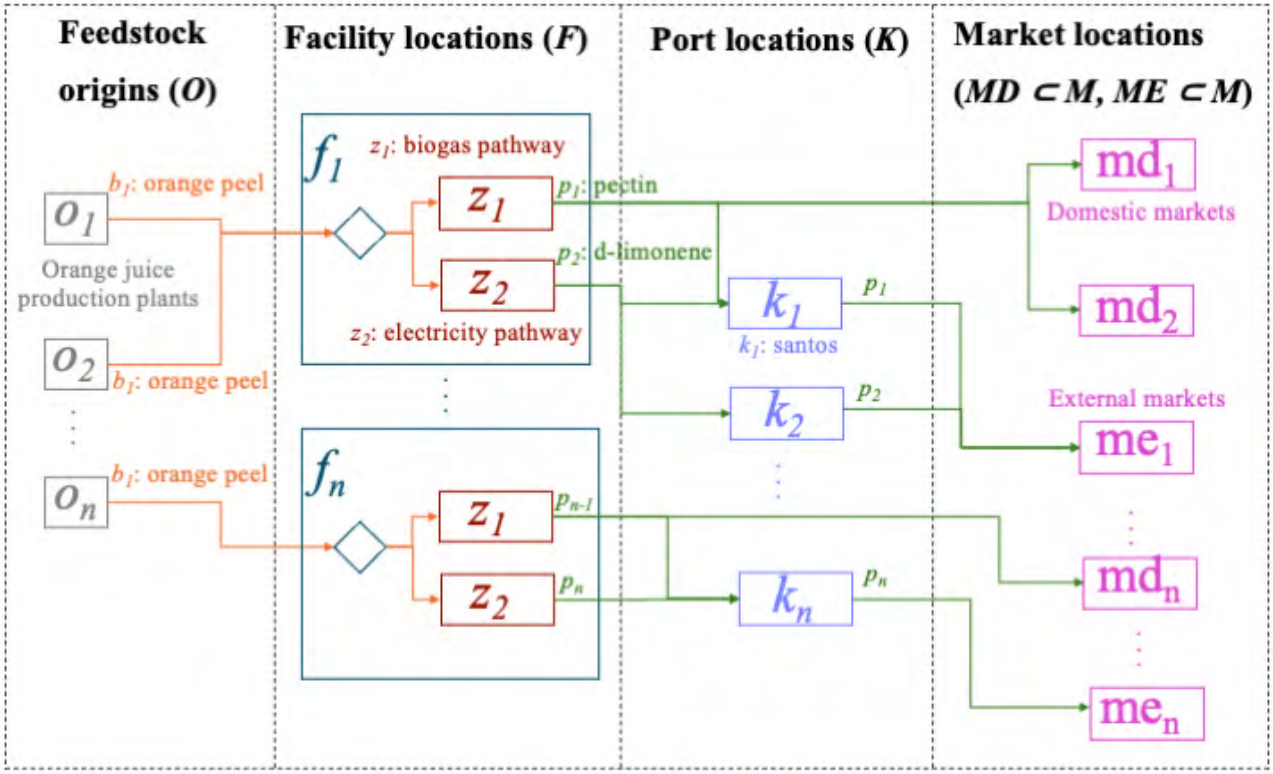

**Figure 1.** Schematic representation of the citrus biorefinery supply chain and associated modeling sets. Orange juice processing plants $o \in O$ generate orange peel residues $b \in B$, which are supplied to candidate biorefinery facility locations $f \in F$ for conversion through technologies $z \in Z$. Marketable products $p \in P$ are distributed to domestic market ($MD \subset M$) and external ($MD \subset M$)markets, with the latter routed via port nodes $k \in K$. Optimization variables determine facility siting, technology selection, and material flows across the network layers.

highlighting the potential for advanced transition products within existing industrial infrastructures. Although these models provide sophisticated insights into regional energy and fuel distribution, they typically prioritize domestic markets and focus on energy products or traditional sugarcane derivatives.

The proposed optimization framework integrates high-value biochemical production with residual energy valorization under a global logistics perspective. By expanding the scope beyond regional energy self-sufficiency, this model incorporates maritime freight indices and port-specific costs to evaluate citrus biorefineries as export-oriented hubs. The use of Special Ordered Sets of type 2 (SOS2) for non-linear investment costs allows the framework to assess how regional biomass density in São Paulo facilitates a strategic shift from market-oriented to feedstock-oriented configurations. This approach seeks to provide a more detailed understanding of the industrial valorization of citrus processing residues by capturing the economic trade-offs between process scale and global distribution requirements.

## METHODOLOGY AND MODEL FORMULATION

A generic supply-chain-level optimization framework is adopted to analyze alternative configurations for the valorization of residues from the orange juice industry. The problem is formulated as a mixed-integer linear programming (MILP) model, designed to support strategic and operational decisions within integrated biorefinery supply chains. The formulation adopts a modular, set-based structure comprising biomass types (set $B$), biomass origins (set $O$), candidate facility locations (set $F$), conversion technologies (set $Z$), products (set $P$), potential domestic and external markets (set $M$), logistic port nodes (set $K$), wastes generated in conversion (set $W$), process inputs (set $I$), consumed utilities (set $U$), and time periods (set $T$). **Figure 1.** presents a schematic overview of the main components and modeling sets considered in the proposed framework.

The supply chain is represented as a multi-echelon network composed of biomass supply origins $O$, candidate

processing locations $F$, domestic markets $MD \subset M$, external markets $ME \subset M$, and port nodes $K$, which act as export gateways. Processing facilities and conversion technologies may be installed in selected municipalities through binary decision variables, while material flows are represented by continuous variables linking the different network layers.

Transportation costs are differentiated by the nature of the origin–destination pair and the specific logistics echelon. For biomass sourcing and domestic market ($MD \subset M$) product distribution, costs are calculated as a linear function of the distance between nodes and the transported mass, using a standardized cost-per-ton-kilometer parameter. Products destined for external markets ($ME \subset M$) are first routed from processing facilities $F$ to port nodes $K$ via road transport. This inland segment follows the same distance-based cost logic as domestic flows, but is supplemented by an export-specific cost layer that incorporates port handling fees and maritime freight to final international destinations. This multi-echelon formulation explicitly distinguishes between domestic and export-oriented logistics, ensuring that the model captures the economic trade-offs associated with different market allocation strategies.

Market allocation is governed by demand limits defined according to the geographic nature of the consumer nodes. For domestic markets ($MD \subset M$), demand is specified at the municipal level, reflecting local consumption. For the export segment ($ME \subset M$), demand is aggregated at representative port nodes for each destination continent. It is assumed that all products are sold within the same period, with no storage of biomass or products. This structure allows the model to capture the trade-offs between fragmented domestic supply and high-volume, port-centric export logistics

Processing capacity is modeled as a continuous decision variable and is directly associated with capital investment. Investment costs are represented using a non-linear cost function with a scaling exponent, following standard capital cost scaling principles [7]. To ensuring the representation of economies of scale within a tractable MILP framework, this non-linear investment function is approximated using a piecewise linear formulation. The approximation is implemented using Special Ordered Sets of type 2 (SOS2) [8], relying on a convex combination of discretized points. The capacity domain is discretized using log-spaced breakpoints, allowing a more accurate representation of the non-linear cost function over a wide range of capacities. Fixed operational costs are assumed to be proportional to the investment cost and are incurred over the planning horizon.

The objective function of the model is defined as the maximization of the net present value (NPV) over the planning horizon and is expressed as follows:

$$max\,\mathrm{NPV} = -\sum_{t\in T}\frac{C_t^{\mathrm{inv}}}{(1+r)^t} + \sum_{t\in T}\frac{\left(R_t - C_t^{\mathrm{op}} - C_t^{\mathrm{tr}}\right)}{(1+r)^t} \quad (1)$$

Where $t \in T$ denotes the time periods of the planning horizon and $r$ is the discount rate. $C_t^{inv}$ represents the investment cost incurred in period $t$, associated with the installation and capacity of processing facilities. $R_t$ denotes the revenue obtained from product sales in period t. $C_t^{op}$ corresponds to operating costs, including fixed and variable components, while $C_t^{tr}$ represents transportation costs associated with biomass supply and product distribution. All cash flows are discounted to their present value using the discount rate $r$.

## Case study: regional citrus waste valorization in São Paulo

The optimization model was applied to a regional case study focused on the valorization of orange peel generated by the orange juice industry in the state of São Paulo, Brazil. This region concentrates the largest installed orange juice processing capacity in the country and exhibits a well-defined spatial structure for biomass generation, logistics, and market access, which made it suitable for a supply-chain-level assessment of alternative biorefinery configurations.

Wet orange peel residue was assumed to be acquired directly from orange processing plants and supplied to conversion facilities without intermediate storage. The alternative valorization routes evaluated in the case study were based on the process configurations developed by [9], describe an integrated biorefinery scheme for citrus processing residues. In this scheme, orange peel is initially processed for the recovery of D-limonene and pectin. After the hydrolysis stage, a solid–liquid separation step is applied to remove residual solids from the hydrolysate prior to pectin precipitation. The resulting solid fraction, hereafter referred to as filter cake, constitutes the residual biomass directed to energy valorization.

In [9], authors propose two alternative energy valorization pathways for the filter cake generated after pectin recovery. In the first pathway, the solid residue is directed to anaerobic digestion for biogas production. In the second pathway, the same residue is routed to a gasification process followed by electricity generation. Accordingly, biogas route integrates the extraction of D-limonene and pectin with biogas production, while electricity route integrates the extraction of D-limonene and pectin with gasification-based electricity generation.

Technological parameters required to represent these routes within the optimization model, including biomass characterization, material conversion factors,

product yields, residue generation rates, and electricity consumption associated with individual process units, were obtained from the study of [9]. Data related to utility consumption, specifically cooling water and steam requirements, were obtained from [10].

Spatially explicit data on biomass availability were obtained from sectoral information reported by CitrusBR [11], including the location of juice processing plants, installed processing capacity, and processed orange volumes.

Market nodes and demand limits were defined to reflect both regional and global consumption patterns. For domestic markets ($MD$), the analysis focused on municipalities in the Southeast region and Goiás, where food, pharmaceutical, and cosmetic industries are concentrated. The domestic pectin and D-limonene markets were estimated using trade data and industrial profiles, resulting in municipal-level demand limits.

To rigorously assess export-oriented configurations ($ME$) the port of Santos was selected as the primary gateway for international flows. External demand was disaggregated into representative port nodes for each destination continent: Houston (North America), Rotterdam (Europe), and Shanghai (Asia). For these destinations, external demand was estimated based on the average historical export volumes of pectin and orange essential oils to each respective continent.

Based on these demand estimations, a base case scenario was defined by satisfying 30% of the modeled domestic demand (Southeast region and Goiás) and 30% of the external demand for each continent (North America, Europe, and Asia).

Logistics costs for the export segment were explicitly modeled to include both inland and maritime stages. The maritime transportation cost factor (BRL/mt.nm) was derived from Drewry's World Container Index [12] and associated maritime route distances. Additionally, port handling costs per product tonne were incorporated based on official reports from the National Agency for Waterway Transportation [13]. This approach ensures a more realistic economic evaluation compared to simplified models, capturing the impact of port-centric logistics on the overall Net Present Value (NPV).

For energy products, it was assumed that all generated output was fully commercialized. Candidate locations for processing facilities were restricted to municipalities with access to natural gas infrastructure or power grid connection, allowing for the direct injection of biogas or the full dispatch of electricity. Under these assumptions, transportation costs for both energy carriers were neglected, as demand was effectively localized at the point of generation. Based on these infrastructure requirements, candidate locations were selected among municipalities either close to biomass sources or major consumption centers, enabling the assessment of trade-offs between feedstock proximity and market access.

Prices for pectin and D-limonene were primarily derived from international trade data. The price of biogas was assumed equivalent to the natural gas price with an additional premium for its renewable origin. Electricity prices were based on representative average values reported by the [14].

To avoid trivial solutions with no installed capacity while preserving the ability of the model to return economically unfavorable configurations, a sufficiently small minimum demand constraint was imposed, allowing scenarios with negative net present values (NPV) to be obtained when economic conditions were not favorable.

## Model implementation

The optimization model was implemented in Python using the Pyomo modeling framework, with input data provided through structured Excel files. The model was solved using Gurobi (version 12.0.3) under an academic license, with a relative optimality gap tolerance of $5.0\times10^{-3}$. Computations were performed on a machine equipped with an Intel® Core™ i7-8559U CPU (4 cores, 8 threads) and 16 GB of RAM. The resulting MILP comprises approximately 15, 946 constraints and 60, 800 variables, including 30 binary variables and SOS2 constraints for piecewise linear cost approximation. The base case was solved within the specified tolerance in approximately 274 s of computation time.

# RESULTS AND DISCUSSION

The base case scenario considers the supply of 30% of domestic demand and 30% of external demand and serves as a reference for evaluating the economic performance and structural configuration of the citrus biorefinery. The optimal processing capacity is 87, 676.06 mt/year of wet orange peel, resulting in the production of around 3, 621.93 mt/year of pectin, 2, 576.43 mt/year of limonene, and 11, 485.56 MW of biogas. Under these conditions, model results indicate a positive net present value (NPV) of approximately BRL 1.27 billion, demonstrating high economic potential of orange residue valorization within the current market framework.

An analysis of the economic structure presented in **Figure 2** reveals that total revenues reach approximately BRL 4.6 billion, with pectin accounting for the largest share (65.23%), followed by limonene (34.70%), while energy products contribute negligibly to total revenue (0.08%). This distribution highlights the strong dependence of system profitability on high-value chemical products, particularly pectin.

Regarding operating expenditures costs at present value, represent the dominant component, totaling approximately BRL 1.88 billion. Within this category, production costs are the primary driver, representing

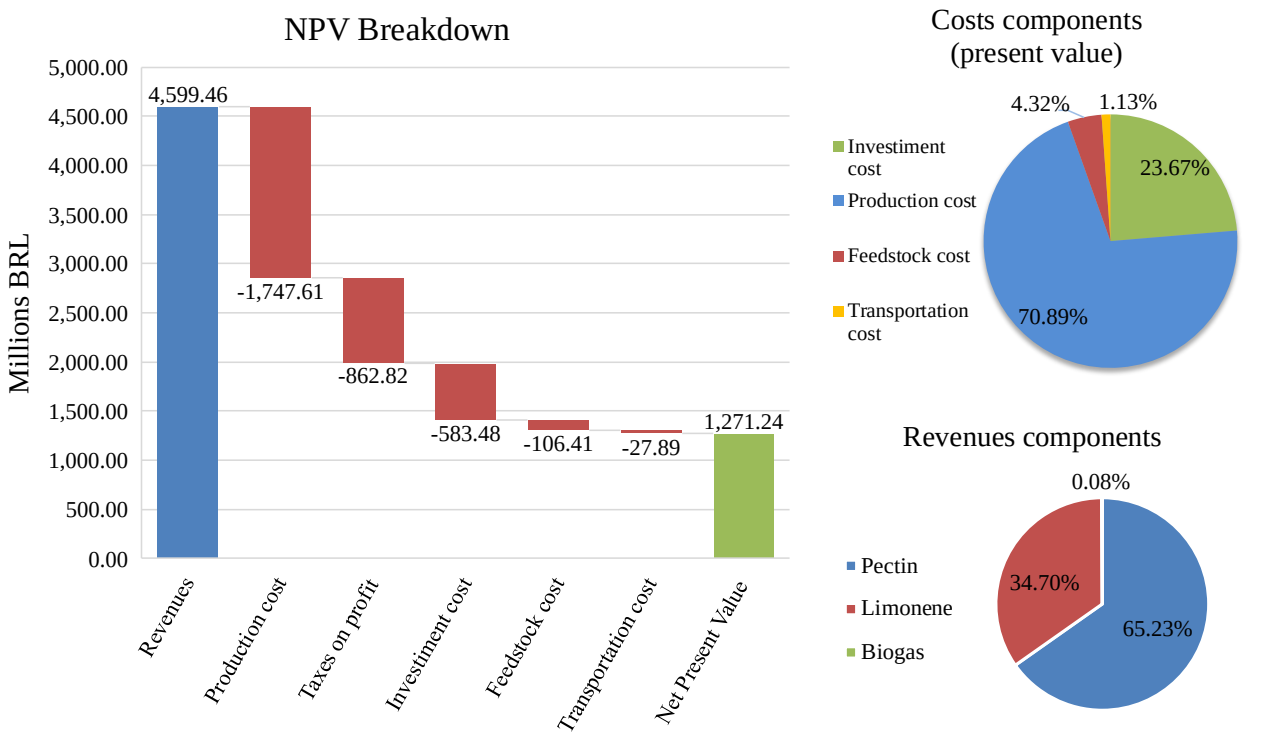

**Figure 2.** Base case NPV breakdown, costs composition at present value, and revenues composition.

70.89% of the total, followed by capital-related expenditures (23.67%) and feedstock acquisition (4.32%). This cost composition indicates that the economic performance of the system is dictated by the high utility requirements and energy intensity of the extraction and solvent recovery stages, rather than by biomass supply costs or logistics. Capital investment (CAPEX) for base case is BRL 5.83 billion and represents a relatively small share of total costs compared to operating expenditures, suggesting that economies of scale are effectively captured in the optimal solution.

The optimal network configuration selects a single processing facility located in Araraquara, utilizing the biogas-based conversion route. This centralized configuration reflects the combined effect of economies of scale and the spatial distribution of biomass availability, which is sufficient to sustain a large-scale facility without requiring decentralization.

The selection of the biogas route is not driven by direct revenues from energy products, which are marginal, but rather by its lower capital investment and utility consumption compared to the gasification-based electricity pathway.

Overall, the base case results highlight that the chain profitability is strongly dependent on high-value product markets, particularly pectin, and production costs, which represent the most significant financial burden. While logistics and feedstock costs play a secondary role in the overall economic outcome, these findings provide a clear baseline for interpreting the sensitivity of the system to key economic parameters explored in the following sections.

## Sensitivity analysis

The sensitivity analysis was performed to evaluate how variations in key economic and operational parameters affect both the profitability and structural configuration of the system, using the base case as reference. **Figure 3** summarizes the impact of each parameter on the net present value (NPV), relative to base case.

The results indicate an asymmetry in the economic drivers of the system, with market-related parameters exerting a stronger influence on performance than cost-related variables. Among these, pectin price has the largest impact on profitability. A 30% reduction in pectin price decreases the NPV from BRL 1.27 billion to BRL 5.14 million, while a 30% increase raises the NPV to about BRL 2.28 billion. These variations occur without changes in system configuration, indicating that price fluctuations primarily affect revenue levels rather than structural decisions. This behavior is consistent with the base case results, in which pectin accounts for the largest share of total revenues.

Market demand affects both economic performance and network configuration. A 75% reduction in demand leads to a decrease in NPV to approximately BRL 59.13

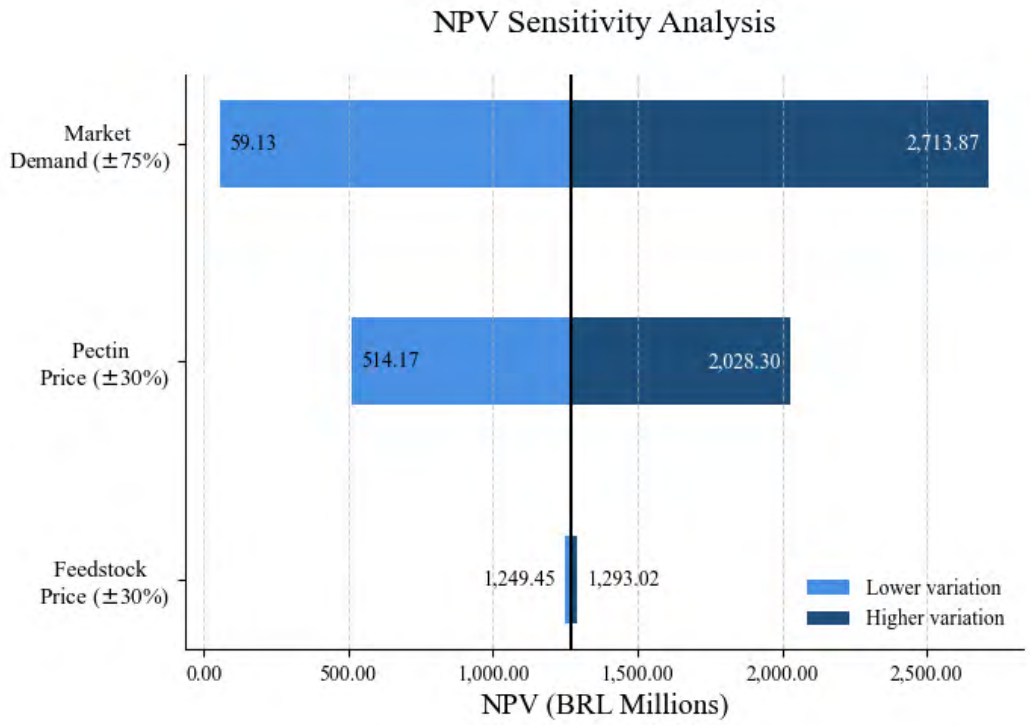

**Figure 3.** Tornado chart illustrating the sensitivity of the Net Present Value (NPV) to variations in market demand (±75%), pectin price (±30%), and raw material price (±30%).

million and a reduction in processing capacity from about 87, 676.06 mt/year to 21, 919.01 mt/year, with the optimal location shifting to Rio Claro. Conversely, a 75% increase in demand raises the NPV to approximately BRL 2.71 billion and increases processing capacity to about 153, 433.10 mt/year, with the model selecting Matão as the optimal location. In the base case, the selected location is Araraquara, with an intermediate capacity level. These findings show that demand influences both production scale and spatial configuration.

This behavior can be explained by the interaction between economies of scale and the spatial distribution of biomass resources. As demand increases, the model favors larger processing capacities, reducing specific investment costs and improving the dilution of fixed operating costs. Although transportation costs represent a small share of total operating costs, they influence spatial decisions due to differences in unit transportation costs. Due to its density, the cost of transporting orange peel residue (BRL 0.83 per mt.km) is higher than that of processed products such as pectin (BRL 0.22 per mt.km) and limonene (BRL 0.21 per mt.km). As a result, the model prioritizes locations with sufficient local biomass availability to supply the plant, reducing the need for long-distance feedstock transport.

At higher demand levels, the impact of economies of scale significantly favors centralized network configurations. The model tends to select a single, large-capacity facility positioned as close as possible to the port of Santos, provided that local biomass availability is sufficient to sustain the required throughput. This siting strategy reflects a fundamental trade-off of the system, where the framework prioritizes the exploitation of scale-related cost reductions while minimizing the transportation of low-density feedstock. In the context of São Paulo, the high regional concentration of residues allows the facility to achieve these economies of scale without triggering the need for a decentralized or market-oriented shift.

In contrast, feedstock-related parameters have a smaller impact on system performance. A ±30% variation in biomass purchase cost leads to changes in NPV between approximately BRL 1.25 billion and BRL 1.29 billion, without affecting plant location, technology selection, or processing capacity. This is consistent with the cost structure observed in the base case, where feedstock costs represent a relatively small share compared to production costs.

## Alternative scenarios

In addition to the sensitivity analysis, a set of alternative scenarios was evaluated to further investigate the structural behavior of the system under specific operational and modeling constraints. These scenarios aim to

assess (i) the robustness of the network under reductions in biomass availability, and (ii) the conditions under which decentralized configurations may emerge due to capacity limitations.

To evaluate the robustness of the system under feedstock scarcity, scenarios with reductions of 30% and 50% in biomass availability were considered under base case demand conditions. The results show negligible changes in economic performance, with NPV remaining approximately constant at around BRL 1.27 billion in both cases. However, a shift in plant location is observed, from Araraquara in the base case to Matão under reduced availability conditions.

These results indicate that biomass availability, while not limiting overall system feasibility, can still influence spatial decisions when local supply becomes relatively more constrained. Under such conditions, the model exhibits patterns similar to those observed in high-demand scenarios, shifting facility locations toward regions with a higher concentration of biomass resources to ensure sufficient feedstock for the required processing capacity. Accordingly, biomass availability does not act as a binding constraint, but can still drive localized adjustments in the optimal network configuration.

To investigate scenarios in which decentralized configurations may emerge, a constraint was imposed on the maximum processing capacity of individual plants, limiting it to 75, 000.00 mt/year of biomass. Under base case demand conditions, the model continues to select a centralized configuration with a single facility in Araraquara, operating at the imposed capacity limit. In this case, total system capacity is reduced from approximately 87, 676.06 mt/year to 75, 000.00 mt/year, leading to a decrease in NPV from BRL 1.27 billion to approximately BRL 1.01 billion. Although the capacity constraint becomes binding, the model still favors a single-facility configuration, even at the expense of reduced throughput and economic performance. Under these demand conditions, the loss of economies of scale associated with splitting capacity across multiple plants outweighs the potential gains from increased product supply.

To further assess decentralization effects, a second scenario was evaluated under higher demand conditions (50% of domestic and 50% of external demand), maintaining the same capacity constraint. In this case, the required processing capacity exceeds the maximum allowable capacity of a single plant, leading to the installation of two facilities, located in Araraquara and Matão. The total installed capacity reaches approximately 146, 126.76 mt/year, with an NPV of approximately BRL 1.94 billion. Despite enabling full demand satisfaction, this decentralized configuration presents lower economic performance compared to the corresponding centralized configuration without capacity constraints. This reduction is primarily associated with the loss of economies of scale and the increase in total capital investment resulting from capacity splitting across multiple plants.

Comprehensively, decentralized configurations emerge only when capacity constraints become binding at higher demand levels.

## General considerations on network configuration

The results obtained across the evaluated scenarios identify consistent structural patterns governing the optimal configuration of the supply chain. Rather than being driven by isolated parameters, facility siting and capacity decisions emerge from a complex interaction between market scale, regional biomass availability, and economies of scale.

Market demand plays a central role in determining both the scale and spatial orientation of the system. At lower demand levels, the model favors locations that balance proximity to major consumption centers with sufficient biomass supply. In this context, Rio Claro emerges as the preferred location, as it represents the most suitable area with significant biomass availability near key demand centers such as Araras, Campinas, Jundiaí, São Paulo, and Santos (external market), which together account for approximately 87% of total demand across all evaluated scenarios.

As demand increases, the system transitions toward plant locations capable of supporting larger processing capacities while remaining reasonably close to the primary consumption hubs. Under these conditions, Araraquara becomes the preferred location, as it represents the nearest region to the main demand centers with sufficient biomass availability to sustain higher throughput levels. This shift reflects the model's behavior of securing feedstock at scale as demand rises. Importantly, this tendency to source the full feedstock requirement from a single location is an emergent behavior of the system under the specific regional context rather than a pre-defined model constraint. In this study, such transitions are possible because biomass is highly abundant and spatially concentrated, allowing several candidate locations to independently supply the full feedstock requirement over a broad range of demand levels. Consequently, minimizing wet biomass transportation remains an important driver of location decisions, as it avoids the significantly higher transport efforts associated with feedstock compared to final products.

Under more restrictive or higher-demand conditions, alternative locations may also emerge. Matão, for example, is selected in specific scenarios due to its substantial biomass supply, stemming from its position as a major national hub for orange processing. This vast local availability allows the facility to sustain the large-scale operations required by high-demand levels without the need for decentralization. Although Matão is less

favorably located in relation to the primary consumption centers compared to Araraquara or Rio Claro, it becomes economically attractive when demand increases significantly, such as in scenarios exceeding the base case by 50% (representing approximately 60% of total combined demand). In these instances, the benefit of concentrated biomass availability at a single node offsets the logistical disadvantage of being further from the market hubs.

Furthermore, the optimization results exhibit a consistent structural preference for centralized configurations as long as individual plant capacity constraints remain non-binding. This behavior is a direct manifestation of the economies of scale embedded in both capital investment and process operations, which prioritize higher throughput levels to maximize the Net Present Value ($NPV$). Decentralized networks emerge only as a necessary alternative when capacity saturation prevents a single facility from meeting the aggregate demand. In such instances, the forced splitting of capacity across multiple sites leads to a measurable degradation of economic performance, as the system loses the significant cost-dilution benefits inherent to large-scale, centralized hubs.

Ultimately, the supply chain architecture is governed by a clear hierarchy of strategic drivers: market demand dictates the required industrial scale, regional biomass density defines the feasible spatial anchors, and economies of scale drive the system toward centralization. The dynamic interplay between these factors provides a robust explanation for the spatial transitions observed between Rio Claro, Araraquara, and Matão across the evaluated scenarios. These findings underscore that for high-value bioproducts like pectin, the citrus-producing region of São Paulo offers a resilient landscape where process-scale advantages outweigh logistical complexities, provided the network design remains aligned with these primary economic drivers.

## CONCLUSIONS

A MILP-based optimization framework was developed and applied to assess the supply chain configuration of citrus residue biorefineries in the state of São Paulo, incorporating a multi-echelon logistics structure that captures both domestic and global market dynamics. The results demonstrate that the proposed biorefinery is highly profitable under the evaluated conditions, achieving a Net Present Value (NPV) of BRL 1.27 billion in the base case. This economic performance is fundamentally anchored by the high-value biochemical market, specifically pectin, which accounts for over 65% of total revenue.

Sensitivity and scenario analyses reveal that market scale and product pricing serve as the fundamental pillars of the supply chain architecture. As demand rises, the network exhibits a distinct preference for facilities sited at locations capable of satisfying the entire feedstock requirement locally, rather than prioritizing proximity to high-demand consumer centers. This structural pattern is intrinsically tied to the regional context of São Paulo, where the exceptional spatial concentration of residues allows the system to minimize the significant logistical effort of high-volume, wet biomass while maximizing economies of scale through centralized configurations. Furthermore, the comprehensive inclusion of multi-echelon logistics including inland transport, port handling, and international maritime freight reveals that total transportation costs represent a mere 1.13% of total expenditures. This marginal share is particularly striking when contrasted with production costs, which constitute the primary economic bottleneck of the system. Given the high utility and energy intensity of the extraction and recovery stages, the relative impact of product distribution is significantly diluted within the overall cost structure. Ultimately, the high value-density of products like pectin effectively absorbs global logistics costs, reinforcing that in regions with high biomass density, strategic success is governed by process efficiency and industrial scale rather than logistical constraints.

Building on these economic interdependencies, this research provides a robust baseline for strategic planning in the citrus bioeconomy. The findings indicate that the most resilient configurations are those that maximize throughput in centralized hubs to exploit non-linear investment scaling. While the system is logistically robust to biomass scarcity due to regional abundance, its long-term viability is strictly contingent upon process efficiency, especially regarding the management of production costs and utility consumption, as well as favorable market positioning for high-value bioproducts. This framework offers a comprehensive tool for sustainable waste valorization in major agro-industrial clusters, supporting the transition toward a circular bioeconomy.

## ABSTRACT

The energy recovery of agro-industrial residual biomass offers a pathway to reduce fossil fuel emissions in thermal processes while valorizing waste. In practice, however, the primary bottleneck is logistical: feedstocks are geographically dispersed, with low bulk density and high moisture content, driving up collection, pretreatment, and transport costs. This work combines geospatial processing with mathematical optimization to design a multi-stage logistics network. The model incorporates intermediate densification options and technology selection (chipping, pelletizing, or briquetting) to supply one or more final waste-to-energy plants. The case study focuses on Northeastern Uruguay, considering forestry residues, meat-processing waste, and rice husks. We formulate a multi-period Mixed-Integer Linear Programming (MILP) model aimed at minimizing the total annualized cost, encompassing transportation, logistical operations, capital investment, and plant O&M, subject to supply constraints, capacities, and maximum transport distances. Results show that the optimal configuration corresponds to the briquetting scenario, which includes a fixed densification facility and processes 200, 160 t/y of biomass from 18 sawmills. Under this configuration, the system generates 276, 954 MWh, with a net margin of USD 5.77/MWh and a net profit of USD 1, 596, 662 over the planning horizon. Sensitivity analysis indicates that the electricity selling price is a critical parameter, with a tolerance margin of only 8%, while mobile densification is not economically viable under current market conditions. Beyond the specific case study, the main contribution of this work is the optimization model itself, whose general and configurable formulation allows its application to other regions, residue types, and market conditions without reformulating its mathematical structure.

## INTRODUCTION

The energy valorization of agro-industrial residues is a key strategy for industrial decarbonization, yet its implementation is often limited by logistical costs. Because of dispersed biomass availability, low bulk density, and high moisture content, the expenses associated with collection and transport can be prohibitive. While densification addresses these issues by increasing volumetric energy density, it introduces significant design challenges: determining where densification should occur, at what scale, and how to optimize biomass flows to the end-user. Optimizing these interrelated decisions requires a spatially explicit framework that integrates road-network data with operational and geographic constraints.

This work proposes a multi-stage logistics network design for residual biomass with intermediate densification. The model is applied to the Tacuarembó–Rivera corridor in Uruguay, evaluating pre-treatment alternatives to identify cost-efficient configurations for facility locations, capacities, and flow allocations. Regarding the state of the art, O'Neill, Geissler, and Maravelias (2024)

| Residue | Generation rate (t/year) | Recoverable fraction (%) | Heating value (kcal/kg w.b.) | Bulk density (kg/m³) | Moisture content (% w.b.) | Harvest period / Seasonality |
|---|---|---|---|---|---|---|
| Rice husk | 261,200 | 80% | 3,520.9 | 125 | 8.50% | February – June |
| Sawmill residues | 412,027 | 54.40% | 4,269.0 | 275 | 15.5% | Annual |
| Rumen content | 81,195 | 100% | 2,153.0 | 770 | 76–82% | Annual |

**Table 1.** Characteristics for the studied residues

integrated logistics networks with biorefinery location and design, demonstrating high sensitivity to spatial variables and incentives. O'Neill et al. (2025) compared bioenergy landscape configurations and logistics networks under transport constraints and mitigation targets, while Zervopoulou et al. (2025) formulated a spatially explicit MILP model to locate plants and allocate flows in biomass-to-fuel supply chains. Similar to our work, these studies address network design and highlight the dependence on resource geography and logistical constraints. Our contribution differs by including intermediate densification as a core design decision, incorporating mobile alternatives with period-by-period relocation, pre-treatment technology selection, and a multi-period planning horizon.

## CONTEXT

Residual biomass can be understood as any organic matter of animal or plant origin that can be valorised for energy or material recovery. This classification facilitates the analysis of agro-industrial residues with different properties and seasonal patterns, all sharing a common objective: their transformation into energy carriers or chemical feedstock.

Nevertheless, the existence of a residue does not guarantee its logistical feasibility. Therefore, this study narrows its scope to three specific streams characterized by high availability, concentration and low current market value: sawmill residues, slaughterhouse rumen content, and rice husks

### Sawmill residues

Sawmill operations produce byproducts such as bark, trimmings, and wood shavings, which are characterized by low moisture content and relatively concentrated generation points. National surveys estimate annual production of approximately 412, 000 tonnes on a dry basis (Gutiérrez et al., 2017).

### Slaughterhouse rumen content

Bovine rumen content stands out among slaughterhouse waste due to its high volume, estimated at 36 kg per head. Its primary logistical constraint is a high moisture content (80%), which significantly inflates transportation costs and limits conditioning alternatives. In 2024, Uruguay processed 2, 256, 123 cattle (INAC, 2024), consolidating beef as the country's primary slaughter category. A local benchmark is the ONTILCOR meat-packing plant, where rumen content is co-fired in boilers alongside firewood without additional drying. This facility reportedly valorizes its entire waste generation (440 t/month), achieving a substitution ratio of 2 kg of residue for every 1 kg of firewood while maintaining steady steam production.

### Rice husk

Generated during the dehulling process, rice husk is concentrates at milling facilities, which provides favorable collection logistics. This residue represents represents roughly 20% of the grain weight and has a reported HHV of 3, 300 kcal/kg (Faroppa, 2010). Its main drawback is a low bulk density (120–130 kg/m³), making the evaluation of densification alternatives essential (Díaz Tovar, 2019). In Uruguay, irrigated rice cultivation maintains average yields of 9, 000 kg/ha, with a harvested area of nearly 150, 000 hectares during the 2023/2024 season (MGAP-OPYPA, 2024).

Table 1 summarizes the key characteristics of the three residues, which are used to parameterize availability and the conditioning and densification alternatives within the model.

### Densification

The model evaluates three densification alternatives. None of these densification alternatives are compatible with rumen content due to its high moisture content.

#### Shredding/Grinding

This is included as a lower-complexity option, though it yields lower improvements in density, heating value, and moisture reduction. It is a particularly relevant technology for processing sawmill residues.

#### Pelletizing

A compaction process that transforms biomass into

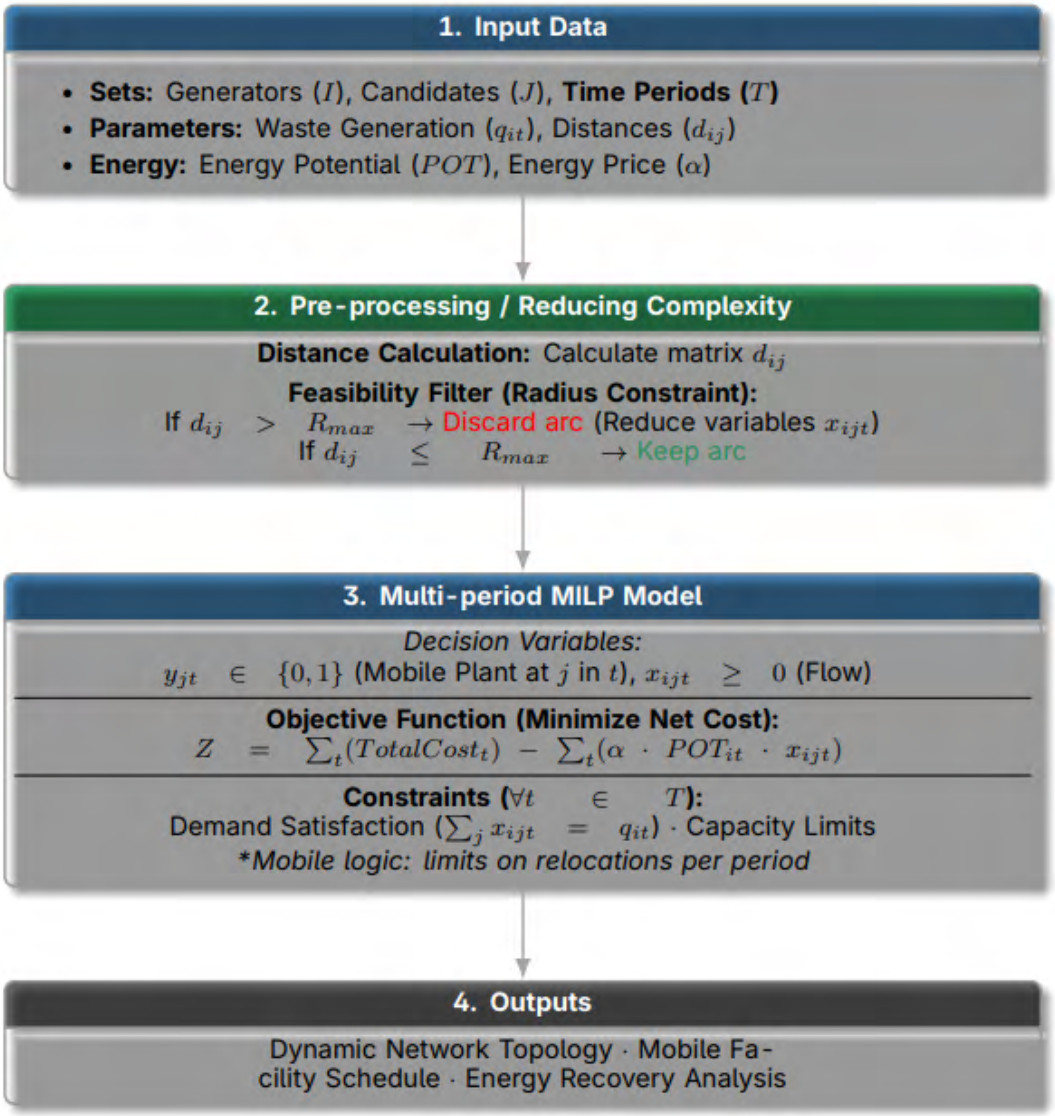

**Figure 1.** Structure of the multi-period optimization framework for mobile plant location.

pellets, significantly increasing both bulk density and volumetric energy density. This alternative requires higher capital investment and more rigorous operational control than the others, often necessitating strict feedstock moisture ranges to achieve acceptable quality standards (Hernández et al., 2017).

### Briquetting

A compaction technology similar to pelletizing but resulting in a larger final product. The mechanical quality of the densified material depends heavily on compaction pressure and the specific properties or blending of the biomass. These factors are critical for technology selection and the definition of operating parameters (Forero-Núñez et al., 2014).

## STUDY CASE

Based on the initial residual biomass survey in Uruguay, a nationwide georeferenced database was developed. This database includes all surveyed meat-packing plants, sawmills, and rice mills, recording specific coordinates and monthly residue generation for each facility. The next step involved identifying regions characterized by both high concentrations of generation points and the logistical viability required to supply a centralized plant. To achieve this, a computational procedure was implemented to analyze spatial clusters within a predefined

radius, calculating the aggregate energy potential by residue type and prioritizing areas with the highest supply density.

The clustering radius was defined based on energy viability criteria for transport: for each residue, the energy content of a fully loaded truck was compared to the energy consumed during transit, yielding a maximum feasible transport distance specific to each material. Among the identified regions, the Tacuarembó-Rivera corridor was selected as the primary case study, with its logistical axis centered on the national highway traversing the area.

Once the region was defined, potential land parcels for an energy valorisation plant were evaluated. Key watercourses within the study area were mapped, and candidate parcels were pre-selected using a weighted multi-attribute scoring scheme. In general terms, the attributes considered included road accessibility for heavy-duty vehicle traffic, proximity to water sources, available water flow, and topographical characteristics. Based on this assessment, the five highest-scoring parcels were selected as candidate sites for the model.

### Network Structure

The study case is defined by the following components, which constitute the input data for the mathematical model developed in the following section. A total of 22 georeferenced generation points are considered: 18 sawmills, 2 rice mills, and 2 slaughterhouses, located in the northeastern corridor of Uruguay between the departments of Tacuarembó and Rivera, with National Route 5 as the main logistical axis. The logistics network includes 6 candidate locations for the final energy recovery plant, 16 candidate nodes for fixed densification plants, and up to 4 mobile densification units. The three densification alternatives evaluated are shredding, pelleting, and briquetting, while the selected valorization pathway is electricity generation through biomass combustion in a steam boiler coupled to a power generation turbine. Biomass transport is carried out using standard trucks.

## METHODOLOGY

The logic of the proposed model is illustrated in Figure 1. The framework is structured as a multi-period Mixed-Integer Linear Programming (MILP) problem, designed to capture the temporal variability of seasonal feedstock supply and to allow for the relocation of mobile plants between periods according to the spatial availability of resources. The model considers three decision levels: generation points ($p \in P$), fixed ($n \in N$) or mobile ($k \in K$) densification plants, and final energy plants ($f \in F$), across time periods ($t \in T$). It incorporates 35 parameters describing costs, capacities, distances, process yields, energy consumption, operational times, and transport factors, assuming trucking as the sole transport mode available in the study region.

The primary decision variables are:

- tp, t- tons of biomass utilized at generation point *p* in period *t* [ton]
- zp, n, f, t binary variable; 1 if residues from generation point *p* are densified at location *n* and sent to final plant *f* in period *t* ; 0 otherwise.
- mk, n, t binary variable; 1 if mobile densification unit kkk is operating at location nnn in period ttt, and 0 otherwise.
- yp, f, t binary variable; 1 if residues are sent directly from generation point *p* to final plant *f* in period *t*; 0 otherwise.
- un, t binary variable; 1 if a fixed densification plant is activated at location nnn, and 0 otherwise.
- dd binary variable; 1 if densification method ddd is selected, and 0 otherwise.
- ff binary variable; 1 if the final energy plant is activated at location fff, and 0 otherwise.

The objective function (see Figure 1) seeks to minimize the total net system cost while accounting for the energetic valorization of the available biomass. The formulation includes the revenues associated with energy production together with the annualized costs of the supply chain. These costs comprise transportation and logistical operations, truck fleet requirements, mobile plant relocation, and the CAPEX and O&M of both densification and final waste-to-energy facilities. As a result, negative objective-function values indicate economically viable configurations in which energy revenues exceed total system costs over the planning horizon.

The model incorporates a comprehensive set of balance, capacity, and technological compatibility constraints to ensure the physical and operational consistency of the network. This includes mass balances at each node and period—accounting for yields and losses associated with densification—alongside capacity limits for fixed plants, mobile units, and the transport fleet. Spatial constraints define maximum allowable distances based on the type and state of the residue. Furthermore, the formulation enforces exclusivity and unique flow allocation conditions, as well as technological compatibility rules; specifically, only sawmill and rice mill residues are eligible for densification, while rumen content is restricted to drying. These constraints guarantee system feasibility and accurately capture the interplay between transport, densification, and energy recovery.

The model was implemented in Python 3.13 using the Pyomo algebraic modeling framework and the HiGHS

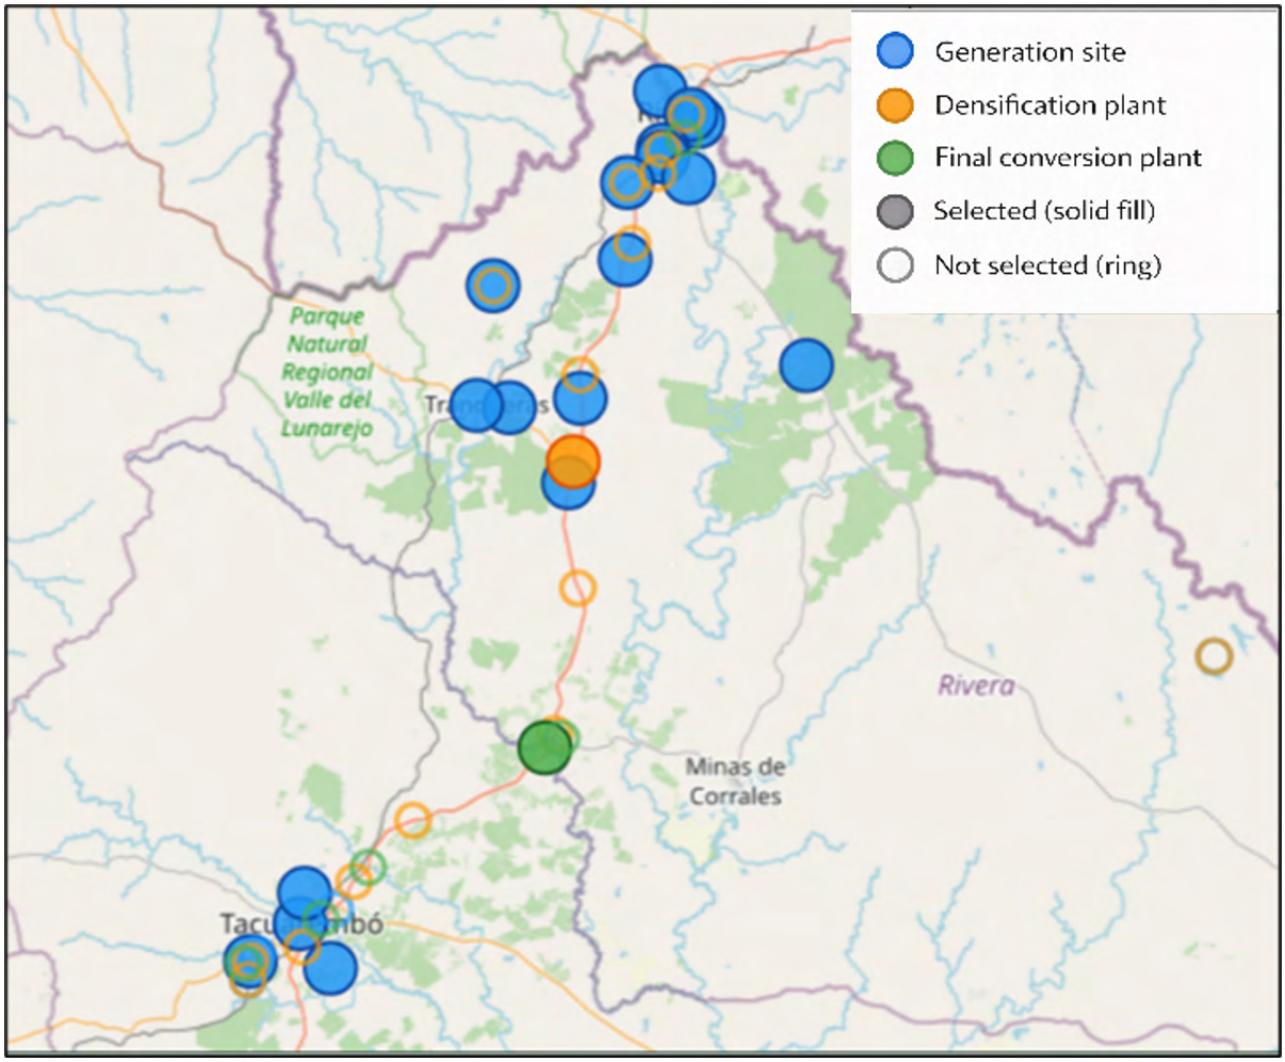

**Figure 2.** Location of the selected plants and active generation points.

MILP solver. Input data are provided through Excel files containing biomass generation points, candidate plant locations, and model parameters. Based on these data, the optimization model is executed to provide the following outputs: the selection of collection points, optimal flow allocation, the location and activation of both densification and final plants, and an estimation of the total energy potential.

## Results

The optimal solution corresponds to the briquetting scenario, in which the model selects the opening of one fixed densification plant and one final energy recovery plant. The resulting logistics network combines direct flows to the final facility with flows requiring an intermediate densification stage, depending on distance and overall network configuration. Under this solution, the system processes 200, 160 tons of biomass per year from 18 active sawmills and generates 276, 954 MWh over the annual planning horizon. The objective function reaches −USD 1, 596, 662, indicating that revenues from energy sales exceed total system costs. Mobile densification is not economically viable under current market conditions.

## CONCLUSION

This work developed and applied a mathematical optimization model to evaluate logistics strategies for the energy valorization of residual biomass in Uruguay. A key finding is that densification is not justified primarily by its direct energetic benefit, but by its logistical role within the supply chain: it expands the effective reach of the network and enables the incorporation of biomass that would otherwise remain outside the feasible system.

The analysis also shows that transport, although not dominant in the base-case cost structure, becomes much more influential as biomass sources become more

geographically dispersed. In addition, the economic viability of the system is highly sensitive to the electricity selling price and to the conversion efficiency of the final plant, with a tolerance margin of only 8%. Under the evaluated conditions, mobile densification does not constitute a viable alternative due to its higher operating cost and limited processing capacity. Beyond the specific results of the case study, the main contribution of this work lies in the optimization model itself, whose general and configurable formulation makes it applicable to other regions, residue types, and market conditions without requiring changes to its mathematical structure.

## ABSTRACT

This study investigates control strategies for the flexible operation of heat pump-assisted distillation processes, focusing on the heat integrated distillation column configuration. The methanol/water separation system was selected as a case study and modelled to achieve 99.9 wt% AA-grade methanol purity. A limiting piece of equipment for flexible operation of heat pump assisted distillation is the compressor. To assess its impact on flexible operation, dynamic simulations in Aspen Dynamics were conducted for two heat integrated distillation column control strategies: one using fixed compressor duty and one using variable compressor duty. The control performance for a 20% throughput disturbance, as well as for a 50% turndown ratio scenario was investigated. Results show that fixed-duty operation maintains robust stability and rapid disturbance recovery even at 50% turndown, while variable-duty operation delivers higher efficiency for moderate load changes but cannot sustain low-load stability. This work supports the electrification of distillation by enhancing the operational flexibility of heat pump-assisted distillation, enabling better integration with intermittent renewable electricity grids.

**Keywords**: Distillation, Energy Efficiency, Dynamic Modelling, Aspen Dynamics, Methanol

## INTRODUCTION

E-methanol produced from green hydrogen and captured $CO_2$ can be used as a versatile chemical building block, transportation fuel, and steel carburizing agent, making it central to the transition toward circular economy [1]. Heat pump assisted distillation (HPAD) enables fully electric purification using compressor shaft work, while significantly lowering energy consumption compared to conventional distillation. A common used HPAD configuration is mechanical vapor recompression (MVR) [2]. Here, the pressure of the overhead vapor of the column is increased such that its latent heat can be used to drive the reboiler. However, the application of MVR is limited to separations of close boiling point mixtures ($\Delta T_b$ = 20 °C), as large compression ratios are needed to overcome the entire temperature lift over the column [2]. Due to the large boiling point difference for methanol-water ($\Delta T_b$ = 34.7 °C) the heat-integrated distillation column (HIDiC) becomes an attractive HPAD technology. HIDiC reduces the required temperature lift and compression ratio by coupling the whole rectifying and stripping sections via internal heat exchange [3]. Nevertheless, very few HIDiC configurations exist at plant scale due to its complex design and structure [3]. Wakabayashi et al. [4] proposed a discretely heat-integrated distillation column (D-HIDiC), removing the need for impractical continuous heat exchange between stripping and rectifying section of HIDiC. This resulted in the first commercial HIDiC. Commercial operation has shown that D-HIDiC can increase control robustness of HIDiC, while maintaining high energy efficiency [4]. Cui et al. have investigated the design of a fully electrified D-HIDiC for the separation of methanol-water [5]. Previous studies on HIDiC process control proposed control structures based on expensive online composition analysers [6]. Cui et al. proposed a single end inferential composition control strategy based on temperature control for D-HIDiC [7]. This strategy manipulates compressor duty for control and showed robust performance under ±20% disturbances in throughput and feed composition. Recently, flexible operation of electrified processes to accommodate variations in electricity prices has gained increased attention, but this has not been investigated for HIDiC.

## PROBLEM STATEMENT

E-methanol plants could operate flexibly to reduce costs by adapting to fluctuating electricity prices, as green hydrogen production is the main cost driver. To prevent the need for large hydrogen holdups, downstream processes could be operated flexibly. In this work, D-HIDiC is chosen as a technology of interest for full electrification of e-methanol purification due to its significant energy savings of up to 80%. Flexible operation of D-HIDiC is challenging, as D-HIDiC's strong thermal integration introduces complex process dynamics: disturbances in feed throughput or composition cause rapid, system-wide shifts in temperature, pressure, and composition profiles [8]. These tightly coupled responses challenge conventional control strategies, especially under flexible operation with frequent turndowns of up to 50%. While Cui et al. demonstrated control with variable compressor duty [7], their strategy requires the compressor to operate over a wide range when operating flexibly (e.g. 50-120% of design capacity), which is often infeasible due to compressor surge/stall limits. They mention that the modular nature of compressor systems could be used to enhance flexibility, but using this approach would increase CAPEX as well as control complexity. Therefore, this study aims to explore an alternative control strategy for D-HIDiC using fixed compressor operation, which is capable of operation at high turndown ratios of up to 50% to enable flexible operation.

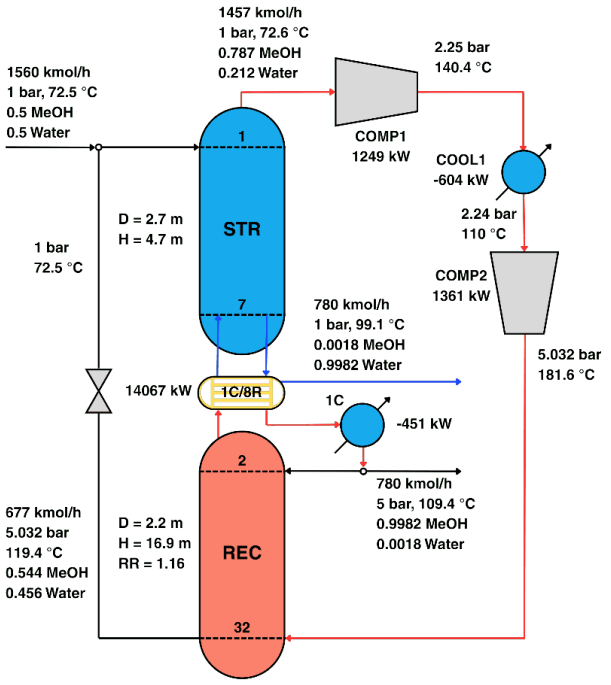

**Figure 1.** D-HIDiC configuration studied

## METHODOLOGY

### Process description

The HIDiC studied in this paper is shown in Figure 1 and is a modified version of the design proposed by Cui et al [5]. The following thermodynamic and hydrodynamic models are used for the process simulations in Aspen Dynamics, based on the work of Cui et al.:

- The thermodynamic model used is non-random two-liquid (NRTL), which is suitable and validated for the methanol water system [9].
- Column pressure drop was based on rigorous calculations using Aspen Plus column internals. To ensure high energy efficiency, low pressure drop Mellapak 350Y packing is used for the column internals.
- The hydrodynamic model is based on equilibrium stage, which is used in various process dynamics studies [10]. It is therefore assumed that each stage reaches vapor liquid equilibrium.
- Liquid holdup is estimated based on design heuristics by Luyben, ensuring a 5 minute holdup time at 50% full [10].

This design is a D-HIDiC, which features heat integration between the reboiler of the stripping section and the condenser in the rectifying section to realize full electrification of the column. Instead of utilizing the compressor interstage cooling duty for heat integration with the column, an interstage cooler is used for improved dynamic performance at a slight decrease in energy efficiency. Still, this design reduces the primary energy consumption compared to a conventional distillation column (CDiC) by 81.6% and has a heat pump coefficient of performance (COP) of 5.39. The D-HIDiC is designed to separate the effluent of an e-methanol reactor consisting of equimolar amount of methanol and water up to an AA grade methanol purity of 99.85 %wt [11]. Due to the maximum allowed mass fraction of water in AA grade methanol, the final purity was set at 99.9 %wt. A 200 kt/y methanol capacity is chosen based on the capacities of planned hydrogen electrolysers in Europe [12].

The D-HIDiC consists of 40 stages, split into an 8-stage low pressure stripping column (STR) and a 32-stage high pressure rectifying column (REC). A compression ratio of 5 was chosen to raise the boiling point of methanol in the high-pressure rectifying column, ensuring a minimum ΔT of 10 °C in the reboiler/condenser heat exchanger. A packed height of 0.5 meter per stage is used. A 20% column cross-section increase is applied to account for factors such as liquid holdup for surge capacity, based on recommendations by Luyben [10]. Furthermore, isentropic compressors with an isotropic

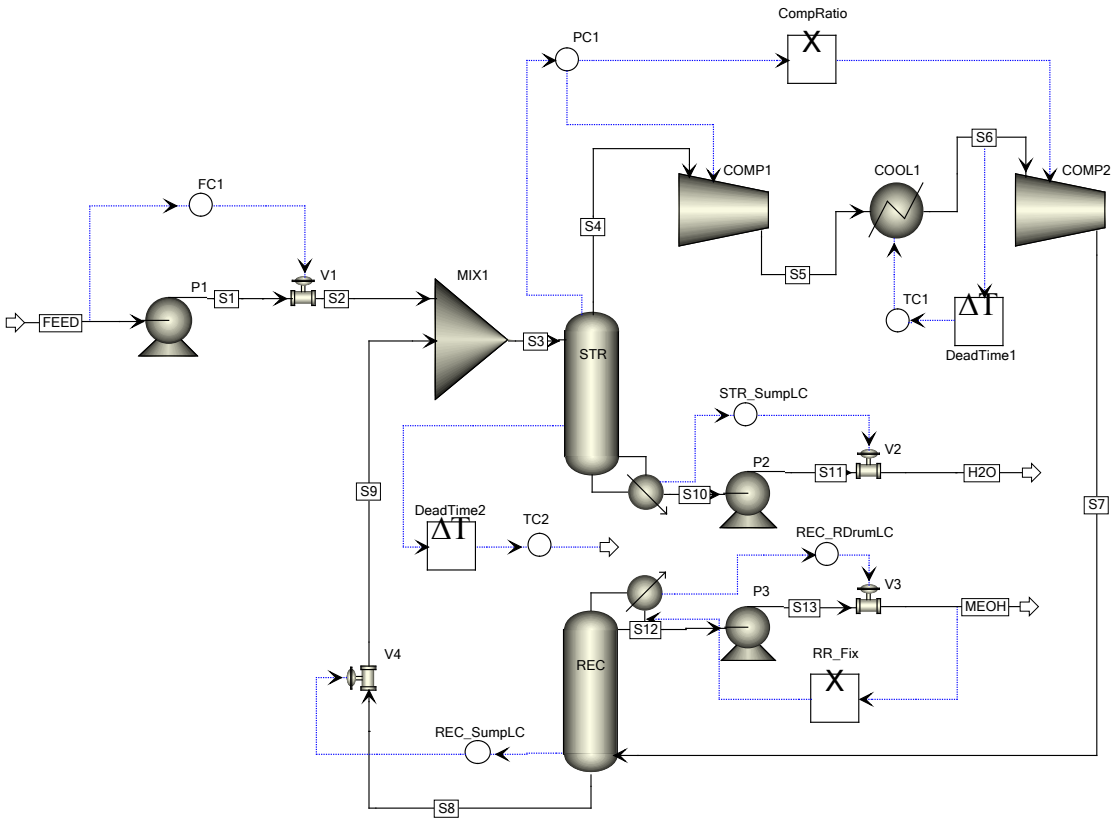

**Figure 2.** Process control structure 1 (PCS 1) utilizing variable compressor duty

efficiency of 80% were used.

## Dynamics and control

Two control structures were evaluated in this work: one employing variable compressor duty based on the work by Cui et al. [7], and one novel control structure utilizing fixed compressor duty. The dynamic performance of both control structures was evaluated for ±20 % throughput disturbances, typical for industrial operation [10]. Composition disturbances were not investigated, as the effluent of a $CO_2$ hydrogenation methanol reactor typically has minor variations in composition. A sensitivity study was done on compressor mass throughput, since compressors have a limited range of operation. The sensitivity study was done for turndown ratios up to 50%, to account for a scenario with high energy prices and/or reduced availability of hydrogen to produce methanol.

### Control basis

The process control structures were modelled using pressure driven simulations in Aspen Dynamics V14. Control valve pressure drops are 3 bar with the valve half open at design flow rates. PI controllers are used, with flow controllers having a $K_c$ of 0.5 and $\tau_i$ of 0.3 min, the level controllers a $K_c$ of 2 and $\tau_i$ of 9999 min based on recommendations by Luyben [10]. The other controllers were tuned using Tyreus-Luyben tuning rules. Temperature controllers are set at a 1 minute deadtime. Stage 5 of the stripper is identified as the most temperature sensitive stage based on the slope criterium [10]. Condenser and reboiler heat integration is done using flowsheet equations (Figure 4 & 5). Reboiler duty is calculated using (1), and then total condenser duty is calculated by adding auxiliary condenser duty to the reboiler duty (2). UA is kept constant. Condenser and reboiler duties then have to be changed from 'fixed' to 'free' in Aspen Dynamics.

$$Q_{reb} = UA(T_{cond} - T_{reb}) \quad (1)$$

$$Q_{cond} = -Q_{reb} + Q_{aux\ cond} \quad (2)$$

Process control structure 1 (PCS 1) is shown in Figure 2 and uses the following control loops:

- Fresh feed is flow controlled (FC1).
- $L_{sump}$ is controlled using bottoms flowrate for both columns (STR_SumpLC & REC_SumpLC).
- $L_{refluxdrum,\ REC}$ is controlled using distillate flowrate (REC_RDrumLC)
- $T_{interstage}$ is controlled by manipulating duty of interstage cooler 'COOL1' (TC1).

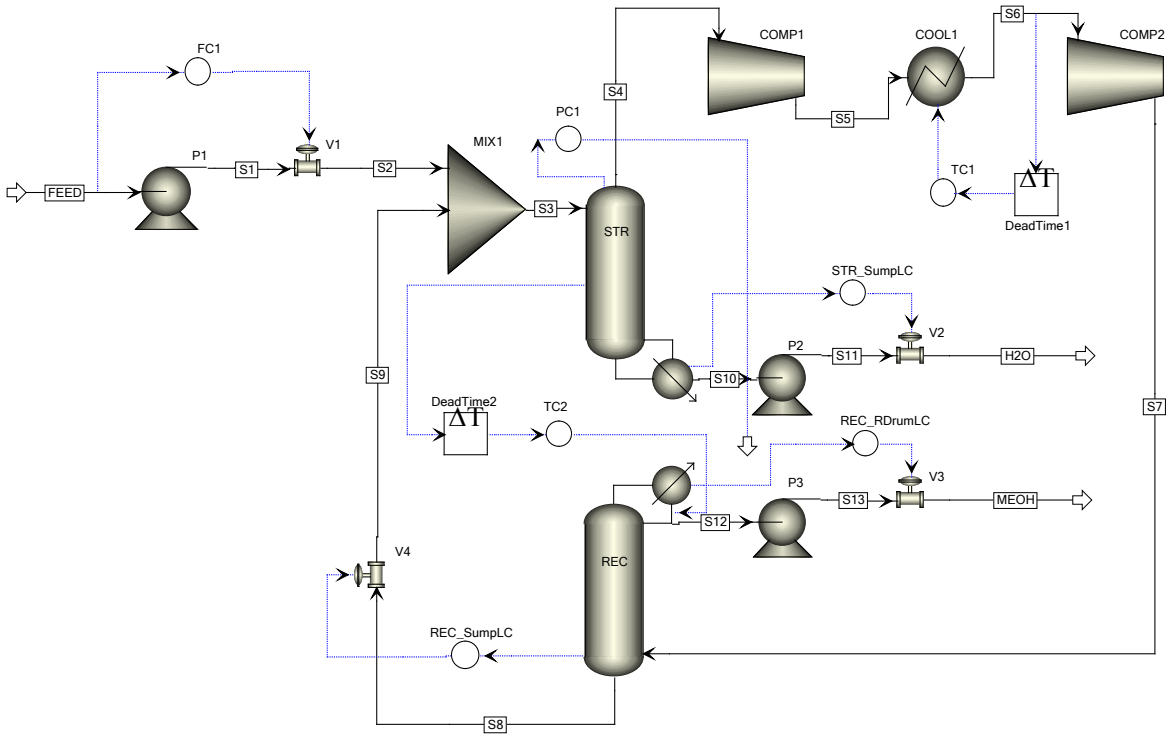

**Figure 3:** Process control structure 2 (PCS 2) utilizing fixed compressor duty

5    blocks("REC").Condenser(1).Q = -blocks("STR").QReb + blocks("PC1").op;
6
```

**Figure 5:** Flowsheet equations PCS 2

- $T_{stage\ 5,\ STR}$ is controlled by manipulating auxiliary condenser duty, see Figure 4 (TC2).
- $P_{stage\ 1,\ STR}$ is controlled by manipulating compressor duty, using a ratio controller to evenly change both compressor duties (PC1).
- P & T in the rectifier floats to allow for effective heat integration between rectifier and stripper
- Reflux ratio is kept constant using a ratio controller setting reflux flow as a ratio of distillate flow.

Process control structure 2 (PCS 2) in Figure 3 uses the same flow, interstage temperature, and level control loops, but has different control loops for stripper T and P:

- $T_{stage\ 5,\ STR}$ is controlled by manipulating reflux flow (TC2).
- $P_{stage\ 1,\ STR}$ is controlled by manipulating auxiliary condenser duty, see Figure 5 (PC1).

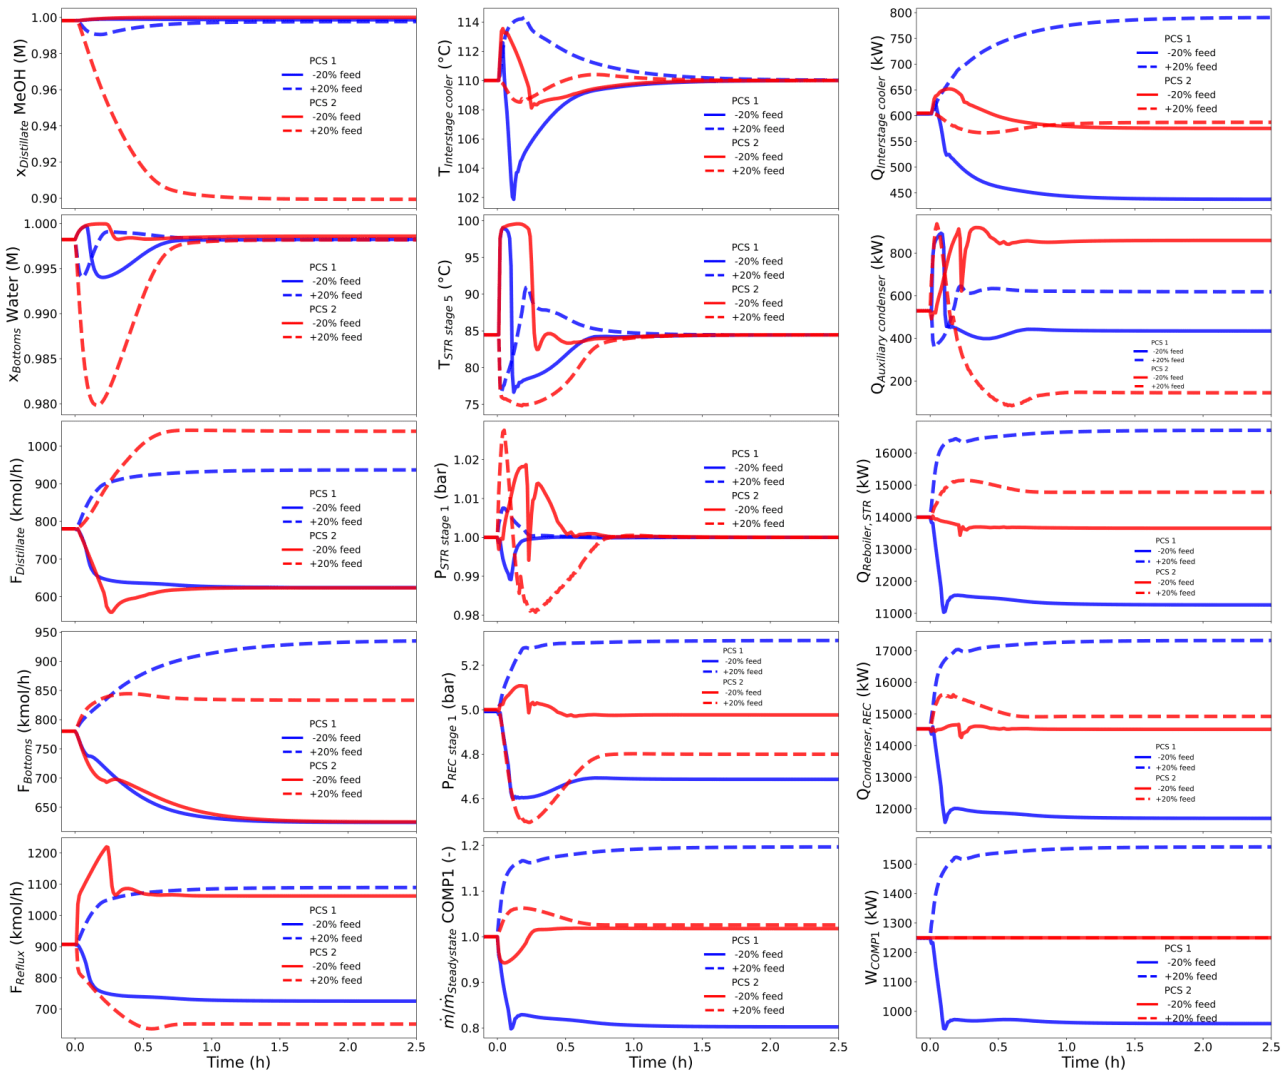

**Figure 6.** Control responses of PCS 1 and PCS 2 for ±20 % feed throughput disturbances

- Reflux ratio is no longer fixed, but instead compressor duty is kept constant.

The closed-loop system is continuously disturbed after 0.1 hr, for a total of 2.5 hr. The results are shown in Figure 6.

### Compressor sensitivity analysis

A compressor feed disturbance sensitivity analysis was done by finding the maximum change of corrected mass throughput for the compressor for step change feed disturbances ranging from 0.5 feed fraction to 1.2 feed fraction. For each step change feed disturbance, a separate simulation run in Aspen Dynamics was done using a continuous disturbance for 2.5 h, after which the maximum change of corrected compressor mass throughput was found. The compressor mass throughput is corrected based on (3) to account for the effect of inlet temperature and pressure changes:

$$\dot{m}_{corr} = \dot{m}\sqrt{\frac{T_{in}}{T_{ref}}} * \frac{P_{ref}}{P_{in}} \quad (3)$$

The results can be seen in Figure 7. An open source high efficiency centrifugal compressor (HECC) map from NASA was included (Figure 8) as an example for surge margins [13]. The data for a vaneless diffuser with 0.018 inch tip clearance was used, as this was the largest dataset with larger surge margin.

## RESULTS AND DISCUSSION

### System control responses

Figure 6 shows that both control structures achieve stable control for feed throughput disturbances, with fast responses and settling times of about 1 hr, due to short liquid holdup times of the packed columns. PCS 1 shows faster pressure control than PCS 2, while temperature

control settling times are similar. For both strategies, a large auxiliary condenser operating range is recommended for fast and robust control. The studied D-HIDiC has an auxiliary condenser duty to total condenser duty ratio of only 4.3%. A feed preheater or higher compressor interstage temperature could be used to increase this ratio, improving control robustness at an efficiency cost.

PCS 2 is a material balance-based control strategy and therefore cannot maintain product purity at increased feed throughput, as the reflux ratio must decrease to keep compressor flow constant. For a 20% feed throughput increase, the reflux ratio changes from 1.16 to 0.63, decreasing distillate purity by 10 mol% and dropping methanol below fuel grade (95 wt%, max 1 wt% water). Because the steady-state reflux ratio is close to 1, the absolute changes in reflux and distillate flow produce a large relative change in reflux ratio; for high reflux ratio columns, this effect would be smaller. Conversely, feed decreases cause over-purification at the same energy expenditure as steady-state production, meaning a 50% turndown ratio results in twice the energy cost per unit of purified methanol compared to steady state.

Despite these disadvantages, PCS 2 has one significant merit: compressor mass throughput is stabilized and step-change feed disturbances are substantially damped at the compressor. PCS 2 is therefore suitable for processes where the economic benefits of flexible operation of electricity-intensive upstream processes outweigh the increased purification cost per unit during turndown. For e-methanol production, about 90–95% of all electric power is consumed by water electrolysis [14], making the cost savings from electrolyzer turndown during electricity price spikes larger than the increased purification costs per unit of methanol incurred by PCS 2.

In general, PCS 2 should only be applied for turndown and the subsequent return to steady-state production, as product purity is maintained during these transient periods. Ramping above design capacity with PCS 2 should be avoided; a different strategy such as PCS 1 should be used instead to prevent distillate purity loss.

## Compressor sensitivity analysis

PCS 1 shows a proportional change of the corrected compressor mass throughput for feed rate changes (Figure 7). This is expected, as the compressor duty is altered to maintain stripping column pressure, matching the change of feed inflow. For PCS 2, the change in compressor mass throughput is damped (Figure 7). For example, a -20% feed step change causes a -5.7% change in compressor mass throughput. Figure 8 shows that for any given operating point, if the pressure ratio is maintained constant and the corrected mass flow rate is halved, the new operating point is beyond the surge limit. Based on this compressor map, PCS 1 is incapable of a 50% turndown ratio. This shows the potential of PCS 2 for flexible operation, especially when using feed ramp changes. Ramp time could be chosen such that the compressor experiences minimal changes in mass throughput. Nevertheless, it should be mentioned that a compressor map is unique for every compressor. Choices can be made in compressor design to increase surge margin at a decrease in efficiency and pressure ratio.

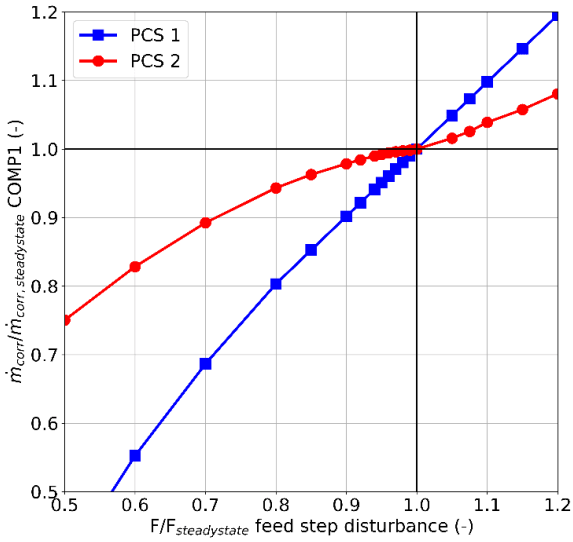

**Figure 7.** Compressor sensitivity analysis

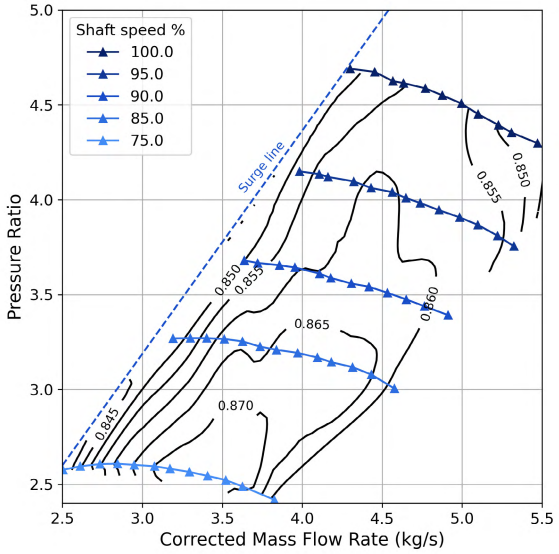

**Figure 8:** HECC compressor map

## CONCLUSIONS

This study has provided a thorough analysis of a control structure based on variable compressor duty (PCS 1) and for a control structure based on fixed compressor duty (PCS 2) for D-HIDiC. Both control structures are based on inferential temperature control and show robust performance for ±20 % feed throughput disturbances. Compressor sensitivity analysis has shown that

PCS 2 damps throughput disturbances for the compressor. PCS 2 can maintain stable compressor operation at 50% turndown ratio, whereas PCS 1 requires a compressor capable of operating at 50% capacity. PCS 2 enables high turndown, but at the cost of losing purity control during production increases and incurring an energy efficiency penalty during turndown. Its application is therefore best suited for scenarios where the economic value of flexibility outweighs these drawbacks.

These findings highlight the potential application of D-HIDiC technology in flexible chemical production systems. This work contributes to further electrification of distillation processes by making D-HIDiC compatible with variations in power availability.

# Long-Cycle Operation for Residue Hydrotreating Processes with Bayesian Optimization

**Pengcheng Zhu[a], Han Wang[b], Gang Chen[b], Bo Chen[b], Fei Zhao[a]*, Xi Chen[a]**

## ABSTRACT

For the long-cycle process industry, operational cycles can be severely affected by equipment aging, catalyst deactivation, and safety limitations. As illustrated by the residue hydrotreating process, metal impurities gradually deposit on the catalyst during residue purification, leading to catalyst poisoning and eventual process shutdown. Such long-cycle processes require dynamic adjustments of operating conditions to balance immediate economics with long-term sustainability. While current practice relies on empirical tuning based on historical data, this work focuses on studying how to obtain an optimal operating trajectory to guide the monthly adjustments of operating variables. The long-cycle simulation of the residue hydrotreating process can be performed using the commercial software, PetroSIM. After adjusting the feed conditions, its embedded mechanistic model can calculate the deviation of average bed temperature from the set point and output the remaining operating time. Since Bayesian optimization (BO) is well-suited to address complex processes with unknown mechanisms and high computational costs, and can effectively seek optimal solutions, a BO framework incorporating constraints evaluated by PetroSIM is proposed in this work to optimize the monthly feed composition and maximize the total profit over the entire operational cycle. The results indicate that the total profit achieved through BO-optimized operation is 17.8% higher than that from empirical operation. The optimized strategy demonstrates practical rationality: in the early stage of high catalyst activity, more residue can be processed; in the later stage, increasing the light oil ratio helps extend the processing cycle. This strategy provides theoretical support for advancing the research toward industrial applications.

## INTRODUCTION

Residue hydrotreating (RHDT) is a process that removes sulfur and metal impurities from heavy oil via catalytic reactions [1]. As the process proceeds, the catalyst gradually deactivates until its activity drops below a specified threshold, requiring a unit shutdown and catalyst replacement [2]. RHDT therefore operates over finite operational cycles. Given the high cost of the catalyst and the time-consuming replacement procedure, it is economically imperative to purify as much residuum as possible within each cycle. The key operational variable is the residuum content in the feedstock. Increasing this fraction lowers feed costs, thereby raising short-term processing profits. However, feeding a higher-impurity feedstock accelerates catalyst deactivation, which shortens the operable duration in the future. Conversely, decreasing the fraction yields the opposite effect: it extends catalyst life and increases process sustainability at the expense of short-term operating profit. This poses a significant trade-off problem: determining how to optimize the operations each month to maximize the total profit across the entire RHDT running cycle.

In this optimization, a critical constraint is the relationship between feed composition and the remaining useful life (RUL) of the catalyst. PetroSIM, a professional software in this field, contains an RHDS module capable of simulating the long-cycle operation of residue hydrotreating [3]. This module incorporates state-space correlations to model catalyst deactivation: it predicts catalyst activity for the subsequent month based on the current state (e.g., catalyst activity) and process inputs

(e.g., feed properties). Using this framework, PetroSIM calculates the minimum temperature rise required to satisfy the product composition constraint, from which the weighted average bed temperature (WABT) is determined. The distance between this value and the predefined threshold, combined with the catalyst deactivation rate, is then used to estimate the current RUL. Hence, distinct operating strategies yield different RUL trajectories. These RUL estimates are generated by the deterministic model embedded within PetroSIM. However, due to the closed architecture of this commercial software, neither the model nor its underlying database is accessible. As a result, analytical derivatives cannot be obtained. This study does not seek to construct a surrogate model for this internal relationship. Instead, we focus on solving the long-cycle operational optimization problem using this black-box simulator, and it is a scenario commonly encountered in industrial practice.

Bayesian optimization (BO) is a widely used black-box optimization algorithm grounded in Bayesian theory [4]. As an iterative framework, it integrating modeling and optimization. Specifically, the algorithm first fits a surrogate model (e.g., Gaussian process regression) for the objective function using an initial set of observed points. Based on this model, the subsequent point is selected by maximizing an acquisition function (e.g., expected improvement) that balances exploration and exploitation. Each newly evaluated sample is incorporated to update the surrogate, thereby progressively reducing uncertainty over the objective function. By repeatedly executing this 'decision-modeling' iteration, Bayesian optimization converges to the optimum with as few function evaluations as possible. Consequently, it is particularly suitable for black-box issues where evaluations are computationally expensive.

For the RHDT process, the operational optimization is conducted via the PetroSIM simulator, which is characterized by its opaque mechanisms and significant computational cost (a full-cycle simulation takes over one minute). If an evolutionary strategy (e.g., genetic algorithm) requiring numerous iterations is adopted, the optimization process becomes time-consuming—at least 16.7 hours for 1000 iterations. Thus, to minimize the number of calls to PetroSIM, this study utilizes BO method to address this operating scenario.

This section outlines the theoretical foundation and overall framework of this study. The remainder of the paper is organized as follows: Section 2 details the methodology for simulating the long-cycle RHDT process using PetroSIM; Section 3 formulates the objective of this study by defining the optimization problem, along with its associated constraints and boundary conditions; Section 4 presents the results and discusses the operational benefits achieved; Section 5 concludes this study and suggests potential directions for future research.

## RHDT PROCESS SIMULATION

Process simulation of residue hydrotreating can be accomplished using the RHDS module in PetroSIM. Figure 1 shows the RHDT process flowsheet developed on this platform. Residuum and hydrogen are fed into the reactor for hydrotreating. The effluent then passes through an ideal separator (modeled as a component splitter) to simulate a high-pressure high-temperature flash drum, assuming complete separation of non-condensable gases ($H_2S$, $NH_3$) from the liquid hydrocarbons based on a defined split fraction. The Peng-Robinson (PR) equation of state with built-in binary interaction parameters is applied throughout the process, as it is widely accepted for hydrocarbon systems containing sour components ($H_2S$, $NH_3$). The liquid stream is subsequently fractionated into products of varying boiling points (gas, naphtha, diesel, and bottoms). In addition, $H_2O$ serves as a wash water stream to rinse metal deposits from the catalyst. HPS functions as a high-pressure vent line to withdraw excess hydrogen feedstock.

**Table 1:** Properties of the feed oil.

| Property | Value |
|---|---|
| Sulfur content | 3.0 ~ 6.0 wt% |
| Conradson carbon content | 11.20 wt% |
| Nickel content | 21.80 ppmwt% |
| Vanadium content | 64.40 ppmwt% |
| Nitrogen content | 0.24 wt% |
| Distillation 1% (TBP) | 273.4 °C |
| Distillation 5% (TBP) | 349.4 °C |
| Distillation 10% (TBP) | 384.6 °C |
| Distillation 30% (TBP) | 459.0 °C |
| Distillation 50% (TBP) | 523.2 °C |
| Distillation 70% (TBP) | 597.6 °C |
| Distillation 90% (TBP) | 694.4 °C |
| Distillation 99% (TBP) | 722.2 °C |
| Specific gravity (Std. Cond.) | 0.977 - |
| Temperature | 260 °C |
| Pressure | 101 kPa |
| Volume flow | 535.7 $m^3/h$ |

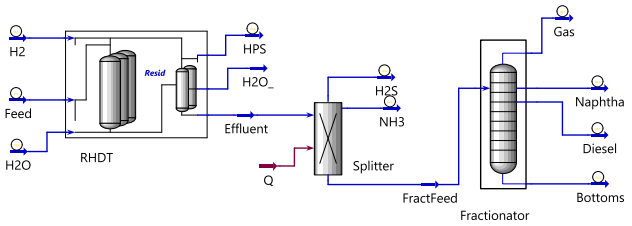

**Figure 1.** Flowsheet of the RHDT process in PetroSIM.

Table 1 presents the properties of the feedstock. The sulfur content is identified as the key factor responsible for catalyst deactivation. Hence, adjusting the

proportion of heavy oil in the feed can be regarded as effectively modifying the sulfur content. According to the review [5], this study specifies the sulfur content of the heaviest feed as 6.0 wt% and that of the lightest feed constituents as 3.0 wt%. As the only manipulated variable, feed sulfur content dominates catalyst RUL and thus drives profitability. Fixed true boiling point (TBP) cut points minimize product yield variation from the separation system, so the ideal splitter simplification has negligible impact on economic conclusions. Due to the requirements of the downstream processes in RHDT, the sulfur content in the bottoms product needs to be maintained below 0.5 wt%, regardless of the feedstock. However, there are price variations: heavy feedstock costs about 350 USD/m³ ($P_H$), light feedstock costs about 600 USD/m³ ($P_L$), and the purified effluent is valued at approximately 800 USD/m³ ($P_B$).

**Table 2:** Parameters of the reactor.

| Parameter | Value |
|---|---|
| WABT (Start of Run) | 360 °C |
| WABT (End of Run) | 420 °C |
| Number of beds | 5 - |
| Catalyst density | 493.7 kg/m³ |
| Catalyst weight | 1656.37 ton |

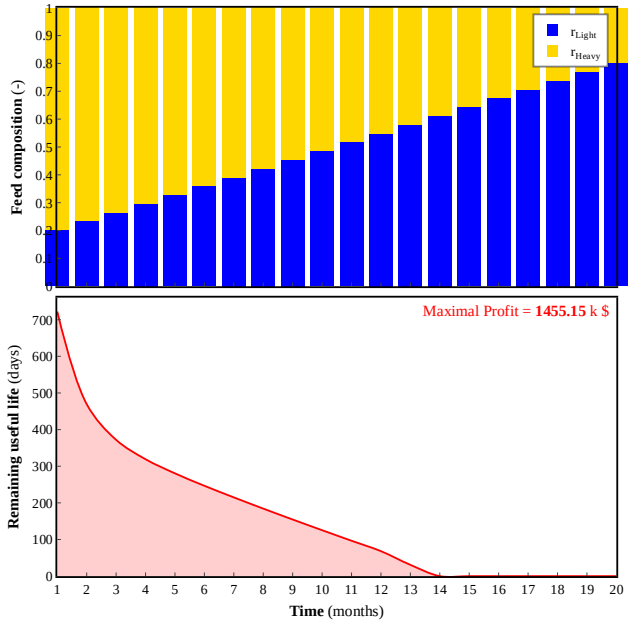

**Figure 2.** Feed composition and RUL trajectory under empirical operation.

In addition, the parameters of the reactor remain constant, as listed in Table 2. It can be seen that the catalyst inventory is held constant. Thus, its activity progressively decreases during residue hydrotreating. In PetroSIM, this effect is reflected by a rise in WABT, as the process must maintain the product sulfur specification. Starting from the first month (WABT=360°C), operating decisions are updated at monthly intervals. The process stops once the WABT exceeds the set value (WABT=420°C). Figure 2 illustrates an empirical operational approach: linearly increasing the light feedstock fraction from 0.2 to 0.8 to compensate for the declining catalyst activity in later periods. However, as can be seen from PetroSIM's estimation, the RUL reaches zero by the 14th month, implying that no profit can be generated from subsequent operations. Therefore, the total profit, calculated as the cumulative monthly product revenue minus feedstock costs, is 1455.15 thousand USD.

## OPERATIONAL OPTIMIZATION

In this study, given that hydrogen is typically supplied in excess during industrial residue hydrotreating and its precise consumption is difficult to quantify, hydrogen-related costs are treated as fixed overheads and excluded from the objective function. Operating conditions influence utility consumption through their effect on WABT; however, the integrated value of total utility cost remains largely unchanged across different operating strategies over the entire processing cycle, allowing minor fluctuations to be neglected in the model. Moreover, catalyst are expensive and consumed in large quantities; frequent replacement not only increases operating expenses but also disrupts the refinery-wide material balance. Industrial practice therefore prioritizes the full utilization of catalyst within each operating cycle. Accordingly, this study optimizes profit over a full single catalyst cycle; as the one-time catalyst replacement cost is independent of operating decisions, it is neglected in the analysis. Based on these assumptions, the objective is to maximize the total profit by optimizing the heavy component fraction in the monthly feed. The optimization problem is expressed in Equation 1. This study sets the total duration to no more than 20 months. The heavy oil fraction in the feed for each month is represented by the set $\boldsymbol{r}_H = \{r_H^{(i)} \mid i = 1, \ldots, 20\}$. The light oil fraction is complementary, such that $r_H^{(i)} + r_L^{(i)} = 1$. A binary decision variable $z_i \in \{0, 1\}$ governs whether the monthly processing profit contributes to the total profit; its value is assigned based on the RUL estimated via PetroSIM: $z_i = 1$ when $RUL > 0$, and $z_i = 0$ when $RUL = 0$. The total feed flow rate $F_{in}$ is set to 535.7 m³/h. The product flow rate of the bottoms $F_B^{(i)}$ is simulated by PetroSIM. $P_B$, $P_H$, and $P_L$ correspond to the prices of the bottoms, heavy feedstock, and light feedstock. Additionally, c is defined as 24*30 (hours*days).

$$\max_{\boldsymbol{r}_H} \sum_{i=1}^{20} z_i * \left(F_B^{(i)} P_B - r_H^{(i)} F_{in} P_H - r_L^{(i)} F_{in} P_L\right) * c \qquad (1)$$

$$z_i, F_B^{(i)} = \text{PetroSIM}\left(r_H^{(i)}, r_L^{(i)}\right), i = 1, \ldots, 20$$

$$r_H^{(i)} + r_L^{(i)} = 1, i = 1, \ldots, 20$$

$$0 \le r_{\mathrm{H}}^{(i)} \le 1$$

$$0 \le r_{\mathrm{L}}^{(i)} \le 1$$

The Bayesian optimization algorithm is applied to optimize this problem. The procedure is illustrated in Figure 3. First, 30 sets of $\boldsymbol{r}_{\mathrm{H}}$ are sampled within the domain using Latin hypercube sampling, and the light feedstock fraction $\boldsymbol{r}_{\mathrm{L}}$ is derived accordingly. For each set, PetroSIM computes the corresponding $F_{\mathrm{B}}^{(i)}$ and $RUL^{(i)}$ (i.e., $z_i$). Subsequently, the values of the objective function are calculated, and the sample with the highest value is denoted as $\boldsymbol{r}_{\mathrm{H}}^{*}$. Gaussian process regression is utilized to fit the mapping from the decision variables to the objective function. The next point to be evaluated is determined via the expected improvement. This process iterates until a predetermined iteration count is met, at which point the optimal solution $\boldsymbol{r}_{\mathrm{H}}^{*}$ is returned.

This framework is implemented via the BoTorch library in Python, and the parameters are presented in Table 3. The RBF kernel, known for its universal approximation capability, is adopted for the Gaussian process, while expected improvement (EI) serves as the acquisition function. A total of 550 iterations are performed, with the initial samples used to initialize the Gaussian process regression constituting about 5.5% of the total iterations.

**Table 3:** Parameters of BO.

| Parameter | Value |
|---|---|
| Gaussian kernel | RBF kernel |
| Acquisition function | EI |
| Number of initial points | 30 |
| Number of iterations | 520 |

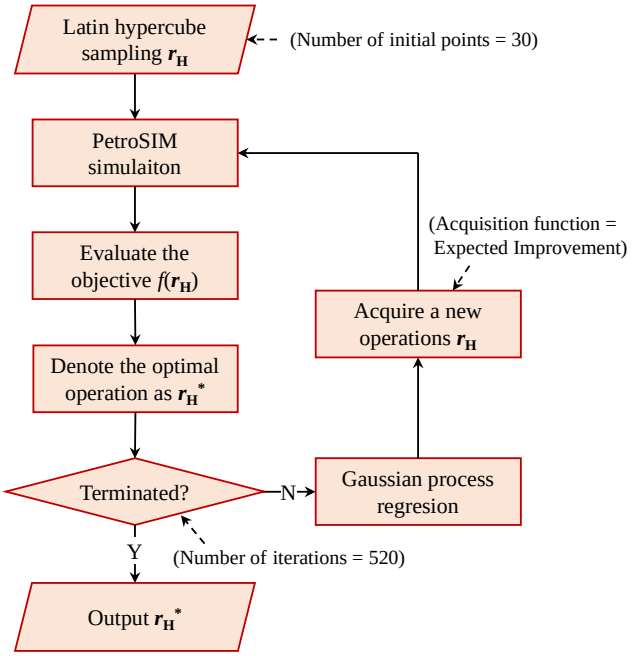

**Figure 3.** Workflow of the BO strategy.

## RESULTS AND DISCUSSION

Figure 4 illustrates the iterative process of the algorithm. The horizontal axis represents the number of objective function evaluations, comprising 30 initial evaluations and 520 iterative evaluations. Total revenue and total cost are shown by cyan and pink bars, respectively. The difference between them, which is the total profit (i.e., objective function value), is plotted as a blue curve. In addition, the green line represents the magnitude of the acquisition function, i.e., the EI value. It is mapped to the right vertical axis, and non-zero values of this line suggest that the subsequent sampling point can improve upon the current $\boldsymbol{r}_{\mathrm{H}}^{*}$. It can be observed from the figure that the green line displays multiple peaks in the initial iterations. The BO focuses on exploring the decision space during this period. This drives the algorithm to quickly locate the promising region for the optimum. In the middle and later stages, BO emphasizes exploitation by sampling around the optimal solution, which serves to improve the accuracy of the surrogate model. The algorithm identified the optimal value at iteration 432, requiring merely 7.2 hours of runtime.

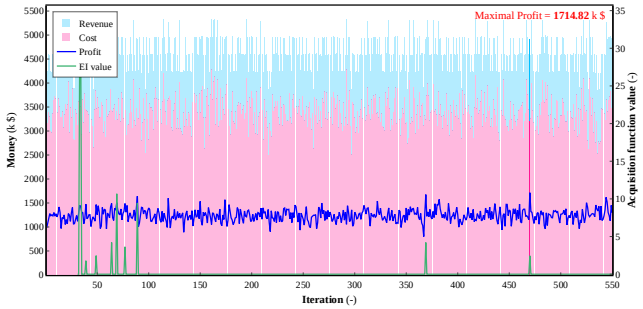

**Figure 4.** Iteration process of BO for Equation 1.

The bars representing revenue and cost associated with the optimal operation are highlighted in Figure 4. The total profit obtained is 1714.82 thousand USD, reflecting a 17.8% improvement over that achieved by the empirical operation. Figure 5 depicts the optimal operation and the estimated RUL. As shown, a higher fraction of heavy oil is fed during the early processing stage, thereby maintaining a lower cost level. Contrary to the empirical operation that continuously increases the fraction of light oil feed, optimized strategies recommend utilizing periods of high catalyst activity to process more residue. Subsequently, the fraction of light oil feed is progressively increased in the mid-to-late periods to prolong the processing time. Compared with the results in Figure 2, the RUL here is sustained for one additional month, resulting in additional profit.

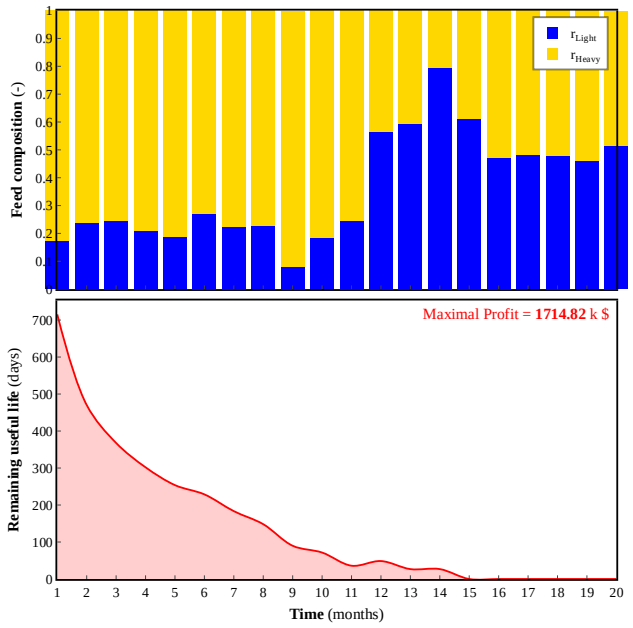

**Figure 5.** Feed composition (with varying $r_H$) and RUL trajectory after BO optimization.

Figure 6 illustrates the iterative process, showing that BO identified the optimum at a relatively early stage. This is attributed to the reduced dimensionality and simpler surrogate modeling in the single-variable problem. As shown in Figure 7, the results suggest that residue should constitute the majority of the feed. Although only 12 months of operation are valid, the profit reaches 1667.83 thousand USD, which is 212.68 thousand USD higher than that of empirical operation. However, this result is inferior to that of the free-feed optimization. The rationale lies in the fact that the optimal solution under this problem is a lower bound solution of Equation 1. Consequently, plants are advised to optimize the supply of light and heavy oils at the supply chain level.

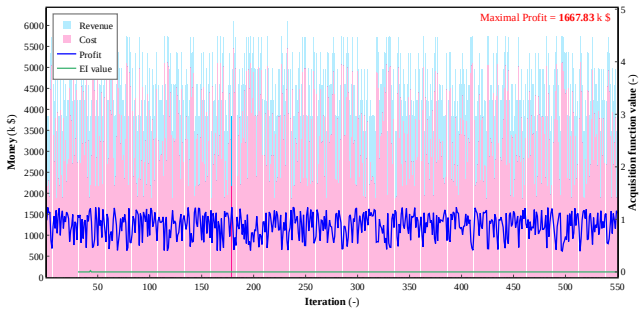

**Figure 6.** Iteration process of BO for Equation 1 under constant $r_H$ constraint.

Additionally, in practical applications, the supply of light oil often lacks flexibility. This implies that the feed composition must be predetermined prior to startup. For comparative purposes, another optimization scenario is investigated: maximizing total profit by optimizing a constant heavy oil fraction in the feed. Mathematically, this is equivalent to adding a constraint to Equation 1: $r_H^{(1)} = r_H^{(2)} = \ldots = r_H^{(20)}$.

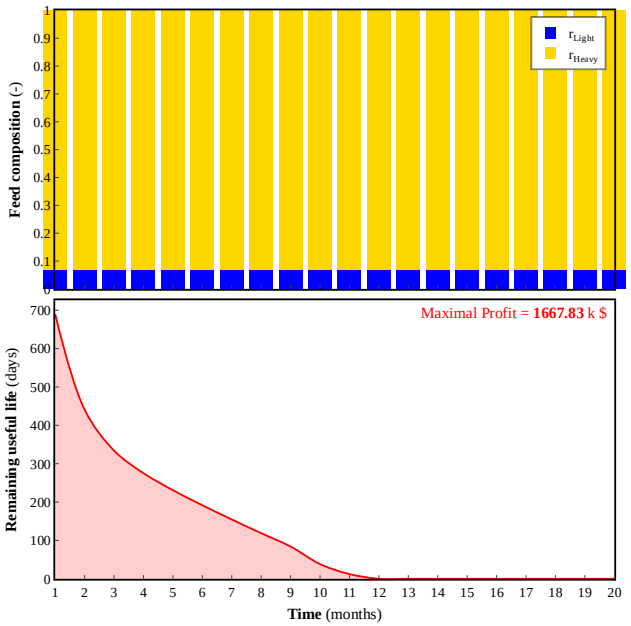

**Figure 7.** Feed composition (with constant $r_H$) and RUL trajectory after BO optimization.

## CONCLUSION

The main contribution of this work lies in developing an optimization framework for long-cycle operating trajectories of residue hydrotreating based on the PetroSIM, a problem essentially characterized by high-dimensional black-box optimization. BO, leveraging a probabilistic surrogate model to actively sample and iteratively update the posterior, enables efficient optimization with minimal objective function evaluations. This study employs BO to address the problem. Following 432 iterations (7.2 hours), BO identifies the optimal solution, yielding a 17.8% profit improvement compared to empirical operation. The optimized results exhibit an operating pattern with a higher heavy oil ratio in the early stage and a higher light oil ratio in the later stage. This pattern is consistent with the decreasing catalyst activity over time and the stronger impact of feed when activity is low. This provides practical guidance: operators can initially set a high throughput and then gradually reduce it based on WABT feedback. Moreover, this study investigates a lower-bound case of the problem by optimizing with fixed operations each month. This is designed for refineries with limited flexibility in light feed supply. The results, though not as good as those from unrestricted operational optimization, still show a 14.6% increase over the unoptimized practice.

Similar optimization problems, balancing immediate

economic returns and future sustainability, are prevalent in various industrial contexts. Additionally, commercial software such as PetroSIM, PRO/II, and Aspen HYSYS do not provide analytical derivatives. The proposed BO framework is general and inherently incorporates uncertainty considerations, laying a foundation for methodological innovations and adaptations to more complex industrial problems.

## ABSTRACT

Centralized monitoring methods experience reduced fault detection sensitivity in large-scale industrial systems due to the masking effect arising from the aggregation of many interconnected variables. Decentralized monitoring, where variables are grouped into subsystems, has been shown to effectively address these limitations. However, the performance of this class of methods critically depends on how the network is partitioned, and the role of its structural factors on fault detection remains poorly understood. This work studies how network topology and causal structure affect decentralized monitoring in high-dimensional systems. Using *SimCaNet*, a DAG-based data simulator, where large-scale systems with 100-1000 variables were generated, we rigorously compared the performance of centralized and decentralized causal log-likelihood monitoring methods under process perturbations and sensor bias faults. Network partitioning is performed using the Leiden community detection algorithm and characterized at the network, community, and node levels. Fault Detection Sensitivity ($AUC_{NORM}$) is quantified per variable, using the normalized area under the curve, which is computed from the true positive rate profiles across fault magnitudes. Results show that $AUC_{NORM}$ is primarily driven by the number and the size of communities across fault types. Smaller communities consistently achieve higher $AUC_{NORM}$ than larger communities, while excessive fragmentation or high modularity degrade performance. Community density and inter-community coupling further enhance fault detection sensitivity. The strength of node-level causal relationships explains most of the variability observed at root nodes for sensor bias faults and their robustness to information loss. Furthermore, ablation studies confirm the robustness of distributed systems to major disruptions in the system: more than 32% of community information can be removed without significantly impacting the fault detection sensitivity. These topology-driven partitioning findings constitute novel and valuable contributions to the theoretical foundations for designing better distributed monitoring systems in complex industrial plants.

## INTRODUCTION

Fault detection in large-scale industrial systems remains a significant challenge with direct implications for safety, efficiency, and operational reliability. As modern processes scale in size and complexity, hundreds or thousands of interdependent variables must be monitored simultaneously. In such high-dimensional settings, small and localized faults are often statistically diluted within global monitoring indices, leading to delayed detection or complete loss of sensitivity [1, 2].

Decentralized monitoring has emerged as a promising strategy to mitigate this limitation, by decomposing large systems into smaller groups monitored locally. By reducing dimensionality and focusing on localized dynamics, decentralized schemes can detect faults before they propagate across the network [3, 4]. However, the effectiveness of decentralization critically depends on system partitioning, where poorly designed partitions can replicate the limitations of centralized monitoring or

introduce excessive false alarms.

Fault propagation and its proper diagnostics are inherently governed by causal relationships between process variables. This motivates the use of causal network representations for monitoring, where directed interactions encode how disturbances propagate through the system [5-7]. While causal monitoring frameworks provide a principled basis for understanding fault propagation, their performance in high-dimensional systems remains limited.

Recent advances in network science have shown that the topological structure of complex systems shapes information flow [8, 9]. Properties such as community structure, internal connectivity, modularity, and node centrality have been shown to influence system dynamics. Fault detection sensitivity in large-scale systems is not only a statistical problem, but also a structural one. Despite this, the role of network topology in decentralized fault detection has not been systematically addressed or characterized. It is still unclear which topological properties govern the sensitivity gains and under what conditions decentralization may fail. Consequently, current monitoring strategies lack topology-aware design principles, limiting their application, scalability, and robustness.

To address this gap, in this work we provide a quantitative analysis of how network topology and causal structure jointly affect decentralized monitoring in high-dimensional systems, with the building blocks described next. A graph-based causal data simulator generates networks reflecting structural characteristics commonly observed in industrial processes. Two representative fault classes are considered: process perturbations and sensor bias faults. Network partitions are obtained using the Leiden algorithm, a modularity-based community detection method, allowing controlled variation of partition size and structure [10]. Monitoring performance is evaluated using a Fault Detection Sensitivity metric that captures node-level fault detection across fault magnitudes, enabling fair comparison between centralized and decentralized schemes.

Our results reveal a consistent relationship between fault detection sensitivity and topological descriptors, including community size, internal density, modularity, and node centrality. Decentralized causal monitoring systematically outperforms centralized approaches in large-scale networks. However, suboptimal partitions may reduce these benefits, highlighting the need to consider structural trade-offs. These findings provide fundamental insights to the systematic design of topology-aware monitoring and demonstrate that fault detection in high-dimensional systems depends fundamentally on network topology.

## METHODOLOGY

This section presents the framework used to assess fault detection sensitivity in large-scale systems. The methodology combines a high-dimensional data simulator, centralized and decentralized monitoring schemes, network partitioning, and a unified fault detection sensitivity metric. The goal is to isolate the impact of network topology, partition structure, and fault type on fault detection performance under fully controlled conditions.

### Network Data Simulator and Fault Types

To assess fault detection sensitivity in large-scale systems, a high-dimensional causal data simulator, called SimCaNet, is used. Existing benchmark simulators for process monitoring are typically limited to low-dimensional settings, which hinders systematic analysis of how network topology affects fault detection sensitivity. Although latent-variable models can handle high-dimensional data, they ignore explicit causal relationships, and are therefore less sensitive and have more limited diagnostic capabilities [7, 11].

SimCaNet generates synthetic datasets using Directed Acyclic Graphs (DAGs) implemented as Structural Causal Models (SCMs) [12]. Each variable is defined as a function of its causal parents, ensuring understandable propagation mechanisms and realistic fault patterns.

Network structures are generated using a preferential-attachment mechanism based on the Barabási-Albert model, producing heterogeneous, hub-dominated topologies closely related to large-scale industrial systems. This choice reflects the non-uniform connectivity and consequently the asymmetric propagation paths, commonly observed in practice. All network structures preserve the DAG property to ensure causal consistency.

Data are generated under Normal Operating Conditions (NOC) following a linear and static SCM formulation, with additive measurement noise to emulate realistic observational conditions. This simplification enables focusing on the identification of critical topological features driving fault detection sensitivity, without the interference of other factors, such as non-linearity and multiscale dynamics. Structural parameters are generated once for each network and kept fixed across experiments, so that observed variations in monitoring performance can be attributed to network topology, partitioning, and fault characteristics.

Two representative fault classes are considered, as summarized in Table 1. Process perturbations are modeled as step changes in root variables (data drift), inducing process disturbances that propagate through the causal network according to its topology. Sensor bias faults are modeled as additive biases affecting only local measurements, without altering the underlying process. Fault severity is controlled through a fault magnitude

parameter proportional to the variability of the faulty variable.

**Table 1:** Types of faults implemented in SimCaNet.

| Type of fault | Meaning | Modified factor |
|---|---|---|
| Process Perturbation | A step change in root nodes, representing e.g., abnormal (but real) variation in raw materials | $\mu_i = \mu_{NOC,i} + k\sigma_i$ |
| Sensor bias | Biased readings caused by a fault in the sensors | $X_i = X_i + k\sigma_{e_i}$ |

## Large-scale Causal Monitoring Methods

This section presents the two causal-based Statistical Process Monitoring methods used in this work to evaluate how network dimensionality and structure affect fault detection sensitivity. Both approaches follow the standard SPM pipeline, including phases of process stability analysis, calculation of monitoring statistics, and fault detection of a new observation via control limits.

### Centralized Causal Log-likelihood monitoring

The Centralized Causal Log-likelihood monitoring (CNc-MSPC) method is based on log-likelihood indices and was adopted as the benchmark for the fault detection performance study. In ref. [13], this methodology was compared with the classical PCA-MSPC approach using both a simulated dataset and an industrial semiconductor manufacturing dataset. The results showed that the causal approach achieved superior fault diagnosis, and better or at least similar detection performance.

In practice, the causal network structure is inferred through causal discovery methods [14]. Here, the causal graph is assumed to be known, as the purpose is to study the impact of network topology (and not discovery accuracy).

Each variable $X_i$ is modelled through a SCM as a function of its causal parents, $\mathrm{Pa}(X_i)$. These yields, $X_i = f(\mathrm{Pa}(X_i)) + e_i$, where the conditional distribution of $X_i|\mathrm{Pa}(X_i)$ corresponds to the error term distribution, $e_i$.

A local log-likelihood index is computed for each observation *j*. Assuming a normal distribution, the log-likelihood for an individual observation $L_i^L(j)$ is defined as:

$$L_i^L(j) = -\frac{\ln(2\pi)}{2} - \frac{\ln(\hat{\sigma}_{e_i}^2)}{2} - \frac{(e_i(j)-\mu_{e_i})^2}{2\hat{\sigma}_{e_i}^2} \quad (1)$$

where $e_i(j)$ is the error term of variable $X_i$ conditioned onto its causal parents, and $\hat{\mu}_{e_i}$ and $\hat{\sigma}_{e_i}$ are the sample mean and standard deviation of $e_i$ calculated from a reference dataset corresponding to normal operating conditions (NOC).

A global log-likelihood index $L^G(j)$ is then obtained by aggregating the local indices across all nodes. Leveraging on the chain rule, the joint (or global) likelihood factorizes into the product of the conditional likelihoods. Therefore, applying logarithms, the global log-likelihood, $L^G(j)$, is obtained in terms of the individual log-likelihoods, as follows:

$$L^G(j) = \sum_{i=1}^{n_{variables}} L_i^L(j) \quad (2)$$

Control limits for fault detection are established using the values of $L^G$ obtained from a validation dataset. A kernel density estimation (KDE) is fitted to approximate the probability density function of this global log-likelihood statistic [14]. The cumulative distribution function (CDF) of the KDE is then used to determine the Lower Control Limit (LCL) by solving the following equation for a predefined Type I error rate, α:

$$\int_{-\infty}^{\mathrm{LCL}} \hat{f}_{KDE}(L^G)\, \mathrm{d}L^G = \alpha \quad (3)$$

where, $\hat{f}_{KDE}(L^G)$ is the estimated probability density function. Since high log-likelihood values indicate proximity to the reference distribution, only the Lower Control Limit (LCL) is needed for fault detection. This threshold is used for monitoring future observations.

### Decentralized Causal Log-likelihood monitoring

The Decentralized Causal Log-likelihood monitoring (CNd-MSPC) method also starts by inferring the causal network. Then, the variables are divided into disjoint communities (groups or clusters) using a community detection algorithm that considers network topology and modularity. Such grouping into strongly connected communities effectively enhances the fault detection sensitivity. However, the selection of the partition and consequently its quality directly impacts the monitoring performance.

Given a network partition, a global log-likelihood metric (Equation 2) and the control limits are computed for each community (sub-level monitoring), denoted as $L_c^G$ for $c = 1, 2, \ldots, n_{communities}$, where $n_{communities}$ is the total number of communities.

To aggregate information from multiple communities, an OR-gate approach is adopted, meaning that a global warning is issued as soon as at least one community-level out-of-control signal is produced.

Each community's control limits are set independently, with the significance level adjusted to maintain the overall false alarm rate across multiple monitoring statistics. To this end, the Šidák correction is applied, setting the significance level for each community as $\alpha_c = 1 - (1-\alpha)^{1/n_{communities}}$ [15]. This ensures that the global alarm reflects true anomalies while controlling the overall Type I error rate (also known as the Family-Wise Error Rate, FWER). CNd-MSPC is particularly well-suited for

**Table 2:** Network-, community-, and node-level descriptors used to characterize the structural, statistical, and causal properties of each potentially faulty variable for a fixed network and partition.

| Feature | Description | Level |
|---|---|---|
| Network Size | Total number of nodes in the network | Network |
| Modularity | Quantifies the quality of the network's division into communities | Network |
| Number of communities | Total number of communities in a partition | Community |
| Number of nodes in the community | Total number of nodes in the community of the faulty variable *i* | Community |
| Density | Quantifies the intra-connectivity in the community of the faulty variable *i* | Community |
| Conductance | Measures the fraction of edges leaving the community of the faulty variable *i* relative to all edges within and leaving the community | Community |
| Cohesiveness | Quantifies the maximum conductance among all connected subsets (size >2) of the community of the faulty variable *i*, capturing the weakest internal connectivity within the community | Community |
| Separability | Measures the ratio of external edges to the internal edges in the community of the faulty variable *i* | Community |
| Clustering Coefficient | The average clustering of nodes within the community containing the faulty variable *i*, quantifying the tendency to form tightly connected triplets | Community |
| Normalized Causal Strength | Quantifies the relative causal influence of the faulty node *i* on its children, normalized by the total parents' influence on each affected child, based on SCM coefficients | Node |
| In-degree | Number of incoming edges to faulty node *i*, indicating how many parent nodes directly influence it | Node |
| Out-degree | Number of outgoing edges from node *i*, indicating how many child nodes it directly influences | Node |
| Is root-node? | Binary indicator for the faulty node *i* | Node |
| Degree centrality | Fraction of nodes that are connected to the faulty node *i* | Node |
| Closeness centrality | Measures how easily other vertices can be reached from the faulty node *i* | Node |
| Betweenness centrality | A measure of how much the faulty node *i* acts as an intermediary in a shortest path between the other node pairs | Node |
| Eigenvector centrality | Measures the influence of faulty node *i* based on the influence of its neighbors | Node |
| Page Rank | Measures the influence of faulty node *i* based on the influence of incoming neighbors, adjusted by the damping factor α | Node |
| Shortest Path to Centroid | Measures how close faulty node *i* is to the three most degree central nodes of the network | Node |

high-dimensional networks, where centralized monitoring often becomes statistically insensitive to localized faults. Although the offline phase (causal discovery, causal inference, process stability analysis) scales with network dimensionality, the online monitoring phase is computationally efficient.

## Network Partitioning and Topological Descriptors

Partitioning the inferred causal graph is a crucial step in CNd-MSPC, as the resulting communities define the structural units used for decentralized monitoring. To generate these partitions, community detection algorithms are employed, leveraging the graph representation of the process. A broad range of algorithms is

**Table 4:** Summary of network partitions used in the Fault Detection Sensitivity study for Process Perturbation (PP) and Sensor Bias (SB) faults.

| Network | Partition | #Communities | Modularity |
|---|---|---|---|
| Network 1 | Centr. | 1 | - |

available, including the Girvan-Newman and Louvain methods, which differ in the principles used to uncover community structure. In this work, the communities were generated through the Leiden algorithm.

The Leiden method improves on the Louvain method by addressing its main limitation: after the aggregation step, the Louvain method can yield communities that are internally disconnected or weakly connected. As for the Louvain method, the Leiden method also optimizes modularity, $Q$, but introduces a refinement step that guarantees connectivity within each community.

$$Q = \frac{1}{2m}\sum_{i,j}\left(w_{ij} - \gamma\frac{k_i k_j}{2m}\right)\delta(c_i, c_j) \qquad (4)$$

In Equation 4, modularity function is represented where *m* is the number of graph edges, $\gamma$ is the resolution parameter controlling the granularity of identified communities, $w_{ij}$ is the edge weight between nodes *i* and *j*, $k_i$ and $k_j$ are their respective degrees, and $\delta(c_i, c_j)$ is a community indicator function (1 if *i* and *j* belongs to the same community, *i.e.*, $c_i = c_j$, and 0 otherwise).

The Leiden method tends to produce communities that are densely connected internally while minimizing connections between communities.

## Topological Descriptors

For a given network and a fixed partition, fault detection sensitivity may vary across fault locations due to the differences in the structural and causal embedding of variables within the network. To systematically analyze these effects, each faulty variable is characterized using a set of network-, community-, and node-level descriptors, summarized in Table 2. These descriptors are subsequently used for exploratory data analysis and pairwise correlation studies, together with the Fault Detection Sensitivity metric, to identify structural properties that drive fault detection under decentralized monitoring.

## Fault Detection Sensitivity Assessment Framework

We developed a unified evaluation framework used to compare fault detection performance across all network sizes, partitioning strategies, fault types, and monitoring schemes. The framework ensures that all results are directly comparable, enabling the analysis of the effects of network topology and partitioning on fault

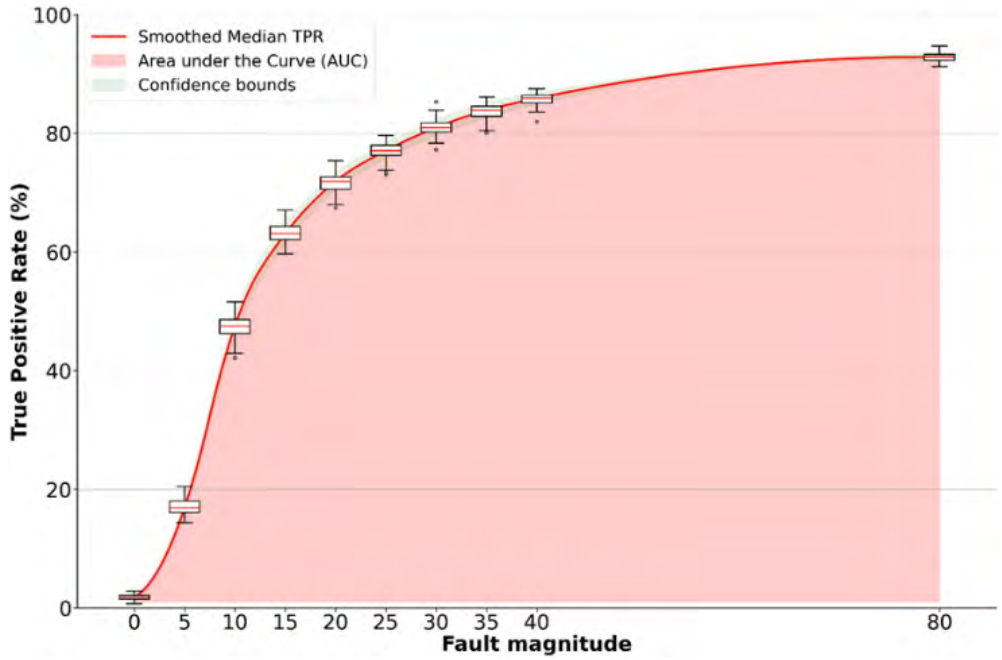

**Figure 1.** Fault detection sensitivity assessment for a sensor bias fault injected in a single network variable. Box plots show the distribution of True Positive Rate values for each fault magnitude. The red curve represents the median TPR versus magnitude, and the shaded red area corresponds to the AUC.

detection sensitivity.

For each network, both centralized and decentralized monitoring schemes are evaluated. Different partition granularities are obtained by varying the resolution parameter, $\gamma$, while centralized monitoring (i.e., no partitioning) is used as a benchmark configuration. Some descriptors of the tested networks are summarized in Table 3.

**Table 3:** Characterization of the four networks under study.

| Descriptor | Network 1 | Network 2 | Network 3 | Network 4 |
|---|---|---|---|---|
| # of nodes | 100 | 300 | 500 | 1000 |
| # of edges | 212 | 875 | 1564 | 3880 |
| # of root nodes | 48 | 152 | 277 | 333 |
| Graph density | 0.0214 | 0.0098 | 0.0063 | 0.0039 |

For process faults, perturbations are injected exclusively at root nodes. Ten fault magnitudes are considered, with a fixed magnitude range across all networks, but that is adapted to each fault type. To account for stochastic variability, each magnitude is simulated 50 times (independent replicates, each consisting of 1000 observations). The signal-to-noise ratio for the additive noise is fixed at 10 dB.For sensor bias faults, the same evaluation pipeline implemented for process perturbation faults is applied, with faults injected independently at each network variable. All monitoring schemes are calibrated to operate at a fixed false alarm rate of α = 0.05 using independent fault-free validation datasets.

Fault detection sensitivity performance is quantified using a Normalized Area Under the Curve ($AUC_{NORM}$) metric. For a given faulty variable (see the Figure 1 as an example), the True Positive Rate (TPR) is computed for each fault magnitude and replicate. The median TPR across replicates is then calculated for each magnitude, yielding a single TPR vs. Fault magnitude curve. The area under this curve defines the AUC, which summarizes the sensitivity of the monitoring scheme across fault magnitudes. To ensure comparability across configurations, AUC values were normalized using a max-min approach, where the maximum AUC corresponds to perfect detection (TPR = 100% for all magnitudes) and the minimum was equivalent to the false positive rate (FPR) when no faults were introduced.

The evaluation pipeline applies this framework to each network and partition, as illustrated in Figure 2. The workflow starts with network selection and data generation under normal operating conditions, followed by partitioning for decentralized monitoring and control limit estimation. The TPR vs Fault magnitude curve is then computed for each variable under the selected partition, and the corresponding $AUC_{NORM}$ is obtained. This procedure yields a single fault detection sensitivity score per variable, per network, and per partition.

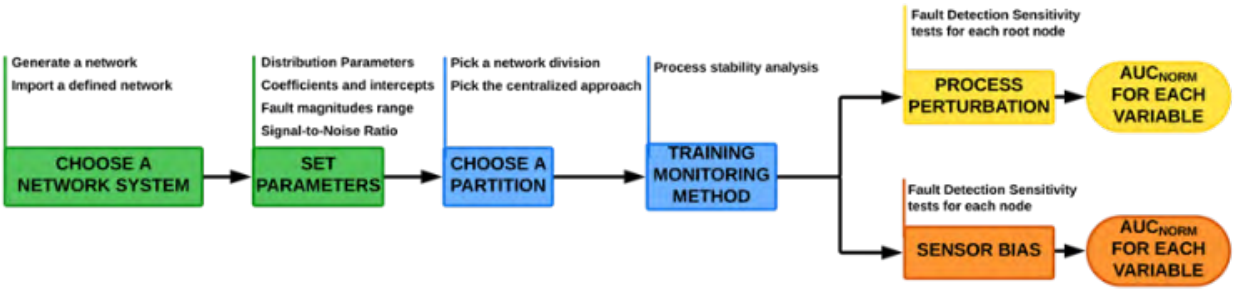

**Figure 2.** Workflow for Fault Detection Sensitivity evaluation.

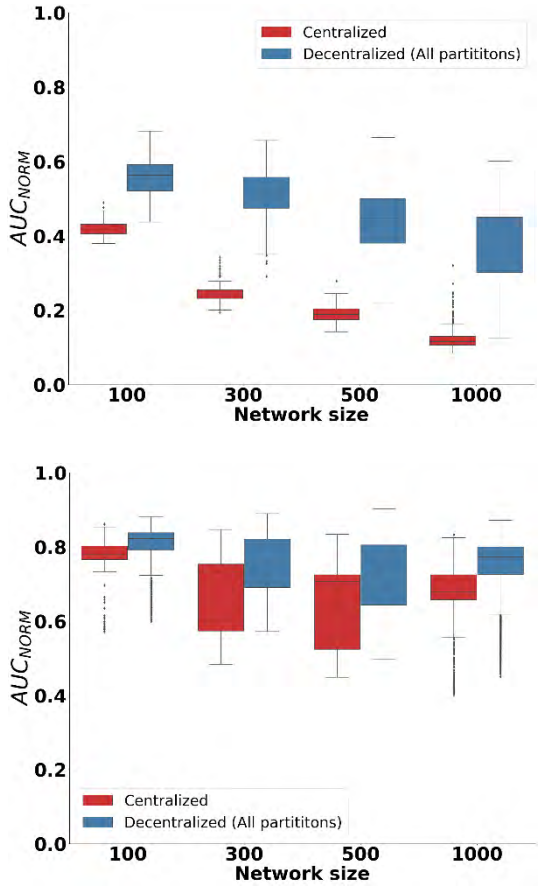

**Figure 3.** Comparison of $AUC_{NORM}$ metric distributions obtained with centralized and decentralized monitoring schemes across different network sizes for process perturbation (top) and sensor bias (bottom) faults. Box plots aggregate $AUC_{NORM}$ values over all faulty nodes and all partitions.

For each network size, six decentralized partitions are considered in addition to the centralized configuration. These partitions are selected to span a broad range of community sizes and modularity values, allowing a controlled analysis of the effect of the resolution parameter $\gamma$ on fault detection sensitivity. Table 4 summarizes the resulting network partitions, reporting the number of communities, modularity values, and the number of faulty variables considered for both Process Perturbation and Sensor Bias faults.

## RESULTS AND DISCUSSION

This section analyzes how network partitioning and topological descriptors impact fault detection sensitivity ($AUC_{NORM}$). Rather than focusing on absolute performance gains, the results aim to identify the structural factors that condition and drive fault detectability and that justify poor performances. Specifically, we show that fault detection is primarily governed by the size and number of communities, followed by internal and external connectivity, and finally by node-level causal factors.

Figure 3 compares the $AUC_{NORM}$ distributions obtained with centralized and decentralized monitoring approaches across all network sizes. For both fault types, centralized monitoring exhibits a clear degradation in fault detection sensitivity as network size increases. This behavior reflects the well-known loss of sensitivity to localized faults in high-dimensional scenarios. In contrast, decentralized monitoring consistently attenuates the $AUC_{NORM}$ degradation across all networks and partitions. The gain is more pronounced for process perturbation faults. Sensor bias faults also benefit from decentralization, although with a smaller relative improvement.

Figure 4 illustrates the relationship between $AUC_{NORM}$ and the *number of nodes in the community* containing the faulty variable for both fault types. A strong and consistent trend is observed, with fault detection sensitivity decreasing monotonically as community size increases. This relationship holds across fault types and network sizes, indicating that community size acts as a first-order control parameter for fault detectability.

Figure 5 explores the relationship between partition *modularity* and fault detection sensitivity for process perturbation faults. Contrary to common assumptions, higher modularity does not systematically lead to improved fault detection performance. In several

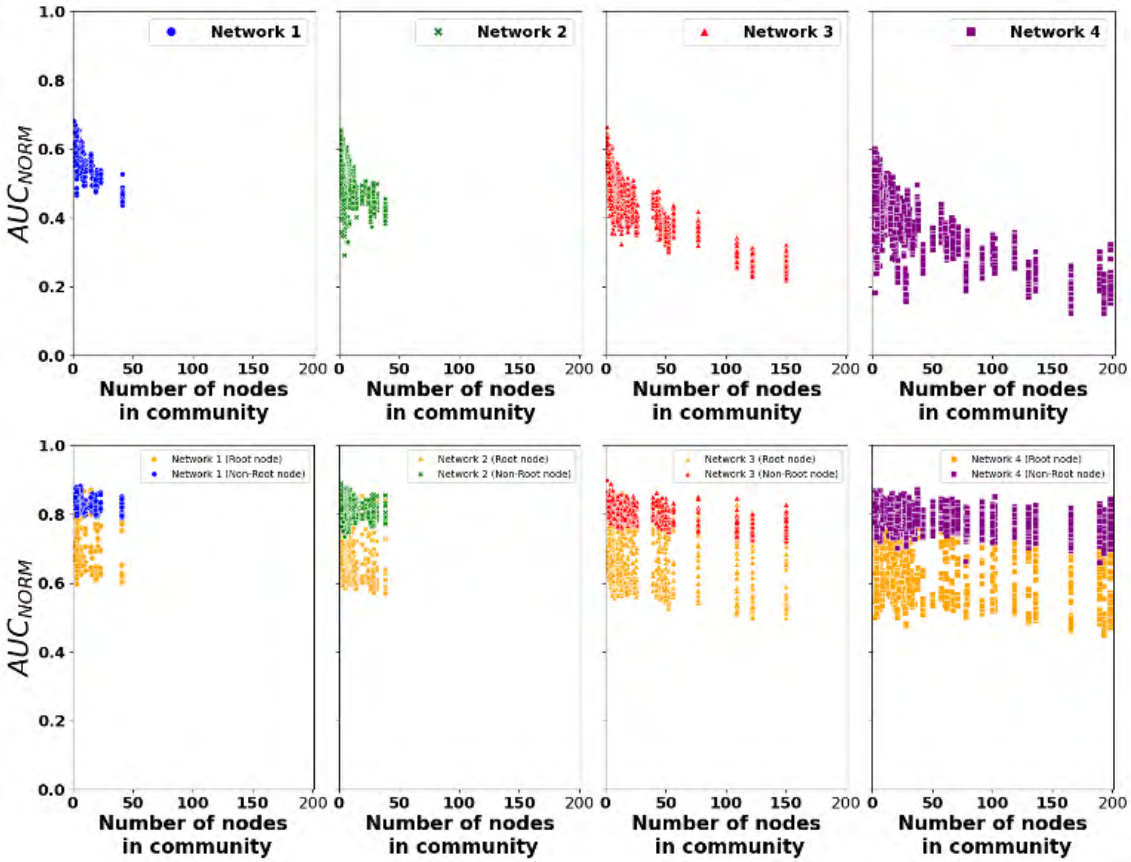

**Figure 4.** $AUC_{NORM}$ vs. Number of nodes in community containing the faulty node for process perturbation (top) and sensor bias (bottom) faults. Each point represents the $AUC_{NORM}$ for each faulty node.

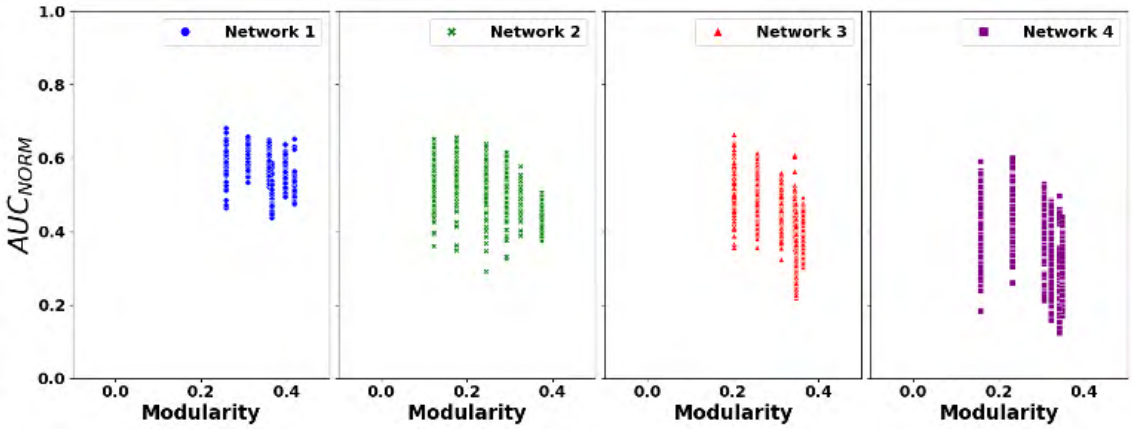

**Figure 5.** $AUC_{NORM}$ vs. Modularity of the tested partition for process perturbation faults.

regimes, partitions with higher modularity exhibit lower $AUC_{NORM}$ scores. This highlights the existence of an optimal range of modularity, that must be considered when establishing design principles for decentralized monitoring. Maximizing modularity alone may therefore yield structurally isolated communities that are suboptimal for monitoring. Sensor bias follows the same trend but is not present here due to space constraints.

The impact of internal community connectivity is analyzed in Figure 6, which relates $AUC_{NORM}$ to the *density* of the community containing the faulty node for process perturbation faults. Higher internal density is associated with increased fault detection sensitivity, indicating that dense communities better preserve the statistical dependencies. A similar qualitative trend was observed for sensor bias faults. These findings reinforce that effective

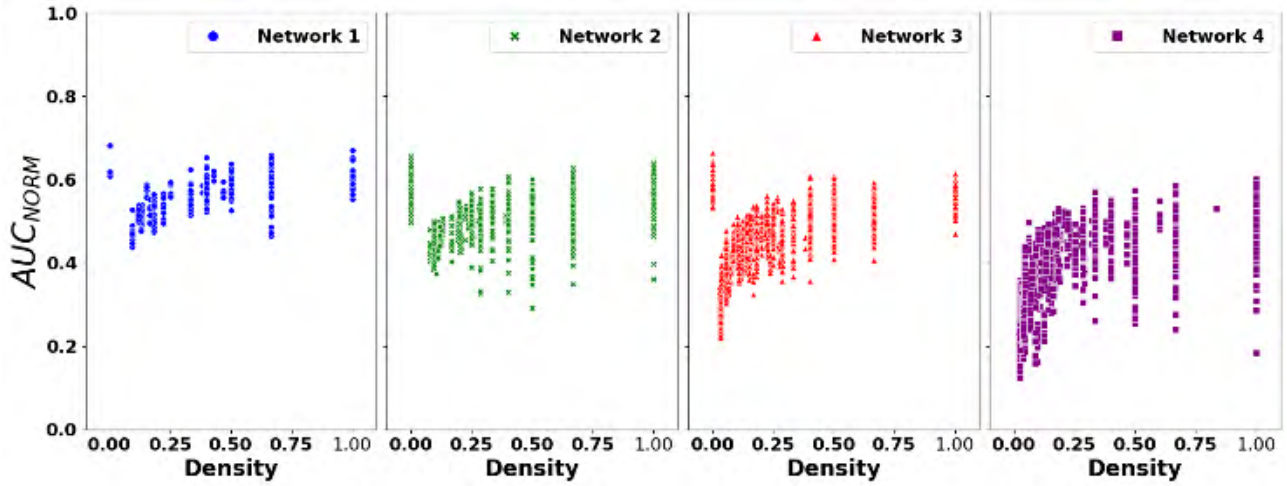

**Figure 6.** $AUC_{NORM}$ vs. Density in the community containing the faulty node for process perturbation faults.

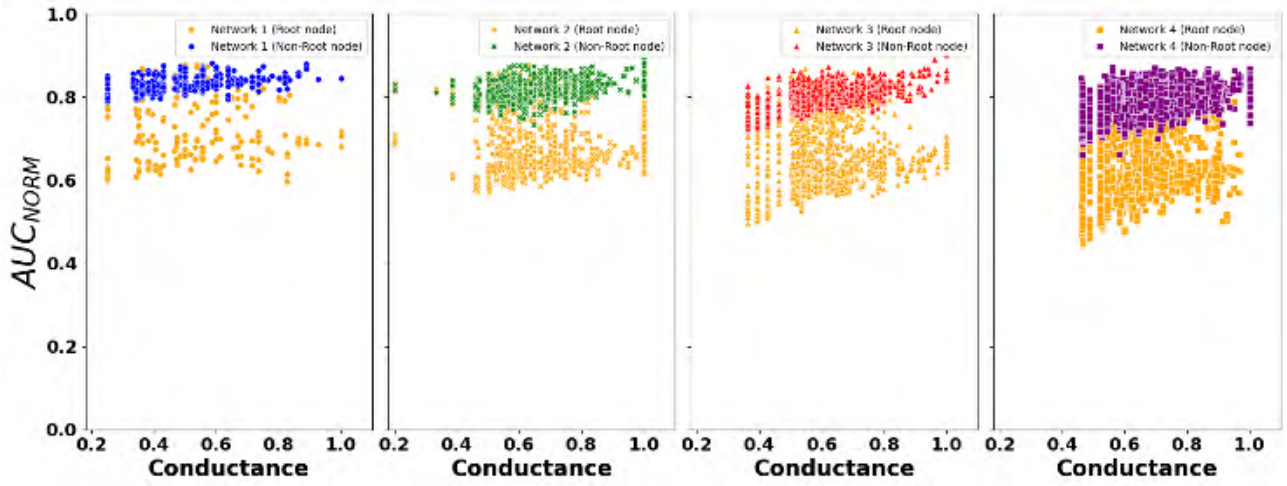

**Figure 7.** $AUC_{NORM}$ vs. Conductance in the community containing the faulty node for sensor bias faults.

decentralized monitoring requires a balance between dimensionality reduction and sufficient internal connectivity.

Figure 7 focuses on the role of *conductance* for sensor bias faults. Communities with low conductance, corresponding to communities well-isolated from the rest of the network, tend to exhibit lower $AUC_{NORM}$ values. Excessively isolated communities hinder the fault propagation, limiting the monitoring performance. It emphasizes that fault detection is not a purely local problem, but that an information exchange between communities is essential to preserve sensitivity. The same trend is observed in process perturbation faults.

Together, density and conductance reveal a fundamental trade-off: effective decentralized monitoring requires communities that are internally dense while remaining sufficiently coupled to the rest of the network to allow fault information to propagate.

In sensor bias faults, root-nodes lead to a broad range of $AUC_{NORM}$ values, indicating that topological descriptors alone are insufficient to fully explain fault detection performance. Figure 8 relates $AUC_{NORM}$ to the normalized causal strength ($\beta_{NORMALIZED}$) of the faulty node for sensor bias faults. Nodes with stronger causal influence on the network exhibit significantly higher detection sensitivity, even when community-level properties are comparable. This explains why purely topological descriptors fail to fully predict fault detectability and motivates the inclusion of causal metrics in topology-aware monitoring design.

Figure 9 presents an ablation study in which community-level information is selectively removed for a sensor bias fault affecting a representative node. Fault detection performance deteriorates sharply only when the community containing the faulty node is removed, while the exclusion of unrelated communities has a limited impact on sensitivity. For instance, in process perturbation faults, excluding up to 15 non-faulty communities

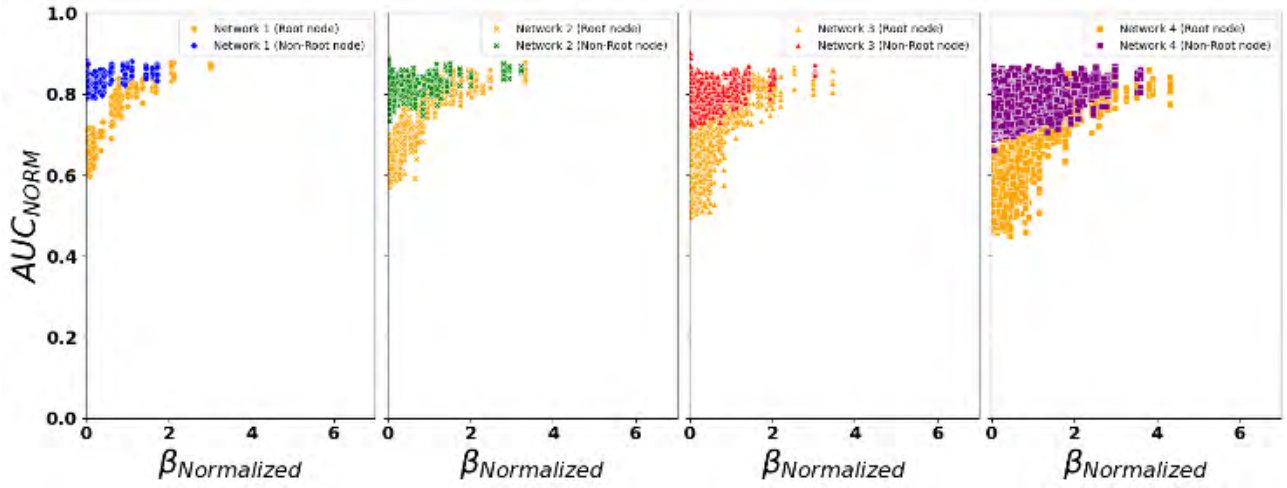

**Figure 8.** $AUC_{NORM}$ vs. Normalized Causal Strength ($\beta_{NORMALIZED}$)of the faulty node for sensor bias faults.

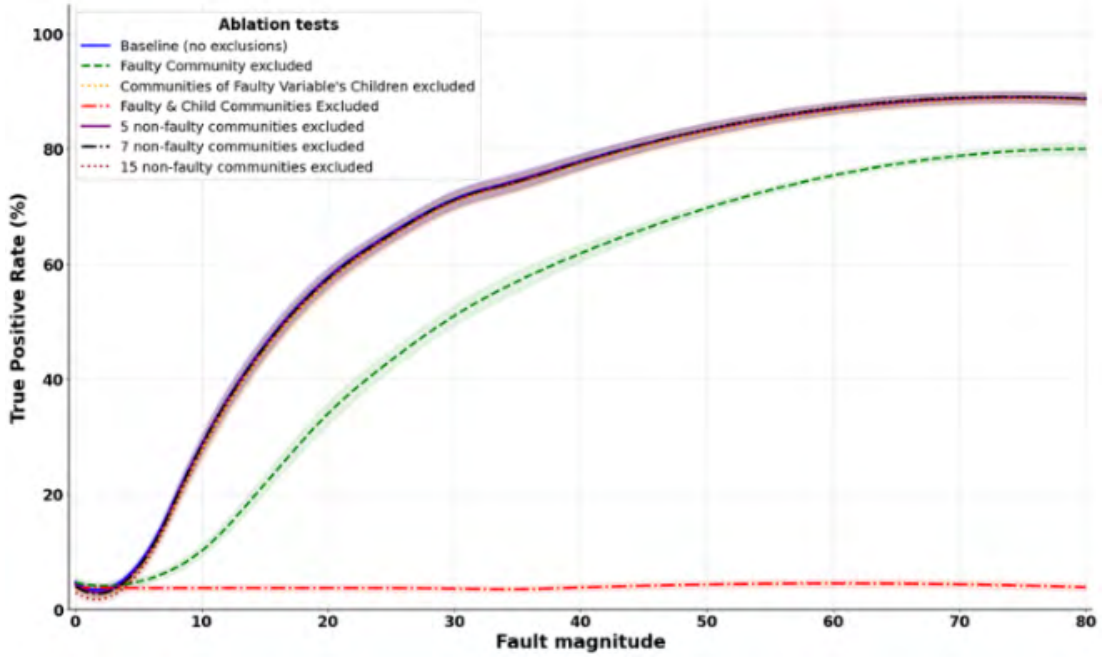

**Figure 9.** Median True Positive Rate vs Fault magnitude for sensor bias faults affecting node *X226* in Network 3, Partition #4, under different community-level information loss scenarios.

(representing over 32% of network communities) results in only marginal reductions in TPR at low fault magnitudes. This confirms that decentralized monitoring relies primarily on local causal information and is inherently robust to partial observability, a critical requirement for scalable industrial monitoring.

## CONCLUSIONS

This study solidly establishes that decentralized causal monitoring substantially enhances fault detection sensitivity in high-dimensional networks compared to centralized approaches. The improvement is statistically significant ($p < 0.00001$) for both process perturbation and sensor bias faults, confirming that network partitioning itself provides a robust mechanism for mitigating the well-known loss of sensitivity in large-scale systems.

Community size and the number of communities emerge as the primary determinants of fault detection: smaller communities preserve sensitivity by limiting aggregation dilution, whereas excessively large communities or overly modular partitions reduce performance. Other topological drivers include internal connectivity and inter-community metrics. Higher community density,

conductance, and separability consistently improve fault detection, while excessive isolation impairs fault detection sensitivity.

Node-level causal influence, quantified by the normalized causal strength ($\beta_{NORMALIZED}$), explains residual variability in the root nodes. For sensor bias faults, root nodes with $\beta_{NORMALIZED}$ < 1.6 exhibit markedly reduced sensitivity, whereas higher $\beta_{NORMALIZED}$ secure high sensitivity through residual propagation to descendants.

Ablation studies further confirm the robustness of decentralized monitoring. Fault detection relies primarily on the local community containing the faulty node. Minimal degradation is observed when unrelated communities, even up to 32% of the network, are removed. For sensor bias, only the simultaneous loss of the faulty community and all descendant communities eliminates fault detection capability, emphasizing the interplay between causal influence and community structure.

Altogether, these results show a range of quantitative design principles for decentralized industrial monitoring: *(i)* maintain community sizes of few nodes (10–25 nodes), *(ii)* balance internal density with moderate inter-community connectivity, *(iii)* avoid excessive modularity (>0.35) and cohesiveness (>0.4), and *(iv)* identify and specially monitor root nodes with weak causal influence.

These guidelines not only support practical implementation of decentralized monitoring but also provide mechanistic foundations for predictive models of fault detection sensitivity, enabling topology-aware, adaptive, and resilient monitoring architectures.

Future work will extend this framework to nonlinear and nonstationary systems, exploring and testing whether the same community-based and causal principles hold in more complex, real-world industrial networks.

## ABSTRACT

This work demonstrates the application of a pulsed microwave system for single-step co-production of ethylene and ammonia from methane. To mitigate inherent production fluctuations from pulsed microwave reactors, a staggered manifold configuration was utilized to stabilize effluent flow for industrial-scale compatibility. Dynamic validation of the ammonia and ethylene purification columns confirmed that a rigorously tuned control strategy effectively rejects ±10% feed disturbances while maintaining process stability and product purity. Ultimately, this systematic approach establishes a robust foundation for the sustainable, electrified production of foundational chemicals by bridging the gap between laboratory-scale pulsing phenomena and industrial-scale operational reliability.

**Keywords**: Process Control, Ethylene, Aspen Dynamics

## INTRODUCTION

Ethylene ($C_2H_4$) is a simple, flammable, colorless, and highly reactive hydrocarbon containing a carbon–carbon double bond, which makes it the smallest and most important alkene. As one of the most widely produced organic chemicals, it is a foundational building block of the petrochemical industry and a crucial feedstock for manufacturing polyethylene plastics, ethanol, ethylene oxide, ethylene glycol, and vinyl chloride [1]. Ammonia ($NH_3$) is a colorless gas with a pungent odor, composed of one nitrogen atom bonded to three hydrogen atoms, with a boiling point of approximately −33°C at ambient pressure. It is highly soluble in water, forming ammonium hydroxide ($NH_4OH$), a weak base, and is a critically important industrial chemical with diverse applications across agriculture, energy, and industrial sectors [2]. Globally, more than 80% of ammonia production is used for nitrogen-based fertilizers such as urea, ammonium nitrate, and ammonium sulfate, which are essential for sustainable agricultural productivity, while additional applications include refrigeration systems, cleaning agents, and emerging roles as a hydrogen carrier for carbon-free energy storage, transportation, and fuel use [2]. Ethylene production currently tops 200 million metric tons annually, fueling a market exceeding $180 billion. This growth is sustained by a 4.1% rise in demand and a 6.2% increase in production capacity, largely propelled by the global requirement for plastics and consumer products [3]. In a similar vein, global ammonia output has surpassed 180 million metric tons per year, anchoring a fertilizer market valued at more than $100 billion while simultaneously representing nearly 2% of total global energy consumption [4]. The production of ethylene and ammonia represents the backbone of the modern chemical industry, though traditional methods remain significantly energy-intensive and carbon-heavy due to their reliance on high-temperature, endothermic reactions.

Microwave (MW) reactor technology represents a sophisticated process-intensification strategy that aligns with the global shift toward chemical process electrification as a replacement for traditional thermal heating [5]. By leveraging microwave catalysis, it is possible to simultaneously activate the highly stable $CH_4$ and $N_2$ molecules, enabling the direct co-production of ammonia and ethylene within a single reactor step [6]. This technology

not only enhances energy efficiency and reduces $CO_2$ emissions by selectively heating the catalyst surface but also introduces operational flexibility through pulsed microwave energy. By deploying microwave reactor technology, it is possible to operate the reactor at two different temperature modes by pulsing the microwave power in periodic intervals. Under microwave power-on mode (heating), an endothermic reaction to produce ethylene can take place whereas under the microwave power-off mode (quenching), an exothermic reaction to produce ammonia can occur.

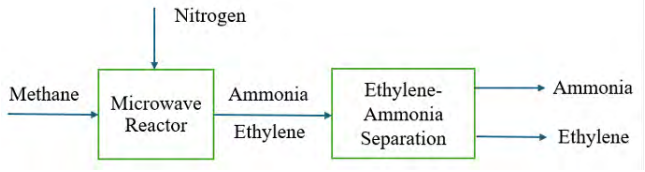

**Figure 1.** Block flow diagram of the simultaneous production of ethylene and ammonia.

The reactor outlet streams are combined and sent to the distillation column train for separation. During plant operation, due to switching between power on and power off modes in the two microwave reactors, the reactor outlets will not be steady. This fluctuation in the flowrate to the distillation column train leads to an inherently dynamic operation and hence it is necessary to design a control system for the separation section that keeps the quality of the products ethylene and ammonia at the desired levels. Based on the concept in Figure 1, a plant-wide steady-state model was constructed and subsequently converted into a dynamic model using Aspen Plus Dynamics. This model integrates a base control strategy consisting of tuned PID loops and parameters to provide a robust foundation for industrial-scale process simulations.

It was recently shown by our group that producing ethylene via novel microwave (MW) technology is economically competitive, with a levelized cost of USD 0.51/kg compared to USD 0.56/kg for conventional methods [7]. While a formal technoeconomic analysis (TEA) for the simultaneous production of ethylene and ammonia is not part of this study, this integrated process has the potential to achieve higher net present value (NPV) than standalone ethylene production since the hydrogen required for ammonia production is produced in the ethylene reaction cycle.

## MICROWAVE REACTOR DESIGN ISSUES

Conventional processes to produce ethylene mostly operate at equilibrium conditions with a continuous heating process to supply the heat requirement for the reaction conditions. But a pulsed microwave heating process is a non-equilibrium process that has the potential to switch between exothermic and endothermic reactions together for simultaneous production of two commodity chemicals. In the pulsing process, the power-on mode (heating) favors endothermic reactions, and the power-off mode (quenching) favors exothermic reactions. The main reactions involved are as follows:

$$2CH_4 \rightarrow C_2H_4 + 2H_2 \text{ (endothermic, 500-700°C)}$$

$$3H_2 + N_2 \rightarrow 2NH_3 \text{ (exothermic, 250-400°C)}$$

As shown experimentally in Rahman et al. [7], small quantities of additional compounds such as acetylene, ethane, carbon dioxide, benzene, and toluene are also produced via side reactions, which need to separated from the main products via a train of distillation columns. The methane coupling reaction produces ethylene and hydrogen comparatively at higher temperature range (500-700°C) in power-on mode. The produced hydrogen reacts with nitrogen at lower temperature (250-400°C) to produce ammonia in the power-off mode. The transition from laboratory-scale pulsed microwave (MW) reactors to industrial-scale production introduces significant complexities in reactor design and process control, primarily due to the inherent fluctuations in product flow that alternately produce ethylene and ammonia. In a continuous industrial facility, equipment such as compressors, separation columns, and heat exchangers is designed for steady-state flows. Rapid fluctuations in mass flow can lead to severe pressure surges, thermal cycling fatigue, and significant challenges in maintaining product purity within distillation sumps. To rectify these fluctuations and stabilize the production rate, a process intensification strategy involving a series of MW reactors operating in a staggered, out-of-phase configuration must be implemented. By coordinating the pulsing intervals of multiple reactors, the peak production of one unit can compensate for the quenching phase of another, effectively dampening the oscillation and delivering a more consistent feed to the downstream processes. Despite this staggered operation, the outlet of the microwave reactor train can fluctuate up to ±10% and it is necessary to develop a control system for the separation train to work effectively despite this fluctuation.

## METHODOLOGICAL FRAMEWORK

A systematic approach was adopted integrating steady-state modeling, dynamic simulation, and advanced process control. Initially, steady-state benchmarks for the intensified microwave-assisted routes were developed in Aspen Plus v14.0 using the NRTL property model [7]. This thermodynamic selection is critical to accurately account for the highly non-ideal liquid-

phase activity coefficients of ammonia within the complex hydrocarbon and light-gas matrix. The outlet of the microwave reactor train has the composition of methane, ethylene, hydrogen, nitrogen, ammonia, acetylene, ethane, carbon dioxide, benzene, and toluene that were determined experimentally and fluctuates with microwave pulsing [5, 6, 7]. Then, a dynamic model in Aspen Plus Dynamics (APDs) v14, was constructed for the separation train based on the steady-state process model [8]. During this stage, all equipment in the process were appropriately sized. Building upon the steady-state architecture, a high-fidelity dynamic model was developed in Aspen Plus Dynamics (APD) v14.0, where all unit operations were sized based on established literature [7, 8]. This phase included the implementation of a foundational control layer and the rigorous fine-tuning of control parameters to achieve optimal response characteristics across diverse operational transients. To validate the model's reliability, it was subjected to extensive disturbance testing, specifically focusing on variations in feed flow rates and compositions [8]. The effectiveness of this control strategy was verified through robustness evaluations under dynamic scenarios, demonstrating a consistent ability to preserve optimal operating conditions.

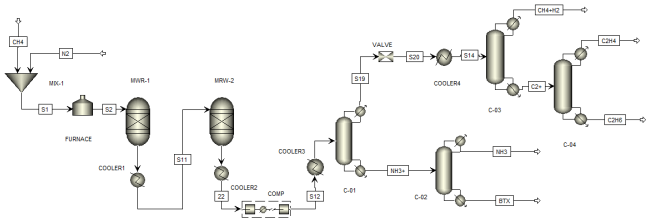

**Figure 2.** Process Flow Diagram of Microwave Assisted Process to Convert Methane to Ethylene and Ammonia.

Figure 2 illustrates the process flow diagram (PFD) that produces ethylene and ammonia simultaneously. In this industrial-scale simulation, a feed stream of methane and nitrogen is initially processed in a yield reactor at 600°C to facilitate co-production. To prevent ammonia decomposition, the effluent is immediately quenched to 280°C before entering a secondary hydrogenation reactor, which operates at the same temperature to convert byproduct acetylene into ethylene, thereby enhancing overall yield. The resulting stream is pressurized to 15 bar via a multistage compressor and fed into the first distillation column (C_01), operating at -15°C and 15 bar. The ammonia-rich bottom stream from C_01 is directed to a purification column (C_02) operating at 39°C and 15 bar to recover high-purity ammonia. On the other hand, the ethylene and methane-rich overhead stream is processed through two subsequent distillation columns (C_03 and C_04) for ethylene purification, following the same separation technique by Rahman et al [7]. A buffer tank to smooth out the reactor outlet fluctuations created by pulsing was not considered primarily because gas-phase streams are highly compressible and occupy large volumes, making physical storage for stabilization both economically and spatially impractical. To evaluate the direct conversion efficiency of the microwave-assisted process, no recycle streams were utilized in this study. Under these conditions, a methane feed of 2500 kg/h successfully yielded 2122 kg/h of ethylene and 955 kg/h of ammonia, both achieving a 99.9% purity level. The rigorous design specifications for the entire four-column separation train are summarized in Table 1.

A dynamic model was developed to account for the fluctuations in the reactor outlet stream. In this simulation, the physical dimensions of the unit operations were established using industry-scale design principles. Distillation column heights were calculated through established heuristics and relevant correlations, while diameters were determined based on estimated flooding velocities to ensure operational stability [8]. Following the completion of equipment sizing, the validated steady-state simulation model was transitioned into a dynamic framework using Aspen Plus Dynamics V14 [8]. To ensure operational stability and robust disturbance rejection, a plant-wide control structure was implemented. This strategy integrates conventional regulatory loops with advanced regulatory schemes, where all controller parameters were optimized using the Tyreus–Luyben autotune variation (ATV) method adjusting the controller's gain ($K_C$) integral time constant ($\tau_I$) and derivative time constant ($\tau_D$) [9]. As illustrated in Figure 3, each distillation column implements a standard control configuration, including top pressure control, reflux drum level control,

and sump level control. For column C_01, condenser temperature is regulated through utility flow adjustment, the reflux drum level is controlled via reflux flow manipulation, and the bottom-stage temperature is maintained by varying the reboiler duty. Additionally, a sump level is controlled by applying a sump level controller at the bottom. An identical control philosophy is implemented for the remaining columns (C_02, C_03, and C_04).

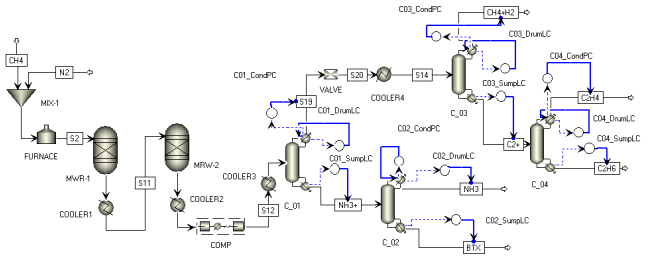

**Figure 3.** Plant wide control strategy for simultaneous ammonia and ethylene production.

## RESULTS AND DISCUSSION

This study evaluates the dynamic performance and controller structure of the ammonia (C_02) and ethylene (C_04) purification columns to ensure process stability during simultaneous production. Given the fluctuating nature of the upstream pulsed microwave reactor effluent, achieving a robust control response in the separation train is critical for maintaining product purity and operational safety.

The initial controller response of column C_02 & C_04 exhibited significant oscillations and sluggish stabilization in both the reflux drum (C_02DrumLC) and the column sump (C_02SumpLC) levels. As shown in Figure 4, the mass flow rates and temperatures showed substantial deviations before reaching a settled state. To mitigate process instability, a rigorous tuning phase was conducted. The controller outputs were optimized to aggressively dampen oscillations, primarily utilizing Proportional-Integral (PI) control structures. The controller gains $K_C$ and $\tau_I$ were evaluated using the Tyreus–Luyben ATV method. Table 2 summarizes the optimized parameters for the reflux drum and sump level controllers for both purification columns.

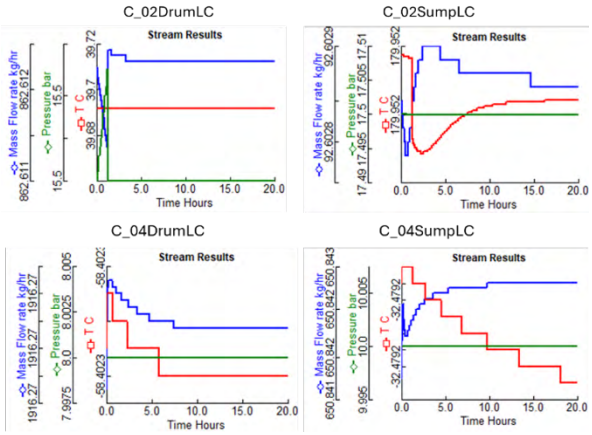

**Figure 4.** Controller response of ammonia and ethylene purification column (C_02 & C_04) before tuning.

| C_04 (Ethylene) | Reflux Drum | 46.35 | 3.96 |
| | Sump | 25.67 | 2.64 |

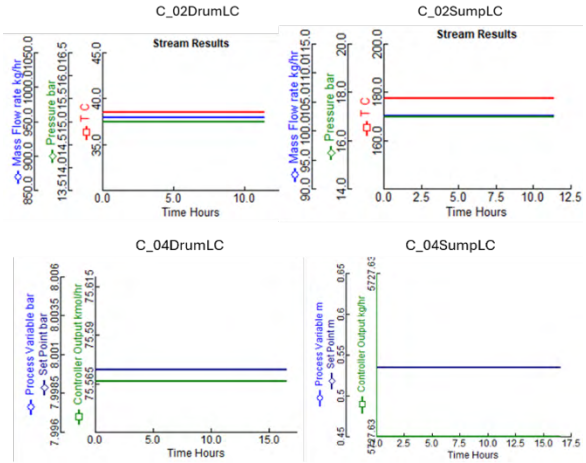

**Figure 5.** Controller response of ammonia and ethylene purification column (C_02 & C_04) after tuning.

Figure 5 shows that both the drum and sump levels reached their respective setpoints with minimal overshoot and zero steady-state error. This stable baseline is essential for the intensified process, as it ensures that the energy-intensive separation of ammonia and ethylene from the hydrocarbon matrix remains consistent despite the inherent transients of the microwave-assisted route

## Controller Performance Analysis

To validate the reliability of the established control strategy, the column was subjected to step changes of ±10% in the feed flow rate. As illustrated in Figure 6, the C_02 control system effectively rejected these disturbances with minimal deviation. Upon a +10% increase in feed, the condenser and reboiler duties adjusted dynamically to stabilize inventory levels, reaching a new steady state shortly after the onset of the disturbance. This transition resulted in a proportional impact on the top and bottom product flow rates, directly reflecting the change in feed throughput. Similarly, the -10% feed variation demonstrated a smooth transition in both the top and bottom product flow rates. This robustness confirms that the integrated control layer can effectively manage process fluctuations while maintaining product quality and system stability.

To verify the reliability of the control strategy for the C_04 column, the system was tested with ±10% step changes in the feed flow rate. As shown in Figure 7, the control loops successfully rejected these disturbances, keeping all process variables stable. When the feed increased by 10%, the reboiler and condenser duties adjusted automatically to maintain the liquid inventory in the sump and reflux drum. This allowed the system to reach a new steady state shortly after the change, with the top and bottom product flow rates increasing to match the higher throughput. A similarly smooth transition occurred during the -10% feed reduction, where the system adjusted to a lower-load operating point without any instability. These results confirm that the integrated control layer effectively preserves column stability and product purity, even under the fluctuating conditions typical of electrified processes.

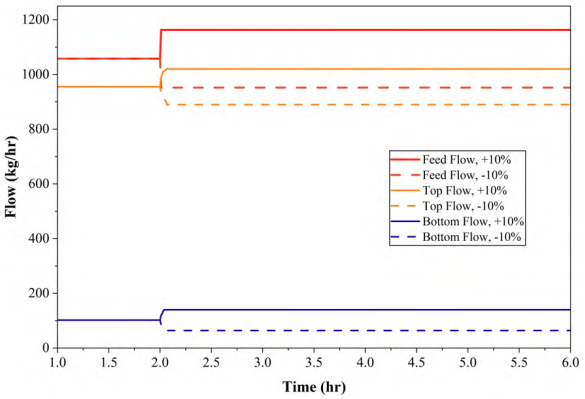

**Figure 6.** Controller response of the ammonia purification column (C_02) to a ±10% step change in feed flow rate

## Controller Sensitivity Matrix for Ammonia Purification Column

Table 3 and corresponding Figure 8 illustrate a parametric sensitivity analysis of the ammonia (C_02) purification column, where Case-1 (Optimized TL-ATV) serves as the performance benchmark. In the dynamic simulation graphs, Case-1 is presented as the most efficient response, that returns the reflux and sump levels to their setpoints with the shortest settling time and minimal overshoot. In contrast, the low-gain scenarios (Case-2 and Case-5) appear on the graph as sluggish, long-duration curves; because a $K_C$ of 5 lacks the proportional response to move control valves decisively, these cases take significantly more time to stabilize and allow for large deviations from the setpoint. On the other hand, the high-gain scenarios (Case-3 and Case-4) demonstrate better response compared to case-2 and case-5.

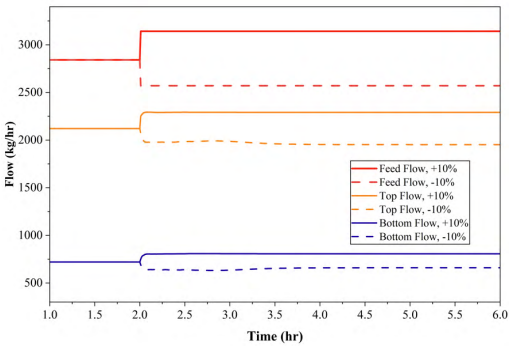

**Figure 7.** Controller response of the ethylene purification column (C_02) to a ±10% step change in feed flow rate

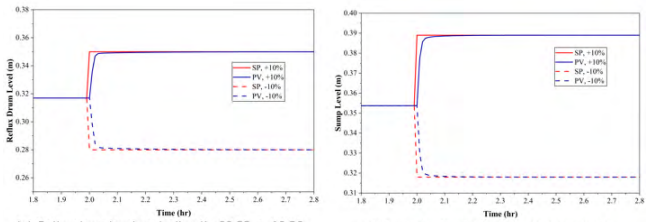
**Table 3.** Controller Sensitivity Matrix for Ammonia Column (C_02)

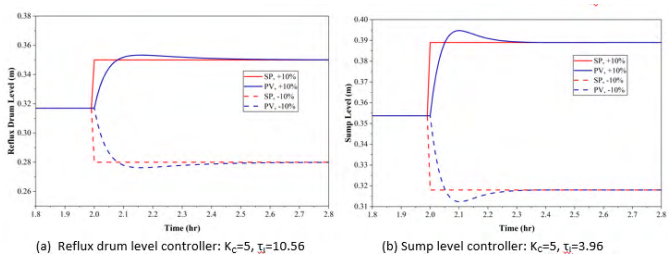
| test Case | reflux drum Level ($K_C$, $\tau_I$) | sump level ($K_C$, $\tau_I$) |
|---|---|---|
| case-1: optimized (TL-ATV) | $K_C$ = 32.55, $\tau_I$ =10.56 | $K_C$ = 24.73, $\tau_I$ = 3.96 |
| case-2: low gain / fast reset | $K_C$ = 5, $\tau_I$ = 10.56 | $K_C$ = 5, $\tau_I$ = 3.96 |
| case-3: high gain / fast reset | $K_C$ = 60, $\tau_I$ = 10.56 | $K_C$ = 60, $\tau_I$ = 3.96 |
| case-4: high gain / Slow Reset | $K_C$ = 60, $\tau_I$ = 60 | $K_C$ = 60, $\tau_I$ = 60 |
| case-5: low gain / slow reset | $K_C$ = 5, $\tau_I$ = 60 | $K_C$ = 5, $\tau_I$ = 60 |

case-1



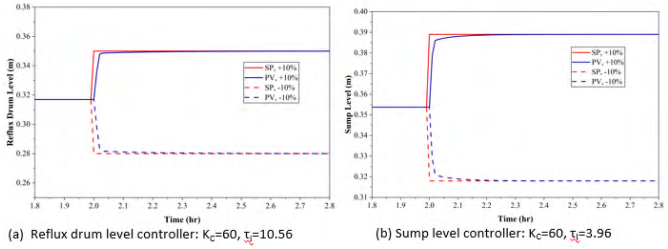
(a) Reflux drum level controller: $K_c$=32.55, $\tau_I$=10.56 (b) Sump level controller: $K_c$=24.73, $\tau_I$=3.96

case-2



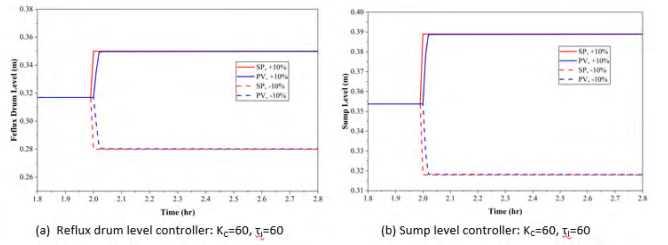
(a) Reflux drum level controller: $K_c$=5, $\tau_I$=10.56 (b) Sump level controller: $K_c$=5, $\tau_I$=3.96

case-3



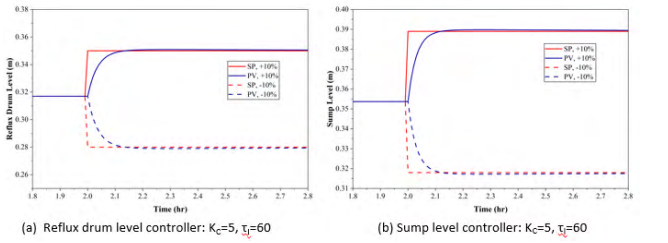
(a) Reflux drum level controller: $K_c$=60, $\tau_I$=10.56 (b) Sump level controller: $K_c$=60, $\tau_I$=3.96

case-4



(a) Reflux drum level controller: $K_c$=60, $\tau_I$=60 (b) Sump level controller: $K_c$=60, $\tau_I$=60

case-5



(a) Reflux drum level controller: $K_c$=5, $\tau_I$=60 (b) Sump level controller: $K_c$=5, $\tau_I$=60

**Figure 8.** Controller response of ammonia column (C_02)

## Controller Sensitivity Matrix for Ethylene Purification Column

Table 4 and the corresponding Figure 9 illustrate the parametric sensitivity analysis for the ethylene purification column (C_04), where Case-1 (Optimized TL-ATV) consistently serves as the most efficient performance benchmark.

In the dynamic simulation graphs, Case-1 demonstrates the superior control response, characterized by high proportional gain and tight integral times ($\tau_I$ = 3.96 and 2.64) that restore the reflux and sump levels to their setpoints with the shortest settling time and minimal overshoot. In contrast, the low-gain scenarios (Case-2 and Case-5) appear as sluggish, long-duration curves; because a $K_C$ of 5 lacks the proportional magnitude to drive the control valves effectively, these cases result in significantly prolonged stabilization periods and allow for large deviations from the setpoint. While the high-gain scenarios (Case-3 and Case-4) demonstrate a more robust initial response compared to the low-gain cases.

## CONCLUSIONS

This study presents a comprehensive framework for the electrification of commodity chemical manufacturing by integrating steady-state and high-fidelity dynamic modeling to identify and rectify the associated challenges. The work successfully demonstrates a single-step co-production pathway that leverages microwave-assisted technology to simultaneously activate stable methane and nitrogen molecules for ethylene and ammonia synthesis. To address the inherent production fluctuations of pulsed microwave reactors, the study highlights a staggered manifold configuration to stabilize effluent flow, ensuring compatibility with industrial-scale downstream operations. Dynamic validation exemplified by the ammonia and ethylene purification column (C_02 & C_04) confirmed that a rigorously tuned control strategy can effectively reject ±10% feed disturbances while maintaining process stability and product purity. Ultimately, this systematic approach bridges the gap between laboratory-scale phenomena and industrial-scale operational reliability, establishing a robust foundation for the sustainable, electrified production of foundational chemicals

## ABSTRACT

A safety-intelligent framework is presented for developing a multiple-input multiple-output (MIMO) risk-based explicit model predictive control (R-eMPC) for metal hydride storage systems (MHSS). These systems are susceptible to thermal runaway during the charging process as a result of the exothermic adsorption reaction within the metal alloy. To address this issue, deterministic and stochastic safety-intelligent control algorithms are designed and implemented by explicitly embedding a dynamic risk index (RI) or risk tolerance ($\alpha$) into the control law and decision-making. In closed-loop analysis, the deterministic R-eMPC regulates both core temperature and hydrogen storage capacity by forecasting fault occurrence, triggering alarms, and reducing the risk index by adjusting the optimal control actions, supply pressure and water flowrate. Meanwhile, the stochastic R-eMPC accounts for uncertainties in core temperature variation by incorporating risk tolerance through chance-constraints. When the temperature exceeds the strict operational limit, stochastic R-eMPC enables continued operation beyond conservative safety boundaries via dynamic updated probabilistic limits. Closed-loop responses demonstrate that the safety-intelligent controllers effectively minimize evolving thermal risks while maximizing storage capacity during charging operation of the MHSS. Overall, the risk-based controllers improve both safety and charging performance, demonstrating the potential of the proposed framework for real-time, safety-intelligent operation of metal hydride systems.

**Keywords**: hydrogen, metal hydrides, model predictive control, process safety, multi-parametric programming, cyber-physical system

## INTRODUCTION

Chemical and energy processes undergo different types of reactions, such as exothermic and endothermic reactions, during operation. When these reactions become uncontrollable, they can cause runaway incidents, leading to catastrophic damages such as fires or explosions, resulting in serious process safety issues [1]. Therefore, it is critical that reactive processes are properly monitored and controlled. However, most existing process control systems do not explicitly incorporate holistic safety metrics, instead treating safety through separate supervisory layers.

Hydrogen energy systems, encompassing production, storage, and utilization are inherently susceptible to hazardous events. Hydrogen storage represents a major safety bottleneck due to high energy density and reactive nature of hydrogen. Solid-state hydrogen storage using metal hydrides has attracted significant attention for fuel cell electric vehicles (FCEVs) because it can store hydrogen at relatively low pressures [2]. However, charging or adsorption process of metal hydride storage system (MHSS) is exothermic, where significant amount of heat is released, leading to rapid temperature rise. The reaction can be expressed in Eq. (1).

$$M + \frac{x}{2}H_2 \leftrightarrow MH_x + \Delta H \quad (1)$$

where $M$ is metal alloy, $H_2$ is hydrogen gas, $MH_x$ is metal hydride formation, and $\Delta H$ is heat of enthalpy.

In transportation application, the US Department of Energy (US DOE) specifies that the operating temperature of hydrogen storage should remain within between 233 K to 358 K [3]. Exceeding this temperature window may degrade system performance or compromise safety. Consequently, effective thermal management and control strategies are essential for MHSS.

Ali et al. [4] introduced a deterministic risk-based explicit MPC (R-eMPC) in which dynamic risk modeling as a function of a safety-critical variable was embedded in the control optimization. The R-eMPC was able to trigger the alarm system ahead of time to ensure enough time for the operators to shut down the system before any safety events occur. Akundi et al. [5] extended the safety-control theory by explicitly accounting for uncertainties by using Bayesian inference techniques and chance-constraints programming. In this study, the controller is allowed to be able to operate by exceeding the safety limit, thereby providing more flexibility in the presence of uncertainties. More recently, Liu et al. [6, 7] demonstrated the applicability of both online risk-based MPC and offline R-eMPC in a cyber-physical system of proton exchange membrane water electrolysis (PEMWE). The dynamic risk index was shown to effectively quantify evolving thermal risk and support real-time safety-aware operation.

Despite these advances, risk-based explicit MPCs have not yet been developed or validated for metal hydride hydrogen system (MHSS), where strongly exothermic reactions and strict thermal limits pose significant runaway risks. Hence, this study aims to develop a safety-intelligent control framework using deterministic and stochastic risk-based R-eMPC for MHSS, with particular emphasis on charging operation, while maintaining applicability to discharging operation and addressing the trade-offs between safety and performance.

## METAL HYDRIDE STORAGE SYSTEM

This study focuses on metal hydride storage system (MHSS) to store hydrogen gas. Figure 1 demonstrates the schematic diagram of the charging process in MHSS with the metal hydride reactor, water tank, and process instrumentations. This analysis follows the schematic for modeling and simulation of the charging (adsorption) process, in which hydrogen gas is supplied from an external source, e.g. water electrolysis or refueling station. Since the reaction is exothermic and releases significant amount of heat, thermal management is incorporated through water supply is embedded in this system. Further, accurate modeling and real-time control implementation are crucial to ensure both safety and performance of the MHSS.

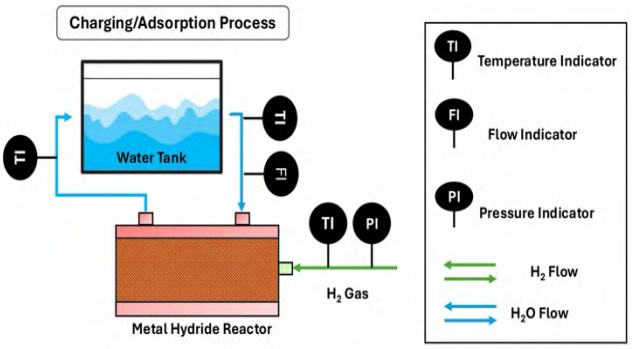

**Figure 1.** Schematic diagram of charging operation of metal hydride storage system.

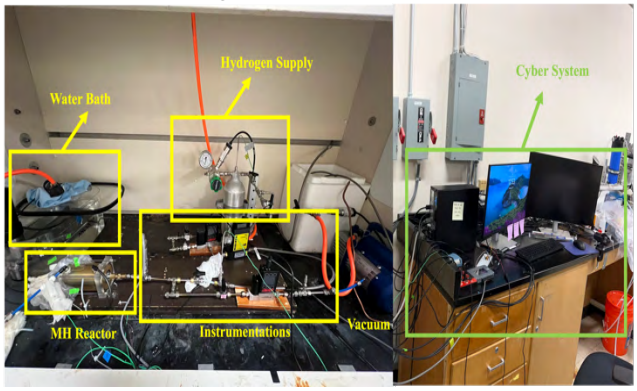

**Figure 2.** Experimental setup of metal hydride storage system.

## High-Fidelity Model

The metal hydride storage model is developed using first-principles based on thermodynamics, reaction kinetics, and heat transfer mechanisms [8, 9, 10]. The governing equations are presented in Eqs. (2)-(10). These equations capture the coupled behavior of hydrogen uptake, reaction heat generation, and heat exchange between the metal hydride bed, reactor wall, and cooling medium.

$$\frac{dm_{H2,g}}{dt} = f_{in,H2} - rm_s \frac{MW_{H2}SC}{MW_{MH}} \tag{2}$$

$$m_{MH} = rm_{solid} \tag{3}$$

$$\left(m_{H2,g}C_{p,H2} + m_s C_{p,s}\right)\frac{dT_{MH}}{dt} = Q - \Delta H_a r_{ms}\frac{SC}{MW_{MH}} \tag{4}$$

$$r = C_a e^{-\frac{Ea}{RT}} \ln\left(\frac{Pa}{Peq}\right)\left(1 - \frac{m_{MH}}{m_s}\right) \tag{5}$$

$$P_{eq} = e^{\left(\frac{\Delta Ha}{RT} - \frac{\Delta Sa}{R} + 0.5\left(\pi\left(\frac{m_{MH}}{m_s} - 0.5\right)\right) + 0.1\right)} P_0 \tag{6}$$

$$m_{wall}C_{p,wall}\frac{dT_{wall}}{dt} = -h_{wall}A_{wall}(T_{wall} - T_{MH}) + Q \tag{7}$$

$$Q = f_{H2O}C_{p,H2O}\left(T_{H_2O,in} - T_{wall}\right) \tag{8}$$

$$v_j \rho_{H2O} C_{p,H2O} \frac{dT_{H2O,out}}{dt} = f_{H2O} C_{p,H2O} (T_{H_2O,in} - T_{H2O,out}) - Q \quad (9)$$

$$m_{H2,g} = \frac{PV_g}{RT} MW_{H2} \quad (10)$$

## Cyber-Physical System

The experimental setup of the metal hydride storage system (MHSS) is illustrated in Figure 2. It consists of several integrated units, including a hydrogen supply (canister tank), metal hydride reactor, water bath, and associated process instrumentation. The system also incorporates a computer, data acquisition hardware, and a microcontroller to enable real-time data exchange and signal processing between the physical and cyber layers.

The cyber component primarily comprises the software and control algorithms used for monitoring, decision-making, and supervisory control. In this work, LabVIEW is employed for real-time data acquisition, signal conditioning, visualization, system identification, control implementation, and alarm monitoring. Measured process variables are continuously communicated to the control layer, where safety-intelligent control actions are computed and transmitted back to the physical system for real-time operation.

# SAFETY-INTELLIGENT CYBER-PHYSICAL CONTROL ARCHITECTURE

For designing the safety-intelligent control strategies, this work adapts the PAROC framework [11] for both modeling and simulation and experimention. Figure 3 presents the framework on implementation of control strategies in cyber-physical system.

First, the system is modeled to capture its dynamic behavior under open-loop simulations. These simulations enable the a *priori* identification of potential safety events, such as thermal runaway, overpressurization, or fuel starvation, before conducting any physical experiments. The high-fidelity model is developed in Siemens Process Academics (Research). Subsequently, a cyber-physical system is developed by integrating both the experimental and cyber setups. The experimental component is designed based on a process and instrumentation diagram (P&ID) or a process flow diagram (PFD). The cyber component consists of a human–machine interface implemented using a customized LabVIEW platform, data acquisition for communication and data exchange, and a microcontroller for real-time control and operation.

Using the outputs and inputs of the open-loop data, a linear or surrogate model is derived using techniques such as system identification, model reduction, machine learning, or Jacobian-based linearization [12, 13, 14]. This linearized model then serves as the basis for designing safety-intelligent explicit model predictive control (MPC) strategies.

The formulations of deterministic and stochastic risk-based explicit MPC (R-eMPC) are presented in Eqs. (11)-(18) and Eqs. (19)-(26), respectively. The objective function aims to minimize the deviations in system outputs (*y*) from their corresponding setpoints, while simultaneously penalizing control efforts of the inputs (*u*). Eqs. (11) and (19) defines the weights for outputs and inputs matrices, *QR* and *R*, and output horizon (*OH*) and control horizon (*CH*), where *k* denotes the discrete timestep in seconds. The state-spaced models are given in Eqs. (12)-(13) and (20)-(21), where *x* represents state vector and *A, B, C,* and *D* are the system matrices. For the charging operation of the metal hydride, the outputs (*y*) correspond to the core temperature and hydrogen adsorbed capacity while inputs (*u*) are supply pressure and water flowrate.

Within the deterministic R-eMPC, dynamic risk assessment is conducted to compute a risk index, *RI*, which is defined as the product of event probability and severity as shown in Eq. (15). The resulting *RI* can be expressed as a function of safety-critical variable, enabling the controller to evaluate the safety level of the system during operation. Based on this assessment, R-eMPC mitigates risk propagation speed and severity, or raise the alarm when runaway reactions cannot be prevented during the operation.

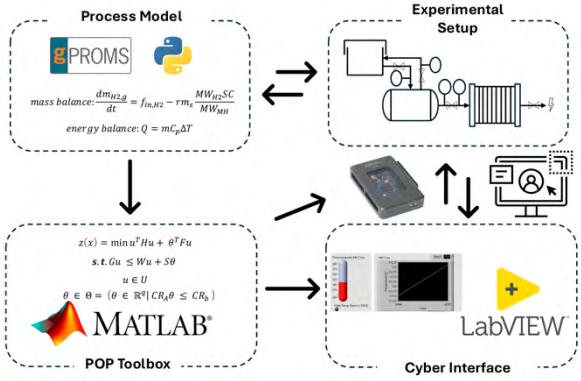

**Figure 3.** Safety-intelligent framework for cyber-physical systems.

$$min. J = \sum_{k=1}^{OH-1} QR(y_k - y_k^R)^2 + \sum_{k=1}^{CH-1} R(u_k - u_k^R)^2 \quad (11)$$

$$s.t. x_{k+1} = A_{xk} + B_{uk} \quad (12)$$

$$y_k = C_{xk} + D_{uk} \quad (13)$$

$$y_{min} \leq y \leq y_{max} \quad (14)$$

$$RI = P(y_{0,k}) \times S(y_{0,k}) \quad (15)$$

$$u_{min} \leq u \leq u_{max} \quad (16)$$

$$\Delta u_{min} \leq \Delta u \leq \Delta u_{max} \quad (17)$$

$$x_{min} \leq x \leq x_{max} \quad (18)$$

$$RI_{min} \leq RI(k) \leq RI_{max} \quad (19)$$

To account for the uncertainties during the operation of a system, stochastic R-eMPC (sR-eMPC) extends the deterministic R-eMPC through incorporation of risk tolerance ($\alpha$) and chance-constraints within the optimization and decision-making framework. The design of sR-eMPC is based on Eqs. (20)-(27). The risk tolerance ($\alpha$) can be calculated based on Bayesian inference in Eq. (22) to capture uncertainties of core temperature variations in metal hydride. As incorporated in Eq. (24), the chance-constraint update dynamic probabilistic limits to allow the system to operate beyond strict limits, thereby preventing unnecessary interventions or shutdown of the system. Further details on designing control optimization of the risk-based controllers can be found in Ali et al. and Akundi et al. [4, 5].

$$min.J = \sum_{k=1}^{OH-1} [QR(y_k - y_k^R)^2 + W(\alpha_k - \alpha_k^R)^2] + \sum_{k=1}^{CH-1} R(u_k - u_k^R)^2$$

$$s.t.\, x_{k+1} = A_{xk} + B_{uk} \quad (20)$$

$$y_k = C_{xk} + D_{uk} \quad (21)$$

$$P[Event|[y_k]] \leq \alpha_k \quad (22)$$

$$y_{min} \leq y_k \leq y_{max} \quad (23)$$

$$y_{0,k} - y_{0,threshold} \leq F^{-1}(\alpha_k) \quad (24)$$

$$u_{min} \leq u_k \leq u_{max} \quad (25)$$

$$\Delta u_{min} \leq \Delta u_k \leq \Delta u_{max} \quad (26)$$

$$x_{min} \leq x_k \leq x_{max} \quad (27)$$

The final step in this framework is to solve the risk-based control optimization via multi-parametric programming using POP Toolbox in MATLAB® [15]. This is an emerging technique to solve MPC explicitly, which means the optimization problem is solved once instead of iterating it every sampling time [16, 17]. Finally, during closed-loop implementation, the control actions is evaluated by computing the parameter vector, which includes hidden states, inputs, outputs, the risk index or risk tolerance, and setpoints. This parameter vector is then used to identify the feasible critical region, from which the appropriate control action is directly applied to the model or system. With the explicit R-eMPC solutions in place, the closed-loop performance of the system can be analyzed to demonstrate the effectiveness of both deterministic and stochastic risk-based control strategies.

# RESULTS AND DISCUSSION

## Open-loop Analysis

The dynamic behavior of the metal hydride storage system (MHSS) during charging is analyzed under open-loop conditions, without any control feedback. The charging or adsorption process involves supplying hydrogen gas to the metal hydride reactor, where $H_2$ is adsorbed within the lattices of the metal alloy, resulting in an exothermic reaction. A comparison between simulated and dynamically optimized responses of the core temperature and hydrogen adsorption capacity is presented.

For the open-loop simulation, the input variables, supply pressure and water flowrate, are set to prescribed values. In contrast, dynamic optimization aims to maximize the hydrogen adsorbed capacity while satisfying the operational constraints specified by the US DOE [3] within 300 seconds charging window.

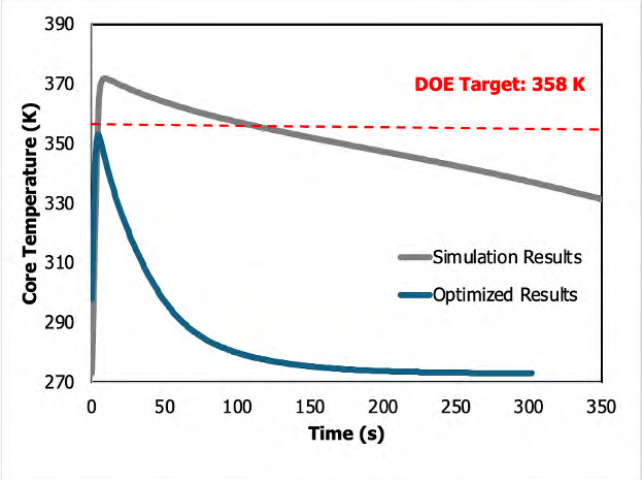

**Figure 4.** Core temperature trajectory during charging of metal hydride storage system during simulation and dynamic optimization.

Figure 4 compares the open-loop responses of core temperature obtained from simulation and optimization. In the simulated case, the supply pressure and water flowrate are set to 14 bar and 5 g/s, respectively. Under these conditions, the core temperature increases and reaches a peak of 378 K within 20 s, exceeding the recommended operating temperature limit of 358 K [3]. By comparison, the optimized response of core temperature peaks at 354 K, below the safety threshold, and achieves rapid cool down of the metal hydride. The optimal input profile determined by the optimization problem corresponds to a supply pressure of 14 bar and 12.46 g/s of water flowrate.

The corresponding hydrogen adsorbed capacity during open-loop simulation and dynamic optimization is shown in Figure 5. At a supply pressure of 14 bar and a water flow rate of 5 g/s, the simulated hydrogen storage

capacity reaches only 0.9 wt.% within 300 s, indicating that the metal hydride does not reach saturation. In this case, the core temperature exceeds the thermal limit while the maximum storage capacity remains unattained. In contrast, the open-loop optimized response achieves a higher hydrogen storage capacity of 1.34 wt.% within the same time horizon. Therefore, these behaviors highlight a critical trade-off between faster charging rate and thermal safety, emphasizing the need for effective thermal management.

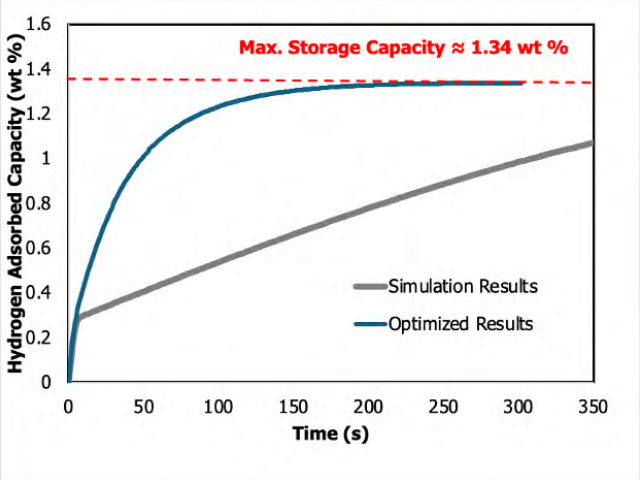

**Figure 5.** Hydrogen stored capacity trajectory during charging of metal hydride storage system during simulation and dynamic optimization.

The open-loop results demonstrate that while supply pressure improves charging efficiency and storage capacity, it also exacerbates thermal risks. These observations motivate the development of risk-based explicit model predictive control strategies to balance performance objectives with safety constraints under dynamic operating conditions.

## Design of Risk-based Control Optimization

Deterministic and stochastic risk-based explicit control strategies were formulated based on the safety-intelligent control and optimization framework. The deterministic risk-based explicit MPC (R-eMPC) is designed according to Eqs. (11)-(18), where the core temperature is identified as the safety-critical variable due to the risk of thermal runaway during the charging process of the metal hydride storage system (MHSS). Figure 6 illustrates the dynamic risk analysis assuming a normal distribution of the core temperature, with a calculated mean (μ) of 290 K, a standard deviation (σ) of 11.35 K, and an upper control limit (μ + 3σ) of 324.05 K. Based on the analysis, the risk index limit is *RI* = 7.36, corresponding to the temperature limit = 358 K. Since the dynamic risk index is a temperature-dependent function that grows exponentially, a piecewise linear approximation is employed to obtain linear expressions suitable for embedding within the decision-making optimization problem.

Meanwhile, the stochastic R-eMPC (sR-eMPC), formulated in Eqs. (19)-(27), extends the deterministic framework by explicitly accounting for uncertainty through risk tolerance (α) based on Bayesian inference. In MHSS, the variation of core temperature is considered to analyze the risk tolerance during dynamic operation. In this formulation, α = 1 represents a fully safe operating condition, while α = 0 indicates a high-risk state. Compared to deterministic R-eMPC, the stochastic formulation provides additional operational flexibility by allowing controlled and temporary exceedance of temperature limits through chance-constraints. The chance-constraints incorporate the dynamically updated risk tolerance and are computed using inverse cumulative distribution function, as shown in Eq. (24), with a threshold temperature limit ($y_{0,\,threshold}$) of 358 K. Therefore, this allows the controller to satisfy the safety limits probabilistically, ensuring that constraints are met with a specified confidence level rather than deterministically.

Overall, the objective function of both safety-intelligent control strategies is to minimize excessive temperature peaks while maximizing hydrogen storage capacity within a finite time horizon during MHSS operation. Once the risk-based explicit MPC problem is solved using multi-parametric programming, explicit solutions to the optimization problem are obtained [15, 17]. These solutions are then implemented for closed-loop analysis of the metal hydride storage system.

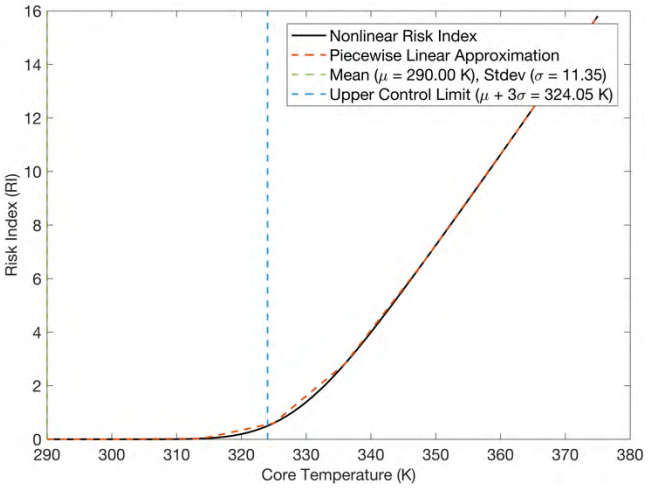

**Figure 6.** Dynamic risk analysis of core temperature during charging of metal hydride storage system.

## Closed-loop Analysis

The resulting closed-loop responses are validated through simulation (*in-silico*) first using gO:MATLAB as the communication protocol between the system model in gPROMS and R-eMPC in MATLAB. The following subsection presents the analysis of both deterministic and

stochastic R-eMPC strategies during charging operation of the metal hydride storage system.

Figure 7 presents the closed-loop responses of the metal hydride system under deterministic risk-based explicit MPC (R-eMPC) in *in-silico* simulations. The core temperature increases gradually and reaches a peak value of 372 K, exceeding the setpoint limit of 358 K. Simultaneously, the hydrogen storage capacity attains the maximum of 1.3 wt.% within 300 s. The risk index exhibits a trend similar to that of the core temperature and exceeds the specified risk limit when the temperature peaks. Although thermal runaway is not completely prevented, the controller effectively attenuates both the risk propagation rate and consequence severity.

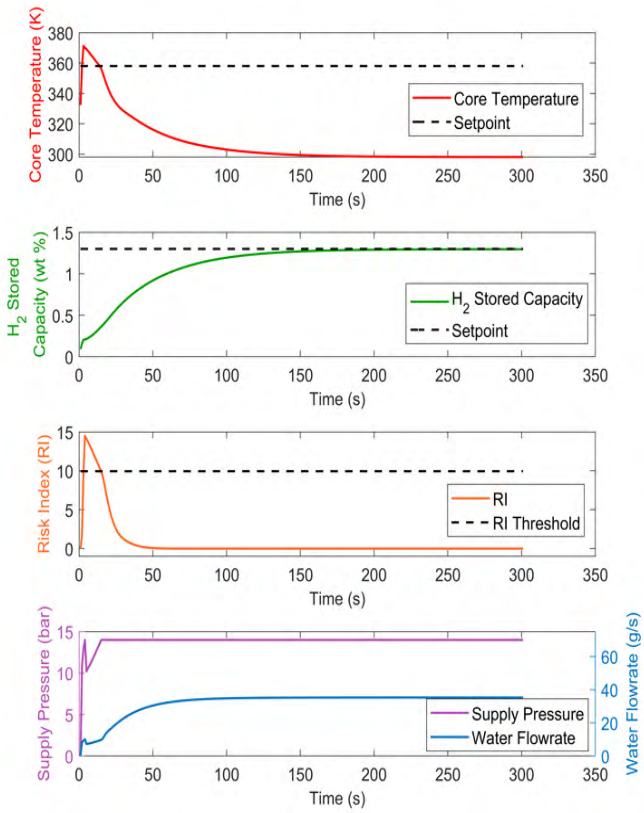

**Figure 7**. *In-silico* application of deterministic risk-based explicit MPC for closed-loop analysis of core temperature, hydrogen stored capacity, risk index and control actions.

At *t = 2 s,* the R-eMPC forecasts the risk index will exceed the limit in the next 10 seconds, which enable to trigger the alarm system ahead of fault occurrence time. While the risk index reaches a high value of *RI* = 14.5 at *t = 5 s,* the controller continues to act and successfully reduces both the risk and fault severity within 15 seconds. Here, the control actions are adjusted accordingly to manage the trade-offs between safety and performance. As a result, the R-eMPC effectively mitigates thermal risk while maximizing hydrogen storage capacity.

Figure 8 shows the in-silico performance of stochastic risk-based explicit MPC (sR-eMPC) during charging of metal hydride. The core temperature reaches a peak value of 367 K. Although this value exceeds the nominal temperature limit of 358 K, it remains below the maximum probabilistic limit of 371 K, demonstrating the increased operational flexibility of the stochastic controller and avoiding the need for a system shutdown.

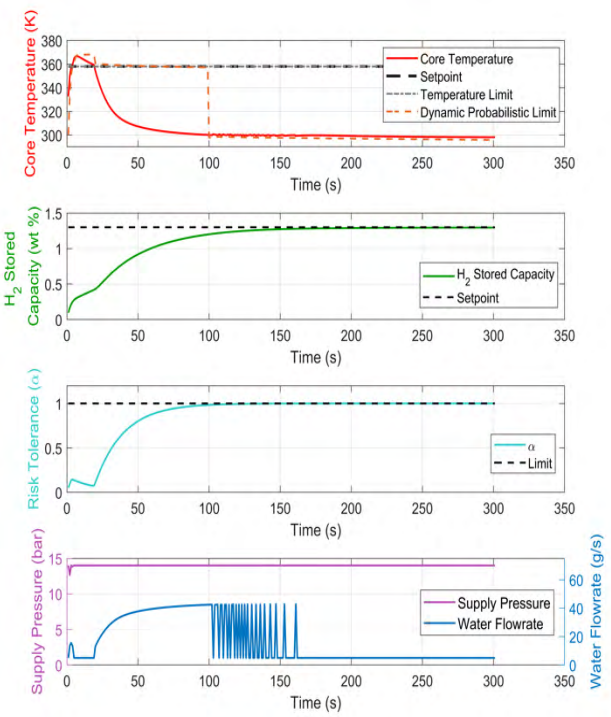

**Figure 8.** *In-silico* application of stochastic risk-based explicit MPC for closed-loop analysis of core temperature, hydrogen stored capacity, risk tolerance and control actions.

Unlike the risk index, the risk tolerance ($\alpha$) evolves differently from the temperature profile. When it peaked at maximum, $\alpha$ = 0.1 indicating system is at state of risk. As adsorption process completes, the temperature gradually cools down and risk tolerance stabilizes to $\alpha$ =1. When the system operates in safe mode, the controller switches to predefined minimum control actions, corresponding to a supply pressure of 14 bar and a water flow rate of 5 g/s. At *t* = 170 s, the control system engages these predefined actions once the system is classified as safe according to the updated dynamic risk tolerance.

Moreover, the optimal control actions during closed-loop operation are provided by the controller to manage safety and performance. To achieve maximum storage capacity, the supply pressure maintains to be 14 bar. Meanwhile, as the temperature rises, the water flowrate increases to dissipate heat and maintain safe

operation. As a result, sR-eMPC is able to allow the system to exceed the temperature limit and achieving full saturation within 300 s while satisfying the dynamic probabilistic limits.

## CONCLUSION AND FUTURE WORK

This work presented dynamic modeling, experimental setup, control and operations of hydrogen storage using metal hydride in real-time. The safety-intelligent controllers, deterministic and stochastic R-eMPC, utilize risk indicators such as risk index and tolerance to assess safety level of the system and account for uncertainties, respectively. These were implemented to minimize the evolving thermal risks while maximizing the hydrogen capacity of metal hydride tank. Future work will include implementation of the stochastic risk-based explicit MPC into the cyber-physical setup of metal hydride storage for closed-loop analysis and validation.

## ABSTRACT

The Dividing Wall Column (DWC) offers significant potential in saving both energy- and capital cost compared to conventional distillation sequences. However, there are some issues regarding flexibility and control that require attention in reducing the risks or uncertainties in achieving the potential benefits in practical operation. This calls for control and optimization methods that rely on the available measurement data and less on simulation models. The “Perturb and Observe” method is a simple algorithm that seems suitable for this on-line optimisation task. A series of experiments have been carried out at the Kaibel-column pilot at NTNU and some key results are presented. The method is combined with a conventional control structure at the regulatory layer.

**Keywords**: Distillation, Optimization, Process Control, Dividing Wall Column, On-line, Perturb & Observe

## INTRODUCTION

The Dividing Wall Column (DWC) is an attractive multicomponent distillation technology that enables energy savings in the ballpark of 20-30% and even similar numbers for capital cost due to more compact size and construction [1, 2]. Still, robust practical control is often listed as a challenge in practical operation. It is therefore needed to show how industrial DWCs can be controlled in realistic environments.

The plant manager needs to be assured that the operation and control can be realized within the organization without extraordinary effort such that not only the plant owner, but also operating personnel such as process engineers and operators can benefit from this kind of energy-saving technology. The operating condition that enables high purity recovery of all products and at the same time minimizes the overall energy consumption is well described theoretically, but in practice it is not so easy. This is because the inevitable real-world’s uncertainties make it difficult to infer the actual operating condition and bring the operation back to and maintain the optimal energy-saving track with high purity products. In a lab-pilot, as well as in industry, there are significant uncertainties in separation performance, heat loss, internal hydraulics and mixing, and in the accuracy of setting the manipulative variables and in the measurements. This implies that it is impossible in practice to pre-calculate the settings that provide the desired operating condition. Some kind of feedback control strategy is required for both the basic control levels and the optimising control levels.

This uncertainty and variation in conditions calls for control and optimization methods that rely on the available measurement data and less on simulation models. The “Perturb and Observe” method is an available algorithm which is simple to realise on-line, and seems suitable for this on-line optimisation task [3]. During a previous simulation study [4], the reboiler vapor rate, that is closely related to column energy consumption, was used as the objective function to be minimized, while simple control loops maintained compositions. In industrial settings, the boilup rate is usually set constant at the capacity limit in the column and a different approach for defining the cost function is needed. In this paper, we will present how the on-line perturb and observe method can be combined with a basic control structure that handles the typical industrial operation condition, and we will show some samples from pilot-column experiments.

## DWC OPERATION CHARACTERISTICS

Consider a typical ternary DWC as illustrated in Figure 1. The feed (F) enters the prefractionator sections (1, 2) and is described by its molar fractions (z) of pure components (A, B, C) and its liquid fraction (q). There are three product specifications, given by the main component purities in each product stream (D, S, B). There are five manipulated variables (MVs): 1) boilup vapor rate (V), 2) reflux rate (L), 3) side product draw rate (S), 4) the liquid split ratio ($R_l$) above the wall and 5) the vapor split ratio ($R_v$) below the dividing wall. The prefractionator shall separate the light key (A) from the heavy key (C) while the intermediate key (B) is distributed to both ends of the "dividing" wall. This leaves separation of A from B in the upper part of the main column (sections 3, 4) and B from C in lower part (sections 5, 6).

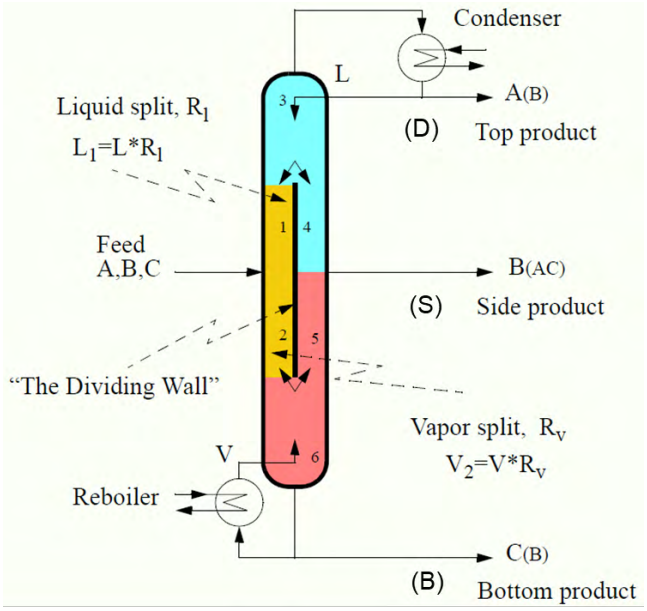

**Figure 1.** Ternay Dividing Wall Column (DWC)

This sounds straightforward, but to obtain the potential minimum vapor operation in practice, it is vital that the prefractionator is operated precisely within its "optimality region". The optimal operating characteristics are described in previous publications [5–7]. Here, just a summary is given as preparation for the optimising control experiments. The Vmin-diagram in Figure 2 is based on the feed properties only and shows how the feed components are distributed to the product ends in an infinite stage binary column as a function of the operational degrees of freedom, selected as vapor rate (V/F) and net top product (D/V=(V-L)/F). For a ternary feed, the left peak represents minimum vapor for a sharp A/BC split, and the right correspond to the AB/C split. In the "valley" between these peaks, we fine the so-called "Preferred split" which is minimum vapor for a sharp A/C split while B is distributed to both ends. The solid lines represent distribution boundaries, that is when a component is about to appear or disappear in one column end as V and/or D is changed such that the operating point crosses the actual line as illustrated with the small columns in **Figure 2**.

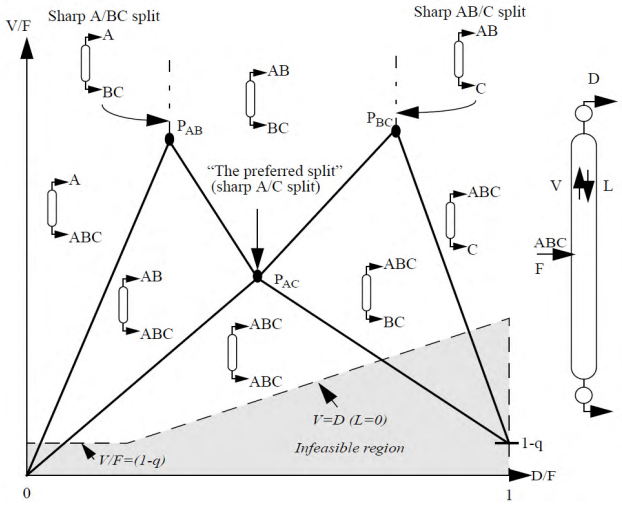

**Figure 2**. Vmin diagram for a ternary feed ABC [6]

With the assumption of ideal mixtures, the information in this diagram can be calculated analytically by the Underwood equations. It is important to recognise that these distribution boundaries are also there for real zeotropic mixtures, which requires some more care when doing the calculations, and which does not have these nice and linear boundaries. Thus, the concept of the distribution regions will still be valid. This holds also when assuming finite number of stages.

### Minimum vapor rate in a DWC

In a DWC, the minimum overhead vapor rate is given by the highest of these two peaks. However, there is a very important requirement to the prefractionator operation: it must be operated in the vicinity of the preferred split when we apply the Vmin-diagram for the prefractionator itself. This is what we denote as the "optimality region". If this requirement is not fulfilled, it will not be feasible to produce all three products at specified purities with the given minimum vapor rate, despite otherwise perfect column sizing for the given feed conditions.

In the previous P&O study [4], the boilup itself has been used as the cost function value to be minimised in search for the optimality region. Minimum boilup is still very important in design calculations, because this is what gives the operating conditions that are the basis for column design. It is also straightforward in simulations without any limits on the available internal vapor and liquid rates, since sub-optimal settings of the split rates will force increased overall reboiler vapor rate to enable pure products.

In [4], the control structure applied the reflux ($L$), side-draw ($S$) and boilup ($V_b$) for product purity control, leaving the liquid and vapor split for optimisation. Since most industrial columns are operated with constant vapor split, this was also applied such that we only consider the one-dimensional search for the minimum cost ($V_b$) by perturbing the liquid split ($R_l$). Feed rate and conditions were regarded as disturbances.

## Proposed control structure for the lab column

In practical operation, the vapor capacity ($V_b$)will be limited, and to ensure as high throughput of feed rate as possible, the reboiler duty is usually set close to maximum capacity. Then, the consequence of sub-optimal splits will *not* be increased vapor rates, but instead it will become infeasible to produce pure products. Thus, the degree of sub-optimality should be measured by the actual product impurities. This could also be "converted" to energy or vapor rate by calculating the amount of extra vapor rate needed to take the actual impure products and purify these in a theoretical DWC distillation column. But minimising directly on the impurity will give the same result.

A basic control loop that uses the top reflux as MV for maintaining a certain temperature location in the top section (3) ensures that the top product becomes reasonably pure even for sub-optimal prefractionator operation. This is equivalent to typical top product purity control in conventional columns. In the bottom, however, the boilup rate is not an available MV, so we may choose to use the side draw rate (S) instead to affect the bottom product purity via the liquid rate towards the bottom.

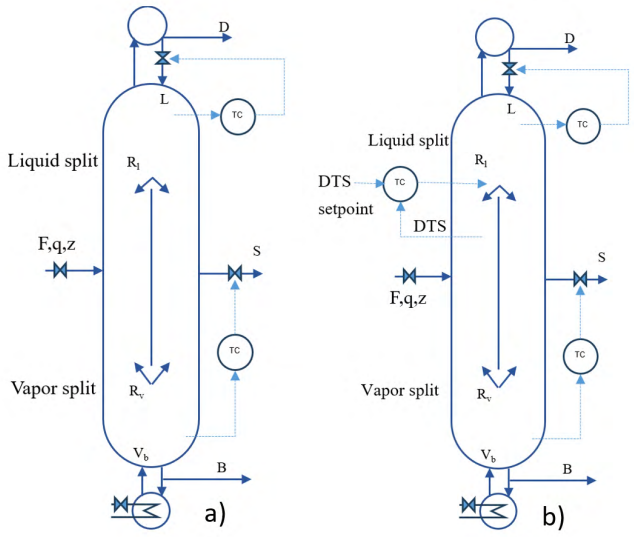

**Figure 3**. a) Basic control structure ensures pure D&B, while side product (S) depends on prefractionator operation. b) Added stabilising feedback for prefractionator by a combination for temperatures (DTS).

This control structure has been analysed by Qian et. al. [8] and show satisfying dynamic performance. The two control loops in the top and bottom are illustrated in Figure 3a. The side impurity is not handled by this basic structure at all. Luckily, this will be taken care of in the prefractionator control since, when it reaches its optimality region such that it performs the desired AB/BC split (no heavy C above the wall and no light A below the wall), the basic 2-loop structure in Figure 3a) will automatically recover all the light (A) in the top product, and all the heavy (C) in the bottom product, and the intermediate (B) has no other exit than through the side stream (S).

The resulting optimisation task becomes slightly different form the previous study [4] when the boilup is fixed. The cost function may be the side-product impurity or some other measure that is closely related to this.

Since we fix the boilup ($V_b$) it is important to set a realistic feed. The minimum vapor to feed ratio is related to the highest peak in the Vmin-diagram, here denoted $(V/F)_{min}$. The real ratio is denoted by just ($V/F$). This gives the following simple relation for the maximum feed capacity that still enables three pure products:

$$F_{max} = V_{b,max} \Big/ \left(V/F\right) \leq V_{b,max} \Big/ \left(V/F\right)_{min}$$

This might look obvious, but it is very practical. If the feed is too high, the side stream cannot become pure since the ($V/F$) in the Vmin-diagram will be below the highest peak and full recovery of all products becomes infeasible. If the feed is lower, this implies that the real $\left(V/F\right) > \left(V/F\right)_{min}$ and we have more reboiler duty than required for pure products (assuming that optimal prefractionator operation is reached). Thus, it is an option to either increase the feed, or in fact reduce the reboiler duty. If not, some of the potential savings are not realised. But there is also some trade-off by running with somewhat higher V/F ratio than required since the optimality region is also widened to a certain extent, allowing for simpler operation at the cost of abandoning some of the potential savings [9].

We should also consider how the real vapor split is set according to the requirement given from the Vmin-diagram. If too low, it can be partly compensated for by reducing the feed (implicitly increasing ($V/F$))

## About cost function selection

It has been shown that an alternative cost function that characterises close to optimal operation is the temperature difference between the lower and upper end of the dividing wall [5], where a maximal difference corresponds to optimal operation. This cost function is usually easily available in practice and is also an intensive measurement.

## Stabilising control of the prefractionator

It is possible to use the liquid split ($R_l$) directly as the MV for optimisation. However, the dynamic response on direct manipulation of internal flow rates in distillation is known to be slow. Then, a better alternative is to use a feedback controller to stabilise the profile and use the setpoint of this controller as the optimiser MV. This is illustrated in Figure 3b). The feedback may be a single point on the prefractionator temperature profile or, as in Figure 3b), the "Difference Temperature Symmetry" measure (DTS) [4, 5], which is a measure of the temperature differences on both side of the wall. This measurement also has so-called "self-optimising" properties, since keeping this value constant maintains operation close to an optimum just by feedback control. The setpoint may need some adjustments from the optimising level since the optimal value depends on the feed properties.

## PERTURB AND OBSERVE (P&O)

The model-free Perturb and Observe (P&O) optimising search method is described in more detail in the previous work [4] and in the three student internship reports [10–12] for the methods used in the lab. The simplest explanation is that P&O perturbs the MV (u) and then measures the change in the measured cost function y=f(u) and from that does a directed search towards a local minimum while obtaining additional information for each step. The method can be refined in how uncertainty can be modelled [13]. Use of model information for feedforward actions is also an option. P&O can also be multidimensional, but only a single dimension is tried out in the lab experiments. In the presented DWC experiments, the perturbing MV (u) is either the manual set value for the liquid split, or when the stabilising DTS controller is used, the P&O-MV is the setpoint to this controller, that uses the liquid split as the controller MV. (See Figure 3)

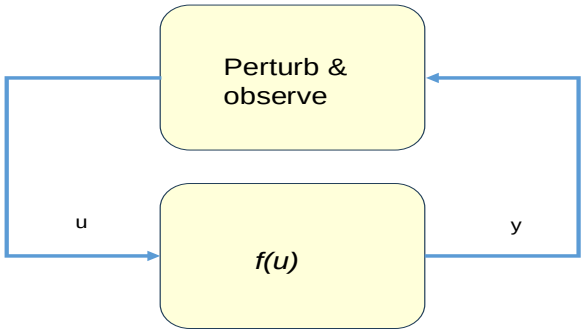

**Figure 4**. Conceptual P&O loop

## LAB COLUMN PILOT

The lab pilot at NTNU (see Figure 5) was first built in 2005 by Strandberg. It has been used for various experimental studies by several PhD and master's students. It has the structure of a 4-product Kaibel-column. In this project, it is used as a ternary DWC by simply closing one side-stream outlet (S2). The feed is Ethanol, 1-propanol and 1-Butanol with boiling points at 78 °C, 100 °C and 117 °C, respectively. The feed can be preheated to a controlled temperature. Changes in feed rate, composition and temperature can be regarded as disturbances.

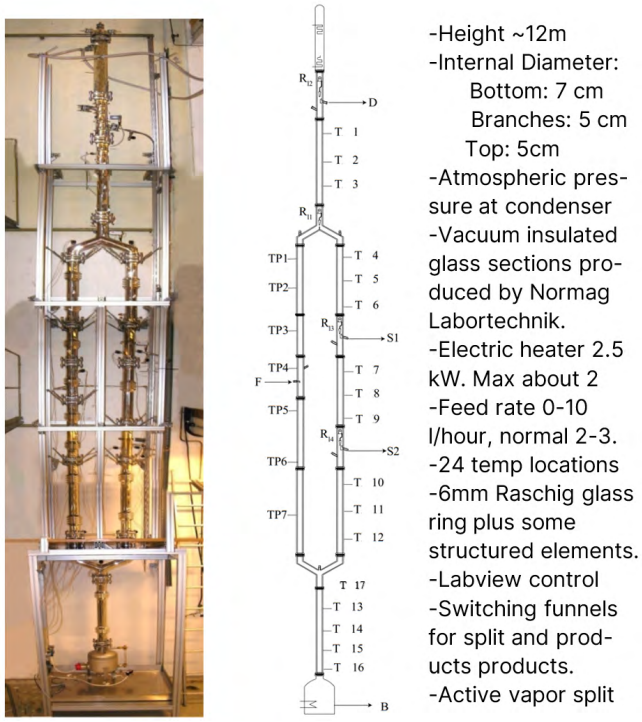

**Figure 5.** The Kaibel column Pilot at NTNU. The left branch is the prefractionator, and the rest makes up the main column. Only one side-draw is used for ternary feed.

A theoretical Vmin diagram is shown in Figure 6. This is just indicative as it will become distorted with real (very few) stages and uncertain packing performances with varying rates. The figure illustrates three possible operational paths (dashed) for three different vapor split values.

However, there is still a minimum side-stream impurity, even for sub-optimal settings for vapor split values so the one-dimensional algorithm will find a local optimum. For a compete DWC optimisation both vapor-split and boilup-to-feed ratio (V/F) need to be used as MVs in addition to the liquid split. This is not considered herein.

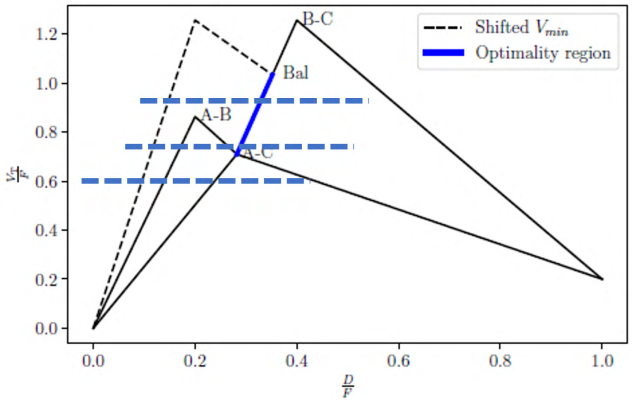

**Figure 6.** Ideal Vmin diagram for the actual feed with molar fractions [0.2, 0.2, 0.6] at room temperature. Changing liquid split moves the operating point horizontally (dashed blue lines). We do not really now the position of this line in practice, and we do not know the real diagram. Consider the real diagram is hidden in "fog".

## EXPERIMENTAL RESULTS

The experiments are described in more detail in the internship reports by Kooy, Bergers and Merlo [10–12]. These reports are available on request. Just a few samples are included here.

The first example from Kooy [10] is an experiment based on the structure in Figure 3a) by using liquid split as MV (u in Figure 4) and an approximated temperature difference over the "wall" (or branches on the wall) as a cost function. See Figure 7, where the cost is given by $\text{Cost}=(TP1+T4)/2-T17$. (The desired cost is temperature difference between liquid split and vapor split locations. Unfortunately, there is no sensor at the liquid split location so the average (TP1+T4)/2 is used instead.) Note that the column settling time will be quite slow when manipulating directly on the liquid split. This gives a rather slow underlying mode during the experiment, resulting in a slow-moving cost function optimum value. Even then the P&O algorithm manage to track the optimum as shown in the sequence in Figure 7.

The second experiment, see Figure 8, is with the stabilising DTS loop as in Figure 3b). The DTS-loop results in a considerably faster settling time for each perturbation of the DTS controller setpoint value.

Bergers and Merlo worked together at several experiments in the autumn of 2025. Figure 9 shows an example of cost function repeatability experiment for the case when DTS control is applied. The setpoint is changed upwards and downwards to explore the cost function and confirm that the function has a minimum. The match is acceptable. However, when running a sequence of experiments where the products are recirculated to the feed there may be some variations in feed properties e.g. due to some material losses (leakages) etc. Thus, it is not so straightforward to ensure the same starting / operating conditions each time.

Bergers also looked into uncertainty based "uP&O" [13]. He proved that the perturb and observe with a closed loop manipulation of $R_l$ tracks the optimum of the same $\text{Cost}=(TP1+T4)/2-T17$.

It is quite important that the underlying regulatory control loops for top and bottom products purity control is properly tuned. An experiment illustrating improved response after tuning is given in Figure 10.

They also performed some basic characterisations for model fitting and measurement calibration and Merlo also worked on fitting an Aspen Plus model in a rather detailed manner.

Merlo verified through Gas Chromatography a mismatch between side stream purity and the optimum of the cost and verified this mismatch via the Aspen Plus model.

The desired cost function, being the side impurity, could not be measured on-line. In some experiments an off-line Gas Chromatography analysis could be performed.

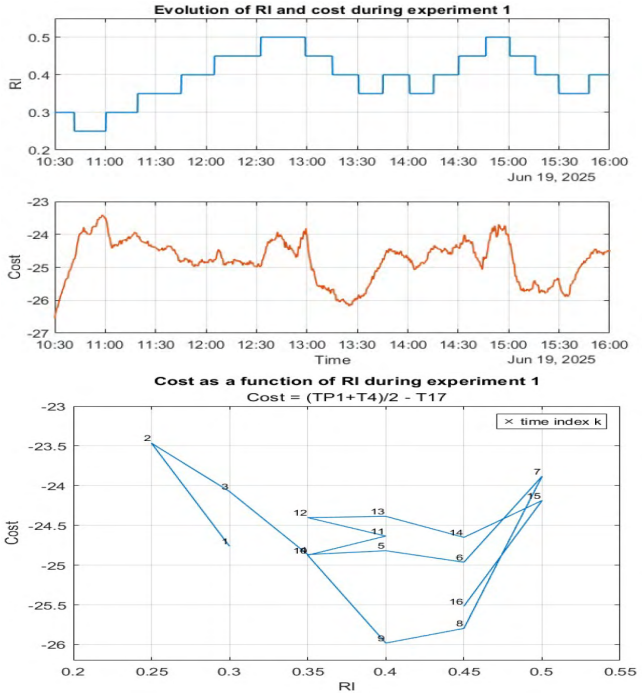

**Figure 7**. P&O experiment by manipulating liquid split (RI) [10]

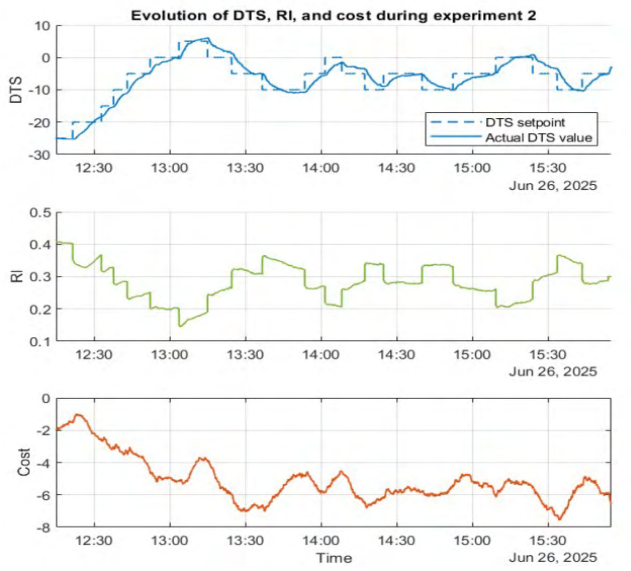

**Figure 8**. P&O experiments with simple P&O with DTS [10]

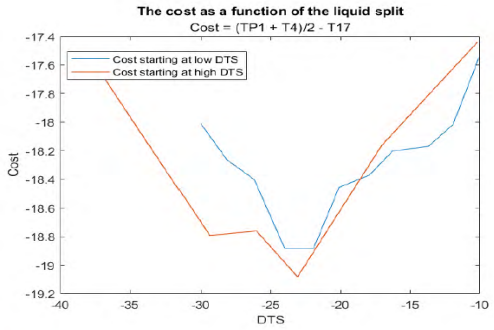

e 7.1: The relation between DTS and cost based on two experiments.

**Figure 9**. Experiments showing cost function vs DTS [11].

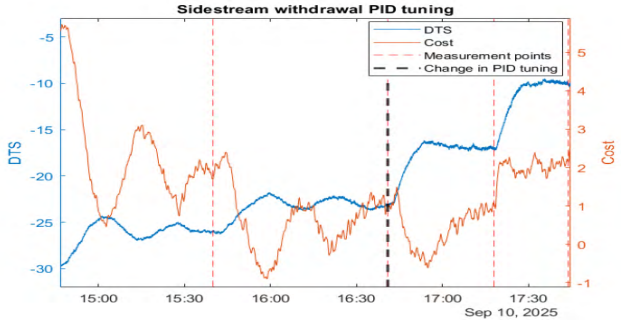

**Figure 10**. Improving basic regulatory PI-tuning [11]

The gas chromatography measurements provided a reference to evaluate the behaviour of the cost function compared to the real objective, as shown in Figure 11.

The minimum of the cost indicator is shifted to higher $R_l$ values compared to the minimum of the impurity. The same phenomenon could be verified in the fitted Aspen Plus model. Figure 12 shows the result of simulations of the fitted model: for analogous operating conditions to those implemented experimentally, taking the average of the stage temperatures around the wall to approximate the measurement at the upper junction along the wall yields a slightly different optimal liquid split than the desired one.

As the available temperature inferential did not perfectly match the side impurity's optimality and online concentration measurements are not available, Merlo suggested to use the total side draw flow rate as a cost function. Since the top and bottom purities are regulated via temperature control, suboptimal steady-state operation will necessarily result in part of the top component A and the bottom component C being recovered together with the middle distillate B in the side stream. Optimal operation, on the other hand, signifies that only B is recovered via the side stream, thus making the side stream flow rate minimal. This is easier to measure than the composition. It is also possible to infer this amount directly from the S-controller outputs and the liquid split.

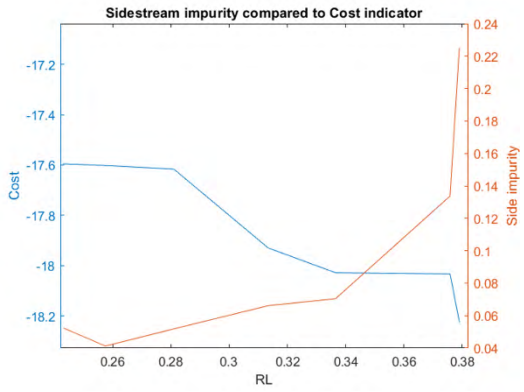

**Figure 11**. Side-stream impurity compared to Cost indicator [12]. Off-line analysis

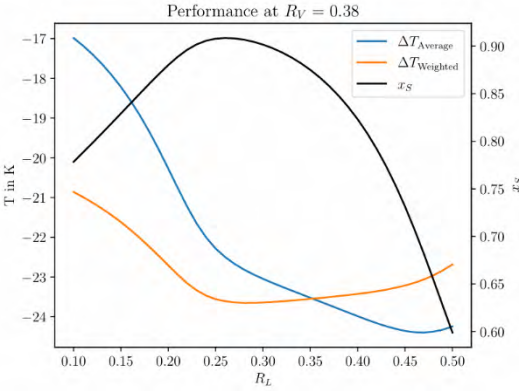

**Figure 12**. Comparing cost function alternatives by simulations with the fitted Aspen Plus model. [12]

## DISCUSSION

The task of searching for the optimal operating condition for a DWC can be compared to navigating in mountain terrain in dense fog. We know that the mountains (Vmin-diagram) are there, but we do not know exactly how they look like (due to model uncertainty) and where our current position is just now (which prefractionator

operating point). However, we have some communication to the outside that can tell the impact of moving our position (the cost function measurement and other external measurements).

If we have an accurate GPS and map, we could easily move to the desired position. This could be for example equivalent of measuring the light and heavy impurities in the bottom and top of the prefractionator. This can be used tell how far the operating point is from the optimality region at the Vmin-diagram boundary line.

The experience from the lab indicates that it is difficult to develop a precise model and even a constant model due to significant uncertainties. First there are some heat losses, partly due to that some section may have lost the vacuum. This has been indicated by IR thermography. There may also be rate dependent variations in HETP and variations due to hydraulics maldistributions. All these uncertainties are likely to be more dominating on this pilot, than in an industrial setting.

The simplest P&O method is able to track the defined cost function despite quite uncertain and non-steady process conditions. The step size and the period between each perturbation step are parameters that need to be tuned.

Experiments were also conducted to investigate possible feed-forward actions. In the simplest form, e.g. if the feed temperature is changed, we might know from the model how the optimum is expected to change. Then, this information about an optimality-change direction can be helpful to move faster to the new optimum. More detailed model knowledge may allow also the expected magnitude of change of the optimisation MV.

In the presented experiments we have used a single perturbation variable, and thereby only considered one-dimensional optimisation search. In further work it is of interest to include impact from the vapor split and to maximise the feed throughput.

## CONCLUSION

A series of experiments have been carried out on the NTNU Kaibel-column pilot during 2025. The goal was to try out the on-line model-free “Perturb and Observe” algorithm in an environment that is similar to an industrial plant. Unlike in simulations where we have quite good control of the external “upsets” when we study the algorithm performance, the lab also includes some of the real-world uncertainties, and sometimes unforeseen and unmodeled behaviour. Despite this, the results are promising.

In addition to collect experiences on how to improve the optimisation algorithms, the results also have resulted in new knowledge on DWC control structure and performance.

The use of P&O is a low-hanging fruit that provides a systematic optimum tracking 24/7 compared to if operators should follow up this manually, enabling realising the benefits of optimisation not only for design but in practical plant operation. It is easily combined with conventional basic control.

At the basic level, some attention should be given to obtaining reasonably fast settling time upon disturbances. This enables faster optimisation too.

And lastly, since the optimisation algorithm requires a measurable cost function, it is required to ensure that the available measured properties used for this function are well representative for the actual process operating cost that we really want to minimise.

Compared to full model-based real time optimisation (RTO), the P&O does not require any on-line model, and functionality for model updating from measurements. Thus, P&O and should thereby be much simpler to implement on an industrial plant. Some risk assessment on the impact of applying expected perturbations must of course be included as for all control upgrade projects.

DWC columns are built to save energy and using on-line optimisation methods like Perturb and Observe give the managers and operators better tools to realise the potential savings in practice.

## ABSTRACT

The extensive use of renewable energy to supply hydrogen production for chemical processes is hindered by the uncertainty in power generation and by strict operational limits.These challenges are addressed through a real-time dynamic optimization approach based on a receding-horizon strategy that provides optimal decision variables. The framework explicitly relies on imperfect weather forecasts and dynamically adapts the hydrogen reference production to guarantee the final productivity target. The optimization methodology focuses on minimizing grid electricity imports, limiting excessive equipment stress, and preventing constraint violations, while ensuring that the hydrogen production target is satisfied.The proposed approach yields competitive economic and environmental performance, with a levelized cost of hydrogen of 3.31 USD/$kg_{H_2}$, well within literature values (1.50–7.50 USD/$kg_{H_2}$) and below typical industrial costs (4–12 USD/$kg_{H_2}$). At the same time, carbon dioxide emissions are reduced by more than 90% compared to steam methane reforming, resulting in specific emissions below 1 $kg_{CO_2}/kg_{H_2}$. These results are supported by a year-long simulation based on CAISO renewable energy data. The optimized system achieves the annual hydrogen production target while respecting all operational constraints, whereas the absence of operational strategy and buffering systems leads to systematic constraint violations. The strategy can be implemented in existing industrial facilities with limited modifications.

## INTRODUCTION

### Global scenario

The urgency surrounding industrial decarbonization has intensified as $CO_2$ emissions from human activities continue to increase. Recent data from 2024 indicate that emissions from energy generation, fuel combustion, and manufacturing operations have reached 37.6 $Gt_{CO_2}$ annually, an 8.4% increase relative to levels observed ten years earlier [1]. Direct emissions from industrial sources (Scope 1) represent approximately 23% of this global total, not accounting for the substantial indirect emissions associated with energy consumption across these operations.

Among industrial sectors, chemical manufacturing presents particularly high carbon intensity. Traditional synthesis pathways for several foundational chemicals result in considerable emission factors: ammonia production generates up to 4.6 $kg_{CO_2}/kg_{NH_3}$, methanol up to 2.8 $kg_{CO_2}/kg_{CH_3OH}$, nitric acid up to 1.6 $kg_{CO_2}/kg_{HNO_3}$, and hydrogen up to 26 $kg_{CO_2}/kg_{H_2}$. When accounting for both on-site emissions and those associated with purchased energy, the chemical industry is responsible for approximately 6.4% of global greenhouse gas releases [2].

Concurrently, the renewable energy sector has undergone substantial expansion. European markets illustrate this transition: the share of renewables in total energy consumption increased from 9.6% in 2004 to 24.5% by 2023 [3]. While this growth trajectory presents opportunities for reducing carbon emissions in chemical production, it simultaneously introduces operational challenges due to the intermittent nature of wind and solar power generation.

### Renewable energy sources

Solar photovoltaic and onshore wind technologies exhibit favorable characteristics for industrial deployment due to their modularity and minimal site-specific requirements. Nevertheless, the temporal variability inherent to these sources necessitates effective energy conversion and storage infrastructure to ensure process continuity.

For renewable-powered hydrogen generation, proton exchange membrane (PEM) electrolysis systems demonstrate superior performance under dynamic operating conditions compared to alkaline technologies, despite the latter's higher technology readiness level and lower capital expenditure. Regarding energy storage architectures, battery energy storage systems (BESS) deliver high round-trip efficiencies and rapid power response characteristics, while compressed hydrogen storage represents the most established and cost-effective approach for hydrogen inventory management.

## Plant design and operation in literature

Existing literature on renewable-hydrogen system design predominantly emphasizes techno-economic optimization under steady-state or quasi-static operating assumptions [4, 5]. Reported levelized costs for hydrogen production typically range from 3 to 4 USD/$kg_{H_2}$, with regional variations driven by resource availability: lower values observed in high-resource regions and elevated costs documented across European installations [6]. The operational performance of these systems under transient renewable supply conditions remains insufficiently characterized.

Current research on operational control strategies frequently relies on deterministic renewable energy forecasts or omits critical process-side constraints [7, 8]. As a result, methodologies capable of addressing renewable variability, equipment operational limits, downstream process requirements, and economic objectives within a unified framework remain underdeveloped.

This study presents a real-time, multi-objective optimization framework for integrated renewable-hydrogen production systems operating under uncertainty. The framework incorporates forecast error propagation, dynamic control variable adjustment, degradation-aware operation, and hydrogen demand satisfaction constraints. The methodology enables techno-economically optimized operation under realistic industrial conditions and is directly applicable to commercial-scale green hydrogen facilities with minimal adaptation requirements.

# METHODOLOGY

## System description

The integrated system for hydrogen production comprises renewable power generation units (wind and solar photovoltaic) coupled with a PEM water electrolysis unit. To attenuate high-frequency power fluctuations, lithium-ion BESS and compressed hydrogen storage vessels are implemented as buffering components. The system interfaces with both the electrical grid and the downstream hydrogen-consuming process.

As illustrated in **Figure 1**, power from the renewable generation and grid connection is distributed between the BESS and the electrolyzer. Hydrogen produced by the electrolyzer is partitioned between the storage vessels and the downstream facility. During periods of insufficient renewable generation, electrical energy and hydrogen are supplied from BESS discharge and tank depletion, respectively.

The system dynamics can be expressed mathematically as follows:

$$E_{ren} + E_{grid} = E_{bess} + E_{el} \tag{1}$$

$$F_{el} = c_{el} \bullet E_{el} \tag{2}$$

$$F_{el} = F_{tank} + F_{plant} \tag{3}$$

$$\frac{dQ_{bess}}{dt} = \eta_{bess} \bullet E_{bess} - \kappa_{bess} \bullet Q_{bess} \tag{4}$$

$$\frac{dm_{tank}}{dt} = \eta_{tank} \bullet F_{tank} - \kappa_{tank} \bullet m_{tank} \tag{5}$$

Each variable corresponds to the mass and energy streams depicted in **Figure 1**. The parameter $c_{el}$ represents the electrolyzer conversion coefficient for hydrogen production, while $\eta$ and $\kappa$ denote the charging efficiency and self-discharge rate for the BESS and hydrogen storage.

Since $E_{ren}$ is determined by exogenous renewable resource availability, the system contains 8 variables. Given 5 governing equations, the formulation exhibits 3 degrees of freedom.

## Approach to the problem

Given weather forecast data over the next $t_{regulation}$ time steps, the system has $3 \bullet t_{regulation}$ degrees of freedom. Following a receding horizon strategy, the optimal decision variable trajectory is computed via optimization, with only the initial time step implemented and subsequent values discarded upon re-optimization [9].

This formulation shares conceptual similarities with model predictive control (MPC) frameworks [10]. However, whereas MPC constitutes an advanced real-time control architecture, the proposed methodology generates optimal reference production trajectories for implementation within existing control systems. In other words, the proposed methodology constitutes a supervisory optimization layer that provides optimal setpoints corresponding to the optimal configuration of the decision variables, while real-time tracking and disturbance rejection are handled by the underlying control system. The design and implementation of such control systems

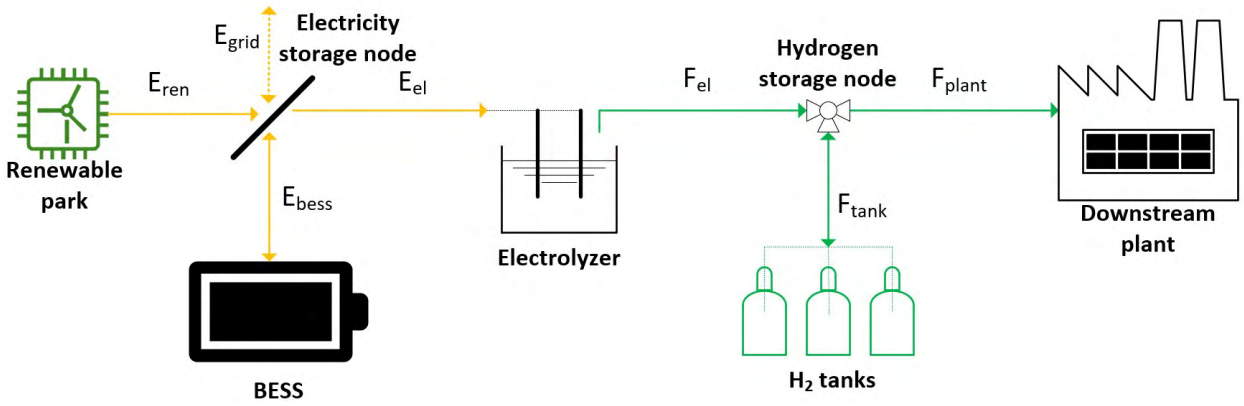

**Figure 1.** Hydrogen production plant scheme.

are beyond the scope of this work, as the focus is on the optimization-based determination of the setpoint.

The optimization requires specification of the three manipulated variables per time step, selected as $E_{bess}, F_{tank}$, and $E_{grid}$ based on their direct controllability. The primary objective ensures that $F_{plant}$ tracks the specified hydrogen demand profile for each time step.

$$f_{rp} = \sum_{t=1}^{t_{regulation}} k_1 \bullet \left| \frac{F_{plant}^{t} - F_{plant}^{rp}}{F_{plant}^{rp}} \right| \tag{6}$$

Additionally, to minimize equipment degradation, solutions exhibiting reduced high-frequency variability are favored. This applies specifically to hydrogen flow to the downstream process, electrical power to the electrolyzer, and charging/discharging rates of the buffer systems.

$$\begin{aligned} f_{var} = \sum_{t=1}^{t_{regulation}} \Bigg( & k_2 \bullet \left| \frac{F_{plant}^{t} - F_{plant}^{t-1}}{F_{plant}^{rp}} \right| + k_3 \\ & \bullet \left| \frac{E_{bess}^{t} - E_{bess}^{t-1}}{Q_{bess}^{max}} \right| + k_4 \\ & \bullet \left| \frac{F_{tank}^{t} - F_{tank}^{t-1}}{m_{tank}^{max}} \right| + k_5 \\ & \bullet \left| \frac{E_{el}^{t} - E_{el}^{t-1}}{E_{el}^{nominal}} \right| \Bigg) \end{aligned} \tag{7}$$

The economic impact of grid interaction must also be incorporated, accounting for electricity import costs and export revenues (which may be positive, negative, or zero depending on market conditions).

$$\begin{aligned} f_{grid} = \sum_{t=1}^{t_{regulation}} \big( & k_6 \bullet \max(E_{grid}^{t}, 0) + k_7 \\ & \bullet \min(E_{grid}, 0) \big) \end{aligned} \tag{8}$$

Operational constraints are imposed to ensure solution feasibility. Two constraint categories are defined: bounds on state and control variables to enforce operational limits and physical constraints, and rate-of-change limitations to restrict ramping behavior. Each penalty term equals the constraint violation magnitude multiplied by an appropriate penalty coefficient, or zero when the constraint is satisfied.

$$P_{value}: \begin{cases} Q_{bess}^{min} \le Q_{bess}^{t} \le Q_{bess}^{max} \\ m_{tank}^{min} \le m_{tank}^{t} \le m_{tank}^{max} \\ E_{el}^{min} \le E_{el}^{t} \le E_{el}^{max} \\ F_{plant}^{min} \le F_{plant}^{t} \le F_{plant}^{max} \end{cases} \tag{9}$$

$$P_{var}: \begin{cases} |E_{bess}^{t} - E_{bess}^{t-1}| \le \delta_{bess}^{max} \\ |F_{tank}^{t} - F_{tank}^{t-1}| \le \delta_{tank}^{max} \\ |E_{el}^{t} - E_{el}^{t-1}| \le \delta_{el}^{max} \\ |F_{plant}^{t} - F_{plant}^{t-1}| \le \delta_{plant}^{max} \end{cases} \tag{10}$$

The complete objective function is formulated as:

$$\Phi = f_{rp} + f_{var} + f_{grid} + P_{value} + P_{var} \tag{11}$$

## Minimization of the objective function

Minimization of the objective function presents computational challenges due to its inherent non-convexity and potentially large dimensionality. Furthermore, variations in the weighting coefficients ($k_1$ to $k_7$) can result in objective function values spanning several orders of magnitude.

The scaling issue is addressed through a double-logarithmic transformation of the objective function, with an offset term to prevent numerical singularities:

$$\hat{\Phi} = \log_{10}(\log_{10}(\Phi + 10)) \tag{12}$$

The non-convexity is handled by exploiting the cusp-like topology of the objective function, as identified through preliminary grid-search analysis. Under these conditions, Powell's conjugate direction method demonstrates robust convergence behavior. Alternatively, genetic algorithms can be employed to guarantee global optimality, albeit with higher computational expense.

The high-dimensional search space is handled through a warm-start initialization strategy [11], wherein the discarded portion of the previous optimization solution provides the initial guess for subsequent iterations:

$$X^{\theta+1}_{first\ guess} = [X^{\theta}_{2}, X^{\theta}_{3}, X^{\theta}_{4}, \dots, X^{\theta}_{t_{regulation}-1}, X^{\theta}_{t_{regulation}}, X^{\theta}_{t_{regulation}}] \quad (13)$$

where $X$ represents an arbitrary decision variable stream. The final time step is replicated since $t_{regulation}$ initial values are required while only $t_{regulation} - 1$ values are available from the previous solution. For the initial simulation step, where no prior solution exists, genetic algorithms are employed due to their lack of initialization requirements.

## Renewable energy forecast modeling

Given the reliance on imperfect renewable energy forecasts and the difficulty in obtaining extended-horizon predictions at high temporal resolution, synthetically generated forecast data are employed in this analysis.

Artificial forecasts are derived from historical renewable generation profiles through application of two sequential perturbations: Savitzky-Golay filtering and time-dependent stochastic deviation.

The Savitzky-Golay filter attenuates high-frequency components while preserving underlying trends, thereby replicating the smoothing effect inherent to forecast models with limited temporal resolution.

Time-dependent stochastic perturbations are subsequently applied to represent forecast degradation with increasing prediction horizon. The filtered profile is modulated by a scaling factor incorporating both temporal distance from the present and normally distributed random variability:

$$\varepsilon_{eff} = (u_1 + u_2 \bullet t) \bullet rand_{normal} \quad (14)$$

$$E^{forecast}_{ren} = E^{SG-filtered}_{ren} \bullet (1 + \varepsilon_{eff}) \quad (15)$$

where the parameters $u_1$ and $u_2$ characterize forecast accuracy, and $E^{SG-filtered}_{ren}$ denotes the Savitzky-Golay-filtered generation profile.

This methodology enables a realistic representation of operational forecast behavior, yielding results consistent with actual forecasting system performance.

## Constraint-correction procedure

Due to discrepancies between optimal solution computed using forecast data and actual system behavior under real renewable generation profiles, constraint violations may occur during implementation despite satisfying constraints during optimization.

To address this issue, a post-processing correction procedure is applied at each time step to enforce constraint satisfaction based on realized operating conditions.

The correction algorithm proceeds hierarchically from downstream process requirements toward upstream renewable generation. For each system variable (flows and inventories), feasibility is evaluated against operational bounds. When violations are detected, the manipulated variables are adjusted to restore constraint satisfaction.

For a generic variable $X$, the corrected value $X^{final}$ and the constraint function $\psi_j$ to be satisfied are defined as:

$$X^{final} = \begin{cases} X^{max} & if\ X > X^{max} \\ X & if\ X^{min} \le X \le X^{max} \\ X^{min} & if\ X < X^{min} \end{cases} \quad (16)$$

$$\psi_j = model^{X}(E_{bess}, F_{tank}, E_{grid}) - X^{final} \quad (17)$$

Where $model^X$ represents the governing equation for variable $X$.

The hierarchical structure processes constraints sequentially. Initially, the constraint function $\psi$ for $F_{plant}$ is enforced through adjustment of $F_{tank}$. Subsequently, two independent subsystems address constraints on $m_{tank}$ and $E_{el}$, coupled respectively with $F_{plant}$ through $F_{tank}$ and $E_{bess}$ adjustments.

Finally, to satisfy the BESS charge constraint $Q_{bess}$, the corresponding function $\psi$ is incorporated into a system coupling $F_{plant}$ and $E_{el}$ constraints, with all three manipulated variables available for adjustment.

During resolution of the $E_{el}$ system, the previously corrected $m_{tank}$ value may not be preserved; however, this does not compromise system feasibility to all operational bounds. Physically, when energy surplus causes tank saturation, excess power is redirected to the BESS rather than the electrolyzer. In the limiting case where electrolyzer power remains above maximum capacity, power reduction yields a tank inventory slightly below maximum but always exceeding the uncorrected optimization result. Analogous reasoning applies to renewable energy deficit conditions, ensuring no operational conflicts arise.

## Productivity target enforcement

The methodology enforces production of a target hydrogen quantity over the simulation period:

$$M^{total}_{H_2} = F^{nominal}_{plant} \bullet \theta_{tot} \quad (18)$$

where $F^{nominal}_{plant}$ denotes the downstream facility nominal flow rate and $\theta_{tot}$ represents the total simulation duration.

To achieve this cumulative production target, the $F_{plant}$ reference production requires dynamic adjustment at each time step to account for deviations from nominal production. The objective is precise attainment of $M^{total}_{H_2}$

rather than production maximization.

The cumulative hydrogen production up to time $\theta$ can be expressed in discrete form as:

$$M_{H_2}(\theta) = M_{H_2}^{\theta} = \sum_{i=0}^{\theta} F_{plant}^{i} \bullet \Delta\theta \tag{19}$$

To satisfy the productivity constraint, the updated reference production $F_{plant}^{rp\ new}$ must compensate for the remaining production requirement:

$$M_{H_2}^{\theta} + F_{plant}^{rp\ new} \bullet (\theta_{tot} - \theta) = F_{plant}^{nominal} \bullet \theta_{tot} \tag{20}$$

Yielding:

$$F_{plant}^{rp\ new} = \frac{F_{plant}^{nominal} \bullet \theta_{tot} - M_{H_2}^{\theta}}{\theta_{tot} - \theta} \tag{21}$$

The updated reference production is subsequently bounded within operational limits $F_{plant}^{min}$ and $F_{plant}^{max}$.

This formulation exhibits fundamental limitations: when the computed reference production saturates at either bound, the productivity target becomes unattainable, as the physically required reference production exceeds the admissible operating range. Additionally, stochastic fluctuations cause the average production to systematically deviate from the reference production when operating at the constraints, progressively amplifying the deviation between ideal and constrained reference production values.

An alternative formulation addresses this issue by distributing the production deficit over a fraction of the remaining horizon rather than the entire duration. The original formulation is designated the "ideal reference production, " representing the constant flow rate that would achieve the target productivity. The modified formulation, with $\alpha$ denoting the fraction of remaining time considered, becomes:

$$F_{plant}^{rp\ new} = F_{plant}^{nominal} + \frac{F_{plant}^{nominal} \bullet \theta - M_{H_2}^{\theta}}{(\theta_{tot} - \theta) \bullet \alpha} \tag{22}$$

This expression is also subject to feasibility constraints within operational bounds.

The revised formulation allows the ideal reference production to converge toward nominal conditions, thereby reducing cumulative productivity deviations.

Both formulations exhibit pronounced oscillatory behavior near simulation termination, as illustrated in **Figure 2**, attributable to the diminishing remaining time in the denominator, which amplifies the sensitivity to production deviations.

**Figure 2** also demonstrates that reference productions persistently exceed nominal production rates throughout most of the simulation period. This phenomenon arises because renewable energy deficits necessitate elevated reference productions, while surplus renewable generation is preferentially allocated to buffer charging rather than production intensification.

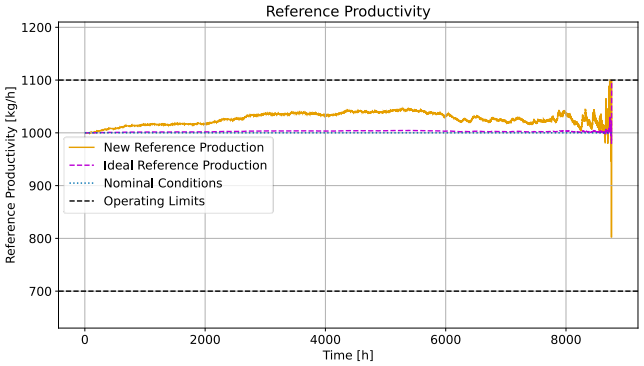

**Figure 2:** Comparison of the reference productions: “new” (solid orange), “ideal” (dashed magenta) and nominal conditions (dotted blue).

## RESULTS AND DISCUSSION

The proposed methodology is validated through a case study focused on hydrogen production for a downstream ammonia plant. Renewable energy availability is derived from data provided by the California Independent System Operator (CAISO) [12] from 2020.

The optimal sizing of the units, the definition of nominal operating conditions for the downstream plant, and the identification of operational constraints are determined using the methodologies developed by Isella and Manca, as described in [13, 14] and subsequently integrated in [15]. Constant parameters are obtained from technical reports and peer-reviewed scientific literature. Weighting factors are fine-tuned based on a combination of parametric analysis and engineering judgment, reflecting the relative importance of each objective term. Parameters such as $t_{regulation}$ and $\alpha$ are selected as compromises between, respectively, model accuracy and computational efficiency, and between error correction speed and reference production oscillations.

The two buffer units and the electrolyzer are assumed to be highly flexible, with no limitations related to rapid variations in ramping rates. Additionally, the self-discharge of both buffer units is considered negligible, and the charging and discharging efficiencies of the hydrogen tank are assumed to be unity, implying no hydrogen losses.

The one-year dynamic simulation required 2106 s of CPU time on a conventional Windows computer (Intel Core i7-1195G7 @ 2.9 GHz, 11th generation, 16 GB RAM), running Python code pre-compiled using Numba JIT. The average computation time per simulation step was 0.24 s, demonstrating that the proposed methodology is compatible with real-time execution.

The results of the case study show that the average renewable and grid power supplied to the battery energy

storage system (BESS) and the electrolyzer is approximately 54.16 MW. This value is consistent with the electrolyzer energy demand under nominal operating conditions, as expressed by:

$$E_{el}^{nominal} = F_{plant}^{nominal}/c_{el} \approx 54\ MW \tag{23}$$

where $F_{plant}^{nominal} = 1000\frac{kg_{H_2}}{h}$ and $c_{el} = 18.5\ kg_{H_2}/MWh$.

Both the BESS and the hydrogen tank exhibit similar seasonal trends, with higher state-of-charge levels during the summer and nearly depleted conditions during the winter. The BESS, however, experiences larger fluctuations due to its smaller capacity. The sizing methodology [15] results in a BESS capacity of 31.81 MWh and a tank capacity of 14.58 $t_{H_2}$. Consequently, the BESS frequently reaches full charge or discharge to mitigate renewable power variability.

As expected, the electrolyzer operates predominantly near its nominal capacity to ensure the target hydrogen production rate of 1000 $kg_{H_2}$/h. Owing to its high flexibility, the electrolyzer exhibits frequent load variations, which contribute to a reduced required BESS capacity relative to the hydrogen tank. The larger tank size is also justified by the stringent constraints imposed by the downstream plant, which require the hydrogen flow rate to remain within the range of 700 to 1100 $kg_{H_2}$/h, as can be seen in **Figure 3**. In this context, the tank plays a crucial role in ensuring operational stability and preventing sudden and large fluctuations in hydrogen supply.

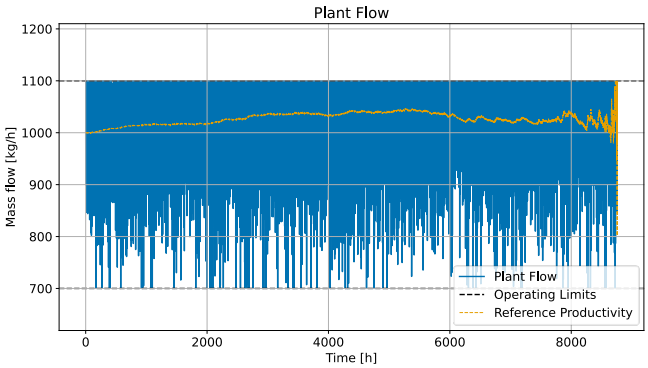

**Figure 3:** Hydrogen flow rate to the downstream plant.

A comparison between the hydrogen flow rate obtained in this scenario and that of a configuration without scheduling and buffer systems highlights the importance of the proposed approach. In the absence of buffers and scheduling, operational constraints are systematically violated, and the plant fails to meet its required operating limits.

From an economic standpoint, the minimum levelized cost of hydrogen (LCOH), accounting only for capital expenditure, is given by:

$$LCOH_{min} = \frac{CAPEX}{M_{H2}^{total}} = \frac{\sum_j size_j \bullet \frac{cost_j}{life_j}}{M_{H2}^{total}} = 3.00\frac{USD}{kg_{H_2}} \tag{24}$$

where the capital cost is defined as the sum of the purchase costs of each unit divided by their respective expected lifetimes.

The actual LCOH also includes the cost of electricity consumption and the effective hydrogen production. In the present analysis, revenues from selling excess electricity to the grid are not considered, and the excess renewable generation is curtailed; therefore, the resulting LCOH represents a conservative estimate. Assuming a constant electricity price of 100 USD/MWh, the final LCOH is:

$$LCOH_{eff} = \frac{CAPEX + cost_{grid} \bullet E_{grid}^{buy}}{M_{H2}^{\theta_{tot}}} = 3.31\frac{USD}{kg_{H_2}} \tag{25}$$

The total hydrogen production over the simulation period amounts to 8759.949 $t_{H_2}$, compared to a target value of 8760 $t_{H_2}$. The discrepancy of 51 $kg_{H_2}$ is considered negligible and can be attributed to forecast–reality mismatches. First, industrial flowmeters typically exhibit an accuracy of approximately 0.25%, corresponding to a minimum detectable deviation of about 22 $t_{H_2}$, which is several orders of magnitude larger than the observed difference. Second, contractual agreements with the downstream plant are assumed to allow for limited operational flexibility, such that a deviation of 0.0006% does not incur penalties. Finally, at the end of the simulation, approximately 670 $kg_{H_2}$ of hydrogen remains available in the tank, allowing the missing production to be compensated without violating any operational constraints and fully compensating for the observed overproduction.

From an environmental perspective, the only emissions associated with hydrogen production in the proposed system originate from grid electricity generation. The simulation indicates a grid electricity consumption of 26.94 GWh, which corresponds to estimated emissions of 0.92 $kg_{CO_2}/kg_{H_2}$, assuming a grid emission factor of 0.3 $kg_{CO_2}$/kWh.

This emission intensity can be compared with conventional hydrogen production pathways, such as steam methane reforming and water-gas shift processes, whose emissions are typically estimated to range from 10 $kg_{CO_2}/kg_{H_2}$ for natural gas-based systems to 26 $kg_{CO_2}/kg_{H_2}$ for coal-based systems. The proposed approach therefore achieves a reduction of more than one order of magnitude relative to conventional technologies.

The current system configuration does not explicitly include the compression stage between the electrolyzer, the hydrogen tank, and the downstream plant. However, a post-processing analysis indicates that incorporating

the compression system would increase the final LCOH by less than 3%.

The specific compression work is evaluated based on the inlet and outlet pressures (corresponding to the electrolyzer outlet pressure and the tank inlet pressure, representing the case with the largest pressure differential), the electrolyzer operating temperature, the compressor efficiency, and the thermodynamic properties of hydrogen:

$$l_{spec}^{comp} = \frac{1}{\eta_{comp}} \cdot \frac{\gamma}{\gamma - 1} \cdot \frac{R}{MW_{H_2}} \cdot T_1 \cdot \left[ \left( \frac{P_2}{P_1} \right)^{\frac{\gamma-1}{\gamma}} - 1 \right] \quad (26)$$

Assuming a pressure ratio of 30, an inlet temperature of 60 °C, and a compressor efficiency of 0.6, the resulting specific compression work is 0.004 MWh/$kg_{H_2}$.

If the required compression energy is supplied exclusively from the grid and only in the absence of renewable energy surplus, the updated LCOH becomes 3.42 USD/$kg_{H_2}$. This corresponds to an increase of less than 3%, or 0.11 USD/$kg_{H_2}$, relative to the configuration without the compression unit.

## CONCLUSIONS

This work presents a novel approach for the scheduling of hydrogen production plants. The proposed framework introduces a robust methodology that solves a multidimensional optimization problem over a receding horizon, enabling the delivery of a target hydrogen flow rate to the downstream plant while simultaneously reducing unit stress and grid electricity consumption, and ensuring strict compliance with all operational constraints.

The use of imperfect renewable energy forecasts significantly enhances the realism of the analysis and demonstrates the robustness of the methodology in managing discrepancies between forecasted and actual energy availability. Despite these mismatches, the system consistently satisfies all operational constraints. A further key feature of the proposed approach is its ability to guarantee the target hydrogen productivity through dynamic adjustment of the operating reference production.

From an economic standpoint, the resulting levelized cost of hydrogen (LCOH) is consistent with values reported in the literature and remains below current industrial hydrogen production costs. From an environmental perspective, the methodology achieves a reduction in carbon dioxide emissions of approximately one order of magnitude compared to conventional hydrogen production pathways, such as natural gas- or coal-based processes.

The proposed approach is fully automated and does not require human intervention during operation, thereby reducing the risk of human-related errors. The operator's role is limited to system supervision and fault detection. Furthermore, the methodology is general in nature and can be readily adapted to existing industrial facilities, offering a practical pathway to improve operational efficiency and overall system performance.

Despite these advantages, several limitations should be acknowledged. First, the renewable energy forecast model lacks full accuracy, as it is derived as a post-processing step from real energy profiles. Additionally, the stochastic component is defined as a fixed percentage of the filtered profile, resulting in increasing absolute deviations at higher renewable generation levels (e.g., during summer periods), even though the relative error remains constant. Second, operational and maintenance costs are not included in the LCOH calculation, which would lead to a higher overall cost estimate. Third, the electricity price is assumed to be constant, whereas in practice it is time-dependent and subject to market variability. Finally, although its contribution is relatively minor, the compression system should be explicitly integrated into the main system model.

Future developments may include the extension of the methodology to islanded systems, where access to grid electricity is not available. In addition, a more detailed and explicit modeling of downstream processes, such as ammonia or methanol synthesis plants, would further enhance the industrial relevance and applicability of the proposed approach.

## ABSTRACT

Early and reliable prediction of convergence to cyclic steady state (CSS) is increasingly important in periodic downstream bioprocessing, where switching and cut decisions are tuned for a repeatable cyclic regime. This work addresses time-to-CSS (TCSS) forecasting and CSS-existence classification for multicolumn countercurrent solvent gradient purification (MCSGP) systems under run-to-run feed variability. We propose a Multi-Feature k-Nearest Neighbours (MF-kNN) framework that performs long-horizon one-shot trajectory forecasting from an early run segment. CSS outcomes are inferred by reapplying a peak-based convergence rule to the predicted trajectory, while CSS existence is predicted via neighbour-label voting. The approach uses multivariate, standardised features, run-level splits, and a windowed neighbour search to reduce computation. Hyperparameters are tuned with a CSS-oriented objective function that balances trajectory fidelity, TCSS error, and misclassification penalties. On an in-silico MCSGP dataset (98 runs; $\Delta t$ = 0.2 s; 6800 steps/run) with varying initial modifier concentration, MF-kNN produces accurate full-run forecasts from early data and enables operationally useful early go/no-go decisions. Across outlets, results support accurate CSS timing inference and high CSS-existence classification accuracy (up to 100% on selected outlets), indicating MF-kNN as a transparent and deployment-ready complement to cycle-to-cycle CSS monitoring and control.

**Keywords**: cyclic steady state, periodic bioprocessing, MCSGP, time-to-CSS forecasting, k-nearest neighbours, one-shot forecasting

## INTRODUCTION

Biomanufacturing is progressively shifting from conventional batch workflows toward increasingly integrated operations that deliver higher productivity with reduced footprint (e.g., via higher volumetric productivity, reduced hold steps, and tighter integration of unit operations) [1, 2]. This evolution is visible in industrial biopharmaceutical manufacturing, particularly in down-stream purification where chromatographic separations have moved from single-column, non-periodic operation to cyclic multicolumn switching schemes, such as capture purification transitioning from batch Protein A chromatography toward periodic counter-current chromatography (PCC) [3], challenging polishing tasks extending from single-column batch gradient operation to multicolumn countercurrent solvent gradient purification (MCSGP) [4], and, more broadly, simulated moving bed (SMB) chromatography employing cyclic switching to sustain periodic operation with improved utilisation relative to single-column batch processing [10]. Because these schemes rely on repeated switching cycles, their analysis and performance assessment hinge on whether the process has reached a repeatable periodic regime, commonly termed cyclic steady state (CSS).

CSS generally refers to the regime in periodic operation where cycle-to-cycle behaviour becomes repeatable within defined tolerances, so that outlet profiles and cycle-level outcomes no longer exhibit systematic drift [5]. In MCSGP, this notion is operationalised by requiring that consecutive-cycle chromatograms and cut outcomes meet repeatability criteria, typically assessed by

comparing feature summaries such as peak maxima, peak areas, retention times, and pool compositions against acceptance thresholds tied to process objectives and analytical variability [5]. This repeatability-based workflow also aligns with process-development and performance-qualification practice, where multiple consecutive cycles are evaluated at a candidate operating point to confirm stable cyclic performance before re-porting yields and purities [6].

With CSS as the target operating regime in such periodic processes, an operationally important question is whether the process will attain a repeatable cyclic pattern within the available operating horizon and, if so, when [5]. The answer affects column switching schedules, fraction collection, solvent usage, and product quality in cyclic downstream operations [5]. Overly conservative actions can waste resources and extend runtime, while premature decisions can degrade purity or yield and disrupt intended continuous operation [5].

These considerations motivate reliable early CSS forecasting and classification to support (i) early run-level go/no-go decisions on continued operation, (ii) anticipatory adjustment of fractionation and recycle policies during the transient approach to CSS, and (iii) improved planning of pooling and resource utilisation (e.g., buffer and hold capacities) in integrated downstream trains.

MCSGP provides a representative case study for periodic CSS decision support: it is a semi-continuous chromatography platform for biomolecule purification that exhibits strongly periodic dynamics under coordinated column switching and solvent gradients [4]. These dynamics are shaped by nonlinear adsorption and mass transfer, while feed variability and initial conditions influence convergence toward CSS [5]. In practice, operating poli-cies such as gradient programs, cut criteria, and recycle routing are typically tuned for the cyclic regime; therefore, uncertainty about CSS convergence and timing propagates into decision un-certainty and disturbances [5]. Accordingly, this work examines whether early-cycle information can enable prospective inference of CSS convergence and timing in MCSGP, shifting beyond retrospective confirmation toward prospective decision support that reduces the latency inherent to cycle-to-cycle monitoring and UV-based control [5].

## 1.1 Literature review: CSS detection and management in periodic bioprocesses

A substantial body of MCSGP work has therefore focused on CSS management via closed-loop operation rather than purely offline certification. Optimisation and control studies treat MC-SGP as a cyclic, hybrid process in which switching and gradient decisions must remain robust under nonlinear adsorption, mass transfer, and delayed measurements, motivating cycle-to-cycle formulations and multi-rate measurement use [5]. Building on this, UV-based closed-loop strategies have been proposed to regulate key cycle outcomes via online peak-tracking and cut adjustment, demonstrating practical controllers that mitigate drift in chromatographic signatures once operation is near the cyclic regime [5]. More recent implementations extend these concepts to improve robustness under disturbances such as feed variability and retention-time shifts, targeting earlier convergence and stable cyclic operation using limited online information [6]. Overall, the MCSGP literature converges on a consistent operational picture: CSS is detected and maintained primarily through cycle-to-cycle repeatability of chromatographic signatures and control actions that keep cycle-level KPIs in-spec [5, 6].

When CSS is addressed predictively, it is most often through model-based simulation and surrogate acceleration rather than prospective inference from early online data. Mechanistic models have been used to simulate MCSGP start-up, CSS attainment, and shutdown behaviour and to predict performance parameters under specified operating conditions, at the cost of repeated-cycle simulation [7]. To reduce this computational burden, hybrid or data-driven surrogates have been developed that target rapid prediction of CSS behaviour for optimisation and decision support (for example, hybrid formulations that achieve CSS predictions substantially faster than high-fidelity models) [8]. Closely related efforts in cyclic adsorption more broadly also emphasise accelerating cyclic-process prediction and synthesis, for instance by physics-informed neural network surrogates designed for cyclic adsorption calculations [9]. These strands primarily support faster CSS computation given a model or training set, rather than early-cycle, forecast-driven go/no-go decisions using only initial-cycle measurements.

Beyond MCSGP, cyclic steady state is a foundational concept in other periodic separations and bioprocess settings. In simulated moving bed (SMB) and related multicolumn chromatography, CSS is often defined formally via periodicity constraints (end-of-cycle states equal start-of-cycle states) and assessed via convergence of cycle-to-cycle outlet profiles and KPIs [10]. The corresponding literature includes dedicated numerical methods for computing CSS efficiently, reflecting the importance of cycle-level periodicity in SMB design and optimisation [11, 10]. Similar convergence logic appears in other cyclic bioprocesses, for example sequencing batch reactors, where steady cyclic operation is assessed when cycle-aggregated performance indicators become repeatable over successive cycles, enabling consistent operation and control [12, 13]. Across these domains, the dominant CSS handling paradigm remains cycle-to-cycle convergence of either (i) observable signatures (peaks, areas, outlet profiles) or (ii) cycle-aggregated KPIs, with control-oriented studies prioritising robust repeatability

under disturbances [5, 10].

### 1.2 Research gaps and contributions

In MCSGP, and more broadly in periodic downstream and cyclic bioprocess operations, CSS decision support is still dominated by repeatability-based confirmation rather than prospective pre-diction from early-cycle information. Despite the mature body of CSS monitoring and control work surveyed in the previous section, a central limitation for early decision support is that CSS is commonly confirmed retrospectively via consecutive-cycle repeatability checks. This retrospective paradigm is not ideal because it:

- Provides limited quantitative information about proximity to CSS and remaining stabilisation time, constraining proactive planning during start-up.
- Introduces an inherent confirmation latency, since a candidate CSS convergence point can only be validated after observing subsequent cycles (or peaks) that satisfy the tolerance.
- Ties switching, cutting, and recycle actions to confirmed repeatability, delaying high-value decisions (e.g., collection start, recycle routing).

While mechanistic models and advanced nonlinear surrogates can, in principle, predict CSS behaviour, such approaches are often computationally heavy and difficult to deploy online under run-to-run variability [15]. As a result, operators may delay high-value actions until CSS is verified or take conservative actions that reduce productivity. These limitations motivate forecast-driven methods that deliver early, computationally light decision support in periodic operation.

This work addresses these gaps with a multi-feature k-Nearest Neighbours (MF-kNN) framework [14], developed and evaluated on MCSGP, for TCSS forecasting and CSS-existence classification. By leveraging multivariate, physically meaningful signals, MF-kNN provides long-horizon one-shot predictions from early-cycle data, enabling earlier decisions than retrospective cycle-to-cycle confirmation and UV-triggered actions. Performance is benchmarked against classical and learning-based forecasting models, alongside a univariate kNN model, to contextualise accuracy and runtime. Specifically, MF-kNN is tailored to CSS decision support through:

- CSS-aligned inference: CSS is inferred from forecasts using a peak-based convergence rule yielding both TCSS estimates and a CSS-existence classification.
- Multivariate similarity over measured chromatographic signals: a feature-weighted distance over multiple online variables (e.g., outlet concentration traces and modifier profiles), with standardisation to keep signals comparable and avoid dominance by any single measurement.
- Localised neighbour search: a ±W windowed neighbour search around the forecast start time that improves relevance and reduces runtime, supporting online use.
- CSS-oriented validation and tuning: a validation objective that jointly scores trajectory accuracy and TCSS error, with explicit penalties for incorrect CSS-existence predictions to reduce optimistic false positives.
- Early-cycle feasibility: early, one-shot prediction using only the initial segment of the run.

## METHODOLOGY

### 2.1 Process overview and dataset

We consider periodic MCSGP runs, where coordinated column switching and a solvent-modifier gradient induce repeated elution cycles. The data was generated in silico using a validated gPROMS model of the MCSGP process under run-to-run variability in the initial modifier setting. The dataset comprises $N_{run}$ = 98 runs totalling 666, 400 timesteps, sampled every $\Delta t = 0.2\,s$, with fixed run length $T$ = 6800 timesteps (approximately 22.67 min/run).

For each run $r \in \{1, \ldots, N_{run}\}$, the recorded signals include inlet and outlet concentration traces for the four tracked components, $\{C_{\mathrm{in},c,r}(t), C_{\mathrm{out},c,r}(t)\}_{c=1}^{4}$, where $c = 1$ denotes the modifier (buffer), $c = 2$ weak impurities, $c = 3$ product, and $c = 4$ strong impurities. The initial modifier value is set at the start of each run and varies across runs; we denote this run-level preset by $C_{\mathrm{in},1,r}(0)$. The corresponding modifier trajectory $C_{\mathrm{in},1,r}(t)$ evolves over the run according to the imposed gradient program. This exogenous run-to-run variability influences both whether CSS is reached within the finite run horizon and the resulting TCSS, thereby complicating reliable early detection and forecasting. Figures 1 and 2 illustrate representative periodic concentration profiles and the distribution of $C_{\mathrm{in},1,r}(0)$ across runs, respectively.

### 2.2 Problem definition

For run $r$, let $\boldsymbol{x}_r(t)$ denote a designated target concentration profile and let $\{\boldsymbol{u}_{r,j}(t)\}_{j=2}^{p}$ denote auxiliary measured trajectories over $t = 0, \ldots, T$. We define the TCSS for run $r$ as $TCSS_r$. At an early initialisation time $t_0 < T - h$, where $h$ denotes the forecast horizon (timesteps), the objectives are to: (i) generate a one-shot forecast of the remainder of the run, i.e., predict $\boldsymbol{x}_r(t)$ for $t = t0 + 1, \ldots, T$; (ii) classify whether CSS will be achieved within the run horizon; and, if CSS is declared, then (iii) estimate $TCSS_r$.

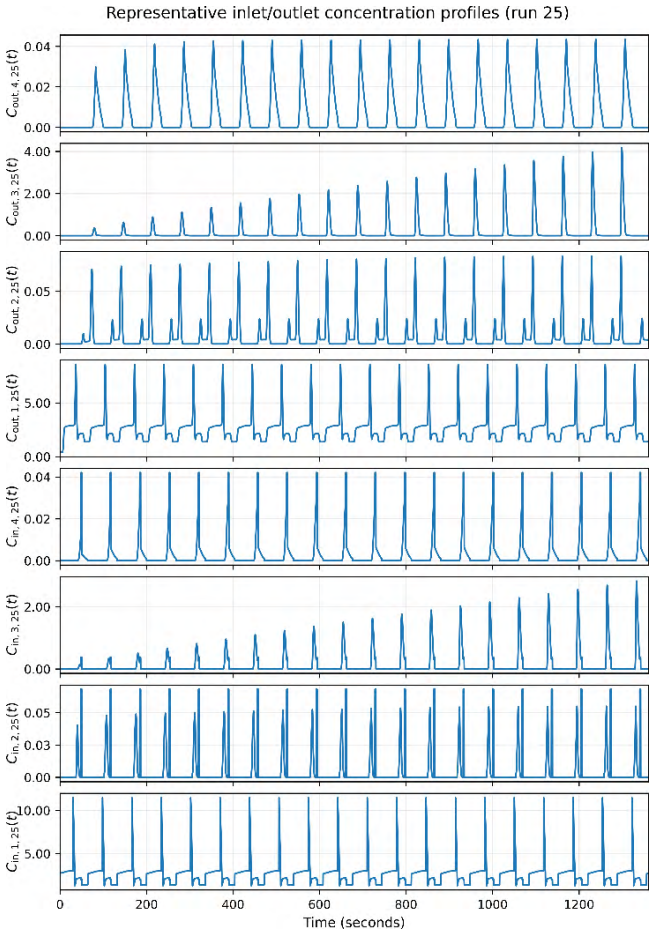

**Figure 1.** Representative concentration profiles for run 25 showing periodic elution cycles and convergence variability.

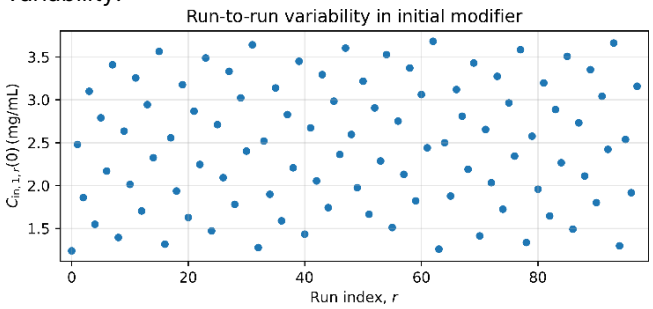

**Figure 2.** Run-to-run variability in the initial modifier concentration

## 2.3 Peak-based CSS detection

Peaks are detected on the target series $\boldsymbol{x}_r(t)$ and filtered to retain only the large peaks. Smaller peaks with amplitudes below a fixed cutoff $\alpha$ are discarded, and only peaks with $\boldsymbol{x}_r(t_{peak}) \geq \alpha$ are retained. Let $\{t_{\mathrm{peak},i}, A_i\}_{i=1}^{N_{\mathrm{peak}}}$ denote the retained peak times and amplitudes, where $A_i$ is the amplitude of the $i$-th large peak. CSS is declared when consecutive large-peak amplitudes remain within tolerance for $q$ successive peak pairs:

$$|A_{i+\ell} - A_{i+\ell+1}| < \varepsilon, \qquad \ell = 0, \ldots, q-1 \tag{1}$$

where $\varepsilon$ is the peak-amplitude tolerance and $q$ is the required number of consecutive satisfactions. If Eq. (1) is first satisfied at peak index $i^\star$, then the TCSS is defined as:

$$T_{\mathrm{CSS},r} := t_{\mathrm{peak},i^\star} \tag{2}$$

A binary CSS-existence label $z_r \in \{0,1\}$ is assigned based on whether CSS is reached within the finite run horizon. As illustrated in Figure 3, the TCSS is taken as the time index of the first peak that satisfies the convergence criterion.

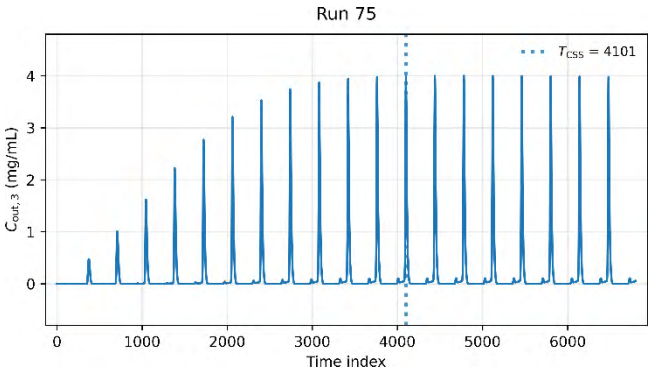

**Figure 3.** Peak-based CSS definition

## 2.4 MF-kNN one-shot forecasting

For run $r$, we construct a $p \times (T+1)$ data matrix by stacking the target and auxiliary signals:

$$Y_r(T) = \begin{bmatrix} x_r(0) & x_r(1) & \cdots & x_r(T) \\ u_{r,2}(0) & u_{r,2}(1) & \cdots & u_{r,2}(T) \\ \vdots & \vdots & \ddots & \vdots \\ u_{r,p}(0) & u_{r,p}(1) & \cdots & u_{r,p}(T) \end{bmatrix} \tag{3}$$

Here, feature index $j = 1$ corresponds to the target $\boldsymbol{x}_r(t)$, and $j = 2, \ldots, p$ correspond to auxiliary trajectories $\boldsymbol{u}_{r,j}(t)$. At an initialisation time $t_0 < T - h$, we represent the recent evolution of each feature using a unified embedding length $m$ (i.e., $m_j \equiv m$ for $j = 1, \ldots, p$). For the target ($j = 1$), we define the embedded evolution segment:

$$\boldsymbol{x}_r(t_0) := [x_r(t_0 - m + 1), \ldots, x_r(t_0)]^{\mathsf{T}} \in R^m \tag{4}$$

Similarly, for each auxiliary feature $j = 2, \ldots, p$, we define:

$$\boldsymbol{u}_{r,j}(t_0) := \left[u_{r,j}(t_0 - m + 1), \ldots, u_{r,j}(t_0)\right]^{\mathsf{T}} \in R^m \tag{5}$$

The multi-feature evolution segment is then formed by stacking the embedded segments as rows:

$$Y_r(t_0) = \begin{bmatrix} \boldsymbol{x}_r(t_0)^{\mathsf{T}} \\ \boldsymbol{u}_{r,2}(t_0)^{\mathsf{T}} \\ \vdots \\ \boldsymbol{u}_{r,p}(t_0)^{\mathsf{T}} \end{bmatrix} \in R^{p \times m} \tag{6}$$

### Multi-feature distance

Given a query run $r$ at initialisation time $t_0$, candidate neighbours are drawn from memory runs $r' \in R_{mem}$. For each memory run $r'$ and admissible endpoint $\tau$, the candidate segment $Y_{r'}(\tau) \in R^{p\times m}$ is constructed identically to $Y_r(t_0)$ by taking the most recent $m$ samples of each feature up to $\tau$, with $\tau$ constrained to $m-1 \le \tau \le T-h$. Similarity between the query segment $\boldsymbol{Y_r}(t_0)$ and a candidate segment $\boldsymbol{Y_{r'}}(\tau)$ is computed via a feature-weighted Euclidean distance. Defining $\Delta\mathbf{Y} := \boldsymbol{Y_r}(t_0) - \boldsymbol{Y_{r'}}(\tau)$, we compute:

$$D\big(\boldsymbol{Y_r}(t_0), \boldsymbol{Y_{r'}}(\tau)\big) = \sqrt{\sum_{j=1}^{p} w_{f,j} \left\|\Delta \boldsymbol{Y_{j,:}}\right\|_2^2} \tag{7}$$

where $\boldsymbol{Y_{j,:}}$ denotes the $j$-th row and $w_{f,j} \ge 0$ with $\sum_{j=1}^{p} w_{f,j} = 1$.

### Neighbour selection

The $k$ candidates with smallest distance $D$ are selected as neighbours, indexed by pairs $\{r_n, \tau_n\}_{n=1}^{k}$. These neighbours are then weighted to favour candidates that are (i) close in the embedded signal space and (ii) close in the run-level initial modifier setting. First, we define the distance proximity score:

$$s_n^{(D)} := \frac{1}{2}\left(1 - \frac{D_n}{\sum_{\ell=1}^{k} D_\ell}\right) \tag{8}$$

Here $D_n := D\big(Y_r(t_0), Y_{r_n}(\tau_n)\big)$. Next, define the modifier proximity score:

$$s_n^{(C)} := \frac{1}{2}\left(1 - \frac{\Delta C_n}{\sum_{\ell=1}^{k} \Delta C_\ell}\right) \tag{9}$$

Here $\Delta C_n := |C_{\text{in},1,r}(0) - C_{\text{in},1,r_n}(0)|$. If a normalising denominator is zero, the corresponding score is set uniformly over the $k$ neighbours. The final aggregation weights are obtained by summing the two scores and normalising to sum to one:

$$\omega_n := \frac{s_n^{(D)} + s_n^{(C)}}{\sum_{l=1}^{k}\left(s_\ell^{(D)} + s_\ell^{(C)}\right)}, n = 1, \ldots, k \tag{10}$$

## One-shot forecast

Finally, the one-shot forecast of the target trajectory is obtained by weighted aggregation of the neighbours' future continuations:

$$\hat{\boldsymbol{x}}_{\boldsymbol{r}}(t_0+1{:}\,t_0+h) = \sum_{n=1}^{k} \omega_n \, x_{r_n}(\tau_n+1{:}\,\tau_n+h) \tag{11}$$

### CSS inference

Because historical runs are labelled with CSS existence, the neighbour set supports classification without an additional model. Let $z^{(n)}$ be the CSS-existence label for neighbour $n$. The CSS-existence decision is then:

$$\hat{z} = I\left(\sum_{n=1}^{k} \omega_n \, z^{(n)} \ge \eta\right) \tag{12}$$

with voting threshold $\eta$ (default $\eta = 0.5$). When $\hat{z} = 1$, the predicted $\hat{T}_{\text{CSS}}$ is obtained by applying the same peak rule (Eq. (1)) to the full reconstructed trajectory; i.e. using measured values for $t < t_0$ and the one-shot forecast for $t \ge t_0$.

## 2.5 Hyperparameter tuning objective

We tune $k$, feature weights $w_f$, and any embedding or window parameters, to balance trajectory fidelity, TCSS accuracy, and CSS-existence correctness. Let $\mathcal{L}_{traj}$ denote a trajectory loss over the forecast horizon. We define:

$$\text{Obj}_1 = \frac{1}{N}\sum_{r=1}^{N} \mathcal{L}_{traj}(\boldsymbol{x_r}, \hat{\boldsymbol{x}}_{\boldsymbol{r}}) \tag{13}$$

$$\text{Obj}_2 = \frac{1}{N}\sum_{r=1}^{N} \begin{cases} |T_{\text{CSS},r} - \hat{T}_{\text{CSS, r}}| & if\ z_r = \hat{z}_r = 1 \\ 0 & if\ z_r = \hat{z}_r = 0 \\ penalty & if\ z_r \ne \hat{z}_r \end{cases} \tag{14}$$

Let $N$ denote the number of validation runs. We combine the trajectory term $\text{Obj}_1$ and the CSS-aligned term $\text{Obj}_2$ into a single scalar objective:

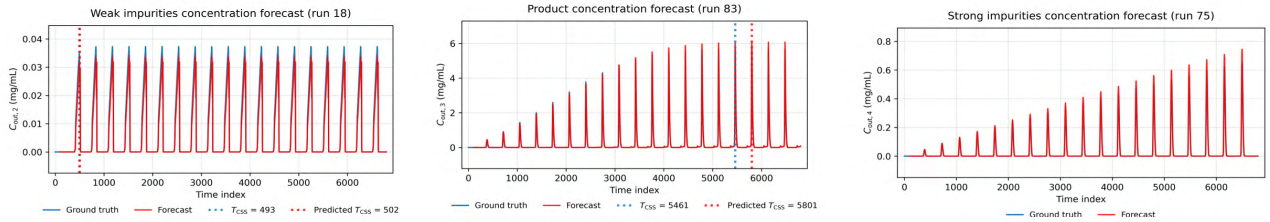
$$\text{Obj}_{\text{overall}} = (1-\beta)\text{Obj}_1 + \beta\text{Obj}_2 \tag{15}$$

where $\beta \in [0, 1]$ controls the trade-off.

## 2.6 Experimental protocol and implementation notes

We use a run-wise split of $80/10/10\%$ for memory/validation/test. For $N_{run}$ = 98, this yields $N_{mem}$ = 78, $N_{val}$ = 10, and $N_{test}$ = 10. The features are standardised to prevent feature scale dominance. Forecasts are computed one-shot using only the first 100 timesteps of the unfolding run.

Hyperparameters are tuned on validation runs using grid search. Tuned parameters include the neighbour count $k \in \{1, 3, 5, \ldots, k_{max}\}$, feature weights $w_{f,j} \in [0, 1]$, the neighbour aggregation scheme (uniform vs. distance-weighted), and window/embedding settings. Candidate combinations are scored using the composite objective in Eq. (15). For computational efficiency, the neighbour search is restricted to a local temporal window around the forecast initialisation time such that when forecasting a run at $t_0$, candidate historical segments are only drawn from memory runs with segment endpoints $\tau \in [max(0, t_0 - W), min(T-1, t_0 + W)]$, where $W$ is a window half-width in timesteps. Distances are computed



(a) $C_{\text{out},2,18}$ (b) $C_{\text{out},3,83}$ (c) $C_{\text{out},4,75}$

**Figure 4.** Representative one-shot forecasts for the outlet concentrations initialised at $t_0$ = 100.

between the query segment ending at $t_0$ and each candidate segment ending at $\tau$, and the $k$ nearest neighbours are selected by which a one-shot forecast is then generated as defined in Eq. (11). We report trajectory error in MSE, TCSS error in RMSE, and CSS-existence classification accuracy in percentage.

## 2.7 Benchmark models and comparative evaluation criteria

To contextualise MF-kNN performance, a comparative one-shot forecasting study was conducted against representative classical and learning-based baselines, alongside a univariate kNN model. All models were evaluated under a common run-wise protocol, where forecasts were initialised at the same $t_0$ timestep, and the prediction horizon was set to the remainder of the run. The forecasting target is the outlet signal $C_{\text{out},3,r}(t)$. Hyperparameters were tuned on the validation runs using model-specific searches.

**Benchmarked models.** The benchmark suite comprises: (i) MF-kNN; (ii) Univariate kNN; (iii) ARMA as a classical stochastic time-series baseline for periodic signals; (iv) Theta as a lightweight statistical forecasting baseline; and (v) LSTM as a representative recurrent neural forecasting model.

**Tuning and scoring.** Hyperparameters were tuned via a fixed number of trials on the validation runs. MF-kNN tunes the neighbour count and feature weights; univariate kNN tunes the neighbour count; ARMA tunes (p, q); Theta tunes θ; and the LSTM tunes hidden-unit configuration. Evaluation considers both (a) trajectory prediction error for $C_{\text{out},3,r}(t)$ over the forecast horizon and (b) error on the derived CSS timing metric from the corresponding predictions, so that models are compared on the same decision-support objective.

# RESULTS AND DISCUSSION

**Qualitative performance.** Figure 4 illustrates representative one-shot forecasts for outlet concentration profiles using only the first 100 timesteps. Across these examples, MF-kNN reproduces the dominant periodic dynamics over the full horizon, correctly distinguishes CSS from no-CSS runs, and yields TCSS estimates that are consistent with the peak-based rule.

**Quantitative performance.** We summarise quantitative results on the held-out test set using three primary metrics. Table 1 reports trajectory accuracy as MSE, TCSS error as RMSE, and CSS-existence classification accuracy (%). Table 2 reports the CSS-existence confusion matrix for $C_{\text{out},3,r}(t)$, from which precision and recall can be computed. As shown in Table 1, MF-kNN achieves consistently low trajectory errors across the outlet signals, indicating that the one-shot forecasts reproduce the dominant periodic structure and amplitude of the concentration profiles. The CSS-existence classification performance is strong overall (average accuracy 96.7%), with perfect classification reported for $C_{\text{out},3,r}(t)$ and $C_{\text{out},4,r}(t)$ and a small degradation for $C_{\text{out},2,r}(t)$ at 90%, suggesting that early segments contain sufficient information to discriminate convergent from non-convergent behaviour in most cases. In contrast, the TCSS RMSE exhibits a clearer dependence on the outlet signal: $C_{\text{out},2,r}(t)$ and $C_{\text{out},3,r}(t)$ show substantially lower timing errors than $C_{\text{out},4,r}(t)$, indicating that CSS timing is harder to infer for $C_{\text{out},4,r}(t)$, likely due to weaker observability of peak stabilisation or greater sensitivity of its peak features to transient dynamics and noise. Overall, this trend highlights that accurate CSS existence prediction can be achieved even when the precise timing of convergence is more uncertain for specific outlets.

**Benchmark comparison.** Under the common one-shot protocol described in Section 2.7, Table 3 shows that MF-kNN provides the most reliable decision-support performance for $C_{\text{out},3,r}(t)$ among the benchmarked methods. Beyond achieving the lowest CSS timing error, MF-kNN is the only method in the benchmark set that simultaneously maintains low trajectory error and high CSS-existence accuracy, which is the key requirement for early operational decisions. The univariate kNN baseline degrades both timing and classification performance relative to MF-kNN, indicating that leveraging additional measured signals in the distance metric improves neighbour relevance and reduces ambiguity in early-cycle matching. The LSTM and ARMA baselines perform poorly in this setting, which is consistent with the difficulty of

learning stable long-horizon dynamics from limited early segments under run-to-run variability without extensive model capacity and careful regularisation. The Theta model performs worst on both timing and classification, suggesting that lightweight univariate statistical structure is insufficient to capture the nonlinear, multivariate transient CSS behaviour of MCSGP. Overall, the benchmark results support the central premise of this work: multi-feature similarity enables robust early matching to historical trajectories, yielding more reliable long-horizon forecasts and CSS timing inference than both univariate similarity and representative statistical or learning-based baselines in the one-shot regime.

**Table 1:** Quantitative performance on the test set.

| Signal | TCSS RMSE (steps) | Time-series MSE ($\times 10^{-3}$) | CSS classification accuracy (%) |
|---|---|---|---|
| $C_{\text{out},2}(t)$ | 157.3 | 0.02 | 90.0 |
| $C_{\text{out},3}(t)$ | 340.0 | 1.15 | 100.0 |
| $C_{\text{out},4}(t)$ | 1356.0 | 0.04 | 100.0 |
| **Avg.** | **617.8** | **0.40** | **96.7** |

**Table 2:** CSS-existence confusion matrix for $C_{\text{out},3}(t)$.

| | Predicted CSS | Predicted No-CSS |
|---|---|---|
| Actual CSS | 20.0% | 0.0% |
| Actual No-CSS | 0.0% | 80.0% |

**Table 3:** Benchmark performance for $C_{\text{out},3}(t)$.

| Model | TCSS RMSE (steps) | Time-series MSE ($\times 10^{-3}$) | CSS classification accuracy (%) |
|---|---|---|---|
| MF-kNN | 340.0 | 1.15 | 100.0 |
| kNN | 537.90 | 14.95 | 40.0 |
| LSTM | 2917.74 | 57.86 | 30.0 |
| ARMA | 2937.48 | 60.62 | 10.0 |
| Theta | 4455.30 | 98.34 | 10.0 |

## CONCLUSION

This paper introduced a MF-kNN framework for early, one-shot forecasting CSS behaviour in periodic downstream bioprocesses, demonstrated on MCSGP system runs subject to run-level variability in the initial modifier concentration. Using only an early segment of each run, MF-kNN forecasts the full-run outlet trajectories, infers TCSS, and predicts CSS existence via neighbourhood voting. The methodology is designed for practical deployment through run-wise splitting, feature standardisation, and a windowed neighbour search that reduces runtime while preserving local relevance.

Across the evaluated outlet signals, MF-kNN yields consistent qualitative agreement with the true periodic profiles and supports accurate early decision support for CSS convergence. In the benchmark study, MF-kNN outperformed representative statistical and learning-based baselines on the CSS timing objective under a common one-shot protocol, reinforcing the value of similarity-based forecasting when long-horizon predictions must be derived from limited early-cycle information.

From an operational perspective, the proposed framework enables earlier switching and cut decisions, earlier initiation of collection, and early termination or alternative actions when convergence is unlikely, with the potential to reduce solvent usage and wasted runtime during non-convergent start-up.

### Future work

Future work will (i) validate the proposed MF-kNN framework on experimental/industrial MCSGP datasets, beyond the current in-silico study; (ii) quantify operational benefits under realistic decision policies, e.g., solvent usage, time savings, and yield/purity impacts from earlier go/no-go and collection-start decisions; (iii) integrate MF-kNN predictions into closed-loop operation, for example as a supervisory layer that adapts cut/collection logic or informs receding-horizon MPC for cyclic operation; and (iv) extend the feature set used for neighbour retrieval to improve robustness and to provide calibrated confidence estimates for TCSS and CSS-existence predictions.

## ABSTRACT

Reinforcement learning (RL) presents a promising alternative to model-based advanced control schemes, such as model predictive control (MPC), whose application can be limited by highly complex system models. However, incorporating constraints in RL remains challenging and formulating a suitable optimization objective is not straightforward. Reinforcement learning from human feedback (RLHF) offers an approach to derive the RL reward function from human expert preferences, enabling the incorporation of process knowledge. In this work, we present the application of RLHF to fine-tune an approximate MPC controller with suboptimal performance. We demonstrate that combining conventional reward formulations with RLHF, along with varying trajectory segment lengths for collecting human feedback, improves the control methodology for a batch bioreactor by enhancing safety and accounting for long-term effects. Furthermore, direct-preference based policy optimization (DPPO) represents a promising alternative for directly fine-tuning learning-based controllers while circumventing explicit reward model design.

**Keywords**: Model predictive control, reinforcement learning, human feedback

## INTRODUCTION

Advanced process control methods, such as model predictive control (MPC), represent a powerful approach as they enable constraint handling and are applicable to nonlinear multivariable processes. However, the high computational demand resulting from repeatedly solving the associated optimization problem makes real-time application challenging for high-dimensional and complex systems. Deep reinforcement Learning (RL) [1] presents a promising data-based approach, as the resulting control policy enables fast evaluation. This policy is learned through interactions with the system environment and guided by a scalar reward. However, formulating a suitable reward encoding the underlying control objective is not always straightforward. Additionally, constraint incorporation remains challenging, posing a problem for safety-critical process industries. Reinforcement learning from human feedback (RLHF) offers a promising method to derive the RL reward from human expert preferences [2] and is commonly applied for fine-tuning large language models [3], as well as in games [4] and robotics [5]. A detailed survey of RLHF is provided by Kaufmann et al. [6].

This work builds on the recent success of RLHF approaches and investigates different fine-tuning strategies for learning-based controllers using human feedback. First, we provide a short introduction to RL, by an overview of methodologies for incorporating human feedback into the fine-tuning process. Subsequently, we illustrate the application of these methods for improving an approximate MPC controller to control a batch bioreactor. We investigate various design parameters of the RLHF approach to improve process security and incorporation of process knowledge. Finally, we summarize our findings and discuss the observed effects.

## BACKGROUND ON REINFORCEMENT LEARNING

In reinforcement learning (RL), an agent learns a mapping from states to actions by interacting with an environment and receiving feedback through a scalar reward $r \in \mathbb{R}$ [1]. Although RL employs distinct notation conventions, we adopt standard control terminology throughout this paper. Accordingly, the terms state and

observation are used interchangeably, as are input and action. The goal in RL is to learn a policy $\pi: \mathcal{X} \rightarrow \mathcal{U}$, mapping the states $x \in \mathbb{R}^{n_x}$ to optimal actions $u \in \mathbb{R}^{n_u}$. The optimization objective is defined to not only maximize the immediate rewards but the accumulated rewards for the following transitions. The RL objective therefore is formalized as:

$$\pi^* = arg\max_{\pi} \mathbb{E}_{\pi}[G] = \arg\max_{\pi} \mathbb{E}_{\pi}\left[\sum_{t=0}^{T} \gamma^t r_{k+t+1}\right]. \quad (1)$$

The optimal policy $\pi^*$ maximizes the expected return $G$, which is defined as the accumulated reward $r$ over an episode of length $T$, where the time instance is denoted by $k$. The discount parameter $\gamma \in (0, 1]$ reduces the influence of future rewards on the cumulative return.

# BACKGROUND ON FINE-TUNING VIA HUMAN FEEDBACK

## Reinforcement learning from human feedback

Designing a suitable reward function in RL that aligns with the underlying goal of the process can be challenging. To circumvent excessive reward shaping, reinforcement learning from human feedback (RLHF) incorporates human preferences to obtain a reward function estimate $\hat{r}: \mathcal{X} \times \mathcal{U} \rightarrow \mathbb{R}$ [2]. Specifically, human feedback is obtained through comparison of two trajectory segments $\{\sigma^1, \sigma^2\}$, sampled from a set of trajectories $\{\tau^1, \ldots, \tau^i\}$. Each snippet $\sigma$ consists of a sequence of state-action pairs of length $L_s$:

$$\sigma = ((x_0, u_0), (x_1, u_1), \ldots, (x_{L_s-1}, u_{L_s-1})) \in (\mathcal{X} \times \mathcal{U})^{L_s}. \quad (2)$$

The human expert compares both trajectories and selects the preferred one. Both segments, together with the indicated label $\mu$, present the triple $(\sigma^1, \sigma^2, \mu) \in \mathcal{D}$, which is stored in a dataset $\mathcal{D}$. In case that the first segment is preferred over the second one, the corresponding judgmental label is defined as with $\mu(1) = \mu(\sigma^1 \succ \sigma^2) = \{1, 0\}$. If the second segment is preferred, it is marked by $\mu(2) = \mu(\sigma^2 \succ \sigma^1) = \{0, 1\}$. When no distinct preference exists, the clips are rated equally with $\mu(\sigma^1 \sim \sigma^2) = \{0.5, 0.5\}$. Following the methodology of Christiano et al. [2], it is assumed that the human preference for one segment is reasoned in a higher sum of underlying reward of the presented state-action pairs. The preference reward estimate $\hat{r}^{\Phi}$, which is typically presented by a neural network (NN) with its parameters $\Phi$, is then trained to maximize the likelihood (MLE) of reward predictions and true estimates, formalized as:

$$\min_{\phi} -\sum_{(\sigma^1,\sigma^2,\mu)\in\mathcal{D}} \mu(1) \log \hat{P}\left[\sigma^1 \succ \sigma^2, \phi\right] + \mu(2) \log \hat{P}\left[\sigma^2 \succ \sigma^1, \phi\right], \quad (3)$$

where

$$\hat{P}[\sigma^1 \succ \sigma^2, \Phi] = \frac{\exp \sum_t \hat{r}^{\Phi}(x_t^1, u_t^1)}{\exp \sum_t \hat{r}^{\Phi}(x_t^1, u_t^1) + \exp \sum_t \hat{r}^{\Phi}(x_t^2, u_t^2)}. \quad (4)$$

The trained preference reward NN can be implemented into any arbitrary RL framework. The described procedure can be iteratively performed until the desired policy performance is achieved.

## Direct preference-based policy optimization

Several challenges arise when using RLHF [7, 8]. The reward model derived from human preferences can fail to capture the true underlying reward of the task [9]. Furthermore, the quality of the learned reward $\hat{r}^{\Phi}$ can only be assessed through evaluation of the resulting fine-tuned policy. Therefore, the entire optimization process not only relies on the supervised reward training, but also on the maximization problem during policy learning [7]. As a result, direct preference-based policy optimization (DPPO) [9] has emerged as an alternative to RLHF, directly optimizing the policy parameters using the preference dataset $\mathcal{D}$ without requiring an explicit reward model. In DDPO the applied score metric quantifies the distance between policy predictions and actions of the labeled trajectory segments by any aggregation of distance $d$. Applying MLE to adjust the policy parameters, the training loss is defined similar to Equation (3):

$$\min_{\theta} -\sum_{(\sigma^1,\sigma^2,\mu)\in\mathcal{D}} \mu(1) \log \tilde{s}\left(\pi^{\theta}, \sigma^1 \succ \sigma^2, \lambda_{\tilde{s}}\right) + \mu(2) \log \tilde{s}\left(\pi^{\theta}, \sigma^2 \succ \sigma^1, \lambda_{\tilde{s}}\right), \quad (5)$$

where

$$\tilde{s}\left(\pi^{\theta}, \sigma^1 \succ \sigma^2\right) = \frac{\exp\left(-d(\pi^{\theta}, \sigma^1)\right)}{\exp\left(-d(\pi^{\theta}, \sigma^1)\right) + \exp\left(-\lambda_{\tilde{s}} d(\pi^{\theta}, \sigma^2)\right)}. \quad (6)$$

The regularization factor $\lambda_{\tilde{s}} \in (0, 1)$ is introduced to penalize the increase of both distances. Without this regularization, the ratio $\tilde{s}$ could stay in a similar range even when the overall distance to both segments increases [9]. A comparison of RLHF with such a direct policy optimization (DPO) [10] method has found that DPO has the potential to outperform RLHF, especially with a sufficient large preference dataset [11]. However, DPO can be sensitive to distribution shifts between the provided preference data and can lead to insufficient generalization [12]. As in RLHF the reward model might provide incorrect high rewards to unseen data, this misspecification can also happen for DPO but directly impacts the policy [12].

# IMPROVEMENT OF APPROXIMATE MPC FOR BATCH BIOREACTOR

## Batch bioreactor model

To investigate the fine-tuning capabilities using human feedback, we consider the batch bioreactor system

from Srinivasan et al. [13], where penicillin is produced by microorganisms. Assuming an isothermal and ideally mixed reactor, the system is described by the following set of ordinary differential equations:

$$\dot{X}_s = \mu_s(S_s)X_s - \frac{u_{\text{inp}}}{\text{V}_\text{s}}\text{X}_\text{s}, \tag{7a}$$

$$\dot{S}_s = -\frac{\mu_s(S_s)X_s}{Y_x} - \frac{\upsilon X_s}{Y_p} + \frac{u_{\text{inp}}}{V_s}(S_{\text{in}} - S_s), \tag{7b}$$

$$\dot{P}_s = \upsilon X_s - \frac{u_{\text{inp}}}{V_s}P_s, \tag{7c}$$

$$\dot{V}_s = u_{\text{inp}}, \tag{7d}$$

where

$$\mu_s(S_s) = \frac{\mu_m S_s}{K_m + S_s + \left(\frac{S_s^2}{K_i}\right)}. \tag{8}$$

The concentration of biomass producing the pharmaceutical product is denoted by $X_s$ and the concentration of penicillin by $P_s$. Substrate at concentration $S_s$ is supplied to the microorganisms via the input feed $u_{\text{inp}}$. The reactor volume is described by $V_s$. Overall, the system is defined by the four physical states $x_{\text{phys}} = (X_s, S_s, P_s, V_s)^T$ and one control input $u_{\text{phys}} = \left(u_{\text{inp}}\right)^T$. The kinetics of the bioprocess are defined by $\mu_m, K_m, K_i$ and $\upsilon$. The microorganisms exhibit substrate inhibition as described by Equation (8), meaning that a higher substrate concentration leads to a decrease of the kinetic term $\mu_s(S_s)$ for biomass growth. The yield coefficients of biomass and penicillin are $Y_x$ and $Y_p$, respectively. The concentration of the inlet feed is denoted by $S_{\text{in}}$.

The process aim is to produce as much penicillin as possible in a fixed batch time, where the concentration of biomass is restricted to $X_{s,\,\max} = 3.7$ mol L$^{-1}$ to ensure sufficient supply of oxygen. The system can be controlled using MPC, where the corresponding stage cost is formalized by:

$$l(x_t, u_t) = -\left(P_{s,t} - \Delta u_{\text{inp},t}^2\right). \tag{9}$$

For smooth control trajectories changes of the control input are penalized, where $\Delta u_{\text{inp},t} = u_{\text{inp},t} - u_{\text{inp},t-1}$.

## Design of approximate MPC

Approximate model predictive control (AMPC) circumvents the computational limitations inherent to conventional MPC by employing NN-based function approximators to learn the mapping from system states to optimal control actions [14]. This enables the deployment of predictive control strategies in time-critical applications where online optimization would be computationally prohibitive. However, the achieved accuracy highly depends on the available training data. We therefore investigate the fine-tuning capabilities using human feedback for an AMPC controller with suboptimal performance.

A MPC controller is designed for the batch bioreactor system according to the stage cost described in Equation (9) and the described constraint with a prediction horizon of $20$ min**.** We apply trajectory-based sampling to obtain a dataset for approximating the optimal control law of the MPC. The input data for the trained NN $\text{x}_{\text{AMPC},t} = \left(x_{\text{phys},t}^T, u_{\text{phys},t-1}^T\right)^T \in X_{\text{AMPC}}$ is defined by the states and preceding control inputs to enable learning the control objective as defined in Equation (9). The output data $u_{\text{AMPC},t} = \left(u_{\text{phys},t}\right)^T \in Y_{\text{AMPC}}$ is defined according to the control actions. To obtain an AMPC with sufficient potential for improvement, $25,000$ data points are used to train a NN with parameters $\theta$ to minimize the following mean square error (MSE) objective:

$$\min_\theta \frac{1}{N}\sum_{i=1}^{N} || \, u_{\text{AMPC},\,0}^{*,[i]} - \pi\left(x_{\text{AMPC},\,0}^{[i]}; \theta\right)||_2^2. \tag{10}$$

## Reward model from human preferences

We now design a reward model from human preference according to Christiano et al. [2] to reflect the intentions of a human expert. Following this approach, a set of trajectories $\left\{\tau^1, \dots, \tau^i\right\}$ is sampled to cut out trajectory segments $\sigma$ out of it. We use MPC trajectories, which are available from training the AMPC, as well as closed-loop evaluations of the AMPC. Overall, multiple iterations are required for reward design until the preference dataset sufficiently covers the state space and the reward model adequately reflects the intended behavior. If the trajectory segments labeled for the preference dataset do not cover sufficiently the state space, incorrect high rewards are might be given to undesired states and control actions. Fine-tuning the policy with this inadequate reward leads to undesired control behavior and is additionally used to generate trajectories. Thus, a broad range of different control trajectories are included in the preference dataset. Different initial conditions from the feasible state space are used to generate the trajectories and the start of each segment is selected uniformly and randomly out of those trajectories. The segment length $L_s$ is set to ten, reflecting $10$ min, sufficient for evaluating the system's current state and estimating its development in this initial investigation. For labeling, $350$ snippets are generated. Two segments are randomly selected from the trajectory set $\{\sigma_1, \sigma_2, \dots, \sigma_{350}\}$, and presented to a process expert, who indicates which trajectory is preferable for system control, or labels them as equally. The segment data and corresponding label are saved automatically and indistinguishable pairs are skipped.

In total $2,133$ preferences are collected for the reward dataset according to the following labeling criteria: Segments with constraint violations (CVs), where biomass concentration exceeds $3.7$ mol L$^{-1}$, are disfavored, though if both segments exhibit CVs, they are rated equally. Similarly, substrate concentrations $S_s \geq 1$ mol L$^{-1}$ are penalized due to substrate inhibition. Further, if one

trajectory's initial penicillin concentration exceeds the other's final concentration, that segment is preferred, as maximizing penicillin production is the primary objective. These decision rules were derived from observed human expert labeling behavior and subsequently implemented as automatic labeling criteria, thereby augmenting the manual expert annotations. Comparisons not meeting these criteria rely on human judgment. The human's expertise is especially interesting in this case study when deciding between the trade-off of higher penicillin concentration and a greater amount of biomass, which promises faster penicillin production in the future.

The collected preferences build the training data for the NN-based reward model. Based on the current observations and actions taken, a reward is obtained from the reward network. Hence, the NN is set up with six inputs $\mathrm{x}_{\hat{r},t} = \left(x_{\mathrm{phys},t}^T, u_{\mathrm{phys},t-1}^T, u_{\mathrm{phys},t}^T\right)^T$, consisting of the four states, the previous and the current control input. The output layer of the network consists of one neuron for the scalar reward $\hat{r}$. The parameters of the preference reward network $\Phi$ are trained by minimizing the RLHF objective as defined in Equation (3).

An ensemble of three separately trained NNs is used, a common approach in RLHF [2, 15] that helps counteract reward hacking [16] and overoptimization [17]. Predictions are obtained by averaging across all models.

## Investigation of different fine-tuning approaches

### Comparison of reward model designs

In a first investigation, the preference reward derived in the previous section is compared to a rigorous encoded reward as typically defined for RL training. Further, a hybrid model combining both approaches is evaluated. The three rewards are formalized as:

$$\hat{r}_{\mathrm{pref}}(x,u) = NN(x,u;\Phi), \tag{13a}$$

$$\hat{r}_{\mathrm{rig}}(x,u) = -l(x,u) - c(x,u), \tag{13b}$$

$$\hat{r}_{\mathrm{hybrid}}(x,u) = \hat{r}_{\mathrm{rig}}(x,u) + NN_{\mathrm{hybrid}}(x,u;\Phi). \tag{13c}$$

The preference reward $\hat{r}_{\mathrm{pref}}(x,u)$ is obtained from human feedback as described in the previous section. The rigorous reward $\hat{r}_{\mathrm{rig}}(x,u)$ is defined as the negative inverse stage cost from Equation (6.4), transforming the MPC minimization objective into an RL maximization objective. A penalization term $c(x,u)$ for constraint violations is added, weighting violations by factor $20$. Both strategies are merged via a hybrid reward $\hat{r}_{\mathrm{hybrid}}$. For this hybrid reward, an NN is trained similarly to how it was described for the preference reward, using the same labeled dataset and loss function for training. However, instead of just passing the NN predictions as reward estimates for the preference calculation according to Equation (3), it is added first to the rigorous reward. The reward for the trajectory segment therefore consists of the rigorous reward penalizing CVs and the NN as an expansion. This hybrid reward is designed to extent the rigorous reward, encoding the main goal and limitations, by the expert knowledge included through the preference dataset.

Evaluating reward models derived from human preference to determine whether they suitably capture the task presents a major challenge in RLHF [7, 8]. As the dimensionality of the present control task is manageable, the reward behavior of reward models can be investigated using heatmaps. Predictions of the three applied reward models are displayed in Figure 1 and 2. Each plot displays the reward prediction dependent on two of the six inputs for reward estimation. The remaining inputs are kept constant.

Figure 1 displays the reward prediction as a function of biomass and penicillin concentration. High concentrations of penicillin are expected to be rewarded, and violations of constraints penalized with small rewards. The rigorous model meets this expectation. As long as the amount of biomass is not violating the constraint, it does not influence the rigorous reward. However, CVs are clearly reflected by the model, as the reward significantly decreases. The penalty for CVs is comparatively much higher than the reward for increasing penicillin concentration. The hybrid model is almost identical to the rigorous reward, but a small influence of the biomass concentration is noticeable. Smaller amounts of penicillin receive higher rewards if a high biomass concentration is present, showing the influence of the preference dataset. The reward predictions from the preference model display a different mapping. The distinction between higher and lower penicillin concentrations becomes more noticeable as CVs are relatively less penalized compared to other points, especially when compared to the rigorous and hybrid reward. Similar to the hybrid model, higher amounts of biomass are favored. From analyzing the dependency of biomass and penicillin concentration, the hybrid model seems to mainly align with the rigorous reward and adopt the rewarding of high biomass concentrations from the human preferences.

Figure 2 plots rewards against penicillin and substrate concentration, depicting more clearly the difference between hybrid and rigorous rewards. The rigorous reward is not influenced by the amount of substrate. A high concentration of substrate hindrances biomass growth and thereby penicillin production. It has been observed that some RL agents get stuck in local maxima, feeding a lot of substrate. This behavior is specifically included in the preference dataset by sampling trajectories from these agents. Therefore, both, preference and hybrid reward yield smaller rewards for large amounts of substrate.

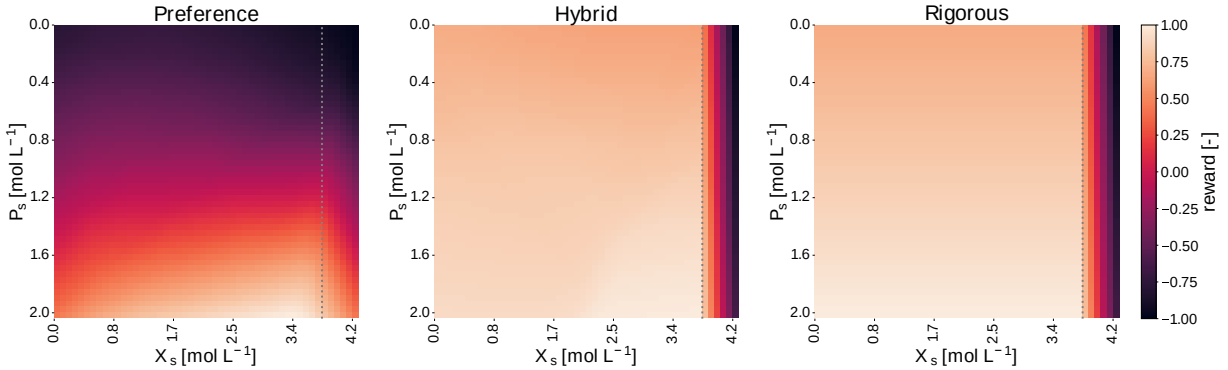

**Figure 1:** Evaluation of reward predictions for the preference reward model from human feedback, hybrid reward and rigorous reward. The reward is predicted in dependence of penicillin concentration $P_s$ and biomass concentration $X_s$, where all other reward inputs are kept constant. Constraint indication by grey dotted line.

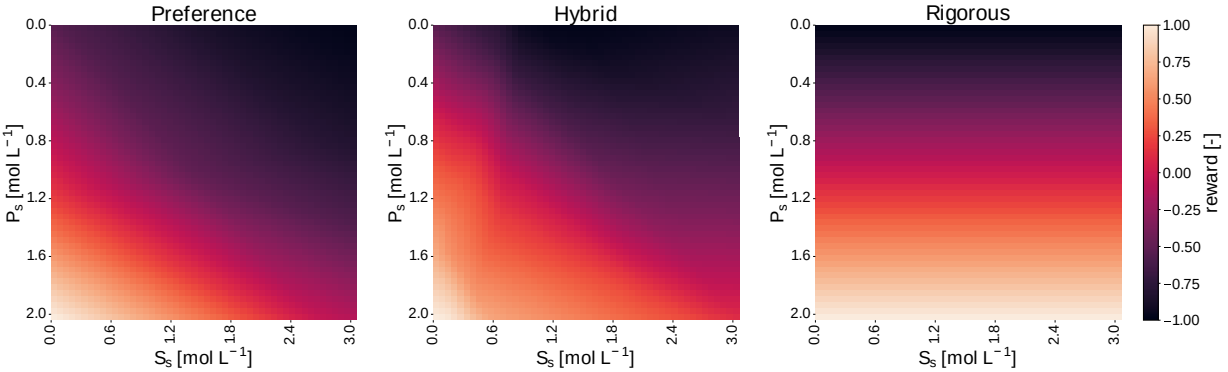

**Figure 2:** Evaluation of reward predictions for the preference reward model from human feedback, hybrid reward and rigorous reward. The reward is predicted in dependence of penicillin concentration $P_s$ and substrate concentration $S_s$, where all other reward inputs are kept constant.

To further investigate the rewards, their fine-tuning capabilities with respect to the previously derived AMPC are investigated. The pretrained AMPC is implemented as the policy in the DDPG algorithm [19] using Stable Baselines3 [20]. For each reward model, 25 agents are learned in parallel with different seeds. Each agent is learned for $5 \cdot 10^5$ transitions, frequently evaluated and the best fine-tuned agents are saved. The closed-loop evaluations of the best three models obtained from each reward are listed in Table 1. The MPC control law $\pi^{\mathrm{MPC}}$ and the AMPC $\pi^{\mathrm{AMPC}}$ serve as benchmarks. Indices refer to the reward used for fine-tuning. To evaluate all obtained policies from the fine-tuned agents, closed-loop trajectories with a length of 150 steps for 100 initial conditions are analyzed. The average return $\bar{G}$ is defined by the undiscounted, accumulated rigorous reward and is used as the evaluation metric, along with its standard deviation. Penalization of CVs is not considered in the return. Furthermore, the number of CVs for all initial conditions is summed up as $n_{\mathrm{CV}}$ and the average deviation $\bar{d}_{\mathrm{CV}}$ from the constraint is computed and listed. None of the best fine-tuned agents violate the constraint in any of the closed-loop trajectories and all agents improve the average return of the AMPC. The hybrid reward leads to the highest average reward. The best agent obtained with the rigorous reward yield a slightly higher average return than the agent learned with the preference reward.

**Table 1:** Evaluation of fine-tuning capabilities of AMPC with different reward designs.

| Reward | Policy | $\bar{G}$ | CV | |
|---|---|---|---|---|
| | | | $n_{\mathrm{CV}}$ | $\bar{d}_{\mathrm{CV}}$ |
| | $\pi^{\mathrm{MPC}}$ | $116.16 \pm 21.66$ | 0 | - |
| | $\pi^{\mathrm{AMPC}}$ | $96.36 \pm 15.97$ | 3 | 0.053 |
| **Preference** | $\pi^{\mathrm{AMPC}}_{\mathrm{pref}}$ | $106.83 \pm 22.32$ | 0 | - |
| | | $106.48 \pm 18.83$ | 0 | - |
| | | $103.46 \pm 18.14$ | 0 | - |
| **Rigorous** | $\pi^{\mathrm{AMPC}}_{\mathrm{rig}}$ | $108.85 \pm 19.57$ | 0 | - |
| | | $105.76 \pm 21.80$ | 0 | - |
| | | $104.19 \pm 17.95$ | 0 | - |
| **Hybrid** | $\pi^{\mathrm{AMPC}}_{\mathrm{hybrid}}$ | $110.05 \pm 21.89$ | 0 | - |
| | | $104.32 \pm 18.27$ | 0 | - |
| | | $100.93 \pm 16.75$ | 0 | - |

## Influence of length of trajectory segments

The previous investigation of different models

revealed that the preference model does not clearly localize the constraint. A snippet is labeled unfavored if a CV takes place at any point. The applied labeling strategy does not differentiate between the severity of constraint violations or when they occur within the segment. Consequently, the preference model may inadequately reward states with favorable biomass concentrations for penicillin production if they are associated with segments containing any constraint violation. It is presumed that with smaller snippets, the localization of the constraint can be more clearly encoded. To investigate the influence of the length of trajectory segments, shorter trajectory snippets of $L_s = 5$ are labeled with the aim to clearly localize the constraint. Longer snippets of $L_s = 20$ are labeled to investigate the representation of long-term effects in the reward model. Furthermore, a combined dataset is compiled by sampling equally from each of the three segment lengths, with each contributing one third of the total data. Both new datasets are generated following the same procedure and triplet count as the initial dataset. Figure 3 shows heatmaps of reward dependency on biomass and penicillin concentration, illustrating the reward mapping and constraint adaptation of all models.

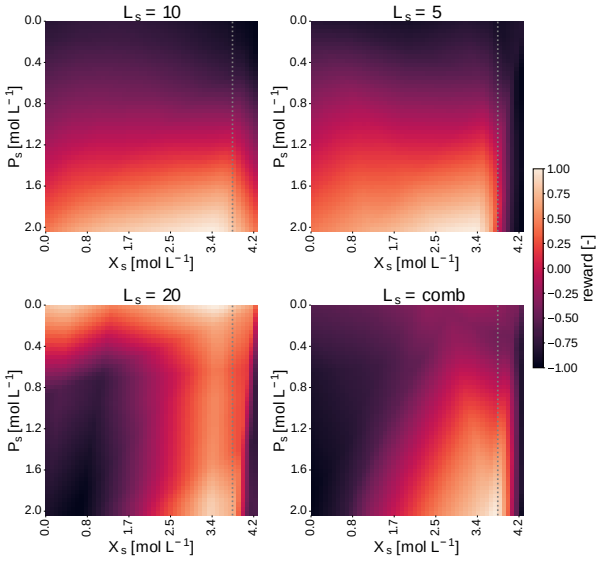

**Figure 3:** Evaluation of reward predictions for the preference reward models derived from different segment length. The reward is predicted in dependence of penicillin concentration $P_s$ and biomass concentration $X_s$, where all other reward inputs are kept constant. Constraint indication by grey dotted line.

The model obtained from shorter trajectory length $L_s = 5$ displays the constraint restriction more clearly than the previous model from a segment length of $L_s = 10$. Slightly before reaching the maximum permitted biomass concentration, the reward decreases. Additionally, the penalization is much higher. Therefore, it is concluded that the shorter segment lengths help to identify and penalize constraints more clearly. The reward model, which is trained based on longer preference segments, also does not identify the constraints sufficiently. However, the penalization for larger violations is stronger than for the preference reward from $L_s = 10$. Furthermore, the reward from $L_s = 20$ differs from the previous models as it mainly rewards high biomass concentrations instead of product concentration. Longer segments better illustrate the development of the system and the slope of penicillin increase can be observed in more detail. Therefore, the human expert often prefers trajectories with a higher biomass concentration, as the slope of the penicillin production indicates a faster production, which is more advantageous in the long term. The incorrect high reward for very low amounts of penicillin is probably reasoned in a sparse representation of this data. The reward model obtained from the mixed dataset combines the different reward estimations. High penicillin concentrations in combination with a high amount of biomass are encouraged the most with a high reward, as a high amount of product is obtained quickly. Similar to the reward model trained with long segments, higher amounts of biomass are favored for constant amounts of product. The constraint for the biomass is clearly encoded and the reward decreases as soon as the constraint is violated.

**Table 2:** Evaluation of fine-tuning capabilities of AMPC with preference rewards trained with different segment lengths $L_s$.

| Reward | Policy | $\bar{G}$ | CV | |
|---|---|---|---|---|
| | | | $n_{CV}$ | $\bar{d}_{CV}$ |
| | $\pi^{MPC}$ | 116.16 ± 21.66 | 0 | - |
| | $\pi^{AMPC}$ | 96.36 ± 15.97 | 3 | 0.053 |
| $L_s = 10$ | $\pi^{AMPC}_{pref}$ | 106.83 ± 22.32 | 0 | - |
| | | 106.48 ± 18.83 | 0 | - |
| | | 103.46 ± 18.14 | 0 | - |
| $L_s = 5$ | $\pi^{AMPC}_{L_s=5}$ | 101.68 ± 31.02 | 0 | - |
| | | 99.20 ± 23.52 | 0 | - |
| | | 94.11 ± 31.22 | 0 | - |
| $L_s = 20$ | $\pi^{AMPC}_{L_s=20}$ | 101.44 ± 17.31 | 0 | - |
| | | 109.21 ± 21.23 | 171 | 0.026 |
| | | 111.53 ± 20.91 | 283 | 0.041 |
| $L_s =$ comb | $\pi^{AMPC}_{L_s=\text{comb}}$ | 108.37 ± 19.45 | 0 | - |
| | | 108.34 ± 20.86 | 0 | - |
| | | 108.18 ± 21.94 | 0 | - |

The three best policies obtained from the different reward models are listed in Table 2, with the previous references. Agents learned with the reward from a segment length of $L_s = 5$ achieve the lowest average return, with only some exceeding AMPC performance. However, no CV occur for these agents. This supports the

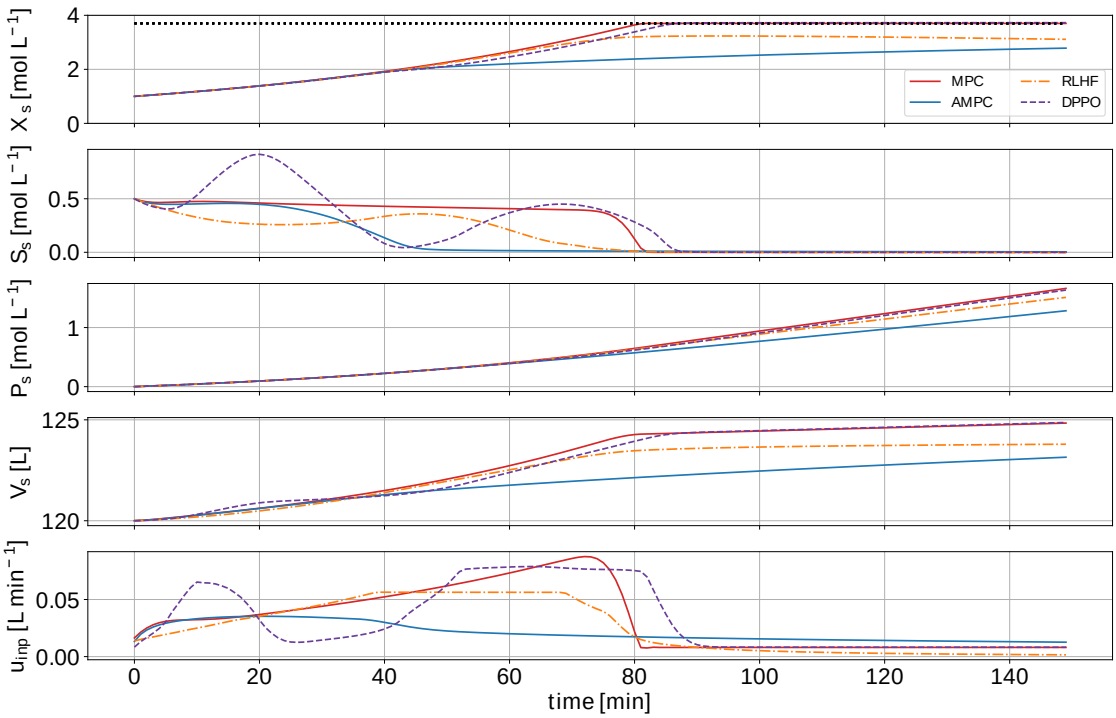

**Figure 4:** Closed-loop trajectories of MPC (red, solid), AMPC (blue, solid), reference policy from fine-tuned policy using RLHF (orange, dash-dot), and optimized policy using DPPO (purple, dashed). The constraint is marked by the dotted black line.

observations from the heatmap, that the constraints are recognized, but high amounts of biomass are not rewarded sufficiently. Correspondingly, the agents, learned with the reward of length $L_s = 20$, produce higher concentrations of penicillin in the same period of time under more CVs. The agents learned with the reward from the mixed dataset achieve the best results in terms of a high return without CVs, combining the strengths of all datasets.

## Comparison of RLHF and DPPO

As the presented RLHF approach is prone to errors arising from the interdependence of reward model design and RL training, we investigate DPPO as an alternative approach to enable human preferences for fine-tuning. To ensure a valid comparison, the same dataset with $L_s = 10$ used for deriving the first preference reward is applied. It has been found that DPPO is sensitive to hyperparameters, especially the regularization factor $\lambda_{\bar{s}}$, which is used in the probability distribution to prevent both distances from increasing [9]. Therefore, a small grid search is performed and the best three fine-tuned agents obtained are listed together with the benchmark policies and reference policies from RLHF in Table 3.

The average return of the best policy optimized with DPPO outperforms the fine-tuned agents from RLHF in terms of the achieved return. However, the total number of CVs is very high for almost all models. The cause for that many CVs becomes evident when considering a closed-loop trajectory as shown in Figure 4. The development of biomass concentration, controlled by the policy optimized with DPPO, shows very similar behavior to the optimal MPC trajectory. It also converges to a high biomass concentration, which leads to a high product concentration. However, the DPPO policy converges to a biomass concentration which is slightly higher than the constraint, resulting in the high return in combination with many, but small CVs. As the optimized policy still presents an approximation, small approximation errors are to be expected.

**Table 3:** Evaluation of fine-tuning capabilities of AMPC with RLHF and DPPO.

| Reward | Policy | $\bar{G}$ | CV | |
|---|---|---|---|---|
| | | | $n_{CV}$ | $\bar{d}_{CV}$ |
| | $\pi^{MPC}$ | $116.16 \pm 21.66$ | 0 | - |
| | $\pi^{AMPC}$ | $96.36 \pm 15.97$ | 3 | 0.053 |
| **RLHF** | $\pi^{AMPC}_{pref}$ | $106.83 \pm 22.32$ | 0 | - |
| | | $106.48 \pm 18.83$ | 0 | - |
| | | $103.46 \pm 18.14$ | 0 | - |
| **DPPO** | $\pi^{AMPC}_{DPPO}$ | $112.19 \pm 20.79$ | 1, 857 | 0.016 |
| | | $111.29 \pm 20.86$ | 4, 376 | 0.022 |
| | | $109.73 \pm 19.60$ | 1, 575 | 0.013 |

## CONCLUSION

In this work, we demonstrated how to implement and enhance reinforcement learning from human feedback for controlling a biochemical batch reactor. Deriving the reinforcement learning reward from a human process expert's feedback enables encoding domain knowledge regarding both safety-critical and long-term behavior. Our case study visualized how different reward model designs and trajectory segment lengths influence the optimization objective. A hybrid reward function effectively combines formalizable constraints with intuitive expert knowledge, while varying segment lengths allows the incorporation of both short- and long-term control strategies. Finally, direct preference-based policy optimization offers a promising fine-tuning alternative that circumvents explicit reward model design.

In future research, we will investigate the potential of multi-trajectory ranking over pairwise comparisons for improving learning-based controllers.

## ABSTRACT

In modern industrial systems, increasing performance requirements and sustainability constraints have intensified the need for advanced optimization methodologies capable of efficiently handling complex process models. The Simulated Moving Bed (SMB) process is a well-established technology for continuous chromatographic separations, offering high productivity and reduced solvent consumption compared to batch operations. However, its optimization is challenging due to the underlying distributed-parameter nature of the process.This work presents the development of a dynamic simulation and parameter optimization framework for the SMB process, implemented in Python using the open-source CasADi framework. The SMB model accounts for axial dispersion and mass transfer using a linear driving force formulation and is discretized in space using the method of lines, resulting in a state-space representation compatible with CasADi's numerical tools. Model accuracy was validated by reproducing a benchmark case from literature and comparing concentration profiles and product purities against results obtained using MATLAB's PDEPE solver.The proposed framework was further applied to a parameter optimization problem involving the separation of fructose and glucose. The objective was to maximize the feed velocity subject to purity and recovery constraints for fructose, with the superficial velocities in each SMB section and the switching time treated as decision variables. The resulting nonlinear programming problem was solved using a direct single-shooting approach and the interior-point optimizer IPOPT. The optimized operating conditions and performance metrics closely match published results, while achieving the solution in less than 90% of the computational time reported for a gPROMS-based implementation.

## INTRODUCTION

In modern industrial systems, the increasing complexity and performance demands of engineering processes have made advanced optimization approaches essential. Optimizing process performance is required not only to improve profitability, but also to enhance sustainability through more efficient use of energy and raw materials, as well as reduced waste and resource consumption.

### Simulated Moving Bed

The simulated moving bed (SMB) process is widely used for continuous chromatographic separations, as it simulates the countercurrent flow of the fluid and solid phases to separate components based on their affinity with the stationary phase [1]. A schematic representation of the process for a four-column configuration is shown in Figure 1. The SMB process can produce high-purity products even under low selectivity conditions, while achieving higher productivity and lower eluent consumption compared to batch chromatography [2]. Representative applications include the separation of chiral molecules [1], such as in the production of formoterol, an antiasthmatic drug [3], functional isomers, such as fructose and glucose [1, 4], and ionic molecules, such as in the production of lysine, an essential amino acid [5].

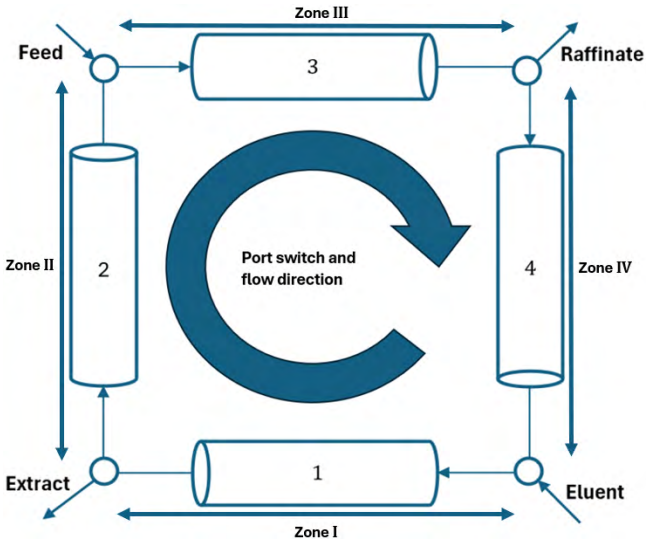

**Figure 1.** Four-column SMB configuration.

### CasADi

CasADi is an open-source software toolbox available for Python that provides automatic differentiation and numerical optimization capabilities for complex dynamical systems described by ordinary differential equations (ODEs) and subject to constraints. The package is user-friendly and has been successfully applied to a wide range of industrial and academic problems, including optimal control of batch chromatographic separation processes [6], modeling of highly complex dynamical systems [7], and optimal control of non-isothermal continuously stirred tank reactors [8].

This work presents the development of a dynamic simulation and optimization framework for the SMB process, implemented in Python using the CasADi framework. First, a detailed simulation model is developed and validated against reference results from the literature. Subsequently, the proposed framework is applied to reproduce and solve a parameter optimization case study reported in the scientific literature.

## SMB COMPUTATIONAL MODELING

The case study considered in this work is the chromatographic resolution of bi-naphthol enantiomers, as reported in the book *Simulated Moving Bed Technology: Principles, Design and Process Applications* [1]. The adsorption equilibrium isotherms, measured at 25 °C, follow a bi-Langmuir model and are presented below. For notational simplicity, the explicit dependence on time is omitted in the subsequent equations, although all state variables remain time-dependent.

#### Isotherm of component A

$$q^*_{A,k}(x) = \frac{2.69\, C_{A,k}(x)}{1+0.0336\, C_{A,k}(x)+0.0446\, C_{B,k}(x)} + \frac{0.1\, C_{A,k}(x)}{1+C_{A,k}(x)+3\, C_{B,k}(x)} \tag{1}$$

#### Isotherm of component B

$$q^*_{B,k}(x) = \frac{3.73\, C_{B,k}(x)}{1+0.0336\, C_{A,k}(x)+0.0446\, C_{B,k}(x)} + \frac{0.3\, C_{B,k}(x)}{1+C_{A,k}(x)+3\, C_{B,k}(x)} \tag{2}$$

The mathematical model employed considers axial dispersion and mass transfer between fluid and solid described by the linear driving force (LDF) model. Radial dispersion and pressure effects are neglected, and the system is assumed to be isothermal at 25 °C, ensuring the validity of the adsorption isotherms. Under these assumptions, the model equations are given by:

#### Fluid-phase mass balance

$$\frac{\partial C_{i,k}(x)}{\partial \theta} = \gamma_k\left(\frac{1}{Pe_k}\frac{\partial^2 C_{i,k}(x)}{\partial x^2} - \frac{\partial C_{i,k}(x)}{\partial x}\right) - \frac{(1-\varepsilon)}{\varepsilon}\frac{\partial q_{i,k}(x)}{\partial \theta} \tag{3}$$

#### Solid-phase mass balance

$$\frac{\partial q_{i,k}(x)}{\partial \theta} = \alpha_i\left(q^*_{i,k}(x) - q_{i,k}(x)\right) \tag{4}$$

#### Boundary conditions

$$C_{in,i,k} = C_{i,k}(0) - \frac{1}{Pe_k}\frac{\partial C_{i,k}(0)}{\partial x} \tag{5}$$

$$\frac{\partial C_{i,k}(1)}{\partial x} = 0 \tag{6}$$

#### Initial conditions

$$C_{i,k}(x) = 0;\ \theta = 0;\ \forall x \in [0,1] \tag{7}$$

$$q_{i,k}(x) = 0;\ \theta = 0;\ \forall x \in [0,1] \tag{8}$$

#### Parameters

$$\gamma_m = \frac{u_m t^*}{L} \tag{9}$$

$$\alpha_i = k_{h,i} t^* \tag{10}$$

$$Pe_m = \frac{u_m L}{D_{ax,m}} \tag{11}$$

$$A = \frac{\pi D^2}{4} \tag{12}$$

$$u_m = \frac{Q_m}{\varepsilon A} \tag{13}$$

#### Feed inlet port

$$C_{in,i,N_F} = \frac{u_F}{u_{III}} C_{F,i} + \frac{u_{II}}{u_{III}} C_{i,N_F-1}(1) \tag{14}$$

$$u_F = u_{III} - u_{II} \tag{15}$$

#### Eluent inlet port

$$C_{in,i,N_E} = \frac{u_{IV}}{u_I} C_{i,N_E-1}(1) \tag{16}$$

$$u_E = u_I - u_{IV} \tag{17}$$

#### Extract outlet port

$$C_{X,i} = C_{i,N_X-1}(1) \tag{18}$$

$$u_X = u_I - u_{II} \tag{19}$$

### Raffinate outlet port

$$C_{R,i} = C_{i,N_R-1}(1) \tag{20}$$

$$u_R = u_{III} - u_{IV} \tag{21}$$

### Internal nodes

$$C_{in,i,k} = C_{i,k-1}(1);\ \forall k = 1,\dots,N_T;\ k \neq N_F, N_E \tag{22}$$

### Performance parameters

$$Purity_{X,B} = \frac{\int_{\theta}^{\theta+1} u_X C_{X,B}(1)d\theta}{\sum_{i=A,B}\int_{\theta}^{\theta+1} u_X C_{X,i}(1)d\theta} \tag{23}$$

$$Purity_{R,A} = \frac{\int_{\theta}^{\theta+1} u_R C_{R,A}(1)d\theta}{\sum_{i=A,B}\int_{\theta}^{\theta+1} u_R C_{R,i}(1)d\theta} \tag{24}$$

Here, $C_{i,k}(x)$ and $q_{i,k}(x)$ denote the system state variables, namely the bulk-phase and adsorbed-phase concentrations, respectively. The indices $i$ and $k$ refer to the component and column number. The variables $x$ and $\theta$ represent the dimensionless axial coordinate and dimensionless time, defined by normalization with the column length $L$ and the switching time $t^*$, respectively. The equilibrium adsorbed concentration is denoted by $q^*_{i,k}(x)$ and is obtained from the isotherm relations.

The inlet concentration of component $i$ to column $k$ is denoted by $C_{in,i,k}$, while $C_{F,i}$ represents the feed concentration of component $i$. The interstitial fluid velocity in section $m$ (I–IV) of the SMB is denoted by $u_m$, and $u_E, u_X, u_R$, and $u_F$ correspond to the eluent, extract, raffinate, and feed velocities, respectively.

The parameter $\alpha_i$ denotes the number of mass transfer units, where $k_{h,i}$ is the mass transfer coefficient of the LDF model. The column cross-sectional area is denoted by $A$, calculated from the column diameter $D$. The Peclet number in section $m$, $Pe_m$, is defined using the axial dispersion coefficient $D_{ax,m}$, while $\gamma_m$ represents the ratio between fluid and equivalent solid interstitial velocities in section $m$. The bed porosity is denoted by $\varepsilon$, and $Q_m$ is the volumetric flow rate in section $m$ of the SMB.

Finally, $N_T$ denotes the total number of columns, while $N_E, N_X, N_R, N_F$ denote the column indices corresponding to the eluent, extract, raffinate, and feed ports, respectively. Depending on the location of the ports and sections that results from port switch, the Peclet number $Pe_k$ and the interstitial velocity ratio $\gamma_k$ in column $k$ are computed accordingly from $Pe_I,\dots,Pe_{IV}$ and $\gamma_I,\dots,\gamma_{IV}$, respectively. The purity is defined as $Purity_{X,B}$, representing the purity of component B in the extract stream with outlet concentration $C_{X,B}$, and $Purity_{R,A}$, representing the purity of component A in the raffinate stream with outlet concentration $C_{R,A}$.

A key challenge in this work is that the SMB process is described by partial differential equations (PDEs), whereas CasADi can only handle ODEs. To address this limitation, the structure of MATLAB's PDEPE solver was adapted to the CasADi framework. PDEPE is a numerical solver for one-dimensional, time-dependent parabolic PDEs. If additional spatial dimensions were required, an alternative modeling and numerical approach would be necessary.

The solver applies the method of lines, discretizing the spatial domain and transforming the PDEs into a system of time-dependent ODEs. The resulting equations, functions and isotherms are presented below.

$$\bar{C}_{i,j,k} = 0.5\left(C_{i,j+1,k} + C_{i,j,k}\right);\ 1 \le j \le n-1 \tag{25}$$

$$\bar{q}_{i,j,k} = 0.5\left(q_{i,j+1,k} + q_{i,j,k}\right);\ 1 \le j \le n-1 \tag{26}$$

### Isotherms

$$\bar{q}^*_{A,j,k} = \frac{2.69\,\bar{C}_{A,j,k}}{1+0.0336\,\bar{C}_{A,j,k}+0.0446\,\bar{C}_{B,j,k}} + \frac{0.1\,\bar{C}_{A,j,k}}{1+\bar{C}_{A,j,k}+3\,\bar{C}_{B,j,k}} \tag{27}$$

$$\bar{q}^*_{B,j,k} = \frac{3.73\,\bar{C}_{B,j,k}}{1+0.0336\,\bar{C}_{A,j,k}+0.0446\,\bar{C}_{B,j,k}} + \frac{0.3\,\bar{C}_{B,j,k}}{1+\bar{C}_{A,j,k}+3\,\bar{C}_{B,j,k}} \tag{28}$$

### Mass balance equations

$$\frac{\partial C_{i,j,k}}{\partial\theta} = \frac{f^{L,C}_{i,j,k} - f^{R,C}_{i,j,k}}{\Delta x} + 0.5\left(s^{R,C}_{i,j,k} + s^{L,C}_{i,j,k}\right);\ 2 \le j \le n-1 \tag{29}$$

$$\frac{\partial q_{i,j,k}}{\partial\theta} = 0.5\left(s^{R,q}_{i,j,k} + s^{L,q}_{i,j,k}\right);\ 2 \le j \le n-1 \tag{30}$$

$$f^{R,C}_{i,j,k} = -\gamma_k\left(\frac{1}{Pe_k}\frac{C_{i,j+1,k}-C_{i,j,k}}{\Delta x} - \bar{C}_{i,j,k}\right);\ 1 \le j \le n-1 \tag{31}$$

$$s^{R,C}_{i,j,k} = -\frac{(1-\varepsilon)}{\varepsilon}\alpha_i\left(\bar{q}^*_{i,j,k} - \bar{q}_{i,j,k}\right);\ 1 \le j \le n-1 \tag{32}$$

$$s^{R,q}_{i,j,k} = \alpha_i\left(\bar{q}^*_{i,j,k} - \bar{q}_{i,j,k}\right);\ 1 \le j \le n-1 \tag{33}$$

$$f^{L,C}_{i,j,k} = f^{R,C}_{i,j-1,k};\ 2 \le j \le n \tag{34}$$

$$s^{L,C}_{i,j,k} = s^{R,C}_{i,j-1,k};\ 2 \le j \le n \tag{35}$$

$$s^{L,q}_{i,j,k} = s^{R,q}_{i,j-1,k};\ 2 \le j \le n \tag{36}$$

### Boundary conditions

$$\frac{\partial C_{i,1,k}}{\partial\theta} = \frac{f^{L,C}_{i,1,k} - f^{R,C}_{i,1,k}}{0.5\Delta x} + s^{R,C}_{i,1,k} \tag{37}$$

$$f^{L,C}_{i,1,k} = \gamma_k C_{in,i,k} \tag{38}$$

$$\frac{\partial q_{i,1,k}}{\partial\theta} = s^{R,q}_{i,1,k} \tag{39}$$

$$\frac{\partial C_{i,n,k}}{\partial\theta} = \frac{f^{L,C}_{i,n,k} - f^{R,C}_{i,n,k}}{0.5\Delta x} + s^{L,C}_{i,n,k} \tag{40}$$

$$f^{R,C}_{i,n,k} = \gamma_k C_{i,n,k} \tag{41}$$

$$\frac{\partial q_{i,n,k}}{\partial\theta} = s^{L,q}_{i,n,k} \tag{42}$$

### Boolean switching functions

$$\gamma_k = \sum_{m=I}^{IV} H_{m,k}\gamma_m \tag{43}$$

$$Pe_k = \sum_{m=I}^{IV} H_{m,k} Pe_m \tag{44}$$

$$C_{i,k}^{F} = H_k^F\left(\frac{u_F}{u_{III}}C_{F,i} + \frac{u_{II}}{u_{III}}C_{i,n,k-1}\right) \quad (45)$$

$$C_{i,k}^{E} = H_k^E\left(\frac{u_{IV}}{u_I}C_{i,n,k-1}\right) \quad (46)$$

$$C_{in,i,k} = C_{i,k}^{F} + C_{i,k}^{E} + \left(1 - H_k^F - H_k^E\right)C_{i,n,k-1} \quad (47)$$

$$C_{X,i} = \sum_{k=1}^{N_T} H_k^X C_{i,n,k-1} \quad (48)$$

$$C_{R,i} = \sum_{k=1}^{N_T} H_k^R C_{i,n,k-1} \quad (49)$$

The variables $\bar{q}_{i,j,k}, \bar{C}_{i,j,k}$, and $\bar{q}^{*}_{i,j,k}$ represent the average values of the adsorbed concentration, bulk-phase concentration, and equilibrium adsorbed concentration, respectively, as defined by the employed discretization scheme. The index $j$ denotes the spatial discretization point along the column axis and ranges from 1 to $n$, where $n$ is the total number of spatial nodes per column. The terms $f_{i,j,k}^{R,C}$ correspond to convective–dispersive fluxes in the bulk-phase mass balance, while $s_{i,j,k}^{R,C}$ and $s_{i,j,k}^{R,q}$ denote source terms associated with mass transfer between the fluid and solid phases. The spatial discretization step is given by $\Delta x$.

The Boolean variables $H_{m,k}, H_k^F, H_k^E, H_k^X$, and $H_k^R$ are used to represent the port-switching logic of the SMB. These variables take binary values and activate the appropriate terms depending on the column position and section configuration. The parameter $\gamma_k$ denotes the column-dependent velocity ratio, obtained as a combination of the section-dependent $\gamma_m$ values through the Boolean mapping $H_{m,k}$. The inlet concentration $C_{in,i,k}$ accounts for all possible inlet contributions to column $k$, including feed, eluent, and internal node streams. The auxiliary variables $C_{i,k}^{F}$ and $C_{i,k}^{E}$ represent the contributions of the feed and eluent streams, respectively, with the corresponding Boolean variables ensuring that only the active one is considered at each switching configuration. Finally, the extract and raffinate outlet concentrations are computed as a sum of the columns' outlet concentrations, where the Boolean variables ensure that only the column connected to the corresponding port contributes to each stream.

Once the model formulation was completed, simulation results obtained with CasADi were validated against those generated using MATLAB's PDEPE solver, which has been previously validated for the simulation of SMB systems [1]. The model parameters and operating conditions used in the simulations are summarized in Table 1, while the integrator settings adopted in this work are reported in Table 2. All remaining integrator settings were kept at their default values, and a configuration of three columns per section was considered.

The concentration profiles of species A (less-retained) and B (more-retained), evaluated at cyclic steady state at the end of a switching period, together with the corresponding product purities, are compared with the reference results in Figure 2 and Table 3.

**Table 1:** Model parameters and operating conditions for the simulation

| Parameter | Value |
|---|---|
| $L$ / cm | 7 |
| $Pe_m$ | 666.67 |
| $D$ / cm | 2.6 |
| $(1-\varepsilon)/\varepsilon$ | 1.5 |
| $k_{h,A}$ / min$^{-1}$ | 6 |
| $k_{h,B}$ / min$^{-1}$ | 6 |
| $Q_I$ / cm$^3$ • min$^{-1}$ | 56.83 |
| $Q_{II}$ / cm$^3$ • min$^{-1}$ | 38.85 |
| $Q_{III}$ / cm$^3$ • min$^{-1}$ | 42.49 |
| $Q_{IV}$ / cm$^3$ • min$^{-1}$ | 35.38 |
| $t^*$ / min | 2 |
| $C_{F,A}$ / mg • cm$^{-3}$ | 2.9 |
| $C_{F,B}$ / mg • cm$^{-3}$ | 2.9 |

**Table 2:** Integrator settings for the simulation.

| Setting | |
|---|---|
| Time integrator | CVodes |
| Time step size | $10^{-2}$ |
| Spatial step size | $2{\cdot}10^{-2}$ |
| Relative tolerance (CVodes) | $10^{-4}$ |
| Absolute tolerance (CVodes) | $10^{-6}$ |

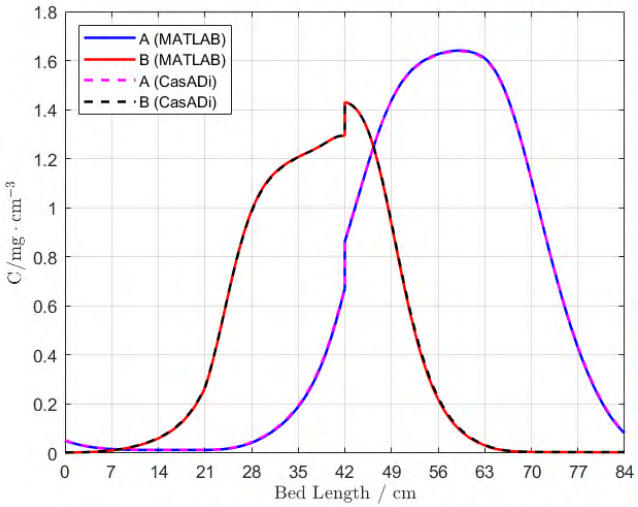

**Figure 2.** MATLAB and CasADi's concentration profiles at the end of a cycle.

**Table 3:** Product purity.

| Performance parameter | MATLAB | CasADi |
|---|---|---|
| A purity in the raffinate / % | 99.1 | 99.1 |
| B purity in the extract / % | 96.8 | 96.7 |

The profiles obtained with CasADi closely match those from MATLAB's PDEPE solver. Similarly, the products purities reported in Table 3 are in excellent agreement, with a maximum deviation of 0.1%, which is consistent with differences expected from the use of distinct numerical integration methods. These results confirm that the CasADi-based extension of the PDEPE approach is functioning correctly.

## SMB OPTIMIZATION PROBLEM

The parameter optimization problem considered in this work focuses on the separation of fructose and glucose. The main objective was to maximize the feed velocity while satisfying terminal cycle purity and recovery constraints for the primary product (fructose) in the extract. The optimization variables included the internal superficial fluid velocities in zones II, III and IV of the SMB and the switching time between steps [9].

It should be noted that, while the overall model structure remains unchanged, the adsorbent mass balance in this problem follows a liquid-phase-based LDF formulation, consistent with the isotherm parameters provided in the reference case. In this approach, the mass transfer coefficient is expressed in terms of fluid-phase concentrations, and the adsorbed concentration is obtained through a liquid-based isotherm relation. Additionally, axial dispersion effects are implicitly accounted for within the mass transfer formulation, and therefore no explicit axial dispersion term or Peclet number appears in the model equations.

Based on the validated model and the formulation described above, the dynamic optimization problem was then defined. The objective function, decision variables, purity and recovery constraints are presented below.

$$\max_{u_{II},u_{III},u_{IV},t^*} u_F \tag{47}$$

$$Purity_{X,f} = \frac{\int_{\theta}^{\theta+1} u_X C_{X,f} d\theta}{\sum_{i=f,g} \int_{\theta}^{\theta+1} u_X C_{X,i} d\theta} \geq 90\% \tag{48}$$

$$Recovery_{X,f} = \frac{\int_{\theta}^{\theta+1} u_X C_{X,f} d\theta}{\int_{\theta}^{\theta+1} u_F C_{F,f} d\theta} \geq 80\% \tag{49}$$

In addition, non-negativity constraints were imposed on all inlet and outlet velocities to ensure physically meaningful operation and to prevent flow reversal during the optimization.

The model parameters, decision variable bounds, and initial guesses used in the optimization are summarized in Tables 4, 5 and 6. The numerical integrator settings employed in the optimization, including time and spatial discretization and solver tolerances, are reported in Table 7.

The adsorption equilibrium for each component is described by linear isotherms. The parameters $K_g$ and $K_f$ denote the equilibrium adsorption coefficients for glucose and fructose, respectively. These coefficients are assumed to be constant and were taken directly from the reference case.

**Table 4:** Model parameters and operating conditions for the optimization problem

| Parameter | Value |
|---|---|
| $L$ / m | 2 |
| $\varepsilon$ | 0.389 |
| $k_{h,f}$ / $s^{-1}$ | $6.84 \cdot 10^{-3}$ |
| $k_{h,g}$ / $s^{-1}$ | $6.84 \cdot 10^{-3}$ |
| $K_g$ | 0.518 |
| $K_f$ | 0.743 |
| $C_{F,f}$ / % | 50 |
| $C_{F,g}$ / % | 50 |
| $u_I$ / m • $h^{-1}$ | 8 |
| Cycles | 60 |
| Columns per section | 1 |

**Table 5:** Decision variables' initial guesses

| Decision variable | Initial guess |
|---|---|
| $u_{II}$ / m • $h^{-1}$ | 5 |
| $u_{III}$ / m • $h^{-1}$ | 5.1 |
| $u_{IV}$ / m • $h^{-1}$ | 3.5 |
| $t^*$ / s | 1140 |

**Table 6:** Decision variables' upper and lower bounds

| Decision variable | Lower bound | Upper bound |
|---|---|---|
| $u_{II}$ / m • $h^{-1}$ | 0.1 | 8 |
| $u_{III}$ / m • $h^{-1}$ | 0.1 | 8 |
| $u_{IV}$ / m • $h^{-1}$ | 0.1 | 8 |
| $t^*$ / s | 0 | - |

**Table 7:** Integrator settings for the optimization problem

| Setting | |
|---|---|
| Time integrator | CVodes |
| Time step size | 1 |
| Spatial step size | $2 \cdot 10^{-2}$ |
| Relative tolerance (CVodes) | $10^{-4}$ |
| Absolute tolerance (CVodes) | $10^{-4}$ |

The parameter optimization problem was transcribed using a direct single-shooting approach and solved using the interior-point optimizer IPOPT. The optimal operating conditions and corresponding performance metrics obtained are summarized in Table 8, together with the associated constraint values and the reference results reported in the original article [9]. The species concentration profiles at cyclic steady state, evaluated at the end of a switching period, are shown in Figure 3. All computations were performed on a Windows 11

workstation equipped with an Intel® Core™ i7 processor and 16 GB of RAM, using Python 3.12.3 and CasADi version 3.7.2.

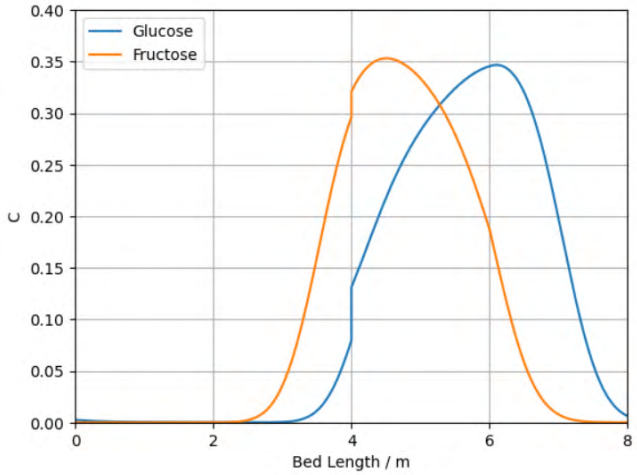

**Figure 3.** Fructose and glucose concentration profiles at the end of a cycle.

**Table 8:** Optimization results and reference values

| | CasADi IPOPT | gPROMS SRQPD |
|---|---|---|
| $u_F$ / m • $h^{-1}$ | 0.5216 | 0.5216 |
| $u_{II}$ / m • $h^{-1}$ | 3.7345 | 3.7361 |
| $u_{III}$ / m • $h^{-1}$ | 4.2561 | 4.2577 |
| $u_{IV}$ / m • $h^{-1}$ | 3.1298 | 3.1259 |
| $t^*$ / s | 1416 | 1415 |
| Fructose purity / % | 89.98 | 90 |
| Fructose recovery / % | 79.99 | 80 |
| Optimization time / min | 10.7 | 111.8 |
| Number of iterations | 21 | 39 |

The parameter optimization results obtained with the proposed CasADi-based framework are in very good agreement with those reported in the reference study. Both approaches converged to the same objective function value, while small differences were observed in the individual decision variables, which can be attributed to the use of different numerical integrators, solvers and tolerance settings. The purity and recovery constraints for fructose in the extract were satisfied to within 0.02% of the specified limits. These minor deviations result from the looser integration tolerances and reduced number of integration steps adopted in the formulation of this optimization problem, reflecting a deliberate trade-off between computational speed and numerical precision. Tighter tolerances and finer temporal resolution could be employed if stricter constraint satisfaction were required.

Despite these minor differences, the overall performance of the optimized solution remains consistent with the reference case. Moreover, the total optimization time was significantly reduced, requiring 10.7 minutes compared to 111.8 minutes reported for the gPROMS-based implementation. This corresponds to a reduction of approximately 90% in computational time, highlighting the efficiency of the CasADi-based approach for parameter optimization of the SMB system.

It should be noted that the trade-off between computational speed and numerical precision was explored only for the CasADi implementation, while the gPROMS results correspond to those reported in the reference study.

A potential limitation of this proposed framework is related to usability. Commercial modelling environments such as gPROMS or MATLAB provide highly integrated modelling interfaces, built-in generic solvers for ODEs and PDEs, and graphical tools that simplify model implementation and debugging. In contrast, Python-based implementations using CasADi typically require a greater level of programming expertise and manual configuration of the simulation and optimization workflow. Also, in the case of models described by systems of PDEs such as the SMB process, the model must be transformed into a system of ODEs via spatial discretization to enable the use of the CasADi framework.

## CONCLUSION AND FUTURE WORK

The proposed CasADi-based framework provides a robust alternative to traditional iterative optimization techniques, such as the triangle theory, for the analysis and optimization of Simulated Moving Bed processes. The developed model is highly flexible and can be readily extended to other tubular flow systems governed by partial differential equations, including plug flow reactors and pressure swing adsorption columns. Moreover, the implementation relies exclusively on open-source tools, enabling the simulation and optimization of complex process systems without the need for commercial software such as gPROMS or MATLAB, thus improving accessibility for process systems engineering applications.

Future work will focus on extending the proposed state-space formulation toward dynamic and real-time optimization of PDE-governed systems, allowing operation under optimal conditions even in the presence of plant-model mismatch.

## ACKNOWLEDGEMENTS

This paper is a result of the project “WAVES - Seawater & Wastewater: Turning Challenges into Resources”, with operation code at the Funds Platform (Balcão dos Fundos), NORTE2030-FEDER-02716600, co-financed by the European Union through the NORTE 2030 Regional Program, of Portugal 2030. ## ABSTRACT

The convergence of artificial intelligence (AI) and chemical process systems engineering is creating unprecedented opportunities to transform current refineries from conventionally operated plants into intelligent, automated, and resilient systems. However, the practical deployment of AI in these complex industrial environments faces several critical challenges. First, most existing process datasets contain minimal labeled data, making it difficult to apply supervised learning techniques that require extensive annotations to generate meaningful insights. Furthermore, refinery data typically consists of high-dimensional, multivariate time series, which pose additional complexities in capturing temporal dynamics and system interactions. Traditional Fault Detection and Diagnosis (FDD) frameworks often struggle to address these complexities, lacking adaptability to evolving process conditions, scalability to large plant networks, and explainability in their diagnostic reasoning. To address these gaps, we propose an integrated framework for unsupervised knowledge discovery, adaptive process monitoring, and AI-assisted fault diagnosis. The approach combines Dynamic Time Warping (DTW) with graph-based layout algorithms to extract and visualize temporal structures and similarities within complex process datasets. The resulting graphs function as an unsupervised model, enabling the identification of operational regimes through process clustering. These models can be deployed online to detect anomalies using adaptive fault thresholding, ensuring robustness to changing process dynamics. When faults are detected, the framework leverages large language models (LLMs) as AI assistants to support fault diagnosis. By bridging domain knowledge—such as piping and instrumentation diagrams (P&IDs) and signal flow diagrams—with data-driven insights, including machine learning metrics and feature contribution scores, the system delivers explainable and accurate diagnostic outputs. This hybrid methodology enhances interpretability and decision-making, offering a scalable and adaptive solution for next-generation AI-enabled refinery operations.

## INTRODUCTION

### Background and Motivation

Chemical refineries are among the most complex and highly automated industrial environments in modern manufacturing. Over several decades, these facilities have adopted advanced process control (APC) technologies—such as proportional–integral–derivative (PID) controllers, multivariable control systems, and model predictive control (MPC)—to maintain operational efficiency, stability, and safety under tightly constrained process conditions. As a result, today's refineries operate with extensive digitization, high sensor density, and continuous streams of multivariate data originating from interconnected unit operations [1]. Despite this progress, current refinery optimization and monitoring practices still rely heavily on deterministic models, periodic calibrations, and human expertise to interpret process behavior and respond to abnormal conditions. These systems, while robust and well-established, show diminishing

returns as they approach their performance limits, motivating the need for more adaptive and intelligent data-driven solutions [1].

The emergence of Industry 4.0 has accelerated interest in leveraging artificial intelligence (AI), machine learning (ML), and advanced analytics to complement or extend the capabilities of conventional refinery control architectures. AI-driven approaches promise improved performance for nonlinear, high-dimensional, and dynamic systems by uncovering patterns not easily expressed in first-principles or optimization-based models. However, the practical implementation of AI in refinery environments remains challenging. Most downstream oil and gas facilities generate large quantities of operational data but very limited labeled data, restricting the use of supervised learning techniques that dominate the ML landscape [1]. Moreover, the datasets are typically highly-dimensional, multivariate time series, often with irregular sampling, complex cross-correlations, and contain evolving process dynamics such as catalyst degradation, feedstock variability, and equipment aging. These characteristics complicate the training of predictive models and reduce their robustness when deployed in real-world operations.

Prior work in industrial digitalization has shown that while Industry 4.0 technologies—such as IoT sensing, big data infrastructures, and cyber-physical systems—can provide transformative value, they must be carefully adapted for continuous process industries such as refining [1]. Traditional machine learning techniques, often developed for domains with abundant annotations and static data distributions often struggle with poor scalability to plant-wide networks, inadequate handling of non-stationary behavior, difficulty capturing temporal relationships, and a lack of explainability in diagnostic outcomes. These shortcomings contribute to slow adoption rates of AI-based FDD systems in safety-critical industrial environments.

At the same time, broader advancements in artificial intelligence highlight both the urgency and the opportunity for integrating more sophisticated AI techniques into process systems engineering. The 2025 Artificial Intelligence Index Report indicates that AI models are rapidly improving in efficiency, accessibility, and reasoning capabilities, with significant adoption growth across industrial sectors [3]. Industries worldwide are increasingly leveraging AI for predictive maintenance, anomaly detection, and decision support, yet concerns about data quality, transparency, and reliability remain prevalent. These concerns are particularly acute in refinery operations, where process deviations can propagate quickly and incur substantial economic or safety consequences.

Finally, sustainability pressures—including energy efficiency demands, emission reduction targets, and global competitiveness—further amplify the need for intelligent, adaptive process monitoring solutions. As highlighted by Ghobakhloo, Industry 4.0 technologies can unlock substantial economic and environmental benefits, but only when deployed through architectures that support scalability, robustness, and meaningful knowledge generation [2]. These requirements align closely with the challenges facing modern refineries, where operators must navigate massive data volumes, interconnected process units, and evolving operational regimes.

Together, these factors illustrate a clear need for frameworks that can:

(1) operate effectively in high-dimensional, minimally labeled data environments

(2) capture complex temporal structures

(3) adapt to shifting process conditions, and

(4) provide explainable and actionable diagnostic insight for the refinery engineers

The framework proposed in this work directly addresses these gaps by integrating unsupervised knowledge discovery, adaptive anomaly monitoring, and AI-assisted diagnostic reasoning within a unified and interpretable architecture. From a process systems engineering perspective, the methodological contribution lies in structuring these components into a cohesive workflow that links data-driven temporal representations with adaptive monitoring and context-aware diagnostic reasoning to support real-time, plant-level decision making.

## PROPOSED FRAMEWORK

### Unsupervised Graph Construction

The first step towards building the unsupervised models is to shift the focus from individual time steps to windows of data. Before this step, the data were preprocessed through standard cleaning procedures, including handling of missing values and normalization to ensure consistent scaling across variables. Then, by analyzing these windows of data—as opposed to just pointwise data—the model can learn temporal dependencies from the sequences of observations. The parameters for this step are straightforward: a window size, W, and a stride, S. Window size is just the fixed length of data in each window and stride is the step size, or percentage of overlap, between consecutive windows. The choice of W and S determine both the temporal resolution of the data and ultimately the computational cost. The next step is to perform dynamic time warping (DTW) calculations in a pairwise fashion for each window of data. DTW is a widely used approach for assessing similarity between time-series sequences that do not share the same duration or pacing. First proposed by Itakura (1975) and later expanded by Sakoe and Chiba (1978), the technique

aligns two signals by flexibly stretching or compressing the time axis to achieve the minimum alignment cost, also known as the DTW distance [4-5]. The resulting alignment costs are then stored in a matrix as shown in **Figure 1**. These will be the basis for the graph model shown later. For these results, the *tslearn* [6] python package was utilized.

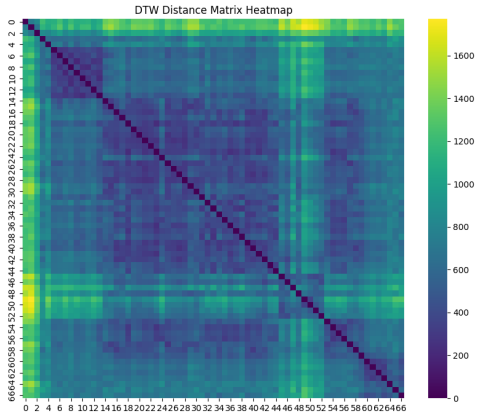

**Figure 1.** Heatmap of pairwise DTW distances between all windows of an example dataset

Once the DTW matrix is obtained, the next step is to represent the similarity structure from the distances as a graph. Utilizing the well-known k-NN algorithm, each window is treated as a node and edges are created by connecting each node to its k most similar neighbors—determined by the DTW distances. This creates a mapping that connects the temporal relationships within the dataset. These maps can be expressed as graphs by utilizing the *NetworkX* package in python [7]. An arbitrary example is shown in **Figure 2**.

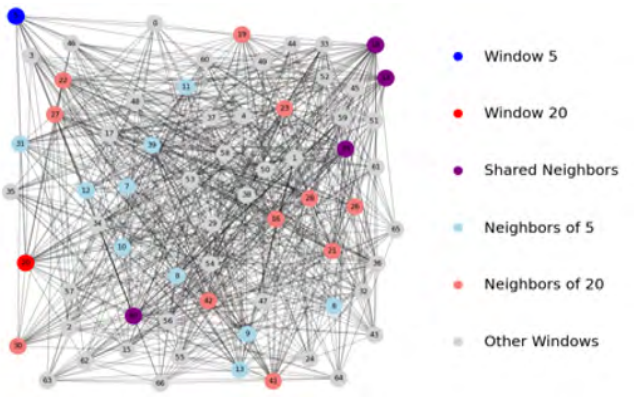

**Figure 2.** Initial graph highlighting nodes 5 and 20 connected by their k=15 neighbors

The issue now is that we have the mapping—however, it is just a tangled mess. It makes sense mathematically, but it serves no use yet as a visual graph. Since the goal is to ultimately cluster the windows based on different operational regimes, the nodes need to be organized in such a way that this can be achieved. *NetworkX* has several graph layout algorithms that help with this arrangement. The spring layout, also referred to as the force-directed layout, was chosen as it is a physics inspired algorithm in which nodes are modeled as mutually repelling particles and edges act as attractive springs. The implementation in *NetworkX* utilizes the Fruchterman-Reingold [8] algorithm in which the node positions are iteratively updated until a low-energy, near-equilibrium state is reached or if the set number of iterations is achieved. The resulting graph clusters similar nodes closer together and sparsely connected nodes and outliers are placed towards the periphery. This can be seen in **Figure 3** when 50 iterations of the spring layout algorithm were applied. The most similar nodes to window 5 are mostly grouped near window 5 (blue cluster), the most similar nodes to window 20 are grouped near window 20 (red cluster), and some of the intermediate windows are placed at the boundary between the clusters (purple). At this point a graph-based embedding of the dataset is created, based upon the warped temporal distances. From here, traditional clustering techniques, KMEANS, DBSCAN, etc., could be applied to formally label the data from the unsupervised graphs generated.

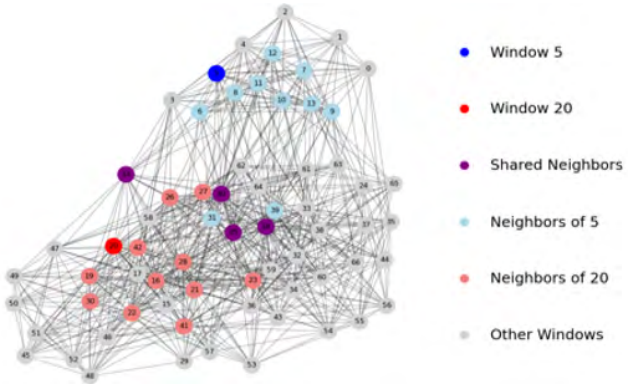

**Figure 3.** Resulting graph after 50 iterations of the force-directed algorithm was applied

## Adaptive Online Monitoring

Since the goal of this framework is to expand beyond just offline modeling to online fault detection, the next step was to see how these graphs could be utilized online. First, the offline models need to be studied and the clusters need to be verified, perhaps by speaking with someone at the plant that is knowledgeable about changes in the process. When a normal operational regime is established, this cluster will be utilized as the baseline for the initial, online graph. Since this is considered normal operations, the natural variation among the distances between these windows will serve great purpose for calculating the initial fault detection threshold. By drawing from the normal cluster, the corresponding

DTW distances for each window can be collected and the distribution can be shown such as in ***Figure 4***. From the distribution, statistical calculations can be performed to highlight the mean, standard deviation, percentiles, etc.

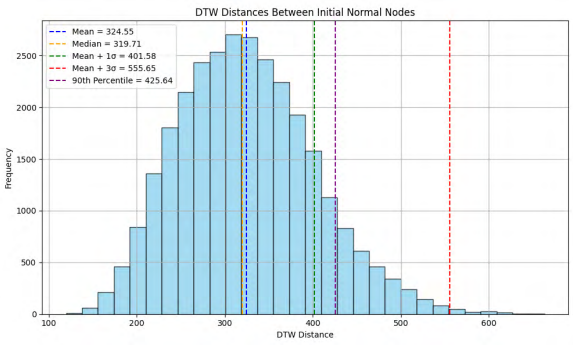

**Figure 4:** Distribution of pairwise DTW distances between initial normal nodes

Ultimately, the threshold was chosen to be adjustable based on the mean and standard deviations as shown in **Equation 1**. Here $\mu$ is the average of the distances, $\sigma$ is the standard deviation, and $X$ is a multiplier of the standard deviation. These parameters can be tuned based on the dataset at hand and the required fault detection sensitivity.

$$Threshold = \mu + X\sigma \quad (1)$$

To tackle the issue with evolving process conditions, the fault threshold is updated dynamically using an exponential moving average (EMA) of recent DTW values. This allows for the threshold to gradually adjust to changes in process conditions while still remaining sensitive to sudden anomalies. A parameter $\alpha$ is chosen as a smoothing factor the controls the responsiveness of the threshold to recent changes. Let $\mu_t$ and $\sigma_t$ denote the running mean and standard deviation of current DTW distance $d_t$:

$$\mu_t = \alpha \bullet d_t + (1-\alpha) \bullet \mu_{t-1} \quad (2)$$

$$\sigma_t = \alpha \bullet |d_t - \mu_t| + (1-\alpha) \bullet \sigma_{t-1} \quad (3)$$

Then the adaptive threshold at time $t$ becomes:

$$Threshold_t = \mu_t + X \bullet \sigma_t \quad (4)$$

If the current distance $d_t$ exceeds the current threshold, the window is flagged as an anomaly. If a window is flagged as normal or if the current threshold is less than the initial threshold, then the threshold is updated. This allows the system to only learn during normal operations while also preventing the threshold from being stuck in a minimum. A third updating condition is applied if a fault persists across a specified number of consecutive windows. This mechanism will serve as an update trigger that will ensure new operating conditions are not persistently flagged as faults. By incorporated them into the threshold learning, the model is prevented from becoming obsolete and can evolve as plant operations change—tackling one of the main objectives of this framework.

## LLM Diagnostic Agents

Up to this point, two stages in the framework are achieved. First, the graph-based embeddings are created and utilized as an unsupervised model. Second, the graph model is prepared and subjected to live data for fault detection. The third stage is to extend to the fault diagnosis portion.

Fault diagnosis is tricky due to complex causal relationships, feedback loops, and misleading indicators. Traditional approaches—physics-based, expert systems, and data-driven ML—each fall short. Models may be rigid, they may be too complicated to create, or they may lack causal grounding. Data-driven methods such as Principal Component Analysis (PCA) contributions, Shapley Additive exPlanations (SHAP) analysis or Subspace Greedy Search (SGS) are often utilized due to their ease of use. By comparing a set of normal conditions to a set of faulty conditions, features with the most contribution can be highlighted. If these always worked, that would be great, however, these methods are purely black-box and often run into the "false contribution" problem. For example, a SHAP analysis may point to a feature that is highly important, but it is just a reactive symptom and not the true root cause of the fault. To overcome this, large language models (LLMs) are suggested as diagnostic agents.

The latest generation of LLMs—such as OpenAI's ChatGPT models, Anthropic's Claude models, or Google's Gemini models, present a significant opportunity for advancing fault diagnosis in process monitoring systems. LLMs are trained on very large text corpora that make them excellent at predicting human like text sequences. In addition, the current stage of LLMs can handle multimodal inputs such as tables, process diagrams, etc. This capability opens the door for LLMs that act as agents that can perform contextual reasoning that mirrors the diagnostic thought process of a human engineer. Venkatasubramanian and Chakraborty deem these context rich LLMs as "Large Knowledge Models (LKMs)" as opposed to the traditional "LLM" nomenclature [9]. These "LKM" agents can bridge the gap between the domain specific knowledge and data-driven ML outputs to support root cause identification, hypothesis generation, and human-in-the-loop decision making in industrial environments.

## Overall Framework

The overall pipeline for this work is shown in **Figure 5**. This summarizes the three stages of the process monitoring workflow including the offline portion where historical data is utilized to build a DTW-based graph, an

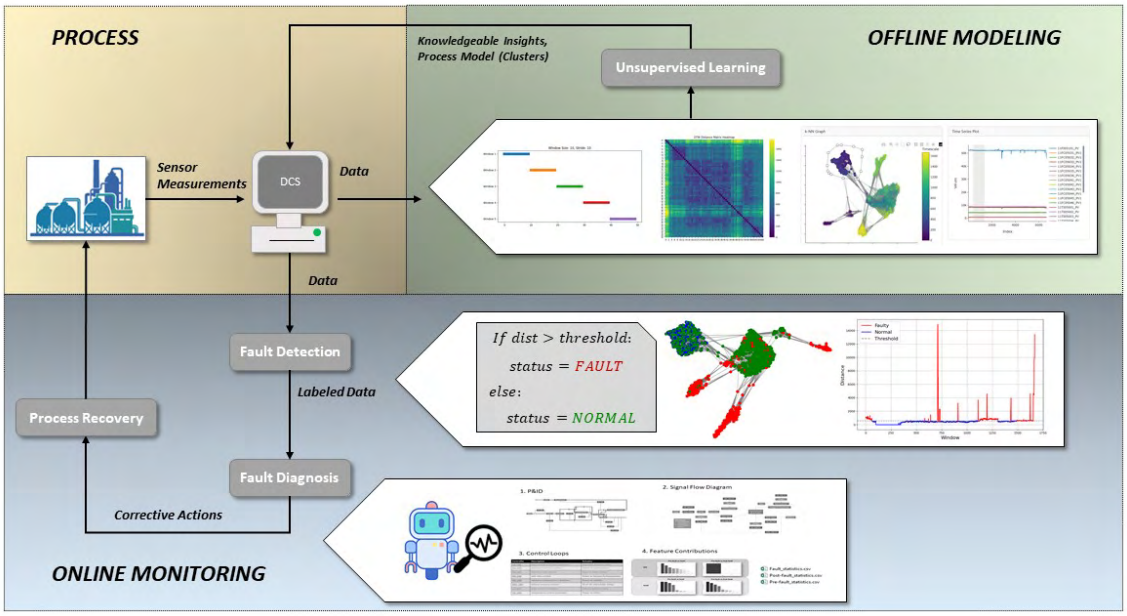

**Figure 5.** Overall Framework for Process Monitoring icluding the three stages: (1) Unsupervised Graph-based Learning, (2)Adaptive Fault Detection, and (3) LLM-assisted Fault Diagnosis

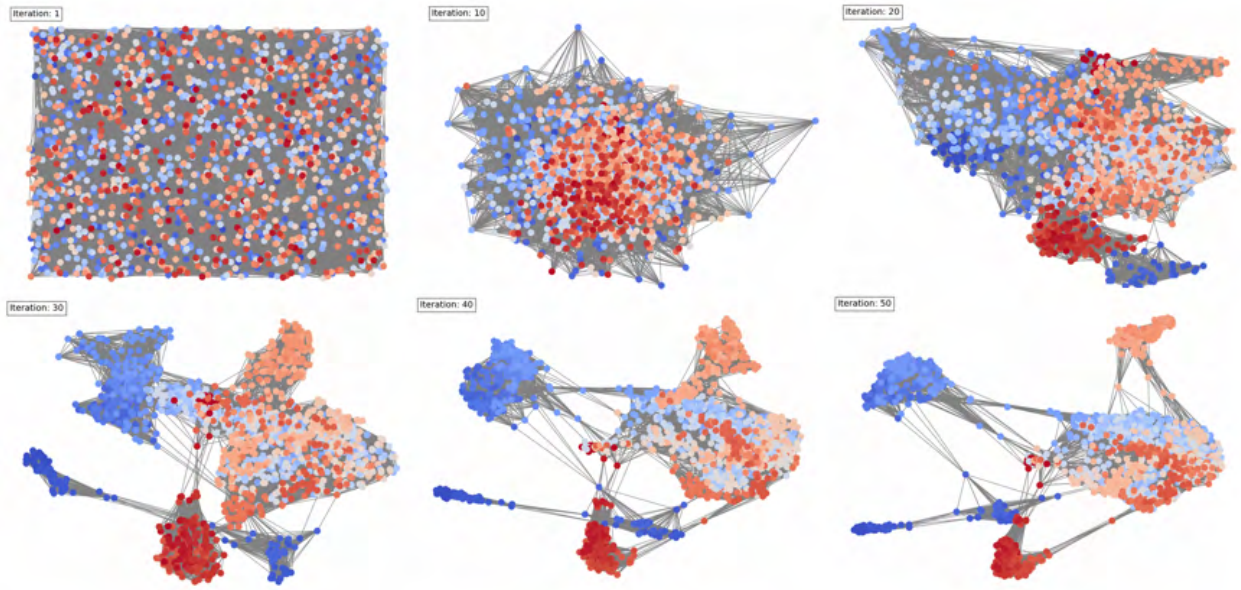

**Figure 6.** Graph evolution over successive iterations of the physics-based layout (colored by timescale).

online portion where live data can be subjected to the graph to generate fault labels while dynamically updating the fault threshold, and a diagnostic portion where LLM's serve as AI-assistants in real time diagnosis.

## RESULTS

The framework was first tested for unsupervised process clustering and process monitoring using data from an industrial-scale pyrolysis furnace that is involved in the production of ethylene from naphtha [10]. The reactor system is housed within a fired furnace where energy is supplied by burning fuel gas. The system consists of six reactor coils through which a mixture of naphtha and steam flows. The mixture is exposed to temperatures approaching 1000 °C, allowing for thermal cracking to produce ethylene. A total of 27 key process variables were monitored at 20-min intervals over a continuous

90-day operating period. Within the batch, there are known start-up and shutdown regimes, noise from a faulty sensor, and gradual drift due to accumulation of coke on the reactor tubes.

## Building Graph Models

The dataset was split into windows of length 5 and a stride of 4, corresponding to window spans of 100 minutes with 20 minutes of overlap. This resulted in 1667 individual windows that were used to create the pairwise DTW matrix. A sensitivity analysis of the k parameter was performed and ultimately a value of k=20 was selected as it provided the most well-structured representation of the underlying graph. The evolution of the graph with W=5, S=4, and k=20 is shown in **Figure 6**. At iteration 1, the nodes are all randomly positioned. As iterations of the spring layout algorithm were applied, the similar nodes were slowly pulled toward each other and dissimilar nodes were pushed away from one another—resulting in an embedding with distinct regimes. Furthermore, the two-dimensional coordinates from the produced by the force directed layout were used as inputs to the HDBSCAN clustering algorithm in order to generate real cluster labels. The clustering hyperparameters—min_cluster_size and min_samples—were again tuned via a sensitivity analysis of the resulting graphs. The values of min_cluster_size and min_samples were eventually set to 5 and 10 respectively for the best result. Under this configuration, six distinct clusters were found, along with a small subset of nodes labeled as noise as shown in ***Figure 7***. This cluster identification remained consistent after repeated trials as well.

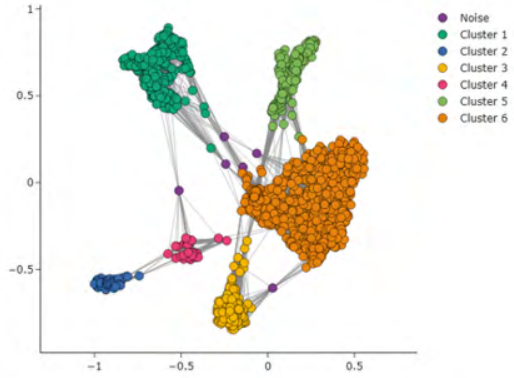

**Figure 7.** Process Model colored by Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) labels resulting in 6 clusters + noise

## Evaluating Graphs for Online Monitoring

To extend the model for online analysis, Cluster 1 was deemed as the normal operational regime. The pairwise DTW distances for this cluster were collected and shown in **Figure 4**. Based on the statistical analysis, the initial fault threshold was set at the mean plus three standard deviations. The graph was then initialized with only the nodes corresponding to Cluster 1. To monitor for faults, the full dataset was then subjected to this initial model and the results are shown in **Figures 8-9**. **Figure 8** shows the graph evolution and **Figure 9** shows the live run chart with the DTW distances for fault detection.

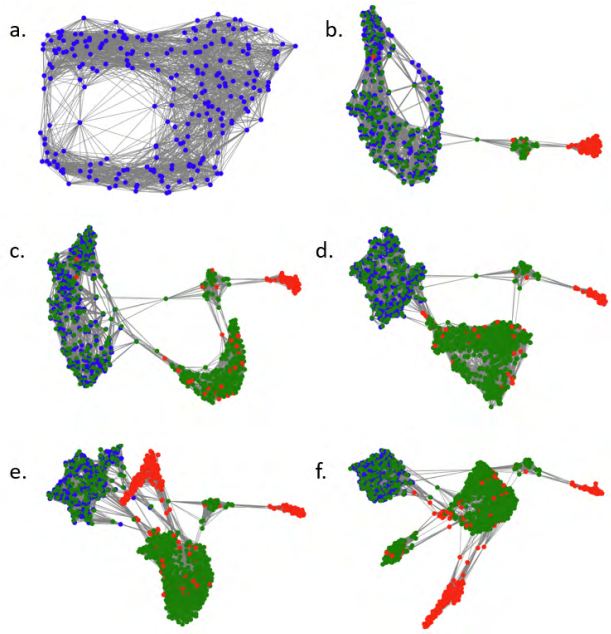

***Figure 8.*** Evolution of the online graph for monitoring (BLUE is initial training nodes, GREEN is live normal nodes, and RED is live faulty nodes)

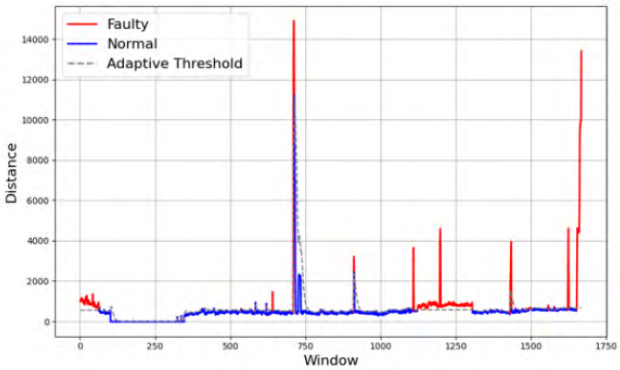

**Figure 9.** Online Fault Chart with Adaptive Threshold ($\alpha = 0.9, X = 3$)

From these results, several things were accomplished. First, the final resulting graph is similar to the initial graph that was built. This shows that the results are reproducible. Second, the faults that were found were accurate to what we know about the process. It flagged the start-up cluster, the spikes or noise cluster from the sensor noise, a separate operational period cluster, and the final shutdown cluster. Importantly, it did not classify

the process drift as noted in Cluster 6 as faults. This is due to the third point—that the online adaptions were successful. This can be better seen by zooming in on the run chart to see how the dynamic threshold was adapting. This can be observed in **Figure 10**.

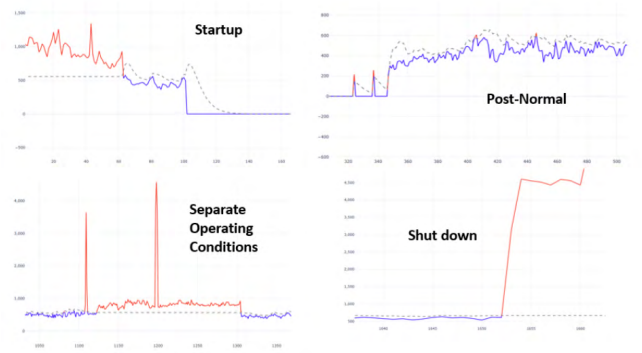

**Figure 10.** Zooming in on run chart to see the online threshold adaptions

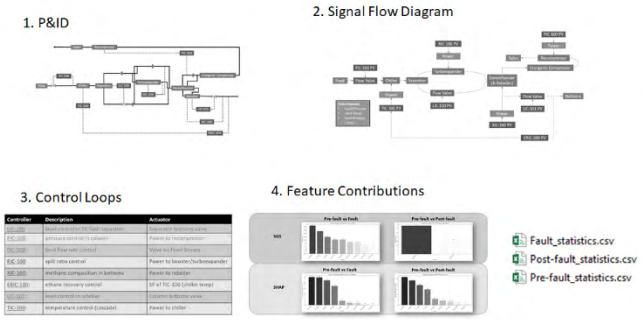

**Figure 11.** Inputs for Agent Prompting

## Utilizing LLMs as Diagnostic Agents

In the final stage, we decided to utilize an ASPEN HYSYS® simulation for an LNG plant for the AI-assisted fault diagnosis. This was chosen since we had the ability to introduce our own faults into the simulation as opposed to relying on only historical datasets. This simulation monitors the operation of a demethanizer column operating under CRR separation conditions. Notably, the simulation has a feed stream defined as natural gas at 4980 kmol/hr supplied at a pressure of 5818 kPa and a temperature of 35 °C. The central unit is a 30-stage distillation tower with an integrated reboiler. A dataset was first created by introducing several faults to the system after running at normal conditions. These faults included a valve malfunction, a sensor bias, a feed disturbance, and a set-point (SP) change. Just like before, the graph model was constructed and the fault threshold was set. Now, when the model was online, the AI-assistant was incorporated. When a set number of faults were labeled, a snapshot of the data was taken and several inputs were collected. These inputs correspond to contextual information such as the P&ID diagram, signal flow diagram, and control loop table as well as the data-driven metrics—the feature contributions from the fault and statistics from the data as shown in **Figure 11**.

These inputs were then sent to the AI-assistant, via OpenAI's API system and using the GPT-4o model. The agent was instructed to use the domain knowledge and the data-driven knowledge to find the root cause of the fault. Specifically, it was prompted to produce a one-page diagnostic report that identifies the root cause, highlights insights, grounds reasoning in domain knowledge, and recommends operator actions. Using this setup, the agent was tested for several fault scenarios. Here, the results are shown for the valve malfunction in **Figures 12-13**.

GPT Response (VALVE MALFUNCTION):

📌 **Fault Type**: Control Error

🔍 **Evidence from inputs**:

- The OP monitoring metrics indicate that FIC-100 is a significant candidate for control loop errors detected by OP trends.
- In the SGS analysis, XIC-100_OP has the highest contribution (18.95%), followed by PIC-100_OP (12.98%) and TIC-100_OP (12.19%).
- However, FIC-100_OP has a very low contribution (0.26%), indicating it is not the root cause.
- The SHAP analysis also shows that FIC-100_OP has a contribution of 10.07%, which is not significantly larger than the others.

🧠 **Root Cause Explanation**:

- The control error is likely due to a malfunction in the FIC-100 control loop, which is responsible for maintaining a stable feed flow rate into the process.
- Given that no significant OP metrics were detected, it suggests that the feed valve may not be responding correctly to the control signals, leading to instability in the feed flow.
- This could be due to a valve malfunction, such as sticking or improper calibration, or a sensor bias affecting the flow measurement.

🛠️ **Recommended Next Steps**:

- Operators should inspect the FIC-100 control loop, focusing on the feed valve and its associated flow sensor.
- Calibration checks should be performed, and the valve should be tested for proper operation.
- If necessary, maintenance should be conducted to ensure the valve is functioning correctly and that the sensor readings are accurate.
- Additionally, monitoring should continue to assess the impact of any adjustments made.

**Figure 12.** Diagnostic report generated by LLM for Valve Malfunction

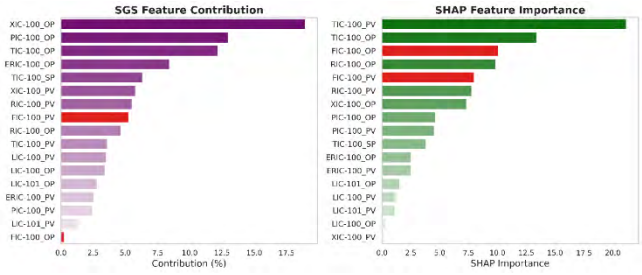

**Figure 13.** Feature Contributions for SGS and SHAP (true fault features in RED)

In this fault, the feed control valve (FIC-100) was

plugged by decreasing the valve coefficient by 10%. The agent analyzed the inputs that were collected and, in the report, accurately described the fault. It began by first discussing evidence from the inputs. For example, it said that "FIC-100 is a significant candidate for control loop errors detected by OP trends". It then went on to say that FIC-100 was not highly ranked in the feature contributions for both SHAP and SGS, causing a discrepancy. It then went on to the root cause hypothesis. Here it ultimately decided that there was most likely a "malfunction in the FIC-100 control loop." Following this, it suggested corrective actions such as the valve should be "tested for proper operation" and specifically "focus on the feed valve and its associated flow sensor."

Overall, this was a pretty good report as the agent only had knowledge based on its initial knowledge and the knowledge learned from the inputs. The prompt included detailed instructions, but no actual information of what faults occurred. In addition, it is important to note that just the standard SGS and SHAP plots would not have captured the true root cause of the fault as it highlighted the FIC-100 control loop first only as the 8$^{th}$ most important in the SGS plot and 3$^{rd}$ most important in the SHAP plot.

## CONCLUSION

In summary, the proposed framework "connects the dots" across key challenges in process monitoring by addressing limited labeled data, capturing temporal dynamics in multivariate time series, adapting to changing process conditions through a dynamic fault threshold, and autonomously generating root-cause hypotheses using LLMs. Together, these elements form a unified, interpretable, and scalable approach for modern refinery operations. The results show that DTW-based graph embeddings effectively reveal operational regimes, the adaptive thresholding reliably separates true faults from natural drift, and the LLM-assisted diagnosis produces context-aware explanations grounded in both domain knowledge and data-driven evidence. Future work will aim at addressing scalability concerns, prompting strategies, and collecting more quantitative results for both the detection and diagnosis portions of the framework. Overall, this work demonstrates the value of integrating unsupervised learning, adaptive monitoring, and AI-assisted diagnosis into a cohesive workflow. Future work will refine LLM prompting strategies, expand multimodal inputs, and evaluate the framework's scalability for broader industrial deployments.

## ABSTRACT

We develop a multi-fidelity soft-sensing framework to reconcile online (low-fidelity) industrial measurements with sparse (high-fidelity) laboratory samples from an alkylation unit in a refinery. A first-principles model is used to generate an additional low-fidelity dataset and train a surrogate that predicts the output variable. We investigate whether incorporating sparse high-fidelity laboratory data with the low-fidelity data improves prediction accuracy. A multi-fidelity predictor forms a corrected output by learning the residual between the high-fidelity observations and the low-fidelity surrogate using Gaussian process regression. The simplest model structure performs best, reducing test prediction error (computed against laboratory samples) by 31.1% relative to the currently deployed industrial analyzer and outperforming a standard high-fidelity-only model trained on laboratory data. Overall, the simplified surrogate model captures the main industrial trends well enough to serve as a reliable low-fidelity input for the multi-fidelity soft sensor.

## INTRODUCTION

Industrial processes operate under tight economic and safety constraints, and their units are expected to run close to optimal conditions for long periods [1]. Deviations from the desired operating point reduce yield, increase utility consumption, and can accelerate equipment wear [2]. At the same time, plants face feed variability, seasonal effects, catalyst aging, and operational interventions that change the process behavior over time [3]. This combination drives operators to rely on monitoring and decision support tools [4] that are reliable, and easy to maintain.

Modern plants are heavily instrumented. Flow, pressure, and temperature measurements are usually available at high sampling rates and are directly usable for monitoring and control. Other variables readings can be harder to obtain. Product quality indicators and stream compositions are often measured by online sensors or by laboratory analyses [5]. Online analyzers provide frequent updates but may drift, show bias, or suffer from maintenance related faults, whereas lab measurements are less frequent but are typically treated as a reference signal. This results in a practical mismatch between what is needed for operation, and what is available as reliable ground truth [6]. Since quality measurements are not collected continuously, plants often operate with wider safety margins, which typically reduces profitability [7].

Data-driven models are a common way to bridge the gap between high-rate process measurements and sparse, reliable quality data, for example through soft sensors that can infer difficult-to-measure outputs from easy-to-measure inputs. In industrial operation, the implemented soft sensor must handle missing values, sensor faults, and operating mode changes. They also need to be interpretable to diagnose failures. Moreover, many industrial soft sensors are deliberately simple and use a small set of engineered regressors that aim to approximate the dominant material and energy balances [8, 9]. Even the best-performing offline model is not useful if it depends on variables that are unreliable, unavailable in real time, or unstable after maintenance [10]. Some recent deep learning soft sensors aim to improve prediction by extracting relevant hidden features while eliminating redundancy and maintaining structure simplicity [11, 12].

First-principles process models can also address

some of these issues because they encode mass and energy conservation laws, phase equilibria, and known reaction pathways. They can provide consistent data under systematic perturbations. In large-scale industrial settings, however, fully accurate mechanistic models are difficult to obtain. Parameter uncertainty, unknown disturbances, unmeasured states, and changing plant conditions often limit predictive accuracy. This makes a direct mechanistic model unrealistic when the goal is a reliable, daily decision-making support [13]. Broader reviews report that implementations of many first-principles models remain constrained by uncertainty and integration or maintenance burden [14].

These constraints motivate hybrid workflows that combine mechanistic structure with data-driven learning. In such workflows, mechanistic models are used to provide physically consistent trends and to expand coverage of the operating space, while plant data compensate unmeasured disturbances [15]. Surrogate model frameworks (e.g., deep neural networks trained on simulation data) are commonly used to retain process trends while reducing computational cost for downstream tasks [16]. In this work, a deliberately simplified first-principles simulator is used to generate an additional fidelity level that supplies trend information beyond routine operation and supports surrogate training. Each of these data sources can be treated as a separate information stream within an MF framework. High-frequency measurements act as a low-fidelity (LF) data that capture dynamics and disturbances. Sparse laboratory samples provide high-fidelity (HF) reference to correct bias. The objective is to explore whether a simple surrogate trained on simulated inputs can explain the measured industrial output.

In this work, we build a workflow that (*i*) uses a mechanistic process model to generate a large synthetic dataset under controlled variations of key control parameters, (*ii*) trains a surrogate model that reproduces the simulator trends at low computational cost, and (*iii*) integrates the predictions with industrial measurements in an MF framework. The main focus is to improve monitoring and a deployable structure with limited number of input variables, and a predictor that can be retrained when an operation point changes.

## PROBLEM STATEMENT

Many industrial regression problems involve multiple information sources with different fidelity. Let $x \in \mathbb{R}^p$ denote the regressor vector (measured variables) and $y \in \mathbb{R}$ the target output variable. An industrial LF dataset provides $T$ online samples $\{(x_t^{\mathrm{LF}}, y_t^{\mathrm{LF}})\}_{t=1}^{T}$, while a HF reference provides only $K$ trusted laboratory samples $\{(x_k^{\mathrm{HF}}, y_k^{\mathrm{HF}})\}_{k=1}^{K}$, with $K \ll T$. In addition, an auxiliary LF' dataset may be available from an alternative source, or model simulation $\{(x_n^{\mathrm{LF}\prime}, y_n^{\mathrm{LF}\prime})\}_{n=1}^{N}$, with $K \ll T \ll \mathrm{N}$. The objective is to use the sparse HF reference to correct predictions from the frequent LF data within an MF framework.

We consider three information sources. Simulation dataset (LF' hereafter referenced as $X^{\mathrm{SIM}}$) generated from variations of key control variables within defined limits. Here, $p$ denotes the number of monitored variables:

$$X^{\mathrm{SIM}} = \{(x_n^{\mathrm{SIM}}, y_n^{\mathrm{SIM}})\}_{n=1}^{N}, x_n^{\mathrm{SIM}} \in \mathbb{R}^p, y_n^{\mathrm{SIM}} \in \mathbb{R}. \quad (1)$$

Industrial LF variables $X^{\mathrm{IND}} = \{(x_t^{\mathrm{LF}}, y_t^{\mathrm{LF}})\}_{t=1}^{T}$ consist of a time series of online measurements with regressors $x_t^{\mathrm{IND}}$, and the output approximation $y^{\mathrm{LF}}$ (e.g., online analyzer) that may be biased or faulty available in real time. Industrial HF samples $X^{\mathrm{LAB}} = \{(x_k^{\mathrm{HF}}, y_k^{\mathrm{HF}})\}_{k=1}^{K}$ are available at sparse time instants, where $y^{\mathrm{HF}}$ is obtained from laboratory analyses.

Let $\theta^{\mathrm{LF}}$ denote the parameters of the surrogate $f^{\mathrm{SIM}}(\cdot;\theta^{LF})$ learned from the simulation dataset $X^{SIM}$ and then evaluated on the industrial data $X^{\mathrm{IND}}$:

$$\hat{y}_t^{\mathrm{LF}} = f^{\mathrm{SIM}}(x_t^{\mathrm{LF}}; \theta^{\mathrm{LF}}). \quad (4)$$

Two model classes, linear and nonlinear, are considered. The role of this step is to provide a dense, physics-consistent prediction over all industrial time points $t = 1, \ldots, T$.

We model the HF-to-LF discrepancy at HF time points $k$ as:

$$\Delta_k = y_k^{\mathrm{HF}} - \hat{y}_k^{\mathrm{LF}}. \quad (5)$$

We train a correction model $g^{\mathrm{IND}}(\cdot)$ on HF residuals, and predict all differences as:

$$\widehat{\Delta}_t = g^{\mathrm{IND}}(z_t^{\mathrm{LF}}; \phi_t^{\mathrm{LF}}), \quad (6)$$

where $z_t^{\mathrm{LF}}$ is defined as a representation of inputs with added information from a best performing surrogate model $f^{\mathrm{SIM}}(\cdot)$:

$$z_t^{\mathrm{LF}} = [x_t^{\mathrm{LF}^{\mathsf{T}}}, \hat{y}_t^{\mathrm{LF}}]^{\mathsf{T}}. \quad (7)$$

The final MF predictor is then defined as:

$$\hat{y}_t^{\mathrm{MF}} = \hat{y}_t^{\mathrm{LF}} + \widehat{\Delta}_t. \quad (8)$$

If we assume a perfect prediction that satisfies $\widehat{\Delta}_{\mathrm{t}} \approx \Delta_t$, then, based on (5) and (8), we can state:

$$\hat{y}_t^{\mathrm{MF}} = \hat{y}_t^{\mathrm{LF}} + \widehat{\Delta}_t \approx \hat{y}_t^{\mathrm{LF}} + \left(\mathrm{y}_t^{\mathrm{HF}} - \hat{y}_t^{\mathrm{LF}}\right) = \mathrm{y}_t^{\mathrm{HF}}, \quad (9)$$

where $\mathrm{y}_t^{\mathrm{HF}}$ denotes the theoretical HF data. Therefore, the MF prediction can be interpreted as a real-time estimate of the HF output $\hat{y}_t^{\mathrm{MF}} \approx \mathrm{y}_t^{\mathrm{HF}}$.

## METHODOLOGY

Following our previous work [17], all models use the

same feature-engineered regressor vector $x \in \mathbb{R}^p$, consisting only of variables that are both statistically relevant and operationally trusted.

Rows containing unusable (i.e. NaN, or out-of-range outliers) values in any regressor or in the corresponding output are removed prior to model training and evaluation. A standardization (zero mean, unit variance) is applied to scale and anonymise the data.

Principal Component Analysis (PCA) is a linear dimensionality-reduction method applied to $z_t^{\mathrm{LF}}$ as a preprocessing step to obtain a smaller set of principal components (PCs). By keeping only the most relevant $q$ components ($q \ll p$). PCA reduces noise and collinearity and yields a compact representation that is easier to model.

We train the surrogate model $f^{\mathrm{SIM}}(\cdot)$ model using two separate approaches:

1. Linear Ordinary Least Squares (OLS) regression is trained and validated on the SIM inputs $x_n^{\mathrm{SIM}}$ and output $y_n^{\mathrm{SIM}}$.

2. Nonlinear Neural network (NN) uses a feed-forward network trained on the same SIM pairs $(x_n^{\mathrm{SIM}}, y_n^{\mathrm{SIM}})$ to provide an alternative $\hat{y}_t^{\mathrm{LF}}$ prediction that, unlike linear models, can capture complex, non-linear relationships and feature interactions within the dataset.

Gaussian Process regression (GPR) is a nonlinear regression method that models an unknown function as a distribution over functions. The model is fully specified by mean $m(x)$, and a covariance function $k(x, x')$ (kernel).

$$g(x) = \mathcal{GP}(m(x), k(x, x')) \tag{10}$$

The kernel defines how strongly two inputs are correlated based on their distance, and tuned hyperparameters (e.g., length scale $\ell$ and signal variance $\delta^2$). A commonly used RBF kernel can be defined as:

$$k(x, x') = \delta^2 exp(-||x - x'||^2 / 2\ell^2). \tag{11}$$

In this work, the GP is used to learn the correction term $\Delta_k$.

Performance is evaluated only at time indices $t(k)$, where HF measurements are available, using Root Mean Squared Error (RMSE) regression metric:

$$\mathrm{RMSE} = \sqrt{\frac{1}{K}\sum_{\forall k}(y_k^{\mathrm{HF}} - \hat{y}_{t(k)})^2}. \tag{12}$$

## CASE STUDY

We study an industrial alkylation unit of our industrial partner, Slovnaft, a.s., (Bratislava, Slovakia), that produces high-octane alkylate by reacting $C_3$-$C_4$ olefins with $i$-$C_4$ isobutane in an $H_2SO_4$ acid-catalyzed process. Fig. 1 shows the simplified layout, where the reactant mixture is cooled and fed to the reactor section, and the effluent is separated to recover and recycle isobutane while the alkylate product is withdrawn.

We focus on the isobutane-to-olefin ratio control as it strongly influences product quality and plant economy. Excess of isobutane is needed to suppress undesired side reactions, however, a key online analyzer ($y_t^{\mathrm{LF}}$) on a recycle stream provides unreliable measurements of $i$-$C_4$ affecting the amount of recycled material. Simply increasing the recycle flows would put unnecessary load on the downstream separation, deteriorating plant economics. A better monitoring strategy is needed.

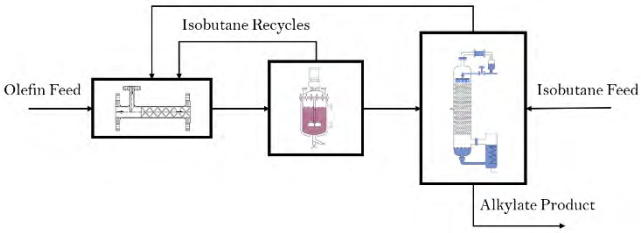

**Figure 1.** Overview of the simplified industrial process.

## IMPLEMENTATION

A simplified plant flow-sheet model is built in the gPROMS ProcessBuilder [18]. A simulation dataset $X^{\mathrm{SIM}}$ is then generated by systematically varying operating parameters in the range of plant operating conditions to obtain the simulation dataset $x_n^{\mathrm{SIM}} \in \mathbb{R}^p$ ($p = 6$) and $y_n^{\mathrm{SIM}}$. Although more steady states could be generated, we limited the simulation set to $N = 5{,}000$ because the simplified first-principles model is used only to supply

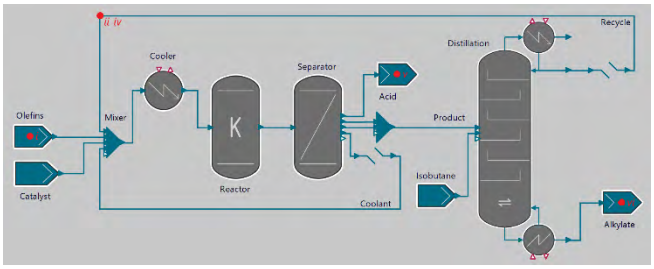

**Figure 2.** Overview of the simplified alkylation unit model developed in the gPROMS environment.

mass-balance-consistent trends for training, while the industrial dataset already provides dense coverage in time ($T > N$). The inputs (red dots in Fig. 2) were iteratively selected in previous work as most relevant to explain the output variable $y_t^{\mathrm{IND}}$. They include four concentrations measured by online analyzers (olefin feed propylene $(i)$, deisobutanizer recycle propane $(ii)$, isobutane $(iii)$, and n-butane $(iv)$) and two flow rates (recycled fresh acid $(v)$, and alkylate to storage $(vi)$).

We compare the simulated and industrial data distributions. The simplified gPROMS model is able to

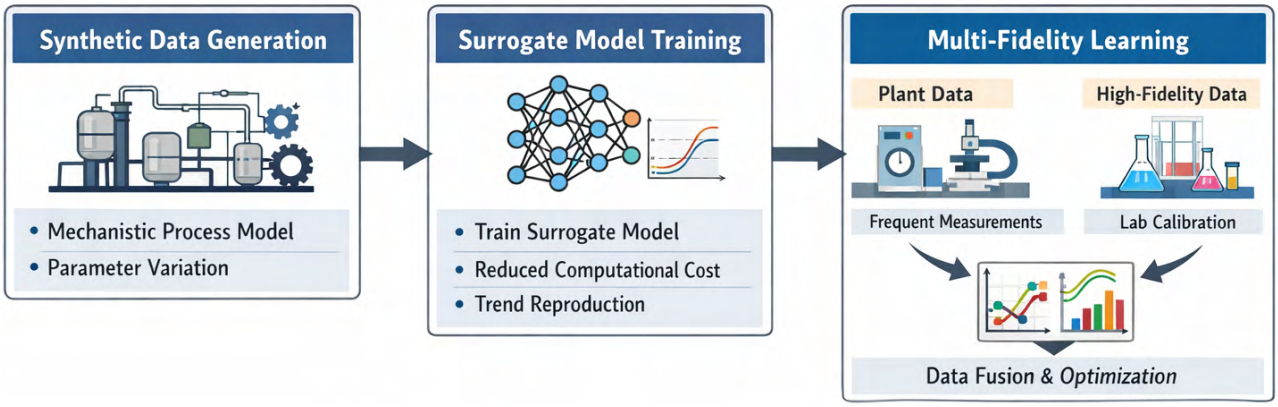

**Figure 3.** Overview of the proposed hybrid multi-fidelity workflow combining multiple fidelity sources.

reproduce the dominant trends of the plant, although some differences in variability and distribution remain.

We partition the simulation data $X^{\mathrm{SIM}}$ $(80/20\%)$ into training (TR) and validation subsets to learn the initial surrogate model. Similarly, the industrial dataset $X^{\mathrm{IND}}$ provides $T = 13,000$ online samples, while the laboratory dataset $X^{\mathrm{LAB}}$ provides $K = 18$ reference samples. Data is split $(60/40\%)$ based on balanced HF indices into training and testing (TS) sets by alternating the HF measurements. Following the flowchart shown in Fig. 3, we train and validate the surrogate models $f^{\mathrm{SIM}}(\cdot)$ in Python using a nonlinear feed-forward NN implemented by `Keras` [19] with four fully connected layers of sizes 6-3-2-1 and activation functions SELU, tanh, SELU, and linear, respectively. The linear OLS regression, i.e., minimizing the sum of squares, is implemented by `scikit-learn` [20].

Trained prediction models are evaluated on the LF industrial dataset $X^{\mathrm{IND}}$ to predict the output $\hat{y}_t^{\mathrm{LF}}$; see (4). The most accurate prediction is subsequently used as an additional input in the MF correction model (8).

To reduce dimensionality, we use PCA on this extended input vector $z_t^{\mathrm{LF}} \in \mathbb{R}^7$. The resulting 4 PCs are used to train a GPR on the HF training points to predict the HF-to-LF differences; as defined in (6).

The MF estimate (8), is obtained by correcting the $\hat{y}_t^{\mathrm{LF}}$ prediction, and performance is reported using RMSE and parity plots. A simple HF model (GPR trained only on HF data) is also trained directly on the HF data $X^{\mathrm{LAB}}$ to replicate standard practice and serve as a reference. The final soft-sensor predictions are evaluated against laboratory measurements $y_k^{\mathrm{HF}}$.

## RESULTS

The presented workflow encompasses two evaluation stages. First, we verify surrogate models on the SIM dataset, where OLS model achieves RMSE (TR) = 0.1772 and RMSE (TS) = 0.1879, while the NN model achieves much lower RMSE (TR) = 0.0136 and RMSE (TS) = 0.0127.

Secondly, we evaluate the trained predictors on the IND dataset against laboratory measurements $y_k^{HF}$ using RMSE on the TR and TS splits. This is visualized in Figure 4 and quantitatively summarized in Table 1. The OLS-based MF model (black points) and NN-based MF model (red points) are presented in the left and right columns, respectively. The top row is TR and the bottom row is TS. The blue diagonal represents a perfect fit.

As a reference, the online analyser $y_t^{\mathrm{LF}}$ evaluated at the HF indices $k$ yields RMSE (TR) = 0.6759 and RMSE (TS) = 0.5557. This confirms a noticeable mismatch between the LF and the HF data.

**Table 1:** Predictors compared to laboratory data $y_k^{\mathrm{HF}}$.

| | RMSE (TR) | RMSE (TS) | reduction % (TS) |
|---|---|---|---|
| $y_{t(k)}^{\mathrm{LF}}$ | 0.6759 | 0.5557 | - |
| $\hat{y}_{t(k)}^{\mathrm{HF}}$ | 0.4757 | 0.4735 | ↓ 14.8% |
| | OLS | | |
| $\hat{y}_{t(k)}^{\mathrm{LF}}$ | 0.5373 | 0.4741 | ↓ 14.7% |
| $\hat{y}_{t(k)}^{\mathrm{MF}}$ | 0.4605 | 0.3831 | **↓ 31.1%** |
| | NN | | |
| $\hat{y}_{t(k)}^{\mathrm{LF}}$ | 1.1921 | 1.3297 | ↑139.3% |
| $\hat{y}_{t(k)}^{\mathrm{MF}}$ | 0.5566 | 0.6127 | ↑ 10.2% |

The simple OLS predictor $\hat{y}_t^{\mathrm{LF}}$ improves the output monitoring, achieving RMSE (TR) = 0.5373 and RMSE (TS) = 0.4741, i.e., a 14.7% reduction on the TS split relative to the analyser. This suggests that, even with a simple linear mapping, the simulator trends and engineered regressors carry useful information that partially explains the HF output.

Adding the OLS $\hat{y}_t^{\mathrm{LF}}$ to the MF correction provides the best overall performance. The MF estimate reaches RMSE (TR) = 0.4605 and RMSE (TS) = 0.3831, corresponding to a 31.1% TS improvement. The improvement over the HF-only model (0.3831 vs 0.4735 on TS)

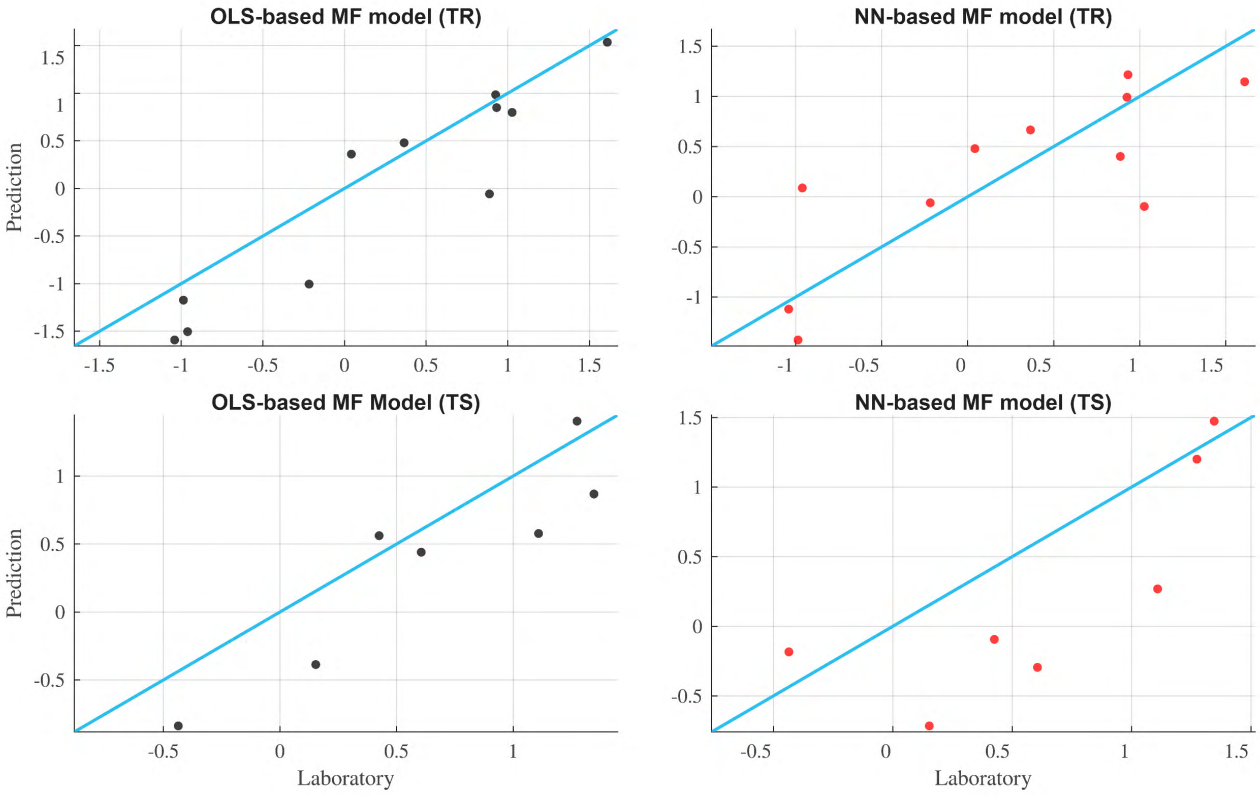

**Figure 4.** Parity plots of MF predictions $\hat{y}_{t(k)}^{\mathrm{MF}}$ compared to the laboratory data $y_k^{\mathrm{HF}}$.

indicates that the correction benefits from the dense LF data, rather than relying on sparse HF data alone.

The simple HF model yields RMSE (TR) = 0.4757 and RMSE (TS) = 0.4735 (14.8% improvement on TS) is comparable with the OLS predictor, but it is worse than MF on the TS split.

Although the NN fits the simulation data accurately (near-zero simulation RMSE), its prediction on the industrial data is poor; RMSE (TR) = 1.1921 and RMSE (TS) = 1.3297 (worse by 139.3%). This may be caused by the domain-shift, where the NN learns simulator-specific nonlinearities that do not map clearly to the real plant (different disturbances, unmodelled constraints).

The MF correction with the NN $\hat{y}_t^{\mathrm{LF}}$ partially improves this mismatch (RMSE = 0.6127 on TS), but it still does not surpass the $\hat{y}_{t(k)}^{\mathrm{HF}}$, nor the $y_{t(k)}^{\mathrm{LF}}$.

Overall, the results show that MF correction is most effective when the predictor provides a reasonable trend-consistent estimate.

## CONCLUSION

A multi-fidelity correction framework was applied to reconcile dense industrial measurements with sparse laboratory references using a simulator-trained surrogate and a Gaussian process corrector. The ordinary least squares-based multi-fidelity model achieves the best performance, reducing test prediction error against laboratory measurements by 31% relative to the industrial analyzer at high-fidelity time points, and outperforming a standard high-fidelity model (soft sensor). These results indicate that, even with a deliberately simplified simulator, the surrogate is able to capture the underlying trend, enabling the multi-fidelity correction to further improve predictions toward laboratory accuracy. The neural network surrogate, despite excellent fit to simulation data, did not transfer robustly to the industrial dataset; limiting the multi-fidelity correction.

Future work should focus on increasing physical realism and coverage of the simulation model to provide more information in the training phase.

## ABSTRACT

Energy management plays a crucial role in achieving efficient and sustainable operation of industrial energy systems. With the increasing integration of renewable electricity and the growing complexity of hydrogen production networks, effective control strategies are required to minimize operational costs and carbon footprint. However, the uncertain nature of renewable energy sources, such as photovoltaic (PV) power, complicates their accurate forecasting and challenges the optimal energy management of system components. To deal with uncertainties, the rolling horizon approach (RHA) provides a practical framework for adaptive decision-making by repeatedly solving optimization problems over moving time windows while updating system data in real time. In RHA-based energy management, linear or linearized system models are often employed and optimized by linear methods to reduce computational complexity; however, these simplifications can compromise physical realism and lead to suboptimal decisions. Although RHA can also incorporate local, or global deterministic and stochastic algorithms for nonlinear problems, such approaches frequently suffer from high computational effort, slow convergence, local optima, and difficulty in ensuring constraint satisfaction in large-scale nonlinear systems. To overcome these limitations, this work employs the novel hybrid optimization method "BO-IPOPT"—a combination of Bayesian Optimization (BO) for global exploration and the Interior Point OPTimizer (IPOPT) for rapid local refinement. Applied to an industrial hydrogen production system, BO-IPOPT outperforms state-of-the-art approaches in accuracy and robustness by achieving lower operational costs at the same CPU time while satisfying all constraints. Finally, the influence of the uncertainties in PV generation on the performance of the energy management system is analyzed.

**Keywords**: Energy management, Rolling horizon approach, BO-IPOPT, Renewable hydrogen system

## INTRODUCTION

Energy utility systems play a central role in industrial operations, and their efficient management is increasingly crucial as sustainable energy technologies are integrated. The growing penetration of renewable energy sources and energy storage systems has increased the system complexity, making optimal energy management essential [1]. Key objectives include minimizing operating costs, reducing $CO_2$ emissions, and improving the overall energy efficiency [2]. However, these goals are challenged by the variability of renewable generation, fluctuating process demands, grid stability requirements, power quality constraints, and uncertainty in energy forecasts [3].

Conventional control strategies, such as PID controllers and rule-based scheduling [4, 5], remain widely used but are inherently limited. These approaches react only to current errors, lack predictive capabilities, struggle with multi-objective optimization and system-wide constraints, and are poorly suited to dynamic and uncertain operating conditions. As a result, more advanced

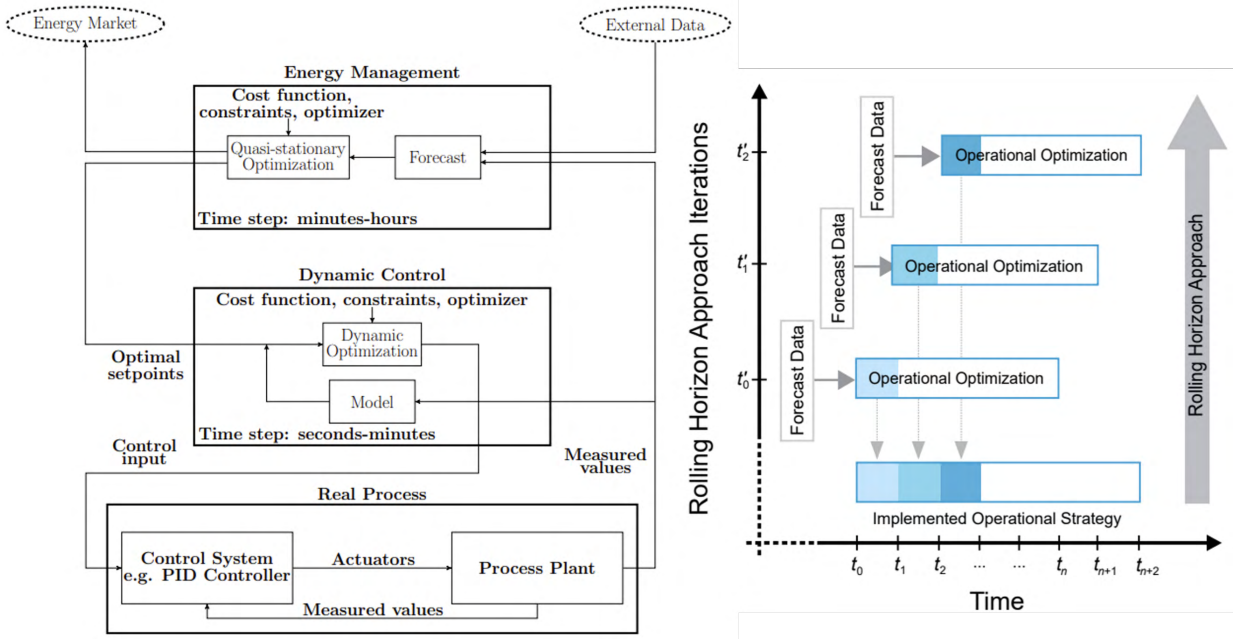

**Figure 1.** Detailed block structure of the different control (time) levels in real-time optimization of industrial processes (**left**) and visualization of the RHA (**right**) [6].

energy management strategies that can anticipate future conditions, coordinate multiple system components, and explicitly account for uncertainty are increasingly necessary.

The role of energy management within the broader framework of real-time optimization is displayed in **Figure 1** on the left [6]. At the highest level, predictive optimization computes optimal setpoints for energy flows, temperatures, and power exchange over time horizons ranging from minutes to hours, with the objective of minimizing operating costs and emissions. These setpoints are passed to the second level, where component-level controllers ensure stable and reliable system behavior by tracking the prescribed targets. The third level describes the physical process itself, including the plant, instrumentation, and actuators that execute the control actions in real time. While all three levels are essential for system operation, this work focuses exclusively on the system (highest) level, i.e., the energy management layer.

To address the uncertainties in energy systems, various methods have been proposed, including stochastic programming, robust optimization, fuzzy logic, and Monte Carlo simulation [6]. Although effective, these methods often entail high computational effort, limiting their applicability in time-sensitive operational contexts. To address this limitation, the rolling horizon approach (RHA) has emerged as a practical and widely adopted solution [6]. By repeatedly solving a finite-horizon optimization problem using updated forecasts and measurements (see **Figure 1** on the right), rolling horizon optimization enables adaptive, real-time decision-making under uncertainty. This makes it particularly well suited for industrial energy systems with high renewable penetration and rapidly changing operating conditions.

The performance of RHA is closely linked to the choice of the optimization method, which governs how decisions are updated as forecasts and system conditions evolve. Most RHA applications rely on linear or mixed-integer linear formulations, as these enable efficient handling of continuous and discrete variables and offer favorable computational scalability [7, 8]. However, the simplifications inherent in linear and linearized models often reduce physical accuracy, particularly in systems exhibiting strong nonlinear behavior, wide operating ranges, or complex component interactions. In such cases, linear approximations may lead to suboptimal operational decisions. In addition, linearization requires careful balance between accuracy and computational efficiency for the grid fineness. Introducing additional variables—particularly in systems exhibiting pronounced nonlinear dynamics or complex component interactions—rapidly transforms linearization into a computationally demanding process.

Nonlinear optimization methods are less frequently adopted in RHA-based energy management due to their computational burden. Deterministic global solvers are generally impractical under real-time constraints because of exhaustive region enumeration and slow convergence, especially for large-scale nonconvex problems [6]. Stochastic global optimization techniques, such as genetic algorithms, have been explored to better capture nonlinearities and avoid local optima, particularly in

renewable and hybrid energy systems. Nevertheless, their high computational cost, extensive function evaluations, and slow convergence limit their suitability for high-dimensional, constrained, real-time applications [6].

To overcome the computational and convergence limitations of conventional stochastic optimization methods, this work incorporates the recently proposed BO–IPOPT algorithm into the energy management framework for industrial systems. BO–IPOPT is a hybrid approach that combines the global exploration capability of Bayesian optimization with the efficient local convergence and constraint handling of IPOPT [9, 10]. Previous studies have shown that this method can reliably solve large-scale, nonlinear, and constrained optimization problems, delivering significantly improved solution quality and robustness compared to existing approaches under comparable computational effort [6, 11].

In this work, BO–IPOPT is applied to the energy management of an industrial hydrogen production system that includes a 40 MW alkaline electrolyzer (AEL), photovoltaic (PV) generation, grid electricity, an organic Rankine cycle (ORC) unit for waste heat recovery, a high-pressure hydrogen ($H_2$) storage, a configuration that is inherently nonlinear. The study benchmarks BO–IPOPT against state-of-the-art optimization methods to evaluate its performance in terms of solution quality, robustness, and computational efficiency under realistic operating conditions. Additionally, the investigation addresses the impact of solar data uncertainties on energy management decisions, examining how prediction errors in PV generation influence operational strategies and the overall system performance.

This paper is organized as follows: Section 2 introduces the considered industrial system and Section 3 the optimization methods whose performance is investigated in this work. In Section 4, the prediction model and strategy for multi-step-ahead forecasting are presented. Section 5 shows the influence of different settings on the energy management performance of the industrial system. Finally, Section 6 summarizes the main conclusions and provides a perspective for future work.

## USE CASE

In this section, the underlying industrial hydrogen production system is briefly introduced as well as the corresponding optimization problem.

### System Description

The industrial system illustrated in **Figure 2** is built around a 40 MW pressurized AEL that supplies hydrogen to a refinery. Its main power source is a PV plant, complemented by electricity generated from refinery waste heat via an ORC unit. When required, additional power can be drawn from the grid as an auxiliary energy source. The AEL comprises eight stacks, each operating at a pressure of 20-25 bar and consuming 5 MW when running at full capacity. The produced hydrogen is compressed and stored in a high-pressure system operating at 350 bar before being delivered to the refinery. The overall operation ensures that the refinery's hydrogen demand is continuously met at each time step.

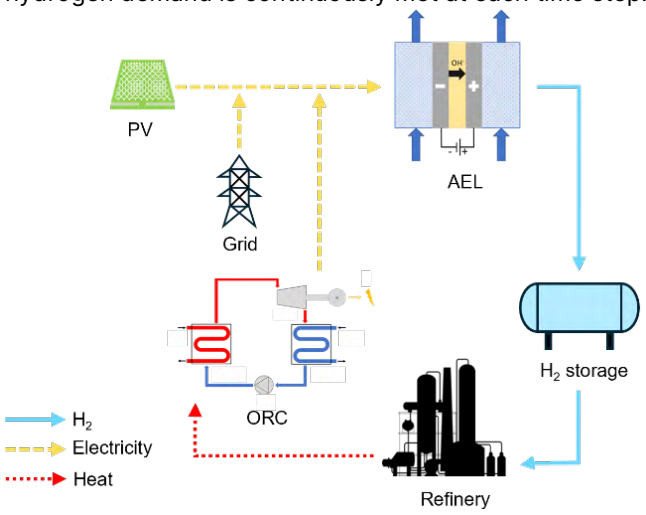

**Figure 2.** Visualization of the industrial hydrogen production system.

### Optimization Problem

For the cost-optimal operation of the industrial hydrogen production system, a constrained, nonlinear, and nonconvex optimization problem is formulated within a multi-period framework. The optimization horizon is discretized into $n$ uniform time steps with the duration $\Delta t$, such that the decision variables are evaluated at discrete time points $t_k$, with $k = 1, \dots, n$. The objective is to minimize the total operational costs consisting of grid electricity costs (first term) and AEL startup costs (second term):

$$\min \sum_{k=1}^{n} P_{\text{grid}}^{k} g_{\text{grid}}^{k} \Delta t + \sum_{k=1}^{n} \sum_{s=1}^{N_{\text{stack}}} g_{\text{su}}^{k,s} z_{\text{su}}^{k,s}, \tag{1}$$

where $P_{\text{grid}}^{k}$ represents the grid electricity consumption, $g_{\text{grid}}^{k}$ the grid electricity price, $g_{\text{su}}^{k,s}$ the cost per startup of an AEL stack, and $z_{\text{su}}^{k,s}$ a binary variable denoting the startup of a stack, with $s$ describing the AEL stack indices. At each time step, the power balances among all generation and consumption units are maintained as:

$$P_{\text{PV}}^{k} + P_{\text{ORC}}^{k} + P_{\text{grid}}^{k} = P_{\text{e}}^{k} + P_{\text{comp}}^{k}, \tag{2}$$

where $P_{\text{PV}}^{k}$ and $P_{\text{ORC}}^{k}$ denote the PV and ORC power generation, $P_{\text{e}}^{k}$ the AEL consumption, and $P_{\text{comp}}^{k}$ the power consumption for hydrogen compression modeled based on [12]. The hydrogen production rate of each AEL stack is given by Faraday's law as:

$$\dot{m}^{k,s}_{\text{prod, stack}} = \frac{\eta^{k,s}_{\text{Faraday}} I^{k,s}_{\text{cell}}}{2F} M_{H_2} N_{\text{cell}} z^{k,s}_{\text{on}}, \quad (3)$$

where $\eta_{\text{Faraday}}$ is the Faraday efficiency, $F$ the Faraday constant, $I_{\text{cell}}$ the cell current, $N_{\text{cell}}$ describes the number of cells in the stack, and $M_{\text{H2}}$ denotes the molar mass of hydrogen [13]. The total hydrogen production is the summation over all stacks:

$$\dot{m}^{k}_{\text{prod}} = \sum_{s=1}^{N_{\text{stack}}} \dot{m}^{k,s}_{\text{prod, stack}}. \quad (4)$$

The AEL power consumption $P^k_e$ is modeled according to [13]. In addition, the AEL operates in on/off/standby modes, which are enforced through AEL operational constraints. The PV power generation is modeled as a function of solar irradiance and ambient temperature:

$$P^k_{\text{PV}} = A_{\text{PV}} G^k_{\text{PV}} \eta_{\text{PV, inv}} \eta^k_{\text{PV, mod}} (1 - x^k_{\text{PV, cur}}), \quad (5)$$

where $A_{\text{PV}}$ is the module area, $G^k_{\text{PV}}$ denotes the solar irradiance, $\eta_{\text{PV, inv}}$ the inverter efficiency, and $\eta^k_{\text{PV, mod}}$ the module efficiency. The latter depends on its part-load behavior, nominal module efficiency, nominal solar irradiance, ambient temperature, and nominal temperature [6]. The variable $x^k_{\text{PV, cur}}$ accounts for the restriction or deactivation of the PV operation. All PV model parameters are taken from [6].

The ORC unit is represented by a surrogate model as a quadratic function of its hot-source temperature $T^k_{\text{ORC,source}}$ and ambient temperature $T^k_{\text{amb}}$:

$$P^k_{\text{ORC}} = f(T^k_{\text{ORC,source}}, T^k_{\text{amb}}). \quad (6)$$

The dynamics of the hydrogen storage are modeled by the differential mass balance:

$$m^k_{\text{sto}} = m^{k-1}_{\text{sto}} + (\dot{m}^k_{\text{sto, in}} - \dot{m}^k_{\text{sto, out}}) \Delta t, \quad (7)$$

where $m^k_{\text{sto}}$ is the amount of hydrogen stored, $\dot{m}^k_{\text{sto, in}}$ denotes the hydrogen mass flow entering the storage, and $\dot{m}^k_{\text{sto, out}}$ the hydrogen mass flow withdrawn from the storage. Additional constraints prevent simultaneous charging and discharging, while $\dot{m}^k_{\text{sto, in}}$ and $\dot{m}^k_{\text{sto, out}}$ are limited by the maximum inlet and outlet flowrates of the storage. The resulting formulation describes a nonlinear, nonconvex optimization problem with continuously differentiable constraints, avoiding binary or integer variables through smooth approximations in the hydrogen storage and the AEL, added as penalty terms in the objective function.

This optimization problem employs two different time resolutions to accommodate the available input data characteristics. Grid electricity consumption, PV, storage dynamics, and AEL operation are controlled at 15-minute intervals to capture short-term fluctuations, while the ORC power output follows an hourly resolution by maintaining the heat source temperature $T^k_{\text{ORC,source}}$ constant over each hour (via additional equality constraints). The 15-minute timestep aligns with common intraday electricity market trading practices [14]. The optimization requires input data including electricity prices, solar irradiance, ORC heat source temperature, hydrogen demand profile, and ambient temperature, with only the solar data forecasted in this work while all other inputs are treated as known.

## OPTIMIZATION METHODS

To solve the aforementioned constrained, nonlinear, and nonconvex optimization problem at each iteration of the RHA, several optimization algorithms are examined. These include one widely known stochastic approach, namely GA; the local deterministic optimizer IPOPT applied in single-start form (with and without warm-starting); and the recently proposed hybrid algorithm BO-IPOPT. Although local deterministic solvers are not commonly employed within RHA-based energy management frameworks, their performance is explored here due to their broad applicability and strong efficiency in solving large-scale problems. Owing to the size and complexity of the optimization problem, global deterministic solvers such as BARON are not considered, as they become computationally impractical for problems of this scale (over 100 decision variables) [10]. The following subsections briefly describe the optimization methods evaluated in this study.

### Stochastic Method

GA is a well-established stochastic optimization technique inspired by natural processes. GA [15] operates by evolving a population of candidate solutions through selection, crossover, and mutation operators. Constraints are typically addressed by incorporating equality and inequality violations into the objective function via penalty terms [16]. While GA is well suited for exploring large and complex search spaces and capable of escaping local optima, it generally requires a large number of function evaluations, leading to high computational effort and long convergence times, particularly in complex optimization settings.

### Deterministic Methods

IPOPT [17] is a deterministic optimization algorithm designed for large-scale nonlinear programming problems. It employs an interior-point framework to enforce constraints and efficiently converges to locally optimal solutions. IPOPT is widely used in scientific and engineering applications due to its robustness and computational efficiency; however, as a local solver, it may converge to suboptimal local minima depending on the initial conditions. Warm-start (WS) strategies are often applied to accelerate convergence by exploiting information from previous solutions, especially when a sequence of related optimization problems is solved, as in RHA-based

approaches [18]. Nevertheless, inappropriate or poorly chosen warm-start information can adversely affect the solution quality.

### Hybrid Method

BO-IPOPT is a hybrid optimization method originally proposed in [9] and further developed in [10], which integrates Bayesian optimization (BO) with IPOPT. The method combines BO's capability for global exploration with IPOPT's strength in local refinement and constraint handling. In this optimizer, BO constructs a surrogate model—based on Gaussian processes—to approximate both the objective function and constraints, guiding the search toward promising regions of the decision space without requiring a highly accurate global surrogate. Even if the surrogate model does not fully capture the objective landscape in high-dimensional spaces, its role in BO-IPOPT is primarily to guide the search, while its impact on the performance of the hybrid method will be further investigated in future work. Constraint handling within BO is achieved using an augmented Lagrangian formulation, where inequality constraints are converted into equalities through slack variables, resulting in a sequence of simpler optimization subproblems. IPOPT is then employed to perform local optimization within these regions while efficiently enforcing the constraints. By alternating between BO-driven global exploration and IPOPT-based local refinement, the BO-IPOPT framework is able to effectively address high-dimensional, constrained optimization problems, overcoming many of the limitations associated with purely stochastic or purely deterministic approaches.

## UNCERTANTIES IN SOLAR DATA

Solar irradiance is inherently uncertain due to its strong dependence on atmospheric conditions and cloud dynamics, directly affecting photovoltaic power generation and operational decision-making. Reliable short-term forecasting is therefore essential for the RHA considered in this work.

As discussed in [6], physical forecasting methods rely on atmospheric modeling, numerical weather prediction, and satellite data, resulting in high computational complexity and significant data requirements. Moreover, physical methods are generally more suitable for long-term prediction horizons (> 6 hours ahead), while data-based approaches have been shown to perform better for short-term forecasts of up to six hours ahead. These characteristics make physical models unsuitable for real-time and iterative optimization frameworks, and they are therefore not considered in this study. Instead, data-based forecasting methods are considered, as they leverage historical time-series data and require substantially lower computational effort.

In [6], several data-driven models were evaluated, including linear and nonlinear regression, statistical methods, and machine and deep learning approaches. The results demonstrated that linear regression provides the most favorable trade-off between forecasting accuracy and computational efficiency, especially for both one-step and multi-step ahead predictions. Consequently, linear regression is selected as the solar irradiance forecasting model in this work. Based on the feature selection presented in [6], the resulting multiple linear regression model (MLR) used to predict solar irradiance is expressed as:

$$G_t = f(G_{t-1}, G_{t-2}, G_{t-3}, G_{t-4}, G_{t-\text{day}}, G_{t-\text{year}}, SD_{t-\text{day}}, T_{t-\text{day}}, p_{t-\text{day}}), \quad (8)$$

where $G$ denotes the solar irradiance, $SD$ the sunshine duration, $T$ the air temperature at two meters, and $p$ the air pressure station level.

To propagate uncertainty over the prediction horizon, a recursive multi-step forecasting strategy is employed. Following the approach described in [6], a single one-step-ahead model is trained and applied iteratively, with each predicted value fed back as an input for the subsequent time step. This process continues until the full forecasting horizon is covered. The one-step-ahead forecast at time $t$ is given by:

$$\hat{G}_t = f(G_{t-1}, G_{t-2}, G_{t-3}, G_{t-4}, G_{t-\text{day}}, G_{t-\text{year}}, SD_{t-\text{day}}, T_{t-\text{day}}, p_{t-\text{day}}), \quad (9)$$

while the two-step-ahead forecast is obtained recursively as:

$$\hat{G}_{t+1} = f(\hat{G}_t, G_{t-1}, G_{t-2}, G_{t-3}, G_{t+1-\text{day}}, G_{t+1-\text{year}}, SD_{t+1-\text{day}}, T_{t+1-\text{day}}, p_{t+1-\text{day}}). \quad (10)$$

## ENERGY MANAGEMENT

This section introduces the scenarios used for the energy management of the industrial hydrogen production system and the corresponding results.

### Scenarios

In this work, two one-week solar data scenarios are considered, representing winter and summer conditions with lower and higher solar irradiation respectively, with a 15-minute resolution. Moreover, the electricity price $g_{\text{grid}}$ is fixed at 0.12 €/kWh and the price $g_{\text{su}}$ per startup event in each AEL stack at 435 €. The chosen scenarios and values are representative for the considered refinery.

### Results

The performance of the energy management strongly depends on the selected optimization algorithm. In this section, we assess the stochastic algorithm "GA",

IPOPT in single-start mode (with and without warm-starting), and the hybrid BO-IPOPT within the RHA-based energy management framework. All methods are implemented in Python 3.12; IPOPT is accessed via Pyomo with default settings, GA uses parameter values recommended in [19], and BO-IPOPT follows the configuration proposed in [10], with the four best candidates selected per outer iteration to match the four available CPU cores. To enhance computational efficiency, the IPOPT evaluations within BO-IPOPT are executed in parallel on four cores using the multiprocessing library, whereas the stochastic search component of BO-IPOPT is kept sequential to ensure a fair comparison with GA. All simulations are performed on a machine equipped with an Intel(R) Core(TM) i7-8665U processor.

In this study, the optimizer CPU running time denotes the fixed time budget assigned to GA and BO-IPOPT at each RHA iteration to compute the best available minimum, i.e., the optimal trajectories for the system setpoints. By contrast, IPOPT and WS-IPOPT are started only once and perform a local search, typically terminating before the end of the fixed time window (average termination time about 40 seconds). Since all considered algorithms contain inherent randomness (e.g., random initializations, sampling), each numerical experiment is repeated 10 times, and the reported results are based on these repeated runs to average out stochastic effects. As a reference configuration, we employ a 24-step optimization horizon, corresponding to 6 hours with 15-minute intervals, resulting in an optimization problem with 4, 248 decision variables. This horizon strikes a balance between incorporating enough future steps for robust operational planning and the accuracy of data-based solar forecasts (limited to ≤ 6 hours ahead). Since the true global optimum is unknown, the best solution obtained among BO-IPOPT and GA with a CPU time of 5 minutes per RHA iteration is used as a benchmark for evaluating all algorithms.

We first investigate the effect of the different optimizers when included in the RHA, neglecting any uncertainty in the input data to ensure a fair comparison. In agreement with the refinery, the CPU time for each optimizer is fixed to 50 seconds per RHA iteration, which was chosen so that the resulting control actions and system responses can be updated sufficiently fast for practical implementation. The optimization outcomes for the winter and summer weeks are summarized in **Figure 3**, which presents box plots of the minimum accumulated objective function values for each method over the repeated trials. The results indicate that BO-IPOPT achieves the lowest operating costs and the tightest spread of values among all algorithms. On average (relative to the median), BO-IPOPT attains a relative error of about 0.01 % with respect to the benchmark in the winter week, whereas GA, IPOPT, and WS-IPOPT exhibit errors of approximately 314 %, 3 %, 0.2 %, respectively. For the summer week, the average error of BO-IPOPT is about 0.2 %, while GA, IPOPT, and WS-IPOPT show relative errors of around 505 %, 4 %, 2 %, respectively.

BO-IPOPT is the only method that consistently reaches the benchmark solution in both weeks. As expected, IPOPT and WS-IPOPT show worse performance than BO-IPOPT due to their single-start limitations and suboptimal warm-starts, which lead to wide variability in objective values, higher operating costs, and the need for multiple restarts.

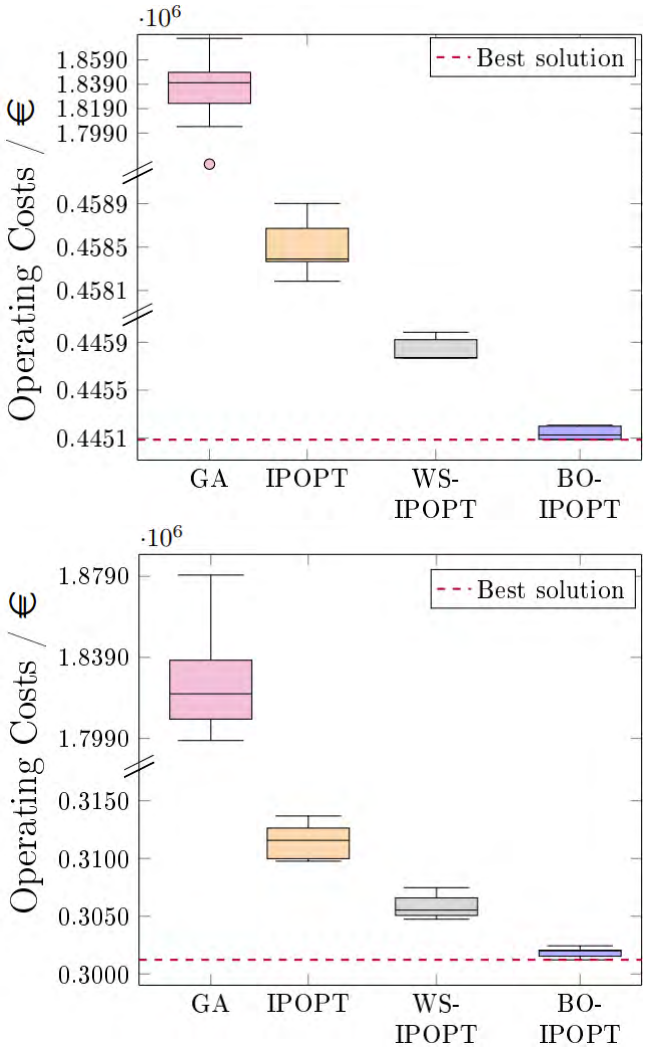

**Figure 3.** Comparison of operating costs over 10 trials for different optimizers in winter (**top**) and summer (**bottom**). The circles in the box plots represent outliers.

Among single-start methods, WS-IPOPT delivers lower objective function values and a tighter range of results than IPOPT, benefiting from more informed starting guesses that reduce sensitivity to starting points and enhance consistency across repeated runs. The stochastic optimizer "GA" encounters significant challenges: its population-based mechanism and random perturbations

demand numerous iterations to find feasible, low objective function solutions. Within the tight per-RHA-iteration time limits, it fails to adequately search the space or address constraint violations—yielding infeasible results with violations on the order of $10^{12}$ and much higher operating costs than the other solvers.

It is worth noticing that higher solar irradiation in summer makes the optimization problem more challenging, adding system variability and operational flexibility, thus widening performance gaps between the solvers.

Although IPOPT and WS-IPOPT are single-start local solvers, they frequently fail to converge on the first try, requiring restarts. In this system, IPOPT needed them in 25 % of winter RHA iterations and 43 % in summer. WS-IPOPT improved to 3 % (winter) and 12 % (summer) restart rates. This further supports the advantage of BO-IPOPT, which improves both the solution quality and the convergence to a feasible solution at each RHA iteration.

Although this analysis assumes perfect input data (no uncertainties), **Figure 4** demonstrates that solar uncertainties handled via MLR remain close to the perfect case, with 0.2 % cost deviations in the winter week and 1.6 % cost deviations in the summer week—making this forecasting model suitable for real-time applications (CPU training time < 1 second).

## CONCLUSION

This study evaluates the effectiveness of the novel hybrid BO-IPOPT method in the energy management of an industrial hydrogen production system introduced in this work. We first compared BO-IPOPT against state-of-the-art optimizers—IPOPT, WS-IPOPT, and GA—assessing their accuracy and robustness. BO-IPOPT consistently outperformed the alternatives, achieving higher accuracy and robustness, without facing any convergence issues or constraint violations. IPOPT and WS-IPOPT underperformed due to reliance on single-start strategies and suboptimal WS initialization. In addition, both solvers often struggled with convergence failures, frequently needing multiple restarts at individual RHA iterations. Beyond these difficulties, both deterministic methods showed substantial variability in the objective values across repeated runs compared to BO-IPOPT. Although WS-IPOPT offered better accuracy and robustness than IPOPT by reducing the restart frequency and outcome variability, these issues were not fully resolved. Moreover, GA failed to satisfy the system's constraints within the defined computational limits, compromising solution quality.

Another important observation from this energy management analysis is that scenarios with higher solar power availability made the optimization problem more challenging due to greater system variability and operational flexibility. Thus, employing a reliable and efficient optimizer like BO-IPOPT proves especially critical in such cases. In addition, uncertainties in solar data have also been incorporated into this work. The simple MLR delivered consistently robust results with very low computational demands. Across both solar scenarios, the linear model limited the operating cost deviations up to 1.6 % relative to perfect foresight cases, rendering it highly suitable for real-time applications requiring rapid retraining.

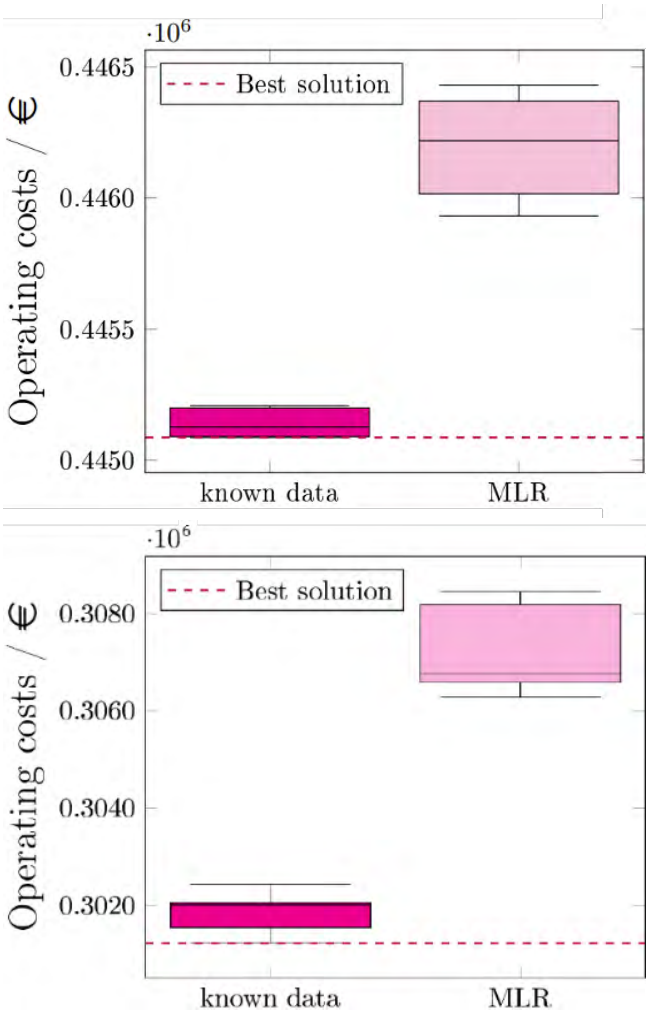

**Figure 4.** Comparison of operating costs over 10 trials using BO–IPOPT with and without uncertainties modeled via MLR for the solar data in winter (**top**) and summer (**bottom**).

Future work will first benchmark BO-IPOPT against Gurobi on a linearized system using experimental data to determine the superior approach, and investigate hybrid methods such as using Gurobi solutions to initialize BO-IPOPT. Next, different optimization horizons will be investigated to balance forecasting accuracy of input data (which decreases with longer horizons) with computational feasibility (which may worsen as the problem size grows with the horizon length) and predictive planning

(larger horizons help incorporate future conditions into the optimal operating strategy). In addition, we aim to incorporate variable electricity prices alongside uncertainties in hydrogen demand and ORC source temperature. Moreover, implementation in a Hardware-in-the-Loop or real plant setup will then evaluate closed-loop performance with real-time sensor feedback. Finally, the performance of BO-IPOPT will be assessed on even larger systems in future research, including the impact of its surrogate accuracy on the method's performance.

## ABSTRACT

Maintaining mother liquor supersaturation at a setpoint within the metastable range is vital for achieving the best production yield in industrial sugar production. However, precise online measurement and control is challenging. In this work, we develop a model-based soft sensor for supersaturation monitoring, and we propose a new feedforward-feedback control structure for batch sugar crystallization. Supersaturation is estimated using standard process measurements, enabling a soft sensor that can be readily adapted to different production units. The soft sensor continuously estimates supersaturation from standard process signals, and the control strategy ensures it remains within the desired operating range, enabling simple and straightforward application to other sugar production units.

**Keywords**: Mass Balance, Energy Balance, Soft Sensor, Feedback Control, Feedforward Control, Supersaturation

## INTRODUCTION

Sugar crystallization is a crucial unit operation in the sugar manufacturing industry, directly influencing the yield and quality of product, and overall process efficiency [1]. Supersaturation is one of the key variables determining crystallization performance, as it regulates crystal growth, nucleation behaviour, and dissolution phenomena. It must be maintained within the metastable zone, typically in the range of $1.00 < \sigma < 1.35$ for the best yield and quality of sugar [2]. Operating outside this window may result in the excessive nucleation, crystal agglomeration, or dissolution, leading to reduced sugar recovery and off-spec crystal size distribution.

Despite its significance, supersaturation is challenging to measure online in industrial crystallizers due to its reliance on several major factors, like temperature, concentration (Brix), purity of the mother liquor, and pressure [3]. As direct measurement is not viable, industrial practice largely relies on indirect indicators, operator experience, or exclusive instruments. At present, the SeedMaster series transmitter [4] is the only commercially available instrument that provides an online estimation of supersaturation. Its applicability is, however, limited by cost, proprietary algorithms, and lack of integration with advanced feedback control strategies.

Several research efforts have addressed the estimation and regulation of other hard-to-measure process properties, such as crystal size distribution and solution conductivity, which are closely linked to supersaturation and can be viewed as different expressions of the same crystallization behaviour, to improve the sugar yield quality using data-driven, model-based, and hybrid soft sensors. Data-driven approaches offer major advantages while capturing complex, non-linear process behaviour using historical or online plant data, thereby improving prediction accuracy without requiring detailed physical descriptions. Leveraging these benefits, Devogelaere et al. [5] demonstrated the use of feedforward neural networks as soft sensors for predicting massecuite electrical conductivity that serves as an indicator of supersaturation, supporting real-time control setpoint adjustments. Likewise, Lu et al. [6] presented an online modeling technique based on multi-input multi-output partial least-

squares support vector machines, achieving simultaneous estimation of massecuite brix and supersaturation.

Model-based approaches contribute to improved interpretability by incorporating fundamental physical relationships into the process description. Bakir et al. [7] proposed a continuous-discrete observer for estimating crystal size distribution in batch crystallization using a reduced population balance equation model. This formulation enables real-time monitoring while supporting control of filterability and flowability. Similarly, Damour et al. [2] introduced a model-based soft sensor for C-stage crystallization, providing online estimates of crystal mass, sucrose concentration, and purity aimed at maximizing sugar exhaustion.

Despite the advantages of data-driven and model-based approaches, their performance is often limited in crystallization processes involving high impurity levels and complex kinetic behaviour. Model-based approaches often suffer from parameter uncertainty, whereas data-driven models typically lack robustness, physical interpretability, and extrapolation capability beyond their training domain. Hybrid modeling frameworks address these limitations by merging mechanistic equations with data-driven components, enabling accurate representation of complex phenomena with limited data requirements. Georgieva et al. [8] proposed a knowledge-based hybrid model for fed-batch crystallization, integrating mass, energy, and population balance equations with artificial neural networks to accurately describe growth, nucleation, and agglomeration processes. Similarly, Meng et al. [9] demonstrated the applicability of data-driven and hybrid models for online estimation of supersaturation, mother liquor purity, crystal content, and crystal size distribution.

Despite the significant progress in data-driven, model-based, and hybrid soft-sensing techniques, their utilization in closed-loop control structures remains limited in industrial environments. The complexity of crystallization kinetics, coupled with uncertainty in process parameters and industrial implementation constraints, has limited the transition from monitoring to active control. Consequently, industrial sugar crystallization processes continue to rely mainly on conventional PI controllers for regulation of level and temperature, while the true control objective—maintaining supersaturation within the metastable zone- is only indirectly addressed through these variables. To the best of the authors' knowledge, no recorded studies have implemented a feedback control framework that explicitly manages supersaturation within the metastable range using model-based estimation. This represents a significant gap, particularly given the increasing demand for improved energy efficiency, higher extraction rates, and consistent product quality in sugar factories [10].

In this work, a model-based soft sensor is utilized to explicitly estimate supersaturation using mass and energy balance equations, incorporating key process variables such as purity, crystal mass, temperature, and concentration. Furthermore, supersaturation is directly regulated through a combined feedback-feedforward control strategy based on a standard PID controller, with the feed flow rate and heating steam supply rate considered as the manipulated inputs. The strength of this study lies in the practical use of simple, well-established control techniques to explicitly estimate and control supersaturation, thereby bridging the gap between theoretical approaches and industrial implementation. Overall, the proposed framework enables online supersaturation estimation and regulation without reliance on specialized measurement systems, offering a practical and industry-ready solution.

## THEORY

This section is focused on the development of a model-based soft sensor of supersaturation using mass and energy balance equations.

### Mass and Energy Balance Equations

The C-stage crystallization process is modelled using the set of five ordinary differential equations, with only the operating conditions and parameter values adjusted to reflect the C-stage operation [2], [12].

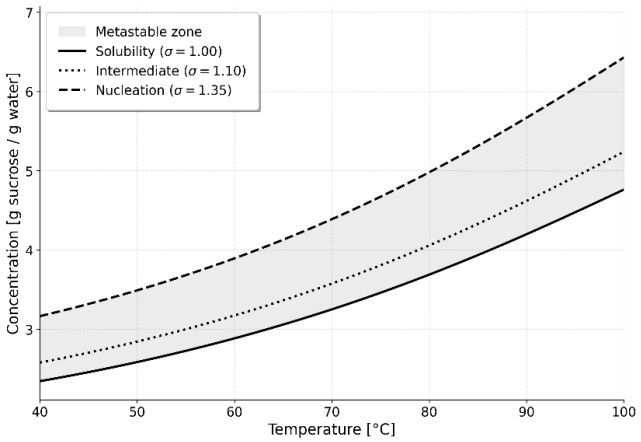

**Figure 1.** Temperature-dependent solubility curve of sucrose [13]

$$\frac{dm_w}{dt} = \rho_{feed} F_{feed}(1 - Bx_{feed}) - \dot{m}_{vap} \quad (1)$$

$$\frac{dm_i}{dt} = \rho_{feed} F_{feed} Bx_{feed}(1 - Pur_{feed}) \quad (2)$$

$$\frac{dm_c}{dt} = cc\left(\rho_{feed} F_{feed} - \dot{m}_{vap}\right) + \alpha_c \quad (3)$$

$$\frac{dm_s}{dt} = (\rho_{feed} F_{feed} Bx_{feed} Pur_{feed}) - \frac{dm_c}{dt} \quad (4)$$

$$\frac{dT_{mag}}{dt} = \frac{W + Q_{hs} + \rho_{feed} F_{feed}(h_{feed} - h_{ml}) - \dot{m}_{vap} L_{vap} + \frac{dm_c}{dt} L_c}{m_{total} Cp_{mag}} \quad (5)$$

Table 1. summarizes the typical operating conditions of an industrial sugar crystallization. Throughout the work, the subscript 'feed' refers to properties associated with the inlet feed stream. Here $m_w, m_i, m_c$ and $m_s$ denote the masses of water, impurities, crystal and dissolved sucrose, respectively. The feed density is depicted by $\rho_{\text{feed}}$, while $F_{\text{feed}}$ represents the feed flow rate. The stirring power W is fixed at 15 kW. In addition, $h$ denotes the specific enthalpy, $L$ the specific latent heat, and $Cp_{mag}$ the specific heat capacity of magma. $\dot{m}_{vap}$ represents mass flow rate of emitted vapour which is defined as $\dot{m}_{vap} = \rho_{cw} F_{vap}$, where $\rho_{cw}$ is the density of condensed water and $F_{vap}$ the emitted vapour mass flow rate, $m_{total}$ the total mass in the magma and is defined as $m_{total} = m_c + m_w + m_i + m_s$, and $Q_{hs}$ the heating power which is brought by the condensation of heating steam and defined as $Q_{hs} = \rho_{cw} F_{cs} L_{cw}$. All the thermal and physical correlations are mentioned below in the appendix. The RHS of eq (3) is the crystallization rate, which is calculated using the moment equations computed from the population balance equations, where $cc$ is the crystal content which can be defined as $cc = m_c/m_{total}$ and $\alpha_c$ is an adjusted parameter according to crystal growth kinetic [14]. All the typical operating conditions are mentioned in Table 1.

**Table 1:** Typical operation conditions of a sugar plant [12]

| Parameter | Description | Values |
|---|---|---|
| $p_v$ | Vacuum Pressure | $0.12 - 0.15$ bar |
| $\text{Bx}_{\text{feed}}$ | Feed Brix | $72 - 76°$ Bx |
| $\text{Bx}_{\text{mag}}$ | Magma Brix | $88 - 95°$ Bx |
| $\text{Pur}_{\text{feed}}$ | Feed Purity | $70 - 75\%$ |
| $\text{Pur}_{mag}$ | Magma Purity | $60 - 65\%$ |
| $\text{Pur}_{ml}$ | Mother Liquor Purity | $0 - 65\%$ |
| $T_{mag}$ | Magma Temperature | $60 - 75$°C |
| $T_w$ | Water Temperature | $60 - 65$°C |
| $T_{\text{feed}}$ | Feed Temperature | $60 - 65$°C |

Direct measurement of gas flow rates in industrial equipment is typically infeasible. Consequently, both the heating steam and emitted vapour flow rates are commonly computed through indirect measurements using simplifying assumptions. The authors [2] suggest simplifying involved heat and mass transfer phenomena by introducing simplifications in a form of correlation factors $\alpha$

1. First, the dynamics between heating steam supply flow rate $F_{hs}$ and condensed steam $F_{cs}$ is considered negligible with respect to the kinetics of the process. Thus:

$$F_{hs} = \alpha_Q F_{cs} \tag{6}$$

2. Second, the emitted vapor flow rates $F_{vap}$ is proportional to the condensed steam flow rate $F_{cs}$ via:

$$F_{vap} = \alpha_{vap} F_{cs} \tag{7}$$

The model framework is strictly governed by mass and energy conservation laws, utilizing standardized correlations (in Appendix) for the enthalpy and density of technical sugar solutions.

## Supersaturation in crystallization processes

Supersaturation is described as the ratio between the mass of sucrose to the mass of water contained in a supersaturated solution ($s = m_s/m_w$) and the mass of the sucrose to the mass of the water which would be present in a saturated solution ($s_{sat}$) at the same temperature and purity [9], [15].

$$SS = \frac{s}{s_{sat} C_{sol}} \tag{8}$$

For a pure saturated solution, it is known that $s_{sat}$ depends on temperature via the brix at saturation $Bx_{sat}$: [13]

$$s_{sat} = \frac{Bx_{sat}}{100 - Bx_{sat}} \tag{9}$$

However, considering the presence of impurities in industrial sucrose solutions, the $s_{sat}$ is adjusted through the introduction of a solubility coefficient $C_{sol}$. The solubility coefficient is a parameter representing the impact of impurities on sucrose solubility. Several researchers have proposed correlations to calculate it [10], [12]. In this work, $C_{sol}$ is determined by the well-known empirical correlation,

$$C_{sol} = a \frac{m_i}{m_w} + b + (1 - b) e^{-c \frac{m_i}{m_w}} \tag{10}$$

where a, b and c are quality parameters of the mother liquor that depend on the amount and composition of local impurities.

Since supersaturation cannot be measured directly and is driven by the strongly interacting dynamics of concentration and temperature [11], the adopted formulation offers a practical and transparent estimation strategy suitable for industrial crystallization processes.

# METHODOLOGY

The proposed model is validated through numerical simulations using synthetic datasets embedded with Gaussian noise to mimic industrial conditions. The flow rate of feed $F_{\text{feed}}$ and heating steam supply $F_{hs}$ are implemented as time-varying, piecewise-constant inputs. This strategy ensures controlled supersaturation while maintaining temperature and level % for model validation.

Given the complexity of the multivariable system, we determined the kinetic parameters using well-established thermodynamic definitions and empirical

correlations reported in the literature (Appendix)[2], [10]. To evaluate the sensitivity of the estimated $\alpha$ parameters to experimental noise, a Monte Carlo Simulation was performed [16]. For each iteration, the parameter set was re-estimated using a Levenberg-Marquardt least-squares minimization (8). This process allows the uncertainty and correlation between parameters to be analyzed.

Here for $\mathrm{Bx}_{ml,exp}$, $\mathrm{Bx}_{mag,exp}$, and $T_{mag,exp}$, we used simulated measurements with added gaussian noise to mimic experimental variability. The parameters are determined by minimizing the difference between these noisy "experimental" values and the corresponding model predictions.

$$\min_{\alpha_c,\alpha_{vap},\alpha_Q} \left(\frac{1}{2}\sum_{j=1}^{N}\left(Bx^{j}_{ml,exp} - \mathrm{Bx}^{j}_{ml,sim}\right)^2 + \frac{1}{2}\sum_{j=1}^{N}\left(\mathrm{Bx}^{j}_{mag,exp} - \mathrm{Bx}^{j}_{mag,sim}\right)^2 + \frac{1}{2}\sum_{j=1}^{N}\left(T^{j}_{mag,exp} - T^{j}_{mag,sim}\right)^2\right) \quad (11)$$

To determine the optimal vector of coefficients, present in supersaturation equation $\theta = [a, b, c]$, a minimization problem is solved using Nelder-Mead optimization algorithm, based on values reported in previous literature. The goal is to align the model's calculated supersaturation at the final batch state with a target supersaturation value ($S_{target} = 1.10$). The targeted supersaturation value is taken from industrial perspective. The objective function, $J(\theta)$, is defined as the sum of the squared error between the calculated and target supersaturation, plus a regularization term, which is added so to keep the estimated value closer to the values available in previous literature [12]:

$$J(\theta) = \left(S_{calc}(\theta) - S_{target}\right)^2 + \lambda \sum_{i\in a,b,c}\left(\theta_i - \theta_{prior}\right)^2 \quad (12)$$

Where $S_{calc}(\theta)$ is the supersaturation computed using the trial parameters, $\lambda$ is a penalty weight and $\theta_{prior}$ represents the original estimates for the coefficients which are taken from the previous literature [10].

Note that these parameters vary from plant to plant, depending on plant design and operating conditions.

**Table 3:** Model parameters and their values

| Parameter | Values |
|---|---|
| $\alpha_{vap}$ | 0.98 |
| $\alpha_Q$ | 1.65 |
| $\alpha_c$ | 0.29 |
| $a$ | -0.00573 |
| $b$ | 1.00939 |
| $c$ | 2.09860 |

## Control strategy

Soft sensor will act as a feedforward part of the controller adjusting the supersaturation measurement with respect to the disturbances such as impurities, variations in temperature, etc. For feedback control procedure, a PID controller is implemented to regulate the supersaturation level inside the batch crystallizer. The control objective is to track a target supersaturation setpoint while compensating for disturbances induced by evaporation and non-linear solubility dynamics.

Here $SS$ is the controlled variable, whereas $F_{\mathrm{feed}}$ is the manipulated variable. The supersaturation tracking error is defined as:

$$e(t) = SS_{target} - SS(t) \quad (13)$$

Where $SS_{target}$ is the desired supersaturation setpoint.

The feed flow rate $F_{\mathrm{feed}}(t)$ is calculated using a standard PID algorithm. The control effort relies entirely on the error dynamics and the integral accumulation to sustain the flow.

$$F_{\mathrm{feed}}(t) = K_p e(t) + K_i \int_0^t e(\tau)\,d\tau + K_d \frac{de(t)}{dt} \quad (14)$$

Where $K_p, K_i$, and $K_d$ are the proportional, integral, and derivative gains, respectively, and are tuned based on simulation studies [17], [18].

In practice, the controller is implemented in discrete time, with the integral and derivative terms in equation (15) approximated numerically at each sampling instant. The heating steam supply rate $F_{hs,forw}$ is applied as a feedforward control signal, based on typical operating settings. To ensure the physical realism, the actual flow rate of feed $F_{\mathrm{feed}}(t)$ applied to the crystallizer is subject to three specific constraints implemented in the simulation:

1. Integral Anti-Windup: To prevent excessive accumulation of error during saturation, the integral term is clamped to a fixed range chosen based on simulation studies and $K_i$ value [19]:

$$-20 \le \int_0^t e(\tau)\,d\tau \le 20 \quad (15)$$

2. Actuator Rate Limiting: The model limits how quickly the feed valve can open or close. The change in output ($\Delta u$) per time step is constrained by a maximum rate ($R_{max} = 0.0001$) for smooth control of the manipulated input. [20]

$$|F_{\mathrm{feed}}(t) - F_{\mathrm{feed}}(t - \Delta t)| \le R_{max} \quad (16)$$

3. Output Saturation: The final flow rate is bounded by the physical limitations of the valve (minimum and maximum flow):

$$F_{\mathrm{feed},min} \le F_{\mathrm{feed}}(t) \le F_{\mathrm{feed},max} \quad (17)$$

4. Shutdown logic: To be in safety thermal limit and level%, the system calculates a dimensionless Shutdown factor, denoted as $\alpha(L)$, which is the function of the crystallizer level percentage $L(t)$. This factor is used to ramp down the steam injection and trigger a

hard stop for the feed.

$$\alpha(L) = \begin{cases} 1.0 & if\ L(t) < 98.0\% \\ \frac{99.5 - L(t)}{99.5 - 98.0} & if\ 98.0\% \le L(t) < 99.5\% \\ 0.0 & if\ L(t) \ge 99.5\% \end{cases} \quad (18)$$

The steam flow rate, which normally follows a step-change Feed forward control $F_{hs,forw}$, is directly multiplied by this factor. This gradually reduces evaporation energy as the tank fills, preventing overheating at the end of the batch:

$$F_{hs}(t) = F_{hs,forw}(t) \times \alpha(L) \quad (19)$$

The feed flow is controlled by the PID loop described above, but it is subject to a separate "Hard Safety Cutoff" strictly when the tank reaches maximum capacity:

$$F_{feed}(t) = \begin{cases} 0.0 & if L(t) \ge 100 \\ u_{PID}(t) & otherwise \end{cases} \quad (20)$$

Without such constraints, the controller becomes aggressive, producing control actions that violate physical realism. This can lead to excessive dilution or overheating, ultimately degrading crystak quality. Variations in $F_{\text{feed}}$ affect the water content and dissolved sucrose concentration, which in turn alter the supersaturation level.

The control strategy was implemented during the batch crystallization, and its performance was evaluated by tracking the evolution of supersaturation, magma temperature, and mass components.

## RESULTS

The simulation was conducted over a batch duration of 8 hours (28800 seconds) with a sampling integration step $(\Delta t)$ of 10 seconds.

For $\alpha$ parameter sensitivity and robustness, a Monte Carlo simulation with 200 iterations was performed, introducing 2% gaussian noise to the nominal simulation data. The results (Figure 2) present the pairwise correlation plots, which illustrate the robustness of the estimated $\alpha$ parameters. Most of the 200 parameters estimates are tightly clustered around the true value, indicated by the red marker, showing that not only the Levenberg-Marquardt algorithm reliably avoids convergence to local minima but also that the parameters are well-identifiable.

A correlation analysis was conducted to examine the relationship among $\alpha_Q, \alpha_{vap}$, and $\alpha_c$. The results indicate a moderate negative correlation between $\alpha_Q$ and $\alpha_{vap}$ $(r = -0.65)$, and a strong negative correlation between $\alpha_Q$ and $\alpha_c$ $(r = -0.93)$. In contrast, $\alpha_{vap}$ and $\alpha_c$ exhibit a strong positive correlation $(r = 0.88)$. The correlation results can be justified by looking at Eq. (3). The parameters mutually align to accurately track crystal mass accumulation. Table 2. suggests that the estimation procedure is numerically stable and that the identified parameters are robust with respect to uncertainty and noise in the data.

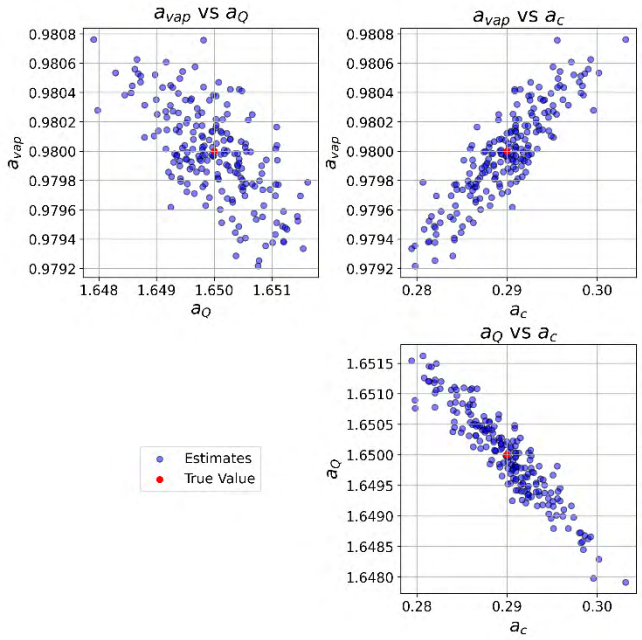

**Figure 2.** Pairwise parameter correlations ($N = 200$ and noise= 2%)

**Table 2.** Parameter estimation statistics

| Parameter | Mean | Standard deviation |
|---|---|---|
| $\alpha_c$ | 0.2899 | 0.0045 |
| $\alpha_{vap}$ | 0.9800 | 0.0003 |
| $\alpha_Q$ | 1.6500 | 0.0007 |

The impurity-dependent coefficients $a, b$, and $c$ in the supersaturation were estimated via Nelder-Mead optimization algorithm (12). Estimated values are mentioned in Table 3. The resulting coefficients were subsequently validated by confirming that the simulated supersaturation dynamics and temperature-dependent solubility profiles aligned with consistent physical behaviour.

The controller performance was analyzed in terms of its ability to regulate supersaturation close to the desired operating region despite varying thermal conditions and changing liquor composition. Since the feedforward heating steam supply flow rate is not violating safety limits, hence the $\alpha(L) = 1$, which concludes that $F_{hs} = F_{hs,forw}$ here (Figure 3.)

The results (figure 3.) indicate that the control strategy provides smooth and stable trajectories, avoiding abrupt oscillations in supersaturation and temperature that could otherwise compromise crystal growth with the supersaturation profile remaining predominantly within the metastable region, indicating that the interaction

between feed addition and evaporation is well balanced. Brief disturbances are observed primarily during adjustment of steam flows; however, these deviations are short-lived and do not lead to uncontrolled nucleation or crystal dissolution. The results are further validated in the solubility curve Figure 3.

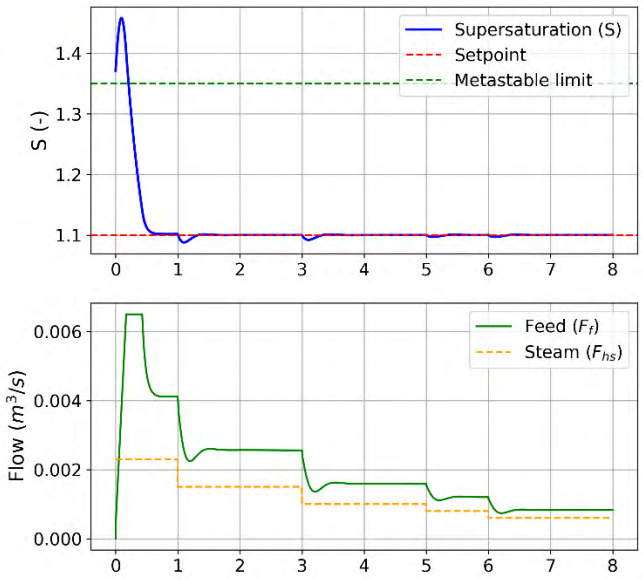

**Figure 3.** Control performance: supersaturation over time (top), manipulated variables (bottom). In addition, the controlled feed policy results in a gradual and consistent increase in crystal mass, reflecting favorable growth-dominated conditions. The absence of sharp oscillations in supersaturation and temperature suggests that the controller effectively mitigates process non-linearities and time-varying behavior inherent to batch crystallization.

Overall, the dynamic profiles indicate a stable operating regime that supports uniform crystal growth and improved product quality. The magma temperature varies within safe thermal limits across a wide operating range, indicating that the proposed soft sensor and control strategy operate effectively under different thermal conditions and maintain proper regulation of the energy balance through coordinated feed-flow control.

## CONCLUSION AND FUTURE WORK

This study shows that supersaturation in batch sugar crystallization can be effectively regulated using constrained feedback control of the feed flow rate combined with feedforward steam supply. The proposed dynamic model captures the coupled mass and energy balances and maintains supersaturation within the metastable range under stable operation. Thermodynamic inconsistencies in commonly used parameter correlations were resolved, resulting in a physically consistent and numerically robust framework. Simulation results reproduce key industrial trends, indicating strong potential for practical application. Future work will focus on parameter estimation using real plant data to further improve predictive accuracy and assess robustness under realistic operating conditions.

## ABSTRACT

We study a data reconciliation problem in a petrol refinery. The problem is to reconcile inventory and flow measurements to estimate true values of measured and unmeasured flows respecting the mass conservation. The problem is formulated as a mixed-integer quadratic program (MIQP). Upon successful problem resolution, a neural network (NN) is trained to mimic the MIQP solver to study potential improvements in CPU time without compromising the solution quality. The results show a significant improvement in refinery monitoring and feasibility of NN-based reconciliation.

**Keywords**: data reconciliation, optimization, neural networks, oil refinery

## INTRODUCTION

A typical inventory infrastructure in a refinery consists of multitude interconnected technological blocks with an extensive network of liquid storage tanks. Although measurements of input and output flows to some of these blocks and tank levels might be available, the precise flows to, from, and between individual storage tanks are not necessarily directly metered. The goal of this work is to design a data reconciliation system coupled to mass balance to estimate the incoming, interconnecting and outflowing streams for product storage tanks in the Slovnaft refinery, an industrial partner.

Effective data reconciliation [1] is a vital tool in process industry to support operational and economic decisions [2]. Over the past years, data reconciliation has been successfully applied in petrol industry [3, 4, 5]. The problem is usually resolved by formulating an optimization problem in a static or dynamic fashion [6, 7]. The optimization problem rectifies the values of measured variables by enforcing the mass and energy balance conservation laws as problem constraints.

In this work, we leverage historical operational data, technical data sheets, and fundamental physical laws to derive the necessary relationships and introduce an optimization problem to design a data reconciliation framework. The data reconciliation needs to assign network topology (pipeline connections) and thus the problem boils down to a mixed-integer quadratic program (MIQP). To study whether a simplified workaround can be used for data reconciliation, we develop a neural network model that mimics the rigorous MIQP solution.

## PROBLEM DEFINITION

Figure 1 shows a simplified scheme of the product storage block that we study in this work. The measured quantities (flows, inventory levels) are depicted in green and unknowns are marked with red question marks. The technological block consists of $m = 7$ tanks with measured hold-ups and there are $n = 17$ inflows into the block. The inflows into tanks are assigned based on operational requirements. The assignment is done manually and is unknown to the plant database. It follows the rule that each input stream leads into a single tank while multiple input streams can be assigned into the same tank. There are $o = 3$ outflowing streams from the block and, analogically, the outflow from a tank leads to a single output flow. Moreover, there are connections between the tanks, whose assignment is also unknown but a connection can be established only between two tanks at a time.

### Data Reconciliation

Data reconciliation is the process of comparing, matching, and balancing data from two or more independent sources to ensure accuracy and consistency across systems [7]. The use of reconciliation in this work can be represented by a flowchart in Figure 2, showing

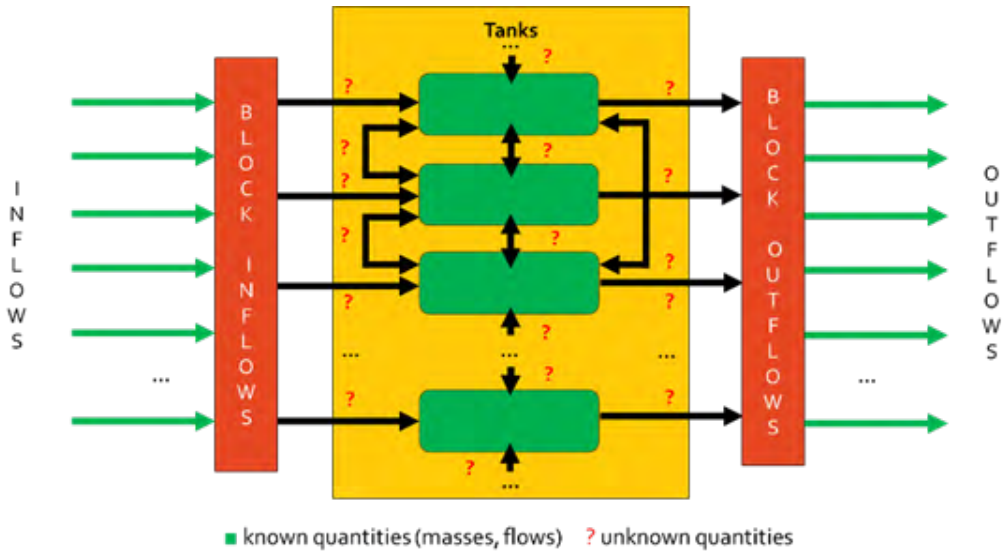

**Figure 1.** Schematic representation of a studied inventory problem, showing measured and unknown quantities.

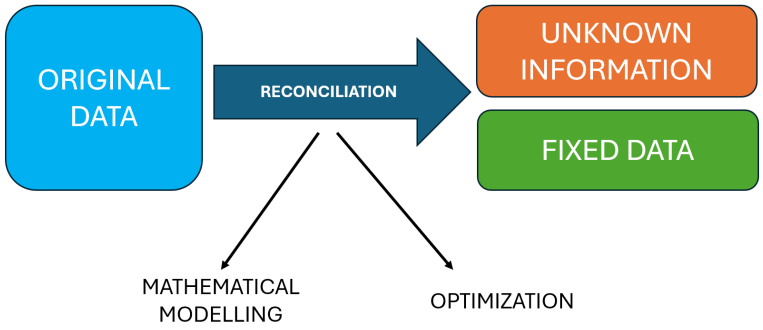

**Figure 2.** Schematic representation of data reconciliation methodology.

that we attempt to estimate unmeasured quantities from the measured quantities. At the same time, we also aim to rectify the value of measured variables so they would follow physical laws such as mass balance. All this is achieved using mathematical modelling and optimization.

The data reconciliation problem is formulated upon the following conditions and assumptions:

- The measured variables are denoted as $y^{meas}$
- The reconciled variables are denoted as $y$
- The dynamic mass balance model assumes the knowledge of actual state (hold-up) of the tanks and the state in the next sampling point
- According to the problem setup, we complement inflow and outflow of each tank with a binary variable in relation to block streams – a stream can either enter the tank or not and the outflow from the tank can enter only one outflow block stream
- The representation of interactions between tanks is realized with and $m$ x $m$ anti-symmetric matrix, representing all the possible inflows/outflows between each tank. The matrix diagonals are zero since they represent flow from/to the tank itself.

The described rules are transformed into the following mathematical relations. The vector

$$y^{meas} = \begin{Bmatrix} \dot{m}_{in}^{meas} \in \mathbb{R}^n \\ m_{tank,k}^{meas} \in \mathbb{R}^m \\ m_{tank,k+1}^{meas} \in \mathbb{R}^m \\ \dot{m}_{out}^{meas} \in \mathbb{R}^o \end{Bmatrix} \quad (1)$$

involves measurements, i.e., masses $m$ and mass flows $\dot{m}$. Subscripts $in, out, tank, k$, and $tank, k+1$ represent inflows, outflows, and current and future tank hold-ups.

Similarly, the vector

$$y = \begin{Bmatrix} \dot{m}_{in} \in \mathbb{R}^n \\ m_{tank,k} \in \mathbb{R}^m \\ m_{tank,k+1} \in \mathbb{R}^m \\ \dot{m}_{out} \in \mathbb{R}^o \\ \dot{m}_{tank} \in \mathbb{R}^{m \times m} \end{Bmatrix} \quad (2)$$

describes the reconciled quantities together with $\dot{m}_{tank}$ signifying interaction flows between the tanks. Further,

$$z = \begin{Bmatrix} Z_{in} \in \{0,1\}^{n \times m} \\ Z_{tank} \in \{0,1\}^{m \times m} \\ Z_{out} \in \{0,1\}^{o \times m} \end{Bmatrix} \quad (3)$$

involves binary variables that represent the network connections. This specifically means the optimization problem for each time step involves a total of 272 variables: 189 binary (119 for inflows, 21 for outflows, and 49 for inter-tank connections) and 83 continuous (representing all mass flows and inventory levels at time $k$ and $k+1$).

The objective of data reconciliation can be formulated as:

$$\min_{y,z \in \{0,1\}} (y^{meas} - y)^{\top} Q (y^{meas} - y) \quad (4)$$

where

$$Q_{ii} := \sigma_y^{-2}, \; Q_{ij} := 0 \quad (5)$$

with $\sigma_y$ representing the vector of standard deviations of measurement errors.

The objective function is subject to the constraints:

$$m_{tank,k+1} = m_{tank,k} + \Delta m \quad (6)$$

$$\Delta m = Z_{in}^{\top} \dot{m}_{in} + Z_{tank} \dot{m}_{tank} \mathbf{1}_{m \times 1} - Z_{out}^{\top} \dot{m}_{out} \quad (7)$$

$$m_{tank,k+1}, \; m_{tank,k}, \; \dot{m}_{in}, \; \dot{m}_{out} \geq 0 \quad (8)$$

$$\forall i \in \{1, \dots, n\}: \quad \sum_{j=1}^{m} Z_{in}(i,j) = 1 \quad (9)$$

$$\forall j \in \{1, \dots, m\}: \quad \sum_{l=1}^{o} Z_{out}(l,j) = 1 \quad (10)$$

$$\forall j \in \{1, \dots, m\}: \quad Z_{tank}(j,j) = 0 \quad (11)$$

$$\forall j \in \{1, \dots, m\}: \quad \sum_{k=1}^{m} Z_{tank}(j,k) \leq 1 \quad (12)$$

$$\forall j \in \{1, \dots, m\}: \quad \sum_{i=1}^{m} Z_{tank}(i,j) \leq 1 \quad (13)$$

$$Z_{\text{tank}}(i,j) + Z_{\text{tank}}(j,i) \leq 1 \quad (14)$$

that represent mass balance (Eqs. (6) and (7)), non-negativity constraints (Eq. (8)), assignment constraints in Eqs. (9) and (10), tank to tank constraints in Eqs. (11) – (13) and binary anti-symmetry in Eq. (14). Note that in Eqs. (6) and (7), we assume aligning the temporal difference $\Delta m$ unit with the flow units.

Reconciled data can be potentially used for neural network training with original data as inputs and reconciliated data as outputs, giving us another tool beside optimization solver. Neural networks could improve real-time reconciliation should the MIQP solver turn out slow.

## IMPLEMENTATION

We use MATLAB for framework implementation. The workflow contains the following steps:

1. Processing time series data with half-hour sampling time, covering several months of refinery operation (13, 726 half-hourly data points in total). Outliers are removed. Missing or removed values are linearly interpolated.

2. Unit and quantity conversion, where volumes and volumetric flows are transformed into masses and mass flows using measured densities.

3. Setting up the problem (4) – (14) using YALMIP [9] and solving it using GUROBI [10].

4. Training a neural network using *feedforwardnet* function in MATLAB (data split training / validation / testing = 70% / 15% / 15%). A feedforward network is created with three hidden layers sized 250, 150, and 80. The training algorithm is set to resilient backpropagation (*trainrp*). Each hidden layer's transfer function is set to *poslin*, which is ReLU. We exclude binary variables and use only continuous ones, because while binary variables are essential in mixed-integer problem definition, it is the set of continuous variables that carries the physical importance of the system. This step makes the problem simpler for neural network training, too. However, this approach makes the NN model topology-specific. If the physical network connections change (e.g., a new pipeline is installed or a tank is rerouted), the NN cannot dynamically adapt its binary logic and the surrogate model must be retrained using a new dataset generated by the updated MIQP formulation. Another specific settings, mostly for early stopping, are specified in Table 1.

**Table 1:** Feedforward neural network settings.

| Parameter | Value |
|---|---|
| Maximum no. of epochs | 2, 000 |
| Sufficient performance | 1E-05 |
| Sufficient gradient | 1E-06 |
| Maximum validations check | 15 |

## RESULTS

### Data Reconciliation using Optimization Solver

We demonstrate results of reconciliation via optimization in Figure 3. Figure 3.a) shows that the MIQP solver was able to find optimal solution in around 98% of the instances, with remaining 2% representing failed attempts, mostly due to numerical problems (98%) and few because of reached time/iteration limit of 60 s (2%).

Figure 3.b) represents the empirical cumulative distribution function of mass balance residuals between reconciled and measured variables. It should be noted that in the MIQP formulation, the reconciled flow is defined by the product of a binary existence variable and a continuous flow rate. While the optimization ensures that

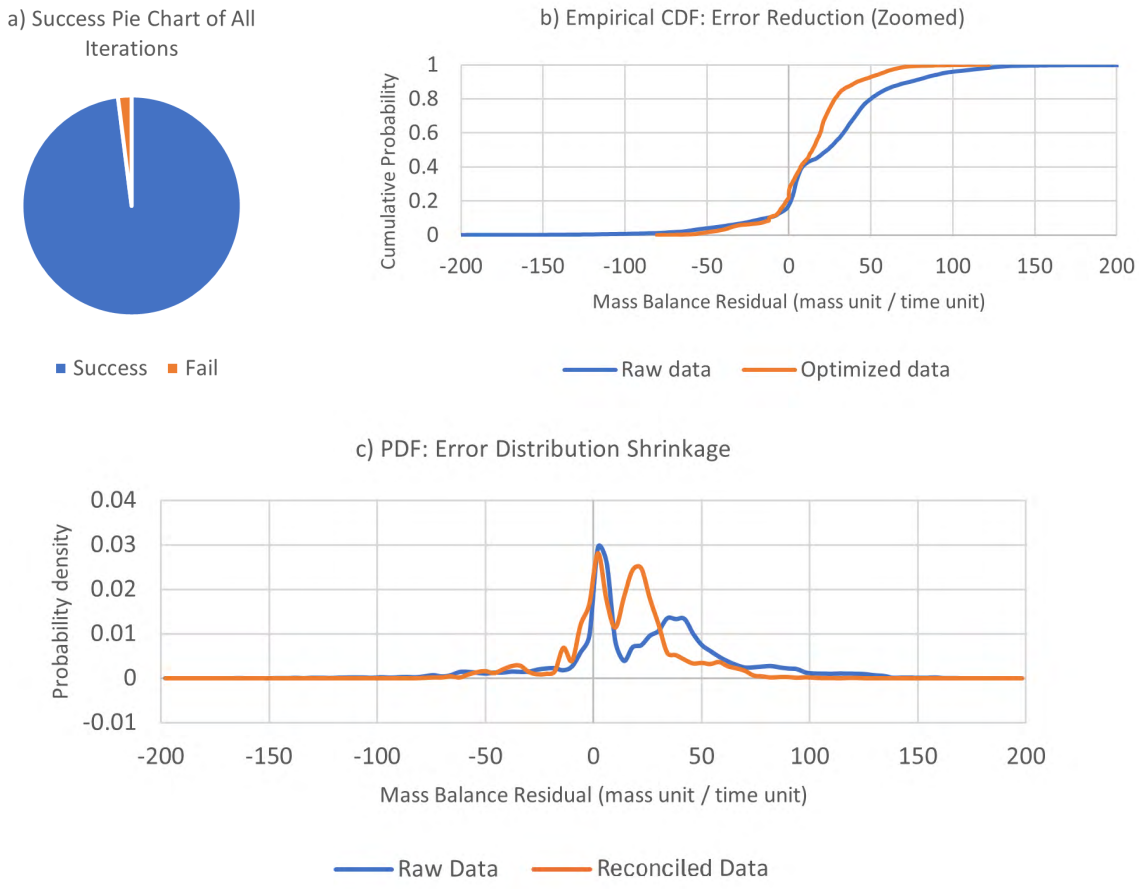

**Figure 3.** Performance plots of data reconciliation.

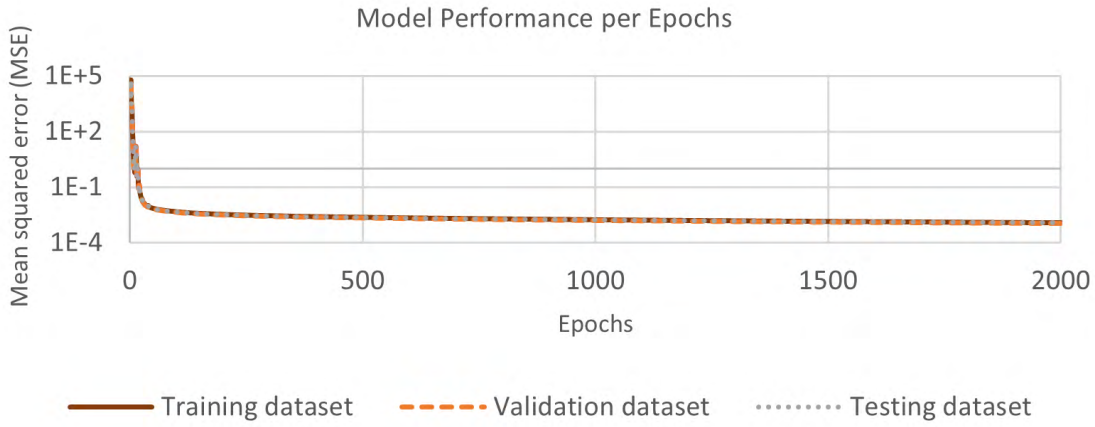

**Figure 4.** NN model performance over the training epochs.

mass conservation is strictly satisfied for these reconciled values, the residuals plotted here represent the deviation of raw plant measurements from this physically consistent logic. The steep slope around zero confirms high reconciliation precision for most observations. Approximately 70% of residuals are positive, indicating that the reconciliation process systematically compensates for under-measured inflows or unmeasured gains to satisfy mass conservation constraints. This indicates systematic (gross) errors and provides plant personnel with valuable monitoring information.

Complementarily, Figure 3.c) illustrates the probability density function (PDF), which showcases a significant reduction of long tails within the reconciliation

process. While the raw measurements exhibit a broad and dispersed noise profile, the optimized residuals are concentrated into two dominant peaks near zero, confirming the effective suppression of random measurement noise. The presence of the secondary peak in the positive region of the horizontal axis further validates the model's handling of the binary-continuous products; it demonstrates the aforementioned systematic inflow errors, indicating that the model successfully identifies and compensates for mass balance inconsistencies within the monitored system by reconciling the raw data toward the enforced physical structure.

### Data Reconciliation using Neural Network

We demonstrate the neural network training and validation performance in Figure 4. The plot illustrates the evolution of the Mean Squared Error (MSE) over the maximum 2, 000 epochs, since requirements for early stopping were not satisfied. The logarithmic scale of the graph highlights the rapid initial convergence and subsequent fine-tuning of the model. The training process successfully reduced the performance metric from an initial value of $8.24 \times 10^{3}$ to a final termination value of $1.15 \times 10^{-3}$ as indicated by the best validation performance achieved at the final epoch.

The high fidelity of the resulting model is further quantified by the regression analysis (not reproduced here), where the network reached a correlation coefficient of $R = 0.9982$ on the independent test dataset. This corresponds to a coefficient of determination $R^2 \approx 0.9964$, signifying that the neural network accounts for approximately 99.64% of the variance in the optimization data. The close tracking of the training, validation, and test curves throughout the 2, 000 epochs confirms a robust learning process with no signs of overfitting, demonstrating that the network has effectively internalized the underlying physical constraints and mass balance logic of the MIQP solver.

Table 2 shows comparison of CPU time as a comparison between optimization solver execution time and neural network inference time, representing potential of neural network for real-time optimization since it is, based on mean values, around 300-times faster. Both minimum and maximum CPU times are exponentially smaller for neural network than for optimization solver.

**Table 2:** CPU time comparison for optimization solver vs neural network.

| CPU time (s) | Optimization solver | Neural network |
|---|---|---|
| Minimum | 0.059903 | 0.007845 |
| Mean | 2.787424 | 0.009257 |
| Maximum | 60.480676 | 0.025399 |

## CONCLUSION

We studied inventory data reconciliation in an oil refinery. The presented approach led to a significant increase in the accuracy of tank inventory monitoring and allowed for the quantification of previously unknown flows within the entire refinery system. Consequently, the resulting model provides a valuable tool for the early detection of anomalies, improvement of mass balance calculations, and real-time optimization of liquid inventory management. The future goal would encompass a use of an SCIP solver [11] that can be licensed freely not only for academic but also for commercial purposes.

## ABSTRACT

This research presents a novel framework for the surrogate-based dynamic optimization of control schemes within chemical separation and purification processes such as the biorefinery downstream processing. The current study investigated the downstream of an enzymatic bioreactor responsible for the synthesis of 5-hydroxymethylfurfural value-added derivatives, focusing on the critical balance between operational costs and productivity. Two high-fidelity long short-term memory neural network-based surrogate models were developed to predict energy consumption and economic gain, both achieving a coefficient of determination ($R^2$) exceeding 0.97. These models were subsequently integrated into a multi-objective optimization architecture to address an operating efficiency testing scenario characterized by stepwise inflow parameter changes. By exploring the resulting Pareto front, an optimal set of operational (control) settings was identified and validated. The results demonstrate that while energy consumption remained nearly constant, the total economic benefit increased by approximately 20% over the whole studied timeframe. Critically, during the transient period between steady-states, the economic benefit surged by nearly 60%, highlighting the potential of surrogate-based dynamic optimization. The high computational efficiency of the developed models (optimal solution obtained in less than three minutes) suggests significant real-time process control application possibilities. Unlike computationally expensive first-principles models, the developed neural architectures allow for virtually instantaneous setpoint adjustments. This paves the way for their integration into model predictive control or real-time process control layers, enabling industrial plants to respond adaptively to feed fluctuations, minimize off-spec product during transitions, and maximize profitability.

**Keywords**: Aspen Plus, Aspen Dynamics, Artificial Intelligence, Optimization, Process Control

## INTRODUCTION

Classic control strategies often fail to maintain their performance under variable conditions as nonlinear processes become more interlinked and data-heavy [1]. This holds particularly true in case of novel complex processes, such as the separation and purification of 5-hydroxymethylfurfural (HMF) derivatives. The design of economical and process-efficient separation sequences with minimal environmental impacts is crucial for the future of such promising green biocatalytic pathways [2]. A shift toward dynamic operation optimization is required due to the intrinsic non-linearity of these separation units and the variability of bio-reactor effluents. Artificial Neural Networks (ANNs), that describe intricate nonlinear input-output interactions without the need for the deep understanding of the underlying process dynamics [3], represent the forefront of this shift.

Recent research on neural network-based surrogate models showed their high-fidelity at orders of magnitude smaller computational requirements, emphasizing their potential for real-time applications [4]. These networks can forecast ideal setpoints of the control loops by training on synthetic and historical information, allowing for proactive rather than reactive control. Furthermore, these surrogate models can be developed to directly forecast the evaluation criteria or objectives for the whole process [5]. The incorporation of temporal dependencies using Long Short-Term Memory (LSTM) networks has been a major development in this field. Due to

their design, LSTMs are most appropriate for handling sequences and time-series data [6]. LSTMs were shown to outperform conventional ANNs in handling the stochastic nature of changing inputs in industrial power research [7]. An excellent surrogate model was developed utilizing LSTM networks for multi-objective optimization in multigeneration systems, increasing operational efficiency by up to 12% in some aspects [8].

In the context of Computer-Aided Process Engineering (CAPE), the smooth integration of advanced surrogates into optimization frameworks remains a challenge, particularly for processes outside the energy sector. To address this, the current study proposes an improved LSTM surrogate model-based dynamic optimization architecture designed for the continuous refinement of operational parameters. The proposed framework aims to enhance the energy efficiency and economic viability of a previously proposed and investigated biorefinery downstream process for bio-based HMF derivatives [2], combining recent advances in machine learning and practical process systems engineering.

# METHODOLOGY

## Case study description

The development of a downstream process for the enzymatic conversion of HMF and 1-phenyle-thylamine (PEAM) was previously proposed and studied. The separation and purification of the resulting mixture of 2, 5-bis(hydroxymethyl)furan (BHMF), 1-phenylethylalcohol (PEA), 1-phenyle-thylamine (PEAM) and 5-(aminomethyl)-2-furanmethanol (HMFA) was discussed [2]. The mentioned process was since enhanced in terms of heat integration and product quality as shown in Figure 1. The enhanced version of the Aspen Plus simulation was implemented in Aspen Plus Dynamics in order to study the control of the process. The dynamic implementation was performed separately for the two non-interacting process lines responsible for the alcohol and amine products, respectively, as can be observed in Figure 1.

## Dynamic model development

The proper functioning of each column was ensured by four control loops responsible for the material and energy balances. Columns C1 and C3 use three mass-balance loops plus a temperature control loop, while columns C2 and C4 employ cooling agent pressure manipulation specific to total-condenser configurations. Further control loops were employed to maintain the optimal conditions of the other unit operations, e.g., flow ratio controller for the liquid-liquid separation. The utilized controllers were conventional PID which were tuned based on various methods, e.g., closed loop (Ziegler-Nichols), open loop (internal model control). The current study focuses solely on the alcohol line of the proposed biorefinery downstream process. The regulatory control layer is driven by the upper control layer, where dynamic optimization of energy and economic indices is performed to provide setpoints for the control loops of the bottom layer.

## Data generation

Two types of simulation were performed in order to obtain the database required for the development of data-driven models. In case of the first type, the parameters of the incoming stream were subjected to a step change, while the operational parameters were kept constant. The inflow parameters considered were the mass flowrate, temperature and mass fractions of the two alcohol products. The boundaries of change for the mass flowrate and mass fractions were defined as -10% and +10%, whereas the temperature was changed by -5 °C to +5 °C compared to the steady-state value. In order to encompass a variety of steady-state conditions, the simulation was not reset before each step changes, but only after three changes were implemented.

In case of the second type of simulation, the operational parameters were subjected to step changes in a similar fashion. The setpoints of the most important control loops were considered, i.e., temperature setpoints of columns C1 and C2 and the pressure setpoint of the COMP1 compressor. The limits for the step change were chosen as -10 °C to +10 °C for column C1, -12.5 °C to +12.5 °C for column C2 and -0.05 bar to +0.05 bar in case of the pressure setpoint. Similarly to the previously described data generation procedure, the simulation was reset to the original steady-state values only after a step change for each of the operational parameters was performed. The proposed tuned control structure resulted in a dynamic transition period of around one and a half hours after a step change (at the upper or lower boundary) was introduced in all cases before reaching steady-state.

In order to best cover the region defined by the step change boundaries in the least number of scenarios, a combined design of experiments (DoE) approach was utilized. The D-optimal design with three levels and the Halton quasi-random sequence were employed to fill out the input space. In this manner, 25 scenarios of the first type and another 20 scenarios of the second type were defined. The sequences of individual step changes were extracted at a five-minute sampling time from the mentioned scenarios. Each sequence contained half an hour of steady-state followed by the step change and a three-hour period which contained both the dynamic evolution and resulting steady-state.

## LSTM model development

A total of 118 data sequences were obtained through the previously described methodology which

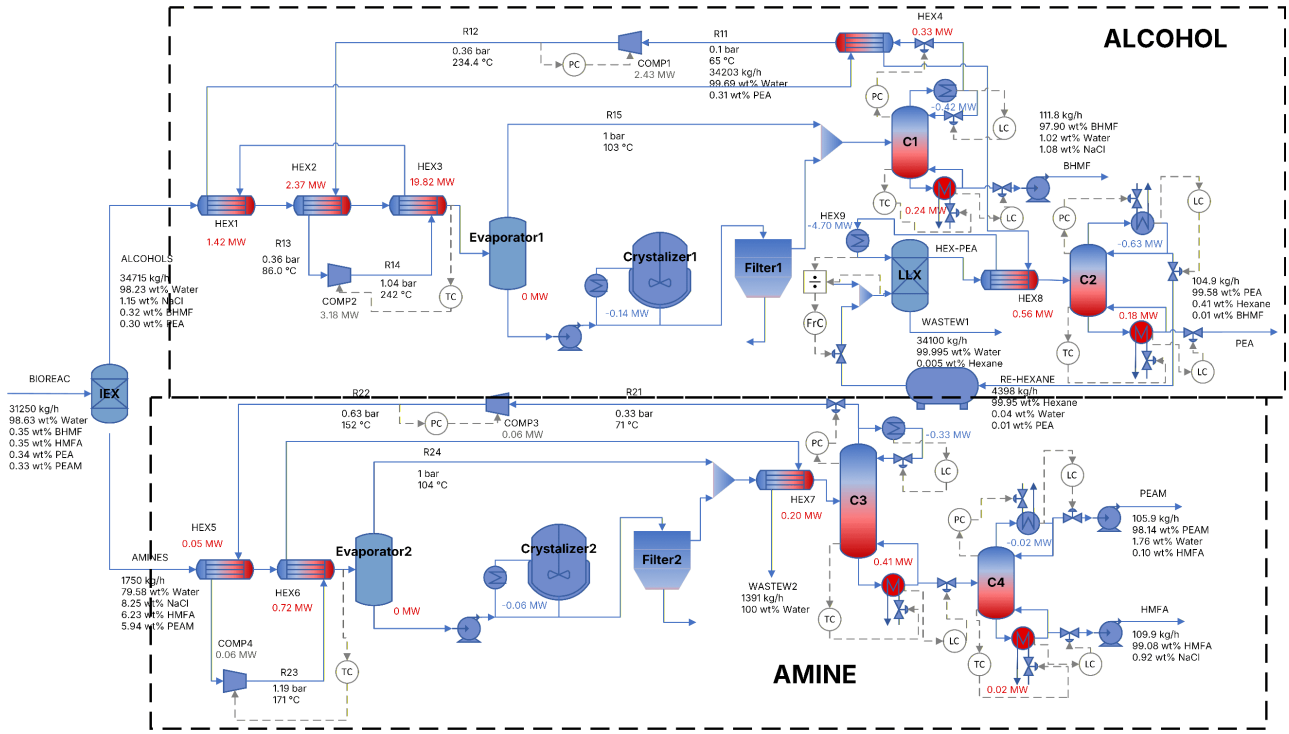

**Figure 1.** Schematic of product separation and purification processes and their control structures implemented in the Aspen Plus and Aspen Plus Dynamics simulation software.

were utilized in the ANN development.

The input features of these models are the seven parameters of interest i.e., the four inflow parameters and the three operational parameters which were varied in the data generation scenarios. The output features of these models were the objective function results for the studied sequences.

These objective functions are presented in the section below. Based on the collected data, a sequence-to-sequence regression model was intended to be developed. Consequently, long short-term memory (LSTM) type networks were chosen as these were developed to map an input sequence to a continuous-valued output sequence of possibly varying length [9]. The prediction capability of this kind of models was proven for similar modelling problems such as forecasting exact numerical values via signal processing [10] or for multi-step time series predictions [11]. The LSTM models were developed as single-output models in the sense that the sequences of only one of the two output features are predicted based on the input feature sequences. Thus, an LSTM model was developed for the prediction of each output feature as single output models were shown to outperform multiple output models [4]. The LSTM models were developed by utilizing 85% (i.e., 100 sequences) of the generated dataset for training, while the remaining 15% was equally divided between validation and testing.

## Dynamic optimization

The optimization of the dynamic downstream process focuses on two aspects of great importance: the energy efficiency and the economic viability. In terms of energy efficiency, both the electric and thermal energy necessities were taken into consideration and expressed in equivalents of thermal energy. Equation 1 shows how this objective was calculated in $kWh_{thermal}$ unit.

$$obj_1 = reb_{C1} + reb_{C2} + 2.5 \bullet (bp_{COMP1} + bp_{COMP2}) \quad (1)$$

where, $reb_{C1}$ and $reb_{C2}$ represent the reboiler duties of columns C1 and C2, while $bp_{COMP1}$ and $bp_{COMP2}$ refer to the brake power of compressors COMP1 and COMP2, and 2.5 was the primary energy factor utilized to convert electric energy to thermal energy equivalents.

In case of the second objective, the economic benefit of the studied downstream process (alcohol line) was evaluated. This gain was expressed as the difference between the value of produced outputs and operational expenses strictly regarding the operation of the process line calculated in € and shown in Equation 2. However, the products have to meet the commercial standards, i.e., BHMF > 97 wt%, PEA > 99 wt% and $BHMF_{Temp}$ < 120 °C. In case these constrains are violated, the calculation of the objective was penalized by considering that the value of the product is zero in that timeframe.

$$obj_2 = 10 \bullet fm_{BHMF} + 3 \bullet fm_{PEA} - 0.1902 \bullet (bp_{COMP1} + bp_{COMP2}) - 25 \bullet (st_{C1} + st_{C2}) \quad (2)$$

**Table 1.** LSTM models evaluation criteria results calculated both on the training and testing datasets.

| Model | Training | | | Testing | | |
|---|---|---|---|---|---|---|
| | $R^2$ | RMSE | MAPE (%) | $R^2$ | RMSE | MAPE (%) |
| LSTM-obj1 | 0.9969 | 41.233 | 0.1285 | 0.9983 | 33.152 | 0.1261 |
| LSTM-obj2 | 0.9732 | 20.248 | 1.3866 | 0.9798 | 19.515 | 3.0366 |

where, $fm_{BHMF}$ is the mass flowrate of BHMF with a value of 10 €/kg, $fm_{PEA}$ is the mass flowrate of PEA with a value of 3 €/kg, 0.1902 is the EU average price of electricity in the first half of 2025 [12], $st_{C1}$ and $st_{C2}$ are the steam necessities for the reboilers of columns C1 and C2 expressed in GJ/h with a true cost of 25 €/GJ.

## RESULTS AND DISCUSSION

### LSTM model results

Several deep neural network architectures were studied; however, the best results were obtained in case of both objectives with the LSTM model containing a lstm layer, followed by fully connected and dropout layers two times. The networks were trained with normalized input and output features and the adaptive moment estimation training algorithm was employed. The best performing models were selected based on their adjusted coefficient of determination ($R^2$), root mean square error (RMSE) and mean absolute percentage error (MAPE). The values obtained in case of the best models for each output feature are summarized in Table 1, demonstrating the satisfactory generalization capabilities of the surrogate-models.

It can be observed that both developed LSTM models maintain the evaluation criteria values obtained at training even in case of a previously unseen dataset, i.e., at testing. In terms of precision, the first objective can be forecast at a higher precision based on the presented results. This can be attributed to a smaller variation of the objective throughout the simulated scenarios. In order to better illustrate the capabilities of the developed models, the linear regression between the modeled and targeted variables are presented in Figure 2 for both output features, in case of both training and testing datasets.

### Optimization results

The two LSTM models were utilized in optimization concerning a new scenario of step changes for the inflow parameters. Conversely to the previous scenarios, all four parameters were subjected to a step change in this case. The final values for these parameters were chosen to be different from those that appear in the generated dataset. The parameter changes applied were of -7.5% for mass flowrate, -4.5 °C for temperature, -5% and -7% for the PEA and BHMF mass fractions, respectively. The operational parameters were chosen as the decision variables, as such the optimal value of the three setpoints was searched for. As the two objectives are in trade-off, due to the fact that at lower energy input the product purity constraints are violated, a multi-objective optimization was performed.

The multi-objective optimization was performed in MATLAB with a genetic algorithm approach, a variant of the non-dominated sorting genetic algorithm II. In this manner, a set of noninferior solutions are found, called the Pareto front, considering the objective function described in Equation 3.

$$min(f_{obj}) = \begin{cases} obj_1 \\ -obj_2 \end{cases} \quad (3)$$

The Pareto front presented in Figure 3 shows the best set of solutions found. The first objective is but slightly affected by the decision variables. These results suggest that the energy consumption of the studied downstream process line is defined almost entirely by the inflow parameters. At the same time, further reduction of the energy consumption results in the decrease of the process' economic viability. This can be attributed to the reduction of the columns reboiler duties, which in turn impact the product purity. At a certain point their reduction results in the violation of purity constraints, i.e., penalties for the second objective function.

Assuming a decision-making process focused on the economic aspect of the downstream process of the alcohol products, the right-most solution (solution 11) was selected for validation on the dynamic model. Solution 11 was chosen as the economic gain is forecast to be best in this case, with a marginal increase in energy consumption compared to the other solutions of the Pareto front.

Firstly, the values of the investigated objectives were averaged over the studied period of time after the step change occurs. The utility of the developed LSTM models and optimization based on these models is evidenced, as the proposed solution 11 increases the economic gain from 209.8 €/h to 250.2 €/h meaning a percentual improvement of more than 19%. As previously mentioned, the two objectives are in a trade-off, consequently, the increase in economic viability comes at the cost of an increased energy consumption. However, the change in the first objective is barely above 1%, thus the chosen solution 11 stands firm considering the benefits

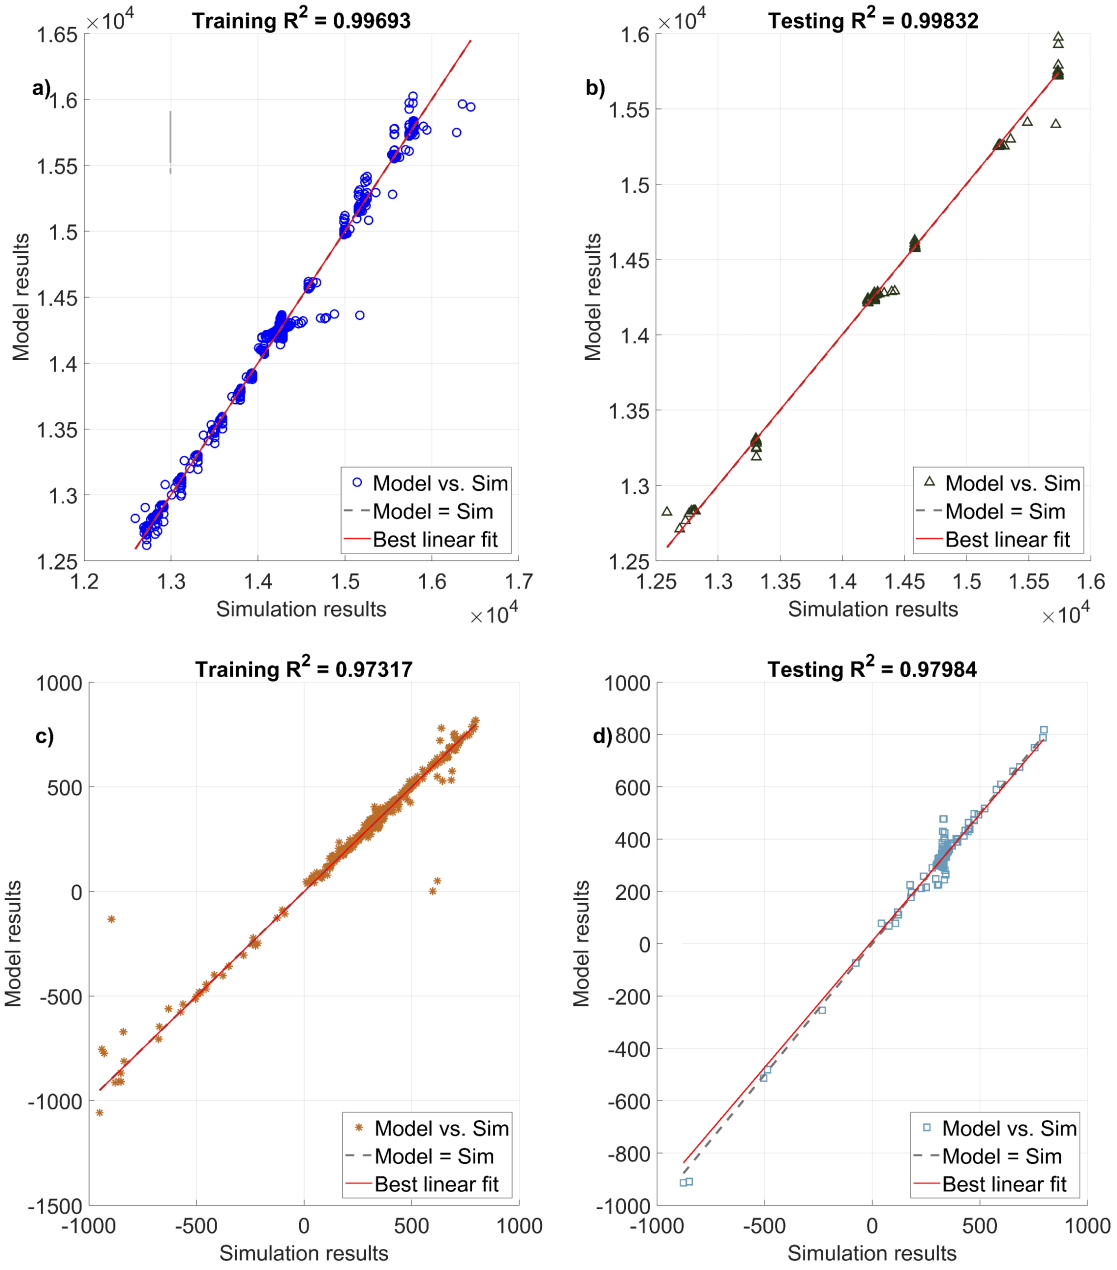

**Figure 2.** Regression of model and simulation results in case of: a) objective 1, training data; b) objective 1, testing data; c) objective 2, training data; d) objective 2, testing data

obtained in the economic aspect.

Secondly, the dynamic simulation was studied in two segments for a better understanding of when and how the proposed solution outperforms the reference scenario. The two segments considered were: i) the first half of the simulation time after the step change occurs (i.e., the first 1.5 hours) when the majority of the dynamic behavior occurs; ii) the second half of the dynamic simulation time when slight changes can occur, however, most of this timeframe can be considered steady-state. Based on the results presented in Table 2, the tested solution heavily outperforms the reference case in the first half of the studied scenario. The optimized control loop setpoints increase the economic gain by 58% at the cost of a 1% greater energy consumption. It is also important to note that the in case of solution 11, the overall and first half values of the objectives are very similar. As such, it is clear that the optimized setpoint values result in a smoother dynamic behavior. The large improvement in economic gain can be attributed to the objective penalties as the reference case settings result in sub-standard product quality, whereas the settings of solution 11

**Table 2.** Dynamic simulation results of the reference case and the tested solution.

| Case | Overall = 3h | | First half = 1.5h | |
|---|---|---|---|---|
| | $obj_1$ ($kWh_{thermal}$) | $obj_2$ (€/h) | $obj_1$ ($kWh_{thermal}$) | $obj_2$ (€/h) |
| Reference | 15258 | 209.8 | 15279 | 157.7 |
| Solution 11 | 15443 | 250.2 | 15432 | 249.3 |

avoid any constraint violation. These results also imply that the reference case outperforms solution 11 in the second half of the dynamic simulation. In which case, the initial operational parameter settings outperform those of solution 11 after steady-state is achieved.

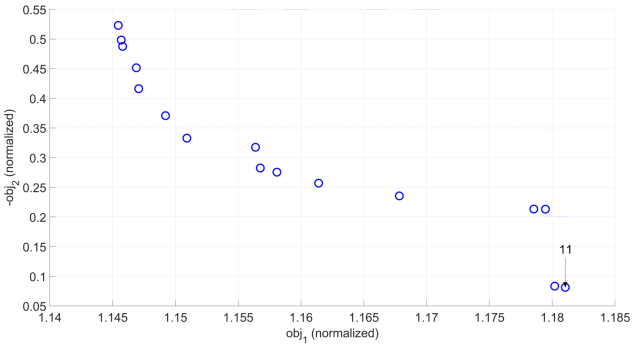

**Figure 3.** Multi-objective optimization results (Pareto front) as the second objective (negative economic gain) in function of the first objective (energy consumption)

The currently developed tools can address the above-mentioned limitation by performing the same optimization process for more sets of decision variables, e.g., one set for each half of the studied simulation timeframe. In this manner, the implementation would resemble that of a real-time optimization (RTO) layer with an optimization horizon of 1.5 hours. On the other hand, this integrated tool offers valuable information on the trade-off between process-wide performance criteria. Such an RTO layer would be able to take into account the dynamic behavior of the system, unlike classic RTO which rely on steady-state models. Another important aspect for the real-time implementations of the developed models is that the solutions presented in Figure 3 were obtained in less than 3 minutes. In these conditions, a selected solution can be adopted at the same time as the changes occur if information is available from upstream and the hydraulic retention time is of at least 3 minutes. However, even without such information an optimal solution can be adopted at the next point in time (as the frequency of the dataset is of 5 minutes), in which case the optimal solutions should be searched for starting from t+1 timestep if the step changes occur at step t. Due to the promptness of the underlying models, the integrated tool shows possible applications in dynamic real-time optimization of process-wide criteria, a combination of RTO and model predictive control (MPC).

## CONCLUSIONS

This study demonstrates the possible advantages and applications of the integrated surrogate model-based multi-objective optimization of a biorefinery downstream process line. The studied tool can be utilized at a RTO hierarchy level with possible economic gain improvements of almost 20% at the cost of around 1% increase in energy consumption, due to its dynamic modelling capability. It shows even greater promise as a complementary tool to existing RTOs, being responsible only for the optimization of dynamic transitions in case of inflow variations. In this type of application in the case study, the economic gain was increased by 58%, with a marginal growth of 1% of the energy consumption. The developed integrated tool can be considered as a first step in combining RTO and MPC for the real-time dynamic optimization of complex industrial systems. Ultimately, the current study proposes a roadmap for actively taking advantage of inflow variations to optimize economic performance (with close to no compromise) in terms of energy efficiency, rather than simply surviving them.

## ABSTRACT

In this work, we propose a methodology for monitoring the performance of model predictive controllers (MPCs). A sequence of binary classification machine learning models, organized in cascade, called Cascade Machine Learning Models (CMLM), is evaluated to give a diagnosis of the control conditions. The proposed methodology was assessed using two case studies: a benchmark problem (the van de Vusse reactor under nonlinear MPC, NMPC) and a simulated industrial debutanizer column under commercial MPC. The ML models evaluated were the Random Forest and the Multilayer Perceptron. The results show that the proposed approach outperforms both a single multiclass model and traditional MPC performance monitoring methodologies, while remaining adaptable and scalable to larger applications.

## INTRODUCTION

Model predictive controllers (MPCs) have become popular in industrial applications. However, just like other control strategies, this kind of controller depends on a healthy closed-loop configuration to perform properly. The satisfactory implementation of an MPC depends on its tuning parameters and mainly on the model representation, and a plant-model mismatch is still a challenge to be identified [1, 2].

Many metrics have been developed to detect and diagnose performance issues in controllers [3, 4]. Indeed, commercial software already has some tools to help monitor the closed-loop operation. However, obtaining a quick and accurate diagnosis remains challenging in industrial processes [5]. Improving data visualization is one of the approaches that has been explored for easing control loop diagnosis [6]. Machine learning (ML) is one of the classes of techniques employed to detect and diagnose control performance issues.

Control degradation is considered part of the fault detection and diagnosis (FDD) field [4], which is already widely exploring ML applications in abnormalities classification [6-8]. Some studies have been conducted to evaluate the applicability of ML tools in monitoring control loops, most of them focusing on SISO loops [10-13], and some on MPC [14-17]. However, there is still a lack of studies that evaluate the use of ML tools applied to nonlinear MPCs (NMPCs) and commercial MPCs.

In this study, we explore the use of ML algorithms applied to detect and diagnose the performance of MPCs. We propose a sequential procedure to evaluate the usage of independent ML models, named Cascade Machine Learning Models (CMLM), to detect and diagnose the performance of model predictive controllers using a data-based approach. To evaluate this approach, a comparison between Random Forest (RF) and Multilayer Perceptron (MLP) Neural Network as candidate ML models is carried out. As case studies, the van de Vusse reactor controlled by an NMPC, a nonlinear benchmark, and a simulated industrial debutanizer column controlled by a commercial MPC, with more variables involved, were used to generate data to train, validate, and test the learning capability of the ML models.

# METHODOLOGY

## System Architecture

Figure 1 shows a schematic representation of the process controlled by an (N)MPC and integrated with the AI-based monitoring system. This proposal aims to evaluate the capability of an IA agency to apply online to an industrial process, giving alerts and suggesting corrective actions to improve control performance.

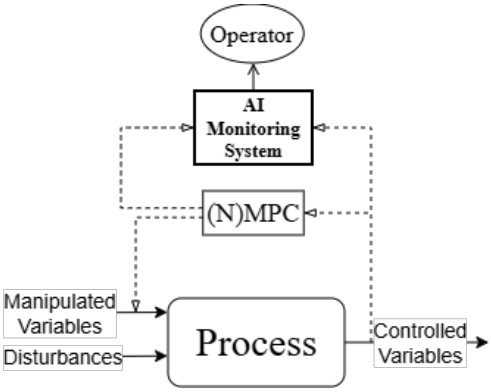

**Figure 1.** Controlled process integrated with the AI-based monitoring system.

## Models in Cascade

Models in cascade have already been used for monitoring MPC performance [15]. However, this methodology has not been widely explored, especially for NMPC's performance monitoring. Figure 2 illustrates how these ML models are organized for the van de Vusse reactor system, while Figure 3 shows how it was designed for the debutanizer column, the case studies of this work. The specific adaptation of the CMLM is based on the physical knowledge of the process and on the main typical source of degradation. Process particularities must be taken into consideration to design the cascade arrangement.

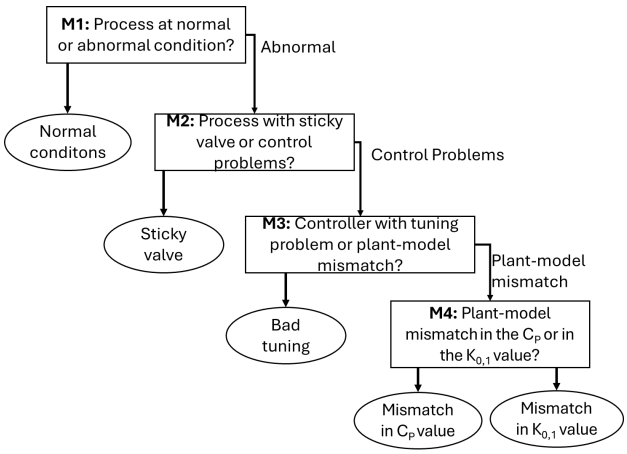

**Figure 2.** Models (M) in cascade for the classification problem for the van de Vusse reactor.

In Figure 2, the CMLM was designed to discriminate between the instrumentation and process problems and the control configuration problem. The first ML model is responsible for detecting whether the closed-loop performance is abnormal. Once abnormalities are detected, the process data goes to the second ML model, which is responsible for diagnosing whether the issue is due to the process actuator, such as valve stiction, or internal control configuration. Once an internal control

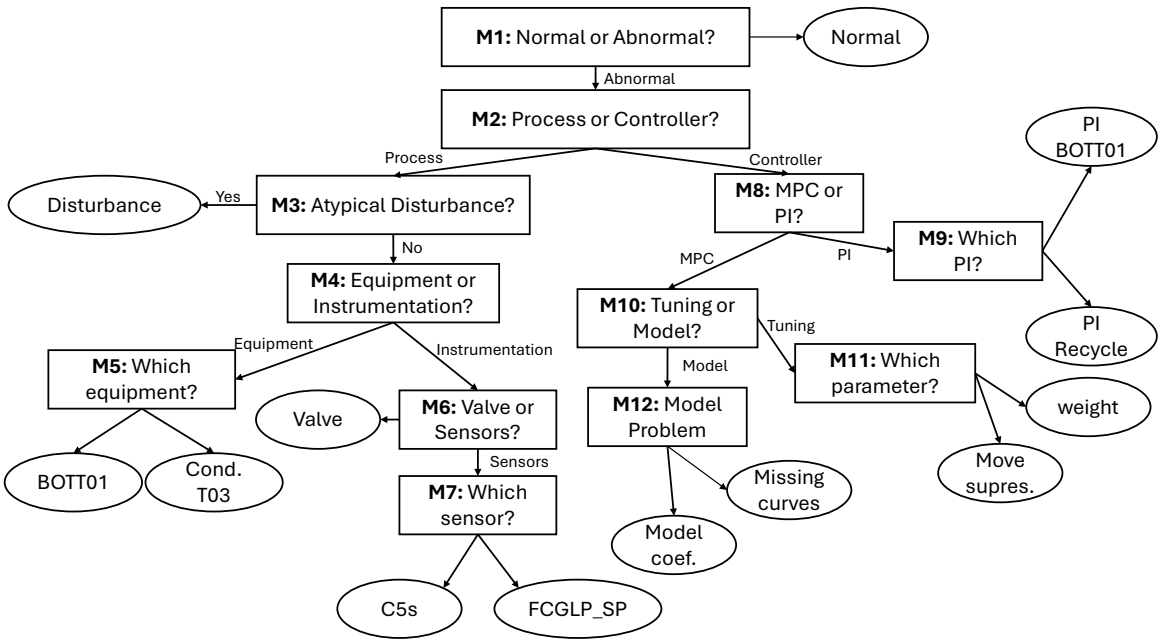

**Figure 3.** Models (M) in cascade for the classification problem for the debutanizer column.

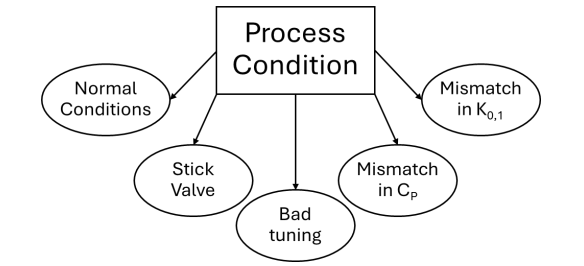
configuration issue is detected, the third ML model is used for diagnosing poor control tuning or plant-model mismatch. Finally, if a plant-model mismatch is identified, the final model is responsible for diagnosing which of the two process model parameters should be evaluated.

The CMLM for the distillation column presented in Figure 3 follows, in general terms, its counterpart developed for the benchmark reactor. However, as the model is now more complex, additional models were included, such as M8 and M9, which deal with PI regulatory control. Additionally, to make the FDD problem more complete, models designed to detect atypical disturbances (M3) and sensor problems (M7) were also included.

This methodology is compared with a single machine learning model (SMLM) for a multiclass classification, in which detection and diagnosis occur at the same model, according to Figure 4. The multiclass approach is used in other studies for MPC status classification.



**a)** Van de Vusse reactor.

**b)** Debutanizer column.

**Figure 4.** ML representation for multiclass classification (diagnosis and detection) problem for each case study.

The main advantage of using CMLM is its facility for maintenance and adaptations. Chemical processes with many variables and controllers in cascade may suffer from a huge number of possible issues in the closed loop. In this case, there is a necessity to update the SMLM structure, and the whole model should be retrained, while the CMLM allows the possibility to update just one of the structures used or include a new model for a new diagnosis.

Besides, CMLM allows the use of different ML algorithms combined, as one technique can be better for one specific diagnosis than others. Furthermore, the technical team can also contribute to the precise diagnosis, removing models from the cascade. For example, if it is certain that the process is not under normal conditions, the operators and engineers can use only the models regarding the diagnosis, skipping the detection model.

Moreover, for each diagnosis, different features are expected to affect each abnormally. For the SMLM, all features that might contribute must be used, resulting in a complex ML model. For the CMLM, in case there is a necessity of reducing model complexity, different features could be used for each model in the cascade, allowing the construction of simpler models.

## Case Study 1: van de Vusse Reactor

To evaluate the CMLM methodology, the van de Vusse reactor was used as a case study. The reaction system produces a substance B from a reagent A, having C and D as byproducts, according to Equation (1).

$$A \xrightarrow{1} B \xrightarrow{2} C \quad 2A \xrightarrow{3} D \qquad (1)$$

The inlet flow enters a CSTR reactor with a temperature $T_{in}$, a concentration $C_{A,in}$ of reagent A, and a flowrate $F$, according to Figure 5. The outlet B concentration ($C_B$) and the reactor temperature ($T$) are the controlled variables (CVs). The heat exchange rate $\dot{Q}$ and the flowrate and reactor volume ratio $F/V$ are used as manipulated variables (MVs). All system parameters were described by Engell and Klatt (1993) [18].

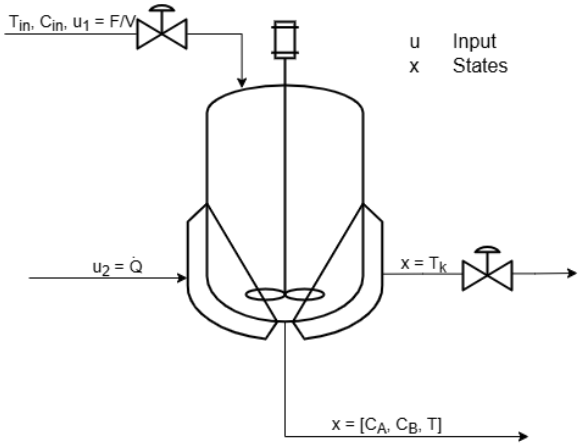


**Figure 5.** van de Vusse reactor.

The reactor is controlled by an NMPC. All simulations were run considering the same steady state as the initial process condition. The simulations were carried out using the same structure used by Lima *et al.* [19]. The concentration $C_{A,in}$ is considered an unmeasured disturbance. A sampling time of 2.5 $\times$ $10^{-3}$ h was adopted.

### Data Generation

The simulation for generating the data was carried out considering four different cases:

1. **Normal conditions:** absence of faults.
2. **Valve stiction:** a dead band was considered.

3. **Poor tuning:** intentional poor tuning was made at the controller.
4. **Plant-model mismatch in $C_P$ or $K_{0,1}$:** difference between the NMPC internal model and the simulated plant for the specific heat of the mixture $C_P$ or for the pre-exponential constant of the B formation reaction rate ($K_{0,1}$) were considered.

Simulations were performed to produce 10, 000 samples for each class. The presence of Gaussian noise in the measurement of the control variables was also applied.

## Case Study 2: Debutanizer Column

The system is based on a Natural Gas Processing Unit (NGPU) that produces Liquefied Petroleum Gas (LPG) from Natural Gas. The system is composed of three distillation columns: a demethanizer, a deethanizer, and a debutanizer column. The main column is the debutanizer column, which processes the liquid from the bottom of the deethanizer to produce LPG and light naphtha.

Figure 6 shows the simplified scheme of the process. The simulation was carried out using Aspen Dynamics, controlled by DMC3, the AspenTech's controller.

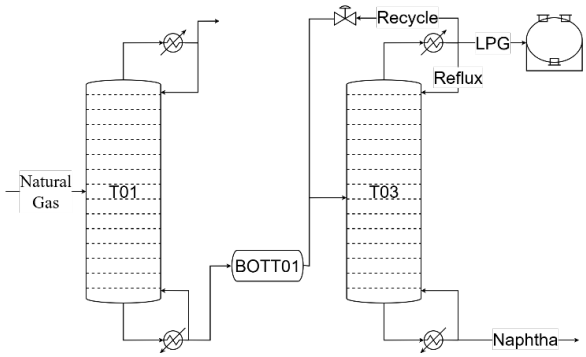

**Figure 6.** Simplified scheme of the NGPU used.

The control system was designed to have an optimization layer, given by the DMC3, and a regulatory layer, represented by different PI controllers present in the process. The main CVs of the process are:

- The ethane content of LPG
- The pentane content of LPG
- The Reid Vapor Pressure (RPV) of Naphtha
- The valve opening of the recycled flow rate of LPG back to the feed flow of the debutanizer column
- The condenser duty at the top of the debutanizer column
- The temperature at the top of the debutanizer column

The MVs for MPC are the setpoints of the variables:

- The reflux flow rate
- The temperature at the bottom of the demethanizer (T01)
- The temperature of the sensitive tray in the debutanizer (T03)
- The recycle flow rate
- The pressure at the top of the debutanizer
- The pressure at the bottom of the demethanizer

The simulation did not consider the presence of measurement noise. All variables were measured every minute without dead time. However, an artificial random noise was added to each sample of each variable to improve generalization.

### Data Generation

The simulation for generating the data was carried out considering 13 different scenarios with 10, 000 samples each. The scenarios include:

1. **Normal conditions:** absence of faults.
2. **Unmeasured disturbance:** a different disturbance applied to the system.
3. **Condenser loss of efficiency:** loss of efficiency in the condenser of the debutanizer column.
4. **Reboiler loss of efficiency:** loss of efficiency in the reboiler at the bottom of the demethanizer column.
5. **Valve stiction:** a dead band was considered in the recycled flow of LPG.
6. **Pentane content measurement error:** an offset in the measurement of pentane content was implemented.
7. **Recycle flow rate measurement error:** an offset in the measurement of recycled flow was implemented.
8. **Change in the PI tuning at the demethanizer column:** changes in the control tuning of the pressure controller.
9. **Change in the PI tuning at the debutanizer column:** changes in the control tuning of the recycle controller.
10. **Change in the MPC weights:** the weights related to the pentane content were modified to decrease the concern regarding this variable.
11. **Change in the MPC move suppression:** more free and aggressive movement of both the recycled flow rate and the temperature of the

sensitive tray in the debutanizer was considered.b

12. **MPC internal curves removed:** the curves describing the relationship between the setpoint of the recycled flow rate and the pentane content, the RPV of Naphtha, and the temperature at the top of the debutanizer were removed to simulate a plant-model mismatch.

13. **Change in model coefficients:** the coefficients of the curve that describe the relationship between the pentane content and the temperature at the sensitive tray of the debutanizer were changed to simulate an outdated model.

## Machine learning algorithms

The original dataset for both case studies was split randomly into data for training, validation, and testing, in the proportions of 64%, 16%, and 20%, respectively.

The input features for ML models, selected based on the physical knowledge of the system, were: the MVs included with up to two time lags; the integral of the time-weighted absolute errors (ITAE), considering the last 5 points of the controlled variables (CVs) with respect to their setpoints, and the prediction errors of these controlled variables. The ITAE of each CV was chosen to capture the error persistence through time, while the lagged MVs were chosen to capture dynamic behavior and the control actions. The prediction error, on the other hand, was chosen to capture model changes and the bias between the prediction and the measurement. This approach leads to a total of 10 features for the van de Vusse case study and 30 features for the debutanizer column.

RF and MLP were used to evaluate their performance in monitoring the NMPC and MPC closed loops. The implementations were carried out in Python. The architecture of each one was obtained by Optuna [20] after 100 trials, with the search conducted as follows:

- RF: The Python function RandomForestClassifier, from Scikit-learn, was used. Cross-validation was performed during optimizations, considering stratified K-folds with 5 folds. The objective function was the average accuracy of the test dataset. The optimized hyperparameters were:
    - Number of estimators between 10 and 100;
    - Maximum depth between 5 and 15;
    - Maximum features among "none", "sqrt", and "log2";
    - Minimum samples at each leaf between 5 and 10;
    - Criterion among "gini", "entropy", and "log_loss".
- MLP: The Python Tensor-Flow library was used. Early Stopping with a patience of 100 and a restore of the best weights was also used, considering the validation accuracy as a parameter. The reduction of the learning rate when accuracy achieved a plateau was also considered. The optimizer considered was Adam, and the batch size was 64. In each layer, a $L_2$ regularizer of 0.0001 was also used. The hyperparameters optimized were:
    - Number of layers between 2 and 4;
    - Number of neurons at each layer between 8 and 64;
    - Activation function among ReLU, LeakyReLU, and ELU;
    - Learning rate between $10^{-4}$ and $10^{-2}$;
    - Batch normalization between each layer: yes or no;
    - Dropout rate between 0.1 and 0.3.

F1-score and Accuracy, Equations (3) and (4), were used to compare RF and MLP results. TP denotes true positives, FP represents false positives, TN indicates true negatives, and FN refers to false negatives. An ideal scenario is one in which FP and FN are rare, while TP and TN are the majority. In such cases, these metrics tend to approach 1.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (3)$$

$$F1\text{-}score = \frac{2\times TP}{2\times TP+FP+FN} \quad (4)$$

The F1-score average used in this work, for both CMLM and SMLM, is the macro average, which calculates the F1-score for each label and then takes their unweighted mean. This average was used because, in this work, all classes are equally important, so they all have the same weight in the final value. Usually, on imbalanced datasets, the high metric score might be due to the correct classification of the majority class, while the minority class might have a poor result. The use of the unweighted average avoids this misinterpretation.

A total of 10 independent training sessions were performed for each ML model.

## RESULTS

Table 1 presents the metrics obtained for the multiclass classification and for each ML model of the CMLM for the Vande Vusse case study. The best results in Table 1, when comparing RF and MLP, are in bold font. It is possible to observe that models specializing in each fault have generally better performance than just a multiclass ML model. Only the first model, responsible for detecting abnormalities, when using MLP, has a slightly lower F1-score. The low standard deviation observed in each model training indicates that the metric values are consistent over the 10 independently trained models.

**Table 1:** Metrics of each ML model for the van de Vusse case study.

| **ML** | **RF** | | **MLP** | |
|---|---|---|---|---|
| Metric | Accuracy | F1 score | Accuracy | F1 Score |
| Multiclass | 0.8087 ± 0.0037 | 0.8128 ± 0.0038 | **0.8491 ± 0.0367** | **0.8502 ± 0.0397** |
| M1: Detection | 0.8379 ± 0.0023 | **0.8351 ± 0.0024** | **0.8789 ± 0.0047** | 0.8073 ± 0.0108 |
| M2: Valve Stiction | 0.9104 ± 0.0029 | 0.8885 ± 0.0038 | **0.9442 ± 0.0059** | **0.9244 ± 0.0078** |
| M3: Tuning | 0.9772 ± 0.0020 | 0.9746 ± 0.0022 | **0.9918 ± 0.0026** | **0.9908 ± 0.0029** |
| M4: Mismatch | **0.9679 ± 0.0019** | **0.9679 ± 0.0019** | 0.9580 ± 0.0025 | 0.9579 ± 0.0025 |

Before analyzing the results, it is important to understand how Accuracy and F1-score values should be compared. Accuracy is less sensitive to imbalanced datasets, and its high value might be due to the excellent performance of the majority class, independently of the minority class results. However, since the F1-score is taking the macro average, this metric is fairer to take into consideration the minority class, as all labels are treated as equally important. In M4 (diagnosing mismatch), where data is perfectly balanced, both the F1-score and Accuracy have similar values. M1 (detection), on the other hand, has a discrepancy between the values of those two metrics, which might be due to the artificial imbalance created in the cascade. Once the problem is turned into a binary classification, normal data becomes the minority class when compared to the other labels for this model. For this reason, F1-score is used as the priority metric to compare MLP and RF, while Accuracy is used to evaluate how well the majority class is being classified.

By comparing the performance of RF and MLP for each diagnostic model, it is possible to observe that RF models were better in diagnosing the parameter of mismatch (M4), while MLP models had slightly better performance in diagnosing valve stiction and poor tuning (M2 and M3). In the first model, responsible for detecting abnormalities in the control loop, the performance of MLP was better in terms of accuracy. However, the F1-score shows that this first model has better results with RF.

The reason for RF having better results in some situations might be due to the nature of this algorithm. RF based its predictions on hard boundaries of each feature, while MLPs are better at capturing nonlinear relationships between variables. For detection (M1) and diagnosis of mismatch (M4), the diagnosis is more based on whether the variables are higher than a given value. For the diagnosis of valve stiction (M2) and poor tuning (M3), which both cause oscillation in the closed-loop, MLP might be better suited to capture this nonlinear interaction.

The main advantage of using CMLM is that it gives a prompt diagnosis without exhaustive data investigation. One of the traditional methodologies applied in industry is using the standard deviation of variables to capture variability changes. This analysis is based on the minimum variance control theory and on the Harris Index [21] to monitor control performance. Aspen Watch and Schneider Electric's EcoStruxure Control Expert also use the variables' standard deviation as one of the metrics to evaluate the closed loop. Figure 7 shows the standard deviation time history of each MV ($F/V$ and $\dot{Q}$) and CV ($C_B$ and $T$) using a moving window of 100 samples (15 min of simulation). Visually, both the normal (blue area) and the valve stiction (green area) have the same range of standard deviation values, except for some samples equal to 0 for the $F/V$. Changes in the NMPC tuning and in its internal model parameters cause the standard deviation range for some variables to be different than those observed in normal conditions, especially regarding the tuning changes. However, the standard deviation gives information regarding a specific variable and does not give a clue to the root cause of this performance degradation.

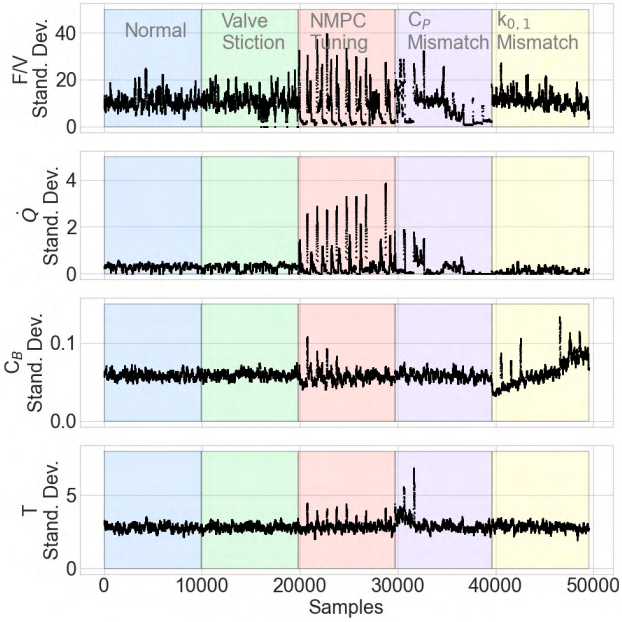

**Figure 7.** Standard deviation of the van de Vusse reactor.

To evaluate the method's scalability for industrial MPC implementations, a similar approach was tested in a debutanizer column. The results obtained are in Table 2, considering the cascade presented in Figure 3. The low standard deviation indicates the stability of the results. The metric values show that most of the models in the

CMLM approach have a better performance than the SMLM. Only the RF M1, responsible for the detection, has significantly lower performance. This may have occurred because the RF algorithm cannot capture the more complex differences between normal and abnormal samples using thresholds.

By comparing the performance between RF and MLP models, the MLP models outperformed RF in most models of the CMLM, even though some of them have just a slight difference. Curiously, the RF models in the CMLM that have a similar or better performance than the MLP models are those responsible for diagnosing between two alternatives of the same type of equipment (M5: which process equipment, M7: which sensor, M9: which PI). This might have happened due to the characteristic of the RF algorithm, which is better suited to classify problems related to a given threshold. Since those alternatives affect different variables in the process, RF can handle the classification properly.

Regarding the computational cost, for the evaluation of 1, 000 random samples for the debutanizer column, the CMLM spends an average of 0.4 seconds per sample for the MLP, with a maximum time of 1.4 seconds. This was evaluated on a computer with Intel(R) Core (TM) i7-12700, CPU 2.10 GHz, and 16.0 GB of RAM. This evidence reinforces the capability of CMLM to be applied to online monitoring.

## CONCLUSIONS

One of the goals of this study is to highlight the potential of using ML models for monitoring and diagnosing MPC performance. The method is more accurate than those currently used in industrial applications. The results show that ML models have the potential to diagnose control performance issues precisely, with CMLM having superior performance to a single multiclass model approach by isolating fault characteristics. By combining independent ML models, it is possible to use different model structures than a single type of ML model, taking advantage of the strengths of each ML tool. The two case studies show that the methodology can be implemented in both small and large industrial MPC applications. Even though the plant-model mismatch classification is too narrow and the source is usually not known, the case studies assume that the source of MPC degradation was limited to a few possibilities to explore how accurate the diagnosis of the ML models is. The diagnosis might be adapted to require the identification of only part of the process, instead of requiring the reidentification of the whole plant.

## ABSTRACT

Predictive maintenance is a promising approach to increase safety and productivity in chemical plants. One notoriously difficult problem in predictive maintenance are hard to predetermine, non-deterministic changes such as drifts. The term "drift" can be found with different definitions in this context. Therefore, it is defined here as changes in variables and parameters that occur orders of magnitude slower than the nominal process dynamics and are not directly measurable. Previous research resulted in a hybrid method that detects and diagnoses drifts from two sources: process and equipment. This method combines model-based and statistical approaches and additional information from the equipment, such as measurement gain or power consumption, is envisioned to reduce uncertainty about the drift cause [1]. First case studies revealed significant problems regarding economically viable integration of additional information. These problems arise due to the amount of information in scenarios with multiple devices, making analysis costly and time-consuming. For solving these problems, an automated evaluation of the information is introduced. It analyzes which additional equipment information is most relevant to distinguish between different drifts, based on sensitivity analyses. Additionally, a drift index - a unique mathematical label for drifts - is defined. The extended method is then successfully applied to a scenario closer to the reality in chemical plants with multiple adjacent devices. It is shown that the additional information is evaluated automatically and drifts are diagnosed more efficiently than in the previous method.

**Keywords**: Fault Detection, Process Monitoring, Drift Diagnosis, Additional Information, Predictive Maintenance

## 1 MOTIVATION

Reliability plays an important role in ensuring the safety and productivity of chemical processes. Increasing reliability by predictive maintenance is especially promising because it helps identifying equipment degradation and health status throughout its life cycle [2], [3]. A significant and challenging issue in predictive maintenance is the occurrence of drifts. The term “drift” has not yet become common in the literature on predictive maintenance. Therefore, it is defined here as not directly measurable changes in variables that occur orders of magnitude slower than the nominal process dynamics. This makes drift-related faults difficult to detect and diagnose. Examples of drifts include fouling of heat exchanger surfaces or the de-calibration of sensors.

To help solving the problem of drift detection and diagnosis, a hybrid fault detection and diagnosis (FDD)-method combining model-based and statistical approaches was developed [1]. This method selects and utilizes additional (freely) available data from the equipment, such as its power consumption, to reduce the uncertainty of assigning drifts as cause of observed faults. But how exactly does this information help distinguish between different drifts? Which additional equipment data is most useful for differentiating between different drifts? How can this information be evaluated?

These questions will be answered during this paper. First, the background of drifts is explained, including their types and definitions. Additionally, the fundamentals of the aforementioned method are presented. Next, the availability and utility of additional equipment information

are examined in more detail. Then the method is extended with an automated evaluation of additional data using sensitivity analysis. Our case study uses real data to investigate whether the automated evaluation of additional information and its implementation are reasonable and satisfactory, particularly in cases involving multiple devices and large amounts of additional information. Finally, the implications of extending the method regarding the overall method and potential future developments, is discussed.

## 2 BACKGROUND

The FDD-methods applied in predictive maintenance detect and diagnose faults for instance by data-driven approaches using principal component analysis and autoencoders [4]. Faults are defined as deviations of a set of observable process variables from an acceptable range [5] that are caused by failures or malfunctions of technical equipment. Faults caused by drifts, that is slow changes in not directly measurable variables are notoriously hard to detect. Firstly, drifts are, per our definition, typically much slower than the nominal dynamics of the process. Secondly, drifts may be attributed both to slow changes in the process (e.g. fouling) or the equipment (e.g. sensor de-calibration). Thirdly, different drifts may occur at the same time and influence or superposition each other.

A hybrid method combining statistical and model-based approaches was developed in [1] for the detection and diagnosis of drifts, even if they occur simultaneously. The model-based part of this approach utilizes a process simulation to generate empirical observations for known drift phenomena. The data provides the basis for a drift-related cluster analysis. The resulting clusters then-after are used to classify the data collected from the real plant. The procedure of the method is shown in Figure 1.

This hybrid method uses additional equipment information to identify characteristics that help distinguish between different drifts. Because drifts manifest themselves in the form of indirect consequences, such as increased energy consumption, less accurate positioning or changes in dynamic behavior. Therefore, with the help of additional information the space for classifying data and diagnosing drifts is defined. But this space is spanned by vectors that specify the different possible drifts. These drift vectors are defined in all available dimensions, that means with help of all measured variables m, consisting of primary and additional information. Thus, for n possible drifts, n drift vectors in m dimensions are spanned. So, an m-dimensional space is spanned with all available data. But for an unambiguously diagnosis of drifts, the n drift vectors must span an n-dimensional space. Therefore, they must be linearly independent of each other. Usually more measured variables are accessible than the required dimensions, so m > n. But when m > n, which information should be used?

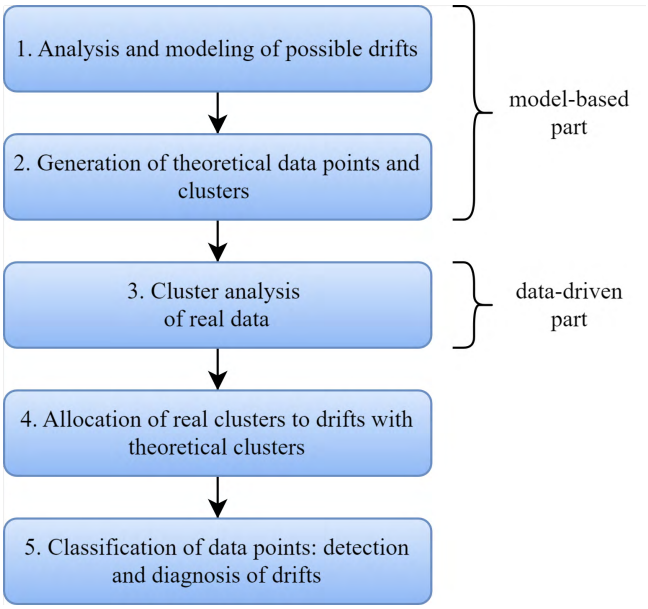

**Figure 1:** Workflow of the hybrid method from [1].

So, depending on how the space is defined in terms of its dimensions and axes, it becomes easier or more difficult to differentiate between drifts. Until now, this has been analyzed manually based on the independence of the drift vectors in different spanned n-dimensional spaces. But when n variables must be filtered out of m variables, the number of possible combinations increases significantly, especially as the number of variables increases. For example, when three drifts occur and five variables are measured, there are 10 possible combinations. If there are six variables, then there are 20 possible combinations. With seven variables, there are 35 combinations. The drift vectors must be defined for each combination of variables, and their independence must be checked. If, in addition, several combinations of variables define independent drift vectors, which combination makes the most sense? A process expert must decide this.

However, this cannot be used in practice because it requires too much computational effort and is too complex, especially in industrial plants with large amounts of data. That's why our goal is to expand the hybrid method with an automated evaluation of all available information to identify the most beneficial information for defining an n-dimensional space and efficiently diagnosing drifts.

## 3 ADDITIONAL EQUIPMENT INFORMATION AND THEIR EVALUATION

Modern devices typically record a lot of additional information to complement the primary measurement

values. Depending on the sensor or actuator being examined, various data is available, such as

- Power consumption,
- Measurement gain,
- Signal-to-Noise Ratio (SNR),
- Feedback of the valve position,
- Pressure to open a valve,
- Internal temperature of the device.

## 3.1 Availability of additional information

There are several ways to make this additional equipment data accessible to the FDD-methods. The traditional way would be to sample the data points via the process control system (PCS) and making it available for FDD on the PCS' process data historian. This is sometimes not possible in chemical plants because effort and demand are too high related to the amount of data. Therefore, there are two options: data reduction to acceptable amount or using a (standardized) side channel. But to reduce the amount of data, it must already be known at this point which data is needed, and which is not. A side channel via the NAMUR open architecture, for example, better addresses the additionality and expected changeability [6], [7].

## 3.2 Evaluation of additional information with the help of sensitivity analysis

In order to identify the most beneficial information for defining an n-dimensional space and efficiently diagnosing drifts, it is necessary to know which measured variables are most sensitive to drifts. A sensitivity analysis (SA) is suggested to do so. Such an analysis is used to investigate how the variation in the outputs of a model come from the variation in the input factors. Sensitivity analysis can be local or global, quantitative or qualitative and one-at-a-time (OAT) or all-at-a-time (AAT) [8]. Different purposes according to [8] are:

- Ranking / Factor Prioritization: the input factors are ranked based on their relative contribution to the variability of the output,
- Screening / Factor Fixing: input factors with negligible influence on the variability of the output are identified,
- Mapping: detection of the area of the input variability space where significant output values are produced.

To find the most beneficial additional equipment information, a SA is suggested that is global, AAT and prioritizes input factors. With a global SA, variations in the entire variability space of the input factors are considered. This is important, because otherwise a nominal value for the input factors would have to be specified. In an AAT method the input factors are varied simultaneously to get variations in the output. So, direct influences of each factor as well as joint influences through interactions are considered [8]. Factor prioritization ranks the contributions of input factors, or in this case, the available information. Thus, it is possible to identify which information is most sensitive to the output, or in this case, the different drifts.

Possible approaches are correlation & regression analysis or variance-based & density-based methods [8]. Here correlation analysis methods are used. In these methods the correlation coefficient between input factor $x_i$ and output $y$ is calculated with the help of statistical analysis of input/output datasets. These correlation coefficients are used as the sensitivity measures [8]:

$$S_i = correlation\,(x_i, y) \tag{1}$$

One type of correlation is the Pearson correlation coefficient (CC). It is for linear relations between the input factors $\boldsymbol{x}$ and the output $y$. Another type is the Spearman rank correlation coefficient (SRCC) for nonlinear relations that are monotonic [8]. Since we initially assume linear relationships, the correlations between the measured variables and the drifts are calculated with the Pearson correlation coefficient.

In this case, the input factors of the SA are the measured variables. This means all primary and additional information. The outputs are the various drifts, along with their corresponding theoretical data points, including the area without a drift. To determine the most sensitive information regarding the SA outputs, they require a unique mathematical labeling. As such a labeling the drift index $Drift_{ind}$ is defined. Each theoretical data point that belongs to a modeled clusters have such an index that is calculated with the following formula:

$$Drift_{ind} = Drift_{num} + l_{Vec,scal} \tag{2}$$

The number of the respective drift to which the data point belongs is denoted as $Drift_{num}$. It is an integer between 0 and n. The data points without drift have a value of 0, and the drift data points have values from 1 to n. Furthermore, the length of the respective data point vector $l_{Vec}$ is calculated. This data point vector is spanned from the zero point to the respective data point. Its scaled length is denoted by $l_{Vec,scal}$. An example of the drift index of theoretical data points in two-dimensional space is shown in Figure 2.

Then the Pearson correlation coefficients are computed and compared. The n measured variables with the highest coefficients are chosen. These are the n out of m variables to which the drifts are most sensitive.

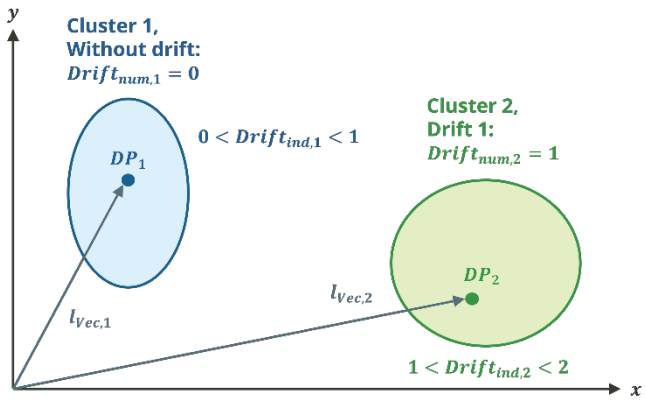

**Figure 2.** Example of the drift index for two data points $DP$ in two dimensions, which are in two different clusters. The indexes are composed of the respective drift number $Drift_{num}$ and the scaled length of the respective data point vector $l_{Vec,scal}$ . $DP_1$ has no drift and therefore a drift index between zero and one. $DP_2$ is part of the drift cluster and has a drift index between one and two.

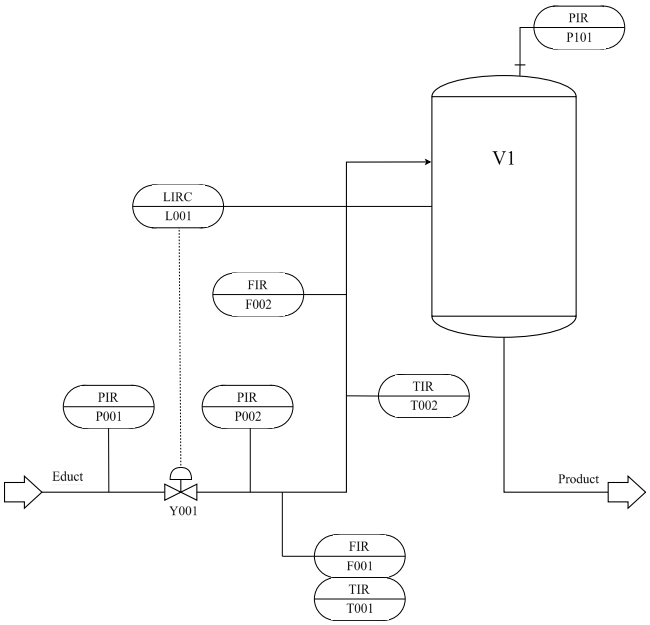

**Figure 3:** P&ID of the investigated case.

The global sensitivity analysis is implemented in an automated manner behind the cluster analysis of real data in Figure 1. In this step it is analyzed which measured variables are most sensitive regarding modeled drifts. Then the dimensions of the real and modeled clusters are adapted. So, all available information is evaluated automatically to identify the most beneficial information. That means only n of the m dimensions are used for assigning the clusters to drifts and the classification of new data points for detecting and diagnosing drifts. Since this selection is made automatically, the computational power and time to get detection and diagnosis results, is reduced.

## 4 CASE STUDY

A case study is conducted to demonstrate that the method with automatic evaluation can be applied to increase the efficiency compared to [3].

**Table 1:** Measured variables of the scenario considered.

| Measured value | TAG | Symbol | Type of information |
|---|---|---|---|
| Flow rate ultrasound | F001 | $F_1$ | Primary |
| Flow rate inductive | F002 | $F_2$ | Primary |
| Temperature 1 of medium | T001 | $T_1$ | Primary |
| Temperature 2 of medium | T002 | $T_2$ | Primary |
| Position of position controller | Y001 | $D$ | Additional |
| Pressure of position controller | Y001 | $P_{Pos}$ | Additional |
| Pressure control air | Y001 | $P_{Air}$ | Additional |
| Calculated actuating value | Y001 | $Y_{Calc}$ | Additional |
| Temperature position controller | Y001 | $T_{Pos}$ | Additional |
| Measurement gain ultrasound | F001 | $G$ | Additional |
| Signal to noise ratio (SNR) | F001 | $SNR$ | Additional |
| Sound velocity | F001 | $V$ | Additional |
| Pressure before valve | P001 | $P_1$ | Primary |
| Pressure behind valve | P002 | $P_2$ | Primary |
| Actuating value of valve | Y001 | $Y$ | Additional |
| Level of tank | L001 | $L_{tank}$ | Primary |
| Pressure in tank | P101 | $P_{tank}$ | Primary |

The case study refers to a real-world chemical plant using the data from several adjacent devices as shown by the P&ID of this configuration in Figure 3. A three-phase liquid with solids due to crystallization and gas bubbles flows through the pipes. The actuator is the control valve Y001 in front of a tank V1. The flow rate into V1 is measured using the ultrasound sensor F001 as well as with the inductive flow sensor F002. The temperature of the medium is measured redundantly with the sensors T001 and T002. The pressure before and after the control valve is measured with the sensors P001 and P002.

Furthermore, there are sensors that measure the level L001 and pressure P101 in the tank. The system runs continuously and automated. The level in the tank L001 is controlled with the valve Y001. Table 1 lists all the variables of the measuring devices considered. It also indicates whether the information is a primary or additional measurement value.

Various drifts can occur in this scenario under the assumption that the temperature and pressure sensors are free from deposits and abrasions. The possible drifts and their effects are described below:

- Equipmentdrift 1 (Eq1): Due to deposits that have slowly accumulated, the control valve is stuck and does not open properly.
- Equipmentdrift 2 (Eq2): Due to aging processes in the valve, it closes less effectively over time until it finally fails to close completely.
- Processdrift 1 (Pd1): The quality of the educts changes over time and deteriorates. Reasons could be increased proportions of gas bubbles or solids as well as other medium changes.
- Processdrift 2 (Pd2): Due to changes in the process, the flow rate has fallen below the desired specification.
- Processdrift 3 (Pd3): Due to changes in the process, the flow rate has increased above the desired specification.
- Processdrift 4 (Pd4): An unforeseen slow change in the process has reduced the temperature of the medium.

The area without any drifts as well as the drift areas are modelled using a mechanistic approach. But parameters, nominal process values and relationships between variables are calculated with the help of available real data. Then, theoretical data points and clusters are generated. Following the available data from the real plant is normalized and clustered. The data points are divided into three clusters and outliers. After that the evaluation of the measured variables with the method described in Section 3 resulted in the following ranking:

1. Signal to noise ratio $SNR$,
2. Sound velocity $V$,
3. Measurement gain ultrasound $G$,
4. Temperature 2 of medium $T_2$,
5. Temperature 1 of medium $T_1$,
6. Flow rate inductive $F_2$.

These six variables are used for all subsequent steps in the method. Half of the variables are additional equipment information, and the other half are primary measurement values. The measurement gain, which was identified as important through sensitivity analysis, can detect the deterioration of the reactant quality over time. This occurs because the presence of additional gas bubbles or solids interferes with the ultrasound measurement and slowly increases its gain over time. Figure 4 shows this phenomenon. The gain increases slowly over two and a half hours, rising from 33 to over 40. This example shows that useful information can indeed be identified through the automatic evaluation.

Then the real clusters are assigned to the drifts. In this case, a cluster is assigned to Processdrift 1. Another cluster is identified as drift-free. The final cluster cannot be assigned to a drift. It is close to Processdrift 1 and far from all the other modeled drifts. The data points of the unassigned cluster, as well as the outliers, do not belong to any drift. They are outside the assigned clusters and therefore possible combinations of drifts. These data points are categorized and their causes are diagnosed using the further procedure from [1]. For this purpose, a combination of real and modeled clusters is used. Only one real drift cluster exists. For the others', modeled clusters are used. The process of diagnosing combinations of drifts will not be explained in detail here. For more information, see [1]. As a result, the following combinations of drifts are diagnosed:

- Eq2 and Pd1,
- Pd1 and Pd3,
- Pd1 and Pd4.

Based on these diagnostic results, it can be concluded that the most common drift is Processdrift 1: The quality of the educts changes over time and deteriorates. One real cluster is assigned to this drift, and it occurs in every combination of drifts. In contrast, equipment drifts rarely occur alone.

But how efficient is the method with automatic evaluation compared to without? If the method were applied to this case without automated evaluation, the following steps would have had to be taken:

- Combination of all possibilities to span a six-dimensional space from 17 measured variables (12, 376 possible combinations)
- Definition of drift vectors for all combinations,
- Checking if the drift vectors are independent,
- Collection of all combinations with independent drift vectors and manual decision which combination is the best by a process expert.

These steps are time-consuming and expensive. In contrast, automated evaluation only requires assigning a drift index to all theoretical data points and performing a

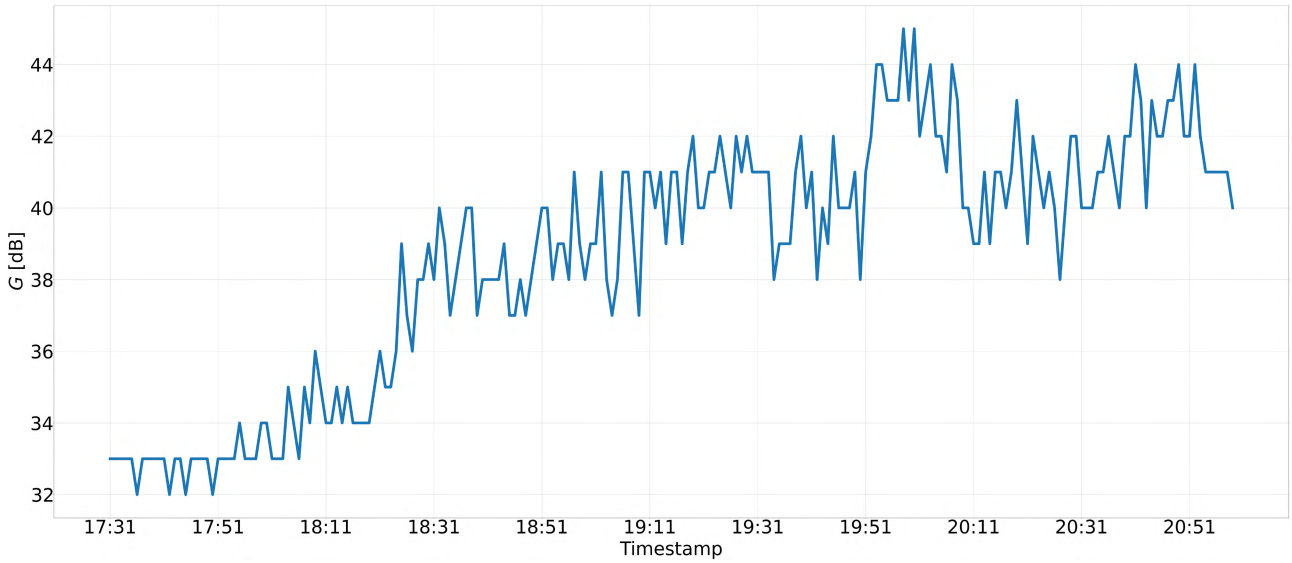

**Figure 4.** The measurement gain $G$ increases slowly over two and a half hours, rising from 33 to over 40. Through the increase in this additional information a change in the quality of the educts can be diagnosed (Processdrift 1).

sensitivity analysis. The variables with the highest sensitivities are then selected. This procedure must only be applied once, making it significantly less time-consuming and costly.

## 5 DISCUSSION AND OUTLOOK

This paper demonstrates how additional equipment information can be used in the most beneficial way for an efficient detection and diagnosis of drifts. A hybrid method for detecting and diagnosing drifts was developed in [1]. This method uses additional information to distinguish between drifts. But to do so, it requires manually selecting the most useful information. This process is time-consuming and costly. This renders the method impractical for use in real-world applications. Thus, an automated evaluation of the additional information was introduced to expand the hybrid method. This evaluation is based on sensitivity analysis; in particular, correlation coefficients are used. Besides that, the drift index is introduced during this process. It represents a unique mathematical designation for data points that have been assigned to specific drifts.

The extended method was successfully applied to a scenario involving multiple adjacent devices. A control valve in front of a tank, along with various flow, pressure, and temperature measurements, were examined. Thus, the method was successfully applied to a more realistic case. Furthermore, it was demonstrated that the automated evaluation of the information increases the method's efficiency compared to [1].

However, the method continues to have problems with processes that have varying process conditions or different dynamics. Changes in drifts or new additions are not considered. Future research should focus on developing strategies for dealing with changes in process conditions and higher process dynamics.

## ABSTRACT

Offshore natural gas compression systems are characterized by strong hydraulic coupling, nonlinear behaviour, and strict safety constraints, particularly in high-$CO_2$ production environments. Conventional decentralized PID control with anti-surge protection ensures reliable local regulation but often leads to poor plant-wide coordination and persistent offsets when multiple compression trains, recycle loops, and separation units interact dynamically. Although multivariable control strategies such as model predictive control can address these issues, their industrial application remains limited by modeling effort, computational demand, and robustness concerns. This work presents a hybrid supervisory control framework in which reinforcement learning (RL) augments an existing PI-based architecture for an offshore gas compression system with membrane-based $CO_2$ separation. A Proximal Policy Optimization (PPO) agent is trained on a dynamic digital-twin model of export, $CO_2$, injection, and bypass compression trains with shared headers, recycle flows, and thermal constraints. The RL agent acts exclusively at the supervisory level, providing bounded incremental adjustments to pressure and bypass setpoints, while all regulatory PI loops, anti-surge protections, and safety logic remain unchanged. Closed-loop simulations under representative disturbance scenarios show that the RL-supervised architecture significantly improves plant-wide coordination. Compared to fixed-setpoint PI operation, total tracking error (IAE) and time-weighted error (ITAE) are reduced by approximately 54% and 56%, respectively, using smooth, low-magnitude supervisory actions. In addition, RL achieves performance close to that of a nonlinear MPC benchmark based on a random-shooting, MPPI (Model-Predictive Path Integral) formulation, while requiring substantially lower online computational effort. The results demonstrate that RL can be effectively integrated as a supervisory layer in offshore gas compression systems without replacing established industrial control infrastructure, although additional safety mechanisms are still required to ensure stricter constraint satisfaction.

**Keywords**: Offshore gas compression, reinforcement learning, supervisory control, PI control

## INTRODUCTION

Natural gas compression systems play a central role in offshore oil and gas production, particularly in fields with high $CO_2$ content such as Brazil's pre-salt reservoirs. In these environments, compression is essential for enabling $CO_2$ separation, gas export, reinjection, and downstream processing, while simultaneously representing one of the largest contributors to onboard energy consumption and operational cost [1, 2]. Modern offshore facilities typically rely on multistage centrifugal compressors operating under tight constraints on pressure, flow rate, rotational speed, and surge margin, which must be satisfied under highly variable operating conditions.

In industrial practice, gas compression trains are commonly controlled using layered architectures based on proportional–integral–derivative (PID) controllers, complemented by anti-surge protection systems and

hard safety interlocks [3]. While such architectures provide reliable local control and are well established in industry, their performance deteriorates in highly coupled systems where multiple compressors, recycle valves, membranes, and headers interact dynamically. In offshore facilities, interactions between parallel compression trains create strong loop interactions, often resulting in oscillatory behaviour, conservative operation, and limited plant-wide coordination [4].

To overcome these limitations, advanced control strategies have been extensively investigated in offshore applications over the last two decades. Model Predictive Control (MPC), in particular, has been successfully applied to gas processing and compression systems, improving constraint handling, multivariable coordination, and operational efficiency compared to decentralized PID control [5, 6]. Nevertheless, the deployment of MPC in large-scale offshore compression systems remains challenging due to the high modeling effort required, the nonlinear nature of compressor maps, frequent changes in operating regimes, the need for robust performance under significant disturbances and uncertainty, and the required computational infrastructure.

At the same time, increasing attention has been given to the environmental impact of offshore gas production. Compression systems are responsible for a substantial fraction of platform-wide energy consumption, typically supplied by gas turbines, which account for the majority of $CO_2$ emissions in offshore installations [7]. In addition, inefficient operation may lead to increased flaring, recycle flows, and pressure violations, further increasing emissions and reducing overall efficiency. As a result, improving the operational efficiency and stability of gas compression systems is directly aligned with broader efforts to reduce greenhouse gas emissions and comply with international climate targets [8].

In this context, data-driven control methods based on Reinforcement Learning (RL) have emerged as a promising alternative for the control of complex, nonlinear, and highly coupled process systems. By learning control policies through interaction with a dynamic environment, RL techniques can address multivariable coordination problems without relying on explicit linearized models, making them attractive for systems characterized by nonlinear dynamics, strong interactions, and changing operating conditions [9, 10]. Recent studies have reported encouraging results for RL-based control and optimization in energy systems and chemical processes, including continuous control problems with constraints, disturbances, and nonlinear dynamics [11]. These works show the potential of modern policy-gradient and actor–critic methods to outperform conventional controllers in terms of tracking performance, efficiency, and adaptability.

Nevertheless, the direct application of RL to safety-critical industrial systems remains limited. Key challenges include guaranteeing constraint satisfaction, ensuring robustness under unmodelled disturbances, maintaining interpretability for operators, and safely integrating learning-based components with existing control infrastructures [12]. These concerns have motivated increasing interest in hybrid and hierarchical architectures that combine RL with conventional control layers.

A pragmatic approach to mitigate these limitations consists in embedding RL within hierarchical control architectures, in which learning-based agents operate at a supervisory level, while conventional controllers remain responsible for direct actuator manipulation. In such hybrid schemes, the RL agent adjusts setpoints or high-level targets, whereas low-level PID controllers, anti-surge loops, and safety interlocks enforce fast dynamics and operational constraints [13]. This structure preserves the reliability and transparency of industrial control systems while enabling adaptive, plant-wide coordination and optimization. Related concepts have been explored in supervisory, economic, and learning-based control layers; however, their application to multistage offshore gas compression systems with $CO_2$ separation and strong hydraulic coupling between trains remains relatively underexplored.

This work proposes a hybrid PI–RL supervisory control strategy for an offshore gas compression system. It comprises multiple interacting compression trains and a membrane-based $CO_2$ separation unit. A dynamic plant model was developed as a simplified digital twin, incorporating centrifugal compressor models, composition-dependent thermodynamics, valve flow dynamics, recycle loops, and operational constraints representative of industrial practice [1, 4]. The RL agent, trained using Proximal Policy Optimization (PPO) [14], acts exclusively on supervisory setpoints related to pressure and capacity, while conventional PI controllers and anti-surge protections remain unchanged.

To ensure learning stability and reflect operational priorities, a structured reward-shaping strategy was adopted. In addition to tracking export flow and key suction pressures, the reward incorporates soft penalties for violations of compressor discharge temperature limits, excessive anti-surge recycle activity, undesirable valve usage, and abrupt setpoint movements. Temperature constraints are enforced through continuous penalties activated beyond predefined soft limits, discouraging sustained operation at elevated discharge temperatures that could compromise equipment integrity and efficiency. This multi-term reward formulation, inspired by fuzzy-logic concepts and robust loss functions, introduces tolerance regions around nominal operating targets while penalizing asymmetric deviations, thereby preventing overly aggressive control actions and improving training robustness under disturbances [15].

The proposed approach was evaluated using closed-loop simulations based on real offshore gas compression system subject to disturbances in inlet flows and operating conditions. Performance was assessed relative to conventional fixed-setpoint PI operation using standard control performance metrics.

# METHODOLOGY

## 1. Case study and control objective

This work considers the offshore gas-compression and high-$CO_2$ management system of an offshore platform. The unit has strong interactions between separation, compression, export, and reinjection. Figure 1 presents the process flow diagram (PFD) used as the reference for the modeling and control design. The system comprises: (i) a membrane-based $CO_2$ separation unit generating retentate (treated gas) and permeate ($CO_2$-rich gas), (ii) export compression, (iii) $CO_2$ compression for reinjection/EOR, (iv) injection compression, and (v) bypass routing that allows partial or full diversion around the membrane unit depending on the operating mode (export vs. injection priority).

The routing and coupling structure that drives the control problem can be seen in Figure 1: after the membrane split step, the retentate flow is routed for compression and exportation, while the permeate flows for $CO_2$ compression. The bypass stream modifies both membrane feed and downstream load. Shared headers link export and injection trains; thus, changes in exportation demand or bypass fraction propagate through suction pressures, discharge pressures, and recycle activity.

The operational goal is to maintain safe and efficient operation under disturbances (production flow swings, routing changes, header pressure shifts) while ensuring:

- Header and train stability: suction/discharge pressures remain within allowable envelopes to prevent compressor trips and surge;
- Export delivery tracking: export flow (or export capacity) follows a target consistent with pipeline constraints and gas quality;

$CO_2$ management: membrane operation and bypass routing are coordinated so that the $CO_2$ content in the treated gas (when exporting) is kept within specification, while $CO_2$-rich permeate is compressed for reinjection when required;

- Coupling-aware coordination: shared headers and routing decisions couple export and injection demands, and membrane permeate pressure is coupled to the suction setpoint of the $CO_2$ train, impacting separation driving force and downstream compression load.

These couplings motivate a hierarchical control architecture. Fast stabilization and protection remain handled by conventional regulatory control (PI loops, anti-surge and operational interlocks), while a supervisory layer performs slower coordination by adjusting a small set of economically and operationally meaningful setpoints (pressures and bypass routing), targeting global feasibility, constraint compliance, and reduced recycle/energy waste.

## 2. Dynamic simulation model

A dynamic simulator was implemented in Python to enable closed-loop testing and training of the supervisory controller. The model follows a simplified digital-twin philosophy: it preserves the dominant pressure–flow accumulation dynamics, train couplings (shared headers, membrane routing), and actuator nonlinearities needed for control design, while remaining computationally efficient for RL rollouts.

### 2.1 Compressor trains and stage calculations

Each compression section is modeled as a series of centrifugal compressor stages, each represented by a performance map embedded within a dynamic mass and energy balance. For each stage, an iterative procedure matches volumetric flow and operating point to compute polytropic head, efficiency, power, and discharge temperature.

Composition effects are captured through mixture properties (molecular weight, Mw, and compressibility factor, $Z$), allowing the simulator to represent performance shifts due to varying $CO_2$ fraction (especially relevant across the membrane split and bypass changes).

### 2.2 Vessel/header pressure dynamics

Dynamic pressure behavior is represented by vessels/headers that capture the dominant accumulation effects in each section, providing the state evolution used by the control loops and the RL observation vector. (These dynamics are exposed to the RL agent primarily through suction and discharge pressures per train, see Section 4.)

### 2.3 Valve and recycle-flow modeling

Valve flows are modeled using a compressible-flow relationship, given by Equation (1).

$$\dot{m} = \phi(u) K p_{up} C_v \sqrt{\frac{(p_{up} - p_{down})^+}{p_{up} T Z}} \tag{1}$$

where $u$ is the valve opening, $\phi(u)$ represents the installed valve characteristic (linear, equal-percentage, or quick-opening), $p_{up}$ and $p_{down}$ are upstream and downstream pressures, $T$ is absolute temperature, $Z$ is compressibility factor, $C_v$ is the valve coefficient, and $K$ is a unit-conversion constant. The "$(\bullet)^+$" operator prevents non-physical negative pressure drops.

Anti-surge behavior is represented through recycle flows per train/stage, which are also included as monitored variables and (optionally) penalized in the reward

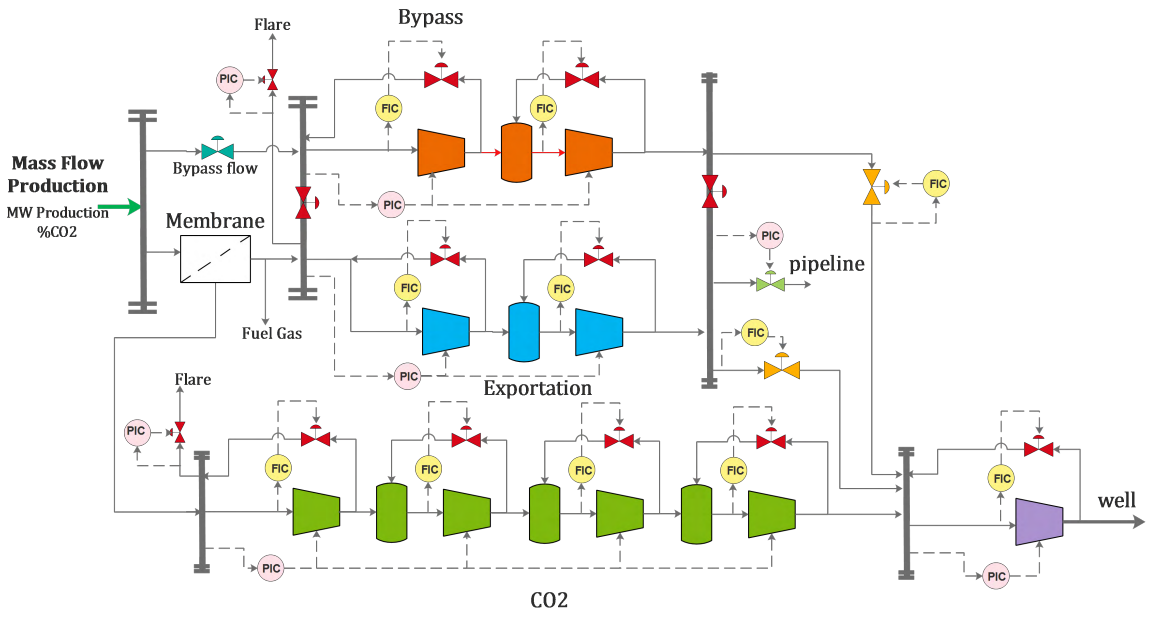

**Figure 1.** Flowchart of the compression system of the real offshore platform.

to discourage unnecessary recycle activity.

### 2.4 Membrane $CO_2$ separation unit

The membrane unit is modeled as a pressure-driven separation process that splits the feed into retentate (treated gas) and permeate ($CO_2$-rich) streams. An empirical bias term is included to represent non-ideal effects such as aging or performance degradation, while outlet molecular weights are updated based on the resulting gas composition.

The retentate is routed to the export compression section, while the permeate is routed to the $CO_2$ compression section. The permeate-side pressure is directly linked to the $CO_2$ compression suction setpoint, explicitly coupling membrane separation performance with downstream compression conditions and supervisory control actions.

## 3. Disturbance modelling

To assess the robustness and system-level coordination of the supervisory controller, a severe load disturbance is considered. At time t=400s, the production mass flow is subjected to a step increase of 20 kg/s. This scenario imposes an immediate thermal and mechanical load on the compression system, leading to increased discharge pressures and temperatures across all compression trains, including the export, $CO_2$, and injection sections.

## 4. Hierarchical control architecture

The proposed control structure is hierarchical and explicitly preserves the regulatory and protection logic of the compression system. The inner layer consists of conventional PI controllers, anti-surge loops at each compression stage, actuator saturation, and split-range logic.

The RL agent operates strictly at the supervisory level and does not bypass or override the inner-loop protections. Instead, it provides bounded adjustments to selected setpoints that are already used by the PI controllers.

### 4.1 Action space

The RL agent operates in delta (incremental) mode, outputting bounded changes to supervisory setpoints at each control interval. This choice enforces smooth behavior, avoiding abrupt operating-point shifts. The action vector and its numerical bounds are defined in Table 1.

**Table 1:** Action space configuration.

| Action | Description | Lower Bound | Upper Bound | Units |
|---|---|---|---|---|
| $\Delta \dot{m}_{bypass}$ | Bypass flow target | -1 | +1 | kg/s |
| $\Delta p^{sp}_{s,exp}$ | Export suction pressure setpoint | -500 | +500 | kPa |
| $\Delta p^{sp}_{d,exp}$ | Export discharge pressure setpoint | -500 | +500 | kPa |
| $\Delta p^{sp}_{s,co2}$ | $CO_2$ suction pressure setpoint | -5 | +5 | kPa |
| $\Delta p^{sp}_{s,inj}$ | Injection suction pressure setpoint | -50 | +50 | kPa |

### 4.2 Observation vector

The observation vector consists of 28 continuous variables, selected to expose the dominant coupling mechanisms, constraint indicators, and dynamic states relevant for supervisory coordination. Specifically, the environment returns:

- Time $t$(s);
- Suction, intermediate, and discharge pressures for the bypass, export, $CO_2$, and injection sections;
- Compressor "rotation proxies" for bypass, export, $CO_2$, and injection trains;
- Mass flows: bypass, membrane outputs to export and $CO_2$, and export inlet flow;
- Treated-to-injection valve opening;
- Recycle volumetric flows for bypass and each compression section/stage;
- Discharge temperatures for export stage 2 and $CO_2$ stage 4;
- Current export capacity setpoint (included as a state variable for consistency).

## 5. Reward design

A multi-term reward is used to align learning with operational goals: (i) tracking/coordination, (ii) anchoring around desired operating targets, and (iii) safety penalties dominated by discharge temperature constraints. The instantaneous reward is defined by Equation (2).

$$r = r_{track} + r_{temp} + r_{soft} \quad (2)$$

### 5.1 Tracking

Tracking terms penalize deviations in suction/discharge pressures and export flow, with weights assigned to reflect operational priorities. In particular, $CO_2$ pressures receive stronger emphasis because they directly affect membrane driving force. An additional target anchoring term penalizes excessive deviation of supervisory setpoints from nominal operating targets.

### 5.2 Temperature constraints

Thermal safety is encoded explicitly through continuous penalties activated beyond stage-specific discharge temperature limits. The following limits are used:

- $T_{lim,bypass} = 390\ K, T_{lim,export} = 410\ K$,
- $CO_2$ stages: $[400, 440, 420, 420]\ K$ (stages 1-4),
- weights: $w_{temp,co2} = 6.0, w_{temp,export} = 2.0, w_{temp,bypass} = 2.0, w_{temp,injection} = 1.0$.

A soft margin of 5 K is applied before the penalty increases steeply, and temperature exceedances are normalized by a 10 K scale.

### 5.3 Soft penalties

Additional soft penalties are included to promote operational efficiency and smooth control behavior. Recycle activity is aggregated from recycle flows across sections: bypass, export (stages 1–2), $CO_2$ (stages 1–4), and injection. Valve usage is represented by the treated-to-injection valve opening, and action smoothness is penalized via the $L_1$ norm of the action vector.

## 6. RL algorithm and training procedure

The supervisory policy is trained using PPO [14] with a multilayer perceptron (MLP) policy consisting of two hidden layers of 256 neurons each.

The main hyperparameters are: learning rate $3\times10^{-4}$, discount factor $\gamma$ = 0.99, GAE $\lambda$ = 0.95, clipping range 0.2, $n_{steps}$ = 2048, $n_{epochs}$ = 10, batch size 256, and random seed 42.

Each episode lasts 3000 simulation steps with $\Delta t$=0.1 s, corresponding to 300 s of plant operation. Training was performed on a CPU-only workstation (24 logical cores) for a total of 200 episodes (≈$6\times10^5$ steps in total).

During training, the best-performing policy is selected based on the rolling mean of episode rewards and saved for post-training evaluation. After training, the selected policy is evaluated in closed-loop simulations using deterministic action selection.

## 7. NMPC benchmark controller

As a benchmark, a stochastic nonlinear model predictive control (NMPC) strategy was implemented using a random-shooting approach inspired by Model Predictive Path Integral (MPPI) control [16].

The same supervisory action space and objective function used by the RL controller was adopted. The final configuration used a prediction horizon of 8 steps and a control horizon of 2 steps, with 16 candidate sequences evaluated every 6 simulation steps, and 4 elite samples used for action selection.

# RESULTS AND DISCUSSION

## 8 Training convergence

The PPO-based supervisory policy converged within approximately 80–100 episodes (Figure 2). With an average simulation throughput of 129 steps/s, the complete training required approximately 77.5 minutes.

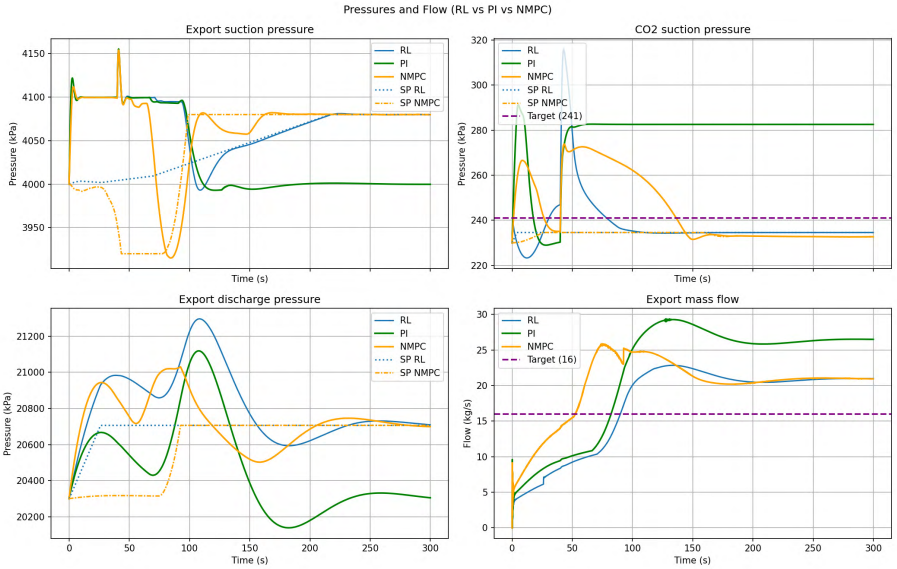

**Figure 3.** Closed-loop pressures and export flow under PI, RL, and NMPC control.

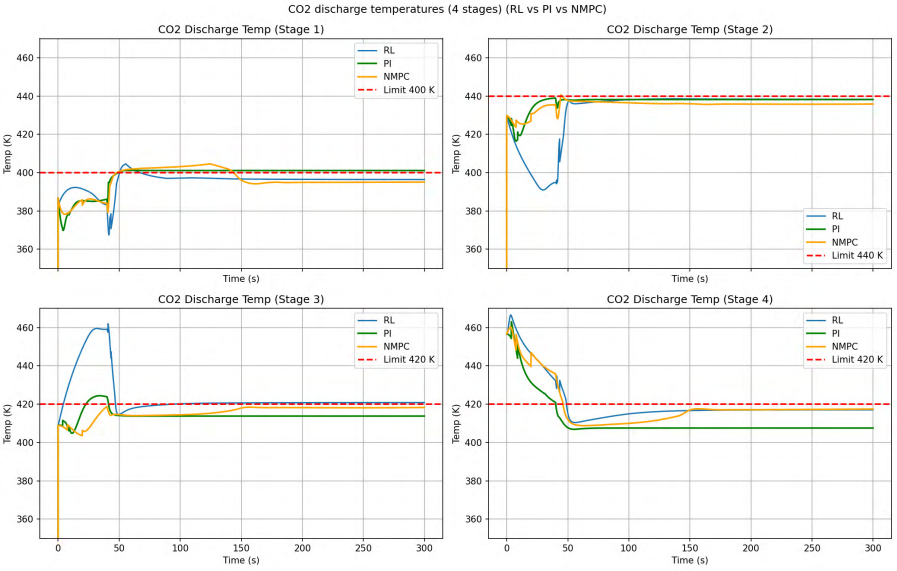

**Figure 4.** $CO_2$ compressor discharge temperatures (stages 1–4) under PI, RL, and NMPC control; dashed lines indicate temperature limits.

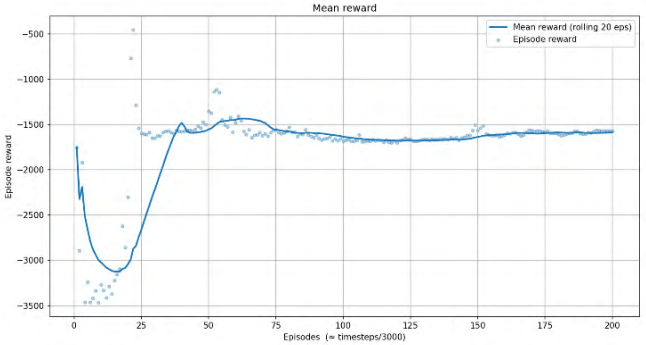

**Figure 2.** Training mean reward versus episodes.

## 9 Closed-loop control

Figure 3 shows that RL and NMPC converge to similar steady states, both outperforming PI. Their main difference is in the transient response: NMPC yields smoother but slower corrections, while RL applies more aggressive initial actions before stabilizing.

Figure 4 highlights that RL produces larger temperature excursions, particularly at $CO_2$ stage 3, where constraint violations are more frequent. These results indicate that RL's aggressive transient actions improve coordination but weaken constraint satisfaction.

## 10 Quantitative performance comparison

Table 2 compares RL, PI, and NMPC in terms of tracking, energy, safety, control effort, and computational cost.

**Table 2:** Controllers' performances.

| Metric | RL | PI | NMPC |
|---|---|---|---|
| IAE | 322, 462 | 699, 682 | 310, 400 |
| ITAE | $48.94\times10^6$ | $111.48\times10^6$ | $46.54\times10^6$ |
| Mean power (HP) | 25, 979 | 25, 090 | 24, 212 |
| Total abs. power change (HP) | 28, 241 | 30, 572 | 31, 115 |
| Temp. violation total count | 5, 701 | 3, 178 | 3, 053 |
| Temp. violation total magnitude | 43, 252 | 35, 423 | 30, 931 |
| $\int u^2\,dt$ | 1202.20 | 0.00 | 2765.63 |
| Evaluation time (s) | 71.04 | 65.28 | 3895.77 |

In terms of tracking, RL and NMPC achieve comparable performance and clearly outperform PI, with similar IAE and ITAE values. From an energy perspective, NMPC achieves the lowest mean power, while RL operates at a slightly higher level. However, RL exhibits the lowest total absolute power variation, indicating less aggressive load changes despite similar steady-state performance.

Regarding safety, RL shows the highest temperature-violation count and magnitude, confirming that the current reward-based formulation allows stronger transient excursions. In terms of control effort, RL is significantly smoother than NMPC, with much lower integral quadratic control effort ($\int u^2 dt$), indicating less aggressive supervisory actions.

Finally, computational cost highlights a key advantage of RL. While RL and PI have similar evaluation times, NMPC is more than one order of magnitude slower.

### 11 Limitations and scope of applicability

The present work is based on a simplified digital twin and does not account for all sources of uncertainty present in real offshore systems, such as sensor noise, actuator degradation, and long-term equipment aging. The evaluation was conducted under a limited set of disturbance scenarios. Although the RL policy generalizes well within this range, its robustness to broader operating conditions remains to be assessed.

Safety is handled through soft penalties, which leads to transient constraint violations. Practical deployment would require additional mechanisms such as hard constraint enforcement or action shielding. Finally, the study considers a single-agent supervisory policy. Extensions to multi-agent formulations, economic objectives, and online adaptation remain open research directions.

## CONCLUSIONS

This work showed the feasibility and benefits of integrating reinforcement learning as a supervisory layer in a multistage offshore gas compression system, improving plant-wide coordination while preserving conventional PI control and safety logic.

The RL-supervised strategy significantly outperforms PI, reducing IAE and ITAE by approximately 54% and 56%, respectively. Its performance is also close to NMPC, with differences of only about 4–5%, and both approaches converge to similar steady-state operating points.

From an operational perspective, RL provides smoother actuation, as the quadratic control effort is reduced by approximately 57% compared to NMPC. In terms of energy, NMPC achieves the lowest mean power consumption, while RL operates about 7% above NMPC and slightly above PI.

A key limitation of the current approach is safety performance. RL exhibits higher temperature violation frequency and magnitude, with approximately 80–90% more violation events and about 40% higher total violation magnitude compared to NMPC. These results reflect the use of soft penalties in the reward function, which allow stronger transient excursions (particularly during early adaptation phases) before converging to safer operation.

Finally, computational cost strongly favors RL. While NMPC requires approximately 55× more evaluation time, the RL policy can be executed with negligible online overhead. Combined with a moderate offline training time (≈77.5 minutes on CPU), this makes RL a computationally efficient alternative for real-time supervisory control.

Future work will focus on strengthening safety guarantees through hard constraint enforcement, extending evaluation across multiple disturbance scenarios, and assessing robustness and transferability toward real offshore operating conditions.

## ABSTRACT

Recurrent neural nets (RNNs) are now commonly used for the surrogate modeling of process systems, leading to better control and faster real-time optimization. However, when trained with small training data sets, most experiments show that RNNs exhibit poor generalization abilities outside the range of the training data space. Nonetheless, recent advances in deep learning research have shown that certain characteristics of the loss landscape of trained models, such as the flatness around the local minimum, tend to relate to generalization ability. This paper investigates this phenomenon for the case of RNN surrogates of the well-known Three Tanks case study, which is representative of many continuous processes. We trained a total of 200 LSTMs (long short-term memory networks) differing in initialization, architecture, and training dynamics on the same data of 500 samples. The number of model parameters ranges from 238 to 11, 353. We estimated the loss curvature of each trained model using the Hessian-vector products method and then evaluated their test accuracy on 100 pre-generated data sets with 50% larger input amplitude than the training data to force extrapolation. We found that the estimate of the top eigenvalue of the Hessian matrix is 75% rank-correlated to the one-step-ahead prediction accuracy averaged on all test data sets. We report other insights on the impact of other Hessian-based metrics to generalization ability. Our study can potentially inform how to control the training dynamics of RNN surrogates to improve their extrapolation ability in the absence of first-principles knowledge.

## INTRODUCTION

Nonlinear system identification tools are now used for the surrogate modelling of continuous industrial processes. Common tools include Koopman models, kernel subspace methods, and neural nets [1]. The recurrent neural net (RNN) is a prominent type of deep learning model suitable for multivariate time series data. Previous works already used RNNs to achieve nonlinear model predictive control (MPC) [2], fault detection [3-4], and process optimization [5] in various case studies.

Despite these applications, the generalizability of RNNs is still poorly understood. In cases where industrial data is scarce or has poor quality, achieving a high validation accuracy does not guarantee good performance during deployment [2]. When the model encounters out-of-distribution data or if it is forced to extrapolate from the training data space, model errors may amplify as it makes future predictions. Yet researchers aim to train valid RNN models from start-up to shutdown [6].

One way to understand the validity of RNNs is to derive generalization bounds. For instance, based on the Rademacher complexity approach [7], RNNs were proven to generalize better with more training samples and simpler architectures. Meanwhile, vanilla RNNs with ReLU (rectified linear unit) activation were shown to generalize better with lower matrix 1-norm and Fisher-Rao norm of the weights, which is consistent with improvements via weight decay and gradient clipping. Recently, [8] obtained tighter bounds on the RNN generalization error using the Frobenius norms of the weights, still pointing to the importance of weight decay in practice.

While theoretical results make clear steps forward in analyzing the validity of RNNs, empirical results are also

helpful especially for finding RNN architectures that generalize well. A recent work validated LSTM surrogates for a boiler, a debutanizer, and two nonlinear reactors [9]. In a polymerization case study, [10] recommends the use of partially input convex RNNs for better accuracy and computational efficiency under MPC. To find good LSTM architectures, [11] advocates for the use of state-of-the-art hyper-parameter optimization methods. This idea is now widely accepted in many LSTM surrogate modeling studies [6], [12].

Aside from architectural choices, there is a growing interest in relating the geometry of the training loss landscape of neural nets to their generalizability. As early as [13], the flatness of the local minima of the training loss was already tied to better generalization (the authors are also the originators of the LSTM), i.e. models that converged on flat minima generalize better than those on sharp minima. In the past, many flatness or sharpness metrics have been defined based on measuring the loss curvature at the minimum, such as the Hessian eigenspectrum [14], Hessian spectral radius, Hessian trace, top Hessian eigenvalue [15], and $\epsilon$-sharpness [16]. Some definitions were motivated by empirical observations while others are more theoretical, such as those based on PAC-Bayes (Probably Approximately Correct-Bayesian) generalization bounds [17]. Some sharpness metrics, however, can be arbitrarily changed by scaling the weights without changing the neural net behavior such as the Hessian eigenspectrum [15]. Hence, scale-invariant metrics are more favorable such as the normalized sharpness [17] or the effective dimensionality (effective rank) of the Hessian of the loss [18], [19]. Due to these works, sharpness has been used to control neural net training to give models that generalize better [20-22].

In terms of regularization, weight decay is known to improve generalization, but the most common $L^2$ regularization is only one approach. Spectral norm regularization of weight matrices [23] is another approach based on the notion that models generalize better if they are insensitive to large input perturbations. For the case of RNNs, penalizing the largest singular value of the recurrent weight matrix was found to provide smoother state transitions [24] which is another form of regularization.

In this paper, we are interested in relating the training loss curvature to generalization in RNNs for surrogate modeling in continuous industrial processes. Our belief that generalization is related to some form of smoothness in RNNs is motivated by our previous work that pitted RNNs against a kernel method for MPC, namely mixed kernel canonical variate analysis (MKCVA) [25]. MKCVA was found to generalize better in the extrapolation regime, despite being at par in terms of median accuracy with LSTMs at the interpolation regime. Hence, MKCVA gave better control than LSTMs at various setpoints. We attributed this superior performance to the use of kernels that encode smoothness properties. Knowing this, our present aim is to attempt to find some geometry-based indicators of test-time error in trained RNNs. Consistent with [18], we do not view kernel methods and neural nets to be competing, rather, we are interested in finding elements of any representation learner that can improve generalization in surrogate modeling.

To achieve this aim, we take a representative industrial case study, namely the Three Tanks system [25], and train numerous LSTMs on a single training data set from a noisy simulation of this system. These LSTMs differ in architecture, training dynamics, and weight initialization. We then compute loss curvature metrics such as the top Hessian eigenvalue, the anisotropy ratio, the effective rank of the Hessian, and including the spectral norm of the recurrent weights of each LSTM, then connect them to 1-step ahead prediction error averaged over 100 pre-generated test data sets from the same noisy simulator but with 50% larger input signals. We hope that our results can help inform the control of LSTM training towards models with better generalization.

## Preliminaries

We consider the vanilla LSTM network defined by:

$$\boldsymbol{z}_k = \sigma_{io}(\boldsymbol{W}_z \boldsymbol{x}_k^* + \boldsymbol{R}_z \boldsymbol{y}_{k-1}^* + \boldsymbol{b}_z) \tag{1}$$

$$\boldsymbol{i}_k = \sigma_{rec}(\boldsymbol{W}_i \boldsymbol{x}_k^* + \boldsymbol{R}_i \boldsymbol{y}_{k-1}^* + \boldsymbol{b}_i) \tag{2}$$

$$\boldsymbol{f}_k = \sigma_{rec}(\boldsymbol{W}_f \boldsymbol{x}_k^* + \boldsymbol{R}_f \boldsymbol{y}_{k-1}^* + \boldsymbol{b}_f) \tag{3}$$

$$\boldsymbol{c}_k = \boldsymbol{z}_k \odot \boldsymbol{i}_k + \boldsymbol{c}_{k-1} \odot \boldsymbol{f}_k \tag{4}$$

$$\boldsymbol{o}_k = \sigma_{rec}(\boldsymbol{W}_o \boldsymbol{x}_k^* + \boldsymbol{R}_o \boldsymbol{y}_{k-1}^* + \boldsymbol{b}_o) \tag{5}$$

$$\boldsymbol{y}_k^* = \sigma_{io}(\boldsymbol{c}_k) \odot \boldsymbol{o}_k \tag{6}$$

where $\boldsymbol{x}_k^* = \{[\boldsymbol{u}_t^T, \boldsymbol{y}_{t-1}^T]^T, t \in [k - \text{lookback}, \dots, k]\}$ are the LSTM inputs, $\boldsymbol{y}_k^* = \{\boldsymbol{y}_t, t \in [k - \text{lookback}, \dots, k]\}$ are the LSTM outputs, $\boldsymbol{u}_t$ and $\boldsymbol{y}_t$ are the inputs and outputs of the process, $\boldsymbol{W}_z, \boldsymbol{W}_i, \boldsymbol{W}_f, \boldsymbol{W}_o$ are input weights, $\boldsymbol{R}_z, \boldsymbol{R}_i, \boldsymbol{R}_f, \boldsymbol{R}_o$ are the recurrent weights, $\boldsymbol{b}_z, \boldsymbol{b}_i, \boldsymbol{b}_f, \boldsymbol{b}_o$ are the biases, $\boldsymbol{c}_k, \boldsymbol{i}_k, \boldsymbol{f}_k, \boldsymbol{o}_k$ are the cell state and gate outputs, $\sigma_{io}$ is the input-output activation, $\sigma_{rec}$ is the recurrent activation, and $\odot$ is element-wise multiplication.

For the metrics derived for LSTMs, we denote $\boldsymbol{H}$ as the local Hessian matrix of the loss, $tr(\boldsymbol{H})$ is the trace, and $\lambda$ is an eigenvalue of $\boldsymbol{H}$. We also measure the singular values of weights matrix in a trained LSTM, which we denote as $\sigma$ with no subscript, to distinguish them from activation functions $\sigma_{io}$ and $\sigma_{rec}$ in the LSTM equations.

## METHODOLOGY

To find the best LSTM surrogate for the process system while also encouraging diversity in the set of models from which to reason about curvature effects, we

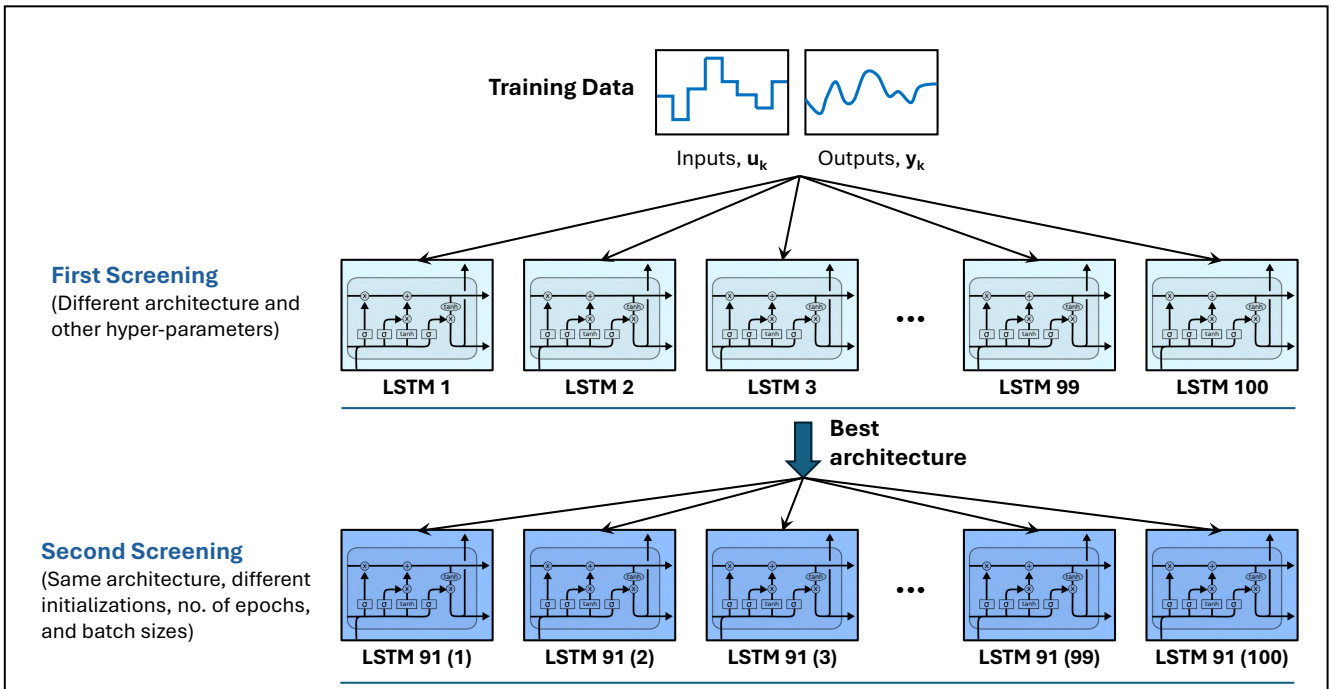

**Figure 1.** Methodology for investigating the relationship of LSTM architecture, training dynamics, and training loss curvature to model generalizability in this work.

designed an experiment that includes two screening stages (see Fig. 1). In the first stage, we train 100 LSTMs all with hyper-parameter tuning via Optuna [11] on the same fixed training data of 500 samples. Table 1 lists the hyper-parameters and their search ranges. To enforce more diversity, we deliberately narrowed the search into various regions of the search range for some LSTMs. For example, some LSTMs were forced to have ReLU input activations only, some were tuned up to 20 Optuna trials only rather than 50, some were stopped at 50 epochs rather than 200, some were forced to search within 30 to 40 hidden units rather than 5 to 45, and so on. Note that all the LSTMs in this study used *sigmoid* as the recurrent activation to maintain the notion that gates must output a value only from 0 to 1. All LSTMs also have some form regularization by using dropout and $L^2$ penalty.

For the second screening stage, we then picked the best LSTM from the first screening and kept its architecture. This stage now trains 100 additional LSTMs on the same training data of 500 samples, all of which have the same architecture (i.e. number of model parameters, activation, and regularization) but with different number of training epochs, training batch size, and initial weights.

The purpose of this stage is to remove the effects of model size and architecture choice and instead focus on sampling the training loss landscape diversely. Table 2 shows the range of number of epochs and batch sizes tried in this stage. Note that even though the batch size differs between LSTMs during training, we evaluated all curvature metrics using the entire batch of 500 samples. All generated data sets start with the same known initial state to remove any errors due to different initial conditions. The lookback is also fixed at 23, as with [25].

**Table 1:** Hyper-parameter search ranges in 1st screening.

| Name | Search Range |
|---|---|
| No. of LSTM units | 5, 6, 7, ..., 45 |
| Input-output activation, $\sigma_{io}$ | Tanh, ReLU, Linear |
| Dropout rate | 0.0, 0.1, ..., 0.5 |
| Recurrent dropout rate | 0.0, 0.1, ..., 0.5 |
| Optimizer | Adam, SGD, RMSProp, Adadelta |
| Batch Size | $2^3$, $2^4$, ..., $2^8$ |
| Validation split | 0.1 or None |
| $L^2$ regularization | 0.001 to 1 |
| No. of training epochs | 50 to 200 |
| No. of Optuna trials | 20 to 50 |

**Table 2:** Ranges used for training LSTMs in 2nd screening.

| Name | Search Range |
|---|---|
| Batch Size | $2^4$, $2^5$, ..., $2^8$ |
| No. of training epochs | 100, 200, 300 |

## Curvature and Smoothness Metrics

We measure the following curvature and local state transition smoothness metrics of all trained LSTMs.

### Top Hessian Eigenvalue, $\lambda_{\max}$

A measure of the local curvature of the loss in the parameter direction where it is sharpest.

**Hessian Trace, $\mathbf{tr}(H)$**

The sum of the eigenvalues of the Hessian.

**Anisotropy Ratio, $\lambda_{\max}/\mathbf{tr}(H)$**

Top Hessian eigenvalue divided by the Hessian trace, indicating the fraction of the total curvature concentrated in the sharpest direction.

**Effective Rank of the Hessian, $R_{\text{eff}}$**

Indicates the true dimensionality of the loss curvature, which we compute as the ratio of the squared Frobenius norm to the squared spectral norm:

$$R_{\text{eff}} = (\Sigma\lambda_i)^2/\Sigma\lambda_i^2 \tag{7}$$

**Recurrent Kernel Spectral Norm, $\sigma_{\max}(R)$**

The largest singular value of the recurrent kernel matrix $[\boldsymbol{R}_z, \boldsymbol{R}_i, \boldsymbol{R}_f, \boldsymbol{R}_o]$ from (1), (2), (3), (5).

Our hypotheses are as follows. If the top Hessian eigenvalue of the loss landscape is low, then the loss is flat along the worst-case (sharpest) direction. The Hessian trace measures the mean overall curvature on all directions, so a low trace also indicates flatness. An anisotropy ratio near 0 means that the curvature is more *spread* out on all directions, and if it is near 1 then the minima is likely a narrow ridge that is flat except for a single sharp direction. Hence, if the anisotropy ratio is near 0 and $\lambda_{max}$ is also low, then the minima is a flat and wide basin. Meanwhile, the $R_{\text{eff}}$ measures the effective number of dominant directions in the curvature. Lower $R_{\text{eff}}$ can also mean flatter minima since the *number* of dominant (sharp) directions is low while the rest of the directions are flat. A lower $R_{\text{eff}}$ can also indicate that the model is more overparametrized, possibly admitting a simplicity bias [18]. By Occam's Razor, simpler models tend to generalize well.

We include the recurrent kernel spectral norm [23] in the analysis since we consider it to be a smoothness metric. The lower the maximum singular value of the recurrent weights matrix, the more insensitive the model is to large changes in the hidden vector $\boldsymbol{y}_k^*$, which is the data being fed back to the LSTM. This means that upon making multi-step-ahead predictions, smoother trajectories are expected.

For the case of different architectures, as in the first screening stage (see Fig. 1), the Hessian trace and the effective rank must be normalized by the number of model parameters to be comparable.

## Approximating the Hessian Metrics

The time and memory cost of computing the full Hessian is quadratic with the model size, making it infeasible for large LSTMs. To address this, most literature use the Hessian-vector products (HVP) method which computes unbiased estimates of the product of the Hessian and an arbitrary vector $\boldsymbol{Hv}$ in linear time [26].

The full set of algorithms are not explained here, but we refer readers to the implementation in PyHessian [27]. In particular, the $\lambda_{\max}$ is calculated using the power iteration method, while the Hessian trace and effective rank use the Hutchinson method, all of which use HVP. We arbitrarily set 30 iterations in the power iteration method and 10 samples in the Hutchinson method.

## Generalization Metrics

To measure generalization, 100 additional data sets each having 500 samples were generated from the simulation of the process that differ in the input signals and noise. Inputs in both training and testing sets are amplitude modulated pseudo-random binary signals, but the test data input amplitudes are 50% larger in range than in the training data to test for extrapolation ability. All test data sets are fixed in both screening stages in Fig. 1.

We calculate the mean squared error (MSE) and $R^2$ accuracies in the 1-step-ahead and 500-step-ahead (or infinite-step) prediction scenarios, as follows:

$$\text{MSE} = \frac{1}{N}\Sigma\left(y_{\text{true}} - y_{\text{pred}}\right)^2 \tag{8}$$

$$\text{R}^2 = 1 - \Sigma\left(y_{\text{true}} - y_{\text{pred}}\right)^2/\Sigma(y_{\text{true}} - \mu_{\text{true}})^2 \tag{9}$$

which are averaged on all outputs, then averaged on all 100 test data sets for a single LSTM. An MSE near 0 and an $R^2$ near 1 means that a model generalizes well.

## Three Tanks Case Study

The system is governed by same differential equations as those written in [25]. Similarly, this paper uses the same two inputs and three outputs. The exact training data set used in this work is shown in Fig. 2.

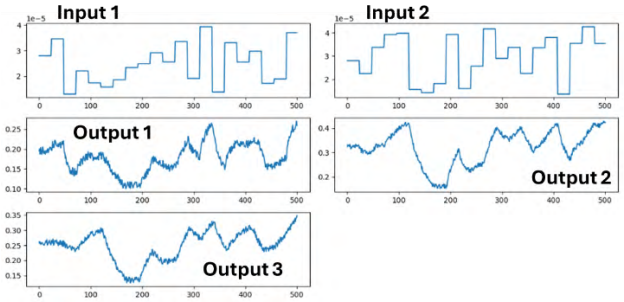

**Figure 2.** The training data set of 500 samples used to train all 200 LSTMs in this work.

# RESULTS AND DISCUSSION

## Correlations between Metrics

Quantifying the correlation between metrics already brings many insights. Fig. 3 shows the Spearman rank correlations between the choices during LSTM training,

curvature and smoothness metrics, and their generalizability for the 100 LSTMs with different architectures in the first screening stage. We chose rank-based correlation rather than Pearson because: (i) some accuracy metrics are too worse that they appear as outliers, hence, we analyzed more about the directions of the interaction rather than their magnitudes, and (ii) we wish to find possibly nonlinear interactions rather than linear ones.

First, we find that a lower top Hessian eigenvalue appears in LSTMs that generalize well, but the normalized trace, anisotropy, and normalized effective rank of the Hessian do not indicate the same. The rest of the Hessian metrics are weakly correlated with the mean MSE and mean $R^2$ for both 1-step-ahead and Inf-step-ahead accuracy. This means that for LSTMs with different architectures, the flatness at the direction of sharpest curvature dictates extrapolation behavior more effectively than the rest of the Hessian metrics. We further checked that the ranges of normalized $tr(\boldsymbol{H})$ (0-0.12) and normalized $R_{\text{eff}}$ (0-0.03) are both close to 0. Hence, we attribute their weak correlation with accuracy to either: (i) possible saturation at already low values for trained LSTMs, or (ii) poor choice of normalizing constant, i.e. the number of model parameters. This needs further study.

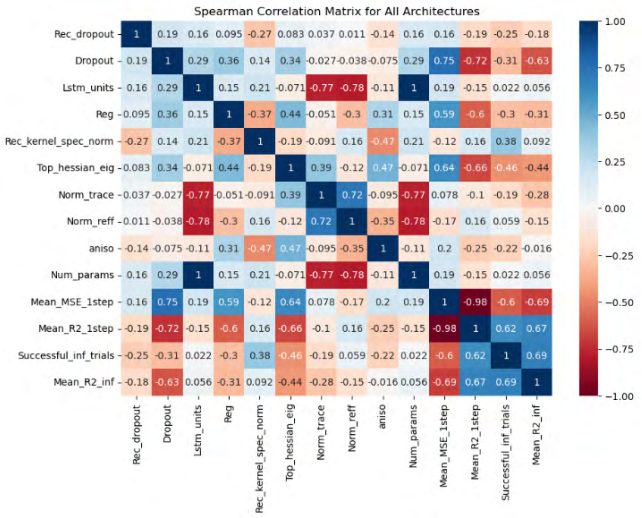

**Figure 3.** Spearman correlation matrix between metrics for LSTMs in the 1st screening (different architectures).

In terms of architecture, Fig. 3 shows that the number of model parameters is also weakly correlated with the test accuracy, meaning that there are extrapolative LSTMs from both small and large networks. We also find that the larger the network, the lower the normalized trace and normalized effective Hessian rank (correlation=-0.77). This means that bigger LSTMs tend to be more over-parametrized after training, i.e. with larger networks, fewer weights matter against the total number.

We chose a particular LSTM with the best accuracy for inf-step-ahead prediction, namely LSTM-91, in the first screening stage. LSTM-91 gained a mean $R^2$ of 82.7% and 85.67% for inf-step-ahead and 1-step-ahead prediction, respectively. Table 3 gives more details on this LSTM. Then, we trained 100 more LSTMs with the same hyper-parameters as LSTM-91, except with different initial weights, no. of epochs, and batch sizes.

**Table 3:** Details of the best LSTM from the 1st screening.

| Hyper-parameter | Value |
|---|---|
| No. of LSTM units | 31 |
| No. of model parameters | 4684 |
| No. of training epochs | 100 (Adam) |
| Input-output activation | Linear |
| Batch size | $2^4$ |
| Recurrent dropout rate | 0.1 |
| Dropout rate | 0.0 |
| $L^2$ regularization | 0.001126 |
| No. of Optuna trials | 50 |

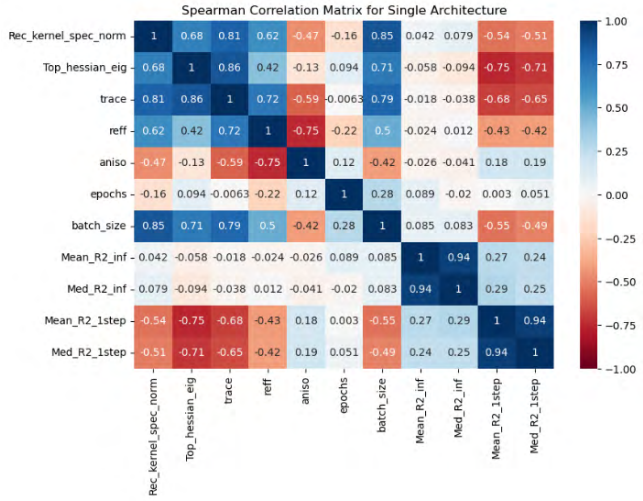

**Figure 4.** Spearman correlation matrix between metrics for LSTMs in the 2nd screening (same architecture).

Fig. 4 shows the Spearman rank correlation matrix for the 2nd screening stage. For the same architecture, we see stronger correlations between curvature, smoothness, and generalizability. Low values of $\sigma_{\max}(\boldsymbol{R}), \lambda_{\max}$, and $tr(\boldsymbol{H})$ all indicate better 1-step-ahead prediction accuracy (in terms of mean and median $R^2$). These metrics are also found to be correlated among each other: smoother model dynamics (low $\sigma_{\max}(\boldsymbol{R})$) correspond with flatter minima (low $\lambda_{\max}$). However, we find that anisotropy and effective rank still do not indicate generalizability. To understand why, we looked at the relationship between the metrics more closely in Fig. 5.

## Studying 100 LSTMs with Same Architecture

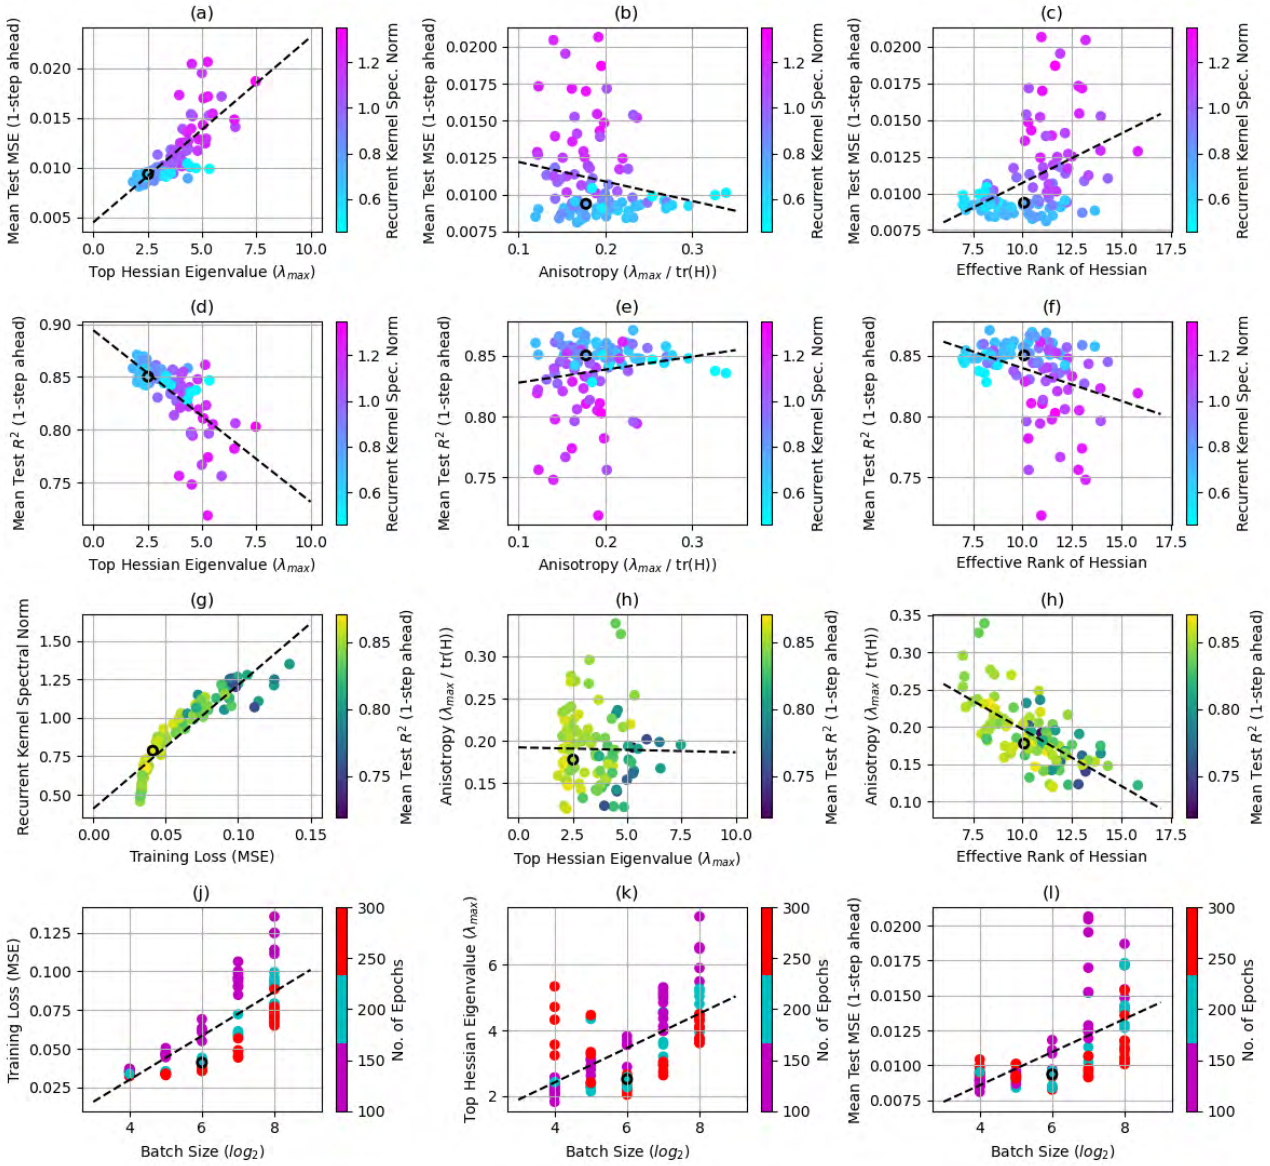

**Figure 5. Second Screening Results:** Scatter plots relating Hessian metrics, recurrent kernel spectral norm, training loss, batch size, and number of epochs to the 1-step-ahead accuracies averaged on 50 test data sets. Dashed line: Best-fit line; Black circle: LSTM with best inf-step-ahead accuracy.

In Fig. 5(a, d), we see that LSTMs with $\lambda_{\max} < 2.5$ and $\sigma_{\max}(\boldsymbol{R}) < 0.8$ are good extrapolators, and the linear correlation with test accuracy is clearer at lower values of $\lambda_{\max}$. Fig. 5(b, c, e, f) show that there are models that do not generalize well despite having lower anisotropy ratio and lower effective rank. Upon inspecting the trend of the recurrent kernel spectral norm in these plots, the reason for weak correlation of $tr(\boldsymbol{H})$ and $R_{\text{eff}}$ with accuracy is the presence of low trace, low rank Hessian models with simultaneously high recurrent kernel spectral norm (pink).

Fig. 5(g) shows that as the model reaches lower minima in the training loss, the recurrent kernel spectral norm also tends to decrease, leading to more accurate models. Fig. 5(h) tells us that anisotropy is not correlated with $\lambda_{\max}$, meaning that the $\lambda_{\max}$ and Hessian trace can be independent in fully trained LSTMs. Next, Fig. 5(i) shows that anisotropy is anti-correlated with $R_{\text{eff}}$, which means that the trained LSTMs converge to either higher effective-dimensional but relatively uniform curvature minima or lower effective-dimensional but non-uniform curvature minima. Still, neither of these ends are indicative of generalizability for 1-step-ahead prediction.

Lastly, we tested some notions from literature about the relationship of batch size, flatness, and test accuracy.

According to [16], large batches are known to drive models to sharper minima and smaller batches lead to flatter minima. Fig. 5(j, k, l) shows that smaller batch sizes tend to converge to lower training loss, but not necessarily flat. We found 3 LSTMs, in particular, each trained with a batch size of 16 using 300 epochs that reached sharper minima ($\lambda_{\max} > 4$) but with roughly the same training loss (~0.03) as those on flat minima ($\lambda_{\max} < 2.5$). These 3 also had the lowest recurrent kernel spectral norms among all LSTMs ($\sigma_{max}(\boldsymbol{R}) < 0.5$, lightest blue dots in Fig. 5(a)). Consistent with [15], these are the sharp-minima LSTMs that still generalize well, but this time owing to low recurrent kernel spectral norms. On the other hand, models with large batch sizes indeed tend to converge to sharper minima, especially those trained with only 100 epochs.

Because we have 100 LSTMs with the same number of model parameters, we can investigate which models are similar in the weight space. We projected the 4, 684 weights of each LSTM in 2-D using t-distributed stochastic neighborhood embedding (t-SNE), a widely used data visualization method. Fig. 6 shows that there is a cluster of LSTMs with roughly equal training loss and similar weights (meaning that they may be "close" to each other in the loss landscape). The other more isolated LSTMs can each be thought of having very different weights distributions. All LSTMs that clustered were found to generalize well in terms of 1-step-ahead test accuracy, but not all of them have flat minima since the 3 sharp-minima LSTMs are also in this cluster. By finding several similar LSTMs clustered together (37 out of 100) despite starting with various initial weights, we believe that there likely exists a low-lying mostly flat basin (with a few sharp minima) in the loss landscape that is relatively easy to find via Adam when training the LSTM-91 architecture (see Table 3) given the fixed training data set.

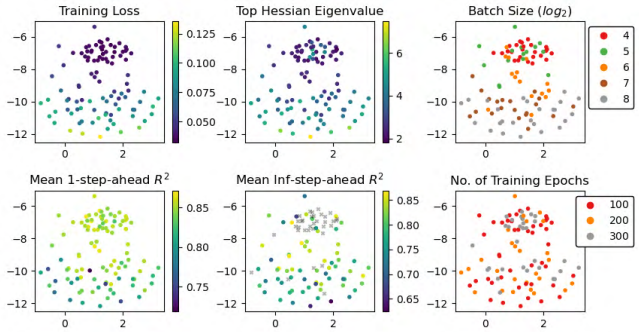

**Figure 6.** A 2-D projection of 4, 684 weights of the LSTMs in the 2nd screening stage via t-SNE, colored by the titles.

We also found that most of the clustered LSTMs did not perform well for multi-step-ahead prediction (see gray x's in the middle bottom box denoting models with negative mean $R^2$ for more than 10 out of 100 data sets). This means that steering LSTMs to be accurate 1-step-ahead predictors still does not guarantee stability.

## CONCLUSION

This work aims to empirically relate the flatness of the local minima of the loss and smoothness of the model local dynamics to generalizability in LSTMs for the Three Tanks case study. We summarize our findings into the following, subject to the limitations of our experiments:

LSTMs that converged to flatter minima tend to generalize better, but mostly when flatness is measured as the top Hessian eigenvalue. This metric rank-correlates with the mean test $R^2$ (at -0.66) regardless of architecture. Better rank-correlation (-0.75) was found when analyzing the loss landscape of a single architecture.

Lower Hessian trace (overall loss curvature) also indicates better 1-step-ahead prediction accuracy (rank-correlation=-0.68), but only among LSTMs with the same architecture.

LSTMs with smooth local dynamics marked by a low recurrent kernel spectral norm also tend to generalize better given a fixed architecture.

Based on these results, it might then be worthwhile to steer the training of LSTM surrogates while being aware of both sharpness and local transition smoothness in terms of the metrics that we found useful in this work. Nonetheless, future work must also validate our results in other processes and with more diverse RNNs.

## ABSTRACT

Multi-stack proton exchange membrane (PEM) water electrolysis systems are increasingly deployed to improve the scalability and flexibility of green hydrogen production. However, sharing balance-of-plant equipment introduces coupling between stacks, and differences in stack performance increase the complexity of plantwide operation. In particular, non-identical efficiencies and safety constraints, such as hydrogen-to-oxygen (HTO) ratio limits, can render single-stack or equal-power-sharing control strategies suboptimal. In this work, the steady-state optimal operating regime of a two-stack PEM electrolysis system is characterized using a plantwide optimization approach and active constraint mapping over a range of system power loads. Performance differences between the stacks are represented through variations in Faraday efficiency to emulate simplified degradation. For identical stacks, the system behaves similarly to a single large electrolyzer, where equal power distribution is optimal, and the active constraint regions closely resemble those of a single-stack system. As the stack performance differences increase, the optimal power distribution becomes asymmetric, with the more efficient stack preferentially loaded. However, HTO safety constraints in the degraded stack may limit the utilization of the more efficient stack and introduce additional active constraint regions, resulting in more complex operating regimes.

## INTRODUCTION

Hydrogen is expected to play a key role in decarbonization, and the development of large-scale, safe, and efficient production technologies is therefore required to meet zero-emission targets. Proton exchange membrane (PEM) water electrolysis is particularly attractive due to its high efficiency, fast dynamics, and suitability for intermittent renewable power. To reach industrially relevant capacities, modern PEM systems employ multiple stacks operating in parallel, often connected through a shared balance of plant (BoP). Such multi-stack configurations improve scalability and cost-effectiveness at high power loads compared to single-stack systems [2]. However, parallel stacks significantly increase system complexity and make plantwide operation more challenging due to coupling effects.

Despite this, most studies on PEM electrolysis focus primarily on single-stack performance. While several works have investigated power distribution strategies for multi-fuel-cell systems, considerably less research has addressed multi-stack PEM water electrolysis [2]. Among the existing studies, Xinyu et al. [11] proposed a daisy-chain power-distribution strategy, Cheng et al. [2] developed a power-adaptive fuzzy PID approach to improve load flexibility, and Guo et al. [5] introduced a rule-based strategy for hybrid PEM–alkaline systems utilizing the hydrogen-to-oxygen (HTO) impurity ratio.

Furthermore, due to manufacturing tolerances, aging, and thermal differences, individual stacks may exhibit different efficiencies. As a result, equal power sharing can be suboptimal and, in the worst case, violate operational or safety constraints. These performance differences should therefore be considered when determining power allocation among stacks [11].

In this work, we determine the steady-state optimal operating regime of a two-stack PEM electrolyzer system by solving a plantwide optimization problem and mapping the resulting active constraint regions across a range of power inputs. This analysis reveals how power should be

distributed between two PEM stacks operating in parallel and how differences in Faraday efficiency affect the optimal power allocation. The goal is to quantify how differences in stack performance affect the system's operating conditions and to provide a foundation for future control development.

## METHODOLOGY

In this section, we briefly describe the two-stack PEM electrolysis system, the underlying process model, and the optimization framework used to determine the optimal power allocation and corresponding active constraint regions.

### Case study and system layout

The system consists of two 60 kW PEM water electrolyzer stacks operating in parallel. Each stack has its own heat exchanger for temperature regulation and a dedicated power converter. The stacks share common BoP equipment, including two gas–liquid separators, a deionized water buffer tank, four pumps, four valves, and a hydrogen compressor. The piping is neglected as its effect on the steady-state operating conditions is negligible. The overall system layout is shown in Figure 1.

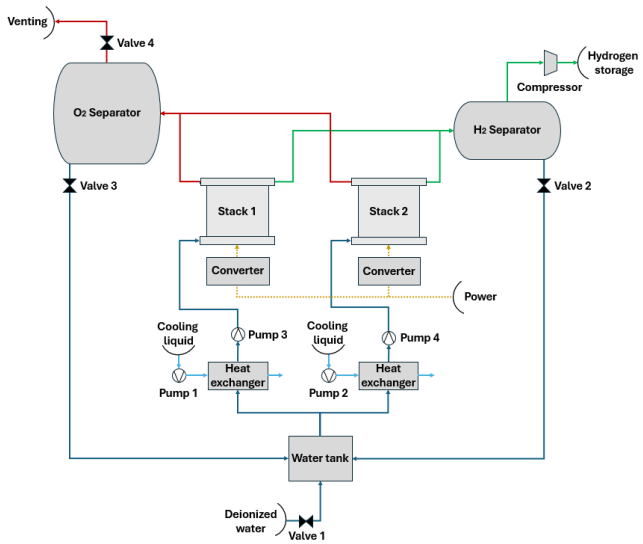

**Figure 1.** System layout of the two-stack PEM water electrolysis system with parallel stacks and shared balance-of-plant equipment.

Deionized water from the buffer tank is cooled in the heat exchangers and then supplied to the stacks, where it is electrolyzed to produce hydrogen and oxygen. The produced gases are subsequently separated from the liquid water in the gas–liquid separators, after which the oxygen is vented, and the hydrogen is compressed for downstream treatment. Finally, the remaining water is recycled back to the buffer tank.

Sharing separators introduces coupling between the stacks and additional operational constraints. In particular, both stacks must operate at similar pressures, limiting independent adjustment of membrane pressure gradients for gas crossover control. Furthermore, the HTO ratio measured at the separator does not directly reflect the HTO within each stack; therefore, stack-level HTO values must be estimated.

### Process model description

The PEM electrolysis system model is adopted from our previous work [4], which combines electrochemical, thermal, and mass-transport stack submodels with standard mass and energy balances for the BoP equipment. For brevity, only the relations most relevant to the steady-state optimization are summarized in this work; for a more detailed model description, we refer to [4].

#### Electrochemical relations

The Stack performance is described using the electrochemical submodel that relates cell voltage ($V_{cell}$) to the current density ($i_{\mathrm{el}}$) at a given power. The cell voltage is expressed as the sum of the reversible potential ($V_{rev}$), and the ohmic ($V_{ohm}$), activation ($V_{act}$), and concentration ($V_{con}$) overpotentials,

$$V_{cell} = V_{rev} + V_{ohm} + V_{act} + V_{con}, \tag{1}$$

where the reversible voltage represents the thermodynamic minimum energy required to drive the reaction, and the remaining terms account for resistive, kinetic, and mass-transport losses. The reversible potential is computed from the Gibbs free energy and corrected for pressure effects using the Nernst equation. Ohmic losses are estimated using an empirical membrane resistance correlation for Nafion 117, while activation and concentration losses are described using Tafel-type kinetics [1, 3, 8].

#### Faraday efficiency and degradation

Hydrogen production is calculated using Faraday's law of electrolysis. To represent performance differences between stacks, a Faraday efficiency factor ($\eta_F$) is introduced as a multiplicative term on the electrochemical gas generation rates,

$$\dot{n}_{\mathrm{gen},H_2} = \frac{i_{\mathrm{el}}A}{zF}\eta_F, \dot{n}_{\mathrm{gen},O_2} = \frac{i_{\mathrm{el}}A}{2zF}\eta_F. \tag{2}$$

$A$ is the active membrane area, $z$ is the number of electrons transferred, and $F$ is the Faraday's constant [3]. Values $\eta_F < 1$ represent parasitic charge consumption (e.g., crossover-related recombination and other side currents), resulting in reduced hydrogen production per unit current. The associated electrical losses are assumed to be dissipated as heat. However, since this study focuses primarily on HTO constraints and steady-state power allocation, additional heat generation is neglected for simplicity.

## HTO ratio and gas solubility

The HTO ratio is defined as the volumetric fraction of hydrogen relative to oxygen. Assuming ideal-gas behavior, this ratio can be estimated directly from the gas-phase composition,

$$HTO = \frac{V_{H_2}}{V_{O_2}} = \frac{y_{H_2}}{y_{O_2}}, \tag{3}$$

where $V$ is the gas volume and $y$ the gas-phase mole fraction.

The gas inventories in the separators are determined by subtracting dissolved gases from the total species inventories. The amount of dissolved gases is estimated using Henry's law with temperature-dependent solubility constants ($H$) obtained from Sander [9],

$$H = H_0 \cdot \exp\left(B\left(\frac{1}{T} - \frac{1}{T_0}\right)\right). \tag{4}$$

$H_0$ is the Henry constant at the reference temperature $T_0 = 298.15$ K, $T$ is the stack/separator temperature, and $B$ is an empirical temperature parameter. Gas solubility within the membrane is described using the correlations presented by Afshari et al. [1] and is assumed constant.

For simplicity, the stack-level HTO is computed using the total hydrogen and oxygen inventories. Due to oxygen's higher solubility in water, HTO values are slightly lower inside the stacks than in the separators, particularly at low pressure and temperature.

## Compression and pump work

Compression and pumping contribute to the total system power consumption and therefore influence the optimal operating regime. Hydrogen leaving the cathode is compressed to 30 barg for downstream handling, while liquid water and coolant are circulated through the stacks and heat exchangers by pumps. Including these auxiliary loads allows the optimization to capture the trade-off between electrochemical stack efficiency and mechanical energy requirements for compression and circulation.

The compressor is modeled assuming multistage compression with intercooling, resulting in approximately isothermal behavior. The required compression work is estimated as,

$$W_c = \frac{\dot{n}_{H_2} R T_{\text{sep}}}{\eta_c} \ln\left(\frac{P_{\text{storage}}}{P_{\text{sep}}}\right), \tag{5}$$

where $\dot{n}_{H_2}$ is the hydrogen molar flow rate, $T_{\text{sep}}$ is the separator temperature, $P_{\text{storage}}$ and $P_{\text{sep}}$ denote the storage and separator pressures, and $\eta_c$ is the compressor efficiency (80%).

The pump work is approximated by,

$$W_p = \frac{\dot{m}}{\rho} \frac{(P_{\text{final}} - P_{\text{initial}})}{\eta_p}. \tag{6}$$

$\dot{m}$ is the mass flow rate, $\rho$ is the liquid density, and $\eta_p$ is the pump efficiency (75%).

## Steady state optimization formulation

To determine the optimal operating policy, a steady-state optimization problem is solved over a range of system power inputs. The total electrical power is treated as an external disturbance representing the available power supply, while the internal power distribution between stacks is optimized. For each load level, the objective is to maximize the hydrogen output subject to the process model and operational constraints.

$$\begin{aligned} \max_{\text{MVs}} \quad & \dot{n}_{H_2} \\ s.t. \quad & \text{Process model equations} \\ & \text{Operational constraints} \end{aligned} \tag{7}$$

The manipulated variables (MVs) correspond to the available actuators in the system, namely valves, pumps, power converters, and the hydrogen compressor. With the liquid inventories in the separators and buffer tank regulated by local control loops and the feedwater flow rates fixed, five MVs remain for the optimizer. These are the oxygen outlet valve ($z_4$), the compressor work ($W_c$), the work of the two cooling liquid pumps ($W_{p3}, W_{p4}$), and the stack power distribution factor ($\alpha$), which determines the fraction of total power supplied to each stack,

$$MVs = [z_4, W_c, W_{p3}, W_{p4}, \alpha]. \tag{8}$$

Operational limits are imposed on stack pressure, temperature, and the HTO ratio to ensure safe operation. Although the lower explosion limit of hydrogen in oxygen is approximately 4 vol.%, the HTO constraint is conservatively set to 2 vol.% to provide a safety margin. Upper bounds on stack pressure and temperature are adopted from Crespi et al. [3]. Additional constraints are imposed on minimum stack power (5% of nominal load) and cooling liquid flow rates to ensure physically feasible operation. The resulting bounds are summarized in Table 1.

**Table 1:** PEM system operating constraints.

| Condition | Lower bound | Upper bound |
|---|---|---|
| Stack power | 3 kW | 60 kW |
| Anode pressure | 0.2 barg | 2.7 barg |
| Cathode pressure | 0.2 barg | 30 barg |
| Temperature | 10 °C | 60 °C |
| Cooling liquid | 0 mol/s | 15 mol/s |
| HTO ratio | 0 vol.% | 2 vol.% |

The optimization problem is solved for 120 evenly spaced values of total power input, ranging from 6 to 120 kW. For each operating point, all constraints are scaled between 0 and 1 and used to identify the corresponding active constraint region. A constraint is considered active when its scaled value reaches either 0 for the lower limit or 1 for the upper limit. This procedure is repeated for multiple Faraday efficiency scenarios to evaluate the

impact of stack degradation and performance differences.

The steady-state optimization problem is implemented in Julia (v1.9.3) using JuMP (v1.29.0) [7]. The resulting problem is solved with the Ipopt (v1.11.0) interior-point solver [10], using the HSL MA57 linear solver [6].

## RESULTS AND DISCUSSION

To evaluate the impact of stack performance differences on optimal operation, active constraint regions are analyzed for three efficiency scenarios. In Scenario 1, both stacks operate with identical Faraday efficiencies of 100%. In Scenarios 2–3, the efficiency of Stack 2 is reduced to 90% and 80%, respectively, while Stack 1 remains at nominal performance. Although these reductions are more severe for the Faraday efficiency than typically observed in practice, they are intentionally introduced to clearly illustrate how stack mismatch influences the optimal power distribution and operating regime. The considered scenarios and the corresponding number of active constraint regions are summarized in Table 2.

**Table 2:** Faraday efficiency scenarios for Stack 2 and the corresponding number of active constraint regions. The efficiency of Stack 1 is fixed at 100%.

| Scenario | Stack 2 Faraday efficiency [%] | Active constraint regions [#] |
|---|---|---|
| 1 | 100 | 2 |
| 2 | 90 | 5 |
| 3 | 80 | 6 |

### Scenario 1 – Identical stacks

The optimal operating regime, active constraint regions, and corresponding power distribution for Scenario 1 are shown in Figure 2.

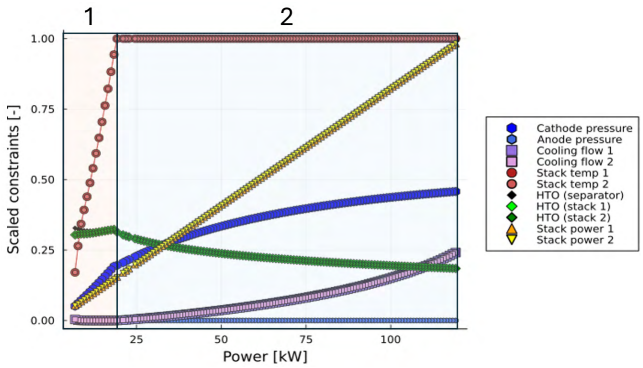

**Figure 2.** Optimal operating regime and active constraint regions for Scenario 1.

When both stacks have identical efficiencies, the optimizer distributes the power evenly between them. This is expected, since operating each stack at a lower individual power load improves hydrogen production per unit of power. Consequently, the two-stack system behaves similarly to a single larger stack.

At low loads, the stack temperatures increase rapidly with power until the upper temperature constraint becomes active at approximately 20 kW. Because higher temperatures improve electrochemical efficiency, the optimizer keeps the cooling flow rates at their lower bounds until the maximum temperatures are reached.

The anode pressure remains at its lower bound across the entire operating range due to the small efficiency penalty associated with elevated pressures. In contrast, the cathode pressure gradually increases with load. This behavior arises because the optimizer utilizes the stack pressure to partially compress the produced hydrogen, thereby reducing the work required by the downstream compressor. Although in-stack compression is generally more energetically favorable than mechanical compression, the compressor is modeled as a highly efficient isothermal unit. As a result, the optimizer prefers using both the compressor and the stack for compression. However, a less efficient compressor would likely result in higher optimal cathode pressures.

The HTO constraint remains inactive throughout this scenario. This is partly due to the low pressure gradients at small loads and partly due to the equal power distribution between the stacks, which results in similar crossover behavior. At very low power levels, the separator HTO is slightly higher than the stack HTO. This difference arises because the stack HTO is computed from the total gas inventories, whereas the separator measurement excludes gases dissolved in the liquid phase.

As both stacks operate under identical conditions, the active constraint regions closely resemble those of a single-stack system [4]. One of the main differences is that the single-stack system exhibits a slightly higher anode pressure at high loads. In the multi-stack configuration, however, increasing the anode pressure requires additional pump work due to the extra feedwater pump, making such operation less favorable.

Consequently, two active constraint regions are identified for the multi-stack system. In Region 1, the temperature constraints are inactive, and the cooling liquid flow rates remain at their lower bounds. As the load increases and the upper temperature constraints become active, the system transitions to Region 2, where additional cooling is required to maintain safe operation. Both regions have two degrees of freedom (DoFs), defined as the number of MVs minus the number of active constraints.

### Scenario 2 – Stack 2 at 90 %

In Scenario 2, the Faraday efficiency of Stack 2 is reduced to 90%, introducing asymmetry between the two stacks. The optimal operating regime, active constraint

regions, and power distribution are shown in Figure 3.

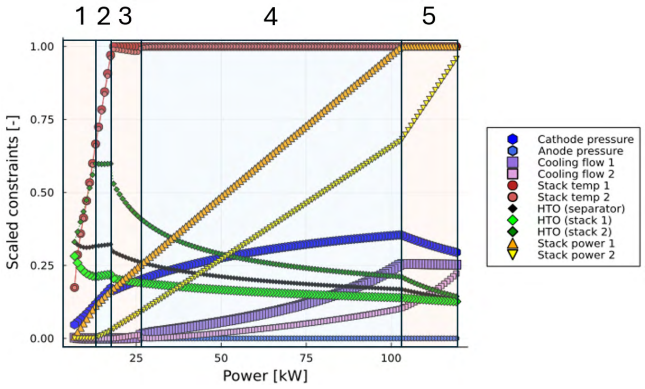

**Figure 3.** Optimal operating regime and active constraint regions for Scenario 2.

Stack 1 is more efficient than Stack 2, therefore the optimizer allocates a larger share of the power load to this electrolyzer. This behavior is expected and consistent with prior work recommending preferential use of the most efficient stack [11].

The HTO ratio of Stack 2 becomes significantly higher than that of Stack 1 at low loads. This occurs because reduced Faraday efficiency lowers oxygen production, thereby reducing hydrogen crossover dilution. At low loads, the HTO in Stack 2 increases rapidly until additional power is allocated to the stack, demonstrating a clear coupling between stack loading and the HTO ratio.

The temperature behavior largely follows Scenario 1. However, Stack 2 operates slightly below its upper temperature limit when Stack 1 reaches its constraint. Since Stack 2 contributes less to the overall hydrogen production in this region, operating at a lower temperature incurs a relatively minor efficiency penalty while slightly reducing downstream compression work. The optimizer also concentrates cooling on Stack 2, effectively allowing one cooling circuit to assist both stacks by overcooling the less efficient electrolyzer.

The cathode pressure remains inactive throughout the operating range and follows the same trend as in Scenario 1, but at lower absolute values. The maximum cathode pressure decreases from 14.84 bar in Scenario 1 to 11.75 bar, while the anode pressure remains fixed at its lower bound.

Scenario 2 has five active constraint regions. Regions 1–2 resemble Region 1 from Scenario 1, where the temperature constraints are inactive. However, in Region 1, Stack 2 operates at minimum power, while in Region 2, its load gradually starts increasing. In Region 3, the temperature constraint on Stack 1 becomes active, and Stack 2 is slightly overcooled. In Region 4, the temperature constraint on Stack 2 also becomes active. Finally, in Region 5, Stack 1 reaches its maximum allowable power, limiting further redistribution. Regions 2–4 have two DoFs, while Regions 1 and 5 have one DoF.

## Scenario 3- Stack 2 at 80 %

In Scenario 3, the Faraday efficiency of Stack 2 is reduced to 80%, further increasing the performance mismatch between the two stacks. The resulting optimal operating regime, active constraint regions, and power distribution are shown in Figure 4.

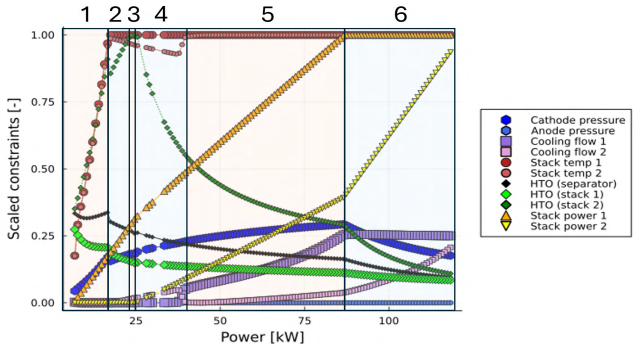

**Figure 4.** Optimal operating regime and active constraint regions for Scenario 3.

The overall behavior follows the same trends observed in Scenario 2, but with more pronounced asymmetry. The optimizer allocates an even larger fraction of the total load to Stack 1, causing Stack 2 to operate at its minimum power over a wider range of low system loads, while Stack 1 remains at its upper power limit for a larger portion of the high-load region.

As a result of this extended low-power operation, the HTO ratio in Stack 2 increases and reaches its upper constraint, which becomes active over a small portion of the operating range. When the HTO limit is reached, the cathode pressure stagnates slightly before the power load of Stack 2 begins to increase. This behavior indicates a clear relationship between the stack HTO, the pressure gradient, and the power load, where either the stack power must be increased or the cathode–anode pressure gradient reduced to maintain the HTO ratio of the degraded stack within safe limits.

Consistent with the reduced utilization of Stack 2, its operating temperature decreases further compared to Scenario 2. The cathode pressure continues to decrease, with the maximum dropping to 9.92 bar, while the anode pressure remains at its lower bound.

The increased stack asymmetry adds another active constraint region as the HTO limit of Stack 2 becomes active, yielding six active constraint regions in Scenario 3. In Region 1, Stack 2 operates at minimum power, with the anode pressure and both coolant flow rates at their lower bounds. In Region 2, the temperature constraint of Stack 1 becomes active, and the coolant flow of Stack 2 leaves its bound. In Region 3, the HTO constraint for Stack 2 becomes active, and it subsequently relaxes in

Region 4 as the lower power limit for Stack 2 becomes inactive. In Region 5, both temperature constraints are active, and in Region 6, Stack 1 reaches its maximum power limit. Regions 1, 2, 3, and 6 have one DoF, while Regions 4 and 5 have two.

## CONCLUSION AND FUTURE WORK

This work investigates how differences in stack performance affect the optimal operating regime and active constraint regions of a two-stack PEM water electrolysis system. For identical stacks, the plant behaves similarly to a large single-stack system, and equal power allocation remains optimal across the entire operating region.

As performance differences are introduced, the optimal allocation becomes asymmetric, with the more efficient stack preferentially loaded. However, this utilization is restricted by safety constraints, particularly the HTO limit in the degraded stack. To maintain safe operation, the system must balance power allocation and pressure levels. This coupling between HTO, pressure, and power leads to additional active constraint regions, fragmenting the operating space and increasing the complexity of the optimal operating policy. These findings highlight the importance of accounting for stack asymmetry when designing control strategies for multi-stack systems.

Future work will use the identified operating regimes and active constraint regions to develop appropriate control structures for multi-stack PEM electrolysis systems using dynamic plant models. Additionally, the impact of extending the framework to systems with more stacks will be investigated.

## ABSTRACT

Carbon dioxide transport is a critical component of the carbon capture and sequestration (CCS) supply chain. Given the substantial energy requirements and dispersed locations of CCS facilities, optimizing pipeline operations is critical to minimize costs. Although $CO_2$ in dense phase is typically favored for long-distance transport, gaseous phase transport is also a possibility for shorter distances and volumes. This study models a gaseous $CO_2$ pipeline system. Since $CO_2$ gas pipelines provide the benefit of line packing, owing to gas compressibility, this work leverages it to maximize throughput in the presence of disturbances. Pipeline pressures within each segment are perceived as an inventory (i.e. form of storage) and a model predictive control (MPC) formulation for optimal inventory management is implemented to maximize throughput. This study applies the formulation to pipelines arranged in series and parallel. It effectively maximizes throughput and optimally drains pipeline pressures in the presence of an inlet flow rate disturbance.

**Keywords**: Process Control, Optimization, Nonlinear Model Predictive Control, Carbon Dioxide Gas Pipelines

## INTRODUCTION

$CO_2$ transport via pipelines is an integral component of carbon capture and sequestration (CCS) due to the spatial distribution of capture and sequestration sites. Additionally, the urgency for decarbonization necessitates minimizing the cost and energy intensity of $CO_2$ transport especially since it accounts for approximately 25% of total CCS costs [1]. One approach to minimize operational costs is to exploit the line pack potential of gaseous $CO_2$ pipelines [2] to maximize throughput in the presence of shifting bottlenecks. Bottleneck here refers to a process constraint preventing further increase in throughput. In essence, this study investigates how pipeline pressures can be used as buffers to delay the impact of disturbances on throughput. Thus, a model predictive approach for inventory (pipeline pressure) control based on Turan, et al. [3] and Kumaraswamy, et al. [4] is implemented in this study to maximize throughput in gaseous $CO_2$ pipelines.

Although $CO_2$ can be transported in various other forms (e.g. ships, trucks, and rail), pipeline transport is one of the most mature and cost-effective technologies for large-scale transport [1, 5]. $CO_2$ is typically transported in liquid or dense phase at high-pressure over long distances as this is cost-effective [6]. Lower pressures result in lower densities and higher pressure drops. However, gaseous $CO_2$ pipelines are a possibility for shorter distances with operating pressures below 48 bar [7]. For example, OGE is developing a 28 km pipeline in Germany from Lägerdorf to Brunsbüttel, operating at a design pressure of 40 bar [8]. With the development of industrial clusters for gathering captured $CO_2$, short distance and low volume low-pressure gaseous pipelines might be preferable for certain pipelines. Several industrial clusters for gathering captured $CO_2$ are in development including industrial sources in the Oslo-fjord region [9], the Coda terminal [10], and the industry in Rotterdam [11]. Such industrial clusters are expected to experience disturbances in $CO_2$ capture flow rates and injection flow rates, owing to the scale and interconnectedness of the system [12]. The proposed control approach in this study is therefore well suited for throughput maximization within industrial clusters, where variability in capture and injection rates must be effectively managed.

Within the field of $CO_2$ transport and injection research, there has been great emphasis on steady-state optimal supply-chain design. Since several CCS projects have been staged for construction and implementation in the upcoming years, optimal design of transportation networks to minimize costs is a critical challenge. Studies have attempted to address this challenge considering

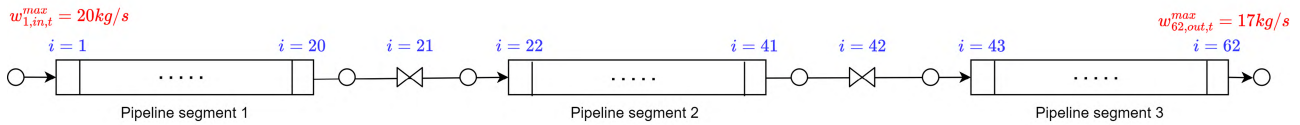

**Figure 1.** Sequential arrangement of pipelines (Case A)

different geographical scales, transport modes, and model complexity. Zhou, et al. [13] provide a detailed review of superstructure-based models for CCS pipeline network design. Ismail, et al. [14] review several studies centered on injection optimization and well control strategies incorporating detailed reservoir modelling.

Although there have been studies carrying out dynamic simulations to investigate the hydraulic and thermodynamic behavior of $CO_2$ in pipelines [15, 16], few studies have focused on methods for control and operational optimization for $CO_2$ transport and injection [17, 18]. This is the focus of the present paper.

Pressures within $CO_2$ pipelines can vary significantly depending on throughput, temperature, and transportation distance. Martynov, et al. [2] developed a correlation estimating line packing times for $CO_2$ pipelines under various pressure and distance conditions. The line packing time can vary between 30 mins to 2 hours for pipeline inlet pressures between 20 to 120 bar. The pressure threshold within the pipeline was set to 10 bar above the inlet pipeline pressure. This emphasizes the operational flexibility that $CO_2$ pipelines can offer in the presence of bottlenecks. It underscores the significance for investigating control strategies to optimally operate low-pressure gaseous $CO_2$ pipelines. While control strategies for optimal operation of gaseous $CO_2$ pipelines remains largely unexplored, it has been studied for natural gas pipeline networks [19–21].

Given the scale and interconnectedness of natural gas pipeline networks, which is also expected for $CO_2$ pipeline networks, studies have investigated the application of model predictive control (MPC) strategies to optimally operate such networks. Baumrucker, et al. [19] developed a non-linear dynamic model for mass flow and pressure in a natural gas pipeline network. An economic MPC was implemented to optimize compressor operation in the presence of varying electricity prices. However, to our knowledge, no study has adopted an optimal inventory control approach to the gas pipeline network process. In this study, pipeline pressures are treated as inventory and an inventory control formulation [3] is applied to maximize throughput from the gas pipeline while respecting pressure constraints.

Inventory control has been explored previously in the literature [22]. The term inventory is defined as any unit with hold-up (e.g. pressure, level). Some work has focused on inventory control strategies for bottleneck isolation. This concept can be simply explained as follows. Consider a pipeline transporting $CO_2$ from a capture site to a terminal for further transportation to a sequestration site. Additionally, consider that the inlet and outlet flow rates for this pipeline are determined by an optimizer. The optimizer is built on the principle that maximizing $CO_2$ transport to the terminal equates profit maximization. If a $CO_2$ capture plant were to shut down temporarily, the optimal inventory management strategy would be to maximize the pipeline outlet flow rate until pressures in the pipeline are at their lower limit. Subsequently, outlet flow rates would be lowered. This approach to isolate bottlenecks in a process has been described in the literature and applied to liquid tank levels. A PID control strategy, termed as the bidirectional control strategy, was formulated in Zotică, et al. [23] for sequential liquid tanks. An MPC approach achieving similar objectives was proposed by Turan, et al. [3] and Kumaraswamy, et al. [4].

In this work, an MPC inventory control approach is selected owing to the non-linearities, scale, and multi-input-multi-output nature of a $CO_2$ gas pipeline network. The inventory control formulation approach from Turan, et al. [3] is applied to two arrangements of $CO_2$ gas pipelines – sequential and parallel. We seek to investigate the effectiveness of this control strategy to optimally operate a $CO_2$ gas pipeline network.

## MODELLING

The non-linear dynamic model in this paper is taken and adapted from a natural gas pipeline network model in [19]. We follow their exposition closely. Consider a pipeline network consisting of pipeline arcs, $P$, and choke valves, $V$. These elements are modelled as a system of arcs connected by nodes. Each arc in the network is indexed by $\forall i \in A$, with its endpoints identified by $\forall k \in \{in, out\}$, and nodes indexed by $\forall j \in J$. For the purposes of this paper, we define the term "pipeline segment" as a control volume formed by aggregating multiple pipeline arcs connected in series. An overview of the two pipeline arrangements investigated in this study are shown in Figures 1 and 2, where the distinction between pipeline arcs and segments are illustrated in these figures. The time horizon is partitioned into several discrete intervals, indexed by $t \in T$, each corresponding to one time step. Material and momentum conservation equations are imposed at arc endpoints. We also assume that each arc

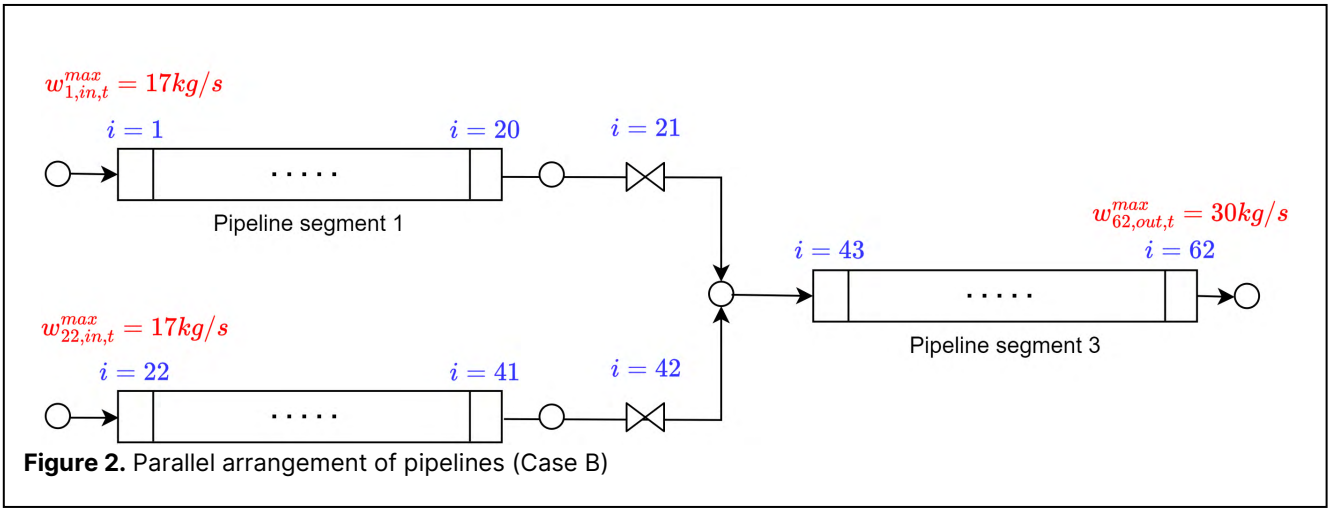

**Figure 2.** Parallel arrangement of pipelines (Case B)

endpoint shares the same pressure as its connected node. Additionally, no mass accumulation occurs at the nodes.

The governing equations are presented below. The material balance equation (eq. 1) is written in integrated form and approximated using the trapezoidal rule.

$$V_i\left(\overline{\rho}_{i,t+1} - \overline{\rho}_{i,t}\right) = \frac{1}{2}[(w_{i,in,t} - w_{i,out,t}) + (w_{i,in,t+1} - w_{i,out,t+1})]\Delta t,$$

$$\forall i \in \mathrm{P},\ t = 1, \ldots, T-1. \quad (1)$$

The material balance equation determines the change in average pipeline arc density, $\overline{\rho}_{i,t}$ $(\frac{kg}{m^3})$, within a pipeline arc of volume, $V_i$ $(m^3)$. This is dependent on the flows entering, $w_{i,in,t}$ $(\frac{kg}{s})$, and leaving, $w_{i,out,t}$ $(\frac{kg}{s})$, the pipeline arc. Pressure drop due to friction is incorporated by implementing the one-dimensional plug flow equation (eq. 2) which calculates the pressure differential, $\left(\frac{dp}{dz}\right)_{i,k,t}$ $(\frac{bar}{m})$, at pipeline arc endpoints.

$$\left(\frac{dp}{dz}\right)_{i,k,t} = -\frac{f_{i,k,t}\, w^2_{i,k,t}}{2 D_i A_i^2 \rho_{i,k,t}\, 10^5},$$

$$\forall \mathrm{i} \in \mathrm{P}, \mathrm{t} = 2, \ldots, \mathrm{T}. \quad (2)$$

Note that only horizontal pressure variations along the pipeline ($z$) are considered and gravitational pressure losses are neglected under the assumption of perfectly horizontal pipelines. The frictional pressure drop is governed by flow-dependent parameters - specifically the friction factor, $f_{i,k,t}$, flow rate, $w_{i,k,t}$, and density, $\rho_{i,k,t}$- as well as pipeline characteristics, namely the cross-sectional area, $A_i$ $(m^2)$, and diameter, $D_i$ $(m)$. Each pipeline arc is assumed to have a diameter of 0.4m. A Reynolds-dependent friction factor is computed based on the Haaland correlation (eq. 3). Absolute roughness, $\epsilon$ $(m)$, is assumed to be $2 \times 10^{-5}$ $m$. Since $CO_2$ exhibits non-ideal gas behavior over the pressure range considered in this study, we have modified the dynamic model by Baumrucker, et al. [19] to incorporate a real gas formulation. Fluid properties – density and viscosity – for each pipe segment is computed using a real gas formulation, where the compressibility factor is represented by a second-order polynomial fitted from regression. The polynomial fit is valid over a range of 5 to 45 bar, corresponding to expected operating ranges of gaseous $CO_2$ pipelines.

$$\frac{1}{\sqrt{f_{i,k,t}}} = -1.8 \log_{10}\left[\left(\frac{\epsilon/D_i}{3.7}\right)^{1.11} + \frac{6.9}{Re_{i,k,t}}\right]$$

$$\forall \mathrm{i} \in \mathrm{P}, \mathrm{t} = 2, \ldots, \mathrm{T}. \quad (3)$$

Pressure changes along pipeline arcs with length, $L_i$, of 1 km, are described using a 2-point Lobatto collocation scheme. This results in expressions for the outlet pressure and average pressure of each arc (eq. 4 and 5 respectively). A detailed derivation can be found in Baumrucker, et al. [19].

$$p_{i,\,\mathrm{out},t} = p_{i,\,\mathrm{in},t} + \frac{L_i}{2}\left[\left(\frac{dp}{dz}\right)_{i,\,\mathrm{in},t} + \left(\frac{dp}{dz}\right)_{i,\,\mathrm{out},t}\right],$$

$$\forall \mathrm{i} \in \mathrm{P}, \mathrm{t} = 2, \ldots, \mathrm{T}. \quad (4)$$

$$\overline{p}_{i,t} = \frac{p_{i,\,\mathrm{in},t} + p_{i,\,\mathrm{out},t}}{2} + \frac{L_i}{12}\left[\left(\frac{dp}{dz}\right)_{i,\,\mathrm{in},t} - \left(\frac{dp}{dz}\right)_{i,\,\mathrm{out},t}\right],$$

$$\forall i \in \mathrm{P}, t = 2, \ldots, T. \quad (5)$$

## MPC CONTROL FORMULATION

Having presented the dynamic model, we now define the control problem. In this study, we apply an inventory control MPC formulation to maximize system outflow and weighted inventories [3]. We seek to maximize the outlet flow rate from a pipeline system and the weighted pressure within each pipeline segment,

$$\min J = \sum_{t=2}^{T}\Bigg\{\underbrace{\sum_{i\in\mathcal{O}} \gamma^t \alpha_i \left(w_{i,out,t} - w^{max}_{i,out,t}\right)^2}_{Outflow\ max.} -$$

$$\underbrace{\left.\sum_{i\in S}\gamma^t\beta_i p_{i,in,t}\right\}}_{Inventory\ max.} + \underbrace{R}_{penalty\ term} \quad (6)$$

In accordance with the weight selection guidelines in Turan, et al. [3], inventories closest to the system outflow are assigned the highest weights. This prioritization emphasizes a high pressure in the pipeline segment connected to the outlet. Consequently, bottleneck isolation can be achieved by sequentially lowering pipeline segment pressures, starting from the segment located furthest from the outlet. While it may initially appear counterintuitive – as flow is typically driven by a pressure gradient from the inlet to outlet – the pressure constraint limits are defined based on expected operating pressures. For instance, in Case A, the maximum pressure limit is highest in segment 1, followed by segments 2 and 3 respectively. By prioritizing inventory weights for segments near the outlet, these critical sections—essential for maintaining flow—are preferentially driven toward their maximum pressure limits.

For the purposes of this paper, pipeline pressures at the midpoint of each segment are chosen for maximization and control. Let us define $S$ as the set of arc indices representing the midpoints of each pipeline segment and $O$ as the set of arc indices representing system outflows. $\alpha_i$ and $\beta_i$ represent the weights for system outflow and inventory (i.e. pressure) level maximisation. Throughput maximisation should be preferred over inventory maximisation to ensure inventories are drained in the presence of an upstream bottleneck. Hence, $\alpha_i$ is always assigned a larger value than $\beta_i$. The term, $\gamma^t$, is a time discount factor which prioritizes minimizing the objective function at earlier time steps.

A fundamental difference between liquid tank inventories, studied earlier and pipeline networks in the present work, is the requirement for boundary conditions. While liquid tank systems can be modelled using only flow rates, pipeline networks require at least one specified pressure boundary condition [24]. Hence, the outlet pressure is fixed in all simulations in this paper. Consequently, the outlet flow rate is determined by the system dynamics and MV movements. Hence, system outflow maximization in this study is formulated as a reference-tracking objective, unlike the liquid tank network where the system outflow is modelled as a manipulated variable (MV). As shown in Figures 1 and 2, the maximum outlet flow rate, $w_{i,out,t}^{max}$, is the setpoint for system outflow reference tracking.

The MVs in this system are the inlet flow rate(s) and valve openings between pipeline segments. These variables are assigned lower and upper bounds. Valves are assumed to have lower and upper bounds of 0.05 and 1 respectively. Lower bounds for the inlet flow rates are 5 $\frac{kg}{s}$ while upper bounds are shown on Figures 1 and 2.

The penalty term comprises of soft constraints on pipeline segment pressures and a damping term on network flow rates, with $\lambda_1$and $\lambda_2$ denoting the corresponding penalty factors.

$$R = \lambda_1 \sum_{t=2}^{T}\sum_{i\in S}\left(p_{i,in,t}^{slack} + p_{i,in,t}^{surplus}\right) + \lambda_2 \sum_{t=2}^{T}\sum_{i=1}^{I}\gamma^t\left(w_{i,in,t} - w_{i,in,t-1}\right)^2 \quad (7)$$

Slack and surplus variables corresponding to violations of the minimum and maximum pressure limits are denoted as $p_{i,in,t}^{slack}$ and $p_{i,in,t}^{surplus}$. At the initial steady-state starting point, all pipeline segment midpoint pressures are at their maximum limit. The pressure range for each segment is defined as 4 bar. In addition, a damping term is introduced to penalize large fluctuations in pipeline flow rates across all arcs. This term promotes smoother MV movement and is included specifically in the pipeline pressure system. Unlike the liquid tank system explored in Turan, et al. [3], gas pipeline networks are sensitive to large and rapid changes in the MVs, which can cause pressure oscillations and instability. Thus, regulated MV movement is necessary. Moreover, inventory levels in gas pipeline networks are inherently coupled. While the liquid level in a tank depends only on its inlet and outlet flow rates, pressure variations in one pipeline segment affect flow rates and pressures across the entire network. Hence, the inclusion of a term to smooth MV movement is desirable.

## RESULTS

The control strategy described above was implemented for two pipeline arrangements – sequential (Case A, Figure 1) and parallel with merger (Case B, Figure 2). In this study, the MPC receives pipeline pressure measurements at intervals of 1 km along the pipeline length. Simulations were carried out with a disturbance in the maximum allowable inlet flow rate to the pipeline at $t = 1h$. In this system, maximum flow rates for the inlet are assumed to be higher than the outlet to demonstrate both pipeline depressurization and pressurization as the bottleneck shifts between the outlet and inlet of the pipeline. Simulations begin at steady-state conditions with all pipeline segment midpoint pressures and the outlet flow rate maximized. Steady-state conditions are obtained by solving the steady-state form of the dynamic model presented above using a non-linear solver, Ipopt. The total simulated time is 22 hours with a time step of 5 minutes for all cases. All computations were performed on a 64-bit system with an Intel Core Ultra 5 135H processor (3.60 GHz) and 16 GB RAM. Each run requires approximately 5 to 10 mins. The dynamic model and MPC were formulated in the Julia programming language, using the JuMP optimization framework, and Ipopt as the non-linear programming solver.

## Sequential arrangement of pipelines (Case A)

As shown in Figure 3, the inlet flow rate to pipe segment 1 reduces immediately because the upper bound on the inlet flow rate was reduced from 17 kg/s to 14 kg/s. Subsequently, the optimizer opens valve 1 to depressurize pipe segment 1. As the pressure in pipe segment 1 approaches its lower limit, valve 2 is opened and valve 1 is closed to depressurize pipe segment 2. Note that although pipe segment 3 has a lower limit of approximately 18 bar, it is limited by the outlet pressure boundary condition of 22 bar. Hence, pipe segment 3 is limited in its ability to depressurize. When further depressurization of the pipe segments is no longer possible, the valve openings reach a new steady-state such that the outlet flow rate reduces to 14 kg/s. At $t = 12h$, when the maximum inlet flow rate is restored to its original value of 20 kg/s, the optimizer increases the inlet flow rate and valve openings to maximize throughput and pressurize the system.

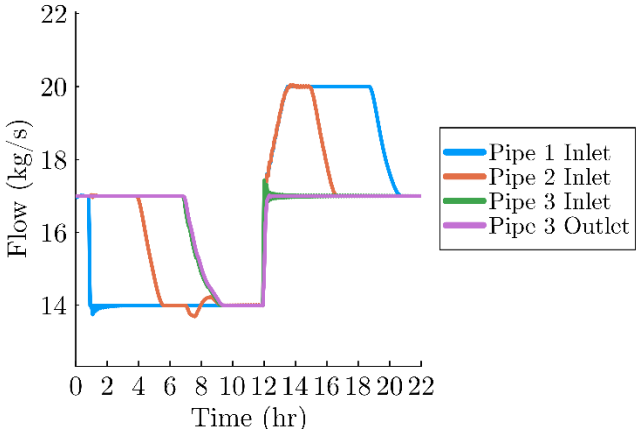

**Figure 3.** Case A – System flow rates

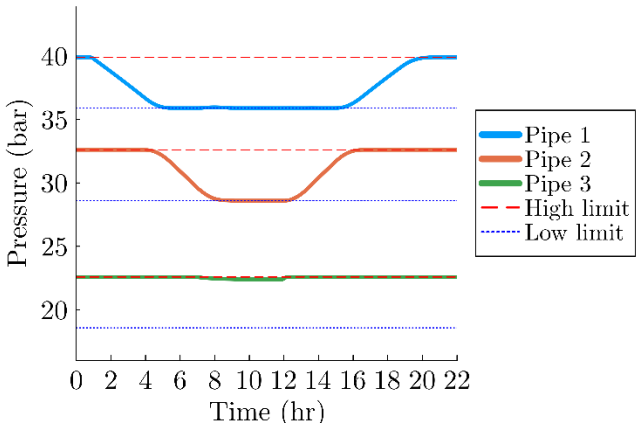

**Figure 4.** Case A – Pipeline segment midpoint pressures

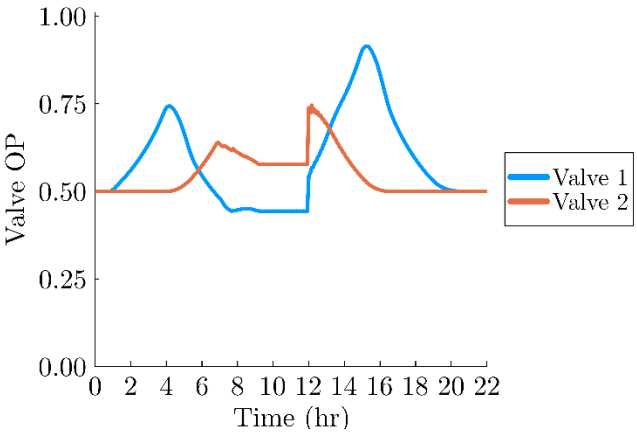

**Figure 5.** Case A – Valve openings

## Parallel arrangement of pipelines (Case B)

For pipeline segments arranged in parallel, the MPC exhibits a similar response. At $t = 1h$, the upper bound on the inlet flow rate to pipe segment 1 is reduced to 10 kg/s. As a result, the optimizer reduces the inlet flow rate to pipe segment 1, increases the inlet flow rate to pipe segment 2, and manipulates the valve openings to depressurize pipe segment 1. Note that we assign the inventory weighting factors ($\beta_i$) such that the pressure in pipe segment 3 has the highest priority for maximisation, followed by pipe segment 2 and pipe segment 1. As shown in Figure 7, pipe segment 1 is depressurized followed by pipe segments 2 and 3. Subsequently, the outlet flow rate is also reduced when pipeline inventories are at their minimum pressures. When the upper bound on the inlet flow rate to pipe segment 1 is restored, the optimizer proceeds to maximize pressures in pipe segment 2 followed by pipe segment 1. The original steady-state throughput of 30 kg/s is restored.

## DISCUSSION

Although throughput maximisation can be economically desirable, this may come at a cost. Firstly, maximising throughput requires aggressive manipulation of the available degrees of freedom (see Fig. 5 and 8). However, this comes with operational wear and higher energy consumption. In systems where rapid MV movement is undesirable or destabilizing, some degree of optimality must be sacrificed. Hence, throughput maximisation should be pursued only as long as the marginal benefit of increased flow outweighs the marginal cost of achieving it.

From a practical perspective, the non-linear dynamic model developed in this study carries inherent assumptions that may limit its application to real-world conditions. Firstly, the pipeline network is assumed to be horizontal. However, real terrain is rarely uniform and incorporating a gravity term into the pressure drop formulation (eq. 2) can improve the model accuracy. In general, a key limitation in the proposed framework is model-plant mismatch, which is an inherent challenge in any model-based control formulation. Despite detailed pressure-flow modelling and the consideration of variable $CO_2$ compressibility, model-plant mismatch could still result in prediction errors and sub-optimal MV movement. In practice, however, this challenge is well-managed through state estimation where real-time measurements are used to continuously reconcile model predictions. Therefore, the inventory control formulation investigated in this study remains a viable and practical approach for throughput maximization in $CO_2$ gas pipeline networks.

## CONCLUSION

In this paper, an optimal inventory MPC formulation for bottleneck isolation was implemented for $CO_2$ gas pipelines. The formulation sought to maximize throughput and the weighted sum of pipeline pressures. The formulation was applied with modifications, including the addition of a pressure boundary condition to accommodate pressure and flow dynamics in a pipeline. A flow damping term was also incorporated to ensure regulated MV movement as well as stable flow and pressure variations. Two arrangements of pipelines – sequential and parallel – were investigated and the MPC effectively maximized throughput in the presence of an inlet flow rate disturbance. Future work will extend the application of this inventory control MPC formulation for throughput maximization to larger-scale and more complex low pressure $CO_2$ gas pipeline networks.

## ABSTRACT

Plastic injection molding is a widely used polymer-processing method. As the requirements for processing accuracy have become increasingly stringent, defect analysis in plastic injection molding is necessary to improve the product yield. Causal discovery has recently gained attention for defect analysis in many processes. Because injection molding is a spatial process involving the distribution of physical quantities, spatial autocorrelation should be considered. Although the linear non-Gaussian acyclic model (LiNGAM) is a well-known causal discovery method, it cannot properly model spatial autocorrelation. In this study, a new causal discovery method for a spatially autocorrelated dependent variable, referred to as the Causal Structure Search for the Spatial Autoregressive Model (CASSPAR), is proposed. It models the causal relationships among the observed points without prior knowledge of the spatial structure. The proposed method represents the causal relationships among the observed points as a causal graph and estimates the adjacency matrix of the graph. The adjacency matrix is estimated using LiNGAM, and the model parameters are estimated using two-stage least squares (2SLS). The usefulness of the proposed CASSPAR was demonstrated using simulation data of a plastic injection molding process to identify the root cause of warpage.

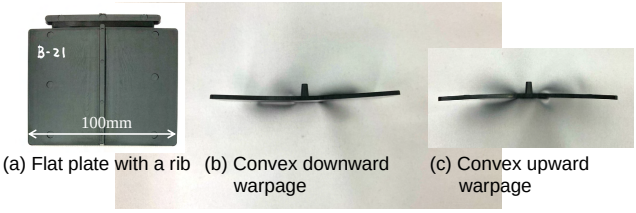
## INTRODUCTION

Injection molding is a widely used polymer processing method in which a molten resin is injected into a mold and solidified to form a product. Warpage is a post-molding product deformation that hinders the manufacture of high-quality products. In Figure 1, warpage may occur in completely opposite directions depending on the process parameters, even for identical products, which makes it difficult to analyze and control the causes of defects. Warpage may be influenced by multiple factors, including the temperature distribution, pressure distribution, product geometry, and materials [1]. Because these mechanisms often vary across individual products, identifying the causes of warpage and modifying the process operations are crucial for improving product quality.



(a) Flat plate with a rib (b) Convex downward warpage (c) Convex upward warpage

**Figure 1:** An example of warpage. A product of the same shape exhibits warpage in opposite directions depending on process parameters

Simulation studies have been successfully applied to predict warpage and optimize the process operations. Chen *et al.* investigated process variables affecting warpage using a design of experiments (DOE) on

simulation data [2]. In addition, the response surface method (RSM) in multi-objective optimization for warpage suppression and cycle time has been reported [3].

Machine learning (ML) techniques have also been applied to defect analysis. For instance, a warpage prediction model was constructed using random forests [4], and neural networks (NN) were trained on time-series data of in-mold pressure [5].

However, ML models and ML model-based optimization often become black boxes. Although they may achieve good performance in warpage prediction, their lack of interpretability makes it challenging to identify the root causes of warpage and develop fundamental countermeasures.

Causal discovery has gained attention for analyzing industrial process data [6, 7]. The linear non-Gaussian acyclic model (LiNGAM) is a well-known causal discovery method that estimates the causal structure among variables as a graph [8]. A key feature of LiNGAM is its statistical identifiability; it can uniquely identify the causal graph from observational data alone without prior knowledge. Various LiNGAM extensions have been proposed, including time-series data [9]. However, existing variants do not take spatial information into account.

Injection molding is considered a spatial process because physical quantities, such as temperature and pressure, are distributed across the product and mold. For example, spatial nonuniformity in temperature and stress can induce warpage [10, 11].

Spatial autocorrelation needs to be considered in spatial data, which means that observations at neighboring points are mutually dependent. This characteristic violates the independence assumption underlying many statistical methods, such as linear regression [12]. LiNGAM estimates also become biased from spatial data because each variable is no longer independent due to spatial autocorrelation. Therefore, a new causal discovery method for addressing spatial autocorrelation is required.

To express the relationship among observed points, a spatial weight matrix $\mathbf{W} \in \mathbb{R}^{N\times N}$ is used, where $\mathbf{W}$ can be defined as the adjacency or distance matrix between two points, and $N$ is the number of points. The spatial autoregressive (SAR) model is a widely used regression method that uses $\mathbf{W}$ to incorporate the dependent variable $y$ at neighboring locations as a predictor.

In most spatial models, $\mathbf{W}$ has to be given in advance, which means that the spatial autocorrelation is already known; however, this assumption is unrealistic for injection molding processes because it is difficult to observe such a relationship during molding. To estimate the spatial weight matrix $\mathbf{W}$ without prior constraints becomes difficult when the number of elements in $\mathbf{W}$ exceeds the number of observed points $N$. Thus, the structure of $\mathbf{W}$ has to be constrained with some assumptions [13]. However, it is unclear whether the injection molding process data satisfy these assumptions.

A key idea of this study is to interpret $\mathbf{W}$ as a representation of causal relationships because the spatial distributions in the injection molding process always follow the causal relationship by physicochemical mechanisms. Thus, $\mathbf{W}$ is regarded as an adjacency matrix of a causal graph. By applying LiNGAM, $\mathbf{W}$ can be uniquely identified and estimated directly from the data.

This study proposes a new causal discovery method for the spatial autoregressive model, referred to as the Causal Structure Search for the Spatial Autoregressive Model (CASSPAR). The proposed CASSPAR reveals causal relationships among locations without prior knowledge of spatial structure. This capability enables more precise defect analysis of warpage, leading to improved product yield and reduced energy consumption and costs. The estimation performance of CASSPAR is demonstrated through its application to simulation data of an injection-molding process.

## METHOD

The proposed CASSPAR interprets the spatial weight matrix $\mathbf{W}$ in the SAR model as a spatial causal structure and estimates $\mathbf{W}$ using LiNGAM. The background on LiNGAM and the SAR model is provided, and the estimation procedure of CASSPAR is explained in the following sections.

### Linear non-Gaussian acyclic model (LiNGAM)

LiNGAM is a causal discovery method that represents causal relationships among variables using a directed acyclic graph. Figure 2 shows an example of a causal graph used to investigate the causes of warpage in injection molding. The strength of the causal relationship is denoted by a coefficient $b$. In LiNGAM, each observed variable $x_i$ is expressed as a linear sum of other observed variables $x_j$ and an error term $e_i$. The causal graph in Figure 2 corresponds to the following structural equations:

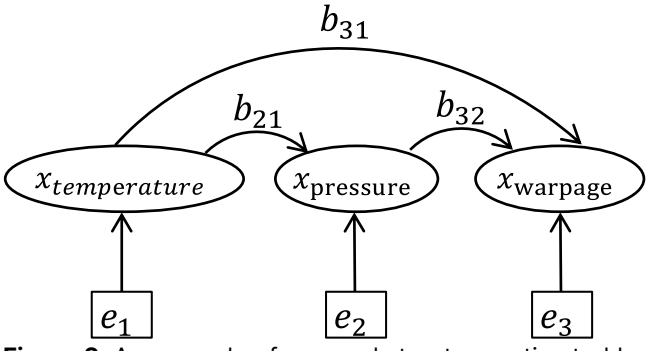


**Figure 2:** An example of a causal structure estimated by LiNGAM, represented as a causal graph.

$$
\begin{aligned}
x_{temperature} &= e_1 \\
x_{pressure} &= b_{21} x_{temperature} + e_2 \\
x_{warpage} &= b_{31} x_{temperature} + b_{32} x_{pressure} + e_3.
\end{aligned}
\tag{1}
$$

This figure illustrates the causal relationships, indicating that warpage is affected by both the process temperature and pressure, and that pressure is also affected by the temperature. In matrix form, Eq. (1) is written as

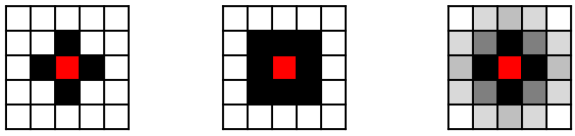
$$
\mathbf{x} = \mathbf{B}\mathbf{x} + \mathbf{e} \tag{2}
$$

where $\mathbf{B} \in \mathbb{R}^{K \times K}$ denotes the adjacency matrix of the causal graph to be estimated, $\mathbf{x} \in \mathbb{R}^K$ is the vector of $K$ observed variables, and $\mathbf{e} \in \mathbb{R}^K$ represents the vector of error terms. To ensure the identifiability of the causal graph, the following assumptions are required: 1) The error variables follow non-Gaussian distributions and are mutually independent. 2) The causal graph is acyclic, which means that no directed cycles exist in the causal graph.

## Spatial autoregressive (SAR) model

Spatial autocorrelation is a key characteristic of spatial data, which is the tendency for observations at neighboring locations to be more similar (or dissimilar) than those at more distant locations. Positive spatial autocorrelation corresponds to a pattern in which neighboring locations have similar values.

The spatial weight matrix $\mathbf{W} \in \mathbb{R}^{N \times N}$ is used to model spatial autocorrelation, which is a matrix representation of the adjacency relationships among $N$ locations. Figure 3 shows typical definitions of $\mathbf{W}$. The element $w_{ij}$ in $\mathbf{W}$ represents the influence of location $j$ on location $i$. The diagonal elements $w_{ii}$ are set to zero to avoid influencing itself. For reasons of computational stability and interpretability, $\mathbf{W}$ is commonly row-standardized so that each row sums to one. Figure 3 (a)–(c) show an example of a typical $\mathbf{W}$ indicating which locations affect the central cell shown in red. Color intensity represents the strength of the influence.



(a) Rook adjacency (b) Queen adjacency (c) Distance based W

**Figure 3.** Typical definitions of the spatial weight matrix $\mathbf{W}$ in 3 × 3 lattice space.

Various spatial regression models can be defined depending on which variable, dependent variable, independent variable, or error term exhibits spatial autocorrelation. This study focuses on the spatial autoregressive (SAR) model, also called the spatial lag model (SLM), which assumes that the dependent variable $y$ is spatially autocorrelated. This assumption is natural for warpage prediction, and the dependent variable y represents warpage. Warpage exhibits positive spatial autocorrelation because deformation at one location typically causes the surrounding areas to deform in the same direction. The SAR model is given by

$$
y_i = \rho \sum_{j=1}^{N} w_{ij} y_j + \boldsymbol{X_i}\beta + e_i \tag{3}
$$

where $y_i$ is the dependent variable at location $i$, $\rho$ denotes the spatial autocorrelation coefficient, $w_{ij}$ represents the spatial weight between locations $i$ and $j$, $\mathbf{X_i} \in \mathbb{R}^K$ is a vector of $K$ independent variables at location $i$, $\boldsymbol{\beta} \in \mathbb{R}^K$ is a coefficient vector, and $e_i$ is the error term at location $i$.

Figure 4 presents a schematic of the SAR model used to predict warpage in injection molding. As shown, the dependent variable $y_i$, which represents warpage, is influenced by neighboring warpages, such as $y_j, y_k, y_l$. In addition, $y_i$ is influenced by other variables $\mathbf{X_i}$ at the same location (e.g., product temperature and pressure), as well as by the error term $e_i$.

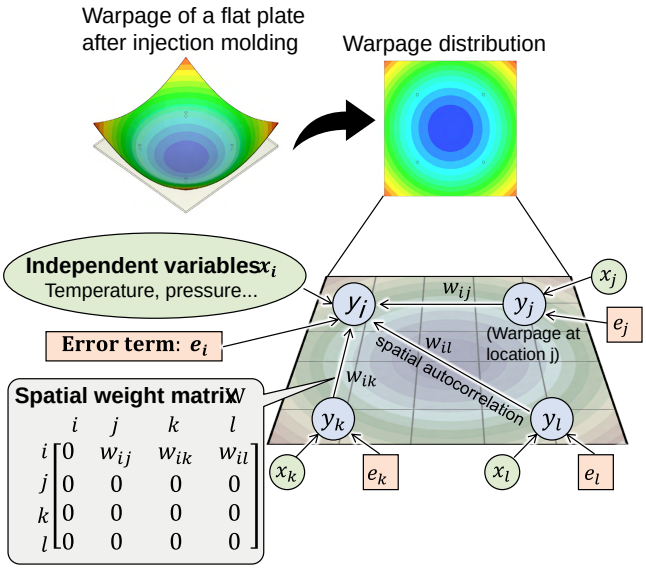


**Figure 4:** A schematic of SAR model for predicting warpage in injection molding.

The spatial autocorrelation coefficient $\rho$ denotes the strength of the influence that a location receives from its neighbors. A large positive value of $\rho$ represents a positive spatial autocorrelation. The term $\sum_{j=1}^{N} w_{ij} y_j$ is called the spatial lag. The variables $\rho$ and $\boldsymbol{\beta}$ are the model parameters to estimate.

## Causal Structure Search for the Spatial Autoregressive Model (CASSPAR).

CASSPAR estimates the spatial weight matrix $\mathbf{W}$ and the SAR parameters: $\rho, \boldsymbol{\beta}$. To apply LiNGAM to spatial data, the SAR model is reformulated. The matrix form of the SAR model is defined as

$$\mathbf{Y} = \rho\mathbf{W}\mathbf{Y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{e} \tag{4}$$

where $\mathbf{Y} \in \mathbb{R}^{T\times N}$ and $\mathbf{X} \in \mathbb{R}^{T\times N\times K}$ denote the measurements of the dependent and independent variables, respectively. $\mathbf{W} \in \mathbb{R}^{N\times N}$ is a spatial weight matrix, $\rho$ and $\boldsymbol{\beta} \in \mathbb{R}^{K}$ are spatial autoregressive coefficient and regression coefficient vectors, and $\mathbf{e}$ is an error term. Note that $\mathbf{W}$ is assumed to be row-standardized and spectrally normalized.

**Algorithm 1** Step 1: Estimation of spatial weight matrix $\widehat{\mathbf{W}}$

1. **Input:**
   Observed dependent variable matrix $\mathbf{Y} \in \mathbb{R}^{T\times N}$
2. **Output:**
   Estimated spatial weight matrix after normalization $\widehat{\mathbf{W}} \in \mathbb{R}^{N\times N}$
3. Apply the Direct-LiNGAM algorithm to $\mathbf{Y}$ and obtain an estimated adjacency matrix $\widehat{\mathbf{A}} \in \mathbb{R}^{N\times N}$.
4. $\widehat{\mathbf{A}}$ is first row-standardized and then spectrally normalized to obtain the normalized matrix $\widehat{\mathbf{W}}$.
5. Return $\widehat{\mathbf{W}}$

By defining $\mathbf{A} = \rho\mathbf{W}$ and $\mathbf{e}' = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}$, SAR can be reformulated in the same form as the LiNGAM model:

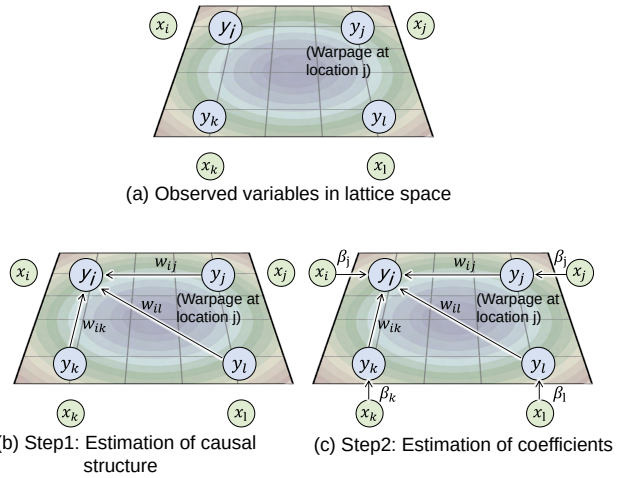
$$\mathbf{Y} = \mathbf{A}\mathbf{Y} + \mathbf{e}' \tag{5}$$

This reformulation allows us to estimate the spatial structure using LiNGAM. However, the following assumptions are required for LiNGAM identification:

**Assumption 1**: Spatial weight matrix $\mathbf{W}$ (and thus $\mathbf{A}$) corresponds to an adjacency matrix of a directed acyclic graph (DAG). In other words, $\mathbf{A}$ can be permuted into a strictly lower triangular matrix. This assumption is natural in the context of injection molding, where the resin flows in one direction, that is, the influence propagates only from upstream to downstream locations.

**Assumption 2**: Each component of the external error vector $\boldsymbol{e}'$ follow a non-Gaussian distribution, and they are mutually independent.

This study proposes a two-step estimation procedure. In step 1, the structure of the spatial weight matrix $\mathbf{W}$ is estimated, and in step 2, the SAR parameters $\rho$ and $\boldsymbol{\beta}$ are estimated. Figure 5 illustrates the procedure of the proposed CASSPAR.



(a) Observed variables in lattice space

(b) Step1: Estimation of causal structure

(c) Step2: Estimation of coefficients

**Figure 5:** Conceptual illustration of the proposed two-step estimation procedure.

## Step 1: Estimation of the spatial weight matrix

The Direct-LiNGAM algorithm [14] is applied to the reformulated LiNGAM model in Eq. (5), and the estimated adjacency matrix $\widehat{\mathbf{A}} \in \mathbb{R}^{N\times N}$ is obtained. Although step 1 estimates the adjacency matrix $\widehat{\mathbf{A}}$, a normalized weight matrix $\mathbf{W}$ is required for step 2. Therefore, $\widehat{\mathbf{W}}$ is obtained by row-standardizing and spectral normalizing $\widehat{\mathbf{A}}$ (Algorithm 1).

## Step 2: Estimation of SAR Parameters via 2SLS

Given $\widehat{\mathbf{W}}$, the SAR parameters $\rho$ and $\boldsymbol{\beta}$ are estimated by an instrumental variables (IV) approach based on two-stage least squares (2SLS). Using the normalized spatial weight matrix $\widehat{\mathbf{W}}$ obtained in Step 1, the original SAR equation is formulated as:

$$\mathbf{Y} = \rho\widehat{\mathbf{W}}\mathbf{Y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{e}. \tag{6}$$

The endogenous problem arises in Eq. (6) because the spatial lag term $\widehat{\mathbf{W}}\mathbf{Y}$ is simultaneously determined with dependent variable $\mathbf{Y}$. Consequently, $\widehat{\mathbf{W}}\mathbf{Y}$ is correlated with the error term $\mathbf{e}$. Due to this endogeneity, OLS estimates biased $\rho$ and $\boldsymbol{\beta}$. Thus, this study adopts the IV method to estimate these parameters, which is a standard estimation method for SAR models [15].

For the convenience of the IV method, Eq. (6) is rearranged as follows: let $\mathbf{y}_t \in \mathbb{R}^N$ and $\mathbf{X}_t \in \mathbb{R}^{N\times K}$ denote the $t$-th sample of $\mathbf{Y}$ and $\mathbf{X}$, respectively, $\mathbf{y}_{\text{stack}} \in \mathbb{R}^{TN}$ and $\mathbf{X}_{\text{stack}} \in \mathbb{R}^{TN\times K}$ are vertically stacked matrices of $\{\mathbf{y}_t\}_{t=1}^{T}$ and $\{\mathbf{X}_t\}_{t=1}^{T}$. The corresponding stacked spatial lag term is defined as

$$\mathbf{S} = [(\widehat{\mathbf{W}}\mathbf{y}_1)^{\top}, \ldots, (\widehat{\mathbf{W}}\mathbf{y}_T)^{\top}]^{\top} \in \mathbb{R}^{TN}. \tag{7}$$

Using $\mathbf{S}$, the SAR model can be expressed as

$$\mathbf{y}_{\text{stack}} = \rho\mathbf{S} + \mathbf{X}_{\text{stack}}\boldsymbol{\beta} + \mathbf{e}_{\text{stack}} \tag{8}$$

where $\mathbf{e}_{\text{stack}} \in \mathbb{R}^{TN}$ denotes the stacked error term.

The instrument variable $\mathbf{Z}$ is constructed from the exogenous variables $\mathbf{X}$ and their spatial lags. For each lag order $\ell = 1, \ldots, L$, the matrices

$$\mathbf{Z}_t^{(\ell)} = \widehat{\mathbf{W}}^{\ell}\mathbf{X}_t \in \mathbb{R}^{N\times K} \tag{9}$$

are defined, and $\mathbf{Z}^{(\ell)} \in \mathbb{R}^{TN\times K}$ is obtained by stacking $\{\mathbf{Z}_t^{(\ell)}\}_{t=1}^{T}$ vertically. The full instrument matrix is then given by

$$\mathbf{Z} = [\,\mathbf{X}_{\text{stack}}, \mathbf{Z}^{(1)}, \ldots, \mathbf{Z}^{(L)}\,] \in \mathbb{R}^{TN\times K(L+1)}. \tag{10}$$

This IV procedure requires the following assumptions about the instruments:

**Assumption 3**: The exogenous variables are uncorrelated with the error term $e, \mathrm{Cov}[Z, e] = 0$, to ensure that the instruments are exogenous and valid for the two-stage least squares (2SLS) estimation.

**Assumption 4**: The instruments are correlated with the endogenous spatial lag term $S, \mathrm{Cov}[Z, S] \neq 0$, which means that the instruments have sufficient relevance for the spatial lag term.

The SAR parameters $\rho$ and $\beta$ can be estimated via the 2SLS method. In the first stage of 2SLS, the endogenous spatial lag term $\mathbf{S}$ is regressed on the instrument matrix $\mathbf{Z}$ by OLS, and the fitted values $\hat{\mathbf{S}}$ are obtained. In the second stage, $\mathbf{y}_{\text{stack}}$ is regressed on $[\hat{\mathbf{S}}, \mathbf{X}_{\text{stack}}]$ by OLS. The coefficient on $\hat{\mathbf{S}}$ and the coefficient vector on $\mathbf{X}_{\text{stack}}$ yield the 2SLS estimates $\hat{\rho}$ and $\hat{\boldsymbol{\beta}}$, respectively. Under Assumptions 1-4, these estimators are consistent with the parameters of the original SAR. Algorithm 2 describes the procedure of SAR parameter estimation.

**Algorithm 2** Step 2: Estimation of SAR parameters $\rho$ and $\beta$ via 2SLS

1. **Input:**
   Normalized spatial weight matrix $\widehat{\mathbf{W}} \in \mathbb{R}^{N\times N}$.
   Observed dependent variable matrix $\mathbf{Y} \in \mathbb{R}^{T\times N}$.
   Observed independent variables tensor $\mathbf{X} \in \mathbb{R}^{T\times N\times K}$.
2. **Output:**
   Spatial autoregressive coefficient $\hat{\rho} \in \mathbb{R}$.
   Regression coefficients $\hat{\boldsymbol{\beta}} \in \mathbb{R}^{K}$.
3. Stack $\mathbf{Y}$ and $\mathbf{X}$ over samples to obtain $\mathbf{y}_{\text{stack}} \in \mathbb{R}^{TN}$ and $\mathbf{X}_{\text{stack}} \in \mathbb{R}^{TN\times K}$.
4. Consider the SAR model with the estimated spatial weight, $\mathbf{y}_{\text{stack}} = \rho\mathbf{S} + \mathbf{X}_{\text{stack}}\boldsymbol{\beta} + \mathbf{e}_{\text{stack}}$ here, $\mathbf{S}$ is the stacked spatial lag term.
5. Construct the instrument matrix for the $t$-th sample: $\mathbf{Z}_t = \left[\mathbf{X}_t,\ \widehat{\mathbf{W}}\mathbf{X}_t,\ \widehat{\mathbf{W}}^2\mathbf{X}_t,\ \ldots,\ \widehat{\mathbf{W}}^L\mathbf{X}_t\right] \in \mathbb{R}^{TN\times K(L+1)}$
6. Apply two-stage least squares (2SLS) to the stacked SAR with the spatially lagged term as the endogenous regressor and $\mathbf{Z}$ as the instrument matrix, Obtain the estimates $\hat{\rho}$ and $\hat{\boldsymbol{\beta}}$.
7. Return $\hat{\rho}, \hat{\boldsymbol{\beta}}$

## APPLICATION TO SIMULATION OF INJECTION MOLDING

In this section, the application results of the proposed CASSPAR to simulation data of injection molding to verify its capability to identify the causes of warpage are reported.

One of the primary causes of warpage is a non-uniform temperature distribution. Figure 6 (a) shows the 3D model of the injection-molding process used in the simulation, and (b)-(d) illustrate the mechanism of product deformation: (b) a temperature difference exists between the top and bottom of the product, which (c) leads to non-uniform resin shrinkage during solidification, and (d) consequently causes product deformation.

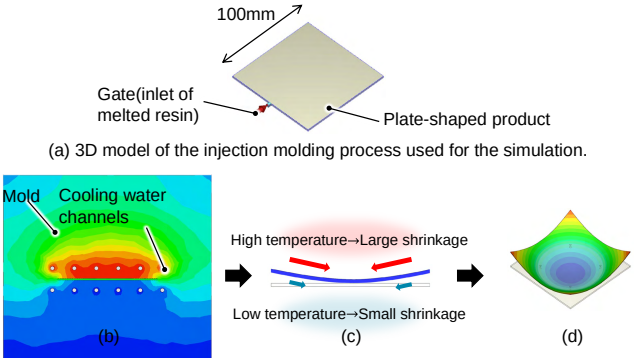


**Figure 6:** (a) 3D model of the injection molding process used for the simulation; (b)-(d) show the mechanisms of warpage.

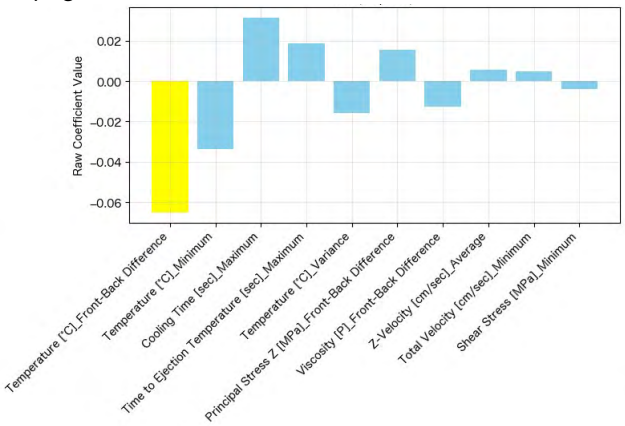

**Figure 7:** The top 10 largest absolute coefficient values estimated by the proposed CASSPAR.

In the simulation, a temperature difference between the top and bottom surfaces was intentionally introduced. A $9 \times 9$ grid of measurement points ($N = 81$) was placed on the plate for data collection. The data included variables such as the warpage, temperature difference between the top and bottom of the product, pressure, and resin flow velocity. The warpage at the 81 locations was treated as the endogenous spatial variable $Y$,

whereas the temperature difference, pressure, and flow velocity were treated as the exogenous variables $X$.

Figure 7 shows the top 10 largest absolute coefficient values estimated by the proposed CASSPAR. The top-ranked variable, "Temperature [°C]_Front-Back Difference, " represents the temperature difference between the top and bottom surfaces of the product. This result indicates that the proposed CASSPAR successfully identified the intentionally introduced temperature difference as the top-ranking causal factor of warpage.

Figure 8 shows the estimated spatial weight matrix W for the warpage, which is expected to exhibit positive spatial autocorrelation because a deformation at one location typically induces deformations in the same direction in the surrounding areas. The estimated $\mathbf{W}$ exhibits a local neighborhood structure similar to contiguity-based matrices, such as rook or queen adjacency.

This result suggests that the proposed CASSPAR successfully captured the physically reasonable spatial interactions underlying the warpage deformation.

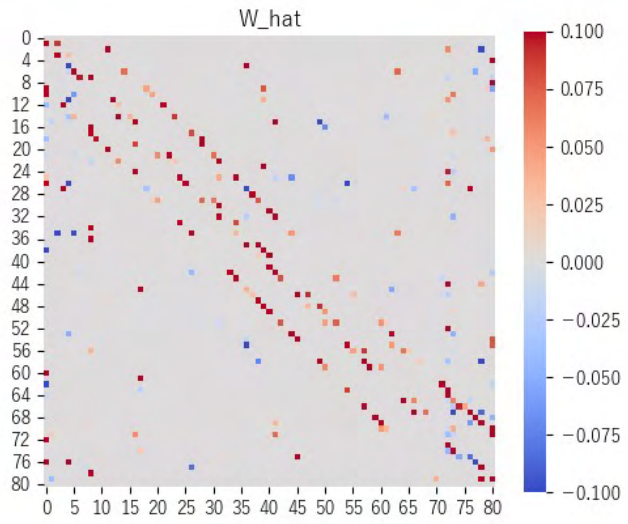

**Figure 8.** Heatmap of the estimated spatial weight matrix $\mathbf{W}$.

## CONCLUSIONS

In this study, a new causal discovery method for spatial data, referred to as CASSPAR, was proposed. A limitation of this study is that CASSPAR considers spatial autocorrelation only in the dependent variable Y. However, in many industrial processes, the independent variables X may also exhibit spatial dependence. CASSPAR can also be applicable to other spatially dependent processes, such as fault diagnosis in chemical plants and semiconductor wafer manufacturing. Future work includes validation in real-world experiments and extension to industrial processes beyond injection molding.

## ACKNOWLEDGEMENTS

This work was based on the results obtained from project JPNP20004, subsidized by the New Energy and Industrial Technology Development Organization (NEDO).

## ABSTRACT

As industries pursue more sustainable and flexible manufacturing strategies, batch processes continue to play a vital role across a wide range of applications. Batch operations offer the ability to handle diverse feedstocks and accommodate varying product specifications. These processes are broadly used in sectors such as pharmaceuticals, specialty chemicals, food production, and bioprocesses, where precise control over reaction conditions and product quality is essential. However, maintaining optimal conditions in a batch process can be challenging due to the minimal opportunities for mid-batch interference. This work focuses on a real industrial batch process that frequently sees batches with poor yields resulting in large financial losses. Despite utilizing a mid-infrared spectrometer analyzing the batch medium in real-time, the reduced product accumulation observed in faulty batches is not evident until over a third of the batch time has passed, by which point the batch is not economically viable to abort. This study applies and compares various machine learning based fault detection strategies, including multiple Principal Component Analysis (PCA) variants and autoencoder variants, to identify faulty batches as soon as possible, since resetting reset the batches earlier can maximize overall productivity. The findings of this study offer faster and more robust fault detection than typical PCA for this industrial batch process, reducing time lost to faulty batches and improving overall productivity. This work supports the transition towards autonomous and digitalized batch manufacturing while providing an in-depth comparison between several online fault detection strategies on real industrial data.

**Keywords**: Fault Detection, Batch Process, Machine Learning, Process Control, Modelling

## INTRODUCTION

Batch processes remain a cornerstone of modern manufacturing systems due to their versatility and robustness, particularly in applications requiring product customization, process flexibility, or adaptability to evolving feedstock supply chains. Despite these advantages, fault detection in batch processes remains challenging due to inherent process complexity, time-varying dynamics, and measurement noise. As a result, distinguishing genuine process faults from normal operational variability requires robust monitoring frameworks capable of reliably identifying true anomalies in real time.

PCA is a well-established multivariate statistical method that has been widely applied to fault detection and process monitoring in batch processes [1–4]. Owing to its simplicity, interpretability, and strong theoretical foundation, PCA serves as a natural benchmark against which more advanced fault detection strategies can be compared. However, conventional PCA treats observations as independent and does not explicitly account for process dynamics, which limits its effectiveness for batch operations.

To address this limitation, Dynamic PCA (DPCA) extends the traditional PCA framework by incorporating time-lagged measurements, such that consecutive datapoints are combined into a single model input. This enables DPCA to capture temporal correlations that are intrinsic to batch processes. In addition, this study considers a gradient-space PCA approach, motivated by the observation that rates of change in process variables can be more informative than raw concentration measurements for identifying abnormal process behavior.

Furthermore, a moving-window Dynamic Functional

Principal Component Analysis (DFPCA) framework is also investigated. DFPCA employs functional representations, that can be nonlinear, to model batch trajectories, allowing intricate process dynamics to be captured while simultaneously smoothing noisy measurements. These capabilities are particularly advantageous in batch environments where measurement noise and nonlinearity can obscure early fault signatures.

Finally, autoencoder-based methods are explored due to their ability to model nonlinear relationships that cannot be captured by linear PCA-based techniques. Autoencoders are Artificial Neural Networks (ANNs) that reconstruct input data after compression through a lower-dimensional latent space. In this study, a dynamic (or lagged) autoencoder variant is considered, where consecutive time points are treated as a single input, analogous to DPCA. As with DPCA and DFPCA, the number of incorporated lags can be adjusted to control the extent to which process dynamics are embedded within the latent representation.

The primary objective of this study is to detect faulty batches as early as possible – ideally before deviations become apparent in the raw process data – while maintaining a clear distinction between normal and faulty operation to ensure confidence in fault detection outcomes. The proposed methodologies are therefore evaluated based on their ability to quickly and reliably distinguish faulty batches from normal operation in real time. The remainder of this paper is organized as follows: the *Methodology* section describes the data structure, the calculation of fault detection metrics, and implementation details of each faut detection strategy; the *Results and discussion* section compares the performance of the different fault detection strategies; and overall *Conclusions* are provided in the final section.

# METHODOLOGY

## Data availability

The thirteen batches recorded in this study span at least 3000 minutes each with concentration measurements of eight components taken every 2.1 minutes using a mid-infrared spectrometer. Three faulty batches have previously been identified; the remaining ten non-faulty batches are partitioned into eight randomly selected training batches and two validation batches. Faulty batches visibly deviate from normal operation around the 1000-minute mark, which this study aims to improve upon using the various process monitoring strategies. Data is passed through a short-span median filter and random-walk Kalman filter, which is well suited to processes with frequent measurements and slow dynamics [5], to smooth data while still being suitable to online application.

## Fault detection metrics

Fault detection can be conducted by monitoring two different metrics over a moving window. If we consider the process data $\mathbf{X}$ to be reconstructed as $\widetilde{\mathbf{X}}$ with residual error $\mathbf{E}$ as in Equation (1):

$$\mathbf{X} = \widetilde{\mathbf{X}} + \mathbf{E}, \tag{1}$$

then through a dimensionality reduction framework, such as PCA, we can calculate both latent space and reconstruction space monitoring statistics. The latent space Hotelling's $T^2$ statistic and reconstruction space $Q$-residual can be calculated as in Equations (2) and (3):

$$T^2 = \mathbf{z}^\top \mathbf{\Lambda} \mathbf{z}, \tag{2}$$

$$Q = \|\mathbf{e}\|_2^2, \tag{3}$$

where $\mathbf{z}$ is the latent score vector, $\mathbf{\Lambda}$ contains latent variances, and $\mathbf{e}$ is the residual vector.

In this study, we consider a 50-input moving window for fault detection as opposed to single points to improve the robustness of fault detection. This study primarily focuses on the Hotelling's $T^2$ metric due to its superior overall performance on this case study.

## Fault detection strategies

In this section, all fault detection strategies are applied to the dataset which is standardised such that the training dataset has a mean of zero and a standard deviation of one, with the exception of gradient-space PCA which is standardized after variable gradients are approximated.

### Principal Component Analysis

Under PCA, the reconstruction of the standardised data matrix $\mathbf{X}$ shown in Equation (1) is therefore written as in Equation (4):

$$\mathbf{X} = \mathbf{Z}\mathbf{P}^\top + \mathbf{E}, \tag{4}$$

where $\mathbf{Z}$ is the matrix of scores in the latent space that correspond to $\mathbf{X}$, and $\mathbf{P}$ is the loading matrix. In this work, Singular Value Decomposition (SVD) is utilized to compute the loading matrix due to its efficiency and computational stability [6].

To keep only essential linear relationships and avoid capturing noise, the Principal Components (PCs) explaining the least variance are removed. The reconstructed dataset using the first $k$ PCs is shown in Equation (5):

$$\widetilde{\mathbf{X}} = \sum_{i=1}^{k} \mathbf{Z}_i \mathbf{P}_i^\top. \tag{5}$$

Although PCA is a widely applied method for process monitoring and fault detection, it is limited by its inability to capture nonlinear and temporal relationships, preventing PCA from incorporating dynamic and complex relationships that can dominate batch processes.

## Dynamic Principal Component Analysis

One way in which PCA can be improved is to incorporate past information, not just current measurements. Dynamic Principal Component Analysis (DPCA) is similar to PCA; the only difference is that the input data for DPCA is not a single vector of current variable values, it is instead a series of consecutive vectors of the variables up to the current measurement. The number of consecutive measurements included in each input is referred to as the number of 'lags'. In this study, we use a 100-lag DPCA approach that allows the DPCA model to capture temporal relationships that can be more informative than raw measurements in batch processes. The PCA dataset $\mathbf{X}$ with $N$ measurements of each process variable can be augmented into a DPCA dataset $\mathbf{W}$ with $L$ lags as in Equations (6) and (7):

$$\mathbf{w}(n) = \left[\mathbf{x}(n)^\top, \mathbf{x}(n-1)^\top, \dots, \mathbf{x}(n-L+1)^\top\right]^\top, \tag{6}$$

$$\mathbf{W} = \begin{bmatrix} \mathbf{w}(L-1)^\top \\ \mathbf{w}(L)^\top \\ \vdots \\ \mathbf{w}(N-1)^\top \end{bmatrix}. \tag{7}$$

## Gradient-Space Principal Component Analysis

Another way in which temporal information can be incorporated is using gradient-space PCA, which is conducted on the derivatives of process variables, as opposed to their actual values. Since batch processes often show first order dynamics, for example in chemical, fermentation, and some crystallization systems, the gradient-space can be more informative than the absolute value of process variables.

The main challenge with gradient-space PCA is the fact that insufficiently smoothed data will see noise amplification in the gradient-space [7]. Therefore, a Locally Weighted Scatterplot Smoothing (LOWESS) filter is used so that smoothness can be tuned by altering the filter span [8]. However, the LOWESS filter span causes a delay between when a measurement is taken and when the corresponding smoothed value is returned. Therefore, gradient-space PCA can only be implemented if the delay is sufficiently small. In this study, measurements are taken frequently, relative to the batch time horizon, and a relatively small span is required, thus facilitating the application of gradient-space PCA.

After data smoothing, the gradient of each process variable $\dot{x}_j^{(v)}(t)$ is approximated as in Equation (8):

$$\dot{x}_j^{(v)}(t) = \frac{x_j^{(v)}(t) - x_j^{(v)}(t-\Delta t)}{\Delta t}, \tag{8}$$

where $x_j^{(v)}(t)$ is the measurement of variable $v$ in batch $j$ at time $t$, and $\Delta t$ is the time between measurements. Thereafter, the gradient-space data is standardised to allow PCA to be conducted.

## Functional Principal Component Analysis

Functional Principal Component Analysis (FPCA) considers each process trajectory as a continuous function over time, rather than a vector of measurements. By modeling the smoothed temporal evolution of the profile, FPCA can better capture nonlinear dynamic patterns. For the multivariate instance where each batch trajectory consists of $V$ functional variables $x_j^{(v)}(t), v = 1, \dots, V$, the variation profile of each process variable is described by the weighted summation of $B_v$ basis functions $\phi_b^{(v)}(t)$ as in Equation (9):

$$\tilde{x}_j^{(v)}(t) = \mu^{(v)}(t) + \sum_{b=1}^{B_v} c_{jb}^{(v)} \phi_b^{(v)}(t). \tag{9}$$

Each observation $j$ collects the vector of coefficients as $\mathbf{c}_j = \left(c_{j1}^{(1)}, \dots, c_{jB_1}^{(1)}, c_{j1}^{(2)}, \dots c_{jB_2}^{(2)}, \dots, c_{j1}^{(V)}, \dots, c_{jB_V}^{(V)}\right)$ which are collected in the matrix $\mathbf{C}$. PCA is applied to the coefficient matrix to yield the loading matrix $\mathbf{P}$ and the matrix of shared multivariate FPCA scores, as in Equation (10):

$$\mathbf{C} = \mathbf{Z}\mathbf{P}^\top + \mathbf{E}. \tag{10}$$

The eigenfunctions $\psi_i^{(v)}(t)$ of variable $v$ are obtained by expressing the appropriate loading block in its basis as in Equation (11):

$$\psi_i^{(v)}(t) = \sum_{b=1}^{B_v} P_{bi}^{(v)} \phi_b^{(v)}(t), \tag{11}$$

where $P_{bi}^{(v)}$ represents the loading rows of $\mathbf{P}$ associated with variable $v$. Multivariate FPCA scores $Z_{ji}$ therefore satisfy Equation (12):

$$Z_{ji} = \sum_{v=1}^{V} \sum_{b=1}^{B_v} c_{jb}^{(v)} P_{bi}^{(v)}, \tag{12}$$

which demonstrates that a single set of scores summarizes the joint variation across all variables. Similarly to PCA, the coefficients that explain the least variance are removed, meaning only $k$ scores remain, as in $\mathbf{z}_j = \left(Z_{j1}, Z_{j2}, \dots, Z_{jk}\right)$, giving the approximate reconstruction of the coefficients $\tilde{\mathbf{c}}_j$ as in Equation (13):

$$\tilde{\mathbf{c}}_j = \sum_{i=1}^{k} Z_{ji} P_{\cdot i}. \tag{13}$$

Ultimately, variable profiles are reconstructed using the multivariate scores and eigenfunctions as in Equation (14):

$$\tilde{x}_j^{(v)}(t) = \mu^{(v)}(t) + \sum_{i=1}^{k} Z_{ji} \psi_i^{(v)}(t), \tag{14}$$

where the scores $Z_{ji}$ are shared across all variables, unlike the coefficients $c_{jb}^{(v)}$ in Equation (11).

Within the FPCA framework described in Equations (9-14) there exist several options, namely different basis function types as well as the period over which the basis functions are fit. This study considers B-spline basis functions due to their flexibility potentially being able to capture complex batch dynamics. However, the

additional flexibility can capture noise, and so this study also considers an orthonormal polynomial approach as such functions can provide a smoother fit. Since this study focuses on thirteen batches, fitting the basis functions to the entire profile would yield just thirteen observations per variable, which is impractical for trying to identify statistically significant faults. Therefore, this study considers a dynamic (moving-window) FPCA (DFPCA) approach where basis functions are fit to the 100-lag segments from the DPCA data $\mathbf{W}$ in Equation (7).

### Autoencoders

Autoencoders are a type of ANN that learn compact representations of higher-dimensional data through data reconstruction. Autoencoders can capture nonlinear relationships, meaning they can potentially uncover the more complex relationships in batch processes that standard PCA cannot. As illustrated in Figure 1, an autoencoder is composed of an encoder that compresses the original data $\mathbf{x}$ onto the lower-dimensional latent space $\mathbf{z}$, which is passed into the decoder that then reconstructs the original input data $\tilde{\mathbf{x}}$.

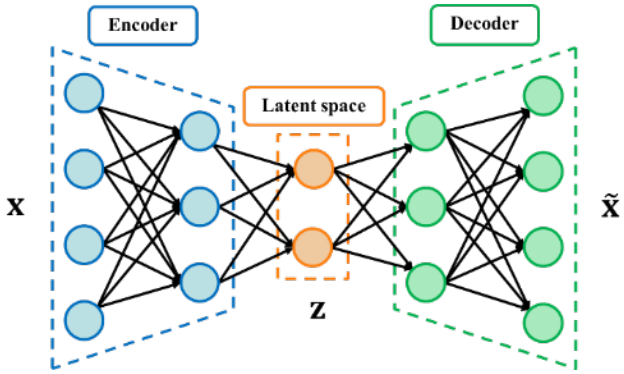

**Figure 1.** Example of an autoencoder architecture with 4-dimensional input, a 3-dimensional hidden layer in the encoder, and a 2-dimensional latent space. The decoder architecture always reflects that of the encoder, but the decder has its own unique weights and biases.

The autoencoder can be described by Equations (15a) and (15b):

$$\mathbf{z} = f_{\text{enc}}(\mathbf{x}), \tag{15a}$$

$$\tilde{\mathbf{x}} = f_{\text{dec}}(\mathbf{z}), \tag{15b}$$

where $f_{\text{enc}}(\cdot)$ is the function representing the encoder and $f_{\text{dec}}(\cdot)$ is the function representing the decoder. Autoencoders can also be trained on the 100-lag segments from the DPCA data $\mathbf{W}$ in Equation (7), so this study also considers a 100-lag autoencoder to capture temporal relationships, not just an autoencoder for modelling $\mathbf{X}$.

Autoencoder training focuses on minimizing the reconstruction loss described by the Mean Squared Error (MSE) loss function over $J$ observations in Equation (16):

$$MSE = \frac{1}{J}\sum_{j=1}^{J}\left\|\mathbf{x}_j - \tilde{\mathbf{x}}_j\right\|_2^2. \tag{16}$$

The number of epochs (times passed through the training dataset during training) can be increased to improve fitting to the training dataset. However, using a higher number of epochs is both more computationally expensive and can lead to overfitting of the training data and poor fitting of the validation dataset. Another way in which the validation performance of the autoencoder can be improved is to introduce a penalization term into the loss function that penalizes the size of the autoencoder weights and biases during training, thus shrinking redundant parameters. In this study, 250 epochs are used alongside L2 regularization (sum of squared weights and biases). Finally, different autoencoder architectures are tested to identify the best performer on validation data.

It is also worth noting that since the autoencoder latent variables are not guaranteed to be orthonormal or centred like PCA scores, the Hotelling-type $T^2$ fault detection metric is approximated using a slightly different formula shown in Equation (17):

$$T^2_{AE} = (\mathbf{z} - \bar{\boldsymbol{z}})^{\top}\boldsymbol{\Sigma}_{\boldsymbol{z}}^{-1}(\mathbf{z} - \bar{\boldsymbol{z}}), \tag{17}$$

where $\boldsymbol{\Sigma}_{\boldsymbol{z}}$ is the latent covariance matrix, and $\bar{\boldsymbol{z}}$ is the latent mean vector.

## RESULTS AND DISCUSSION

### Principal Component Analysis performance

As mentioned in the *Fault detection metrics* section, we consider a 50-input moving window for fault detection. In this window we monitor the percent of datapoints that exceed the 99% confidence limit of the $T^2$ statistic for both normal (training and validation) and faulty batches. The earliest window that demonstrates the clearest distinction between normal and faulty batches is chosen as the best fault detection window, the results of which are illustrated in Figures 2-4.

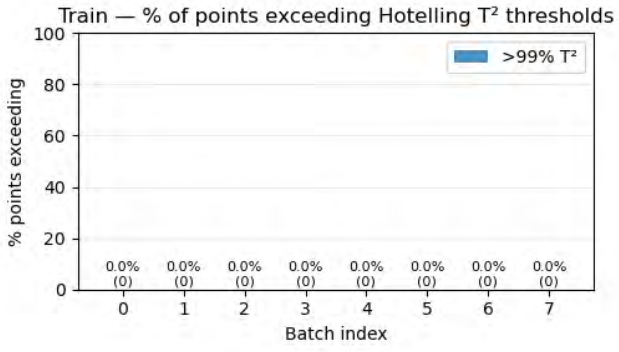

**Figure 2.** Bar chart showing percent of datapoints in each (normal operation) training batch where $T^2$ threshold is violated.

Looking at Figures 2 and 3, it is evident that the PCA does not flag any of the datapoints within this 50-datapoint window as exceeding the 99% confidence limit of the $T^2$ statistic, meaning PCA can correctly classify both the training and validation batches as normal operation.

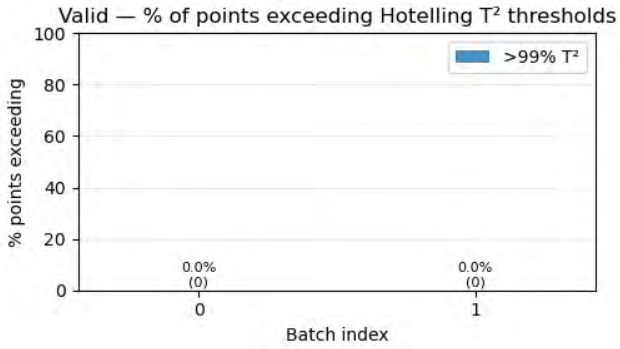

**Figure 3.** Bar chart showing percent of datapoints in each (normal operation) validation batch where $T^2$ threshold is violated.

Moreover, Figure 4 shows that PCA uncovers several instances where data within the fault detection window exceeds the 99% confidence limit of the $T^2$ statistic, therefore providing clear distinction between the normal and faulty batches.

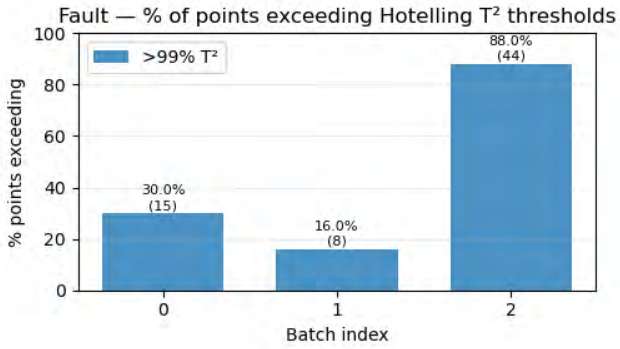

**Figure 4.** Bar chart showing percent of datapoints in each faulty test batch where $T^2$ threshold is violated.

The optimal fault detection window for the benchmark PCA requires data up to the 638$^{th}$ minute, a significant improvement upon observing faulty batches through raw data at around 1000$^{th}$ minute. If $\%FP$ is the highest percent of faults detected in any single normal batch and $\%TP$ is the lowest percent of faults detected in any single faulty batch, the fault detection margin $\%FDM$ is calculated as in Equation (18):

$$\%FDM = \%TP - \%FP. \tag{18}$$

The fault detection margin for the PCA benchmark is therefore 16% (since $\%FP = 0\%$, and $\%TP = 16\%$ for the benchmark PCA). The higher the fault detection margin, the more robustly the faulty batches can be distinguished from normal operation. Despite PCA reducing the time for faulty batch detection, there is still room for improvement in terms of both fault detection time and fault detection margin. This motivates the need to investigate more state-of-the-art process monitoring strategies.

## Comparison of fault detection strategies performances with benchmark PCA

For the remaining fault detection strategies, performance is compared to the benchmark PCA in Table 1.

**Table 1:** Overall comparison between fault detection methods, showing online fault detection time and fault detection margin. The DFPCA abbreviations *Spln*. And *Poly*. stand for *B-spline* and *orthonormal polynomials*, respectively.

| Model | Online fault detection time / min | Fault detection margin / % |
|---|---|---|
| PCA (*benchmark*) | 638 | 16 |
| 100-lag DPCA | 460 | 100 |
| Gradient-space PCA | 355 | 42 |
| 100-lag DFPCA (*Spln.*) | 439 | 52 |
| 100-lag DFPCA (*Poly.*) | 407 | 100 |
| Autoencoder | 344 | 0 |
| 100-lag Autoencoder | 386 | 52 |

Looking at Table 1, all dynamic methods (those involving lagged data or operating in the gradient-space) outperform the benchmark PCA in terms of online fault detection time and margin. In fact, the only method that does not improve upon the benchmark PCA is the regular autoencoder. The stronger performance of gradient-space and lag-based strategies is likely because they better incorporate temporal relationships which can be more informative of the true state of a batch process.

It can also be seen that the two best performing approaches, in terms of fault detection margin, are 100-lag DPCA and 100-lag orthonormal polynomial DFPCA. Although the lag-based models use a substantially larger input space, due to the inclusion of time-lagged variables, it can achieve stronger dimensionality reduction than standard PCA, yielding a latent space that more effectively captures the system dynamics. For example, to explain 95% of the data variance, the benchmark PCA has an input dimension of 8 and latent space dimension of 6 (25% reduction), whereas the 100-lag DPCA has an input dimension of 800, and a latent dimension of just 18 (97.75% reduction). The inability for the latent space to capture system dynamics for lower-dimension inputs could be the reason that the standard autoencoder fails to distinguish faulty batches from normal operation, meanwhile the higher-dimensional 100-lag autoencoder

performed strongly with a 250 minute reduction in the fault detection time and 36-point reduction to the fault detection margin with respect to benchmark PCA.

The 100-lag DFPCA performs stronger when using orthonormal polynomials than B-splines, with a fault detection time reduction of over 30 minutes and a 48-point improvement in fault detection margin. Evidently, the use of smoother functions better describes the system which implies that the more flexible B-splines are capturing excessive noise instead of additional process information.

Although the fastest fault detection strategy is gradient-space PCA, it performs weaker than all the lag-based fault detection strategies in terms of fault detection margin, which is likely due to the aforementioned noise amplification in the gradient-space. This indicates that more smoothing is required to reduce the noise in the original data, however increased smoothing will both require a larger LOWESS filter span, thus raising the fault detection time, while also inadvertently removing some useful process dynamics.

Overall, the best performing fault detection strategy for this industrial batch process is found to be that using the 100-lag orthonormal polynomial DFPCA approach due to its excellent fault detection margin of 100% and a competitively low fault detection time of 407 minutes.

## CONCLUSIONS

As batch processing continues to play a vital role in modern manufacturing and sustainable production, ensuring consistent and normal operation is becoming increasingly important. Through the use and comparison of these machine learning techniques, faulty batch detection can be achieved within the first 400 minutes; a significant improvement upon the 1000 minutes taken when observing the raw data and 638 minutes when utilizing standard PCA. In addition, a more statistically significant distinction can be found between faulty and non-faulty batches, meaning that fault detection robustness has been notably improved in comparison with the benchmark PCA. This study also demonstrates the benefits of utilizing fault detection strategies that exploit lag-based and gradient-space foundations for fault detection in batch processes. This study therefore paves the way for fault detection in industry-scale batch processes.

## ABSTRACT

Modern semiconductor manufacturing requires extreme precision as yield margins narrow in the "More-than-Moore" era. While physics-based models (PBMs) provide high-fidelity insights into plasma etching, their computational intensity—often requiring hours per simulation—renders them impractical for direct iterative optimization. This work demonstrates a hybrid framework that utilizes data-driven surrogate models to enable rapid, cost-effective process optimization. A 2D axisymmetric fluid model of an inductively coupled $O_2$ plasma (ICP) reactor was developed to generate a training dataset for two neural architectures: a Multi-Layer Perceptron (MLP) and a Kolmogorov-Arnold Network (KAN). These surrogates predict radial etching rates across a wide operating window of power, pressure, gas flow, and bias voltage. By replacing the expensive PBM with these high-speed surrogates, derivative-free optimization algorithms (Nelder-Mead and Powell) successfully identified a profit-maximizing operating point (2000 W, 10 mTorr) orders of magnitude faster than direct physical simulation. The results confirm that surrogate-based optimization effectively captures dominant physical trends, such as ion-flux limited regimes, while providing a "Confidence Gap" through model disagreement to flag epistemic uncertainty. This methodology offers a scalable blueprint for reducing the computational burden of process design, transitioning from expensive trial-and-error to efficient, physics-validated autonomous discovery.

## INTRODUCTION

The semiconductor industry is currently navigating a “More-than-Moore” era. Until recently, critical dimensions kept shrinking until they reached a scale below the 5 nm node, where the economic and technical constraints on device fabrication have intensified. Yield margins are becoming increasingly narrow, requiring strict process control and optimization. Thus, the ability to precisely model and optimize fabrication steps is no longer merely advantageous but essential for maintaining economic viability in high-volume manufacturing [1].

Low pressure plasma, an electrically neutral ionized gas, is formed in a low pressure environment (typically 1-100 mTorr) by applying voltage between two electrodes or through coil excitation. Characterized by complex physical and chemical interactions, these discharges enable unique surface modifications unmatched by other commercial methods [2]. Among the various configurations, inductively coupled plasmas (ICPs) are of particular importance in semiconductor manufacturing [3].

Plasma etching is an essential dry fabrication process in modern integrated circuit production. It uses reactive species and energetic ions to selectively remove material from surfaces, enabling highly anisotropic and controllable pattern transfer from lithographic masks [2]. In an ICP reactor, an oscillating magnetic field is generated by a coil which in turn induces a strong electric field

capable of sustaining high plasma densities. Furthermore, wafer biasing controls the energy of ions reaching the wafer, enabling high etching rates and selectivity [4].

Numerical simulations of these reactors have become an important tool [5], which enables an improved understanding of the process and allows replacing in-situ measurements which are expensive or even impossible [6]. However, accurate predictions of spatially varying etching rates are challenging due to the complex interplay of the governing physics. This challenge is compounded by the significantly nonlinear nature of the problem, which elevates the complexity of optimization process requiring multiple iterations of the computationally expensive physics-based model (PBM).

To address these challenges, the industry is increasingly looking toward "virtual metrology" and digital twin technologies [1]. Currently, two distinct modeling paradigms exist. PBMs offer high fidelity and interpretability but are computationally expensive, often requiring hours to simulate a single operating point. Data-driven Machine Learning (ML) model approaches offer rapid inference speeds suitable for real-time control but typically suffer from poor generalizability outside their training data, a lack of physical interpretability and reliability which is directly correlated to the accuracy and the volume of the training data.

## PHYSICS BASED MODEL

Fluid model plasma simulations have been proved to give valid approaches of plasma processes with typical ICP chambers of pressures in the order of $10\ mTorr$ [6].

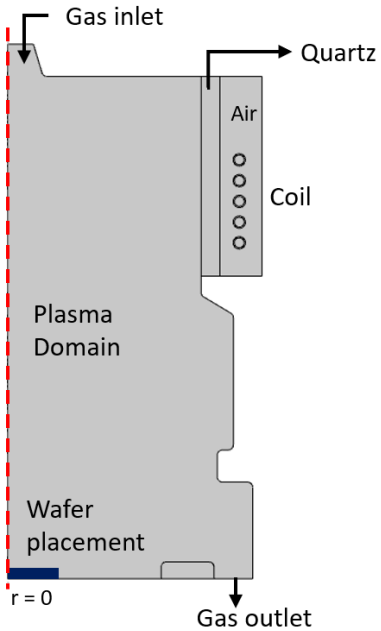

**Figure 1.** Computational domain of the *COBRA* reactor showing its major parts.

In this paper, a fluid model is developed, for the simulation of the plasma gas phase at low pressure conditions, focusing on etching PMMA blanket samples by $O_2$ gas within Oxfords Instruments' *PlasmaPro 100 Cobra* ICP plasma reactor. In this system, a 5-turn coil, placed behind a dielectric window, driven by a 13.56 MHz RF generator, couples energy electromagnetically into the plasma.

In the fluid model, species densities, electron density, and electron energy evolve in response to key operating conditions: coil power, pressure, gas feed rate, and wafer bias voltage. Given the reactor's axial symmetry, the problem is modeled in 2D axisymmetric coordinates. Figure 1 illustrates the computational domain representing the reactor geometry.

Briefly, for the electromagnetic field, Maxwell's equation set is solved. Ampere's law [eqs. (1)-(2)] is used to calculate the magnetic vector potential in the plasma region, in the dielectric window, in the coil domain and in the air contained in the domain covering the antenna

$$\nabla \times \mathbf{B} = \mu_0 \mu_r \mathbf{J_{tot}} \tag{1}$$

$$\mathbf{B} = \nabla \times \mathbf{A} \tag{2}$$

where $\mathbf{A}$ is the magnetic vector potential, $\mu_0$ and $\mu_r$ are the permeability of free space and the domain material (quartz or air) respectively, and $\boldsymbol{B}$ is the magnetic flux density. $\mathbf{J_{tot}}$ is the vector of the total current density in each domain. For the electric potential, Poisson's equation [eq. (3)] is utilized

$$-\nabla^2 V = \frac{\rho}{\epsilon_0 \epsilon_r} \tag{3}$$

where $\epsilon_0$ and $\epsilon_r$ is the permittivity of free space and material respectively, and $\rho$ is the charge density in the plasma domain.

The electrical conductivity of each domain is a key model parameter. Known values are used for air and quartz, while copper's conductivity is assigned to the coil. For the plasma domain, the conductivity is updated dynamically at each time step according to eq. (4)

$$\sigma_{plasma} = \frac{N_e q^2}{m_e(\upsilon + j\omega)} \tag{4}$$

where $N_e$ refers to the electron density, $q$ is its charge, $j$ is the unit imaginary number and $\omega$ stands for the angular frequency of the antenna. The total collision frequency $\upsilon$ is computed by summing all electron impact reaction rates and dividing by the electron density.

Regarding the electron impact reactions, their rate constants are calculated by integrating the product of the electron energy distribution function (EEDF) and the reaction-specific cross-section over the electron energy spectrum as given by eq. (5). For the $O_2$ plasma, the EEDF is approximated as Maxwellian, consistent with ref.

[7], thus

$$k_{e,i} = \int_0^\infty \sqrt{\frac{2q}{m_e}} \epsilon \sigma_i f(\epsilon) d\epsilon \quad (5)$$

where $\epsilon$ is the electron energy, $\sigma_i$ is the $i$-th electron impact reaction cross section and $f$ is the EEDF.

The mass balances for heavy species (neutral or ionic) are also solved in the model as shown, for a species $k$, in eq. (6)

$$\frac{\partial(\rho w_k)}{\partial t} = R_k - \nabla \cdot \mathbf{\Gamma}_k - \nabla \cdot (\rho \boldsymbol{u} w_k) \quad (6)$$

where $\rho, w_k, R_k$, and $\mathbf{\Gamma}_k$ are the gas mixture density, the mass fraction of species $k$, the production/consumption rate due to reactions in the gas phase, and the flux of $k$ respectively. $\boldsymbol{u}$ is the fluid velocity. The flux is given from the drift-diffusion approximation [5] and the velocity is computed from the continuity and momentum conservation equations. The gas temperature is calculated by solving the gas energy balance, which accounts for heating contributions from electron–neutral collisions, thermochemical reactions, Joule heating, and the Frank–Condon mechanism, based on ref. [8]. The PBM is implemented and numerically solved using COMSOL Multiphysics.

The set of reactions employed for the $O_2$ plasma is based on ref. [7]. A comprehensive description of the underlying reaction mechanisms is omitted for brevity. Briefly, it includes elastic collisions of $O_2$ and O with electrons, electron impact ionization, $O_2$ dissociation, and excitation reactions. At the walls, ions are neutralized and excited states return to their corresponding ground state. Electrically, the inner walls are set to ground potential, while the inlet and outlet boundaries maintain zero net current. A no-slip condition is applied to all wall surfaces, and the inlet and outlet are modeled with a fully developed velocity profile.

At the wafer level, the PMMA etching surface model follows the framework of ref. [9]. The dominant mechanism is ion-enhanced etching, driven by the interaction of adsorbed neutral oxygen with ions. Under typical plasma etching conditions, ion enhanced etching dominates over physical sputtering and pure chemical etching. In this mechanism, the oxidation of carbon in the PMMA polymer acts as the rate-determining step, while the desorption of volatile reaction products is rapid. Consequently, the overall etching rate depends on the fluxes of both ions and neutrals, as well as the ion energy.

## SURROGATE MODELING

### Multi-Layer Perceptron

The trained Multi-Layer Perceptron (MLP) has as input the $4$ operating conditions and predicts $10$ etching rates across the wafer radius.

**Table 1:** Process operation parameters' range

| Parameter | Lower Bound | Higher Bound |
|---|---|---|
| ICP Power (W) | 500 | 2000 |
| Pressure (mTorr) | 10 | 100 |
| Feed (sccm) | 40 | 150 |
| Voltage Bias (V) | 0 | 700 |

The PBM was run iteratively 2000 times under varying operating conditions to generate an ensemble of data for model training. The simulation inputs were sampled from the operation windows presented in Table 1. The solution of the PBM for a single set of operating conditions requires ~1h (Threadripper 3960X, 264GB RAM). Following each simulation, 10 radial etching rate values along the wafer are exported. The dataset was partitioned into training (60%), validation (20%), and testing (20%) sets. To rigorously assess model generalization, the test set deliberately occupied a distinct subspace comprising edge cases of the parameter space. This ensured the model was evaluated on challenging, unseen conditions rather than interpolated data points.

To ensure stable and efficient network training, all input and output variables were min-max normalized to a $[0, 1]$ range [10]. This scaling prevents features with wider numerical ranges (e.g., etching rate) from dominating the learning process and helps the optimizer converge faster by mitigating gradient instability. The implemented model was a fully connected MLP with a rather simple architecture of an input layer with 4 neurons, two hidden layers with 20 neurons each, and an output layer with 10 neurons. The hidden layers utilized the Rectified Linear Unit (ReLU) activation function to introduce non-linearity while maintaining stable gradient flow during backpropagation. Experimental fine-tuning indicated that ReLU hidden layers with an Exponential Linear Unit (ELU) [11] activated output layer, had the best performance with a smooth, continuous regression at the output.

Weighted mean squared error (MSE) was implemented with L1 regularization which is ideal for regression tasks as a loss function [12]. The L1 penalty term, controlled by the hyperparameter $\lambda$, was applied to network weights to improve generalization. During training $\lambda$ was set to $10^{-3}$. The function is formalized as

$$L = \frac{1}{N} \sum_{m=1}^{N} \sum_{j=1}^{10} \frac{1}{10} \left(y_{m,j} - \hat{y}_{m,j}\right)^2 + \lambda |W_k| \quad (7)$$

where $10$ is the set of output etching rate points, $N$ the batch size, $W_k$ refers to the model weights and $y_{m,j}, \hat{y}_{m,j}$ are the true and predicted values for the sample $m$ and radial position $j$.

Training was performed using the Adam optimizer [13], with an initial learning rate of $3 \cdot 10^{-3}$ and a weight decay of $2 \cdot 10^{-5}$. A scheduler was configured to monitor the validation loss and reduce the learning rate by a factor of 10 if no improvement was observed over 5 epochs.

To prevent overfitting, early stopping was employed based on validation loss, to terminate the training if no improvement was observed, reverting the model to the state with the best validation performance. The batch size of training was set to 32. The initial learning rate, the weight decay and the batch size were optimized via grid search based on minimizing the loss. Figure 2 shows the MLP model accuracy with high $R^2$ (0.97). Points cluster tightly along the ideal line, confirming the model captures process physics well. Minor divergence at data edges is expected due to sparse training in those regions and greater uncertainty in the PBM itself. The training and inference times are quite low; 10 min and < $10^{-3}$ s respectively (Threadripper 3960X, 264GB RAM).

**Table 2:** Comparison of KAN and MLP architectures

| Aspect | MLP | KAN |
|---|---|---|
| Activation Location | On nodes | On edges |
| Activation Type | Fixed (ReLU, etc.) | Learnable (B-splines) |
| Nonlinearity source | Stacked layers | Flexible edge functions |
| Smoothness | Not guaranteed | Inherently smooth |
| Parameter efficiency | Lower | Higher |
| Interpretability | Limited | Improved |

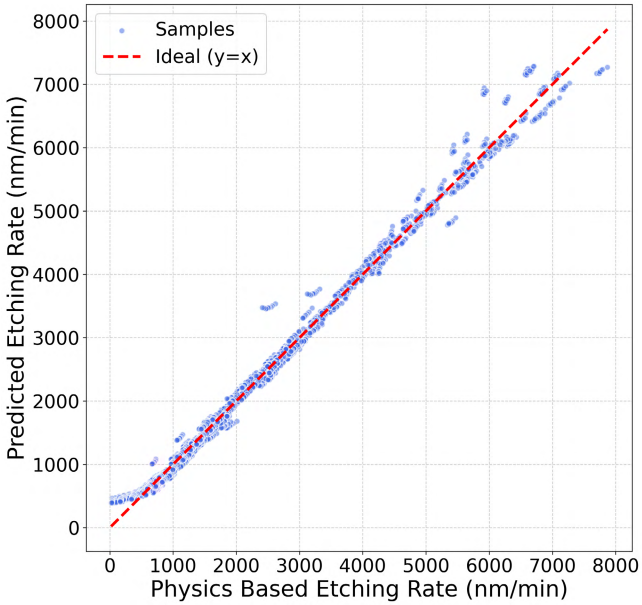

**Figure 2.** Scatter plot of the MLP model (4 inputs, 10 outputs). Model scores: $R^2 = 0.97$ and a MSE of 0.002.

## Kolmogorov-Arnold Network

We also employed Kolmogorov-Arnold Networks (KANs) [14] as our base architecture for etch rate prediction. This model's training time was 5 minutes on a GeForce Titan RTX, requiring about 1GB of GRAM.

Unlike traditional MLPs that apply fixed activation functions (e.g., ReLU, sigmoid) on nodes, KANs place learnable activation functions on edges. Each edge activation is parameterized by B-spline basis functions

$$\phi(x) = \sum_{j=1}^{G+k} c_j B_j^k(x) \quad (8)$$

where $B_j^k$ are B-spline basis functions of order $k$ defined on a grid with $G$ intervals, and $c_j$ are learnable coefficients. This allows KANs to adaptively learn activation shapes suited to specific input-output relationships, rather than relying on predefined fixed nonlinearities.

### Advantages of B-Spline Parameterization

The B-spline parameterization offers several advantages for scientific modeling tasks, such as smoothness, local support and parameter efficiency. B-splines are inherently smooth functions, making them well-suited for approximating continuous physical quantities where abrupt discontinuities are not expected. Also, each basis function has compact support, enabling efficient local adaptation to input variations without causing global interference in other regions of the input space. Lastly, KANs can achieve comparable or superior accuracy with fewer parameters than MLPs, as the flexible learnable activation functions can capture complex nonlinear relationships more efficiently than stacking many layers with fixed activations.

### Plasma-Encoded Formulation

To enable continuous spatial prediction, we adopt a position-encoded formulation

$$\hat{r}(p) = KAN([x, p]) \quad (9)$$

where the radial position $p \in [-1, 1]$ is concatenated with process parameters as network input, $x \in R^4$ denotes the same operating parameters as previously, and $\hat{r}(p)$ is the predicted etch rate at normalized radial position $p$.

This pointwise formulation transforms the problem from predicting a fixed-length output vector to learning a continuous function over spatial coordinates. Rather than training a model to output $[r_1, r_2, \ldots, r_{10}]$ simultaneously, we train it to predict the etching rate at any given position, allowing:

- **Arbitrary resolution:** Prediction can be made at any spatial location, not just the measurement points.
- **Implicit spatial coherence:** The continuous function representation naturally enforces smooth transitions between nearby positions.
- **Better generalization:** The network learns the underlying continuous mapping rather than memorizing discrete point correspondences.

The KAN's smooth B-spline activations further

promote smooth spatial variations in the output, which is consistent with physical expectations for plasma etching processes where etching rates vary continuously across the wafer surface.

# OPTIMIZATION

## Objective Function Formulation

The optimization problem is formulated to maximize the net economic value generated by the etching process per unit time ($€/s$). The objective function, $J(x, y)$, accounts for both the value of the processed wafer and the operational expenditures. It is defined as

$$J(x, y) = P_{Efficiency} - P_{Cost} \tag{10}$$

$$x = Power, Pressure, Feed, VBias \tag{11}$$

$$y = Er_{radial} \tag{12}$$

where the decision vector $x$ includes the controllable operation parameters (Source Power, Pressure, Feed Flow, Bias Voltage) and $y$ represents the predicted radial etching rate profile derived from the surrogate models.

The efficiency term $(P_{Efficiency})$ maps the physical output to monetary gain. It is defined as the product of the mean etching rate $(Er_{mean})$ normalised to the wafer area, the effective process yield $(Y)$, and the economic value per unit of etched thickness $(G_h)$:

$$P_{Efficiency} = Y \cdot Er_{mean} \cdot G_h \tag{13}$$

In this context, yield represents the fraction of wafer surface area that falls within strict uniformity tolerance bounds; while high etching rates increase throughput, the function degrades rapidly if the radial profile deviates from the wafer center maximum, ensuring speed is not prioritized at the expense of critical dimension uniformity.

The cost term $(P_{Cost})$ consists of the power, material and environmental harm costs. The power cost $(C_{Power})$ includes the RF power (source and bias) and facility baseloads. We observe that the total power cost variance is minimal across the parameter space, as the fixed power consumption of auxiliary systems (e.g., pumps, cleanroom infrastructure) outweighs the variable RF load.

$$P_{Cost} = C_{Power} + C_{Mat} + C_{Env} \tag{14}$$

The material cost $(C_{Mat})$ accounts for the consumption of process gases. While the optimization strictly controls the flow of the reactive precursor (Feed), the total material cost is largely driven by the steady-state consumption of inert carrier gases required for the reactor's operation. Similar to the power term, the relative variance of material costs remains low across the parameter bounds, despite constituting a significant fraction of the absolute operational expenditure. The environmental term $(C_{Env})$ calculates costs associated with the Global Warming Potential (GWP) of the effluent. In the studied $O_2$ plasma, GWP costs are negligible, though the framework is designed to scale for more complex chemistries where environmental abatement is a dominant cost driver.

The objective function can be readily augmented to include upstream lithography parameters (e.g., mask selectivity interactions) or auxiliary economic terms such as equipment maintenance cycles, thereby enabling a holistic optimization of the broader patterning module without altering the fundamental control logic.

## Optimization Strategy

The optimization of the reactor setpoints is implemented within Python as a derivative-free optimization (DFO) problem. Given the non-convex nature of the neural network response surfaces and the discontinuities introduced by the yield penalty function $(Y)$, gradient-based methods are prone to instability or premature convergence to local optima. Consequently, we validate our findings by executing the optimization task using two independent direct-search algorithms: Nelder-Mead (NM) and Powell's Conjugate Direction (PCD) methods [15, 16].

Rather than relying on a single solver, conducting separate, independent optimization searches with these distinct methods serves as a critical verification. The simplex-based approach of NM and the directional line-search approach of PCD operate via different mechanisms; their convergence to a common basin of attraction, despite their differing search trajectories, increases our confidence in the optimality of the identified solution and independence from algorithmic artifacts.

The optimization is constrained within a hyper-rectangle defined by the physical limits of the training data, presented in Table 1. To facilitate unbiased exploration, both solvers are initialized using a "Warm Start" strategy originating from the centroid of the hyperparameter space. This neutral initialization point prevents the optimizer from being prejudiced toward specific high-power or high-pressure regimes, allowing the objective function gradient to naturally drive the trajectory toward the most profitable operating window.

## Optimization Results

The optimization results for both surrogate architectures are summarized in Tables 3 and 4. For each respective surrogate model, both the NM and PCD algorithms converged to the same operating point. Combined with the multistart method, this confirms that the identified solutions represent the true global maximums of the respective neural network response surfaces, independent of the optimization method employed.

**Table 3:** MLP Optimization Results

| **Optimal Conditions** | $J\ [=]\ €/s$ | **10.55** |
|---|---|---|

| | | | |
|---|---|---|---|
| Power (W) | 2000 | $P_{Efficiency}$ | 13.64 |
| Pressure (mTorr) | 10 | $C_{Power}$ | $3.15\ e^{-4}$ |
| Feed (sccm) | 40 | $C_{Mat}$ | 3.09 |
| Voltage Bias (V) | 700 | $C_{Env}$ | $2.18\ e^{-8}$ |

**Table 4:** KAN Optimization Results

| **Optimal Conditions** | | $J\ [=]\ €/s$ | **10.47** |
|---|---|---|---|
| Power (W) | 2000 | $P_{Efficiency}$ | 13.57 |
| Pressure (mTorr) | 10 | $C_{Power}$ | $3.14\ e^{-4}$ |
| Feed (sccm) | 105 | $C_{Mat}$ | 3.09 |
| Voltage Bias (V) | 686 | $C_{Env}$ | $5.72\ e^{-8}$ |

Figure 3 illustrates the optimization convergence, highlighting the prohibitive cost of direct optimization. Since a PBM prediction takes about an hour, the numerous iterations required would be computationally impractical to run. In contrast, the surrogate models allowed the entire process to complete on a mid-tier CPU in approximately 3-4 minutes per method employed.

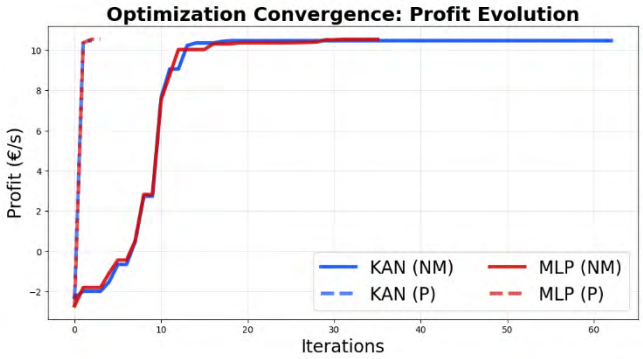

**Figure 3.** Optimization Convergence of each method

To validate the accuracy of these solutions, the optimal etching rate profiles predicted by both surrogates are compared against the PBM ground truth in Figure 4. The PBM reference profile was generated using the optimal conditions identified by the MLP surrogate. As illustrated, both the MLP and KAN surrogates yield radial profiles that closely align with the physical baseline, despite the divergence in their secondary Feed Flow parameters.

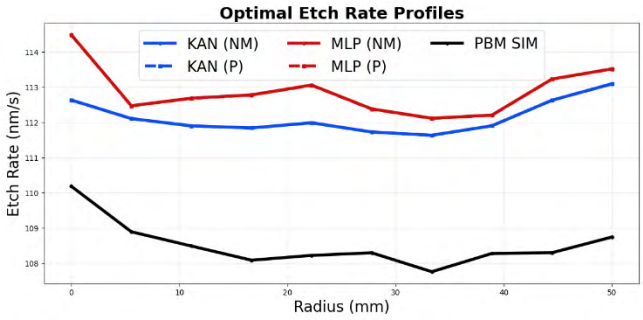

**Figure 4.** Etching rate profiles for both models and optimization methods, compared to PBM profile.

## Sensitivity Analysis and Exploration

While the optimization algorithms converged effectively, the divergence in the final setpoints necessitates a closer examination of the surrogate response surfaces. To understand the reasons behind the different optimal conditions, local sensitivity sweeps are performed around the high-power/low-pressure $(2000\ W, 10\ mTorr)$ area where both models agreed.

As established in the optimization results, both surrogates identified Power and Pressure as the primary control levers. Sensitivity sweeps confirm that both the MLP and KAN correctly approximate the PBM gradients in these dimensions, identifying the upper bound of power and the lower bound of pressure as the trajectory for maximizing etching rate. This alignment confirms that both architectures successfully captured the global trend of the dominant variables.

A minor discrepancy was observed in the Bias Voltage, where the MLP model converged to $700\ V$ while the KAN settled at $686\ V$. Despite this offset, the behavior of both models remains largely consistent, reaffirming the parameter's critical influence on the objective function. To verify this, a sensitivity sweep was conducted by varying Voltage Bias across its design limits while holding the rest of the parameters at their optimal values, shown in Fig. 5. This isolation reveals the distinct response surfaces of each surrogate: while both models correctly and similarly identify the parameter importance, the KAN response exhibits a stagnation effect near the upper bound, whereas the MLP maintains a steeper gradient.

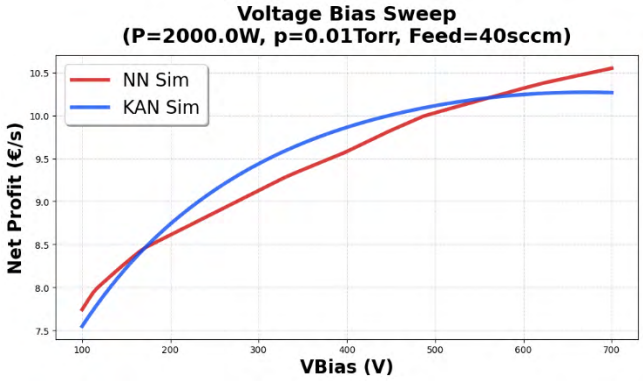

**Figure 5.** VBias response profiles: MLP(NN) and KAN

The most significant divergence occurred for the Feed parameter $(40\ sccm\ vs\ 105\ sccm)$. To analyze this, the Feed was swept across the design space while holding other inputs at their optimal values, shown in Figure 6; it reveals a distinct conflict in functional approximation. The Ground Truth for the surrogates, i.e., PBM, behaves near-linearly, showing a slight preference for lower flow rates. It also showcases the impact of the slight profile

difference between the PBM and the surrogates, as shown in Figure 4, on the objective function. The MLP surrogate is closer to mimicking the PBM linear behavior. It correctly identifies the negative slope and directs the optimizer toward the lower bound, effectively matching the true physical optimal point. The KAN surrogate introduces an artificial curvature. While its predictions are closer to the PBM at the boundaries, it significantly deviates in the center of the domain, creating a parabolic shape that drives the optimizer towards the middle.

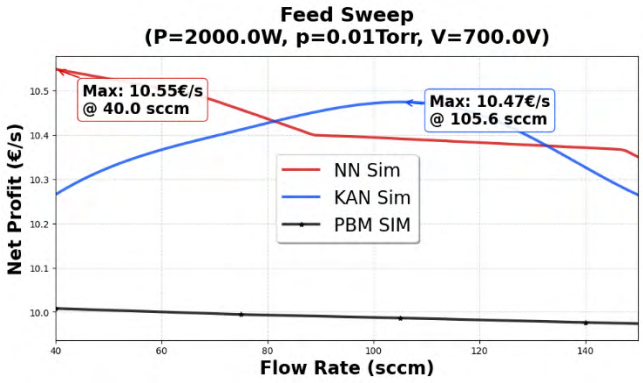

**Figure 6.** Feed Flow response profiles: MLP(NN) and KAN surrogates vs. PBM.

## DISCUSSION

### Data Sparsity

The divergence in the Feed Flow optimization highlights a fundamental difference in how the two architectures handle interpolation in sparse data regions. Despite both models being trained on the exact same dataset, the KAN architecture likely attempted to fit a higher-order non-linearity where none existed, whereas the MLP maintained a simpler linear approximation that proved more robust in this specific scenario.

This behavior could be attributed to the "Edge Effect." The optimal operating point $(2000\ W, 10\ mTorr)$ lies at the corner of the training hypercube. Neural networks are notoriously prone to high variance at the boundaries of their training domain. The KAN architecture, which utilizes learnable spline functions, is designed to be highly flexible in capturing local non-linearities. However, the results indicate that in this specific boundary region, this flexibility may have resulted in the model capturing stochastic noise rather than the true physical trend. On the other hand, the MLP appears to have defaulted to a smoother, more global approximation. In this instance, the simpler structure of the MLP likely acted as a constraint, preventing the model from inferring a local optimum where the physical landscape is effectively flat.

### Physics Validation

From a plasma physics perspective, the PBM's insensitivity to Feed (and the MLP's resulting preference for the lower bound) is physically consistent with an ion-driven etching regime. At low pressures, the mean free path of species increases, and the etching mechanism becomes dominated by directional ion bombardment (controlled by Power and Bias) rather than chemical etching by neutral radicals (controlled by Feed Flow).

Consequently, variations in the gas flow have a negligible impact on the etching rate compared to the ion density. The PBM correctly reflects this "flat" landscape. The fact that the optimizer identified the correct high-power/low-pressure window proves that the framework successfully isolated the primary physics drivers, even if the secondary parameters had a diminished effect.

### The Confidence Gap

The disagreement between the models in the Feed value raises a critical question regarding reliability. If a single model had been used, the optimizer would have returned a result with high apparent confidence, while it could still be misleading. The existence of this "Confidence Gap" between the two models is important. It suggests that in industrial applications, model disagreement should be treated as a proxy for epistemic uncertainty. This underscores the necessity for future frameworks to integrate Uncertainty Quantification. By flagging regions where the MLP and KAN diverge, the system could automatically trigger "active learning, " requesting targeted PBM simulations to resolve the ambiguity before finalizing the optimization, while also improving the models.

## CONCLUSIONS

This work presents a framework for the optimization of plasma etching processes, aimed at bridging the fidelity of Physics-Based Models (PBMs) with the computational efficiency of data-driven surrogates. The core contribution of this study extends beyond the specific etching recipe identified; it demonstrates that integrating diverse neural architectures into the optimization loop provides a necessary proxy for prediction reliability, a critical step toward fully autonomous process discovery.

The application of this framework successfully identified a high-value operating regime characterized by high power $(2000\ W)$ and low pressure $(10\ mTorr)$. This result is physically consistent with an ion driven etching mechanism, where maximizing ion energy and density dominates value creation. Furthermore, the use of two distinct surrogate architectures (MLP and KAN) confirmed the robustness of these setpoints; both models agreed on the primary drivers, while disagreeing regarding the rest.

Beyond the specific framework, this study validates the feasibility and efficiency of surrogate-based optimization for complex industrial processes. We

demonstrated that by training neural networks on a targeted dataset of PBM simulations, it is possible to achieve global optimality orders of magnitude faster than direct physics simulation. This workflow offers a practical blueprint for reducing the computational burden of process design, allowing engineers to explore vast parameter spaces without the prohibitive time costs associated with traditional physics solvers or experimental trial-and-error.

Future work will transition from static modeling to a hybrid active learning loop. The PBM could be integrated directly into the optimization process, utilizing prediction uncertainty as a trigger. Instead of relying solely on pre-trained surrogates, the system will dynamically query the PBM whenever the certainty of a prediction drops. This creates a self-correcting workflow that autonomously improves model accuracy in high-value regions, ensuring that the final operating point is validated by physics while keeping computational costs minimal.

## ABSTRACT

Reliable process operation under uncertainty remains a fundamental challenge in chemical and pharmaceutical manufacturing. Variability arising from feed fluctuations, material properties, external disturbances, and uncertain model parameters can significantly impact feasibility and performance when operating ranges are designed under nominal assumptions. Design Space Identification (DSI) addresses these limitations by defining a Probabilistic Design Space (PDS), within which process constraints are satisfied with a prescribed confidence level. However, identifying and extracting robust and practically usable nominal operating ranges (NORs) from complex, high-dimensional, and nonconvex PDSs remains computationally demanding. This work proposes a novel reinforcement learning (RL)–based framework for automated identification of the largest robust hyper-rectangular NOR fully contained within a given PDS. The design centering problem is formulated as a sequential decision-making task and solved using the Proximal Policy Optimization (PPO) algorithm. By interacting with a probabilistic feasibility environment, the RL agent adaptively adjusts the location and size of the NOR to maximize its area while enforcing probabilistic constraint satisfaction. Deep neural network policies enable efficient exploration of nonlinear feasibility boundaries without exhaustive sampling or gradient-based optimization. The approach is demonstrated on a tablet lubrication case study with parametric uncertainty. Results show rapid convergence to well-located, near-maximal NORs using substantially fewer probabilistic feasibility evaluations than conventional grid-based or Monte Carlo methods. The proposed PPO-based framework provides a scalable and data-efficient solution for robust operating range identification in uncertainty-aware process design.

**Keywords**: Probabilistic design space (PDS), Nominal Operating Range (NOR), Reinforcement Learning, Operational flexibility, Proximal Policy Optimization

## 1. INTRODUCTION

Chemical and pharmaceutical manufacturing is undergoing rapid transformation driven by the need for increased process efficiency, reduced development timelines, and improved product quality [1-2]. Within this evolving context, the Quality by Design (QbD) paradigm has emerged as a central framework for modern process development, emphasizing systematic process understanding and risk-based decision-making [3-4]. Central to QbD is the establishment of quantitative relationships among Critical Quality Attributes (CQAs), process parameters, and material attributes, enabling reliable and reproducible operation across a range of conditions [5-6].

Achieving such robustness is inherently challenging due to multiple sources of uncertainty, including raw material variability, feed disturbances, unmeasured process dynamics, and uncertain model parameters. To explicitly account for these uncertainties, Design Space Identification (DSI) methodologies have been developed to characterize the regions of feasible operation that satisfy all process and quality constraints. In recent years, DSI extends this concept by defining a Probabilistic Design Space (PDS), comprising operating conditions that satisfy all process and quality constraints with a prescribed confidence level $\alpha$ (e.g., $\geq 95$ %) [7-10].

While probabilistic DSI provides a rigorous uncertainty-aware framework, the resulting PDSs are often irregular, nonconvex, and disconnected, particularly in

nonlinear and high-dimensional systems. As a result, PDSs are difficult to use directly in industrial practice. Instead, operation typically relies on a Nominal Operating Range (NOR), commonly defined as a hyper-rectangular region fully contained within the PDS. NORs are interpretable, easily implementable, and well aligned with control strategies and regulatory documentation.

Identifying the largest feasible NOR within a PDS corresponds to the classical design centering problem. However, ensuring probabilistic feasibility throughout an entire operating region is not merely at isolated points, it renders this problem computationally prohibitive for conventional approaches such as exhaustive grid searches, Monte Carlo sampling, or heuristic expansion, especially as dimensionality increases. Moreover, point-based optimization strategies often yield operating conditions that appear optimal in simulation but lack robustness under real-world disturbances [11-12].

These limitations motivate the development of methods that directly characterize feasible regions and efficiently navigate complex probabilistic design spaces. In this work, we propose a novel reinforcement learning (RL)–based framework for automated design centering within PDSs. Recent advances in RL for process systems engineering have demonstrated its potential for control, scheduling, and optimization under uncertainties [3, 13-15]; however, its application to probabilistic design space exploration and robust operating range identification remains largely unexplored. This work bridges that gap by introducing a scalable, data-efficient, and uncertainty-aware RL methodology for robust NOR identification, offering a practical pathway for translating probabilistic design concepts into actionable operating guidelines. By formulating NOR identification as a sequential decision-making problem, an RL agent iteratively refines the location and size of an operating region candidate while enforcing probabilistic feasibility constraints. Proximal Policy Optimization (PPO) is employed to enable stable and sample-efficient exploration without requiring explicit gradients, convexity assumptions, or exhaustive enumeration of feasible points.

# 2. METHOD

## 2.1 Problem Statement and Scope

This work addresses the design centering problem within a given PDS. The PDS is assumed to be available *a priori*, having been identified using established probabilistic design space methodologies, as reported in previous work [9]. The objective is to determine the NOR that is fully contained within the given PDS while satisfying a prescribed probabilistic confidence level.

The NOR is parameterized as a hyper-rectangular region in the space of operating variables and is defined by its center and half-widths in each dimension. The design centering task therefore consists of identifying these parameters such that the resulting NOR maximizes operational flexibility while remaining probabilistically feasible throughout its entire extent. The NOR is defined as

$$NOR = \{x \in \mathbb{R}^n | \mu - \Delta \leq x \leq \mu + \Delta\} \quad (1)$$

where $\mu$ denotes the center of the operating region and $\Delta$ represents the vector of half-widths.

## 2.2 Design Centering Optimization Problem

The design centering objective is to identify the NOR parameters $(\mu, \Delta)$ that maximize the area (or hypervolume) of the hyper-rectangular operating region while ensuring probabilistic feasibility throughout the entire NOR. This objective can be formulated as

$$\max_{\mu,\Delta} V(\Delta) = \prod_{i=1}^{n} 2\Delta_i \quad (2)$$

Subject to

$$\mathbb{P}_\theta(C(x,\theta) \leq 0) \geq \alpha, \forall x \in NOR \quad (3)$$

Unlike pointwise feasibility checks, constraint (3) requires that all operating conditions within the NOR satisfy the probabilistic constraints, rendering the problem highly challenging. The feasibility boundary is implicit, nonconvex, and typically requires repeated uncertainty propagation. As a result, conventional optimization, sampling-based, or gradient-based approaches become computationally prohibitive, particularly in high-dimensional settings. These challenges motivate the use of adaptive, data-driven approaches that can directly characterize and exploit the feasible region, rather than relying on dense sampling of the full design space.

# 3. METHODOLOGY: REINFORCEMENT LEARNING FRAMEWORK FOR DESIGN CENTERING

To address the design centering problem defined above, the NOR identification is formulated as a sequential decision-making problem and solved using RL. This formulation enables efficient exploration of complex probabilistic design spaces without relying on convexity assumptions or explicit gradient evaluations.

## 3.1 Markov Decision Process Formulation

The design centering task is reformulated as a continuous-state, continuous-action Markov Decision Process (MDP), in which an agent iteratively modifies the parameters of a candidate NOR and receives feedback based on probabilistic feasibility and operating range size.

**State Space.** At iteration $t$, the state is defined as,

$$s_t = [\mu_t, \Delta_t],$$

where $\mu_t$ denotes the current NOR center at iteration $t$ and $\Delta_t$ represents the corresponding half-widths along each dimension.

**Action Space.** The action space corresponds to incremental updates of the NOR parameters,

$$a_t = [\Delta\mu_t, \Delta\Delta_t],$$

allowing the agent to shift the NOR center and expand or contract its dimensions.

**State Transition.** Given an action, the environment updates the NOR parameters and evaluates probabilistic feasibility using constraint (3). The updated parameters constitute the next state $s_{t+1}$. Infeasible transitions result in penalization and episode termination.

This formulation allows the agent to iteratively refine the location and size of the NOR while interacting directly with the probabilistic feasibility landscape.

## 3.2 Reward Function Design

The reward function is designed to promote identification of large, well-located NORs while strictly enforcing probabilistic feasibility. At each iteration, the RL agent receives a scalar reward defined as

$$R_t = w_1 V(\Delta_t) - w_2 \mathbb{I}(\text{violation}) - w_3 d_{\text{boundary}}, \qquad (4)$$

where $V(\Delta_t) = \prod_{i=1}^{n} 2\Delta_{t,i}$ represents the hypervolume (area in this 2D problem) of the nominal operating region, $\mathbb{I}(\text{violation})$ is an indicator function equal to one if probabilistic feasibility is violated, and $d_{\text{boundary}}$ is a boundary-based shaping term that penalizes proximity to infeasible regions.

The first term directly encodes the design centering objective, while the penalty terms ensure strict constraint satisfaction and promote robustness margins. The weighting coefficients $w_1, w_2,$ and $w_3$ balance the competing objectives of maximizing operating range size and maintaining robust feasibility. Specifically, $w_1$ scales the hypervolume objective to encourage expansion of the NOR, $w_2$ imposes a strong penalty on probabilistic feasibility violations to discourage infeasible actions, and $w_3$ penalizes proximity to the PDS boundary to maintain a robustness margin. The weights are selected empirically to ensure that feasibility violations are strongly discouraged while still allowing the agent to expand the operating region within the feasible domain. Infeasible actions terminate the episode, ensuring that learned policies prioritize feasibility over aggressive expansion.

In addition to reward-based penalization, hard termination criteria are enforced to ensure strict feasibility. Episodes are terminated if (i) the NOR center lies outside the probabilistic design space at initialization, (ii) an action results in the NOR center escaping the PDS, or (iii) the updated hyper-rectangular region intersects or extends beyond the PDS boundary. These termination rules prevent infeasible policy updates and focus learning on robust and interpretable operating regions.

The resulting learning problem involves continuous state and action spaces, nonconvex feasibility boundaries, and discontinuities due to constraint violations. To address these challenges, PPO is employed. PPO provides stable and sample-efficient learning through a clipped surrogate objective that limits overly aggressive policy updates, making it well suited for exploration in complex PDSs. Without specialized constraint-handling mechanisms, the PPO agent adaptively refines the NOR parameters and converges toward a large, well-located operating region within the given PDS.

## Case study: Tablet Lubrication process

Lubrication plays a critical role in tablet manufacturing, particularly in direct compression process, as it facilitates tablet ejection during compression. However, excessive lubrication can adversely affect tablet mechanical properties, most notably tensile strength. The interaction between lubrication extent and compaction pressure therefore represents a key trade-off in tablet manufacturing, where increased lubrication may reduce tensile strength, a loss that can be partially compensated by higher compaction pressures.

In this work, a tablet lubrication and compaction model previously reported in the literature is adopted [16-17]. Tablet tensile strength is modeled as:

$$\sigma = \sigma_{sf=0.85,0}\big((1-\beta) + \beta exp(-\gamma k)\big) \qquad (5)$$

$$\sigma_{sf=0.85,0} = a_1 exp\big(b_1(1-sf)\big) \qquad (6)$$

$$\beta = a_2(1-sf) + b_2 \qquad (7)$$

where $\sigma_{sf=0.85,0}$ denotes the tensile strength at a solid fraction of 0.85 in the absence of lubrication, $\beta$ represents the fraction of tensile strength loss attributable to lubrication, $\gamma$ is the lubrication rate constant, $k$ denotes the lubrication extent, and $sf$ denotes the solid fraction. The model involves five uncertain parameters, $\theta = [a_1(MPa);\ b_1(-);\ a_2(-);\ b_2(-);\ \gamma(dm^{-1})]$ and captures the effects of solid fraction and lubrication extent on tablet tensile strength.

In the present study, solid fraction and lubrication extent are treated as CPPs, while tablet tensile strength is considered as a CQA. The PDS for this process, accounting for parameter uncertainty and probabilistic constraint satisfaction, has been previously identified and reported in Yewale et al. (2025)[9]. Here, this probabilistic design space is taken as a fixed feasibility domain, and the proposed reinforcement learning framework is applied to automatically identify a robust and well-located nominal operating range.

# 4. RESULTS

## 4.1. Probabilistic Design Space Characterization

The probabilistic design space (PDS) for the tablet lubrication case study, previously identified using nested sampling [9], is shown in Fig. 1 in the space of porosity and lubrication extent. Each sampled operating condition is classified according to the probability of satisfying all quality constraints, highlighting regions of high confidence (α ≥ 0.95), intermediate feasibility, and infeasible operation. The resulting PDS exhibits a distinctly nonconvex and asymmetric geometry, with feasibility rapidly degrading near the upper porosity boundary and at high lubrication extents. This irregular structure highlights the limitations of conventional pointwise feasibility analysis and local expansion strategies, which are ill-suited to capture the global structure of such complex probabilistic design spaces.

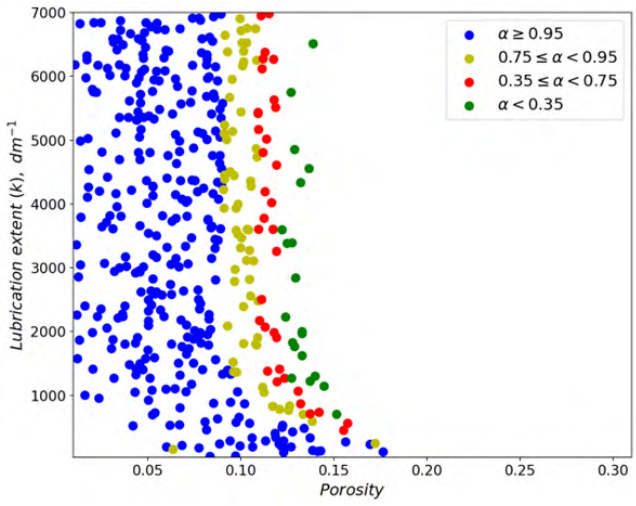

**Figure 1.** PDS identified using Nested sampling (Yewale et al 2025 [9])

## 4.2. Learning Dynamics and Convergence Behavior

The training and evaluation performance of the PPO agent are summarized in Fig. 2(a) and Fig. 2(b), respectively. During training, the mean episodic reward increases rapidly within the initial phase, indicating effective early exploration and rapid identification of feasible regions within the PDS. This phase is characterized by relatively high reward variance, reflecting exploratory behavior and frequent interactions with feasibility boundaries.

As training progresses, reward trajectories gradually stabilize, reflecting a transition from exploration toward exploitation and policy refinement. Occasional reward fluctuations persist due to stochastic exploration, but the overall trend reflects consistent improvement in the agent's ability to identify large, feasible operating regions.

The results shown in Fig. 2(b) exhibit significantly reduced variance and sustained high reward levels, confirming that the learned policy generalizes well beyond individual training episodes. This behavior confirms that the learned policy generalizes well beyond individual training episodes and reliably identifies large, feasible operating regions. Importantly, convergence is achieved using substantially fewer probabilistic feasibility evaluations than would be required by exhaustive grid-based or Monte Carlo design centering approaches, underscoring the computational efficiency of the proposed RL framework.

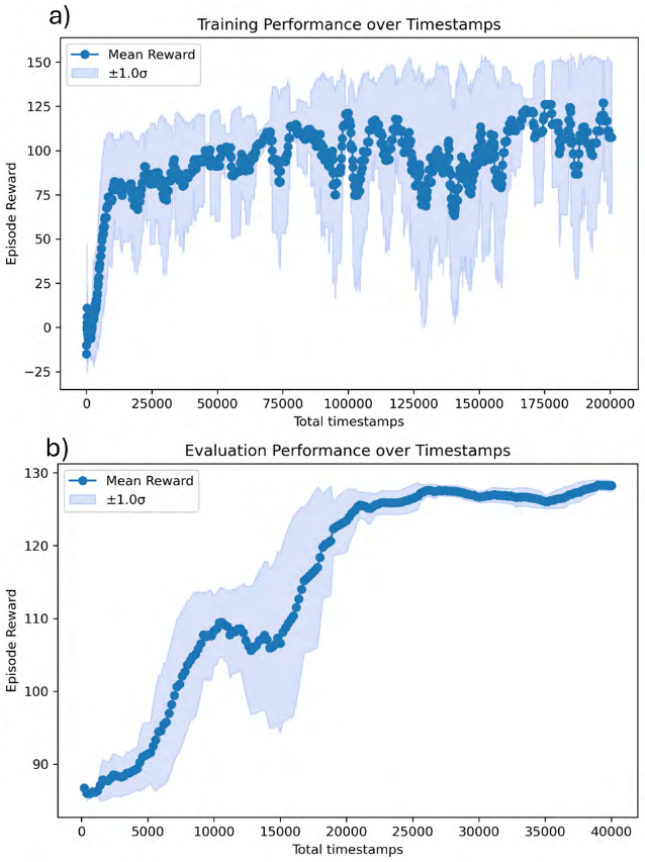

**Figure 2.** Training and evaluation performance of the PPO agent

## 4.3. Policy Behavior and Trajectory Analysis

A representative sample of the PPO trajectories across multiple episodes is shown in Fig. 3, illustrating the episodic refinement of the NOR within the PDS during learning. Each episode begins from a randomly initialized NOR center, indicated by a blue circular marker, located within the probabilistic design space, resulting in diverse starting points across the feasible region. The red cross denotes the terminal NOR center at the end of the

episode, corresponding to the final operating region returned by the policy after the sequence of updates.

During early learning episodes, the agent executes a sequence of incremental updates to the NOR center and dimensions, guided by the reward structure and feasibility feedback. The resulting trajectories exhibit exploratory behavior, including corrective movements away from nearby infeasible boundaries and directional adjustments toward regions of higher feasibility. These exploratory steps reflect the agent's interaction with the underlying PDS geometry, as it learns to balance NOR expansion with constraint satisfaction. Importantly, the trajectories remain confined to feasible regions, indicating that boundary violations are effectively penalized during learning.

As learning progresses, the trajectories become shorter, smoother, and more directed, converging toward a common region near the interior of the PDS. This transition reflects policy stabilization, where the agent has acquired an internal representation of the feasible region and no longer requires extensive exploration. The resulting trajectories consistently terminate at similar NOR centers, demonstrating convergence toward a well-located and robust operating region.

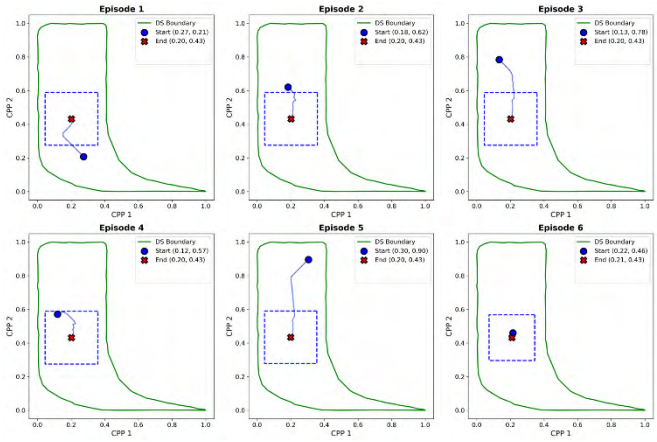

**Figure 3.** Representative PPO trajectories showing episodic refinement of the NOR within the PDS

The final and best-performing NOR identified by the trained PPO agent is shown on Fig. 4. The resulting hyper-rectangular operating region is fully contained within the PDS and is well-located relative to the feasibility boundaries. The identified NOR achieves a near-maximal feasible area while maintaining a clear margin from infeasible regions, highlighting the effectiveness of the boundary-aware reward design. Notably, repeated training runs converge to nearly identical NOR centers and dimensions, providing strong evidence that the PPO-based framework identifies a globally robust solution rather than a local or initialization-dependent optimum. This repeatability is particularly important for industrial deployment, where reproducibility and interpretability of operating ranges are critical.

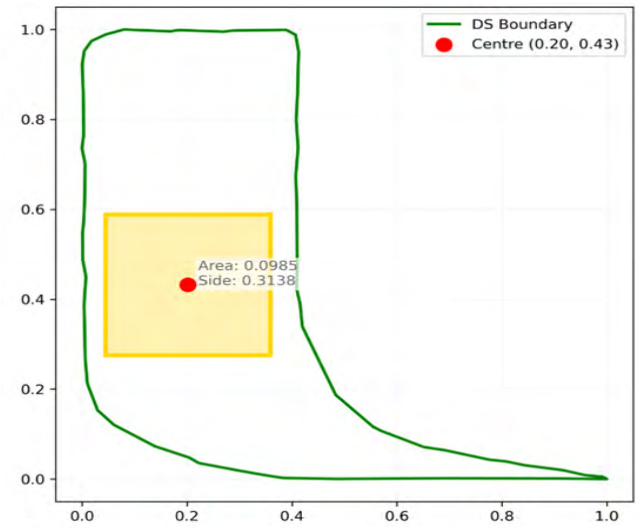

**Figure 4.** Best-performing nominal operating range identified by the PPO agent, fully contained within the probabilistic design space

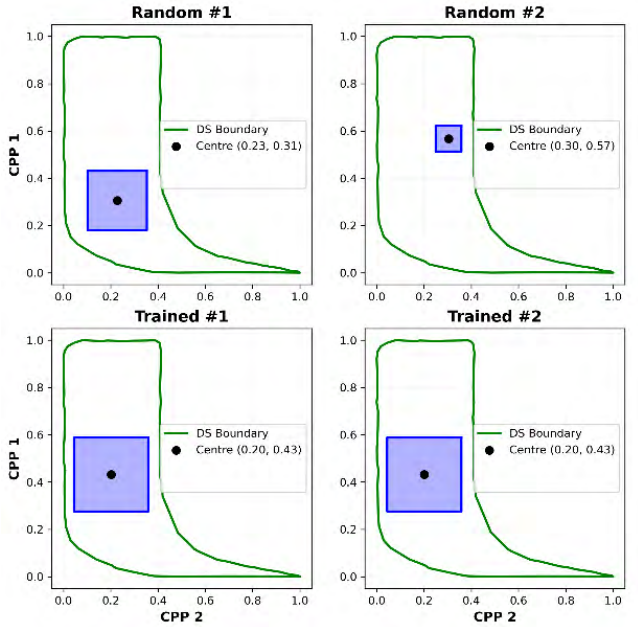

**Figure 5.** Comparison between randomly initialized operating regions and NORs identified by the trained PPO policy

To further assess robustness, Fig. 5 compares NORs obtained from randomly initialized centers with those identified by the trained PPO policy. Random initialization leads to highly variable operating regions, many of which either intersect the PDS boundary or yield overly conservative ranges that fail to exploit available operational flexibility. In contrast, the PPO-based approach consistently produces similar NOR centers and

dimensions across independent runs, demonstrating robustness with respect to initialization and stochasticity.

## 5. CONCLUSION

This work introduced a novel RL-based framework for automated identification of robust nominal operating ranges within the probabilistic design spaces. By formulating the design centering problem as a sequential decision-making task and solving it using PPO, the proposed approach enables efficient exploration of complex, non-convex feasibility regions under uncertainty.

Application to a tablet lubrication case study demonstrated rapid convergence to well-located, near-maximal NORs using substantially fewer probabilistic feasibility evaluations than conventional methods. The learned policy exhibited strong robustness, repeatability, and insensitivity to initialization, all of which are critical for industrial deployment.

The proposed framework provides a scalable and data-efficient alternative to traditional design centering techniques and offers a practical pathway for translating probabilistic design spaces into actionable and robust operating ranges. Future work will extend the approach to higher-dimensional systems and investigate integration with digital twins and adaptive process design workflows.

## ABSTRACT

Physics-Informed Neural Networks (PINNs) offer a promising approach for integrating first-principles modeling with data-driven methods, especially in dynamic thermal systems. This study introduces a hybrid PINN framework for a one-dimensional heating rod governed by heat transfer equations. Unlike traditional PINNs that rely on time-dependent automatic differentiation, this approach employs numerical derivatives to bypass gradient saturation and enhance robustness. The proposed model demonstrates accurate extrapolation and generalization with limited training data and is effectively used as a surrogate in a Model Predictive Control (MPC) framework for rod-tip temperature regulation. Additionally, a plan is outlined to apply physics-informed dimensionality reduction and model order reduction to improve computational efficiency and enable real-time application. The findings affirm PINNs' potential as control-oriented reduced models for thermal processes.

**Keywords**: Physics-Informed Neural Networks, Heat Transfer, Model Predictive Control, Model Order Reduction, Thermal Systems

## INTRODUCTION

The importance of modeling and system identification has increased as modern process systems have grown more complex. First-principles modeling requires extensive domain expertise and is often time-consuming and costly to implement, particularly for complex or poorly characterized systems. Data-driven black-box models alleviate some of these challenges by relying solely on available measurements; however, they typically suffer from poor extrapolation performance and limited physical interpretability [1].

Neural networks, while flexible and expressive, are highly sensitive to data quality and initial parameter values, and their training may converge to local minima. To address these limitations, Physics-Informed Neural Networks (PINNs) incorporate governing equations directly into the learning process, thereby reducing data requirements and improving generalization. Since the seminal work of Raissi et al., PINNs have been successfully applied to a wide range of differential-algebraic and partial differential equation (PDE) systems [2].

Some studies predict the thermophysical properties of chemical components by imposing physical constraints on the neural network model structure [3].

PINNs have been successfully employed to enforce heat-transfer physics in complex thermal-flow problems, demonstrating their ability to solve PDEs with limited or no training data in a specific domain [4].

Recent literature demonstrates a growing interest in physics-informed neural networks for thermal systems and control applications, ranging from building energy systems [5] and thermal energy storage [6] to real-time MPC implementations in industrial processes [7], [8]. Despite these advances, integrating PINNs as lightweight, control-oriented surrogate models for dynamic thermal systems, while avoiding time-dependent automatic differentiation and maintaining robustness, remains an open challenge. PINNs are mostly used in time-series modelling for batch processes, since common automatic differentiation approaches require time values as inputs to the surrogate model.

This work addresses this gap by developing a PINN framework for a one-dimensional heating rod system that

leverages numerically evaluated derivatives to enforce physical consistency, achieves reliable extrapolation with sparse data, and enables efficient deployment within a model predictive control scheme.

## METHODS

This section discusses the methods, case study, data, and model structure to implement a PINN-MPC controller.

### Physics-Informed Neural Network Framework

Physics-informed neural network architectures have been extended toward control-oriented recurrent structures, enabling improved generalization and robustness in predictive control applications [9].

The proposed PINN follows a hybrid modeling strategy in which first-principles heat transfer equations guide the learning process, while a neural network approximates the unknown system dynamics. In contrast to conventional PINN formulations that explicitly treat time as a network input and rely on automatic differentiation, the present framework enforces physical consistency through numerically evaluated derivatives. This strategy improves robustness, mitigates gradient saturation from monotonic time inputs, and enhances extrapolation performance, making the model suitable for control-oriented applications.

#### Network Representation

The neural network is used to approximate the system input–output relationship and is represented as:

$$\hat{y}(t) = f_\theta(u(t), x(t)), \quad (1)$$

where $f_\theta(\cdot)$ denotes the neural network parameterized by $\theta, u(t)$ represents the heater duty cycle, and $\hat{y}(t)$ corresponds to the predicted rod-tip temperature. The network architecture is kept deliberately compact to support real-time control applications [10].

#### Physics-Informed Training Objective

Physical knowledge is incorporated into the learning process through a composite loss function of the form

$$L = L_\theta + \lambda L_{res}, \quad (2)$$

where $L_\theta$ enforces agreement with measured data and $L_{res}$ penalizes violations of the discretized heat transfer equations. The weighting parameter $\lambda$ balances data fidelity and physical consistency. Figure 1 illustrates the PINN framework.

#### Numerical Derivative Enforcement

Unlike classical soft-constraint PINNs that rely on time-dependent automatic differentiation, this work employs numerical differentiation to evaluate temporal derivatives in the governing equations. This choice avoids activation function saturation caused by ramp-like time inputs in continuous thermal systems and leads to improved training reliability and prediction for continuous processes.

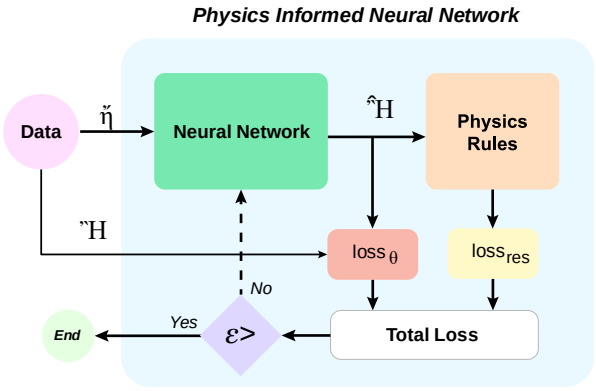

**Figure 1.** A schematic of the training process in a physics-informed neural network

### Heating Rod Case Study

The case study considered in this work is a one-dimensional heating rod, which serves as a benchmark for thermal processes commonly encountered in industrial heating, furnaces, and laboratory-scale thermal systems. Heat transfer along the rod is governed primarily by conduction, with heat input applied through an electrical heater and heat losses occurring due to convection and radiation at the boundaries.

The system dynamics can be described by a one-dimensional transient heat conduction equation with appropriate boundary and initial conditions. These governing equations provide the physical foundation that is embedded in the learning process of the proposed PINN framework. A schematic of the system is shown in Figure (2).

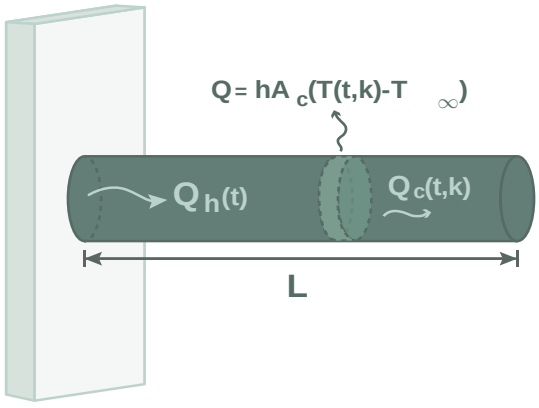

**Figure 2.** Heating rod schematic.

## Data and Training Setup

Training data for the PINN model are obtained from simulated temperature of the heating rod under varying heater duty cycles. The dataset is intentionally limited in size to evaluate the extrapolation capability of the proposed physics-informed approach. Input–output trajectories are split into training and validation sets, ensuring that the validation data include operating conditions outside the training range.

The neural network is trained with the Adam optimizer, and physical constraints are incorporated via a physics-informed loss term. At the end of the training session, the SLSQP optimization method was used to fine-tune the model weights. Hyperparameters are selected to balance model accuracy, robustness, and computational efficiency. A summary of model hyperparameters is presented in Table 1. The neural network model uses the location between zero and the rod length, along with past temperature measurements and heater duty, as the manipulated variable to predict the system output temperature in the next timestep. The input and output data are normalized.

**Table 1.** Summary of the PINN model structure

| # | Layer Type | Unit | Activation Function |
|---|---|---|---|
| 1 | Dense | 3 | - |
| 2 | Dense | 10 | tanh |
| 3 | Dense | 10 | tanh |
| 4 | Dense | 1 | linear |

The proposed framework aims to identify dominant thermal dynamics while maintaining physical consistency, enabling reduced-order, control-oriented modeling [11]. The learning rate decreases from $10^{-3}$-$10^{-5}$ based on the number of epochs to improve the convergence and create a smooth training loss curve.

### Performance Metrics

Model performance is evaluated using standard regression metrics, including mean squared error (3), as well as a qualitative assessment of extrapolation behavior.

$$\mathrm{MSE} = 1/\mathrm{n}\ \sum_{\mathrm{i}=1}^{\mathrm{n}}(\hat{y_i} - y_i)^2 \qquad (3)$$

An early-stopping criterion of 10 epochs is used to prevent overfitting on the training data. Particular emphasis is placed on the model's ability to produce physically consistent predictions beyond the training domain.

## PINN-MPC Controller Design

### Control Strategy

Recent studies have integrated physics-informed neural networks into nonlinear model predictive control frameworks, demonstrating improved tracking performance and computational efficiency [12]. At each sampling instant, a model-predictive control problem is formulated, using the trained PINN as a surrogate for the system dynamics. The objective function penalizes deviations of the predicted rod-tip temperature from the desired setpoint over a finite prediction horizon, while a move-suppression term is included to limit aggressive changes in the heater duty cycle. System evolution over the prediction horizon is governed by the PINN model, and the optimization is solved in a receding-horizon fashion, with only the first control action applied to the process.

This formulation is the minimal formulation for the MPC optimization problem:

$$\min_{u_k} \sum_{k=0}^{N_p}\left(\hat{y}_k - y_k^{ref}\right)^2 + \rho\ \sum_{k=0}^{N_c} \Delta u_k^2 \qquad (4)$$

subject to:

$$\hat{y}_{k+1} = f_{\mathrm{PINN}}(\hat{y}_k, u_k) \qquad (5)$$

where:

$N_p$: prediction horizon

$N_c$: control horizon

$y^{ref}$: temperature setpoint

$\rho$: move-suppression weight

### Constraints and Implementation

Input constraints on heater duty are enforced to reflect physical actuator limits. A limit on the maximum change in heater duty at each controller action is applied. The optimization problem is solved using a receding-horizon approach, and only the first control action is applied at each sampling instant.

## RESULTS AND DISCUSSION

The trained PINN demonstrates accurate prediction performance both within and outside the training domain. Figure 3 illustrates the model's ability to extrapolate beyond the training dataset while maintaining physical consistency. The heating rod model was reduced to a lower-order dimension using a PINN, since the surrogate model can predict the temperature at each location on the heating rod by getting the distance from the base as the input.

The proposed PINN model is embedded as a surrogate model within a Model Predictive Control (MPC) framework. The controller manipulates the heater duty to regulate the rod-tip temperature. This concept can be applied to industrial cases, where the cooling profile of the final product affects its quality. Figure 4 shows successful setpoint tracking performance under closed-loop operation. The PINN-MPC controller forecasts the dynamic behavior of the controlled variable (CV) and determines the optimal control action to meet the setpoint with

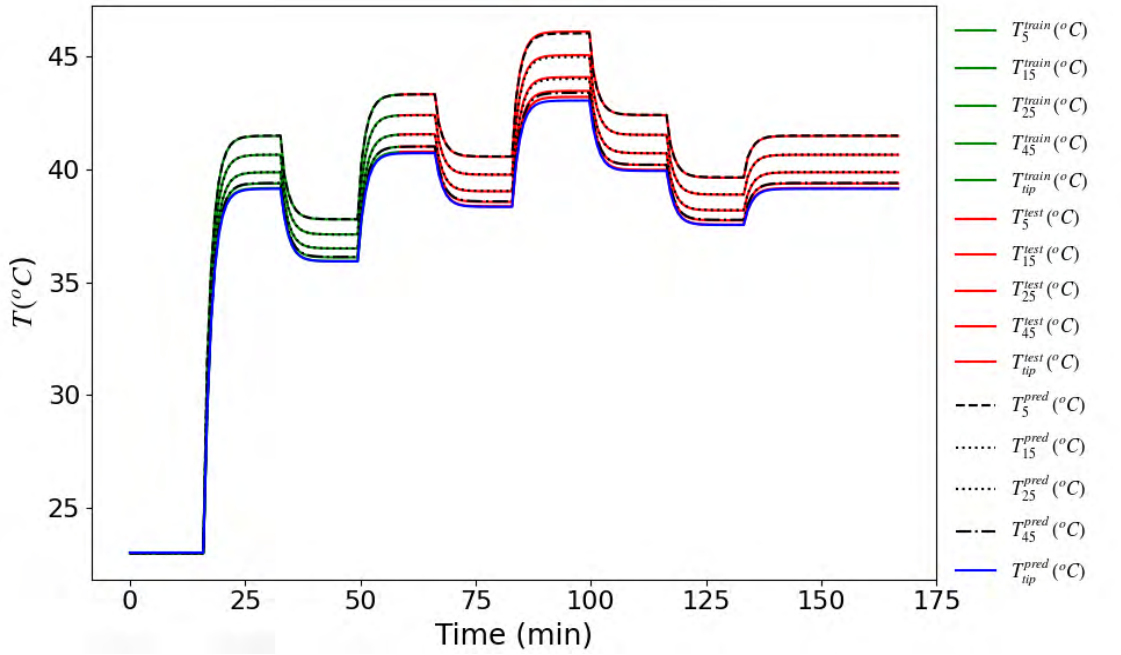

**Figure 3.** The prediction results from the PINN heating rod model against training and validation data at different locations on the rod

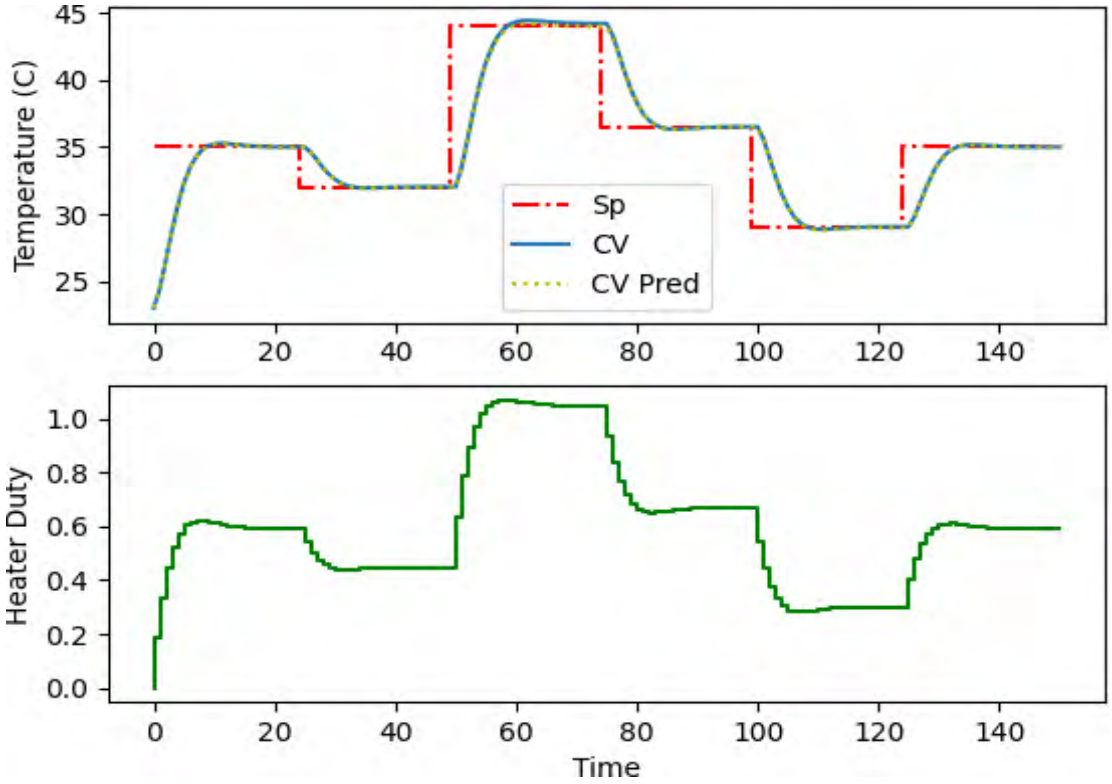

**Figure 4.** Setpoint tracking performance of PINN-MPC for the heating rod system.

acceptable overshoot. The penalty applied to control action in the MPC objective function avoids the oscillation around the setpoint, as shown in Figure 4.

## CONCLUSION

This work presented a hybrid Physics-Informed Neural Network framework for thermal system identification and control. By enforcing physical constraints through numerically evaluated derivatives, the proposed approach achieves reliable prediction and extrapolation

performance using limited training data, while improving robustness compared to time-dependent PINN formulations. The developed PINN model was successfully employed as a control-oriented surrogate within a Model Predictive Control framework, enabling efficient real-time temperature regulation of a one-dimensional heating rod system.

Beyond the considered case study, the proposed framework provides a foundation for integrating physics-informed dimensionality reduction and feature selection techniques. For high-dimensional thermal systems, incorporating model-order reduction methods within the network architecture can significantly reduce computational complexity while preserving dominant dynamics. Future work will focus on extending the approach to multi-dimensional thermal processes, incorporating uncertainty quantification, and exploring advanced neural architectures, such as attention-based and transformer models, to further enhance modeling accuracy and control performance.

## ABSTRACT

With the ongoing advances in generative artificial intelligence (GenAI), the initial skepticism surrounding its tools is gradually diminishing. In fact, tools such as ChatGPT, Copilot and similar, are often used in everyday tasks, both in our personal lives and in educational contexts. Educators may use them for content creation, grading exams, or automating repetitive tasks. Students resort to them to better understand a topic, get feedback on an assignment and brainstorm ideas. Research has shown that, if used correctly, these tools can spur and support both teaching and learning. However, these continuous advancements and the increasing number of available tools also require more research to benchmark all these models and, if possible, provide quantifiable indications of which tool is better to use for which specific subtopic. As such, we created *FermBench,* a dataset of fermentation knowledge, which can be used to benchmark various large language models (LLMs). The models selected for the experiment are: GPT-5 mini, Claude Sonnet 4.5, Gemini 3 Flash, Mistral Small 3.2, and DeepSeek-V3.2. The performance of the models is scored using the LLM-as-a-Judge approach, with GPT 5.2 and Claude Opus 4.5 as judges. The LLMs agree that the model used in the free tier of ChatGPT is the most factually accurate. DeepSeek and Gemini outperform the other models in readability and helpfulness, while Claude and Gemini provide the most concise answers. Overall, we conclude that the quality of the responses generated is satisfactory for educational contexts. We also provide students with practical guidelines on how to be more critical of responses generated by LLMs and to improve their prompts. All code and curated data are open-source.

**Keywords**: Education, Artificial Intelligence, Fermentation, Industry 4.0, Large Language Models, Benchmark

## INTRODUCTION

Large language models (LLMs), powered virtual assistants, such as ChatGPT and Microsoft Copilot, have been widely adopted in various educational contexts worldwide. Consequently, educational research has been increasingly examining the potential opportunities and limitations that these models could pose to teaching and learning. For example, these tools have enabled educators to digitize course materials, thereby enriching the students' educational experience as well as their engagement [1]. Moreover, LLMs can deliver customized student support [2], leading to improved understanding and academic success.

Recent research investigated the effectiveness of LLMs as educational tools, indicating a likely future role for this technology in engineering education [3]. In chemical engineering, LLMs have also been successfully applied to educational contexts, ranging from performing pharmaceutical audits [4] to answering questions about fermentation [5]. However, with many models being available and the constant release of new ones outperforming the competitors, research should be conducted to estimate the reliability of the information provided by different LLMs.

In this work, we leverage a dataset previously developed by the authors, *FermBench* [6]. The dataset was created to benchmark LLMs on fermentation knowledge; it contains 118 questions across various topics, including modelling and reactor design. *FermBench* is then used to benchmark multiple state-of-the-art LLMs and assess their performance using a mixed-methods approach, including quantitative and qualitative analyses. This complementary approach offsets the limitations of each anal-

**Table 1:** Details of the models selected for this study.

ysis and provides an overall more rounded and robust understanding of the current reliability of these models.

In this work, we expand on this investigation by comparing more models and performing a per topic analysis. The LLMs selected for the experiment are the models behind some of the most widely used generative artificial intelligence (GenAI) chatbots.

The overarching goal of the work is to provide a reference for students and educators on which of the commercially available virtual assistants are more reliable on this topic. Finally, we also investigate whether any LLM is better in specific subtopics, such as solving coding tasks, answering mathematical questions, or possessing deeper theoretical knowledge.

## BACKGROUND

### LLMs in Education

Recent research has started to methodologically investigate the use of LLMs by students. Results vary slightly across the studies; however, the trend seems to be stable, suggesting that the use of chatbots appears to be widespread among students [7]. According to a recent study [7], 47.7% of the respondents agreed that the chatbots they used made them more effective learners; however, only 17.3% found a positive effect of chatbots on improving their grades. Additionally, the study also finds that over 50% of students are positive about chatbots but have concerns about their potential use [7-8]. Another study highlights that 65% of students do not find the responses of GenAI chatbots trustworthy enough for academic purposes, adding that students actively use these tools but want guidance to use them more effectively [9].

It is therefore evident that more research is required to ensure the correctness, trustworthiness, and reliability of the generated responses and to further investigate which chatbot is better in specific domains.

### Selected LLMs

In this work, we investigate five different LLMs: OpenAI's GPT-5.2 mini [10-11], Anthropic's Claude Sonnet 4.5 [12], Google's Gemini 3 Flash [13-14], DeepSeek's DeepSeek-V3.2 [15-16], and Mistral AI's Mistral Small 3.2 [17]. These models have been selected because they are

the LLMs used in the free version of the respective chatbots. Although some flagship models are also used in the free tiers, they have very limiting usage limits before downgrading to the fallback models (the LLMs used in this study, as of January 2026). *Table 1* summarizes the core information describing these models, such as the name of the chatbot that users can use to interact with the LLMs, the developer, the original release date, the name of the model, and the country of provenance.

All the models are Transformer [18] based generative LLMs, so they necessarily share some similarities, but also present some differences. All models have a decoder-only architecture. Further justification for the model selection can be found in [6].

Throughout the manuscript, we might refer to the model with the name of the LLM or the name of the chatbot leveraging that LLM interchangeably: we purposefully adopt this nomenclature to help students and educators to identify with the results and the findings, rather than only appealing to the technical AI community.

## METHODS

The dataset used in this study, *FermBench*¸ was previously created by the authors. It consists if 118 questions about various subtopics within fermentation. Further details regarding the data acquisition and completion process can be found in [6]. In this work, we further expand the dataset and use it to benchmark the previously described LLMs. Figure 1 shows the distribution of the various questions contained in the dataset.

## LLM-AS-A-JUDGE APPROACH

The gold standard for evaluating knowledge and information, including LLMs ability to respond to domain-specific questions, is by having expert (human) evaluation. However, this approach has some limitations, including the fact that it is very costly and time-consuming [19].

To address this challenge, a method that is starting to be commonly used is to use state-of-the-art LLMs as a surrogate for humans. Research has shown that these models already exhibit strong human alignment (within specific, well-defined tasks), and therefore can be used to evaluate open-ended, generated responses from chatbots [19]. For example, [19] found that strong LLM judges can match both controlled and crowdsourced human preferences well, achieving over 80% agreement, the same level of agreement between humans. They conclude that this approach is a scalable and explainable way to approximate human preferences for general-purpose tasks like open-ended QA and summarization.

This approach, however, also presents some bias and drawbacks [20-22]. According to recent research [19], LLM judges often exhibit strong self-preference, so that, for example, GPT-4 as a judge tends to favor GPT-3.5 responses over those from non-OpenAI models, even when human raters disagree. Similar trends are observed with other model families (e.g., Claude favoring Anthropic models, Mistral favoring Mistral variants). This can happen due to different factors, such as model training on similar datasets (leading to overlapping stylistic or structural preferences), optimization for similar loss functions (e.g., helpfulness, harmlessness) so that the judge may over-reward behaviors it was explicitly trained to recognize, and lack of diversity in data during training limiting a model ability to fairly evaluate out-of-distribution responses.

Although some of these biases cannot be avoided, we tried to mitigate some of these by: (i) selecting more than one judge, (ii) randomizing the responses, and (iii) avoiding giving the model information regarding the LLM that scored each question. Moreover, in another experiment previously conducted and published in [6], we performed a calibration study with human annotators, to verify that, overall, the LLM-as-a-judge approach is reliable.

In this work, the Judges are instructed to perform the following task:

- Multi-Point Rubric approach: Score the responses given by the LLMs according to the following parameters: factual accuracy, comprehensiveness, coherence to the question asked, concision, readability, helpfulness, insightfulness, and overall quality. The scores should be assigned according to these parameters on a Likert scale (1-5, where 5 is best).

As the judges, we select two LLMs: **GPT-5.2 and Claude 4.5 Opus**. These models were selected because they are currently outperforming all other LLMs in multiple benchmarks.

The code used to generate the results presented in this manuscript is written in Python; all the LLMs (the five selected to generate responses and the two used to evaluate the other LLMs) are used through their APIs.

## RESULTS

*Table 2* presents the results of the experiment, showing the average score for each of the defined parameters, as reported by the two LLMs-as-judges (GPT-5.2 and Claude 4.5 Opus), for the five LLMs. Although the two judges do not fully agree on the best-performing models, they share some trends. For factual accuracy, GPT-5 Mini, behind ChatGPT, yields the highest results. Both judges also agree that the model provides comprehensive answers, for GPT-5.2 on par with DeepSeek-V3.2 and for Claude Opus 4.5 on par with Gemini 3 Flash. Claude scores the highest for concision according to GPT

**Table 2:** Results of the different LLMs according to the LLM-as-a-Judge approach. The parameters reported are, respectively: factual accuracy, comprehensiveness, coherence, concision, readability, helpfulness, and overall quality. We also report the average (Avg.) of the scores.

| **Gemini** | 4.87 | 4.95 | 4.91 | 3.81 | 4.95 | 4.94 | 4.81 | 4.84 | 4.76 |
| **DeepSeek** | 4.90 | 4.91 | 4.86 | 3.43 | 4.90 | 4.90 | 4.78 | 4.79 | 4.68 |
| **Le Chat** | 4.61 | 4.88 | 4.68 | 3.57 | 4.83 | 4.75 | 4.00 | 4.48 | 4.48 |

5.2, while the judge Claude scores Gemini 3 Flash the highest. DeepSeek and Gemini are the most readable and helpful, while Gemini is the most insightful (for GPT 5.2 on par with ChatGPT). Overall, as also shown in *Figure 2*, judge GPT assigns the highest scores to ChatGPT, while judge Claude to Gemini.

*Figure 3* presents an analysis of the various topics contained in the dataset. The results suggest that all models excel in the topic of "biochemistry and operations", DeepSeek-V3.2 is best at "sector applications", where Claude has the lowest scores, and GPT-5 mini obtains the highest scores in the "fundamentals". Interestingly, Claude Sonnet 4.5 is not the best-performing model in "modelling and optimization", but it is surpassed, above all, by Gemini 3 Flash and GPT-5 mini. This is surprising considering that this model is widely considered the best at solving coding tasks, which modelling often contains. However, the questions in our dataset are formulated more *logically* than purely *programmatically*, and therefore this might provide an explanation for why the other models outperform Claude Sonnet 4.5.

## DISCUSSION

The aim of this work is to provide students with a quantifiable comparison and practical guidelines on which chatbots to use. The results were averaged across multiple questions and re-runs of the model, therefore we can confidently say that, for a specific judge (e.g., GPT 5.2), one LLM is better than another on a specific parameter (e.g., DeepSeek for helpfulness). However, given that there is not an overall consensus among the judges in this particular study, and given the overall quite high average scores obtained by all LLMs, we conclude that the knowledge currently embedded in these models is overall quite satisfactory. This is also supported by a previously published calibration study with human annotators [6], in which we compare the preferences of expert annotators with those of various LLMs on the same dataset and using the same set of parameters.

This study highlight that the decision of which AI assistant to use should not be made solely based on performance, but should also be informed by institutional and governmental guidelines, as well as by personal preferences. In this work, we define a system of 8 parameters (*factual accuracy, comprehensiveness, coherence to the question asked, concision, readability, helpfulness, insightfulness,* and *overall quality*) to help guide students in making an informed decision. For example, students can also decide whether they prefer a more verbose or concise response, or if they value helpfulness higher than factual accuracy.

Ethics and fairness are also relevant considerations to make, therefore, we advise students to read more about the models, including the terms and conditions, and their developers.

While generating the results, we noticed something interesting. Claude refused to answer certain questions due to safety policies. The questions are:

- "Are you interested in changing product manufacturing by modeling the fermentation?"
- "How to use fermentation to produce a product that is toxic to cells?"
- "While modelling for bacterial production of a product intended for food industry, what should be considered?"

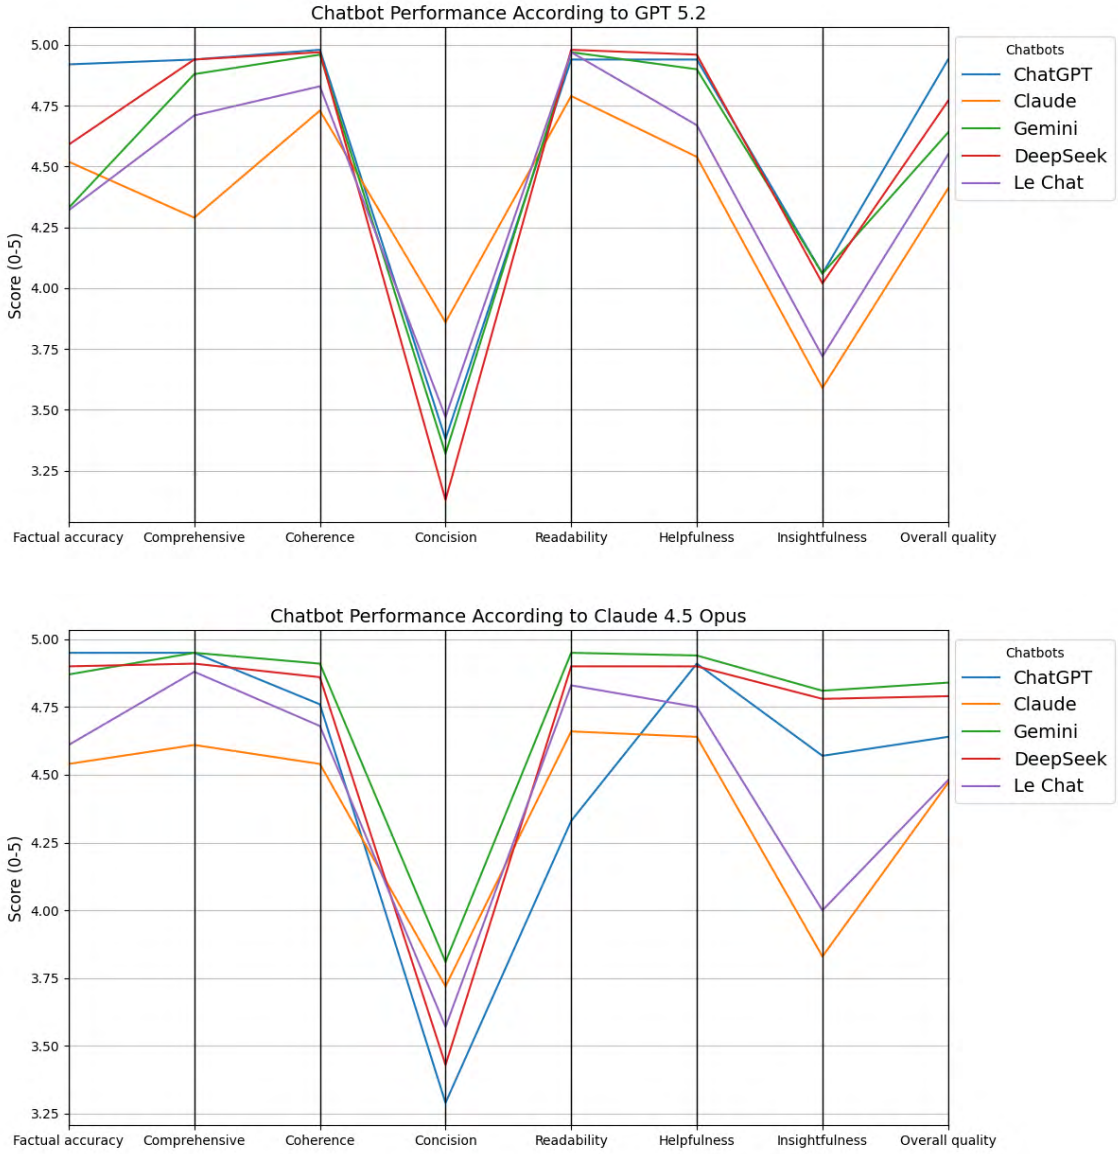

**Figure 2:** Performance of the five selected models according to the LLM-as-judges GPT 5.2 and Claude 4.5 Opus.

- "What parameters should I consider in a model for food-grade protein production by bacteria?"

The motivation behind the refusal is related to Claude's content policies around: (i) biosafety concerns (producing toxic substances), (ii) food safety (potential contamination/harm), and (iii) dual-use risks (information that could be misused).

We agree that these are legitimate safety guardrails. Questions 2 and 4 explicitly ask about toxic/harmful production, which Claude refuses to answer on principle. We consider it beneficial that LLMs refuse to answer certain questions when the risk of providing a response is too high, and we hope to see other LLMs adopt a more critical assessment of potential risks as well.

## CONCLUSION

This work aims to contribute to the advancement of educational research. To achieve this, we benchmark five LLMs powering widely used generative AI chatbots: ChatGPT, Gemini, Claude, DeepSeek and le Chat. To evaluate the generated answers, we use the LLM-as-a-Judge method, using more powerful LLMs to evaluate the output generated by other, smaller, LLMs.

Although the two judges do not totally agree on the best performing models, some trends are shared. For factual accuracy, ChatGPT, obtains the highest results. The model also provides comprehensive answers, followed by DeepSeek and Gemini. Claude and Gemini

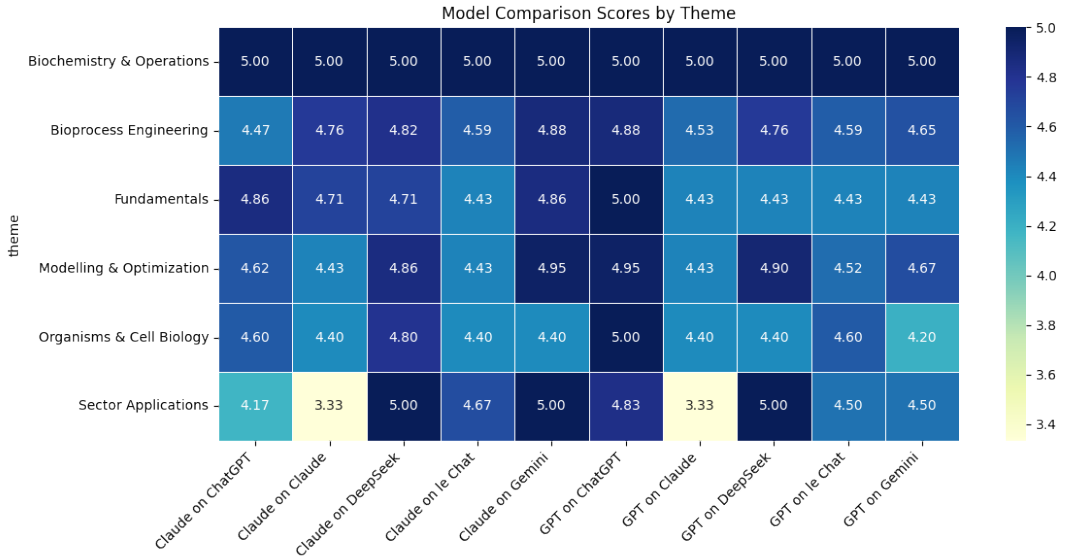

**Figure 3:** Performance per theme of the five selected models according to the LLM-as-judges.

score the highest for concision, DeepSeek and Gemini for readability and helpfulness. The rest of the parameters are generally contended between Gemini and ChatGPT. We also present an analysis of the subtopics contained in the dataset. The results suggest that all models excel in the topic of "biochemistry and operations", DeepSeek is best at "sector applications", where Claude has the lowest scores, and ChatGPT obtains the highest scores in the "fundamentals". Interestingly, Claude is not the best-performing model in "modelling and optimization", but it is surpassed, above all, by Gemini and ChatGPT.

Overall, we conclude that the difference in performance between the various LLMs is not significant, and thus the current knowledge embedded within these models is adequate. Therefore, in conjunction with institutional or government guidance, the results suggest that the choice of chatbot can also be based on individual preferences. We provide in-depth parameter specifications for these models to help students navigate their priorities and make informed decisions.

## FUTURE WORK AND LIMITATIONS

A limitation of this type of work is that LLMs continually improve, and educational research often cannot keep up. To tackle this issue, we publish all the code and data, with the resolution to frequently update the leaderboard of models benchmarked on *FermBench* and, therefore, provide an updated point of reference for students wishing to learn fermentation.

## DIGITAL SUPPLEMENTARY MATERIAL

The dataset used for the study *FermBench* [6], as well as all the code used to produce the results discussed in the manuscript, are open-source on GitHub at github.com/FiammettaC/FermBench-ESCAPE. The repository will be made public upon acceptance of this manuscript.

## ABSTRACT

Workflow automation platforms connect applications and services to automate data transfer and multistep processes. Although widely used in engineering research and institutional administration, including engineering institutions, they are rarely integrated into undergraduate engineering curricula, and their educational adoption introduces ethical, technical, and pedagogical risks. This paper proposes a practical framework for developing, deploying, and assessing workflow-automation-enabled learning tools coupled with generative AI, with explicit attention to institutional constraints and learning outcomes. As a conceptual case study, we present it in a second-year chemical engineering course (Heat and Mass Transfer) to support learning of heat conduction. The platform includes instructor-approved assets such as content slides, solved problems, pre-prompts, and a validated question database, through an automation pipeline that issues structured API calls to a generative AI system and returns explanations and worked examples. A subject matter expert (SME) authors and tests prompt modules aligned with learning outcomes mapped to Bloom's taxonomy levels (understand, apply, analyze, evaluate) and aligned with accreditation expectations. Effectiveness metrics are proposed to estimate learning gains, and a tool quality audit and an SME review are used to verify conceptual correctness and computational validity. To assess risks, we apply a likelihood–impact risk matrix and define five categories: data privacy and protection, transparency, pedagogical impact, institutional compliance, and ethical considerations. Preliminary analysis suggests potential concept gains from structured prompt/content integration but indicates that numerical problem reliability depends strongly on question-database coverage. The highest perceived risks relate to privacy and transparency, followed by pedagogical impact, motivating mitigations such as anonymization protocols, restricted data pathways, and human verification throughout the lifecycle.

**Keywords**: Workflow automation platforms, Generative AI, Bloom taxonomy, risk assessment, effectiveness assessment

## INTRODUCTION

Workflow automation platforms and tools can enhance, and even reduce, administrative tasks and provide structured learning as well as instantaneous follow-up support across many settings.

This paper proposes a framework to guide the design, deployment, and assessment of workflow automation platforms used for engineering education in the teaching and learning domains. As a conceptual case study, we present an integrated platform for a second-year chemical engineering course (Heat and Mass Transfer) focused on steady-state and transient heat conduction. The platform includes instructor-approved content and a validated question database powered by an automation pipeline that delivers structured API calls to a

generative AI tool, with learning outcomes mapped to Bloom's taxonomy and aligned with accreditation expectations.

The inherent risks of using this platform were assessed using a likelihood–impact risk matrix across five categories, including data privacy and protection, transparency, pedagogical impact, institutional compliance, and ethical considerations. We later propose mitigation measures for the identified and quantified high-risk areas.

## BACKGROUND

### Workflow Automation Platforms in Engineering

Workflow automation platforms (WAPs) are complex integration tools designed to connect multiple applications and execute multistep processes automatically via a flexible, centralized layer. These platforms allow "unskilled people to produce applications with little or no coding" through low-code approaches [1]. They have transformative potential, as they can drive operational efficiency, process consistency, and scalability across diverse industries [2]. The main capabilities of these platforms include: (i) defining workflows via triggers, actions, and conditional logic; (ii) supporting API integration; (iii) routing/connecting data across heterogeneous tools; (iv) maintaining execution histories, and (v) standardization and scaling of routine tasks. These platforms are efficient for streamlining complex operational processes across engineering, academic, and business environments.

Workflow automation platforms have been increasingly adopted in engineering and education to streamline routine/repetitive processes and enhance data consistency and reproducibility. An example of a recent use and implementation of WAPs includes the use of Robotic Process Automation to transform pedagogical practices by automating repetitive tasks, shifting the focus of education toward high-value instructional strategies [3]. Thus, automated design systems reshape learning outcomes by enhancing conceptual modeling, accelerating prototyping, and improving interdisciplinary collaboration [4]. Though this automation has proven beneficial in different settings, caution is advised when implemented, with warnings of an "automation abyss" predicting the erosion of core learning processes when overreliance on this technology [5]. Design automation should be used as a supporting tool rather than replacing human agency and critical thinking.

### Risks for Education Automation

When workflow automation platforms integrate with generative AI, risks escalate, creating systemic issues that can pose challenges in educational settings. Thus, a single learning interaction can now involve multiple services, data stores, and decision points, increasing potential vulnerability points [6], including logs and cached prompts that can retain information for longer.

Another inherent risk of WAP adoption and implementation is institutional sensitivity, as many tasks, such as submissions, performance signals, and identifiers, may cross boundaries into external APIs outside the institution's "official" and intrinsically protected environment. A governance-risk approach is then required to set compliance constraints, such as protections for learning management systems (LMSs) and data residency requirements. Risk management, therefore, requires data transfer permissions, clear policies, consent mechanisms, and retention practices.

Generative AI (GenAI) in educational settings introduces transparency and accountability risks that can distort learning practices [6] and even erode teacher-student trust. AI's non-deterministic outputs create substantial challenges in tracing decision-making processes, potentially leading to unfair perceptions [7]. Addressing these issues and risks requires audits/accountability mechanisms, versioned prompts, clear pedagogical transparency, and institutional oversight [8].

In general, AI in education poses critical pedagogical risks by promoting shortcut behaviors (bypassing) that might undermine the learning process and diminish problem-solving and critical thinking skills [9] .Thus, students might prioritize quick answers over deep conceptual and/or fundamental understanding, again, undermining analytical reasoning and consequently, critical thinking [10]. Pedagogical safeguards are then designed and implemented to mitigate these risks, requiring students to reason and cross-validate AI responses and "reasoning".

Bloom's taxonomy can be used to explain why WAPs introduce pedagogical risks. Thus, when coupled with AI, they provide students with immediate outputs, potentially bypassing the lower-to-mid levels of Bloom (remembering, understanding, applying, and analyzing), which, when scaffolded in our learning process, lead to higher-order performance [11]. The "shortcut" behaviour then appears as students achieve a solution that has not been reasoned, so learning is not durable due to overreliance and an "automation abyss" [5]. The central risk is not simply incorrect AI output, but misaligned cognition, as metacognitive monitoring is paused and learning transfer is broken, as students do not build the mental models required to analyze variants [12]. To minimize these risks, a Bloom-aligned mitigation strategy is required to design "gated" assistance strategies that lead students to demonstrate understanding, reasoning, and justify choices while automation speeds up the solution-generation process, in a way that automation is seen and used as a supportive tool, rather than replacing the cognitive work that the curriculum is meant to develop [13].

## FRAMEWORK AND CASE STUDY

In this work, we propose a framework to guide the development, implementation, and assessment of AP-based learning tools coupled with Gen AI. The framework includes four phases: (i) design and policies, (ii) build and integration, (iii) implementation and monitoring, and (iv) assessment and iteration. This lifecycle allows decisions to be fully auditable.

In the design and policies phase, the teaching team defines the learning scope and outcomes, mapped to Bloom's cognitive levels, and estimates the required student data (if any). Constraints/rules are specified, including approved data and consent requirements, which limit the pipeline's inputs. In the build and integration phase, the WAP is used to connect learning assets and establish tool interactions. The platform executes tasks using approved content and structured prompts to a generative AI API, returning outputs to an interface. A fixed set of question databases and prompt templates is provided. Some basic technical safeguards are also implemented at the workflow level, such as error handling, to keep the system "error-free". In the implementation and monitoring phase, the system is constrained within the provided context and guidance to students on appropriate use. Monitoring is performed on both technical performance (for instance, drift in responses) and off-track patterns (such as overreliance, bypass, or scaffolding use). A subject-matter expert (SME) oversees the review process, especially when solving numerical problems. In the assessment and iteration phase, metrics and risk assessments are used to determine whether the platform enhances learning while aligned with ethical/institutional standards. Feedback from this phase is returned to the design phase, including refined prompts, expanded question databases, and enhanced risk mitigation strategies. Figure 1 shows the conceptual architecture of the WAP for our case study.

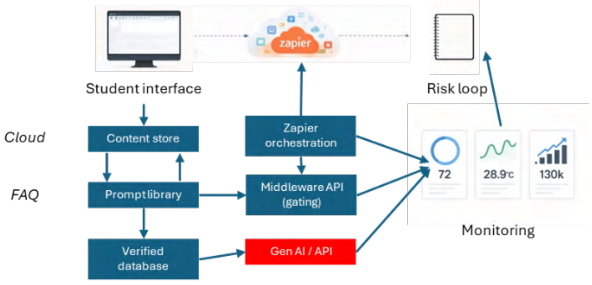

**Figure 1.** Conceptual architecture of the WAP

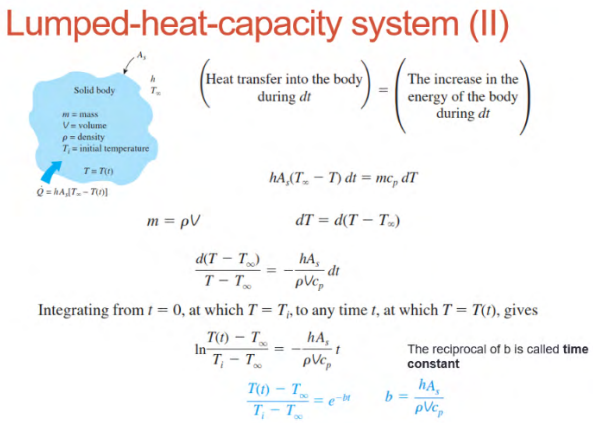
In the architecture, students are "directed" (via Zapier or similar) into a request package built from the teaching team assets, prompt templates, and a question database. A middleware API layer applies governance and pedagogical controls (such as gating, validation, and logging) before calling the GenAI API. Outputs are then returned as modular learning components and are monitored through SME verification and a risk-assessment feedback loop to support transparency, safety, and iterative refinement.

Our conceptual case study is drawn from a core second-year undergraduate course in chemical engineering, Heat and Mass Transfer, focusing on heat conduction. Heat conduction is well-suited for implementing this framework because it combines conceptual understanding (including physical meaning of temperature gradients and boundary conditions) with numerical problem-solving (steady versus transient conduction, 1D conduction with various geometries, and thermal resistance analogies). The learning design process, therefore, requires both accurate understanding and reliable computations.

Figure 2 shows an example of content, template prompts, and the question database input in our platform.



(a)

```
You are a Heat Transfer TA.
Problem: {{problem_text}}
Student work: {{student_work}}
Course snippets: {{retrieved_snippets}}
Return exactly:
1) Assumptions (max 4)
2) Model choice + why (mention Bi/Fo if relevant)
3) Next 3 steps (no full solution)
If the student says "full solution", then provide it with units.
```

(b)

A solid sphere (radius $r_0 = 2.0$cm) is initially at a uniform temperature and is suddenly exposed to convection in air with h = 60 W/m²K. The sphere has k = 0.20 W//mK. Should the lumped-capacitance method be used?

A) Yes, because $Bi \approx 0.02$(lumped is valid)
B) Yes, because $Fo$is always the only criterion
C) No, because $Bi \approx 6$(internal gradients are significant)
D) No, because lumped is only valid for plane walls

**Correct answer:** C

(c)

**Figure 2.** Example of (a) content, (b) template prompts, and (c) question database input in out platform.

The platform uses instructor-controlled learning assets such as lecture slides and notes, solved problems, and a verified question database. These assets are paired with a library of "pre-prompts" that define the "instructor" role and required output workflow. The SME is responsible for maintaining prompt modules to ensure alignment with course/subject learning outcomes.

Learning outcomes are organized in the cognitive domain and mapped to Bloom's taxonomy at the levels of understand, apply, analyze, and evaluate for the studied topic. This mapping is crucial because it ensures the platform supports students in developing understanding and structuring solution scaffolds, as supporting tasks for their learning. Table 1 presents the learning outcomes mapped to Bloom levels and platform links.

**Table 1.** Learning outcomes mapped to Bloom levels and platform links.

| Bloom level | Outcome | Platform support |
|---|---|---|
| Understand | Explain Fourier's law physically; interpret temperature gradients; state key assumptions | Brief concept explanation |
| Understand | Identify boundary conditions; state implications | Method outline through boundary conditions checklist |
| Apply | Compute heat flow for steady 1D conduction and use thermal resistance analogies | Method outline, steps, and fully worked solution |
| Apply | Apply lumped-capacitance and oner-term approximation | Method outline, steps, and fully worked solution |
| Analyze | Select the correct model (transient versus steady state) | Method outline through decision tree |
| Evaluate | Compare solution approaches and support assumptions | Conceptual explanation |

The workflow automation pipeline is designed to treat generative AI as one component within a controlled instructional system. First, the teaching team's assets are "uploaded" to a structured content store, organized by topic and subtopic. Second, the question database is included, with relevant examples and constraints (e.g., geometry, boundary conditions, steady/transient, required units). Third, the automation layer assembles a request package that includes the appropriate prompt template and the selected question or student query. This package is then sent to the GenAI API to improve repeatability.

This workflow is also designed to support graduate attributes, aiming to produce evidence through auditable outputs aligned with outcomes, while maintaining a risk layer.

Students' interaction is modular, with a conceptual module that emphasizes assumptions and physical interpretation, a practical module that generates problems from the database, and an assessment module that focuses on quality checks (e.g., boundary conditions, alternative solution pathways). The pipeline includes a verification layer, in which the SME reviews a random/representative sample of outputs across modules to verify correctness and validity.

Despite our case study being conceptual, we have preliminary proposed effectiveness metrics to assess the future implementation of this tool. Thus, conceptual learning gains can be quantified using, for instance, pre/post multiple choice concept checks (aligned with the Bloom outcomes). Skill gains from numerical problems can be assessed using specific rubrics that focus on reasoning, model/calculation description, etc. The platform can also quantify the correct solutions and explain the sources of errors. Indicators of overreliance are also proposed, including the number of repeated requests for solutions, the omission of intermediate reasoning, etc. These flags will eventually allow adjusting the scaffolding and determining whether the platform supports learning.

Finally, the proposed framework and case study pipeline motivate a risk assessment, discussed in the next section, as the platform navigates across different systems (content stores, automation tooling, and external APIs) and modifies students' learning experience.

## RISK ASSESSMENT

We use a risk matrix to score risks based on likelihood and impact. This assessment supports course planning decisions while aligning with all stakeholders. The scope of this exercise included the platform lifecycle described in the previous section (content, automation workflow, Gen AI/API calls, output, monitoring, and validation practices). Risk scenarios are defined by the teaching team and mapped to the following categories: (I) data privacy and protection, (II) transparency, (III) pedagogical impact, (IV) institutional compliance, and (V) ethical considerations.

In the data privacy and protection category, we consider risks/scenarios related to the disclosure, leakage, retention, or misuse of student data during transfers between systems.

In the transparency category, we consider risks/scenarios incorrect/unclear/difficult to audit GenAI outputs, unusual workflow logic, etc.

In the pedagogical impact category, we consider risks and scenarios in which the platform might undermine learning outcomes or promote overreliance.

In institutional compliance, we consider risks/scenarios in which institutional policies, as well as ethics/consent processes, are or might be violated.

In ethical considerations, we evaluate risks and scenarios in which automation (e.g., tool availability) might affect bias, fairness, and/or inequitable access.

Each risk scenario is scored along two dimensions

on a 1–5 scale: likelihood (L) or probability that the risk scenario occurs during the tool deployment, and impact (I) or severity of harm if the scenario occurs (to students, teaching team, and the institution).

The overall risk score (R) is estimated as R = L x I, producing values from 1 to 25. Scores are binned as follows: low (1-5), moderate (6-10), high (11-15), and critical (16-25). Scoring is conducted by the teaching team and the SME.

Mitigation actions are then defined, a responsible owner is assigned, and progress of implementation is tracked. Mitigations are prioritized by risk score and feasibility, and the assessment records the residual risk after mitigation (e.g., changes from high risk to moderate). Mitigation actions include design, technical, and human controls.

A summary of the risk assessment is shown in Table 2.

**Table 2.** Summarized risk assessment

| Scenario | Category | L | I | R | Mitigation |
|---|---|---|---|---|---|
| Data transmitted to external services | I | 4 | 5 | 20 | Anonymization, protect LMS, retention policy |
| Incorrect numerical solutions | III | 4 | 4 | 16 | Human verification, include limitations and disclosure |
| Overreliance | III | 4 | 4 | 16 | Define scaffolding; provide pre-assumptions |
| Protected data rerouted | IV | 3 | 5 | 15 | Increase restrictions |
| Inequitable outcomes | V | 3 | 3 | 9 | Standardization of templates; provide other references beyond Gen AI |
| Drift after prompt | II | 3 | 3 | 9 | Maintain prompt templates and question database |

## RESULTS AND DISCUSSION

While the course is still not deployed, a preliminary analysis by the teaching team and the SME of the heat conduction module suggests that structuring GenAI interactions through instructor-suggested prompts and verified content can enhance conceptual clarity. For instance, slide-aligned definitions and worked examples support coherent narratives around core concepts such as Fourier's law, boundary conditions, and thermal resistance analogies. This framework is therefore expected to yield measurable benefits in concept checks targeting "understand" outcomes (e.g., interpreting the meaning of a temperature gradient) and "apply" outcomes (e.g., selecting the correct governing equation and solving a standard 1D conduction problem).

However, early testing highlights an important limitation for numerical problem solving, since solution reliability depends strongly on the diversity/rep–resentativeness of the question database and, hence, the benchmark set. When the database is small or limited (e.g., includes little or no information about mixed boundary conditions, changing geometry assumptions, or unit conventions), the system is more likely to produce apparently "reasonable" but incorrect steps and to omit assumptions. Numerical outputs should be treated as scaffolded rather than "linear", as flagged by the SME review.

When applying the risk matrix, risks are mostly clustered in three categories: data privacy and protection, transparency, and pedagogical impact. Privacy risk is quite elevated because automation platforms can unintentionally "leak" sensitive information through connectors, logs, intermediate files, or external APIs. Transparency risk is also elevated because it might be difficult for students to interpret limitations and for instructors to audit pipeline behavior. Finally, the pedagogical risk is elevated because the platform can indeed encourage shortcut-like behaviors unless scaffolding is provided and students are guided toward reasoning and assumptions.

Other categories, such as institutional compliance risk and ethical considerations, are moderate and depend on a specific scenario. Thus, with minimal data, institutional compliance declines, while LMS data routed through unapproved connectors may pose elevated risks. Ethical considerations can also be relative, as prompting skills might differ (e.g., expertise), leading to perceived inequities. Some recommended mitigation actions include: (i) minimal data pathways (e.g., student data anonymization, protected LMS routing, clear document retention and logging policies and practices), (ii) SME constant verification for numerical problems and periodic review of questions database, (iii) maintain/update prompt templates and content, and provide students with clear limitations on expected results, (iv) implement pedagogical scaffolding (provide several examples), and (v) standardize templates to ensure equity in terms of prompting expertise.

Although the heat conduction module presents specific risks, these can be easily extrapolated to other subjects; hence, the risk categories and scoring approach presented in this work are useful for transfer to other engineering education contexts where automation and coupled WAP/GenAI are introduced. The specific likelihood and impact values will, inevitably, vary by deployment details and risk team. Nonetheless, the evaluation's structure provides a reliable mechanism for adoption decisions across courses and departments.

The results are preliminary and primarily conceptual, relying on SME-designed testing rather than large-scale classroom trials. Therefore, learning gains are proposed rather than empirically established, and risk scores reflect expert judgment under stated assumptions only.

Future work should validate effectiveness metrics in a controlled pilot, test the platform with representative student use patterns, and refine mitigation strategies based on observed behaviors.

## CONCLUSIONS

This paper presents a GenAI-aligned workflow automation platform designed to support modular, instructor-aligned learning outputs for undergraduate engineering courses. By combining validated content, assistance, and verification/monitoring, our approach aims to improve consistency and transparency when delivering outputs while reducing risks related to correctness, over-reliance, and data privacy. The framework also provides a practical pathway to document evidence aligned with CEAB Graduate Attributes.

## ABSTRACT

As Industry 5.0 (I.D. 5.0) reshapes the engineering education landscape, Higher Education Institutes (HEIs) have evolved to integrate Generative Artificial Intelligence (GenAI) via strategic curriculum revamps to meet Education 5.0 (E.D. 5.0) competencies. EN.540.202 (Introduction to Chemical & Biological Process Analysis) is the first core course at Johns Hopkins University and was revamped in Fall 2025 to create more rigorous course content and the conscious creation of new weekly graded problem sets, which did not rely on prior course content/textbook-based solved examples. Problem sets were fed as Effective Prompt Engineering (EPE) inspired prompts to ChatGPT, and AI-elicited responses were compared. AI was able to perform fundamental calculations, offer detailed explanations, unit conversions/checks, proactive information (outside the problem scope), and graphical information. Key challenges and pitfalls observed were terminology misinterpretation, lack of visual representation, data acquisition issues, and ambiguity when tackling open-ended problem prompts, which pose a potential threat of incorrect learning if students exclusively rely on ChatGPT. Quantitative benchmark comparisons of AI performance spanning across various prompt categories indicate a significant 73% performance gap. While AI demonstrates 88% accuracy on standard problems, the success rate plunges to 15% on complex mass/energy balances involving non-ideal recycle streams and constraints. Introduction of EPE and Chain-of-Thought (CoT) strategies mitigated these risks, restoring AI accuracy to 91% in instructor-led trials. To ensure academic integrity, a dual-layer Quality Assurance (QA) audit was implemented using Turnitin's AI-writing detection; analysis shows a mean AI-probability of <12% in derivation sections, suggesting students successfully used AI for structural brainstorming, while maintaining technical ownership of engineering execution. Anonymous student-filled instructor teaching evaluations capture a strongly positive perception of preparedness, better student engagement, and recognition of potential risks of over-reliance on AI-led Large Language Models (LLMs), potentially leading to AI-led misdirected learning (unless students can distinguish between correct/incorrect AI responses). Despite the intellectual challenge of the course being rated as high, overall course quality and instructor teaching effectiveness metrics were ranked high, signalling a successful case of AI-led curriculum revamps, capturing a thoughtful integration of EPE into the undergraduate curricula at HEIs. This work provides a scalable framework for HEIs to modernize engineering pedagogy, positioning AI as a collaborative tool that augments and empowers, rather than replaces, critical human-centric engineering judgment.

## INTRODUCTION

The Fifth Industrial Revolution is uniquely characterized by rapid advances in Artificial Intelligence (AI) and Machine Learning (ML), propelling global growth. This revolution has led to the creation of Industry 5.0 (I.D. 5.0), where industry skills are constantly evolving, rendering past skillsets obsolete, ushering in new ones. This has

necessitated the creation of Education 5.0 (E.D. 5.0), a unique education/academic framework, to mirror and match I.D. 5.0 demands. This has most notably been observed using strategic curriculum revamps, observed across universities and Higher Education Institutes (HEIs), especially at the undergraduate level. Such initiatives have especially ramped up since 2022, coinciding with the release of ChatGPT, swiftly followed by other AI-based search engines such as Copilot, Gemini, DeepSeek, etc. However, one of the notable (and unintended) consequences of students relying on AI is that they may use these chatbots to solve problem sets and tutorial questions. While such outcomes are appealing to a student and perhaps even beneficial on a short-term basis (a quick solution), they have long-term repercussions. Today's students already suffer from a short attention span (a consequence of frequent information consumption via reels on Instagram, TikTok, and other social media platforms), which becomes a challenge when learning and developing fundamental knowledge in core engineering fields. Specifically, within the context of chemical engineering (which is the field this paper focuses on) and in STEM (Science, Technology, Engineering, and Mathematics) fields, such short attention span is extremely counterproductive towards the development and retention of fundamental conceptual knowledge, yet such is the reality of the world we currently inhabit. In this work, we demonstrate how to work with these systemic conditions and perform a curricular revamp of a fundamental chemical engineering course, EN.540.202 (Introduction to Chemical & Biological Process Analysis), at Johns Hopkins University. As we will demonstrate, students appreciated our AI-assisted curriculum revamp and recognized the value in such initiatives. We begin by presenting a short literature review detailing the evolution of the engineering education/pedagogical literature and why this work captures one of the most nascent yet impactful initiatives for AI-assisted curriculum revamps. Next, we present the strategy of our curriculum revamp by creating novel questions that tackle fundamental mass and energy balances (the backbone for performing any process calculations for a chemical engineer). Responses generated by AI vs. instructor solutions are compared in the analysis methodology, which then paves the way towards discussions to examine the impacts of our work.

## LITERATURE REVIEW

The advent of the Fifth Industrial Revolution is characterized by massive techno-economic leaps fuelled by advances in AI and ML. As these initiatives have propelled the landscape of skillsets that the industry perceives as employable, it has resulted in a scenario where new skillsets emerge as valuable, while older ones are rendered obsolete. This is termed as Industry 5.0 (I.D 5.0) and consequently, transformed the education landscape at universities and Higher Education Institutes (HEIs) to its corresponding version, Education 5.0 (E.D 5.0). E.D 5.0 [1] is uniquely characterized by the role of AI/ML in shaping and personalizing student learning experiences. Attempts have been made to map out E.D 4.0/E.D 5.0 competencies to I.D 4.0/I.D 5.0 skillsets [2], and the contributions of AI, ML, the Internet of Things (IoT), Big Data, Virtual Reality (VR), and Augmented Reality (AR) emerge as undisputed champions, catalyzing this global change. This impact is implemented by HEIs primarily through the strategy of curriculum revamps in their traditionally structured courses, as E.D 4.0 conclusively shifts to E.D. 5.0 [7]. As an example, efforts have been documented to (i) improve student perception of the Oil & Gas (O&G) Industry by updating the curriculum by talking about greener bioreactor/biofuel type initiatives by the industry [3], (ii) incorporating Agile methodology to a data-based modelling course of AI/ML [5], (iii) revamping Chemical Process Design to meet the targets of E.D 5.0 [11], and, (iv) employing variables interaction effects to educate students about lithium-ion battery ageing [12]. Such initiatives have been well received by students, highlighting the success of such initiatives if one chooses to incorporate them.

Of particular importance is the fact that, despite the world currently experiencing the Fifth Industrial Revolution, the reality of AI-led advances is more an identifier for economies that hail from the affluent Global North power bloc, as opposed to the Global South. Recent work has captured the existence of an AI implementation gap between these blocs, which further exacerbates when two Global South innovation drivers (India and China) are excluded from the analysis [6]. This lacuna needs to be resolved to unite E.D 5.0 with I.D. 5.0 [18]. Integration of these frameworks directly leads to the recognition of sustainability/sustainable development as a key trackable attribute towards economic prosperity [4, 8]. The eventual vision is to attain Society 5.0, which is characterized by a human society capable of AI-assisted advances that solve global-scale problems, including (but not limited to) the climate crisis [9, 10, 13]. Such a perfect amalgamation of I.D 5.0 and Society 5.0 [17] builds on each other, in a process called co-evolution [14]. Thus, it becomes extremely useful to identify and implement pedagogy-backed curriculum revamps to attain this vision, and incorporating AI-based teaching models is one recently discovered framework to realize this target [15]. This transformation is indeed a key limitation that present-day society is urged to proactively overcome, to shift I.D 4.0 to I.D 5.0 [16], which then ushers in opportunities towards the attainment of Society 5.0 [21]. A recent review of the literature also identifies and assesses the online environment for the attainment of E.D 5.0 [20] and

encourages instructors/faculty to navigate from traditionally siloed to more inclusive learning, shifting the focus from STEM (Science, Technology, Engineering and Mathematics) to STEAM (Science, Technology, Engineering, Arts and Mathematics) centric learning. To realize Education 5.0, AI and AI-powered Large Language Models (LLMs) based platforms such as ChatGPT, Gemini AI, Copilot, DeepSeek, etc. have emerged. Today, AI serves as a major framework to implement curricular revamps at HEIs, since it overwhelmingly encompasses a student's learning and university experience [18, 19]. In this work, we will also utilize this very strategy and employ ChatGPT as a comparative framework to compare instructor solutions. To the best of our knowledge, this is a first initiative within both the chemical engineering and engineering education/pedagogical literature, where such a cohesive AI-comparison/integration into a course is tracked.

## CURRICULUM REVAMP STRATEGY

EN.540.202 (Introduction to Chemical & Biological Process Analysis), or more commonly, Mass and Energy Balances (MEB) is the first core or fundamental chemical engineering course (4 credits) taken by freshmen/sophomores at the Department of Chemical & Biomolecular Engineering at Johns Hopkins University. This mandatory course often serves as a platform to develop their fundamental understanding in chemical engineering, which later paves the way for more rigorous courses such as Transport Phenomena, Reaction Engineering & Kinetics, and Engineering/Chemical Thermodynamics. In Fall 2025, the course was offered to 47 enrolled students, separated into 4 sections of 10-13 students each. Each session had weekly tutorial sessions (primarily in-person) led by 4 Teaching Assistants (TAs), who covered problems that built on the corresponding lecture content. In addition to this, all TAs offered weekly office hours which students from any section could attend. The primary assessment of this course relied on 4 in-person quizzes and a final examination. Additionally, students worked in 5-6-member teams to calculate mass and energy balances on a simplified chemical industry process such as the Contact Process (sulfuric acid production), the Haber-Bosch Process (ammonia synthesis), the Baeyer Process (alumina production), and the Water Gas Shift Reaction (synthesizing blue hydrogen). The final course grade was a composition of multiple assessments: tutorial attendance and participation (5%), problem set submissions (20%), research presentations (7.5%), final report (15%), 4 quizzes (total 30%), and a final examination (22.5%). The curriculum revamp was specifically performed for the problem set component of this course.

For Fall 2025, this course was revamped in the following ways. Firstly, the course content was made more rigorous, with substantial questions testing the foundations of mathematics in students (especially iterative numerical methods, algebra, differential and integral calculus). The instructor taught the course content from three textbooks, as opposed to the conventional choice of using one textbook. Secondly, there was a conscious creation of new problems in quizzes and problem sets, thereby not using previous year content or solved textbook examples. This is not an easy task and constantly requires the creation, solution, and checking of questions before sending it to students. To ensure that students adhered to academic policy and integrity, a plagiarism check (5%, excluding references and bibliographic information on Turnitin) was performed on all problem sets and deliverables in this course (and students were made aware of this from the very start of the course). The instructor (Sourojeet Chakraborty) also ensured that the solutions to these problems were grounded in physical reality and representative of the physics, mathematics, and process dynamics of real-time process engineering operations, as valid within chemical engineering firms. The content of the material was also expanded, with more mass and energy balance topics/problems covered consciously, to set the foundations for engineering thermodynamics, which these students would take in Spring 2026.

## ANALYSIS METHODOLOGY

Analysis of problem sets was performed to compare AI vs. human (instructor) responses. Nine such problems were formulated, each encompassing several domains and fields, all involved testing some key concept of mass and energy balance, as well as analysis and mathematical skills, as summarized in **Table 1**.

**Table 1:** Problem set question themes and concepts tested.

| Q. # | Question Theme | Concepts Tested |
|---|---|---|
| $Q_1$ | Unidirectional flows | Calculus (Differentiation and Integration) |
| $Q_2$ | $H_2SO_4$ synthesis via the Contact Process | Stoichiometry, Generation Consumption Analysis |
| $Q_3$ | Heat Exchanger Design | Algebra, Newton-Raphson (iterative numerical methods) |
| $Q_4$ | Change of maple leaf colors (fall colors) at Algonquin National Park, Canada. | Writing, solving mass balances. Utilizing boundary conditions and Newton-Raphson method |

| | | |
|---|---|---|
| $Q_5$ | Synthesis of blue hydrogen in Abu Dhabi, United Arab Emirates | Balancing and adding chemical equations, Atom Economy, Process Economy, Degree of Freedom analysis for unsteady state mass balances |
| $Q_6$ | Egyptian blue lotus and its impacts on humans | Mass balances, recycle of process streams for steady state mass balances. |
| $Q_7$ | Environmental impact of Chlorinated Volatile Organic Compounds (CVOCs) on Earth | Solving thermodynamic non-ideal Equations of State (EOS). Evaluation of pressure, volume and temperature. Information utilization to evaluate unsteady mass balances. |
| $Q_8$ | Dr. Jane Goodall, and her contribution to understand chimp behavior at Gombe National Park. The problem also investigates mercury accumulation by Lake Tanganyika, situated nearby. | Unit conversions (SI to FPS), unsteady state mass balances with volume to mass conversions (and vice-versa). Integral calculus, Ordinary Differential Equations (ODEs) such as the Leibnitz linear form. Enthalpy calculations with thermodynamic and steam tables based linear interpolation. |
| $Q_9$ | The gold of the 18th dynasty Pharaoh King Tutankhamun, found in 1922 by Howard Carter. | Energy balances requiring enthalpy/heat calculations to synthesize the 1200 kgs. Of gold discovered in the tomb of King Tut. Vapor-Liquid Equilibria (VLE) calculations. |

For each problem detailed above, the instructor solved the problem first manually and then fed it as an effective prompt into ChatGPT, leading to an AI-elicited response. In this context, it is important to recall that the extent to which an LLM-powered search engine can correctly provide a solution depends on the exactness and rigor of the search/prompt criteria fed to the AI – this is known as Effective Prompt Engineering (EPE). Responses and solutions obtained from ChatGPT were extracted and compared with the human (instructor) response, and valuable insights were obtained on what areas the AI excels at, prompts it faces challenges with, and conditions where the AI solution substantially deviates from the correct version. Such insights become extremely valuable, providing a tangible roadmap for instructors to train themselves on EPE for their courses, and design and track personalized as well as collaborative curricular revamps across HEIs. To our best knowledge, there is no evidence in the engineering education/pedagogical literature of a similar work being performed, to consciously compare and track AI vs. human responses, as well as investigate AI response success based on EPE.

## RESULTS & DISCUSSION

We may now present our key results, having compared AI vs. human responses, as summarized in **Table 2**. A direct comparison of these responses reveals valuable insights into the AI's thinking and response process, its thinking patterns, and recommendations. Comparing with human responses, we see that EPE plays a strong role in impacting the correctness of the AI's outcome. This insight is useful when investigating the pros/cons of human vs. AI responses from LLM-powered search engines. The table also captures the diverse spectrum of core chemical engineering topics covered.

## AI PERFORMANCE & ACADEMIC INTEGRITY

To validate the effectiveness of the revamped curriculum and address AI-proofing of core engineering problems, a systematic quantitative benchmark was implemented. ChatGPT's performance was compared across two problem archetypes: Standard Problems (single-unit balances) and AI-Proof Problems (more complex, multi-stage processes with recycles and non-ideal constraints), as summarized in **Table 3**. We observe a 73% performance gap when AI is presented with AI-proof problems without guided prompting. This compelling evidence justifies the curriculum's focus on EPE as a necessary skillset for the I.D. 5.0 future workforce. To ensure rigorous Quality Assurance (AI), all student submissions were also checked for plagiarism using a two-pronged audit strategy, using Turnitin's Similarity Match report and AI-Writing Detection tools. The average similarity score was found to be 4.2% (excluding biography and references), below the instructor's set 5% threshold for all deliverables on Canvas. 85% of student submissions in the AI-Writing audit showed an AI-written probability of <12% for the derivation/analysis sections. So, while students utilized AI for structural brainstorming, technical execution, and critical analysis remained strongly human-driven. However, we also observe instances when AI hallucinates when it incorrectly interprets the definition of 'infinity', which is different in the chemical engineering vs. the mathematical context. In chemical engineering, infinity is used to denote the far-field temporal evolution profile.

**Table 2:** AI vs. human-response summary for EN.540.202 problem sets in Fall 2025.

| Q. No. | Human-response | AI response |
|---|---|---|
| $Q_1$ | Differentiation showed with all steps correctly.<br>Calculations are supported by commentary. Terms cancelling out are highlighted to the reader. Detailed derivation of calculus (no steps skipped) to arrive at a proper solution to equate the left- and right-hand sides. Indefinite integration. Proper boundary conditions to obtain the final integrated solution. | AI clearly shows all steps of differentiation and integration and obtains the correct answer.<br>ChatGPT further asks the user if they wish to verify all units or plot the unidirectional flow velocity profiles. |
| $Q_2$ | The first step is to balance the equations for the Contact Process to arrive at the overall balanced equation.<br>Following this, all assumptions are clearly stated and a generation consumption table formed to explain all variables assumed. Simultaneous solution for assumed variables, following which, the generation consumption table is updated. | AI provides unit checks prior to performing the calculations. Extracts values from the question and performs straightforward correct calculations to calculate desired parameter values. |
| $Q_3$ | Evaluation of Reynolds and Prandtl numbers. Uses the Dittus-Boelter equation to calculate the convective heat transfer coefficient from the Nusselt number. Calculates the Darcy-Weisbach friction factor numerically using the Colebrook-White equation. Initial guess for the friction factor is obtained from reading the Moody's chart. Newton-Raphson type calculations to compute numerically the friction factor, until values show computational convergence. | Correctly performs the integration to obtain volumetric flow rates.<br>Compares analytical and numerical integration values and confirms equality between both these approaches. |
| $Q_4$ | Block Flow Diagram (BFD) to capture the overall picture of the process. AI is unable to generate a BFD.<br>Logically details out the steps needed to arrive at differential equations for this problem, from general mass balances.<br>Clearly states any made assumptions. Identifies the ODE as a Leibnitz linear form, and then, correctly integrates to obtain solution profiles. Applies boundary conditions to obtain the unique solution profile.<br>For the last part of the question, the problem obtains the numerical or transcendental equation form and applies the Newton-Raphson method till the solution converges. | AI lays out all made assumptions and correctly integrates and applies boundary conditions to obtain a unique solution profile.<br>Identifies the last part of the question as solving a transcendental equation. Correctly performs the Newton-Raphson method to obtain the solution.<br>Lastly, ChatGPT also offers to show graphical plots of the solution profiles or offers to show the calculations in much more detail. |
| $Q_5$ | Generation consumption analysis performed to obtain the overall balanced equation for the Water Gas Shift Reaction (WGSR).<br>Atom and process economies defined and then evaluated. This is also supplemented by a Degree of Freedom (DOF) analysis for both steady and unsteady states.<br>Correct identification of process variables to solve for the mass of each species in the given problem. | ChatGPT correctly balances the equations to obtain the overall WGSR equation.<br>Atom and process economies are correctly calculated (but poorly defined). The AI assumes the user to have this knowledge.<br>Ideal Gas Law assumption made by the AI, before performing a DOF analysis for both steady/unsteady cases. However, the AI also proactively provides additional theoretical content after solving the problem (few sentences summarizing its chosen approach to solve).<br>Lastly, the AI interface also offers to plot the obtained solution profiles, which were obtained by integrating the ODE. |
| $Q_6$ | Begins by creating a Block Flow Diagram (BFD). The instructor taught a ten-point solution methodology in class and utilizes this sequence to solve this problem. A set of simultaneous linear equations are solved using matrix solution. This problem is also an example of how to set up sequential balance equations.<br>Lastly, balances are checked and the BFD updated with the calculated mass balances, proving that the law of mass conservation holds. The operation is again repeated, this time with a …<br>**[row continues on next page]** | AI identifies the problem domain, states clear assumptions, and then, details out the steps of the solution. Performs correct mass balances and verifies it by checking for mass conservation. Despite the problem being clear, AI interprets the second part of the problem (with recycle line) as ambiguous. But it still makes correct assumptions and solves the mass balances correctly. Lastly, ChatGPT then … |

Instructor evaluations for this course demonstrate that students in general found this pedagogical revamp useful (see **Table 4**). Information via conversations also

**Table 2 Continued:** AI vs. human-response summary for EN.540.202 problem sets in Fall 2025.

| Q. No. | Human-response | AI response |
|---|---|---|
| ...$Q_6$ | .... recycle line. Again, it is shown that the law of conservation of mass holds. | ... summarizes its mass values, and provides key conclusions arising from the analysis. Lastly (and remarkably), the AI prompts the user if they wish to rerun calculations with different process conditions, or with more recycle lines. |
| $Q_7$ | Starts by identifying that the Ideal Gas Law does not apply for the problem. Calculations are to be performed using the Peng-Robinson Equation of State (PR-EOS). Converts all process parameters to SI units and calculates the final form of the cubic polynomial (all non-linear equations of states can be reduced to a cubic EOS). Solves for the volume without skipping any steps. Correctly obtains the three roots, and chooses the correct one, based on physical reality and numerical feasibility. This is indicative of the conscious creation of engineering logic and judgement in students via a problem set. Using the molar volume calculated from the PR-EOS, an unsteady-state mass balance is performed to capture the solution profile Finally, the student is presented with a temporal mass accumulation profile. | The AI extracts all useful information from the question prompt and correctly performs thermodynamic calculations. The correct root is then chosen, based on proper reasoning (so, complex conjugate roots are neglected, since this is not a real solution). Provides additional theoretical content (2-3 short lines) to explain its choice and summarizes additional resources that the user can read up on.<br>The AI is fallacious in the second part of the problem, and ends up performing an infinite summation, effectively rendering the problem as a steady-state one. This is not what the question asks, so the AI predicts an incorrect solution for this case. So, the AI incorrectly interprets a simple ODE integration as an infinite summation. If the user is unaware of these two domains, they will not be able to discern between a correct and an incorrect solution. |
| $Q_8$ | Starts by identifying the Normal Temperature and Pressure (NTP) conditions. Correctly identifies the Leibnitz linear ODE form for mass conservation Integrates, and then assimilates suitable boundary conditions to obtain the mass accumulation profile in Lake Tanganyika, presented in MS-Excel. Lastly, performs calculations to demonstrate that even at low concentrations, the mercury leached into the lake can exceed the permissible environmental limits. | The AI correctly obtains enthalpy data from the formula and recognizes the ODE form correctly. Integrates correctly.<br>Beyond the question scope, ChatGPT performs additional calculations and shows that the accumulated mercury will exceed the permissible limits in 5 hours! This is not asked in the original problem. Additionally, the AI further calculates the mass profile by performing a weighted, rather than an arithmetic average, to obtain the average mass. This is a classic case of the AI over-interpreting the search prompt and performing additionally useful (but not needed) calculations. Lastly, a mercury accumulation plot is also shown by the AI. |
| $Q_9$ | Starts by drawing a BFD for the overall gold extraction process. Obtains the balanced chemical equation correctly.<br>Employs mass balances (via back-calculation) to evaluate how much feed is needed to produce 1200 kgs. of gold.<br>Vapor-Liquid Equilibria (VLE) information is utilized to correctly obtain the enthalpies of all species, to calculate the heat of reaction. Assuming adiabatic conditions, a fourth order polynomial is calculated, and the correct (physically and mathematically meaningful) value of the adiabatic flame temperature is presented.<br>Finally, the process is compared to case when the specific heat capacities are constant (which would not require one to integrate). | The AI identifies the problem as one involving a complex interaction of mass balances, stoichiometry, and thermochemistry. It correctly adds equations to obtain the balanced equation for the overall process. Provides two very different interpretations of the (intentionally) ambiguous problem and proceeds with one approach. The AI summarizes key mass and energy balances at inlet/outlet conditions. Extracts the standard enthalpies of formation from the NIST database and thermodynamic tables. For one species that the AI is unable to find enthalpy data online, it assumes a plausible value. Incorrectly calculates the adiabatic flame temperature. Notably though, the AI recognizes that the calculated value does not make sense owing to having made infeasible assumptions and asks the user if they wish ChatGPT to perform more realistic, rigorous calculations. In the second iteration, the AI takes more time but correctly extracts the specific heat capacity of the species it had assumed earlier. Calculations are repeated, and this time, a correct adiabatic flame temperature is reported. Lastly, ChatGPT offers the user to perform further calculations, with an even more rigorous search on the enthalpies, and/or to summarize its calculations and results as a PDF file that might prove useful to put in a report/appendix file. |

shows that students continued to use the lecture slides/content from this course as an additional resource in Spring 2026, specifically for EN.540.203 (Engineering Thermodynamics). This is direct evidence of the

attainment of higher levels of Bloom's taxonomy (content retention/replication), which serve as indicators of Fink's model of significant learning.

While variations are observed across the four sections taught in Fall 2025, mean instructor metrics (mean course quality of 4.3425, mean teaching effectiveness of 4.275, and mean intellectual challenge of 4.4425) capture a successful pedagogical revamp of this course. For context, a score of 4 out of 5 is considered a high indicator of course quality at Johns Hopkins University.

**Table 3:** ChatGPT performance vs. problem complexity & prompt strategy.

| Problem Type | Prompt Strategy | Conceptual Accuracy (1-5) | Math Precision (%) | Success Rate |
|---|---|---|---|---|
| Standard | Zero-Shot (Direct) | 4.2 | 88% | 85% |
| AI-Proof | Zero-Shot (Direct) | 1.8 | 32% | 20% |
| AI-Proof | Contextual (EPE) | 3.5 | 64% | 55% |
| AI-Proof | Chain-of-Thought (CoT) | 4.6 | 91% | 88% |

**Table 4:** Summary of instructor evaluation via anonymous student responses (Likert scale 1-5) for EN.540.202 (Fall 2025).

| Assessment Metric | Section | This course | Department Level | School Level |
|---|---|---|---|---|
| Course Quality | 1(N = 13) | 4.25 | 4.14 | 4.22 |
| | 2(N = 12) | 4.25 | | |
| | 3(N = 12) | 4.17 | | |
| | 4(N = 10) | 4.70 | | |
| Teaching Effectiveness | 1(N = 13) | 4.25 | 4.19 | 4.27 |
| | 2(N = 12) | 4.00 | | |
| | 3(N = 12) | 4.25 | | |
| | 4(N = 10) | 4.60 | | |
| Intellectual Challenge | 1(N = 13) | 4.58 | 4.32 | 4.27 |
| | 2(N = 12) | 4.09 | | |
| | 3(N = 12) | 4.50 | | |
| | 4(N = 10) | 4.60 | | |

## CONCLUSIONS

Several pivotal conclusions arise from direct human vs. AI responses. To begin, AI-powered LLM platforms such as ChatGPT appear to be doing a great job when solving elementary (or straightforward) mass and energy balance calculations. The success of the AI solution depends on the prompt fed to the search engine. The more rigorous the prompt, with detailed information, the more accurate the AI solution. However, as the questions become progressively more difficult, abstract, and less defined, the AI falters and sometimes fails to produce a correct solution. When this is the case, we observe that AI responses are completely different from the actual solution. This is important to note, since this is something that students should be made aware of. Therefore, the success of an AI prompt heavily relies on the skill of Effective Prompt Engineering (EPE). In fact, this work is direct evidence of why instructors are actively encouraged to teach and integrate EPE into their curricula. Since it is now well established that students use AI platforms to catalyze their personalized learning experience, learning about EPE skills (which, we propose, is an E.D. 5.0 competency) can help them to empower their learning experiences at HEIs.

Next, the long-term impacts of this curricular revamp are now becoming evident to the instructor. In Spring 2026, several of his students thanked him for teaching them these principles, especially thermodynamic concepts, which appear to be enriching their learning experience in EN.540.203 (Engineering Thermodynamics). To a faculty, this is the best reward one can expect from their students. Students also ranked the instructor's performance highly in their Fall 2025 evaluations. For context, courses are assessed on a 1-5 Likert scale rating at the Whiting School of Engineering, at Johns Hopkins University. A score of 4 or above is considered a high one and is indicative of good instructor performance. Students ranked the overall course quality as 4.3425, the instructor's teaching efficacy as 4.275, and the intellectual challenge of the course as 4.4925. This reveals that despite students rightly perceiving this course as a hard, 4-credit, fundamental course, they also appreciated the curricular revamps we implemented. Future initiatives such as these play a crucial role in bridging the E.D. 5.0 – I.D. 5.0 gap, which will directly lead to the realization of Society 5.0 worldwide.

Lastly, we wish to emphasize that, as of now, it appears that AI-led LLM-powered platforms are still not totally capable of replacing the traditional classroom-learning environment in totality. But this is not necessarily a bad outcome, since it implies that in the current context of the academic/HEI landscape, a conscious and thought-out assimilation of AI into an otherwise traditional curriculum holds potential to revamp and personalize student learning experiences to their benefit. Thus, the authors encourage the reader to envision AI from a more synergistic, rather than antagonistic, lens. When utilized proficiently and strategically, AI has the potential to rapidly transform the university learning environment, bringing it close towards E.D. 5.0. Expanding beyond the content and context of one course, if such revamps are systematically implemented throughout the curriculum, younger generations of students (Gen Z and Gen Alpha)

can swiftly be trained in E.D. 5.0, which will help them be perceived as valuable (i.e., employable) by I.D. 5.0, upon their graduation from universities. Long-term, we envision such a conscious, proactive integration of E.D. 5.0 and I.D. 5.0 to lead mankind towards accomplishing the Society 5.0 global vision.

## ABSTRACT

Data extraction and processing constitute the cornerstone of quantitative management and operational analysis in industrial process plants. However, most manufacturing facilities currently lack efficient data extraction systems, relying instead on engineers to manually write and execute database queries, which is time-consuming, error-prone, and inflexible when handling diverse data formats or large-scale equipment networks. To address these limitations, this work presents a novel Large Language Model (LLM)-based intelligent framework designed for data extraction and basic data of industrial equipment. The system integrates natural language understanding capabilities with process database schemas, enabling users to perform complex data queries and analyses through natural language prompts. Specifically, it can perform data mining, time-dependent analyses, equipment comparisons, and cross-period performance evaluations when process information is provided. By integrating the process context, the system can further interpret the analysis results to suggest potential operational conditions or abnormalities occurring in the system. Developed in collaboration with a process industry partner, the proposed system was evaluated using six months of real-world operational data from 10 heat exchangers. Experimental results demonstrate that the framework achieves an extraction accuracy exceeding 99% in the online mode and ranging from 92% to 96% in the privacy-preserving offline mode, with a reduced retrieval latency of approximately 2.64 seconds for local inference. Unlike generic chatbots, this framework targets process-specific reasoning, acting as a cognitive assistant that empowers users to interact intelligently with industrial systems. The findings confirm that LLM-assisted extraction effectively addresses the rigidity and inefficiency of conventional approaches while maintaining high reliability and scalability for industrial analytics.

**Keywords**: Large Language Model, exchangers, data extraction, prompt

## INTRODUCTION

The pace of digitalization across various industrial sectors has positioned Large Language Models (LLMs) as a transformative technology capable of driving fundamental changes in Process Systems Engineering (PSE) and manufacturing operations. Following the public release of ChatGPT by OpenAI in late 2022, LLMs have attracted widespread attention due to their capabilities in comprehending, reasoning over, and generating sophisticated natural language. When combined with complementary technologies such as external tools, databases, and domain-specific knowledge bases, these models enable novel research directions and practical applications across diverse domains.

Nevertheless, the deployment of LLMs in industrial environments remains at an early stage and encounters considerable challenges. Process industries are characterized by wide variations in unit operations, safety regulations, and exceptionally stringent requirements for reliability and precision; any erroneous prediction or misinterpreted analysis can result in severe economic losses, safety incidents, or environmental damage. One of the most prominent limitations of current LLMs is their ten-

dency to produce "hallucinations, " i.e., plausible-sounding but factually incorrect or fabricated outputs. To counteract this issue, researchers have explored several mitigation strategies, including fine-tuning on industry-specific datasets [1], retrieval-augmented generation (RAG) [2], integration with structured knowledge graphs for fact-checking and long-term contextual grounding, and hybrid neuro-symbolic approaches that combine language models with deterministic reasoning engines.

To date, most LLM-based research in process systems engineering and related fields has concentrated on qualitative and knowledge-intensive tasks, such as professional question-answering systems, fault diagnosis support, process flowsheet generation, reaction mechanism prediction, molecular or catalyst design assistance, and educational tools for thermodynamics or unit operations [3–6]. Notable examples include cognitive assistants for troubleshooting in the textile industry using GPT-3.5 [3], in-context learning to support user queries [4], root-cause analysis in semiconductor fabrication [5] and multimodal reasoning frameworks such as PaLM-E [6].However, before moving to the reasoning and analysis phase, it is essential to have a precise and flexible data extraction system. In most manufacturing facilities, there is a high daily demand for data extraction across various process parameters and timeframes. This necessitates dynamic data retrieval and basic analyses, such as data anomaly detection and trendline identification. For now, contemporary LLMs are not inherently equipped to directly ingest or query large volumes of raw industrial time-series data stored in relational databases. Engineers and operators must still rely on complex database systems that require advanced SQL proficiency or specialized software interfaces. This technical barrier significantly increases the time and effort needed for data extraction, delays insight generation, and ultimately hampers agile, data-informed decision-making on the plant floor.

The present work seeks to close this gap by leveraging the natural-language understanding and generation strengths of LLMs to create intuitive interfaces between process engineers and industrial databases. Rather than requiring users to write structured queries or navigate rigid dashboards, the system allows practitioners to interact with operational data through ordinary conversational prompts. Specifically, We focus on the data extraction process for industrial equipment, selecting the heat exchanger as a primary case study with real industrial data.

The objective of this research is therefore to enable process engineers, shift supervisors, and plant managers to perform complex data retrieval, trend analysis, cross-unit comparisons, and basic performance diagnostics far more efficiently than with conventional methods, ultimately improving real-time supervision, early anomaly detection, and overall production effectiveness. Moreover, the proposed system architecture is intentionally designed to be modular and generalizable, offering a reusable framework that can be adapted to quantitative data challenges involving other unit operations (distillation columns, reactors, compressors, dryers, etc.). The principal contributions of this study are as follows:

1. Dual-Mode Architecture: A flexible system design that supports both an Online Mode (utilizing high-capacity cloud-based LLMs for superior reasoning depth) and an Offline Mode (local deployment of smaller open-source models to guarantee strict data privacy and control in sensitive industrial settings).
2. Robust Prompt Engineering with Self-Correction: Specialized prompting strategies, including a closed-loop self-correction mechanism for SQL generation, that substantially reduce hallucinations and improve reliability even when using resource-constrained local LLMs.
3. Systematic Decomposition of Complex Analytical Queries: A structured methodology that breaks down nested, multi-step, and interdependent engineering questions into simpler, sequentially solvable subtasks, thereby enabling accurate handling of realistic, real-world process data analysis scenarios.

## METHODOLOGY AND SYSTEM FRAMEWORK

### System Architecture

The overall system design prioritizes flexibility and adaptability through a dual-mode architecture that incorporates distinct Online and Offline modes. This approach effectively addresses the diverse requirements of industrial applications, balancing high computational performance against strict data privacy constraints while supporting different data storage formats. Users can explicitly select the desired mode depending on their operational priorities and security policies.

In the Online Mode, the system leverages cloud-based APIs to access high-performance Large Language Models, such as GPT-4o. This configuration minimizes local hardware requirements and takes full advantage of the model's extensive 128k token context window, enabling it to process highly complex instructions and maintain coherent, long-running conversational histories. By contrast, the Offline Mode is essential for industrial environments that enforce strict data sovereignty and prohibit any transmission of proprietary process data to external networks. In this mode, open-source Large Language Models are deployed and executed entirely on local workstations, ensuring complete isolation of sensitive information. However, local deployment is inherently lim-

ited by available hardware resources. For example, a typical industrial workstation equipped with 16–32 GB of system RAM and a mid-to-high-end consumer GPU (providing 8–24 GB of VRAM) is generally restricted to running quantized 7B-parameter models (commonly 8-bit quantization). While quantization enables feasible inference on such hardware, it inevitably reduces reasoning depth and makes these models less capable of handling complicated, multi-step prompt logic compared to their full-precision, cloud-based counterparts.

To mitigate the performance disparity between the two modes, the system implements two complementary function-calling protocols: a JSON-based format and an SQL-based format. The JSON format supports rich, hierarchical, and expressive function definitions with detailed parameters and intermediate reasoning steps, but it requires strong semantic understanding and precise output formatting from the model. The SQL format, on the other hand, provides a more rigid, structured, and directive interface that aligns closely with predefined database schemas, making it significantly easier for smaller-parameter local models to generate correct and executable statements. Accordingly, the system defaults to the flexible JSON-based protocol in the high-performance Online Mode, while the Offline Mode defaults to the SQL-based protocol to better match the capabilities of constrained local models. A fallback mechanism is integrated to automatically attempt the alternative protocol if the default fails (e.g., due to syntax errors, semantic misalignment, or execution failure). Users also retain the ability to manually override the default and select their preferred processing method at runtime. The overall system architecture is illustrated in Figure 1 and is organized into three tightly integrated layers:

1. Storage Layer: Manages the underlying operational data, supporting both lightweight SQLite databases for structured time-series records and Excel files for legacy or ad-hoc datasets commonly found in industrial settings.
2. Data Processing Layer: Acts as the central orchestration engine of the system (detailed in Figure 2). This layer receives natural-language queries, translates them into structured executable statements according to the active mode and protocol, invokes the appropriate data retrieval and computation functions, processes the returned results, and generates coherent natural-language responses enriched with engineering context and derived insights.
3. Presentation Layer: Serves as the user-facing interface, enabling text query input, audio query input, mode selection and display of conversational history. This layer ensures intuitive interaction and full traceability of the analytical process.

This modular and layered design guarantees scalability, maintainability, and robustness, allowing the system to deliver efficient, personalized, and context-aware data analysis tailored to the complexities of real-world industrial processes.

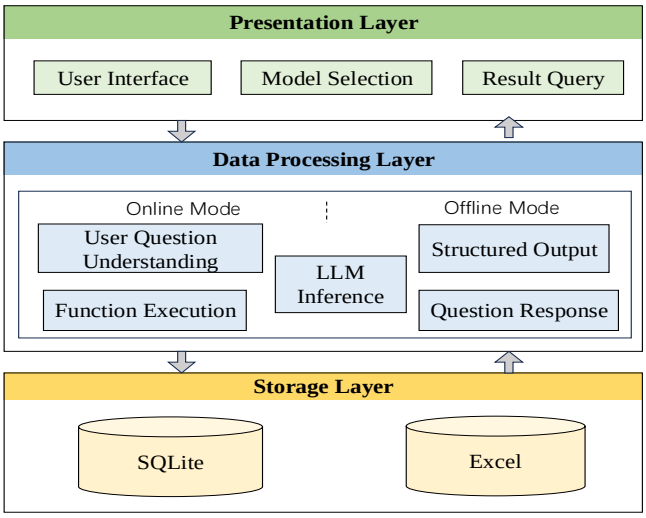

**Figure 1.** The architecture of the system framework.

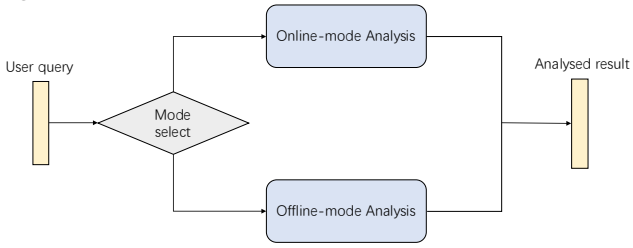

**Figure 2.** The flowsheet of the Data Processing Layer.

## Prompt engineering

In the domain of PSE, effectively bridging the gap between complex industrial queries and precise machine execution requires robust prompt engineering. Standard instructions often fail to capture the strict logical dependencies and engineering-specific constraints inherent in process parameters. To overcome this limitation, the proposed system implements targeted prompting strategies designed to structure and guide the model's reasoning process in a manner that mirrors the systematic workflow of experienced process engineers.

For complex analytical tasks, the system employs Chain-of-Thought (CoT) prompting [7], which compels the model to explicitly illustrate its intermediate reasoning steps before producing a final answer. For example, when diagnosing a potential heat transfer anomaly, the model is guided through a logical sequence such as: 1. Retrieve and verify inlet and outlet temperatures; 2. Calculate the temperature difference; 3. Compare the result against predefined operational limits; 4. Identify any deviations and their possible implications.

This step-by-step reasoning closely replicates the

diagnostic approach of a human process engineer, significantly reducing logical errors in performance analysis, improving result reliability, and ensuring full transparency of the decision-making process for operators and supervisors.

In addition, the system utilizes Decomposed Prompting to effectively handle nested and interdependent engineering queries [8]—for instance, "Find the maximum temperature difference during the period of highest flow rate." A single, monolithic prompt frequently confuses the model in such cases due to the entangled dependencies. To address this, the framework breaks the complex request into independent, sequentially solvable sub-tasks. In the above example, the system first instructs the model to: "Identify the time period during which the flow rate reaches its maximum value." The output of this sub-task (the identified time window) is then passed as a precise constraint to the subsequent prompt: "Within the identified time period, compute the maximum temperature difference across the heat exchanger."

By isolating each engineering sub-task and enforcing sequential dependency, the system achieves high accuracy for individual variables before synthesizing them into a final, comprehensive report. This decomposition strategy proves particularly effective for managing the intricate, interdependent data relationships that are characteristic of chemical process operations.

## Dual-Mode Strategy

The framework adopts a dual-mode strategy that tailors the data retrieval and execution mechanism to the specific inferential capabilities and constraints of the underlying language model. In the Online Mode, the system employs a JSON-formatted function-calling protocol optimized for high-performance cloud-based models. This structured format is inherently well-suited to Chain-of-Thought architectures, as it enables reasoning steps and intermediate results to be explicitly encapsulated within distinct key-value pairs. By mapping logical sub-steps to clearly defined JSON fields, the schema enforces systematic decomposition of complex industrial queries into discrete, interpretable units, greatly enhancing both the precision of the analysis and the transparency of the reasoning trace. Moreover, a specialized placeholder mechanism allows the output of one function call to be directly passed as input to a subsequent operation, thereby supporting the multi-hop reasoning required to resolve deeply nested engineering questions. The detailed patten is shown on the Figure 3.

Conversely, the Offline Mode relies on a SQL-based approach, which provides a more rigid and prescriptive structural framework better aligned with the syntactic and reasoning limitations of smaller, locally deployed models. Because local models frequently struggle with precise SQL syntax generation, especially under quantization and memory constraints, the system incorporates a robust self-correction mechanism (illustrated in Figure 4). When an initial SQL query fails to execute successfully against the database, the system automatically captures the exact error message returned by the SQLite engine and feeds it back to the model together with the original invalid query and the user's natural-language intent. This closed-loop feedback enables iterative refinement: the model is explicitly instructed to focus solely on correcting syntax and schema errors while preserving the analytical objective. The process repeats until a valid, executable SQL statement is produced or a predefined maximum number of correction attempts is reached. This mechanism substantially increases reliability in resource-constrained environments, ensuring dependable data retrieval even when using 7B-parameter models with limited reasoning depth.

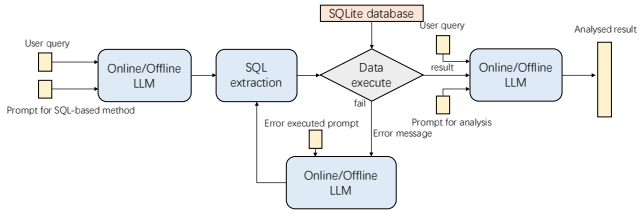

**Figure 4.** Framework design for SQL-based data analysis.

## System Interface

The user interface is carefully engineered to deliver an intuitive, efficient, and accessible experience for industrial operators, engineers, and managers. It is implemented as a desktop application using the Qt framework and Python, providing a robust and cross-platform primary interaction point for the system.

A key design goal is to enable seamless mode

switching: users can toggle between Online and Offline computation modes directly from the main interface, depending on immediate operational needs, such as prioritizing maximum reasoning capability in non-sensitive settings or enforcing strict data sovereignty during critical production periods. To accommodate diverse working environments (e.g., noisy control rooms, hands-free operation, or office-based analysis), the interface supports dual-channel input methods: standard keyboard-based text entry for precise query formulation, and voice input powered by the Whisper automatic speech recognition model, allowing operators to issue natural-language commands hands-free while monitoring equipment or performing field tasks. The resulting interface is illustrated in Figure 5.

The interface maintains a persistent, scrollable chat-style history that displays both user queries and the system's full responses in chronological order. This conversational log preserves context across extended analytical sessions, enables users to revisit earlier results, and supports verifying of the interaction flow—an important requirement for traceability and validation in industrial decision-making processes. To further enhance system robustness, the interface is equipped with error-handling capabilities that automatically detect out-of-scope queries and provide corrective prompts to users.

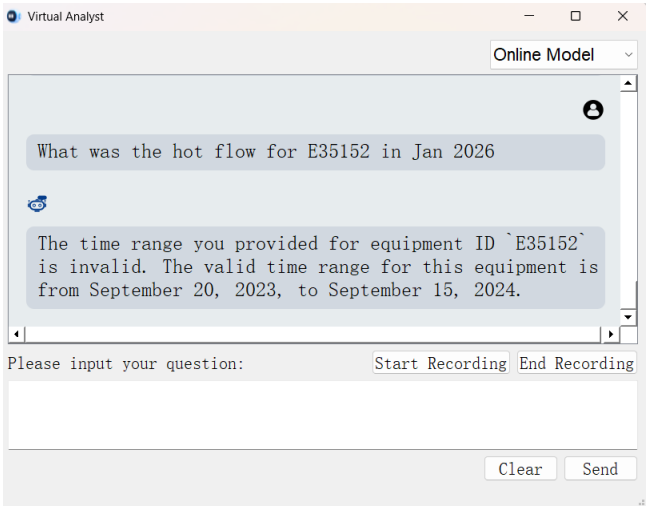

**Figure 5.** The interface of the data extraction system. This figure shows an example of the system's error-handling capability when encountering an out-of-bounds timeframe request.

## INDUSTRIAL CASE STUDY: HEAT EXCHANGER PROCESS DATA

### Dataset

The proposed system was rigorously validated using a comprehensive, real-world operational dataset obtained through close collaboration with a plant in process industries. The dataset spans six consecutive months of continuous production records and covers ten distinct shell-and-tube heat exchanger units operating under typical plant conditions. The dataset integrates key measured thermodynamic and process parameters, including: Inlet and outlet temperatures (hot and cold streams), Mass flow rates of both process fluids, Derived performance indicators, such as the Overall Heat Transfer Coefficient (U) and Logarithmic Mean Temperature Difference (LMTD).

All records are stored in a structured relational database environment (SQLite) designed to faithfully replicate the schema and access patterns of a standard industrial information management system. This setup ensures that evaluation results reflect realistic query execution behavior encountered in actual process plants. To guarantee reproducible and representative performance measurements for the Offline Mode under practical hardware constraints, all local inference experiments were conducted on a high-end workstation equipped with an NVIDIA RTX 5090 GPU (32 GB VRAM) and sufficient system RAM to support quantized 7B-parameter models without excessive swapping. This configuration represents a realistic upper bound for on-premises deployment in many industrial facilities as of 2026.

To systematically assess the system's natural-language understanding, logical reasoning, and data extraction accuracy, a dedicated benchmark dataset was constructed comprising 300 natural-language queries. These queries were carefully stratified into three complexity categories, with 100 queries per category, to probe different aspects of model capability:

1. Simple queries: Direct, single-parameter retrieval tasks (e.g., "What is the average cold-side outlet temperature for exchanger E35112 during January?").
2. Parallel queries: Requests that require simultaneous extraction and reporting of multiple independent parameters without interdependency (e.g., "Report the average flow rate, inlet temperature, and overall heat transfer coefficient for unit E35142 over the past month.").
3. Nested queries: Multi-step reasoning tasks in which the result of one computation serves as a constraint or input for a subsequent operation (e.g., "Count the days in January where the UA for E35112 is greater than the average.").

This stratified benchmark provides a robust and comprehensive framework for evaluating not only overall extraction accuracy and inference latency, but also the effectiveness of the self-correction mechanism and error-handling behavior across varying levels of analytical difficulty.

### Conversational Examples

To evaluate the practical utility of the model, we utilized the aforementioned benchmark dataset consisting of 300 test cases, which are categorized into simple, parallel, and nested queries. Our system is designed to support four core operational capabilities that are essential for plant personnel to flexibly extract and analyze data: data retrieval, trend analysis, cross-unit comparisons, and basic performance diagnostics. Focusing on these four practical aspects, we conducted a series of case studies. The representative conversational interactions between the user and the system are illustrated in Figures 6, 7, 8 and 9.

1. Data Retrieval: This foundational capability enables users to extract specific historical or real-time process parameters without requiring knowledge of database structures or query languages. Shift supervisors can quickly obtain current operating values for critical equipment, while process engineers can retrieve statistical summaries such as averages, maxima, or cumulative totals over custom time windows. Beyond simple lookups, the system supports conditional queries (e.g., periods where a parameter exceeded a threshold) and arithmetic combinations of multiple variables, allowing users to perform ad-hoc calculations on the fly. By transforming manual, error-prone reporting into instantaneous, on-demand access, this capability accelerates routine monitoring, daily reporting, and troubleshooting investigations.
2. Trend Analysis: Beyond single-point extraction, the system allows users to examine how process variables evolve over time. Operators can identify gradual performance drifts such as fouling trends in heat exchangers by querying time-series patterns of key indicators like overall heat transfer coefficient or temperature differentials. Engineers can analyze cyclical behaviors (e.g., daily or batch cycles) or compare distinct operational phases (e.g., before and after maintenance, or across different feedstock grades) to assess intervention effectiveness. The system can also compute rates of change, detect monotonic trends, and flag sustained deviations from baseline behavior. This capability supports proactive decision-making by transforming raw time-series data into actionable insights about process stability, equipment degradation, and long-term performance trajectories.
3. Cross-Unit Comparisons: To support system-level oversight, the system enables simultaneous evaluation of performance across multiple equipment units. Process engineers can benchmark the efficiency of parallel units to identify underperforming assets, validate consistency across identical process lines, or assess the impact of differing maintenance schedules. Plant managers may request comparative summaries such as top-performing units by efficiency or units with the highest deviation from setpoints to prioritize maintenance activities and allocate resources effectively. The system can also aggregate data across groups of units (e.g., all exchangers in a specific area) to provide fleet-level statistics. By abstracting the complexity of multi-table joins and conditional aggregations, this capability facilitates holistic monitoring and supports data-driven decisions about equipment utilization, operational parity, and capital planning.
4. Basic Performance Diagnostics: As a practical extension of data extraction, the system provides preliminary diagnostic support through univariate anomaly detection. Operators can swiftly identify when a measured parameter deviates beyond established statistical thresholds (e.g., three-standard-deviation limits), flagging potential malfunctions without requiring advanced analytical training. Engineers can investigate the timing, duration, and magnitude of such deviations to correlate them with external events, operational changes, or emerging fault patterns. The system can also highlight recurring anomalies across multiple units or time periods, helping to prioritize deeper root-cause analysis. While not a substitute for detailed modeling, this capability serves as an effective tool, enabling rapid detection of abnormal conditions and focusing expert attention on areas most likely to require intervention.

Together, these four capabilities exemplified in the representative conversational interactions shown in Figures 6 (data retrieval), 7 (trend analysis), 8 (cross-unit comparisons), and 9 (basic performance diagnostics) demonstrate how the system bridges the gap between complex industrial data stores and the diverse informational needs of plant personnel, enabling more agile, informed, and collaborative operational decision-making.

## RESULTS AND DISCUSSION

### Performance Evaluation

We conducted tests in both online and offline modes to verify the system's robustness across different operational scenarios. For this evaluation, two primary metrics were established: Execution Accuracy and Inference Latency. Accuracy is emphasized as the paramount indicator, given that in safety-intensive process industries, any hallucination or incorrect data retrieval can lead to flawed decision-making and potential operational hazards. Meanwhile, Inference Latency is critical to assessing the system's viability for real-time interaction, particularly when deployed on resource-constrained local hardware for immediate anomaly detection.

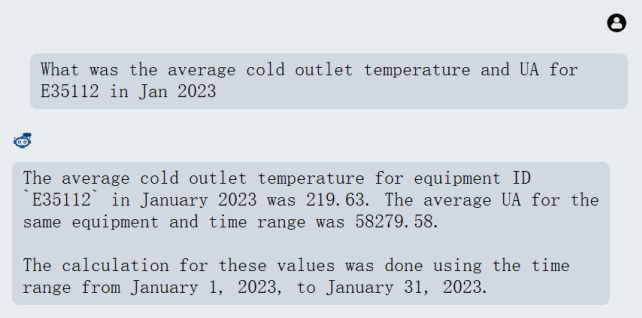

**Figure 6.** Dialog example of Data Retrieval.

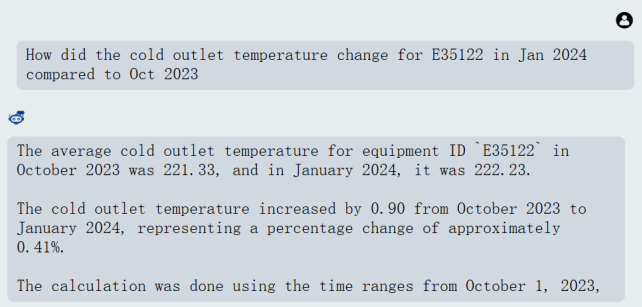

**Figure 7.** Dialog example of Trend Analysis.

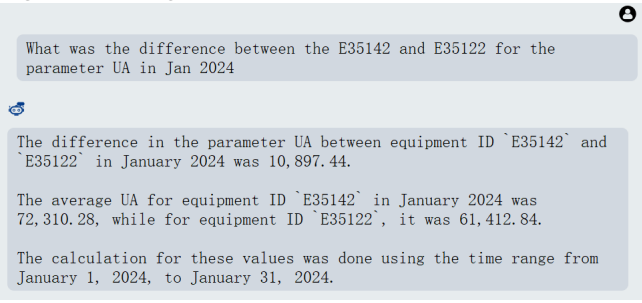

**Figure 8.** Dialog example of Cross-Unit Comparisons.

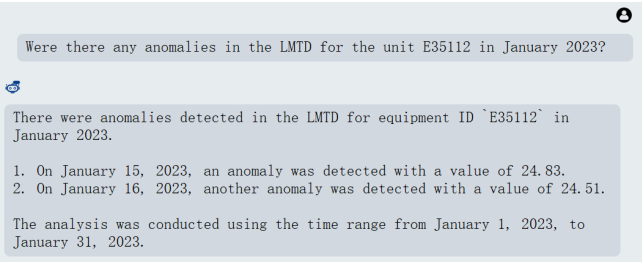

**Figure 9.** Dialog example of Basic Performance Diagnostics.

To have a more quantitative result, A benchmarking was conducted across Simple, Parallel, and Nested query categories. As detailed in Tables 1 and 2, the Online Mode achieved near-perfect accuracy, exceeding 99% across all query types. This superior generalization is attributed to the high-parameter count of the cloud model, which effortlessly managed complex nested logic. However, this high fidelity involved a latency trade-off, with average response times ranging from 3.90s to 5.09s due to network overhead. Conversely, the Offline Mode delivered commendable performance, with accuracy rates ranging from 92% for simple queries to 96% for parallel queries. Notably, the local deployment significantly outperformed the online configuration in processing speed, averaging an inference time of 2.64s for simple tasks. This characteristic makes the Offline Mode highly suitable for time-sensitive edge applications where data privacy and rapid response are paramount. The primary sources of error in the offline setting were identified as minor formatting inconsistencies and occasional parameter hallucinations (e.g., incorrect column name generation), which the self-correction mechanism largely mitigated but did not entirely eliminate.

**Table 1:** Evaluation results across various query categories in Online Mode.

| Dataset | Accuracy | Average time cost |
|---|---|---|
| Simple question | 100% | 3.90s |
| Parallel question | 99% | 5.09s |
| Nested question | 99% | 4.96s |

**Table 2:** Evaluation results across various query categories in Offline Mode.

| Dataset | Accuracy | Average time cost |
|---|---|---|
| Simple question | 92% | 2.64s |
| Parallel question | 96% | 2.95s |
| Nested question | 93% | 5.19s |

Furthermore, to scientifically validate the contribution of specific prompt engineering components, an ablation study was performed using the Online Mode as a baseline. The results, presented in Table 3, demonstrate that the full prompt configuration yields the optimal balance of precision and efficiency.

1. Chain-of-Thought Guidance: Removing CoT resulted in a moderate increase in inference time (approx. 60%) and a marginal dip in accuracy. This suggests that explicit reasoning steps are crucial for streamlining the model's internal logical processing.
2. Few-Shot Examples: The removal of few-shot demonstrations led to catastrophic performance loss, especially for Nested queries where accuracy hit 0%. This confirms that few-shot examples are essential for teaching the complex JSON schemas required for multi-hop reasoning.
3. Rules and Constraints: While removing explicit constraints did not severely impact accuracy, it significantly increased latency. Without predefined bound-

**Table 3:** Ablation study results quantifying the individual contributions of Chain-of-Thought (CoT), Few-Shot prompting, and Constraints to the system's overall performance in Online Mode.

| Prompt config | Question Type | Accuracy | Format Acc. | Function Acc. | Time Acc. | Parameter Acc. | Average time cost |
|---|---|---|---|---|---|---|---|
| Full prompt | Simple | 100% | 100% | 100% | 100% | 100% | 3.90s |
| | Parallel | 99% | 100% | 100% | 99% | 100% | 5.09s |
| | Nested | 99% | 100% | 100% | 99% | 100% | 4.96s |
| w/o CoT | Simple | 93% | 100% | 100% | 93% | 100% | 4.62s |
| | Parallel | 94% | 100% | 100% | 94% | 100% | 8.29s |
| | Nested | 96% | 100% | 100% | 96% | 100% | 9.15s |
| w/o Few-Shot | Simple | 53% | 55% | 100% | 98% | 100% | 6.51s |
| | Parallel | 60% | 63% | 100% | 97% | 100% | 7.07s |
| | Nested | 0% | 0% | 100% | 98% | 75% | 8.22s |
| w/o Rules | Simple | 99% | 100% | 100% | 99% | 100% | 5.60s |
| | Parallel | 99% | 100% | 100% | 99% | 100% | 11.54s |
| | Nested | 98% | 100% | 100% | 98% | 100% | 9.17s |

aries, the model required more iterative "thought" cycles to arrive at the correct structured output.

## Comparison with Generic Frameworks

To further validate the necessity of the proposed specialized architecture, a benchmarking study was conducted against LangChain [9], a widely adopted framework for building LLM applications. To ensure a fair comparison, the generic framework was evaluated under identical hardware constraints using the same Mistral-7B model deployed in the Offline Mode. The comparative analysis reveals that the proposed direct-calling framework significantly outperforms the generic LangChain implementation in both execution accuracy and inference efficiency.

Initial experiments utilizing LangChain's default SQL chain resulted in a critical failure to generate valid executable queries, yielding a 0% accuracy rate across all test categories (Table 4). This failure was primarily driven by dialect mismatches, where the generic prompts defaulted to standard SQL syntax incompatible with the strict requirements of the local SQLite environment. Additionally, the generic approach induced frequent schema hallucinations, where the model attempted to query non-existent columns or functions prohibited by the local schema definition.

To isolate the impact of prompt quality, the robust, optimized prompts developed for our system were subsequently injected into the LangChain pipeline. Despite this enhancement, performance remained significantly suboptimal, with accuracy rates failing to exceed 50% even for simple queries (Table 5). This persistent performance gap suggests that LangChain's internal abstraction layers—which often encapsulate user instructions within generic system roles or append significant token overhead—tend to dilute the strict instruction adherence required by smaller, parameter-constrained local models. In contrast, our proposed framework's direct "Generation-Correction" loop provides the fine-grained control necessary to enforce syntax constraints on 7B-parameter models.

**Table 4:** Evaluation results based on the LangChain framework using its default SQL prompt templates.

| Dataset | Accuracy | Average time cost |
|---|---|---|
| Simple question | 0% | 4.46s |
| Parallel question | 0% | 5.35s |
| Nested question | 0% | 5.54s |

**Table 5:** Evaluation results based on the LangChain framework using self-designed prompts.

| Dataset | Accuracy | Average time cost |
|---|---|---|
| Simple question | 47% | 5.60s |
| Parallel question | 9% | 4.34s |
| Nested question | 22% | 5.05s |

Furthermore, regarding computational efficiency, the LangChain implementation demonstrated an average inference latency approximately 50% higher than our custom framework. These results underscore that while generic frameworks aid rapid prototyping, specialized industrial edge applications necessitate the bespoke optimization presented here to ensure reliability and real-time performance.

## CONCLUSIONS

This study addresses the critical bottleneck of manual data extraction in process industries by introducing a novel, LLM-based Intelligent Analysis System specifically tailored for heat exchanger. Through a flexible Dual-Mode Architecture, the proposed framework effectively resolves the trade-off between complex reasoning capabilities and strict data privacy requirements.

The Online Mode, leveraging JSON-based Chain-of-Thought prompting, demonstrated exceptional fidelity in handling nested engineering queries, achieving over 99% accuracy. Conversely, the Offline Mode ensured complete data sovereignty while delivering reliable performance (92–96% accuracy) and superior real-time response (~2.64s). This was achieved through a specialized SQL "Generation-Correction" mechanism designed to mitigate the hallucinations common in smaller local models. Furthermore, comparative benchmarking against LangChain confirmed the necessity of this specialized architecture, as the proposed system significantly outperformed the generic framework in both syntax validity and inference efficiency under identical hardware constraints.

Beyond immediate technical performance, this work has broader implications for the democratization of industrial data analytics within the context of Industry 5.0. By abstracting complex database interactions into intuitive natural language, the system serves as a domain-specific cognitive assistant that significantly lowers the technical barrier for process engineers and operators. This capability not only facilitates efficient knowledge transfer and workforce empowerment but also bridges the critical gap between raw operational data and actionable decision-making. Ultimately, this framework provides a scalable foundation for human-AI collaboration, paving the way for future integration with digital twins and autonomous anomaly detection systems across the process industry.

## ABSTRACT

The Imperial College Integrated Design Project reframes the chemical engineering capstone as a structured educational journey that develops professional competence rather than simply delivering a final technical report. The programme is grounded in four pedagogical pillars—authenticity, integration, impact, and reflection—which align with the graduate attributes required by the Institution of Chemical Engineers. Authenticity is achieved through open-ended problems drawn from industrial partners and emerging research needs; integration connects knowledge from across the curriculum into a coherent systems perspective; impact emphasises user-centred, sustainable solutions; and reflection cultivates metacognitive awareness of decision making and learning from failure. A mentored-autonomy model supports student teams through weekly checkpoints, skills workshops, and access to disciplinary experts. Assessment deliberately balances artefact quality with evidence of process, rewarding reasoning under uncertainty, ethical judgement, and communication alongside technical performance. Ethics, safety, and sustainability are embedded through lifecycle analysis and HAZOP requirements rather than treated as add-ons. The four-phase structure—scoping, feasibility, detailed design, and deployment—scaffolds increasing complexity while maintaining measurable progress and accountability. A 2024 project on renewable-powered green ammonia illustrates how students integrate decision-making methods, simulation tools, and stakeholder negotiation within a realistic professional context. Educational outcomes include strengthened systems thinking, collaboration, project leadership, and the ability to justify design choices in social and environmental terms. Institutional benefits include deeper industry engagement and improved graduate readiness. The paper argues that capstones should be judged by the quality of learning processes as much as by final designs, and that this model produces reflective engineers equipped for interdisciplinary practice and responsible innovation.

## INTRODUCTION

As stated by Lewin et al [1]: “The capstone design course in chemical process design, together with its associated design project is the acid test to gauge the mastery of trainee chemical engineers. There is no other component in the chemical engineering curriculum that performs this function to this degree.” The design project lies at the heart of chemical engineering education because it invites students to think creatively, critically, and boldly beyond the limits of what they have learned in individual courses [2, 3, 4]. It challenges them to work as genuine engineering teams, where ideas must be debated, refined, and transformed into practical solutions. By bringing together topics that are usually taught separately, the project reveals how interconnected the discipline really is and helps students see chemical engineering as a living, integrated profession rather than a collection of isolated subjects [5]. Through this experience, students gain the confidence and imagination needed to shape future technologies. They learn to confront real and emerging challenges: working with alternative raw materials and renewable energy sources, designing processes that can adapt to changing markets, and ensuring that innovation is guided by strong commitments to ethics, health and safety, and sustainability. The design project therefore becomes more than an academic exercise—it is a first step into professional life, where technical knowledge meets responsibility, creativity meets constraint, and engineering meets the needs of

society [6].

This paper presents a flagship, scaffolded final-year design experience that transforms the capstone process design project from a single deliverable into a holistic, industry-engaged, research-informed, and student-centered incubator of professional competence. The project is intentionally ambitious: it integrates multidisciplinary teams, real-world stakeholders, ethical and sustainability considerations, and measurable learning outcomes to prepare graduates who can design, implement, and communicate complex engineered systems with societal impact. The design balances creative freedom with robust assessment and mentorship so every student leaves not only with a detailed design project but with the practical judgment and adaptive skills expected of 21st-century engineers.

## PEDAGOGICAL PRINCIPLES

At its core, the project is built on four pillars: authenticity, integration, impact, and reflection. Authenticity requires problems drawn from real industrial, environmental, or public-sector partners and from open research questions; integration demands teams that learn from professional practice; impact-prioritises user-centered, sustainable solutions with clear pathways to deployment; and reflection embeds continual metacognitive practice, so students articulate decisions and learn from failure. These pillars map directly to graduate attributes and the requirements of the Institution of Chemical Engineers: technical competence, systems thinking, communication, ethics, and lifelong learning.

Pedagogically, the programme uses mentored autonomy. Weekly checkpoints (rapid written updates and short presentations to facilitators) promote accountability and peer learning. Workshops teach professional skills — negotiation, risk management, regulatory pathways, intellectual property basics, and science communication. Assessment mixes artifact quality (technical reports, validated simulations), process evidence (design logs, decision rationales), and communication (technical presentations). Weighting emphasizes process and evidence of learning as much as the final product, rewarding reasoning under uncertainty.

Ethics, sustainability, and safety are integrated rather than appended. Each project includes a basic lifecycle analysis estimating $CO_2$ emissions, embodied energy, and end-of-life impacts, which are mitigated as far as possible. Safety engineering reviews are required, in the form of a HAZOP and other hazard assessments. Assessment design balances rigor and creativity. Rubrics clarify expectations across technical depth, innovation, integration, and communication. External examiners from industry and academia review a sample of projects to ensure standards align with professional expectations.

## PROJECT PERSONEL

The final year design (FYD) project is a task undertaken by each 4$^{th}$ year cohort of students at the Chemical engineering Department at Imperial College, who are divided into twelve design teams of approximately 12 students each. The teams are explicitly balanced in terms of overall grade, male / female ratio and home / overseas fee status via an optimisation algorithm implemented in GAMS. Each team has a faculty facilitator, who is responsible for two teams, each of which is assigned a project brief set by the facilitator. The student teams meet once a week with their facilitator and can in addition set meetings with the six faculty experts in the key areas of process analysis, economics, reactor design, separation systems design, control system design, and safety and environment. They also have access to graduate teaching assistants (GTAs), some of whom provide technical clinics. Others who are returning to Imperial to conduct a PhD and have done the project previously, act as student coaches who can also assist with general timelines as well as providing support.

## PROJECT TIMETABLE

The Integrated Design Project follows a structured timeline designed to scaffold student progress while maintaining sustained engagement with industrial stakeholders. Prior to the commencement of the project there is an externally hosted away day involving teambuilding activities, where students are encouraged to reflect upon their individual strengths, weaknesses, and what they could get out of the project. Project briefs are released via Blackboard on at the beginning of week one, followed by an initial meeting with facilitators during the first week. Lectures by each of the specialist experts follow within the first two weeks to align expectations and methods. The opening two weeks focus on problem scoping and negotiations with “investors”, for which the students are expected to have produced a preliminary budget and at which they will also agree pricing for key feedstocks, utilities, and a carbon price. These meetings continue throughout the project. A key early milestone is the submission of the intermediate report at the end of the third week. February includes a scheduled interruption for the Frank Morton sport event, during which no project meetings are allowed to be arranged, permitting students time to attend, and for recovery. For readers unfamiliar with the UK context, the event is named after Frank Morton, a well-known Professor of Chemical Engineering who taught at Birmingham University until 1956 before moving to UMIST (now the University of Manchester). A keen sports enthusiast with close links to both universities, he went on to organise the first of these sports days in 1961. The 2024 event was hosted by the University of

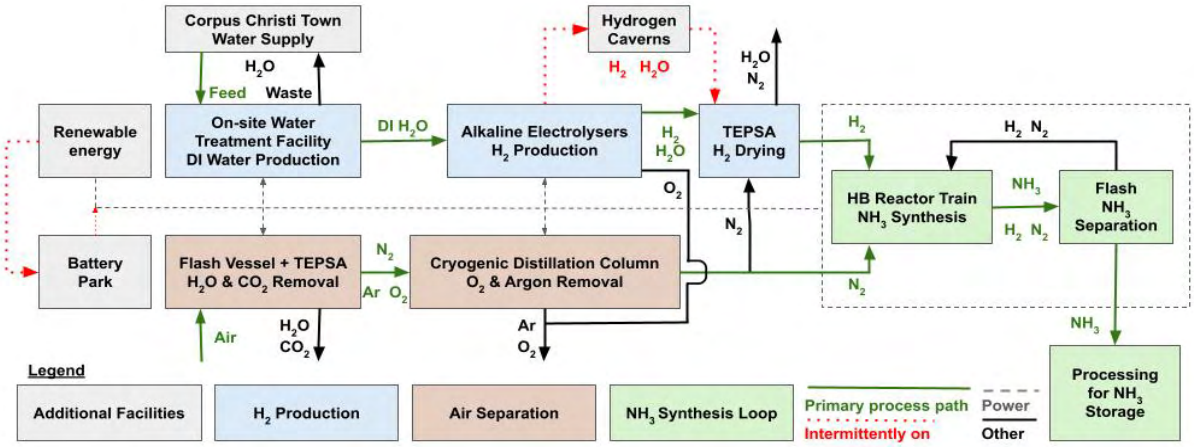

**Figure 1:** Block Flow Diagram of Group 4's Ammonia Production Process

Swansea. The project culminates in the submission of the final report on around ten weeks in, with final presentations held early in the next week. Informal social activities follow later in March, reinforcing cohort cohesion, while a formal feedback session in May provides reflective closure and supports continuous improvement of the programme.

## PROJECT STRUCTURE

Project structure is phased to support increasing complexity while maintaining measurable progress. Table 1 presents the six projects addressed by the Class of 2024.

**Table 1:** Project Subjects Addressed in 2024.

| Assigned Groups | Project |
|---|---|
| Groups 1 and 2 | Sustainable metal organic frameworks (MOF) |
| Groups 3 and 4 | Ammonia from Air and Water |
| Groups 5 and 6 | Fuel production from atmospheric $CO_2$ |
| Groups 7 and 8 | Animal-free microbial dairy cheese production |
| Groups 9 and 10 | VLP-Based Antigen Display for Cancer Vaccine Bioproduction |
| Groups 11 and 12 | Levothyroxine production |

Phase 1 (Scoping and Stakeholder Alignment) equips teams to define a clear problem statement, success metrics, and stakeholder map, together with the location of their plant, based on key business metrics (working under uncertainty). Phase 2 (Concept and Feasibility) focuses on concept generation, risk analysis, and a basic feasibility study, developed in ASPEN, but without full implementation at this stage. Phase 3 (Detailed Design and Validation) delivers robust engineering artifacts (simulation, safety and environmental analysis data, control philosophy, etc.). Phase 4 (Deployment Strategy and Handover) culminates in a deployment plan, a sustainability statement, and a handover package suitable for the sponsoring partner. Each phase has significant interactions with both "experts" and "facilitators".

For example, consider the highlights of one of the design projects set in 2024, which required the design of a 2, 000 MTD of Green Ammonia using only air and water as feedstocks and relying on renewable energy, and more specifically, the activities and design decisions of one of the two student teams, Group 4, engaged in that project, per phase:

### Phase 1: Scoping and Stakeholder Alignment

In this phase, the teams define a clear problem statement, success metrics, and stakeholder map, together with the location of their plant, based on key business metrics.

The economic basis for the project relies on negotiation of prices of raw materials and energy between the design teams and the staff member responsible for economics mentoring, serving as the "representative" of so-called "Hawkes Industries." The principal methodology utilized in this step is Multi-criteria Decision-making (MCDM), combining Analytical Hierarchy Process (AHP) and Technique for Order of Preference by similarity to Idea Solution (TOPSIS) to select the best alternative for each required decision.

For example, using these techniques, Group 4 chose to plan their process to be constructed in Corpus Christi, Texas, primarily because of the state's bountiful renewable energy resources. Furthermore, based on MCDM, they opted to rely on Alkaline Electrolysis (AEL) for hydrogen production, and cryogenic distillation for nitrogen production, and a heat-integrated, ammonia synthesis

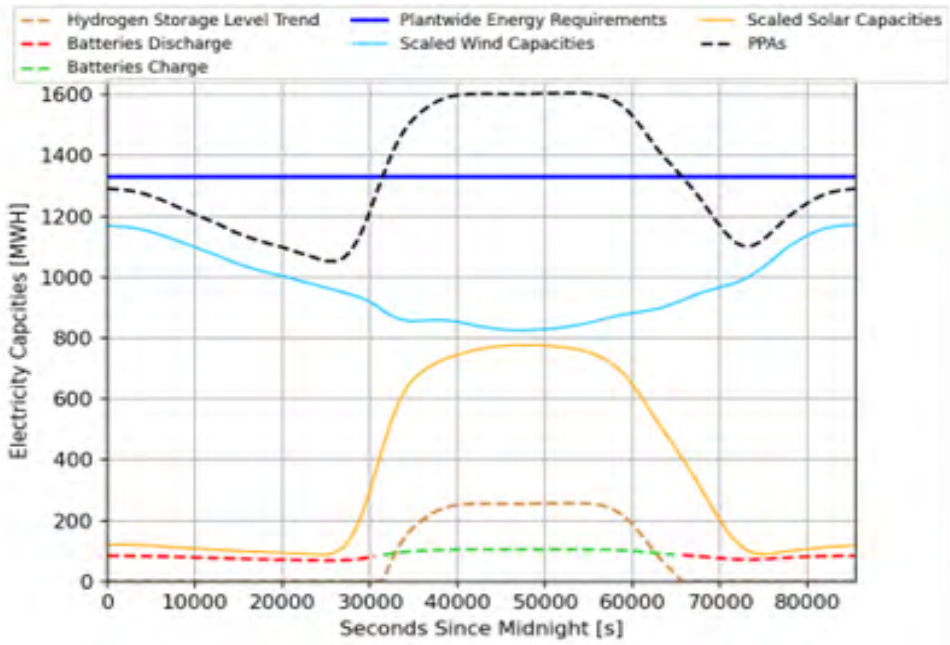

**Figure 2:** Optimised energy hourly system operation developed by Group 4

loop relying on the Haber-Bosch process, operating at a relatively low-pressure, to be set by economic considerations. It is noted that many of these decisions are often predefined in most design projects as set to students.

## Phase 2: Concept and Feasibility Analysis

Focuses on concept generation, risk analysis, and a basic feasibility study, developed in ASPEN, but without full implementation at this stage. By the end of this phase, the student groups should have developed a simplified flowsheet, with many of the operating units being represented by approximate models and have developed a rudimentary economic analysis.

## Phase 3: Detailed Design and Validation

By the end of this phase, a complete process simulation will have been completed. This typically involves a detailed ASPEN flowsheet, now combining rigorous unit models, especially in what concerns separation units, and occasionally more approximate specific units, for example the depiction of the AEL system. Typically, the reactor is modelled and optimized in a separate MATLAB model, as was the case for Group 4. The crucially important selection of the reactor pressure was made considering the overall economics of the synthesis loop. Figure 1 shows an overview of the process designed by Group 4, including all its main components, distinguishing between continuous and semi-continuous operation of its components. In this regard, as shown in Figure 2, note Group 4's typical daily scheduling of the various sources of renewable energy and their coordination to ensure the fixed plantwide energy requirements are satisfied by optimizing a balance of power purchase agreements (PPAs), battery energy storage systems, and oversizing the AEL to capture excess power production and mitigate deficits from inherently intermittent green energy systems (wind and solar generation).

## Phase 4: Deployment Strategy & Handover

The culmination of the Integrated Design Project is the production of a comprehensive Final Year Design Report, which serves as the principal vehicle for deployment, handover, and professional evaluation. The report is structured around a set of core design domains that collectively demonstrate end-to-end process development: process synthesis; detailed design of key reactor and separation units; plant operation and control; safety, layout, and environmental impact; and economic assessment and business planning. Each domain is presented as a distinct section, developed logically and coherently, with explicit justification of design decisions, assumptions, and the strength of conclusions. Where decisions are informed by computer-based calculations or simulations, relevant results are extracted and presented in clear tabular or graphical form to support transparent engineering judgement.

Although assessed separately, the design sections are tightly integrated through systematic cross-referencing, reflecting the interconnected nature of real chemical plant design. Safety-critical issues arising during start-up or operation are addressed in the Safety section with explicit reference to operating strategies developed in the

Control section, while mechanical or sizing considerations are linked back to the relevant Reactor or Separation Design sections. Scheduling considerations influencing equipment sizing and layout are treated within process synthesis, whereas operational scheduling is addressed within plant-wide control. Each section refers where appropriate to the Process Flow Diagram (PFD), stream tables, and design data sheets contained in the Supporting Documentation, and includes its own references to ensure technical traceability and completeness. The Supporting Documentation forms a structured handover package that enables both rapid appraisal and detailed technical scrutiny by external examiners, industrial stakeholders, and future departmental users. This documentation includes the negotiated design brief, a concise process description, PFDs and stream tables, a plant-wide control survey, detailed process design data sheets for key equipment, site layout drawings, HAZOP records, and a comprehensive economic evaluation including all contracts with "investors". Together with appended meeting minutes, these materials ensure that the report provides a coherent narrative of the design, sufficient depth for expert assessment of individual subsystems, and a durable record of the project suitable for professional and institutional use. The final stage of the project is the production of the report. Group 4's final report was one of the best submitted in 2024 and was selected as Imperial College's entry to the IChemE's annual MacNab-Lacey Prize for Student Design Projects in 2025 and was awarded the prize.

## OUTCOMES

Expected outcomes are multi-layered. For students: mastery of end-to-end design thinking, sharpened collaboration and project management skills, and a demonstrable, deployable final report. Polling of the Class of 2026 has been conducted to assess the degree to which these outcomes are perceived by the students. For faculty: stronger industry ties, richer research opportunities grounded in practice, and improved graduate employability metrics. For partners: tested solutions, early access to talent, and case studies. For the institution: a flagship capstone that attracts top applicants, strengthens alumni engagement, and elevates Imperial's role in socially relevant engineering.

Implementation risks include unequal team contribution, scope creep (the tendency of some students to make things more complicated than they really need to be). Mitigation strategies include setting clear roles and expectations, discussion throughout all years at Imperial of the importance of both contributing to the team, and of bringing to the attention of the leadership team any lack of performance so that this can be corrected as soon as possible, mandatory scope reviews, and a conflict mediation process run by experienced academics, at a range of levels of escalation. This is a rare problem, but it needs to be handled properly.

Finally, the programme embeds continuous improvement. End-of-year stakeholder debriefs, and a repository of project outcomes create a feedback loop that evolves problem briefs, rubrics, and support structures.

## STUDENT PERCEPTIONS

A pre-FYD survey was carried out between 10th November and 12th December 2025, before students began working on the 2026 FYD project, with a second post-FYD survey carried out between 12th and 16th March 2026, just before the termination of the project. Due to space limitations, we summarize the responses of the students to two key questions in the survey Question 1: Self-assessed abilities, and Question 4: Anticipated Challenges. Only five of the 135 students did not consent to having their responses used for research purposes and were not included in this reporting. A CID ("College/Student ID") field was present and populated in both datasets, enabling respondent pairing. Duplicate CIDs (repeat submissions) occurred in both pre-FYD and post-FYD survey responses; duplicates were resolved by retaining the most recent response per CID (of the latest recorded timestamp). After deduplication, there were 127 usable responses from the pre-FYD responses, and 110 in the post-FYD survey. When limited to the responses which returned matched CID in the two surveys, 100-101 paired responses were retained for Question 1, and 98 retained for Question 4.

### Question 1: Self-Assessed Abilities (Confidence Ratings)

In Question 1, students rated their confidence in seven skill areas on a Likert scale from 1 (low) to 5 (high):

1. Tackling complex, open-ended engineering problems
2. Collaborating effectively as part of a project team
3. Leading a design discussion
4. Writing a clear and well-structured technical report
5. Integrating multiple factors in solving a design problem
6. Planning and managing project tasks to meet deadlines
7. Awareness of professional and ethical responsibilities

Table 2 summarizes the responses received for Question 1 in the two surveys. The means and standard deviations returned in the two surveys are presented, as

well the Z-test results comparing the responses in the two surveys, as well as 95% confidence limits in the differences in the paired responses. Overall, the class reported fairly high confidence across most areas in both surveys, with average ratings generally above 4.0.

**Table 2**: Comparing Survey Responses for Question 1

| | n | Pre-FYD ($\mu\pm\sigma$) | Post-FYD ($\mu\pm\sigma$) | Z | 95% CL |
|---|---|---|---|---|---|
| 1 | 101 | 3.94±0.93 | 4.10±0.87 | 1.26 | [0.00, 0.32] |
| 2 | 101 | 4.32±0.80 | 4.38±0.76 | 0.56 | [-0.05, 0.17] |
| 3 | 100 | 3.58±0.93 | 4.09±1.00 | 3.73 | [0.30, 0.72] |
| 4 | 100 | 4.03±0.83 | 4.19±0.84 | 1.35 | [-0.04, 0.36] |
| 5 | 101 | 3.93±0.90 | 4.19±0.77 | 2.21 | [0.06, 0.45] |
| 6 | 101 | 4.08±0.87 | 4.15±0.78 | 0.60 | [-0.04, 0.18] |
| 7 | 101 | 4.27±0.96 | 4.29±1.00 | 0.14 | [-0.13, 0.17] |

The highest self-assessed competencies were teamwork (Skill 2) and ethical responsibility (Skill 7), whereas leading design discussions (Skill 3) received the lowest confidence rating on average. Students generally feel most confident in teamwork and ethics. About half the class (62 out of 127 in the pre-FYD survey) gave a rating of 5 (highest confidence) for working effectively in a team, and even more (66 students) did so for being aware of their ethical responsibilities. In contrast, far fewer students (only 19, around 15%) felt fully confident (rating 5) in their ability to lead a design discussion. This indicates that leadership in design discussions is a key area where many students see room for growth, whereas teamwork and ethical awareness are perceived as personal strengths for most. It is clearly noted that only two issues showed a statistically significant improvement in skills resulting from the project experience: most notably, in the perceived ability to lead design discussions (Z = 3.73), and to a lesser degree in the perceived ability to integrate multiple factors when solving design problems (Z = 2.21).

## Question 4: Anticipated Challenges (Ranked Competencies)

Students rank-ordered six competency areas by how challenging they expected each to be in the 4th Year Design Project (1 = most challenging, 6 = least challenging). The aggregated results (lower average rank = more challenging) for the pre-FYD survey are summarized below from most to least challenging:

1. **Project Management** – This emerged as one of the top challenges, with an average rank of 3.03. A significant number of students (28) selected project management as their most challenging area, indicating concerns about planning, organizing tasks, and meeting deadlines. This is consistent with the students' perception of their weakest ability, being leadership of team discussions.
2. **Systems Thinking** – Also highly challenging, with an average rank of 3.09. In fact, 32 students (the highest count for any category) ranked systems thinking as the most challenging aspect. This suggests many expect difficulty in considering the broad, interconnected aspects of the design problem (i.e. thinking about the "big picture" and how different components influence each other).
3. **Communication** – Average rank 3.19. About 20 students ranked communication as their top challenge. While not the number one concern for the majority, a fair portion of the class is apprehensive about effectively communicating ideas, whether in writing or orally, during the project.
4. **Problem-Solving** – Average rank 3.21. This is very close to communication in perceived difficulty. 25 students chose problem-solving as the most challenging. It appears that applying engineering science to open-ended problems and finding creative solutions is a significant hurdle for many.
5. **Teamwork** – Average rank 3.44. Fewer students see teamwork as their greatest challenge (15 ranked it #1), and its average difficulty rating is on the higher side (meaning lower concern). This aligns with the confidence findings in Q1 – most students feel quite capable working in teams, so they are less worried about teamwork issues going into the project.
6. **Ethics** – Average rank 5.05, clearly the least challenging area in students' eyes. Only 6 students ranked ethical considerations as the top challenge, whereas an overwhelming majority (81 students) put it last (ranked #6). This indicates that most students do not expect ethical decision-making to pose much difficulty during the project, likely because they already feel comfortable handling ethical responsibilities or see it as less immediately problematic than the technical and teamwork aspects.

The responses for Question 4 received in the post-FYD survey where similar, with statistically insignificant differences compared to the pre-FYD survey

## CONCLUSIONS

In conclusion, the fourth-year design project reframes the final-year project as a public, professional activity. It insists that capstones be judged not just by final reports and presentations but by the quality of reasoning, ethical awareness, and readiness for complex professional practice. When implemented with careful resourcing, transparent governance, and a relentless focus on learning, this model produces graduates who are not only technically excellent but also prepared to lead interdisciplinary projects that matter.

An increase in the level of collaboration with industry is the next main aim for the project, with independent industry experts now acting as facilitators within a number of projects.

Mild to medium increases in self-reported competencies in a number of fields were observed across the board. The greatest (and only statistically significant) increases were in the specific areas relating to design, which is somewhat unsurprising.

There were no strong changes in the rankings of the different challenges within the design project pre and post project. This is likely since the students at Imperial conduct many different team projects in their time at the University, and (though more challenging than other projects) they are aware of the likely potential problems which they might encounter

## ACKNOWLEDGEMENTS

The authors acknowledge the excellent work carried out on the project in the 2024 academic year by the entire class, and especially the work of Group 4, whose project results are included in this paper. The Group 4 members were: Sinclair Mabon, Alex Glover, Chow Rouxuan, Gabriela Trisno, Rohan Shenoy, Serene Boonasitha, Qing Li Wei, Shihabuddeen Waqar, Amanda Wong, Zhenran Zhang, and Kabishan Sivarasan. It is of note that Group 4's project won the IChemE's annual MacNab-Lacey Prize for Student Design Projects in 2025.

## DECLARATION OF AI

A small portion of the manuscript text was generated using ChatGPT and subsequently verified and modified by the authors.

## ABSTRACT

A survey was conducted of 103 students and lecturers who had recently participated in chemical engineering design courses concerning their opinions on the use of Generative Artificial Intelligence (Gen-AI) in their capstone design education. Participants were at universities in Europe, the Middle East, North America, and South America, from at least eight different language groups. The survey found little difference in responses between students and lecturers, except for uptake, in which students reported higher rates of familiarity and adoption of Gen-AI tools than instructors. Both groups were net-positive generally on the use of Gen-AI in the classroom, reporting relatively high confidence in the ability to assess results, the general positive benefits of using Gen-AI in their chemical process design education, and the likelihood of using them in the future. However, participants reported that their trust in the results of Gen-AI tools was relatively low.

**Keywords**: Education, Artificial Intelligence, Process Design

## INTRODUCTION: A DISRUPTIVE TECHNOLOGY IN EDUCATION

The rapid emergence of Large Language Models (LLMs) and generative artificial intelligence (Gen-AI) tools such as ChatGPT has sparked widespread debate across higher education, particularly in fields traditionally rooted in quantitative rigor and design creativity such as chemical process engineering [1]. Tao et al. [2] provide a framework enabling the efficient application of LLMs in PSE involving three strategies: standardized prompt structure, task decomposition, and iterative generation. They provide several example applications of these strategies, among them process flowsheet visualization, process simulation and HEN synthesis. As a typical example of the capabilities of LLMs in process design, consider the contribution of Vogel et al. [3], who developed an LLM-based methodology for autocompletion of chemical flowsheets.

As an illustrative example, we used ChatGPT to synthesize an ammonia production process (Haber-Bosch type), stipulating air and water as the feedstocks. The chat record is available in the supplementary material for the curious reader. With just a few simple prompts, it synthesized the process with a general block flow diagram, provided some numerical calculations about approximate material requirements based on stoichiometry, provided approximate energy requirements, opportunities for heat exchange (and offered to run a pinch analysis to synthesize the heat exchanger network), safety notes, control system notes, and produced a cost analysis, with plots, including the levelized cost of ammonia as a function of various market and technology assumptions. After each prompt, it provided a list of steps to be conducted next and offered to do many more tasks. It also told us “You’re doing great” after the first prompt. The total computational workload was less than 2 minutes, encompassing a process that would normally take months for a student in a process design course toward the end of many years of engineering study. The potential value of the tool is profound.

Trust in the correctness of Gen-AI results is also a serious concern. The ChatGPT ammonia synthesis example produced 15 pages of results with bold confidence, but with opaque explanations. It could require weeks or even months for an expert to check each and every step of ChatGPT's results and its thought process. The ability to even check or certify the results at all assumes that ChatGPT would be able to sufficiently provide explanations throughout its process and do so in a deterministic way. The probability of some inaccuracy seems high, not just in mistakes in logic or technical knowledge but even basic math and data. For example, in the preparation of this work, the authors found that leading Gen-AI tools generated hallucinated references that did not exist, reported that the molecular weight of air was 18.02 g/mol (which is for water), and said there were two "r's" in the word "strawberry" (in the 5$^{th}$ and 9$^{th}$ positions), all while projecting confidence. This problem is not just due to potential inaccuracies of the LLM, but also due to the lack of or inaccuracies in open data in process systems engineering on which the models are trained [4]. Note, the LLM is purely trained on language-based data without any physics-informed decision layer. That is, the LLM parameters are obtained over a large dataset not only for process engineering but many unrelated areas, even Ozzy Osbourne's hard rock metal lyrics. Contrary to popular belief, ChatGPT is not simply just relying on available online information which it harvests by live lookup but has the capability of at least performing preliminary computations for itself. For the example interaction, ChatGPT explains that it arrives at the numerical values it reports on response to the user prompts by performing stoichiometric material balances and relies on cost exponents for CAPEX estimation, among other simple calculations.

This example presents an existential question for chemical engineering design education. From a purely pedagogical perspective, the advantages to the students could include having a tool that guides them through the process, offers ideas and starting points, provides always-available technical support and personalized tutoring, and of course an incredible speed-up in results generation. The sheer rapidity of results could permit students to solve much bigger and deeper problems that are simply impossible to do in in a design course with pre-ChatGPT technology.

The disadvantages and concerns for pedagogy are also myriad. These include the erosion of deep understanding, the outsourcing of critical thinking, and an increased temptation toward plagiarism. The temptation to use them as a replacement for the hard work of personal learning is evident. It is reasonable to surmise that these would lead to very poor educational outcomes and produce insufficiently competent engineers, creating a downward spiral of skill.

Suppose that even if the personal development concerns of the student are mitigated. Since results can be generated so quickly but trust in the results is a major concern, does this mean our chemical engineering design courses should primarily focus on training students to check and certify Gen-AI results rather than the art and science of designing it themselves? Will this be sufficiently motivating to encourage students to enter the process design profession, or even to develop their own skills generally?

To get a better handle on these issues, we conducted a survey of students and lecturers who took or taught capstone chemical process design recently about their opinions and experiences of Gen-AI. The goal is to get the perspective of students and instructors as to where they think the technology is going and how they are using it now. There are no such recent surveys on chemical engineering capstone-level design courses to the author's knowledge.

## RECENT RELATED SURVEYS

In a study focusing on Gen-AI usage in a second-year chemical engineering course, Verret [5] polled students on their perceptions on the degree of assistance they received from Gen-AI on assignments related to design, finding that about half of the students polled made no use of AI, and that those that did mostly used it to edit documents, for problem solving, and to critically evaluate information. As for their concerns in reliance of Gen-AI, of those students that used it, the issues that most concerned them centered around the low quality of information obtained, the academic integrity of the information obtained, and the possibility of fabricated, incorrect, or missing citations.

Chans et al. [6] used pre-tests and post-tests that book-ended a four-hour beverage design problem exercise in a chemical engineering product design course. The exercise was primarily a brainstorming session, guided by the lecturer who provided Gen-AI tools and prompts for them to use. They reported a general increase in the students' perceived usefulness of Gen AI-tools but did not find a significant increase in other metrics. The sample size was small (9 students) and there was no control group, so general conclusions cannot be made about the ability of Gen-AI to increase design thinking, creativity, and innovation.

Huang [7] surveyed students in a course in chemical process control for three modules related to coding, Laplace transforms, and PID controller tuning. Students were instructed to engage with ChatGPT during the workshops. Students reported slightly net-positive outcomes in their perceived understanding of the theoretical topics at hand, but strong net-positive responses in understanding how AI can be applied to chemical engineering problems. Students also had negative responses

concerning confidence in the AI-generated results and noted they needed more guidance in how to check. Some of these results will be echoed in the results of this survey on process design.

Although not about education specifically, 86 engineers practicing in the UK were asked if they thought ChatGPT should be taught in engineering higher education [8]. Although 82.5% agreed that engineers generally needed training in ChatGPT, only 55.7% felt that it should be explicitly "embedded" in university courses. Although still net-positive, it does not signal a huge push for explicit educational integration. Similar attitudes were found among our student and lecturer survey participants, as explained in the following sections.

## CHEMICAL PROCESS DESIGN SURVEY

Given the recent emergence and rapid spread of Generative AI tools, their role in process design curriculum is still developing. To gain a first overview on current practices as well as a comparison between the associated perceptions of lecturers and students, we conducted a survey of students and lecturers in chemical engineering design programs between December 4, 2025 and January 25, 2026. It consists of questionnaires distributed to chemical engineering students as well as their instructors, asking about familiarities with Gen-AI tools, current use, view on opportunities and challenges in their application, as well as opinions on recommended future development. The lecturers and students received parallel questionnaires, covering the same topics, but with different wordings appropriate to the role of the survey participant. The survey was open to the public and taken via an internet website. It was announced through direct email of colleagues, posts on relevant professional network websites and listservs, and in multiple languages. Responses were received from participants in Catalan-, Danish-, Dutch-, English-, French-, German-, Hebrew-, Portuguese-, and Spanish-speaking institutions or countries, whose chemical engineering design courses are either conducted in the relevant national/regional language or in English. The survey itself was conducted in English. The question sets and the associated raw data are posted in the supplementary material.

### Demographics of Survey Participants

Participants were asked for their current university and status as a lecturer or student. Participants who selected "Student currently taking a course in chemical engineering design, or have done so, or expecting to take it over the next year" are classified as a Student (S), with 81 responses. Participants who selected "Lecturer currently teaching chemical engineering design, has taught it recently, or is expecting to teach it in the next year" are classified as a Lecturer (L), with 22 responses. 1 participant selected the "Neither of the Above" option and was discarded from the analysis.

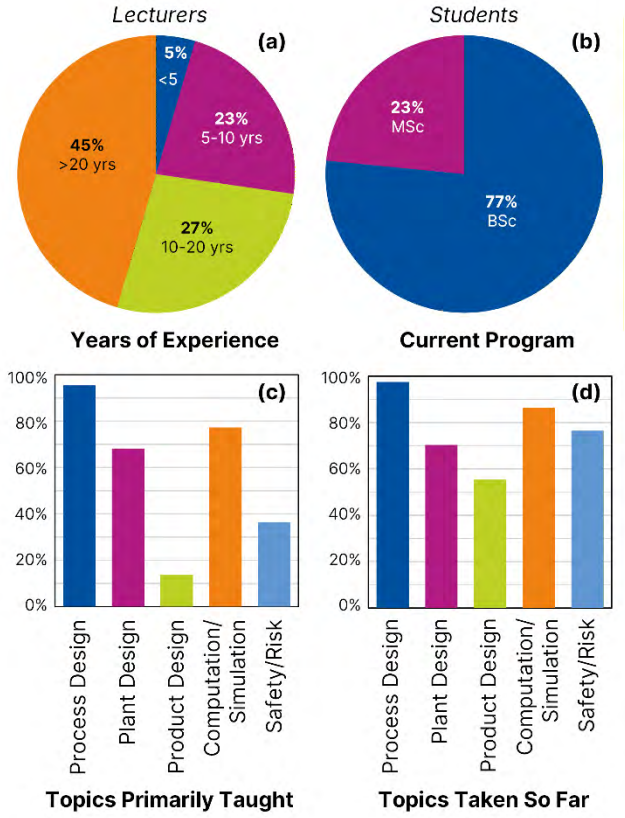

**Figure 1.** Participant demographics. (a) Years of experience in chemical process design instruction of lecturers; (b) The current level of the degree program of student participants; (c) The topics primarily taught by lecturers; (d) The topics studied by students. (*N*=103)

Questions 1 and 2 asked participants about the relevant areas of chemical engineering design that they either teach (L) or have taken so far (S). Students were asked about their current degree program, and lecturers were asked about the numbers of years of experience they have teaching process design. Participants were presented with multiple-choice lists. A summary of the results is shown in Figure 1. The vast majority of the lecturer participants had at least 5 years of experience, with almost half having at least 20. With regard to the topic involvement, few lecturers selected product design, but the question specifically asked what instructors *primarily* teach. Conversely, most student respondents indicated they had studied product design previously. This disparity in responses could simply mean that instructors do not consider product design to be a primary aspect of their instruction, but students are exposed to it nevertheless.

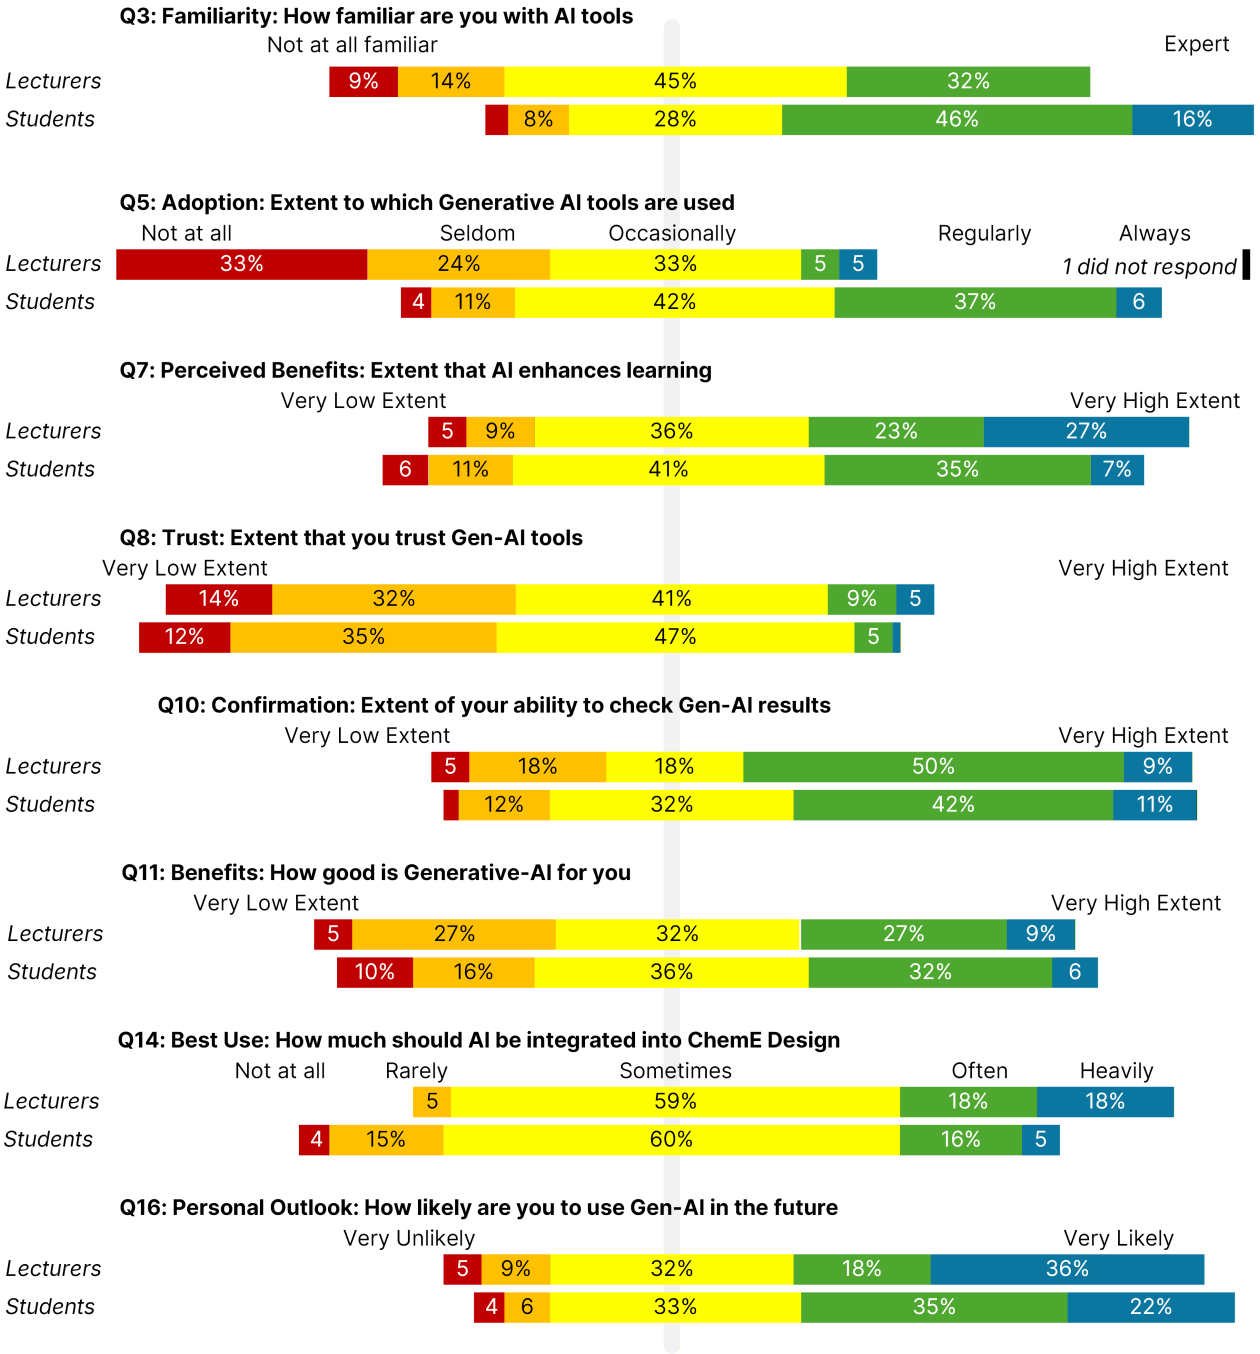

**Figure 2.** Resposes to Likert scale questions (Q3, Q5, Q7, Q8, Q10, Q11, Q14, Q16). *N=103*

Because the question asking participants to state their university had a free text field for an answer, not all responses could be accurately understood (because of acronyms and initials), so these are not included in the formal analysis.

## Responses to AI-Related Questions

The following questions ask participants about their opinions concerning Gen-AI in chemical process design. Recipients were asked to respond using a 1 to 5 Likert scale, where 1 indicates "to a very low extent/I never use, " to 5 indicating "to a very high extent/I always use." Responses are summarized in Figures 2, 3, and 4. Comments on individual questions follow.

- ***Q3: The degree to which S/L are familiar with Gen-AI.*** L averaged 3.00, while S averaged 3.66. Z-test value is 2.97, indicating S feel significantly more familiar with Gen-AI tools than L.

- ***Q4: Which specific Gen-AI tools are used?*** The most commonly used tools are ChatGPT (91% of L, 95% of S) and Copilot (L: 50%, S: 43%). Responses are summarized in Figure 3.

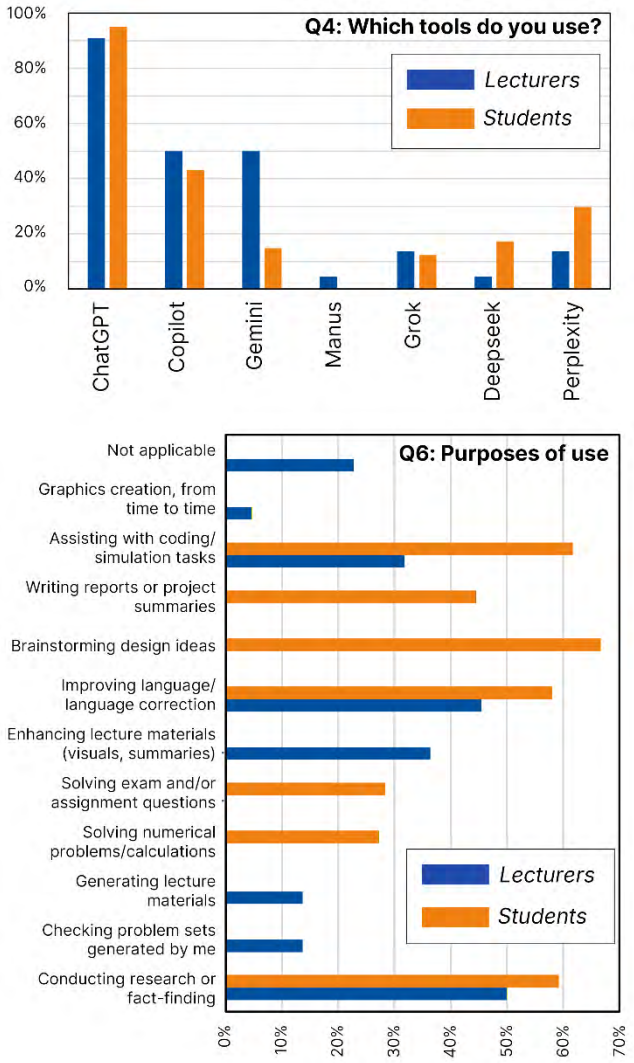

**Figure 3.** Responses to Q4 and Q6. *N*=103

- ***Q5: The extent to which Gen-AI tools are used in the design courses.*** The average L response was 2.14, close to "I seldom use, " while the average S response was 3.31, equivalent to more than "I use them occasionally." Note that one third of L do not use Gen-AI in their design courses at all. Statistically the two distributions score a Z-test value of 4.47, meaning that the students use Gen-AI tools quite significantly more than the lecturers do. These responses are consistent with those received for Q3 given that both questions indicate higher uptake in the S class.
- ***Q6: For which purposes are Gen-AI tools used***? Most popular use for S is "brainstorming" (67%), while this usage scores 0% for L. Perhaps the lecturers do not consider brainstorming with AI to be brainstorming, and students include AI into teamwork and they of course do. Next most popular for S is "Assisting with coding/simulation tasks" (62%), while this scores only 32% for L. Of the rest, both use if for "Conducting research or fact-finding" (L:50%, S: 59%), and for "Improving language/language correction" (L: 45%, S: 58%).
- ***Q7: The extent of perceived benefit of Gen-AI in the process design courses***. Both L and S average about the same (L: 3.59, S: 3.26), and perceptions are statistically indistinguishable. The large majority of participants indicate that there are at least some benefits.
- ***Q8: The degree to which S/L trust Generative-AI in their process design courses.*** Both L and S average about the same (L: 2.59, S: 2.48), and perceptions are statistically indistinguishable. This finding can be surprising, but this same result was found by Đerić et al. [9] whose recent study designed to address this specific point also found no statistical difference between students and lecturers in their level of trust in Gen-AI. Trust skews heavily negative for both L and S.
- ***Q9: The degree to which lecturers favour results given by Generative-AI over other sources***. The question was removed from the analysis due to a technical issue with the survey tool.
- ***Q10: The extent of the perceived ability of S/L to check the results of Gen-AI.*** Both L and S average about the same (L: 3.41, S: 3.47), and perceptions are statistically indistinguishable. Both groups self-reported a relatively high confidence in their ability to determine the correctness of the output given by Gen-AI. This could partially explain why students have a relatively high adoption rate of Gen-AI tools, despite a relatively low level of trust in its output. This however would not explain why lecturers have a relatively low adoption rate of Gen-AI in their courses, since they too have high a self-perception of their own ability to determine correctness.
- ***Q11. The degree to which S/L believe Gen-AI is a "net good" for their education***. Both L and S average the same (L:3.09, S: 3.09), and perceptions are statistically indistinguishable.
- ***Q12: Which are the benefits of using Gen-AI tools?*** Highest scores were for "Getting explanations in simpler terms" (L:59%, S: 54%). Other but less mentioned benefits included "Saving time of assignments" (L:41%, S: 44%), "Bridging gaps in prior knowledge" (L:36%, S: 28%), and "Improving creativity" (L:36%, S: 25%).

- ***Q13: Which are the greatest risk and challenges of using Gen-AI tools?*** Similar perception of L and S with the highest scores being for "Over-reliance on AI /Becoming too dependent on AI" (L:91%, S: 80%), "Inaccurate or misleading outputs" (L:73%, S: 73%), and "Students bypassing fundamental steps" (L:64%, S: 59%).

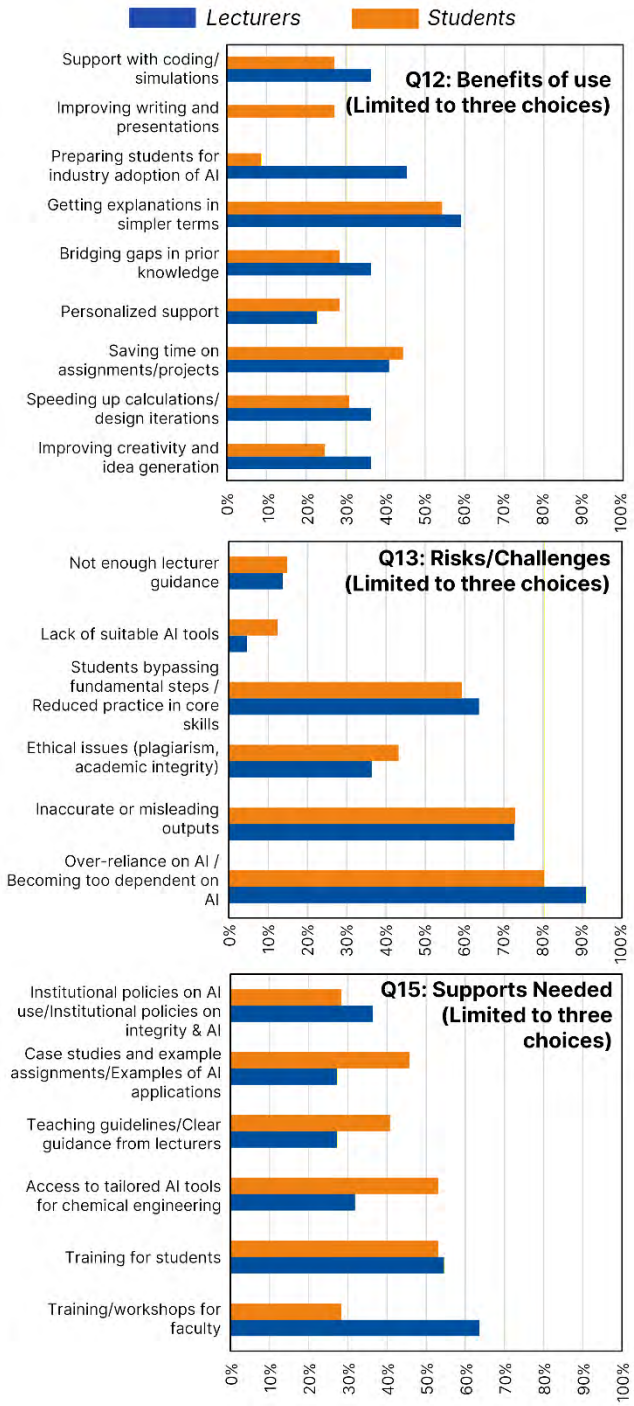

**Figure 4.** Responses to Q12, Q13, and Q15. *N*=103

- ***Q14. How much should AI be integrated into process design?*** L average response is 3.50, while the average response for students is lower at 3.04. Note that L are more enthusiastic about the introduction of Gen-AI in design education than students, and the difference in perception is statistically significant (Z-test = 2.31). This could in part be due to self-selection bias in those who chose to answer the survey. These results mirror the survey results of engineering employers [10] who also had a middle-of-the-road opinion that ChatGPT (specifically) should be integrated into engineering higher education.

- ***Q15: What kind of support is needed for Gen-AI usage?*** L opinion that support is needed most for training for faculty (64%) and students (55%). S think that support is needed most for "Training for students" and "Access to tailored AI tools for chemical engineering" (both 53%) and for Case studies and examples (46%). It would appear that students have put more thought into integrating Gen-AI than have the lecturers.

- ***Q16. How likely are you to use generative AI in future?*** Both L and S average about the same (L:3.73, S: 3.65) that were the highest scores in the survey, with perceptions being statistically indistinguishable.

## Open-ended Responses

One question allowed responders to make closing remarks. Here are a few of the more noteworthy comments from the lecturers:

- "The whole purpose of education is to get students to think for themselves, and to understand the principles of engineering science well enough that they can either do their own calculations (using generic tools such as Excel) or check calculations made using specialist computer software. They need a good level of fundamental understanding so they can look at a design and answer the questions "does this make sense?" and "is this a feasible and safe design?" This requires development of an internal structure of knowledge, and my experience of AI is that it is devoid of any understanding of the structure of knowledge. Another major issue with AI is hallucinating references. **If you can't tell where the underlying information is coming from, how can you trust the output?** Every month or two, I see stories in the press or elsewhere about lawyers getting fined because their pleadings (generated by AI) contain either references to completely fabricated cases, or the real cases quoted don't support the arguments made in the pleading. Because lives are at stake in engineering, similar issues are much more serious in our field. We

wouldn't just lose money…"

- "While **AI is a great help in numerous aspects**, ranging from the simple improvement of text quality to providing significant assistance in solving complex problems, it is also true that, currently, it frequently introduces changes that modify the meaning of texts, makes incorrect assumptions, and tends to attempt to fulfil the request, sometimes even at the expense of 'falsifying' some results. In many instances, **locating these errors is not trivial** (even for experts), **which poses a significant risk**, particularly for students. In my prompts, I often add phrases such as 'do not invent anything, ' 'justify all your steps, ' 'always include the source from which you obtained the data, ' and even then, I do not always succeed. Generally, it is a tremendous tool that must be leveraged at all levels (i.e., research and teaching), but as in all cases, the responses must be analyzed with a critical spirit, and this applies to both experts and novices."
- "The main point to be explored**: the different way students and instructors use Generative AI and ask it questions** (I'm reluctant to use the term "prompt engineering" to refer to understanding the problem and asking the right questions in the precise way by understanding the rules of grammar and logics, which is the real issue)."
- "There are clear differences between architecture/programming AI and Instantiation on AI application. Those differences are not clear for the university staff, and consequently students don't learn about it. Another question is the theoretical overlooking about ethical aspect without ethical day-by-day practices by the staff. A third urgent question is how the students will learn and practice the **Law of Unintended Consequences** on pervasive AI."

The survey has highlighted what appears to be a student body that at least perceives itself to be significantly more familiar with Gen-AI tools than their teachers, with about a third of the professors not using Gen-AI in process design education at all (Q3 and Q5). As both students and lecturers agree that Gen-AI will be utilized at an increasing extent in process design education (Q16), it would appear to be incumbent on lecturers to increasing integrate these tools into their teaching. Perhaps a good summary would be that offered by of one of the lecturers, who commented that:

- "We need to get on with it, or we will be left behind. But, one year before official retirement, I am not the professor to do this anymore ;-)"

## Limitations to the Methodology

The limitations of the survey should be considered in its interpretation. The number of lecturers who participated was not as high as would be preferred, and subject to self-selection bias since those who both hear about and choose to participate may be skewed toward a class of people who are connected to the outreach networks used in participant recruiting. The number of student responses was sufficiently high but varied widely by institutions. Although many institutions were represented by at least one student participant, a few universities had large response rates, likely due to direct encouragement by the class instructor. Thus, responses of the S class as a whole will be skewed toward these universities. Much larger sample sets and participation rates would allow greater confidence in the S class and would allow us to create profiles representative of the institutional level.

# CONCLUSIONS

The emergence of generative AI represents a fundamental shift in the environment in which process design is taught and practiced. Tools capable of producing flowsheets, calculations, code, and technical text within seconds are no longer peripheral aids but active participants in the design process. The results presented in this paper confirm that their use is already widespread among students and that adoption is likely to increase further in the near future.

The survey reveals a clear asymmetry between students and lecturers. Students report significantly greater familiarity with generative AI and make more frequent use of it in design courses, particularly for brainstorming and coding support. Lecturers, in contrast, remain more cautious and in many cases have not yet integrated these tools into their teaching. Despite this difference in usage, both groups express remarkably similar views regarding the perceived benefits, the limited level of trust in AI-generated results, and the risks of over-reliance and inaccuracy. This shared ambivalence suggests that the central challenge is not whether AI will be used, but how it can be used responsibly.

The pedagogical opportunities are substantial. Generative AI can provide cognitive scaffolding, personalized explanations, and exposure to alternative design options that may enrich creativity. At the same time, the risks identified—erosion of core engineering skills, propagation of errors, and threats to academic integrity—cannot be ignored. Process design education has always aimed to develop judgment, accountability, and the ability to verify results; these goals become even more critical in an AI-assisted context.

The findings point to several priorities. First, educators need support and training to engage confidently with these technologies. For example, both students and

lecturers may need detailed training in effective prompt engineering. This approach is currently in development in other areas of chemical engineering [10]. Second, assessment methods must evolve to emphasize critical evaluation and transparent workflows rather than final answers alone. Third, students must be explicitly taught how to question and validate AI output as part of professional responsibility.

Generative AI should not replace the need for sound engineering reasoning, but it will reshape how that reasoning is exercised. The task ahead is to integrate these tools in ways that strengthen, rather than weaken, the intellectual foundations of process design education.

## SUPPLEMENTARY MATERIAL

# Understanding Student's Preferences for Computational Tools in Chemical Engineering Assessment

**Sakiru Badmos**

Department of Chemical Engineering, University College London, Torrington Place, London WC1E 7JE, United Kingdom
Corresponding Author: s.badmos@ucl.ac.uk

## ABSTRACT

Computational tools are widely used in solving engineering problems and are now embedded within chemical engineering education. At the UCL Department of Chemical Engineering, students are taught gPROMS ModelBuilder in modules requiring coding; however, many choose alternative tools such as MATLAB, Python, or Polymath for coursework and capstone design project reactor design. This study investigates the reasons behind these preferences using a survey of fourth-year students who had completed their third-year design project. The results show that perceived ease of use, availability of external resources, and ease of debugging could strongly influence tool selection. The findings highlight the importance of accessibility, community support, and perceived relevance in shaping sustained student engagement with computational tools.

**Keywords**: Technology Adoption, Computational tools, Matlab, Python, Polymaths, Engineering Education, gProms

## INTRODUCTION

Computational tools have been part of chemical engineering education for several decades, supporting the solution of algebraic equations, differential equations, and optimisation problems in core areas such as reaction engineering, separation processes, and process control [1-2]. What has changed in recent years is not their presence in the curriculum, but the *type of tools used, their accessibility, and how students engage with them*. The emergence of open-source programming environments, large online user communities, and data-driven methods has expanded the range of tools available to students and influenced how they approach computational problem-solving [3].

A range of platforms is currently used in undergraduate chemical engineering programmes. Tools such as POLYMATH remain effective for solving numerical problems, particularly in reaction engineering, due to its simplicity, presenting minimal challenges when picked up by students without prior knowledge of programming [4]. MATLAB is widely used in academia and industry for numerical methods, process modelling, and control because of its powerful numerical solvers, extensive libraries and visualisation capabilities [5-7]. More recently, Python has gained significant traction as an open-source alternative, supported by extensive scientific libraries and a large community of users, making it attractive for both teaching and independent learning [3]. The integration of Jupyter notebooks has made it attractive for teaching in undergraduate engineering programs [8-12].

Alongside these tools, commercial process modelling environments such as gPROMS ModelBuilder are increasingly used to represent industrial workflows, particularly for dynamic modelling, optimisation, and parameter estimation [13].

At University College London (UCL), gPROMS is taught within the undergraduate programme to expose students to equation-oriented modelling approaches used in industry. However, unlike widely used scripting tools, gPROMS requires a licence and has a relatively smaller user community and fewer openly available learning resources. These differences may influence how students engage with the tool, particularly when they have a choice in assessment. Despite being taught gPROMS, many students choose alternative tools such as MATLAB, Python, or POLYMATH for their coursework and design project reactor designs. This raises an important question: *why do students move away from tools that are formally taught, even when support is provided?* While prior studies have explored the pedagogical value of individual tools [5–12], less attention has been given to students'

tool preferences in assessments, where time constraints, confidence, and access to support play a significant role.

This study investigates the factors influencing students' choices of computational tools in chemical engineering assessment, using gPROMS ModelBuilder as a case study. Drawing on principles from the Technology Acceptance Model [14], this work examines how perceptions of ease of use, usefulness, and access to support shape students' decisions. The study addresses three research questions: (i) what factors influence students' decisions to use alternative tools when gPROMS is taught, (ii) how students perceive the teaching and support provided for gPROMS, and (iii) what changes could improve engagement with computational tools in the curriculum.

## METHODOLOGY

A Mentimeter survey was presented to the fourth-year students (n = 40) of the 2025/2026 academic year, who had completed their design projects in the previous year. This cohort was chosen because they had direct experience applying a computational tool in their coursework and the third-year design project. The survey consists of 9 questions of different types including multiple choice and an open-ended question using a five-point Likert scale. Ethical approval was obtained from UCL's Research Ethics Office to process and publish the results of this survey. The survey questions are as follows:

- Q1 – Which primary tool did you use for your Year-3 design project reactor design?
- Q2 – Which primary tool did you use for other coursework e.g CREII?
- Q3 - How confident did you feel using your primary tool for design project and coursework?
- Q4 - Why did you choose that tool?
- Q5 – What is the most important factor to consider when choosing a tool for your work
- Q6 - How adequate was the gPROMS teaching you received before the design project?
- Q7 - How important is tool popularity/community in your decision?
- Q8 - How important is tool popularity/community in your decision?
- Q9 - What would make gPROMS more usable/attractive for students?

**Free texts from students' responses to Q9**

- T1: 'Better UI'
- T2: 'Make the interface more user friendly and intuitive'
- T3: 'Better interface (why model and process? One would be simpler)'
- T4: 'More tutorials with solution'
- T5: 'I prefer to learn code from online sources like stack overflow examples and github and YouTube videos. gPROMS doesn't have this in the same way as Python and even MATLAB'.
- T6: 'Popularity – it is so unnecessarily hard to find help for this'
- T7: 'Clearer availability of support/more support sessions'

## RESULTS AND DISCUSSION

Chemical engineering education has computational tools as integral part of the undergraduate curriculum. These tools are used for solving problems involving numerical methods, ordinary differential equations (ODEs), optimisation, and, in some cases, dynamic simulation. Traditionally, software such as MATLAB, Excel, and Visual Basic has been used for this purpose, with more recent additions including Python, gPROMS, and GAMS. At UCL Chemical Engineering Department, students are taught GAMS and gPROMS within core chemical engineering modules, while MATLAB is introduced through the Mathematical Modelling and Analysis (MMA) module delivered by the faculty as part of the Integrated Engineering Programme (IEP). These tools are embedded in the curriculum to satisfy accreditation requirements set by the Institution of Chemical Engineers (IChemE) [15]. The skills developed using these tools are applied across several modules throughout the undergraduate programme. Further details on how the tools are taught can be found in Kamel et al. [16].

Despite students being introduced to gPROMS from their first year, they appear to show low enthusiasm towards the tool both in teaching and learning and in applying it for their coursework. When given the opportunity to select a preferred software, many students will choose alternative tools, even though gPROMS is taught on the programme. This pattern is observed in both the second-year Chemical Reaction Engineering module (CREII) and the third-year capstone design project, where students are required to implement reactor models computationally. Although gPROMS is supported through teaching sessions, questions and answers (Q&A) and forums on the learning platform (Moodle), students are permitted to use other tools if they feel more comfortable doing so.

From the survey results, as shown in Figure 1a, 50% of the respondents (20 students) designed a reactor as part of their design project, and among these, 90% used MATLAB or Polymath, while only 10% used gPROMS. This occurred despite the availability of dedicated

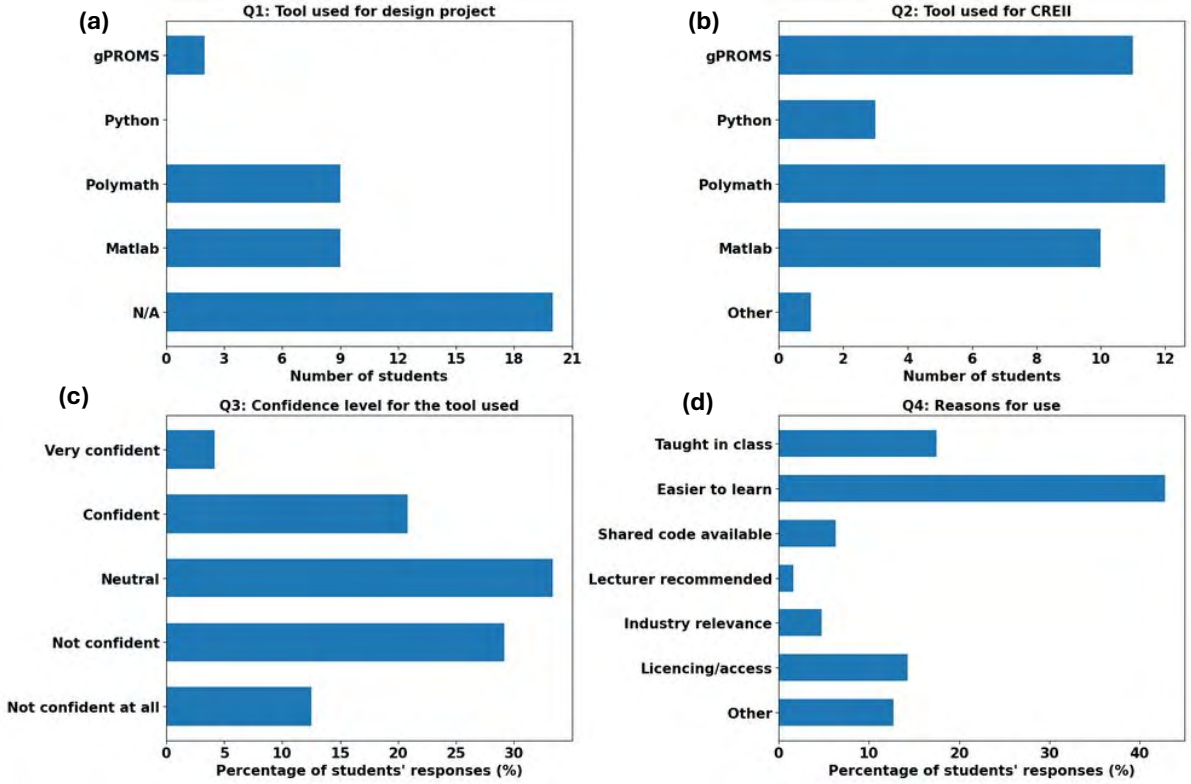

**Figure 1.** Students' responses to Q1 – Q4. N/A (n=20) in panel 1a indicates respondents who designed a separator during the detailed design of their third-year design project and does not require coding.

computational support for gPROMS on the design project. Similarly, in CREII, where all students must implement a reactor model in a software, approximately 70% selected a tool other than gPROMS (Figure 1b). These results indicate a clear reluctance to use gPROMS and suggest that factors beyond simple availability of support influence students' choices.

Confidence in using computational tools also appears to be an important issue. Figure 1c shows that although students were free to choose their preferred software, around 42% reported that they were not confident in using the selected tool, and a further 33% were uncertain about their confidence level. This suggests that students may be selecting tools based on short-term use rather than genuine competence. It also points to a possible need to review current teaching approaches or to provide additional learning resources to better support students in developing confidence with the tools they are taught.

The survey results indicate that students' tool selection is shaped by a combination of practical and perceived benefits. As shown in Figure 1d, ease of learning was the most influential factor, with approximately 42% of respondents identifying this as the main reason for their choice. About 30% selected their tool because it was taught in class, which likely corresponds to those who used MATLAB or gPROMS, as these are the two scripting tools formally introduced during the programme. Licensing and access were also relevant, with 14% of students citing this as a determining factor. Smaller proportions identified the availability of shared code, industry relevance, lecturer recommendation, and other factors as influencing their decision.

When asked what factor should be prioritised when selecting a tool for assessment, students again emphasised ease of learning and external support. As shown in Figure 2a, 27% selected ease of learning as the most important criterion, while 23% selected the availability of resources and community help. Ease of debugging and industry employability were each selected by 18% of respondents, and supervisor preference by 14%. These responses suggest that students tend to prioritise immediate academic needs over longer-term considerations such as industrial relevance. This may reflect a focus on completing assessments efficiently rather than on developing skills perceived as valuable for future employment. It may also indicate limited awareness of the tools commonly used in professional practice, or a tendency to defer such concerns until later stages of their studies.

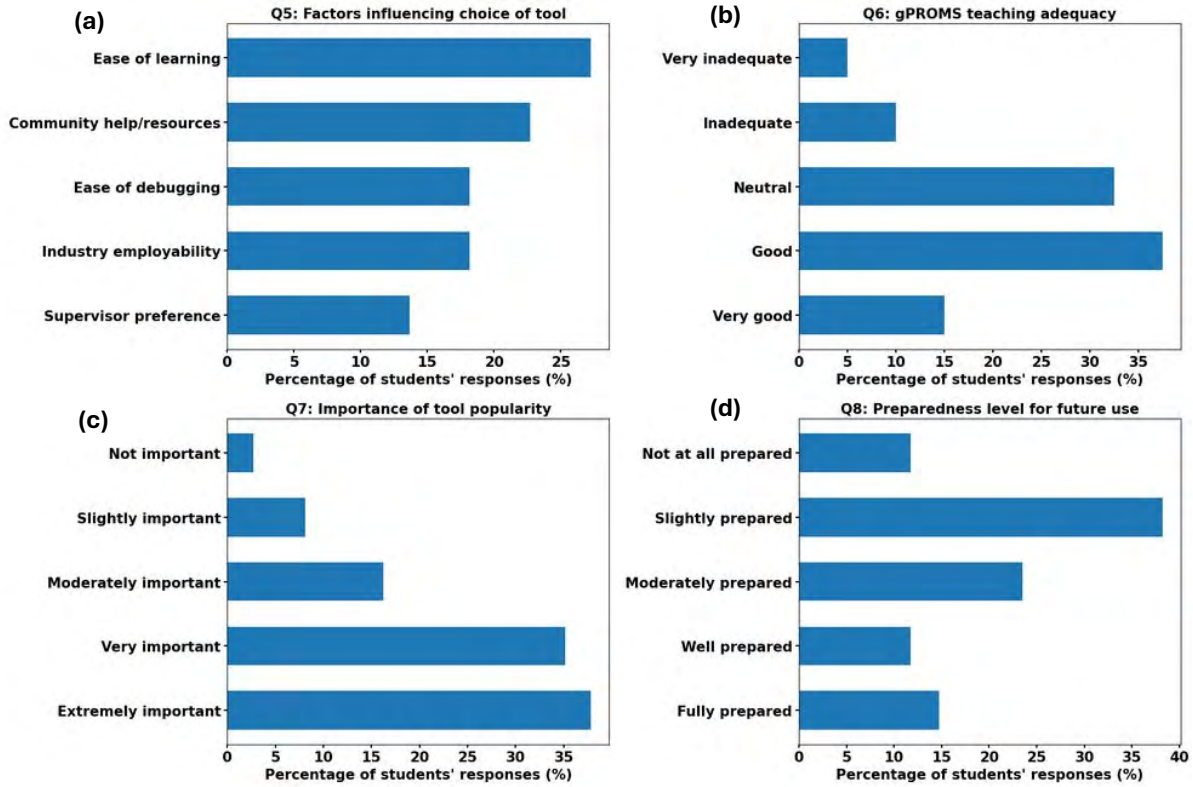

**Figure 2.** Students' responses to Q5 – Q8 on factors affecting choice of tools (2a), adequacy of gPROMS teaching (2b), importance of tool popularity in their decision making (2c) and their level of preparedness for using the tool in future roles (2d)

The importance placed on external resources and community support highlights the role of informal learning environments in students' decision-making. Large user communities and readily available online examples make tools such as Python and MATLAB particularly attractive, especially when students encounter errors or difficulties. Availability of template codes in Fogler's Reaction engineering textbook makes Polymath a good choice. These features directly affect their ability to complete coursework within limited timeframes and were therefore prioritised. A substantial number of students also valued ease of debugging and the potential for transferability of skills for industrial applications. At the same time, some students preferred to follow lecturer recommendations, possibly viewing these as aligned with assessment expectations.

Figures 1a and 1b show that most respondents used tools other than gPROMS for both the design project and CREII assessment, with only 10% selecting gPROMS for reactor design in the capstone project. To explore whether this preference resulted from inadequate teaching instructions, students were asked in Q6 to evaluate the adequacy of gPROMS teaching and support. As shown in Figure 2b, 52% considered the teaching and learning provision was sufficient to support their use of the software, while 32% were unsure and only 16% felt that support was inadequate. This suggests that dissatisfaction with teaching provision alone does not fully explain the low uptake of gPROMS. Instead, the findings indicate that students' choices are more strongly influenced by perceived ease of use and perceived usefulness, consistent with the Technology Acceptance Model (TAM). Even where formal teaching and support are available, students may still avoid a tool if it is perceived as difficult to use, slow to debug, or poorly supported by external resources. This implies that improving uptake may require more than simply increasing teaching hours or technical support through forums and Q&A sessions. Factors such as user interface design as reflected in free-text responses from respondents (T1–T3 in Q9 responses), access to examples and tutorials (T5), size of the user community (T6), and licensing constraints also play an important role in students' decisions.

Tool popularity further reinforces these trends. Students were asked how much popularity influenced their choice of tool, and as shown in Figure 2c, 38% reported it as extremely important, 35% as very important, and 16% as moderately important. Only 8% considered it slightly important and 3% not important. This indicates that perceived popularity, which is closely linked to the

availability of learning resources and external help with debugging, significantly affects students' selection of computational tools.

Students were also asked how well the teaching and learning of computational tools has prepared them for future industrial roles. As shown in Figure 2d, majority of respondents felt adequately prepared, while only 12% reported feeling unprepared. This reinforces the overall effectiveness of the current teaching approach to computational tools within the UCL chemical engineering programme. However, it also suggests that there may be value in reviewing the specific tools taught, particularly with regard to accessibility and long-term sustainability, and in considering a gradual transition towards more open-source alternatives.

Overall, the results suggest that students' preferences for computational tools in assessment are shaped by a complex interaction of pedagogical, technical, and social factors. While gPROMS is formally embedded in the curriculum, its lower adoption compared with MATLAB, Python, and Polymath appears to be driven primarily by perceptions of difficulty, limited external support, and usability rather than by deficiencies in teaching provision. Although the sample size does not allow for definitive conclusions, this study provides a preliminary basis for further investigation. It highlights the need for educators to consider not only what tools are taught, but also students' experience, particularly in relation to workload, error handling, and access to help beyond the classroom.

## REFLECTION

My experience in teaching computational tools suggests that students often adopt a grade-driven approach to assessments and learning. As educators, we should encourage students to recognise the value of learning that extends beyond immediate assessment outcomes. This can be better addressed through the lens of constructive alignment [17], where intended learning outcomes, teaching activities, and assessment tasks are deliberately aligned. If assessments primarily reward correct outputs rather than the modelling process, tool selection, and problem-solving approach, students are more likely to prioritise efficiency over critical thinking. Aligning assessment with the intended development of computational thinking, modelling skills, and tool fluency may encourage students to engage more meaningfully with the tools taught, rather than selecting alternatives based solely on convenience or familiarity.

## CONCLUSION

This study examined the factors influencing students' preferences for computational tools in chemical engineering assessments, using gPROMS ModelBuilder as a case study. The results show that students' choices are driven primarily by perceived ease of learning, availability of external support, and ease of debugging, rather than by formal exposure to a tool within the curriculum. Although gPROMS is taught and supported, it is used by only a small proportion of students when alternative tools are allowed. This suggests that technical capability alone is insufficient to ensure adoption. Instead, usability, community support, and perceived relevance play a significant role. These findings highlight the need for educators to consider not only what tools are taught, but how they align with students' learning priorities and future employability. Rather than focusing solely on introducing advanced tools, there is a need to rethink how these tools are integrated into the curriculum. This could include providing earlier exposure to modelling environments, embedding gPROMS more consistently across multiple modules, and designing scaffolded learning activities that gradually build confidence before assessments. In addition, integrating more guided examples, improving access to reusable code templates, and creating opportunities for peer learning may help reduce the initial barrier to engagement. Consideration could also be given to combining proprietary tools with open-source alternatives to support flexibility and independent learning. Future work will explore how these targeted curriculum adjustments influence students' confidence, engagement, and sustained use of computational tools.

# Empirical survey among experts on the relevance of various criteria for optimizing modular electrolysis systems

**Hannes Lange[a]*, Lucien Beisswenger[b], Daniel Erdmann[b], Isabell Viedt[a], and Leon Urbas[a]**

a TUD Dresden University of Technology, Process-to-Order Group, Helmholtzstraße 10, 01069 Dresden, Saxony, Germany

## ABSTRACT

Electrolysis systems must be constructed from multiple stack units. This modular system of stack units (modular electrolysis system) requires systematic optimization of its composition. This optimization depends on numerous, and sometimes conflicting, criteria. While such criteria have already been evaluated for modular plants in the process industry, they must be re-assessed in the context of modular electrolysis systems. To address this challenge, an expert survey was conducted within two research networks ($H_2$Giga and DECHEMA e.V. Research Network) and the VDMA P2X4A.The evaluation followed the two-stage process: After ranking the categories *costs, flexibility*, *process engineering* and *time-to-process* according to their overall importance a ranking of individual criteria within each category was conducted. The survey reveals a clear prioritisation: costs are in first place with 35.9%, followed by flexibility (25.4%), process technology (23.2%) time to process (15.4%). This ranking provides a structured overview of the most important factors guiding the optimisation of modular electrolysis systems. Another finding of the survey is how electrolysis systems should be operated in the future. Here, the focus was primarily on electrolysis systems related to fluctuating renewable energies, with a top-2-box result of 81% in each case. Based on this prioritisation, weightings for possible application in multi-criteria optimisation can now be derived. This makes it possible to determine suitable compositions of electrolysis stack unit systems when scaling systems and to refine optimisation efforts. The expert survey thus contributes to the optimised design of electrolysis systems and thereby supports the ramp-up of hydrogen production.

**Keywords:** modular electrolysis, modularization, requirements prioritization, expert survey, process equipment assemblies

## INTRODUCTION

Electrolysis-based green hydrogen is widely regarded as a key enabler for decarbonizing energy-intensive industries because it provides a low-carbon feedstock and energy carrier that can substitute fossil-derived hydrogen and support new synthesis routes. Industrial deployment, however, requires electrolysis plants in the multi-hundred-megawatt to gigawatt range, which cannot be realized as a single stack and therefore relies on number-up of stacks and balance-of-plant subsystems [1–3]. As plant capacity increases, the overall system complexity rises disproportionately due to replicated auxiliaries and control layers, which makes engineering and integration a dominant cost and schedule driver.

Modularization has the potential to mitigate this complexity by structuring the plant into repeatable process units with defined interfaces, similar to the Process Equipment Assembly (PEA) concept that is established in modular process engineering [4, 5]. Despite the strong interest in modular electrolysis, requirements for electrolysis systems are often specified implicitly or inconsistently, and optimization targets for module boundaries remain unclear, which hampers the systematic development of modular architectures.

## METHODOLOGY

This work applies a requirements-driven evaluation approach by repeating an expert survey that was originally developed for Process Equipment Assembly (PEA) selection in the process industry and transferring it to the German electrolysis sector. PEAs in modular plants can be easily adapted to changing boundary conditions. A PEA is a modular process unit that is mostly self-sufficient in terms of automation and provides a process engineering step [1]. The survey retained the same four high-level evaluation categories, namely 'cost', 'flexibility', 'process engineering', and 'time-to-process', while individual criteria were adapted where necessary to reflect electrolysis-specific characteristics and terminology [6]. Data collection was performed as a nationwide expert survey in Germany, with participation from 63 professionals/experts working in Research and Development (R&D) or engineering, sales, and project management and representing plant manufacturers, plant operators, component manufacturers, and research institutions within the Power-to-X for Applications of VDMA e.V. (VDMA P2X4A) network and the DECHEMA/$H_2$Giga project environment [7]. Figure 1 shows the distribution of experts across industries, and Figure 2 shows the distribution of experts within the field of work along the electrolysis value chain. Experts ranked the categories and criteria by relative importance using a rank-based point allocation comparable to the Simos approach [8], and the resulting point sums were normalized to obtain weights that can be interpreted as relative priorities for system optimization. With the completion of the expert survey, a rank could be determined for each category and criterion. To determine the rank, points are assigned for each rank. The points per rank are derived from the number of categories and are assigned in descending order. Subsequently, the weighting of the category or criterion is calculated according to formula (1) [6, 8]:

$$w_a\,[\%] = \frac{\sum_{i=1}^{n} p_{a,i}}{\sum_{i=1}^{n} (p_{a,i} + p_{b,i} + p_{c,i} + p_{d,i})} \qquad (1)$$

## RESULTS

### Ranking of optimisation criteria

The distribution of functional roles indicates a strongly engineering-oriented sample, as 62% of the participants work in R&D or engineering, while 11% work in sales, 8% in project management, and 19% in other roles. This composition is consistent with the current technology ramp-up phase, in which architectural and integration decisions are predominantly shaped by development and engineering organizations. With respect to organizational background, component manufacturers form the largest group with 46%, followed by plant manufacturers with 18%, research institutions with 12%, plant operators with 11%, and other organizations with 13%, which reflects the current industrial focus on stack and balance-of-plant scaling.

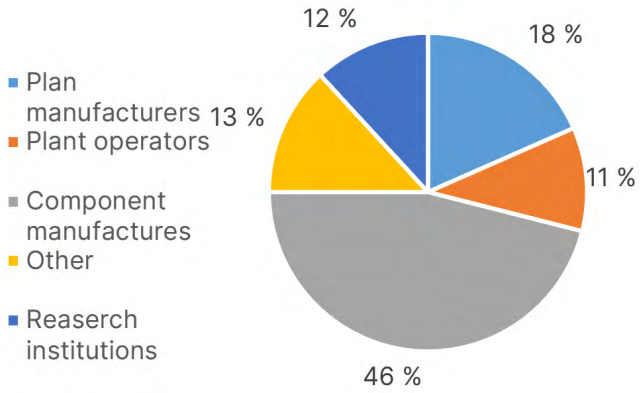

**Figure 1.** Branch of participating industry experts

The category weighting reveals that cost is the dominant requirement group with an overall share of 35.9%, whereas flexibility reaches 25.4%, process engineering reaches 23.2%, and time-to-process reaches 15.4%, which jointly define a quantitative priority profile for modular electrolysis optimization. Figure 3 shows the entire distribution of categories with their criteria in a sunburst diagram.

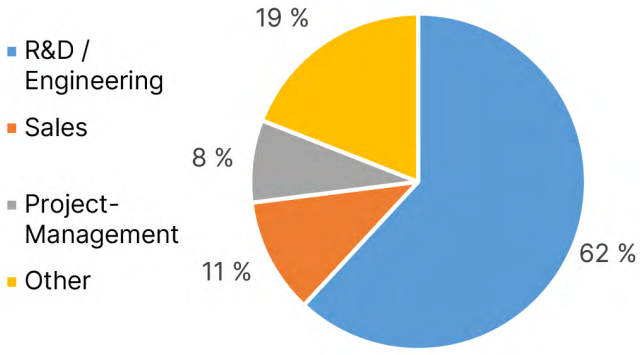

**Figure 2.** Work field of participating industry experts

Within the cost category, operating and maintenance costs contribute 19.08% to the overall weighting, corresponding to 53.1% of the cost category, while investment costs contribute 16.85% and therefore account for 46.9% of the cost category, which indicates that both CAPEX and OPEX reduction are considered nearly equally important.

Flexibility is primarily driven by capacity flexibility with 8.72% and dynamic operation capability with 8.28%, while location flexibility reaches 4.66% and product specification flexibility reaches 3.77%, which confirms

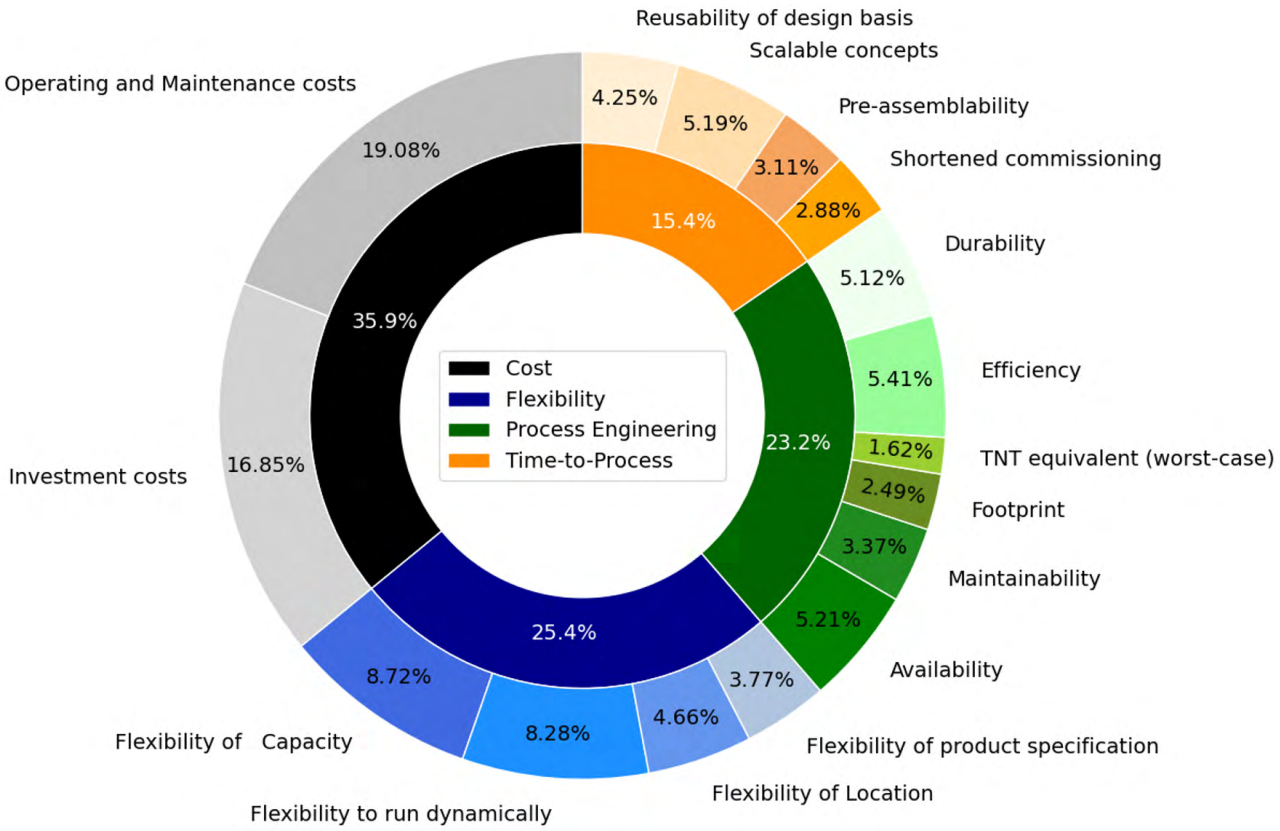

**Figure 3.** Sunburst diagram: Categories are shown in the inner circle. These are identical to the categories from the process industry. The criteria for later optimization of electrolysis systems are in the outer circle.

that electrolysis plants are expected to provide both scalable capacity and load-following behavior in volatile electricity systems.

Process engineering requirements are dominated by efficiency with 5.41%, availability with 5.21%, and durability with 5.12%, whereas maintainability reaches 3.37%, footprint reaches 2.49%, and the TNT-equivalent worst-case safety indicator reaches 1.62%, which highlights the importance of robust long-term operation and energy conversion performance.

Time-to-process is led by scalable concepts with 5.19% and reusability of the design basis with 4.25%, while pre-assemblability reaches 3.11% and shortened commissioning reaches 2.88%, which suggests that the main schedule benefits are expected from reuse and scaling strategies rather than from commissioning acceleration alone.

A comparison with the original process-industry survey shows that cost remains the most important category in both sectors, yet electrolysis assigns substantially higher relevance to flexibility and correspondingly lower relevance to time-to-process. In the process-industry results, cost accounts for 31%, time-to-process for 27%, process engineering for 25%, and flexibility for 17%, whereas the electrolysis survey shifts flexibility to the second rank and places time-to-process last. This shift can be attributed to the system role of electrolysis as a Power-to-X converter that must operate efficiently under fluctuating renewable power availability, which makes operational flexibility a first-order design driver rather than a secondary feature. Both the process industry and the electrolysis sector place a significant focus on flexible production volumes. However, in the process industry, flexibility is equated with the reconfiguration of production plants and varying product specifications that can be manufactured within a single plant [9]. In contrast, flexibility in the electrolysis sector is understood as the ability to respond to fluctuating power inputs while maintaining constant product specifications [10]. Figure 5 shows a summary comparison of the categories from [6] from the process industry compared with the results of the survey from this study for the electrolysis industry.

## Expert assessment of grid connection concepts for electrolysers

This section summarizes expert ratings on the relevance of four electrical grid connection and operation concepts for electrolyzer systems. Respondents

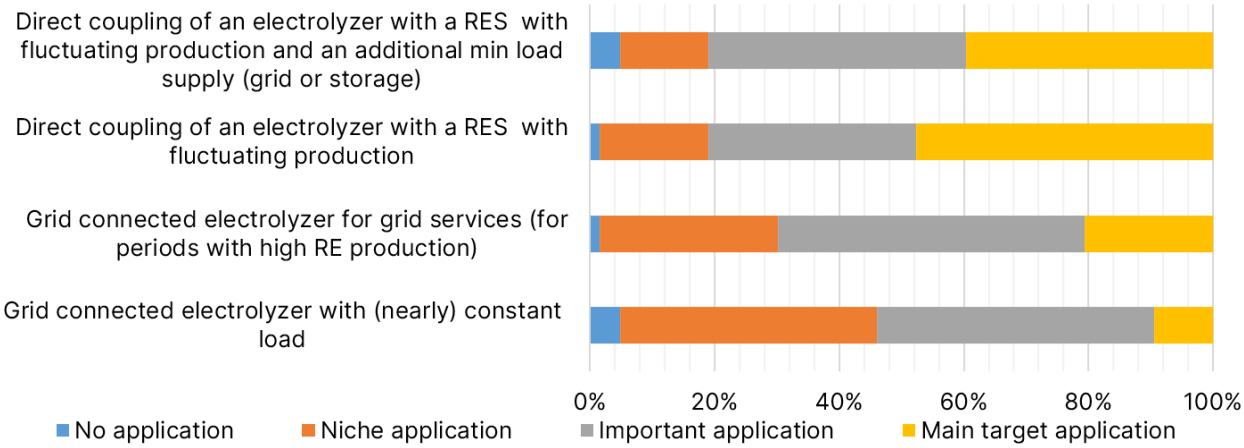

**Figure 5.** Evaluation of the expert survey on the future electrical connection and grid integration of electrolysis systems

classified each concept on an ordinal four-level scale ("No application", "Niche application", "Important application", "Main target application"). The provided dataset contains normalized response shares per concept (each row sums to 1.0), corresponding to 63 expert responses. For comparative interpretation, an additional mean relevance score was computed by mapping the four levels to 0–3 (0 = No application, 3 = Main target application).

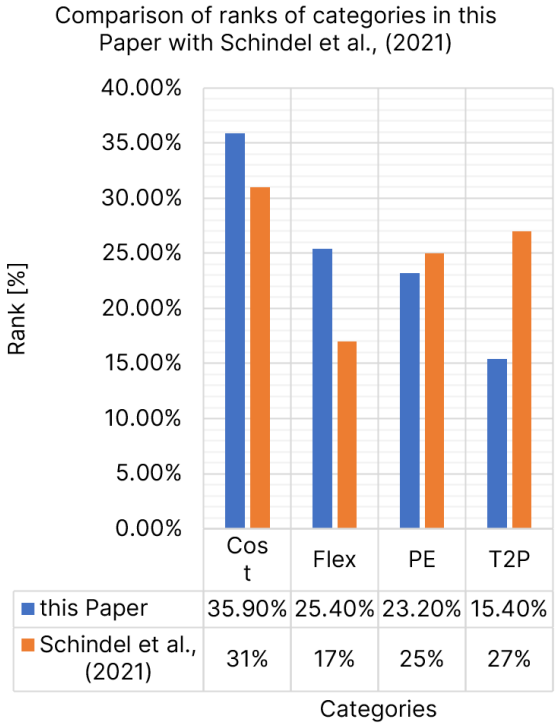

**Figure 4.** Comparison of categories with [6]. Abbreviations: Flexibility (Flex), Process Engineering (PE), Time-to-Process (T2P)

## Results and ranking

Across all concepts, experts clearly prioritized configurations that enable direct integration with renewable energy sources (RES). The concept "direct coupling with fluctuating RES production" achieved the highest share of "Main target application" (47.6%) and the highest mean relevance score (2.27/3). A closely related hybrid concept—direct coupling with fluctuating RES production plus an additional minimum-load supply via grid or storage—was rated almost equally relevant (39.7% "Main target", mean score 2.16/3). Both direct-coupling options reach an identical top-2-box share of 81.0%, indicating broad consensus that these concepts should be treated as important-to-primary use cases rather than edge scenarios. The top 2 box share is the proportion of respondents who scored one of the two highest answer categories on an ordinal scale - e.g. Select "Main target application" and "Important application". It is therefore an aggregated agreement/positivity figure in percent that compresses the "high" rating of a statement. The higher the top-2-box share, the higher the consensus strength in the upper valuation range.

Grid-connected operation aimed at grid services (operation in periods with high renewable generation) occupies an intermediate position (mean score 1.89/3, Top-2 box 69.8%). While only 20.6% selected it as the main target, nearly half of respondents (49.2%) still considered it an important application, suggesting that flexibility-oriented grid-connected operation is widely valued but not universally seen as the dominant design point.

In contrast, a nearly constant-load, grid-connected electrolyzer is the least preferred concept (mean score 1.59/3) and is most frequently characterized as niche (41.3%). Only 9.5% rated constant-load operation as the main target application. This pattern indicates a shift away from a baseload-centric view toward operational

regimes dominated by variability, flexibility, and power-system interaction. The results can be found in Figure 4.

### Interpretation and implications for system requirements

The observed ranking strongly suggests that future electrolyzer system design—and, by extension, requirement prioritization—should be anchored in dynamic operating conditions rather than steady-state operation. High relevance assigned to direct RES coupling implies that experts expect electrolyzers to (i) tolerate strongly fluctuating power input, (ii) operate efficiently across a broad load range, and (iii) maintain performance and lifetime under frequent transients (start/stop cycles, ramping, and partial-load operation [10]). The comparable relevance of the "minimum-load supply" variant indicates that practitioners anticipate technical or economic constraints that motivate stabilizing measures (e.g., minimum turndown limits, stack protection strategies, or process integration requirements), achievable through either grid backup or buffering (electrical storage, hydrogen storage with operational control, or hybrid supply architectures).

The relatively high 'Important' share for grid-service operation highlights an additional requirement cluster: electrolyzer systems are expected to interact with the power system beyond simple consumption. This typically translates into needs for advanced control strategies capable of responding to market or grid signals (e.g., absorbing renewable peaks, participating in flexibility products, or managing curtailment). Even if not the dominant main-target case for all respondents, its broad 'important' rating suggests that 'grid-interactive' capability can be a meaningful differentiator in system architectures and should be considered in modular interface and control design.

Finally, the low prioritization of nearly constant-load operation implies that optimizing solely for steady-state efficiency at a single design point may not match the dominant deployment expectation in the surveyed expert community. Instead, robust performance across operating regimes - and the ability to integrate fluctuating RES supply - emerges as a central design intent. For a modularization-oriented development approach, these findings support emphasizing modules and interfaces that enable (i) flexible power conversion and grid/RES interfacing, (ii) transient-capable process control.

## SURVEY LIMITATIONS

One limitation of the evaluation is that it only contains aggregated distributions at respondent level. Subgroup effects, such as the examination of connections between interest groups and the level of a rated category or criterion, have not yet been taken into account here. This means that statistical conclusions that go beyond a descriptive ranking cannot be evaluated here. Another limitation of the survey is the broad spectrum of perspectives. However, this is still focused on technology development and component supply, which is due to the expert networks of VDMA P2X4A and the DECHEMA network in the H2Giga lead project. This should be taken into account when interpreting the relative weighting of the technical criteria.

## CONCLUSIONS

The transferred survey method provides an empirically grounded prioritisation of requirements for modular electrolysis systems in Germany and thereby clarifies optimisation targets for module decomposition. The optimisation criteria should focus on the efficiency, dynamic operation and levelized cost of hydrogen of the electrolysis system. The modular approach of small-scale electrolysis systems should be transferable to large-scale systems. In particular, electrolysis systems that can cope with fluctuating power inputs and operate efficiently over a wide 'Load Flexibility' range should be investigated.

The approaches to modularising process engineering systems pursue different goals in the process industry and in the electrolysis industry. Cost reduction remains the overarching objective, but the high weighting of flexibility and the strong process engineering emphasis on efficiency imply that modular concepts must simultaneously support dynamic operation, reliable performance and scalable concepts. In the process industry, the approach to standardised modules seems to be more about the rapid realisation of products in order to secure market share.

## OUTLOOK

Future work should implement the derived weightings in the optimisation of electrolysis systems and evaluate the modular system approach for scaling under realistic fluctuating operating profiles. To support this, a standardised test signal/operating profile combined from different components (e.g. from a step, ramps, a pseudo-random binary sequence/'sawtooth function' and a synthetic solar profile) can be developed to optimise consistency across different electrolysis system sizes. In this way, modular heterogeneous electrolysis systems of different technologies and power ratings can be investigated in terms of system efficiency, operating flexibility and levelized cost of hydrogen. The consistent test signal allows investigation of whether the modular system approach represents a scalable concept.

Another field of research is the investigation of hybrid electrolysis systems with storage integrated into the process, consisting of a battery-electric and a hydrogen

storage system. After all, the experts rated the 'grid-connected electrolyser for grid services (for periods with high RE production)' with a top-2-box value of 69.8%, which argues for a high storage share that can be divided among different technologies.

## ACKNOWLEDGEMENTS

We would like to thank the German Federal Ministry of Research, Technology and Space and the project management organization Jülich for their financial support within the framework of the eModule research project (FKZ 03HY116A) of the $H_2$Giga lead platform. Furthermore, the P2O-Lab Learning Factory of the TUD Dresden University of Technology is thanked for its support.

## ABSTRACT

The rapid shift toward Industry 4.0 and data driven manufacturing has prompted universities to reshape chemical engineering programmes, yet the scope and coherence of "Digital Chemical Engineering" (DCE) within UK curricula remain unclear. This study qualitatively maps DCE provision across five IChemE accredited MEng degrees to identify which digital skills are taught, how they progress across programme stages, how skills are distributed between core and elective content or taught versus applied learning, and how well provision aligns with accrediting frameworks. The analysis is structured around eight domains: (D1) programming and computation; (D2) data literacy and statistics; (D3) process modelling and simulation; (D4) optimisation and process systems engineering; (D5) control, automation and instrumentation; (D6) AI, machine learning and digital twins; (D7) software engineering practices; and (D8) data governance, ethics and cybersecurity. Results show institution dependent digital skills coverage. Some programmes introduce a broad digital skill set from Year 1, while others concentrate digital content in later years or adopt a more progressive distribution. Across institutions, D7 is consistently underrepresented. Foundational skills in D1, D2 and D8 are typically embedded throughout programmes, whereas more advanced domains D3 to D6 are introduced at later stages. Domains D1 to D4 demonstrate a stronger balance between teaching and application, while D5 to D8 are predominantly taught, with application increasing in later years. Optional fourth year modules play a significant role in shaping graduate digital profiles. Overall, DCE provision broadly aligns with IChemE and AHEP4 guidance, where expectations for D1 to D4 are more explicitly articulated

## INTRODUCTION

Digitalisation and Industry 4.0 are reshaping chemical engineering practice across the industries, with increasing reliance on data-driven decision-making, advanced modelling, automation, and digital twins [1]. These developments are transforming how processes are designed, operated, and optimised, and are redefining the skills expected of graduate chemical engineers. Historically, undergraduate programmes have introduced students to well-established tools such as process simulation and basic programming, with the expectation that deeper digital expertise would be developed post-graduation in the workplace. However, recent studies and employer surveys indicate that this model is no longer sufficient. Employers increasingly report skills gaps in digitalisation and now seek explicit evidence of digital competence during graduate recruitment [2].

In response, universities are embedding digital skills like modelling, process simulation, coding and statistics

more deliberately within chemical engineering curricula [3], often in collaboration with industry and professional bodies. Nonetheless, there remains considerable uncertainty regarding what constitutes appropriate "Digital Chemical Engineering" (DCE) coverage, how digital skills should progress across degree programmes, and how consistently these expectations are implemented across institutions. While prior work has explored the pedagogical value of specific digital tools and surveyed academic and industrial perspectives on digitalisation in education, these studies largely focus on individual modules, tools, or localised curriculum reform [4-7].

Within the UK context, this issue is closely linked to accreditation requirements. IChemE accreditation establishes shared learning outcomes and standards for professional formation, while allowing flexibility in curriculum design. Accreditation guidance highlights importance of systems thinking, and the ability to work with modern engineering tools and data-rich environments [8]. However, it provides limited explicit direction on the depth, sequencing, or balance of digital skills across the curriculum, potentially leading to uneven provision between institutions despite a common accreditation framework.

This study provides a sector-level mapping of DCE coverage across MEng programmes in the UK that are accredited by the Institute of chemical Engineers (IChemE) and in alignment with the Engineering Council's Accreditation for Higher Education Programmes guidelines (AHEP4). This study evaluates the baseline for digital readiness in UK chemical engineering education and provides evidence to inform departmental curriculum review and the future evolution of accreditation guidance. The purpose of this work is to map DCE, provide an overview of the digital landscape, and draw potential trends, helping practitioners understand more about their curriculum. This work is not providing recommendations, ranking one approach over another or setting a precedence.

## METHODOLOGY

### Data Collection and Curriculum Mapping

Following from the outcome of a survey on the views on key skills for chemical engineers from academic and industrial stakeholders [2] and using informed judgement and discussions across contributors who are all heavily involved with curriculum design in their respective institutions, DCE provision was classified across eight domains: (1) programming and computation: ability to understand, write, and execute code. (2) data literacy and statistics: understanding of statistical principles, use of data visualisation for effective data communication. (3) process modelling and simulation: use of specialised software to develop models and simulate unit operations. (4) optimisation and process systems engineering: use of systems engineering principles and algorithms to identify best possible variables. (5) control, automation and instrumentation: design and implementation of control systems to monitor and maintain process variables towards safe and stable plant operation. (6) artificial intelligence, machine learning, including digital twins: use of tools and software to identify patterns, development of virtual, real-time depiction of a process or plant that can be updated using process data, predict performance and diagnose issues in a simulated environment. In this context digital twins represent artificial intelligence or machine learning enabled, data-driven operational replicas of the process. (7) software engineering practices (version control, testing, reproducibility): tracking and managing changes to code over time, reverting to previous versions, ensuring reliable reproducibility. (8) data governance, cybersecurity, and ethics around digital tools: understand the importance of data storage, quality, security and access, address moral implications around the use of digital tools.

It is important to point out that the domains focus on elements of the curriculum directly related to digital skills, rather than fundamental chemical engineering knowledge that would be taught in traditional core modules. The Universities offering accredited degrees in chemical engineering or related courses at BEng and MEng level that participated in this curriculum mapping activity were: Aston University, University of Manchester, University of Nottingham, University of Sheffield, University College London (two departments each with their own degree programmes; Chemical Engineering (CE) and Biochemical Engineering (BE)). Representatives from each participating university in this study mapped the DCE curriculum provision for their offered courses in chemical engineering against each domain, per year of study (years 1-3 for BEng courses and 1-4 for MEng courses). This was done by analysing publicly available information in module descriptors and learning outcomes, supplemented on occasion by additional knowledge of modules and assessment based on their knowledge of teaching specific courses or from communications with academics involved in teaching specific courses. Each institution was responsible for providing and checking data for their course(s), with all data being collated in a shared document. DCE curriculum mapping was done in a qualitative manner at this stage, indicating a "yes/no", and providing examples or comments of how each domain content is covered where relevant. With the understanding of content being covered formally in the curriculum, i.e. core/taught and formatively assessed as a learning outcome, and informally, as by-product/applied, i.e. taught but not assessed, or implicitly expected in later years of study, mapping was designed to recognise both dimensions. It is important to note that the mapping was done by a representative academic of each university rather than all module leaders of all courses,

hence there might have been details on specific learning activities or assessments that were overlooked or underestimated. This could result in the mapping not being completely definitive, but nevertheless sufficient to highlight trends and perhaps differences in DCE coverage across the examined curricula. In addition to curriculum mapping, publicly available IChemE and AHEP4 accreditation guidelines [8, 9] were mapped against the domains.

## Data Analysis and Visualisation

Once mapping was completed qualitatively, it was assessed and validated through comprehensive discussions across all collaborators to ensure as much uniformity as possible, a scoring system was introduced, to bridge the qualitative mapping with a quantitative approach. An "instructional intensity" metric was developed to distinguish between the presence of a tool and the formal pedagogical delivery of a skill. Each module-year intersection was evaluated against two criteria:

- **Core/Taught (Primary Intensity):** The domain is a formal part of the curriculum with explicit, assessed Learning Outcomes. Students receive dedicated instruction (e.g., a Python module).
- **Byproduct/Applied (Secondary Intensity):** The domain is utilised as a tool for another engineering subject (e.g., using Excel in a lab report) without new formal instruction.

For the purpose of the **Digital Maturity Curve**, the Index focuses on **Core/Taught** instances, representing the "Instructional Load" of new digital competencies introduced at each level. The quantification process followed a three-step aggregation logic:

1. **Binary Mapping:** Each of the eight domains was assigned a binary value (1 for Core instruction, 0 for absent) for every university at every level.
2. **Summation and Normalisation:** For a given Academic Year (Y), the raw intensity score ($S_y$) was calculated as the sum of active domains across all participating institutions (n):

$$S_y = \sum_{i=1}^{n} \sum_{d=1}^{8} D_{i,d}$$

Where $D_{i,d}$ is the binary state of Domain d at University i. Sy was used for calculating scores and generating the Digital Coverage Heat Map (Figure 1) and the Digital Maturity Curve (Figure 4).

3. **Weighted Aggregation:** To account for elective specialisations in Year 4, the score was bifurcated into Core Intensity (mandatory/core modules) and Potential Intensity (elective modules).

For the construction of the Digital Coverage Heat Map, the scale range was defined from 0 to 3. (0) corresponded to absence of evidence, moving to evidenced presence of domain activities as curriculum by-products with no formal assessment (1) and as optional modules including assessed learning outcomes (2), and ending with evidenced domain activities in core modules with formally identified learning outcomes (3). For the accreditation guideline mapping, absence of a specific domain was marked with 0, 1 corresponded to vague reference and 2 corresponded to clear evidencing of a domain to the accreditation guidelines. Data was processed and analysed using Python (version 3.14.2) for visualisation and trend identification per domain and per year. It is important to note that the quantitative analysis (scoring) was performed by one member of the team, to ensure consistency.

# RESULTS AND DISCUSSION

Analysis of the digital curriculum heatmap (Figure 1) revealed substantial variation in the breadth and depth of digital skills coverage across universities and degree levels. Across all five universities, digital domains traditionally embedded within chemical and process engineering curricula, namely process modelling and simulation (D3) and control/automation and instrumentation (D5), were the most consistently represented. These domains were commonly embedded as core assessed modules or optional assessed offerings particularly in senior programme years. Data literacy and statistics (D2) was also widely present across almost all universities, typically embedded within assessed modules. In contrast, under emerging digitalisation domains (e.g., AI/ML and digital twins (D6), software engineering practices (D7), and data governance, ethics and cybersecurity (D8)), coverage was considerably more even. These domains were frequently either absent or delivered indirectly without assessment and appeared in isolated cases rather than as integrated features of coherent programme pathways.

Institution-level patterns further highlight the uneven digital landscape. Aston demonstrated relatively strong provision in D1-5, and D8 from the early years through to MEng level, yet provided limited coverage of D6, with some provision in Year 1 and more application or presence in optional modules in later years. Manchester showed a similar pattern, with strong coverage in D3-5 and limited progression in emerging domains; D6 appeared only in two units with formally identified learning outcomes. At Nottingham, D2 and D3 are embedded and assessed throughout the programme. D1 develops progressively, while D4 and D5 are mainly introduced in later years. In contrast, D6 is only indirectly addressed, and D8 appears only at MEng level. Sheffield exhibited strong coverage of D2-3 and D8 throughout the curriculum and intermittent coverage of D1, D4-5, while D6 and D7 had

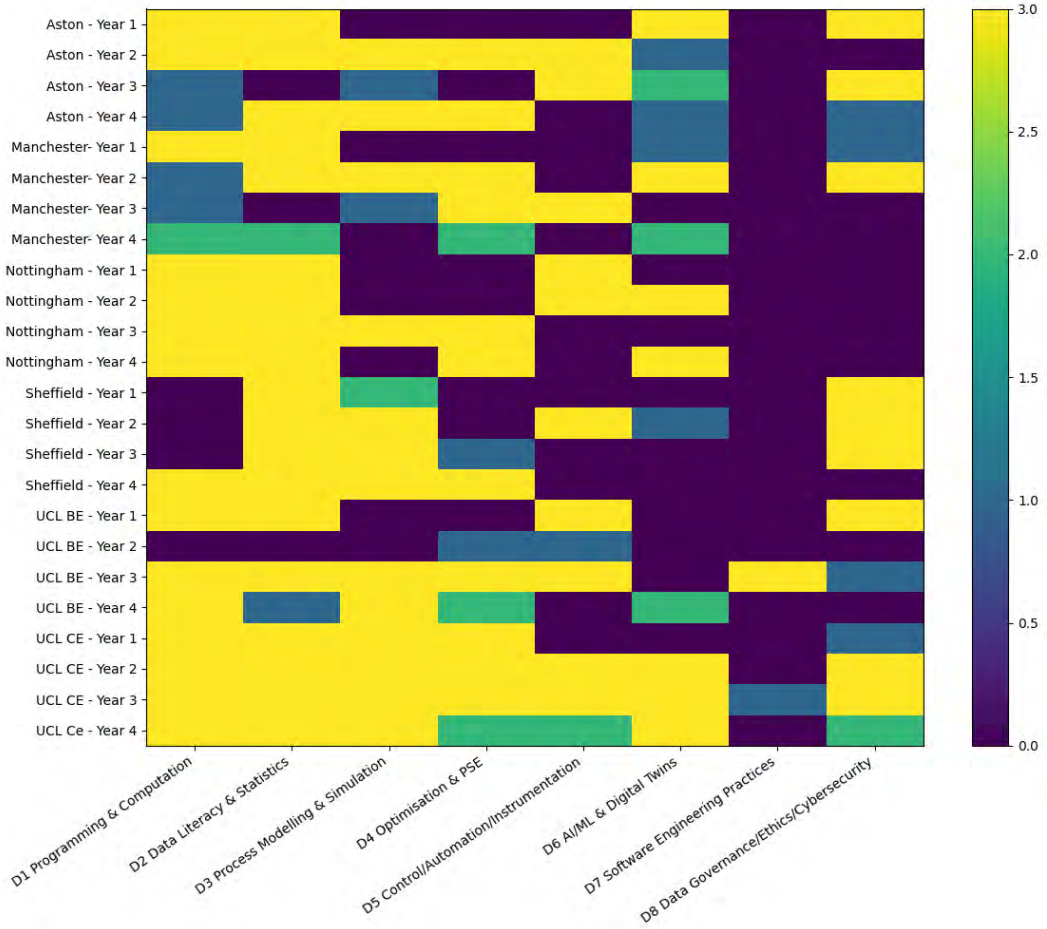

**Figure 1.** Heatmap of curriculum digital coverage across examined programmes at the five Universities, per year of study and domain. Scale range is from 0/dark blue indicating absense of coverage to 3/yellow indicating skill covered by formally identified learning outcomes.

limited evidence of engagement. UCL, across both biochemical (BE) and chemical engineering (CE) routes, presented strong late-stage coverage in D1-5, but did not incorporate substantive coverage of D7. UCL BE's biology-focused modules differ from traditional chemical engineering due to the department's distinct remit and scope, and while a digital agenda is embedded throughout the programme, its unique nature leads to observable differences compared with conventional chemical engineering curricula. UCL CE showed strong inclusion of D1-4 throughout all years of the degree programme, whilst domains D5, 6 and 8 were included in Year 2 onwards exemplifying a significant digitalisation emphasis.

Digital skills coverage demonstrates institution-dependent sequencing. Some universities (e.g., UCL) introduce a broad range of digital competencies from Year 1, whereas others (e.g., Nottingham, Sheffield) concentrate digital learning in senior years and a third group (e.g., Aston, Manchester) distribute coverage more progressively across the programme.

Further analysing the spread of digitalisation skills in the degree programme, Figure 2 shows an overall mean convergence score for each domain in each year across all degree programmes considered in the study. From this four approaches to how domains are covered can be identified:

- Coverage is consistent and significant across the degree programme - D1, D2, D8
- Coverage is initially low and is built up throughout the degree programme - D3, D4
- Coverage is focused most significantly in a specific year or two - D5, D6
- Coverage is very limited - D7.

It is clear that core digital skills of D1 Programming and Computation and D2 Data literacy and statistics are covered immediately in year 1 and that these skills are continually included and built upon throughout the degree programme. This is reasonable since these skills align with core mathematical knowledge that students

develop and apply throughout their studies.

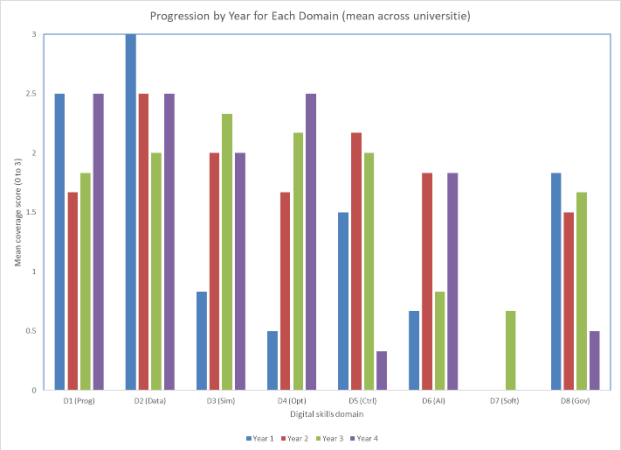

**Figure 2.** Progression of domain coverage per year of study across D1-8. D1: programming and computation, D2: data, literacy and statistics, D3: process modelling and simulation, D4: optimisation and PSE, D5: control automation and instrumentation, D6: artificiall intelligence, machine learning and digital twins, D7: software engineering practices, D8: data governance, ethics and cybersecurity.

Interestingly, Figure 2 shows that Data Governance, Ethics, Cybersecurity (D8) is represented in each year with almost equal coverage of D8 in year 1 compared to year 2 and 3, although with a drop in year 4. The heat map in Figure 1 shows D8 to be included in the degree programme when many digital skills have yet to be taught or developed. This could be explained through the open-ended interpretation of data governance, ethics and cybersecurity. It is likely that some form of cybersecurity and GDPR training is included in introductory courses as part of induction training. However, specific relation of these domains to chemical engineering, such as the impact of a breach of cybersecurity in the safe operation of a chemical plant and recommended mitigating actions are likely not included until later years, if at all. Equally, interpreting ethics is also considerably open-ended. It can be acknowledged that some form of ethics is included at the start of the degree programme, specific inclusion of ethics related to digital skills cannot be guaranteed but equally cannot be ruled out. For example, the ethics of the use of AI in one's studies or the ethical impact of using AI on a workforce in a mini design problem could be included at the beginning of the degree programme. Specific information to rule these considerations in or out based on information available in published module descriptions and intended learning outcomes, which are often limited in number and format by individual university regulations, can be the cause of varied interpretation of this domain.

Considering domains that are initially covered less and built upon throughout the degree programme seem reasonable when the specific domains are examined. Process Modelling and Simulation (D3) and Optimisation and PSE (D4) are more advanced applications of digital skills once more fundamental digital, mathematical and process unit operation skills are introduced earlier in the programme. Equally, considering domains that have a focus in a specific year or two, such as Control/Automation/Instrumentation (D5) and AI/ML and Digital Twins (D6) is also reasonable since this aligns with material and prior knowledge to which these domains relate. For example, Control/Automation/Instrumentation is often introduced, taught in detail and applied once initial concepts have been introduced, but are then less of a focus in electives in later years. On the other hand, considering D6, there seems to be a focus in year 2, which is not then revisited until digital-focused electives in the final year.

Finally, there is consideration of domains for which there is little recognition throughout the degree programme, such as Software Engineering Practices (D7) with only some indication of coverage in Year 2 or 3 at a couple of universities. This may be down to how the domain itself is formulated and the implicit inclusion of this domain to achieve learning outcomes of other domains. For example, software engineering practices, such as tracking and managing changes to code or documents over time, are not an explicit learning outcome of specific modules, but successful software management is needed to carry out large, open-ended, group design projects and meet the D3-related learning outcomes.

Looking at the DCE coverage across core/taught components where defined learning objectives were used to assess student learning, and curriculum by-products/applied where understanding of tools and knowledge taught at earlier years was assumed and students were expected to apply it to solve problems, there is an interesting trend revealed (Figure 3). There is prominence of distinct Digital Domains in both teaching and of application and the striking underrepresentation specific digital domains in the curricula.

Software Engineering Practices (D7) including open-source code sustainability, version control, testing, reproducibility are minimally integrated across the programmes investigated. This is followed by Data governance, Cybersecurity and Ethics (D8) and AI/ML and Digital Twins (D6) domains, which are primarily taught as part of the core curriculum. In contrast, Programming and Computation (D1), Data literacy and Statistics (D2), Process modelling and simulation (D3) domains are overrepresented in both the taught and the applied components of the curriculum, followed by Optimisation and Process Systems Engineering (D4) and Control, Automation and Instrumentation (D5).

An interesting aspect of our analysis elucidated the sensitive balance between the taught and the applied

components of the content covered in these domains.

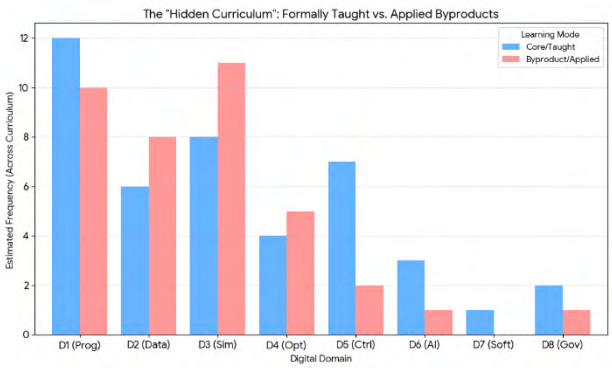

**Figure 3**. Comparison between DCE coverage across all domains for core/taught components and components evidenced as byproducts.

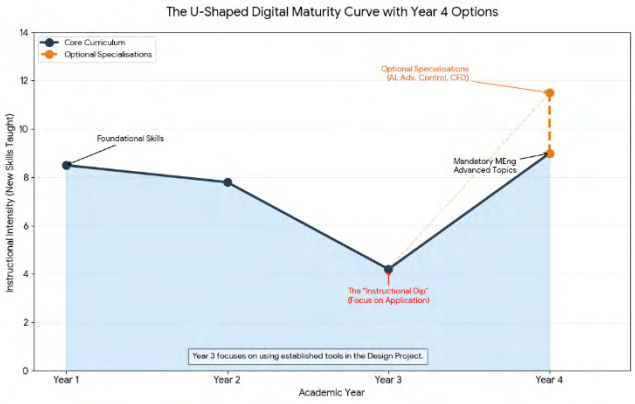

**Figure 4**. Digital "maturity" curve of DCE provision.

We note that the digital content is not only taught and assessed but has become an integral part of the learning curriculum since they are frequently utilised as part of the application demanding their use, even without necessarily being assessed directly. We observe a heavy focus on application in domains D2-4, possibly emerging from the nature of the digital capabilities covered by these domains. Concepts such as data science, process modelling and simulation and optimisation, once basic concepts are introduced, mostly remain applied concepts in the curricula in a range of areas, consequently serving to support digital capacity building and training primarily through application. These domains are closely followed by D1. While D1 and D3 find a wide range of application areas as expected, they are also an integral component of the core teaching of the curriculum and are widely implemented across different programmes.

Looking at the totality of DCE coverage from a progress-per-year point of view (Figure 4), another interesting trend emerges across the four years of study, highlighting a "U" shape maturity trendline. The left peak (Years 1 and 2) is the "Input Phase." Universities front-load digital skills (Python, MATLAB, Excel, Statistics) to ensure students have the "mathematical literacy" required for engineering science modules. In this phase, new digital competencies are introduced. The curve dips in Year 3 because the focus shifts from learning new digital skills to applying existing ones (primarily for the high-stakes Design Project).

Students are at their busiest digitally, but they aren't learning new software; they are refining their use of Aspen Plus or HYSYS. From a "new instruction" perspective, digital maturity appears to stall before spiking again in Year 4 with advanced industrial specialisations like AI and Molecular Modelling.

For MEng students, the curriculum in many cases introduces high-level concepts that are currently industry-leading, such as Machine Learning, Computational Fluid Dynamics, and Digital Twins. While the core Year 4 curriculum already sees a resurgence in digital instruction (e.g., mandatory Advanced Process Control, Computational Modelling, or Sustainability Modelling), the dotted line shows the peak maturity reached through electives like Advanced Machine Learning (AI), Computational Fluid Dynamics, and Digital Twin Design. It should be noted that the "gap" between the solid and dotted points at Year 4 highlights that digital competency in the final year is highly dependent on student choice, allowing for a deeper technical "spike" compared to the broad foundational skills of Years 1 and 2. It should also be noted that during this analysis we did not account for cases where the final year research project, the highest credit-contributing module in Year 4, was purely focused on one or more of the DCE domains rather than on research areas not as heavily intertwined with digitalisation.

Having completed the DCE mapping of the curricula of participating Universities, the eight domains were used to map the degree accreditation guidelines from the IChemE and AHEP4, marking absence of mention as a 0, vague mention as 1 and clear coverage as 2 (Figure 5).

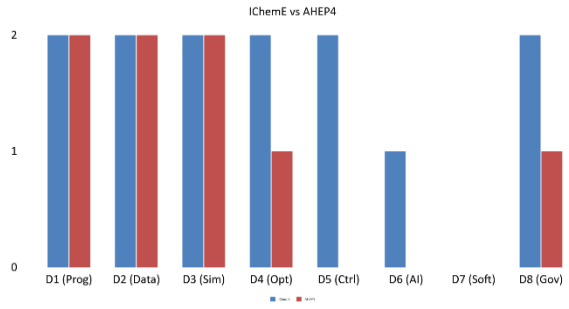

**Figure 5**. Mapping of IChemE and AHEP4 accreditation guidelines.

The IChemE provides information that effectively discusses the need for educational provision when it comes to domains D1-5. For AI/ML and Digital Twins (D6) the guidelines of "AI approaches" that can very vaguely

link to this particular domain.

When it comes to Software engineering practices (D7), it is unclear whether the accreditation guidelines include this domain. The guidelines mention the need to "understand system dynamics, being able to determine the dynamic response to changes in a process, design measurement and control functions, and determine its performance" which can vaguely link to D7 but not clearly. Last but not least, while there is clear mention of the need for prospective graduates to become aware of ethical considerations, there is no explicit mention or relevance to ethics around the use of digital tools. When it comes to big data or or cybersecurity there is acknowledgement of how the profession is changing.

A notable difference between the IChemE and AHEP4 accreditation guidelines is that whilst D1-4 are clearly covered under both schemes, D5-D7 are not mentioned in the AHEP4 guidelines. This could be because at least D5 and D6 might be deemed discipline-specific while AHEP4 caters for all engineering disciplines. When it comes to data governance, cybersecurity and ethics, AHEP4 mentions the importance of ethics, but not necessarily relating that to the digital space.

## REFLECTIONS

The DCE curriculum mapping of the Universities participating in this study shows clear trends in the provision of education on digital tools. Undeniably, all programmes considered have embedded the majority of the eight examined domains in their curriculum, at different years of study and in different ways, following accreditation guidelines. What is interesting to note is that there is very limited coverage of Software Engineering Practices (D7) across the studied programmes, which also aligns with the absence of this domain from the accreditation guidelines. This could potentially be attributed to limited relevant educational capabilities across module leaders, or even to the fact that this domain, at least within the remit of chemical engineering, has not been a well-established area to allow for development of relevant educational content. The lack of D7 presence in the chemical engineering curriculum could be pointing towards the need for faster adoption of industrial needs within taught curricula and provision of training to educators when it comes to digital tools, with the aim of ensuring the more holistic preparation of future workforce.

It is worth pointing out that while mapping the curricula it became evident that ensuring accurate DCE mapping in terms of domain presence and intensity was cumbersome. This could be attributed to the “hidden curriculum” effect where it was tricky to differentiate between taught content that was formally assessed and content that was expected to be understood and applied but without formal assessment for a particular module. Furthermore, in complex module cases, such as the Design Project and Research Project that students usually undertake in Year 3 and Year 4 respectively, this effect was even more evident, as there are cases where such modules could contain very strong digital-focused components at an individual level rather than a cohort one. Accreditation guidelines indicate the baseline programmes are expected to evidence around learning outcomes and specific attributes; however, there is no expectation of where in the curriculum such elements should be embedded, or the intensity of their coverage. For a discipline with such profound industrial relevance, it is imperative for educators to work closely with accrediting bodies and industry, and continually track industrial needs, ensuring that the attributes of graduate chemical engineers are on par with the professional expectations. Furthermore, it is relevant to note that updated IChemE accreditation guidelines, which align more explicitly with AHEP4, will be released in the coming year.

## CONCLUSIONS AND FUTURE WORK

This work has revealed that there is substantial variation in the breadth and depth of digital skills coverage for domains 1 to 6 and domain 8 across institutions and programmes evaluated. However, all programmes evaluated showed limited coverage of domain 7 on software engineering practices, followed by domain 6 on ML/AI and digital twins. This evidence shows the misalignment of the provision of these emergent skills with the evolving industrial sector.

Traditional digital domains aligned with core mathematical knowledge such as programming and computation and data literacy and statistics (D1 and D2) are commonly introduced in the first year of the programmes. Process modelling and simulation and optimisation, process systems engineering, control, automation and instrumentation and AI/ML and digital twins (D3-6) however are preferentially introduced after students are familiarised with process unit operations and fundamental programming skills. Governance, ethics and cybersecurity are covered evenly across the first three years, but more enquiry on the scaffolding in depth and specialisation in this domain is required to understand the student readiness for the sector. The provision of digital skills shows a front-loading in year 1 and 2 mainly related to inputting domains D1 to D5, followed by a drop in year 3 where application takes the main stage. Finally, in year 4 the incorporation of advanced chemical engineering skills and specialisation introduces a new instruction phase in the learning of digital skills.

Domains early introduced in the programme and traditionally requested by the IChemE accreditation (D1-D4) show a good balance between being taught and being

embedded, integrated and largely applied in later stages. On the contrary, domains D5-8, which are introduced at later stages, are mainly being taught with lesser opportunities for application. Overall, the digital chemical engineering provision broadly aligns with IChemE and AHEP4 guidance, where expectations for D1 to D4 are more explicitly articulated.

The present work is a cornerstone in the mapping of digital skills that has evidenced the need to enquire about potential barriers affecting underrepresented domains such as domain 7. It also underscores the importance of examining further the breadth and depth for all domains through a more comparative quantitative or semi-quantitative analysis across the years and institutions. The intention of this work is not to provide recommendations but rather provide an overview of digital skills presence in chemical engineering education. The insights generated here will support future evaluation of how programmes align with the forthcoming IChemE accreditation guidelines, which integrate expectations from the Engineering Council's AHEP4 framework, and may ultimately serve as a tool for assessing digital-skills provision within accredited chemical engineering programmes and sector needs.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge colleagues from each academic institution, for valuable insight and discussions that contributed to our understanding and mapping of DCE in our curricula. In particular, DD would like to thank Dr Marco Cardoso Marques, ER and MZ would like to thank Ben Pearson, MGM would like to thank Dr Zoran Visak and MM would like to thank John Turner.

## ABSTRACT

As high-throughput experimentation (HTE) becomes a cornerstone of modern materials research, undergraduate and postgraduate curricula increasingly require students to possess Python programming skills to operate automated liquid-handling robots, such as the Opentrons OT-2 and Flex. However, the high cost of this hardware often necessitates shared equipment use during hands-on lab sessions, creating a significant pedagogical barrier: students lack the individual time required to iteratively test and debug their protocols on physical robotic platforms for automated material synthesis. Furthermore, we observe that the scarcity of robotic platforms creates an imbalance in group dynamics, where students with more coding experience often lead protocol development, while those with less experience remain disengaged. To address these challenges, we developed an interactive simulator that translates Python protocols into 2D animations on personal laptops. Using gold nanoparticle (AuNP) synthesis as a case study, we demonstrated how this platform enabled visualisation, captured common programming mistakes, and refined the efficiency of the code before implementation using the physical robot. By shifting the 'trial-and-error' phase from the lab to the laptop, the simulator showed potential to democratise students' access to automation education and ensure equitable skill application across the cohort.

**Keywords**: automation, simulation, material synthesis, visualisation, robotic, nanoparticles

## 1.0 INTRODUCTION

Industry 5.0 emphasises collaboration between humans and machines to develop innovative and sustainable solutions [1]. In chemical engineering, this paradigm is reflected in the use of robotic platforms to automate high-throughput chemical synthesis, curate large datasets for process optimisation, and support sustainability initiatives [2, 3]. The integration of these technologies into undergraduate and postgraduate curricula is becoming increasingly common, with students programming liquid-handling robots using Python-based protocols to automate experiments for high-throughput material synthesis. Data-Driven Materials Manufacturing is one of the core modules taught at UCL's MSc Digital Manufacturing of Advanced Materials (DMAM) programme. This module aims to teach students how to program liquid-handling robots, such as the Opentrons OT-2 and Flex, using Python.

However, several challenges were identified while teaching with the liquid handling robots. The first challenge arises from the limited infrastructure of the lab, where the necessity of sharing a single robot among five or six students results in a fragmented learning experience. Coding for automation is a skill that demands constant experimentation and immediate feedback; however, the current setup forces long wait times between code execution and physical observation. This lack of consistent access prevents students from developing coding skills through iterative testing. Furthermore, students with strong programming backgrounds often dominate the code development stages, thereby marginalising peers with limited or no prior coding experience. This imbalance raises a significant pedagogical concern and calls for more inclusive teaching strategies to ensure equitable participation and learning outcomes for all students [4]. Additionally, because students have limited opportunities to build basic computational skills, it is difficult to incorporate sustainability and optimisation principles into laboratory education. As a result, we observed

excessive use of pipette tips and other consumables due to inefficient protocol design by students. These challenges highlight the need for accessible digital solutions to support coding for liquid-handling robots and to create inclusive learning environments.

In this study, a 2D desktop-based simulation platform was proposed to overcome the pedagogical barrier of limited access to robots. By allowing students to run code and receive individual assessments virtually, the simulator reduces reliance on physical hardware and fosters independent programming. This extra time enables students to move beyond simply writing functional code, allowing them to design efficient liquid transfer steps that minimise pipette tips waste and reinforce principles of sustainability.

The aim of this paper is to share the development and perceived use of the simulator in the classroom environment. The simulator can be used to simulate both the Opentrons OT-2 and Flex, but this paper focuses on its application with the Opentrons Flex. Here, we explain how the simulator was used to visualise a Python protocol for gold nanoparticle (AuNP) synthesis, a material of growing importance in renewable energy and healthcare applications [5].

## 2.0 DESIGN OF GOLD NANOPARTICLE SYNTHESIS PYTHON PROTOCOL

The Python protocol for synthesising gold nanoparticles was designed according to the Turkevich method [6]. The experimental steps of this method involved stirring and heating gold (III) chloride trihydrate ($HAuCl_4$) and trisodium citrate ($Na_3Ct$) solutions within a 96-well plate (reaction plate). The experimental design explored three significant factors of the Turkevich method that influence AuNPs size: initial $HAuCl_4$ concentrations, the molar ratio of $HAuCl_4$ to $Na_3Ct$, and temperature. The full factorial design of the experiment is shown in Table 1, with levels chosen based on the literature [6].

**Table 1:** Full factorial design of experiment for gold nanoparticles synthesis.

| Factor | Levels |
|---|---|
| C (mM) | 0.20, 0.25, 0.50, 0.75 |
| $n_{ratio}$ | 1.00, 1.25, 1.50, 2.00, 2.40, 2.80, 3.20 |
| T (°C) | 60, 70, 80, 100 |

C is initial concentration, $n_{ratio}$ is molar ratio, and T is temperature.

To perform experiments with the Opentrons Flex liquid handling robot, the Python protocol specified a sequence of liquid transfer steps. First, $HAuCl_4$ and diluent were transferred from the solvent reservoirs to the reaction plate using an eight-channel pipette. After filling the reaction plate with diluted $HAuCl_4$, the Python protocol instructed the robot to move the plate onto the Heater-Shaker Module with a gripper. The protocol specified the temperature and shaking speed. After heating, the reaction plate was moved back to the initial position. Then, the heated $HAuCl_4$ mixture was supplemented with different volumes of $Na_3Ct$ and heated again with the Heater-Shaker Module. Note that each run of the protocol tested only one temperature, so to assess all four temperatures specified in Table 1, three additional runs of the protocol with different temperature values were conducted. Finally, the product was transferred from the reaction plate to a 360 uL Corning 96-well plate.

By transferring precise volumes of various reagents, the reaction plate was filled with reagents in the configuration shown in Figure 1. In this setup, each well in columns 1 through 4 represents a unique combination of $HAuCl_4$ concentration and the $HAuCl_4$ to $Na_3Ct$ molar ratio; these combinations were repeated in triplicate across columns 5-8 and 9-12. Wells in row H were left empty, except for wells H1 through H4, which were filled with water to serve as blanks for UV-Vis analysis.

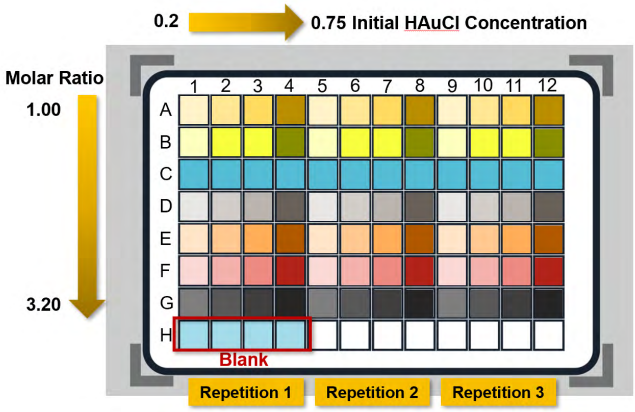

**Figure 1**. Layout of the conditions in AuNPs synthesis reaction plate.

## 3.0 SIMULATING THE PYTHON PROTOCOL

### 3.1 Basic Simulator Functions

Before rendering animation, the simulator first converts the Python protocol into a text file using the Opentrons-simulate package. The Opentrons-simulate package allows users to preview the steps taken by the robot in text form, as demonstrated below:

```
Latching labware on Heater-Shaker
Picking up tip from G1 of Opentrons Flex 96
Filter Tip Rack 1000 µL on slot B1
Aspirating 40.0 uL from A1 of NEST 12 Well
Reservoir 15 mL on slot D3 at 716.0 uL/sec
```

```
Dispensing 40.0 uL into G1 of NEST 96 Deep
Well Plate 2mL on slot D2 at 716.0 uL/sec
```

The simulator then works with this text to generate the animation. Essentially, the simulator employs web technologies for the graphical interface. JavaScript was used to drive the real-time animation of the robotic process, handling the dynamic updates to the deck layout. Cascading Style Sheets were used to style both the static and dynamic elements of the simulator's user interface, ensuring that the visual representation of the Opentrons Flex deck, labware (plates, tips), and pipette modules was accurately sized, positioned, and clearly visible, contributing to a realistic and easily understood user experience.

## 3.2 Visualising Liquid Aspiration and Dispense

The simulator simulates liquid being aspirated from or dispensed into a well by changing the height of the rectangle that represents the liquid level. At startup, the simulator initialises each well's current volume as either empty (0 uL) or as the maximum liquid volume a well can hold. When rendering the animation, every aspirate or dispense command triggers an update routine that changes the current volume of the affected well by subtracting or adding the transferred volume, respectively. The visual representation of liquid filled is derived from a level fraction ($L_f$) defined as:

$$L_f = \frac{V_{current}}{V_{capacity}} \quad (1)$$

where $V_{current}$ is the current well volume and $V_{capacity}$ is the total liquid volume each labware well could hold. For rectangular reservoirs, this fraction determines the height $h_{fill}$ of a bottom-anchored filled rectangle, computed as:

$$h_{fill} = L_f \bullet H_{well} \quad (2)$$

$$Y_{top} = Y_{well} + (1 - L_f) \bullet H_{well} \quad (3)$$

with $H_{well}$ being the constant pixel height of the well. The top Y-coordinate of the filled region is therefore given by ensuring proportional visual depletion or filling as volume changes. A sequence of frames where the coloured rectangle height decreases as $HAuCl_4$ solution was aspirated from the reservoir is shown in Figure 2.

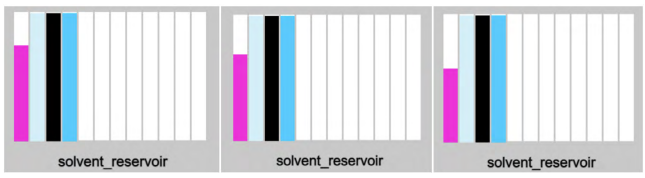

**Figure 2**. Animation of reduction in liquid height as 120 uL was being aspirated from solvent reservoir well A1.

## 3.3 Visualising Dilution and Liquid Mix

Colour-coding is used to indicate the presence of liquid within a well. For example, the well plates were initialised as empty and therefore appeared uncoloured. Conversely, the reservoirs were initialised as full and displayed in blue, reflecting the standard practice of pre-filling reservoirs with solvents or solutions at the start of a protocol. The simulator also initialised all liquid colours as blue, as shown in Figure 3(a).

Although the simulator has a default setting for labware, it also allowed this initial state of the labware to be customised. As shown on the right-hand side of Figure 3(b), for the AuNP protocol, the $HAuCl_4$ solution was set as bright pink, the diluent was set as dark blue, $Na_3Ct$ was set as black, and water remained blue. Other wells were selected as "empty", so the wells were uncoloured. While the diluent in solvent reservoir A2 was set as dark blue in Figure 3(b), there was a difference in colour between the colour set in the right panel and the colour being shown in the animation on the left. This was because solvent reservoir A2 was set to be a "diluent", so the simulator replaced the diluent with light blue instead.

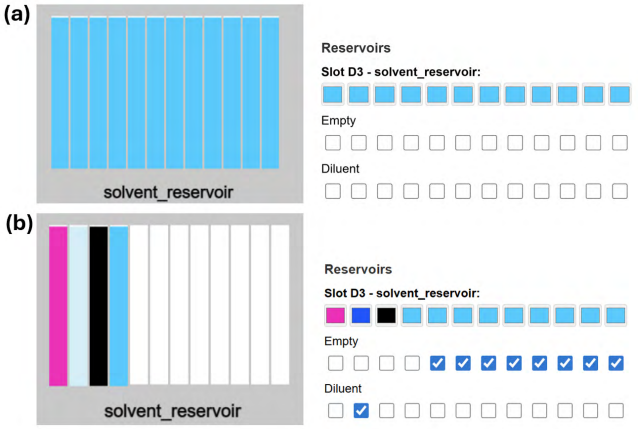

**Figure 3.** (a) Default setting of reservoir and (b) user setting of reservoir.

When $HAuCl_4$ was transferred to the reaction plate, the wells in the reaction plate were coloured bright pink to indicate the presence of $HAuCl_4$. Upon the addition of a diluent, the simulator calculated the ratio of non-diluent to current liquid volume in the well using Equation 4 and updated the opacity of the well's colour accordingly:

$$\kappa_{final} \propto \frac{V_{non-diluent}}{V_{total}} \quad (4)$$

where $V_{total}$ is the total liquid volume in the well, $V_{non-diluent}$ is the volume of non-diluent liquid in the well, and $K_{final}$ is the final opacity.

As a result, when diluent was added to $HAuCl_4$, the colour changed across the column and repeated every four columns. When $Na_3Ct$ was added to the wells, the volume of $Na_3Ct$ added to each row was the same, resulting in uniform colour across each row. However, the

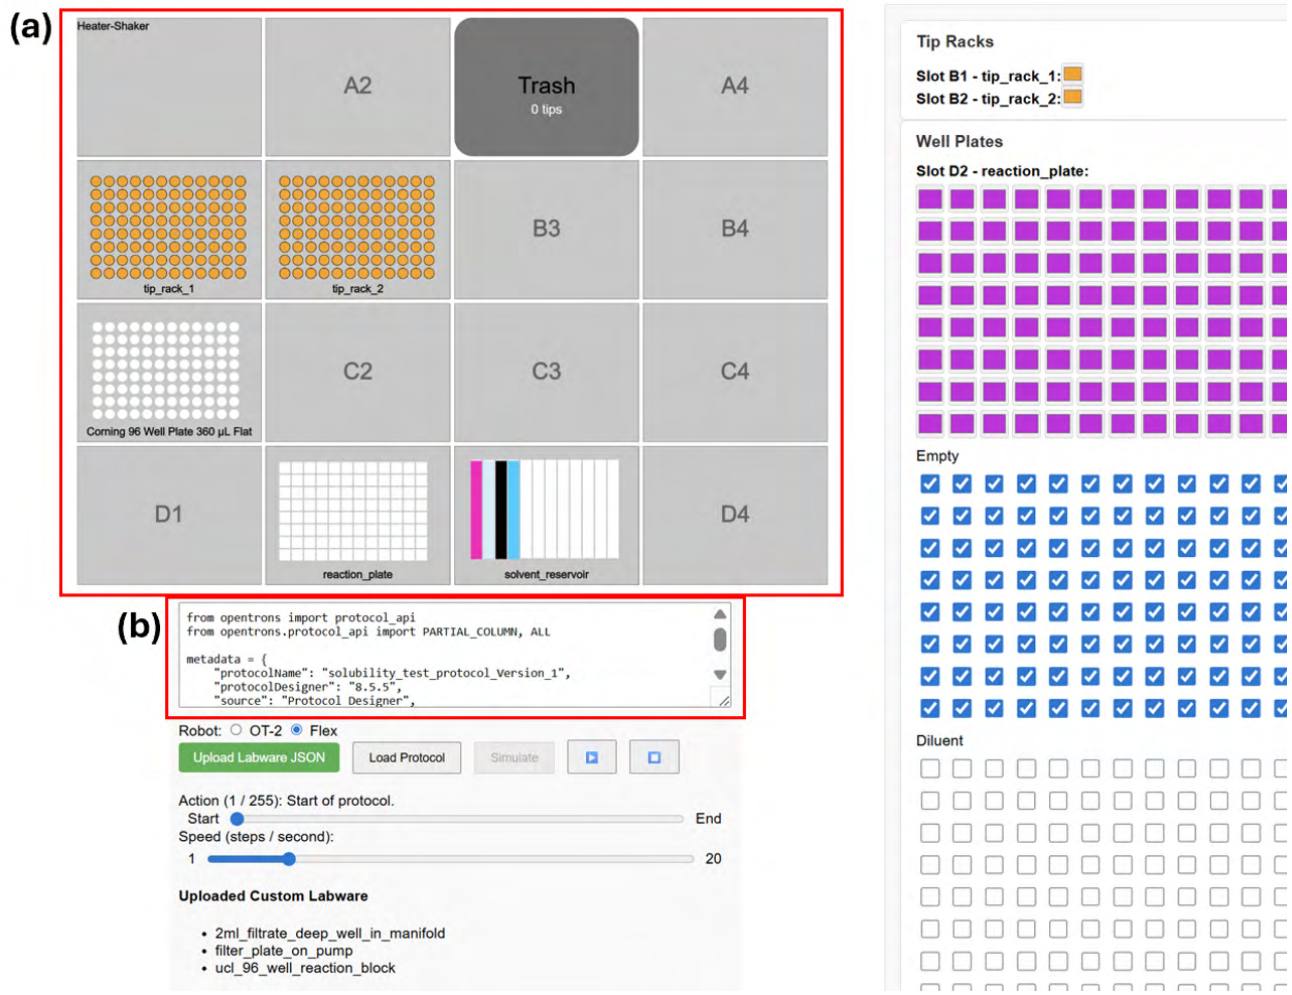

**Figure 4.** The simulator's user interface consists of several key sections: (a) the animation area and (b) the code editor where the Python protocol for AuNP synthesis is uploaded. Below the code editor, users can select the robot model (OT-2 or Flex) and use a dedicated button to upload JSON files for custom labware. Clicking 'Load Protocol' triggers the system to either display an error message or signal that the 'simulation is ready'. In the latter case, the 'Start Simulation' button becomes active. Adjacent to this are the pause and restart controls for the animation. The execution timeline is displayed under the 'Action' panel, which includes a slider to adjust the animation speed. Finally, the right-hand panel specifies the initial state of the labware based on three parameters: colour, fill status (empty), and diluent type.

volume varied between rows, producing differences in colour down the plate. This difference was captured by the simulator through colour blending. When dispensing liquid that is not labelled as a diluent, the simulator took the red, green, and blue channel intensity (RGB) of the $Na_3Ct$ and the RGB of the previously diluted $HAuCl_4$ and averaged them based on their respective volume using Equation 5:

$$R_{final} = \frac{R_{source} V_{source} + R_{dest} V_{dest}}{V_{total}} \quad (5)$$

where $R_{final}$ is the resulting RGB of the new mixture, $R_{source}$ is the RGB of the liquid being poured in, $V_{source}$ is the volume of the liquid being poured in, $R_{dest}$ is the RGB of the liquid already present in the destination container, and $V_{dest}$ is the volume of the liquid already present in the destination container.

Figure 4 displays the entire simulator's user interface. When a user uploads a Python protocol for AuNP synthesis into the code editor, the simulation deck (Figure 4(a)) will update to show each piece of labware at the position specified in the Python protocol.

## 3.4 Simulating Gripper

The function of the gripper was to move the reaction plate from its starting slot D2 onto the Heater-Shaker

Module when heating was needed. The simulator simulated this movement by detecting command lines that instructed the robot to move labware, such as:

```
Moving nest_96_wellplate_2ml_deep to Heater-
ShakerContext at Heater-Shaker Module GEN1
on A1 lw None
```

Once a movement command was detected, the system converted this movement of labware into a step of reassigning the labware from its current slot to the new slot. When this step was parsed to the function that ran the animation. Because the function rendered labware based on their assigned slot positions in the dictionary, the labware appeared to move instantly to the new location on the screen as the slot position in the dictionary changed as illustrated in Figure 5. This allowed visualisation of the reaction plate's movement to any position on the deck, including on top of the Heater-Shaker Module.

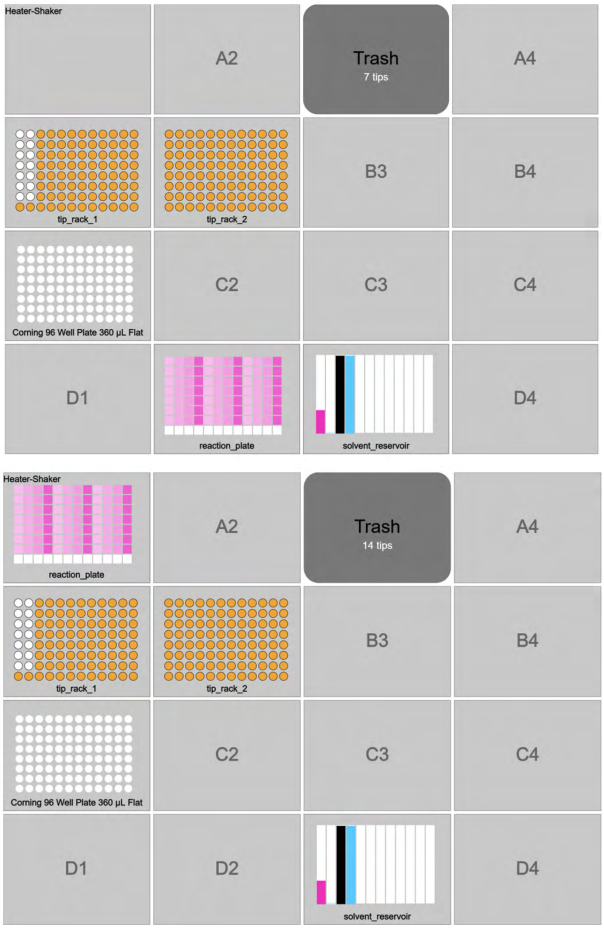

**Figure 5**. Gripper moving reaction plate from D2 (top) to the Heater-Shaker Module in A1 (bottom).

3.5 Simulating Heater-Shaker Module

In the Python protocol for AuNPs, the Opentrons Heater-Shaker Module was used for heating and mixing the diluted $HAuCl_4$ and $HAuCl_4/Na_3Ct$ mixture. The Heater-Shaker has two parameters: temperature and shaking speed. In the Python protocol, the parameters were set using the following code:

```
hs_mod.set_and_wait_for_shake_speed(300)
hs_mod.set_and_wait_for_temperature(60)
protocol.delay(minutes=10)
```

The simulator recognised this instruction from the Python protocol to extract the Heater-Shaker temperature and speed settings. It then broke them into a sequence of smaller, increasing values so that the animation showed the temperature and shaking speed rising to the target values (Figure 6). The animation started at a low baseline (23 °C for temperature or 0 RPM for the shaker), pushed intermediate values that stepped up slowly at first and faster later (small increments under a threshold, larger ones above), and then finally reached the exact target value.

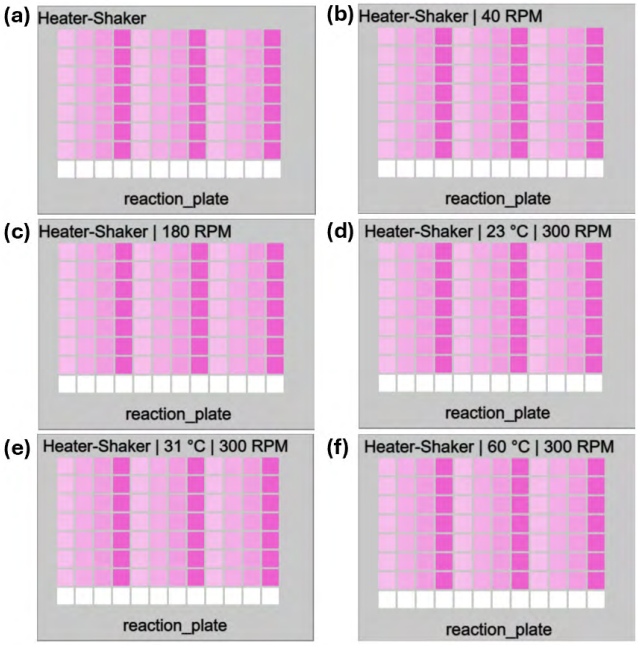

**Figure 6**. Chronological demonstration of heating and shaking process for the heater-shaker module during animation from (a) to (f).

After both temperature and shaking speed reached their target values, according to the Python protocol, the protocol would pause for 10 minutes. The simulation does not pause for 10 minutes. Instead, a pop-up window informs the user that the protocol was delaying for 10 minutes and 0.0 seconds. Upon clicking the "Ok" button, the simulator skips the waiting period and proceeds with execution. Overall, these features enable the simulation of the Heater-Shaker module.

## 4.0 CAPTURING COMMON MISTAKES WITH SIMULATOR

The simulator captured several mistakes made in the Python protocol for AuNP synthesis without running it on a physical robot. The first mistake was transferring liquid to the wrong well. A typo in the Python protocol, such as “A1” instead of “A2”, was hard to capture by human eyes reading through each line of code, especially in nanoparticle material synthesis where the code and simulated text could be complex and long. Although this mistake could be captured with a dry run, a single dry run took around 15 minutes, and one would have to perform several dry runs if there were multiple typos. The simulator speeds up this trial-and-error process by capturing unintended liquid transfers on the screen. In the classroom, students would be able to capture multiple errors in one simulation and change their code accordingly. This is much faster than testing the code on the robot.

The second mistake was transferring more liquid from the solvent reservoir to the reaction plate than the maximum amount of liquid a reservoir well could hold. Keeping track of how much liquid was aspirated from the reservoir by reading through lines of code was challenging; thus, one common mistake was designing a Python protocol that tried to aspirate more liquid than the maximum volume. During AuNPs synthesis, drying up the reservoir well could cause inaccurate transfer of liquid into the reaction plate and inevitably mess up the molar ratio or concentration of reactants. Note that this mistake could not be captured with a physical dry run or the Opentrons-simulate package, as both do not keep track of how much liquid was aspirated from a reservoir well.

The simulator kept track of the volume in each well and showed changes in liquid level by calculating how much liquid was left in the well. Building on this basic function, we added a feature to stop the simulation when the liquid level falls below 0 uL after aspiration. This would allow students to notice that more diluent than the maximum well volume was drawn by the Python protocol and fix their code accordingly before deploying it on the robot.

## 5.0 USING THE SIMULATOR IN CLASSROOM AND WIDER EDUCATIONAL IMPACT

The simulator enables a structured, multi-stage pedagogical workflow that integrates digital laboratory automation into teaching and training activities. In the initial phase, students receive instruction on the manual synthesis of AuNPs, including discussion of key experimental variables such as reaction temperature, initial $HAuCl_4$ concentration, and the molar ratio between $HAuCl_4$ and $Na_3Ct$. Building on this foundational knowledge, each student then independently develops a Python protocol on their personal laptop and evaluates its performance using the simulator. This allows students to iteratively test, debug, and refine their protocols in a low-risk virtual environment prior to working with the physical robotic system.

The iterative cycle—develop, simulate, evaluate, and improve—not only strengthens computational thinking skills but also creates an accessible and scalable approach to teaching laboratory automation. The simulator additionally provides quantitative feedback not available in existing tools (e.g., tracking pipette tip usage), enabling assessment based on efficiency, sustainability, and resource optimisation.

Once students complete the simulation stage, they implement their protocols on the Opentrons Flex robot. Small-group review and peer critique of protocols foster collaborative problem-solving and mirror engineering practices. This supports teamwork while preserving individual accountability. In settings without access to robotic hardware, the simulator supports fully remote learning, with students submitting both their protocols and screen-recorded simulations for assessment.

### 5.1 Extended Educational Impact Across Programmes

The impact of the simulation tool extends beyond the immediate classroom environment. Postgraduate researchers within the School of Pharmacy and chemistry have adopted the simulator to upskill new starters whose research involves the use of liquid-handling robots with similar operational principles. By engaging with the simulator prior to accessing physical instruments, these students report increased confidence, reduced anxiety, and improved preparedness for hands-on experimentation. This has proven particularly valuable for students transitioning into laboratory automation with limited prior programming experience. The simulator has been used to validate developed code deployed for applications in combinatorial chemistry, solvent screening, and the assessment of solubility for various chemicals in selected solvents.

Furthermore, the simulator has now been fully integrated into the Digital Manufacturing of Advanced Materials (DMAM) MSc programme, where it supports training in automation-ready digital workflows. Its inclusion strengthens the programme’s emphasis on computational methods, digital manufacturing, and reproducible laboratory practices. Early feedback indicates that students benefit substantially from the ability to repeatedly practise and refine automated protocols outside of scheduled laboratory hours.

There is also ongoing discussion with the School of Pharmacy to incorporate the simulator more formally into postgraduate-taught training. This integration would extend its impact to a broader cohort of students, embedding digital laboratory automation into curricula where traditionally wet-lab skills dominate. The simulator’s

alignment with digital skills agendas and its accessibility on standard laptops make it an attractive teaching tool for programmes seeking to modernise laboratory education.

### 5.2 Industrial Upskilling and Professional Training

Beyond academic environments, the simulator has also been identified as a valuable tool for upskilling industrial workers. In a recent funding bid submitted by the Institute of Robotics, the simulator was highlighted as a resource capable of supporting workforce development in automated laboratory processes. Its ability to train users remotely, safely, and without access to expensive hardware makes it suitable for industrial training pipelines, particularly in sectors where laboratory automation is expanding rapidly.

The tool thus supports a continuum of training—from taught postgraduate students to incoming researchers, to professionals requiring automation-related reskilling. Its scalability positions it as an enabling technology for modern laboratory education and industrial digital transformation.

### 5.3 Advancing Research Reproducibility and Digital-First Laboratory Practices

The simulator contributes to ongoing efforts to improve research reproducibility. Challenges in experimental reproducibility increasingly arise from undocumented implicit knowledge, variability in manual procedures, and inconsistent reporting of protocol parameters. By requiring users to encode all steps in a Python-based, machine-readable protocol, the simulator encourages a level of procedural precision difficult to achieve through traditional textual descriptions alone. The ability to directly execute these digital protocols on automated liquid-handling platforms further ensures that methods can be reproduced with high fidelity across laboratories, institutions, and time.

The simulator also supports the adoption of digital-first laboratory practices that are central to emerging frameworks and experimental workflows. In environments where liquid-handling robotics are increasingly integrated with electronic lab notebooks and laboratory information management systems, the simulator can act as a bridge between conceptual training and real-world digital infrastructure.

Moreover, the quantitative performance data generated by the simulator—such as consumable usage, timing estimates, and workflow efficiencies—enable users to evaluate protocols using metrics that are rarely captured in traditional laboratory teaching. These data create opportunities for optimisation-driven teaching and research, where experimental design can be informed by resource efficiency, sustainability considerations, and throughput modelling. Incorporating such metrics into training better prepares learners to operate within modern research laboratories, where cost-aware and sustainability-oriented decision-making is increasingly prioritised.

## 6.0 CONCLUSION

This study presented the development of a 2D desktop-based simulation tool designed to enhance robotics and automation education in chemical engineering. By translating Python-based Opentrons protocols into real-time animations, the simulator effectively addresses the pedagogical barriers of limited hardware access and uneven group dynamics. Using gold nanoparticles (AuNPs) synthesis as a case study, we demonstrated the platform's ability to visualise complex liquid-handling steps, track consumable usage, and capture critical programming errors (such as volume deficits) that dry runs overlook.

This work serves as a blueprint for other UCL modules seeking to bridge the gap between theoretical coding and physical implementation. Programmes in Biochemical Engineering, material science or computer science can look to this model to provide equitable access to high-cost hardware. By decoupling code development from hardware availability, modules can ensure that students with less prior programming experience are not marginalised by "dominant" peers in a group setting. It demonstrates that digital competency is best fostered when students have the autonomy to fail and iterate in a low-stakes, individual digital environment before moving to the physical laboratory.

For UCL programmes aiming to embed the UN Sustainable Development Goals (SDGs) into their curricula, this manuscript illustrates how "Digital Twins" can directly reduce the carbon footprint of laboratory education in terms of minimising waste. Other modules involving high resource consumption, such as chemistry or synthetic biology, can adopt similar simulation-based assessments in which resource efficiency is used as a graded learning objective. By providing quantitative feedback on consumable usage (e.g., plastic tips and chemical reagents) during the simulation phase, departments can train a new generation of engineers who view optimisation and waste minimisation as core components of experimental design rather than afterthoughts.

Future research will focus on integrating more visualisation features to provide a more immersive experience and expanding the library of supported labware and modules to cover a broader range of high-throughput experimentation (HTE) workflows. Additionally, we aim to implement an automated feedback system that provides students with real-time suggestions for optimising reagent efficiency and protocol duration. In the context of

HTE, this simulator serves as a scalable digital twin, enabling researchers and students alike to validate complex, data-driven experimental designs before physical deployment, thereby reducing waste and accelerating material discovery.

## ACKNOWLEDGEMENTS

The authors would like to thank University College London (UCL) and the Department of Chemical Engineering for providing the laboratory facilities, the robotic hardware (Opentrons Flex), and computational resources necessary for the development and testing of this simulation platform. We also acknowledge the MSc Digital Manufacturing of Advanced Materials (DMAM) cohort for their participation and feedback during the pilot implementation of this tool.

# A Techno-economic Analysis of Simulated Wind Farms

**Isaac N. James[a], Laura Edwards*[a], and Dhurjati Chakrabarti[a]**

[a] The University of the West Indies, Department of Chemical Engineering, St. Augustine, Trinidad and Tobago
* Corresponding Author: laura.edwards@uwi.edu

## ABSTRACT

The implementation of processes that use renewable energy requires that a techno-economic analysis be performed beforehand to determine its economic and technical feasibility. A techno-economic analysis was performed proposed wind farms in Trinidad and Tobago using the System Advisor Model simulation software. Metrics included the annual energy production in kWh, capacity factor, net present value in US$ and internal rate of return. From the above, the number of households that can be powered each month by the farms were calculated. The results showed that rotor diameter, which defines the swept area has a significant impact on annual energy production as a 33 m difference translated into a 27.3 GWh and 22.9 GWh difference in output. The results are promising and show that the oil and natural gas-based economy can be diversified.

## INTRODUCTION

As climate change and its effects become more profound, the term green technology has been used frequently in everyday discussions. Government bodies, corporations and the public have begun to become more aware of climate change, the negative effects of pollution and depletion of natural resources. It has also gathered significant interest from investors who are looking to invest mainly in companies that produce or utilize green technology. Green technology or more commonly called “green tech, ” is a broad term used to describe technology that one would consider environmentally friendly from its production process to its usage [1].

The move to reduce emissions has continued to date and global agreements such as the Paris Agreement and frameworks have been made between countries to steer progress for dealing with climate change in the right direction. The production of fossil fuels must drop by approximately 45% between 2020 and 2030, for countries who have pledged to attain net zero emissions by 2050 to realistically achieve that goal. Net zero refers to decreasing global emissions as close to zero as humanly possible while allowing the remaining emissions to be absorbed by natural sources such as forests and oceans [2].

A technical-economic analysis (also called techno-economic analysis or TEA) is a method used to analyze the technical and economic performance of an industrial process or product being developed. It is carried out to answer questions such as “is it technically feasible?” and “will it make money?”. It provides the business/organization estimates of the operating and capital costs as well as the expected revenue that stems from financial and technical parameters input into process specific software [9].

When companies are deciding if a project is a good investment or not, they calculate the net present value (NPV) and the internal rate of return (IRR) as two of the main indicators as to whether the project will generate net profits for the company. The NPV (in $) is obtained by discounting future cash flows using a variable discount rate and summing their present values. Cash flows are statements that report the cash spent and generated during a certain period. It gives a breakdown of the movement of money in and out the business/project. It is comprised of three sections which are operating, investing and financing activities [12].

A study has been done by Chadee and Clark (2017) in which the levelized cost of electricity (LCOE) generation from the wind for 2 sites with long term wind measurements were determined. Their results showed that the generation of electricity through tall, large wind turbines are cost competitive with the electricity generated through the burning of natural gas. The LCOE has units of US$/kWh and is frequently used to compare and

assess alternative methods of energy production, this metric determines if a project will be profitable or break even and enables financial analysts to compare various energy producing methods such as solar and wind. To calculate the LCOE for any energy project, the annual energy production (AEP) is required, this can be calculated by entering technical information specific to the energy generation process into software [3]. According to Chadee (2017), at 80 m above ground, the annual mean wind speeds were approximately 6.93 m/s at Crown Point and 5.86 m/s at Piarco.

To obtain the required technical inputs for a wind farm, a wind resource assessment will have to be carried out and the data analyzed. Through calculation of the LCOE and other financial metrics, decisions made by the relevant stakeholders.

## BACKGROUND

The methods of electricity generation in Trinidad employed at the Penal power station makes use of a combined cycle power plant (PowerGen 2019a). Here, two 7E gas turbines fueled by natural gas each have their exhausts (comprised of a hot air-fuel mixture) captured by heat recovery steam generators (HRSGs). These HRSGs creates steam from the exhaust and this steam is sent to a steam turbine where its blades are spun, thereby turning its drive shaft that is connected to a generator in order to generate additional electricity (General Electric 2019). These gas turbines require atmospheric air and natural gas to operate (Trinidad Generation Limited 2017).

In May 2023, a workshop took place to highlight the findings of a European Union (EU) funded study that indicated that Trinidad's offshore areas held a large potential of wind resources that would decarbonize the industry as well as aide the transition towards an economy depending less on fossil fuels. Reference was drawn to the use of 8% of the country's produced natural gas for electricity generation.

While offshore wind resource assessments are complex due to the rough marine environment, cost and timeframe of data collection, collaboration and alignment between research institutions, the government, investors, local communities and industry is crucial [11].

Suitable locations in Trinidad and Tobago were analyzed and potential onshore and offshore wind farm sites identified using wind resource data from the Global Wind Atlas as well as available local data. These sites were then ranked based on their LCOE and suitability. Onshore wind power has a potential capacity of 2.75GW while offshore has a capacity of 32GW. However, a Wind Resource Assessment Programme (WRAP) will need to be undertaken to confirm the actual wind speeds at the various locations to enable appropriate siting and approximate energy yields (Sakellariou 2023, 16, 19-20).

The team stated that large scale wind projects require infrastructure to ease the development process and lower the project risks. Heavy duty cranes, equipment capable of transporting the heavy turbine parts over the land in addition to specially designed ocean vessels for lifting and installing the turbines offshore would be required. As Trinidad and Tobago has a well-established petrochemical sector: several sea ports exist that can accommodate large cargo vessels, expertise in inland transportation logistics have been accrued as well as a skilled workforce and strong demand for energy. The country will be able to capitalize on the above strengths in order to generate electricity with a lowered carbon footprint and thus use the remaining natural gas to create other products of higher value (Sakellariou 2023, 20, 27).

Model inputs include: the location of a project, operating, maintenance and installation costs, discount rate and other factors such as system specifications. Outputs include: annual electricity generation (kWh), the levelized cost of electricity, payback period, net present value, internal rate of return as well as a cash flow table with accompanying customizable graphs. SAM can model a single wind turbine as well as a wind farm, it also has a module and inverter database. The user has the option to use from a predefined set of turbines or to define their own turbine characteristics such as hub height, rated output, cut-in and cut-out wind speed (National Renewable Energy Library 2018).

The economic and technical comparison of wind and solar farms will be appropriate as the Covid-19 pandemic has resulted in the closure of many businesses and increased unemployment. The results could validate the feasibility of wind farms in Trinidad and Tobago, create employment opportunities in different sectors, shed light on the necessary legislation amendments and show that the local oil and natural gas-based economy can be diversified. This incorporates the use of the System Advisor Model (SAM) for simulating and obtaining data, a unique method to approach this type of research data collection.

SAM uses various performance and financial models, based on the inputs provided, the performance model will run a simulation to calculate the system's electrical output. The corresponding financial model uses that system output to calculate the annual project cash flows and other financial metrics. There are performance models for wind power, photovoltaic systems, solar water heating and other renewable energies.

## METHOD

In the absence of a wind resource file, the wind speed Weibull distribution option was chosen. The wind resource was defined in terms of the average annual

wind speed, Weibull k (shape) factor and the reference height for those values. From these values, System Advisor Model (SAM) displayed a graph of the Weibull probability distribution function (pdf) [4].

The Weibull pdf is a theoretical model recommended by the International Electrotechnical Commission's IEC 61400-12 standard to represent the empirical wind speed distributions at a site [3]. This pdf is comprised of a scale (c) and shape (k) factor and apart from representing the wind speed distribution, it is used to calculate the monthly/annual energy output of a wind turbine or wind farm. Values of average annual wind speed, Weibull k factor and reference height from Chadee (2017) for 2 locations were used. The 2 locations were the MET offices in Piarco, Trinidad and at Crown Point, Tobago.

The wake model chosen was the simple wake model as it calculated the deficit in wind speed at turbines positioned in the wake of upwind turbines. The turbulence coefficient which indicated the variation in wind speed due to the terrain and thermal effects was set at a value of 0.2 [4]. The turbine layout was defined in terms of turbines per row and number of rows.

A degradation rate of 1.6%/year was entered based on a study of 10 years of data from 282 wind farms in the UK [5].

In the uncertainty tab of SAM, the uncertainty model could be enabled to specify uncertainty as a percentage of energy production. However, for the scope of this work, this model was not enabled.

In the revenue tab of SAM is where time of delivery (TOD) factors, capacity and curtailment payments as well as the PPA price could be entered. There were no capacity nor curtailment payments and due to a fixed PPA, the PPA multiplier values were set to one. The PPA price chosen was fixed at 0.13$/kWh, similar to a 2014 wind project in Jamaica [10].

The turbine cost included the purchase, transportation and assembly of the rotor, nacelle and tower modules. The balance of system (BOS) costs included, but were not limited to the foundation, electrical infrastructure, permitting, engineering and project management costs. Financial costs such as contingency and construction finance were added together with the BOS costs to give a final BOS value. After selecting land-based installation, under the capital costs subsection, the turbine costs in USD/kW were entered. The turbine and BOS costs for the turbines ≥3MW were different from those <3MW.

The study executed by Chadee and Clark (2017) determined the LCOE generation for 2 sites with long term wind measurements. These sites are Crown Point in Tobago and Piarco in Trinidad. The LCOE is frequently used to compare and assess alternative methods of energy production.

Six turbines [6] will be used. Two turbines each fall into the 2MW, 2.5MW and ≥3MW category, the variation in cut in, cut out wind speeds, rotor diameters and hub heights will allow comparisons to be made. Metrics such as annual energy produced, NPV, IRR, number of homes powered, etc. will be analyzed and conclusions drawn. Tables 1 and 2 below provide wind turbine characteristics, rated power and number of turbines.

**Table 1:** Characteristics of wind turbines to be used [6]

| Model | Rated Power (kW) | Rotor Diameter (m) | Hub height (m) |
|---|---|---|---|
| Enercon E-101 | 3050 | 101 | 99.0 |
| Enercon E-82 E3 | 3000 | 82 | 98.0 |
| Enercon E-115 | 2500 | 115 | 92.5 |
| Fuhrlander FL-2500 | 2500 | 100 | 85.0 |
| Enercon E-82 E2 | 2000 | 82 | 78.0 |
| AN Bonus 2000/76 | 2000 | 76 | 60.0 |

**Table 2:** Rated power and number of turbines at farm capacities [3, 7]

| Farm Capacity (MW) | Turbine rated power (MW) | Number of turbines |
|---|---|---|
| 21.35 | 3.05 | 7 |
| 21.00 | 3.00 | 7 |
| 20.00 | 2.50 | 8 |
| 20.00 | 2.00 | 10 |

## RESULTS AND DISCUSSION

The metric tables on the next page (Tables 3-5) show increased turbine performance in Crown Point as opposed to Piarco, all the turbines, regardless of positive or negative financial metrics, had higher AEPs in Crown Point. This is due to several site factors such as annual average wind speeds, wind power densities, shear exponents and Weibull scale factors. Apart from site factors, turbine characteristics such as rotor diameter, hub height, cut in and cut out speeds and drive train design also affect the AEP. The 99m hub height of the Enercon E-101 is approximated to the 100m height in the following analyses.

The net capital costs in tables 3-5 represent the total installed costs which are the product of the total installed costs in ($/kW) and the farm capacity in (kW). The total installed costs ($/kW) are the sum of the turbine, BOS and financial costs. The general trend of a decrease in turbine costs ($/kW) with the larger rated power

**Table 3:** Metric table for AN Bonus and E-82 E2

| Metric | Units | AN Bonus 2000/76 - Crown Point | AN Bonus 2000/76 - Piarco | Enercon E-82 E2 - Crown Point | Enercon E-82 E2 - Piarco |
|---|---|---|---|---|---|
| Annual AC energy in year 1 | (kWh) | 26,950,970 | 17,369,464 | 47,606,796 | 32,423,356 |
| Capacity factor in year 1 | (%) | 15.4 | 9.9 | 27.2 | 18.5 |
| Real LCOE | (¢/kWh) | 15.73 | 22.63 | 10.30 | 13.62 |
| NPV | ($) | -16,779,614 | -25,738,878 | 2,534,781 | -11,662,615 |
| IRR in year 20 | (%) | -1.04 | -7.09 | 6.84 | 1.41 |
| IRR at project end | (%) | 0.62 | -4.40 | 7.71 | 2.79 |
| Net capital cost | ($) | 44,880,000 | 44,880,000 | 44,880,000 | 44,880,000 |

**Table 4:** Metric table for FL-2500 and E-115

| Metric | Units | Fuhrlander FL-2500 - Crown Point | Fuhrlander FL-2500 - Piarco | Enercon E-115 - Crown Point | Enercon E-115 - Piarco |
|---|---|---|---|---|---|
| Annual AC energy in year 1 | (kWh) | 51,755,068 | 35,327,020 | 67,740,368 | 49,401,364 |
| Capacity factor in year 1 | (%) | 29.5 | 20.2 | 38.7 | 28.2 |
| Real LCOE | (¢/kWh) | 8.82 | 11.43 | 7.50 | 9.09 |
| NPV | ($) | 12,285,037 | -3,076,142 | 27,232,228 | 10,084,192 |
| IRR in year 20 | (%) | 10.76 | 4.64 | 15.83 | 9.95 |
| IRR at project end | (%) | 11.36 | 5.67 | 16.20 | 10.60 |
| Net capital cost | ($) | 37,300,000 | 37,300,000 | 37,300,000 | 37,300,000 |

**Table 5:** Metric table for E-82 E3 and E-101

| Metric | Units | Enercon E-82 E3 - Crown Point | Enercon E-82 E3 - Piarco | Enercon E-101 - Crown Point | Enercon E-101 - Piarco |
|---|---|---|---|---|---|
| Annual AC energy in year 1 | (kWh) | 40,457,064 | 27,038,680 | 57,065,672 | 39,587,860 |
| Capacity factor in year 1 | (%) | 22.0 | 14.7 | 30.5 | 21.2 |
| Real LCOE | (¢/kWh) | 9.57 | 12.72 | 7.80 | 9.82 |
| NPV | ($) | 5,833,378 | -6,713,589 | 20,830,120 | 4,487,350 |
| IRR in year 20 | (%) | 8.81 | 2.32 | 14.93 | 8.15 |
| IRR at project end | (%) | 9.51 | 3.52 | 15.32 | 8.90 |
| Net capital cost | ($) | 31,521,000 | 31,521,000 | 32,046,350 | 32,046,350 |

turbines is observed. As the BOS costs were taken as 30% of the turbine cost, the turbine costs strongly influence the total installed costs (in $/kW and $). This is seen as the 2MW E-82, 2.5MW E-115 and 3MW E-82 have turbine costs of 1600$/kW, 1330$/kW and 1057$/kW and total installed costs of $44.9 million, $37.3 million and $31.5 million respectively. The 3.05MW E-101 has a higher rated power and farm capacity than the 3MW E-82, hence its higher installed cost of $32 million.

For the Enercon E-82 E3 variation of the farm, the

turbines cost 70.4% of the total installed cost while the Enercon E-115 variation cost 71.3% of the total installed cost.

The net present value (NPV) is a value in $ that includes revenue and expenses, it is positive if a project is economically feasible, and negative if infeasible. The NPVs in tables 3-5 are the after-tax cumulative NPVs in year 25.

SAM produced a cash flow table that could be exported to Microsoft Excel to examine the formulae, the $C_n$ is the sum of the pre-tax and after-tax project returns for a particular year. It was observed that the pre-tax returns for Crown Point were nearly double that of Piarco's. The sum of the cash flow from operating, investing and financing activities made up the pre-tax returns, for these simulations, the investing and financing activities had cash flows of $0.

The cash flow from operating was the earnings before interest, taxes, depreciation and amortization (EBITDA), this value was the revenue minus the total expenses. The total expenses were the sum of the O&M capacity-based expenses and property tax. The capacity-based expense was the same for all the farms with similar capacity and the effect of the property tax was minimal compared to the effect the revenue had on the EBITDA.

The revenue is made up of the PPA revenue and the production-based incentives (PBI), it was mentioned in the methodology that the PBI was set at zero since these are not available in Trinidad and Tobago. The PPA revenue is the product of the net production (AC kWh) and the PPA price (¢/kWh), since the PPA price was constant throughout each simulation, the net production had a significant impact on the revenue. It was already discussed which turbine and site characteristics lead to the AEP being higher at Crown Point. This impact trickled down to the EBITDA which affected the total pre-tax returns and Cn, which ultimately affected the NPV.

The NPV in year zero was the negative of the installation cost and since the NPV was a cumulative value, a low AEP in the following years would mean a lower NPV got added to the previous negative value. This is why a lot of the NPVs for Piarco are negative, from the 2MW AN Bonus having a low AEP of 17.4 GWh with an NPV of -$25.7 million to the 3.05MW E-101 having an AEP of 39.6GWh and an NPV of $4.5 million and finally the 2.5MW E-115 having an AEP of 49.4GWh and an NPV of $10.1 million. While the same turbines at Crown Point had higher AEPs and thus higher NPVs.

On the financial parameters tab in SAM, the PPA price was specified as 0.13¢/kWh and SAM calculated the IRR each year to meet that PPA price. The 20th year was chosen to display its IRR in the metrics tables. The IRR was a cumulative after-tax value, so much like the NPV, it increased each year. The IRR values of the AN Bonus in Table 3 are both negative as the NPVs are quite low, a trend is seen throughout the metric tables that as the NPV increases, the internal rate of return (IRR) does as well as they are from the same formula. The highest IRR is seen from the highest NPV which occurs with the E-115.

From a technical and economic perspective, the best wind farm option is the one comprised of the Enercon E-115 both at Crown Point and Piarco. As was mentioned before, although the 2.5MW E-115 is less than 3MW, its larger (115m) rotor diameter and tall (92.5m) hub height grant it access to a larger swept area and higher, more consistent wind speeds at both sites. This significantly increased its AEP which in turn ensured a high NPV and by extension high IRR. Compared to the rated wind speeds of the E-82 E3 and E-101, the E-115 has a lower value which decreased its LCOE making it even more attractive for investment. The second-best option would be the 3.05MW E-101 owing to its large 101m rotor diameter and 99m hub height, while the worst option would be the 2MW AN Bonus resulting from its short 76m rotor diameter and 60m hub height.

## CONCLUSIONS

The monthly energy production outputs of the wind farms were used to calculate the number of households that could be powered each month. The results obtained via the simulations are promising and were validated by various sources including a report by the NREL. They show that with proper legislative amendments and public education, RE energy projects such as wind and solar farms can create employment opportunities in different sectors, reduce carbon emissions in the three main emitting sectors and diversify the local oil and natural gas-based economy.

## ABSTRACT

Advancing student understanding of process design requires a balanced integration of theoretical knowledge with real-world industrial applications. This study introduces system design thinking-based learning through an engineering clinic approach that bridges the gap between classroom concepts and chemical engineering practice. Using an industrial multiproduct oil pipeline operation as a case study, students are exposed to real-world industrial systems, identify bottlenecks in a process, draw similarities between systems at different scales, and implement control strategies to address a practical industrial problem. In this study, we highlight the collaborative efforts between faculty, students, and industry partners to provide experiential learning in process design, modeling, and control to address the challenge of minimizing product loss during flushing operations in multiproduct petroleum pipeline systems.

## 1. INTRODUCTION

### 1.1 Motivation

The chemical industry is vast, spanning more than 70, 000 products, including ceramics, food, fuels, industrial gases, petrochemicals, pharmaceuticals, plastics, and textiles [1]. Recent advancements in chemical engineering practices have evolved towards increasingly integrated, complex, and data-rich systems operating under tight economic, thermodynamic, environmental, and safety constraints. Modern process industries require engineers who can reason across interconnected systems, predict dynamic interactions, and make informed decisions under uncertainty and variability [2]. Consequently, there is a growing need for systems and holistic design thinking approaches in both industrial practice and engineering education.

### 1.2 Gap in undergraduate process design and modeling instructions

Despite the shift in modern industrial practices, many undergraduate courses in process design and modeling often remain fragmented. Process design is typically taught as a capstone experience focused on steady-state analysis, equipment sizing, safety, and economic evaluations. Process modeling, on the other hand, is often introduced in the curriculum, with an emphasis on mathematical formulation and analytical solution techniques. Although each course addresses essential competencies, the lack of explicit integration can limit students' ability to understand how design decisions influence the dynamic behavior, operability, and optimization of real processes. Considering the traditional process design and modeling curriculum, students are frequently exposed to modeling in abstract contexts, with limited opportunities to validate models against physical systems and experimental data. In addition, modeling instances for some students is regarded as a purely mathematical exercise rather than a decision-support tool [3].

This disconnect is evident when students encounter industrial problems that do not conform to textbook assumptions. Real systems are subject to transient behavior, nonideal mixing behavior, uncertainties in measurements, equipment limitations, and complex operational

constraints and performance objectives [4]. In such contexts, mathematical models alone are not sufficient; engineers continuously validate theories with experimental data, revise assumptions, and evaluate trade-offs to refine established mathematical models to capture the entire system behavior. Traditional coursework often relies on well-defined problems with complete information and predetermined solutions. In contrast, industrial problems are typically constrained by incomplete data, uncertainties in measurements, design flaws, practical limitations, and operational inefficiencies, as in the case of trial-and-error in most industrial applications.

Thus, it highlights the importance of systems design thinking, an approach that emphasizes understanding interactions among system components, recognizing feedback and nonlinearities, and iteratively refining solutions based on data and constraints. Systems design thinking expands beyond component-level optimization of processes to systems-level performance, enabling students to reason about cause-effect relationships, nonlinearities, and uncertainties associated with processes. This is a critical aspect in chemical engineering because of the coupled nature of process units, material properties (physical, chemical, structural, and thermodynamic), control strategies, and operational decisions and constraints.

### 1.3 Contributions of systems-oriented process education

This paper presents a systems-oriented, engineering clinic-based approach to teaching process design and modeling. The approach integrates systems design thinking with engineering clinics and project-based environments, emphasizing the direct application of classroom concepts, design, experimentation, and system-level decision-making.

The contributions of this study are threefold. First, this study articulates a structured engineering clinic framework that embeds systems design thinking into the undergraduate curriculum. The framework emphasizes problem identification, experimental setup, stem boundary definitions, and trade-off analysis, enabling students to think holistically about complex processes. Second, it demonstrates how engineering clinics and project-based learning can be used to operationalize this framework through collaborative, industry-inspired problem-solving that mirrors professional industrial practice. Finally, a case study is introduced to demonstrate how pilot-scale experimentation and modeling efforts can be integrated to support iterative design refinements and operational optimization. These contributions are demonstrated through an industrially motivated case study focused on minimizing product loss during flushing operations in petroleum pipelines. The case study requires students to integrate fluid dynamics, process scale-up and scale-down, mixing behavior, experimental analysis, and modeling to minimize product loss, operational downtime, and enhance overall operational productivity.

## 2. SYSTEMS DESIGN THINKING LEARNING APPROACH

### 2.1 Motivation for systems design thinking

Process design and modeling are inherently system-level activities. Teaching these concepts requires students to operate at multiple levels of abstraction, often simultaneously. Students must reason from physical intuition to mathematical representation, from component to system-level performance, and from theoretical concepts to practical design decisions. The systems design thinking framework addresses the challenge of the traditional approach to process design and modeling by structuring how students connect, organize, and apply classroom knowledge during design processes and decision-making. Rather than treating design as a culminating activity that follows analysis, the framework positions design thinking as a principle that integrates modeling, design, analysis, and experimentation. This strategy supports cognitive learning [5] by helping students develop mental models of how process units and signals interact and how design decisions propagate in real systems.

Process design and modeling are rarely linear activities; assumptions evolve, models are refined, and design objectives are revisited based on newly acquired data. Thus, systems design thinking legitimizes this iteration as a core learning activity, urging students to treat design, modeling, and experimentation as complementary tools for understanding and improving system performance. This approach mirrors the way engineers approach complex industrial problems. Hence, students learn not only how to model or design a process, but also why a particular modeling approach is appropriate, what its limitations are, and how it informs design decisions. In essence, systems design thinking serves as a bridge between foundational engineering science and real-world design practice. The framework provides students with a repeatable cognitive strategy for navigating complexity, enabling them to approach complex and new problems with confidence, adaptability, and engineering decision-making.

### 2.2 Engineering Clinic-Based Approach

#### 2.2.1 Concepts of engineering clinics

The engineering clinic program provides a sustainable approach to engineering education that fosters an understanding of theoretical concepts and their application. This is deeply rooted in the top skills defined by the World Economic Forum for being a great engineer. These skills include critical thinking, creativity, people

management, problem-solving, and teamwork [6]. A defining feature of the engineering clinic program is its integration with the core concepts of systems design thinking. Within the clinic projects, students are introduced to an authentic context where systems design thinking can be practiced, tested, and refined.

The engineering clinic program is a hallmark of the undergraduate curriculum at Rowan University. Students are introduced to the clinic program early on, thus spanning the first to final year of their educational journey. Within the clinic program, students:

- Work on open-ended, industry-relevant problems,
- Get the opportunities to engage with stakeholders from federal agencies and industries,
- Get the opportunity to collaborate in multidisciplinary teams,
- Engage with real data, physical constraints, and uncertainties to provide solutions to real-world problems,
- Apply systems design thinking concepts in modeling, experimentation, and design decisions.

These experiences, coupled with classroom concepts, provide a perspective that is essential for preparing students for contemporary industrial and research environments.

### 2.2.2 Engineering clinics layout

The engineering clinic primarily encompasses dynamic collaboration between student teams (graduate and undergraduate), faculty, and industry, creating a rich educational environment. The Chemical Engineering Department at Rowan University maintains a research-intensive culture and partnerships with diverse federal and industrial organizations. Notable collaborations are with the petrochemical industry, such as ExxonMobil and Valero Energy Corporation; pharmaceutical industry, such as Eli Lilly, AstraZeneca, Bristol Myers Squibb, and Pfizer; food and beverage industry, such as Nestle; specialty chemical industry, such as DuPont and PennAKem; and federal agencies, such as U.S. Environmental Protection Agency (EPA), U.S. Department of Energy, U.S. Army amongst others.

Within the first year, students are introduced to foundational engineering skills designed to develop analytical thinking and support reason-based learning. Building on this foundation, the second year emphasizes technical communication, with focused instruction on technical writing, data presentation, and oral communication—skills essential for effective documentation and professional practice. By the third and final year, students have accumulated sufficient theoretical knowledge and experiential learning to engage in discipline-specific and open-ended research projects. These projects are conducted under the joint supervision of graduate student mentors and faculty advisors, allowing students to integrate their prior coursework with applied research and design activities.

This curricular progression enables process design and modeling to be taught as integrated, system-level activities that reflect how engineering problems are addressed in professional and industrial settings. As students transition into upper-level clinics and research experiences, they are no longer positioned as passive recipients of problem statements but as active participants in defining, interpreting, and refining engineering challenges. Projects are initiated with an emphasis on understanding the overall system objectives, operational context, and performance criteria, often through direct engagement with industrial partners. These interactions expose students to realistic constraints, competing objectives, and evolving project requirements, reinforcing the necessity of system-level thinking from the outset.

In this environment, process design and modeling emerge as complementary tools for reasoning about complex systems rather than isolated technical deliverables. Students use models to formalize their understanding of a system, evaluate design alternatives, and anticipate system behavior under varying operating conditions. Design decisions are revisited iteratively as new experimental data, pilot-scale observations, and stakeholder feedback become available. This iterative refinement mirrors industrial design workflows, where models evolve alongside system understanding and are continuously validated against the physical behavior. Through sustained engagement in this end-to-end design process, students develop a holistic perspective of how process modeling informs design, optimization, and decision-making within complex engineered systems.

### 2.2.3 Student grading and assessment rubric

While the clinic framework defines how students engage with systems-oriented design problems, meaningful learning also depends on the performance evaluation of the students. To ensure alignment between instructional objectives and student outcomes, assessment strategies must reflect the iterative, integrative, and collaborative nature of clinical experiences. Accordingly, a structured grading rubric was developed to evaluate student performance across technical, analytical, and professional dimensions [7]. The rubric was informed by the work of Drs. Kevin Dahm, James, and Heidi Newell emphasize that effective assessment of complex engineering tasks requires clearly defined performance criteria, explicit achievement levels, and consistency across evaluators. Their framework highlights the importance of moving beyond purely outcome-based grading toward assessment approaches that capture students'

reasoning, decision-making, and progression over time.

Consistent with this perspective, the rubric used in this study decomposes student performance into measurable categories aligned with the learning objectives of systems-oriented process design and modeling. These categories include problem formulation and system definition, appropriateness and justification of the modeling assumptions, integration of experimental data, quality of design decisions, and effectiveness of technical communication. Each category is evaluated using descriptive performance levels that articulate expectations for novice, developing, and proficient work. This structure enables evaluators to assess both the quality of the final deliverables and the rigor of the underlying design process, while also improving transparency for students and enhancing reliability in a team-based, open-ended learning environment.

## 3. CASE-STUDY OVERVIEW

Here, we present a case study grounded in Computer-Aided Process Engineering (CAPE), integrating process modeling, flowsheet synthesis, and systems-level design. Students develop and simulate flowsheets, scale-down industrial processes to pilot scale, and create CAD-based representations, with emphasis on instrumentation, control, and model-informed decision-making to bridge design and implementation. The scope of the project is to minimize oil downgrade during flushing operations in multiproduct petroleum pipelines. Batch transportation is mainly used in multiproduct oil pipelines, which refer to a network of interconnected pipelines for the continuous transport of several types of oil products in succession [8, 9]. The case study presented in this section explores the lubricant oil industry, which is a subsidiary of the petroleum industry. Unlike conventional pipeline systems, lubricant pipelines accommodate multiple oil grades with stricter quality tolerances and navigate intricate network layouts with bends, filters, and varied geometries, as illustrated in **Figure 1**.

One of the major operational challenges in multiproduct pipelines is product cross-contamination at the interface between oil product batches. The sequential transport of different petroleum products through the same pipeline results in a certain degree of mixing at the interface, leading to a mixture known as transmix or commingled oil. This transmix must be managed carefully to avoid contamination of the products, often requiring reprocessing, which increases operational costs.

A typical lubricant oil industry produces between 1, 500–2, 000 varied products annually. This production process is often segmented across distinct product lines, all converging into a single packaging line as illustrated in **Figure 1**, where residues from previous batches can accumulate and adhere to the walls of the pipelines. As highlighted previously, the issue of interfacial mixing becomes a problem where, due to the mode of transport, there is residue accumulation, impacting the quality of subsequent products. The residues not only compromise product quality and yield but also result in significant financial losses. To mitigate this, industries employ intermittent cleaning between product changeovers, known as flushing. Industries with aqueous or solid-based products usually rinse pipelines with water or inert gas, followed by drying before the next cycle. Unfortunately, oil-based systems found in lubricant manufacturing and blending pose a unique challenge because aqueous media cannot be used for cleaning [10].

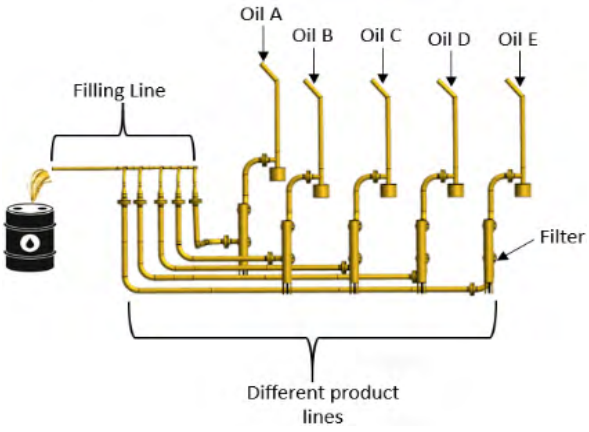

**Figure 1**. Schematic of a multiproduct pipeline with several products connected to a common filling line for lubricant oil packaging.

The products produced are often destined for sensitive applications, such as in automotive engines and turbines, where even small amounts of contamination would impair performance. Hence, pipeline flushing is a frequently scheduled operation to avoid contamination and mixing of consecutive product batches. The lubricant oil industry usually employs a product changeover operation that involves two stages: (i) removal of the previous (residual) oils from straight sections via the pipeline inspection gauges (PIGs), which is 97% efficient in residual displacement, and (ii) oil removal from the sections with varying diameters, auxiliary equipment, bends, and turns, often known as the unpiggable sections. Stage (ii) is usually accomplished by passing the new oil through the unpiggable section until the residual oil is displaced from the pipeline [9, 11]. This process inevitably leads to the formation of mixed oil segments, which are of limited economic value and must be carefully managed.

At present, flushing operations in lubricant pipelines remain empirical, relying on operators' experience and trial-and-error approaches to determine flush times and volumes. Even at this, industrial practices themselves differ significantly; each facility adopts unique operational procedures, flush volumes, and sequencing protocols

based on experience rather than predictive understanding. This lack of standardization across operators results in inconsistent outcomes, and suboptimal use of resources. This lack of predictive capability results in long hold times, downgrading of high-value products, and substantial capital losses. The operational inefficiency of current practices, combined with the complexity of lubricant pipeline networks, highlights the need for environmentally friendly, cost-effective, and energy-efficient solutions to optimize flushing operations.

Having established the industrial context and technical scope of the case study, the following section describes how the project was intentionally structured to guide students through the core stages of process design and modeling using a systems design thinking approach.

# 4. SOLUTION DEVELOPMENT

## 4.1 Experiential learning: engagement with stakeholders and design objectives

Following an initial preview of the industrial challenge, students were guided to move beyond a qualitative problem statement toward the formulation of explicit engineering objectives using a systems design thinking approach. Upon visits to the plant and engagement with stakeholders, students identified persistent inefficiencies during product changeovers in multiproduct pipelines, where flushing operations relied heavily on trial-and-error practices, leading to excessive use of resources, oil for flushing, extended downtime, large volumes of mixed oil formation, and inconsistent product quality. From this context, students were tasked with translating the operational inefficiencies into quantifiable and actionable engineering goals. Two primary objectives emerged: (i) the development of a standardized, repeatable flushing protocol applicable across a range of operating conditions, and (ii) the replacement of heuristic decision-making with a model-based framework capable of supporting smart, data-driven operations.

To achieve these objectives, students engaged in structured and iterative interactions with multiple stakeholders, including plant operators, process engineers, and technical managers. These engagements were conducted through scheduled meetings, progress reviews, and informal technical discussions, providing students with firsthand exposure to professional communication in an industrial setting. Through this process, students learned to elicit requirements, negotiate technical expectations, and reconcile conflicting constraints, which are key competencies in requirements engineering. Importantly, students quickly recognized that any proposed solution would need to be economically viable and minimally disruptive to existing operations, reinforcing the necessity of designing under real-world constraints rather than idealized assumptions. As part of the experiential learning process, students explored alternative approaches to conventional flushing strategies and evaluated their feasibility relative to cost, scalability, and operational complexity. Some of the potential flushing alternatives explored included pipeline coating [12], fluid blasting [13], gel pigging [14], amongst others. These explorations revealed significant limitations associated with intrusive process modifications, prompting a shift toward low-cost, adaptable solutions. This realization ultimately motivated the decision to replicate industrial operations at pilot scale, enabling controlled experimentation while preserving fidelity to real plant behavior. Through this phase, students internalized systems design principles by learning to balance technical ambition with economic and operational realities.

## 4.2 Pilot plant architecture: design constraints, equipment, and validation approach

A central element of the project involved the design and construction of a pilot plant capable of mirroring the dynamics of the industrial flushing operation. Students were introduced to a fundamental question in process design: how do we design a system mimicking the industrial operation? [15] and tasked with translating conceptual objectives into a physical system. This required decisions regarding equipment selection, piping configuration, sensor placement, control architecture, and data acquisition systems, all of which were informed by both classroom theory and industrial input.

The pilot plant was intentionally designed to serve as both a physical testbed and the foundation of a cyber-physical system. Students evaluated which unit operations and components were essential to replicate industrial behavior, and which could be simplified without compromising system integrity. Key considerations included flow regimes, viscosity contrasts between fluids, the right choice of pump considering the nature of lubricant oils, and the impact of pipeline geometry on mixing behavior. Scaling down from industrial to pilot scale required students to apply principles of similitude and dimensional analysis, assessing the effects of flow rates, pipe geometries, and fluid properties on fluid transport and the ability to replicate the larger system. Product purity determination is done through viscosity testing, as it reflects the functional performance of the lubricant oil product. For instance, if the oil viscosity deviates from specification, it may fail to reduce friction, prevent wear, and dissipate heat.

At industry, this is tested through sampling at the end of each flush operation. As part of the equipment installed on the pilot plant, students installed an in-line viscometer for continuous viscosity measurement during the flushing. The interactions of all equipment installed

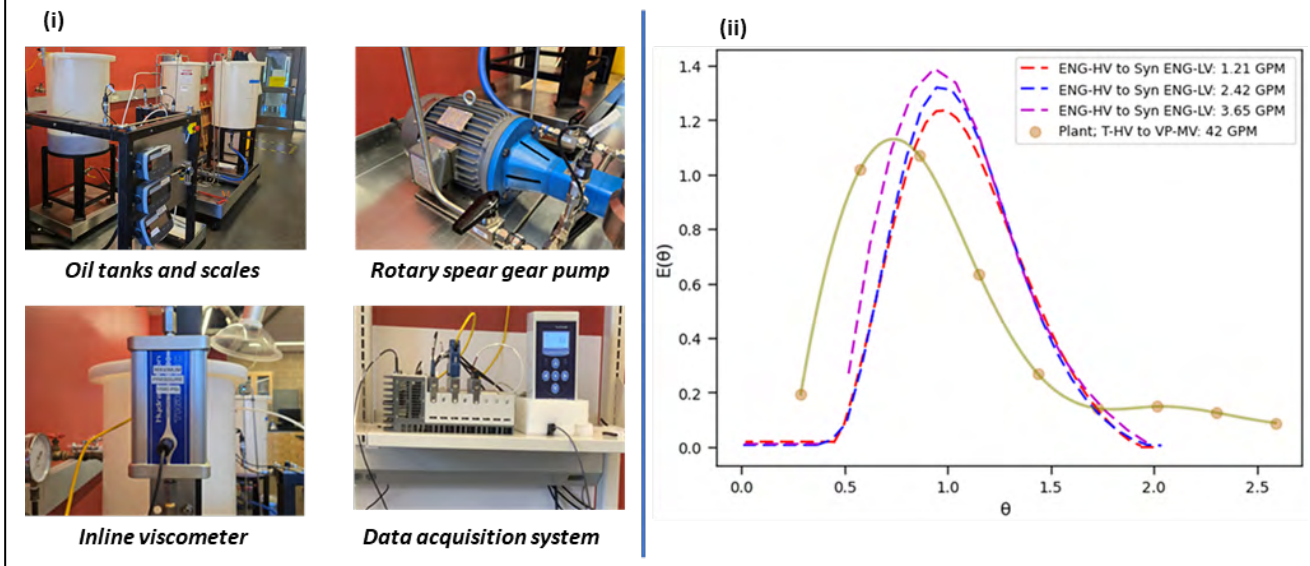

**Figure 2**. Developed 1/5th industrial-scale pilot plant illustrating (i) the equipment installed in the pilot plant (oil tanks, scales-for mass balance; rotary spear gear pump-for pumping the high viscous lubricant oils; inline viscometer-for real-time viscosity measurement; and data acquisition system-for seamless integration of all measurements and data collection) and (ii) the validation between pilot and industrial plant through residence time distribution studies-a plot of dimensionless RTD, E($\Theta$) against dimensionless time, $\Theta$.

are through a data acquisition system, which integrates all these components in LabVIEW programming to collect data across multiple channels. Simultaneously, students are introduced to the fundamentals of process instrumentation and data acquisition framework, selecting sensors capable of capturing relevant process variables such as pump power, pressure, viscosity, temperature, and change in mass. Emphasis was placed on understanding how different signals are generated, interpreted, and integrated to produce actionable insight.

To validate the fidelity of the pilot plant, students conducted residence time distribution (RTD) studies comparing experimental results against theoretical expectations and industrial data. These experiments provided a concrete mechanism for students to assess whether the scaled system accurately reflected industrial dynamics [9, 16]. This phase of the project tightly coupled classroom concepts, transport phenomena, process dynamics, and control, with hands-on engineering design. By building a physical system that directly informed modeling efforts, students experienced the full lifecycle of process design, from abstraction to implementation. This is depicted in **Figure 2**. The pilot plant thus became a critical educational bridge, reinforcing systems thinking while anchoring modeling activities in observable, real-world behavior.

## 4.3 Modeling strategy: systems-level decision support tool

With experimental infrastructure in place, students transitioned to the development of process models intended to capture the flushing dynamics observed in the pilot plant. Rather than prescribing a single modeling approach, students were guided to evaluate alternative strategies, including mechanistic, data-driven, and hybrid models. This evaluation required students to reflect on the purpose of the model prediction, optimization, or decision support and to select an approach consistent with available data, computational complexity, and interpretability. A critical aspect of the process modeling is what is referred to as "*know-how*" for processes. Thus, students were exposed to the theories of process dynamics: how a process changes over time; process identification: building a model from process data; and process control: what are the parameters of interest to keep the process at desired conditions, all of which are key in understanding and developing a model for the flushing process. Emphasis was placed on ensuring that the model assumptions were clear and consistent. Students were encouraged to justify assumptions related to flow behavior, mixing efficiency, and parameter estimation, and to assess the impact of these assumptions on the model accuracy. Parameter identification was performed using experimental data obtained from the pilot plant, reinforcing the iterative relationship between modeling and experimentation. Through this process, students learned that models are not static representations, but evolving tools that must be continually refined as new data becomes available.

From an instructional standpoint, modeling was

framed as a decision-making tool rather than an abstract mathematical exercise. Students evaluated model limitations, explored sensitivity to key parameters, and assessed the trade-off between model fidelity and usability. This approach helped students develop an appreciation for "fit-for-purpose" modeling, where the goal is not maximum complexity, but actionable insight. Results from the developed models on some test case flushing experiments are depicted in **Figure 3**.

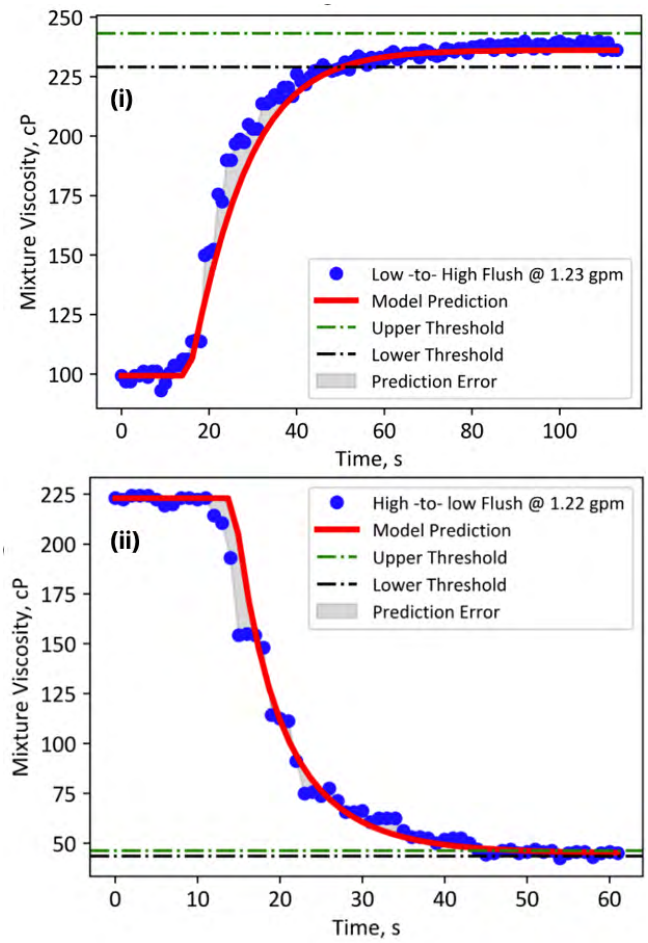

**Figure 3.** Sample model results validated against experimental flush data performed on the pilot plant for (i) a change from a low viscosity oil to a high viscosity oil and (ii) a change from a high viscosity oil to a low viscosity oil.

The final stage of the project focused on translating validated models into decision support tools capable of informing operational strategy. Students employed their models to evaluate economic, temporal, and performance-based metrics associated with different flushing scenarios. These analyses included minimizing flushing time, enhancing the effective use of oil during flushing, and identifying operating conditions that balance efficiency with robustness.

Optimization was introduced as an extension of design thinking rather than a purely mathematical construct. Students explored trade-offs between competing objectives and learned to interpret optimization results within the broader system context. This systems-level perspective reinforced the idea that optimal solutions are contingent on constraints, uncertainty, and stakeholder priorities.

Through this stage, students completed the full cycle of process design and modeling from problem formulation to decision support, demonstrating how systems design thinking can be effectively embedded within undergraduate education. The case study thus served not only as a technical challenge but as a structured learning environment in which students developed professional competencies essential for modern process engineers.

## 5. STUDENT LEARNING OUTCOMES AND CONCLUSION

This case study demonstrates how a research-integrated clinic framework can be intentionally structured to teach process design and modeling as interconnected, systems-oriented competencies rather than isolated technical skills. By exposing students to critical industrial challenges, the project enabled students to experience the full engineering design lifecycle from problem definition and stakeholder engagement to modeling, experimentation, and decision support. Rather than receiving predefined objectives or idealized datasets, students were required to translate ambiguous operational challenges into structured engineering goals, reinforcing the central role of problem formulation in professional practice. From a learning perspective, the project fostered student development across multiple dimensions. Early engagement with industrial stakeholders strengthened professional communication skills and exposed students to requirements engineering under real-world constraints. Students learned to negotiate technical feasibility, economic limitations, and operational practicality while maintaining alignment with overarching system objectives. These experiences directly supported the development of systems thinking, as students were required to consider how design choices influenced overall process performance.

The design and validation of the pilot plant played a critical role in bridging theory and practice. Through scaling analysis, equipment selection, and residence time distribution studies, students applied foundational concepts from transport phenomena and process dynamics in a real-world setting. The developed pilot plant reinforced the importance of experimental and model validation, exposing students to the limitations of purely theoretical models. Also, students gained experience in data acquisition systems and interpreting real process signals, skills that are increasingly essential in modern, data-rich

industrial environments. Modeling activities further deepened student understanding by reframing models as decision-support tools rather than purely predictive constructs. By comparing mechanistic, data-driven, and hybrid approaches, students developed an appreciation for model selection, assumption transparency, and parameter identification. Sensitivity analysis and model validation exercises helped students recognize the trade-offs between fidelity, interpretability, and usability, ensuring critical judgment in model-based decision-making.

Overall, the case study illustrates how process design and modeling can be taught holistically through experiential, industry-engaged learning. Students completing the project demonstrated measurable gains in systems thinking, professional communication, experimental design, and model-based reasoning. More importantly, they developed a mindset aligned with contemporary engineering practice, one that values integration, iteration, and informed decision-making under uncertainty. These outcomes and exposure ensured that students are prepared for the multifaceted challenges of modern process engineering, while the clinic framework provides a replicable model for experiential learning at other institutions.

## ABSTRACT

The accelerating social, environmental, and economic challenges of the twenty-first century call The growing complexity of sustainability challenges calls for educational approaches that integrate technical analysis with multi-stakeholder decision-making. Industrial ecology (IE) provides a relevant framework by combining systems thinking, resource flow analysis, and socio-environmental considerations. However, it is still predominantly taught through traditional lecture-based methods, limiting students' ability to engage with real-world complexity. This paper proposes and evaluates an experiential pedagogical framework based on industrial ecology, combining stakeholder role-play, industrial symbiosis scenario design, and multi-criteria decision analysis (MCDA). Implemented in a semester-long course, the framework enables students to collaboratively design and evaluate resource-exchange networks while representing different stakeholder perspectives. Results show significant improvements in both technical skills (systems analysis, resource flow evaluation) and transversal competencies (communication, negotiation, reflexivity). The approach enhances student engagement and highlights the role of value judgments in sustainability decision-making. The framework offers a transferable methodology for sustainability education in engineering and related disciplines.

## I. PEDAGOGICAL CONTEXT

### 1.1. Industrial Ecology as a Discipline

Industrial ecology (IE) conceptualizes industrial systems by analogy with natural ecosystems, emphasizing the circulation of materials, energy, and information across production and consumption networks. Emerging in the late 20th century, it aims to move beyond linear resource use toward circular and regenerative models [1]. At its core, IE studies how industrial processes interact with the environment and how waste from one system can become a resource for another, thereby reducing overall environmental impacts.

A defining feature of IE is its systemic perspective. Rather than focusing on isolated processes, it situates them within broader socio-technical and environmental contexts. Tools such as material flow analysis (MFA), life-cycle assessment (LCA), optimization, and input-output analysis enable the evaluation of resource use and environmental impacts across multiple scales [2].

IE also incorporates socio-economic and institutional dimensions, as the implementation of industrial symbiosis depends on governance, economic incentives, and collaboration between actors [3]. As an interdisciplinary field bridging engineering, natural sciences, and social sciences, IE aligns with sustainability science.

In this work, industrial ecology is used as the central conceptual framework, providing a systemic approach to analyze resource flows and interactions between industrial actors. Within this framework, sustainability represents the overarching objective, while industrial symbiosis constitutes a key operational strategy to improve resource efficiency through exchanges of materials, energy, and water.

### 1.2. Pedagogical approaches to sustainability

Teaching sustainability in higher education requires approaches that reflect the complexity and multi-dimensionality of real-world challenges. Traditional lecture-based methods are often insufficient to prepare students

for integrative and participatory decision-making contexts [4]. As a result, active and experiential learning approaches are increasingly adopted.

Problem-based learning (PBL) encourages students to address open-ended problems, fostering critical thinking and autonomy [5]. Similarly, experiential learning frames education as a process combining experience, reflection, and application, helping students connect theory with practice [6].

Role-play exercises are particularly relevant in sustainability education. By assigning students to different stakeholders, they expose learners to diverse perspectives and highlight the negotiation processes inherent in sustainability governance [7]. These activities develop communication, systems thinking, and the ability to handle conflicting objectives.

Together, these approaches support transformative learning, fostering reflexivity, value awareness, and collaborative problem-solving skills [8]. They enable students to combine analytical tools with the interpersonal competencies required for multi-actor sustainability decision-making.

### 1.3. Decision-making in sustainability contexts

Sustainability challenges are characterized by complexity, uncertainty, and conflict among diverse objectives. Decisions in this domain rarely involve clear and solutions, rather, they require balancing environmental, economic, and social dimensions while reconciling the interests of multiple stakeholders. This complexity demands structured decision-support approaches that can make trade-offs explicit, enable transparent evaluation of alternatives, and facilitate negotiation among actors with divergent priorities.

One widely used tool in sustainability contexts is multi-criteria decision analysis (MCDA). Unlike single-objective optimization methods, MCDA allows decision-makers to assess alternatives across multiple, often conflicting criteria [9]. In sustainability applications, these criteria might include cost, different environmental impacts (especially when dealing with Life cycle assessment approaches LCA), social equity, and feasibility. By assigning weights to criteria and scoring alternatives, MCDA provides a structured framework to illuminate tensions, clarify stakeholder preferences, and identify options that balance competing objectives. These methods do not eliminate conflict but instead makes value judgments explicit, thereby fostering more informed and transparent discussions.

Beyond quantitative tools, decision-making in sustainability also relies heavily on deliberative and participatory approaches. These methods emphasize the inclusion of diverse perspectives in decision processes, acknowledging that technical expertise alone cannot determine sustainable outcomes [10]. Stakeholder engagement, negotiation, and dialogue are therefore critical components of sustainability governance, helping to build legitimacy, trust, and shared understanding. Role-play exercises in higher education mirror these dynamics, offering students a platform to practice the skills of advocacy, compromise, and consensus-building.

The integration of MCDA with participatory approaches represents a promising pathway for both real-world sustainability governance and pedagogy. While MCDA structures the technical assessment of trade-offs, participatory methods ensure that social values and actor perspectives are incorporated.

### 1.4. Gaps in current pedagogy

Despite growing interest in innovative approaches to sustainability education, significant gaps remain in how higher education prepares students to confront the complexity of sustainability challenges.

A key gap lies in the integration of technical and soft skills. Engineering and environmental programs frequently emphasize analytical tools, such as life-cycle assessment or material flow analysis, without providing opportunities for students to apply these tools in socially and institutionally complex settings. Conversely, pedagogical activities focused on dialogue or values exploration may neglect the technical rigor required for sustainability decision-making. Few educational models successfully combine both dimensions, leaving students either technically competent but low prepared for negotiation, or socially aware but lacking in analytical capabilities.

Another limitation concerns the representation of multi-actor dynamics. Sustainability problems are rarely solved by single actors and most classroom exercises do not capture these dynamics. It can lead to a lack of preparedness when graduates enter professional contexts where collaboration and conflict resolution are critical.

Finally, sustainability pedagogy has often underutilized the potential of industrial ecology as a teaching platform. While IE's systemic and interdisciplinary nature makes it highly relevant for experiential learning, its application in classroom exercises remains relatively limited compared to more established approaches such as case studies or project-based learning. Addressing these gaps requires educational models that merge technical analysis with stakeholder engagement, thereby reflecting the intertwined realities of sustainability transitions.

## II. METHODOLOGY: PEDAGOGICAL FRAMEWORK

Designing a pedagogical framework that both reflects the complexity of sustainability challenges and equips students with practical skills requires careful

consideration of teaching methods, learning environments, and assessment strategies. The approach presented here combines role-play, scenario design, and decision-support tools within the broader conceptual lens of industrial ecology (Fig.1). The framework is structured to simulate the dynamics of real-world sustainability governance while grounding student activities in the analytical tools of systems thinking. This section outlines the four main components of the approach: role-play and stakeholder simulation, scenario design and industrial symbiosis modeling, integration of decision-support methods, and organization of the learning environment including assessment.

## 2.1. Role-Play and Stakeholder Simulation

At the core of the pedagogical design is the use of role-play to represent the perspectives of diverse stakeholders. Students are divided into groups, with each group assigned to a specific role such as an industrial firm, a local authority, a non-governmental organization (NGO), or a community organization. The selection of roles reflects the variety of actors typically involved in industrial ecology initiatives and broader sustainability governance.

The role-play format serves several purposes. First, it compels students to adopt perspectives that may differ from their own, fostering empathy and the ability to understand conflicting values. For example, a group representing a manufacturing company may prioritize cost efficiency and competitiveness, while a community group might emphasize environmental justice or local employment. Second, role-play highlights the interdependencies between actors, as no single group can achieve sustainability objectives in isolation. Students must therefore engage in negotiation and coalition-building to advance their positions. Each group represents a distinct stakeholder rather than a single company. These stakeholders may include industrial firms, local authorities, NGOs, or community representatives, each reflecting different roles, interests, and decision-making perspectives within the eco-industrial system.

Role descriptions are designed to provide both structure and flexibility. Each group receives a background brief outlining its objectives, constraints, and potential strategies. These briefs include information on resource availability, financial limitations, and political pressures, ensuring that students grapple with realistic trade-offs. At the same time, students are encouraged to exercise creativity in developing arguments and strategies, thereby enhancing engagement and ownership of the learning process.

## 2.2. Scenario Design and Industrial Symbiosis Simulation

Following the role-play introduction, students are tasked with designing scenarios for an industrial symbiosis—networks in which waste or by-products from one industry become inputs for another. The exercise requires groups to collectively design a system of exchanges that balances environmental, economic, and social objectives. Scenario design is typically iterative: groups first propose preliminary ideas, then refine them through negotiation and systems analysis.

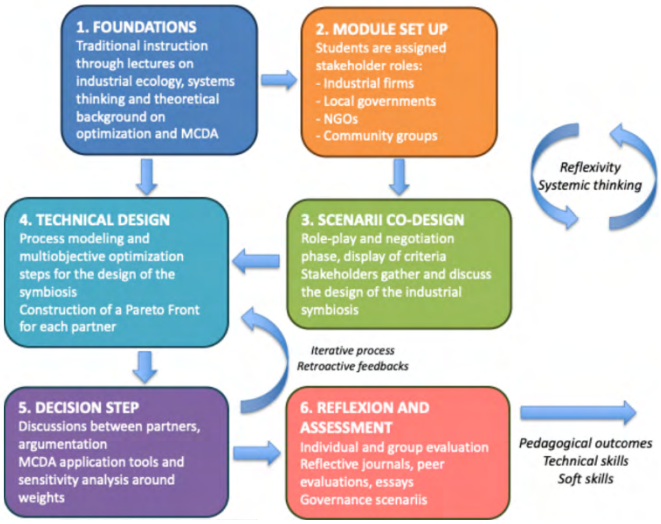

**Figure 1.** Implemented methodology

This stage emphasizes the systems perspective central to industrial ecology. Students must consider not only bilateral exchanges between firms but also the broader implications of network design, including resource efficiency, resilience, and social impacts. For instance, a proposed energy exchange between two companies may reduce carbon emissions but raise concerns about cost allocation or local employment effects. Students learn to map these interconnections and to identify synergies and conflicts.

The scenario design culminates in a simulation exercise in which the proposed system is tested through qualitative and quantitative analysis. Tools such as material flow analysis (MFA) or simplified life-cycle assessment (LCA) can be incorporated, depending on the technical background of the students. This analytical component ensures that the scenarios are evaluated not only on the basis of negotiation outcomes but also on their environmental and economic feasibility. By bridging stakeholder negotiation with technical evaluation, the exercise reflects the multi-dimensional character of real-world sustainability transitions.

## 2.3. Decision-Support Tools in the Classroom Learning Environment and Assessment

To structure the negotiation and scenario design process, decision-support tools are introduced, with particular emphasis on multi-criteria decision analysis

(MCDA). MCDA provides a formal framework for evaluating alternatives across multiple dimensions, thereby making explicit the trade-offs inherent in sustainability decision-making.

In practice, the exercise proceeds by defining a set of evaluation criteria that represent the interests of different stakeholders, such as greenhouse gas emissions, operational costs, social equity, and local employment. Each group assigns relative weights to the evaluation criteria through a structured discussion process reflecting their stakeholder priorities. This process may involve direct allocation (e.g., distributing 100 points across criteria) or qualitative ranking followed by normalization. Differences in weights between groups are preserved to reflect conflicting perspectives and to support subsequent negotiation.

The introduction of MCDA has several pedagogical benefits. It compels students to translate qualitative arguments into quantitative or semi-quantitative terms, thereby sharpening analytical skills. It also highlights the value-laden nature of sustainability decision-making: results vary depending on the weights assigned to different criteria, and no scenario is universally optimal. This reinforces the importance of negotiation, compromise, and reflexivity. In addition, the use of MCDA familiarizes students with a widely applied decision-support tool, enhancing their methodological repertoire for future professional contexts.

While MCDA is the central tool in this framework, other decision-support methods can be incorporated, including scenario analysis, cost-benefit analysis, or stakeholder mapping In practice, MCDA is implemented using simple spreadsheet-based tools or scoring matrices adapted to the students' level. Additional tools such as simplified MFA calculations, qualitative LCA indicators, or stakeholder mapping may also be used depending on course objectives and available time.

### 2.4. Learning Environment and Assessment

The successful implementation of this pedagogical framework requires careful design of the learning environment. The exercise is typically embedded in a semester-long course on industrial ecology or sustainability systems, with the role-play and scenario design component spanning several weeks. This duration allows for iterative negotiation, technical analysis, and reflection. Class sizes of 20–40 students are manageable, enabling multiple stakeholder groups while maintaining opportunities for instructor guidance. All groups participate in the evaluation process; however, the level of quantitative analysis may differ depending on the stakeholder role. Technically oriented groups (e.g., industrial actors) may perform more detailed calculations, while other stakeholders focus on qualitative assessment and interpretation of results.

The physical and digital learning environment is also significant. Face-to-face interaction supports negotiation and collaboration, while digital platforms can be used for scenario modelling, data sharing, and documentation. Hybrid or online adaptations are possible but require deliberate facilitation to ensure engagement.

Assessment is based on a combination of group and individual components. Group performance is evaluated through the quality, feasibility, and coherence of the proposed symbiosis scenario, including its technical and sustainability performance. Individual assessment is conducted through reflective reports, where students analyze their learning process, stakeholder role, and decision-making strategies. In some cases, peer evaluation is used to ensure balanced participation within groups.

Finally, the framework emphasizes formative feedback throughout the exercise. Instructors play a facilitative role, guiding discussions, posing critical questions, and helping students connect their experiences to broader theoretical concepts. Feedback sessions allow students to iteratively improve their scenarios and reflect on their group dynamics. Such scaffolding enhances the depth of learning and ensures that both technical and soft skills are developed in tandem.

## III. RESULTS AND DISCUSSION

The implementation of the pedagogical framework described in the previous section generated insights into both the acquisition of technical knowledge and the development of essential soft skills among students. By integrating role-play, scenario design, and decision-support tools within an industrial ecology context, the course fostered multidimensional learning experiences. This section presents and discusses the outcomes observed, highlighting the benefits, challenges, and broader implications for sustainability education.

### 3.1. Technical knowledge acquisition

One of the most significant outcomes of the exercise was the enhancement of students' technical understanding of industrial ecology concepts. The process of designing industrial symbiosis scenarios required students to engage deeply with material and energy flows, environmental impacts, and resource optimization strategies. Tools such as material flow analysis (MFA) and simplified life-cycle assessment (LCA) allowed students to quantify the efficiency of proposed exchanges and to evaluate environmental trade-offs systematically.

For example, groups representing industrial firms were able to identify potential waste streams that could be repurposed for other industries, reducing both costs and environmental footprints. Similarly, students in community and NGO roles highlighted the importance of local environmental quality and social equity, prompting teams

to adjust scenarios to mitigate negative externalities. Through these exercises, students developed the ability to integrate ecological, economic, and social considerations into the design of industrial networks. This aligns with prior studies emphasizing the value of experiential approaches in fostering systems thinking and applied technical knowledge (Graedel & Allenby, 2010; Chertow, 2000).

Moreover, the iterative nature of the scenario design encouraged students to refine their understanding of technical concepts. Initial proposals often revealed inefficiencies or conflicts that could only be resolved by revisiting calculations, redesigning material flows, or reconsidering energy exchanges. This iterative process mirrors real-world engineering practice, where problem-solving is seldom linear, and decisions must account for interdependencies and constraints.

## 3.2. Development of soft skills

Equally important were the gains in soft skills, which are critical for sustainability governance but often underemphasized in technical curricula. Through stakeholder role-play and group negotiation, students practiced communication, collaboration, and conflict resolution in a structured environment. Negotiation exercises required groups to advocate for their assigned priorities while engaging with competing perspectives, promoting empathy and the ability to understand others' motivations.

**Table 1.** Summary of observed learning outcomes

| Learning dimension | Observed outcomes |
|---|---|
| Technical skills | Improved understanding of MFA, LCA, resource flows |
| Systems thinking | Ability to identify interdependencies and trade-offs |
| Communication | Enhanced argumentation and negotiation skills |
| Collaboration | Active participation in multi-stakeholder discussions |
| Reflexivity | Increased awareness of value-based decision-making |

The multi-actor nature of the exercise illuminated the challenges of consensus-building. Students frequently encountered conflicting objectives, such as balancing cost efficiency with environmental responsibility or reconciling industrial growth with community well-being. These tensions prompted discussions not only about technical feasibility but also about ethical considerations, power dynamics, and social responsibility. By navigating these interactions, students enhanced their capacity for collaborative problem-solving and developed an appreciation for the complexity inherent in multi-stakeholder decision-making (Table 1).

Reflective assignments and debriefing sessions further reinforced these soft skills. Students were asked to evaluate their own negotiation strategies, identify points of tension, and propose ways to improve communication and decision-making. Many reported heightened awareness of group dynamics, leadership roles, and the importance of framing arguments in terms understandable to diverse audiences. These outcomes are consistent with literature suggesting that experiential learning fosters both cognitive and interpersonal competencies [7, 8].

## 3.3. Student Engagement and Reflexivity

The combined technical and interpersonal focus of the exercise contributed to high levels of student engagement. Role-play and scenario design provided a sense of ownership and agency, motivating students to invest effort in both the analytical and negotiation components. Anecdotal observations and course feedback indicated that students were particularly responsive to the opportunity to see how individual decisions impacted the broader system, fostering a sense of responsibility and connection to real-world sustainability challenges.

Reflexivity was another important outcome. By participating in structured negotiation and decision-support exercises, students became aware of the underlying value judgments embedded in sustainability decisions. For instance, the use of multi-criteria decision analysis (MCDA) made explicit how differing stakeholder priorities influenced outcomes. Students recognized that "optimal" solutions are context-dependent and contingent upon the relative weighting of environmental, economic, and social criteria. This awareness of subjectivity in decision-making is crucial for preparing future professionals to engage constructively in contested sustainability arenas.

## 3.4. Challenges and Limitations

Despite the benefits, several challenges were identified in implementing the framework. First, the complexity of the exercise required careful scaffolding to prevent students from becoming overwhelmed. Some groups initially struggled to manage multiple criteria, stakeholder perspectives, and technical calculations simultaneously. Instructors played a critical role in guiding discussions, clarifying technical concepts, and facilitating negotiation to maintain momentum.

Second, participation levels varied within groups. While some students emerged as proactive leaders, others assumed more passive roles, highlighting the need for assessment strategies that capture both individual and collective contributions. Reflection journals and peer evaluations were useful in mitigating this issue, but variability in engagement remained a concern.

Third, time constraints limited the depth of analysis possible within a semester-long course. While students

were able to explore material flows, energy exchanges, and social impacts, more advanced modeling or quantitative assessment would require extended time or dedicated laboratory sessions. Nonetheless, the exercise successfully demonstrated the value of experiential learning even with these temporal limitations.

Finally, the exercise occasionally revealed tensions between realism and pedagogical objectives. While the scenarios aimed to simulate real-world complexities, simplifications were necessary to ensure accessibility for students with diverse technical backgrounds. Balancing fidelity to industrial ecology principles with the practical constraints of classroom implementation remains an ongoing challenge.

### 3.5. Comparative Reflection with Other Pedagogical Methods

Compared to traditional lectures or case-study approaches, the integrated role-play and scenario-based framework offers several advantages. It actively engages students in both technical and social dimensions of sustainability, bridging a gap that is often left unaddressed in conventional curricula. Unlike static case studies, which present resolved scenarios, this approach exposes students to dynamic negotiation, iterative problem-solving, and multi-stakeholder complexity.

Furthermore, the combination of MCDA with role-play provides a structured yet flexible framework for decision-making. Students are able to quantitatively evaluate trade-offs while simultaneously navigating qualitative stakeholder interactions. This dual emphasis fosters integrative thinking and mirrors professional contexts in sustainability engineering, where analytical rigor and interpersonal skills are equally important.

Nevertheless, the framework complements rather than replaces traditional methods. Foundational lectures, readings, and theoretical instruction remain essential to provide the conceptual grounding that supports applied exercises. The strength of the approach lies in its ability to translate theory into practice, illustrating the interconnectedness of environmental, social, and economic considerations while cultivating both technical and soft skills.

## IV. CONCLUSIONS AND PERSPECTIVES

The outcomes of the pedagogical framework presented in this study carry significant implications for the design and delivery of sustainability education in higher education. First, the integration of industrial ecology with experiential learning demonstrates the value of interdisciplinary approaches in preparing students to address complex, multi-dimensional challenges. By combining technical analysis with stakeholder engagement and negotiation exercises, the framework moves beyond traditional siloed instruction, reflecting the interconnected realities of sustainability practice. This suggests that engineering and environmental curricula can benefit from embedding experiential modules that actively connect theory to practice.

Second, the framework underscores the importance of developing both technical and soft skills. Modern sustainability challenges require professionals who can not only analyze material and energy flows but also navigate diverse stakeholder interests, communicate effectively, and mediate conflicts. The role-play and decision-support components of the exercise provide structured opportunities for students to cultivate these capabilities. Importantly, students develop a heightened awareness of the value-laden nature of sustainability decisions, gaining insight into how social, economic, and environmental priorities intersect and sometimes conflict. Integrating these skills into higher education curricula equips graduates to engage meaningfully in real-world decision-making contexts, enhancing their employability and professional effectiveness.

Third, the framework highlights the potential of experiential learning for fostering systems thinking and reflexivity**.** Students are required to evaluate the broader implications of their decisions within interconnected industrial networks, encouraging them to consider long-term, cross-scale consequences. Reflective assignments and debriefing sessions amplify this effect, prompting students to critically assess their assumptions, strategies, and learning processes. This aligns with the broader goal of sustainability education to produce graduates who are not only knowledgeable but also capable of adaptive, reflective problem-solving in complex and uncertain environments.

The framework also suggests avenues for scaling and adaptation**.** While developed for industrial ecology courses in engineering or environmental programs, the approach can be adapted to other disciplines concerned with sustainability, including business, policy, or urban planning. The combination of role-play, scenario analysis, and decision-support tools is sufficiently flexible to accommodate varying student backgrounds, learning objectives, and institutional contexts. Moreover, hybrid or digital implementations are possible, potentially expanding access to larger or more geographically distributed cohorts.

Finally, the study highlights the value of structured pedagogical innovation**.** Implementing such experiential frameworks requires careful planning, resources, and instructor facilitation. Success depends on balancing realism with manageability, scaffolding technical content alongside soft-skill development, and providing timely feedback. Institutions seeking to incorporate similar approaches must recognize that meaningful learning outcomes emerge not solely from the content itself but from the deliberate design of interactive, reflective, and

integrative learning experiences.

# Closing the Digital Gap: A Scaffolded Pathway for Developing Digitalisation Skills in Undergraduate Chemical Engineering Curricula

**E. Routoula[a], J. Bestenlehner[a], and M. Zandi[a]***

[a] University of Sheffield, School of Chemical Materials & Biological Engineering, Sheffield, UK

## ABSTRACT

Digital competency is now core to chemical engineering practice, yet the extent and coherence of digitalisation skills provision across undergraduate curricula remain uneven. This study maps qualitatively and qualitatively digital learning outcomes across undergraduate chemical engineering programmes at the University of Sheffield, against a digital skills framework (data analysis, process simulation, process automation & control, reproducible workflows, programming, data governance). In recent years, digital skills education within chemical engineering education has advanced considerably, driven by the broader industrial shift toward Industry 4.0 and reinforced by the global challenges. Academic institutions have begun to integrate digitalisation-related content more deliberately within syllabus, in alignment with degree programme accreditation requirements and industry needs. Beyond introductory spreadsheet manipulation and basic programming, many courses are now embedding more advanced digital capabilities, including data engineering, scientific programming, process analytics, and optimisation techniques. Results of this study reveal a scaffolded digital pathway, where students are exposed gradually through core taught content and applied knowledge activities to a variety of digital tools across their years of study in a by-design approach at earlier years that becomes organic later on. From limited exposure and credit correlation in Year 1, students complete Year 4 having at least quadrupled their exposure to digital tools, with higher credits awarded to "digital" in the case of particular elective modules or research projects. This study offers a methodology and a worked example for chemical engineering programmes seeking measurable uplift in Industry 4.0 readiness and impact on chemical engineering graduate outcomes.

## INTRODUCTION

The practice of chemical engineering is being fundamentally altered by Industry 4.0 and the rise of digitalisation. The industry relies more and more on automation, digital twins, advanced modelling, and data-centric decision-making strategies [1]; innovations that not only revolutionise how processes are designed and optimised, but are also redefining the core competencies expected of new graduates. Traditionally, undergraduate curriculums of chemical engineering programmes have included foundational tools like excel-based tools, drawing tools and use of industry-approved process simulation software [2], operating under the assumption that advanced digital proficiency would be acquired during employment. However, employer feedback and recent studies suggest this model is now inadequate, as companies increasingly identify gaps in digital skills competence of graduate recruits and have started requiring proof of digital competency during the recruitment phase [3].

In reaction to these demands, universities have integrated statistics, coding, process simulation, process systems engineering and optimisation into chemical engineering programmes [4], working alongside profes-

sional accreditation bodies and industry partners. Despite this, there is still significant ambiguity regarding the definition, progression, and consistent implementation of "Digital Chemical Engineering" (DCE) across different institutions, as digital skills is an emerging area not as well defined as others, especially given that digitalisation is under continuous development.

At the University of Sheffield, the undergraduate curriculum of chemical engineering underwent a major transformation in 2017 [5], introducing three curriculum pillars, Core Knowledge, Practical & Design, Enabling Science, each covered by revamped or newly-introduced modules. Alongside and intertwined with these pillars, employability skills were also envisioned as a key component, to ensure that graduates would have a strong technical and transferable skillset to add value to the workforce. Since then, substantial work has been done to ensure that employability is fully embedded into the curriculum [6, 7], without however discussing explicitly the emerging importance of digital skills or attempting a mapping of what and how much of is included in the curriculum in terms of digital skills.

In the UK, the accreditation guidelines of the Institute of Chemical Engineers (IChemE) and the Engineering Council with their Accreditation for Higher Education Programmes (AHEP4) guidelines set standards and expectations when it comes to programme-wide learning outcomes while allowing for flexible curriculum design. While both accreditation bodies mention digital tools and refer to particular digital skills, there is no clarity on the expected coverage of such skills in the curriculum.

This study delivers a qualitative and quantitative mapping of DCE content within IChemE-accredited chemical engineering programmes offered at the University of Sheffield, establishing a baseline for digital readiness and a mapping tool that can be used from other institutions.

## METHODOLOGY

### Data Collection and Curriculum Mapping

Following from output of a survey deployed to both industry and academic stakeholders in the chemical engineering sector to identify digital skills of importance and the level of graduate readiness across these skills [2], and using informed judgement and discussions across contributors who are all heavily involved with curriculum design in their respective institutions, DCE provision was classified across eight domains:

1. programming & computation: ability to understand, write, and execute code.
2. data literacy & statistics: understanding of statistical principles, use of data visualisation for effective data communication.
3. process modelling & simulation: use of specialised software to develop models and simulate unit operations.
4. optimisation & process systems engineering: use of systems engineering principles and algorithms to identify best possible variables.
5. control, automation & instrumentation: design and implementation of control systems to monitor and maintain process variables towards safe and stable plant operation.
6. AI/ML & digital twins: use of tools and software to identify patterns, development of virtual, real-time depiction of a process or plant that can be updated using process data, predict performance and diagnose issues in a simulated environment.
7. software engineering practices (version control, testing, reproducibility): tracking and managing changes to code over time, reverting to previous versions, ensuring reliable reproducibility.
8. data governance, ethics & cybersecurity: understand the importance of data storage, quality, security and access, address moral implications around the use of digital tools.

Using analysis of available information in module descriptors, learning outcomes, and assessment briefs where possible, supplemented by additional information based on knowledge of teaching specific courses or from communications with other module leaders, a mapping of the DCE curriculum provision for chemical engineering courses offered at the University of Sheffield was done against each domain, per year of study (years 1-3 for BEng courses and 1-4 for MEng courses). Mapping was done in a qualitative manner, indicating a "yes/no", with the option to provide representative examples or comments of how each domain content is covered where relevant. With the understanding of content being covered formally in the curriculum, i.e. core/taught and formatively assessed as a learning outcome, and informally, as by-product/applied, i.e. taught but not assessed, or implicitly expected in later years of study, mapping was designed to recognise both dimensions. Furthermore, a quantitative mapping approach was attempted, using module credits and/or hours of engagement, and the available information of the type and weight of assessment. Where such information was not readily available, an educated assumption was made. For example, for a 15 credit module that comprises of an assignment worth of 30% of the final mark, which has a clearly stated task of using a modelling software (ASPEN) worth of 20% of this assignment mark, the calculation of the credit resulted in

0.9 credits towards "process modelling & simulation" (D3). Given the rough correspondence of one credit to ten hours of learning activities, this would imply that at least nine hours of student learning would be devoted to D3 on this occasion.

Given the nature of the project, it is important to note that there might have been details on specific learning activities or assessments that were overlooked or underestimated resulting in mapping not being completely definitive, but nevertheless sufficient to highlight areas of more or less DCE coverage across the examined curricula.

## Data Analysis and Visualisation

Once mapping was completed, data was processed and analysed using Python (version 3.12.12) with matplotlib (version 3.10.0) and numpy (version 2.0.2) for visualisation and trend identification per domain and per year. Considering the qualitative nature of the mapping, an "instructional intensity" metric was developed to distinguish between the presence of a tool and the formal pedagogical delivery of a skill.

For the construction of the Hidden Curriculum Graph, a scale range was defined from 0 to 3, starting with absence of evidence (0), moving to evidenced presence of domain activities as curriculum byproducts with no formal assessment (1), as optional modules including assessed learning outcomes (2), and ending with evidenced domain activities in core modules with formally assessed learning outcomes (3). This range was used to quantify domain presence across the curriculum, with one entry per year. For example, for Domain X, if there was at least one module per year that contained formally assessed components relevant to that domain, the value on the graph would be 3 times 4, resulting in 12. Similarly, again for Domain X, if there was a module that required existing knowledge to be utilised but there was not formal assessment for that knowledge, the associated value would be 2. If there were two such modules in the same year, the associated value would still remain as 2.

# RESULTS AND DISCUSSION

Analysis of the curriculum mapping across domain and year of study (Figure 1) shows that all domains except Software Engineering Practices (D7) are covered through the chemical engineering curriculum of programmes offered at Sheffield. It is important to point out that this figure evidences the presence of a domain during a year group in at least one module, rather than the coverage of the domain, i.e. how well it is covered. Domain coverage will be discussed later on. For domains D2-5 and D8 there is coverage across multiple years, whereas D1 and D6 are covered only within a particular year through associated modules.

Especially for domains focusing on data literacy and statistics (D2), process modelling and simulation (D3) and data governance, ethics and cybersecurity (D8), presence in multiple year groups is expected, as knowledge contained within these domains (understanding of statistical principles, development of models and unit operation simulations, and an ethical approach to data management) forms the basics of chemical engineering education.

Looking into the areas of the curriculum where DCE was present in core taught content with formal assessment, analysis of the corresponding credit (Figure 2) indicated that DCE is worth credits in Years 1 and 2 with limited domain diversity (D2, D3 and at a very small fraction D5 are covered), but when reaching Years 3 and 4 the domain diversity and credit is higher (D1-D5 are covered). Data literacy and statistics (D2) accounts for the highest number of DCE credits across the curriculum, closely followed by process modelling and simulation (D3). It is worth pointing out that there is a very small credit value (0.027) accounted for D8 in Year 3, as a small part of one assessment component during the Design Project that discusses cybersecurity. Credit calculation took place through assessment briefs where available. According to the Quality Assurance Agency for Higher Education, 1 credit is roughly equal to 10 hours of notional learning. Figure 2 showcases the hours students are expected to engage with DCE within formally assessed elements of the curriculum, for example submission of process simulations using Aspen or other software as part of design projects, or assignments based on coding tools, or engagement with Excel as part of formulating a lab report. As a validation case study, looking at the "Process and Product Design" module students undertake in Year 2 and where they are introduced to the use of commercial simulators like Aspen for the first time, the calculated credit relevant to D3 for that module is 2.3, which corresponds to 23 hours. During this module, there are 14 hours of planned, guided tutorials on the use of Aspen, which implies that the rest 9 hours are based on self-study. This number might be a bit higher, given that there is an assignment and a Design Project Week students need to complete during this module, where the production of an Aspen model for a given process is a formal part of the assessment for both activities.

When looking at credit calculation across all domains per year (Figure 3, top left graph), it is evident that credit attributed to DCE raises per year of study, with a jump from Year 1 to Year 2 and another jump from Year 3 to Year 4.

This is expected, as the way the curriculum is currently structured at Sheffield is to focus on the fundamentals during earlier years of study and introduce more complex concepts and application of concepts later on. It

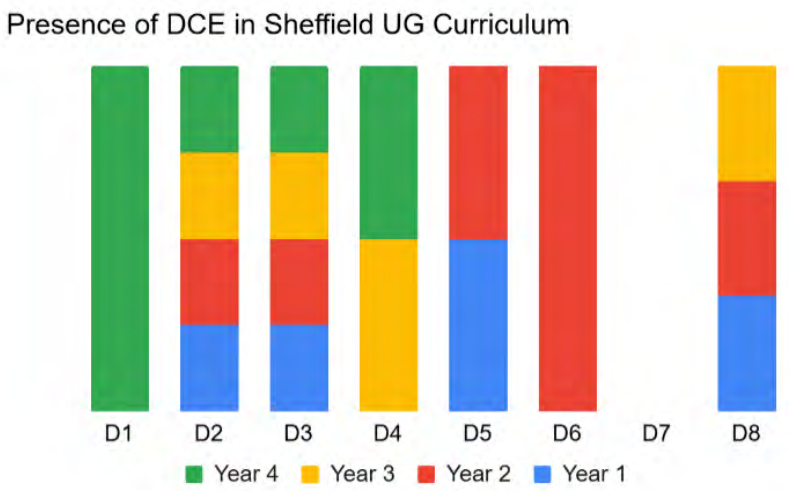

**Figure 1.** Coverage of DCE domains D1-8 in the Sheffield UG curriculum. D1: programming and computation, D2: data, literacy and statistics, D3: process modelling and simulation, D4: optimisation and PSE, D5: control automation and instrumentation, D6: artificial intelligence, machine learning and digital twins, D7: software engineering practices, D8: data governance, ethics and cybersecurity.

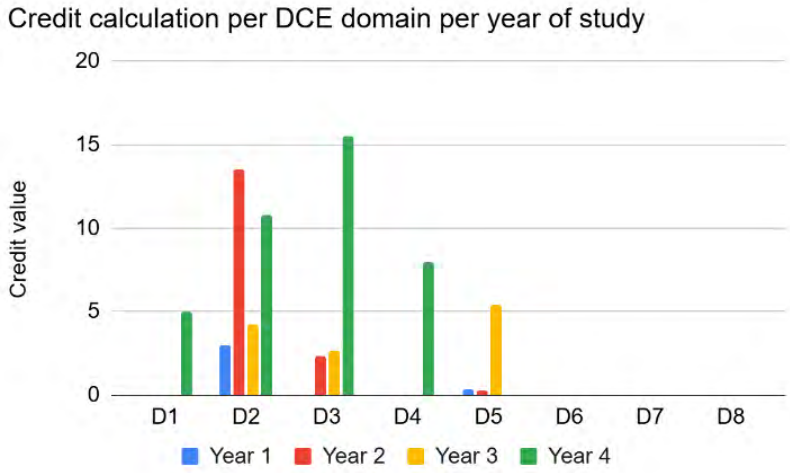

**Figure 2.** Credit calculation per DCE domain per year.

is interesting to note the slightly reduced credit attributed to digital skills between Year 2 and Year 3. This can be explained by the fact that during Year 3 students undertake the year-long Process Design Project, where they are called to apply their understanding and skills, so the curriculum is deliberately allowing them space to do so rather than overload them with more new skills.

The scaffolded approach towards development of digital skills through the curriculum is even more evident if we look at the credit attributed to DCE cumulatively per year (Figure 3, top right). There is an almost equal step between Years 1, 2 and 3, with a much bigger step towards Year 4. This is mainly attributed to two DCE-heavy core modules available at MEng level of study, "Advanced Process Modelling" and "Simulation and Optimisation". When looking at the cumulative credit attributed per domain (Figure 3 bottom), Data Literacy and Statistics (D2) and Process Modelling and Simulation (D3) are the domains with the highest presence. It is important to mention that the step change between Year 3 and Year 4 is attributed to the Final Year Research project as well, as a big component of its assessment is on data analysis, statistics, and data visualisation which relate to D2. The caveat here is that depending on the specific research area and projects students choose, the exposure to DCE might be even bigger. To illustrate the point better, we conducted a quick analysis of proposed research project

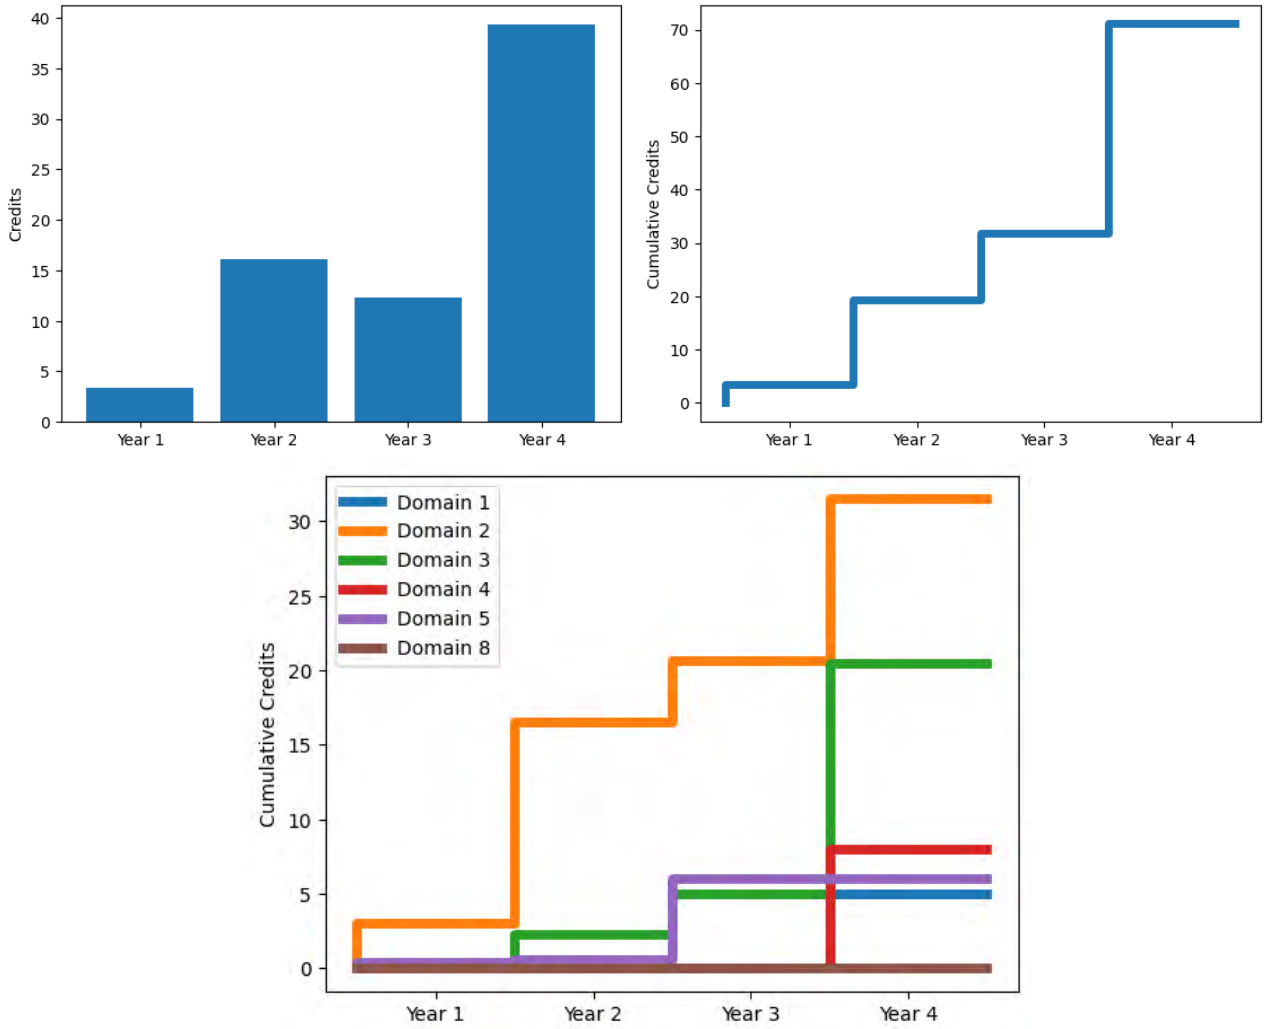

**Figure 3.** Top left graph: Credits accounted to DCE per Year of study. Top right graph: Cumulative credits accounted to DCE after each Year of study. Bottom graph: Cummulative credits accounted to DCE per domain where credits are atributed, per year of study.

topics over the last couple of years. We assessed the topics in terms of being fully computational (i.e. research and data collection based on simulations) and whether there was explicit mention of elements relating to any of the DCE domains (i.e. need to learn a new analysis software, partially computational research etc). Over 50% of projects offered over two consecutive years were fully computational, and around 70% across offered projects had relevance to DCE, additionally to the expected data analysis and statistics component. This shows that for majority of students, the DCE offering in Year 4 would be even higher compared to what was calculated previously as a baseline. It is very tricky to quantify in terms of credits the additional DCE exposure a student would get during their final year research project, aside of the already accounted component relevant to D2. The only other component where we could see and evaluate DCE coverage during a research project would be the methodology section of the final report students are asked to submit. In this section students describe the methods they used, adapted, or developed towards collecting the data necessary to conduct their project. In the case of computational projects, in the methodology section, students would discuss what software they used, how they developed their models or code, how they decided on their parameters and range of importance, potential optimisation they went through, if/how they ensured reproducibility. Depending on the project topic, there could be particular relevance to particular domains, however, overall, DCE exposure would certainly be higher compared to non-computational-heavy projects, and could result up to

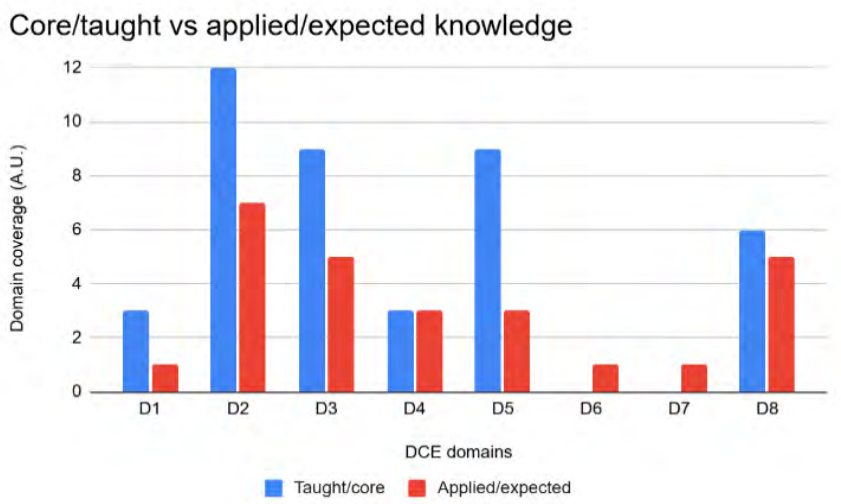

**Figure 4.** Hidden curriculum of digital chemical engineering: a comparison between content formally taught and assessed (blue) and content expected to be applied outside of formal assessment (red). Domain coverage was calculated as discussed in Methodology section.

10.8 more credits, according to the weight of the methodology section component to the overall mark for this module. This would bring the credit attributed to DCE during Year 4 to over 40 credits in certain cases. As a reminder, a typical year during an undergraduate degree in the UK has 120 credits, so an over-40 credit attributed to DCE illustrates a third of the year being devoted to digital competency development.

If we now look at content that is taught in core modules and assessed with credit-bearing assignments, compared to content or knowledge that is expected to be understood and applied outside of formal assessment, we can see an interesting trend showing (Figure 4). This figure reveals a "hidden curriculum", where we can see presence, elaborate or not, of all domains of digital chemical engineering. Compared to assessed content under credit-bearing activities, the applied or expected knowledge has a small presence in AI/ML and Digital Twins (D6) and Software Engineering Practices (D7). For example, students in Year 2, during the Experimental Investigation module, are introduced to the Diamond Pilot Plant facility, where they get to see unit operations of a tablet manufacturing process, including a digital twin version of the physical plant. There are assessed laboratory activities built around the operation of the pilot plant, however these do not include the operation of the digital twin.

Another example is in Year 4, during the Computational Modelling module, where students are expected to understand and use practices such as version control, although this activity is not formally assessed and does not form a learning outcome of this or other modules. It is interesting to note that the domains with highest level of applied or expected knowledge align, with the exception of D5, with domains where knowledge is delivered as core content and assessed accordingly (D2, D3, D8 in Figure 4). Another interesting point specific to the Engineering Curricula at Sheffield is the coverage of Data Governance, Ethics and Cybersecurity (D8). Students on chemical engineering programmes discuss about ethics, with brief coverage of digital ethics, during a Year 1 module, Principles of Chemical Engineering. Then, they revisit ethics and discuss cybersecurity during Year 3, in the Process Design project, where a small part of the assessment is on the cybersecurity provisions for their hypothetical process design. While these are the only examples of D8 coverage in the chemical engineering curriculum, there are another two spaces where ethics and cybersecurity are discussed. All Year 1 and Year 2 students registered on any engineering programme at the University of Sheffield participate in the compulsory yet non-credit-bearing Project Weeks that take place just before the beginning of the Spring semester. During these weeks, students are grouped together in teams with multidisciplinary membership and are given open-ended briefs around real-life engineering challenges. They are then asked to produce an engineering solution to solve the given challenge, using their skills and knowledge up to this point in their programme and working collaboratively. One aspect they need to discuss while developing their solution is cybersecurity, which relates directly to D8.

## REFLECTIONS, CONCLUSION AND FUTURE WORK

This work shows the Digital Chemical Engineering coverage at the chemical engineering programmes offered at Sheffield. Results show that all the eight identified domains are present in the curriculum, although not all of them are covered at the same extend or with equal links to formal assessment and learning outcomes. The review of the curriculum with a focus on digital skills showed that in the first and second years of study students are all introduced to the same curricular digital exposure by design, attending core modules with specific learning objectives and activities around digital competencies. As the course progresses students have the opportunity to engage more with the development of their digital competencies through elective modules, the design project, and ultimately, the choice of their final year research project. The question of whether the curriculum transformation at the University of Sheffield has been successful in addressing the demand for Industry 4.0 is now rephrased to "how can the chemical engineering curriculum at Sheffield ensure that graduates are equipped at a high level across the DCE domains to contribute to Industry 4.0".

Process simulation and modelling, integral parts of modern chemical engineering practice, require and generate data to design, simulate, and optimise chemical processes. These are fundamentally linked to data analysis, statistics, and management. These data-driven processes connect tightly to Digital Twins, integrating real-time data with virtual models for predictive maintenance and operational efficiency. Machine Learning, traditionally the domain of Data and Computer Science, remains underrepresented in the curriculum. Version control is also highly relevant to data management and coursework reporting. Across programming languages with wide use across engineering programmes, python is likely the best programming language for Domain 1, as it is currently the most popular programming language reflected by its extensive applications in AI and ML. In addition, Cybersecurity is a growing requirement for understanding the digital risks to physical infrastructure, such as protecting Industrial Control Systems from cyber threats.

Traditionally, the Chemical Engineering degree has covered a wide breadth of industries and sectors. We now need to ensure that it covers digitalisation in sufficient depth so that chemical engineering graduates are well equipped with digital skills necessary to communicate effectively with computer scientists and software engineers, working together within the Industry 4.0 framework.

Future work would need to focus on a thorough curriculum review, with the intention of perhaps enriching the digital coverage offering in earlier years of study to incorporate exposure to mode digital domains with a more embedded and formally assessed approach. Students then would progress to subsequent years with a better understanding around artificial intelligence and machine learning principles, digital twins, programming, and cybersecurity. One way of ensuring that the taught – and applied- content is current and relevant, would be to continue engagement with employers, alumni, and industry advisory boards, and develop work-related learning activities targeting exposure in specific domains of digital interest.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge their colleagues from the School of Chemical Materials and Biological Engineering, for valuable insight and discussions that contributed to our understanding and mapping of DCE in our curriculum.
